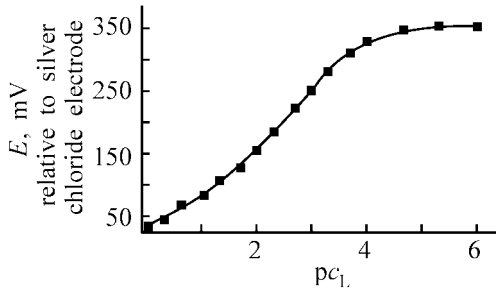
Analysis of Eq. (10) in the general form is difficult; however, in the ranges of predominance of certain complex forms of cobalt porphyrin, the equation is simplified. At low ligand concentrations, when the inequalities $K^Rc_L << 1$ and $(K^0_1c_L + K^0_1K^0_2c_L) << 1$ hold true, Eq. (10) takes the form $E = E^{0'}$. Under these conditions, the forms $Co(III)TPP^+$ and Co(II)TPP are predominant, and the oxidation potential is independent of the ligand concentration ($\partial E/\partial pc_L = 0$). With increasing pyridine concentration in the external solution, the inequalities $K^Rc_L << 1$ and $1 << K^0_1c_L >> K^0_1K^0_2c^2_L$ become good and Eq. (10) takes the form $E = E^{0'} - \vartheta\log(K^0_1c_L)$. In this case, the compounds $Co(III)TPPL^+$ and Co(II)TPP predominate and the dependence of E on pc_L is expressed by the equation $\partial E/\partial pc_L = \vartheta$ (at 25°C ϑ = 59 mV). With the pyridine concentration increasing further, the inequalities $K^Rc_L << 1$ and $1 << K^0_1c_L << K^0_1K^0_2c^2_L$ hold true. In this case, Eq. (10) takes the form $E = E^{0'} - \vartheta\log(K^0_1K^0_2c^2_L)$. Under these conditions, the complex forms Co(III)TPPL and Co(II)TPP predominate. The dependence of E on pc_L is described by the equation $E = E^{0'} + \vartheta\log(K^Rc_L) - \vartheta\log(K^0_1K^0_2c^2_L)$, whence follows $\partial E\partial pc_L = \vartheta$. Analysis of Eq. (10) shows that the curve describing the dependence of $\partial E\partial pc_L$ when the above inequalities hold true must consist of several straight portions with slopes equal to 0, ϑ, 2ϑ, and ϑ, connected by smooth bent curves.

A study of the properties of a solid-contact electrode consisted in determining the dependence of its potential on the pyridine concentration in the external solution at constant pH of the working solution (7.0). The buffer capacity was maintained using the sodium salt of *N*,*N*-piperazinebis(ethanesulfonic acid) (PIPES). As supporting electrolyte served 0.1 M KCl solution. All measurements were done at 20 ± 1°C.

The experiment was carried out on a solid-contact electrode with a membrane of composition cobalt porphyrin : PVC : plasticizer : graphite = 1 : 2 : 4 : 8. It was shown that the electrodes of this composition are



Potential E of the solid-contact electrode vs. pc_L.

favorably distinguished by high sensitivity to pyridine concentration and fast stabilization of electrode potentials. Furthermore, these electrodes exhibit to a lesser extent the so-called "cathode response," i.e., a short-time rise in potential on passing to concentrated pyridine solutions, which is due to diffusion of pyridine into the membrane phase.

The experimental data obtained are represented in the figure as a dependence of the electrode potential on the pyridine concentration pc_L. The E–pc_L curve shows no clearly pronounced straight portions, which indicates that the constants K_1^0, K_2^0, and K^R are close. However, the run of the curve and the manner in which the derivative $\partial E/\partial pc_L$ varies suggest that the following complex forms of cobalt porphyrin predominate in the membrane phase with increasing pyridine concentration: Co(III)TPPL$^+_{(s)}$, Co(III)TPPL$^+_{2(s)}$, and Co(II)TPPL$_{(s)}$. The respective complexation constants calculated by fitting with the help of Eq. (10) are as follows:

$$\log K_1^0 = 4.3 \pm 0.2, \quad \log K_2^0 = 3.3 \pm 0.2, \quad \log K^R = 2.0 \pm 0.2.$$

CONCLUSIONS

(1) A study of a solid-contact electrode based on cobalt tetraphenylporphin demonstrated that the potential E of the electrode depends on the pyridine concentration in solution, and this dependence is satisfactorily described by the E–pc_L equation presented.

(2) The experimental data obtained can serve as a basis for developing a potentiometric sensor for determining the pyridine concentration.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrical Conductivity of Carbon in Porous Glasses

V. N. Pak, S. V. Sukhanov, and Yu. Yu. Gavronskaya

Herzen Russian Pedagogical University, St. Petersburg, Russia

Received March 5, 2002

Abstract—The electrical conductivity of carbon-containing porous glasses obtained by gas-phase treatment of sodium–borosilicate glasses with a mixture of *n*-hexane and carbon tetrachloride at 480°C was studied.

To indubitable advantages of porous glasses obtained by acid–base etching of liquating glasses of the sodium–borosilicate system [1–4] belong widely controllable parameters of the porous structure, narrow pore radius distribution, and availability in the form of mechanically strong articles of various configurations (wafers, tubes), rather than as powders only. Making porous glasses electrically conducting opens up new possibilities of their use in electrocatalysis, electrosorption purification, concentration, and membrane separation. Among possible variants is chemical modification of porous glasses with carbon. "Passing" from the silica surface of glasses to a carbon surface allows fabrication of articles differing both in the spatial-geometric structure and in the content of carbon distributed over walls of through channels in supports. The methods for synthesizing carbon layers on the surface of solids, reported in the literature, mainly involve high-temperature processes [5]. At the same time, with porous glasses used as supports, the deposition temperature should be limited (< 500°C) to prevent support caking. The temperature of carbon formation can be lowered to within the above limits by using a gaseous reaction mixture of hydrocarbons and their chloro derivatives, and CCl_4 in particular [6–8]. The results obtained in testing one of the possible variants of carbon synthesis in bulk porous glasses and in measuring the electrical conductivity of the compounds obtained are presented in this communication.

Porous glasses with parameters listed in the table were obtained in the form of 10 × 10 × 1 mm plates by varying modes of preliminary thermal treatment and conditions of the subsequent acid–base etching of DV-1 sodium–borosilicate glass [1–4]. As components of the reaction mixture for preparing carbon served [8] *n*-hexane and carbon tetrachloride, taken in molar ratio $C_6H_{14}/CCl_4 = 0.07$. These substances were delivered by the dosing unit of the evaporator into an evacuated reactor in which the glass plates to be treated were mounted perpendicularly to the reagent flow. With account of the characteristic kinetic features of carbon growth in porous glasses [8], the time of treatment at 480°C was varied between 5 and 200 min. The excess amounts of reagents and gaseous reaction products were caught with a zeolite trap cooled with liquid nitrogen. After synthesis was complete, the samples obtained were cooled in a vacuum. The amount q_C of carbon deposited into porous glasses was determined gravimetrically, and the adsorption-structural parameters of the starting and carbon-containing porous glasses (CPG), by the known techniques [2–4, 9]: the specific surface area S_{sp} was found from low-temperature adsorption of argon; pore volume δ, from moisture capacity in a saturated water vapor; and pore radii r_p, from parameters of the hysteresis loop in isotherms of water adsorption and by mercury porosimetry. The currents flowing along the pore walls in CPG (across the plates) and voltage drops across the samples were measured in the dc mode with a P136 stabilized power supply and V7-27A/1 voltammeter. To eliminate the possible leaks,

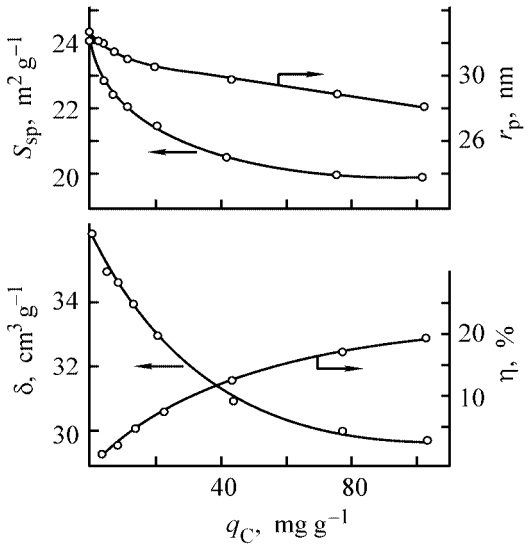

Fig. 1. Specific surface area S_{sp}, pore radius r_p, pore space volume δ, and degree of its filling, η, vs. content q_C of carbon synthesized in porous glasses.

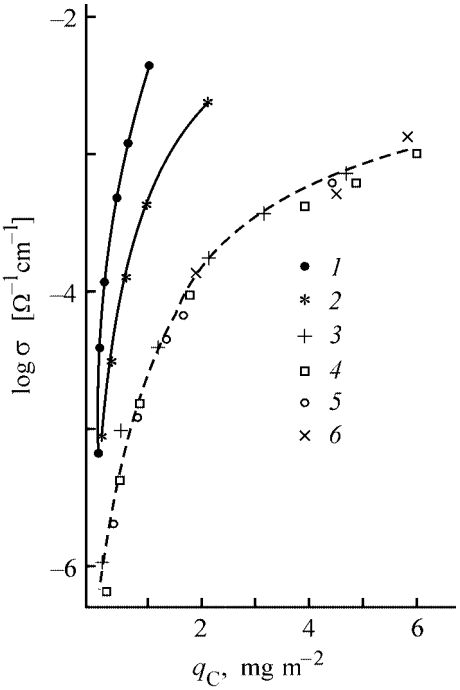

Fig. 2. Electrical conductivity σ of CPG vs. amount of carbon, q_C, synthesized in porous glass. Pore radius r_p (nm): (*1*) 4.1, (*2*) 8.2, (*3*) 16.3, (*4*) 32.6, (*5*) 47.3, and (*6*) 68.7.

the lateral parts of CPG plates were preliminarily ground off. Pressure contacts (pressed with constant force of 200 g cm^{-3}) in the form of polished copper discs with silver-plated surface were employed [10]. The electrical conductivity σ was calculated, to a first approximation, with account of the real dimensions of the CPG plates. The thus obtained values characterize the behavior of a sample as a whole; relating them to the conducting component requires model estimates of the effective cross-section and length of carbon inclusions, which is beyond the scope of the present study.

In all cases, the increase in the carbon content was accompanied by a gradual decrease in the specific surface area, volume, and effective radius of pores. Figure 1 presents this change in porous structure parameters for a number of CPGs obtained on a support with initial r_p = 32.6 nm. One more quantitative characteristic of carbon distribution within CPG is the degree of pore space filling with carbon, η (%), (Fig. 1), calculated as

$$\eta = \frac{\delta - \delta^*}{\delta} \times 100, \quad (1)$$

where δ^* and δ are, respectively, the pore volumes of a CPG sample and initial (pure) porous glass.

The characteristic monotonic run of the dependences of the structural parameters on the carbon content q_C up to substantial (η = 20%) degrees of pore space filling with carbon (Fig. 1) points to favor of a uniform distribution of the growing layer over the entire silica surface of the support. If it is assumed that carbon is mainly formed on the outer, open surface of a porous glass and in mouths and possible constrictions of pores, then a relatively small amount of carbon would be sufficient for a significant decrease in measured values of S_{sp} and δ because of a decrease in the accessibility of the internal volume of CPG. It is not improbable that important factors in carbon structure formation are the well-pronounced electron-acceptor ability of silica [11] and lateral interactions ensuring, taken together, a predominantly layer-by-layer growth. It is very important in this context that the pore radius decreases nearly linearly with increasing q_C (Fig. 1), which disproves the assumption that porous carbon has island structure. The data obtained and their interpretation are in good agreement with the previously studied [8] specific features of the carbonization kinetics of porous glasses and with changes in the isotherms of water adsorption onto CPG with increasing q_C.

The through (measured across the plates) electrical conductivity of CPG is due to carbon distributed over channel walls; the resistivity of the initial porous glasses is beyond the possibilities of measurement (R > 10 GΩ). The absence of polarization and the linearity of current–voltage characteristics for all the CPG samples point to the electronic nature of conduction. Figure 2 shows the conductivity σ as a func-

tion of carbon content reduced to unit surface area of the conducting channels. It is important to note that a dramatic increase in σ is observed in the earliest stages of synthesis, when the amount of the conducting component is much smaller than that necessary for a solid conducting layer to be formed. For example, in the range q_C = 0.1–0.5 mg m^{-2}, where a pronounced rise in electrical conductivity is observed, the average number of carbon atoms per unit area of 100 $Å^2$ changes from 5 to 25. It should be noted that the carbon packing "density" in layers of the hexagonal lattice of graphite is 42 atoms per 100 $Å^2$ [12]. The feature revealed suggests that extended carbon chains with high degree of delocalization of π-electrons can be formed even at very low degrees of filling of the surface of the porous glass, which are far from those for a conventional graphite-like monolayer. It may be assumed that that these chains are gradually jointed in the course of synthesis, to give a two-dimensional conducting layer of carbon. This growth mechanism is promoted both by the increasing conjugation area and by the electron-acceptor effect of silica [11], with these two factors leading to predominance of the layer-by-layer mechanism of carbon condensation.

Before comparing the electrical conductivities of CPGs with different in spatial-geometric characteristics, an attempt is to be made to evaluate the density d_C of the carbon synthesized, using the relation

$$d_C = q_C/(\delta^* - \delta). \quad (2)$$

The determinations performed demonstrate that only a weak tendency for d_C to grow with increasing mass of synthesized carbon is observed in each CPG sample: the densification does not exceed 5% in all the q_C ranges. This indicates that the carbon structure is determined by synthesis conditions and by the orienting action of silica supports, being mainly preserved (reproduced) in the process of growth. A more interesting and important factor is that the carbon density depends on pore radii in porous glasses. The d_C values presented in Fig. 3, averaged over CPG samples, grow more than twofold with r_p increasing from 4.1 to 68.7 nm. With account taken of the identical chemical nature of the porous glass surface in all cases, the established specific feature should be related to the effect of the dimension factor: steric hindrance to fixation of a dense carbon layer is created in narrow pores with strong surface curvature. Moreover, the run of the curve in Fig. 3 indicates that the main change in d_C occurs in the pore radius range studied, with further rise in r_p leading, in all probability, to only a minor increase in the carbon density. On the whole, the specificity of porous glasses as supports and the synthesis conditions employed ensure formation of carbon structures with low density.

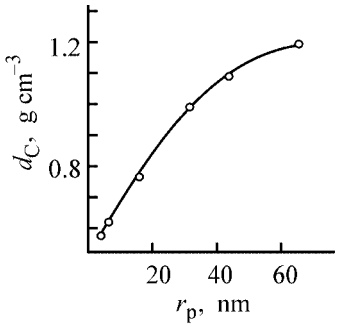

Fig. 3. Averaged density d_C of carbon synthesized in porous glass vs. pore radius r_p of the supports.

Reverting to the results presented in Fig. 2, it should be emphasized that the electrical conductivity of equal amounts of carbon is the highest in pores of small radius, despite its lowest density (the relative σ values of CPG samples are the same when the dimension of q_C is mg g^{-1}). It is rather difficult to explain unambiguously the observed behavior of the systems under study. It is not improbable, however, that the decrease in r_p to about several nanometers predetermines a substantial increase in the average length of conducting carbon chains in the direction of the applied electric field (along the channels) and makes smaller the number of breaks between the chains. It is significant that a 2–4-fold increase in pore radius is accompanied by a pronounced decrease in the σ values measured for pore carbon, but σ remains virtually unchanged with r_p increasing further (r_p = 16.2–68.7 nm) (Fig. 2). The manifestation of the dimension factor in the electrical conductivity of CPG is, therefore, limited to a narrow range of pore radii. It may be assumed that the decrease in channel wall curvature, occurring in porous glasses beyond this range, results in the predominance of the radial (along the channel perimeter) component of carbon growth. This leads to the observed rise in carbon density (Fig. 2), but favors an increase in the through electrical conductivity to a lesser extent.

CONCLUSIONS

(1) A number of carbon-containing porous glasses were synthesized by gas-phase treatment of silica supports with a mixture of *n*-hexane and carbon tetrachloride at 480°C. The nature of changes in the porous structure parameters of carbon-containing porous glasses, which accompany carbon growth, indicates

that carbon is uniformly distributed over walls of through channels in porous glasses.

(2) A substantial increase in the electrical conductance of carbon-containing porous glasses at small degrees coverage of silica surface with carbon and the dependence of the electrical conductivity δ on pore radius in a narrow range r_p = 4.1–16.3 nm were established.

(3) The use of porous glasses with small pore radii predetermined the increased electrical conductivity of carbon deposited into these pores, with carbon density being much lower in this case. An assumption is made that the orienting action of narrow pores favors an increase in the length of conducting carbon chains.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution of Ni50Zn Alloy in the Presence of Mixtures of Organic Additives with Sodium Chloride

A. G. Berezhnaya, V. V. Ekilik, and E. A. Tugolukova

Rostov State University, Rostov-on-Don, Russia

Received April 26, 2001; in final form, June 2002

Abstract—Electrochemical behavior of nickel and nickel–zinc alloy in an acidic perchlorate media was studied as influenced by some organic additives, sodium chloride, and their binary mixtures.

Nickel-zinc alloys with low or medium content of nickel [Ni], used to prepare Raney catalysts, are promising in replacement of cadmium coatings. The stability of these alloys grows with increasing nickel content above 50 wt %, and, similarly to pure nickel, they are inclined to undergo passivation [1]. Data on the effect of individual organic compounds on the electrochemical behavior of the Ni50Zn alloy ([Ni] = [Zn] = 50 wt %) are scarce. Only its selective and uniform dissolution, predominantly in chloride media, has been investigated [2, 3]. In this study, we analyze the electrochemical behavior and passivation of the Ni50Zn alloy in perchlorate media as influenced by some organic additives, sodium chloride, and their mixtures.

The alloy reinforced in Teflon was trimmed with an abrasive paper with decreasing grain size and degreased with ethanol. The potentiostatic measurements were carried out in a three-electrode cell with separated cathodic and anodic volumes at 25°C in a 0.1 M $HClO_4$ + 0.1 M $LiClO_4$ solution (preliminarily deaerated with argon). The resulting electrode potentials E are given with respect to a saturated silver chloride reference electrode.

As inhibitors we used 1,2-dimethyl-3-octyloxymethyl-5-methoxybenzimidazolium chloride (**I**), 1-heptyl-2-immonio-3-(2-methoxyethyl)benzimidazoline chloride (**II**), 1-methyl-4,6-di(4-ethoxycarbonylmethoxyphenyl)pyrylium perchlorate (**III**), sodium chloride, and their mixtures.

III

The working concentration c_s of surfactants **I**–**III** was varied within 2×10^{-5}–10^{-4} M. The effect of surfactants was evaluated by the inhibition coefficient $\gamma = i_0/i_a$, where i_0 and i_a are the rates of alloy dissolution in electrolyte with and without additive, respectively.

The alloy dissolves uniformly. The polarization curves of the alloy and metallic nickel are similar. They dissolve in the active state up to E = –0.20V, and at $E \geq 0.05$ V they occur in the passive state. The critical current i_{cr} and the current of complete passivation i_{cp} of the alloy, are, respectively, 200 and 30 times greater than those of metallic nickel.

The effects of additives **I**–**III** on the cathodic evolution of hydrogen i_H on the alloy and nickel are different. The dependence of γ on the concentration and

nature of organic additive obtained, for the alloy, is partially illustrated in Table 1.

Compound **II** acts as inhibitor in the entire concentration range studied, its effects on i_H for both alloy and metallic nickel are similar, and, depending on c_s and *E*, γ varies within the range 1.2–3.4, decreasing with increasing *E*. Compound **I** inhibits hydrogen evolution at the lowest c_s, whereas at higher c_s it accelerates this process. Sodium chloride and compound **III** make i_H higher in the entire concentration range studied. Comparison of the effect of compounds **I**, **II**, and NaCl on the cathodic process suggests that, taking into account different types of influence exerted by organic cations and the chloride anion on the ψ-potential, the effect of the cation is predominant in the case of **II** (i_H decreases at any content of surfactant c_s), whereas for **I**, the anion effect is predominant and i_H increases, especially at high c_s. The stronger influence exerted by the anion in surfactant **II** is probably due to the effect of the third nitrogen atom (position 2 in benzimidazole), which must increase both the effective charge on the nitrogen atom and the contribution of physical adsorption. In accordance with [4], the stimulating effect of the pyrylium cation is due to its sorption on the surface regions free of sorbed hydrogen or on regions of energetically nonuniform alloy surface with the minimal metal–hydrogen bonding energy (E_{M-H}), which makes higher the average E_{M-H} and facilitates the cathodic process. This is possible when the metal–surfactant system is characterized by specific interaction or chemisorption. The pyrylium cations tend to be chemisorbed on transition metals, including nickel.

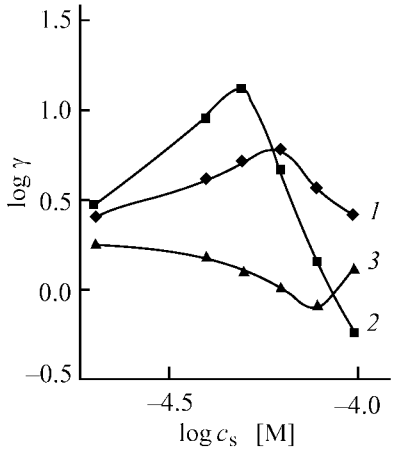

Fig. 1. Protective effect of additives on Ni50Zn alloy in relation to their concentration: (*1*) **I**, (*2*) **II**, and (*3*) **III** (E = –0.26 V). (γ) Inhibition coefficient and (c_s) surfactant concentration.

Compounds **I** and **II** decelerate the alloy dissolution in the active region, and the dependence of γ on c_s passes through a maximum (Fig. 1). They differ only in the effect on the critical potential E_{cr} and passivation current i_{cr}. Depending on concentration, compound **I** shifts E_{cr} by 0.05–0.1 V toward the anodic region and makes i_{cr} lower by a factor of 1.1–5.6. Compound **II** also raises E_{cr} by 0.1–0.2 V, but makes i_{cr} higher by a factor of 1.1–6.2. Compound **III** does not affect E_{cr} and dissolution of the alloy in the active region, but inhibits its ionization in the transition region. The coefficient γ varies from 1.2 to 3.0, depending on *E* and inhibitor concentration. Sodium chloride does not affect noticeably the alloy dissolution in the active region, promotes ionization in the transition region, and raises i_{cr} by a factor of 2.0–6.0, whereas E_{cr} remains unchanged. At low concentrations, all the additives studied do not affect the process, whereas at higher c_s the rate of the alloy dissolution in the passivation region increases by a factor of 1.2–2.0, i.e., the organic compounds studied hinder formation of a passive film. At equal concentrations, γ decreases in the order **II** > **I** > **III** > NaCl (Fig. 2). As seen, NaCl and compound **I** show no similarity in the effect on i_H. Hence, certain role in the protective effect

of **I** and **II** belongs to the organic cation, whose sorption on the positively charged alloy surface must be hindered. Adsorption of organic cation in **II** is weaker than that of the cation in **I**, in accordance with their structural, which is manifested in their different effects on E_{cr} and i_{cr}. The chloride anion in compounds **I** and **II** probably acts as a bridge and favors an increase in the contribution of physical adsorption.

Addition of NaCl to organic additives **I**–**III** changes their behavior. In the cathodic potential range and in the case of active dissolution, mixtures of **I** and **II** with NaCl accelerate the process, whereas in the passive region, the inhibiting effect is observed. The mixture of **III** with NaCl decelerates the process in the entire potential range studied. The coefficient of mutual effect, χ, calculated from the equation $\chi = \gamma_m/\gamma_i\gamma_{NaCl}$, where γ_m, γ_i, and γ_{NaCl} are the inhibition coefficients of the mixture and components, i = **I**–**III**, shows the follows. In mixtures of chloride-containing organic additives with constant concentration of sodium chloride, the effect is mainly antagonistic, and with additive **III** it is synergistic at any of the anodic potentials studied (Table 2).

At constant concentration of salt **III** and varied concentration of sodium chloride, their mixtures exert protective influence with mutual enhancement observed at all potentials except E = 0 (Table 3).

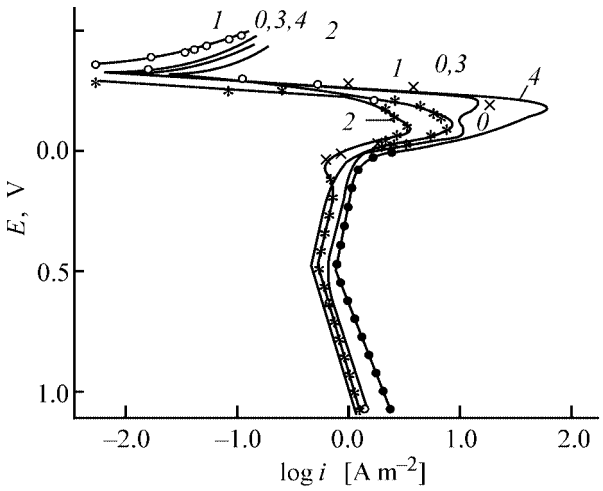

Fig. 2. Polarization curves of the alloy in the presence of additives: (*0*) none, (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) NaCl. (*E*) Electrode potential and (*i*) process rate.

CONCLUSIONS

(1) 1,2-Dimethyl-3-octyloxymethyl-5-methoxybenzimidazolium chloride and 1-heptyl-2-immonio-3-(2-methoxyethyl)benzimidazoline chloride inhibit active dissolution of Ni50Zn alloy and this effect is almost completely eliminated in the presence of NaCl. Mixtures are effective in dissolution of the alloy under study in the passivation region.

(2) The dependence of the protective influence exerted by the individual organic additives on their concentration passes through a maximum.

(3) The protective effect of 1-methyl-4,6-di(4-ethoxycarbonylmethoxyphenyl)pyrylium perchlorate is insignificant, it is strongly enhanced in the presence of sodium chloride.

Abstract—The dependence of the pH of the medium on the partial pressure of CO_2 and temperature in the system constituted by low-carbon steel and NaCl (3%) and the effect of pH variation on the corrosion rate were studied. The mechanism of carbonic acid corrosion of ferrous metals in oxygen-free mineralized aqueous media was analyzed. The possibility of prognosticating the rate of steel corrosion on the basis of partial pressure of CO_2 and pH value was considered.

The corrosion activity of mineralized aqueous media is determined by the content of dissolved carbon dioxide causing intensive corrosion of oil-and-gas production equipment. The mechanism of metal corrosion under the action of CO_2 still remains the matter of discussion, despite numerous investigations in this field.

The aim of the present study was to discuss further the mechanism of carbonic acid corrosion of ferrous metals in oxygen-free mineralized media [1, 2].

Commonly, the effect of CO_2 is related to acidification of the medium [2–7]. As is known, the pH of the medium and, in the end, the corrosion danger are determined by the concentration of carbon dioxide in the stratal water, which, in turn, depends on the partial pressure of CO_2, p_{CO_2}, in the system. In this case, the following reactions are common to all aqueous media in the working range of p_{CO_2}:

$$CO_2 + H_2O \rightleftarrows H^+ + HCO_3^- \rightleftarrows H_2CO_{3(sol)}, \quad (1)$$

in solution [8] and

$$CO_{2(sol)} = CO_{2(ads)}, \quad (2)$$

$$CO_{2(ads)} + H_2O \rightarrow RH_2CO_{3(ads)} \quad (3)$$

on active centers on the metal surface [9].

With increasing p_{CO_2} and varying pH of the medium, the total and relative concentrations of the molecular and ionic forms (HCO_3^-, CO_3^{2-}, H_2CO_3) in the solution bulk and in adsorbed state change. As is known [10–12], the possible depolarizers in oxygen-free aqueous media saturated with CO_2 are, in addition to hydroxonium ion, H_2CO_3, HCO_3^-, and $CO_2 \cdot H_2O$.

Using the known nomograms [8, 13–15] describing the dependence of the equilibrium relation between H_2CO_3, HCO_3^-, and CO_3^{2-} on pH, the form (molecular or ionic) in which carbonic acid is present in solution can be determined. In [16], equilibrium constants of chemical reactions occurring in CO_2 dissolution in water were used to plot dependences of the share of each species in the analytically determined total concentration c_{CO_2} of carbonic acid on solution pH:

$$c_{CO_2} = [CO_2 \cdot H_2O] + [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}].$$

In media with pH < 5, dissolved carbon dioxide is present virtually in the molecular form, 99.5% H_2CO_3 (25°C) [8], and, therefore, carbonic acid acts under these conditions mainly as a depolarizer:

$$H_2CO_{3(ads)} + e = H_{(ads)} + HCO_{3(ads)}^-. \quad (4)$$

When the cathode process occurs in accordance with Eq. (4), regeneration of carbonic acid proceeds simultaneously [9, 17]:

$$HCO_{3(ads)}^- + H_3O^+ = H_2CO_{3(ads)} + H_2O. \quad (5)$$

In this case, hydroxonium ions, also involved in the cathode process, may be formed both in the solu-

1070-4272/02/7510-1625 $27.00 © 2002 MAIK "Nauka/Interperiodica"

tion bulk and in adsorbed state, as a result of hydrolysis of carbonic acid [9]:

$$H_2CO_{3(ads)} + H_2O = H_3O^+_{(ads)} + HCO_3^-. \quad (6)$$

Presumably, with increasing concentration of hydroxonium ions in the adsorption and near-surface layers, the part played by competing reactions in the cathode process becomes more important:

$$H_3O^+ + e \rightleftarrows H_{(ads)} + H_2O, \quad (7)$$

$$H_3O^+_{(ads)} + e \rightleftarrows H_{(ads)} + H_2O. \quad (7a)$$

At pH ~6.5, about 30% H_2CO_3 and 70% HCO_3^- are present in solution [8]. In this case, the cathode process may occur by several pathways simultaneously [Eqs, (4), (7), (7a), (8), and (8a)]:

$$HCO^-_{3(sol)} + e \rightarrow H_{(ads)} + CO_3^{2-}, \quad (8)$$

$$HCO^-_{3(ads)} + e \rightarrow H_{(ads)} + CO_3^{2-}, \quad (8a)$$

$$2H^+_{(ads)} \rightarrow H_2\uparrow.$$

With increasing p_{CO_2} in the system, the share of reactions (7a) and (8a) in the overall cathode process will, presumably, grow.

At pH > 6.8 up to 99% HCO_3^- is contained in aqueous media [8]. Under these conditions, depolarization is mainly effected by HCO_3^- ions from solution in accordance with Eq. (8).

The increase in the concentrations of carbonic acid and HCO_3^- ion makes higher the rate of the cathode process, but does so only until the layer of corrosion products formed on the steel surface as a result of the concurrent anode process reaches its critical thickness.

At pH ≥ 7, reaction (9) becomes important, in addition to Eq. (8), in the cathode process [3, 4, 6]:

$$2H_2O + 2e \rightarrow H_2\uparrow + 2OH^-. \quad (9)$$

Accumulation of OH^- ions in solution creates favorable conditions for formation of carbonate ions by the reaction

$$HCO_3^- + OH^- \rightarrow H_2O + CO_3^{2-}. \quad (10)$$

As a result, the CO_3^{2-} concentration in solution grows, which favors formation of $FeCO_3$ and gives rise to a protective layer of siderite, lowering the total rate of the corrosion process, on the metal surface. However, the danger of local corrosion is preserved because of the local acidification of the medium within pores of corrosion products via, in particular, reaction (6).

In the general case, the rate of the cathode reaction in CO_2-containing media is given by the known relation [7, 9]

$$i_c = K_c c_{CO_2} \exp[-\alpha FE/(RT)].$$

The reversible potential of the cathode reactions considered depends on pH and is described by the equation

$$E_{rev} = -0.059\,pH - 0.295 \log p_{H_2}.$$

The total pressure in the system is in fact a sum of partial pressures of gases present (under the conditions of the experiment, these are pumped-in CO_2 and H_2 formed in the cathode process). Therefore, it may be concluded that the rate of the cathode process will grow with increasing total or partial CO_2 pressure in the system only to a certain critical value p_{CO_2}, above which the rate starts to decrease because of the hindrance to electrode processes associated with hydrogen evolution.

It is believed [9–11, 16] that depolarizer reduction proceeds in carbonate corrosion of ferrous metals depending on conditions of activation and diffusion control. The control is, as a rule, of activation type in the initial stage on a clean metal surface, and of diffusion type in the presence of a layer of corrosion products on the surface.

The anode process is intimately associated with the cathode process. Analysis and generalization of a wide variety [6, 9–12, 17–24] of schemes describing the anode process in aqueous media with CO_2 and without O_2 suggest the following. The overall anode electrochemical reaction for ferrous metals is as follows

$$Fe + 2H_2O \rightarrow Fe(OH)_{2(s)} + 2H^+ + 2e. \quad (11)$$

In media with pH < 5, a competing process is direct reaction of iron with the acid

$$Fe + 2H_2CO_3 \rightarrow Fe(HCO_3)_2 + H_2\uparrow. \quad (12)$$

Hydrocarbonates are unstable and, in the course of time, decompose to give carbonates:

$$Fe(HCO_3)_2 \rightarrow Fe^{2+} + 2HCO_3^-, \quad (13)$$

$$HCO_3^- \rightarrow H^+ + CO_3^{2-}. \quad (14)$$

Fe^{2+} ions formed in this stage interact with CO_3^{2-} by the reaction

$$Fe^{2+} + CO_3^{2-} \rightarrow FeCO_{3(s)}. \quad (15)$$

This leads, in the end, to formation of a siderite layer on the metal surface and to hindrance to both the cathode and anode processes.

In media with high HCO_3^- (pH > 6.8), iron carbonate may be formed by direct reaction of HCO_3^- with iron

$$Fe + HCO_3^- \rightarrow FeCO_{3(s)} + H^+ + 2e \quad (16)$$

and iron(II) hydroxide formed in an earlier stage of the process by reaction (11):

$$Fe(OH)_2 + HCO_3^- \rightarrow FeCO_{3(s)} + H_2O + OH^-. \quad (17)$$

Iron carbonate, in its turn, reacts with HCO_3^- to give a soluble complex compound:

$$FeCO_{3(s)} + HCO_3^- \rightarrow [Fe(CO_3)_2]^{2-} + H^+. \quad (18)$$

This, presumably, accounts for the fact that the siderite-hydroxide film loses its protective properties in media with higher HCO_3^- content, and the medium is acidified, eventually catalyzing the process.

It should be noted that all the reactions described above, and the related formation of the film and a deposit of corrosion products proceed in the course of time.

Another important factor determining the rate and mechanism of carbonic acid corrosion is temperature [9, 11, 18–24]. In contrast to the case of acid corrosion, the temperature dependence of carbonate corrosion is ambiguous: with the temperature increasing to 40–60°C, the corrosion rate grows, and then the process is hindered [9–12, 17–19]. This was attributed in [9–11, 18] to a change of mechanism. At 25°C, an unstable, porous oxide-hydroxide film of corrosion products, occasionally with inclusions of iron carbonate, is formed. The film is permeable to the depolarizer. The rate of the process is determined by the stage of H_2CO_3 and HCO_3^- discharge [Eqs. (4) and (8)]. At a temperature of about 60°C, the film of corrosion products becomes denser and acquires protective properties [23, 24]. This is due to the formation of films of another composition: carbonate-hydrocarbonate and purely carbonate (with inclusion of cementite) films are formed instead of oxide-hydroxide films at high temperature (>100°C), with the nature of the rate-determining stage changed. The solubility and permeability of corrosion products become key factors controlling the corrosion rate, which, in turn, is governed by the stage of chemical dissolution of siderite $FeCO_3$. It is known [13, 15, 16] that the solubility of siderite grows with increasing p_{CO_2}, and falls when pH or temperature become higher.

The concepts presented above can account for the phenomena observed in carbonic acid corrosion. First, the damage to production equipment much exceeds that expectable only on the basis of the effect of acidification of the medium by carbon dioxide. Second, the opinion that at pH > 7 there is virtually no danger of steel corrosion under the action of CO_2 in mineralized media is erroneous. Previously, it has been shown for low-carbon steel in carbonate-hydrocarbonate buffer solutions with free access of oxygen [1, 2] that the danger of local corrosion is preserved in the alkaline region. The present study considers in terms of the above-described mechanism of CO_2 action on the metal the variation of the pH of mineralized water (without access of oxygen) with increasing partial pressure of CO_2 in the system or temperature and the influence exerted by this variation on corrosion of low-carbon steel. Attention is also paid to another practically important question concerning the possibility of prognostication of the steel corrosion rate on the basis of partial values of CO_2 and pH in the system.

EXPERIMENTAL

Tests were performed in a 3% solution of NaCl by the procedure accepted in oil and gas industries [25, 26] under steady-state conditions in 6-l autoclaves whose bottom part was filled with 500 ml of the solution. The autoclaves were hermetically isolated from the atmosphere, and purged with nitrogen to remove air and then with a mixture of N_2 and CO_2 under pressure of 0.7–1.0 MPa. The autoclave was thermostated at a temperature of (25–80) ± 2°C. The total duration of an experiment was 96 h. Three 2-cm^2 cylindrical samples of St.3 low-carbon steel were placed in the solution in special holders. Prior to experiments the samples were polished with no. 3–0 sandpaper, degreased with ethanol, and kept in a desiccator over calcined CaO for 24 h. After tests the sample surface was inspected visually under a microscope at 400× magnification and washed with water, corrosion products were removed from the surface with a rubber, and then the samples were weighed. The pH of a 3% aqueous solution of NaCl, stationary potential E_{st}, and corrosion rate V_c were recorded in relation to the time of sample tests in solution at various partial pressures (p_{CO_2} = 0.7–1.0 MPa) and temperature.

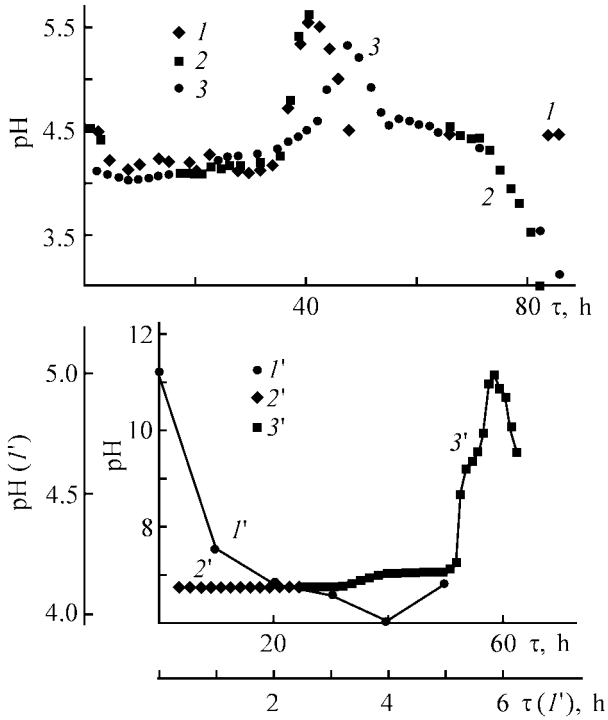

Fig. 1. PH of 3% NaCl solution vs. test time τ. p_{CO_2} (MPa): (*1*) 0.7, (*2*, *3*') 0.8, (*3*) 0.9, and (*1*', *2*') 1.0. *T* (°C): (*1–3*, *1*') 25 and (*2*', *3*') 80.

The corrosion rate was evaluated from the loss of sample mass during an experiment [25]. Changes in the stationary potentials were recorded with a PI-50-1 potentiostat connected to an LKD-4-003 XY recorder. A silver chloride electrode served as reference. The potential was recalculated relative to the standard hydrogen electrode.

Variation of p_{CO_2} in the range 0.7–1.0 MPa strongly affects, as also does the duration of tests, the pH of an aqueous NaCl solution. At a comparatively low p_{CO_2} (0.7 MPa) the pH values are somewhat higher. However, with increasing partial pressure, the solution pH decreases (Fig. 1) only during the initial stage of tests. For example, a rather low pH value of 4.3 is attained at 25°C in tests with duration of up to 5 h in the p_{CO_2} range studied (Fig. 1, curve *1*') because of the occurrence of reactions (1)–(3). The shift of pH to the acid region at 25°C with time (>40 h) (Fig. 1, curves *1–3*) is presumably due to parallel occurrence of reactions (16) and (18). This means that, when the metal is kept in solution for a long time, the solution pH starts to be determined by electrochemical and chemical reactions proceeding on the metal surface and in the near-surface layer.

Table 1. pH of 3% NaCl solution

T, °C	pH value at indicated p_{CO_2}, MPa	
	0.8	1.1
25	4.23	4.06
40	6.91	7.00
60	6.60	6.75
70	6.71	6.75
80	6.74	6.75
90	6.76	6.76

The longer the action of dissolved CO_2 upon the metal, or the more intensive this process, e.g., under the influence of temperature, the larger the amount of corrosion products formed both on the metal surface and in the solution bulk. Accumulation of oxidation products on the metal surface and their subsequent dissolution under the action of HCO_3^- ions [reaction (18)] changes the pH of the medium and enables occurrence of other reactions and reaction (17), in particular. At 80°C and $p_{CO_2} \geq 0.8$ MPa, a higher pH value (6.8–7.0) is observed. This value remains virtually unchanged during 24 h, with subsequent abrupt shift into the alkaline region to pH 11 on keeping the metal in solution for more than 2 days (Fig. 1, curves *2*' and *3*'), which can be regarded as resulting from the occurrence of reaction (17).

It should be noted that, previously, no equally high pH values have been observed in these same systems, modeling the carbon dioxide media at oil and gas fields, on keeping samples in the medium for a shorter time [3, 12, 21]. These data indicate that at least one of the conditions for formation of a protective siderite film is lacking. This means that there is no changeover of corrosion mechanism at 80°C, suggested in [9–11, 18]. It is known [9, 12, 16] that conditions for siderite formation are created at $T > 60$°C, with the film of corrosion products improving its protective properties. Indicative in this regard are the data in Table 1. A characteristic abrupt change in pH is observed at 40°C; beginning with 60°C, raising the temperature has virtually no effect on the pH value, which is presumably due to the change of reactions governing the pH of the medium, occurring at 40–60°C.

The thermodynamic conditions for formation of a dense siderite film are as follows: pH range 6–8, temperature interval 60–100°C, range of potentials –0.5…–0.6 V. Only the first two of these are satisfied in the experiment. In particular, on keeping the electrode for a long time (60–67 h) at $p_{CO_2} \geq 0.8$ MPa and temperature of 80°C, the pH value was 11, and the stationary electrode potential, –0.419 V. The sta-

tionary electrode potential coincides with the potential of γ-Fe_2O_3 oxide formation by the equation [14–16]

$$2Fe_3O_4 + H_2O = 3\gamma\text{-}Fe_2O_3 + 2H^+ + e. \quad (19)$$

The presence of Fe_3O_4 in the oxide film can apparently be attributed to the preceding decomposition of $Fe(OH)_2$ by the reaction

$$3Fe(OH)_2 \rightarrow Fe_3O_4 + 2H_2O + H_2. \quad (20)$$

The stationary potential in the pH ranges 5–6.3 (25°C) and 7–11 (80°C) is described by the equation $E_{rev} = 0.09 - 0.06pH$, which points to the possibility of occurrence of the reaction

$$Fe + CO_3^{2-} \rightarrow FeCO_3 + 2e. \quad (21)$$

The shift of stationary electrode potential at 25°C and p = 0.9 MPa during 10-h tests toward the positive region, from –0.34 to –0.23 V (Fig. 2, curve *3*), may indicate that the ratio of the oxide-hydroxide and carbonate components changes as a result of a change of the order of the occurring reactions (11)–(18). Further stabilization of the potential on keeping the electrode in the medium for a long time might indicate the completion of protective layer formation. However, no stabilization is observed under the experimental conditions: by contrast, at 25°C the stationary potential oscillates with a certain amplitude relative to the horizontal line at E = –0.22 V.

At 80°C the electrode potential shifted from –0.35 to –0.42 V, with increasing partial pressure of CO_2 in the system, and the amplitude of oscillations grew higher in the course of time (Fig. 2, curve *2*'). This points to activation of, in the first place, the cathode process because of the occurrence of reactions (4) and (7), and the related anode process [reaction (18)], changing the film composition, impairing its protective properties, and raising its permeability.

More positive values of the stationary potential, established at 25°C, and the nature of its variation with increasing p_{CO_2} may point to existence of a critical partial CO_2 pressure in the system, above which the concentration of depolarizers in the system does not change. For the system under study this critical pressure is, presumably, 0.8 MPa.

It has been noted previously [11] that a characteristic feature of passivation processes occurring on the iron surface in carbonate corrosion is the existence of a relatively high "corrosivity" threshold, which is to be overcome for a certain corrosion rate to be reached.

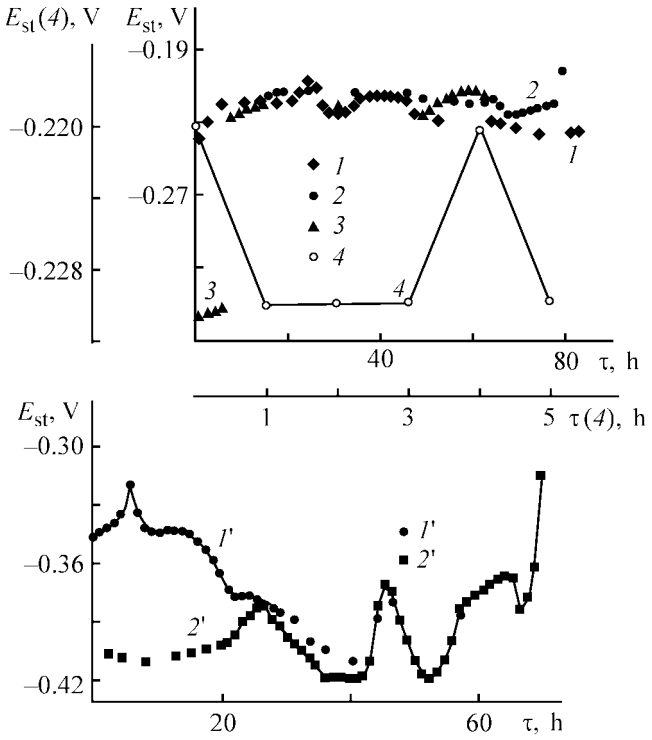

Fig. 2. Stationary potential E_{st} of St.3 steel vs. time τ of tests in 3% NaCl solution. p_{CO_2} (MPa): (*1*, *1*') 0.7, (*2*) 0.8, (*3*) 0.9, and (*4*, *2*') 1.0. T (°C): (*1*–*4*) 2.5 and (*1*', *2*') 80.

This threshold is determined by the "critical corrosion potential," above which a protective layer of deposits starts to be formed. The good solubility of corrosion products makes higher the critical corrosion potential required for the so-called pseudopassive state to be achieved [9, 11]. Presumably, the observed behavior of E_{st} with time at a temperature of 25°C can be related to the onset of the pseudopassivation state, which is not achieved at 80°C.

The positive shift of the stationary electrode potential in the initial period and its decrease and oscillations in the course of time are due to the occurrence of the chemical and electrochemical reactions considered above both directly on the metal surface and in the solution bulk, which leads to growth and subsequent dissolution of carbonate-oxide films on the steel surface. A vast body of data on the nature of films formed on steel in CO_2-containing solutions, summarized in Table 2, has been accumulated [3, 4, 9–17]. Analysis of published data and comparison of these with the results obtained under the experimental conditions shows the following. Films formed on the metal surface in the system under study at 25 and 80°C differ in outward appearance and, presumably, composition. In the course of time, changes in the out-

Table 2. Composition, properties, and formation conditions of films formed on iron and low-carbon steels in CO_2-containing aqueous media

Composition, outward appearance, and properties of a film	Formation conditions	Determination method	Reference
Amorphous phase $FeO \cdot FeCO_3$ (corrosite). Poorly soluble black compound, loose, easily permeable, electrically nonconducting, with magnetic properties	Condensation water of gas-condensate wells, distilled water; as a result of reactions occurring within the adsorption layer and on the metal surface	Analytical	[7]
$FeCO_3$ (siderite). Light gray compound, dense, impermeable, with protective properties	Condensation water of gas-condensate wells, distilled water; as a result of deposition from the near electrode layer	"	[7]
FeC_3 (cementite). Phase with cubic (spinel) structure isomorphic to siderite structure	Synthetic stratal water, g l^{-1}: 17.0 NaCl, 0.14–0.20 $CaCl_2$, 0.20 $MgCl_2$, 0.10–0.80 $NaHCO_3$; p_{CO_2} = 0.4–101 MPa; as a result of reactions occurring within the adsorption layer and on the metal surface	Microprobe X-ray fluorescence analysis, X-ray phase analysis	[20]
Cementite layer	1 M NaCl, pH 3.7–6.2, 70°C, τ = 24 h, p_{CO_2} = 1 bar, E = –0.675 V (standard calomel electrode); as a result of reactions on metal surface	Energy-dispersive X-ray diffraction (EDX)	[23]
Matrix of insoluble steel cementite, filled with siderite	In 1% solutions of NaCl, p_{CO_2} = 1×10^5 Pa, 50°C; as a result of reactions on metal surface	"	[21]
Oxyhydroxide $FeO_x(OH)_{3-2x}$ (as small inclusions in a two-layer film), gray-brown. Intermediate product of α-FeOOH formation. Forms in large amounts at room temperature, and medium amounts at 95°C	Tap water, p_{CO_2} = 0.83 MPa, 95°C; 4% solution of NaCl + 1–14 mg l^{-1}, p_{CO_2} = 0.83 MPa	Micrographic method (SEM)	[22, 23]
Hematite α-Fe_2O_3. Paramagnetic, insulator. Color from brick-red to black	3% solution of NaCl (pH 3.7); 0.55 M NaCl, 0.013 M $CaCl_2$, 0.0062 M $MgCl_2$, 0.005 M $NaHCO_3$ (pH 5), $T \geq 80$°C	Electron-probe microanalysis (EPMA), SEM, EDX	[10, 26]
Lepidocrocite γ-FeOOH. Paramagnetic, insulator. Brown. Transforms into α-FeOOH	3% solution of NaCl (pH 3.7); 0.55 M NaCl, 0.013 M $CaCl_2$, 0.0062 M $MgCl_2$, 0.005 M $NaHCO_3$ (pH 5); τ = 20 h, p_{CO_2} = 0.1 MPa, E = –0.60 V; –0.65 V (SCE); 23, 65, 80°C	"	[10, 26]
Layer of siderite $FeCO_3$. Formed in large amounts at 90°C, and in medium amounts at room temperature. Dense, protective films. Paramagnetic, insulator. Color from yellow to black	1 M NaCl + 3 M $NaHCO_3$ (acidified with HCl), pH 4–6.2, $Fe^{2+} < 5$ mg $^{-1}$, 70°C, 68 h, p_{CO_2} = 1 bar. Tap water p_{CO_2} = 0.83 MPa, 20–90°C; ~100°C, above 150°C	EPMA, SEM, ESCA, EDX	[23, 26]
α-$Fe_2O_3 \cdot H_2O$; magnetite Fe_3O_4 (as inclusions). Ferromagnetic, electrically conducting	Water saturated with CO_2, at T > 180°C; 0.5 M NaCl (pH 3.7); 0.5 M NaCl + 0.0062 M $MgCl_2$ + 0.005 M $NaHCO_3$ (pH 5.0), 80°C; as a result of surface reaction	ESCA	[10, 26]

ward appearance and protective properties, as indicated by stationary potentials and corrosion rates, are observed even at one and the same temperature. The samples are covered, after being kept in the medium for 96 h at 25°C, with a solid black film of corrosion products, probably of oxide-carbonate nature (corrosite), and, after 72 h at 80°C, with a brown-black film of, presumably, hematite or oxide-hydroxide nature, as follows from analysis of the data in Table 2. The solution contains a suspension of brown corrosion products.

It is indicative that the experimental average corrosion rates obtained in the tests are rather high (even at pH 10–11) over the entire range of partial pressures of CO_2 and temperatures. In this case, an increase in p_{CO_2} has virtually no effect on the total corrosion rate of low-carbon steel, found gravimetrically. The insignificant variation of the experimental corrosion rates with partial pressure of CO_2 at constant temperature possibly indicates that there occur no substantial changes in the protective properties of the film. Contrary to expectations, raising the temperature from 25 to 80°C does not exert strong influence on the rise in total rate of steel corrosion in the carbon dioxide medium. Insignificant differences may indicate that, contrary to expectations, a film formed at high temperature has no protective properties and does not prevent activator and depolarizer from penetrating to the metal surface. This is also indicated by the above-mentioned potential oscillations. Thus, with account of the high corrosion rates, values of stationary potential and its oscillations with time, and the outward appearance of the samples, it may be concluded that, under the experimental conditions, no protective film of siderite is formed on the steel surface.

The data obtained on how the corrosion rate varies with time at different partial pressures and pH values furnish an opportunity to consider the problem of prognostication of the corrosion rate of ferrous metals at different p_{CO_2} and pH values for the example of a simple model system. For this purpose, the corrosion rate and pH were calculated for the system under study by the equations proposed previously. In particular, then best-known of these is the de Waard–Milliams equation [18]

$$\log V_c = 7.96 - \frac{2320}{273.2 + T} - \frac{5.55T}{1000} + 0.67 \log p_{CO_2}, \quad (22)$$

where V_c is the average rate of metal corrosion in terms of the corrosion depth factor (mm yr^{-1}), p_{CO_2} is the partial pressure of carbon dioxide (bar), and T is temperature (°C).

Kuznetsov [7] proposed equations for calculating the rate of corrosion, V_c, in the condensation water of gas and gas-condensate wells in the presence of CO_2

$$\log V_c = 0.7493 \log p_{CO_2} - 0.5060, \quad 25°C; \quad (23)$$

$$\log V_c = 0.7493 \log p_{CO_2}, \quad 80°C, \quad (24)$$

and the pH of condensation water

$$\log \mathrm{pH} = 0.6902 - 0.792 \log p_{CO_2}, \quad 25°C, \quad (25)$$

$$\log \mathrm{pH} = 0.7410 - 0.0986 \log p_{CO_2}, \quad 80°C, \quad (26)$$

where p_{CO_2} is the partial pressure of carbon dioxide (bar).

A calculation of the corrosion rate by Eqs. (22)–(24) demonstrated a discrepancy of the calculated and experimental corrosion rates at 25°C, with the former being an order of magnitude lower than the latter.

Only at 80°C, calculation by the de Waard–Milliams equation gives values close to the experimental corrosion rates. At the same time, a satisfactory agreement between the experimental and calculated values at low temperature is obtained for the pH (Table 3). At high temperature the calculated values are lower than the experimental values. Presumably, Eqs. (23), (24), and (26) disregard the influence of corrosion products accumulated on the metal surface and in solution in the case of keeping the metal in the medium for a long time at elevated temperature.

In [11], the problem associated with deposit formation and stabilization of the rate of carbonate corrosion in time was considered. An equation was proposed, relating the initial (V_0) and final (V) corrosion rates to the thickness l of a film on the metal surface

$$\tau = \frac{2l}{R(V + V_0)}, \quad (27)$$

where τ is the test duration, R is "the ratio of molar volumes of iron in the metal and in deposits," depending on the type of deposit (3 for $FeCO_3$ below 60°C, and 4.3 for $FeCO_3$ above 60°C).

Equation (27) disregards changes in p_{CO_2} and pH in the system, but allows calculation of the initial corrosion rate at constant pH and CO_2 pressure from the film thickness and final corrosion rate. With the film thickness taken to be 1 mm [9], calculations by Eqs. (23) and (24) for 25 and 80°C yield for both 25 and 80°C an initial corrosion rate of 25 mm yr^{-1}, i.e., the calculated initial rate of corrosion coincides with the average experimental rate of corrosion (Table 3). In this connection, it should be noted that that the corrosion rate attained in the course of tests is determined by its initial value.

As already noted, an opinion has been formed that the pH range 10–11 is safe as regards corrosion. However, according to the results obtained in the present study, even average values of the total corrosion rate at 25–80°C in aqueous oxygen-free carbon dioxide media remain rather high at p_{CO_2} = 0.7–1.0 MPa and pH 4–11. Previously [1, 2], a high rate of local corrosion has been observed in carbonate–hydrocarbonate buffer solutions at high pH values (10–11).

CONCLUSIONS

(1) The mechanism of the corrosion process occurring on the steel surface in mineralized aqueous media under the action of CO_2 is considered in terms of variation of the pH of the medium.

(2) It is shown that changing the temperature and time of testing in a corrosive medium affects more strongly the variation of the pH of the medium and the rate of steel corrosion, than changing the partial pressure of CO_2 does.

(3) It is demonstrated that high total rates of corrosion of low-carbon steel, determined by the initial rate, are observed in a 3% solution of NaCl at $p_{CO_2} >$ 0.8 MPa and T = 25–80°C. A steel kept at high temperature in the model oxygen-free carbon dioxide medium for a long time is in the active state, with no protective film formed on its surface and danger of corrosion under the action of dissolved CO_2 persisting.

(4) The experimental rates of St.3 steel corrosion in the carbon dioxide medium under study are much higher than those predicted by equations disregarding the growth of a film of corrosion products on the metal surface. This indicates that it is difficult to use these equations for prognosticating the rate of low-carbon steel corrosion on the basis of p_{CO_2} for real systems with metal kept in the corrosive medium for a long time.

(5) The possibility of calculating the pH from the known partial pressure of CO_2 in aqueous oxygen-free media at low temperature is shown.

Abstract—A set of equations, describing the dependence of the activity of supported catalysts on the content of the active component, specific surface area of the support, and preparation method, is proposed. The model is applied to optimize the composition and preparation method of chromium-magnesium-fluoride catalyst for hydrofluorination of chlorohydrocarbons.

A search for new catalyst formulations is commonly conducted by performing a thorough experimental study of their activity in relation to the content of the active components (AC) and specific surface of a support at a chosen preparation procedure. This search can be much accelerated by employing a calculation procedure allowing prognostication of the relationships of interest.

This can be done using Zaidman's [1, 2] inversely proportional dependence of the dispersity of AC, equal to the ratio of the number N_s of its surface atoms responsible for catalysis to their total number N, on the surface concentration c_s ($g_{AC}\ m_{sup}^{-2}$, i.e., the AC concentration related to unit surface area of the support S_{sup} ($m^2\ g_{sup}^{-1}$):

$$1/D = N/N_s = 1 + K_t c_s = 1 + K_t n/S_{sup}, \quad (1)$$

where K_t is the crystallization constant ($m_{sup}^2\ g_{AC}^{-1}$), D is the dispersity, and n is the mass fraction of AC in the catalyst ($g_{AC}\ g_{cat}^{-1}$).

The applicability of this relation has been demonstrated for widely diverse catalysts, Ni, Pt, Pd, Fe, etc., supported by aluminum, silicon, and chromium oxides, with the AC concentration varied widely, between (0.2–2.0) and (0.4–50)%.

However, the calculation of the surface concentration by the formula $c_s = n/S_{sup}$ in [1, 2] disregarded the variation of the fraction of the support itself in the catalyst with the AC concentration. For this reason, the specific surface area of the AC and, consequently, its activity too would have increased steadily with the AC concentration increasing up to 100%. Therefore, as noted in [2], Eq. (1) is valid "at not too high AC concentrations."

However, this dependence commonly shows a maximum for supported catalysts [1–3]. When the maximum is reached, the tendencies for the specific surface area of AC to increase because of its increasing concentration and for the same area to decrease because of the decreasing AC dispersity cancel out each other. Therefore, the model proposed in [4] is based on the equation

$$1/D = 1 + K_t n/[(1 - n)S_{sup}], \quad (2)$$

This model, applying Eq. (2) to supported metallic catalysts, allows, as shown in [4, 5], prognostication of how the specific surface area of a sample and its dispersity, and, consequently its activity too, depend on the AC content of the sample, on the basis of the specific surface area of metal in the sample. However, measuring the AC dispersity (at relatively low AC content of less than 10 wt %) with sufficient accuracy is rather problematic for supported acid-base catalysts, to which belong, for example, hydrofluorination catalysts (chromium hydroxo chlorofluorides) for khladon synthesis. Therefore, a modified version of the given method for prognostication of properties of such catalytic systems is proposed, and its essence is as follows.

Catalyst samples with varied AC content are prepared on the same support with known specific surface area, and their activity is measured. Then the expected dependence of a activity of a catalyst on its AC content is calculated on the basis of the following considerations.

In accordance with the model of [4], the variation of the activity W ($mol\ g_{cat}^{-1}\ s^{-1}$) of the catalyst with the content of AC in it is described by the equation

[1] Reported at 3rd International Conference "Chemistry, Technology, and Use of Fluorine Compounds," St. Peterburg, June 6–9, 2001.

1070-4272/02/7510-1634 $27.00 © 2002 MAIK "Nauka/Interperiodica"

$$W = W_s S_{AC} = W_s S_{max} n/\{1 + K_t n/[(1 - n)S_{sup}]\}, \quad (3)$$

where W_s is the specific catalytic activity of a unit surface area of AC (mol m_{AC}^{-2} s^{-1}), S_{AC} is the specific surface area of AC (m_{AC}^2 g_{cat}^{-1}), and S_{max} is the maximum possible specific surface area of an AC with unit dispersity (m_{AC}^2 g_{AC}^{-1}),

$$S_{max} = 6.02 \times 10^{23}\omega/M_{AC}. \quad (4)$$

Here ω is the surface area of crystallographic face per molecule (or atom) of AC (m^2 $molecule^{-1}$), and M_{AC} is the molecular (or atomic) mass of AC (g mol^{-1}).

The surface area of the crystallographic face is found from X-ray structural data [6] or approximately calculated using the formula

$$\omega = \{[M_{AC}/(d_{AC} \times 6.02 \times 10^{23})]^{1/3}/100\}^2, \quad (5)$$

where d_{AC} is the true density of AC (g_{AC} cm_{AC}^{-3}).

In linearized coordinates, Eq. (3) takes the form

$$n/W = 1/(S_{max} W_s) + [K_t/(S_{sup} S_{max} W_s)][n/(1 - n)]$$
$$= A[n/(1 - n)] + B, \quad (6)$$

$$A = K_t/(S_{sup} W_s S_{max}), \quad (7)$$

$$B = 1/(S_{max} W_s). \quad (8)$$

Provided that W_s (G.K. Boreskov's rule) and the specific surface area of the support are constant, Eq. (6) must be linear.

From the intercept on the ordinate axis in the coordinates of Eq. (6), the coefficient B is calculated and, in its turn, used to calculate in accordance with Eq. (8) the W_s value, which is substituted in Eq. (7) to find K_t.

The results of mathematical processing of experimental data obtained for a wide variety of catalyst in CO_2 hydrogenation on a nickel-chromium catalyst [3], liquid-phase hydrogenation of unsaturated sulfone on an aluminum-palladium catalyst [7], dehydrogenation of cyclohexane on aluminum-molybdenum [8] and aluminum-platinum catalysts [9] are presented in Figs. 1a–1e, respectively. It can be seen that the cal-

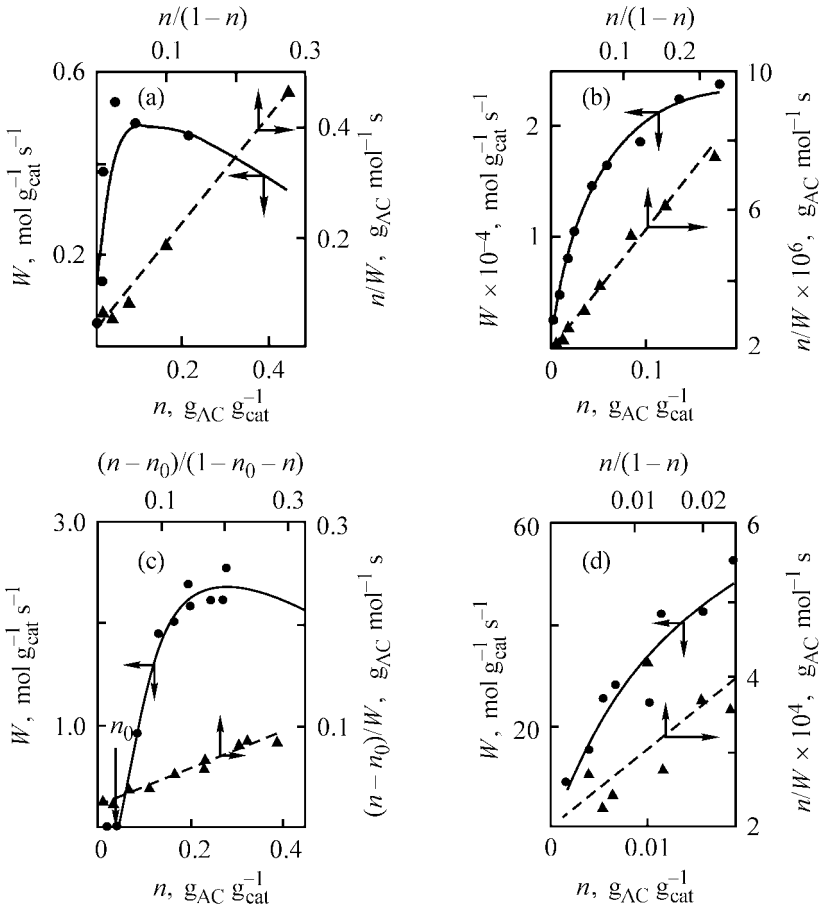

Fig. 1. AC activity W vs. AC concentration n, plotted in the coordinates of Eqs. (3) and (6), in reactions of (a) CO_2 hydrogenation [3], (b) liquid-phase hydrogenation of unsaturated sulfone [7], and (c, d) dehydrogenation of cyclohexane [8, 9]. Catalyst: (a) nickel-chromium, (b) aluminum-palladium, (c) aluminum-molybdenum, and (d) aluminum-platinum.

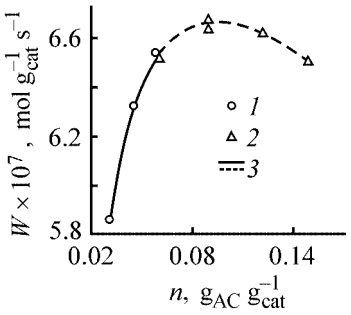

Fig. 2. Activity *W* of chromium-magnesium-fluoride catalyst in hydrofluorination of perchloroethylene vs. AC content *n* in the catalyst. Catalyst preparation method: (*1*) wet mixing [10] and (*2*) method under study; (*3*) calculation by Eq. (3).

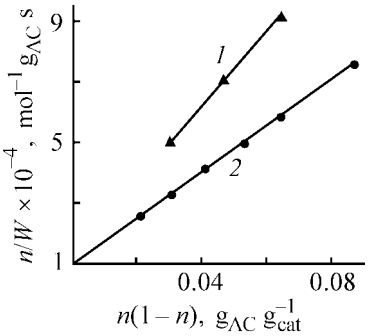

Fig. 3. Activity *W* of chromium-magnesium-fluoride catalyst prepared by the technology described previously in [10] in hydrofluorination of (*1*) polychloroethylene and (*2*) TCP vs. AC concentration *n* ?in the catalyst, plotted in the coordinates of Eq. (6).

culated and experimental values are in good agreement, which furnished an opportunity to apply this optimization method also to chromium-magnesium-fluoride catalysts obtained by the so-called "wet" mixing technique [10, 11]. It should be noted that this technique cannot be used to introduce more than 6.0–6.5 wt % Cr(III) because of the limited solubility of chromium chloride in water.

Results of tests of chromium-magnesium-fluoride catalysts prepared on MgF_2 in synthesis of khladons from polychloroethylene (temperature 380°C, pressure 0.3 MPa, molar ratio HF : C_2Cl_4 = 10 : 1, S_{MgF_2} = 95 m^2 g^{-1})

C(III), mass fraction	*Q*, $g_{C_2Cl_4}$ l_{cat}^{-1} h^{-1}	$\alpha_{C_2Cl_4}$, %	$W \times 10^7$, $mol_{C_2Cl_4}$ g_{cat}^{-1} s^{-1}
3.0	503	69.5	5.86
4.5	506	74.6	6.32
6.0	510	76.6	6.55

Hydrofluorination of perchloroethylene was carried out on these catalysts to obtain khladons 123, 124, and 125.

The catalyst activity *W* (mol g_{cat}^{-1} s^{-1}) was calculated by the formula

$$W = Q\alpha/(\Delta M_{C_2Cl_4} \times 3600 \times 100), \quad (9)$$

where *Q* is the load ($g_{C_2Cl_4}$ l_{cat}^{-1} h^{-1}), α is the conversion of C_2Cl_4 (%), Δ is the bulk density of the catalyst (kg l^{-1}), and $M_{C_2Cl_4}$ is the molecular weight of perchloroethylene.

The results obtained in testing the catalysts in synthesis of khladons by hydrofluorination of perchloroethylene are presented in the table and Fig. 2.

It can be seen from Fig. 2 that, with the above technique used to produce the catalyst, its activity steadily grows with increasing AC content, but does not reach the maximum value.

Processing of the experimental data obtained (see table), plotted in the coordinates of linearized Eq. (6) (Fig. 3), yields the following values of the constants: $B = 1.32 \times 10^4$, $W_s = 1.04 \times 10^{-7}$ mol m_{AC}^{-2} s^{-1} and $A = 1.23 \times 10^6$, $K_t = 8825$ m_{sup}^2 g_{AC}^{-1}.

The optimal content of the active component, n_{max}, in a catalyst, which ensures its maximum activity W_{max}, is found by differentiating Eq. (3):

$$dW_{AC}/dn = S_{max} W_s [1 - 2n - n^2(b-1)]/[1 + n(b-1)]^2, \quad (10)$$

where $b = K_t/S_{sup}$.

At the point of maximum, $dW_{AC}/dn = 0$ and, since $S_{max} \neq 0$ and $W_s \neq 0$,

$$n_{max} = 1/[1 + (K_t/S_{sup})^{1/2}] = 0.094 \ (9.4 \text{ wt \%}). \quad (11)$$

With Eq. (11) substituted into (3), the maximum activity of the catalyst can be calculated by the equation

$$W_{max} = W_s S_{max} n_{max}^2. \quad (12)$$

The calculations performed established that, with a support having a specific surface area of 95 m^2 g^{-1}, the catalyst activity must be at a maximum upon introduction 9.4% Cr(III), which cannot be ensured by the wet mixing method. In this context, it became necessary to develop another way to produce highly concentrated chromium-magnesium-fluoride catalysts.

The tests of catalysts produced by the new technique confirmed the results of calculations (Fig. 3). The use of the model proposed for prognosticating the

properties of supported catalysts allowed prediction and implementation of the possibility of raising their activity. More than that, it was found that the new, more concentrated catalysts have a longer service life because of the possibility of a greater number of regenerations, during which AC is partially lost in the form of volatile compounds of chromium(VI).

Another way to raise the activity of a catalyst is to vary the porous structure of its support, e.g., by making larger the specific surface area of the support.

Figure 4 presents the calculated dependence of the maximum possible relative activity of the catalyst on the specific surface area of the support at the optimal content of chromium fluoride for each value of the specific surface area. For example, raising the specific surface area of the support (magnesium fluoride, in the case in question) from 100 to 200 $m^2\ g^{-1}$ by, e.g., changing the method of its preparation, or raising its thermal stability, may lead to nearly a twofold increase in activity.

This makes understandable the reason for the decrease in the activity of the chromium-magnesium-fluoride catalyst during its operation, which is associated, in the first place, with caking of magnesium fluoride, which lowers the specific surface area under the action of high temperature, especially in the course of regeneration.

The pattern revealed makes it possible to assess the nature of variation of the specific surface area of the AC itself and its dispersity with the catalyst composition. Equation (3) and the W_s value obtained for chromium fluoride were used to calculate its specific surface area S_{CrF_3} ($m^2\ g_{cat}^{-1}$) in relation to the catalyst composition by the formula

$$S_{CrF_3} = W/W_s. \quad (13)$$

The specific surface area of chromium fluoride itself, S'_{CrF_3} ($m^2_{CrF_3}\ g^{-1}_{CrF_3}$), dispersity D, and crystallite size d_{cr} of chromium fluoride (nm) were calculated by the formulas

$$S'_{CrF_3} = S_{CrF_3}/n, \quad (14)$$

$$D = S'_{CrF_3}/S_{max}, \quad (15)$$

$$d_{cr} = 5 \times 10^3/(S'_{CrF_3} d_{CrF_3}). \quad (16)$$

The calculated data are presented in Figs. 5 and 6, whence it can be seen that, with increasing content of the AC in the catalyst, the specific surface area of chromium fluoride itself decreases steadily because of its decreasing dispersity and increasing crystallite size. At the same time, the specific surface area of chromium fluoride (Fig. 5) and its activity (Fig. 2), both related to unit catalyst mass, are the highest at

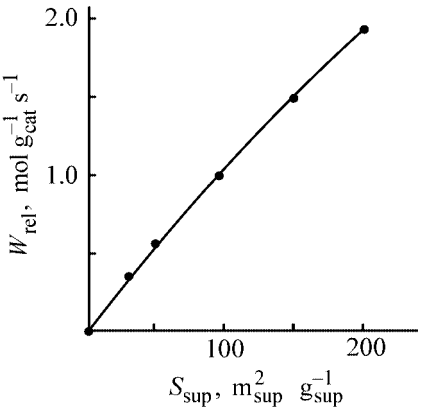

Fig. 4. Relative activity $W_{rel} = W_{max}/W_{max(S_{sup} = 95\ m^2\ g^{-1})}$ of chromium-magnesium-fluoride catalyst vs. specific surface area of magnesium fluoride, S_{sup}, at the optimal content of AC for each value of the specific surface area of the support.

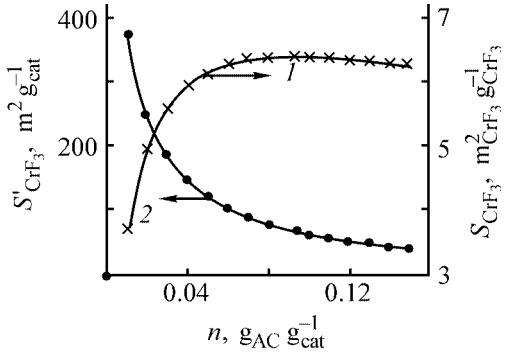

Fig. 5. Specific surface area of chromium fluoride, related to (*1*) unit catalyst mass, S_{CrF_3}, and (*2*) unit mass of chromium fluoride, S'_{CrF_3}, vs. AC content n.

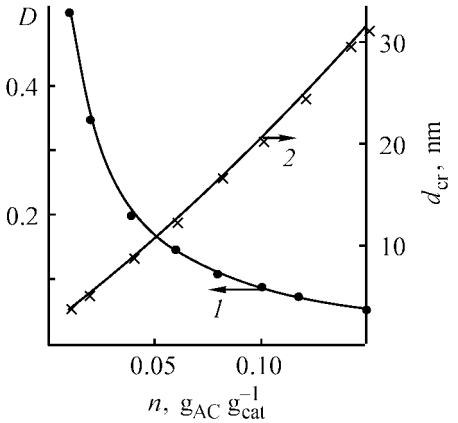

Fig. 6. (*1*) Dispersity D of chromium fluoride and (*2*) size d_{cr} of its crystallites vs. the AC content n of the chromium-magnesium-fluoride catalyst.

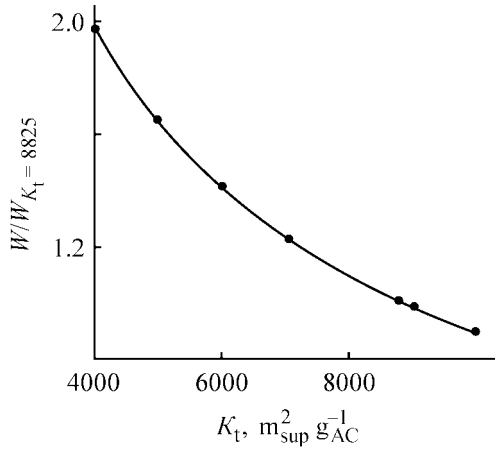

Fig. 7. Relative activity of the chromium-magnesium-fluoride catalyst vs. its crystallization constant K_t for n = 9.4 wt % Cr(III) and S_{sup} = 95 $m^2\ g^{-1}$.

one and the same optimal content of AC, equal to 9.4 wt % Cr(III).

The dispersity of chromium fluoride at its optimal content in the catalyst produced on a standard support with specific surface area of 95 $m^2\ g^{-1}$ is 0.09 (Fig. 6). Thus, only 9% of all the AC atoms are involved in khladon synthesis. Hence follows that the catalyst activity can be raised significantly by making higher the dispersity of magnesium fluoride on the catalyst, e.g., by introducing dispersants into the active phase.

The catalyst preparation conditions may also strongly affect the dispersity and, consequently, the activity of AC. The key factor is the crystallization constant and, whenever possible, it is appropriate to lower it to the minimum (Fig. 7). It can be seen that lowering K_t by half must raise the activity by no less than a factor of 1.5.

Similar dependences were obtained on the same catalyst samples in hydrofluorination of 1,1,1,3-tetrachloropropane (TCP) to trifluoropropene (Fig. 3).

The catalysts were tested in a flow-through reactor under the following conditions: catalyst mass 25–26 g; consumption of TCP and hydrogen fluoride 0.003 and 0.03 mol min^{-1}, respectively; and synthesis temperature 250°C.

The obtained values, K_t = 8694 $m^2_{sup}\ g^{-1}_{AC}$ and optimal AC content of 9.6%, are close to those found previously in studying hydrofluorination of perchloroethylene. This means that the model proposed for prognostication and optimization of the properties of supported catalysts is adequate.

CONCLUSIONS

(1) A calculation procedure for optimizing the composition of supported catalysts with constant specific catalytic activity and prognosticating the dependence of their activity, specific surface area of the active component, and for its dispersity on composition, specific surface area of the support and catalyst preparation method was proposed.

(2) The applicability of the model was demonstrated for the example of supported aluminum-palladium, aluminum-platinum, nickel-chromium, and aluminum-molybdenum catalysts.

(3) Processing the experimental dependences of the activity of the chromium-magnesium-fluoride catalyst in hydrofluorination of hydrocarbons on its composition made it possible to calculate the optimal composition of the catalyst, find a new method for its preparation, and determine how the dispersity of the active component varies with its increasing concentration.

CATALYSIS

Activity of Palladium Catalysts Based on FIBAN K-1 Fibrous Sulfonic Cation Exchanger in Reaction of Hydrogen Oxidation

V. Z. Radkevich and Yu. G. Egiazarov

Institute of Physical Organic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received January, 10, 2002

Abstract—For palladium catalysts based on FIBAN K-1 fibrous sulfonic cation exchanger (Li^+, Na^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Ba^{2+} forms) the dispersity and depth distribution of palladium metal in the fiber and the activity of the catalyst in hydrogen oxidation were studied in relation to the conditions of the synthesis and activation.

We have shown previously that physicochemical and ion-exchange properties of fibrous sulfonic cation exchangers strongly depend on the exchanging cation [1, 2] and that the palladium catalysts based on FIBAN K-1 sulfonic cation exchanger (barium form) exhibit high activity in hydrogen oxidation [3, 4]. However, the effect of the exchanging cation on the reactivity of metal-containing catalysts applied to sulfo cationites has been studied insufficiently.

In this study, we prepared palladium catalysts applied to sulfonic cation exchangers with various exchanging cations and analyzed how the exchanging cation and activation conditions affect the degree of reduction, dispersity, and depth distribution of palladium metal in the fiber and the activity of the catalyst in hydrogen oxidation.

EXPERIMENTAL

FIBAN K-1 fibrous sulfonic cation exchanger (H form) was prepared by radiation-induced bulk grafting of styrene (98%) and divinylbenzene (2%) copolymer to propylene stapel, followed by sulfonation of the resulting matrix with concentrated sulfuric acid [5].

The completely substituted M^{z+} forms of K-1 (M^{z+} = Li^+, Na^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Ba^{2+}) were prepared from the H form by passing 1 N solution of an appropriate metal chloride (taken in excess amount) through a column packed with the ion exchanger until the pH of the filtrate became equal to the pH of the starting solution. After the exchange was complete, the ion exchanger was washed with distilled water until the wash water became free of Cl^- and dried in air at room temperature for 12 h and then at 40°C for 4 h. The sample swelling was determined by centrifugation.

The Li^+, Na^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Ba^{2+} cations were replaced with $[Pd(NH_3)_4]^{2+}$ ion by treating an ion exchanger sample with a calculated volume of a solution of palladium(II) tetrammine chloride (0.001 N), which provided uniform depth distribution of metal in the fiber. The weighed portions of the initial ion exchanger were varied depending on the equivalent weight at a constant volume of the contacting solution, so that, after exchange, the content of palladium(II) tetrammine cations amounted to 1.5% of the exchange capacity in all the samples.

The samples of the ion exchanger were preliminarily kept in distilled water for 30 min (up to complete swelling); then the exchange was performed by addition of a calculated volume of palladium(II) tetrammine chloride with vigorous stirring at room temperature for 30 min. In the process, the pH of the contacting solution was maintained within 8.0–8.5 {$[Pd(NH_3)_4]^{2+}$ is stable in aqueous ammonia at pH ≥ 8.0 [6]}.

The Pd(II) concentration before and after the exchange was monitored spectrophotometrically [7]. Catalysts were reduced with a 10% aqueous solution of hydrazine hydrate (40°C, 30 min), washed with water to neutral reaction, and dried in air at room temperature for 12 h and then at 40°C for 4 h.

The degree of palladium(II) reduction in the cationite samples was monitored by treatment with an excess amount of 1 N NaCl to complete transfer of exchangeable palladium ions into the solution, followed by determination of the palladium(II) content in the solution.

The depth distribution of palladium in the fiber was determined by X-ray fluorescence microanalysis on

an MS-46F Cameca instrument. An X-ray phase analysis (XPA) was performed on a DRON-1 X-ray diffractometer with Cu_{K_α} radiation. For analysis, reference samples containing 1.0 wt% Pd were prepared.

The hydrogen oxidation in the presence of catalysts synthesized was performed in a flow-type glass reactor (inner diameter 20 mm) with automatically controlled electric heating. A 12-cm^3 portion of a compacted catalyst was charged into the reactor (the bed height and weight were 40 mm and 0.9–1.2 g, respectively).

The catalysts were tested as follows. The reaction mixture was fed into the reactor at room temperature, the temperature was raised to 100°C at a rate of 5 deg min^{-1} and kept at this level for 15–20 min, and after that the catalytic activity was determined.

The hydrogen conversion was calculated as the difference between its content in the gas flow before and after the reactor; the hydrogen content was monitored with a Gazokhrom-31 chromatograph.

The specific activity A ($cm^3\ g_{Pd}^{-1}\ s^{-1}$) of palladium was calculated by the formula

$$A = V_{H_2}\alpha/m_{Pd},$$

where V_{H_2} is the rate of hydrogen feed ($cm^3\ g_{cat}^{-1}\ s^{-1}$), α is hydrogen conversion (vol. fraction), and m_{Pd} is the content of reduced palladium in the catalyst ($g_{red.Pd}\ g_{cat}^{-1}$).

The table shows that the content of palladium(II) in catalysts based on ion exchangers with various cations amounts to 0.176–0.250 wt % [the palladium(II) content in one equivalent of the ion exchanger is the same for all samples].

The catalysts are characterized by high degree of Pd(II) reduction (92-98%), but noticeably differ in catalytic activity (see table). Since the degree of palladium reduction is similar in all the samples, this is probably due to different sizes of reduced palladium particles.

Since traditional methods are unsuitable for determining the palladium particle size in catalysts based on organic ion exchangers, the degree of palladium crystallinity was measured by XPA. These data allow estimation of the relative metal dispersity.

The X-ray diffraction pattern of a 1% Pd/Li–K-1 catalyst exhibits sharp narrow reflections with d = 2.234, 1.958, 1.367, and 1.166 Å, characteristic of the crystalline phase of palladium metal. For 1% Pd/Mg–K-1 and 1% Pd/Na–K-1, the reflections are broader, which indicates lower crystallinity of the metal. Cesium, rubidium, calcium, and barium-containing samples are X-ray-amorphous, i.e., palladium is characterized by higher dispersity in these catalysts.

Presumably, the different palladium dispersities are due to the fact that, in the bulk of ion exchangers with different cations, conditions for migration of finely dispersed palladium clusters formed by reduction of the catalyst with an aqueous solution of hydrazine hydrate are different. We believe that the cation size is the major factor. Large cations hinder migration of palladium clusters more strongly than small cations do. In the latter case, the clusters formed can migrate faster to the fiber periphery and aggregate into particles of varied size and degree of crystallinity, depending on the ion exchanger form.

This assumption is confirmed by X-ray fluorescence microanalysis. It follows from Fig. 1a that palladium(II) tetraammine cations in the 1.0% Pd/Ba–K-1 catalyst before reduction are uniformly distributed across the fiber. After reduction, the metal concentration in the fiber periphery increases slightly (Fig. 1b). After activation in a hydrogen flow (100°C, 30 min),

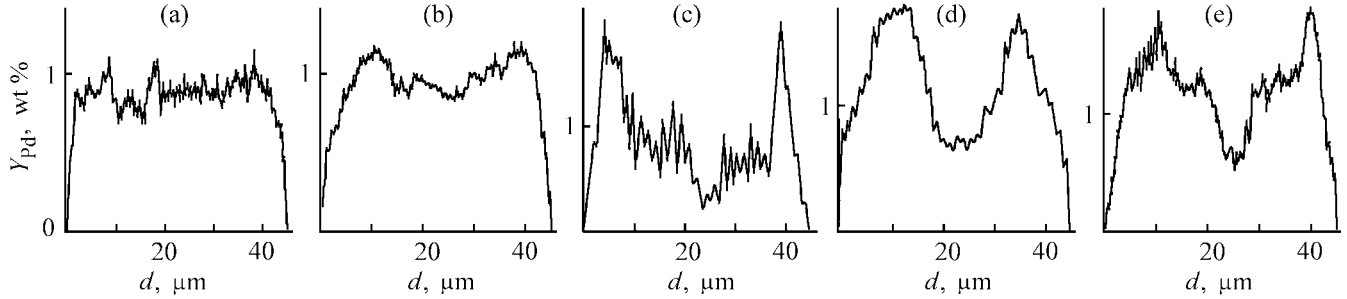

Fig. 1. Depth distribution of palladium in fibers of FIBAN K-1 sulfonic cation exchanger. (Y_{Pd}) Palladium content and (d) coordinate across the fiber. Catalyst based on the Ba form of the ion exchanger: (a) before reduction, (b) after reduction with hydrazine hydrate, and (c) after activation in a hydrogen flow; catalyst based on the Li form of the ion exchanger: (d) after reduction with hydrazine hydrate and (e) after activation in a hydrogen flow.

the main part of palladium concentrates in the ~10 μm surface layer of the fiber (Fig. 1c). Catalysts based on Ca, Rb, and Cs forms of the ion-exchanger behave similarly. Another pattern is observed with a 1.0% Pd/Li–K-1 catalyst. After its reduction with a hydrazine hydrate solution, the major part of palladium is concentrated in the 15–20-μm peripheral layer of the fiber (Fig. 1d). Activation in a hydrogen flow causes no significant changes (Fig. 1e). Similar palladium distribution patterns were obtained for catalysts based on Mg and Na forms of the ion exchanger.

Thus, the data obtained confirm our assumption that the migration of finely dispersed palladium clusters in ion exchangers with small exchanging cations is intense already in the stage of catalyst reduction with hydrazine hydrate solution.

We have shown previously [1] that catalysts containing finely dispersed palladium in the thin surface layer of the fiber exhibit the highest activity in hydrogen oxidation. It follows from the aforesaid that such palladium distribution is characteristic of catalysts based on ion exchangers with relatively large exchanging cations.

The dependence of the catalyst specific activity on the radius of the exchanging cation (Fig. 2) is complex. On the whole, the catalyst activity grows with increasing cation radius. However, a sharp break divides this dependence in two linear portions. This is obviously due to the fact that, along with cation radius, another factor (most likely, the degree of swelling) affects the intensity of migration and aggregation of finely dispersed palladium clusters.

The size of cations and their amount and charge affect the degree of ion exchanger swelling. It follows from the table that the degree of swelling decreases with increasing cation size at the same amount of alkali metal cations. The amount of alkaline-earth metal cations in the ion exchanger is half that of alkali metal ions, which must decrease the volume occupied by them and, hence, make higher the degree of swelling. At the same time, double-charged cations can bind sulfonic groups of different polystyrene chains of the ion exchanger, which must decrease the degree of swelling.

As seen from the table, samples of the ion exchanger in the Li, Mg, and Na forms are characterized by relatively high degree of swelling (130, 91, and 97%, respectively), while for the Ca, Ba, and Cs forms it is substantially lower (from 55 to 65%).

Thus, for the first group of catalysts, based on ion exchangers with small exchanging cations, the high degree of swelling favors more intense migration of palladium clusters, while, for the second group, the low swelling inhibits migration and aggregation, which results in a sharp bend in the activity-cation radius dependence.

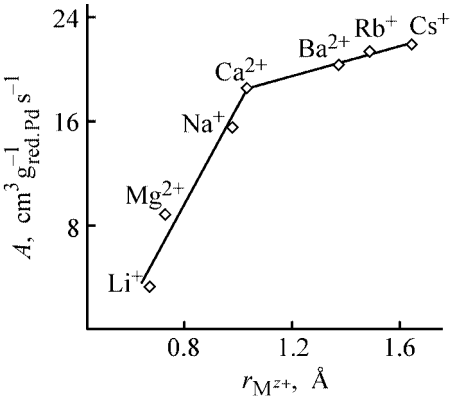

Fig. 2. Specific activity A of catalysts based on various cationic forms of the ion exchanger as a function of cation radius $r_{M^{z+}}$.

CONCLUSIONS

(1) In the stage of reduction with hydrazine hydrate of palladium catalysts based on Li, Na, and Mg forms of the sulfonic cation exchanger, finely dispersed palladium clusters migrate and aggregate into relatively large particles with low activity in hydrogen oxidation. In reduction of the catalysts based on the Ca, Ba, and Cs forms of the ion exchanger, palladium migration is virtually absent.

(2) Activation of reduced catalysts based on the Ca, Ba, and Cs forms of the ion exchanger at 100°C in a hydrogen flow is accompanied by migration of palladium clusters to the periphery of the fiber and formation of highly active particles of finely dispersed metal.

(3) The palladium dispersity and depth distribution in the fiber, which depend on the exchanging cation radius and the degree of the ion exchanger swelling, affect the catalyst activity in hydrogen oxidation.

CATALYSIS

Tin-containing Systems as Catalysts for Deep Oxidation of Hydrocarbons

S. I. Galanov, I. N. Mutas, L. N. Kurina, and V. N. Popov

Tomsk State University, Tomsk, Russia

Received January 30, 2001

Abstract—MO_x–SnO_y (M = Zn, Cu, Co, Mn, Ce) systems were studied in the reaction of deep oxidation of propane and butane.

The development of new methods for full oxidation of hydrocarbons (reverse process, which enables accumulation of the heat of oxidation and catalytic burning of hydrocarbon fuels) imposes strict requirements upon catalysts [1, 2]. A catalyst must (a) induce combustion of a fuel–air mixture at as low a temperature as possible, (b) have activity sufficient for full oxidation to occur at the lowest initial temperature and highest velocity of the gas–air flow, (c) retain its activity at elevated temperature during long service life, and (d) show stable operation in stoichiometric hydrocarbon–air mixtures (containing no excess of oxygen). Catalysts based on platinum metals satisfy the above requirements, being, however, labor consuming in manufacture and expensive, which makes topical a search for active and thermally stable catalytic oxide systems containing no noble metals.

EXPERIMENTAL

The study is concerned with catalysts based on tin dioxide, with equimolar MO_x : SnO_2 ratio, where M = Zn, Cu, Co, Mn, or Ce, obtained by mixing tin(IV) hydroxide and appropriate metal nitrates, drying at 200°C, and calcination in air at 600°C for 3 h. Tin(IV) hydroxide was obtained from a 1 M $SnCl_4 \cdot 5H_2O$ solution by precipitation with 25% aqueous ammonia and subsequent washing to remove chloride ions.

The catalytic properties of the samples obtained were studied on flow-through and flow-through-circulatory catalytic installations with fixed catalyst bed at 100–850°C. The reaction products were analyzed chromatographically on a Tsvet-100 instrument with flame-ionization detector and LKhM-80 chromatograph with katharometer as detector.

The volumetric flow rate of the feed mixture was varied in the range 10 000–20 000 h^{-1}, the concentration of a hydrocarbon (propane or butane) was 1 vol % at stoichiometric content of oxygen and oxygen excess factor α = 1.1, with nitrogen the rest. The thermal stability of the samples was determined by comparing the activities of systems kept in a reaction mixture flow at 600 and 800°C for 100 min.

It is known that tin-containing systems promoted with metals of basic nature are thermally stable catalysts for oxidative dimerization of methane at $T \approx$ 800–850°C [3, 4]. It may be assumed that introduction of metals with variable oxidation state into the SnO_2 structure can give active catalytic systems for deep oxidation of hydrocarbons, which would retain their high catalytic activity at elevated temperature. Mn, Ce, Cu, Co, and Zn oxides, both in individual state and combined with other oxides, are known as active catalysts for full oxidation of hydrocarbons and CO [5, 6], which predetermined their being chosen for synthesis of tin-containing catalysts. As a criterion served, in addition to the high activity, preservation of the catalytic properties of the systems at high temperature (600–800°C) and in operation with mixtures characterized by low content of oxygen.

Pretreatment of tin-containing catalysts with a hydrocarbon–oxygen mixture at 600–800°C changes their activity: the temperatures of 50 and 100% conversion of propane increase (Fig. 1) and the rate of butane oxidation decreases (see table) for Co-, Zn-, and Cu-containing systems. Thermal treatment of Ce- and Mn-containing catalysts changes their specific surface area only slightly, but their activity in oxidation of hydrocarbons grows (see table and Fig. 1), i.e., the catalysts are thermally activated. A similar effect has been observed in full oxidation on manganese ox-

Ce	24.0	21.2	24.0	355.0	16.0	283.5

ides supported by aluminum or zirconium oxide, because of the thermal dispersion of the forming oxides. An increase in the activity of Sr–SnO_x-containing systems as a result of decomposition of strontium orthostannates to give strontium metastannates and oxide has also been observed in oxidative dimerization of methane. Manganese orthostannates formed in preparing catalysts based on the tin–manganese system decompose at elevated temperatures in the reaction medium to give finely dispersed manganese oxides distributed over the surface, which may improve the catalytic activity of the systems [8]:

$$Mn_2SnO_4 \xrightarrow{T} MnSnO_3 + Mn$$

$$\xrightarrow{O_2} MnSnO_3 + Mn_2O_3 + Mn_3O_4.$$

Similar processes may occur in Co- and Cu-containing systems, but the copper and cobalt oxides formed undergo caking at temperatures above 600°C, which makes smaller the specific surface area of the catalysts and impairs their catalytic activity [5, 9].

Together with the maximum conversion of hydrocarbons, achieved at low temperature, factors characterizing the efficiency of catalysts of burning include release of the minimum amount of incomplete combustion products in the reaction. Deep oxidation of hydrocarbons, especially in the case of equimolar mixtures with oxygen, commonly occurs via destruction of an oxidized molecule to give compounds with smaller molecular weight, and their subsequent additional oxidation to CO_2 and H_2O [5].

As seen from Fig. 2, temperature treatment of a Mn-containing system affects its catalytic properties and the extent of butane oxidation. On a sample not treated with the reaction mixture, C_2-hydrocarbons (ethane and ethylene) and methane accumulate in the reaction products with increasing reaction temperature and butane conversion; and only when the 100% conversion of butane is reached, the concentration of C_2-hydrocarbons decreases to zero. Full oxidation of the forming methane only occurs at temperatures exceeding 650°C. Treatment of the catalyst with the reaction mixture at 600°C makes higher the selectiv-

ity of deep oxidation of butane: the content of ethane in the mixture decreases to a minimum, and methane undergoes afterburning at lower temperature. However, the content of ethylene in the reaction products is rather high in the range 300–400°C. Raising the treatment temperature to 800°C (Fig. 2) improves the oxidizing properties of the system, the content of destruction products decreases, and full oxidation is observed at 550°C. Thus, high-temperature treatment of Mn-containing systems, together with making higher their activity (see table), improves the selectivity of full oxidation of hydrocarbons.

In most of catalytic processes for deep oxidation, the highest working temperature is 700–800°C [5, 9], in which context Mn- and Ce-containing systems may be promising catalysts for multipurpose catalytic devices, with the activity of these catalysts increasing in the course of operation.

CONCLUSION

Operation in a stoichiometric hydrocarbon–oxygen mixture at 600–800°C improves the catalytic activity of Mn- and Ce-containing systems.

Received February 19, 2002

Abstract—The effect of modification of ZSM-5 type high-silica zeolites on their acidity and selectivity in formation of lower olefins and arenes in conjugate conversion of propane-butane fraction and methanol was studied.

Low-molecular-weight alkanes convert into higher hydrocarbons at high temperatures (700–850°C) on high-selective catalysts with endothermic effect [1]. By contrast, methanol converts into hydrocarbons on zeolite-containing catalysts with considerable heat evolution, which severely complicates the process design [2]. The process temperature and heat release can be decreased by introduction of methanol into the reaction mixture and choice of a selective catalyst [3]. The zeolite acidity can be controlled by isomorphous substitution of Si atoms in the zeolite skeleton with atoms with effective charge other than 4. Variation of the substituting cation allows construction of acid-base centers with varied strength and selectivity [4].

In this context, the study and development of a process for conjugate conversion of methanol and a broad fraction of light hydrocarbons (BFLH) into olefins and arenes on zeolite-containing catalysts are of interest.

EXPERIMENTAL

High-silica zeolites (HSZ) with silicate ratio SiO_2/Al_2O_3 = 30 and elementoaluminosilicates (EAS) with $SiO_2/(Al_2O_3 + E_nO_m)$ = 30 were prepared hydrothermally from alkaline aluminosilicate gel with introduction of structure-forming organic cation by the method described in [5]. In the EAS synthesis, a part of Al(III) was substituted with B(III), P(V), and Fe(III) and samples B-Al-HSZ, P-Al-HSZ, and Fe-Al-HSZ, respectively, were prepared. The samples of HSZ and EAS were converted into the H form by treatment with a 25% aqueous solution of NH_4Cl for 2 h at 90°C, dried at 110°C, and calcined for 8 h at 550°C (Na_2O content less than 0.1%). An H-B-HSZ sample was prepared by impregnation of HSZ H form with a boric acid solution; the boron content amounted to 2 wt % in terms boron oxide. According to IR spectral and X-ray phase analysis (Mo anode, Ni filter), the HSZ and EAS synthesized were zeolites of ZSM-5 type with 90–95% crystallinity.

As raw material served commercial methanol (produced by Metanol Ltd.) and BFLH containing (wt %): ethane 1.7, propane 61.4, *n*-butane 32.4, and isobutane 4.5. They were converted in a flow-type catalytic device containing a quartz reactor with fixed catalyst bed (5 cm^3, 1–2 mm grains). The overall experimental cycle included three stages: catalyst activation, conjugate conversion of methanol and BFLH, and catalyst regeneration.

The zeolite activation and regeneration were performed in air flow under similar conditions. Preliminary experiments showed that, in the presence of H-HSZ, the optimal methanol : BFLH weight ratio at which the yield of lower olefins is the highest, amounts to 4 : 1. The subsequent experiments were carried out at this ratio. The conjugate conversion of methanol and BFLH was studied within the 500–650°C temperature range. At temperatures higher than 650°C, the yields of CO, CH_4, and coke increase sharply. The initial substances and products were analyzed on an LKhM-80 chromatograph equipped with a thermal conductivity detector.

The acidity of silicates was studied by temperature-programmed ammonia desorption at linear heating

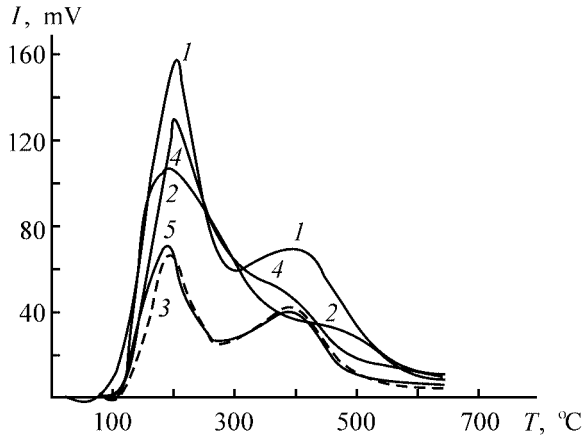
rate of 10 deg min^{-1} [6]. The yields of conversion products and the amount of the acid centers in the catalysts were determined chromatographically with a ±2.5 % error.

It follows from Table 1 that, as the temperature increases from 500 to 650°C, the ethylene and propylene yields grow on all the zeolites studied except iron aluminosilicate, for which the temperature dependences of the ethylene and propylene yields pass through a maximum. The maximal yield of C_2–C_4 alkenes is achieved at 550°C, when their content amounts to 48.0%. The temperature dependence of the yield of butenes has a maximum at 550°C for all of the catalysts studied (Table 1).

B-Al-HSZ show the maximal activity with respect to the yield of C_2–C_4 alkenes: their content reaches almost 60% at 650°C (Table 1). No acetylene and diene hydrocarbons are present in gaseous products of conjugate conversion of methanol and BFLH, which indicates that diene and triene hydrocarbons are hydrogenated into the corresponding olefins in the presence of HSZ and EAS. The low hydrogen yield (less than 0.5 wt %) confirms this suggestion.

As seen, catalysts modified with nonmetals B and P exhibit higher catalytic activity and selectivity in formation of C_2–C_4 alkenes as compared to the initial Pentasil. For instance, at 650°C the ethylene and propylene yield on B-Al-HSZ is higher by 4.8 and 4.1 wt %, respectively, than that on H-HSZ. With H-B-HSZ sample prepared by impregnation, the ethylene and propylene yields increase by 2.6 and 3.8 wt %, respectively, which is comparable with the activity of phosphorus-containing EAS.

With Fe-Al-HSZ, the alkene yield is lower; however, this catalyst exhibits enhanced aromatizing power. The yield of arenes on Fe-Al-HSZ is about 34.5% at 600°C. This is probably caused by formation of new catalytic centers containing iron cations [7]. They can participate in oligomerization of alkenes formed and in further conversion of the oligomers into aromatic hydrocarbons [8].



Temperature-programmed desorption spectra of ammonia adsorbed on various HSZ at 100°C: (*I*) intensity and (*T*) temperature. Catalyst: (*1*) H-HSZ, (*2*) Fe-Al-HSZ, (*3*) B-Al-HSZ, (*4*) H-B-HSZ, and (*5*) P-Al-HSZ.

Such a difference in the catalytic action of the Pentasils studied may be associated with their acid properties. A study of the acid properties of zeolites by temperature-programmed ammonia desorption showed that the temperature-programmed desorption curve obtained with the initial H-HSZ contains two peaks corresponding to two adsorption forms of ammonia: low-temperature form I, corresponding to weak Lewis acid centers with peak temperature T_{max} of 208°C, and high-temperature form II with T_{max} of 411°C, corresponding to strong Brønsted acid centers (see figure). The concentrations of acid centers, determined from the amount of desorbed ammonia, are 683 and 532 μmol g^{-1} for forms I and II, respectively (Table 2).

Nonmetals B(III) and P(V) introduced into the zeolite matrix in the synthesis stage (samples B-Al-HSZ and P-Al-HSZ, respectively) decrease T_{max} of both forms I and II, especially for the boron-containing sample. The concentration of acid centers also sharply decreases, especially that of weak acid centers (form I).

Table 2. Acidity of zeolite-containing catalysts

Catalyst	T_{max} of peak, °C		Amount of acid centers, μmol g^{-1}		
	form I	form II	form I	form II	total
H-HSZ	208	411	683	532	1215
B-Al-HSZ	196	396	259	271	530
H-B-HSZ	208	401	616	308	923
P-Al-HSZ	198	398	210	240	450
Fe-Al-HSZ	201	464	630	237	867

Impregnation of the initial H-HSZ with boric acid changes the shape of the ammonia temperature-programmed desorption spectrum. The H-B-HSZ zeolite gives a spectrum with a pronounced maximum at 208°C and a shoulder at 401°C. Impregnation of the initial H-HSZ with boric acid also lowers the total acidity of HSZ, but mainly due to a decrease in the amount of strong acid centers. Substitution of a part of Al(III) with Fe(III) shifts T_{max} of form I to lower temperature (201°C), and that of form II, to higher temperature (464°C). In this case, the amount of acid centers decreases, especially that of strong acid centers (by more than a factor of two).

Thus, B(III) and P(V) introduced into the zeolite in the stage of hydrothermal synthesis make the strength and concentration of the acid centers lower and the yield of low-molecular-weight alkenes higher. This may be due to a decrease in the acidity of strong Brønsted acid centers of zeolite (form II), on which lower alkenes mainly oligomerize and transform into aromatics. By contrast, iron-containing EAS has sufficiently strong acid centers (form II) able to catalyze formation of aromatic hydrocarbons. It should be noted that the higher selectivity of B-Al-HSZ, compared with HHSZ, with respect to formation of C_2–C_4 alkenes may be due to a change not only in acid properties, but also in the lattice parameters, since the radius of the B atom is substantially smaller than that of the Al atom [9]. It is established that Brønsted centers lying within the zeolite channels [8] play the decisive role in oligomerization and aromatization of olefins. Then, narrower channels make B-AlHSZ more selective with respect to alkene synthesis.

CONCLUSIONS

(1) A relationship was revealed between the acid and catalytic properties of catalysts based on ZSM-5 type zeolites in conjugate conversion of the propane-butane fraction and methanol.

(2) B(III) and P(V) introduced into ZSM-5 zeolites in the stage of the synthesis decrease the strength and concentration of the acid centers and increase the yield of lower olefins C_2–C_4. By contrast, Fe(III) introduced into the zeolite makes the strength of strong Brønsted acid centers higher, which increases the selectivity of formation of aromatic hydrocarbons in conjugate conversion of lower alkanes and methanol.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Fundamental Aspects of Heavy Metal Absorption by Activated-Sludge Microorganisms

I. V. Zykova, V. P. Panov, T. G. Makashova, and A. K. Baigel'dinov

St. Petersburg University of Technology and Design, St. Petersburg, Russia

Received May 29, 2002

Abstract—Patterns of heavy metal absorption by activated-sludge microorganisms were studied, and the possible mechanisms of the process were considered.

Biological treatment of process wastewater contaminated with heavy metals involves accumulation of these latter by activated sludge microorganisms. Understanding of the quantitative aspects of accumulation of heavy metal ions by activated sludge microorganisms is necessary for controlling the treatment process and efficiently extracting heavy metals from excess activated sludge intended for agricultural utilization [1].

A large proportion of the ions accumulated is bound by active segments of cell membranes, and only an insignificant proportion permeates inside the cell. Copper, selenium, aluminum, and iron ions are accumulated on the surface of *Micrococcus*, *Pseudomonas*, *Mycobacterium*, *E. Coli*, and other bacteria. About 90% of the silver ions absorbed are localized in the shell and cytoplasm membrane fractions of *Micrococcus luteus* and *Azotobacter* cultures, and 99% of lead ions, in the cell wall and membrane fraction. Mercury ions, unlike other ions, are bound by a small number of active segments on the cell wall, but these bonds are highly specific [2].

Ions can permeate through a membrane by the mechanisms of facilitated diffusion [Ca(II), Mg(II), Co(II), Mn(II), Cu(II), Ag(I)], primary active transport, or secondary active transport [3, 4].

It has been reported previously [5] that the energy of adenosine triphosphate (ATP) can be spent for transport of Mg(II), Mn(II), and other double-charged ions [5].

However, the available systematic data on the influence of physicochemical factors on the accumulation by microorganisms of metal ions and, in particular, that from process wastewater are insufficient, which motivated this study.

The objects of our investigation were *Pseudomonas* and *Micrococcus* genus microorganisms dominant in the biocenosis of activated sludge from biological treatment plants. We used suspensions of *Micrococcus* and *Pseudomonas* microorganisms containing 1.134×10^8 and 1.017×10^8 cells per liter, respectively. We studied model solutions containing, along with the suspension, Cu(II), Co(II), or Cr(III) ions in appropriate concentrations. The parameters varied were pH, temperature, process time, and initial concentration of metal ions in the model solution. After the experiment, a suspension of microorganisms was separated on a glass frit with pore size of 5–10 μm. The process was monitored by recording the pattern of variation of the metal ion concentration in the aqueous phase, which was determined on a Perkin-Elmer atomic-absorption spectrophotometer by standard procedures.

The microorganisms are saturated with metal ions within 40 min in amounts depending on the initial concentration of the absorbed ions in the model solution. The higher the initial concentration of metal ions, the greater the amount absorbed by the microorganisms within the same period (Fig. 1).

Under the experimental conditions, the metal ions are absorbed by microorganisms to a certain residual concentration varying insignificantly with their initial concentration in water (Fig. 2). Similar results were obtained with *Micrococcus* microorganisms.

We calculated the averaged rate of the metal ion extraction by microorganisms and found that it is at a maximum in the first minutes of the process. The longer the phase contact time, the slower the extraction. The metal ion extraction tends to accelerate with the initial concentration increasing to 60 mg l^{-1}, whereupon raising the concentration of metal ions in the aqueous phase ceases to accelerate their removal by microorganisms.

The primary stage in the extraction of metal ions by microorganisms is their absorption by active segments of the cell surface. Taking this into account, we used our experimental results for plotting the isotherms of adsorption by *Pseudomonas* microorganisms as an example (Fig. 3). The experimental data on the metal ion adsorption by *Micrococcus* microorganisms are presented in Table 1.

The adsorption isotherms suggest that the amount of the metal ions adsorbed, a (mmol m^{-2}), can be described by the Freundlich equation for *Pseudomonas* and *Micrococcus* microorganisms.

$$a = Kc_p^{1/n}.$$

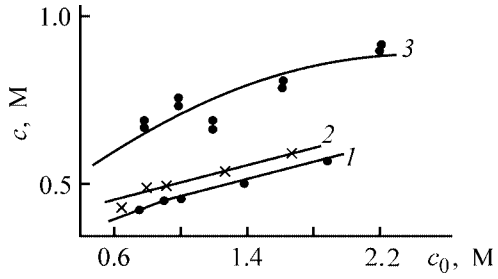

Fig. 2. Residual concentration of metal ions in the aqueous phase, c, vs. initial concentration c_0, in adsorption by *Pseudomonas* microorganisms.

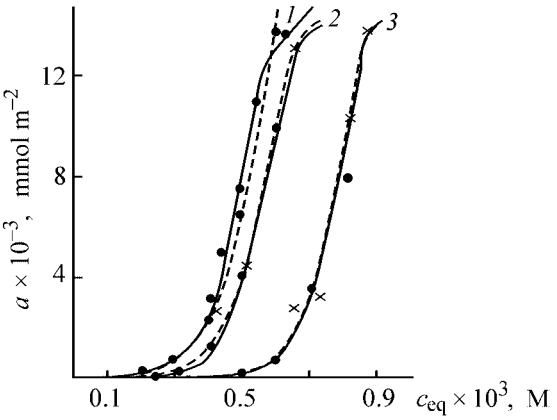

Fig. 3. Isotherms of metal ions adsorption by *Pseudomonas* genus microorganisms at pH 6 and T = 293 K. (a) Adsorption and (c_{eq}) equilibrium concentration.

Here, c_{eq} is the equilibrium (residual) concentration of the metal ion; n and K are constants; K determines in vivo the degree of affinity of the metal for microorganisms [6]. Table 2 lists the coefficients n and K at 293 K and pH 6.0.

0.400	2.41	0.403	1.96	0.677	0.80
0.450	3.46	0.456	2.86	0.750	1.83
0.428	5.12	0.463	4.17	0.715	3.80
0.502	7.41	0.554	6.11	0.831	6.13
0.373	11.47	0.598	8.46	0.808	9.67

Table 2. Coefficients in Freundlich equation*

Coefficient	Cu(II)	Co(II)	Cr(II)	Coefficient	Cu(II)	Co(II)	Cr(II)
K	1.5×10^5 / 5.62×10^4	1.4×10^5 / 1.45×10^5	3.7×10^4 / 5.01×10^4	n	0.188 / 0.245	0.227 / 0.231	0.147 / 0.141

* Numerator is the coefficient for *Pseudomonas*, and denominator, that for *Micrococcus* microorganisms.

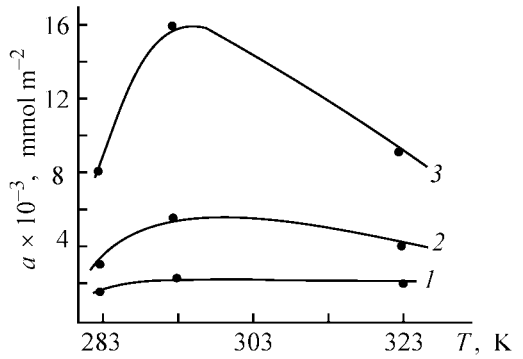

Fig. 4. Metal ion adsorption a by *Pseudomonas* genus microorganisms vs. temperature T. Equilibrium concentration of Cu(II) ions, mM: (*1*) 0.3, (*2*) 0.5, and (*3*) 0.7.

The theoretical adsorption isotherms plotted using the coefficients we determined agree well with the experimental data for both *Pseudomonas* and *Micrococcus* microorganisms in the metal ion concentration range studied, namely, up to 100 mg l^{-1} (Fig. 3, dashed lines). We failed to describe the process by the above-given equation at high *Pseudomonas* concentrations. This may be due to cell lysis with increasing metal ion concentration in the aqueous phase (>100 mg l^{-1}) or to metal ion sorption by *Pseudomonas* microorganisms by other (energy-dependent) mechanisms. *Micrococcus* microorganisms did not exhibit such a phenomenon, evidently, owing to the different structures of the cell shell of Gram-positive and -negative bacteria [7].

As shown by the constants calculated, the metal ions can be ranked, with respect to their affinity for the microorganism surface, in the following order: Cu(II) > Co(II) > Cr(III) for *Pseudomonas* and Co(II) > Cu(II) > Cr(III) for *Micrococcus* microorganisms.

Taking Cu(II) and *Pseudomonas* microorganisms as an example, we studied the accumulation as influenced by temperature varied within 283–323 K, and pH, within 3–9. Using the experimental data, we determined the constants for the Freundlich equation

T	283	293	323
K	3.7×10^4	1.5×10^5	7.3×10^4
n	0.262	0.188	0.184
pH	3	6	9
K	1.1×10^5	1.5×10^5	3.7×10^4
n	0.227	0.188	0.173

A decline in the metal ion adsorption by microorganisms with increasing pH (particularly prominent at pH 6–9) at high concentrations of metal ions in the aqueous phase is evidently due to formation of metal hydroxide species. At pH 3–7, complex metal ions such as $[Cu(H_2O)_3OH]^+$, $[Co(H_2O)_5OH]^+$, etc. are formed, and at pH above 7, formation of precipitates and colloids of metal hydroxides is possible.

The plot of the metal adsorption by microorganisms against temperature has a maximum (Fig. 4) owing to the change in the living conditions for *Pseudomonas* and *Micrococcus* mesophylls.

The results of the experimental study of the patterns of accumulation of Cu(II), Cr(III), and Co(II) ions by activated sludge microorganisms as influenced by various physicochemical parameters allows process control with the aim to achieve the maximal or minimal accumulation of heavy metals by activated sludge microorganisms.

CONCLUSIONS

(1) Microorganisms are saturated with metal ions within 40 min, and the amount of metal ions adsorbed depends on their initial concentration in the model solution.

(2) The primary stage in the extraction of metal ions by microorganisms consists in their adsorption by active segments of the cell surface. This makes it possible to describe the amounts of the adsorbed metal ions by the Freundlich equation for both *Pseudomonas* and *Micrococcus* microorganisms at metal ion concentrations in the aqueous phase within 1–100 mg l^{-1}.

(3) With Cu(II) ions and *Pseudomonas* microorganisms as an example, we studied the accumulation process as influenced by temperature within 283–323 K and pH within 3–9. The optimal conditions for accumulation are T = 293 K and pH 6–7.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Modeling of the Concentration Field of Solid Phase in a Hydrocyclone in Suspension Separation by Pressure Flotation

V. O. Yablonskii and G. V. Ryabchuk

Volgograd State Technical University, Volgograd, Russia

Received October 12, 2001; in final form, February 2002

Abstract—A mathematical model of suspension separation by pressure flotation in a hydrocyclone was developed. The continuity equation was solved numerically for a flux of particles of the solid phase in a flow of a non-Newtonian suspension in a hydrocyclone. The concentration field of solid particles was determined. The effect of the defining similarity criteria on the distribution of concentrations was studied.

Hydrocyclones are used to separate heterogeneous systems in chemical and other industries. Carrying out separation processes in a centrifugal field allows their significant intensification. At present, development of mathematical models of separation processes in a centrifugal field is necessary in order to substantiate theoretically their optimal modes. Modeling of the concentration field in a hydrocyclone for obtaining theoretically substantiated and experimentally verified results should be carried out with the flow hydrodynamics calculated using complete Navier-Stokes equations or equations of rheodynamics of a non-Newtonian fluid.

In [1], the flow structure and separation processes in a hydrocyclone were studied numerically on the basis of Navier–Stokes equations. The transfer of the dispersed-phase momentum was described in terms of the theory of multiple-velocity continuum. It was noted that separation processes in a hydrocyclone with a freely formed surface of the liquid phase had not been described by that time.

At present, pressure flotation is widely used for separation of heterogeneous systems. This process can be carried out most intensively in a centrifugal field. Carrying out the pressure flotation in a centrifugal field in a film flow mode raises the efficiency of separation of finely dispersed suspensions. This was substantiated in [2], where the dependence of the number of possible collisions between particles and bubbles on the centrifugal acceleration was demonstrated and a conclusion was made that the centrifugal field is a factor making greater the number of collisions between particles and bubbles, with the result that the rate of the flotation process becomes higher.

In [3, 4], a procedure for calculating separation characteristics of a hydrocyclone-flotator by solving the equation for the radial motion of a particle–bubble system was proposed. However, these studies disregarded the flow of a suspension being separated in a hydrocyclone with freely formed surface, with the calculation of separation characteristics being only approximate. The flow hydrodynamics of a film of a non-Newtonian suspension in a cylindrical direct-flow hydrocyclone was modeled with the use of complete rheodynamics equations in [5]. The rheological properties of the suspension were described in terms of Ostwald de Ville's power-law rheological equation. Dependences of the fluid film thickness on the axial component, and the velocity and pressure fields in the apparatus at different values of the defining similarity criteria and rheological properties of the suspension were found.

In [6, 7], a conclusion was made that the rheological equation of state of a non-Newtonian fluid, commonly written in the form of Ostwald de Ville's exponential equation, is applicable to multiphase heterogeneous systems. Consequently, the field of solid particle concentrations can be modeled and the basic characteristics of separation by pressure flotation in a hydrocyclone can be calculated using the results obtained in [5] in modeling the flow hydrodynamics of a non-Newtonian suspension in a hydrocyclone with the use of a power rheological law.

To find the concentration distribution of solid particles in a hydrocyclone, analytical expressions were

1070-4272/02/7510-1653 $27.00 © 2002 MAIK "Nauka/Interperiodica"

obtained for the axial and circumferential velocity components (the radial velocity component was neglected, its calculated values being two orders of magnitude smaller than the axial velocity component), together with an expression describing how the suspension film thickness depends on the axial component at certain values of similarity criteria and rheological properties of the suspension. For this purpose, the results of calculations were approximated with analytical expressions in the whole range of variation of the rheological properties of the suspension and of the similarity criteria characterizing the flow.

The approximating dependences for the axial and circumferential flow velocity components were found in the following form:

$$\left.\begin{aligned} H(\bar{r},\bar{z}) &= H_{\max}(\bar{z})\left[1-\left(1-\frac{1-\bar{r}}{\bar{\delta}}\right)^{m}\right] \\ \varphi(\bar{r},\bar{z}) &= \varphi_{\max}(\bar{z})\left[1-\left(1-\frac{1-\bar{r}}{\bar{\delta}}\right)^{l}\right] \end{aligned}\right\} \quad (1)$$

where $H(\bar{r}, \bar{z}) = V_z/U_0$, $\varphi(\bar{r}, \bar{z}) = V_\varphi/U_0$ are the dimensionless axial and circumferential flow velocity components; V_z and V_φ are the axial and circumferential flow velocity components ($m\ s^{-1}$); U_0 is the mean flow velocity in the inlet pipe of the hydrocyclone ($m\ s^{-1}$); $H_{\max}(\bar{z})$ and $\varphi_{\max}(\bar{z})$ are the maximum dimensionless axial and circumferential flow velocities; $\bar{z} = z/R$ and $\bar{r} = r/R$ are the axial and circumferential coordinates; $\bar{\delta} = \delta/R$ is the dimensionless thickness of a suspension film; δ is the film thickness (m); R is the hydrocyclone casing radius; m and l are exponents found by processing the radial profiles of the axial and circumferential flow velocity components by the method of selected points with the subsequent piecewise-linear approximation of the dependences of m and l on the axial coordinate $\bar{z}$.

The approximating dependences for determining $H_{\max}(\bar{z})$ and $\varphi_{\max}(\bar{z})$ have the form of fourth-order polynomials. $H_{\max}(\bar{z})$ and $\varphi_{\max}(\bar{z})$ were calculated using the least-squares method.

To approximate the dimensionless thickness $\bar{\delta}$ of the suspension film as a function of the axial component $\bar{z}$ by integrating the dependence approximating the distribution of the axial flow velocity component along the radial coordinate, a formula was obtained allowing calculation of $\bar{\delta}$ at known $H_{\max}(\bar{z})$ and m for a given cross-section on the basis of the condition that the fluid flow rate is invariable in the axial direction:

$$\bar{\delta} = \frac{m(m+2) - \sqrt{[m(m+2)]^2 - [(m+2)(m+1)-2](m+2)(m+1)\dfrac{\bar{Q}}{H_{\max}(\bar{z})}}}{(m+2)(m+1)-2}, \quad (2)$$

$$\bar{Q} = Q/(\pi R^2 U_0) = (bh)/(\pi R^2). \quad (3)$$

Here $\bar{Q}$ is the dimensionless flow rate, Q is the flow rate of the suspension being separated ($m^3\ s^{-1}$), h is the height of the inlet pipe of the hydrocyclone (m), b is the radial dimension of the inlet pipe (m), and g is the acceleration of gravity ($m\ s^{-2}$).

The axial and circumferential velocity components found by approximating all the quantities appearing in (1) were in good agreement with the results of numerical calculations at arbitrary axial and radial coordinates in that part of the flow for which the calculations were done. The maximum discrepancy of the calculated and approximating values did not exceed 3% for the axial and 5% for the circumferential flow velocity components.

The obtained approximating dependences of the suspension film thickness on the axial coordinate, and of the flow velocity components on the axial and radial coordinates, form a basis for modeling the concentration field in a hydrocyclone and for calculating the principal separation parameters.

The pressure flotation in a centrifugal field can be used to manufacture protein-vitamin concentrates (paprin, gaprin, meprin), obtain suspensions of biomass, syrup, and SiC_3, and purify wastewater to remove oil, grease, and other substances.

The pressure flotation occurs as follows: a preliminarily aerated suspension is fed under elevated pressure (up to 0.8 MPa) into a hydrocyclone tangentially, along the generatrix, through the inlet pipe in the upper part of the hydrocyclone. Inside the hydrocyclone, the suspension flows down circling along its walls, being characterized by the circumferential V_φ, axial V_H, and radial V_r velocity components. When the pressure is lowered to its atmospheric value, the suspension becomes supersaturated with dissolved air and "boils-up." Solid particles move under the action of the centrifugal force to the wall of the hydrocyclone casing, and air bubbles, in the opposite

direction, toward the film surface. Collisions of solid particles with air bubbles give floated complexes carrying solid particles to the film surface into the froth, removed through the upper pipe of the hydrocyclone. The amount of floated complexes formed and their transport toward the film surface are determined by hydrodynamic parameters of the preliminarily swirled suspension film flowing down the vertical cylindrical wall of the hydrocyclone casing under the action of the gravity force and pressure created by the centrifugal force, which, in the end, determines the efficiency of pressure flotation. Clarified suspension is removed from the apparatus through the bottom discharge. The height of the working zone of the hydrocyclone, for which the velocity and pressure fields were calculated in [5], is 30 apparatus casing diameters. According to [5], the swirling motion of the suspension terminates at this distance in all hydrocyclone operation modes and the thickness of the flowing-down film becomes invariable.

The problem was formulated mathematically under the following assumptions [8]: (1) monodispersed air bubbles of equal size, distributed uniformly throughout the film volume, are evolved when aerated suspension is fed into the hydrocyclone; (2) the bubbles are formed along a negligibly small part of the hydrocyclone height during an equally short period of time; (3) there is no coalescence of air bubbles; (4) particles of the substance being extracted are distributed uniformly within the inlet pipe of the hydrocyclone and their concentration at the hydrocyclone inlet is c_{h0}.

The concentration field in separation of finely dispersed suspensions by pressure flotation is modeled mathematically using continuity equations for the fluxes of solid particles and air bubbles. These equations can be written as follows

$$\left.\begin{aligned} V_{rh}\frac{\partial c_h}{\partial r} + V_{zh}\frac{\partial c_h}{\partial z} &= -J_h \\ V_{rg}\frac{\partial c_g}{\partial r} + V_{zg}\frac{\partial c_g}{\partial z} &= -J_g \end{aligned}\right\} \qquad (4)$$

where V_{rh} and V_{zh} are the radial and axial components of the particle motion velocity (m s^{-1}); V_{rg} and V_{zg} are the radial and axial components of the bubble motion velocity (m s^{-1}) c_h and c_g are the concentrations of particles and bubbles in the suspension (m^3 m^{-3}); $J_h = K_h c_g c_h$, $J_g = K_g c_g c_h$ are the intensities of the bulk discharge of particles and bubbles (s^{-1}); K_h and K_g are the kinetic constants of the pressure flotation process (s^{-1}), determined by the number of collisions between solid particles and air bubbles (depending on the solid particle and air bubble diameters and physical properties of solid particles, air bubbles, and dispersion medium) and found, according to [9], under the condition that monoflotation process occurs in the apparatus, i.e., one particle is extracted by one bubble; r and z are the radial and axial coordinates (m); the indices mean the following: h, solid particles; l, dispersion medium; g, gas bubbles.

The system of partial differential equations (4) was solved for two practically important cases.

(1) The concentration of air bubbles much exceeds that of solid particles: $c_g > c_h$. In this case, the second equation in the system (4) can be excluded by taking c_g = const, and the system is reduced to a single equation. In view of the fact that pressure flotation is the most efficient at insignificant difference in density between solid particles and dispersion medium, it can be assumed with sufficient exactness that solid particles move in the axial direction without inertia, i.e., the axial velocities of solid particles and the dispersion medium coincide, $V_{zh} = V_{zl}$. Under this assumption the equation has the form

$$V_{rh}\frac{\partial c_h}{\partial r} + V_{zl}\frac{\partial c_h}{\partial z} = -K_h c_g c_h, \qquad (5)$$

where V_{zl} is the axial component of the flow velocity of the dispersion medium.

(2) The concentrations of gas bubbles and solid particles are equal: $c_g = c_h$. In this case, the first and second equations of the system (4) are equivalent and the system is also reduced to a single equation with account of the fact that $V_{zh} = V_{zl}$:

$$V_{rh}\frac{\partial c_h}{\partial r} + V_{zl}\frac{\partial c_h}{\partial z} = -K_h c_h^2. \qquad (6)$$

The boundary condition for the differential equations (5) and (6) has the form

$$z = 0, \quad R - b \le r \le R, \quad c_h = c_{h0}. \qquad (7)$$

The velocity of radial sedimentation of a particle was found by the formula [10]

$$V_{rh} = \left[\frac{2}{9}\left(\frac{d_h}{2}\right)^{n+1}(\rho_h - \rho_l)V_{\varphi l}^2\frac{\psi(n)}{rk}\right]^{1/n}, \qquad (8)$$

where $V_{\varphi l}$ is the circumferential component of the flow velocity of the dispersion medium; n is the nonlinearity factor of the flow curve for a non-Newtonian dispersion medium described by Ostwald de Ville's law; k is the thickness index (Pa s^n); d_h is the solid particle diameter (m); ρ_h is the density of solid par-

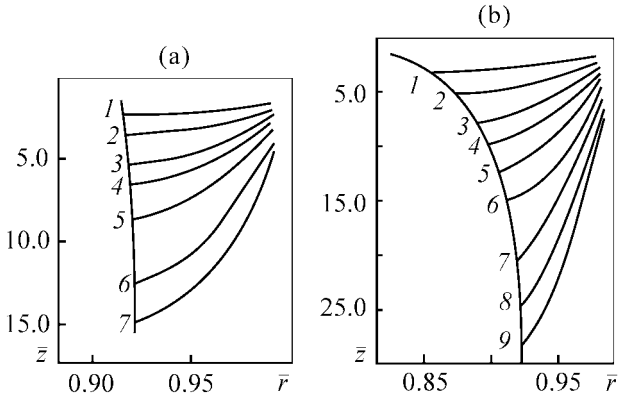

Fig. 1. Distribution of solid particle concentration in suspension film at $Re_n = 4000$, $\bar{Q} = 3.98 \times 10^{-2}$. $(\bar{z}, \bar{r})$ Dimensionless axial and radial coordinates; the same for Figs. 2–5. Fr: (a) 32.6 and (b) 293.6. Isoconcentration lines at $\bar{c}$: (*1*) 0.8, (*2*) 0.6, (*3*) 0.4, (*4*) 0.3, (*5*) 0.2, (*6*) 0.1, (*7*) 0.05, (*8*) 0.02, and (*9*) 0.01.

ticles, and ρ_l, that of the dispersion medium (kg m^{-3}); $\psi(n)$ is the correction factor found from the data presented in [11].

Bringing the differential equations to the dimensionless form with account of formula (8) yields:

$$\frac{\partial \bar{c}_h}{\partial \bar{r}} + \frac{H(\bar{r}, \bar{z})}{\mathrm{Re}_n^d [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} \frac{\partial \bar{c}_h}{\partial z} = -\frac{1}{F_g [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} \bar{c}_h, \tag{9}$$

for the $\bar{c}_g > \bar{c}_h$ case, with $\bar{c}_g$ assumed to be constant, and

$$\frac{\partial \bar{c}_h}{\partial \bar{r}} + \frac{H(\bar{r}, \bar{z})}{\mathrm{Re}_n^d [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} \frac{\partial \bar{c}_h}{\partial z} = -\frac{1}{F_h [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} \bar{c}_h^2, \tag{10}$$

for $\bar{c}_g = \bar{c}_h$. Here $\bar{c}_h = c_h/c_{h0}$ is the dimensionless concentration of solid particles in a suspension flow; $\mathrm{Re}_n^{sed} = \left[\frac{2}{9}\left(\frac{d_h}{2}\right)^{n+1}(\rho_h - \rho_l)\frac{\psi(n)}{Rk}\right]^{1/n} U_0^{\frac{2-n}{n}}$ is the Reynolds number characterizing the sedimentation of a solid particle in a centrifugal field in a non-Newtonian dispersion medium; $F_g = \frac{\mathrm{Re}_n^{sed} U_0}{A_g R}$, $F_h = \frac{\mathrm{Re}_n^{sed} U_0}{A_h R}$ are dimensionless complexes; $A_g = k_h c_g$, $A_h = k_h c_{h0}$ are the modified kinetic constants of pressure flotation (s^{-1}).

The first-order partial differential equations (9) and (10) were solved using the method of characteristics, which reduces a partial differential equation to an equivalent system of ordinary differential equations [12]. This yielded for the case $\bar{c}_g > \bar{c}_h$, under assumption that $\bar{c}_g$ = const, the following

$$\left.\begin{aligned} \frac{\partial \bar{r}}{\mathrm{Re}_n^{sed} [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} &= \frac{\partial \bar{z}}{H} \\ d\bar{r} &= -F_g [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n} \frac{\partial \bar{c}_h}{\bar{c}_h} \end{aligned}\right\} \tag{11}$$

For the case $\bar{c}_g = \bar{c}_h$

$$\left.\begin{aligned} \frac{\partial \bar{r}}{\mathrm{Re}_n^{sed} [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n}} &= \frac{\partial \bar{z}}{H} \\ d\bar{r} &= -F_h [\varphi(\bar{r}, \bar{z})]^{2/n} \bar{r}^{-1/n} \frac{\partial \bar{c}_h}{\bar{c}_h^2} \end{aligned}\right\} \tag{12}$$

The boundary condition (7) for the systems of ordinary differential equations (11) and (12) has the form

$$\bar{z} = 0, \quad 1 - \bar{b} \le \bar{r} \le 1, \quad \bar{c}_{h0} = 1, \tag{13}$$

where $\bar{c}_{h0} = 1$ is the dimensionless concentration of solid particles in the inlet pipe of the hydrocyclone; $\bar{b} = b/R$ is the dimensionless radial dimension of the inlet pipe.

The first equations in the systems (11) and (12) define the trajectory of particle motion in the suspension, which depends on the place of particle entry into the apparatus, i.e., specify the direction of the characteristic, and the second equations determine the values of the function, i.e., the concentrations of solid particles.

The systems of differential equations (11) and (12) were solved by the Runge–Kutta method.

Based on modeling of the velocity and pressure fields in a flow of a non-Newtonian suspension in a hydrocyclone [5] and subsequent approximation of the results obtained, the field of solid particle concentrations in suspension purification in a hydrocyclone by pressure flotation was modeled by solving the systems (11) and (12) of differential equations numerically under the boundary conditions (13) at widely varied values of the defining criteria. The suspension flow in the hydrocyclone was characterized by the centrifugal Froude criterion (separation factor) [5], an analogue of the Reynolds criterion for power fluids, Re_n, and also by the dimensionless flow rate $\bar{Q}$.

The results of mathematical modeling of the concentration field in a hydrocyclone, presented here, refer to the case of $c_g > c_h$ under assumption that c_g = const.

Figures 1a and 1b present the distribution of solid particle concentrations in suspension separation by pressure flotation in a swirling film flowing down

along the hydrocyclone wall at Fr criteria of, respectively, 32.6 and 293.6.

Analysis of Fig. 1a shows that the concentration of solid particles in the suspension being separated decreases along the apparatus axis with increasing distance from the inlet pipe, with the steepest decrease observed near the apparatus wall, which is accounted for by the most complete extraction of particles by air bubbles moving in the opposite direction in the field of centrifugal forces. Along the free surface of the film, the concentration of solid particles also decreases with increasing distance from the inlet pipe, but does so less steeply. The concentration of solid particles also decreases in the radial direction, from the free surface toward the apparatus wall, which is accounted for by capture of particles by air bubbles, to form floated complexes, and their transportation to the free surface. This pattern is preserved at any value of the defining similarity criteria.

When the Fr criterion becomes larger, which is accompanied by an increase in the suspension film thickness [5], the concentration of solid particles in the suspension film grows. This is due to an increase in the number of solid particles per unit length of the film in the axial direction as a result of a rise in the hydrocyclone throughput at higher mean velocity of the suspension, U_0, in the inlet pipe.

The increase in the Fr criterion causes a simultaneous rise in the velocity of radial sedimentation of solid particles and the corresponding increase in the number of collisions of particles with air bubbles and in the number of floated complexes formed, which results in the corresponding increase in the number of solid particles extracted from the suspension [9]. The interaction of these contrary factors predetermines the insignificant change in the concentration of solid particles at the lower boundary of the region for which the calculations are performed and in the extent of recovery upon a change in the separation factor. With the separation factor in the hydrocyclone increased by raising the rate of suspension feed into the apparatus, the flow rate of the suspension being separated and the hydrocyclone throughput can both be made higher. With the separation factor raised by diminishing the radius of the hydrocyclone casing, the apparatus can be made more compact.

Figures 2a and 2b present the distribution of solid particle concentration in the suspension film at Re_n criteria of, respectively, 2260 and 18070. With increasing Re_n, the suspension film thickness [5] decreases because of a decrease in its effective viscosity characterized by the thickness index k. The axial component of the flow velocity grows, and the concentration of solid particles in the suspension film at the lower boundary of the flow region being calculated becomes higher, which is due to the decreasing residence time of solid particles in the separation zone. Consequently, higher extents of recovery can be achieved in separation of suspensions with higher effective viscosity.

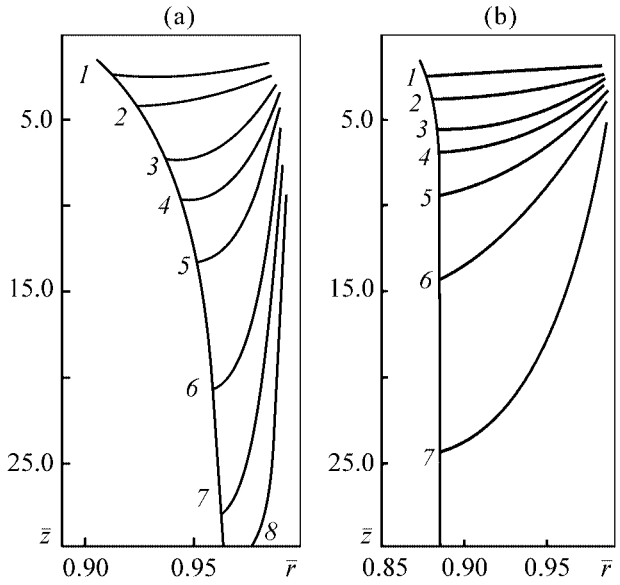

Fig. 2. Distribution of solid particles in suspension film at Fr = 73.4, $\bar{Q} = 3.98 \times 10^{-2}$. Re_n: (a) 2260 and (b) 18070. Isoconcentration lines at $\bar{c}$: (*1*) 0.8, (*2*) 0.6, (*3*) 0.4, (*4*) 0.3, (*5*) 0.2, (*6*) 0.1, (*7*) 0.05, and (*8*) 0.02.

Isoconcentration lines at $\bar{c}$: (a) (*1*) 0.7, (*2*) 0.3, (*3*) 0.1, (*4*) 0.05, and (*5*) 0.01; (b) (*1*) 0.7, (*2*) 0.5, (*3*) 0.3, (*4*) 0.2, (*5*) 0.1, and (*6*) 0.05.

Figures 3a and 3b present the distributions of solid particles in a suspension film at dimensionless flow rates $\bar{Q}$ of, respectively, 3.09×10^{-3} and 99.0×10^{-3}. When $\bar{Q}$ grows, with a simultaneous increase in

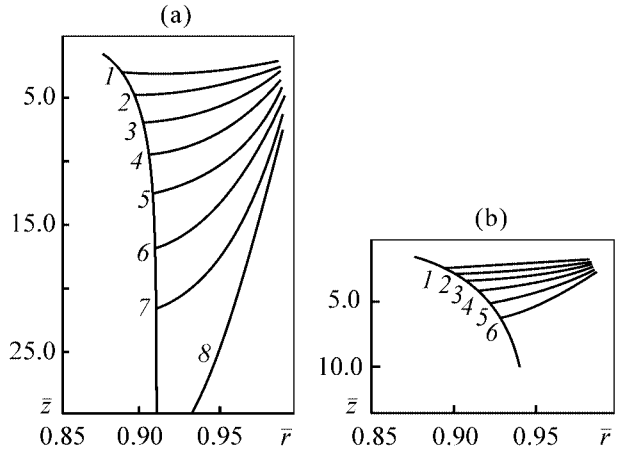

Fig. 4. Distribution of solid particles in suspension film at $F_g = 4.12 \times 10^{-1}$, Fr = 73.4, $Re_n = 4000$, $\bar{Q} = 3.98 \times 10^{-2}$ Re_n^{sett}: (a) 0.763×10^{-3} and (b) 0.970×10^{-2}. Isoconcentration lines at $\bar{c}$: (a) (*1*) 0.9, (*2*) 0.8, (*3*) 0.7, (*4*) 0.6, (*5*) 0.5, (*6*) 0.4, (*7*) 0.3, and (*8*) 0.2; (b) (*1*) 0.5, (*2*) 0.3, (*3*) 0.2, (4) 0.1, (*5*) 0.05, and (*6*) 0.02.

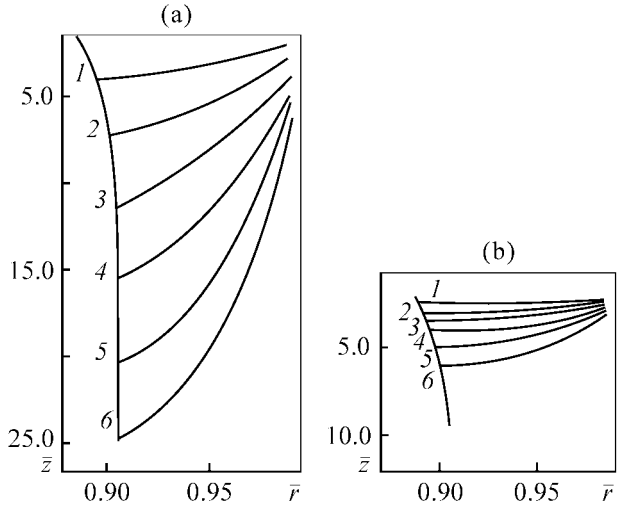

Fig. 5. Distribution of solid particles in suspension film at $Re_n^{sett} = 2.24 \times 10^{-3}$, Fr = 73.4, $Re_n = 4000$, $\bar{Q} = 3.98 \times 10^{-2}$. F_g: (a) 1.35 and (b) 8.98×10^{-3}. Isoconcentration lines at $\bar{c}$: (a) (*1*) 0.99, (*2*) 0.97, (*3*) 0.95, (*4*) 0.93, (*5*) 0.91, and (*6*) 0.89; (b) (*1*) 0.6, (*2*) 0.4, (*3*) 0.2, (*4*) 0.1, (*5*) 0.05, and (*6*) 0.02.

the suspension film thickness [5] (resulting from an increasing ratio of the cross-sectional area of the inlet pipe to that of the apparatus casing), the concentration of solid particles in the suspension becomes higher. This is due to an increase in the number of solid particles per unit suspension film length in the axial direction, resulting from the increasing film thickness. As seen from the calculated data, the necessary height of the working zone of the hydrocyclone is determined by the dimensionless flow rate $\bar{Q}$, characterizing the ratio of the basic geometric dimensions of the inlet pipe and the apparatus casing, and by the desired extent of recovery at the exit from the working zone of the hydrocyclone. This is so because analysis of Figs. 1–3 shows that the strongest change in the field of solid particles in the suspension film is observed when varying the dimensionless flow rate $\bar{Q}$.

In addition to the criteria characterizing the flow hydrodynamics, the process of separation of a non-Newtonian suspension in a hydrocyclone by pressure flotation is characterized by the Reynolds criterion Re_n^{sed} describing solid particle sedimentation in a non-Newtonian fluid and by dimensionless complexes F_g for the case $\bar{c}_g > \bar{c}_h$, $\bar{c}_g$ = const and F_h for the case $\bar{c}_g = \bar{c}_h$, characterizing the kinetics of pressure flotation.

Figures 4a and 4b presents the distributions of solid particle concentration in the suspension film at Re_n^{sed} of, respectively, 0.763×10^{-3} and 0.970×10^{-2}. Comparison of the concentration distributions shows that, with increasing criterion Re_n^{sed}, which characterizes the ratio of the centrifugal inertia force acting on solid particles to viscous friction forces, the concentration of solid particles in the suspension film decreases. This is accounted for by the fact that, with the velocity of radial sedimentation of solid particles growing because of the increase in the centrifugal inertia force or decrease in viscous friction forces, the particles travel to a longer distance in the fluid in unit time and, as a result, the number of their collisions with air bubbles becomes greater. Thus, with increasing diameter and density of solid particles and with decreasing effective viscosity of the dispersion medium, the extent of particle extraction at the lower boundary of the calculated flow region grows.

Figures 5a and 5b present the distributions of solid particle concentration in a suspension film at F_g complexes of, respectively, 1.35 and 8.98×10^{-3}. Comparison of the concentration distributions shows that, with decreasing complex F_g characterizing the kinetics of pressure flotation, the concentration of solid particles in the suspension film decreases owing to the growing number of collisions between solid particles and air bubbles. This occurs because of an increase in the modified rate constant of the process of pressure flotation, A_g, which characterizes the number of collisions of particles and bubbles in unit time or an increase in the Re_n^{sed} criterion appearing in the complex F_g. The influence of this criterion on the concentration field was analyzed above. Consequently, the rate of suspension input into the hydrocyclone in pressure flotation, appearing in the complex F_g and determin-

ing the throughput of the apparatus, must be determined by the rate constant of the process, which depends on a number of factors characterizing the process [9], and by the necessary extent of recovery at the exit from the working zone of the hydrocyclone.

According to the calculated data obtained, the same basic patterns of variation of the solid particle concentration on changing the defining similarity criteria (at higher concentrations of solid particles) are valid for the case $c_g = c_h$, which is accounted for by lower concentration of air bubbles in unit suspension volume and the resulting formation of a smaller number of floated complexes. Consequently, the height of the working zone in the hydrocyclone should be raised in this case compared with the case of $\bar{c}_g > \bar{c}_h$, $\bar{c}_g$ = const.

CONCLUSIONS

(1) A mathematical model of pressure flotation of a non-Newtonian suspension in a centrifugal field, based on continuity equations for fluxes of solid particles and air bubbles in a flow of a film of a non-Newtonian suspension with free surface in a hydrocyclone, was developed.

(2) For two practically important cases, which occur depending on the ratio of concentrations of solid particles and air bubbles, the effect of defining similarity criteria on the distribution of solid particle concentration in the film of a non-Newtonian suspension was studied.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidant Properties of Unsymmetrical Sulfides Based on ω-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)alkanethiols

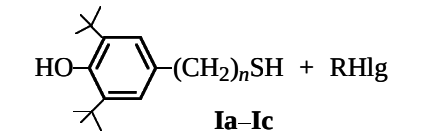
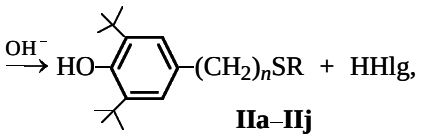
Received January 10, 2002

Abstract—Unsymmetrical sulfides were prepared by reactions of ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-alkanethiols with various alkyl halides, and their antioxidant activity with respect to thermal autooxidation of lard was studied in relation to their structure.

SO-3 antioxidant {bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfide} is a well-known high-performance versatile inhibitor of oxidative degradation of organic and bioorganic substrates [1–4]. It is a bifunctional antioxidant; its molecule contains two phenolic moieties exhibiting antiradical activity and one sulfide moiety with antiperoxide activity. It has been shown previously that, with respect to some model systems, the antioxidant activity (AOA) of SO-3 is lower than that of its structural analogs containing the same number of sulfide and phenolic fragments [4–6]. In this connection, we prepared from ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkanethiols **I** and alkyl halides a series of unsymmetrical sulfides **II** and compared their antioxidant power with respect to oxidation of lard as a model reaction:



Ia–**Ic**



IIa–**IIj**

where n = 2 (**Ia**), 3 (**Ib**), 4 (**Ic**); n = 2, R = Bu (**IIa**); n = 3, R = Me (**IIb**); n = 3, R = Et (**IIc**); n = 3, R = Pr (IId); n = 3, R = Bu (**IIe**); n = 3, R = *s*-Bu (**IIf**); n = 3, R = *t*-Bu (**IIg**); n = 3, R = $C_{18}H_{37}$ (**IIh**); n = 3, R = CH_2Ph (**IIi**); n = 4, R = Bu (**IIj**).

The initial thiols **Ia**–**Ic** were prepared from the corresponding alkyl halides as described in [7]. The reactions of thiols **I** with primary and secondary alkyl halides were performed in ethanol in the presence of NaOH at approximately equimolar ratio of the reactants. The yields of sulfides **IIa**–**IIf** and **IIh**–**IIj** were 72–86%.

There were certain problems with synthesis of the *tert*-butyl sulfide **IIg**. This compound could not be prepared from **Ib** and 2-chloro- or 2-bromo-2-methylpropane under the above-described conditions because of vigorous dehydrohalogenation and evolution of 2-methylpropene. Sulfide **IIg** could be prepared in 43% yield only in the absence of bases at 150°C and elevated pressure (sealed ampules).

The composition and structure of all the compounds **II** were confirmed by elemental analysis and spectroscopy.

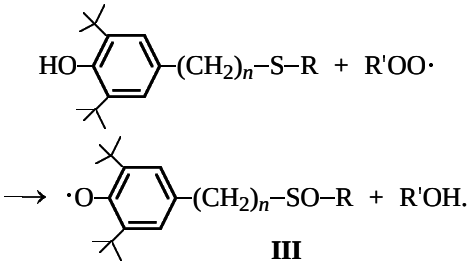
The relationship between the structure and the antioxidant power was studied for sulfides **II** with thermal autooxidation of lard as a model reaction. As references we used SO-3, Ionol (2,6-di-*tert*-butyl-4-methylphenol), and a 1 : 1 mixture of Ionol with didodecyl sulfide. The rate of lard oxidation was monitored by accumulation of primary oxidation products (hydroperoxides), and the AOA was judged from the induction period τ (time in which the lard was oxidized to a peroxide number of 0.1). The results are obtained listed in the table.

All the sulfides **II** synthesized exhibited pronounced AOA, surpassing that of both Ionol and its mixture with didodecyl sulfide. The striking lack of synergistic effect in this mixture is most probably due to specific features of lard as oxidation substrate.

1070-4272/02/7510-1660 $27.00 © 2002 MAIK "Nauka/Interperiodica"

It is known [9] that lard contains a large amount of unsaturated fatty acid residues [in particular, oleic (41–54%), linoleic (5–16%), and linolenic and arachidonic (up to 2%)] whose hydroperoxide derivatives are thermally unstable. Because of the relatively high oxidation temperature in our model system, the rate of decomposition of hydroperoxides appears to be considerably higher than the rate of their reaction with didodecyl sulfide; as a result, the antioxidant effect of didodecyl sulfide is not manifested, and AOA of the synergistic mixture of Ionol and dodecyl sulfide is determined essentially by the antiradical activity of Ionol. Since neither SO-3 nor its structural analogs surpass Ionol in the antiradical activity [10], their high AOA can be accounted for only by the internal synergism (bifunctional antioxidant activity).

The internal synergism of SO-3, sulfides **II**, and their structural analogs [11, 12] is probably due to the favorable steric arrangement of the phenolic and sulfide moieties, owing to which the hydroperoxide molecule formed by reaction of the generated radical with the phenolic group of the inhibitor is activated by the sulfide moiety, having no time to escape to the bulk of the substrate:



III

Thus, the reaction of the antioxidant with an active radical yields a thermally stable alkanol instead of hydroperoxide acting as a chain-branching agent.

According to the generally accepted mechanism of the effect of phenolic antioxidants, phenoxyl **III** can react with peroxy radical to form quinoid peroxide **IV** or quinone **V**, with the former pathway presumably being preferable [13]:

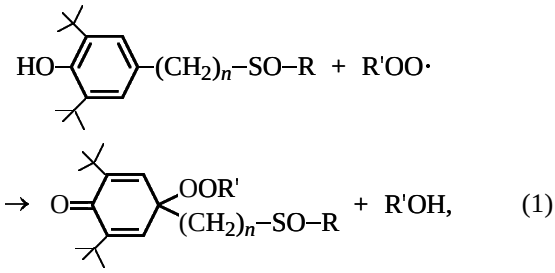
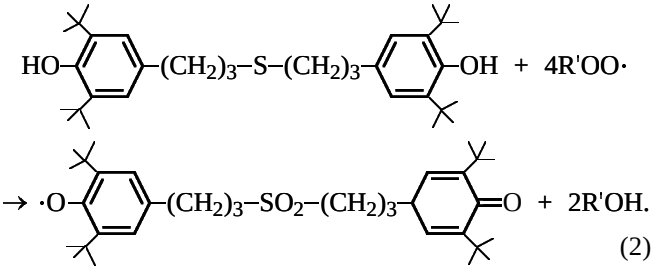
* R = 3,5-di-*tert*-butyl-4-hydroxyphenyl.

In this connection, the oxidative transformations of sulfides **II** and SO-3 in reactions with peroxy radicals can be represented by schemes (1) and (2), respectively:



(1)



(2)

Under the conditions chosen by us for oxidation of lard, the antioxidant activities of SO-3 and sulfides **II** are similar (the induction periods differ by no more than 20%), which is quite consistent with the assumed mechanism [reactions (1), (2)]. Despite the lower sulfur content in SO-3, its sulfide moiety, similar to

that in unsymmetrical sulfides **II**, is capable of deactivating all the hydroperoxide molecules formed with the participation of the phenolic groups of the antioxidant. Therefore, SO-3 and sulfides **II** exhibit similar degrees of internal synergism. The capability of sulfoxide **IV** to reduce a second hydroperoxide molecule formed in the substrate without participation of the antioxidant does not contribute noticeably to the inhibiting effect, as shown by data on the antioxidant activity of didodecyl sulfide (see table).

Among sulfides **II**, sulfide **IIj** appeared to be the most effective as inhibitor of lard oxidation; AOA grew in the order **IIa**–**IIe**–**IIj**, i.e., with increasing number of methylene units linking phenolic and sulfide moieties [10]. The effect of alkyl substituent R on AOA of sulfides **II** is most probably determined by its electron-donor power. For example, there is a reliably detected trend toward an increase in the antioxidant activity in the order **IIe**–**IIf**–**IIg** and in going from **IIb** to **IIc**, i.e., with an increase in the electron density on the sulfur atom and, hence, in the reactivity of the sulfide moiety toward hydroperoxides.

On the whole, sulfides **IIa**–**IIj** can be considered effective polyfunctional antioxidants.

EXPERIMENTAL

The ^{1}H NMR spectra were taken on a Bruker spectrometer (500 MHz, $CDCl_3$, external reference TMS), and the IR spectra, on a Vektor 22 Fourier spectrometer [neat samples, CCl_4 solutions, or KBr pellets (150 : 1).

The melting points were determined with a PTP device.

Butyl 2-(3,5-di-*tert*-butyl-4-hydroxyphenyl)ethyl sulfide IIa. 1-Chlorobutane (1.9 ml, 18.3 mmol) was added dropwise at room temperature to a solution of 4.5 g (16.9 mmol) of thiol **Ia** and 0.71 g (17.7 mmol) of NaOH in 25 ml of ethanol. The mixture was refluxed for 2 h, cooled, and treated with toluene. The extract was washed with water and dried over Na_2SO_4; the solvent was distilled off, and the residue was vacuum-distilled. Yield of sulfide **IIa** 4.03 g (74%), bp 159–161°C (1 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.01–1.04 t (3H, $CH_2\underline{Me}$), 1.51–1.53 m (2H, $C\underline{H}_2Me$), 1.55 s (18H, *t*-Bu), 1.68–1.69 m (2H, $C\underline{H}_2Et$), 2.63–2.66 t (2H, $SC\underline{H}_2Pr$), 2.87–2.90 m [4H, $Ar(C\underline{H}_2)_2S$], 5.17 s (1H, OH), 7.12 s (2H, Ar–H). IR spectrum (KBr), ν_{max}, cm^{-1}: 3646 (PhOH).

Found, %: C 74.63, H 10.78, S 10.17.
$C_{20}H_{34}OS$.
Calculated, %: C 74.47, H 10.62, S 9.94.

Methyl 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfide IIb was prepared similarly to **IIa** from 5 g (17.8 mmol) of thiol **Ib** and 1.2 ml (19.2 mmol) of iodomethane; yield 4.11 g (78%), bp 145°C (1 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.40–1.43 s (18H, *t*-Bu), 1.89–1.90 m (2H, $ArCH_2C\underline{H}_2$), 2.10 s (3H, S–Me), 2.51–2.54 t (2H, $CH_2S\underline{Me}$), 2.61–2.64 t (2H, $ArC\underline{H}_2$), 5.04 s (1H, OH), 6.98 s (2H, Ar–H). IR spectrum (KBr), ν_{max}, cm^{-1}: 3644 (PhOH).

Found, %: C 73.47, H 10.32, S 11.06.
$C_{18}H_{30}OS$.
Calculated, %: C 73.41, H 10.27, S 10.89.

Ethyl 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfide IIc was prepared similarly to **IIa** from 5 g (17.8 mmol) of **Ib** and 1.5 ml (18.5 mmol) of iodoethane; yield 4.0 g (73%), bp 150–151°C (1 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.23–1.26 t (3H, $CH_2\underline{Me}$), 1.43 s (18H, *t*-Bu), 1.85–1.91 m (2H, $ArCH_2C\underline{H}_2$), 2.53–2.57 m (4H, CH_2SCH_2), 2.61–2.63 t (2H, $ArC\underline{H}_2$), 5.03 s (1H, OH), 6.98 s (2H, Ar–H). IR spectrum (thin film), ν_{max}, cm^{-1}: 3645 (PhOH).

Found, %: C 73.84, H 10.51, S 10.55.
$C_{19}H_{32}OS$.
Calculated, %: C 73.97, H 10.45, S 10.39.

Propyl 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl sulfide IId was prepared similarly to **IIa** from 5 g (17.8 mmol) of thiol **Ib** and 2 ml (22.6 mmol) 1-chloropropane; yield 4.32 g (75%), bp 155–157°C (1 mm Hg). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.96–0.99 t (3H, $CH_2\underline{Me}$), 1.39–1.47 s (18H, *t*-Bu), 1.58–1.62 m (2H, $C\underline{H}_2Me$), 1.86–1.89 m (2H, $ArCH_2C\underline{H}_2$), 2.47–2.55 m (4H, CH_2SCH_2), 2.61–2.64 t (2H, $ArC\underline{H}_2$), 5.03 s (1H, OH), 6.98 s (2H, Ar–H). Lard was oxidized at 130°C in an oxidation cell with bubbling oxygen, as described in [14]. The amount of lard placed in the cell was 50 g, and the concentration of antioxidants, 1 μmol per gram of lard. The progress of oxidation was monitored

by accumulation of peroxide compounds whose concentration was determined iodometrically [15] and expressed in peroxide numbers. The initial peroxide number of the lard was 0.002% iodine. The induction periods were determined graphically from the kinetic curves.

CONCLUSIONS

(1) The alkyl ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkyl sulfides synthesized exhibit high inhibiting activity, which is due to the bifunctional mechanism of the antioxidant effect and to the internal synergism.

(2) Under the conditions of the model reaction used in this study, the antioxidant activity of the sulfides grows with increasing length of the hydrocarbon chain linking the phenolic and sulfide moieties and with increasing electron-donor power of the aliphatic substituent.

(3) The compounds synthesized are of interest as antioxidants preventing development of oxidation processes in fats.

Abstract—The methods of the Kerr effect and solution hydrodynamics were applied to study the electrooptical and hydrodynamic properties of samples of disubstituted polyacetylenes, poly(1-trimethylsilyl-1-propynes), prepared by polymerization of 1-trimethylsilyl-1-propyne with $NbCl_5$ and $TaCl_5$/BuLi as catalysts. The experimental electrooptical characteristics of polymers were compared with those calculated by PM3 semiempirical quantum-chemical method.

1,2-Disubstituted polyacetylenes catalytically synthesized from the corresponding derivatives of acetylenes [1–3] are used in new membrane technologies [4, 5] and show promise for establishing the microstructure–properties correlation in polymer physics. The reason is that synthesis of these compounds can yield *cis* or *trans* blocks of regular sequences of double carbon–carbon bonds, since the main chain of these polymers is built from alternating ordinary and double bonds $–[–C(CH)_3=C(R)–]_n$. Masuda *et al.* [1, 2, 6] showed that halides of Group V and VI elements are suitable as catalysts for preparing organometallic disubstituted polyacetylenes, in particular, poly(1-trimethylsilyl-1-propynes) (PTMSPs) with $R = –Si(CH)_3$, which are the subjects of this study. It was found that different catalysts yield polymers differing in the solubility in organic solvents, as well as in the molecular weight *M*, heat resistance, and glass transition temperature [6]. This variability of the physical properties of PTMSPs motivated a study of the microstructural features of the chains of these polymers as dependent on the synthesis conditions. However, traditional approaches to solving this problem proved hardly applicable. For example, X-ray diffraction analysis of films with the aim to determine the stereoregular structural elements was found to be inefficient. This is due to the fact that PTMSP samples synthesized using various catalytic systems are noncrystallizing polymers with virtually identical percentages of *cis–trans* configurations of the C=C bonds in the chains [4, 7].

Revealing the microstructural features of the PTMSP molecules required a method sensitive to the degree of intramolecular ordering of the chemical bonds in polymer chains. In polymer physics, such experimental methods include those involving measurements of the induced optical anisotropy of polymers in solutions. These methods show good performance in studying the physical properties of stereoregular polymers with different tacticities [8].

In this work, we studied the optical anisotropy induced by an external electric field (electrooptical Kerr effect) in solutions of PTMSP samples prepared using tantalum and niobium salts as catalysts. Also, we compared the conformational characteristics of these polymers, on the basis of the results obtained in diffusion and sedimentation analysis of their solutions.

The PTMSP samples were synthesized by the procedure described in [6]. Table 1 summarizes the conditions of catalytic synthesis, *M*, and the *cis–trans* ratio for C=C bonds in the PTMSP samples synthe-

Table 1. Conditions of synthesis of PTMSP-1 and PTMSP-2 samples

Sample	Catalytic system	*cis–trans* ratio for C=C bonds	$M \times 10^3$
PTMSP-1	$NbCl_5$	60 : 40	159
PTMSP-2	$TaCl_5$/BuLi	40 : 60	1340

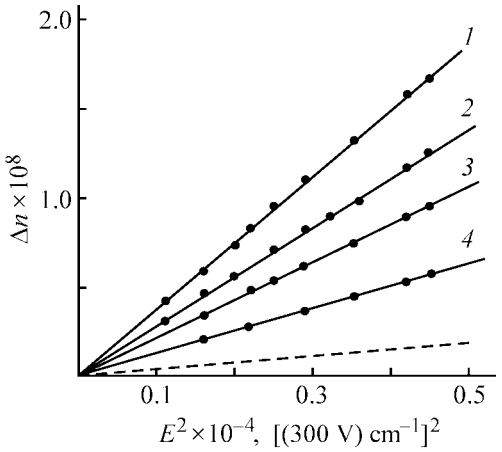

Fig. 1. Birefringence Δn vs. squared field intensity E^2 for PTMSP-1 fraction no. 1 in CCl_4. Solution concentration $c \times 10^2$, g cm^{-3}: (*1*) 1.317, (*2*) 0.92, (*3*) 0.653, and (*4*) 0.332. *Dashed straight line*: data for the pure solvent.

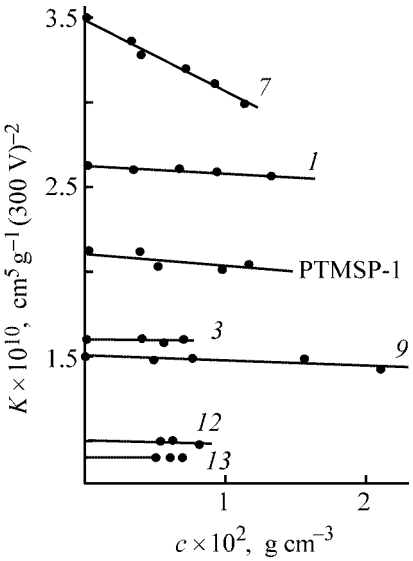

Fig. 2. Specific Kerr constant K for PTMSP-1 fractions and for nonfractionated PTMSP-1 sample in CCl_4 vs. concentration c. Curve numbers are fraction numbers in Table 2.

sized. The average *cis–trans* C=C ratio was estimated by ^{13}C NMR spectroscopy from the intensity ratios of the signals of carbon atoms from C=C bonds with different configurations [solutions in $CDCl_3$, MSh-300 (Bruker) spectrometer, 75.47 MHz]. The molecular weight M of the samples was determined from the data on diffusion and sedimentation in solutions of cyclohexane (CH) (for PTMSP-1 sample) and heptane (for PTMSP-2 sample) [9].

The initial samples were subjected to fractional precipitation from solution in a 1 : 1 toluene–CCl_4 mixture in the case of PTMSP-1 and from toluene solution in the case of PTMSP-2. Ethanol served as the precipitant. Fractionation yielded 13 fractions of PTMSP-1 and 5 fractions of PTMSP-2. In view of the fact that silicon-containing disubstituted polyacetylenes are selectively soluble in organic solvents [1, 6], a study of the molecular properties of such polymers required selecting a polymer–solvent system dissolving all the isolated fractions of the initial samples. Therefore, we studied the electrooptical properties of the PTMSP-1 fractions in CCl_4, and those of PTMSP-2 fractions, in toluene.

The electrooptical Kerr effect [9] was studied in pulsed electric field; the duration of the rectangular pulse was 1–2 ms at a voltage applied to the Kerr cell of up to 1 kV. The measurements were carried out in a glass cell with 2-cm-long parallel-plate titanium electrodes separated by 0.05 cm. The optical birefringence of the polymer solution was recorded photoelectrically, by the compensation procedure used to measure the Kerr effect [9]. The light source was a He–Ne laser ($\lambda = 6328 \times 10^{-8}$ cm); a thin mica plate with intrinsic phase difference of $0.01 \times 2\pi$ served as compensator.

In this study, we discuss the equilibrium (i.e., independent of the electric pulse repetition frequency and duration) electrooptical properties of polymers. These are conventionally characterized by the specific Kerr constant K defined by

$$K = \lim_{\substack{E\to 0 \\ c\to 0}} [\Delta n - \Delta n_0)/E^2 c], \qquad (1)$$

where, $\Delta n - \Delta n_0$ is the difference between the field-induced birefringences in a solution of the substance under investigation (with concentration c) and in the solvent, respectively, and E is the electric field intensity.

In PTMSP solutions, we observed a positive (in sign) electrooptical effect, which was proportional to the squared electric field intensity and exceeded the contribution to the observed birefringence from the solvent.

Figure 1 shows a typical plot of the birefringence Δn vs. the squared electric field intensity E^2 for solutions of PTMSP-1 fraction no. 1 in CCl_4. Figure 2 presents the concentration dependences of the specific Kerr constant for PTMSP-1 fractions in CCl_4. By extrapolating these plots to $c = 0$, we estimated the constant K.

The hydrodynamic characteristics of the fractions and of the nonfractionated PTMSP-1 sample were measured in cyclohexane solutions. Cyclohexane afforded the maximal refractive index increment dn/d_c =

* The M_{SD} parameter for fraction nos. 2, 6, 8, and 11 of the PTMSP-1 sample were estimated using the relationship $[\eta]_{CH} = 2.59 \times 10^{-2}\ M_{SD}^{0.68 \pm 0.07}$ which was experimentally determined for this homologous series; the $[\eta]_{CCl_4}/[\eta]_{CH}$ ratio was taken equal to 1.04 for the fractions on the average.

0.16 for the polymer–solvent system, ensuring appropriate precision of methods based on optical and polarization-optical techniques [9, 10]. Shtennikova *et al.* [11] studied the hydrodynamics of PTMSP-2 molecules for the homologous series of its fractions.

Accelerated sedimentation was studied on an MOM 3180 analytical ultracentrifuge in a one-sector cell at rotor rotation rate $n = 40 \times 10^3$ rpm. For details of the procedure for recording sedimentation boundary and of the method for measuring the translational diffusion used in this work, see [10]. The sedimentation coefficients S were calculated by the formula

$$S = \omega^{-2}(\Delta \ln X/\Delta t),$$

where ω is the angular velocity; X, the position of the sedimentation boundary at instant of time t; and $(\Delta \ln X/\Delta t)$, the rate of displacement of the sedimentation boundary with time, determined experimentally from the slope of the time dependence of $\Delta \ln X$.

The translational diffusion was studied in a Tsvetkov's diffusometer by the classical method for forming the solution–solvent boundary whose position was recorded at certain time intervals using a polarization interferometer [9, 10]. The diffusion interferograms were processed by the method of maximal ordinate and area [10]. The diffusion coefficient $D = (1/2)(d\sigma^2/dt)$ was calculated from the slope of the experimental dependence of the diffusion boundary variance σ^2 on experiment duration t. The S and D parameters estimated for several concentrations were extrapolated to zero concentration of the solutions. Therefore, we provided with subscripts 0 the diffusion and sedimentation coefficients to be used below (D_0 and S_0, respectively).

The molecular weights of the PTMSP-1 and PTMSP-2 samples and fractions were calculated by the Svedberg formula [9, 10]

$$M_{SD} = [RT/(1 - \nu\rho_0)](S_0/D_0), \qquad (2)$$

where R is the universal gas constant; T, the absolute temperature; ν, the specific partial volume of the polymer in solution; and ρ_0, the solvent density.

The specific partial volume ν of the nonfractionated PTMSP-1 sample in cyclohexane was estimated picnometrically to be 0.995 $cm^3\ g^{-1}$ [10].

The intrinsic viscosities $[\eta]$ of nonfractionated samples and fractions were determined from the Huggins plots [10]

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c,$$

where $\eta_{sp} = (\eta - \eta_0)/\eta_0 = (t - t_0)/t_0$; η and η_0, the solution and solvent viscosities, respectively; t and t_0, the outflow times for, respectively, the solution and solvent in an Ostwald viscometer; and k', the Huggins constant.

Table 2 presents the hydrodynamic characteristics of the PTMSP-1 fractions studied. The viscometric

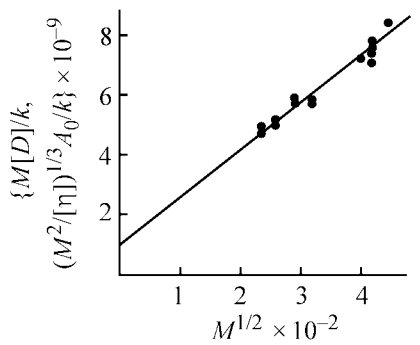

Fig. 3. Plot of $M[D]/k$ and $(M^2[\eta])^{1/3}A_0/k$ vs. $M^{1/2}$ for PTMSP-1 fractions and nonfractionated PTMSP-1 sample in cyclohexane. Both dependences for seven fractions and nonfractionated PTMSP-1 sample were approximated by the same curve for estimating A and d.

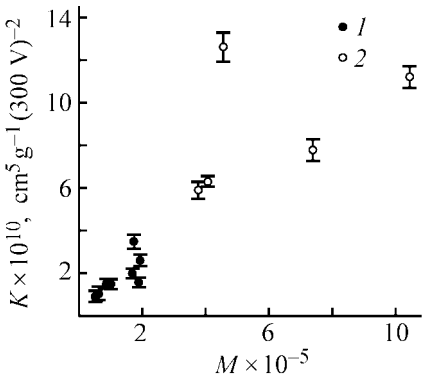

Fig. 4. Specific Kerr constant K in the Gaussian region of M for (*1*) PTMSP-1 fractions in CCl_4 and (*2*) PTMSP-2 fractions in toluene. The experimental inaccuracies in determining K are significantly smaller than the scatter in the K values for individual fractions of PTMSP-1 and PTMSP-2.

and diffusion measurements were carried out at 25 ± 0.1°C, and fractionation and electrooptical measurements, at 21 ± 0.1°C.

One of our goals was to estimate the equilibrium rigidity (or the length of the Kuhn statistical segment A [10]) of the PTMSP-1 molecules. The conformations of the PTMSP-2 molecules were characterized in [11]. The equilibrium rigidity of the chains of the PTMSP-2 molecules A was estimated to be 90 ± 10 Å, and the hydrodynamic chain diameter d, to be 7.5 ± 0.5 Å [11].

The equilibrium rigidity of the PTMSP-1 molecules was estimated in terms of the theoretical model of translational friction of persistent chains, as it was done previously for PTMSP-2 [11]. Figure 3 shows the plot constructed for the relation

$$[S]N_A = M_{SD}[D]/k = (M_{SD}^2/[\eta])^{1/3}A_0/k$$
$$= P_0^{-1}(M_L/A)^{1/2}M_{SD}^{1/2} + (M_L/3\pi)[\ln(A/d) - \varphi(0)], \quad (3)$$

where $[S] = S_0\eta_0/(1 - \nu\rho_0)$; $[D] = D_0\eta_0/T$; N_A is the Avogadro number; k, the Boltzmann constant; P_0 = 5.11 [9, 10]; $A_0 = 3.31 \times 10^{-10}$ g cm^2 s^{-2} deg^{-1} mol$^{-1/3}$, the average experimental hydrodynamic invariant [9] for this series of fractions; M_L, the weight of the chain length unit; $\varphi(0)$ = 1.056 [12]; and $\varphi(0)$ = 1.431 [13].

Relation (3) was used for estimating the length of the Kuhn statistical segment A and the hydrodynamic chain diameter d of the PTMSP-1 molecules in terms of the theory of translational friction of polymer chains modeled by worm-like cylinders [12] or a worm-like necklace [13]. The slope of the curve extrapolating the dependence of the hydrodynamic characteristics MD_0 or $(M^2/[\eta])^{1/3}$ on $M^{1/2}$ can be used for estimating the Kuhn segment length, and the intercept on the ordinate axis, for estimating the hydrodynamic diameter of the polymer chain [9].

The Kuhn segment length A for PTMSP-1 molecules was estimated to be 67 ± 7 Å both from the experimental data on the translational mobility and intrinsic viscosity of the fractions of this sample and by substituting $M_L = 44.8 \times 10^8$ g mol^{-1} cm^{-1} from [11] in relation (3). The parameter A for PTMSP-1 molecules is smaller than that for PTMSP-2 molecules. Using the plot from Fig. 3, the hydrodynamic diameter d of the PTMSP-1 molecules was estimated to be 4 ± 2 Å in [12] and 3 ± 1.5 Å in [13]. These values disagree with the calculated value, but, in our case, this can be attributed to the small number of the members in the homologous series of fractions and to only fourfold variation range of their M, which is responsible for significant inaccuracy in determining the conformational parameters of the polymer chains [9, 10].

Thus, the hydrodynamic behavior of the PTMSP samples prepared with different catalysts interpreted in terms of the same model, showes that the conformational characteristics of their chains are different and that the equilibrium rigidity of the PTMSP-1 molecules ($NbCl_5$ catalyst) is smaller than that of the PTMSP-2 molecules ($TaCl_5$/BuLi catalyst).

A study of the equilibrium electrooptical properties of the PTMSP-1 and PTMSP-2 fractions showed the following. First, the Kerr effect for solutions of PTMSP-2 fractions exceeds several times that for PTMSP-1 fractions (Fig. 4). Second, in both fraction

series the specific Kerr constant K is variable for fractions with M belonging to the Gauss region of properties, which is absolutely untypical of polymer homologs [9]. The fact that the specific Kerr constant is independent of M in the region where the polymer chains are described by the Gauss statistics has been confirmed theoretically for a number of models and experimentally for various polymer classes [9]. With nonfractionated PTMSP samples as an example, it has been shown that the above-mentioned feature of the electrooptical properties of PTMPS cannot be attributed to the solvent effect, since the difference in the K values for samples is independent of the thermodynamic quality of the polymer–solvent system. All the above-mentioned facts suggest that the isolated fractions are, evidently, nonhomologous in their microstructures, e.g., in the average number of the monomeric units constituting the regularly structured blocks. The different degrees of the intramolecular ordering of the bonds may be responsible for differences in the optical and dipole characteristics of the macromolecules of individual fractions of PTMSP-1, 2.

The possible differences in the conformational characteristics of the PTMSP chains as dependent on the presence of *cis* or *trans* stereo blocks in the polymer chains were analyzed for decameric chain fragments by the PM3 semiempirical quantum-chemical method [14, 15]. We found that, for both all-*cis* and all-*trans* decamers, the most energetically advantageous are coiled conformations. Specifically, for all-*trans* decamer this is a 4_1 coil, in which four monomeric units constitute the coil pitch, and for the all-*cis* decamer, a more strongly folded 3_1 coil in which the chain segment of the length identical with 4_1 coil accommodates a larger number of monomeric units (Fig. 5). By calculating the polarity and anisotropy of the optical polarizability of such chains, it is possible to reveal the specific features of the PTMSP molecules essential for the electrooptical properties.

Table 3 presents the calculated dipole moments μ of the propagating chain of the all-*cis* and all-*trans* decamers of PTMSP. It is seen that, in the case of coiled conformation, the longitudinal components of the dipole moments tend to accumulate (add) with each new coil turn along the chain propagation direction and the corresponding perpendicular components of the dipole moments of the PTMSP monomeric units almost totally cancel out each other. The reason is that the dipole moment component along the chain propagation direction, μ_x, is much greater than μ_y and μ_z. Therefore, the most polar coiled segments of the PTMSP chain must be oriented by the external

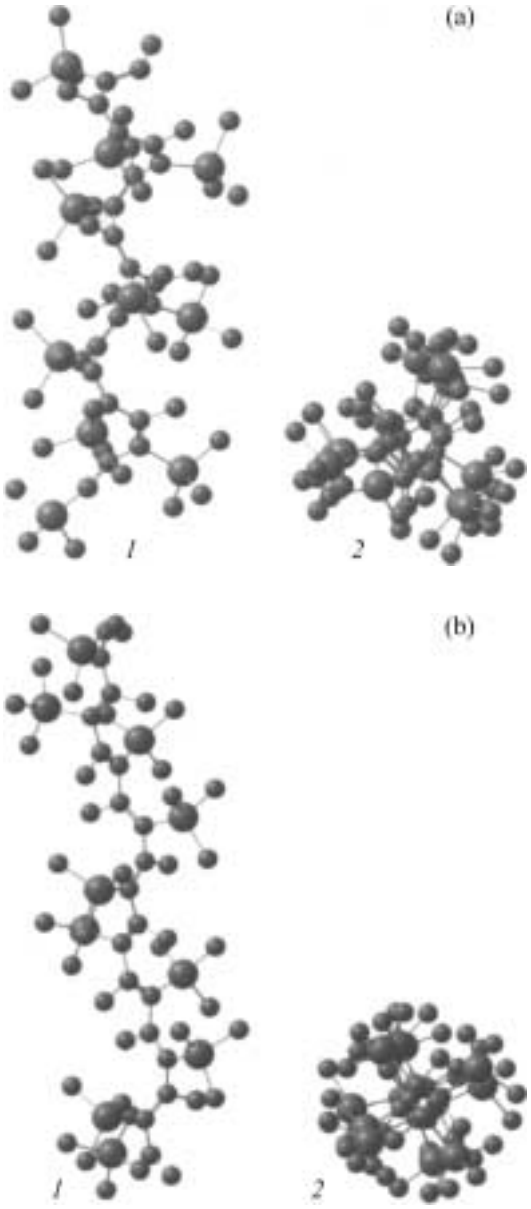

Fig. 5. Two projections of the conformations of (a) 3_1 coil of the decameric fragment of the all-*cis* PTMSP chain and (b) 4_1 coil of the decameric fragment of the all-*trans* PTMSP chain as optimized by the PM3 method. electric field to a greater extent than noncoiled (randomly folded) segments for which the total dipole moment will be significantly smaller and the μ_x, μ_y, and μ_z components will be in another proportion. Thus, the PTMSP segments assuming the coiled conformation with the total dipole oriented along the coil axis, evidently, make the major contribution to the observed electrooptical effect owing to their orientation induced by the pulsed electric field.

* The conformations of *n*-mers are fully optimized and represented by 3_1 coils (for $n \geq 3$, *cis* *n*-mer of PTMSP) and 4_1 coils for $n \geq 4$ (*trans* *n*-mer). The *x* axis corresponds to the longitudinal coil axis.

According to the calculated data (Table 3), the polarity of the regular segment of the PTMPS chain is directly related to its length. This fact is of decisive importance for electrooptical properties of this class of polymers, since the specific Kerr constant K is related to the constant dipole moment of the independently oriented chain unit as [9]

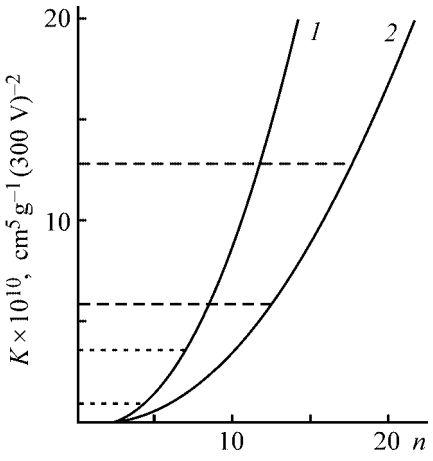

Fig. 6. Variation of the calculated Kerr constant K with the number of monomeric units, n, in independently oriented (*1*) all-*cis* and (*2*) all-*trans* fragments of the PTMSP chain. *Dashed straight lines* indicate the variation ranges for the experimental Kerr constants K of the fractions of PTMSP-1 (CCl_4 as solvent) and PTMSP-2 (toluene as solvent) samples studied.

$$K = \frac{2\pi N_A (n_0 + 2)^2 (\varepsilon_0 + 2)^2 \rho_0}{1215 kT n_0 M} \Delta\alpha \times \left[2\Delta\alpha + \frac{\mu^2}{kT}(3\cos^2\beta - 1)\right], \quad (4)$$

where M is the molecular weight of the independently orienting chain unit; Δα and μ, the anisotropy of optical polarizability and constant dipole moment, respectively; β, the angle between the dipole moment direction and the axis of the largest optical polarizability of the isolated chain fragment, respectively: n_0, ε_0, and ρ_0, the refractive index, dielectric permittivity, and density of the solvent, respectively.

Figure 6 shows how the Kerr constant K calculated for the polymeric chain of PTMSP varies with the number of monomeric units; it was assumed that its chain fragment independently oriented in the electric field corresponds to a *cis* stereo block comprising 3–10 monomeric units or to a *trans* stereo block comprising 4–10 monomeric units. In calculations, we used formula (4) and the μ, Δα, and β values from Table 3. The experimentally determined and calculated Kerr constants K agree well for the PTMSP-1 and PTMSP-2 fractions studied (Fig. 6). This suggests that these fractions can constitute polar stereo blocks of variable length, whose orientation in the electric field is responsible for the observed difference in their electrooptical properties.

Table 4. Geometric parameters* and parameters characterizing the polarity and polarizabilty anisotropy of the chains for all-*trans* and all-*cis* PTMSP decamers (PM3 calculations)

Decamer	l_{coil}	d_{coil}	μ, D	Δα, Å^3	β, deg
	Å				
trans-PTMSP, 4_1 coil	9.3	8.2	3.4	37.7	4.4
cis-PTMSP, 3_1 coil	5.4	9.5	4.0	34.9	6.5

* l_{coil} is the coil period, and d_{coil}, the coil diameter.

Table 4 lists the calculated geometric parameters and the parameters characterizing the polarity and anisotropy of the optical polarizability for the fully optimized *cis* and *trans* decamers of the PTMSP chain. It is seen that the dipole moments μ and the anisotropy of optical polarizability, Δα, for both types of regular decameric fragments of the PTMSP chains are close (despite the difference in the geometry of the 3_1 and 4_1 coils). This must be manifested in closely similar electrooptical properties of the PTMSP samples containing coiled fragments of both all-*cis* and all-*trans* chains with close numbers of their constituent double carbon-carbon bonds (see in Table 3 the characteristics of the PTMSP chains with identical numbers of the monomer units). Clearly, the observed difference in optical birefringence in the electric field between solutions of PTMSP-1 and PTMSP-2 fractions must be only due to the difference in the lengths of the polar regular sequences of the C=C bonds assuming the coil conformations which are part of the chains of these polymers.

The variation ranges for the experimentally determined constant K for PTMSP-1 fractions in CCl_4, $(0.9–3.5) \times 10^{-10}$ cm^5 g^{-1} (300 V)$^{-2}$, and for PTMSP-2 fractions in toluene, $(5.9–12.6) \times 10^{-10}$ cm^5 g^{-1} (300 V)$^{-2}$, were compared with the corresponding calculated constants K (Fig. 6). The comparison showed that PTMSP-1 fractions may contain regular *cis* or *trans* sequences of C=C bonds comprising 4–7 monomer units, and the fractions of the PTMSP-2 sample may contain longer regular blocks comprising 11–18 monomer units.

The fact that the PTMSP-2 chains contain longer, compared to the PTMSP-1 chains, coiled (and thus more rigid) fragments is consistent with the enhanced equilibrium rigidity of the PTMSP-2 macromolecules, compared to PTMSP-1, as suggested by the hydrodynamic data.

CONCLUSIONS

(1) Electrooptical and hydrodynamic properties of the fractions of samples of poly-(1-trimethylsilyl-1-propynes)-1 and -2 samples with close average *cis–trans* ratios for C=C bonds were studied. The molecular characteristics of these polymers in solutions are governed by the presence in their chains of rather long coiled regular sequences of C=C bonds, strongly differing in the polarity and rigidity from randomly folded chain segments.

(2) The microstructure of the chains of poly-(1-trimethylsilyl-1-propynes) depends on the catalyst used for polymerizing the initial monomer, 1-trimethylsilyl-1-propyne.

(3) The electrooptical characteristics of the fractions of poly-(1-trimethylsilyl-1-propynes)-1 and -2 vary in the Gaussian region of molecular weights. This suggests a significant polydispersity of the samples with respect to the length of regular *cis* or *trans* sequences of C=C bonds (stereo blocks) and uniformity of their distribution in the chains of poly-(1-trimethylsilyl-1-propynes) synthesized using the above-mentioned catalysts.

ACKNOWLEDGMENTS

The authors are grateful to V.S. Khotimskii for providing samples of poly-(1-trimethylsilyl-1-propynes) for fractionation and the data on the average *cis–trans* ratio for C=C bonds in their composition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Acrylamide with Sodium 2-Acrylamido-2-methylpropanesulfonate in Aqueous Salt Solutions

V. F. Kurenkov, O. A. Antonovich, and A. F. Khusainova

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 8, 2002

Abstract—The kinetics of radical copolymerization of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate in water and in 1 M NaCl solutions at pH 9 and 30–50°C was studied. The kinetic data were interpreted with account of the state of the ionic groups and conformations of growing polymeric chains in the reaction mixtures.

Owing to high resistance to salts and heat, and high thickening and flocculating power, water-soluble copolymers of acrylamide (AA) with sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS) are widely used in drilling, petroleum production, and water treatment [1, 2]. The practical importance and specific features of copolymerization of ionic monomers in ionizing solutions [3, 4] invite a study of copolymerization of AA with Na-AMS in various media. The copolymerization of these monomers in aqueous solutions has been studied previously [5–7], but data on copolymerization in aqueous salt solutions are scarce [8]. In this work, we studied the kinetics of radical copolymerization of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate in aqueous salt solutions in the range 30–50°C as influenced by the state of the ionic groups and conformations of growing polymeric chains in the reaction mixtures.

EXPERIMENTAL

In our work we used acrylamide purchased from Mitsubishi Chem. Ind. Ltd. (Japan) (mp 84.5°C), H-AMS purchased from Lubrizol Corp. (United Kingdom) (mp 185°C), and other reagents of chemically pure grade. Sodium 2-acrylamido-2-methylpropanesulfonate was prepared by potentiometric titration of aqueous H-AMS solutions with aqueous solution of NaOH to pH 9; the resulting salt was used as aqueous solution.

The copolymerization procedure was similar to that described in [6]. The reaction at 50°C was initiated with potassium persulfate ([PP] = 5.9×10^{-3} M); the effect of temperature on the copolymerization in the 30–50°C range was studied using the PP–sodium hydrosulfite (SHS) redox initiating system ([PP] = 5.2×10^{-4} M, [SHS] = 3.5×10^{-4} M).

The process kinetics was monitored dilatometrically. Copolymerization was performed in 7-ml glass dilatometers; the shift of the meniscus of the reaction mixture in a dilatometer capillary in the course of reaction was monitored with a KM-8 cathetometer. The conversion of monomers into copolymer x (%) was calculated from the following expression:

$$x = \Delta V/(VK) \times 100,$$

where V and ΔV are the initial volume of the reaction mixture in the dilatometer and its change with time, respectively; and K is the contraction factor of copolymerization,

$$K = K_1\omega + K_2(100 - \omega).$$

Here K_1 and K_2 are the contraction factors for homopolymerization of Na-AMS and AA, respectively, and ω is the content of Na-AMS in the initial monomer mixture.

The factors of K_1 and K_2 were determined using the equation

$$K_1,\ K_2 = (\rho_p - \rho_m)/\rho_p,$$

where ρ_p and ρ_m are the densities of the polymer and monomer, respectively.

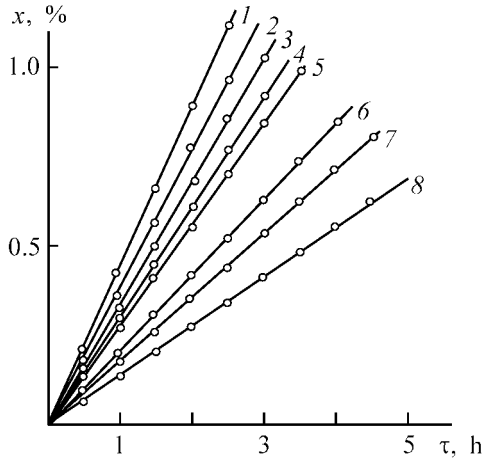

Fig. 1. Initial portions of the kinetic curves of copolymerization of AA with Na-AMS; $[M_1] + [M_2] = 10\%$. (x) Conversion and (τ) time. Mole fraction of AA in the initial monomer mixture M_1: (*1*) 0.8, (*2*) 0.7, (*3*) 0.6, (*4*) 0.5, (*5*) 0.4, (*6*) 0.3, (*7*) 0.2, and (*8*) 0.1.

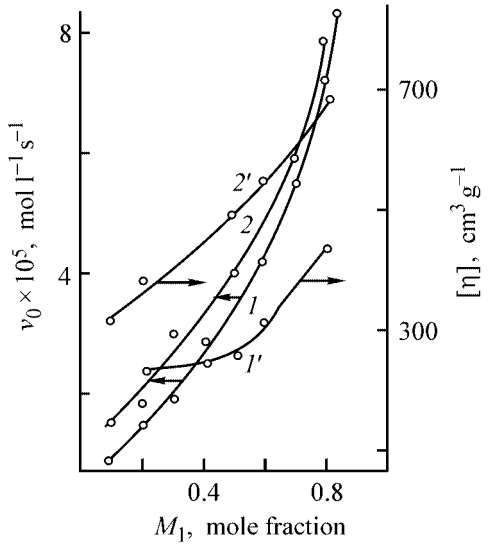

Fig. 2. (*1*, *2*) Initial copolymerization rate v_0 and (*1*′, *2*′) intrinsic viscosity of solutions [η] of AA copolymers with Na-AMS (τ = 2 h) vs. AA mole fraction in the initial monomer mixture M_1. $[M_1] + [M_2]$ = 15 wt %, [PP] = 5.92×10^{-3} M. Medium: (*1*, *1*′, *2*′) water and (*2*) 1 M aqueous NaCl. Temperature, °C: (*1*, *1*′, *2*) 50 and (*2*′) 30.

The conversion was calculated using the correction factor:

$$K = K[1 + \alpha_m(T_1 - T_2)],$$

where α_m is the volume expansion coefficient of the monomer solution; and T_1 and T_2 are, respectively, the temperatures at which the experiment was performed and the dilatometer was filled.

After copolymerization, the resulting polymers were precipitated from aqueous solutions (containing unchanged monomers) with acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum. The yield of the copolymers was determined gravimetrically. The content of Na-AMS units in the copolymers was determined from the content of sulfur [9].

The molecular weight of copolymers was evaluated from the intrinsic viscosity [η] of their solutions, which was measured in a 0.5 M NaCl solution at 25°C using a VPZh-3 viscometer (d_c = 0.43 mm).

The solution acidity was measured with a pH-121 pH-millivoltmeter equipped with an ESL-63-07 working glass electrode and an EVL 1M-3 silver chloride reference electrode.

Copolymerization of AA (M_1) with Na-AMS (M_2) was carried out in concentrated solutions ($[M_1] + [M_2]$ = 10–15%) of the monomers in water and 1 M NaCl at pH 9. Maintaining pH 9 during copolymerization with PP initiator and PP-SHS initiating system [10] is necessary to provide the constant rates of initiation at changing ionic strength μ (due to changes in the Na-AMS concentration and at NaCl addition [11]) and to hinder imidization of the amide groups [12] and hydrolysis of Na-AMS [13].

Our preliminary experiments confirmed the absence of copolymerization without initiator. In the presence of initiators, copolymerization in water and in 1 M NaCl solution proceeded under the homogeneous conditions at any conversions, owing to high solubility of both copolymer and monomers.

The influence exerted by the composition of the initial monomer mixture on copolymerization was studied at $[M_1] + [M_2]$ = 10%, all other experimental conditions being the same. The initial portions of the kinetic curves of copolymerization in water, obtained by the dilatometric procedure, are shown in Fig. 1. Using the kinetic data at low conversions (x < 4%), we determined the initial copolymerization rates v_0, which are plotted in Fig. 2. As seen, v_0 of copolymers grows with increasing concentration of AA in the reaction mixture both in water (Fig. 2, curve *1*) and in 1 M aqueous NaCl (Fig. 2, curve *2*). Such a shape of the kinetic dependences $v_0 = f(M_1)$ indicates a higher reactivity of AA in the course of copolymerization as compared to Na-AMS. The higher reactivity of AA is, apparently, responsible for the increase in the copolymer yield with increasing AA content in the initial monomer mixture. The effect of AA content (M_1) on the yield of its copolymer with Na-AMS in copoly-

merization for 2 h ($[M_1] + [M_2] = 30\%$, [PP] = 5.92×10^{-3} M) is illustrated below:

M_1, mole fraction	0.1	0.2	0.3	0.4	0.7
Yield, %	67	69	90	96	93

Figure 2 shows that (a) with increasing content of AA in the initial mixture, both v_0 and [η] grow (curve *1'*); (b) higher-molecular-weight copolymers are obtained in mixtures enriched in AA; and (c) with μ increasing upon addition of NaCl, v_0 grows in a wide range of compositions of the initial monomer mixture (passing from curve *1* to curve *2*).

To explain the observed trends in copolymerization of Na-AMS with AA, we consider the ionization equilibrium of the ionic groups in Na-AMS and its units in the macroradicals in aqueous salt solutions:

$$\underset{\text{I}}{A^-X^+} \rightleftarrows A^- \parallel \underset{\text{II}}{X^+} \rightleftarrows \underset{\text{III}}{A^-} + X^+, \qquad (1)$$

where A^- is the anion of the monomer or macroradical; X^+ is the cation; and I, II, and III are the contact ion pairs, ion pairs separated with a solvent, and free ions, respectively.

As known, the ionic groups in Na-AMS and its units in the copolymer chain are completely ionized in aqueous solutions. On adding NaCl, μ and the degree of binding of Na^+ cations with polysulfonate anions increase, shifting the ionization equilibrium (1) to the left. This changes the content of various ionic species in the reaction mixture, decreases the electrostatic interaction, and affects the conformation state of the growing chains and, thus, the reactivity of ionic monomers and their macroradicals in copolymerization. In should be noted that, in the system studied, the reactivity of AA and the corresponding radical is virtually independent of μ in the course of copolymerization [14].

In copolymerization of AA with Na-AMS, raising μ decreases the electrostatic repulsion between similarly charged species in chain propagation (in reaction of Na-AMS with a macroradical containing the terminal Na-AMS unit) or termination (in reaction between macroradicals with terminal Na-AMS units), and thus increases the constants of chain propagation k_p and termination k_t. In this case, the greater increase in k_p as compared to k_t, which is confirmed by the increase in the molecular weight of the resulting copolymers (Fig. 2, curve *1'*), causes an increase in v_0 with growing μ.

The effect of μ on the conformation of macroradicals is confirmed by viscometric data for solutions

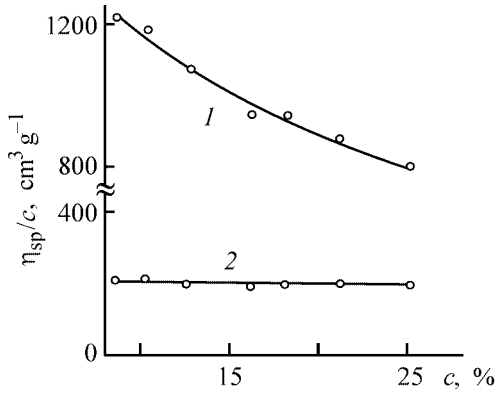

Fig. 3. Reduced viscosity η_{sp}/c of AA copolymer with Na-AMS vs. its concentration c in (*1*) water and (*2*) 1 M NaCl at 30°C. [η] = 225 cm^3 g^{-1}, 75% Na-AMS units, the same for Fig. 6.

of AA copolymer with Na-AMS (Fig. 3). Upon dilution of the copolymer solution with pure water, the $\eta_{sp}/c = f(c)$ dependence has a shape typical of polyelectrolytes (curve *1*), which is due to the increasing size of macromolecular globules as a result of stronger electrostatic repulsion of fixed charges along the polymer chain at higher degrees of ionization of the ionic groups. The increase in μ on addition of NaCl decreases the electrostatic repulsion between the sulfonate anions of the macromolecules shielded by Na^+ counterions and thus decreases the size of the polymer aggregates. In this case, the $\eta_{sp}/c = f(c)$ dependence can be described by the Huggins equation [15] (curve *2*). Hence, with increasing μ, the decrease in the chain charge and aggregate size (passing from curve *1* to curve *2*, Fig. 3) probably results in higher local concentration of Na-AMS monomer near the active centers in the course of copolymerization and thus in increased k_p and v_0.

The influence exerted by the composition of the initial monomer mixture on the instantaneous composition of copolymers was evaluated at ($[M_1] + [M_2]$ = const), other experimental conditions being the same. As seen from Fig. 4, in a wide range of the compositions of the initial monomer mixture, copolymerization in water (curve *1*) and 1 M NaCl (curve *2*) yields the copolymers enriched in AA units. This corresponds to the case when $r_1 = k_{11}/k_{12} > 1$ for AA and $r_2 = k_{21}/k_{22} < 1$ for Na-AMS, which is well consistent with published data [5]. The dependence in Fig. 4 indicates a higher reactivity of AA in copolymerization as compared to Na-AMS; with increasing AA content in the monomer mixture, the content of AA units in the copolymer grows. This suggests that, for given $[M_1]/[M_2]$ ratios, the content of Na-AMS units in the copolymer increases on adding NaCl (passing

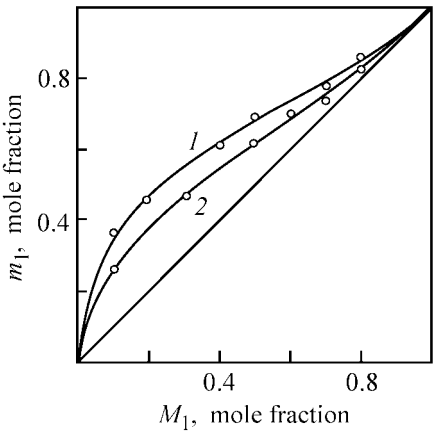

Fig. 4. Mole fraction of AA units in copolymer m_1 at x < 3% vs. conversion AA mole fraction in the initial monomer mixture M_1 at copolymerization of AA and Na-AMS in (*1*) water and (*2*) 1 M aqueous NaCl.

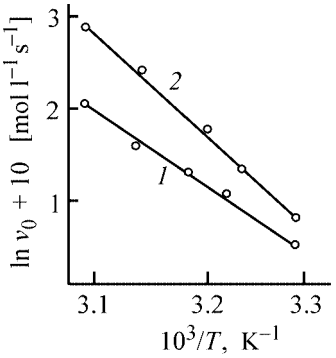

Fig. 5. Initial rate of copolymerization v_0 of AA with Na-AMS in (*1*) water and (*2*) 1 M NaCl vs. temperature T. Initial molar composition: $[M_1]/M_2] = 7:3$; $[M_1] + [M_2] = 15\%$.

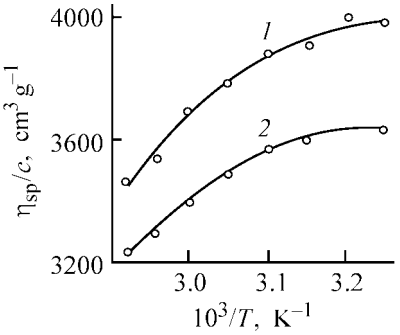

Fig. 6. Reduced viscosity η_{sp}/c of aqueous solutions of AA copolymer with Na-AMS vs. temperature T. c, %: (*1*) 0.18 and (*2*) 0.25.

from curve *1* to curve *2*), probably owing to an increase in μ. In this case, the rate constant of one of the four elementary reactions of chain propagation k_{22} (addition of Na-AMS to macroradical with terminal Na-AMS unit) increases, and a copolymer enriched in ionic units is formed. It should be noted that r_1 and r_2 in the system studied were not determined. This is due to the nonisoionic copolymerization conditions (changing μ), resulting from variation of the concentration of the ionic monomer in the initial reaction mixture and in the course of copolymerization, which affects the copolymerization constants r_1 and r_2. As a result, the process cannot be described by the classical equations [4].

The effect of temperature on copolymerization of AA and Na-AMS in water and in 1 M NaCl was studied in the range 30–50°C at $[M_1] + [M_2]$ = const and $[M_1]/[M_2]$ = const, all other conditions being the same. The experimental data, given in the Arrhenius coordinates (Fig. 5), correspond to an effective overall activation energy of copolymerization E_a of 57.4 and 79.7 kJ mol^{-1} in water and 1 M NaCl, respectively. It should be noted that the changes in the conformational state of the macroradical with temperature affect the above values, which is confirmed by viscometry (Fig. 6). As seen from Fig. 6, the linear size of macromolecules decreases with increasing temperature, which is due to the weakening of electrostatic repulsion of fixed charges along the chain with decreasing ionization of the ionic groups. This, in turn, results in that the local concentration of Na-AMS near the active centers and, hence, v_0 increase with temperature. Figure 5 also shows that on passing from water to 1 M NaCl (curves *1*, *2*), E_a increases too. This is probably due to changes in the electrostatic interaction of the reacting species and conformational state of macroradicals in the course of copolymerization. With increasing temperature, [η] of the polymers prepared decreases in a wide range of concentrations of the initial monomer mixtures (Fig. 2, curves *1'*, *2'*), in agreement with common trends observed in radical copolymerization.

CONCLUSIONS

(1) The copolymerization rate v_0, yield, and intrinsic viscosity [η] of copolymers grow with increasing concentration of acrylamide in the initial monomer mixture.

(2) The v_0 values increase with temperature and on adding NaCl, [η] grows with decreasing temperature.

(3) Copolymers enriched in acrylamide units are formed in a wide range of compositions of the initial monomer mixture, and their content grows with increasing initial concentration of acrylamide and on passing from 1 M NaCl to water.

Abstract—The kinetics of homogeneous graft polymerization of *N*-vinylpyrrolidone on chitosan, initiated by ammonium peroxodisulfate, was studied in relation to the reactant concentrations. The reaction orders with respect to the monomer, initiator, and matrix polymer were determined. The compositional nonuniformity and microbiological stability of the copolymer were evaluated.

Poly-*N*-vinylpyrrolidone (PVP) is a hemocompatible water- and plasma-soluble synthetic polymer exhibiting a wide spectrum of biological activity; it is used in clinical practice. The natural polymer chitosan (CAN) is biocompatible; it causes no allergic reactions and exhibits antimicrobial effect, lacking in the case of PVP. Chitosan films are used in surgery for treating wounds, in particular, those originating from burns. Such films not only mechanically protect the wound from the environment, but also stimulate regeneration of the damaged tissue, favoring formation of fibroblasts, histiocytes, and immunocompetant cells. As a result, the wounds heal faster, with decreased formation of fibrous tissue [1]. Combination of the properties of PVP and CAN in single compound would be useful for developing multifunctional biomaterials for wound healing and carriers for various drugs. The most convenient way of combining PVP and CAN is to prepare graft copolymers.

Graft copolymers of PVP and acrylic monomers are used for preparing fiber-forming materials [2]. In this case, polymerization is performed under homogeneous conditions (heating in the presence of peroxide initiators). Copolymers with grafted pendant PVP chains are prepared under heterogeneous conditions in aqueous solutions of *N*-vinylpyrrolidone (*N*-VP), with radiation or redox initiation. Copolymers of this kind with cellulose exhibit good dyeability [3]. Grafting of PVP to polymethylsiloxane with the aim to prepare new complexing materials was performed in toluene (AIBN initiator). The process started in solution, with transition to a two-phase disperse system. The content of PVP in the graft copolymer reached 50% [4].

Copolymerization of CAN with various monomers is performed to improve the elastic properties of films [5], prepare microspheres with incorporated drugs [6], and enhance the mechanical characteristics of membranes [7]. Cerium compounds, redox systems, or peroxo salts are used as initiators. The possibility of formation of PVP–CAN copolymers in the course of radical polymerization of *N*-VP in the presence of CAN was mentioned in [8], but neither the course of graft polymerization nor composition of the copolymers were reported.

In this work, we studied graft polymerization of *N*-VP on CAN in acetic acid solution in the presence of ammonium peroxodisulfate initiator in relation to the reactant concentrations and examined the compositional nonuniformity and microbiological stability of the copolymers.

EXPERIMENTAL

N-Vinylpyrrolidone was distilled in a vacuum; the fraction with bp 81.1–81.5°C (5 mm Hg) was taken. Ammonium peroxodisulfate (APS) was recrystallized from water. Chitosan was isolated from North Sea crimp shells; degree of deacetylation 0.88, molecular weight 1.87×10^5. Graft polymerization was performed under homogeneous conditions at 333 K without stirring. The reaction mixture was prepared from appropriate amounts of CAN (4% solution in 2% ace-

1070-4272/02/7510-1678 $27.00 © 2002 MAIK "Nauka/Interperiodica"

tic acid) and monomer, which were stirred with a magnetic stirrer; the initiator was added last, after which the mixture was transferred into a temperature-controlled Hoeppler viscometer. The reaction time was measured from the moment when the temperature of the reaction mixture reached 333 K. The reaction kinetics in relation to the concentrations of *N*-VP, APS, and CAN was monitored by variation of the bromine number in samples taken at regular intervals and by the dynamic viscosity of the reaction mixture. The viscosity was measured in parallel experiments.

The compositional nonuniformity was studied by successive extraction of films prepared from the reaction mixture with water and chloroform, and also by thin-layer chromatography. Separation was performed with TLC plates on Polygram MN 300 DEAE supports (Masherey-Nagel, Germany). The spots of CAN, PVP, and the copolymer were developed with a solution of iodine in chloroform. The homopolymers and copolymer were separated by step chromatography in a chamber filled with nitrogen; the first eluent was ethanol (up to a height of 8 cm), and the second eluent, 2% acetic acid (additional 5 cm). Under these conditions, PVP moves with the ethanol front, and CAN, with the acetic acid front. A compound whose adsorption properties differ from those of the homopolymers, i.e., the copolymer, remains at the start.

The microbiological stability of the copolymers was tested with respect to *E. coli K 12*, *Vibrio spp. X*, *Serratia marcescens*, and *Bacillus subtillus SHgw* bacteria using 0.35% copolymer solutions. Solutions of test samples (5 ml) were seeded with appropriate amounts of bacteria and incubated at 298 K for 7 days. The bacterial growth was judged from the growth of the optical density of the medium as compared to the initial medium.

Preliminary blank experiments on measurement of the dynamic viscosity of 1% CAN solutions in PVP (molecular weight 12×10^3) in the presence of the initiator showed that the viscosity of the CAN solution decreases with time, whereas that of the PVP solution remains unchanged. This fact reflects the sensitivity of bonds in the polymer backbones to degradation in the presence of APS; the glycoside bonds between the CAN monomeric units are cleaved, whereas the C–C bonds in PVP are stable under the reaction conditions.

Figure 1 shows how the dynamic viscosity varies with time in reaction mixtures containing CAN, *N*-VP, and their mixtures in various proportions, with various amounts of APS initiator added. It is seen that, in copolymerization experiments, the viscosity

passes through a minimum at a time depending on the concentrations of the initiator and monomer and corresponding to the induction period. Radicals arising from decomposition of APS initiate both degradation of CAN and polymerization of *N*-VP. These processes exert opposite effects on the viscosity of the reaction mixture; the viscosity minimum corresponds to the moment when polymerization of *N*-VP starts to prevail over degradation. This moment can be considered the end of the induction period, although the bromine number of the reaction system starts to decrease even within 15 min after the reaction temperature is attained.

However, the reaction kinetics cannot be monitored by variation of the dynamic viscosity, because the variations are noticeable only in the initial period, and after 60 min either the viscosity flattens out or gelation occurs. Therefore, the reaction kinetics was monitored in further experiments by variation of the bromine number of the reaction mixture.

Figure 2 shows the kinetic curves of graft polymerization of *N*-VP at constant concentrations of

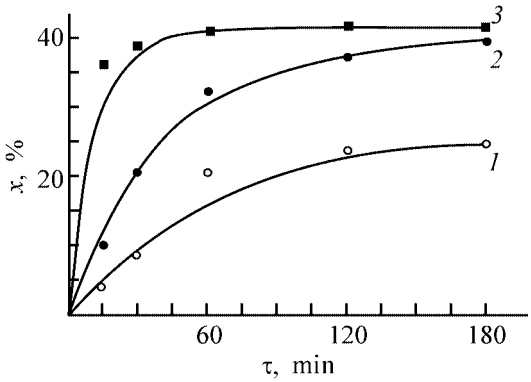

Fig. 3. Kinetic curves of graft polymerization of *N*-VP on CAN at 333 K, [CAN] = 0.06 M, and [APS] = 2.4 mM. [*N*-VP], M: (*1*) 1.19, (*2*) 1.78, and (*3*) 2.38.

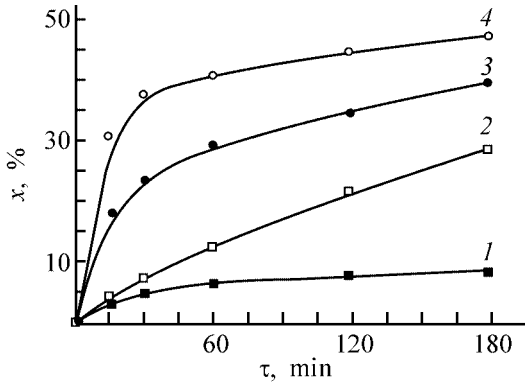

Fig. 4. Kinetic curves of graft polymerization of *N*-VP on CAN at 333 K, [*N*-VP] = 1.19 M, and [APS] = 2.4 mM. [CAN], M: (*1*) 0.03, (*2*) 0.06, (*3*) 0, and (*4*) 0.12.

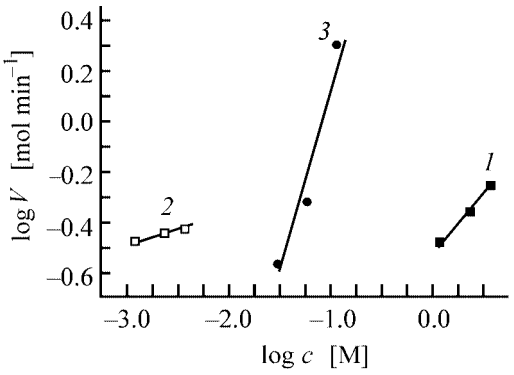

Fig. 5. Rate *V* of graft polymerization of *N*-VP on CAN at 333 K vs. concentrations *c* of (*1*) *N*-VP, (*2*) APS, and (*3*) CAN (log–log plots).

CAN and *N*-VP and different concentrations of the initiator. It is seen that the initial reaction rate and the final conversion of the monomer grow with increasing concentration of the initiator. The maximal conversion, equal to 53%, is attained at [APS] = 3.6 mM.

As the *N*-VP concentration is increased, the initial reaction rate grows, but the limiting conversion is reached faster, i.e., increased concentrations of *N*-VP favor chain termination reactions. Apparently, propagating PVP chains are mainly terminated by disproportionation. This is indicated by increased yield of the homopolymer at high [*N*-VP]. The limiting conversion of the monomer is attained in 120 min at [*N*-VP] = 1.19 M, 60 min at [*N*-VP] = 1.78 M, and 30 min at [*N*-VP] = 2.38 M (Fig. 3).

Increased concentrations of CAN, under equal other conditions, cause both the initial reaction rate and the final conversion of the monomer to increase (Fig. 4). The reaction reaches the steady-state mode within 30 min at any CAN concentrations. However, the promoting effect of CAN amino groups, noted in [9] for grafting of vinyl acetate on CAN, becomes appreciable only at [CAN] = 0.12 M. Only at this CAN concentration the initial rate and final conversion of the monomer become higher than those in polymerization of *N*-VP in the absence of CAN (Fig. 4, curve *3*). Apparently, deceleration of the polymerization of *N*-VP at low concentrations of chitosan is due to the consumption of radical ions generated by decomposition of APS for oxidation and cleavage of the CAN polymer chains, which levels out the activating effect of amino groups on the double bond in *N*-VP. Only at [CAN] = 0.12 M the loss of radicals in the system is compensated for.

On the whole, it should be noted that the monomer conversion remains low at all the reactant concentrations tested. The final product is a transparent viscous solution or (at [APS] = 3.6 mM) a gel. The 3D structure of the gel is formed by recombination of the propagating grafted PVP chains, which becomes possible when the number of growth points on the matrix polymer becomes sufficiently large. Such conditions are provided at high concentration of the initiator (in our system, at [APS] = 3.6 mM).

From the kinetic curves, we calculated the initial rates of graft polymerization at various concentrations of the reactants, constructed the log–log plots of these rates vs. reactant concentrations (Fig. 5), and determined from their slopes the reaction orders with respect to each of the reactants. We found that graft polymerization of *N*-VP on CAN is described by the equation

$$V = k[N\text{-VP}]^{0.46}[\text{APS}]^{0.11}[\text{CAN}]^{1.45},$$

where k is a coefficient.

Results of microbiological stability tests for PVP and CAN samples

Sample	CAN content, %	Variation of optical density, ΔD_{535}			
		Vibrio sp.X	*Esherichia coli K12*	*Serratia marcescens 218*	*Bacillus subtilis SHgw*
PVP	0	0.131	0.165	0.240	0.217
CAN	100	0.059	0.027	0.017	0.025
PVP–CAN mixture	30	0.077	0.028	0.019	0.034
PVP–CAN copolymer	25	0.089	0.047	0.038	0.045
PVP–CAN copolymer	10	0.103	0.066	0.055	0.073

Comparison with a similar dependence for grafting of vinyl acetate (VA) on CAN under comparable conditions [9],

$$V = k[\mathrm{VA}]^{1.03}[\mathrm{APS}]^{0.14}[\mathrm{CAN}]^{-0.08}$$

shows that, with *N*-VP, the reaction order with respect to the monomer is lower by a factor of 2, the orders with respect to the initiator are the same, and the orders with respect to CAN differ cardinally. This means that the matrix polymer affects grafting of VA and *N*-VP differently. Increased CAN concentrations negatively affect all the parameters of VA grafting, whereas grafting of *N*-VP is intensified by increased concentrations of CAN and, at certain [CAN], the rate of graft polymerization becomes higher than the rate of *N*-VP polymerization under comparable conditions in the absence of CAN.

From the reaction mixtures, we prepared transparent elastic films by drying in air in Petri dishes. Evidences of phase separation were detected neither in solutions nor in films. This indicates that PVP, CAN, and their copolymers are well compatible both in solution and in the solid phase.

Determination of the compositional nonuniformity of films by extraction with chloroform and water showed that the reaction mixtures contain both PVP homopolymer and CAN–PVP copolymer. Thin-layer chromatography also revealed these (and no other) components. The efficiency of graft polymerization did not exceed 50%. This means that homopolymerization and graft polymerization occur simultaneously with similar rates.

The results of microbiological tests of samples containing CAN as a mixture or copolymer with PVP are listed in the table.

Microbiological tests of solutions of CAN–PVP copolymers and equiconcentrated solutions of CAN, PVP, and their mixture showed that bacteria do not grow noticeably in the CAN solution but actively propagate in the PVP solution. A 70/30 mixture of PVP and CAN behaves similarly to straight CAN, i.e., it does not support the bacterial growth. In the copolymers containing 25 and 10% CAN, the bacteria propagate more slowly than in the PVP solution but faster than in the solutions of straight CAN and 70/30 mixture of PVP and CAN. These tests suggest that the microbiological stability of the copolymer or mixture under consideration depends on the CAN content and is independent of the PVP state (free or covalently bound).

CONCLUSIONS

(1) 1% CAN solutions undergo at 333 K oxidative degradation under the action of APS, whereas equiconcentrated PVP solutions are stable under these conditions.

(2) The kinetics of homogeneous graft polymerization of *N*-vinylpyrrolidone on chitosan, initiated with ammonium peroxodisulfate, was studied in relation to the concentrations of the monomer, initiator, and matrix polymer. The reaction orders with respect to each of the reactants were determined.

(3) Tests of the microbiological stability of aqueous solutions of chitosan, polyvinylpyrrolidone, and their mixture and copolymers with respect to a series of bacteria showed that the bacterial resistance of the preparations is determined by the content of chitosan in the mixture or copolymer, irrespective of the presence of a chemical bond between chitosan and polyvinylpyrrolidone.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Procedure for Measuring the Viscosity of Formulations Based on Oligourethane Acrylates for UV-Curable Protective Coatings of Fiber Light Guides

A. A. Zamyatin, A. N. Makovetskii, and Yu. S. Milyavskii

Institute of Radio Engineering and Electronics, Russian Academy of Sciences, Fryazino, Moscow oblast, Russia

Received June 18, 2002

Abstract—A capillary viscometric procedure was developed for measuring the viscosity of formulations based on oligourethane acrylates for UV-curable protective coatings of fiber light guides. The temperature dependences of the viscosities of these formulations were studied. The moduli of elasticity of fibers prepared from these formulations after UV curing were measured. These formulations can be stably applied, using a die, to the surface of fiber light guides in the course of their drawing at a drawing rate of up to 100–120 m min^{-1}.

It is known that, to preserve the initial mechanical strength of quartz fiber light guides (FLGs), their drawing should be combined with application of protective coatings (one- or two-layered), in particular, of polymeric coatings. Preparation of a protective coating includes two steps: application, using a die, of a liquid thermosetting or UV-curable (polymerizable) compound on the FLG surface and curing of this film in an oven or by UV irradiation.

In this work, we studied the viscosity characteristics of some UV-curable formulations for FLG protective coatings. Their study is of practical interest, since the viscosity largely governs the choice of the FLG drawing conditions. For example, the maximal drawing rate in the case of a die with liquid outflowing under gravity is restricted by the limiting shear rate in the die channel; if this rate is exceeded, the "meniscus" in the die tube is disrupted, which results in nonuniform thickness and rough surface of the coating [1, 2]. On the other hand, the minimal drawing rate is determined by the kinetics of the so-called capillary disintegration of the applied liquid film and also depends on the properties of the liquid formulation (viscosity and surface tension) [3].

Several methods have been developed for measuring the viscosity of liquids: that based on using various types of plastometers, falling ball method, and vibratory method. The corresponding devices (viscometers) are available for industrial purposes and scientific research. The oldest and the most widely used method is capillary viscometry; there are several modifications of this method suitable for various viscosity ranges [4]. Here we developed a new capillary viscometric procedure based on monitoring the movement of a liquid column in a capillary under the action of applied rarefaction.

THEORY

Consider the movement of an incompressible Newtonian liquid in a capillary under the action of rarefaction created, e.g., with a vacuum pump (Fig. 1). Let us introduce the following designations: $l(t)$, height of the liquid column at instant of time t from the start

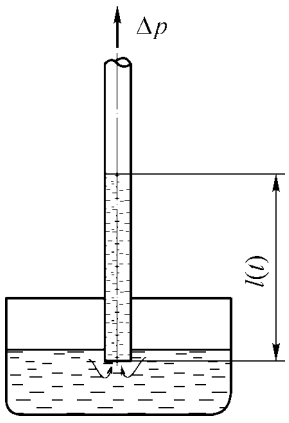

Fig. 1. Scheme of the liquid rise in a capillary under the action of applied rarefaction.

1070-4272/02/7510-1683 $27.00 © 2002 MAIK "Nauka/Interperiodica"

of the movement; μ and ρ, dynamic viscosity and density of the liquid, respectively; R, inner diameter of the capillary; Δp, rarefaction inside the capillary; and g, acceleration of gravity.

According to the Poiseuille formula, the instantaneous flow rate of a liquid $Q(t)$ at time t is given by

$$Q(t) = \frac{\pi}{8}\frac{\Delta p(t)}{l(t)}\frac{R^4}{\mu}, \quad (1)$$

where $\Delta p(t) = \Delta p - \rho g l(t)$ is the pressure in the capillary column at time t. The increment in liquid volume, $\Delta V(t)$, in the capillary in time Δt can be expressed as $\Delta V(t) = Q(t)\Delta t$. At the same time, $\Delta V(t) = \pi R^2 \Delta l(t)$, where $\Delta l(t)$ is the increment in the liquid column in time Δt. Equating both expressions for $\Delta V(t)$, we obtain

$$\Delta l(t) = \frac{1}{8}\frac{\Delta p - \rho g l(t)}{l(t)}\frac{R^2}{\mu}\Delta t. \quad (2)$$

Dividing both sides of Eq. (2) by Δt, we obtain at $\Delta t \to 0$ a differential equation for $l(t)$:

$$l'(t) = \frac{1}{8}\frac{\Delta p - \rho g l}{l}\frac{R^2}{\mu}, \quad (3)$$

which can be supplemented with the initial condition

$$l(0) = 0. \quad (4)$$

The solution to (3) and (4) is given as an implicit function of time:

$$l(t) + \frac{\Delta p}{\rho g}\log\left(1 - \frac{\rho g l(t)}{\Delta p}\right) + \frac{\rho g R^2}{8\mu}t. \quad (5)$$

Note that, for practically significant cases, Δp = 0.2–0.9 atm, ρ = 1.0–2.0 g cm^{-3}, and l = 10–20 cm.

The pressure of the liquid column $\rho g l$ is much less than the rarefaction Δp, i.e., $\rho g l/\Delta p << 1$. Using the asymptotic expansion of the function $\ln(1 + x) = x - x^2/2 + o(x)$ at $x \to 0$, we can simplify Eq. (5) and finally bring it to the following form:

$$l(t) \cong \frac{R}{2}\sqrt{\frac{\Delta p}{\mu}}\,t. \quad (6)$$

From Eq. (6) follows the formula for estimating the viscosity of an incompressible Newtonian liquid:

$$\mu \cong \left(\frac{R}{2}\right)^2 \Delta p t. \quad (7)$$

Thus, to estimate μ, it suffices to measure the time t in which a liquid rises in a capillary of radius R to a chosen level l under the action of Δp, and then to calculate the viscosity by formula (7).

Note that, if a liquid wets the capillary in an actual experiment, the pressure due to the surface tension forces acts on the liquid column in the same direction as the applied rarefaction Δp does. This pressure is given by the Laplace formula $P_L = 2\sigma\cos Q/R$, where σ is the surface tension and Q, the wetting angle. Therefore, generally speaking, the Laplace pressure should be added to the applied rarefaction in formulas (1)–(5). However, for the liquids under consideration, as will be shown below, P_L was actually always much less than Δp and was therefore neglected.

EXPERIMENTAL

The procedure was tested in experiments on measuring the viscosity of formulations for UV-curable FLG coatings.

As starting substances we used oligourethane acrylates mixed with the monomer, propylene glycol acrylate (PGA) [5]. Depending on the length of the chain linking the functional groups, oligomers are subdivided into low-molecular-weight and high-molecular-weight substances. Among low-molecular-weight oligomers, the best is bis(3-acryloyloxypropyl) 2,4-toluylenediurethane (APT), and among high-molecular-weight oligomers, OUA-2000T (molecular weight 2718). Depending on the ratio of OUA-2000T and APT, the materials are suitable for primary (soft), single-layer (intermediate-modulus), and secondary (hard) coatings. Formulations with the ratio of OUA-2000T to APT from 90 : 10 to 98 : 2 are used for primary FLG coatings; those with the ratio of OUA-2000T to APT from 15 : 85 to 25 : 75, for secondary coatings; and those with intermediate ratios, for single-layer coatings.

Propylene glycol monoacrylate (APG) is used as active diluent making lower the viscosity of formulations and thus accelerating application of coatings. APG is added to the oligomers in the ratio from 3.0 : 1 to 7.5 : 1, with the optimal ratio ranging from 4.0 : 1 to 5.0 : 1.

In the process, aromatic ketones generating free radicals in photolysis are used as photoinitiators. In this study, we used 2,2'-dimethoxy-2-phenylacetophenone (DMAP); its content was 2–3%, which is the best for curing the formulations at drawing rates of up to 100–120 m min^{-1}.

To measure the viscosity of liquids by our procedure, we assmebled a setup shown in Fig. 2. An NVR-5D roughing pump *1* created rarefaction in a vacuum tube *2* at closed valve *4* connecting the tube to the capillary *3*. The rarefaction was varied in the range

0.1–0.9 atm with reducer *5* and was monitored with manometer *6*. The end of the vacuum tube with the connected capillary was fixed on adjustment stage *7* with the aid of which the tip of the capillary was submerged in a test liquid.

The measurements were performed as follows. First, a prescribed rarefaction was created in the vacuum tube at valve *4* closed. Then, using the adjustment stage, the tip of the capillary was submerged by 0.5–1.0 mm in a test liquid, after which valve *4* was opened simultaneously with starting a stopwatch. The resulting rarefaction in the capillary was determined with the manometer and used in calculations. After the liquid column in the capillary reached a certain level *l*, the time *t* was registered. Then valve *4* was closed, and air was admitted into the capillary through valve *8*. The filled capillary was removed from the vessel with the liquid and detached from the vacuum tube.

Preliminary experiments were performed for selecting R, Δp, and l for one of formulations (no. 3) for single-layer coating. It was found that, for the range of measured viscosities from 1.0 to 50.0 Pa s, the optimal ranges of rarefaction, capillary radius, and liquid column height are Δp = 0.3–0.8 atm, R = 0.2–0.5 mm, and l = 40–100 mm; the measurement time under these conditions is 10–300 s. The choice of l is governed by the necessity for attainment of the steady-state mode of the liquid flow, and the chosen ranges of Δp and R ensure fairly high accuracy of measuring t.

As an illustration, we present below the results obtained in measuring the viscosity of formulation no. 3 for single-layer coating at various l (Δp = 0.285 atm, R = 0.245 mm):

l, mm	30	40	50	60	70	80	90
t, s	24.5	41.5	65.5	94.5	128.5	164.5	207.5
μ, Pa s	11.35	10.84	11.0	11.0	11.0	10.8	10.8

It is seen that the results of single measurements differ from the mean value by no more than ±3.5%.

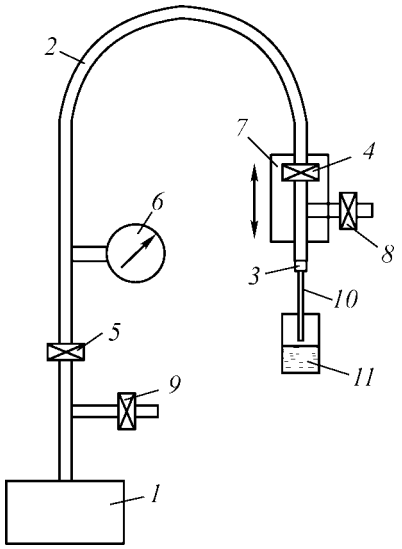

Fig. 2. Scheme of experimental setup for measuring the viscosity of liquids: (*1*) NVR-5D vacuum pump, (*2*) vacuum tube, (*3*) fitting for vacuum-tight connection of the capillary to the vacuum tube, (*4*) valve for detaching the capillary volume from the vacuum pump, (*5*) reducer for controlling the rarefaction, (*6*) OMBI1-160 manometer, (*7*) adjustment stage for submerging the capillary in a test liquid, (*8*) valve for admitting air into the capillary, (*9*) valve for admitting air into the vacuum pump, (*10*) capillary, and (*11*) vessel with a test liquid.

The results obtained in measuring the viscosity of the initial components (OUA-2000T, APT, APG) and several formulations based on them for primary (pr. no. 1), single-layer (s.l. nos. 1–5), and secondary (sec. nos. 1 and 2) coatings at room temperature (20°C) are listed in the table, together with the results for DS-5471-3-14 formulation (DeSolite) for single-layer coating (for comparison).

As seen from the table, although the viscosities of the initial components differ by 4–5 orders of magnitude, the viscosities of the formulations for primary, single-layer, and secondary FLG coatings vary in a relatively narrow range, 4.0–18.0 Pa s. Thus, the conditions for applying these coatings will be similar,

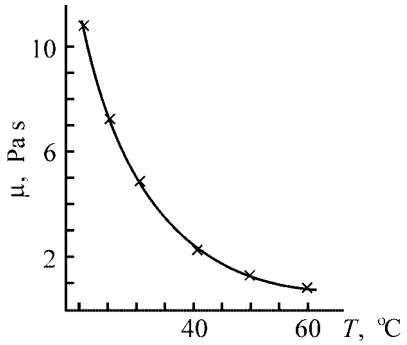

Fig. 3. Temperature dependence of the viscosity of compound no. 3 for single-layer coating of FLGs: (μ) viscosity and (*T*) polymer temperature.

which is favorable for preparing high-quality protective coatings on FLGs.

To evaluate the accuracy of our procedure, we measured the viscosity of glycerol at room temperature (20°C); the resulting value, 1.3 Pa s, is in reasonable agreement (within 15%) with the tabulated value of 1.5 Pa s [6].

Our procedure is also suitable for measuring the viscosity at varied temperature. We have studied the $\mu(T)$ dependences for several formulations. For this purpose, a cell with a test liquid was placed, together with the measuring capillary, in a quartz tubular furnace with with a coil-type heater; the motion of the liquid column in the capillary could be observed through the coil. The temperature *T* inside the furnace was maintained with an accuracy of ±0.2°C using an RTP-3M automatic temperature control unit. Figure 3 shows as an example a $\mu(T)$ plot for single-layer formulation no. 3 in the temperature range 20–60°C. For the other formulations, the $\mu(T)$ dependences were similar.

Figure 3 shows that, as the temperature is increased from 20 to 60°C, the viscosity of single-layer formulation no. 1 decreases by an order of magnitude, from 10.8 to 0.83 Pa s. At room temperature (20°C), this formulation can be successfully applied onto the FLG surface with an open die at drawing rates of up to 30 m min^{-1}. When extrusion is performed at elevated pressure and temperature (40–50°C), the drawing rate can be increased to 100–120 m min^{-1}.

Note that the capillaries filled in viscosity measurements were used for preparing fiber samples from the UV-cured formulations. For this purpose, the liquid in the capillaries was cured in a four-lamp UV irradiator used for curing FLG coatings. We used DRT-230 tubular mercury arc lamps; the lamp current I_l was about 2 A, and the exposure time, 5–10 s. After curing of the liquid core, the thin-walled capillary (50–60 μm) was broken, and the surface of the cured core was cleaned to remove glass crumb.

The thus prepared fiber samples were used for measuring the Young modulus as one of the main mechanical parameters of the coating material. The results of the measurements for a series of cured formulations at 2.5% relative elongation are listed below:

Young modulus of materials of cured formulations

Material	Pr. no. 1	S.l. no. 1	S.l. no. 2	S.l. no. 3	S.l. no. 4	S.l. no. 5	Sec. no. 1	Sec. no. 2	DS-5471-3-14
E, MPa	5.1	25.7	33.2	70.0	145.0	160.0	1700	1900	53.0

Let us comment on the effect of the surface tension σ on the results of viscosity measurements. We did not measure μ directly but evaluated the Laplace pressure in the capillary P_L from the height of the liquid rise *h*: $P_L = \rho gh$. For example, for single-layer formulation no. 3 ($\rho \approx 1.2$ g cm^{-3}) at $T = 20$°C and $R = 0.24$ mm, $h = 27$ mm, which corresponds to $P_L \approx 118$ Pa, whereas the rarefaction used in the experiment was $\Delta p \approx 29400$ Pa (0.3 atm). Thus, the contribution of the Laplace pressure can be neglected.

Let us estimate the flow shear rates in the liquids under consideration in the course of viscosity measurements. For a steady-state flow of a Newtonian liquid in a capillary, the shear rate is the highest at the capillary walls and is determined by the formula $\gamma_m = (P/L)(R/2\mu)$, where *P* and *L* are the applied pressure and the capillary length, respectively. In our case, the flow is not steady, especially in the initial period. Therefore, it is appropriate to average the shear rate over the measurement time:

$$\langle\gamma_m\rangle = \frac{l}{t}\int_0^t \gamma_m(\tau)\,d\tau. \quad (8)$$

After substituting $P \to \Delta p$ and $L \to l(t)$ [formula (6)] in the integrand and performing integration, we obtain

$$\langle\gamma_m\rangle = 2\sqrt{\frac{\Delta p}{\mu t}}. \quad (9)$$

Estimation of $\langle\gamma_m\rangle$ for the case of our viscosity measurements gives a value of 10–100 s^{-1}.

CONCLUSIONS

(1) A fast capillary procedure was developed for estimating the viscosity of Newtonian liquids, which does not require large sample volumes and washing of the viscometer in going from one sample to another; the measurement requires only 1–3 ml of a test liquid and a 15–20-cm-long capillary with an inner diameter of 200–1000 μm.

(2) By this procedure, the viscosity characteristics of UV-curable formulations based on oligourethane acrylates for protective coatings on fiber light guides were evaluated; formulations were found for primary (soft), single-layer (intermediate-modulus), and secondary (hard) FLG protective coatings, which can be stably applied with a die at FLG drawing rates of up to 100–120 m min^{-1}.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Rheological and Electrophysical Characteristics of Solutions of Polyvinyl Alcohol and Water-Soluble Carboxymethyl Cellulose

T. G. Lazareva and E. V. Shinkareva

Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received December 5, 2001; in final form, March 2002

Abstract—The flow and viscosity curves of solutions of polyvinyl alcohol and water-soluble carboxymethyl cellulose of various brands, and also of their mixtures are studied over the temperature range 30–70°C.

Water-soluble polymer and, in particular, polyvinyl alcohol (PVA) and carboxymethyl cellulose (Na-CMC) are widely used in the pulp-and-paper, varnish-and-paint, and other branches of industry. In the pulp-and-paper works, their 1–5% solutions are used for paper sizing. In this context, it is of interest to compare rheological characteristics of such solutions, as dependent on the polymer brand and concentration and the solution temperature. A study of the flow and viscosity curves as influenced by the temperature and electric and magnetic fields is necessary to evaluate the operational capacity of polymer solutions [1, 2]. The rheological properties of polymer solutions are also of interest for elucidating their structural features related to the system of intermolecular interactions, conformational transformations, and stereoregularity. Finally, the initial parameters of polymer solutions largely control the mechanical and performance characteristics of the resulting products (coatings, fibers, special-purpose paper, paints, etc.) [3].

Here we report generalized data on the rheological properties of polyvinyl alcohol and water-soluble carboxymethyl cellulose of various brands and formulations on their base.

EXPERIMENTAL

Rheological measurements were carried out with a Rheotest-2 rotary viscometer over wide the shear rate (D_r from 1 to 1350 s^{-1}) and temperature ranges (from 30 to 80°C). Mechanical action on the polymer solutions was effected by rotation of the inner cylinder of the rotary cell of the viscometer. The electrical conductivity æ and dielectric loss tangent tan δ were determined on an E7-15 instrument at a frequency of 1 kHz.

It was demonstrated experimentally that, in PVA solutions, the shear stress τ_v linearly depends on the shear rate D_r over the concentration range 1–20 wt %. Such a dependence, known as the flow curve, is one of the main rheological characteristics of fluid media. The flow curves allow classification of liquids with Newtonian or non-Newtonian fluids. For ordinary (Newtonian) fluids, the dependences of the viscosity η and shear stress τ_v on the shear rate D_r are linear, and η is independent of the shear rate and shear stress. The viscosity of non-Newtonian fluids is not constant, being dependent on the shear rate or stress [4].

In PVA solutions, the plots of η vs. D_r are different in shape, depending on the PVA brand (Fig. 1). For PVA manufactured in Japan, η at 30°C initially increases and then level off (Fig. 1, curve *1*). At 70°C, the flow curves are similar in shape. It may be suggested that, under shearing load at low shear rate,

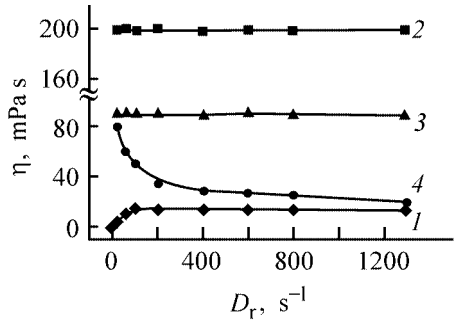

Fig. 1. Viscosity η vs. shear rate D_r in 16% PVA solutions. PVA manufacture: (*1*) in Japan and (*2–4*) in Russia (16/1). Temperature (°C): (*1*, *2*) 30, (*3*) 45, and (*4*) 70.

structural transformation of the macromolecules proceeds via rearrangement of the system of intermolecular interactions, resulting in an increase in viscosity. Such a trend is typical of non-Newtonian dilatant fluids, e.g., highly concentrated suspensions prepared by mixing a PVC emulsion with some liquid plasticizers (to obtain a paste) [5]. Other examples are electro- and magnetorheological media based on dispersions of polymers and metal oxides in oils or polymeric binders [1, 2].

Solutions of PVA 16/1 (Russia) demonstrate no dilatant behavior at low temperatures (30–45°C). In this temperature range, the viscosity is independent of the shear rate (Fig. 1, curves *2*, *3*). However, with the solution temperature increasing to 70°C, the dynamic viscosity decreases with increasing shear rate (Fig. 1, curve *4*). In this case, the liquid becomes readily structured, acquiring some plastic properties, as well as the capability of orientation ordering at certain shear rates.

Figure 2 shows the temperature dependences of the dielectric loss tangent. In the PVA 16/1 solutions, tan δ increases at temperatures above 60°C, which can be attributed to weakening of hydrogen bonding in the system, and, therefore, to increasing molecular flexibility of the macromolecules. As a result, the liquid becomes more readily structured, which is reflected in a change in the shape of the flow curves at the corresponding temperature (Fig. 1, curve *4*).

The structure of aqueous PVA solutions strongly depends on the polymer concentration. There are several concentration intervals characterized by specific solution structures (see table). The effect of concentration on the viscosity is more clearly pronounced in highly viscous solutions of PVA 16/1: the viscosity only slightly changes at concentrations below 5 wt %; within the concentration range 5–10 wt %, the viscosity initially grows rapidly and then more slowly again; in the PVA concentration 15–20 wt %, the viscosity increases rapidly.

The results obtained suggest that 1–20% PVA solutions can be classified with structures intermediate between Newtonian and non-Newtonian fluids. For these structures, the shear stress is still independent of the shear rate, but some anomalies are already observed in the flow curves. Evidently, the anomalous behavior is associated with structural effects occurring with increasing temperature or polymer concentration. In dilute solutions, the macromolecules are not associated. With increasing concentration, a network of hydrogen bonds is formed. Therefore, the system of intermolecular interactions and, quite possibly, the physical structure of the macromolecules [3] depend on the solution concentration, which is reflected in the features of the solution flow in the mechanical field.

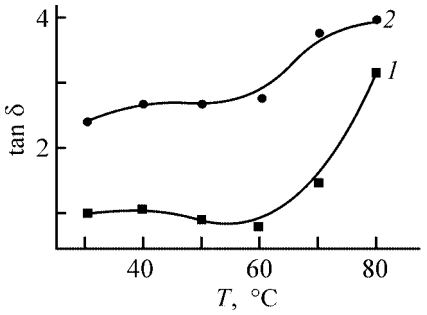

Fig. 2. Dielectric loss tangent tan δ vs. the temperature T in (*1*) 1% and (*2*) 5% PVA (16/1) solutions.

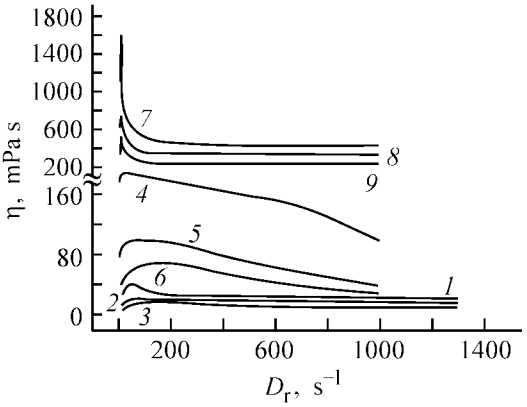

Fig. 3. Viscosity η vs. shear rate D_r in 1% Na-CMC solutions. Na-CMC grade: (*1–3*) 7MF, (*4–6*) 9M31F, and (*7–9*) 7HOF. Temperature (°C): (*1, 4, 7*) 30, (*2, 5, 8*) 50, and (*3, 6, 9*) 70.

Let us analyze the dependences of the viscosity on the shear rate for Na-CMC solutions. The flow curves considerably depend on the Na-CMC grade and solution temperature. The dependences of the viscosity at various temperatures on the shear rate for 1 wt % Na-CMC 7MF (low-viscosity grade) are given in Fig. 3 (curves *1–3*). In these curves, there is a portion of increasing viscosity at low shear rates; with increas-

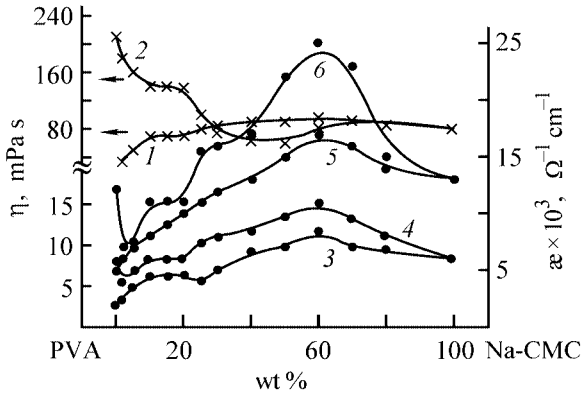

Fig. 5. (*1, 2*) Viscosity η and (*3–6*) conductivity æ vs. polymer weight ratio in mixtures obtained from (*1, 3, 4*) 5% or (*2, 5, 6*) 10% PVA and 1% Na-CMC. (*1, 2*) D_r = 16.2 s^{-1}. Temperature (°C): (*1–3, 5*) 30 and (*4, 6*) 80.

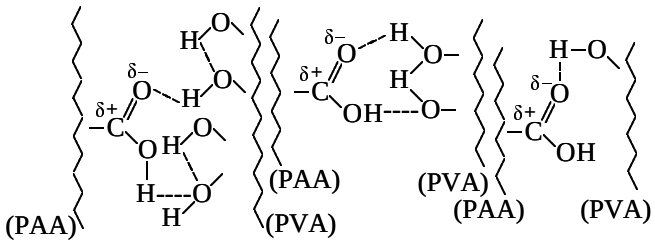
ing temperature, the viscosity maxima shift toward higher D_r (Fig. 3, curves *2*, *3*). The flow curves for Na-CMC of medium viscosity, specifically Na-CMC 9M31F, are shown in Fig. 3 (curves *4–6*). They are characterized by a diffuse peak in the range 1–1000 s^{-1}. For more viscous Na-CMC 7HOF, a strong peak is observed at low D_r, followed by rapid decrease in the viscosity (Fig. 3, curves *7–9*).

The results obtained suggest that the mechanical shear load has a considerable effect on the structure and properties of the Na-CMC solutions. With Na-CMC of low- and medium-viscosity brands, at a shear rate from 1 to 1000 s^{-1}, the initial system of intermolecular interactions can change under the action of the mechanical field with the formation of new supramolecular structures. With increasing solution viscosity, such processes occur at lower shear rates, and, at a shear rate of about 1 s^{-1}, an afterflow portion is already observed in the flow curve, as a result of the orientation of macromolecular aggregates.

The rheological properties of mixtures of PVA with water-soluble Na-CMC were studied. The mixtures were prepared from 5 or 10% PVA (16/1) and 1% Na-CMC (86/600) solutions.

It is known [3] that structures of three types can be distinguished in mixed polymer solutions. At low concentrations, the solution consists of a mixture of free macromolecules of both polymers. At higher concentrations, the solution consists of two phases, being a mixture of associated macromolecules. The effect of one polymer on the degree of association or, in other words, on the short-range order of the other polymer is reflected in structural transformation of each polymeric phase in the mixture, which is accompanied by change in the crystallization temperature, glass transition temperature [6, 7], and density of the mixture [8].

Complexes can be formed on mixing polymers with different functional groups, e.g., of PVA with polyacrylic (PAA) and polymethacrylic acids or CMC (both in the acidic and salt forms). PVA can form complexes of various structures with polyacids through hydrogen bonding. For example, Chatterjee and Malhotra [9] suggested several possible mechanisms for their formation:



Complexation is followed by formation of associates with definite arrangement of polymer macromolecules.

In Fig. 4a, the shear stress is plotted as a function of the shear rate for mixtures prepared from 10% PVA and 1% Na-CMC. Introduction of even small concentrations of Na-CMC (PVA : Na-CMC = 95 : 5; Fig. 4a, curve *2*) changes the initial flow curve of PVA.

The resulting mixture demonstrates a behavior typical of non-Newtonian fluids. Even stronger effect of Na-CMC addition is observed in the dependence of the viscosity on the shear rate (extension of the afterflow portion) (Fig. 4b).

In Fig. 5, the viscosity η and conductivity æ of mixtures prepared from 5% or 10% PVA (16/1) and 1% Na-CMC are plotted against the polymer weight ratio. In the mixtures studied, anomalous behavior (deviation from the additive model) of the viscosity was observed, which is the most clearly pronounced at low shear rates. The anomalous behavior is reflected in the appearance of peaks and dips in the viscosity curves. The anomalies are also observed in the dependences of the electrical conductivity (Fig. 5).

The results obtained can be interpreted in terms of the concept of complexation between PVA and Na-CMC macromolecules [9]. The extension of the afterflow portion in the viscosity curves is associated with orientation of the macromolecules in the mechanical field, suggesting the formation of anisotropic structures from macromolecular associates.

CONCLUSIONS

(1) Solutions of polyvinyl alcohol and carboxymethyl cellulose of various brands differ in the nature of the viscosity and flow curves, demonstrating pseudoplastic and dilatant properties.

(2) Complexation between PVA and Na-CMC macromolecules controls the viscosity and flow behavior, as well as the electrophysical and rheological characteristics of the mixed polymer solutions. In a mechanical field, the solution acquires properties of a non-Newtonian fluid. The deviation of the electrophysical and rheological properties from the additive model is associated with the formation of anisotropic structures from macromolecular associates.

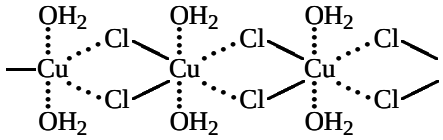
Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received April 4, 2002

Abstract—Rheological and electrical properties of polyvinyl alcohol solutions containing copper(II) and cobalt(II) chlorides are studied. Anomalous behavior of these properties is associated with complex formation, depending on the component ratio and temperature.

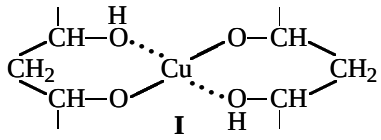
Polyvinyl alcohol–based composites with transition metals, such as Cu, Co, etc., can find use for preparation of materials for various purposes (polymerization catalysts, membranes, thermochromic materials, paints, and fibers) [1]. Inorganic coordination chemistry of copper, cobalt, and iron has been quite thoroughly studied [2], while the chemistry of hybrid organo-inorganic complexes became a subject of extensive investigation only recently.

It is known [2] that Cu^{2+} can form both cationic and anionic octahedral complexes (coordination number 6). For example, blue aqua complexes $[Cu(H_2O)_6]^{2+}$ are formed in dissolution of copper(II) salts in water or by reaction of CuO or $Cu(OH)_2$ with acids. Copper(II) crystal hydrates are also mostly blue, e.g., $Cu(NO_3)_2 \cdot 6H_2O$. But they may be green and deep brown too. In this case, the coordination sphere of the cation includes both water molecules and anions. For example, in green $CuCl_2 \cdot 2H_2O$, copper atoms are surrounded by two water molecules and four chloride anions:

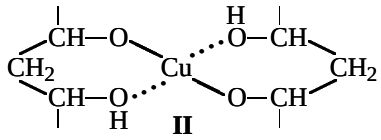


With addition of water to $CuCl_2 \cdot 2H_2O$, the solution changes its color to blue as a result of the formation of the aqua complex $[Cu(H_2O)_6]^{2+}$.

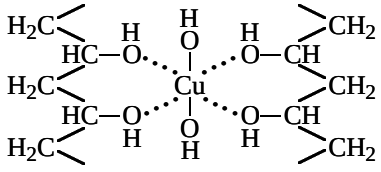
Complexation in the system polyvinyl alcohol (PVA)–Cu^{2+} has been studied in a number of works. Chelate complexes PVA–Cu^{2+} have been synthesized by adding $Cu(NO_3)_2$ and NaOH to a dilute aqueous PVA solution [3–7]. Complexation of PVA with Cu^{2+} in the presence of ammonia and *n*-alkylamines has also been studied. In this case, ammonia is believed to act not only as a deprotonating agent for PVA, but also as a complex-forming agent. Godard [1] suggested three possible structures for PVA–Cu^{2+} complexes obtained by deprotonation.



I



II



III

Moneva and Ivanova [8] studied complexation and gelation in the PVA–Cu^{2+} system. It was demonstrated that complexation includes two stages with the formation of a positively charged blue complex and a green deprotonated complex. The green complex is formed through loss of two protons, which is accompanied by transition to a compact conformation. The pH and free energy of the conformation transition were determined.

1070-4272/02/7510-1692 $27.00 © 2002 MAIK "Nauka/Interperiodica"

Previously, we studied the rheological and electrophysical properties of PVA-based composites with copper(II) chloride and orthophosphoric acid [9]. It was suggested that complexation may occur in such materials at certain component ratios. The present study is concerned with the rheological and electrical properties of PVA-based composites with copper(II) and cobalt(II) chlorides.

EXPERIMENTAL

In the experiments we used composites prepared at room temperature from 5 or 10% aqueous PVA 16/1 solutions and copper(II) and cobalt(II) chlorides at various component ratios. The rheological characteristics were determined with a Rheotest-2 rotary viscometer at 30–80°C in the range of the shear rates from 3 to 1.3×10^3 s^{-1}. The electrical characteristics of the fluid composites (electrical conductivity æ and dielectric loss tangent tan δ) were measured with an E7-15 instrument at a frequency of 1 kHz.

The viscosity η in the PVA–$CuCl_2$ system at a shear rate of 16.2 s^{-1} is shown in Fig. 1 as a function of the component ratio. The composites were prepared by dissolution of copper(II) chloride in 5 or 10% aqueous PVA solutions. The experimental curves deviate from the additive model; peaks and dips are observed in certain concentration ranges. In 5% PVA, at 30 and 70°C, the peaks are found at 15, 35, and 60 wt % $CuCl_2$; and in 10% PVA, at 25, 40, and 60 wt % $CuCl_2$.

In Fig. 2, the viscosity η at 30°C of the PVA–$CuCl_2$ system of various compositions is plotted against the shear rate $\dot{\gamma}$. As seen, the viscosity is strongly dependent on the shear rate, which is typical of non-Newtonian fluids. The viscosity rapidly increases at low shear rates (up to 10 s^{-1}) and then decreases.

In Fig. 3, the electrical characteristics (dielectric loss tangent tan δ and electrical conductivity æ) are given as functions of the system composition. In the composition range where æ shows maxima, tan δ, quite the contrary, takes the minimal values.

The results show that complexation in the PVA–$CuCl_2$ system strongly influences the rheological behavior and electrical characteristics. The viscosity curves suggest that complexes of various compositions are formed in the system, depending on the component ratio.

We obtained similar results for the PVA–$CoCl_2$ system, too. Figure 4 shows the viscosity as a function of the cobalt chloride concentration in 5 and 10% PVA. The anomalous behavior of the viscosity is reflected in the appearance of extrema in the curves. In 5% PVA (30°C), peaks are observed at 10,

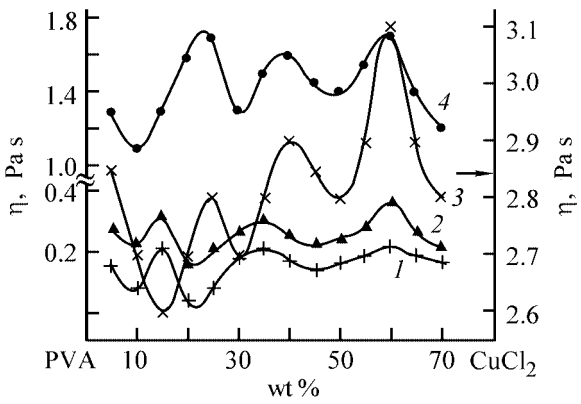


Fig. 1. Viscosity η vs. the composition of the PVA–$CuCl_2$ system based on (*1*, *2*) 5 and (*3*, *4*) 10% PVA solutions. Shear rate 16.2 s^{-1}; solution temperature (°C): (*1*, *3*) 30 and (*2*, *4*) 70; the same for Fig. 4.

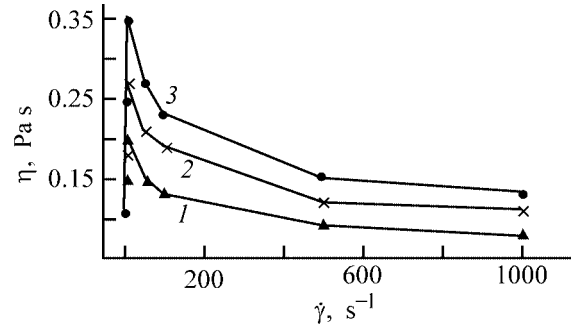

Fig. 2. Viscosity η vs. the shear rate $\dot{\gamma}$ in the PVA–$CuCl_2$ system based on 5% PVA solution. Temperature 30°C. Copper chloride concentration (wt %): (*1*) 15, (*2*) 40, and (*3*) 60.

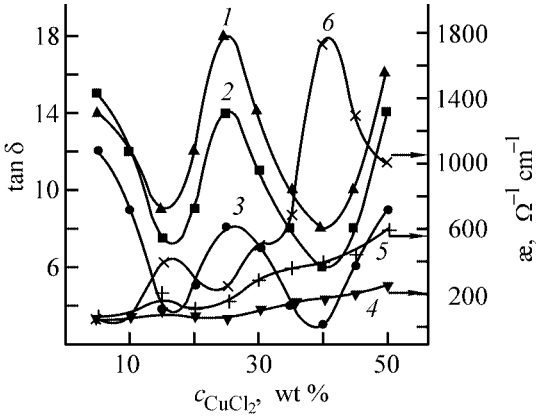

Fig. 3. (*1*–*3*) Dielectric loss tangent tan σ and (*4*–*6*) electrical conductivity æ vs. the $CuCl_2$ concentration c_{CuCl_2} in the PVA–$CuCl_2$ system based on 10% PVA solution. Temperature (°C): (*1*, *4*) 30, (*2*, *5*) 50, and (*3*, *6*) 80.

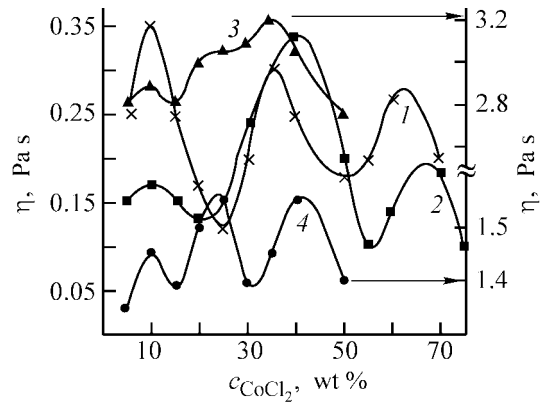

Fig. 4. Viscosity η vs. the $CoCl_2$ concentration c_{CoCl_2} in the PVA–$CoCl_2$ system based on (*1*, *2*) 5 and (*3*, *4*) 10% PVA solutions.

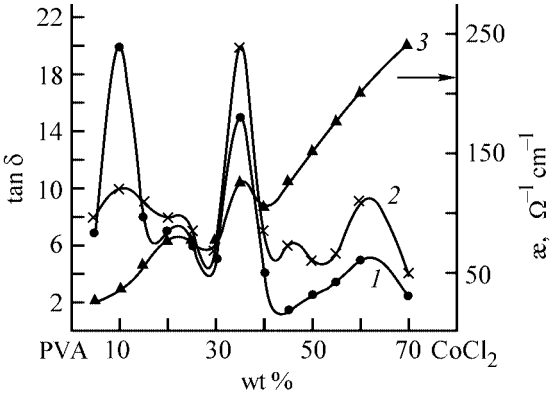

Fig. 5. (*1*–*2*) Dielectric loss tangent tan δ and (*3*) electrical conductivity æ vs. the composition of the PVA–$CoCl_2$ system based on 10% PVA solution. Temperature (°C): (*1*, *3*) 30 and (*2*) 70.

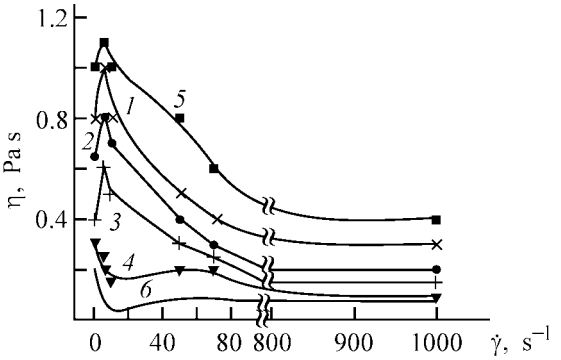

Fig. 6. Viscosity η vs. the shear rate $\dot{\gamma}$ in the PVA–$CoCl_2$ system based on 5% PVA solution. Cobalt chloride concentration (wt %): (*1*, *4*) 10, (*2*) 30, (*3*, *6*) 60, and (*5*) 40. Temperature (°C): (*1*–*3*) 30 and (*4*–*6*) 70.

35, and 65 wt % $CoCl_2$ (curve *1*). Raising the temperature to 70°C changes somewhat the viscosity pattern. The peak at 40 wt % $CoCl_2$ becomes stronger than that at 10 wt %, and a weak peak at 70 wt % appears instead of that at 65 wt % (curve *2*).

For the system PVA–$CoCl_2$ prepared from 10% PVA (30°C), we observed a weak peak at 10 wt % $CoCl_2$ and a broad peak at 20–40 wt % (Fig. 4, curve *3*). With this system, again, raising the temperature to 70°C alters the shape of the viscosity curve. In this case, three peaks at 10, 25, and 40 wt % $CoCl_2$ are observed (curve *4*).

In Fig. 5, the dielectric loss tangent tan δ and electrical conductivity æ are shown as functions of the system composition. At 30°C, two weak peaks are found in the æ curve at 20–25 and 35 wt % $CoCl_2$ (curve *3*), and three peaks in the tan δ curve at 10, 35, and 60 wt % (curve *1*). Raising the temperature to 70°C weakens the effect at 10 wt % and strengthens that at 35 and 60 wt % (curve *2*).

In Fig. 6, the viscosity of the 5% PVA–$CoCl_2$ system is plotted against the shear rate for various $CoCl_2$ contents. At a $CoCl_2$ content of 10, 30, and 60 wt % (30°C, curves *1*–*3*) and of 40 wt % (70°C, curve *5*) peaks are found at low shear rates, followed by monotonic smooth decrease with the shear rate increasing further. At a $CoCl_2$ content of 10 and 60 wt % (70°C, curves *4*, *6*), we observed an anomalous behavior of the viscosity. The peaks and dips in the flow curves can be interpreted as being due to structural reorganization of the polymer macromolecules in the mechanical field. It may be suggested that, in the indicated composition ranges, the structural organization of the solution is optimal for fluid flow to occur under the action of the mechanical shear load provided by rotation of the inner cylinder of the measuring cell. In this case, we can find in the flow curve a clearly pronounced portion of afterflow (flow of readily structured anisotropic solution), followed by a portion corresponding to the flow of associates oriented in the mechanical field. Note that, for the initial PVA, the flow curves behave similarly in the temperature range near 70°C [10–12].

The optical characteristics of 10% PVA (16/1) containing various concentrations of $CoCl_2$ are listed in the table below. It is seen that the optical density *D* and absorption peak area *S* depend on the $CoCl_2$ concentration nonlinearly.

The solution acidity grows with increasing $CoCl_2$ concentration. Below is given the dependence of pH of 10% PVA solutions on the $CoCl_2$ concentration.

c_{CoCl_2}, %	10	20	30	50	60
pH	6.08	6.06	5.84	5.41	5.19

Optical characteristics of 10% PVA solutions containing $CoCl_2$

c_{CoCl_2}, %	λ_{max}	Optical density D	Peak area S
10	507	0.926	108.37
20	509	1.338	153.341
30	510	2.025	224.32
50	522	3.0	437.239
60	537	3.0	417.107

The results suggest the interaction between PVA and the salt additive.

Complex formation between PVA and MCl_2 affects the rheological and electrical properties of PVA solutions, resulting in an anomalous behavior. It is clear that addition of the salt additives changes the structural organization of the polymer macromolecules. Applying a mechanical field causes further reorganization of the solution structure, as demonstrated by the appearance of peaks at low shear rates (up to 10 s^{-1}) and of the afterflow portion in the viscosity curves.

CONCLUSIONS

(1) The anomalous behavior of the rheological and electrical properties in PVA solutions containing Cu^{2+} and Co^{2+} ions is associated with complex formation in the systems studied.

(2) The long-range order in PVA solutions and their flow behavior depend on the content of copper(II) and cobalt(II) chlorides in the system.

Received April 24, 2002

Abstract—Coagulation recovery of kraft lignin from aqueous solutions with oxotitanium sulfate, aluminum sulfate, and a composite coagulant based on their mixture was studied in a wide range of coagulant concentrations and solution pH values.

Wastewater from kraft cellulose production is characterized by high contamination level and multicomponent composition. One of the main contaminants is kraft lignin (KL), imparting to water deep color and high chemical oxygen demand (COD). Wastewater from kraft cellulose production is usually supplied to centralized biological treatment. However, biological treatment fails to remove KL and completely thus to decrease the coloration and COD of wastewater to the prescribed level. To achieve the permissible concentrations of KL in the discharged water, additional physicochemical treatment of wastewater is required [1, 2]. Among the procedures for physicochemical treatment, the most widely used are coagulation and flocculation. In wastewater treatment, aluminum sulfate is commonly used as a coagulant [3–5]. The treatment process can be intensified and its efficiency can be raised by using modified (prehydrolyzed) coagulants (e.g., OKhA) [6] and composite coagulants (a mixture of salts of aluminum, iron, and other metal) [7]. Recently, the use of coagulants based on Ti(IV) salts, having some advantages over aluminum and iron salts, for water and wastewater treatment has been reported [8–16]. However, these reports do not describe the composition of these coagulants and the mechanism of their interaction with contaminants.

In this work, we studied coagulation of KL with oxotitanium sulfate $TiOSO_4 \cdot 2H_2O$, aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$, and their mixture (composite coagulant) in a wide range of coagulant concentrations and pH values.

EXPERIMENTAL

KL was taken from the Solombal' Paper and Pulp Combine and was purified to remove substances insoluble in alkali (pH 12). The model wastewater was a solution of KL in 0.01 N NaOH (100 mg l^{-1}). A solution of $TiOSO_4$ and $Al_2(SO_4)_3$ in 0.01 N H_2SO_4 was used as a mixed coagulant. The concentrations of Ti(IV) and Al(III) in the initial solution were 2.5 and 1 M, respectively. The pH was adjusted with 0.1 N solutions of H_2SO_4 and NaOH. Mixing of the model wastewater with coagulant solutions and with the composite coagulant components was performed instantaneously. All the chemicals were of analytically pure grade. The efficiency of KL recovery was determined from the residual concentration of KL in the solution, c_s, and in the filtrate, c_f. Filtration was carried out through blue-band paper filters. The concentration of KL in solution was determined spectrophotometrically with an SF-46 spectrophotometer at a wavelength of 480 nm and pH 11. The experimental procedure was described in more detail in [1, 2].

To elucidate the processes occurring in recovery of KL from the model wastewater under the action of a mixed coagulant, we first studied the behavior of KL in the presence of $TiOSO_4$ or $Al_2(SO_4)_3$, taken separately, in a wide range of their concentrations and pH values.

The pH dependences of the residual concentration of KL in the presence of $TiOSO_4$ before and after

1070-4272/02/7510-1696 $27.00 © 2002 MAIK "Nauka/Interperiodica"

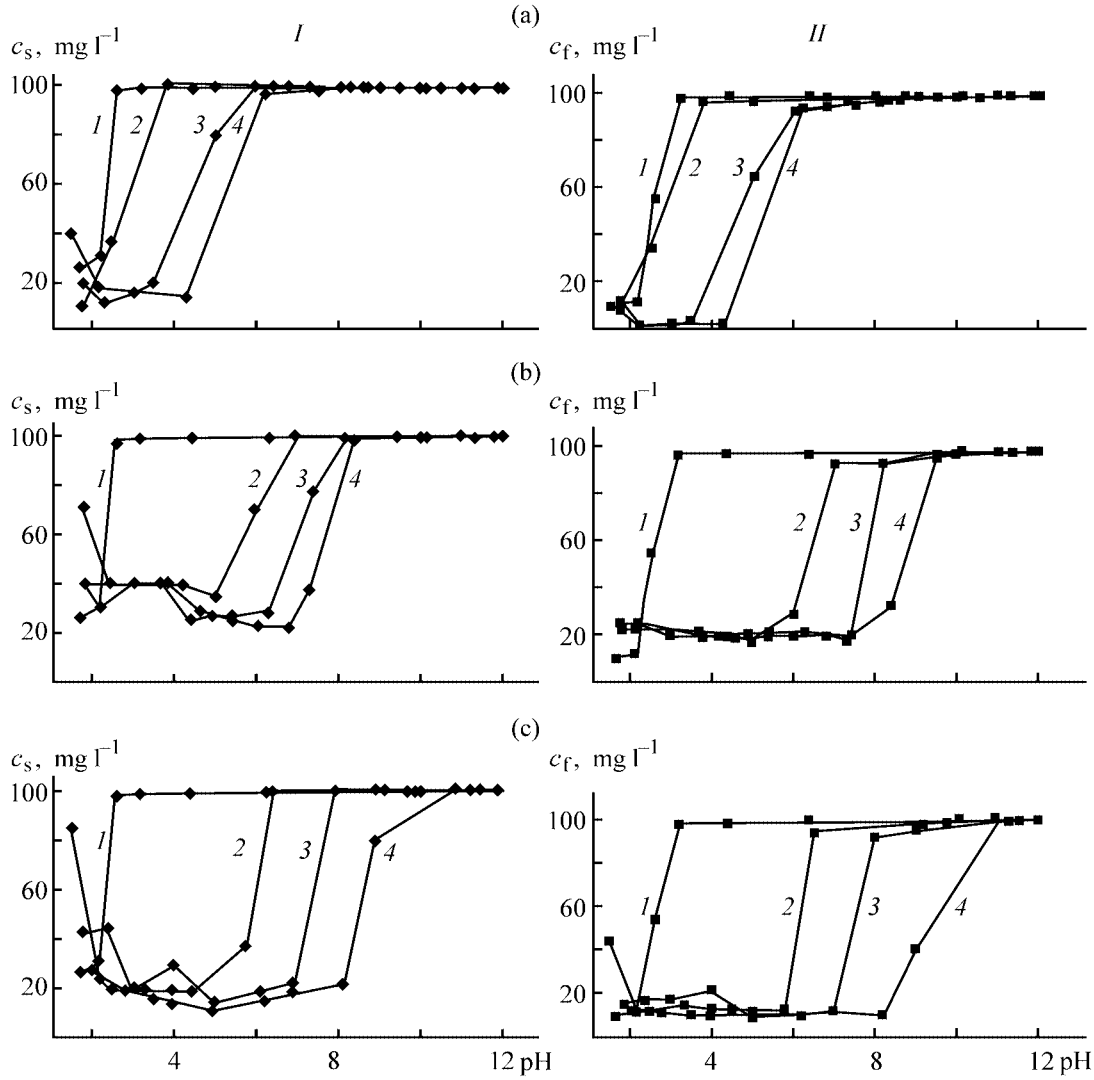

Fig. 1. Residual concentration of KL in the systems (a) KL–$TiOSO_4$, (b) KL–$Al_2(SO_4)_3$, and (c) KL–$TiOSO_4$–$Al_2(SO_4)_3$ (*I*) before filtration, c_s, and (*II*) after filtration, c_f, vs. pH. (a) $TiOSO_4$ concentration, M: (*1*) 0, (*2*) 10^{-4}, (*3*) 5×10^{-4}, and (*4*) 10^{-3}. (b) $Al_2(SO_4)_3$ concentration, M: (*1*) 0, (*2*) 10^{-4}, (*3*) 5×10^{-4}, and (*4*) 10^{-3}. (c) Concentrations of $TiOSO_4$ and $Al_2(SO_4)_3$, M: (*1*) 0, (*2*) 10^{-4}, (*3*) 5×10^{-4}, and (*4*) 10^{-3}.

filtration are shown in Fig. 1a. The pH at which the coagulation recovery of KL starts in the absence of a coagulant is approximately 3.1 (Fig. 1a, *II*, curve *1*), in good agreement with published data [17, 18]. This value was defined as pH at which the residual concentration of KL in the solution after its filtration starts to decrease. The presence of 10^{-4} M $TiOSO_4$ shifts the pH of the onset of coagulation recovery of KL to a less acidic range (approximately to pH 3.7). However, the maximal efficiency of KL removal remains virtually the same as that in the absence of $TiOSO_4$ (Fig. 1a, *II*, curves *1* and *2*). Raising the concentration of $TiOSO_4$ to 5×10^{-4} M and then to 10^{-3} M results in a regular shift of the pH of the onset of KL recovery to approximately 6.2; in this case, the efficiency of sedimentation recovery of KL in the range pH 2.1–4.2 increases to 90%, and upon filtration, to virtually 100% (Fig. 1a, *II*, curve *4*).

According to published data, the recovery of KL in the presence of $TiOSO_4$ proceeds by the heterocoagulation mechanism as a result of interaction of KL particles with the products of $TiOSO_4$ hydrolysis (PTH). Since the KL particles are negatively charged, the heterocoagulation is the most active at low pH (at low negative values of ζ-potential of KL and PTH particles). This can account for the narrow pH range of KL recovery observed in the experiments.

The dependences of the residual KL concentration on pH in the presence of $Al_2(SO_4)_3$ before and after

filtration are shown in Fig. 1b. As seen, the efficiency of KL removal at pH 2–7 reaches 80% in the case of filtration. The mechanisms of KL recovery with aluminum sulfate have been considered and discussed previously [18]. It should be noted that, in contrast to $TiOSO_4$, KL is recovered most completely in the presence of $Al_2(SO_4)_3$ in a wider pH range 2–7 (curves *2*–*4*). This is due to the fact that, in contrast to the KL–$TiOSO_4$ system, KL particles and hydrolysis products of $Al_2(SO_4)_3$ have opposite charges in this pH range [18, 19].

Our results show that, with $TiOSO_4$ as a coagulant, KL can be recovered virtually completely, but in a narrow pH range 2–4. The working pH range for aluminum sulfate is significantly wider; however, the use of aluminum sulfate allows recovery of KL from the model wastewater with an efficiency not exceeding 80%.

The treatment efficiency was must improved and the working pH range made significantly wider by using $TiOSO_4$ and $Al_2(SO_4)_3$ in combination. The dependence of the residual concentration of KL on pH before and after filtration, with $TiOSO_4$ and $Al_2(SO_4)_3$ present simultaneously, is shown in Fig. 1c. It is seen that, at concentration of the salts of 10^{-4} and 5×10^{-4} M (curves *2* and *3*), the pH range in which the mixed coagulant is the most effective is the same as in the case of $Al_2(SO_4)_3$. At metal concentrations of 10^{-3} M (curve *4*), this range is wider (pH 2–8) than that with $Al_2(SO_4)_3$ taken alone (pH 2–7). Furthermore, addition of the mixed coagulant results in ~10% higher efficiency of coagulation recovery of KL than with $Al_2(SO_4)_3$ taken alone, which corresponds to a decrease in the residual concentration of KL in solution by a factor of 2 (from 20 to 10 mg l^{-1}). The apparent enhancement of the coagulation effect of the mixed coagulant as compared to $Al_2(SO_4)_3$ widely used in practice is due to parallel occurrence of several heterocoagulation processes in the resulting multicomponent disperse system containing negatively charged particles of KL and PTH and positively charged hydrolysis products of the aluminum salt.

CONCLUSIONS

(1) Oxotitanium sulfate has high coagulation power with respect to aqueous solutions of kraft lignin. However, the pH range in which it is effective is rather narrow (pH 2–4).

(2) The use of a mixed coagulant based of oxotitanium sulfate and aluminum sulfate significantly expands the pH range (pH 2–8) in which kraft lignin can be effectively (to an extent of up to 90%) recovered from aqueous solution.

Abstract—Cellulose acetomyristates of varied composition were studied. The sample volume abnormally increases in high-temperature stretching and after swelling in benzene. Cellulose acetomyristates can be used as membranes for separating aromatic and aliphatic hydrocarbons.

Natural polysaccharides, in particular cellulose, attract growing attention. Polymorphism of cellulose and its derivatives has been extensively studied [1–5]. Of special interest are determination of the ratio of I_α and I_β modifications and conditions of phase transition of metastable I_α modification into I_β, II, III_I, III_{II}, IV_I, and IV_{II} phases [2, 4].

It is known [6, 7] that the properties of cellulose derivatives are determined not only by the structure of the initial cellulose and degree of its ordering but also, and to a greater extent, by the structure of substituents and the number of residual free hydroxy groups.

As determined by IR spectroscopy [6], free hydroxy groups of highly substituted cellulose derivatives are involved, irrespective of the nature and volume of the substituents, in intramolecular hydrogen bonding and stabilize the shape and rigidity of the glucoside skeleton, not affecting the mobility of substituents of any size. Hence, it is possible to prepare, by gradual substitution of hydroxy groups, cellulose homologs with various amphiphilic, physical and chemical properties, which can be used in various branches of nanotechnology, including the Langmuir–Blodgett process [7–9]. More reliable interpretation of the structural data requires a systematic study of macro- and Langmuir–Blodgett films of mixed cellulose esters, acetomyristates (CAM), with account of their polymorphic nature [9, 10].

A comprehensive study of celluloses with different composition is a topical task, since both Langmuir–Blodgett and macrofilms can be used in pervaporation and gas separation [11, 12].

In this work, we studied the structural, thermomechanical and mass exchange properties of three CAM derivatives prepared from natural cellulose and containing residues of acetic (indicated in the numerator) and myristic (indicated in the denominator) acids: CAM 290/10, CAM 275/25, and CAM 250/50. Cellulose diacetate (CDA) was also studied.

EXPERIMENTAL

Cellulose acetomyristate was prepared by acylation of linter cellulose with a mixture of acetic and myristic acid in trifluoroacetic acid. Trifluoroacetic acid anhydride was added to induce formation of acid anhydrides and to promote their reaction with cellulose [13]. The molecular weight of the samples, estimated by sedimentation and diffusion procedures, was $(350 \pm 30) \times 10^2$ [14].

The degree of esterification of cellulose with acetic and myristic acids was determined by ^{1}H NMR spectroscopy. The ^{1}H NMR spectra were recorded in $CDCl_3$–10% CD_3OD solutions on a Bruker AC-200 spectrometer operating at 200 MHz. CAM films 25–100 μm thick were prepared by casting a chloroform solution of the celluloses on a glass support with subsequent drying at room temperature.

To determine the thermomechanical properties, the linear sizes of free and uniaxilly stretched samples were measured in a forevacuum with heating from 20 to 400°C at a rate of 5 deg min^{-1} [15]. The absolute measurements error was 10 μm. The samples were film strips 30 mm long, 4 mm wide, and 24–25 μm thick.

To determine the influence of the repeated thermomechanical treatment on the density and structure of CAM, the size of a single sample was measured after the following treatments at the softening point: (a) primary stretching of the initial samples at a stress σ = 2.9 kg cm^{-2}; (b) repeated heating of the samples after removing the load; and (c) repeated stretching at a load equal to that in the first experiment. The volume change (V_1/V_0, where V_0 and V_1 are the volumes before and after stretching) caused by the thermomechanical treatment was determined from the linear sizes measured after the primary and the secondary stretching.

The X-ray diffraction study was performed on a DRON-2.0 diffractometer using Cu_{K_α} radiation. The samples were stacks of 10–20 film strips. Low-angle X-ray scattering patterns were obtained on an Amur-K diffractometer with a position-sensitive detector.

The transport properties of 20–25-μm films were studied in an self-contained laboratory cell for studying membranes with working surface area of 13 cm^2. In this cell, the mixture being separated or pure compounds were stirred at definite temperatures. The residual pressure under the membrane was 0.2 mbar. The permeate vapor (flow passed through the membrane) was condensed in a receiver cooled with liquid nitrogen. The membrane throughput was calculated from the weight of the condensate. The composition of the permeate formed in separation of a benzeneheptane mixture was determined by refractometry or chromatography (Reoplex column). The selectivity coefficient was calculated by the equation

$$\alpha = \frac{X_A/X_B}{Y_A/Y_B},$$

where X_A and X_B are, respectively, the weight of benzene and heptane in the permeate; and Y_A and Y_B are, respectively, the weights of benzene and heptane in the initial mixture.

The thermomechanical curves of CAM films are shown in Fig. 1. Curve *1* measured in primary stretching of a CAM film contains the following portions:

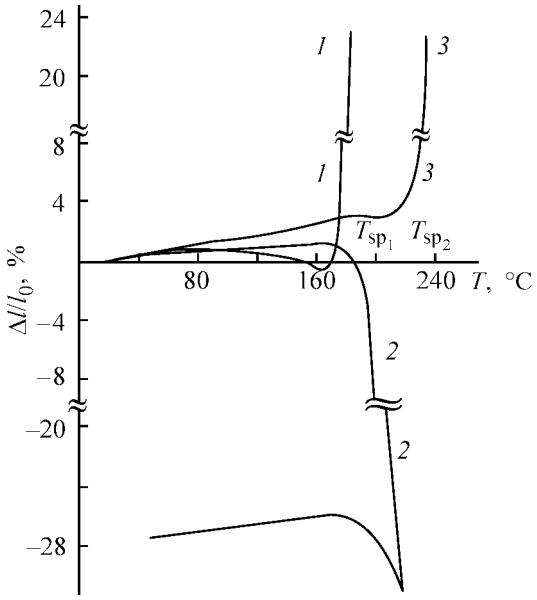

Fig. 1. (*1*, *3*) Thermomechanical curves and (*2*) curve of free contraction of a CAM film. ($\Delta l/l_0$) Deformation and (T) temperature; (T_{sp_1}, T_{sp_2}) softening points. (*1*) Primary stretching, σ = 2.9 kg cm^{-2}; (*2*) heating to 210°C and cooling to 40°C in the unloaded state; (*3*) secondary stretching, σ = 2.9 kg cm^{-2}.

thermal expansion of a solid film, slight contraction owing to disappearance of the residual stresses developed when the film was dried on the support, and the steep (almost vertical) portion due to sample softening at the softening point T_{sp_1} = 168°C. Curve *2* was measured with heating to 210°C of unloaded samples subjected to primary stretching and subsequent cooling to 40°C. Up to 160°C, thermal expansion of the sample is observed. On further heating, the samples sharply contract owing to the disappearance of the orientation stretching, which indicates a highly elastic deformation under primary stretching. In the first cooling step, abnomal elongation is observed. Only below 160°C, the samples contracts with decreasing temperature, which is presumably due to its structural ordering. Polymers with semirigid fragments of macromolecular chains behave similarly at low degrees of stretching. Bel'nikevich *et al.* observed self-orientation processes in films and fibers of some highly substituted cellulose derivatives [16]. In our case, an insignificant orientation of the film, retained upon heating up to 210°C, could result in structural transformation and self-ordering upon cooling. The softening point of the sample subjected to the secondary stretching under the same stress (curve *3*) is higher (T_{sp_2} = 222°C). Negligible contraction is observed at temperatures from 180°C to the onset of the steep ascent.

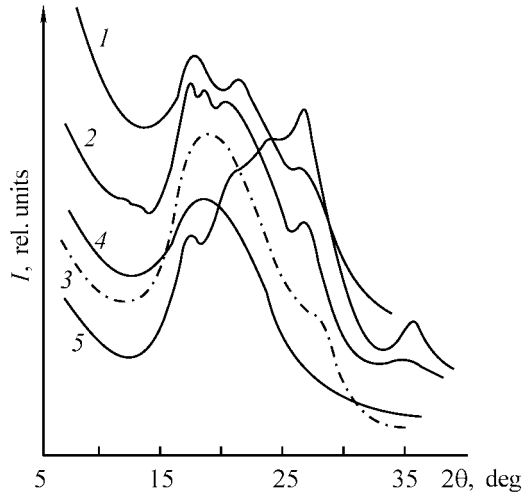

Fig. 2. X-ray diffraction patterns of (*1–3*) unoriented and (*4*, *5*) oriented CAM 275/25 films. (*I*) intensity and (2θ) Bragg's angle. (*1*) Initial sample; (*2*, *3*) films swollen in benzene for 1 h; (*4*, *5*) equatorial and meridional scattering regions of the sample stretched in benzene (λ = 1.8).

The presence of this portion in curve *3* confirms the proposed interpretation of abnomal thermal expansion (curve *2*) upon cooling from 210 to 160°C. This unusual behavior upon heating to above 200°C is due to disordering of the structure formed on cooling.

After the primary stretching the volume of a CAM film increased by 25%. No cracking was observed under this strong deformation. As determined by optical microscopy, the film surface remained smooth after the first stretching and contained no visible defects. A negligible turbidity was probably due to development of film porosity. The film volume did not change after contraction of the unloaded film. Strong densification, reaching 17% (V_1/V_0 = 0.83), was observed under repeated stretching. This indicates a two-step structural transformation of the film in the course of high-temperature stretching. Loose structure formed in the first step becomes denser after repeated stretching.

Appreciable loosening of the film under deformation may be due to development of microporous structure. To confirm this assumption, the thickness and weight of a CAM film swollen in benzene for 1 h were determined in the course of drying of the film at 30°C for 7 days. The swollen film 5, 15, and 30 min after removal from benzene was thicker than the initial film by 54, 30, and 27%, respectively. In the equilibrium state, attained in 2 h, the film thickness corresponded to a 24% increase in the film volume. Since, by this time the film weight returned to the initial value owing to almost complete removal of benzene, the increased volume of the sample was due to structural transformations. These data agree quantitatively with the thermomechanical curves measured in primary stretching.

Analysis of the shape of low-angle X-ray scattering patterns of CAM 275/25 before and after swelling in benzene shows that the interplanar spacing increases from 2.4 to 2.9 nm after swelling, the size of the ordered regions decreases, and the degree of disordering of the polymer increases. These structural transformations indicate, on the whole, an increase in the free volume of the sample swollen in benzene.

The structural transformations of oriented and unoriented (λ = 1.8) CAM films with varied thickness (20–130 μm) were studied by X-ray diffraction. The X-ray diffraction pattern of the initial thin film (Fig. 2, curve *1*) contains weak reflections with 2θ 17°–18°, 21°–22°, and 26°–27° against the background of an amorphous halo. The X-ray diffraction pattern remains virtually the same after heating the samples to 150, 200, and 250°C. The reflections of the swollen samples, corresponding to *d* 0.514, 0.336, and 0.256 nm are sharper than those of the initial thin film (Fig. 2, curve *2*). By contrast, 100–130-μm films swollen in benzene for 20 h become X-ray amorphous (Fig. 2, curve *3*).

The meridional and equatorial regions of the X-ray diffraction pattern (Fig. 2, curves *4*, *5*) of the oriented film swollen in benzene for 10–15 min were analyzed. The sharpest meridional reflections with *d* 0.514, 0.336, and 0.256 nm may be due to 002, 003, and 004 planes with a period *c* = 1.04 nm along the stretching axis. This spacing is close to the lattice parameter *c* of two polymorphous forms of cellulose triacetate (CTA) [5]. However, the X-ray diffraction patterns of CAM, unlike those of highly ordered CTA-I and CTA-II, also contain a 003 reflection (2θ = 26.5°). This is due to the fact that the skeleton of the CAM macromolecule loses 2_I symmetry, i.e., the twofold screw axis disappears. The loss of the 2_I symmetry of CTA-II macromolecule because of the high conformation mobility of the side groups was taken into account in calculation of the structural parameters of CTA [5]. However, the lack of odd 001 reflections along the stretching axis indicates the preservation of the 2_I screw axis in crystalline regions of CTA-II, which is typical of ordered natural cellulose. An amorphous halo is observed in the equatorial region (2θ = 17°–22°) of the X-ray diffraction pattern of oriented CAM (Fig. 2, curve *4*).

The presence of sharp meridional reflections and an equatorial amorphous halo indicates that the rigid

fragments of the macromolecules are strongly ordered along the stretching direction and the recurrent fragments of this chain are azimuthally disordered [17]. In CAM films, side acetate and myristate fragments are randomly distributed relative to the skeleton of the cellulose chain, thus favoring formation of a mesomorphous structure (so-called amorphous texture [17]).

Let us turn to interpretation of the results of mechanochemical and X-ray diffraction studies and the solvent effect on swelling of CAM films. Absorption of some solvents by films and fibers of CDA, CTA, and mixed cellulose esters does not obey Fick's law [18, 19]. These processes are characterized by unusual swelling curves. Structural transformations of polymers in these systems involve both ordering and spontaneous shrinkage of the samples. Intramolecular bonds restricting the mobility of the macromolecules are ruptured after absorption of a small amount of the solvent. As a result, filaments and films of not only highly substituted CDA and CTA, but also mixed cellulose esters of varied composition are spontaneously elongated owing to ordering of their macromolecules [16, 18]. A similar effect was observed when cellulose acetates were cooled to the glass transition temperature [18].

The reflections assigned to the ordering along the polymeric chain become sharper in the X-ray diffraction patterns of unoriented CAM samples swollen in benzene, which points to long-range ordering in this direction. Bel'nikevich *et al.* [16] found that the abnormal sorption kinetics results in rupture of intermolecular bonds, which favors formation of new intermolecular interactions. Since myristate fragments are highly mobile, a new structure is formed upon even negligible changes in the initial intermolecular bonds during swelling or thermal treatment. Indeed, the volume of 24–25-μm CAM films increases by 20–25% during the thermomechanical measurements. CAM films of thickness 100–130 μm become amorphous after swelling in benzene for 1 h and subsequent drying to constant weight at 30°C.

The direction of selective mass transfer during pervaporation correlates, as a rule, with the equilibrium swelling of the membrane material in the pure components of the mixtures to be separated. In going from CDA to CAM 290/10, 275/25, and 250/50 the swelling in benzene increases from 10 to 38%; the heptane absorption ranges from trace amounts to 5%, respectively. At a higher content of the myristate fragments in CAM, the equilibrium swellings in benzene and heptane sharply increase and approach each other. For this reason, CAM films containing more than 50% myristine fragments are unsuitable for separation of a benzene–heptane mixture by pervaporation.

The transport properties of CDA and CAM membranes with respect to benzene, heptane, and their mixture (50/50 wt %) at 40°C (sample nos. 1–4) are presented in the table. As seen from the table, the permeability of the membranes increases monotonically and the selectivity of the separation decreases with increasing content of myristate fragments. These results correlate with data on equilibrium swelling of the membranes. Clearly, the deterioration of the separating properties of the membranes is mainly due to their plasticization with benzene having higher thermodynamic affinity for the CAM examined than heptane.

At the same time, as shown above, the membrane permeability may increase owing to supramolecular structural transformations of CAM. This is confirmed by results of successive pervaporation experiments with a CAM 275/25 membrane (table, sample nos. 5 and 6) activated by stationary diffusion of benzene for 30 min. The permeability of this membrane to benzene at 40°C was 2.4 kg m^{-2} h^{-1} (sample no. 3). The permeability of the activated membrane (absorbed benzene was not removed from the samples) to heptane and a heptane–benzene mixture was studied in the pervaporation cell (sample nos. 5–7). Under these conditions, the permeability to heptane (sample no. 6) and its mixture with benzene (sample nos. 5 and 7) increases as compared to the initial values (sample no. 3).

It should be noted that the benzene content in heptane passed through the activated membrane was constant (8–10%) within 3 h. This suggests that benzene in the activated membrane is partially bound to the macromolecules. This assumption is confirmed by stabilization of the volume of the CAM sample after its swelling in benzene and drying in air. Similarly, both free and bound solvent is present in the ethyl acetate–nitrocellulose system [20]. The ethyl acetate diffusion in this system is believed [20] to be abnormal and to be controlled by relaxation of the nitrocellulose structure. Clearly, the presence of bound benzene in CAM promotes formation of diffusion channels. This is confirmed by the fact that not only the permeabilities but also the α parameters of membranes 3 and 5 differ. At the same time, the permeability to heptane of the activated membrane dried in the evacuated cell at 40°C for 1 h (sample no. 8) returns to the initial values, which is clearly due to complete removal of benzene from the membrane and the resulting restoration of the initial structure of the sample.

CONCLUSIONS

(1) The volume of cellulose acetomyristate films increases abnormaly (by 25%) after primary high-temperature stretching. After secondary stretching, the structure of the sample becomes denser. A similar transformation is observed on drying a sample swollen in benzene.

(2) Cellulose acetomyristate membranes show promise for pervaporation separation of benzene–heptane mixtures.

Abstract—Compound latexes based on amine-containing styrene–acrylate copolymers and hollow particles of a polystyrene-based copolymer as a filler were studied. With this filler, it is possible to prepare antistatic pigmented coatings with increased surface hardness, decreased density, and surface resistivity ρ_s of the order of 10^8 Ω.

We have shown previously [1, 2] that film-forming cationic amine-containing styrene–acrylate latexes can form antistatic coatings with surface resistivity ρ_s within 10^7–10^{11} Ω on the surface of insulators; the antistatic properties of the coatings are preserved for a long time. The process and environmental advantages of polymeric coatings based on aqueous latexes are obvious. Certain limitations are associated with the low glass transition point (T_g) of the polymer, which results in decreased surface hardness of the coating and sometimes in its stickiness. At the same time, with latexes based on high-T_g polymers, elevated temperatures are required to obtain a high-quality coating.

The problem can be solved by adding a finely dispersed filler to enhance the hardness and eliminate stickiness of the coatings; furthermore, fillers can impart to the coating certain specific properties. Of special promise is the use of solid polymeric fillers in the form of a latex. In this case, the procedure for introducing a filler into an antistatic coating is very simple (mixing of two low-viscous latexes), and uniform distribution of filler particles in the polymeric binder is provided.

In this study, we used as filler a latex with hollow solid particles of polystyrene-based copolymers. We expected that such a filler would not only enhance the coating hardness, but also impart to it additional useful properties. The presence of voids (~400 nm in diameter) in the filler decreases the density of the material and simultaneously imparts a white color to the coating because of the intensive light scattering on voids filled with air. It is known [3, 4] that hollow submicron polymeric particles are effective polymeric pigments and can substitute titania and other inorganic pigments.

The goal of this study was to develop a procedure for compounding a cationic amine-containing latex with a hollow-particle latex (HPL) and to study the properties of antistatic coatings prepared from the compound latex. The major the difficulty originated from the fact that the most of commercially available latexes, including HPLs, are anionic, and their mixing with cationic latexes, as a rule, results in partial or complete coagulation of the system. As for cationic HPLs, they are known, but the reported procedure for their preparation [5] is unsatisfactory because of the formation of a large amount of coagulum, which results in decreased content of the dry matter in the latex and makes preparation of concentrated compound latexes from these HPLs impossible. Therefore, we chose another approach based on recharging of an anionic HPL with a cationic surfactant, followed by mixing with a cationic latex of an amine-containing copolymer.

EXPERIMENTAL

Cationic latexes were prepared from copolymers of styrene, *n*-butyl acrylate, and *N*,*N*-dimethylaminoethyl methacrylate as described in [2]. Latex particles were uniform or had a core–shell morphology (to enrich the surface layers of the particles with amino groups ensuring the antistatic effect of the coatings). The characteristics of the latexes are listed in Table 1.

* ST, styrene; BA, *n*-butyl acrylate; EGDMA, ethylene glycol dimethacrylate; DMAEMA, dimethylaminoethyl methacrylate.

As HPL we used commercially available (Rorm & Haas, the United States) anionic styrene–acrylate latex Ropaque HP-543. The experimentally determined characteristics of the latex are as follows: dry residue 30.6 wt %, particle diameter 500 nm, relative volume of the void 43 vol %, Brookfield viscosity 13 cP, and ζ-potential of particles –42 mV. The geometric parameters of the particles were determined by electron microscopy.

To recharge HPL, we used cationic surfactants purchased from Fluka Chemie AG: trimethyldodecylammonium chloride (TMDAC) and trimethyldodecylammonium bromide (TMDAB). Recharging was performed in a 0.2–0.5-l glass vessel by adding aqueous solutions of cationic surfactants to the latex over a definite period of time with vigorous stirring (800–1000 rpm) at room temperature. The content of dry matter in the latex was determined according to GOST (State Standard) 25709–83; the coagulum content, according to GOST 24923–81; the Brookfield viscosity of latexes and their compounds, with an LVDV-I$^+$ Brookfield viscometer (spindle no. 2, rotation rate 50 rpm, 20°C); the relative hardness, by the pendulum method according to GOST 5233–89; and the surface resistivity ρ_s, according to GOST 20214–74. The density of a polymeric coating was determined for a free latex film from its weight and size (area and thickness). The covering power of the hollow pigment in coatings was determined according to GOST 8784–75. The ζ-potential was measured by macroelectrophoresis using a Barton cell suitable for latexes. As side liquid we used 0.025 N aqueous potassium chloride. Measurements were performed at a 7 wt % concentration of a polymer in a latex. The ζ-potential was calculated by the Helmholtz–Smoluchowski equation

$$\zeta = 4\pi\eta U_0/D,$$

where η and D are, respectively, the viscosity and dielectric permittivity of the dispersion medium (water), and U_0 is the electrophoretic mobility of particles, calculated by the formula

$$U_0 = Ul/E,$$

in which U is the velocity of the latex–side liquid boundary in electrophoresis; l, interelectrode distance; and E, voltage difference.

The most complicated problem in recharging of particles is to maintain the colloidal stability of a latex system when passing through the isoelectric state in which the particles lose their electric charge. The possibility of recharging of negatively charged particles is determined by several factors, the most important of which are concentration of the cationic surfactant and the rate of its addition to anionic HPL. To avoid strong dilution of HPL and, ultimately, of the system formed by HPL and the amine-containing latex, we used concentrated surfactant solutions. The advisability of using latexes with high content of dry matter for preparing highperformance coatings has been shown previously [1, 2].

The figure shows how the ζ-potential of HPL particles varies with the amount (35–50 wt %) of added aqueous solution of TMDAB. It is seen that the isoelectric state occurs at a surfactant content of about 2 wt % relative to the polymer. At a surfactant content of 3 wt %, the particles become positively charged, with a ζ-potential of +20 mV. However, the recharged latex acquires colloidal stability only at a ζ-potential of about +30 mV, which corresponds to 7 wt % content of TMDAB relative to the polymer. The necessity of adding this amount of surfactant to the latex is determined by the maximum observed in the plot of HPL viscosity vs. TMDAB concentration. As seen from Table 2, the HPL viscosity increases drastically at lower amounts of the surfactant, which complicates its compounding with the amine-containing latex.

As already noted, the most important factor is the rate of introduction a cationic surfactant into the latex.

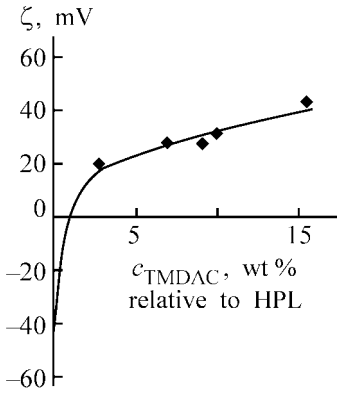
* Relative humidity.

** Assuming that the density is an additive quantity and the apparent density of hollow particles is 0.66 g cm^{-3}.

*** The designations are the same as in Tables 1 and 2.

This rate determines the time in which the system passes the isoelectric state. If this time is too long, the latex particles have time to come in coagulation contact, and the system loses stability. This is illustrated by data in Table 2. At slow surfactant addition, the latex undergoes complete or partial coagulation, despite the fact that the amount of the surfactant added is quite sufficient to attain the required ζ-potential. At a rate of surfactant addition increased to 2.0 wt % s^{-1} (relative to the dry latex polymer), no coagulum is formed at all.

Recharged HPLs were readily compounded with cationic amine-containing latexes without any decrease in the colloidal stability of the system, to form compound latexes for preparing antistatic coatings containing hollow latex particles as filler. The compositions of the compound latexes and the properties of coatings prepared from them are listed in Table 3. As expected, addition of hollow solid particles to a polymeric binder enhances the coating hardness and decreases its density. It should be noted that, at low content of hollow particles, the coating density is approximately equal to the calculated value, whereas at a high content of hollow particles the deviations from the calculated values are appreciable and negative, suggesting the formation of a porous coating (insufficiently close packing of particles). Furthermore, at a high content of hollow particles the antistatic properties of the coating are drastically impaired.



Variation of the ζ-potential of HPL on adding TMDAC.

Our results show that the content of hollow particles in the filled coatings should not exceed 20 wt %. In this case, the viscosity of the compound latex is close to that of the latex of the amine-containing copolymer, and the filled coatings have good antistatic properties (close to those of the unfilled coatings). The stickiness of the coatings is eliminated even on adding small amounts of the filler. From the viewpoint of light scattering, the optimal size of the voids is about 400 nm; in this case, the covering power of the coating is as high as 40–50 g m^{-2} in terms of dry pigment.

CONCLUSIONS

(1) A procedure was developed for preparing compound latexes for antistatic coatings by compounding cationic amine-containing styrene–acrylate latexes and anionic latexes with hollow particles acting as a white polymeric pigment and filler, with the aim to decrease the density and enhance the surface hardness of the coatings.

(2) The necessary condition for avoiding coagulation in compounding is preliminary recharging with a cationic surfactant of the anionic latex consisting of hollow particles.

(3) Compound latexes containing 40–50 wt % dry matter were prepared. The density of the resulting coatings is 0.80–1.16 g cm^{-3}; relative hardness, 0.4–0.6; and covering power, 40–50 g m^{-2} recalculated to dry "hollow" pigment. At the optimal content of the "hollow" pigment of 20 wt %, the surface resistivity ρ_s of the coating is 2×10^8 Ω.

Thermal Expansion of Arsenic

V. A. Ananichev, A. E. Voronova, and L. N. Blinov

St. Petersburg State Technical University, St. Petersburg, Russia

Received April 15, 2002

Abstract—The temperature dependence of molar volume of arsenic was studied in the range 293–1410 K.

It is commonly believed that the systematic decrease, with increasing atomic number, in the density drop upon melting of Group V elements is due to the growing metallization of the melt [1–3].

Phosphorus can exist at atmospheric pressure in several modifications, among which white phosphorus has been studied in most detail. White phosphorus has a cubic structure [4] and melts at 317 K. The increase in the molar volume upon melting is 0.593 $cm^3\ mol^{-1}$ [4], and the decrease in density, 3.3% [3]. The structure of the white phosphorus melt has been studied at 319 and 499 K [5]. At these temperatures, the atomic radial distribution function (ARDF) shows peaks at 2.25, 3.9, and 5.9 Å, at $Z_1 = 3$. It was concluded that pyramidal P_4 molecules are structural elements of the melt.

Arsenic has a rhombohedral structure at atmospheric pressure. It melts under elevated pressure at 1090 K [4]. The change in the molar volume upon melting has not been determined experimentally. The value calculated from the Clapeyron equation is 0.8 $cm^3\ mol^{-1}$ [4]. The calculated decrease in density is 5.4%, which is questionable [6]. The structure of As in the liquid state is unknown [5].

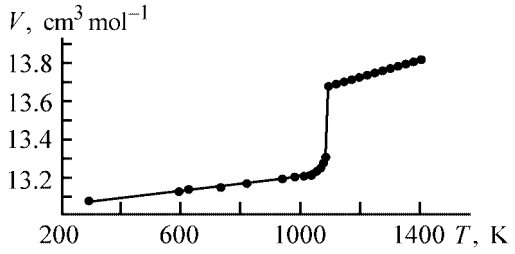
Antimony has at atmospheric pressure a rhombohedral structure, similar to that of arsenic, and melts at 903 K [4]. The experimental change in the molar volume upon melting is 0.2 $cm^3\ mol^{-1}$. The value calculated by the Clapeyron equation has the opposite sign and is equal to $-0.11\ cm^3\ mol^{-1}$ [4]. The relatively small decrease in the Sb density upon melting (0.95% [6]) was attributed in [3] to incomplete metallization of the melt. The structure of liquid antimony was described in detail in [5]. A study of the intensities of X-ray scattering by liquid and crystalline antimony revealed a similarity, even if incomplete, of short-range orders in Sb in the crystalline and molten state. Analysis of experimental data on the short-range atomic order suggests [5] that melting of antimony is accompanied by rupture of covalent bonds between atoms in layers of the crystal lattice to give a short-range order whose main structural properties can be described in terms of a diffuse primitive cubic lattice. This melt structure is stable over a wide temperature range. The packing density of atoms in an antimony melt is higher than that in a crystal, but lower than that in liquid metals.

Bismuth has at atmospheric pressure a rhombohedral structure similar to that of As and Sb. It melts at 544 K [4]. The volume drop upon melting, calculated by the Clapeyron equation ($\Delta V = -0.84\ cm^3\ mol^{-1}$), and its experimentally determined value ($\Delta V = -0.85\ cm^3\ mol^{-1}$) [3, 6] are in good agreement. The increase in density upon melting (3.42%) was attributed in [1, 3] to a decrease in the covalent component of the chemical bond in Group V elements, which results in metallization of the Bi melt. Heating the melt to 1087 K leads to an increase in the coordination number to 9.4 and to broadening of peak II in the ARDF curve [5]. At 1103 K the distribution of atoms in the melt becomes quasi-uniform. With account taken of the structural similarity between semimetals in the molten and crystalline states, it has been concluded [5] that groups with short-range order isostructural to that in crystalline bismuth are present among various atomic groups in the melt.

In this study, the molar volume of As at 293–1410 K was determined experimentally and a correlation between the numerical value of the volume change upon melting and the change in the nature of the interatomic bond in Group V elements was established.

Measurements were performed on an installation of design similar to that used for measuring the coefficient β of volume thermal expansion [7]. The dif-

1070-4272/02/7510-1709 $27.00 © 2002 MAIK "Nauka/Interperiodica"



Molar volume V of an As vs. temperature in the range 293–1410 K.

ference was as follows: an ampule with As was placed on a balance arm at an angle of 45°. The total length of the ampule was 60 mm; its inner diameter, about 8 mm; and the column of the As melt in the ampule, approximately 50 mm high. The sample volume at 298 K was 1 cm^3. The ampule with As was heated to 1410 K and kept at this temperature for 5–10 min. The measurements were done under cooling or heating at a rate of 0.3–0.5 deg min^{-1}. The upper part of the ampule was maintained at a temperature higher by 60 ± 5 K than the temperature of the bottom part. Under these conditions, the pressure in the free part of the ampule at the melting point of As was 50–100 bar [4]. The temperature in the middle part of the ampule was taken as the sample temperature. The sample volume was calculated by identically equating expression (1) from [8]

$$\beta = (V_2 - V_1)/V_1(T_2 - T_1)$$

(where V_2 and V_1 are the sample volumes at T_2 and T_1) to expression (1) from [7]

$$\beta = \gamma(P_2 - P_1)/P(T_2 - T_1),$$

where γ is the vessel constant; P_1 and P_2 are balance readings at T_1 and T_2, respectively; and P is the sample mass.

The temperature dependence of the change in the molar volume of an As sample is presented in the figure.

Most probably, the sample volume increases within the range 293–1030 K owing to thermal expansion of As. For the given temperature range, the bulk thermal expansion coefficient of arsenic, averaged over three crystalline samples, $\beta = (14.5 \pm 0.1) \times 10^{-6}$ K^{-1}, in good agreement with the data of [7].

A marked increase in the volume at 1030–1089 K has not been explained unambiguously so far. Arsenic melting at 1089 ± 2 K is accompanied by a stepwise increase in volume by $2.8 \pm 0.1\%$.

Further heating of As to 1410 K is accompanied by a steady increase in volume, which is probably due to thermal expansion of the melt. In the range 1090–1410 K, the bulk thermal expansion coefficient of As $\beta = (33.9 \pm 0.1) \times 10^{-6}$ K^{-1} and it is virtually pressure independent.

The linear thermal expansion coefficient of Group V elements with rhombohedral structure grows steadily with increasing principal quantum number, as is readily seen from comparison of its values for P, As, Sb, and Bi ($\alpha_P = 124.5 \times 10^{-6}$, $\alpha_{As} = 4.7 \times 10^{-6}$, $\alpha_{Sb} = 8.5 \times 10^{-6}$, and $\alpha_{Bi} = 13.4 \times 10^{-6}$ K^{-1} [7]). The coefficient of linear thermal expansion of white phosphorus (having cubic structure) is higher by an order of magnitude than that of As, Sb, and Bi, and, therefore, falls out of this sequence.

The drop in the molar volume of Group V elements upon melting (cm^3 mol^{-1}): 0.59 for P[6], 0.39 for As [this study], 0.2 for Sb [6], and –0.84 for Bi [6], decreases steadily with increasing principal quantum number.

Analysis of the data presented shows that the chage in volume with increasing temperature is governed in As, Sb, and Bi by their crystal structure and the nature of interatomic bonds, which is determined for *p*-elements by both covalent and metallic components.

Production of Nitrogen-containing Sorbents from Wood Waste

M. V. Efanov, D. V. Dudkin, and A. I. Galochkin

Altai State University, Barnaul, Russia

Received January 14, 2002

Abstract—The sorption capacity for Fe(II), Cu(II), Cd(II), and Zn(II) ions of nitrogen-containing derivatives of birch wood, obtained by different variations of oxidative ammonolysis, was studied.

Nitrogen-containing derivatives of lignin exhibit ion-exchange properties and can be used as sorbents of heavy metal ions and organic dyes [1]. The main drawbacks of these products are their relatively low exchange capacity and low mechanical strength.

To produce nitrogen-containing sorbents in quantitative yield, hydrolyzed lignin has been treated with ammonia solution of ammonium peroxodisulfate under mild conditions at 20°C for 1–5 days [2]. Along with hydrolyzed lignin, poor wood (aspen or birch) can be used as an accessible raw material for production of nitrogen-containing sorbents.

Nitrogen-containing sorbents based on sawdust of aspen wood have been obtained mechanochemically by reaction with ammonia solution of ammonium peroxodisulfate, and their sorption capacity for certain heavy metal ions has been studied [3]. It was found that the resulting nitrogen-containing derivatives of wood exhibit enhanced sorption capacity for the metal cations studied.

In this communication, we present results of a comparative study of nitrogen-containing derivatives of birch wood, produced mechanochemically by oxidation of wood with an ammonia solution of ammonium peroxodisulfate and atmospheric oxygen in an ammonia medium.

Nitrogen-containing sorbents were obtained from secondary waste of wood in two ways. According to the first procedure, the sawdust of birch wood, combined with ammonium peroxodisulfate (0.2 g of available oxygen per 1 g of wood), was subjected to intensive mechanical crushing in a ball mill in 25% aqueous ammonia (0.9 g of NH_3 per 1 g of wood) for 10–100 min. According to the second, the sawdust combined with aqueous ammonia (0.9 g of NH_3 per 1 g of wood) was subjected to intensive mechanical crushing in a ball mill under air pressure of 3 atm for 10–100 min.

The content of nitrogen in the products obtained was determined by Kjeldahl's semimicromethod [4], and the number of carboxy groups, by back conductometric titration [5].

The sorption capacity of the resulting products was studied by the static method [6]. Nitrate solutions of appropriate metals, with concentration of 0.01–0.1 g-equiv dm^{-3}, were taken as starting solutions. When the equilibrium was attained (in 24 h), the concentration of the corresponding cation in solution was determined complexometrically. The exchange capacity of the sorbents was calculated by the formula:

$$\mathrm{SEC} = (c_0 - c_e)V/1000g,$$

where SEC is the static exchange capacity (mg-equiv g^{-1}); c_0, the concentration of metal ions in the starting solution (g-equiv dm^{-3}); c_e, the concentration of metal ion in equilibrium solution (g-equiv dm^{-3}); V, the volume of equilibrium solution (cm^3); and g, the sorbent mass (g).

Comparison of the functional compositions of the products obtained by oxidative ammonolysis of wood (procedures 1 and 2) shows that, in the case of an ammonia solution of ammonium peroxodisulfate, the oxidation is more complete and the amount of nitrogen and the number of carboxy groups in the wood derivatives obtained is larger (Table 1).

The results of the experiments performed show that the nitrogen-containing wood derivatives obtained by procedures 1 and 2 have high sorption capacity for the metal ions studied (Table 2). Their exchange capacity, depending on the content of nitrogen and the number

1070-4272/02/7510-1711 $27.00 © 2002 MAIK "Nauka/Interperiodica"

Table 1. Content of nitrogen and number of carboxy groups in nitrogen-containing derivatives of birch wood, obtained by procedures 1 and 2

t, min	Content, %	
	N	COOH
10	1.76/1.10*	3.63/1.72*
50	3.11/1.17	5.47/2.88
100	5.32/1.38	16.3/6.7

* Procedure 1/procedure 2; the same for Table 2.

Table 2. Influence of the concentration of metal ion in solution on the sorption capacity of nitrogen-containing derivatives of birch wood, obtained by procedures 1 and 2

c_0, g-equiv dm^{-3}	SEC, mg-equiv g^{-1}			
	Cu(II)	Cd(II)	Zn(II)	Fe(II)
0.01	5.88/4.22	5.27/3.47	4.17/3.11	3.08/2.06
0.05	5.95/4.25	5.34/3.54	4.26/3.13	3.16/2.09
0.1	6.13/4.29	5.36/3.56	4.32/3.16	3.24/2.14

of carboxy groups incorporated into them, is comparable with that in oxycellulose (Tables 1, 2), in agreement with published data [3].

It was found that the sorption capacity of the nitrogen-containing derivatives of birch wood, obtained by oxidative ammonolysis, is somewhat higher in the case of procedure 1, compared with that for procedure 2 [3.1–6.1 and 2.1–4.3 mg-equiv g^{-1}, respectively (Table 2)].

The sorption capacity of sorbents obtained by oxidative ammonolysis of wood for the metal ions studied depends on their concentration only slightly, increasing in the order Fe(II) < Zn(II) < Cd(II) < Cu(II) (Table 2). The absorption of metal ions by nitrogen-containing wood derivatives from solutions makes lower the pH value of aqueous solutions obtained after their sorption. The decrease in the pH value of the filtrates after sorption and the high content of carboxy groups in nitrogen-containing wood sorbents suggests that mobile hydrogen cations incorporated into them can be substituted by heavy metal ions, i.e., the obtained sorbents bind metal cations by the ion-exchange mechanism.

CONCLUSIONS

(1) The sorption capacity of nitrogen-containing derivatives of birch wood, obtained by oxidative ammonolysis of wood, is somewhat higher in the case of procedure 1, compared with procedure 2 (3.1–6.1 and 2.1–4.3 mg-equiv g^{-1}, respectively).

(2) The sorption capacity of nitrogen-containing derivatives of birch wood, obtained by various procedures, for heavy metal ions depends on their concentration only slightly and increases in the order Fe(II) < Zn(II) < Cd(II) < Cu(II).

(3) Sorption of the metal cations studied by nitrogen-containing wood sorbents from aqueous solutions makes lower the solution pH, thus indicating the ion-exchange mechanism of sorption.

BRIEF COMMUNICATIONS

Electrodeposition of Palladium–Zinc Alloy from Aminoacetic Electrolyte

S. V. Kabanov and Yu. P. Perelygin

Penza State University, Penza, Russia

Received April 4, 2002

Abstract—The influence of the electrolysis conditions and electrolyte composition on the cathodic current efficiency by the alloy and on the alloy composition was studied for electrodeposition of the palladium–zinc alloy from an aminoacetic electrolyte.

The industrial use of palladium alloys with nickel, indium, and some other metals in coatings is due to lower consumption of the noble metal and enhanced physicomechanical and chemical properties of the coatings [1, 2]. The metallurgical palladium–zinc alloy is a complex system comprising a solid solution at zinc content of less than 6% and several chemical compounds at higher zinc content [3].

The possibility of obtaining a palladium–zinc alloy with up to 8% zinc from ammonia–trilonate electrolyte has been shown previously [4]. Since intermetallic compounds have enhanced physicomechanical properties [1–3], it is of certain practical and theoretical interest to obtain the given alloy with higher content of zinc.

The alloy was electrodeposited from an aminoacetic solution in a 100-ml rectangular glass bath with graphite anodes. The content of zinc in the alloy was determined by complexometric titration after separating palladium in the form of palladium dimethylglyoximate [5].

Preliminary experiments showed that quality coatings are formed solely in a saccharin-containing electrolyte. Addition of 0.25–1 g l^{-1} saccharin considerably decreases (from 10 to 2.5 MPa) the internal stresses in deposits and increases somewhat (by 1–2%) the content of zinc in a coating.

The influence of the electrolysis conditions and electrolyte composition on the cathodic current efficiency (CE) by the alloy and on the alloy composition was studied at 30°C, current density of 0.5 A dm^{-2}, and pH 7 from a solution containing (g l^{-1}): palladium chloride 20, zinc chloride 3 (in terms of metal), ammonium chloride 20, aminoacetic acid 40, and saccharin 0.5.

With increasing zinc concentration $c_{Zn^{2+}}$ in an electrolyte, zinc content in a coating, c_{Zn}, grows and the cathodic CE by the alloy falls:

$c_{Zn^{2+}}$, g l^{-1}	0.5	1	2	3
c_{Zn}, %	7.7	9	12.8	15.8
CE, %	88.5	84	82	77

The ratio of metal contents in the alloy as a function of the ratio of concentrations of their ions in the electrolyte is described by the equation [6]:

$$\log\frac{[Pd]}{[Zn]} = 0.37 + 0.457\log\frac{[Pd^{2+}]}{[Zn^{2+}]}.$$

The correlation coefficient of the equation is $R = 0.987$.

With zinc concentration in the electrolyte increasing further to 5 g l^{-1}, the current efficiency by the alloy decreases from 77 to 65%, and the content of zinc in the coating increases to 20%. Lowering the palladium concentration in the electrolyte under these conditions results in deterioration of the deposit quality.

When the cathode current density is lowered from 0.25 to 1 A dm^{-2}, the CE by the alloy falls from 90.5 to 72% (Fig. 1, curve *1*), with the zinc content decreasing only slightly (from 15.8 to 17%). At higher current densities the coating quality deteriorates because of the cracking resulting from the build-up of considerable internal stresses.

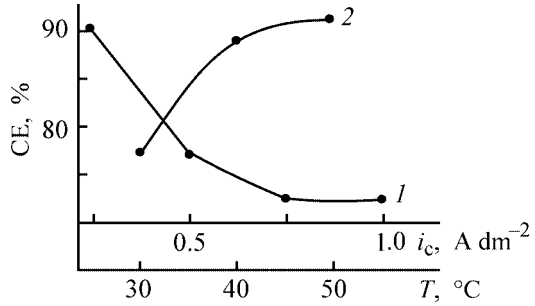

Fig. 1. Current efficiency CE by the alloy vs. (*1*) cathode current density i_c and (*2*) temperature T.

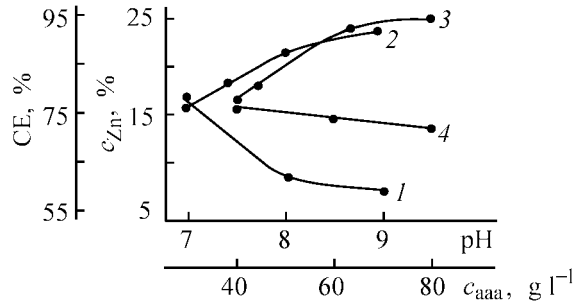

Fig. 2. (*1, 3*) Current efficiency CE by the alloy and (*2, 4*) content of zinc in the alloy, c_{Zn}, vs. (*1, 2*) pH and (*3, 4*) concentration c_{aaa} of aminoacetic acid.

Raising the temperature from 30 to 50°C leads to an increase in CE from 77 to 91% (curve *2*). In this case, the composition of the alloy is virtually unaffected, and the coating quality is improved. Owing to the high internal stresses, high-quality deposits cannot be obtained at temperatures below 30°C.

On changing the solution pH from 7 to 9, the CE by the alloy decreases from 77 to 58% (Fig. 2, curve *1*) and the zinc content increases from 15.8 to 24% (curve *2*). In this case, the quality of the coating is deteriorated somewhat.

Raising the aminoacetic acid concentration from 40 to 80 g l^{-1} (Fig. 2, curve *3*) leads to an increase in the CE by the alloy from 77 to 94% and a decrease in the content of zinc in the coating to 13.5% (curve *4*).

At aminoacetate acid concentrations lower than 40 g l^{-1} the cathodic CE does not exceed 55%.

Changing the ammonium chloride concentration in the electrolyte from 20 to 40 g l^{-1} does not affect significantly the alloy composition and the CE by the alloy.

Thus, for deposition of semilustrous alloy coatings with zinc content from 7 to 16%, an electrolyte containing (g l^{-1}): palladium chloride 20, zinc chloride 0.5–3.0 (in terms of metal), ammonium chloride 20–40, aminoacetic acid 40–80, and saccharin 0.5–1.0 can be recommended. The electrodeposition should be performed at 30–40°C, current density of 0.25–0.5 A dm^{-2}, and pH 7. Under these conditions, the current efficiency by the alloy is 90–77%.

The contact electrical resistance of the alloy with zinc content of 15–16% is 0.038 Ω at a contact load of 0.5 N and decreases to 0.03 Ω with load increasing to 2 H. The microhardness of alloy coatings with zinc content of 7.7 and 15.8% is 220 and 278 kg mm^{-2}, respectively.

The wear resistance of the obtained alloy coating with 15–16% zinc, as measured on an installation described in [7] at a contact load of 2H, is 40 000 switchings, i.e., is 2 times that for pure palladium.

Abstract—The possibility of preparing fluorinated oligomeric derivatives of ε-aminocaproic acid by reaction of polyfluorinated telomeric alcohols $H(CF_2CF_2)_nCH_2OH$ (n = 1–4) with ε-caprolactam under conditions of homogeneous catalysis (triethylamine, dimethylformamide) was examined. The thermal stability of the oligomers was studied in relation to the fluorine content.

Reactions of ε-caprolactam with saturated monohydric alcohols have been studied previously under conditions of heterogeneous (lead oxide, lead powder, zinc powder [1]) and homogeneous (triethylamine, TEA; dimethylformamide, DMF [2]) catalysis. The resulting oligomeric esters are of interest as matrices for preparing substances with biomedical activity [2]. With fluorinated alkoxy groups, these compounds show promise for preparing materials with decreased combustibility [3], enhanced resistance to aggressive media and organic solvents [4], and decreased friction coefficient [5].

The goal of this study was to prepare fluorinated oligomers by reaction of ε-caprolactam with polyfluorinated telomeric alcohols of the general formula $H(CF_2CF_2)_nCH_2OH$, where n = 1 (PFA1), 2 (PFA2), 3 (PFA3), and 4 (PFA4), and to analyze their physicochemical properties.

EXPERIMENTAL

The reaction of ε-caprolactam with polyfluorinated alcohols was performed at a molar ratio ε-caprolactam : alcohol = 1 : 1.2 in the presence of catalytic amounts (0.05 mol) of lead oxide, TEA, or DMF at high temperature (260°C). At lower temperatures, the oligomer yield is low.

Kinetic experiments were performed with PFA2; we monitored the amounts of unchanged ε-caprolactam (as described in [1]) and polyfluorinated alcohol, which was isolated by vacuum distillation. Also, we determined the yield of the oligomer after its isolation by filtration. The oligomer was recrystallized from acetic acid.

The structure of the oligomer was determined by IR and NMR spectroscopy. The IR spectra were recorded with a Specord M82 spectrometer (mulls in mineral oil, NaCl or KBr cells). The ^1H NMR spectra were taken on a Tesla BS487 spectrometer (100 MHz, internal reference HMDS, solvent dimethyl sulfoxide).

The thermal stability of polyfluorinated oligomers was studied with an MOM derivatograph (Hungary). Samples were heated to 500°C over a period of 50 min.

Polyfluorinated telomeric alcohols react with the lactam in the presence of DMF to give esters of alcohols and ε-aminocaproic acid oligomers:

$$H(CF_2CF_2)_nCH_2OH + HN(CH_2)_5C{=}O \rightarrow H[NH(CH_2)_5C(O)]_mOCH_2(CF_2CF_2)_nH,$$

where n = 1–4, m = 2, 3.

The yield of polyfluorinated oligomers increases with decreasing length of the fluorocarbon chain, being 32–41% with PFA1 and PFA2 and 10–13% with PFA3 and PFA4. It is convenient to purify the oligomers by recrystallization from hot acetic acid. Trimers precipitate upon cooling; their melting points (°C) are as follows: PFA1, 192; PFA2, 204. Dimers

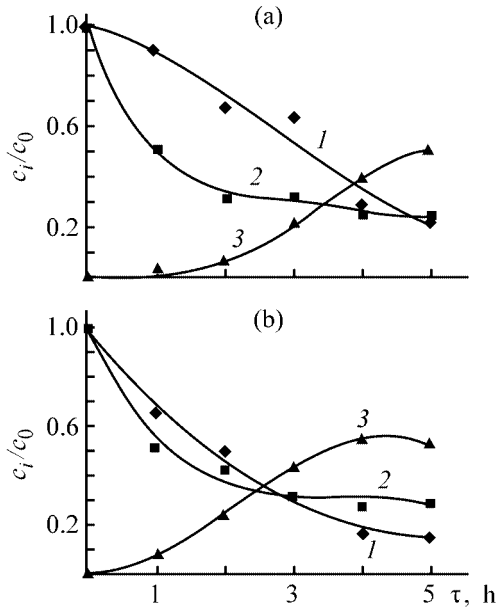

Fig. 1. Variations with time τ of the relative concentrations of reactants, c_i/c_0, in the reaction of caprolactam with octafluoropentanol at 260°C. Catalyst: (a) TEA and (b) DMF. (*1*) Lactam, (*2*) alcohol, and (*3*) oligomer.

are readily soluble in acetic acid, and their melting points (°C) are lower: PFA1, 172; PFA2, 193; PFA3, 185; PFA4, 178–180.

Oligomers have light brown color due to impurities of dehydrofluorination products. The color is the most intense with lead oxide or TEA as catalyst, and the least so with DMF as catalyst. The catalyst was chosen on the basis of kinetic studies. The kinetic curves for the reaction of PFA2 with ε-caprolactam (1 : 1) in the presence of TEA, describing the consumption of polyfluorinated alcohol and ε-caprolactam and accumulation of the oligomer, are shown in Fig. 1a.

It is seen that, in the initial period, polyfluorinated alcohol is consumed considerably faster than lactam. This is due to the side reaction of dehydrofluorination, yielding an unsaturated compound which subsequently polymerizes to give a colored product.

In contrast to the reaction in the presence of TEA, the consumption of PFA2 with DMF as catalyst exceeds only slightly the consumption of ε-caprolactam in the first 2.5 h (Fig. 1b), which indicates that the extent of dehydrofluorination is small.

However, the consumption of the lactam starts to appreciably exceed the consumption of PFA2 after 2.5 h. This is due to the fact that, in this period, formation of the dimer becomes the major reaction pathway:

$$\text{Lactam} + H_2N(CH_2)_5C(O)OCH_2(CF_2CF_2)_2H \rightarrow \underset{\text{(Dimer)}}{H[HN(CH_2)_5C(O)]_2OCH_2(CF_2CF_2)_2H}.$$

After 2.5 h, the accumulation of the oligomer becomes noticeable. Longer (10 h) reaction results in accumulation of trimers:

$$\text{Dimer} + \text{Lactam} \rightarrow H[HN(CH_2)_5C(O)]_3OCH_2(CF_2CF_2)_2H.$$

The IR spectra of esters of polyfluoroalkanols with ε-aminocaproic acid dimer and trimer contain bands originating from stretching vibrations of ester carbonyls [ν(C=O)] at 1733–1750 cm^{-1}, with their frequencies growing with increasing length of the fluorocarbon chain (n = 1, 1733 cm^{-1}; n = 4, 1750 cm^{-1}). The terminal C–H group in the alcohol moieties gives a stretching vibration band at 3055 (n = 1) to 3067 cm^{-1} (n = 4), which is broadened and split owing to hydrogen bonding.

The amide groups [5] give bands at 3300 (NH), 1640 (amide I), and 1545 cm^{-1} (amide II).

In the ^1H NMR spectra, the HCF_2CF_2 group gives a triplet of triplets (δ 6.28 ppm, J 52 and 6 Hz).

Esters of PFA1 and PFA2 with oligomers of ε-aminocaproic acid decompose more slowly than polycaproamide and n-butyl ester of α-aminocaproic acid trimer do. The weight loss in 20 min at 300°C is 4% for the PFA1 ester and about 5% for the PFA2 ester. However, the decomposition rate drastically increases at higher temperatures: at 350°C, the weight loss in 25 min is 12.5% for the PFA1 ester and 10% for the PFA2 ester.

At 400°C, the weight loss in 30 min is 15% for the octafluoropentyl ester, and about 30% for polycaproamide under comparable conditions. The enhanced thermal stability of polyfluorinated esters of ε-aminocaproic acid oligomers is due to less intense intra- and intermolecular decomposition of oligomeric molecules with the release of ε-caprolactam, and also to decreased contribution of hydrolytic cleavage of peptide bonds.

CONCLUSIONS

(1) Fluorinated esters of ε-aminocaproic acid oligomers were prepared by the reaction of polyfluorinated telomeric alcohols $H(CF_2CF_2)_nCH_2OH$ (n = 1–4) with ε-caprolactam in the presence of homogeneous catalysts. The reactivity of the alcohol de-

creases with increasing length of the perfluorinated chain.

(2) Dimethylformamide is a more selective oligomerization catalyst than triethylamine, ensuring smaller contribution of dehydrofluorination processes.

(3) Introduction of fluorinated groups into the oligomer molecule enhances its thermal stability.

Synthesis of *N*-Benzylacrylamide

V. A. Builov, V. V. Popova, A. S. Shevchuk, and V. A. Podgornova

Yaroslavl State Technical University, Yaroslavl, Russia

Received February 11, 2002

Abstract—A procedure was developed for preparing *N*-benzylacrylamide in quantitative yield in a single stage from acrylonitrile and benzyl alcohol.

N-Substituted acrylamides derived from acrylic and methacrylic acids are important monomers [1–4]. One of these, *N*-benzylacrylamide (*N*-BAA), imparts valuable properties to polymeric materials, making them more elastic and more resistant to water, chemicals, and heat and enhancing the adhesion and antistatic properties of polymeric films. Development of new procedures for preparing *N*-BAA is an urgent problem, and study of its physical and chemical properties can reveal new interesting fields of its application in polymer chemistry.

There are numerous patents concerning synthesis of *N*-substituted (meth)acrylamides starting from amides, esters, and chlorides of unsaturated acids [5]. However, the proposed precursors are expensive and difficultly available, and isolation of target products is complicated.

The goal of this study was to develop a procedure for preparing *N*-BAA from cheaper and more available precursors: acrylonitrile (AN) and benzyl alcohol (BA). AN reacts with BA in the presence of an acid catalyst at relatively low temperatures:

$$CH_2{=}CH{-}CN + HO{-}CH_2{-}C_6H_5 \rightarrow CH_2{=}CH{-}CO{-}NH{-}CH_2{-}C_6H_5.$$

Acidic medium and elevated temperatures favor formation of by-products: acrylamide and dibenzyl alcohol. To prevent polymerization, the synthesis is performed in the presence of a polymerization inhibitor, $CuCl_2 \cdot 2H_2O$.

As catalysts, we tested both mineral (H_2SO_4, H_3PO_4, HCl) and organic (acetic, *p*-toluenesulfonic) acids; 3.2 M sulfuric acid proved to be the most effective. At lower acid concentrations, the reaction is slow, and at higher concentrations it is too vigorous, so that the evolved heat cannot be efficiently removed and the reaction is accompanied by polymerization. The influence of temperature on the *N*-BAA yield was studied in the range 20–50°C, at the reaction time of up to 3 h and constant molar ratio AN : BA : H_2SO_4 = 3 : 1 : 1 (see table).

The optimal temperature, at which the maximal yield is attained in 60 min, is 50°C. Higher temperatures are not appropriate because of polymerization.

The AN : BA molar ratio was varied from 0.5 : 1 to 5 : 1 at 40°C, reaction time of 3 h, and constant acid concentration. Experiments showed that the reaction occurs considerably faster with excess AN; at the molar ratio AN : BA = 5 : 1, the maximal yield is attained already in 1 h. However, higher concentrations of AN are not appropriate because of the increased expenses for its utilization.

Thus, we have found the best conditions for preparing *N*-BAA in quantitative yield. *N*-Benzylacrylamide is a white crystalline substance, $C_{10}H_{11}NO$, M = 161.20, mp 64–65°C. Yield based on loaded benzyl alcohol 96.4%; yield based on reacted AN 87.5%. Main substance content 96.6 wt %.

We used technical-grade AN [GOST (State Standard) 11 097–73], which was purified by distillation, bp

Variation of *N*-BAA concentration in the course of synthesis

T, °C	*N*-BAA amount, wt %, in indicated time, min				
	15	30	60	120	180
20	2.83	11.06	16.24	22.68	27.24
30	12.53	16.88	26.75	31.76	31.82
40	22.39	27.61	30.29	33.82	34.75
50	31.70	34.43	35.75	36.05	36.31

1070-4272/02/7510-1718 $27.00 © 2002 MAIK "Nauka/Interperiodica"

78.5–79°C (760 mm Hg), d_4^{20} 1.045, n_D^{20} 1.5396; pure grade sulfuric acid (GOST 4204–77); and pure grade solvents.

Synthesis was performed in a four-necked batch reactor equipped with a stirrer, thermometer, reflux condenser, and dropping funnel. The reactor was charged with the required amount of AN, and the inhibitor was added. The mixture was cooled with stirring to 0°C, after which a mixture of BA with a catalyst was added through a dropping funnel, avoiding warming of the reaction mixture to above 0–1°C. After adding the reactants, the mixture was heated to the required temperature on a water bath. After reaction completion, the mixture was poured into cold water, and the organic layer was separated, washed with 0.5% NaOH, and dried over Na_2SO_4.

The crystalline product was recrystallized from toluene; mp 64–65°C. The reaction mixture was analyzed by gas–liquid chromatography on a Chrom-5 chromatograph (flame ionization detector, 5000 × 3-mm glass column, stationary phase 25 wt % SKTFT-50Kh methylsiloxane trifluoropropyl elastomer on Chromaton N-AW). The calibration coefficients for all the components were determined by standard computer processing of the data for reference mixtures. *N*-Benzylacrylamide was identified by bromination; its molecular weight, ~161.0, was determined by cryoscopy. The IR spectrum of *N*-BAA was recorded on an IKS-14a device (NaCl prism, mull in mineral oil). The IR spectrum contains absorption bands characteristic of various functional groups, ν, cm^{-1}: 700–800, monosubstituted benzene ring; 1240, C–N; 1410, CH_2=CH–; 1500, C_6H_6; 1540, N–H; 1620, C=C; 1650, C=O; 3050, CH=; 3300, N–H; 2950 and 1450, bands of mineral oil. Consistent analytical data were obtained.

CONCLUSION

A procedure was developed for synthesis of *N*-benzylacrylamide in quantitative yield in a single stage by reaction of acrylonitrile with benzyl alcohol (50°C, 1 h, acrylonitrile : benzyl alcohol molar ratio 5 : 1), and also for isolation and purification of the product.

Henri Moissan (To 150th Anniversary of His Birthday)

Professor H. Moissan made an outstanding contribution to the development of quite a number of branches of applied chemistry in the late XIX–early XX century. He obtained fluorine in free state for the first time, studied a number of its compounds, designed an electric arc furnace (having thereby laid the foundation of high-temperature chemistry), synthesized a great number of high-melting compounds, and isolated boron and other elements by reducing their oxides.

Ferdinand Frederic Henri Moissan was born on September 28, 1852, in Paris; his father was a minor official at the Eastern Railroad Company. In 1864, his family moved to a small town Meaux in northern France, Department of Seine-et-Marne, where Henri entered a municipal college. The scientist-to-be revealed strong interest in mathematics and natural sciences, especially chemistry. In 1870, he graduated from the college, and, desiring to become independent as soon as possible, started to work in Paris as apprentice pharmaceutical chemist. In 1872, Moissan transferred to the Museum Natural History, laboratory of Edmond Fremy (1814–1894), a known chemist, member of the Paris Academy of Sciences (since 1857), and a corresponding member of the St. Petersburg Academy of Sciences (since 1856). Fremy's investigations were concerned with a wide variety of problems associated with technical chemistry. In particular, he worked on synthesis of artificial precious stones, development of technology for manufacture of glass, cement, and mineral fertilizers, studied saponification of fats, obtained hydrofluoric acid, made an attempt to isolate fluorine in free state, and established that ozone is an allotropic variety of oxygen. Moissan's stay at Fremy's laboratory was short, but, in our opinion, had impact on his subsequent scientific activities.

Soon after, Moissan transferred, within the same Museum, to the agrochemical laboratory headed by Pierre-Paul Deherain (1830–1902), where he carried out, together with his supervisor, a study in physiology of plants. However, the work concerned with this subject was, in fact, the only one, and the young scientist paid his primary attention to inorganic chemistry and technology. Simultaneously, influenced by

Deherain, Moissan occupied himself with completion of his education. In 1874, he received bachelor's degree, and became Licencie des Sciences in 1877. This, still preserved in France, scientific degree, intermediate between those of bachelor and doctor of science, gave the right of teaching and delivering lectures at higher and secondary school institutions.

In 1879, Moissan was given the rank of first-class pharmaceutical chemist, By 1890, he completed a set of studies in chemistry of iron and chromium oxides and backed his doctoral dissertation devoted to this subject. Young scientist's works received approval and support of leading French chemists of that time, H. Saint-Claire Deville (1818–1881) and H.J. Debray (1827–1888), members of the Paris Academy of Sciences.

In 1879–1883, Moissan occupied the position of an assistant at a higher pharmaceutical school in Paris, and in 1886, he was elected a professor (of toxicol-

1070-4272/02/7510-1720 $27.00 © 2002 MAIK "Nauka/Interperiodica"

ogy); in 1889, he became a professor of inorganic chemistry. Beginning in 1900, he was professor of inorganic chemistry at Paris University.

It is impossible to reflect in full the diversity and scale of experimental investigations carried out by Henri Moissan. More evidence about his life and scientific activities can be found in a detailed communication by German scientist Alfred Stock (1876–1946), who worked for some time at Moissan's laboratory and was well-acquainted with him [1]. Let us mention the basic directions of investigations carried out by the French scientist.

In 1884, Moissan started detailed studies of fluorine compounds. He was the first to synthesize and describe quite a number of fluorine compounds with nonmetals, e.g., PF_5, POF_3, PF_3Br_2. Before Moissan, many researchers, beginning with the outstanding English chemist G. Davy (1778–1829), had made unsuccessful attempts to obtain fluorine. In 1886, Moissan could solve this problem. He isolated fluorine by electrolysis of an anhydrous mixture of hydrofluoric acid and potassium chloride. The electrodes employed were fabricated from a platinum–iridium alloy, and the electrolysis was carried out in a platinum vessel. Much later (1899), Moissan demonstrated the possibility of using cheaper copper apparatus in electrolysis. In cooperation with the English physicist James Dewar (1842–1923), Moissan obtained fluorine in liquid (bp 187°C) and solid (mp 233°C) states.

Moissan synthesized and studied a number of fluorine- and carbon-containing compounds. These included carbon tetrafluoride, methyl fluoride, and isobutyl fluoride. He also obtained organofluoric compounds for the first time.

In 1891–1892, Moissan concerned himself with isolation of boron. By that time, boron had not been isolated in pure form, with the content of boron in formulations obtained not exceeding 70%. Moissan could improve the purity of boron to 95% by reducing boron oxide with magnesium, and to 99% in the case of its reduction with hydrogen.

Since the time when it was shown that diamond is pure carbon, attempts had started to obtain artificial diamonds [2]. The classical investigations in this field belong to Moissan. They were based on Debray's assumption that diamonds had formed in nature at high temperatures and pressures. In addition, reports appeared in 1892 about diamond inclusions contained in a meteorite found in the U.S. Moissan made an attempt to obtain diamonds by fast cooling of iron saturated with carbon at temperatures of up to 3500°C. In this case, a high pressure developed within the ingot. Prolonged chemical treatment of a solidified mass removed iron, graphite, and, possibly, carbides, with only fine crystal particles (up to 0.5 mm in size) remaining in very small amounts. The crystals had very high hardness and were nearly completely burnt out in oxygen, with their density falling within the range 3.0–3.5 g cm^{-3}. The minute dimensions of the crystals gave no way of applying crystallographic methods, and synthesis of artificial diamonds by Moissan cannot be considered a proven fact.

However, the electric arc furnace designed by the scientist for heating iron (1892), have found exceedingly wide application. It became possible for the first time to carry out various high-temperature investigations. Reduction of metal oxides with carbon was used to obtain uranium, tungsten, vanadium, chromium, and manganese (1893); titanium and molybdenum (1895); niobium (1901); tantalum (1902); and thorium (1906). Beginning in 1894, Moissan obtained, using his furnace, 28 carbides, 9 borides, and 6 silicides of various metals [1, 3]. A number of compounds had been unknown before that time. The compounds were synthesized directly from pure components or by reduction of metal oxides with carbon, boron, or silicon. Moissan also developed an industrial technique for obtaining calcium carbide. The scientist studied the chemical properties of carbides and the action of water and acids on them. He also synthesized hydrides of calcium and alkali metals, and pointed to their high reducing capacity. Moissan's pioneering studies attracted to him pupils not only from France, but also from other European countries.

The main Moissan's works are the following *Le four èlectrique* (Paris, 1897), *Le fluor et ses composès* (Paris, 1900), and a five-volume course of organic chemistry *Traite de chemie minèrale*, Paris, vols. 1–5, 1904–1906), written by him with participation of his pupils.

By recommendation of academicians N.N. Beketov and F.F. Bel'shtein, Moissan was elected a foreign corresponding member (department of physics) of the St. Petersburg Academy of Sciences in 1904 [4]. The recommendation written in hand by Beketov read "... Moissan's investigations enriched the science with quite a number of valuable and reliable facts." Earlier, in 1888, the scientist was elected a member of the Academy of Medicine in France and became a member of the Paris Academy of Sciences in 1891. Moissan was also a member of the Royal London, British chemical, German chemical, and many other scientific societies. In 1906, Moissan was awarded the Nobel Prize in chemistry "in recognition of the great services

rendered by him in his investigation and isolation of the element fluorine, and for the adoption in the service of science of the electric furnace called after him" [5]. His presentation by the Swedish Royal Academy of Sciences read "The whole world has admired the great experimental skill with which you have isolated and studied fluorine... With the aid of your electric furnace you have solved the riddle of how diamonds are formed in nature. You have unleashed a mighty wave into the world of technology, a wave which has not yet attained its full height." Before that Moissan had received the Davy medal of the Royal London Society (1896) and the Hoffman medal of the German chemical society (1903). In 1900, the scientist was awarded the Order of the Legion d'Honneur. In 1896 and 1902, Moissan was elected the President of the French chemical society.

Henri Moissan passed away after brief illness on February 20, 1907. Many years' work with toxic substances had affected adversely his health. Moissan himself spoke about this as follows: "Fluorine deprived me of 10 years of life." Brief biographic evidence about the scientist is contained in publications of different years [3, 6–8] and numerous reference books [5, 9–11].

In the beginning of 1907, the world's chemical community suffered severe loss, when such its outstanding representatives as D.I. Mendeleev (2.02.1907), N.A. Menshutkin (5.02), H. Rosebohm (8.02), H. Moissan (20.02), and M. Berthelot (18.03) passed away.

BOOK REVIEWS

Yanko, E.A., *Anody alyuminievukh elektrolizerov* (Anodes of Aluminum Electrolyzers), Moscow: Ruda i Metally, 2001, 670 pp.

Anodes, playing an important part in the technology of aluminum manufacture by electrolysis, affect the energy consumption and the level of environment protection. In the last three decades, the aluminum industry of quite a number of largest countries–aluminum manufacturers has mostly or completely changed over to energy-saving technologies with the maximum possible level of environment protection. The key measure in such a conversion is to install electrolyzers with high power (up to 200–300 kA) with prebaked anodes. This makes it possible to raise somewhat the current efficiency (to 93–95%), make lower the energy expenditure per ton of aluminum by 1500–2000 kW h, and, what is the most important, to resolve with more success the ecological problems. With baked anodes, it becomes possible to diminish to a minimum the discharge of fluorides into the atmosphere and preclude entirely the discharge of aromatic hydrocarbons and tars, including carcinogens. In Russia, up to 90% of aluminum is manufactured with the use of self-baking anodes. In the foreseeable future, reconstruction of the Russian aluminum pants seems to be unlikely. In this connection, a topical task is to improve the technology of operation of electrolyzers with self-baking anodes and to lower the discharge of noxious compounds to admissible levels. E.A. Yanko's monograph, summarizing the experience gained in working with both types of anodes and discussing their advantages and disadvantages, is of indubitable interest for Russian aluminum manufacturers. The book comprises an introduction, 11 chapters, and a list of references.

A brief introduction (pp. 3–8) considers the transport-technological schemes for production of the anode mass for self-baking anodes and for manufacture of baked anodes. It is the analysis of the elements of these schemes that mainly constitutes the monograph, which has purely industrial orientation.

The first chapter (pp. 9–55) describes raw materials for production of the anode mass and anodes—coal-tar pitch and electrode coke. The properties of both the components and requirements to them are presented with exhaustive completeness. The second chapter (pp. 56–125) gives an equally detailed description of coke calcination procedure. By this term is meant coke treatment at high temperature (1150–1350°C) in a reductive atmosphere. Under these conditions, moisture and volatiles are removed, the coke structure becomes denser, and there occurs partial graphitization. Main attention is given to describing the process technology. A small third chapter (pp. 126–139) considers storage coal-tar pitch and its preparation for the technological process, with much attention given to monitoring of its quality and to its aggregative state. The fourth chapter (pp. 140–204) mainly describes the apparatus used in preparing stock for manufacture of the anode mass. All kinds of apparatus for crushing and milling are described in ample detail.

The fifth chapter (pp. 205–250) presents evidence concerning the formulations of the anode mass. Theoretical foundations of the anode structure formation, the optimal granulometric composition of the anode mass, and dosage of stock components are discussed. The sixth chapter (pp. 251–310) considers technologies for anode mass mixing and mixing apparatus. The seventh (pp. 311–353) and eighth (pp. 354–469) chapters describe the processes for forming and baking of the anode units. The ninth chapter (pp. 470–522) describes in detail the procedures used in dismantling worked-out anodes and mounting new ones. The tenth (pp. 523–595) and eleventh (pp. 596–655) chapters compare the advantages, disadvantages, and specific features of baked and self-baking anodes. The author noted, in particular, that electrolyzers with self-baking anodes have not exhausted their potentialities and can be regarded as a promising object of further modernization. In the author's opinion, it is apparently advisable to use electrolyzers of this kind for manufacture of aluminum in regions that are remote from large settlements and are not subject to stringent ecological requirements.

The bibliography (pp. 656–666) contains references to 246 studies by domestic and foreign researchers.

The book contains a vast body of reference material and describes in detail the apparatus and technologies used in manufacture of anodes. Less successful are separate inclusions of physicochemical and electrochemical nature. The book is very well printed.

Properties of Carbon Materials and Their Use in Chromatography

L. A. Kartsova and A. A. Makarov

St. Petersburg State University, St. Petersburg, Russia

Received July 24, 2002

Abstract—Sorption properties of graphite, fullerene, and nanotubes were considered, as well as the pattern of variation of the sorption properties of fullerene C_{60} in complexing with various macrocycles. The use of these materials as stationary phase in chromatography and in solid-phase concentration of microimpurities of aromatic hydrocarbons was discussed.

Carbon exists in four allotropic modifications, namely, diamond, graphite, fullerenes, and linear carbon polymer (Karbin). Graphite and diamond were discovered in the nature as early as the XVIII century (the relations between diamond and graphite were studied in detail by French physicists Antoine Loraine Lavoisier and Louis Bernard Guyton de Morveau). Karbin [1] and fullerenes were prepared in laboratories in recent decades. In the 1960s, white Karbin crystals were detected in natural graphite, and in 1992 it was found that the Karelian mineral shungite (amorphous carbon) contains a fullerene impurity (~0.001%). Diamond and graphite had found wide practical application long before their structures were elucidated. However, these structures were established conclusively only after development of the appropriate physicochemical methods (X-ray and electron diffraction analyses, etc.). The situation with Karbin and fullerenes is the opposite: Their structures have been established fairly reliably, but possible applications based on their expected process characteristics are still the matter of discussion rather than commercial implementation. Such allotropic modifications of carbon as diamond, graphite, and Karbin can be regarded as infinite systems with a regular three, two-, and one-dimensional structure, respectively. By contrast, fullerenes form a family of individual polyhedral molecules with a closed structure [2]. The scheme in Fig. 1 shows the hierarchy of the carbon structures.

The IUPAC recommends that fullerenes be defined as closed spherical polyhedra formed exclusively by three-coordinate carbon atoms with 12 pentagonal and (n/2 – 10) hexagonal faces, where $n > 20$. Fullerenes are termed [60]fullerene, [70]fullerene, etc. Any other closed spherical polyhedra formed exclusively by three-coordinate carbon atoms were termed quasifullerenes. The most stable are fullerenes whose structure is described by the isolated pentagon rule, with each pentagon surrounded by five hexagons.

The appearance and the physical and chemical properties of the above-mentioned carbon modifications strongly vary with the type of the bonds between the carbon atoms in the molecules of these substances (Table 1; l is the bond length, and ρ is the density).

Graphite. The sp^2-hybridized carbon atoms in graphite form infinite planes composed of regular hexagons, and in fullerenes they form closed shells including a certain number of atoms. Real graphite bodies contain a certain amount of disordered atoms intercalated in the interlayer space. These atoms can occur in the sp-, sp^2-, or sp^3-hybridized states.

The ideal structure of graphite is, essentially, an infinite series of mutually parallel layers composed of hexagons formed by carbon atoms. Mutual displace-

ment of these layers by two different modes yield two different forms, hexagonal and rhombohedral. In the former, the layers alternate by the A–B–A–B... scheme, and in the latter, by the A–B–C–A–B–C–... scheme. In naturally occurring graphites, the content of the rhombohedral form can reach 30%, and in artificial, this form is virtually lacking. Any neighboring carbon atoms in the layer plane are separated by 0.142 nm, and the neighboring layers, by 0.335 nm. Each atom in the layer is connected with three neighboring atoms, and the bond angles are 120°. The bonds involve three of the four valence electrons, and the remaining electrons form a common electron cloud. This structure is responsible for anisotropy of the physical properties of graphite, i.e., their difference in directions going parallel and perpendicular to the layers. Graphite ranks among the softest minerals. It should be mentioned that the above-described structure is characteristic of graphite single crystal. Real bodies contain a multitude of areas comprised of the ordered carbon atoms, which have finite dimensions differing by several orders of magnitude for different samples of carbon bodies with graphite or graphite-like structures. The structures of these areas can approach that of the ideal graphite lattice or differ therefrom owing to intralayer distortions and irregular alternation of the layers.

Graphite can form intercalation compounds with certain molecules, when these latter are inserted between the graphite layers. The reactant molecules can be linked to carbon atoms by covalent, coordination, or ionic bonds. These structures involve, in particular, intercalation compounds in which graphite layers (matrix) are separated by alkali metal clusters (matrix-isolated particles). Depending on the type of the forming bonds, the layered compound can preserve or lose the electrical conductivity characteristic of the initial graphite.

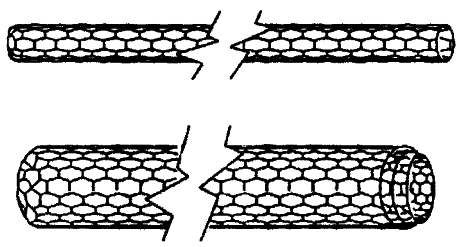

Fig. 2. Single- and multilayer nanotubes.

Nanotubes. Nanotubes (or tubulenes) were first prepared in 1991 by Japanese scientist Sumio Iijima by electric-arc vaporization of graphite under argon. In that experiment, carbon needles 4–30 nm in diameter up to 2 μm long grew on the graphite cathode [3]. In the optimal mode, the yield of nanotubes from the cathodic carbon black is 60%. This class of compounds has diverse structures. Nanotubes consist of two fullerene halves and a cylinder made up by hexagons. The cylinder, in turn, is, essentially, a rolled-up graphite layer. There exist single- and multilayer, open- and closed-ended nanotubes differing in the length and diameter. The interlayer spacing in multilayer tubes is equal to 0.34 nm, like in crystalline graphite. Multilayer graphite nanotubes differ from single-layer nanotubes by a greater diversity of shapes and configurations [4, 5]. Figure 2 shows single- and multilayer nanotubes [6]. An ideal nanotube is, essentially, a graphite plane rolled up in a cylinder, with the surface consisting of regular hexagons. The resulting structure is governed by the orientation angle of the graphite plane with respect to the nanotube axis. The orientation angle governs the chirality of the nanotube (Fig. 3).

The specific structure is responsible for a number of specific features of nanotubes. For example, open-ended nanotubes, when immersed in molten lead, get partially filled with lead (owing to the capillary effect) [7]. Early studies into capillary phenomena revealed a connection between the surface tension of a liquid and the possibility of its drawing into the nanotube channel. Laser vaporization of graphite in the presence

of certain metallic catalysts yields both nanotubes and C_{60} (in particular, those inside nanotubes), as shown by high-resolution electron-microscopic studies.

Observation of capillary effects requires opening nanotubes, which can be done by two ways: annealing at 850°C for several hours in a CO_2 flow (opening 10% of all nanotubes) and keeping in concentrated HNO_3 for 4.5 h at 240°C (80% of nanotubes). Oxidation of nanotubes yields carbonyl and carboxy groups on the nanotube surface.

Isolation of individual nanotubes still remains a fairly complicated task, as most of nanotubes are insoluble in the known solvents. Only single-layer nanotubes form solutions [8].

Fullerene. The spherical structure of fullerene and identity of all the 60 carbon atoms were confirmed by NMR spectroscopic and high-resolution electron-microscopic studies. Only truncated icosahedral structure suggested for C_{60} affords so highly symmetrical arrangement of the carbon atoms that all the strains are distributed uniformly. Of all the possible three-dimensional structures, the C_{60} molecule exhibits the highest symmetry [9]. The accessible interior space has a radius of 1.7 Å. The sphere circumscribed around the fullerene molecule is 7.1 Å in diameter [10, 11].

Fullerene is soluble (though fairly poorly) primarily in organic [12, 13], better aromatic, solvents (Table 2 in [5]).

Study of the solubility of fullerenes in organic solvents is the starting point for their separation and purification. The structures of fullerenes with different compositions differ only slightly, which makes them close in solubility and adsorbability. At the same time, efficient isolation and separation of fullerenes are based specifically on the distinctions in these properties.

The solubility in water for carbon molecules such as C_{60} cannot be high, but it can be improved by "incorporating" the carbon molecules into appropriate water-soluble molecules, e.g., cyclodextrins (CDs). α- and β-CDs cannot accommodate the entire hydrophobic molecule such as C_{60}. When dissolved in excess γ-cyclodextrin, fullerene forms a "host–guest" complex existing as a yellowish colloidal solution [16, 17] (Fig. 4).

Adsorption properties of fullerene-containing materials (FCMs). Samonin and Marakulina [18] found that FCMs can adsorb water (approximately a monomolecular layer) and inorganic ions. Studies of the sorption potential of fullerene C_{60} with respect to various organic and organometallic compounds in aqueous solution showed the following. Fullerene adsorbs *N*-methylcarbamates, phenols, polycyclic aromatic hydrocarbons, and amines with the efficiency of about 60%, depending on the nature of the sorbate. It should be mentioned that, in these applications,

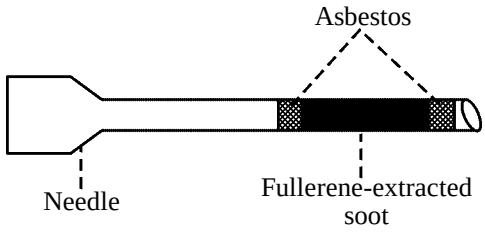

Fig. 5. Scheme of the adapter for SPE.

conventional sorbents such as XAD-2 or foamed polyurethane surpass C_{60} in the sorption efficiency [19]. Nevertheless, organometallic compounds (metallocenes and organic compounds of lead) are quantitatively adsorbed by C_{60}, forming neutral complexes or chelates. A comparative assessment of the adsorption of organometallic complexes on sorbents such as inverted C_{18} phase and silica gel 100 shows the superiority of C_{60} [19].

The fullerene extraction residue (fullerene-extracted soot, FES) was suggested as adsorbent for collecting volatile organic components from ambient air. The retention characteristics of FES were measured for 17 volatile organic components [20].

High affinity of fullerenes for aromatic hydrocarbons and their functional derivatives could be of use for environmental monitoring: When utilized in the solid-phase extraction mode, fullerene could serve for identifying the above-mentioned compounds. For this purpose, we used a specially prepared needle containing a ~7-mm layer of fullerene black (yielded by fullerene production), through which a gas mixture containing benzene, toluene, and *p*-xylene vapors was pumped (Fig. 5). The volume of the gas mixture was varied from 50 to 200 ml. The needle was placed into the vaporizer of a chromatograph, where thermal desorption (for 5–10 min under stopped carrier gas flow) and chromatographic analysis (after resuming the carrier gas flow) were run. It was shown that, despite a high density of the needle filling (which hinders gas passage), the above-described adapter is suitable for concentration in analysis of aromatic compounds.

High filling density poses, however, a number of limitations on application of this device. In particular, it is unsuitable for analyzing aqueous samples whose thermal desorption takes much time.

Use of carbon materials in chromatography. Graphite finds application in chromatography as activated carbons or graphitized thermal carbon blacks (GTCBs). Activated carbons are used primarily for separation of light gases; they are distinguished by highly developed pore structure. One recognizes micropores (1–2 nm), mesopores (5–10 nm), and macropores (>100 nm). The specific surface area of micropores reaches 1000–1200 (sometimes 1800), that of mespores, up to 100, and that of macropores is of the order of 1 $m^2 g^{-1}$. In gas chromatography, preference is given to carbons for which the surface area of micropores is at a maximum [21].

Graphitized thermal carbon blacks are nonspecific adsorbents with a small specific surface area of 6–12 $m^2 g^{-1}$. GTCBs are not very strong mechanically. Hence, to make GTCB handling more convenient and to improve the separation efficiency, the carbon black particles are covered with pyrocarbon by hydrocarbon pyrolysis in a flow of a gas passing through a carbon black layer. This yields fairly strong mechanically macroporous adsorbents, Carbochrome A (from GTCB) and Carbochrome B (from nongraphitized thermal carbon black). The surface properties of these Carbochromes are very close to those of GTCB. Based on a more finely dispersed and chemically heterogeneous channel black, it is possible to prepare by the same procedure Carbochrome C, a mechanically strong adsorbent with a much greater specific surface area of ~80 $m^2 g^{-1}$. Carbochrome C has a fairly uniform and nonspecific surface, especially after an additional treatment with hydrogen [22].

GTCBs and Carbochrome are efficient in separation of isomeric cyclanes, unsaturated and aromatic hydrocarbons, halogenated alkanes, and diverse structural isomers whose molecules contain primary, secondary, and tertiary carbon atoms.

Such properties of fullerene as thermal stability (C_{60} vaporizes at ~800°C and sublimes without decomposition; after heating to 980°C for over 10 min the fullerene crystals degrade into amorphous carbon [23]), resistance to oxidation, spherical shape of the molecule, and capability for donor–acceptor interac-

tions make it a candidate sorbent for gas chromatography.

Fullerene C_{60} was for the first time used in capillary gas chromatography in 1993. The capability of fullerene C_{60} for dispersion interactions was measured.

The free energy of sorption of the methylene unit of *n*-alkanes (Table 3) was estimated and compared with those of other gas-chromatographic phases. This allowed an interesting conclusion, namely, that the operation mode for C_{60} is of the gas–liquid, rather than of the gas-adsorption type. The C_{60}-based stationary phase is close to nonpolar phases, Apiezon and Squalane [24].

The thermodynamic characteristics of adsorption of various organic substances on the surface of crystals of fullerenes C_{60} and C_{70} were determined by gas chromatography. It was shown that adsorption properties of fullerenes differ from those of graphitized carbon black. The surface of fullerene crystals exceeds in polarity that of graphitized carbon black; adsorption on fullerene involves stronger, compared to graphitized carbon black, interaction with electron- and proton-donating molecules [25, 26].

Fullerene-based stationary phase in which C_{60} is chemically immobilized on polysiloxane via the amide bond (Fig. 6) was used in gas chromatography for analyzing substituted aromatic compounds [27, 28].

The fullerene C_{60} grafted chemically to the silica gel phase was used as stationary phase in liquid chromatography for analyzing polycylic aromatic compounds and polychlorinated biphenyls [28], as well as for separating calixarenes (with methanol–water mobile phase), benzene, anthracene, diphenyl, etc.

Gas-chromatographic analyses on columns packed with C_{60} revealed sharp weakening of the dispersion interactions relative to Carbochrome-based stationary phase. By contrast, polar organic compounds exhibit higher retention parameters with C_{60} compared to graphitized carbon black and SE-30. High thermal stability of fullerene allowed operation of the chromatographic column over a wide temperature range, but the selectivity in analysis of mixtures containing fairly volatile low-boiling organic substances was low.

One way to extend the selectivity range is to prepare mixed-composition phases. Surface modification of carbonic sorbents serves to modify the sorbate–sorbent interactions. By choosing appropriate modifier, it is possible to increase the contribution from

Table 3. Free energy of sorption of the methylene unit $\Delta G(CH_2)$ of *n*-alkanes in gas chromatography

Phase	$-\Delta G(CH_2)$, J mol^{-1}	T, °C
Fullerene C_{60}	2018	100
Apiezon L	2124	120
Squalane	2179	120
Acetylene carbon black modified with pyrocarbon (Carbochrome AC)	4914	100
Graphitized carbon black	4511	100

dipole–dipole, donor–acceptor, and π–π interactions, etc. [29].

Modifiers should be fairly strongly retained by the carbon material, so as to decrease its gradual washing off by the carrier gas flow. To this end, covalent linking can be used. Another way is to take advantage of complexes that can be formed by the modifier and the substance being modified. In particular, fullerenes are known to form complexes with certain macrocycles.

Fullerene is capable of complexing with various organic and inorganic molecules, thus acting as electron acceptor [30, 31].

Incorporation of the C_{60} guest into appropriate host molecule is the first step toward synthesis of supramolecules comprising fullerenes. Supramolecular complexes were obtained from cyclic host macromolecules such as cyclodextrins, crown ethers, and cycloveratrylenes, having voids able of accommodating the guest fullerene. It was shown that the properties of such intercalation compounds depend on the

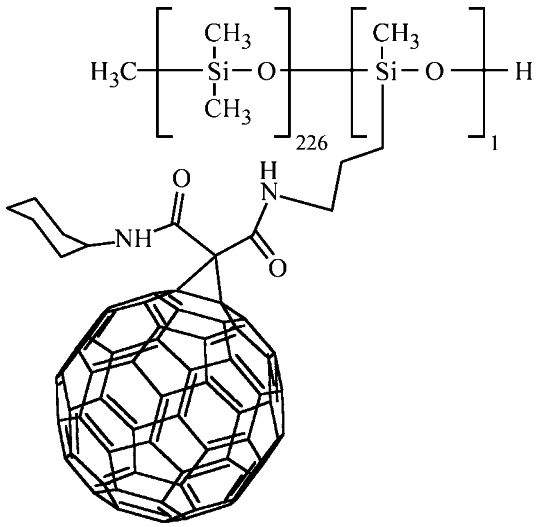

Fig. 6. C_{60}-based stationary phase.

π–π, –OH $\rightarrow$ π, and $\sigma \rightarrow \pi$ interactions. Of great importance is understanding of the interactions between the fullerenes and macromolecules, as this affords preparation of water-soluble complexes for potential biological and medical applications. Also, complexes of this type are suitable for purification and isolation of certain fullerenes from ordinary carbon black for the synthesis of new materials to be used in electronic devices.

The complex formed by C_{60} and γ-cyclodextrin [32–34] was studied by NMR spectroscopy [33] and mass spectrometry [35], as well as by electrochemical and spectrometric methods [36].

Murthy and Geckeler [37] reported on a stable sandwich-type complex formed by β-CD and fullerene C_{60}. Kawaguchi *et al*. [38] discussed the interaction between fullerene and various calix[*n*]arenes. It was found that certain calix[*n*]arenes (n = 5, 6), as well as calix[3]arenes with *tert*-butyl substituents, can interact with C_{60} in solution. The molecules of calixarenes typically take the conical form, and the benzene rings are arranged in a way favorable for intercalation of C_{60} [39, 40]. It was shown that the complex is stabilized by *tert*-butyl or benzyl substituents [41]. Formation of complexes between certain calix[8]arenes and fullerenes C_{60} and C_{70} was proven in [42, 43]. Also, fullerenes can form host–guest complexes with other molecules such as metacyclophane [44] and with dendrimers [45].

It can be assumed that large crown ethers (dibenzo-24-crown-8, dibenzo-30-crown-10), similar to β- and γ-cyclodextrins, can form sandwich-type complexes with [60]fullerene, but this assumption requires independent verification. This should take into account the fact that complexes of fullerene with certain macrocycles are stable only in the solid state [39].

To extend the selectivity range of fullerene-based phases, chromatographic phases of mixed composition were prepared and tested, namely, those containing 10% C_{60} and dibenzo-24-crown-8, or C_{60} and dibenzo-30-crown-10. The polarity of these phases is intermediate between those of fullerene and individual crown ethers. These columns allow highly efficient and highly selective separation of positional isomers and of aliphatic and aromatic organic compounds containing various functional groups (OH, NH_2, NO_2, Cl) and boiling in a wide temperature range without preliminary chemical transformation.

Thus, sorbents based on fullerene and macrocycles allow the advantages of both fullerene itself (thermal stability and high performance) and the macrocycle (high selectivity) to be preserved and realized.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Formation of the Compound La_2BaCuO_5 ($La_4Ba_2Cu_2O_{10}$)

Abstract—Synthesis of the compound La_2BaCuO_5 ($La_4Ba_2Cu_2O_{10}$), whose X-ray diffraction pattern is identical to that available in the literature for the solid solution $La_{3.6}Ba_{2.4}Cu_{1.8}O_{9.6}$, was studied.

The main elements of the phase diagram of the ternary system La_2O_3–BaO–CuO had been obtained [1] before the region of solid solutions $La_{2-x}Ba_xCuO_4$, which become superconducting at 30–35 K, was found in this system in 1986 [2]. After this discovery, intensive search for new oxide superconductors started at numerous research centers all over the world. This search culminated in 1987 in that the compound $YBa_2Cu_3O_{7-\delta}$ with the superconducting transition temperature T_c of 93 K was synthesized [3].

Since the T_c of the compound $YBa_2Cu_3O_{7-\delta}$ much exceeds that of $La_{2-x}Ba_xCuO_4$ solid solutions, the primary attention of researchers has been focused on the system Y_2O_3–BaO–CuO. As a result, phase equilibria in the system La_2O_3–BaO–CuO have been studied to a much lesser extent than those in the system Y_2O_3–BaO–CuO [4–6].

The observed pronounced dissimilarity between the phase diagrams of the systems La_2O_3–BaO–CuO and Y_2O_3–BaO–CuO is, probably, mainly due to difference in size between the La^{3+} and Y^{3+} ions. For example, in the system Y_2O_3–BaO–CuO there exists a nonsuperconducting "green" phase Y_2BaCuO_5 (211 phase) with orthorhombic structure, which plays an important part in solid-phase synthesis of the superconducting compound $YBa_2Cu_3O_{7-\delta}$. No green phase of this kind is formed in the system La_2O_3–BaO–CuO, with solid solutions $La_{4-2x}Ba_{2+2x}Cu_{2-x}O_{10-2x}$ ($0.15 \le x \le 0.25$) crystallizing instead. These solid solutions have tetragonal structure and brown color [1, 7]; they are characterized by a certain deficiency of copper and can be regarded as derivatives of the stoichiometric compound $La_4Ba_2Cu_2O_{10}$ (422 phase) whose formula is doubled in comparison with the La_2BaCuO_5 phase. In [8], the $La_{2-x}Ba_{1+x}CuO_{5-x/2+\delta}$ solid solutions ($0.1 \le x \le 0.8$) were revealed. It has been reported that there exists an $La_4Ba_2Cu_2O_{10}$ phase with the lattice constants *a* and *c* of, respectively, 6.8447 and 5.8637 Å. It has been established [10] that the La_2BaCuO_5 solid phase is formed in incongruent melting of $LaBa_2Cu_3O_{7-y}$ at 1353 K.

The green (211) phase is formed in all R_2O_3–BaO–CuO systems (R is rare earth) except those with R = Nd and Pr [4, 6, 11]. In the system Nd_2O_3–BaO–CuO, as also in La_2O_3–BaO–CuO, there exists a "brown" tetragonal phase, $Nd_{4-2x}Ba_{2+2x}Cu_{2-x}O_{10-2x}$ ($0 \le x \le 0.1$) [4, 12].

It should be noted that the compound $Nd_4Ba_2Cu_2O_{10}$, whose composition corresponds to the simplest formula Nd_2BaCuO_5, has also been obtained in the given system at $x = 0$. The tetragonal crystal structure and some properties of this compound were described in [13, 14].

The goal of this work was to analyze by the method of diffusion pairs the reaction of La_2BaO_4 with La_2CuO_4. It was assumed that mutual diffusion of Ba^{2+} and Cu^{2+} ions would give $La_2Cu_{1-x}Ba_xO_4$ and $La_2Ba_{1-x}Cu_xO_4$ solid solutions based on, respectively, La_2CuO_4 and La_2BaO_4. However, as shown by the results of X-ray fluorescence analysis, the reaction of La_2BaO_4 with La_2CuO_4 gives a phase whose composition is invariable across the diffusion layer and can be expressed by the simplest formula La_2BaCuO_5. Therefore, this compound was also analyzed as a component of mixtures with various oxide phases.

EXPERIMENTAL

The compounds La_2BaO_4 and La_2CuO_4, whose reaction was studied by the method of diffusion pairs, were synthesized by calcining in air at 1223 K for 8 h

1070-4272/02/7511-1732$27.00 © 2002 MAIK "Nauka/Interperiodica"

pellets compacted from mixed powders of $BaCO_3$ + $2La(OH)_3$ and CuO + $2La(OH)_3$. Then the samples obtained were ground in an agate mortar and the resulting finely dispersed powders were compacted into pellets 10 mm in diameter and 5–6 mm high. The pellets were calcined in air at 1273 K for 8 h. The edge surfaces of the sintered La_2BaO_4 and La_2CuO_4 pellets were polished with diamond paste. Pairs of pellets of these two different compounds were put one upon another, with polished faces in contact, placed in an Alundum tube, and introduced, together with the compression unit, into a furnace heated to 1223 K. After 24 h, the entire content of the tube was rapidly removed from the furnace.

After calcining, the diffusion pair was divided into the initial pellets, with the reaction layer remaining on the La_2CuO_4 pellet. This pellet was cut in two, perpendicularly to the edge surfaces, and the cuts were polished with diamond paste.

A Cameca MS-46 electron-microprobe X-ray fluorescence analyzer was used to determine the distribution, across the reaction layer and at a certain distance from it, of characteristic X-ray emission from, simultaneously, two elements: La, Ba and Cu, Ba.

The intensities of characteristic X-ray emission of these elements were invariable across the reaction layer (Fig. 1). Hence follows that the reaction of La_2CuO_4 with La_2BaO_4 yields not the $La_2Cu_{1-x}Ba_xO_4$ solid solution, but a compound whose cationic composition is approximately expressed by a simple formula La_2BaCuO_5.

Figure 2 shows the Gibbs triangle of the ternary system La_2O_3–BaO–CuO, in which point *a* lies in the middle of the straight line connecting points with coordinates corresponding to the compositions of the compounds La_2BaO_4 and La_2CuO_4.

Point *a* corresponds to a solid solution $La_2Ba_{0.5}Cu_{0.5}O_4$, which would be formed if there occurred mutual diffusion of Ba^{2+} ions from the crystal lattice of La_2BaO_4 into that of La_2CuO_4 and of Cu^{2+} ions from the La_2CuO_4 phase into the La_2BaO_4 phase. However, such a solid solution is unstable and, if formed, would decompose into La_2O_3 and La_2BaCuO_5 phases (Fig. 2, point *b*) by the scheme

$$2La_2Ba_{0.5}Cu_{0.5}O_4 \rightarrow La_2O_3 + La_2BaCuO_5.$$

For such a mechanism of the reaction between La_2BaO_4 and La_2CuO_4 to be operative, the reaction layer must consist of two phases. However, this layer is actually single-phase.

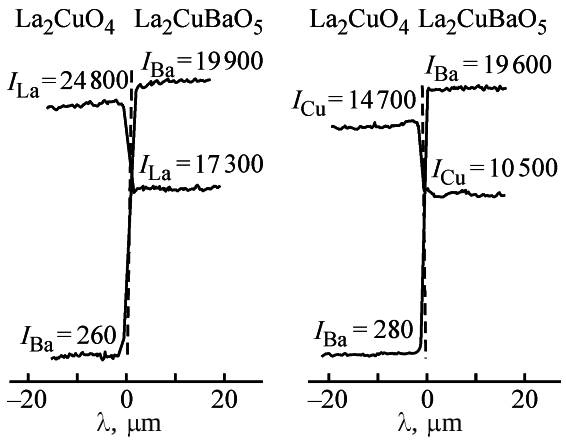

Fig. 1. Intensity distribution of characteristic X-ray emission from (*1*) Ba, (*2*) La, and (*3*) Cu across the reaction layer of the diffusion pair La_2CuO_4–La_2BaO_4 calcined at 1223 K for 24 h. (λ) Coordinate across the layer. The reaction layer is on the La_2CuO_4 pellet. The dashed line denotes the phase boundary between La_2CuO_4 and the reaction layer.

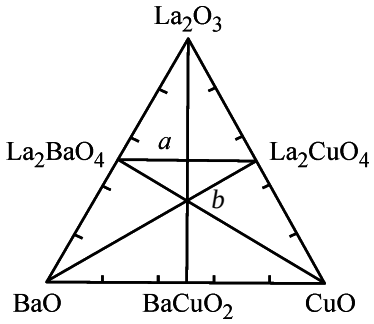

Fig. 2. Gibbs triangle of the system La_2O_3–BaO–CuO.

Consequently, it may be suggested that this single-phase reaction proceeds by the mechanism of one-way diffusion of one of the ions, Ba^{2+} or Cu^{2+}, and electrons of oxygen ions. In view of the fact that the reaction layer is formed on the La_2CuO_4 pellet, it is barium and oxygen ions that diffuse, in all probability, despite the much larger size of Ba^{2+} ions, compared to Cu^{2+} ions, from the crystal lattice of La_2BaO_4 into that of La_2CuO_4. The La_2BaCuO_5 phase is formed from the latter, and lanthanum oxide crystallizes in the porous surface layer of the La_2BaO_4 pellet. This process can be represented as

$$La_2BaO_4 = La_2O_3 + Ba^{2+} + 2e + 1/2O_2$$

(on La_2BaO_4 pellet),

$$La_2CuO_4 + Ba^{2+} + 2e + 1/2O_2 = La_2BaCuO_5$$

(on La_2CuO_4 pellet),

Relative intensity *I* of X-ray reflections, interplanar spacings *d* of the compound obtained, La_2BaCuO_5 ($La_4Ba_2Cu_2O_{10}$), and published data for the phase $La_{3.6}Ba_{2.4}Cu_{1.8}O_{9.6}$

Experimental data		Published data [16]			Experimental data		Published data [16]

–	–	2.038	3	311					

or

$$La_2BaO_4 = La_2O_3 + Ba^{2+} + O^{2-}$$
(on La_2BaO_4 pellet),

$$La_2CuO_4 + Ba^{2+} + O^{2-} = La_2BaCuO_5,$$
(on La_2CuO_4 pellet)

It is known that the reaction of ferrite $BaFe_2O_4$ with Fe_2O_3, yielding hexaferrite $BaFe_{12}O_{19}$, also proceeds via one-way diffusion of larger Ba^{2+} ions, rather than small Fe^{3+} ions [15]. This fact may serve as circumstantial evidence in favor of the suggested mechanism of the solid-phase reaction between La_2BaO_4 and La_2CuO_4.

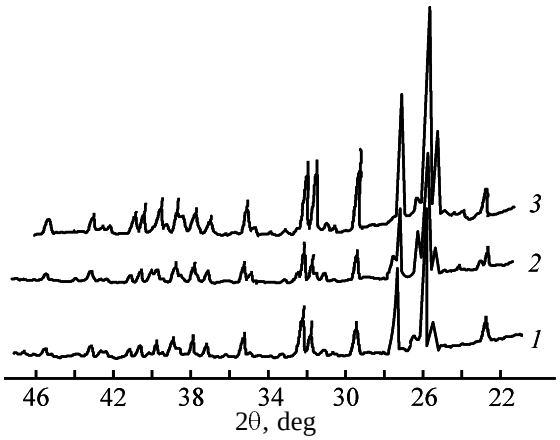

Fig. 3. X-ray diffraction patterns of products formed by reaction at 1373 K for 6 h in mixtures (*1*) La_2BaO_4 + CuO and (*2*) La_2CuO_4 + $BaCO_3$; (*3*) the diffraction pattern of La_2BaCuO_5 ($La_4Ba_2Cu_2O_{10}$) obtained by calcination at 1323 K for 24 h of the mixture $BaCO_3$ + CuO + $2La(OH)_3$. (2θ) Bragg angle.

To confirm the existence of the compound La_2BaCuO_5 ($La_4Ba_2Cu_2O_{10}$), it was also prepared by heating a mixture of $BaCO_3$, CuO, and $La(OH)_3$ powders taken in the molar ratio of 1 : 1 : 2. After thorough mixing in a vibrating mill, the stock was compressed into pellets and calcined at 1223, 1273, and 1323 K for 4, 8, 24, and 48 h at each temperature. The phase state of the calcination products under study was monitored by X-ray phase analysis on a DRON-3 instrument (CuK_α radiation).

The X-ray diffraction patterns obtained demonstrated that a compound with the same X-ray reflections is formed in all cases. The interplanar spacings *d* calculated from these reflections correspond to the values reported in the literature for the $La_{3.6}Ba_{2.4}Cu_{1.8}O_{9.6}$ phase [16] (see table).

Lines corresponding to compositions belonging to three quasi-binary systems La_2BaO_4–CuO, La_2CuO_4–BaO, and La_2O_3–$BaCuO_2$ pass in the Gibbs triangle (Fig. 2) through point *b* corresponding to the compound La_2BaCuO_5. Consequently, this compound can be synthesized by the reaction between two components of each of these systems. In this connection, pellets compacted from powder mixtures of the compositions La_2BaO_4 + CuO, La_2CuO_4 + $BaCO_3$, and $La(OH)_3$ + $BaCuO_2$, thoroughly mixed in a vibrating mill, were calcined in air at 1373 K for 6 h.

The X-ray diffraction patterns of these three calcined mixtures were virtually the same and coincided with that of the compound La_2BaCuO_5, obtained by calcining a mixture of the composition $BaCO_3$ + $2La(OH)_3$ + CuO (Fig. 3).

To study the homogeneity region of La_2BaCuO_5 with respect to the cations, we prepared variable-composition phases $La_{2-x}Ba_{1+x}CuO_5$, $La_{2+x}Ba_{1-x}CuO_5$, $La_{2-x}BaCu_{1+x}O_5$, and $La_{2+x}BaCu_{1-x}O_5$ (x = 0.05, 0.1). The synthesis was done in air at 1373 K from a mixture of powdered $BaCO_3$, $La(OH)_3$, and CuO. As shown by X-ray phase analysis, only samples containing an excess amount of barium(II) at the expense of lanthanum(III) content ($La_{2-x}Ba_{1+x}CuO_5$) were single-phase. Other samples contained minor amounts of other phases.

CONCLUSION

Solid-phase reaction in air at 1223 K in vitrified pellets of double compounds La_2BaO_4 and La_2CuO_4 yields at the $La_2BaO_4 | La_2CuO_4$ phase boundary a layer of the ternary compound La_2BaCuO_5 ($La_4Ba_2 \cdot Cu_2O_{10}$) whose cationic composition is determined with an electron-microprobe X-ray fluorescence analyzer. The reaction occurs via one-way diffusion of Ba^{2+} and O^{2-} ions or electrons from the crystal lattice of La_2BaO_4 into the crystal lattice of the cuprate La_2CuO_4.

The compound can also be synthesized by calcining in air in the temperature interval 1223–1373 K powder mixtures of the compositions $BaCO_3$ + $2La(OH)_3$ + CuO, La_2BaO_4 + CuO, La_2CuO_4 + $BaCO_3$, and $2La(OH)_3$ + $BaCuO_2$. The X-ray diffraction patterns of the final product are the same for all of the mixtures and coincide with published data for the $La_{3.6}Ba_{2.4}Cu_{1.8}O_{9.6}$ phase. The single-phase state of $La_{2-x}Ba_{1+x}CuO_5$ is preserved on raising the content of barium(II) by 10% because of the equivalent decrease in the content of lanthanum(III).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Chemical Modification of Ultradispersed Copper Powders on Electrical Conductivity of Formulations on Their Base

I. I. Obraztsova, G. Yu. Simenyuk, and N. K. Eremenko

Institute of Coal and Coal Chemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received March 13, 2002

Abstract—Ultradispersed powders of copper were obtained by reducing various copper salts with glycerol, and formulations on their base were prepared. The effect of various modifiers on the dispersity, stability, and electrical conductivity of copper powders was examined.

Synthesis and study of ultradispersed powders (UDPs) of metals and development of electrically conducting materials on their base is a topical direction of research in modern science. Recently, increasing attention has been given to copper [1, 2], which is virtually as good as noble metals as regards its electrical conductivity [3–5] and much less expensive. However, copper powders exhibit rather high activity and are oxidized in the course of time, which inevitably impairs the conductivity. This problem can be solved by optimizing the preparation process, modifying the surface of copper UDPs, and creating formulations on their base, whose electrically conducting properties are preserved for a long time. Data on the longevity of electrically conducting formulations are virtually lacking from the literature.

Previously, two methods for obtaining copper UDPs have been developed [6, 7]. These methods are based on reduction of copper sulfate with glycerol. The optimal temperature, time, and reagent concentrations were determined. Also, the influence exerted by organic acids with reducing properties (ascorbic, citric, etc.) on the reaction of copper sulfate with glycerol and on the properties of the copper powders obtained was examined. It was established that additions of these acids accelerate the reaction by a factor of 5–6, allow the process temperature to be decreased by 20–40°C, and ensure enhanced stability and electrical conductivity of the resulting copper UDPs.

It was also found that, upon an appropriate treatment with solutions of hydroquinone and stearic acid in ethanol or pentane, copper UDPs possess increased dispersity (average particle size 20–30 nm), stability, and electrical conductivity. Furthermore, powders treated with pentane can be stored for a long time not only in solution, but also in air.

In this work, we prepared UDPs from various copper(II) salts and examined the influence exerted by chemical modification of copper UDPs on the electrical conductivity and stability of formulations on their base. The data obtained in the study are compared with those published previously [8, 9]. New data on the formulation longevity are presented.

EXPERIMENTAL

Copper UDPs were prepared by reducing various copper salts with glycerol by the method described in [9]. However, it was found that complete reduction of readily decomposing salts (acetate, basic carbonate, and tartrate) requires smaller amount of glycerol, lower temperature T_r, and shorter reaction time τ_r. The results obtained at different copper salt to glycerol mass ratios A are presented in Table 1. It can be seen that the reduction of copper basic carbonate, acetate, and tartrate is the most effective, and their formulations with novolac show high electrical conductivity and are stable for a long time (more than 5 years) without addition of any stabilizers. Here, copper UDP is presumably stabilized in the course of the reaction by glycerol itself.

It also follows from Table 1 that, in reduction of copper(II) sulfate, the electrical conductivity of the resulting formulations falls dramatically when no additional stabilizers are introduced into the resin (experiment no. 1). When, however, modifiers are introduced (experiment no. 2), the formulations obtained

*** No copper powder is formed.

compare well in the electrical conductivity and stability with pastes based on copper UDPs produced by reduction of readily decomposing copper salts (experiment nos. 3–5).

In the case of reduction of copper(II) nitrate, the UDP formed is very rapidly oxidized in the course of the reaction, which markedly diminishes the yield of the metallic phase.

In reduction of copper(II) chloride, no metallic copper is formed, even upon addition of an initiator, ascorbic acid (up to 0.5 g per gram of copper). In the reaction with copper chloride, glycerol undergoes extensive tarring to give a black viscous mass solidifying on cooling.

The aforesaid suggests that it is preferable to use copper sulfate for commercial preparation of electrically conducting materials. On the one hand, other copper salts are less readily available and more expensive, and, on the other, $CuSO_4$-based formulations with various modifiers are virtually as good as pastes prepared from other copper salts, as regards their stability and electrical conductivity.

The effect of chemical modification of the surface of copper UDPs was studied in different stages: in synthesis, treatment, storage, and formulation preparation.

It was shown previously [9] that introduction of organic acids with reducing properties (ascorbic, oxalic, citric, and formic) into the reaction mixture much intensifies the reduction process. It was found here that addition of acetylsalicylic acid in amount of 5 wt % relative to copper sulfate pentahydrate makes it possible to diminish the process time even more (10-fold). Furthermore, it was found that the nature of the acid also affects the particle size. For example, the highest dispersity is observed when acetylsalicylic acid is added as initiating agent, since the major part of particles are 10–40 nm in size (according to electron microscopy). In the case when ascorbic acid is used, a minor amount of 100–200-nm aggregates are present together with the highly dispersed phase, and introduction of citric acid leads to formation of 40–300-nm particles. It was found that the dispersity grows with increasing acid concentration. This is due to the following facts: (i) particle agglomeration becomes weaker under milder reaction conditions; (ii) in some cases, introduction of acids instantaneously initiates reduction to give a large number of nuclei of the metallic phase; and (iii) organic acids may enter into the composition of intermediate reaction products, thereby changing the structure of copper UDPs formed on their base.

Prolonged storage of copper UDPs in air or in ethanol may lead to partial oxidation of the surface layer, with the electrical conductivity of formulations decreasing dramatically. It was found that the electrical conductivity can be easily restored in this case by treating the copper UDP with formic acid (1–2 ml of HCOOH per gram of copper). No UDP oxidation is observed in the case of storage in pentane.

The copper UDPs obtained were used to prepare electrically conducting formulations with epoxy or novolac resins. The formulations were cured in accordance with the polymerization mode of the resin employed. A study of the influence exerted by reduction of copper sulfate with glycerol on the electrical conductivity of the formulations demonstrated that the number of conducting chains in formulations with

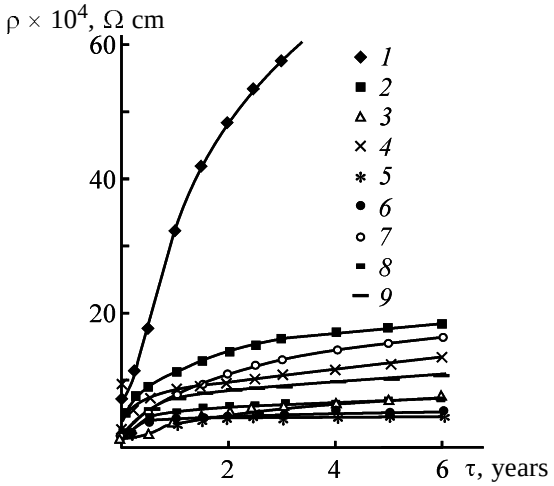

Fig. 1. Electrical resistivity ρ of formulations comprising SF-010 novolac resin, copper UDP, and organic acid vs. testing time τ. Curve nos. are sample nos. in Table 1.

epoxy resin is sufficient for stable electricity transfer even at metal concentration of 55%. In the case of novolac resin, a higher content of metal is necessary (65–70%). However, at a metal content of 75–80% the electrical conductivities of composites based on these resins become comparable.

It was established that copper formulations obtained using different methods and different modifiers markedly differ in the electrical conductivity and stability (Figs. 1, 2). Table 2 lists the results obtained in studying the influence exerted by introduction of a number of organic acids (initiating agents) at different mass ratios B ($CuSO_4 \cdot 5H_2O$: glycerol : initiating agent) on the parameters τ_r and T_r of the copper UDP preparation process.

As follows from Fig. 1 and Table 2, introduction of various organic acids (ascorbic, oxalic, citric, formic, or acetylsalicylic) markedly shortens τ_r of copper reduction with glycerol (by a factor of more than 10 in the case of acetylsalicylic acid) and yields formulations with novolac resin that are characterized by high stability (for more than 6 years) and low resistivity (compared to sample no. 1 prepared without introduction of initiating agents). It can also be seen that the electrical conductivity and stability of the formulations grow with increasing concentration of any of the organic acids (sample nos. 3, 5, 6, and 8).

The effect of various stabilizing additives on the electrical conductivity and stability of formulations with epoxy resin is illustrated in Fig. 2a. It can be seen that all formulations with addition of 1-naphthol or *p*-aminophenol retain unchanged high electrical conductivity for more than 10 years (curves *2*–*6*), and formulations with 1-naphthol have the lowest electrical resistivity of $(0.8–1.2) \times 10^{-4}$ Ω cm, close to that of the metal. Formulations with Diaphene (curve *7*) have high initial electrical conductivity, but, after 4 years, the properties of the formulation deteriorate dramatically. With other stabilizers (curves *8*, *9*), the longevity of formulations was even lower.

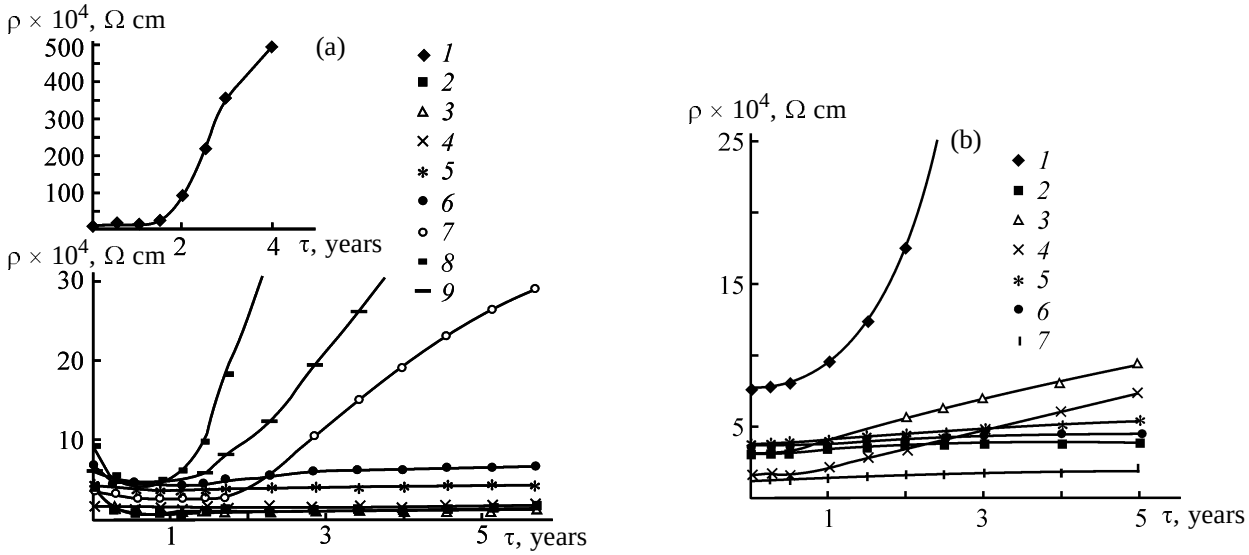

Fig. 2. Effect of stabilizers on the dependence of the electrical resistivity of formulations with (a) EDP epoxy resin and (b) SF-010 novolac resin on the testing time τ. (a) (*1*) Without stabilizer; stabilizer: (*2*–*4*) 1-naphthol, (*5*, *6*) *p*-aminophenol, (*7*) Diaphene, (*8*) *p*-phenylenediamine, and (*9*) 1-naphthylamine. Copper UDP : EDP : stabilizer mass ratio: (*1*) 100 : 40 : 0, (*2*) 100 : 40 : 1.0, (*3*) 100 : 35 : 1.0, (*4*) 100 : 25 : 1.0, (*5*–*7*, *9*) 100 : 30 : 1.0, and (*8*) 100 : 32 : 1.0. (b) (*1*) Without stabilizer; stabilizer: (*2*) 1-naphthol, (*3*) *p*-aminophenol, (*4*) ascorbic acid, (*5*) hydroquinone, (*6*) formic acid, and (*7*) 1-naphthol + glycerol (plasticizer). Copper UDP : SF-010 : stabilizer mass ratio: (*1*) 100 : 25 : 0, (*2*–*5*) 100 : 25 : 1.0, (*6*) 100 : 25 : 5.0, and (*7*) 100 : 25 : 1.0 : 3.0 (3 wt parts of glycerol).

Table 2. Effect of initiator on the conditions of preparation of copper UDPs

Sample no.	*B*	Initiator (acid)	τ_r, min	T_r, °C
1	1 : 10.0 : 0	–	300	180–190
2	1 : 10.0 : 0.003	Ascorbic	85	160–165
3	1 : 7.5 : 0.020	″	40	140–145
4	1 : 5.0 : 0.010	″	40	150–155
5	1 : 7.5 : 0.100	Oxalic	70	160–165
6	1 : 7.5 : 0.060	Citric	100	170–175
7	1 : 7.5 : 0.030	Formic	80	160–165
8	1 : 6.7 : 0.120	″	55	160–165
9	1 : 10.0 : 0.050	Acetylsalicylic	25	155–160

Thus, a conclusion can be made that the best stabilizers for epoxy formulations are 1-naphthol and *p*-aminophenol, which are known [10] to be effective inhibitors of oxidation with molecular oxygen, used to prevent aging of polymers and stabilize jet-engine fuel in prolonged storage.

For formulations with novolac resin, the effect of various stabilizers is illustrated in Fig. 2b. It can be seen that all of the modified samples have lower resistivity and are more stable than the initial sample (curve *1*), with the lowest resistivity observed for the formulation stabilized with a mixture of glycerol and 1-naphthol (curve *7*). The introduction of glycerol, presumably, makes lower the brittleness of the novolac formulations and improves their adhesion characteristics, which makes higher their electrical conductivity. In contrast to [9], where stability data were reported for a time period of only 3 months, we report here the data obtained during the last 5 years. It is clear that not all of the formulations studied possess stable characteristics, but only those stabilized with 1-naphthol (curve *2*), formic acid (curve *6*), hydroquinone (curve *5*), and a mixture of glycerol and 1-naphthol (curve *7*). As in the case of epoxy formulations, the best oxidation inhibitor is 1-naphthol, and addition to this compound of glycerol in 1 : 3 ratio yields formulations comparable in electrical conductivity (resistivity 1.2×10^{-4} Ω cm) with the best samples with epoxy resin (Fig. 2a) and novolac formulations with addition of organic acids (Fig. 1) or those obtained from readily decomposing copper salts (Table 1).

CONCLUSIONS

(1) Ultradispersed powders prepared from readily decomposing copper salts and formulations synthesized on their base retain high electrical conductivity for more than 5 years.

(2) The best stabilizer for ultradispersed copper powders obtained from copper sulfate is 1-naphthol or its mixture with glycerol.

(3) Chemical modification of ultradispersed copper powders results in that epoxy formulations prepared on their base retain their high electrical conductivity for more than 10 years.

(4) The enhanced stability and low cost of these copper-based materials makes them promising for use in modern nanoelectronics instead of composites based on noble metals.

Abstract—Conditions for the formation of a polynuclear copper sulfite complex were studied by spectrophotometry, conductometry, and chemical analysis. The composition of the forming sulfites was determined, and the equilibrium constant of formation of the polynuclear copper sulfite complex and its dissociation constant were calculated.

The reaction between $CuSO_4$ and Na_2SO_3 aqueous solutions results in the precipitation of $Cu_2SO_3 \cdot 4.5H_2O$ at $T \le 40°C$ and $Cu_2SO_3 \cdot CuSO_3 \cdot 2H_2O$ at $T \ge 40°C$ [1]. These sulfites are prepared at the molar ratio $Na_2SO_3(H_2SO_3)/CuSO_4 \approx 1$ (pH ≥7) [1, 2]. However, when copper sulfite is obtained using sulfur dioxide, the residual sulfuric acid acidity of up to 1.05 wt % suggests that copper sulfite can form at lower pH values than it follows from the reaction equation, which is of importance for the removal of copper ions from copper–nickel solutions [4]. The unit cell parameters of $Cu_2SO_3 \cdot CuSO_3 \cdot 2H_2O$ have been determined [5]. The composition and stability of the mononuclear copper(I) sulfite complexes $[CuSO_3]^-$, $[Cu(SO_3)_2]^{3-}$, and $[Cu(SO_3)_3]^{5-}$ in aqueous solutions were studied [6]. However, conditions for the formation of the polynuclear copper complex in aqueous solution and its composition were not studied.

The aim of this work was to find optimal conditions for the formation of the polynuclear copper sulfite complex and to determine its composition and stability.

EXPERIMENTAL

The $CuSO_4$–Na_2SO_3–H_2O system was studied by spectrophotometry and chemical analysis [7]. The experimental technique was described earlier in [8].

To determine the optimal pH of the solution, we measured the optical densities at 790 nm for several solutions of the complex and copper(II) sulfate with equal concentrations but different pH. The maximal difference in optical densities of the complex and copper(II) sulfate was observed in the pH range 2.8–3.2; therefore, subsequent experiments were carried out in this range.

To study the composition of the copper complex with sodium sulfite, we first prepared an isomolar series of solutions with the total concentration of components of 0.140 M and ionic strength of 0.70. The maximal yield of the complex corresponded to the ratio $c_{Cu} : (c_{Cu} + c_{SO_3^{2-}}) = 0.62$; in this case, the optical density reached a maximum of 2.88 (Fig. 1, curve *1*). A minimum of conduction was detected at $c_{Cu}/(c_{Cu} + c_{SO_3^{2-}}) = 0.60$ (Fig. 1). Hence, we can assign the composition $n_{Cu} : n_{SO_3^{2-}} = 3 : 2$ to the complex. However, as shown by N.P. Komar', the ratio of stoichiometric coefficients of a reaction determined by the method of isomolar series is often inconsistent with the formula of the resulting complex compound. It is particularly typical for complexes having an absorption maximum shifted to the left- or the right-

hand side of the isomolar diagram. Therefore, we used additional spectroscopic methods to elucidate reliably the composition of the complex.

The most common technique for studying complex compounds is the method of molar ratios. Our experimental data, used to determine the composition of the complex by this method, are given in Table 1. The breakpoints in the experimental curves (Fig. 2) correspond to the ratio of stoichiometric coefficients, which is equal to the ratio of concentrations of reacting components in the abscissa of the equivalent point. According to curves *1* and *2*, the ratios $c_{Cu}/c_{SO_3^{2-}}$ and $c_{SO_3^{2-}}/c_{Cu}$ are 1.5 and 0.67, respectively. It is evident that the complex with the composition $c_{Cu} : n_{SO_3^{2-}}$ = 3 : 2 is formed.

The data required for the determination of the composition of the complex by Starik–Barbanel' method [10] are given in Table 2. Unlike the method of isomolar series, this method allows determination not of the ratios of the stoichiometric coefficients, but of their absolute values. It is applicable to any stoichiometric reaction. It follows from Table 2 that the maximal yield is observed at $\Delta D/c_{Cu}$ = 9.233, which corresponds to $\Delta D/\Delta D_{lim}$ = 0.67, and at $\Delta D/c_{SO_3^{2-}}$ = –32.2, which corresponds to $\Delta D/\Delta D_{lim}$ = 0.497. The calculation by equations [7] for the complex formation reaction $mM + nM \rightleftarrows M_mR_n$ gives m = 3.04 and n = 1.99.

The reaction of a weak acid with metal ions can be represented for the system under study in the following generalized form:

$$mM^{n+} + pHL^- \rightleftarrows [M_mL_p]^{mn-2p} + pH^+. \quad (1)$$

Therefore, we can write the equilibrium constant for process (1) as

$$K = \frac{c_c[H^+]^p}{(c_M - c_c)^m (c_L - c_c)^p}. \quad (2)$$

where c_c is the equilibrium concentration of the complex; c_M, total concentration of metal ions M^{n+}; c_L,

total concentration of weak acid ions HL^-; and p, amount of displaced hydrogen ions.

Replacing c_c by the equal value $c_M D/D_{lim}$, provided that equimolar solutions of a metal salt and a ligand were taken in the experiments, we transform Eq. (2) to the following form [11]:

$$K = \frac{c_M D/D_{lim}[H^+]^p}{(c_M - c_M D/D_{lim})^m (c_L - c_M D/D_{lim})^p}. \quad (3)$$

Using the notation

$$\frac{c_M D}{D_{lim}(c_M - c_M D/D_{lim})^{m+p}} = A$$

after taking the logarithm of Eq. (3), we obtain Eq. (4).

$$\log K = \log A - p\text{pH}. \quad (4)$$

The solution of Eq. (4) with respect to p for two experiments gives Eq. (5).

$$p = \frac{\log A_i - \log A_k}{\text{pH}_i - \text{pH}_k}. \quad (5)$$

The data calculated by Eqs. (3) and (5) for various pH values are given in Table 3.

It is seen from Table 3 that p is close to two for all the combinations of experiments. Thus, the formula of the compound formed in solution can be represented as $[Cu_3(SO_3)_2]^0$ or $[Cu_3(SO_3)_2]_{aq}$. Alternatively, the equilibrium constant of reaction (1) can be written as

$$K = K_{a_2}/K_i, \quad (6)$$

where K_a is the dissociation constant of HSO_3^- and K_i is the overall instability constant of $Cu_3(SO_3)_2$. Then

$$K_i = K_{a_2}/K. \quad (7)$$

With $K_{a_2} = 6.31 \times 10^{-8}$ [12] we obtain

$$K_i = \frac{(6.31 \times 10^{-8})^2}{8.69 \times 10^3} = 4.58 \times 10^{-19}.$$

The chemical analysis of the resulting yellow-green precipitate has shown that its composition corresponds to the formula $Cu_2SO_3 \cdot 5H_2O$:

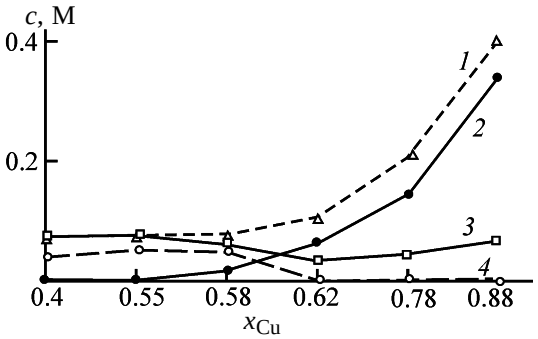

Fig. 3. Dependences of concentrations c of (*1*) Cu_{total} ($Cu^+ + Cu^{2+}$), (*2*) Cu^{2+}, (*3*) Cu^+, and (*4*) SO_3^{2-} on the copper mole fraction x_{Cu}.

Method of determination	Cu^+ content, %	SO_3^{2-} content, %
Analysis	48.2	27.2
Calculation	48.2	26.9

According to the X-ray phase analysis, the salt $Cu_2SO_3 \cdot 5H_2O$ is X-ray amorphous.

It is probable that the complex $[Cu_3(S_2O_3)_2]_{aq}$ formed at 25°C is unstable at low temperatures and decomposes to form the $Cu_2SO_3 \cdot 5H_2O$ precipitate. The dependences of the concentrations of Cu^+, Cu^{2+}, Cu_{total}, and SO_3^{2-} on the copper content x_{Cu} (mole fraction) in solution at a constant initial concentration of sulfite ions are shown in Fig. 3. It is seen that Cu^+ and SO_3^{2-} ions prevail in solution up to $x_{Cu} = 0.55$. Therefore, when the ionic product $[Cu^+]^2[SO_3^{2-}]$ is greater than $SP_{Cu_2SO_3 \cdot 5H_2O}$, only $Cu_2SO_3 \cdot 5H_2O$ is precipitated. In the range $x_{Cu} = 0.55–0.62$, the concentration of Cu^{2+} ions start to increase, but the concentrations of Cu^+ and SO_3^{2-} ions decrease, the latter decreasing much faster, reaching almost zero in the point $x_{Cu} = 0.62$. The ionic product exceeding the solubility product of the corresponding salt ($Cu_2SO_3 \cdot 5H_2O$ or $Cu_2SO_3 \cdot CuSO_3 \cdot 2H_2O$) is reached only for $Cu_2SO_3 \cdot 5H_2O$. Margulis and Rodin [1] qualitatively explained its precipitation by its lower solubility at $T \leq 40$°C compared to $Cu_3(SO_3)_2 \cdot 2H_2O$, which agrees with the data of this work. The corresponding data on SP and K_i are also close to each other, which is attributable to the fact that, for the reaction

$$[Cu_3(SO_3)_2]_s \rightleftarrows [Cu_3(SO_3)_2]_{aq},$$

the following equality is valid:

$$K = [Cu_3(SO_3)_2]_{aq} = SP[Cu_3(SO_3)_2]_s/K_i \approx 1.$$

A certain discrepancy between the numbers of water molecules in the formulas of the precipitates seems to result from different drying conditions. In this work, we dried precipitates in a desiccator over concentrated sulfuric acid at room temperature.

CONCLUSIONS

(1) The reaction of $CuSO_4$ with Na_2SO_3 in aqueous solution at 25°C in the pH range 2.8–3.2 results in the formation of the complex $[Cu_3(SO_3)_2]_{aq}$, which then dissociates to give $Cu_2SO_3 \cdot 5H_2O$.

(2) The equilibrium constant of 8.69×10^3 for the formation of the complex $[Cu_3(SO_3)_2]^0$ was determined. The overall constant of 4.58×10^{-19} for dissociation of $[Cu_3(SO_3)_2]_{aq}$ was calculated.

(3) Copper sulfates under study can be obtained in more acidic medium than it follows from the reaction equation, which opens up new opportunities for removal of copper ions from multicomponent solutions.

Abstract—Hydrolysis of the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O system was studied by spectrophotometry, pH-metric titration, and sorption methods. The mutual influence of the cations on the hydrolytic and sorption behavior was discussed in terms of heteronuclear complex formation.

Iron(III) salts are widely used in water and sewage treatment, e.g., for removal of mercury(II) by coprecipitation with iron(III) hydroxide.

The study of hydrolytic interaction of Fe(III) and Hg(II) ions [1] showed that, during the hydrolysis of Fe^{3+} ions, Hg^{2+} ions precipitate also. The kinetics of the hydrolysis of simultaneously present Fe^{3+} and Hg^{2+} ions was studied, and the parameters of this process were found to differ essentially from the parameters of the hydrolysis of individual ions.

The sorption of Fe^{3+} and Hg^{2+} ions from Fe^{3+}–Hg^{2+}–NO_3^-–H_2O solutions was studied in [2], and the formation of a heteronuclear iron(III)–mercury(II) hydroxo complex was found by dialysis.

In this work, the hydrolysis of cations in the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O system was further studied by spectrophotometry, pH-metric titration, and sorption.

EXPERIMENTAL

Solutions of iron(III) and mercury(II) nitrates were prepared by dissolving metallic mercury and carbonyl iron in chemically pure grade nitric acid. The concentration of metal ions in the Hg^{2+}–NO_3^-–H_2O and Fe^{3+}–Hg^{2+}–NO_3^-–H_2O systems was 0.01 M, in the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O system their total concentration was 0.02 M at the Fe^{3+} : Hg^{2+} molar ratio of 1 : 1; the temperature was 25 ± 0.1°C, and the ionic strength, 0.3 M (KNO_3).

To determine the Fe^{3+} content in solution, we used direct complexometric titration with sulfosalicylic acid in acetate buffer solution [3], The Hg^{2+} content was determined by complexometric back-titration with a zinc salt [3]. The contents of simultaneously present Fe^{3+} and Hg^{2+} were determined by complexometric back-titration of the sum of the two ions followed by displacement of Hg^{2+} ions from the complex with potassium iodide and titration of the released ethylenediaminetetraacetate (EDTA) with a zinc salt [3]. The content of free HNO_3 in the starting solutions was determined by potentiometric titration in the presence of EDTA [4]. The error of concentration determination was 0.9%.

Solutions of iron(III), mercury(II), and iron(III)–mercury(II) with various OH/M molar ratios were prepared from the stock solutions of iron(III) and mercury(II) nitrates. From the determined concentrations of metal ions and free nitric acid, we calculated the amount of KOH necessary to neutralize the free acid and to fix a particular OH/M ratio, and the amount of KNO_3 necessary to maintain the constant ionic strength. Then we mixed the calculated amounts of the starting metal solutions, 0.2 M KOH, and 1 M KNO_3. When the free acid was neutralized partially, we designated the OH/M molar ratio with the negative sign. After preparation, we thermostated the solutions for 7 days to reach an equilibrium and then measured the equilibrium pH of each solution.

To study the hydrolysis, we used pH-metric titration, spectrophotometry, and sorption. The pH values were measured on an I-160 pH-meter equipped with a microprocessor and a temperature-controlled pH-metric cell connected to a UTU-2.84 universal ultrathermostat. We used an ESL-43-07 glass electrode as an indicator electrode and an EVL-1M1 silver chloride electrode as a reference electrode. Absorption spectra were recorded on an SF-46 spectrophotometer with a microprocessor.

We used KU-2-8chS cation exchanger (ultrapure

1070-4272/02/7511-1744$27.00 © 2002 MAIK "Nauka/Interperiodica"

KU-2 cation exchanger containing 8% divinylbenzene) and KB-4P-2 cation exchanger in the H^+ form. The resins were pretrated by the generally accepted procedure [5], and their moisture content was determined [6]. We studied the sorption at 25 ± 0.1°C under static conditions and always proved the attainment of the equilibrium of metal ion distribution between the solution and the resin. The solution–resin contact time was 7 days. We calculated the sorption *S* of metal ions by the resins (mmol per gram of resin dried to constant weight at 105°C) from the results of chemical analysis of equilibrium solutions.

The absorption spectra of mercury(II) solutions with various OH^-/Hg^{2+} molar ratios are shown in Fig. 1. In all the curves in the UV range, an edge of a medium-intensity absorption band is observed (at λ = 255 nm ε ~ 150). This band was assigned to charge transfer [7]. As the OH^-/Hg^{2+} ratio (i.e., pH) increases, the absorption band is shifted bathochromically, suggesting the occurrence of equilibria involving protons [7]. In the pH range under study (1.86–2.67 [8]), mercury(II) exists in the form of aqua ions and $HgOH^+$ and $Hg(OH)_2$ hydroxo complexes. Correspondingly, changes occurring in the spectra as pH increases are attributable to the formation of hydrolyzed mercury(II) species.

In the absorption spectra of Fe^{3+}–NO_3^-–H_2O solutions (Fig. 2, curves *3–7*) an edge of a strong absorption band is observed, which is usually assigned to activated iron(III) ions and is accounted for by the ligand-to-metal charge transfer H_2O–Fe(III) [7]. In the spectra of the solutions with the OH^-/Fe^{3+} ratio from –1 to 0.5 (pH 1.93–2.27), a shoulder is observed in the range of wavelengths 300–320 nm, assignable to mononuclear iron(III) hydroxo complexes [9]. As the OH^-/Fe^{3+} ratio increases to 1 (pH 2.29), the light absorption increases and the shoulder disappears, suggesting formation of polynuclear hydroxo complexes. These data are in good agreement with our previous results and allow us to refine the pH value at which the polynuclear iron(III) complexes in solution start to be manifested in the absorption spectrum.

The light absorption of iron(III) is considerably stronger than that of mercury(II); therefore, we recorded the spectra of Fe^{3+}–Hg^{2+}–NO_3^-–H_2O solutions under the same conditions (*b* = 0.5 mm) as the spectra of Fe^{3+}–NO_3^-–H_2O solutions (Fig. 2, curves *1* and *2*). Since hydroxides were precipitated from solutions at the ratio of $OH/\Sigma M > 0$, only the spectra with $OH/\Sigma M$ –1 and 0 are shown. The light absorption of Fe^{3+}–Hg^{2+}–NO_3^-–H_2O solutions is appreciably lower than that of Fe^{3+}–NO_3^-–H_2O solutions with the same

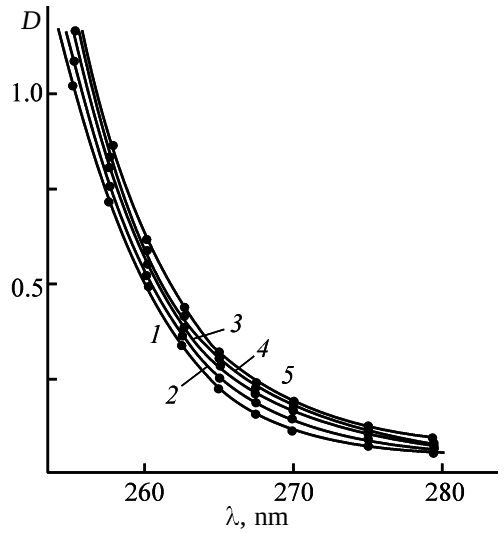

Fig. 1. Absorption spectra of Hg^{2+}–NO_3^-–H_2O solutions: (*D*) optical density and (λ) wavelength; the same for Fig. 2. Molar ratio OH/M: (*1*) –1, (*2*) –0.5, (*3*) 0, (*4*) 0.5, and (*5*) 1.

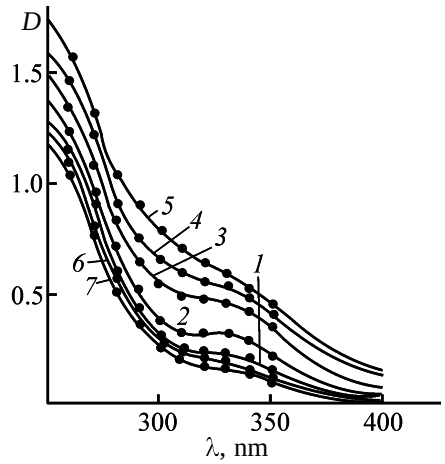

Fig. 2. Absorption spectra of solutions: (*1, 2*) Fe^{3+}–Hg^{2+}–NO_3^-–H_2O and (*3–7*) Fe^{3+}–NO_3^-–H_2O. Molar ratio OH/M: (*1, 3*) –1, (*2, 5*) 0, (*4*) –0.5, (*6*) 0.5, and (*7*) 1.

iron(III) concentration. In this case, the absorption in the region of the shoulder at 330 nm decreases noticeably, suggesting smaller fraction of mononuclear iron(III) hydroxo complexes. Thus, our results indicate that Hg^{2+} ions affect the hydrolysis of Fe^{3+} ions. These data are in good agreement with the previous studies [2], where "weakening" of iron(III) hydrolysis in the presence of mercury(II) was found by dialysis.

When acidified solutions of Fe^{3+}, Hg^{2+}, and Fe^{3+}–Hg^{2+} are titrated with an alkali, free HNO_3 and metal ion hydroxo species are neutralized, and hydroxides precipitate. The curves of pH-metric titration (the titrant was 0.2 M NaOH solution) are given beginning with the ratio $OH/\Sigma M = 0$, since no discontinuities

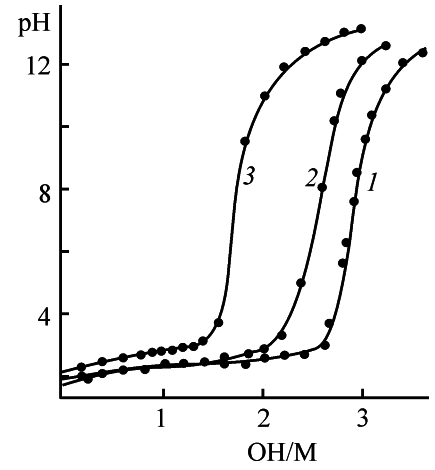

Fig. 3. Curves of pH-metric titration of solutions: (*1*) Fe^{3+}–NO_3^-–H_2O, (*2*) Hg^{2+}–NO_3^-–H_2O, and (*3*) Fe^{3+}–Hg^{2+}–NO_3^-–H_2O.

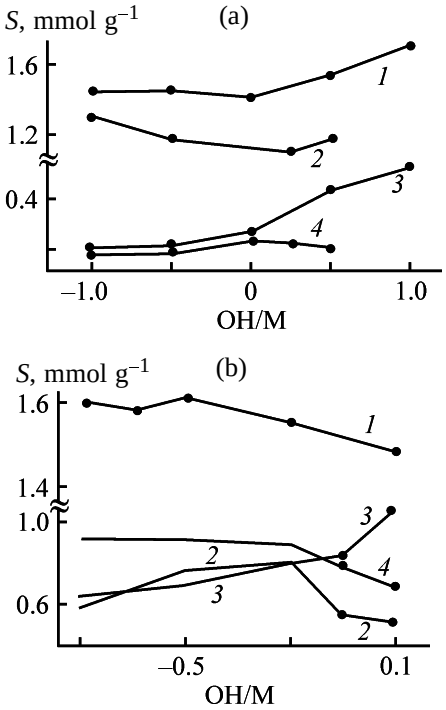

Fig. 4. Sorption *S* of (a) iron(III) and (b) mercury(II) by cation exchangers (*1*, *2*) KU-2-8chS and (*3*, *4*) KB-4P-2. Solution: (a) (*1*, *3*) Fe^{3+}–NO_3^-–H_2O and (*2*, *4*) Fe^{3+}–Hg^{2+}–NO_3^-–H_2O; (b) (*1*, *3*) Hg^{2+}–NO_3^-–H_2O and (*2*, *4*) Fe^{3+}–Hg^{2+}–NO_3^-–H_2O.

were observed in them up to the completion of free nitric acid neutralization (Fig. 3). The pK_a values for $Fe(H_2O)_6^{3+}$ and $Fe(H_2O)_5OH^{2+}$ ions are 2.2 and 3.46, respectively, and for $Hg(H_2O)_6^{2+}$ and $Hg(H_2O)_5OH^+$, 3.4 and 2.77, respectively [8]. Hence, the differentiated titration of these ions and of free HNO_3 is impossible. In all three curves we observed a single titration jump. The equivalence points corresponded to the ratios OH^-/Fe^{3+} = 2.8 (curve *1*) and OH^-/Hg^{2+} = 1.7 (curve *2*). Iron(III) hydroxide began to precipitate at pH ~3, i.e., at the beginning of the jump in the titration curve. The solution of mercury(II) grew turbid at OH^-/Hg^{2+} = 0 and pH ~2. In the titration curve of the Fe^{3+}–Hg^{2+} solution, we also observed a jump with an equivalence point at $OH^-/\Sigma M$ = 2.5. In this case, the precipitation began at $OH^-/\Sigma M$ = 0 as in the case of Hg^{2+}. The obtained data do not allow us to judge the behavior of the simultaneously present ions before hydroxides start to precipitate; however, they indicate that, under the action of alkali, iron(III) and mercury(II) precipitate simultaneously.

The sorption of iron(III) by the KU-2-8chS strongly acidic cation exchanger (Fig. 4a, curve *1*) is almost independent of the OH^-/Fe^{3+} ratio in the range from –1 to 0 and somewhat increases in the range from 0.5 to –1. The KU-2(H^+) resin, as shown previously [10], sorbs all the iron(III) species except polynuclear ions. Therefore, our spectrophotometric data suggest that, in the acidity range under study, the sorbable species are, most probably, iron(III) aqua and mononuclear hydroxo complexes.

The KB-4P-2 weakly acidic carboxylic cation exchanger sorbed iron(III) ions in appreciably smaller amounts, and, as the ratio OH^-/Fe^{3+} increased, the sorption substantially increased (Fig. 4a, curve *3*). The KB-4(H^+) resin, as shown previously [10], selectively sorbs mononuclear iron(III) hydroxo species. The data of this work agree well with each other and with the data of [10]: at the OH^-/Fe^{3+} ratio exceeding 0.5, noticeable increases in the light absorption at 300–320 nm, resulting from the appearance of mononuclear iron(III) hydroxo complexes, and in the sorption occurred simultaneously.

The sorption of Fe(III) ions by the KU-2-8chS cation exchanger from the solutions containing iron(III) and mercury(II) is a little lower than the sorption from the solution containing iron(III) only (Fig. 4a, curves *2* and *1*). In this case, the dependence of sorption on the $OH/\Sigma M$ ratio remained virtually the same. At the same time, the sorption of iron(III) by the KB-4P-2 cation exchanger as a function of the $OH/\Sigma M$ ratio appreciably differs for the Fe^{3+}–NO_3^-–H_2O and Fe^{3+}–Hg^{2+}–NO_3^-–H_2O systems (Fig. 4a, curves *3* and *4*). In the range of $OH/\Sigma M$ from –1 to 0, the curves ran in parallel, whereas at higher $OH/\Sigma M$ ratios the trends became opposite. Since the KB-4P-2 resin absorbed predominantly mononuclear iron(III) hydroxo complexes, a decrease in iron(III) sorption

in the presence of mercury(II) can be accounted for by the fact that, in the presence of Hg(II) ions, as follows from the spectrophotometric data, the concentration of mononuclear Fe(III) hydroxo complexes decreased.

The sorption of Hg(II) ions by the KU-2-8chS cation exchanger somewhat decreased as OH^-/Hg^{2+} increased (Fig. 4b, curve *1*), which seems to result from predominant sorption of mercury(II) aqua complexes, and the sorption by the KB-4P-2 resin increased (Fig. 4b, curve *3*). This fact can be associated only with a change in the state of mercury(II) ions on pH variation, as in the range under study the ionization of the resin carboxy groups is negligible. According to [2], at pH > 2 the fraction of mercury(II) aqua ions in solution decreases at the expense of the formation of polymeric species. Consequently, an increase in the mercury(II) sorption by the KB-4 resin, especially at $OH^-/Hg^{2+} > -0.5$ (pH > 2.01), is determined by the participation of mercury(II) polymeric forms in the process.

In the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O system, the sorption of mercury(II) by the KU-2-8chS cation exchanger noticeably decreased (Fig. 4b, curve *2*), and the character of its sorption by the KB-4P-2 resin changed (Fig. 4b, curve *4*). The sorption of mercury(II) from the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O system on the both resins at $OH/\Sigma M > 0$ noticeably decreased, suggesting an increase in the concentration of nonsorbable polymeric species in the solution.

Thus, in hydrolysis, iron(III) and mercury(II) exert a strong mutual effect, manifested in changes in their absorption spectra and sorption behavior. Starting with $OH/\Sigma M = 0$, a noticeable and parallel decrease in sorption of both ions by both strongly and weakly acidic ion exchangers was observed. Since the strongly acidic KU-2-8chS resin sorbs all iron(III) ionic species except polynuclear ions [10], a noticeable decrease in the iron(III) sorption in the presence of mercury(II) at $OH/\Sigma M > 0$ suggests binding of iron(III) active species into nonsorbable polynuclear complexes. Since this was not observed in pure iron(III) solutions, we suggest formation of iron(III)–mercury(II) heteronuclear hydroxo complexes in the Fe^{3+}–Hg^{2+}–NO_3^-–H_2O solution. At the same time, a decrease in the sorption of mercury(II) by the KB-4P-2 resin in the presence of iron(III) also suggests binding of mercury(II) sorption-active polymeric species into a new compound, which was not sorbed. These data are in good agreement with the data of [2], where the formation of iron(III)–mercury(II) heteronuclear complexes at pH > 2.15 was found by dialysis. Thus, we suggest that these complexes are formed from mononuclear iron(III) hydroxo complexes and homopolynuclear mercury(II) complexes.

CONCLUSIONS

(1) In the Fe(III)-Hg(II) solution, mutual influence of ions on their sorption and hydrolytic behavior takes place, which is determined by their interaction.

(2) The heteronuclear complex formed in the solution is not sorbed by KU-2-8chS and KB-4P-2 ion exchangers.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Decrease of HF Concentration in Process Solutions before Extractive Separation of Tantalum(V) from Niobium(V)

A. I. Nikolaev, V. G. Maiorov, and I. V. Baklanova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received June 13, 2002

Abstract—To improve separation of tantalum(V) from niobium(V) in their extraction from fluoride solutions, different ways for decreasing the fluoride ion concentration in the aqueous phase were tested. The efficiency of decomposition of rare-metal concentrate in continuous countercurrent process with several equilibrium decomposition stages was studied.

In industrial production of tantalum(V) and niobium(V) compounds, the separation and purification of these metals is mainly performed by extraction. Two types of extraction flowsheets are used. The first type includes joint extraction of tantalum(V) and niobium(V) followed by their separation in the backwashing stage. The second type is based on successive selective recovery of tantalum(V) and niobium(V). The second flowsheet is preferable owing to simpler process control and lower cost of the process [1]. However, for selective recovery of tantalum(V) with its separation from niobium(V), the hydrofluoric acid content in the aqueous phase must be minimized. To improve extractive separation of Ta(V) from Nb(V), an additional mineral acid (as a rule, sulfuric acid) is added into the solution. The H_2SO_4 concentration in this solution should be relatively low, and the lower, the stronger the extractant basicity. However, to ensure complete dissolution of Ta(V) and Nb(V) in decomposition of a rare-metal concentrate, a large excess of acids, especially HF, is required [2]. Therefore, in some cases, to improve the extractive separation of niobium(V) from tantalum(V), the HF concentration in the solution should be decreased. In this work we studied the main approaches to solution of this problem.

The procedures for preparing solutions, performing experiments, analyzing target metals, and safely handling aggressive hydrofluoric acid solutions were reported in detail previously [2, 3]. Separation of Ta(V) from Nb(V) was performed by extraction with *n*-octyl alcohol (OCL) whose main characteristics were reported in [4].

The data on the effect of the HF_{free} concentration and ratio of the organic and aqueous phases $V_o : V_{aq}$ on extractive recovery of Ta(V) and Nb(V) are listed in Table 1. In this table, HF_{free} is the HF concentration calculated as the difference between the total HF concentration and the HF amount combined in the prevailing complexes $HTa(Nb)F_6$, H_2TiOF_4, and H_2SiF_6 formed in the solutions under consideration [3]. The Ta(V) and Nb(V) concentrations in the solutions used in our experiments are close to those in solutions obtained by decomposition of pyrochlore. With increasing HF_{free} concentration by 2 M, the extraction recovery of Ta(V) decreases by 7–8%, whereas the Nb(V) recovery increases by 4–6%. We found that the most efficient separation of these metals is reached at $c_{HF_{free}} \leq 0$ M. The fact that in some cases the $c_{HF_{free}}$ value calculated by us is less than zero shows that, along with above-noted fluoride

complexes, other complexes with a lower content of fluoride ions are formed also. This explanation is consistent with the data reported in [1]. The addition of H_2SO_4 improves separation of Ta(V) from Nb(V). In extraction of these metals with OCL, the optimal sulfuric acid content in the aqueous phase is about 2 M [4]. It was reported [5] that, in extraction with a stronger base, tributyl phosphate, the efficient separation of Ta(V) from Nb(V) can be reached without addition of H_2SO_4 ($c_{HF_{free}} < 0$ M).

The simplest way to decrease the HF_{free} concentration is dilution of the initial solution (Table 2). The initial solutions were prepared by dissolving columbite [2] (Table 2, run nos. 1–7) and hydrated cake (HC) [a mixture of Ta(V), Nb(V) and Ti(IV) hydroxides] obtained by treating loparite concentrate with nitric acid [6] (Table 2, run nos. 8–11). The latter solutions containing a large amount of HF_{tot} and Ti(IV) were also used in the experiments (Tables 3, 4).

In extraction of metals from solutions obtained immediately after columbite decomposition, Ta(V) and Nb(V) are recovered jointly (Table 2, run nos.1 and 4). After dilution of these solutions by a factor of 2–3, Ta(V) is recovered to 85–86%, and Nb(V) to 14–16% (Table 2, run nos. 3 and 6). Such a difference in the extractability of the metals allow the quantitative recovery of Ta(V) in a counterflow mode at minor passing of Nb(V) to the organic phase. Fairly efficient separation of Ta(V) from Nb(V) was reached also in the experiments involving preliminary evaporation of the initial solution to remove excess hydrofluoric acid and subsequent dilution of the remaining solution (Table 2, run nos. 7 and 11).

To decrease the free hydrofluoric acid content in the solutions, we also introduced in them the metal cations capable of binding fluoride ions into poorly soluble compounds or strong complexes (Tables 3, 4). In these experiments, 45 g of HC or LC was added to 200 ml of HF-containing solution with stirring at 60°C. Introduction of these substances significantly decreases the HF_{free} concentration. An especially large effect was observed on treating the solutions with a loparite concentrate LC (rare-earth niobates), which is caused by binding of excess fluoride ions by titanium(IV) and rare-earth elements(III). A drawback of HC, consisting mainly of titanium(IV) hydroxide,

** In parentheses is the degree of precipitation of fluoride anions, calculated assuming that La(III) and Ca(II) are completely converted to LaF_3 and CaF_2, respectively.

*** Precipitated at ~0°C.

is precipitation of Ta(V), and especially Nb(V), caused by binding of fluoride ions into stronger insoluble titanium fluoride complexes [1].

Fluoride anions were precipitated in the form of poorly soluble fluorides of appropriate cations introduced in the solution in the form of their carbonates. Metal carbonates were gradually added with stirring to 50 ml of solution containing fluoride anions. The resulting slurry was kept for several hours and then filtered, washed with water, and dried at 100°C. As seen from Table 4 (run no. 4), with increasing carbonate amount and raising temperature, the degree of precipitation of fluoride anions increases and the HF_{free} content in the solution decreases. On precipitating fluoride ions by adding calcium carbonate, the degree of precipitation of fluoride ions exceeds that expected in the case that CaF_2 is formed only. We found that, under these conditions, the relatively large Ti(IV) amount is precipitated also (Table 4). X-ray phase analysis showed[1] that this precipitate is $CaTiF_6 \cdot 2H_2O$ containing CaF_2 as impurity (Fig. 1b, interplanar spacing 3.16 Å). At the same time, the X-ray pattern (Fig. 1a) shows that, in precipitation of fluoride anions by La(III) carbo- nate, LaF_3 is formed only. An IR study of the precipitates showed that they contain no CO_3^{2-} anions, i.e., fluoride anions completely replace carbonate anions in La(III) and Ca(II) carbonates. The use of $La_2(CO_3)_3$ (actually carbonates of the sum of rare-earth elements from processing of loparite) is preferable, because lanthanide fluorides are compounds of commercial interest. In this process, the loss of Ti(IV) considerably decreases (Table 4).

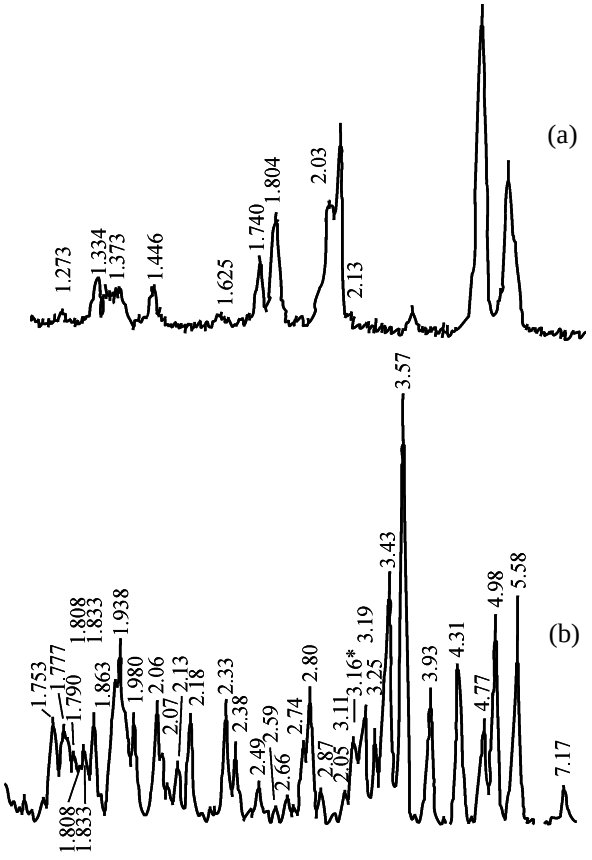

Fig. 1. X-ray diffraction patterns of (a) LaF_3 and (b) $CaTiF_6 \cdot 2H_2O$ (containing CaF_2 impurity) precipitated in treating the process solutions with $La_2(CO_3)_3$ and $CaCO_3$, respectively.

The procedures used for decreasing the free hydrofluoric acid concentration in Nb(V)- and Ta(V)-containing solutions have several drawbacks: increase in process solution volume due to dilution, power consumption in the evaporation stage, filtration of precipitates, and losses of Ta(V) and Nb(V) because of partial precipitation of their poorly soluble fluorides.

[1] X-ray diffraction patterns were obtained and treated by V.Ya. Kuznetsov.

Therefore, decomposition of rare-metal concentrate must be performed in a continuous countercurrent process with several equilibrium stages, similar to multistage continuous countercurrent extraction widely used in processing multicomponent aqueous solutions. The multistage flowsheet provides repeated recovery of the target metals from the intermediate partly decomposed concentrate with fresh portions of the decomposing solution at every decomposition stage. This decomposing solution contains a large excess of acid (hydrofluoric acid or a mixture of hydrofluoric and sulfuric acids). Multistage flowsheet is economically preferable owing to lower reagent consumption, and, what is more, to lower HF_{free} content in the process solution.

Model experiments on decomposition of the rare-metal concentrate using a two-stage batch flowsheet were carried out by the Alders technique [7]. Our results on distribution of Nb(V) and Ta(V) at different stages of the process are noted in the scheme. In experiments on multistage decomposition, we used a tantalite concentrate of the following chemical composition (wt %): Ta_2O_5 19.28, Nb_2O_5 26.26, SiO_2 3.89, WO_3 0.36, SnO_2 21.00, TiO_2 4.30, ZrO_2 0.50, Fe_2O_3 12.44, MnO 4.30, Al_2O_3 0.95, CaO 0.34, and MgO 0.42. Mineralogical analysis showed that the rare-metal concentrate contained also several other minerals as admixtures: columbite, cassiterite, zircon, rutile, monazite, sodium feldspar, and apatite.

Filtrate for extraction: 85 ml, 1.36 M Nb(V), 0.52 M Ta(V)	Intermediate filtrate: 117 ml, 0.58 M Nb(V), 0.20 M Ta(V)	Decomposing solution: 113.4 ml, 0 M Nb(V), 0 M Ta(V)
← → Decomposition no. 1	← → Decomposition no. 2	← →
Rare-metal concentrate: 63.0 g, 23.71 wt % Nb_2O_5, 10.47 wt % Ta_2O_5	Precipitate no. 1, intermediate: 35.35 g, 15.15 wt % Nb_2O_5, 13.14 wt % Ta_2O_5	Precipitate no. 2 for washing: 23.31 g, 2.51 wt % Nb_2O_5, 4.38 wt % Ta_2O_5

The rare-metal concentrate was decomposed with a solution containing HF (19.5 M) and H_2SO_4 (2 M). The HF consumption was 90% of the stoichiometric amount. The HF stoichiometric consumption was calculated assuming that the main metals are bound into fluoride complexes $HTaF_6$, $HNbF_6$, FeF_2, MnF_2, H_2SiF_4, AlF_3, and H_2TiOF_4. Taking into account that cassiterite remains virtually unchanged in our process, the HF consumption associated with tin complexing was neglected.

Decomposition of the rare-metal concentrate was carried out in a fluoroplastic vessel equipped with a lid and a mixer at the 1 : 1.8 ratio of the solid and liquid phases. A solution formed in the second decomposition stage was poured into the vessel, and then a fresh portion of the rare-metal concentrate was added at 60°C. After that the mixture was heated to the prescribed temperature and kept for 4 h with stirring. The liquid phase was separated from the precipitate and used for extractive recovery of Nb(V) from Ta(V). To increase the degree of recovery of the target metals, the precipitate remaining after the first decomposition stage was filtered and transferred to the second decomposition stage for treatment with a fresh portion of the $HF–H_2SO_4$ mixture under the conditions identical to those in the first decomposition stage. The final precipitate was washed with water. Under these conditions, a steady state was reached within four cycles.

In the course of decomposition of the rare-metal concentrate, the liquid phase volume decreases due to evaporation. After continuous two-stage counterflow decomposition, the weight of the rare-metal concentrate decreases by 63%. After the first decomposition stage, the washed precipitate contained 35.9% of Nb(V) and 70% of Ta(V) relative to the initial concentrate. After the second decomposition stage, these values decreased to 3.9 and 15.2% for Nb(V) and Ta(V), respectively. Thus, after the two-stage decomposition, 96.1% of Nb(V) and 84.8% of Ta(V) was removed from the concentrate (see flowsheet). Our calculation show that the three-stage decomposition scheme provides more than 99 and 98% recovery of Nb(V) and Ta(V), respectively, which meets the requirements of the industrial process. In passing from one-stage to countercurrent process, the Nb(V) and Ta(V) content in the final solutions increases, whereas the HF_{free} content decreases (<0 M). To increase the degree of recovery of the target metals in the one-stage process, a substantial excess of HF is required.

As reported in [2, 8], in the one-stage decomposi-

tion of the concentrate whose chemical compostion was close to that of the concentrate used in this work, the degree of recovery of Nb(V) and Ta(V) exceeded 97% only at the HF_{free} concentration higher than 1 M, which corresponds 100–120% consumption of HF relative to the stoichiometry. In extractive processing of this solution, Nb(V) and Ta(V) are extracted jointly.

As opposed to solutions formed after one-stage decomposition of the rare-metal concentrate, those formed in multistage decomposition contain the minimal amount of HF_{free} and, therefore, are suitable for selective recovery of Ta(V). For example, Ta(V) was selectively separated from Nb(V) in extraction with OCL at $V_o : V_{aq}$ ratio of 1 : 1. To improve the stability of the process solutions and prevent precipitation of the target metals, the initial solutions were diluted prior to extraction by a factor of 1.4. With increasing ratio of the organic and aqueous phases, the degree of recovery of Ta(V) increases from 82.1 to 88.6% and that of Nb(V), from 6.3 to 8.4%, which shows that the extraction system preserves high separation efficiency. Thus, our experiments showed that continuous countercurrent decomposition of the rare-metal concentrate allows efficient recovery of the target metals at decreased power and reagent consumptions.

CONCLUSION

(1) A decrease of the hydrofluoric acid concentration in the niobium- and tantalum-containing solutions by their dilution, evaporation, or precipitation of poorly soluble metal fluorides allows improvement of the extractive separation of tantalum(V) from niobium(V).

(2) Decomposition of the rare-metal concentrate in the continuous countercurrent mode allows production of the target metal solutions with a minimal content of fluoride anions.

Abstract—Factors were examined that determine passing of lanthanides into solution during nitric acid leaching of phosphohemihydrate obtained in the course of production of wet-process phosphoric acid from Khibiny apatite concentrate by the hemihydrate technique. The data obtained were compared to the results of sulfuric acid leaching.

It is known [1, 2] that, in the course of production of wet-process phosphoric acid from Khibiny apatite concentrate by treatment with sulfuric acid, the main part of lanthanides passes to the phase of dihydrate $CaSO_4 \cdot 2H_2O$, whereas in the hemihydrate process they pass to the phase of calcium sulfate hemihydrate $2CaSO_4 \cdot H_2O$. In practice, these calcium sulfates are usually termed phosphogypsum (PDH) and phosphohemihydrate (PHH), respectively, which underlines the fact that they were obtained by processing of phosphate raw material and have increased content of phosphates.

The leaching of lanthanides from them with nitric acid solutions was studied in [3, 4] (Table 1). Table 1 shows that 10–20% solutions of nitric acid (here and hereinafter, the concentrations are given in wt %) efficiently extract lanthanides from PDH; however, their content in the leaching solutions was low. When sulfuric acid was used, the extraction of lanthanides was much lower [5].

On leaching of rare-earth elements from PHH with solutions based on calcium nitrate, their extraction into solution was slightly increased (Table 2), but the REE concentration remained low [4].

The addition of calcium nitrate to nitric acid solutions somewhat increased the extraction and concentration of lanthanides (Table 2), in spite of the fact that the consumption of chemicals much exceeded the stoichiometric amount.

The 79.3% extraction of lanthanides from PHH was reached using a solution containing 60 g l^{-1} (5.8%) of HNO_3 and 70 g l^{-1} of $Ca(NO_3)_2$, l : s = 2–3. In this case, the solution contained (g l^{-1}): Ln_2O_3 1.28, P_2O_5 4.1, and fluoride ions 1.2 [6].

The leaching of lanthanides from precipitates formed by evaporation of wet-process phosphoric acid obtained by dihydrate processing of apatite from Phalaborwa deposit (Republic of South Africa) was studied in [7] (Table 3). The precipitates, which were carefully washed with water to remove phosphoric

acid, seem to be products based on anhydrite or PHH containing 2.8–8.3% of the sum of lanthanides. When a solution containing 2 M HNO_3 (11.8 %) and 0.5 M $Ca(NO_3)_2$ was used for leaching at the ratio l : s = 2 and temperature of 20°C, the Ln_2O_3 extraction reached 76%. The extraction increased as the HNO_3 concentration increased from 1 to 3 M, but decreased at the concentration of 4.5 M. The temperature rise from 0 to 100°C reduced the extraction by a factor of more than 13, with the concentrations of Si(IV) and fluoride ions in leaching solution increasing. When temperature was increased from 20 to 100°C, the concentration of Si(IV) increased from 0.12 to 0.20 M, and the concentration of fluoride ions, from 0.64 to 0.97 M. If $Ca(NO_3)_2$ was not added to the solution (<0.5 M), only 33% of lanthanides was extracted at 20°C. In enlarged tests, leaching conditions were considerably changed, but the results did not become worse (Table 3).

Preston *et al*. [7] assumed that the effect of calcium ions consists in binding of fluoride ions present in leaching solutions by the reactions

$$HF = H^+ + F^-, \quad (1)$$

$$SiF_6^{2-} = SiF_4 + 2F^-, \quad (2)$$

$$Ca^{2+} + 2F^- = CaF_2\downarrow, \quad (3)$$

preventing formation of poorly soluble lanthanide fluorides:

$$Ln^{3+} + 3F^- = LnF_3. \quad (4)$$

The addition of aluminum and iron(III) compounds to the nitric acid leaching solution had no effect on the extraction of lanthanides.

Preston *et al*. also proposed another explanation of the increase in the extraction in the presence of calcium ions [7], according to which a high concentration of calcium ions in solution favors the ion-exchange extraction of lanthanides from calcium sulfate in which lanthanides isomorphously substitute calcium ions. However, it does not account for a sharp decrease in the extraction of lanthanides as the leaching temperature is increased to 100°C.

Thus, as a rule, the high extraction of lanthanides in solution was reached at medium concentrations of nitric acid and high l : s ratios, but in this case the resulting solutions were difficult to process further because of their large volumes and low concentrations of lanthanides in them. The extraction of lanthanides from such solutions is rather expensive, being complicated by a high content of calcium ions. The low concentration of lanthanides in leaching solution, the

attainment of reasonable extraction only at high l : s ratios, and also a sharp decrease in the extraction of lanthanides from PDH with increasing concentration of nitric acid from 20 to 25% remain to be explained.

As the hemihydrate process, which is more economically expedient than the dihydrate process, is widely used in Russia, we studied the factors limiting the extraction and concentration of lanthanides in solutions in their nitric acid leaching from PHH. Furthermore, the interest in these studies has increased because, except for higher content of lanthanides in PHH as compared to PDH [1, 2] (Table 4), the sum of lanthanides extracted from PHH is enriched with yttrium and middle-group lanthanides.

EXPERIMENTAL

In the work, we used PHH from Voskresenskie Mineral'nye Udobreniya (Voskresensk Mineral Fertilizers) Joint-Stock Company with the 10–11 wt % moisture content. The content of lanthanides in this product appeared to be lower (0.43–0.53%) than in PHH from Ammofos Joint-Stock Company (0.57%). The experimental technique was described earlier [5].

Treatment of PHH for 1 h with 2% nitric acid (Table 5) resulted in higher extraction and concentration of lanthanides than those reached in [4] (Table 1). Increase in the concentration and extraction of lanthanides were attained when the concentration of nitric acid was increased to 8%; in this case, a considerable amount of PHH passed into solution (as in the case of PDH dissolution in nitric acid [8], the content of CaO and SO_3 corresponded to $CaSO_4$). Fairly high extraction of lanthanides was reached even with 4% HNO_3: in this case, 4.64% of PHH passed into the solution.

Lanthanide nitrates are readily soluble in nitric acid solutions, including highly concentrated solutions [9]. Therefore, we examined the possibility of increasing the concentration of lanthanides by using the same portion of a leaching solution for successive processing of several PHH portions. However, in this case the efficiency of leaching lanthanides sharply decreased, even when nitric acid was added to the solution (Table 6).

The concentration of lanthanides in solution increased and reached 2.14 g l^{-1}. As the solution contained a significant amount of calcium sulfate after the first treatment stage, the dissolution of PHH sharply decreased as the concentration of nitric acid increased only slightly.

Table 5. Nitric acid leaching of lanthanides from PHH (s : l = 1 : 3, 1 h, Ln_2O_3 content 0.43%)

HNO_3 %	Concentration in solution, g l^{-1}		Extracted, %	
	Ln_2O_3	Ca(Sr)O	Ln_2O_3	Ca(Sr)O
2	0.76	3.81	53.0	2.96
4	1.10	5.97	76.7	4.64
6	1.15	7.87	80.2	6.11
8	1.20	8.10	83.7	6.30

In successive acid leaching of the same PHH portion by fresh portions of nitric acid (Table 7), we were able to transfer into solution a total of 96.28% of REE, but only 7.82% of Ca(Sr)O contained in PHH. This proves the fact that the main part of lanthanides is not cocrystallized isomorphously with PHH [10] and exists in it as independent phases.

Preliminary washing of PHH with water (l : s = 2, 0.5 h) allowed us to increase the extraction of lanthanides in the single-stage leaching with 2–6 wt % solutions of HNO_3 (Table 8). Passing of calcium sulfate into solution increased simultaneously, which is due to the conversion of PHH to PDH in solution during washing with water and, probably, to the higher solubility of PDH in nitric acid solutions.

Grinding of PSH before leaching sharply increased the extraction of lanthanides.

Table 6. Nitric acid leaching of lanthanides from PHH with reuse of leaching solution (l : s = 1 : 3, 1 h, Ln_2O_3 content 0.53%)

* PHH was preliminarily ground.

We have studied the effects of various additives on the efficiency of the nitric acid leaching (Tables 9, 10).

The expected effect of additives was either salting-out of sodium and potassium hexafluorosilicates with sodium and potassium compounds or binding of fluoride ions in stable complexes and poorly soluble compounds (excess of calcium ions). In this case, we took into account the following series of stability of complex fluorides in solutions: $SiF_6^{2-} < AlF_6^{3-} < BF_4^-$ [11].

Our and published data suggest that, for leaching lanthanides from PHH, it is sufficient to use solutions containing 4–6% HNO_3. Increase in the l : s ratio and also in leaching time favors the extraction. This fact agrees with the data of Kuzina *et al*. [12], who showed that the hydrated orthophosphates of lanthanides (Ce, La, and Nd) slowly dissolve in 1.5–5 M HNO_3.

We can assume that, when $Ca(NO_3)_2$ solutions are used, lanthanides are leached with a dilute solution of nitric acid formed by the reaction of calcium nitrate with sulfuric and phosphoric acids remaining in PHH after washing. It is likely that the leaching of lanthanides from PHH with calcium nitrate can be described by the reactions

$$Ca(NO_3)_2 + H_2SO_4 = 2HNO_3 + CaSO_4\downarrow, \quad (5)$$

$$3Ca(NO_3)_2 + 4H_3PO_4 = 6HNO_3 + Ca(H_2PO_4)_2 + 2CaHPO_4, \quad (6)$$

$$2LnPO_4 \cdot 0.5H_2O + 6HNO_3 = 2Ln(NO_3)_3 + 2H_3PO_4 + H_2O, \quad (7)$$

Lanthanides were not leached with calcium nitrate solutions from PHH that had been carefully washed with water.

In the case of the single-stage process, lanthanides are leached with nitric acid solutions from PHH or PDH more effeciently than with sulfuric acid solutions [5], as not only lanthanide phosphates, but also their double sulfates (first of all those of lanthanum and cerium) with alkali metals are readily soluble in nitric acid [13]. Furthermore, the solubility of hydrated forms of calcium sulfate in nitric acid is much higher than in sulfuric acid, which facilitated the access of leaching solution to the grains of an REE-enriched phase covered by a PDH or PHH crust. The presence of such crusts is confirmed by the fact that the extraction of lanthanides under similar leaching conditions is much higher from an additionally ground PHH sample, as compared to a sample that was not subjected to such a treatment (Tables 8, 9).

When the same portion of nitric acid solution was used for successive leaching of several portions of PHH, lanthanides were accumulated more slowly than with the use of sulfuric acid solutions. Probable reasons are a decrease in the solubility of lanthanide nitrates in nitric acid solutions in the presence of calcium sulfate; a decrease in dissolution of calcium sulfate in the second and subsequent stages due to saturation of the leaching solution with it even in the first stage; and the lower concentration of nitric acid used in the experiments.

The concentration of calcium sulfate in nitric acid leaching solutions increases with increasing concentration of nitric acid [8]. This hinders the subsequent isolation of lanthanides from the solutions.

It is difficult to explain a sharp decrease in the extraction of lanthanides from PDH at HNO_3 concentration in the leaching solution of about 25% [3]. This is hardly due to precipitation of lanthanides in the form of fluorides [reactions (1), (2), and (4)]. This decrease is attributable to the fact that the process was carried out at elevated temperature (~80–90°C), and it was accompanied by the conversion of PDH to PHH [14], which could make the leaching of lanthanides more difficult.

We have calculated the equilibrium concentrations of fluoride ions in HNO_3 solutions at room temperature assuming that the activity of the ions in solutions is equal to their concentration and that the solubility of Na_2SiF_6 in nitric acid solutions is equal to its solubility (0.7%) in water. We took into account the

Table 10. Effect of potassium salts on the efficiency of nitric acid leaching of lanthanides from "fresh" PHH (s : l = 1 : 3, 1 h, Ln_2O_3 content 0.43%, HNO_3 concentration 4 wt %)

overall reaction of SiF_6^{2-} hydrolysis

$$SiF_6^{2-} + 2H_2O = SiO_2 + 4H^+ + 6F^-.$$

Several authors have found its equilibrium constant to be within 10^{-27}–10^{-28} [15]. In our calculations we accepted the maximal value $K = a_{H^+}^4 a_{F^-}^6 / a_{SiF_6^{2-}} = 2.3 \times 10^{-27}$, as in this case the equilibrium content of fluoride ions in solution is the highest. The calculated data are given below:

c_{HNO_3}, %	1	2	4	6	8	10
c_{F^-}, mg l^{-1}	2.5	0.86	0.54	0.41	0.36	0.29

According to these data, the concentration of fluoride ions formed by hydrolysis of SiF_6^{2-} in nitric acid solutions at room temperature is very small. Comparison with the data of [16] suggests that lanthanide fluorides should not precipitate in the course of nitric acid leaching of PHH or PDH. It is probable that the hydrolysis of SiF_6^{2-} ions increases with temperature to such an extent that the concentration of fluoride ions becomes sufficient for the formation of lanthanide fluorides. This can account for a sharp decrease in the degree of leaching of lanthanides at 50–100°C, which was observed in [7] for nitric acid leaching solutions containing up to 12.2 g l^{-1} fluoride ions at room temperature.

The addition of sodium and potassium salts (sodium and potassium sulfates and potassium chloride), which salt-out sodium and potassium hexafluorosilicates, did not increase the lanthanide leaching efficiency. With sodium and potassium sulfates added, the passing of lanthanides into solution was slightly reduced, apparently at the expense of decreasing solubility of calcium sulfate crusts blocking the grains of lanthanide-rich phases (Tables 9, 10).

An essential increase in the extraction with sodium tetraborate added (Table 9) is attributable to preliminary regrinding of PHH, which made the grains of REE-rich phases accessible for the solution. The addition of boric acid or aluminum nitrate did not change the degree of lanthanide leaching. Addition of calcium nitrate did not noticeably affect the leaching of lanthanides from PHH (in contrast to the data of [7]). Finally, high content of phosphate and fluoride ions in nitric acid leaching solutions, which considerably exceeded their content reached in the sulfuric acid leaching of PHH, did not hinder attainment of a high concentration of lanthanides.

An essential drawback of the nitric acid process of lanthanide extraction is that removal of nitrate ions from phosphogypsum to the required degree is difficult. The permissible content of nitrate ions in nonutilizable waste is much lower than that of sulfate ions. It is also necessary to examine the possibility of reusing nitric acid solutions in leaching of PHH after isolation of lanthanides from them, as these solutions are difficult to utilize at plants processing Khibiny apatite concentrate by the sulfuric acid technique.

CONCLUSION

(1) In the single-stage process, nitric acid leaches lanthanides from phosphohemihydrate more effecient-ly than sulfuric acid. The higher degree of extraction is due to high solubility of double sulfates of lanthanides (first of all, of cerium and lanthanum) with sodium and potassium in nitric acid solutions and also to elevated solubility of calcium sulfate in nitric acid.

(2) The accumulation of lanthanides in the case when the same portion of solution is reused for successive leaching of several PHH portions is less intense in nitric acid solutions than in sulfuric acid solutions.

(3) The impurity composition of phosphohemihydrate (phosphate ions and sodium and potassium hexafluorosilicates) affects the efficiency of lanthanide leaching with nitric acid leaching solutions to a lesser extent than with sulfuric acid solutions.

(4) The efficiency of lanthanide leaching from nitric acid solutions, as well as from sulfuric acid solutions, sharply decreases if grains of the phases enriched with lanthanides are blocked by a calcium sulfate crust. Such a crust seems to be formed owing to unstable course of the hemihydrate decomposition of the apatite concentrate.

Abstract—Thermal gravimetric, X-ray phase, IR spectroscopic, and chemical analyses were applied to study the reaction of yttrium and neodymium oxides with NH_4HF_2.

Fluorides of rare-earth elements (REE) are used in electrochemical recovery of these metals by electrolysis of molten salts and in production of glasses for active and passive waveguides; they are of interest for production of laser media based on complex REE fluorides [1–4].

A study of the reaction of REE oxides with ammonium hydrofluoride, including identification of the intermediates, is of interest not only for controlling the process, but also for developing and optimizing the hydrofluoride synthesis of complex fluorides of the composition $M_mLn_nF_{m+3n}$, where M is an alkali metal and Ln is an REE, to be used as stock for growth of single crystals.

A disadvantage of the conventional method for obtaining REE fluorides by precipitation from solution is the relatively high content of oxygen-containing anionic impurities.

Use of ammonium hydrofluoride as a fluorinating agent has a number of advantages, since NH_4HF_2 is close in reactivity to anhydrous hydrogen fluoride, is inexpensive, and can be readily dehydrated and regenerated from gaseous components, and reactions involving this agent can be carried out without complex equipment [5–7].

Despite extensive published data on hydrofluoride synthesis of REE fluorides, there is no common opinion concerning the scheme of the reactions in the literature. Therefore, we performed in this work a detailed study of reactions of yttrium and neodymium oxides with ammonium hydrofluoride and examined the composition and order of thermal decomposition of the intermediates formed. In addition, the methods for obtaining yttrium, neodymium, and gadolinium fluorides by (a) hydrofluoride synthesis and (b) precipitation from solutions were compared with respect to the concentration of oxygen-containing anionic impurities in the final products.

As starting substances we used REE oxides of analytically pure grade and twice recrystallized NH_4HF_2 of the same grade. Thermogravimetric studies were carried out on a Q-1500D derivatograph in platinum crucibles, with weighed portions of 350–400 mg. As reference served calcined Al_2O_3. Measurements were done in dynamic and quasi-isothermal modes at a heating rate of 5 deg min^{-1}. X-ray phase analysis was carried out on a DRON-3 diffractometer with CuK_α radiation. IR absorption spectra were recorded on a UR-20 spectrophotometer. Chemical analysis for fluoride ions was performed by pyrohydrolysis followed by potentiometric determination (with F^--selective electrode). Analysis for metals was done by flame emission spectrometry. The content of ammonia was determined by the Kjeldahl method. The concentrations of oxygen-containing anionic impurities in the final synthesis products was found using linear voltammetry in halide melts [8]. The measurements were done under isothermal conditions in an argon atmosphere. The fluorides synthesized were introduced into a KCl–KF melt of eutectic composition. A glassy carbon (SU-2000) crucible with the melt was placed in a hermetically sealed stainless steel retort. The crucible simultaneously served as a counterelectrode. Molybdenum was used as material of the quasi-reference electrode. Voltammograms were measured on a glassy carbon (SU-2000) electrode using an Autolab computerized electrochemical

1070-4272/02/7511-1760$27.00 © 2002 MAIK "Nauka/Interperiodica"

complex. The residual current densities found from voltammograms of the supporting melt characterized its purity; for oxygen, these current densities were about 5 mA cm^{-2}.

In [9], complex yttrium fluorides were studied thermogravimetrically, and it was demonstrated that the reaction of Y_2O_3 with NH_4HF_2 starts at 60–80°C to give $NH_4Y_2F_7 \cdot NH_4F$, which dissociates into $NH_4Y_2F_7$ and yttrium trifluoride upon heating. In [10], no formation of $NH_4Y_2F_7 \cdot NH_4F$ in the reaction of Y_2O_3 with NH_4F was observed, but yttrium compounds of the composition $(NH_4)_3Y_2F_9$ and $NH_4Y_2F_7$ were synthesized.

A thermogram of a mixture of Ln_2O_3 with NH_4HF_2 in 1 : 6 molar ratio is shown in Fig. 1a. The reaction is accompanied by a series of exo- and endothermic effects. The endothermic effect at 145°C can apparently be attributed to melting of ammonium hydrofluoride, which intensifies the reaction. At 236°C, excess NH_4HF_2 boils, giving an endothermic peak in the DTA curve. Hydrofluorination is complete at a temperature of about 350°C.

To elucidate the scheme of the reaction between Y_2O_3 and NH_4HF_2, we also performed measurements in the quasi-isothermal mode. Figure 2a shows a typical thermogravigram of a mixture of Y_2O_3 and NH_4HF_2 in 1 : 4.5 molar ratio, in which three plateaus can be observed. An analysis of the experimental Δm values corresponding to each of the plateaus revealed the following scheme of the process:

$$Y_2O_3 + 4.5NH_4NF_2 \rightarrow (NH_4)_3Y_2F_9 + 1.5NH_3 + H_2O, \quad (1)$$

$$(NH_4)_3Y_2F_9 \rightarrow NH_4Y_2F_7 + 2NH_3 + 2HF, \quad (2)$$

$$NH_4Y_2F_7 \rightarrow 2YF_3 + NH_3 + HF. \quad (3)$$

The theoretical weight losses corresponding to each stage of synthesis and amounting to, respectively, 16.5, 31.8, and 39.5 wt % are in good agreement with the experimental values (Fig. 2a).

The products formed at 170, 250, and 350°C were analyzed by the methods mentioned above; the results obtained confirmed the reaction scheme represented by Eqs. (1)–(3).

Figure 3 shows X-ray diffraction patterns of $Y_2O_3 : NH_4HF_2$ mixtures with the molar ratio of 1 : 4.5, measured at different temperatures. The results of X-ray phase analysis of the products formed at 170 and 250°C (Figs. 3a, 3b) are in good agreement with [10] and indicate formation of, respectively,

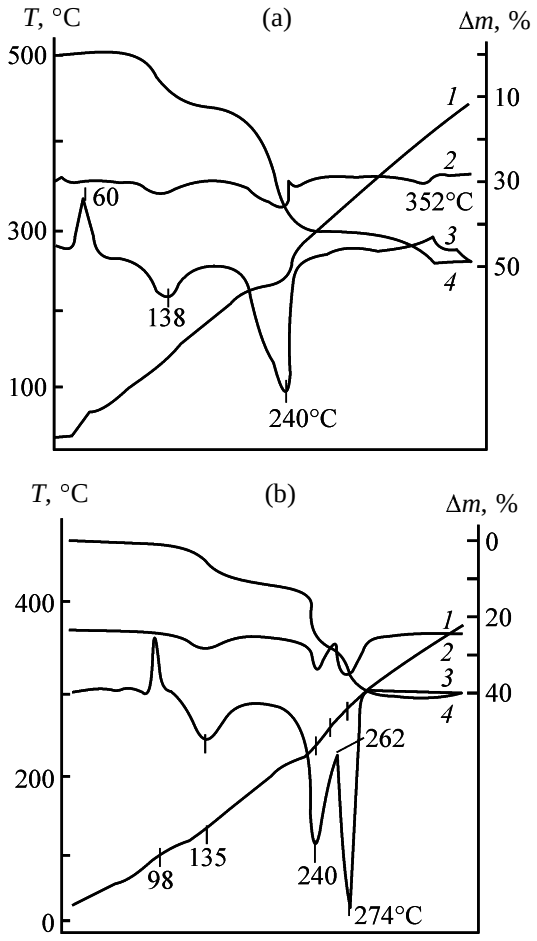

Fig. 1. Thermograms of Ln_2O_3 mixed with NH_4HF_2 in 1 : 6 molar ratio: (T) temperature and (Δm) weight loss; the same for Fig. 2. (a) Yttrium oxide and (b) neodymium oxide.

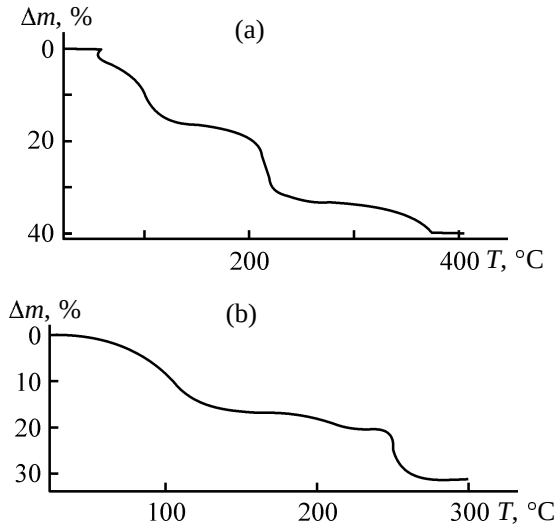

Fig. 2. Thermograms of Ln_2O_3 mixed with NH_4HF_2: (a) yttrium oxide, 1 : 4.5 molar ratio, and (b) neodymium oxide, 1 : 4 molar ratio.

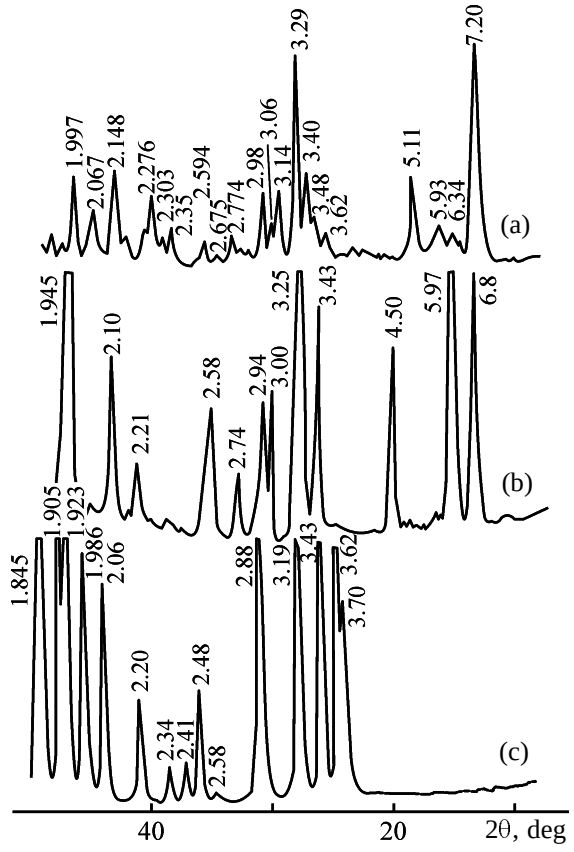

Fig. 3. X-ray diffraction patterns of reaction products formed from a $Y_2O_3 : NH_4HF_2 = 1 : 4.5$ mixture. (2θ) Bragg angle. (a) $(NH_4)_3Y_2F_9$, synthesis temperature 170°C; (b) $NH_4Y_2F_7$, 250°C; and (c) YF_3, 350°C.

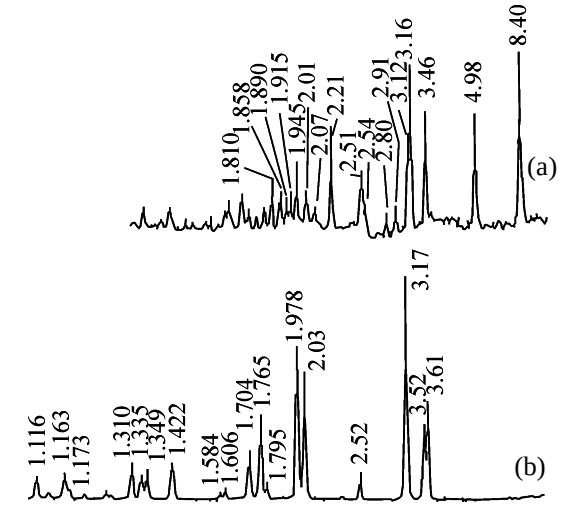

Fig. 4. X-ray diffraction patterns of reaction products formed from an $Nd_2O_3 : NH_4HF_2 = 1 : 4.5$ mixture. (a) NH_4NdF_4, synthesis temperature 150°C, and (b) NdF_3, 250°C.

$(NH_4)_3Y_2F_9$ and $NH_4Y_2F_7$. Figure 3c presents an X-ray diffraction pattern of yttrium trifluoride formed at 350°C.

The results of chemical analysis of intermediate synthesis products also confirm the formation of $(NH_4)_3Y_2F_9$ and $NH_4Y_2F_7$.

Data on the reaction of Nd_2O_3 with ammonium trifluoride were reported in [10], where a compound of the composition NH_4NdF_4 was obtained by keeping a mixture of Nd_2O_3 and NH_4F at 130–150°C for 1–3 days. Rakov presented in his review [6] data obtained by Polish researchers who established that this reaction proceeds in stages to give, in the first stage, the compound $(NH_4)_3NdF_6$, and then, at 350–400°C, NH_4NdF_4, which decomposes at 500°C to yield NdF_3 [6].

A thermogram of a mixture of Nd_2O_3 and NH_4HF_2 in 1 : 6 molar ratio is shown in Fig. 1b. The reaction, accompanied by a series of endo- and exothermic effects, is complete at temperatures higher than 270°C.

The results obtained in studies in the quasi-isothermal mode are presented in Fig. 2b. The thermogravigram of a mixture of Nd_2O_3 and NH_4HF_2 in 1 : 4 molar ratio is characterized by the presence of two plateaus. With account of the experimental values of Δm corresponding to each plateau, the presumed scheme of the process is as follows:

$$Nd_2O_3 + 4NH_4HF_2 \rightarrow 2NH_4NdF_4 + 3H_2O + 2NH_3, \quad (4)$$

$$2NH_4NdF_4 \rightarrow 2NdF_3 + 2NH_3 + 2HF. \quad (5)$$

The theoretical weight losses of 15.6 and 28.7 wt %, corresponding to reactions (4) and (5), are in good agreement with the experimental values (Fig. 2b).

The products of synthesis at temperatures corresponding to the plateaus in the thermogravimetric curve were subjected to X-ray phase analysis. X-ray diffraction patterns of $Nd_2O_3 : NH_4HF_2$ mixtures with the molar ratio of 1 : 4 at 150 and 250°C are shown in Fig. 4. The X-ray diffraction pattern of the product formed at 150°C is in agreement with the results of [10] and indicates the formation of NH_4NdF_4.

As an example of the measurements performed, the table presents the results obtained in determining oxygen in gadolinium fluoride, together with summarized data on the content of oxygen in yttrium and neodymium fluorides prepared by different methods.

With increasing content of gadolinium, neodymium, and yttrium oxides in the melt, the peak corresponding to the oxidation wave of oxygen-containing

halide complex of a rare-earth metal in voltammograms measured at polarizing voltage sweep rate of 0.1 V s^{-1} becomes more pronounced. Figure 5a shows a typical family of curves for the above process, measured with gadolinium oxide added to the melt. On reaching the limiting solubility of REE oxide (gadolinium oxide in the given case), the anode current at the peak corresponding to oxidation of the oxygen-containing halide complex levels off (Fig. 5a, curves *5*–*7*). The dependences $j_p^a = f([Ln_2O_3])$ show a portion corresponding to constant j_p^a (Fig. 5b). The initial linear portion (before leveling-off of the anode current) is described by the equations

$$j = 294.020c \text{ for gadolinium oxide,} \quad (6)$$

$$j = 38.617c \text{ for yttrium oxide,} \quad (7)$$

$$j = 71.323c \text{ for neodymium oxide,} \quad (8)$$

where j is the anode current density at the peak corresponding to oxidation of the oxygen-containing ion (mA cm^{-2}), and c is the oxide content of the melt (wt %).

Addition of an REE oxide to a melt under study in amounts *a fortiori* exceeding the maximum soluble

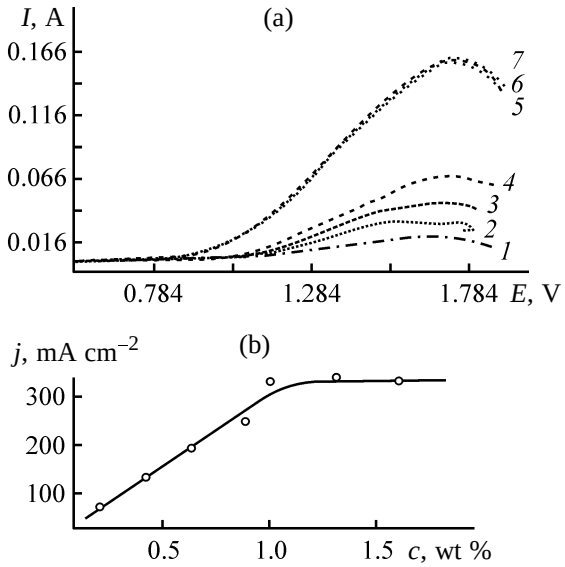

Fig. 5. (a) Voltammograms of oxidation of an oxygen-containing complex of gadolinium in a KCl–KF–Gd_2O_3 melt at 735°C on a glassy carbon electrode relative to a molybdenum quasi-reference electrode and (b) oxidation current j of oxygen-containing gadolinium complex vs. Gd_2O_3 content c in a melt of the KCl–KF eutectic at 735°C. (a) Polarization rate 0.1 V s^{-1}. (*I*) Current and (*E*) potential. Electrode area (cm^2): (*1*–*3*) 0.23 and (*4*–*7*) 0.27. Gd_2O_3 content (wt %): (*1*) 0.21, (*2*) 0.425, (*3*) 0.638, (*4*) 0.896, (*5*) 1.012, (*6*) 1.32, and (*7*) 1.617.

amount (about 5 wt % in the case in question) and sampling for determining the content of Ln_2O_3 made it possible to plot the temperature dependences of the limiting solubility of the REE oxides. The functions obtained are described by the equations

$$c_{lim} = 0.0015T - 0.0794 \text{ for gadolinium oxide,} \quad (9)$$

$$c_{lim} = 0.0136T - 8.4549 \text{ for yttrium oxide,} \quad (10)$$

$$c_{lim} = 0.0139T - 0.2602 \text{ for neodymium oxide,} \quad (11)$$

where c_{lim} is the limiting content of Ln_2O_3 in the melt (wt %), and T is the temperature of the melt (°C).

The use of dependences (6)–(8) and evaluation of the content of oxygen in fluorides of the above-mentioned REEs made it possible to give preference to the hydrofluoride method of LnF_3 preparation in an inert atmosphere [oxygen content of the REE fluoride was $(0.12–1.88) \times 10^{-4}$ mol %].

CONCLUSIONS

(1) Reactions of Y_2O_3 and Nd_2O_3 with ammonium hydrofluoride were studied. Intermediate complex ammonium fluorometallates were isolated and identified.

(2) The content of cationic impurities in the final products, trifluorides of rare-earth elements, was found to be determined by their content in the starting oxides; the content of anionic impurities (oxygen-containing in the first place) can be lowered by creating an inert or fluorinating atmosphere in synthesis. A comparison of various methods for the synthesis of yttrium, gadolinium, and neodymium fluorides as regards the content of oxygen-containing anionic impurities in the final products demonstrated that the best results are obtained with the hydrofluoride method. The content of oxygen was $(0.12–1.88) \times 10^{-4}$ mol %. The use of glassy carbon materials lowered to a minimum the contaminating effect of the apparatus.

ACKNOWLEDGMENTS

The study was carried out in accordance with the project "High-Temperature Chemical and Electrochemical Syntheses of New Compounds Based on Less-Common and Rare-Earth Metals," within the framework of the integrated program of the Russian Academy of Sciences.

Abstract—The integral molar excess Gibbs energy and the enthalpy of mixing of liquid alloys of the ternary system nickel–copper–iron at 1600°C were calculated by various methods from data on boundary binary systems.

The nickel–copper–iron system in a liquid state is of interest for various processes of nonferrous metallurgy. It is a basis of matte obtained in reprocessing of copper–nickel sulfide raw materials. Data on thermodynamic properties of liquid alloys of this ternary system are virtually lacking. Experimental data for a large number of ternary systems with different character of component interaction show that the thermodynamic properties of liquid ternary systems can be estimated with a reliability sufficient for process calculations from data on boundary binary systems using geometric models and polynomials [1–5]. The thermodynamic properties of liquid alloys of the boundary systems nickel–copper, copper–iron, and iron–nickel are fairly well studied.

The phase diagram of the Ni–Cu system is characterized by formation of the solid solutions over the entire composition range and unlimited solubility of the components in the liquid state. Various methods, including emf measurements with molten or solid electrolytes, saturated vapor pressure measurements, and high-temperature calorimetry, were used for studying thermodynamic properties of the Ni–Cu liquid alloys. Published data on this system are analyzed in detail in [6]. In accordance with the phase diagram, the activity isotherms show moderate positive deviations from Raoult's law (Fig. 1a).

The thermodynamic properties of liquid alloys of the system Ni–Cu–Fe were calculated from data [7, 8] on the Ni–Cu system. In [7], the effusion method was used to measure the saturated vapor pressure over liquid alloys of nickel with copper at 1430°C. The saturated vapor pressure of copper exceeds that of nickel by more than two orders of magnitude; therefore, copper is a major evaporating component. Nonetheless, the authors introduced the correction for evaporation of nickel. The nickel activity and the integral thermodynamic properties of the Ni–Cu liquid alloys were calculated using the Gibbs–Duhem equation. In [8], the system Ni–Cu was studied calorimetrically (with a high-temperature isoperibolic calorimeter) at 1480°C. The excess Gibbs energy ΔG^{E} and the enthalpy of mixing ΔH at 1600°C were estimated from data of these works.

In the system copper–iron, the liquidus curve lies nearly horizontally in the central region of compositions, which can be considered as confirmation of the separation tendency. This leads, in turn, to the positive deviations of the component activity isotherms (Fig. 1b), and the enthalpies of mixing are also positive. Data of [10], where both emf measurements with the molten oxide as electrolyte (1460°C) and the high-temperature calorimetry (at 1600 and 1637°C) were used for studying thermodynamic properties of liquid alloys, were recommended for the Cu–Fe system in a handbook [9]. The latter method allowed direct experimental determination of the partial molar enthal-

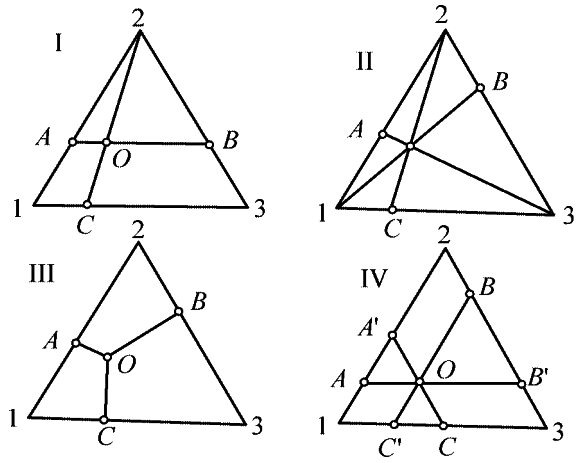

Fig. 2. Geometrical models for calculating integral thermodynamic properties of the ternary systems from data on boundary binary systems. For explanation, see text.

pies of mixing of iron, which made it is possible to recalculate for higher temperature (1600°C) the activities determined by the emf method. Thermodynamic properties of liquid alloys of the system Cu–Fe are also analyzed in [11].

The phase diagram of the iron–nickel system shows that, in the liquid state and in the solid state at high temperatures, except for a very narrow composition range adjacent to iron, the component miscibility is unlimited. A computer calculation of the phase diagram of the Fe–Ni system on the basis of thermodynamic data showed that the solidus and liquidus lines are very close and sometimes virtually coalesce [12]. Such a phase diagram, arising from closeness of the atomic radii of iron and nickel (0.126 and 0.124 nm, respectively), predetermines the minimal deviations of the component activities from the ideal values (Fig. 1c).

Thermodynamic properties of liquid alloys of the system Fe–Ni have been repeatedly studied by various methods [13]. Comparison of the data on the component activity coefficients for liquid alloys of this system obtained by various authors, along with the results of our studies, were reported in [14]. The majority of data refers to 1600°C. Published data on the general character of the concentration dependence of activity, activity coefficients, excess and total Gibbs energy, and on their numerical values are in reasonable agreement. Data on the enthalpies of mixing of liquid alloys are less reliable [15–17]. In calculations we used the values recommended in [13, 18].

Four geometrical models (I–IV) and the Redlich–Kister polinomials (V) were applied to calculating the integral molar thermodynamic characteristics of liquid alloys of the ternary system from data on boundary binary systems. The geometrical models are schematically shown in Fig. 2. Point *O* designates the composition of a ternary alloy (x_1, x_2, x_3) for which the integral thermodynamic property is calculated. Because the models for calculating ΔG^E, ΔG, and ΔH were similar, let us designate any of these thermodynamic functions as $\Delta\Phi$. Points *A*, *B*, and *C* indicate compositions of the boundary binary systems for which the integral quantities $\Delta\Phi_{12}$, $\Delta\Phi_{23}$, and $\Delta\Phi_{31}$ are used in the calculations. The mathematical expressions corresponding to the geometrical models are presented below. Model IV (Colinet's method) allows two calculation procedures: the "left" method and the "right" method using the $\Delta\Phi_{ij}$ values at points *A*, *B*, and *C* or at points *A*', *B*', and *C*', respectively. As a rule, both calculation methods are used simultaneously, with the results averaged (the coefficient 0.5 in the equation for model IV). All the calculations were done along the secants of the concentration triangle at a constant $x_{Ni} : x_{Fe}$ ratio.

Algorithms for calculating integral molar thermodynamic properties of the ternary system from data on boundary binary systems

$$\text{model I: } \Delta\Phi = \left[\frac{x_1}{1-x_2}\Delta\Phi_{12} + \frac{x_3}{1-x_2}\Delta\Phi_{23}\right]_{x_1, x_1/x_3} + (1 - x_2)[\Delta\Phi_{13}]_{x_2=0, x_1/x_3};$$

$$\text{model II: } \Delta\Phi = (x_1 + x_2)[\Delta\Phi_{12}]_{x_1/x_2} + (x_2 + x_3)^2[\Delta\Phi_{23}]_{x_2/x_3} + (x_1 + x_3)^2[\Delta\Phi_{31}]_{x_3/x_1};$$

model III:

$$\Delta\Phi = \frac{4x_1x_3}{(2x_1 + x_2)(2x_3 + x_2)}[\Delta\Phi_{13}]_{x_3 + x_2/2} + \frac{4x_2x_3}{(2x_3 + x_1)(2x_2 + x_1)}[\Delta\Phi_{23}]_{x_2 + x_1/2} + \frac{4x_1x_2}{(2x_2 + x_3)(2x_1 + x_3)}[\Delta\Phi_{12}]_{x_1 + x_3/2};$$

model IV:

$$\Delta\Phi = 0.5\left(\frac{x_1}{1-x_2}[\Delta\Phi_{12}]_{x_2} + \frac{x_2}{1-x_3}[\Delta\Phi_{23}]_{x_3} + \frac{x_3}{1-x_1}[\Delta\Phi_{13}]_{x_1} + \frac{x_2}{1-x_1}[\Delta\Phi_{12}]_{x_1} + \frac{x_3}{1-x_2}[\Delta\Phi_{23}]_{x_2} + \frac{x_1}{1-x_3}[\Delta\Phi_{13}]_{x_3}\right).$$

Table 1. Results of the calculation of ΔG^E and ΔH for the Ni–Cu–Fe ternary system at 1600°C

0.30	3.15 ± 0.10	2.60 ± 0.38	3.75 ± 0.02	3.79 ± 0.47	5.01 ± 0.04	6.54 ± 0.47
0.40	4.26 ± 0.09	3.51 ± 0.28	4.88 ± 0.02	4.53 ± 0.34	6.00 ± 0.04	6.77 ± 0.35
0.50	4.90 ± 0.10	3.96 ± 0.17	5.48 ± 0.04	4.82 ± 0.25	6.42 ± 0.04	6.49 ± 0.23
0.60	5.05 ± 0.12	3.99 ± 0.08	5.60 ± 0.10	4.85 ± 0.09	6.30 ± 0.05	5.96 ± 0.10
0.70	4.70 ± 0.11	3.66 ± 0.08	5.24 ± 0.13	4.38 ± 0.06	5.77 ± 0.09	5.27 ± 0.03
0.80	3.85 ± 0.08	2.92 ± 0.06	4.35 ± 0.10	3.58 ± 0.07	4.80 ± 0.08	4.30 ± 0.07
0.90	2.38 ± 0.03	1.75 ± 0.02	2.70 ± 0.04	2.20 ± 0.03	2.99 ± 0.03	2.69 ± 0.08

The Toop's method (model I) belongs to asymmetrical methods, i.e., the results of the calculation are to a certain extent dependent on the choice of a specified position of components. The Kohler's, Muggiani's, and Colinet's models (II, III, and IV, respectively) are symmetrical with respect to the numbering of the system components (Fig. 2; see algorithms). The calculation results for all the four geometric models are reasonably consistent. The average values of the integral thermodynamic functions, ΔG^E and ΔH, for the system Ni–Cu–Fe, along with the averaged deviation, are given in Table 1. The analysis shows that none of the four methods is in preference for the given system, and it is unreasonable to consider any of them as inadequate. The lines of the equal values of ΔG^E and ΔH are plotted in Figs. 3a and 3b.

To express analytically the concentration dependence of the integral molar excess Gibbs energy and the enthalpy of mixing in the binary systems Ni–Cu, Cu–Fe, and Fe–Ni at 1600°C, the data were formalized with the following polynomials:

$$\Delta G^E = x_1(1 - x_1)[b + c(2x_1 - 1) + d(2x_1 - 1)^2],$$

$$\Delta H = x_1(1 - x_1)[b' + c'(2x_1 - 1) + d'(2x_1 - 1)^2].$$

Special calculations [19] showed that it is unnecessary to use the higher degrees of the polynomials of this type to describe the thermodynamic properties of liquid binary metal systems with different character of component interaction. For a series of the binary systems considered, the coefficients obtained are given below.

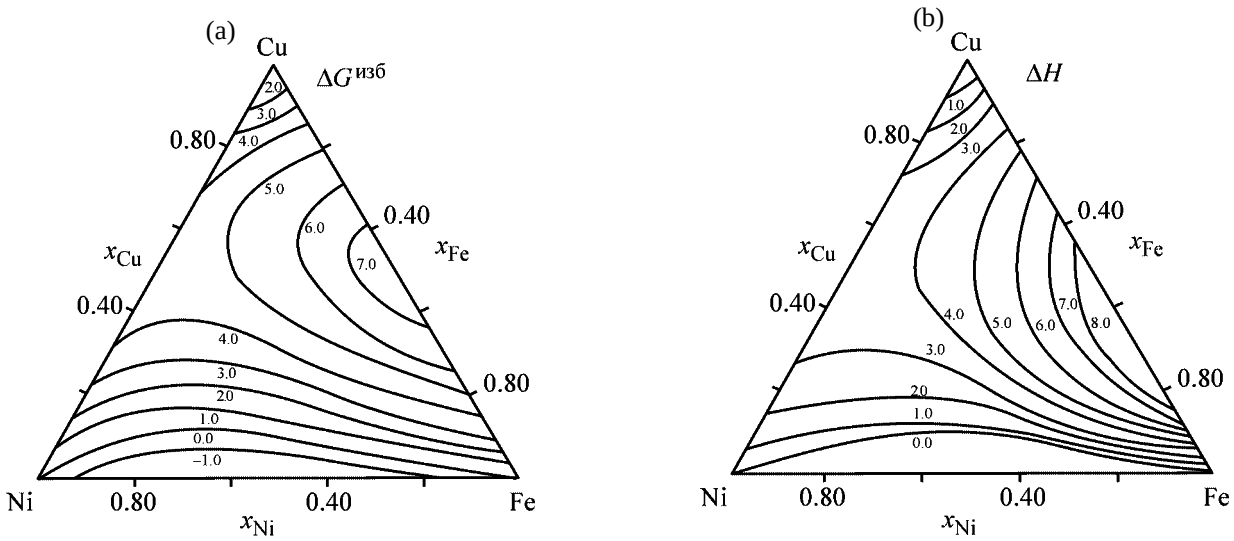

Fig. 3. Lines of the equal values of (a) integral molar excess Gibbs energy ΔG^E and (b) enthalpy of mixing ΔH in the ternary system Ni–Cu–Fe at 1600°C (kJ mol^{-1}).

Table 2. Results of the calculation of ΔG^E and ΔH in the ternary system Ni–Cu–Fe at 1600°C using polynomial expressions

x_{Cu}	$x_{Ni}:x_{Fe} = 3:1$		$x_{Ni}:x_{Fe} = 1:1$		$x_{Ni}:x_{Fe} = 1:3$

* Correlation coefficient.

The excess Gibbs energy in the ternary system can be presented as the following sum of independent contributions [1, 2]:

$$\Delta G^E = \Delta G^E_{12} + \Delta G^E_{23} + \Delta G^E_{31} + \Delta G^E_{123}.$$

To estimate the first three contributions, it is necessary to know the coefficients b_{ij}, c_{ij}, and d_{ij} of the corresponding binary systems. Determination of ΔG_{123} needs the minimum amount of data on the ternary system. At the same time, the calculations performed for a number of experimentally studied systems showed that the ΔG^E value for a ternary system can be sufficiently reliably estimated from data on boundary binary systems only [1, 20, 21]. The enthalpy of mixing in ternary systems is estimated similarly. Thus, the final equations for calculating ΔG^E and ΔH in ternary systems contain solely the coefficients entering into the equations for the binary systems:

$$\Delta G^E = x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2] + x_2x_3[b_{23} + c_{23}(x_2 - x_3) + d_{23}(x_2 - x_3)^2] + x_3x_1[b_{31} + c_{31}(x_3 - x_1) + d_{31}(x_3 - x_1)^2],$$

$$\Delta H = x_1x_2[b'_{12} + c'_{12}(x_1 - x_2) + d'_{12}(x_1 - x_2)^2] + x_2x_3[b'_{23} + c'_{23}(x_2 - x_3) + d'_{23}(x_2 - x_3)^2] + x_3x_1[b'_{31} + c'_{31}(x_3 - x_1) + d'_{31}(x_3 - x_1)^2].$$

The parameters x_1–x_3 in these equations characterize the composition of the ternary alloy. The results of the calculations are given in Table 2. The values obtained are in reasonable agreement with the results of the geometric models. The discrepancies were observed only in the composition region adjacent to the Fe–Ni side, because ΔG^E and ΔH change sign.

CONCLUSION

The calculations of the integral molar excess Gibbs energies and the enthalpies of mixing in liquid alloys of the nickel–copper–iron system at 1600°C by four different geometric models from data on boundary binary systems yield consistent results. The calculation of these functions with polynomials yields, on the whole, similar results.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculating Density of Molecular Liquids Using Agrawal–Thodos Equation

I. B. Sladkov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received November 1, 2001

Abstract—The correlation between the parameters of the Agrawal–Thodos equation and the fundamental constants of a substance are established. A modified equation is proposed, in which the minimum set of easily measurable properties of the substance is used as input data.

The majority of molecular compounds under normal conditions exist in the liquid state. The most important characteristic of such compounds is liquid density. Data on the density are necessary for theoretical calculations and for process development and control, including calculation of heat exchangers, distillation columns, and all the equipment for fluid control.

A number of correlations allowing prediction of the density of molecular liquids on the saturation line in the entire range of existence of the liquid phase have been reported. These include the Mathias [1], Goldhammer [1], Spencer–Danner [2], Campbell–Thodos [3], and Eselev–Krupskii equations [4]. To these correlations also belongs the Agrawal–Thodos equation [5] derived from the following prerequisites.

Based on experimental data on the density of liquid Ar, Ne, H_2, O_2, N_2, CO, and CH_4, Agrawal and Thodos found that the temperature dependence of density, if plotted in the coordinates $\ln(1 - T_{red})$ vs. $\ln(\rho_{red} - 1)$, is the simplest (linear) dependence over the entire region of existence of the liquid phase. Here, $\rho_{red} = \rho/\rho_{cr}$ is the reduced density; $T_{red} = T/T_{cr}$, reduced temperature; and ρ_{cr} and T_{cr}, critical density and temperature, respectively. As a result, the temperature dependence of the liquid density is described by the following equation:

$$\rho = \rho_{cr}[1 + \alpha(1 - T/T_{cr})^{\beta}]. \quad (1)$$

Agrawal and Thodos found that, for the above substances, the temperature dependence of the liquid density can be described with sufficient accuracy by Eq. (1) with properly chosen individual constants α and β. The errors averaged over the whole temperature range (T_m–T_{cr}) were from 0.4 (for Ne) to 1.3% (for CH_4).

The Agrawal–Thodos equation is advantageous over analogous equations, because it allows the temperature dependence of the liquid density to be obtained in a simple and compact form; it does not require data on the vapor density (unlike Mathias–Goldhammer equations), critical pressure (unlike Spencer–Danner equation), or saturated vapor pressure (unlike Eselev–Krupskii equation); as compared to the Campbell–Thodos equation, it contains considerably smaller number of fitting parameters.

All the above shows that the Agrawal–Thodos equation is, without doubt, promising and efficient for predicting the density of molecular liquids. At the same time, the authors' proposal to use the experimental temperature dependence of the liquid density for determining α and β limits practical application of Eq. (1) to a small number of thoroughly studied substances. This equation has practical value and can be applied solely in the case when α and β can be determined from calculation rather than from experimental data on the liquid density.

The goals of this work were (a) to establish a correlation between the parameters α and β and the fundamental constants of a substance and, as a result, to derive equations for calculating the above parameters without data on liquid density, (b) to propose a modification of the Agrawal–Thodos equation allowing prediction of the liquid density from the minimum amount of easily accessible data, and (c) to study potentials of this modified equation on substances belonging to different classes of chemical compounds.

Solving this problem would make the Agrawal–Thodos equation more versatile and applicable to poorly studied substances.

Let us consider the main relationships underlying

1070-4272/02/7511-1770$27.00 © 2002 MAIK "Nauka/Interperiodica"

the method proposed. Basically, the parameters α and β of Eq. (1) can be expressed in terms of the parameters of two reference points: $T = 0$, and, consequently, $\rho = \rho_0$ and $T = T_b$, and, consequently, $\rho = \rho_b$. First, we write Eq. (1) for $T = 0$, then, for $T = T_b$, and, after appropriate transformations, we obtain the following relationships:

$$\alpha = \rho_0/\rho_{cr} - 1, \quad (2)$$

$$\beta = \ln[(\rho_b/\rho_{cr} - 1)/\alpha]/\ln(1 - T_b/T_{cr}). \quad (3)$$

As seen from Eq. (2), determination of α needs data on the ρ_0/ρ_{cr} ratio, where ρ_0 is zero density, i.e, a hypothetical density of a liquid at absolute zero, and ρ_{cr}, critical density. The ρ_{cr} is difficult to determine, and data on ρ_0 are even less accessible. We found that the ρ_0/ρ_{cr} ratio and the boiling point of a substance correlate. For example, for carbon tetrafluoride having T_b = 145.2 K ρ_0/ρ_{cr} = 3.60, whereas for tin tetraiodide having T_b = 622.5 K, ρ_0/ρ_{cr} = 4.02.

By assuming that the correlation between the ρ_0/ρ_{cr} ratio and the boiling point is linear,

$$\rho_0/\rho_{cr} = aT_b + b,$$

we minimized the error in calculating the liquid density by Eq. (1) to derive the parameters of this dependence. For this purpose, we used the experimental data on the temperature dependence of the liquid density. For the temperature range from the melting point to the boiling temperature, such data are available for many molecular inorganic compounds [6]. We chose 50 well-known substances, for which, apart from the liquid density, all necessary data for the calculation by Eq. (1) are available: hydrides CH_4, B_2H_6, GeH_4, SnH_4, NH_3, and N_2H_4; fluorides CH_4, MoF_6, WF_6, and UF_6; chlorides CCl_4, $SnCl_4$, $GeCl_4$, $TiCl_4$, PCl_3, PCl_5, $BiCl_3$, S_2Cl_2, and HCl; bromides BBr_3, PBr_3, and $SnBr_4$; iodides BI_3, SiI_4, and SnI_4; mixed halides CCl_3F, CCl_2F_2, $CClF_3$, CBr_2F_2, $CBrF_3$, $PClF_2$, PCl_2F, $SiBrCl_3$, and $SiBr_2Cl_2$; hydrohalides CH_3Cl, CH_3Br, CH_3I, $CHCl_3$, $CHClF_2$, $SiHCl_3$, and $SiHBr_3$; oxyhalides PCl_3O, PBr_3O, SCl_2O, ClO_3F, and WCl_4O; oxides CO, N_2O, SO_2, and H_2O.

The parameters a and b were determined by the following procedure: For each substance the calculations were performed for 10 temperatures in the range from the melting point to the boiling point, and the relative error was averaged in absolute values over the whole range. Then, the errors obtained were averaged over all the 50 substances. The resulting error, which is the average value over 500 experimental points, is denoted as Δ.

The calculations performed showed that the minimal value of Δ is provided by the equation

$$\rho_0/\rho_{cr} = 1.055 \times 10^{-3}T_b + 3.38, \quad (4)$$

which, taking into account Eq. (2), yields

$$\alpha = 1.055 \times 10^{-3}T_b + 2.38. \quad (5)$$

In what follows, we show that the calculations by Eq. (1), in which α and β are calculated by Eqs. (5) and (3), provide reliable prediction for molecular liquids.

In the next stage, we examined the possibility of using more accessible input data. The above method of calculating density needs comprehensive input data on the substance under study, including boiling point, critical temperature, density of the liquid at boiling point, and critical density. Among these data, critical temperature and critical density are difficult to determine.

Because the boiling-point parameters are more accessible than the critical parameters, we studied the possibility of replacing the critical temperature by the boiling point and the critical density by the liquid density at the boiling point. For this purpose, we studied the relationships [6] between the critical-point and boiling-point parameters:

$$T_{cr} = T_b + 0.89T_b^{0.2\psi + 0.92}, \quad (6)$$

$$\rho_{cr} = \rho_b/(2.69 + 1.067\psi), \quad (7)$$

where ψ is the factor of complexity of intermolecular interaction [6],

$$\psi = 0.1\ln T_b - 0.122\ln V_b + 0.006, \quad (8)$$

where V_b is the molar volume of liquid at boiling point ($cm^3\ mol^{-1}$).

As a result, we obtained the modified Agrawal–Thodos equation based on Eqs. (1), (3), and (5)–(8) with the minimum amount of easily accessible input data (boiling point and molar volume of a liquid at boiling point).

The calculations by the above two procedures were performed on a data set obtained for the 50 abovementioned substances covering a broad range of molecular compounds of different classes, with different types of intermolecular interaction. All numerical values of the physicochemical constants were taken from a handbook [6].

Table 1. Error in calculating liquid density using different sets of input data

Calculation method	Calculation formulas	Input data	Δ, %
1	(1), (3), (5)	T_b, ρ_b, T_{cr}, ρ_{cr}	0.94

The calculation accuracy for the set of 50 substances is given in Table 1. The typical results for 10 substances are given in Table 2 for more detailed characterization of different calculation procedures. The choice of substances in Table 2 intended to illustrate the potentials of the calculation procedures was governed by three criteria: the compounds belong to different classes of molecular inorganic compounds; their polarity varies within a wide range; and, finally, experimental data on the density of these compounds over the entire range of existence of the liquid phase are available.

It is seen that both calculation procedures provide sufficient accuracy in calculating the density. In both the low-temperature (from the melting point to the boiling point) and high-temperature (from the boiling point to the critical point) ranges, the accuracy is virtually constant. This shows that both procedures provide reliable prediction of the density over the entire range of existence of the liquid phase.

It is important that the calculation method using boiling-point parameters as input data does not virtually differ in accuracy from that using critical constants. This considerably expands the potential of the Agrawal–Thodos equation for predicting the density of poorly studied substances.

The polarities of the 50 substances chosen vary within a wide range. One of important results is that the accuracy of the proposed modifications of the Agrawal–Thodos equation is polarity independent (Table 2): for strongly polar substances (SO_2, HCl, and NH_3) the error in calculating density is simlar to that obtained for nonpolar substances (CF_4, BBr_3, and SnI_4).

The substances chosen are molecular inorganic compounds. It is known that approximate methods, as applied to different classes of substances [7], can yield different errors in prediction of physicochemical properties. Therefore, it was of interest to study the applicability of the Agrawal–Thodos equation to other classes of molecular substances (including organic and organometallic compounds).

To do this, among the compounds of the above classes we selected 10 well-known substances for which experimental data on the liquid density are available [8–12]. Table 3 shows that, in the temperature range from the melting point to the boiling point, the accuracy of the considered modifications of the Agrawal–Thodos equations is high for both organic and organometallic compounds.

In the high-temperature range ($T > T_b$), procedure 2 can yield higher error for certain organic substances with a marked polarity. This is explained by the fact that, in going to more accessible input data in method 2, we used correlations obtained for inorganic

compounds. These correlations, when applied to organic compounds, are less accurate and can yield increased error in calculation by method 2. As seen from Table 4, for the nonpolar compound C_3F_8 the error of method 2 in the temperature ranges T_b–T_{cr} and T_b–T_{cr} is virtually the same. At the same time, for strongly polar compound C_2H_5OH the error of method 2 at $T > T_b$ markedly increases and considerably exceeds that of method 1.

CONCLUSIONS

(1) The correlation between the parameters α and β of the Agrawal–Thodos equation and the fundamental constants of the substance is established, allowing calculation of the liquid density using a limited set of experimental data.

(2) The modification of the Agrawal–Thodos equation based on only two easily accessible parameters, boiling point and liquid density at boiling point, is proposed.

(3) The proposed modification considerably extends the applicability of the Agrawal–Thodos equation, making it suitable for predicting the density of poorly studied substances.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Modeling of Liquid–Vapor Equilibrium in Systems Including a Light Oil–Gas Component and Aromatic and Polyaromatic Hydrocarbons[1]

I. V. Prikhod'ko and I. V. Vinogradova

St. Petersburg State University, St. Petersburg, Russia

Received March 25, 2002

Abstract—The Victorov–Smirnova's hole lattice quasichemical group-contribution model (HM) is used to simulate the vapor–liquid equilibrium in binary and ternary mixtures systems composed by aromatic (benzene, toluene) and polyaromatic (naphthalene, phenanthrene) hydrocarbons and light oil–gas components (carbon dioxide, hydrogen sulfide, nitrogen, methane, ethane, propane). Eighteen binary and two ternary systems are examined. New group parameters for these systems are estimated. The results of modeling are compared with the experimental data and those predicted by the Peng–Robinson equation of state.

Designing of oil-and-gas production and processing requires reliable methods for predicting phase equilibria over wide temperature and pressure ranges in mixtures composed by a lot of components different in their chemical nature. Among the systems frequently occurring in petrochemical and coal-mining industries are binary mixtures of aromatic (or polyaromatic) hydrocarbons with typical light oil–gas components (lower alkanes, nitrogen, carbon dioxide, and hydrogen sulfide).

In design engineering, cubic equations of state (EOS) of the van der Waals type hold much favor. For the above-indicated systems these are the Peng–Robinson and Soave–Redlich–Kwong equations and their multiple modifications. All the equations of the van der Waals type used in practice are insufficiently universal and hardly suitable for description of the systems with long-chain, polar, and associated components. The questions related to developing equations of state and their practical use in modeling fluid phase equilibria are examined in the review [1]. Among the most valid (from the molecular standpoint) equations of state one can distinguish those based on the perturbation and numerical modeling theories and also on the lattice fluid models. One of the up-to-date lattice models was developed by Smirnova and Victorov [2–4]. In practice, the model can be used as its group-contribution modification.

The common in all the group models is that molecules of components are represented as a combination of some chemical groups that are thought to provide additive contributions to thermodynamic characteristics of the system. The appeal of the group-contribution approach is caused by the fact that great diversity of molecules is composed by relatively small amount of chemical groups. As a result, compared to the number of molecules, considerably lesser amount of groups is needed to represent a great number of multicomponent systems occurring in the practice. Just these models are best suited for prediction of thermodynamic properties and phase equilibria in cases when experimental data are lacking.

In this work, we selected the Victorov–Smirnova's hole lattice quasichemical model (HM) and an equation of state derived on its basis. The HM was already successfully tested for modeling systems with specific intermolecular interactions, particularly, for pure and mixed fluids such as various hydrocarbons, alkanols, acetone, acetic acid, water, nitrogen, hydrogen sulfide, and carbon dioxide [2–10]. The model proved to be quite adequate in simulating phase equilibria in diverse binary and multicomponent mixtures. In particular, it appeared to be useful in predicting phase equilibria in ternary systems water–subcritical vapor–organic component [9]. Kuranov *et al*. [11] extended HM to include the electrostatic contribution and modeled the liquid–vapor equilibria at elevated pressure in the ternary systems CO_2–methyldiethanolamine–water and H_2S–methyldiethanolamine–water

[1] Results were presented in part at the IV International Conference on Oil and Gas Chemistry, Tomsk (Russia), October 2–6, 2000.

1070-4272/02/7511-1774$27.00 © 2002 MAIK "Nauka/Interperiodica"

with acid–base reactions in the liquid phase. Hofman *et al.* [12] proposed a simplified version of the Victorov–Smirnova's group-contribution EOS with a smaller number of parameters as compared to the original model. With the modified HM they performed a great body of calculations of the thermodynamic properties and phase equilibria for pure alkanes and ethers and their binary mixtures.

HM was not used till now for systems composed by aromatic (or polyaromatic) hydrocarbons and light oil–gas components, since necessary parameters of the model were not determined. Therefore, the main goal of this work is to describe the vapor–liquid equilibria in the binary systems aromatic hydrocarbon (benzene, toluene)–light oil–gas component (CO_2, H_2S, N_2, CH_4, C_2H_6, C_3H_8) and polyaromatic hydrocarbon (naphthalene, phenanthrene)–light oil–gas component (N_2, CH_4, CO_2) over wide temperature and pressure ranges using HM. Solution of this task included determination of new corresponding group parameters and evaluation of potentialities of the model for predicting phase diagrams of the above-mentioned binary systems and a series of ternary systems. The results of modeling were compared with the experimental data and those predicted by the Peng–Robinson equation of state.

The equation of state derived from HM is written as

$$\frac{pv^*}{RT} = -\ln(1-\rho) + \rho\left(\sum_{i=1}^{n} x_i l_i\right)\left(\sum_{i=1}^{n} x_i r_i\right)^{-1}$$

$$+ 0.5z\left\{1 - \rho\left[1 - \left(\sum_{i=1}^{n} x_i q_i\right)\left(\sum_{i=1}^{n} x_i r_i\right)^{-1}\right]\right\} - z\ln X_0,$$

where p is the pressure; v^*, molar volume per single lattice site; x_i, mole fraction of the ith component; $l_i = -z(q_i - r_i)/2 - (r_i - 1)$, molecular bulkiness factor; z, coordination number of the lattice; r_i and q_i, geometrical parameters characterizing the volume and surface area of the ith molecule which are related to the corresponding values of the groups composing the molecule by $r_i = \Sigma \nu_s r_s$ and $q_i = \Sigma \nu_s q_s$ (ν_s is the number of groups of the s type in the ith molecule); $\tilde{\rho} = v^* \sum_{i=1}^{n} x_i r_i / v$, reduced density ($v$ is the molar volume); and X_0, solution of the system of quasichemical equations $X_s \Sigma \alpha_t X_t \exp[-(\Delta\varepsilon_{st}/kT)] = 1$, where the indices s and t refer to the molecular surface sites (groups) whose interaction is described by the interchange energies $\Delta\varepsilon_{st}$ [$s = 0$ for lattice vacancies (holes)] and α_t is the fraction of the surface area occupied by the groups of the t type in the system.

The $\Delta\varepsilon_{st}$ depends on the temperature:

$$\Delta\varepsilon_{st}/(kT) = w_{st} + h_{st}(T_0 - T)/T + c_{st}[\ln(T_0/T) - (T_0 - T)/T],$$

where w_{st}, h_{st}, and c_{st} are energy parameters of the model (free energy, enthalpy, and interchange heat capacity, respectively) expressed in the kT_0 units and T_0 is some standard temperature.

Therefore, calculations by HM require a set of the geometrical (r_s and q_s) and energy group parameters (w_{st}, h_{st}, and c_{st}).

Here we will not dwell upon the details of HM and calculation procedure by this model, since they are reported in detail in [2, 4]. Note that HM represents a generalized solution of the Barker's lattice model for systems with vacancies, taking into account the size and shape of the molecules composing the system and also the orientation effects associated with energy inhomogeneity of the molecular surface. It should be pointed out that, on the assumption of random distribution of molecules and holes between the points of the quasilattice, the above, complex in appearance, equation of state is reduced to the Sanchez and Lacombe's equation as a particular case [13], and at $p \to 0$, the Victorov–Smirnova's equation is reduced to the equation of state for the ideal gas.

As a first step in modeling liquid–vapor equilibria, it was necessary to select some binary systems for which the experimental data are available. These data were then used for validation of the equations of state and optimization of the model parameters. In making efforts on collection and systematization of experimental data on the phase equilibria in binary and multicomponent mixtures containing oil–gas components, a data bank of phase equilibria in oil–gas systems has been developed.[2] The data bank covers data on more than 1300 binary and multicomponent systems (more than 5000 datasets). Among them are mixtures with *n*- and *iso*-alkanes, benzene, toluene, hydrogen sulfide, carbon dioxide, water, and solutions of subcritical and supercritical components in aqueous–organic solvents. For the indicated systems, the data bank is one of the most complete in the Europe. Note that the bank contains not the experimental data files, but their detailed specification, including references to the literature sources, type of the equilibrium, experimental conditions, and data format in the original

[2] Over a period of years, this work is being intensively conducted at the Laboratiry of Nonelectrolyte Solutions, Chair of Physical Chemistry, St. Petersburg State University.

source. We intensively used the data bank for estimating parameters of the Victorov–Smirnova's quasichemical model. This allowed selection of the most representative and reliable data. Analysis of all the available data on binary mixtures of oil–gas components revealed specific features of the phase behavior in the indicated systems in the subcritical range.[3]

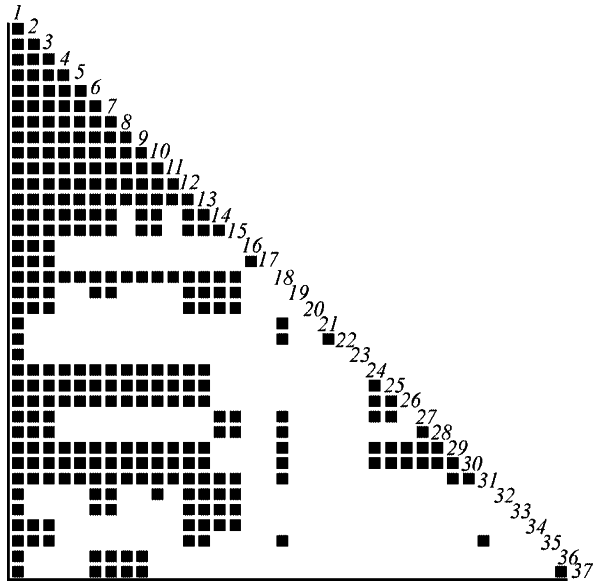

Fig. 1. Matrix of group parameters of HM. Filled elements refer to available parameters. (*1*) Hole, (*2*) CH_2, (*3*) CH_3, (*4*) S (H_2S), (*5*) H (H_2S), (*6*) C (CO_2), (*7*) 2O (CO_2), (*8*) N_2, (*9*) C_1, (*10*) C_2, (*11*) C_3, (*12*) O (H_2O), (*13*) 2H (H_2O), (*14*) O (alkanols), (*15*) H (alkanols), (*16*) CH_3COO, (*17*) H (CH_3COOH), (*18*) ACH (aromatics), (*19*) CH_2=CH(alkenes), (*20*) C≡C (alkynes), (*21*) ACCOO, (*22*) H (ACCOOH), (*23*) CH_3CH_3CH–, (*24*) =CH–, (*25*) C_3H_6 (acetone), (*26*) O= (acetone), (*27*) N (NH_3), (*28*) 3H (NH_3), (*29*) CH_3O (MeOH), (*30*) H (MeOH), (*31*) CCH_3 (toluene), (*32*) C_2H_5 (EtOH), (*33*) C_3H_7 (*i*-PrOH), (*34*) OCH_2CH_2–, (*35*) N– (pyridine), (*36*) CH= (polyaromatics), and (*37*) >C= (polyaromatics).

In the recent decade, researchers gained a great body of experimental data on the liquid–vapor equilibria in the systems aromatic hydrocarbon–light oil–gas component, and considerably lesser, on mixtures of polyaromatic hydrocarbons with oil–gas fluids. These data are mostly either sets of the pressure–composition isothermal data ($P - x$) or data on the solubility of components. Over a wide range of conditions, methane and nitrogen are permanent gases, while the other light oil–gas fluids can occur both in the sub- and supercritical states. In this work we examined 18 binary and two ternary mixtures with attraction of about 110 published experimental datasets.

Following the group-contribution approach used in HM, molecules of the components were divided into groups in the following way: CO_2 and H_2S were divided into two types of groups each (O and C, and H and S); benzene, into six ACH groups; toluene, into five ACH groups and CCH_3–; and naphthalene and phenanthrene were represented as combinations of the CH and >C= groups. It was accepted also that the geometrical parameters of the ACH and CH groups in aromatic and polyaromatic hydrocarbons are the same. The nitrogen and lower alkane molecules were not divided into groups. In HM calculations, the molar volume of the standard segment was accepted to be v^* = 14.244 $cm^3\,mol^{-1}$ and the lattice coordination number, z = 10. For cyclic structures, including those of polyaromatic hydrocarbons, the molecular bulkiness factors were taken equal to unity. The geometrical and energy parameters of groups of the above-indicated components (except for the polyaromatic compounds) were reported earlier [3–5, 8]. For naphthalene and phenanthrene, these parameters of HM were obtained in this work from data on the saturated vapor pressure and density of the liquid phase [14–17]. These data and the saturation line parameters of these compounds are given in Table 1. The number of energy parameters (interchange energies) of the model is smaller than that of the types of contacts between the groups, since some averaged parameters are introduced that refer to only a few nonspecific contact types.

In addition to simulation of the vapor–liquid equilibria in the indicated binary systems, HM was applied to model the phase behavior in these systems, and the results obtained were compared with the experimental data. Figure 1 shows the matrix of group

parameters of HM obtained in this work and previously, which reflects the specific features of division of the component molecules into separate chemical groups. The list of binary mixtures examined in this work is given in Table 2, also including the binary interaction parameter k_{ij} of the Peng–Robinson equation [18]. This parameter was varied for both every temperature from the experimental dataset and for a wide series of isotherms. Because of its negligible value in the systems H_2S–aromatic hydrocarbon, k_{ij} was accepted to be zero for these systems. In the systems N_2–aromatic hydrocarbon, k_{ij} appeared to be somewhat higher as compared to other binary mixtures. We estimated the vapor composition and equilibrium pressure at fixed temperatures and solution compositions. The vapor–liquid equilibrium simulation results are summarized in Table 2. Some examples of the phase diagrams of binary systems estimated by HM and PR EOS are presented in Figs. 2–4. The energy parameters of HM estimated from the experimental data on the liquid–vapor equilibria in the binary systems are listed in Table 3.

It follows from Table 2 and Figs. 2–4 that both equations of state used are suitable for description of all the binary system of the indicated type over a wide temperature range. We did not include the mean absolute deviation of the experimental vapor composition from the estimated value in Table 2, since the vapor practically totally consists of the light oil–gas component.

Figure 5 shows the vapor pressure in the CO_2–benzene–naphthalene system, predicted by HM and PR EOS, and the experimental values taken from [22].

The results show that HM better reproduces the experimental data than PR EOS. For the CO_2–toluene–naphthalene system, HM provides a reasonable prediction for the liquid–liquid–vapor equilibrium. For example, the heterogeneous region is predicted at T = 308–313 K and P = 7.1–8.0 MPa, which is consistent with the experimental data from [23] (note that there are only a few experimental data on the phase equilibria in ternary systems containing the fluids under consideration).

The simulation results obtained with HM and PR EOS show that the maximal deviations between the theoretical and experimental vapor pressures are observed in the vicinity of the critical point. Note that this is a common drawback of any classical equation of state, including HM and PR EOS. With examples of the systems considered in this work, one cannot draw an unambiguous conclusion what equation of state is the best suited. Nevertheless, it may be stated that HM more precisely reproduces the density of the liquid phase. Furthermore, it was demonstrated that HM gives good results in systems with polar, particularly, associated fluids, where equations of the van der Waals type are mostly unsuitable. A group-contribution version of the hole model, developed by Victorov and Smirnova, demonstrates good predictive potential, as demonstrated by the examples of the binary and ternary systems studied. At the same time, PR EOS is considered essentially as a tool for presentation (correlation) of experimental data. To conclude, the hole lattice group-contribution model can be recommended for practical use as a tool for *a priori* predictions.

CONCLUSIONS

(1) The Victorov and Smirnova's hole lattice group-contribution model appeared to be quite applicable to description of some binary and ternary systems containing light oil–gas components and aromatic and polyaromatic hydrocarbons.

(2) The database of group parameters of the model was extended, to simulate phase equilibria in oil–gas systems with the indicated components.

(3) The model allows reasonably accurate prediction of the fluid phase equilibria in the systems under consideration.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Carbon Tetrachloride on Pyridinium Montmorillonite

S. Z. Muminov, D. B. Gulyamova, and E. A. Seitova

Institute of General and Inorganic Chemistry, Academy of Sciences of Uzbekistan, Tashkent, Uzbekistan

Abstract—Effect of substitution of Na^+ by pyridinium on the surface and pore structures of montmorillonite is studied by CCl_4 vapor adsorption.

Growing practical use of natural mineral sorbents causes the need in the study of these adsorbents, particularly, the features of the surface and pore structure of minerals forming their basis. A special attention is paid to clay sorbents modified with various surfactants, including the effect of the low-molecular-weight cationic surfactants on the sorption and energy characteristics of clay minerals.

Various organo clays were obtained [1]. These materials, particularly organo derivatives of montmorillonite, hold promise, since they can be used as adsorbents, fillers in paints and plastic materials, supports in gas chromatography, and also for deactivation.

Treatment of clay minerals of the layer (montmorillonite, vermiculite, and kaolin) and layer–ribbon structures (palygorskite) with alkylammonium and alkyldiammonium salts strongly modifies their surface structure [2]. The adsorption properties of pyridinium montmorillonite were studied in [3–5]. Berezin [6] reported application of organo montmorillonite of this type for separation of three xylene isomers, and Van Olphen [7] employed it as a model adsorbent, to make a quantitative estimate for hydrocarbon liberation from oil strata.

In this work we studied CCl_4 adsorption on dehydrated pyridinium montmorillonite (PyMt). The data obtained on the adsorption isotherms and the heat of adsorption were compared with those for sodium montmorillonite (NaMt).

The pyridinium montmorillonite was prepared by the method described in [3]. A 2% suspension of Azkamar white bentonite consisting essentially of NaMt was treated with 0.02 N aqueous pyridine hydrochloride. The basal interplanar spacing in PyMt was found by XRD to be 1.327 nm, which corresponds to the distance between the basal silicate layers of the neighboring stacks (Δd_{001}) of 0.367 nm.

The CCl_4 vapor adsorption isotherms were obtained using a McBain balance, and a series of isosteres, on an isosteric experimental setup [8] with a small dead volume. Prior to measuring the adsorption, PyMt was dried and heated in a vacuum at 293, 423, and 523 K; and NaMt, at 423 K to a residual pressure in the system of about 1.3×10^{-3} Pa.

The isotherms of CCl_4 adsorption on NaMt and PyMt are shown in Fig. 1. Adsorption of CCl_4 on NaMt, like that of benzene on this clay mineral, is controlled essentially by its surface. At medium and high CCl_4 relative pressures P/P_s, hysteresis loops are observed in the isotherms, corresponding to formation of polylayers and a capillary condensate of CCl_4 in the secondary pores formed by the platelike mineral

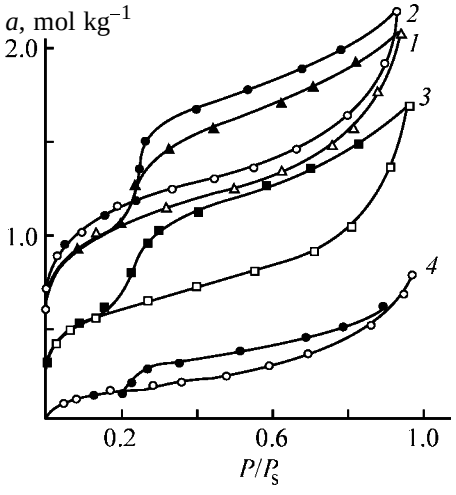

Fig. 1. Isotherms of CCl_4 vapor adsorption at 293 K on heat-treated (*1*–*3*) PyMt and (*4*) NaMt. (*a*) Adsorption and (P/P_s) CCl_4 relative pressure.

particles. The width of the hysteresis loops is nearly constant for all the PyMt samples, and that for the NaMt sample is considerably narrower. For PyMt, the adsorption isotherms at low CCl_4 pressure rise steeply, which is typical of microporous adsorbents. At very low CCl_4 pressures, the pyridinium cations in PyMt still tightly fix the aluminosilicate layers, and adsorption of CCl_4 occurs on the outer surface. The interlayer space in PyMt starts to open at $P/P_s > 0.005$ to $\Delta d_{001} = 0.546$ nm as a result of the vertical orientation of the pyridinium cations [4], thus favoring the adsorption of CCl_4.

Keeping PyMt in a vacuum at room temperature (293 K) results in the removal of the major amount of physically adsorbed moisture. In this case, the initial (at low P/P_s) adsorption of CCl_4 considerably increases relative to that on NaMt. Thermal treatment of PyMt at 423 K provides some increase in the adsorption. The sorption capacity of PyMt heat-treated at 523 K significantly decreases because of thermal degradation of the organic component.

Both NaMt and PyMt demonstrate a reversible adsorption at $P/P_s < 0.2$ (initial sections of the isotherms). The shape of the hysteresis loop in the CCl_4 adsorption isotherms can be related to the B type by the De Boer classification [9]. This type of hysteresis can be initiated by adsorption in slotlike micropores open from all sides. At $P/P_s \sim 0.21–0.22$, the desorption isotherms are steeply curved, which is associated with disordering of the thixotropic structure [10] formed upon saturation of the sorbents.

The sorption volumes of the heat-treated PyMt samples with respect to CCl_4 at P/P_s 0.2 (W), 0.4 (W_0), and 1.0 (V_s), and also the mesopore volumes $W_{me} = V_s - W_0$ estimated from the adsorption isotherms are given in the table below. For comparison, we included the sorption data for NaMt dehydrated at 423 K.

It is seen that the micropore volumes W_0 of sample nos. 1 and 2 amount to only 59% of the total pore volume, and that of sample no. 3, to even 44%. With thermal treatment at 293–423 K, W_0 of PyMt increases by about 5% (from 0.116×10^{-3} to 0.122×10^{-3} $m^3\ kg^{-1}$). Thermal treatment of PyMt at 523 K leads to a considerable decrease in the micropore volume. Based on the micro- to mesopore volume ratios, PyMt should be classified with micro-mesoporous adsorbents.

The changes in the surface and pore structure of montmorillonite initiated by substitution of Na^+ by $[C_5H_5NH]^+$ can be judged from data on the heat of CCl_4 adsorption on the initial and modified montmorillonite samples. The heat of adsorption was determined from the temperature dependence of the adsorption, i.e., from the CCl_4 adsorption isosteres obtained over the temperature range 260– 340 K at fillings from fractions of V_s to the saturation (sample nos. 2,

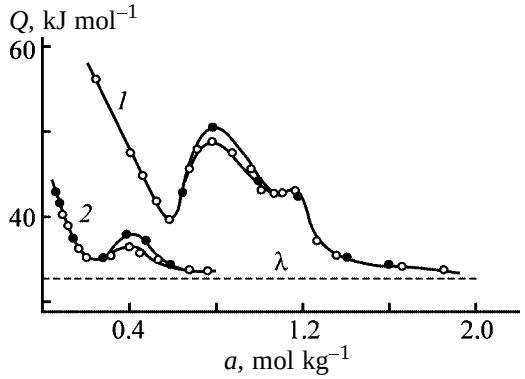

Fig. 3. Differential isosteric heat of adsorption of CCl_4 on (*1*) PyMt and (*2*) NaMt as a function of the amount of adsorbed CCl_4. (Q) Heat of adsorption, (a) adsorption, and (λ) heat of condensation.

4). For example, Fig. 2 shows a series of the CCl_4 adsorption isosteres obtained for sample no. 2 and plotted in the coordinates $\log P$–T^{-1}. The isosteres are fitted by straight lines, indicating that the heat of adsorption is temperature-independent over the experimental range. The upper line gives the dependence of the saturated vapor pressure of bulk CCl_4 on the reciprocal temperature. The slopes of the isosteres depend on the CCl_4 adsorption. The differential isosteric heats of adsorption Q_a and desorption Q_d in the systems CCl_4–PyMt and CCl_4–NaMt were calculated using the Clausius–Clapeyron equation from the slope of the isosteres. The results are presented in Fig. 3.

The dependences of Q_a and Q_d on the CCl_4 adsorption in the systems under consideration steeply decrease to a minimum at low fillings, then increase reaching a maximum at intermediate fillings, and finally decrease gradually, approaching the heat of condensation of the bulk CCl_4 (33.2 kJ mol^{-1}). Over the entire range, the heat of CCl_4 adsorption on PyMt is considerably higher than that on NaMt. The initial decrease in Q at low fillings in both the CCl_4–PyMt and CCl_4–NaMt systems is probably due to inhomogeneity of the outer surface of the adsorbent.

Taking into account the similarity of the initial sections in the $Q = f(a)$ curves for the two systems, it appears reasonable to estimate the heats of CCl_4 adsorption on PyMt and NaMt by extrapolation to zero filling ($\theta = 0$). Such extrapolation gave 74.5 and 45.6 kJ mol^{-1} for PyMt and NaMt, respectively. Comparison of these values suggests higher inhomogeneity of the PyMt outer surface as compared to NaMt. Since the CCl_4 molecules are insensitive to dehydration of, for example, silica [11], it should be assumed that the heat liberation in adsorption of CCl_4 on PyMt is caused essentially by interaction of the adsorbate molecules with $[C_5H_5NH]^+$ and residual Na^+ ions, and that on NaMt, with Na^+ ions. The initial decrease in the heat of adsorption of CCl_4 on PyMt could be even steeper if it were not partly compensated by increase in the heat by virtue of strengthening interaction of the adsorbed molecules. For example, Kiselev *et al.* [12] have demonstrated that the heat of nonspecific adsorption of CCl_4 on graphitized thermal black increases with increasing adsorption as a result of the adsorbate–adsorbate interaction. In the CCl_4–PyMt system, the $Q = f(a)$ dependence shows a minimum (Q_a^{min} ~38.5 kJ mol^{-1}) at a = 0.60 mol kg^{-1} (i.e., at $\theta = a/a_0 = 0.55$, where a_0 is the adsorption at $P/P_s = 0.4$). In the system with NaMt, the minimum (Q_a^{min} ~33.6 kJ mol^{-1}) is observed at a = 0.30 mol kg^{-1}. The minimal value is close to the heat of condensation of the bulk CCl_4. After reaching the minimum, the heat of CCl_4 adsorption on PyMt rapidly rose to a maximum at $\theta = 0.67$ (Q_a^{max} ~47.5 kJ mol^{-1}). In this case, the difference between the minimal and maximal values is 9.0 kJ mol^{-1}.

In another system, the heat of adsorption shows a maximum at a ~0.4 mol kg^{-1} (Q_a^{max} ~36.5 kJ mol^{-1}). With increasing adsorption from 0.3 (a of the minimum) to 0.4 mol kg^{-1}, Q_a increased by 2.9 kJ mol^{-1}, i.e., to a considerably lesser extent than in the CCl_4–PyMt system. Evidently, the increase in Q_a in the CCl_4–NaMt system within the indicated filling range is caused by the interaction between the adsorbate molecules on the outer surface and in the secondary pores of the mineral. Data on the heat of adsorption on PyMt show that, over the indicated filling ranges, the heat of desorption increases to a greater extent than the heat of adsorption, so that the difference $\Delta Q^{max} = Q_d^{max} - Q_a^{max}$ was 4.5 and 1.3 kJ mol^{-1} in the systems CCl_4–PyMt and CCl_4–NaMt, respectively.

With further increasing CCl_4 adsorption on PyMt to 1.01 mol kg^{-1}, Q_a and Q_d decreased to 42.5 kJ mol^{-1} and then remained practically unchanged over the filling range 1.01–1.19 mol kg^{-1}. The constancy of the heats of adsorption and desorption at the adsorption close to the complete filling of the micropores suggests a uniform distribution of the active sites throughout the slotlike micropore structure and also the formation of ion–molecule complexes. At higher CCl_4 adsorption on PyMt and NaMt (a > 1.2 mol kg^{-1} and a > 0.4 mol kg^{-1}, respectively), polylayers and a capillary condensate are formed in the secondary pores of the adsorbent. As a result, the heats of adsorption

gradually approach the heat of condensation of bulk CCl_4.

CONCLUSIONS

(1) The effect of substitution of Na^+ by pyridinium on the adsorption properties of dehydrated montmorillonite clay is studied. The isosteres of CCl_4 vapor adsorption and desorption are obtained. From the changes in parameters of the adsorption equilibrium over a wide occupancy range, the differential isosteric heats of adsorption/desorption are estimated.

(2) Increase in the heat of adsorption of CCl_4 induced by substitution of Na^+ by pyridinium is a result of the formation of a highly developed slotlike micropore structure in the interlayer space of montmorillonite; CCl_4 adsorption on pyridinium montmorillonite occurs essentially in the micropores through formation of ion–molecule complexes.

SORPTION AND ION-EXCHANGE PROCESSES

Dynamics of Copper(II), Nickel(II), and Iron(III) Ion Exchange

S. I. Pechenyuk, A. A. Kondakova, and T. G. Kashulina

Received June 18, 2002; in final form, September 2002

Abstract—The degree of utilization of the static exchange capacity of KU-2 × 8 × 12 cation exchanger with respect to copper(II), nickel(II), and iron(III) cations was considered as a function of the solution flow velocity through the column cross section.

Ion exchange is widely used for concentrating elements from aqueous solutions and for treating water [1, 2]. Large-scale ion-exchange processes (especially in industry) are performed in columns under dynamic conditions. It is known that the static exchange capacity (SEC) of ion exchangers cannot be utilized completely under the dynamic conditions. Two dynamic exchange capacities are considered: exchange capacity to breakthrough (DECB) and total dynamic exchange capacity at saturation (DECS). For water treatment, DECB is the most significant. It depends on the properties of the ion (charge, radius, polarizability, hydration) and ion exchanger structure (mainly pore size at swelling). The DEC value can depend of the solution flow velocity, since the ion exchange rate is limited by the diffusion within the ion exchanger grain or through the solution–resin grain boundary. Despite the practical importance of this question, papers in which it is discussed as applied to particular ion exchangers are scarce. A study of the dynamics of copper(II) and nickel(II) sorption and desorption on Amberlite IRC-718 cation exchanger under conditions of water treatment [3] can be such an example. It was found that this chelating resin efficiently recovers copper(II) from water but is inefficient with respect to nickel(II).

In this work, the degree of utilization of SEC of widely used Russian cation exchanger KU-2 × 8 × 12 with respect to Ni^{2+}, Cu^{2+}, and Fe^{3+} was studied at various velocities of the effluent flow through the column cross section.

EXPERIMENTAL

The H form of KU-2 × 8 × 12 cation exchanger (without sieving; prevailing fractions: d = 0.63–1.0 mm 45.5%, 0.4–0.63 mm 47.6%, 0.25–0.4 mm 4.8%) pretreated as described in [2] (equilibrated with water, washed successively with acid, alkali, again acid, and water to neutral reaction, and then washed to remove dust) was used. Two glass columns with a resin bed height l 86 (I) and 66 (II) cm and cross section S 1.13 and 2.00 cm^2, containing 71.5 and 97.5 g of the cation exchanger (calculated for air-dry resin), respectively, were used. Stoichiometric solutions of nickel(II) nitrate, copper(II) sulfate, and iron(III) chloride and a $FeCl_3$ solution acidified with HCl to 1 M were used as eluents. The chemicals were of analytically pure grade, and all the solutions had the same normal concentration of 0.7 g-equiv l^{-1}. SEC of the cation exchanger was determined for each above solution by the known method [2]; it was (mg-equiv g^{-1}) 8.03 [Ni(II)], 9.25 [Cu(II)], 7.47 [Fe(III)], and 6.45 [Fe(III) + HCl].

To determine DECB (Fig. 1), at equal intervals (25 ± 3 min) we took samples of the effluent, determined the content of ions {Ni(II) and Fe(III), spectrophotometrically [4] on an SF-26 spectrophotometer, and Cu(II), by atomic absorption method} in each of them, and calculated the average velocities of the solution flow and the amounts of cations adsorbed. When the concentration of the unsorbed cation began to steadily increase in the effluent, the process was stopped, and the column was washed with water to disappearance of the sorbate in the wash water and regenerated (washed with the acid) for the next experiment. The results obtained are presented in the table and in Figs. 1 and 2.

The shape of the output curve corresponding to column operation in the frontal mode is shown in Fig. 1. Here, the effluent volume V_b corresponds to breakthrough of the cation, V_s, to saturation, i.e.,

complete utilization of SEC, and V', V'', and V''', to arbitrary instants in which the experiment was terminated (in the period of steady increase in the unsorbed cation concentration in the effluent). After termination of the experiment, the column was washed with water until concentration of the unsorbed ions decreased practically to zero. This is reflected in Fig. 1 by dashed lines corresponding to V', V'', and V'''. Thus, the output curve has the concentration peak. Usually, the effluent flow was stopped when the cation concentration reached 10–15% of the initial concentration (2–3 g l^{-1}). The shape of the output curves illustrates the steepness of the sorption front. The lower the effluent velocity, the steeper is the sorption front, and vice versa. Smearing of the sorption front is the weakest for nickel(II) cations and the strongest for iron(III) cations in the acidified solution (Fig. 2).

It follows from the table that SEC is different for the ions studied. For the copper(II) and nickel(II) cations, whose radii are 0.74 and 0.8 Å, respectively [5], the SEC is higher than for iron(III) cation with a radius of 0.67 Å. This may be due to the fact that less hydrated nickel(II) and copper(II) cations more readily and deeper penetrate into the resin pores. In addition, their bidentate coordination is less sterically demanding than tridentate coordination of Fe(III). SEC for Fe(III) in the acidified solution is lower than in the stoichiometric solution; this may be due to competition of Fe^{3+} and H^+ cations for the ion-exchanging groups.

In all the cases, the degree of utilization of SEC clearly decreases with increasing solution flow velocity, especially in the case of Fe(III) (see table). This is quite natural taking into consideration the larger size of the hydrated ion Fe^{3+}_{aq} as compared to Ni^{2+}_{aq} and Cu^{2+}_{aq} ions and hence the lower rate of its diffusion.

Since Fe^{3+} is very susceptible to hydrolysis [6], we should consider this factor. The first stage of Fe^{3+} hydrolysis is described by the equation of the acid

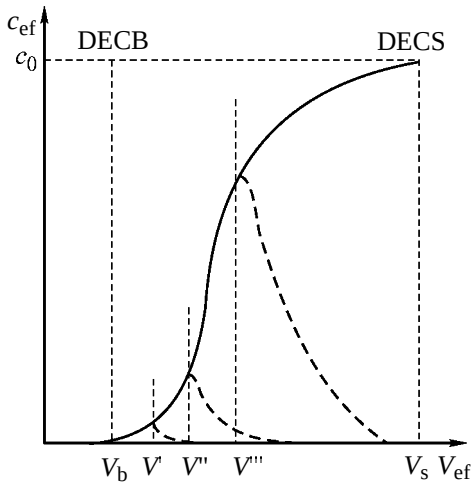

Fig. 1. General view of output curve at frontal mode of ion-exchange column operation. (c_{ef}) Effluent concentration; (V_{ef}) effluent volume; (c_0) initial effluent concentration; (V_b) effluent volume before breakthrough; (V_s) effluent volume at column saturation; and (V', V'', V''') effluent volumes at arbitrarily taken instants between breakthrough and saturation. Dashed lines show decrease in the sorbate concentration when the effluent at the inlet was replaced by water.

dissociation of the iron(III) hexaaqua ion

$$[Fe(H_2O)_6]^{3+} \rightleftarrows [Fe(H_2O)_5OH]^{2+} + H^+$$

with the equilibrium constant of 10^{-3}. Calculation showed that, in a 0.23 M stoichiometric solution of $FeCl_3$, the degree of the hydrolysis amounts to 15.4%, and in the solution additionally containing 1 M HCl it is 0.66%. In both solutions, $[Fe(H_2O)_6]^{3+}$ is the prevailing species, and thus the hydrolysis should not appreciably affect the ion exchange. The hydrolysis affects the exchange of Ni(II) and Cu(II) cations with hydrolysis constants of about 10^{-3} [7, 8] still more weakly. Therefore, at concentrations higher than 0.2 M, to recover iron(III), we should use lower flow velocity than in recovery of nickel(II) but higher velocity than in recovery of copper(II).

However, with decreasing effluent concentration, the hydrolysis should become more pronounced. To estimate this effect, it is sufficient to calculate the solution composition from data on the first stage of the hydrolysis. For instance, in a 0.023 M solution of $FeCl_3$ the degree of the hydrolysis is 93.6%, e.g., the $[Fe(H_2O)_5OH]^{2+}$ ion is the prevailing species, and the Fe(III) behavior becomes similar to that of double-charged cations. In the acidified solution of $FeCl_3$, degree of the hydrolysis is 0.015%, and the difference in the behavior of the acidified and stoichiometric $FeCl_3$ solutions is very pronounced.

CONCLUSIONS

(1) The dynamic exchange capacity of KU-2 × 8 × 12 cation exchanger for metal cations weakly depends on the flow velocity; however, the degree of utilization of the static exchange capacity does not exceed 60% for nickel(II), 50% for iron(III), and 40% for copper(II) at equal effluent concentrations and flow velocities.

(2) At increased velocities of the effluent flow, the degree of utilization of the static exchange capacity for nickel(II) and copper(II) weakly decreases. For iron(III), this effect is more pronounced as a result of stronger diffusion resistance for the cation with a larger hydration shell.

(3) At concentrations of the cations studied close to 1 g-equiv l^{-1}, the hydrolysis does not affect the ion exchange.

SORPTION AND ION-EXCHANGE PROCESSES

Optimal Conditions of Ion-Exchange Synthesis of Cobalt(II) Hydroxide with AV-17-8 Anion Exchanger in the OH Form

S. V. Saikova, M. V. Panteleeva, R. B. Nikolaeva, and G. L. Pashkov

Received Oktober 31, 2001; in final form, April 2002

Abstract—Ion-exchange synthesis of cobalt(II) hydroxide by treatment of aqueous solutions of cobalt salts with OH form of AV-17-8 anion exchanger was studied. The influence of time, anion of cobalt salt, number of precipitation stages, and anion exchanger swelling on the degree of cobalt(II) precipitation was examined.

It is convenient to synthesize cobalt-containing substances (including salts) from cobalt(II) hydroxide, which readily dissolves in acids and does not participate in side redox reactions. As a result, pure salts are formed. Traditional preparation of cobalt(II) hydroxide by exchange of cobalt salts with a small excess of alkali gives the product contaminated with anions of the initial cobalt salt and cations of the precipitant, whose removal requires special separation procedures. In a strongly alkaline medium, $Co(OH)_2$ is readily oxidized into cobalt(II, III) hydroxide whose dissolution proceeds under more rigid conditions and is accompanied by redox reactions, which is unacceptable in preparation of certain cobalt-containing substances.

Basing on reference data [1], we assumed that cobalt(II) hydroxide can be prepared using an anion exchanger in the OH form. Because of sufficiently strong binding of anions of cobalt salt with the anion exchanger, $Co(OH)_2$ can be prepared in a weakly alkaline medium, avoiding noticeable oxidation of cobalt(II).

In the case of $CoCl_2$ solution, such a process can be described by the equation

$$2R\text{–}OH + CoCl_2 \rightarrow 2R\text{–}Cl + Co(OH)_2.$$

In [2], we showed that the use of an anion exchanger, indeed, allows the synthesis of cobalt(II) hydroxide at pH 6–7.

We also found that, for efficient precipitation of cobalt(II) hydroxide as a separate phase, it is necessary to use strongly basic anion exchangers, which, in contrast to weakly basic sorbents, have a high Donnan potential (the positive surface charge of the anion exchanger matrix inhibiting penetration of cations). In addition, the sorbent should have gel-like structure containing no macropores. This decreases formation of the $Co(OH)_2$ precipitate in the anion exchanger phase. We found that AV-17-8 anion exchanger exhibits such properties.

The goal of this work is to study the effect of the process time, anion of the initial cobalt(II) salt, number of precipitation stages, and degree of anion exchanger swelling on $Co(OH)_2$ precipitation from cobalt(II) salt solutions with strongly basic anion exchanger AV-17-8 in the OH form.

EXPERIMENTAL

Initially, the AV-17-8 anion exchanger was transformed into the OH form by four 1-h treatments with 2 M NaOH at the volume ratio of the liquid to solid phase of 3 : 1, followed by 1-day treatment under similar conditions. Then, the sorbent was washed with water to pH 6–7 and dried at 60°C,[1] and its total exchange capacity (TEC) was determined by the reaction with excess 1 M HCl (TEC 2.72 mg equiv g^{-1}; determination error ≤2%).

The anion-exchange precipitation of $Co(OH)_2$ was performed by the method described in [2]: A threefold molar excess of the anion exchanger was added to a 0.25 or 0.5 M solution of the cobalt(II) salt. Precipitation proceeded at 20 ± 2°C for the time from 30 min to

[1] In certain experiments, the anion exchanger was not dried; in these cases TEC was related to 1 ml of the swollen anion exchanger.

1 day. Then, the phases were separated by filtration, initially through a sieve with 0.5-mm mesh (to separate the anion exchanger) and then through a paper filter "blue tape" (to separate the hydroxide). The amount of cobalt in each phase was monitored complexometrically, photocolorimetrically, or by atomic absorption analysis. Then, the mole fraction of cobalt χ_{Co} was calculated as the ratio of the cobalt content in each phase to the total cobalt content in the system.

We have examined the dependences of the degree of cobalt hydroxide precipitation on the time of phase (anion exchanger and solution) contact, anion of the cobalt salt, and degree of preliminary swelling of the anion exchanger. To increase the yield of the precipitate, in certain experiments the synthesis was performed in three stages, since, as shown earlier [2, 3], the degree of cobalt(II) precipitation with anion exchanger from dilute solutions at single phase contact is low. In the three-stage precipitation, the total amount of the anion exchanger used in single-stage precipitation was divided in three portions, and each of them was contacted with a $CoCl_2$ solution (after separation of the preceding portion by filtration) for 1 h. The results as average values of three replicate experiments are listed in Tables 1–5 (relative error <5%).

To explain the effect of the anion on the degree of $Co(OH)_2$ precipitation, we studied the kinetics of Cl^-, NO_3^-, and SO_4^{2-} sorption with AV-17-8 from 0.1 N solutions of HCl, HNO_3, and H_2SO_4, respectively, and of the corresponding sodium salts, and also from mixed solutions of acid (H^+ concentration 0.1 M) and salt (anion concentration 1 M). The static exchange capacity of the anion exchanger SEC for the above anions was related to 1 ml of the swollen anion exchanger.

Table 4. Effect of the number of stages of the anion-exchange synthesis on the degree of $Co(OH)_2$ precipitation from 0.25 M $CoCl_2$ solution

Total		0.04	0.54	0.04	0.35
1*	0.055	0.22	0.37	0.03	0.38

* Single-stage process.

The ion-exchange isotherms for solutions of Na_2SO_4, $NaNO_3$, and NaCl were also measured. The anion concentration was taken within the 0.05–1 M range, since for the efficient anion-exchange synthesis of $Co(OH)_2$ the concentration of the cobalt(II) salt should be higher than 0.1 M [2]. The results are presented in Table 5 and Figs. 1 and 2.

It follows from Table 1 that the anion-exchange synthesis is complete in 3 h. Therefore, this time was taken for the subsequent experiments (Tables 2–4).

The degree of $Co(OH)_2$ precipitation decreases in the series $CoSO_4 > Co(NO_3)_2 > CoCl_2$, which is in agreement with the data on the anion exchange, listed in Table 5 and Figs. 1 and 2. In anion exchange from neutral solutions and solutions with high ionic strength, i.e., under conditions close to $Co(OH)_2$ anion-exchange synthesis, the rate of the exchange and exchange capacity (EC) for sulfate ion are higher than those for nitrate and chloride ions. This fact

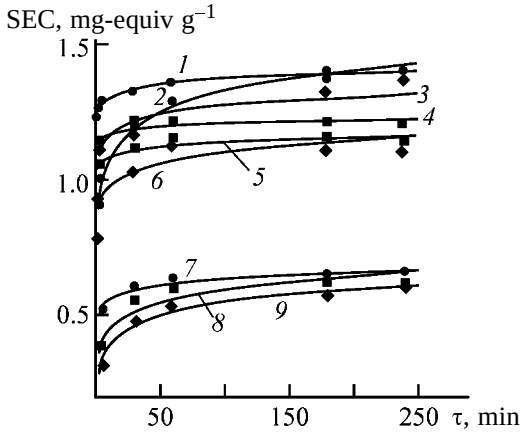

Fig. 1. Rate of anion exchange on AV-17-8 anion exchanger from 0.1 N salt and acid solutions and their mixtures. (SEC) Static exchange capacity and (τ) time. Solution: (*1*) $H_2SO_4 + Na_2SO_4$, (*2*) H_2SO_4, (*3*) HCl + NaCl, (*4*) $HNO_3 + NaNO_3$, (*5*) HNO_3, (*6*) HCl, (*7*) Na_2SO_4, (*8*) $NaNO_3$, and (*9*) NaCl.

Table 5. Effect of anion concentration *c* and pH on SEC of AV-17-8 anion exchanger

c, M	pH	SEC for indicated anion, mg-equiv ml^{-1}		
		Cl	NO_3^-	SO_4^{2-}
0.1	7	0.46	0.51	0.60
	1	1.12	1.17	1.30
1	7	0.51	0.63	0.70
	1	1.20	1.22	1.30

reflects the so-called electroselectivity of ion exchangers (prevalent absorption of anions with the higher charge). The lower EC of Cl^- as compared to NO_3^- may be due to the higher degree of Cl^- hydration (Table 2).

It follows from Table 3 that the amount of the hydroxide precipitate decreases by almost 40% when

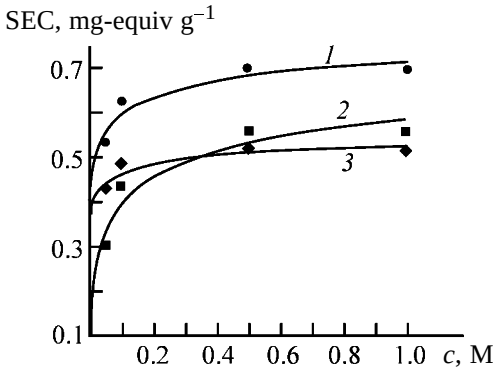

Fig. 2. Isotherms of anion exchange of AV-17-8 anion exchanger with 0.1–1.0 M solutions of (*1*) Na_2SO_4, (*2*) $NaNO_3$, and (*3*) NaCl. (SEC) Static exchange capacity and (*c*) solution concentration.

the swollen anion exchanger is used. When anion exchanger swelled for 1 day (time required for complete unwrapping of chains in the grain), the negative effect was weaker. Three stages are enough to obtain 96% of cobalt(II) as a hydroxide precipitate [the residual Co(II) concentration in the solution is 0.008 M], while in the single-stage procedure, only 80% Co(II) is precipitated at the same consumption of the anion exchanger. In the three-stage synthesis, the amount of the $Co(OH)_2$ precipitate is also larger (by about 20%), with the amount of Co(II) in the anion exchanger phase increasing insignificantly.

CONCLUSIONS

(1) In $Co(OH)_2$ synthesis with AV-17-8 anion exchanger, the degree of cobalt(II) precipitation increases by no more than 6% when the time of phase contact is increased from 3 h to 1 day.

(2) The degree of $Co(OH)_2$ precipitation increases from 59 to 74% in the series $CoCl_2 < Co(NO_3)_2 < CoSO_4$, which coincides with the series of the selectivity of AV-17-8 anion exchanger with respect to these anions.

(3) Performing the process in three stages istead of one stage increases the degree of $Co(OH)_2$ precipitation from 80 to 96%.

SORPTION AND ION-EXCHANGE PROCESSES

Anion Exchangers Based on Glycidyl Derivatives of Aromatic Diamines and Some Allyl Halides

E. E. Ergozhin, A. K. Chalov, R. A. Iskakova, and S. K. Sarsenov

Received April 9, 2002

Abstract—Polyfunctional three-dimensional network anion exchangers were prepared by condensation of tetraglycidyl-4,4'-diaminodiphenylmethane with allyl halides and amines. The optimal preparation conditions were determined; the properties of the resulting product as influenced by the nature of the initial monomers were evaluated.

Owing to high static exchange capacity (SEC) and thermal and chemical stability, polyelectrolytes based on nitrogen-containing epoxy compounds are widely used in hydrometallurgy of rare metals, in recovery of metal ions from spent solutions and wastewaters, and in other branches of industry.

Condensation of tetraglycidyl diamines with polyethylenepolyamine (PEPA), polyethylenimine (PEI), polyxylylenepolyamine, and hexamethylenediamine (HMDA) in methanol yielded selective polyfunctional anion exchangers with high exchange capacity [1–3]. Utilization of long-chain aromatic nitrogen-containing epoxy resins in combination with heteroatoms of –S–, SO_2–, or –O– type between phenyl rings improves the sorption and kinetic properties of the resulting sorbents with respect to polyvanadate ions [4, 5].

To obtain ion-exchange materials possessing high thermal and radiation stability, we prepared anion exchangers based on glycidyl derivatives of 4,4'-diaminodiphenyl sulfide, 4,4'-diaminodiphenyl oxide, PEPA, and PEI [6].

The goal of this work was to prepare highly porous three-dimensional network anion exchangers based on tetraglycidyl-4,4'-diaminodiphenylmethane (TGDADPM), allyl halides (AHs), and di- and polyamines.

EXPERIMENTAL

TGDADPM was synthesized according to [7]; the content of the epoxy groups was determined by the procedure given in [8].

The condensation of AH with TGDADPM was performed in dimethylformamide (DMF) at 13–25°C with subsequent curing at 80–120°C. Then, the gel was crushed, sieved, and the fraction with a particle size of 0.25 mm was taken.

The static exchange capacity (mg-equiv g^{-1}), moisture content, swellability γ, and thermal and chemical stability of the resulting anion exchangers were determined by the standard procedures [9].

The IR spectra of the initial and final products (thin films or KBr pellets, 200 mg KBr per 1 mg compound) were recorded on a Specord M 80/M 85 spectrophotometer.

To determine the optimal preparation conditions, we examined the effect of various factors such as the ratio of the initial components, temperature, curing conditions, and process time on the product properties.

The effect of the initial component ratio is of particular importance, because the content of amine in the polymer determines the properties of the resulting product. It was found that, with increasing content of amine, both SEC and swellability increase, and the strongest effect is observed with PEPA, which is probably due to its structure. As seen from the NMR data [10, 11], PEPA contains significant amounts of diethylenetriamine with two primary and one secondary amino groups. Since primary amino groups are the most reactive, they are involve in the reaction first. In the case of PEI, despite significant content of nitrogen (16%), more branched structure of the polyamine causes strong cross-linking and thus hinders accessibility of the corresponding functional groups. Double bonds, a certain fraction of which is cleaved with atmospheric oxygen [2], also strongly affect the

PMVP	5.0	2.8	5.0	2.7	4.7	2.5

* SEC with respect to 0.1 M HCl.

structure of the resulting polyelectrolyte. The optimal ratios of the initial components TGDADPM : allyl bromide (AB) : amine (weight fraction) for the anion exchangers based on PEPA, PEI, and poly-2-methyl-5-vinylpyridine (PMVP) are 1.5 : 1.0 : 2.0, 1.5 : 1.0 : 3.5, and 1.5 : 1 : 3.0, respectively. With increasing HMDA concentration above 1 wt part, soluble products are formed.

It was found that the SEC of anion exchangers based on TGDADPM increases in the order PMVP < HMDA < PEI < PEPA. The capacities of the resulting anion exchangers prepared at the above optimal ratios of the initial components are 5.0, 5.2, 8.8, and 9.4 mg-equiv g^{-1}, respectively. Thus, PEPA and PEI allow preparation of anion exchangers with the exchange capacity of 8–10 mg-equiv g^{-1}. As seen from the experimental data, the anion exchanger with the highest exchange capacity simultaneously exhibits the highest swellability. For example, SEC of the polyelectrolyte based on TGDADPM, AB, and PEPA is 9.4 mg-equiv g^{-1}, and its swellability reaches 5.8 ml g^{-1}, whereas the swellabilities of the anion exchangers based on PEI and PMVP are significantly smaller: 3.0 and 2.8 ml g^{-1}, respectively.

The halogen in allyl compound does not noticeably affect SEC. For example, in the case of allyl chloride, the maximal SEC of anion exchangers based on PEI and TGDADPM is 9.1 mg-equiv g^{-1}.

Our experimental data on the effect of precondensation temperature and time on the SEC of the resulting anion exchanger showed that polyelectrolyte with the highest SEC is formed at 25°C in 40 min; the yield of the product is 90%.

Owing to different reactivity and to concentration and steric effects, polymers resulting from condensation of polyfunctional compounds contain unchanged functional groups. Thus, it is necessary to determine the optimal curing temperature at which all the functional groups in the initial monomers will be involved in the reaction.

As seen from Table 1, increasing curing temperature deteriorates the physicochemical properties of the resulting anion exchanger. In the case of the anion exchanger based on PEPA, SEC decreases to 7.9 mg-equiv g^{-1} at 110°C; at the same time, the exchange capacity and swellability of the anion exchangers based on PEI, HMDA, and PMVP vary insignificantly. Certain decrease in SEC with increasing curing temperature is due to compression of the polymer structure. Strong decrease in the exchange capacity of the anion exchanger based on PEPA is probably due to heterogeneous composition of the amine reagent and increase in the content of low-molecular-weight and soluble amines during polyelectrolyte treatment.

The structure of the initial tetraglycidyl compound and final products was studied by IR spectroscopy. The presence of the epoxy groups in oligomers of polyglycidyl derivatives of aromatic amines is confirmed by characteristic absorption bands at 745, 865, 935, and 970 cm^{-1}. There are no such absorption bands in the spectra of the resulting anion exchangers, which suggests their chemical transformation. At the same time, new absorption bands appear at 3600–3300 and 1650–1550 cm^{-1}, which correspond to the stretching and bending vibrations of the aminogroups of various basicity. The stretching vibrations of the C–N bonds in the aromatic amino groups are observed in the 1350–1300 cm^{-1} range. The absorption bands at 1510 cm^{-1} belonging to the stretching vibrations of the C=C bond and at 3030 cm^{-1} (stretching vibrations of the =C–H bonds in the benzene ring) confirm the presence of aromatic fragments in the resulting compounds. The spectra of the polymers in question also contain the characteristic absorption bands belonging to the antisymmetric (2940 cm^{-1}) and symmetric (2840 cm^{-1}) stretching vibrations of the CH_2

group and to the C–H bending vibrations at 1470–1460 cm^{-1}. The absorption bands at 1600–1560 and 1500 cm^{-1}, characteristic of the stretching vibrations of the C=C and C=N bonds in the pyridine ring, also undergo certain changes.

The functional groups in the anion exchangers are characterized by the degrees of protonation, which depend on several factors, primarily on the solution pH [13, 14]. The functionality and basicity of the resulting three-dimensional network polyelectrolytes were studied by potentiometric titration. The values of pK_a (Table 2) and empirical coefficient *m*, characterizing the interchain interaction in the polymer, were determined from the potentiometric titration curves using the Henderson–Hasselbach equation [15]. The shape of the titration curves determined by the nature of di- and polyamine and concentration of the functional groups in the anion exchanger showed that the compounds in question based on the polyglycidyl amine are polyfunctional.

The thermal and chemical stability was evaluated by variation in the SEC of the anion exchangers in 2.5 M H_2SO_4, 5 M NaOH, and 10% hydrogen peroxide solutions. As seen from Table 3, the anion exchangers based on TGDADPM are chemically stable in concentrated acids and bases; SEC decreases by no more than 6%. The chemical stability of polyelectrolytes decreases in the order: PEI > HMDA > PMVP > PEPA.

Some physicochemical properties of the anion exchangers change after their boiling in water. In this connection, we studied the thermal stability of compounds in the 80–100°C range at a treatment time of 4–12 h. As seen from Table 3, after such treatment the relative SEC decreases by no more than 5%, and the most stable are the anion exchangers based on PEI and HMDA.

Certain increase in the thermal stability of the polymers in question is probably due to the regular structure of the polyelectrolyte and incorporation of the stable aromatic fragments into the polymer structure. The thermal stability of the resulting anion exchangers decreases in the following order: HMDA > PEI > PMVP > PEPA.

The sorption of the transition metal ions was studied by EDTA titration of the residual amounts of copper(II), cobalt, and nickel in the filtrate after a contact with the anion exchanger for 24 h. The dependence of the sorption capacity of the polyelectrolyte on the acidity of the metal salt solutions (Fig. 1) showed that at pH 5–7 the anion exchanger based on

Table 2. pK_a and *m* of the anion exchangers based on TGDADPM, AB, and amines

Amine	pK_a	*m*
PEPA	7.0	2.1
PEI	7.8	2.2
HMDA	6.2	1.9
PMVP	7.4	2.1

Table 3. Relative SEC of the anion exchangers based on TGDADPM, AB, and amines as influenced by the solution composition and heat treatment time

Amine	Relative SEC, %					
	NaOH	H_2SO_4	H_2O_2	4 h	7 h	12 h
PEPA	100	100	94	100	96	95
PEI	100	100	98	100	100	100
HMDA	100	100	97	100	100	100
PMVP	100	100	94	100	100	98

TGDADPM, AB, and PEPA exhibits the highest sorption capacity for copper(II), nickel, and cobalt ions.

The sorption kinetics of copper ions on the anion exchangers based on TGDADPM and AB was studied using 0.05 N solution of copper(II) sulfate. It was found (Fig. 2) that the fastest sorption is observed with the polymer based on PEPA, which sorbs up to 80% of copper in 0.5 h. This is probably due to the formation of the more elastic three-dimensional network, which provides high swellability and makes the functional groups in the polymer bulk more accessible.

CONCLUSIONS

(1) Procedures for preparing thermally and chemically stable polymeric anion exchangers based on allyl

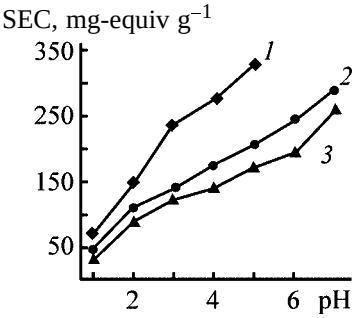

Fig. 1. SEC of the anion exchanger based on TGDADPM, AB, and PEPA for (*1*) Cu^{2+}, (*2*) Ni^{2+}, and (*3*) Co^{2+} as a function of solution pH.

SORPTION AND ION-EXCHANGE PROCESSES

A Mixed Phase C_{60} + Dibenzo-24-crown-8 for Gas Chromatography

L. A. Kartsova and A. A. Makarov

St. Petersburg State University, St. Petersburg, Russia

Received April 24, 2002

Abstract—Stationary phases for gas chromatography were prepared: 10 wt % fullerene C_{60} on Inerton N-AW (deposition from saturated toluene solution) and a mixed phase C_{60} + dibenzo-24-crown-8. These phases were tested in a wide temperature range (40–280°C) with selected organic compounds containing various functional groups and with their mixtures.

Active recent efforts were aimed at searching for new selective chromatographic phases allowing separation in one chromatographic run of multicomponent mixtures of compounds differing in the nature of functional groups, polarity, and boiling point.

Development of an electric-arc procedure for preparing fullerenes in a fairly high yield stimulated active studies of the chemical and physicochemical properties of the new modification of carbon. Chromatographic studies of interactions between fullerenes and organic compounds furnish useful information concerning both the physicochemical properties of fullerenes themselves and their possible use as chromatographic sorbents.

The high hydrophobicity of C_{60} in combination with its thermal stability, resistance to oxidation, and capability for donor–acceptor interactions make this substance promising as a stationary phase for gas chromatography.

The selectivity range in analysis of multicomponent mixtures can be extended by using mixed phases. Combining fullerenes with crown ethers will not only affect the physicochemical characteristics of the carbonaceous stationary phases (solubility, hydrophobicity, capability for various specific interactions with functional groups of components of complex mixtures being separated), but also furnish new data on complexation with macrocycles.

EXPERIMENTAL

Stationary phases were prepared from fullerenes C_{60} and C_{60} + C_{70} (Astrin Joint-Stock Company, St. Petersburg) and dibenzo-24-crown-8 (DB-24-C-8, Reaktiv-Servis Scientific and Production Complex, Limited Liability Company, Moscow).

Fullerene C_{60} tested as stationary phase for gas chromatography was applied onto Inerton N-AW support (grain size 0.20–0.315 mm) in an amount of 10 wt % from toluene. A toluene solution of fullerene was added to Inerton N-AW placed in a porcelain cup in an amount fully covering the solid (0.5-cm layer of the liquid over the solid); the cup was placed on a water bath and carefully stirred until the solvent was fully evaporated. The mass obtained after the solvent evaporation was dried in the air thermostat of a Tsvet-500M gas chromatograph at 100°C for 3 h. Then it was sieved through standard sieves, and the 0.20–0.25-mm fraction was used as packing for a 3000 × 2-mm glass column. The packed column was conditioned in a carrier gas flow (N_2, 30 ml min^{-1}; stepwise heating from 70 to 270°C).

The mixed C_{60} + DB-24-C-8 phase was prepared as follows. Fullerene was applied onto Inerton N-AW (0.20–0.25 mm) as described above, after which 10 wt % DB-24-DC-8 was applied from a chloroform solution (at the reverse application order, i.e., first DB-24-C-8 from chloroform and then C_{60} from toluene, the characteristics of the resulting sorbent were similar). After complete evaporation of the solvents, the packing was dried in the air thermostat of a Tsvet-500M gas chromatograph at 70°C for 3 h. Then it was used as packing for a 3000 × 2-mm glass column. The packed column was conditioned in a carrier gas flow (N_2, 30 ml min^{-1}; programmed heating from 80 to 200°C and keeping at 200°C for 5 h).[1]

[1] Experiments were performed with the participation of I.K. Khmel'nitskii.

Mean polarity and performance of stationary phases for gas chromatography, containing C_{60} and DB-24-C-8, and of some commercial phases

Stationary phase	Mean polarity	Performance (HETP), cm	Retention factor *k*
DB-24-C-8	423	0.43	35.8
C_{60}	260	0.12	9.2
DB-24-C-8 + C_{60}	390	0.19	33.3
SE-30	3	0.33	–
Carbowax 20M	462	0.42	31.6
Tricresyl phosphate	284	0.47	39.5

The retention indices were measured with a Tsvet-500M gas chromatograph equipped with a flame ionization detector and a 3000 × 2-mm glass packed column. The column temperature was varied from 60 to 230°C (for the column packed with 10 wt % C_{60} on Inerton N-AW) or from 90 to 180°C (for the column packed with 10 wt % C_{60} + 10 wt % DB-24-C-8 on the same support); the vaporizer temperature was 150–250°C. Carrier gas (nitrogen) was passed at a rate of 20 or 30 ml min^{-1}; auxiliary gases (air, hydrogen) were fed to the flame ionization detector at rates of 30 and 300 ml min^{-1}, respectively. The electrometer working scales in the course of chromatographing model mixtures were varied from 128×10^7 to 32×10^8. The paper feed velocity was 600 mm h^{-1}. Samples (0.2–0.8 μl) were injected with an MSh-1 microsyringe. From the measured retention distances of the organic compounds and appropriate reference *n*-alkanes, we calculated the Kovats retention indices [1]. The reproducibility of the retention indices in replicate experiments was 3–5 units for the retention times exceeding 5 min and 10–15 units for retention times of 2–5 min.

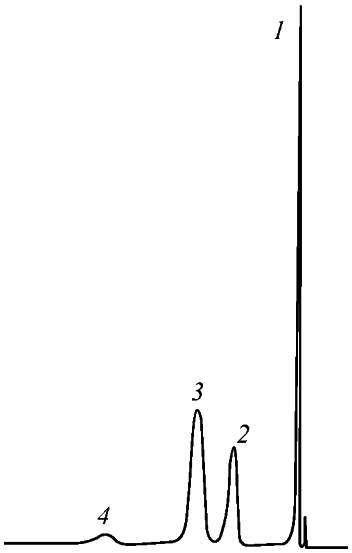

Fig. 1. Chromatogram of a model mixture. Conditions of chromatographic analysis: Tsvet-500M chromatograph, 10 wt % DB-24-C-8 + C_{60} on Inerton N-AW, carrier gas N_2, 30 ml min^{-1}, flame ionization detector; the same for Figs. 2 and 3. Column temperature 150°C. Peaks: (*1*) benzene, (*2*) *N*,*N*-dimethylaniline, (*3*) aniline, and (*4*) phenol.

The polarity of the prepared and studied chromatographic phases was evaluated by the MacReynolds constants using the following test substances: benzene, 1-butanol, nitropropane, pyridine, and 2-pentanone [1].

The mean polarities of our chromatographic phases are compared in the table with those of polyethylene glycol, Carbowax 20M (polar stationary phase), tricresyl phosphate (medium-polarity stationary phase), and SE-30 (nonpolar stationary phase).

The column performance was evaluated by the number of theoretical plates *n*, calculated as

$$n = 5.54(l/\omega_{0.5})^2,$$

where *l* is the retention distance (from the start mark, mm), and $\omega_{0.5}$ is the full width at half-maximum of the chromatographic peak, mm.

The height *H* equivalent to the theoretical plate was calculated by the formula

$$H = L/n,$$

where *L* is the column length, cm.

The performance (with respect to tetradecane) of the columns packed with our phases is compared in the table with that of the selected commercial phases.

To prepare the associate DB-24-C-8 + C_{60}, equimolar amounts of fullerene and DB-24-C-8 were dissolved in the minimal amount of toluene, and the solution was placed in a penicillin vial, which was hermetically sealed and kept at 100°C for 1 h. After cooling, the vial was opened and allowed to stand until the solvent fully evaporated, after which the resulting associate was dried at 120°C for 2 h.

The "fullerene" phase appeared to be more polar than Carbochrome [2] and SE-30 silicone elastomer (see table). Despite the hydrophobic character of C_{60}, the dispersion interactions drastically decreased: The retention times of alkanes were appreciably shorter than those on graphitized carbon black (Fig. 1). On the contrary, polar organic compounds had longer retention times on C_{60} than on graphitized black.

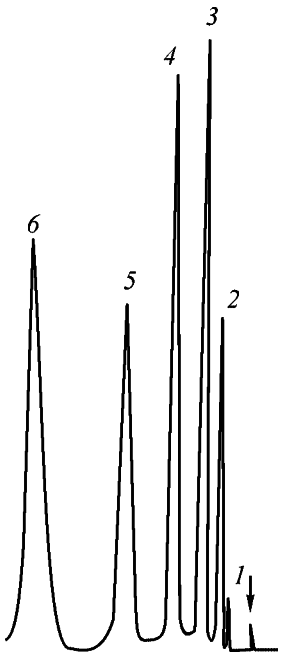

Fig. 2. Chromatogram of a mixture of C_2–C_7 alcohols. Column temperature 120°C; the same for Fig. 3. Peaks: (*1*) ethanol, (*2*) 1-propanol, (*3*) 1-butanol, (*4*) 1-pentanol, (*5*) 1-hexanol, and (*6*) 1-heptanol.

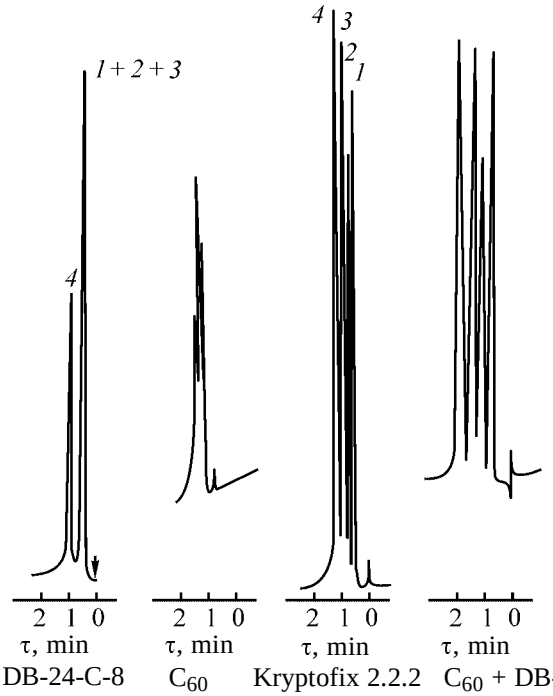

Fig. 3. Chromatogram of a mixture of isomeric butyl alcohols: (*1*) 2-methyl-2-propanol, (*2*) 2-butanol, (*3*) 2-methyl-1-propanol, and (*4*) 1-butanol.

We found that the C_{60} column exhibits increased affinity for aromatic hydrocarbons and their derivatives. The high thermal stability of fullerenes allowed the column to operate in a wide temperature range. The calculated performance of the chromatographic column with the fullerene phase appeared to be higher compared to the other tested phases (see table; the performance is the higher, the lower HETP); however, in analysis of complex mixtures, its selectivity was apparently insufficient.

Thus, our goal was to increase the selectivity with respect to various classes of organic compounds, preserving the obvious advantages of fullerene sorbents (high performance, stability of chromatographic characteristics in a wide temperature range).

The selectivity range can be often extended by using mixed phases. We prepared a mixed phase containing 10 wt % C_{60} + DB-24-C-8 on Inerton N-AW.

Dibenzo-24-crown-8 was tested previously [3] and showed high performance in analysis of highly polar organic compounds: phenols and aromatic amines. The crown ether was applied from chloroform onto the sorbent preliminarily modified with fullerene. The prepared sorbent was tested in the gas-adsorption (90°C) and gas–liquid (120, 150, 180, 200°C) modes.

The mixed chromatographic phase appeared to be suitable for selective analysis of polar and nonpolar organic compounds boiling in a wide temperature range: aliphatic and aromatic hydrocarbons, alcohols, phenols, chlorinated phenols, and aromatic amines (Figs. 1, 2). Many of the above substances are priority ecotoxicants. With respect to the arbitrary mean chromatographic polarity, the mixed stationary phase is inferior only to Carbowax 20M and substantially surpasses SE-30. The mean polarity of C_{60} + DB-24-C-8 is intermediate between the polarities of the stationary phases based on C_{60} and DB-24-C-8 taken separately (see table). The mixed phase showed a high performance characteristic of the C_{60} column. With the C_{60} + DB-24-C-8 phase, it is possible to separate structural and geometric isomers, which is impossible with C_{60} and DB-24-C-8 taken separately, i.e., a synergistic effect is observed. Figure 3 shows the chromatograms of a mixture of isomeric butyl alcohols on several individual phases (Kryptofix 2.2.2 [4], DB-24-C-8, C_{60}, all 10 wt % on Inerton N-AW) and on the mixed phase C_{60} + DB-24-C-8.

The fullerene in the mixed phase may act as support modifier or may form an associate with the crown ether.

It should be also borne in mind that, in thin-layer chromatography with the same elution system, straight silica gel plates and plates modified with different

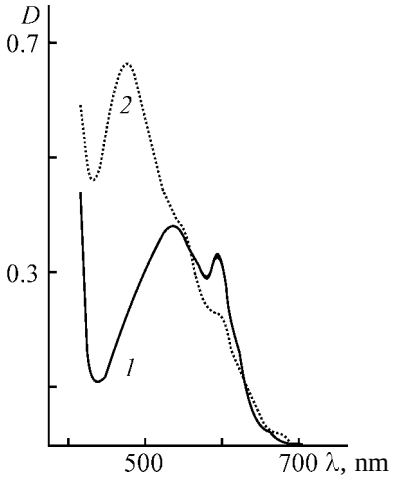

Fig. 4. Absorption spectra of (*1*) C_{60} and (*2*) mixture of C_{60} with DB-24-C-8. (*D*) Optical density and (λ) wavelength.

macrocycles (DB-24-C-8, DB-18-C-6, DB-15-C-5; crown compounds containing labile hydrogen atoms, e.g., diaza-18-C-6) show different performance in separation of a mixture of carbon clusters: stronger sorption and better separation of C_{60} and C_{70} are observed with DB-24-C-8.

In view of these facts, we performed the following experiment in the HPLC mode: Through a chromatographic column packed with a polar sorbent based on silica gel, we passed for a certain period a mobile phase containing DB-24-C-8. The sorbent surface was thus modified with DB-24-C-8. Experiments on separation of a mixture of C_{60} and C_{70} showed that the separation performance of the modified sorbent was appreciably higher than that of the initial sorbent.

A similar trend was observed in [5] with an HPLC column modified with tetraphenylporphyrin. Separation of fullerenes C_{60} and C_{70} was accounted for by formation of a host–guest complex of the porphyrin with fullerene.

To independently detect possible interactions between DB-24-C-8 and C_{60}, we measured the UV/Vis and IR spectra of the individual components and their associate [6]. The UV/Vis spectrum of the mixture (Fig. 4) contains a new absorption band with a maximum at $\lambda = 474$ nm, absent in the spectra of the components taken separately.

CONCLUSION

The mixed C_{60} + DB-24-C-8 stationary phase for gas chromatography shows high selectivity and high performance in separation of mixtures of organic compounds with various functional groups, so that their derivatization is not required.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Organic Compounds for Preparing Lustrous Tin Coatings

G. I. Medvedev, N. A. Makrushin, and A. N. Dubenkov

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received February 7, 2002

Abstract—Organic compounds for preparing lustrous tin coatings were selected taking into account their ionization potential. The best electrolyte composition for plating these coatings was determined.

Various organic compounds are added to sulfate electrolytes for tin-plating [1]. To obtain dense finely crystalline dull or lustrous coatings, these electrolytes should contain colloid-forming compounds (glue, gelatin) and wetting agents (e.g., ethylene oxide condensation products) along with other organic compounds. Unsaturated alcohols, ketones, aldehydes, and products of the electrochemical synthesis are used for preparing lustrous tin coatings [1–3]. It should be noted that organic compounds for plating lustrous tin coatings are selected empirically.

Nechaev *et al*. [4–7] showed that the sorption on the surface of tin and other metals is caused by not only electrostatic interactions but also chemical bonding. The chemisorption is maximal when the energy of electronic levels of the metal is similar to that of the molecular orbital of the organic compound, which provides formation of donor–acceptor bonds between the molecules of the additive and the metal surface. Under these conditions the occupied molecular orbitals of the adsorbent and the adsorbate overlap to form a common electronic system. The correlation between the adsorption properties of organic compounds and the energy of the highest occupied molecular orbital (MO) can be quantitatively characterized by the first ionization potential *I*.

According to [4–7], the range of *I* of organic compounds optimal for their sorption on tin is 7.74–7.96 eV. The second maximum is observed at *I* = 9.6 eV. To explain this phenomenon, Nechaev and Volgina suggested [8] that the tin surface consists of pure and oxidized regions. However, the dependence of the adsorption energy on *I*, measured on cathodically polarized tin whose surface is constantly renewed (oxide formation is thermodynamically forbidden), also has two maxima. It was suggested that not only highest occupied MO characterized by the first *I* but also other occupied orbitals are involved in the bonding. Dull finely crystalline tin coatings were plated from sulfate electrolyte containing organic compounds with *I* = 7.8–8.0 eV [4, 5, 10]. Introductions of compounds with *I* = 9.5–9.7 eV makes the coatings compact, uniform, and semilustrous. Organic compounds with *I* other than 7.8–8.0 and 9.5–9.7 eV do not inhibit tin-plating. No high-quality coating are formed in their presence.

In this work, taking into account *I* of organic compounds, we selected such compounds or their mixtures that provide plating of lustrous tin coating from sulfate electrolyte.

For this purpose we mainly used an electrolyte containing 30 g l^{-1} $SnSO_4$ and 100 g l^{-1} H_2SO_4. The coatings were plated at 20–22°C with or without stirring of the electrolyte with a mechanical stirrer.

The tested organic compounds are presented in the table.

Condensation products Syntanol DS-10 (*I* = 9.4 eV), OP-7, OP-10 (*I* = 9.3 eV), OS-20 (*I* = 9.2 eV), VA-20 smoothing agent (*I* = 9.5 eV), hide glue, and gelatin (*I* = 7.5 eV) were also studied.

The ionization potentials of the tested organic compounds ranged from 6.88 to 12.2 eV. The concentration of these compounds was varied from 1 to 15 g l^{-1}. Saturated solutions of difficultly soluble compounds were used. The ionization potentials of organic compounds were taken from [6, 7] or calculated by the PM3 method [11].

The most precise experimental procedure for determining ionization potentials of atoms and molecules is PES [12]. In this work, the *I* values determined by PES were correlated with those calculated quantum-chemically. First, we examined how semiempirical

methods for calculating the electronic structure (MNDO, AM1, and PM3) and *ab initio* methods with STO-3G and 3-21G basis sets describe PES data.

We found that the PM3 method [11] gives the most satisfactory results. In this case, the ionization potentials of organic molecules can be calculated by the equation

$$I = 1.075I_{PM3} - 1.1679. \quad (1)$$

The correlation coefficient is 0.979.

The ionization potentials calculated by Eq. (1) from the PM3 data are given in the table (the corresponding compounds are denoted with asterisks).

The degree of luster of the coatings was measured on an FB-2 photoelectric luster meter. The polarization curves were recorded with a P-5828 potentiostat under the potentiodynamic conditions. In the course of tin-plating, the capacitance of the electrical double layer was measured with a P-5021 ac bridge operating at 30 kHz in the successive substitution mode. Tin coatings 6–9 μm thick were plated on copper supports.

High-quality coatings were obtained in the presence of none of the tested organic compounds whose concentrations were varied in a wide range. The use of the glue and gelatin gave similar results. Dull finely crystalline coatings are formed in the presence of the condensation products in the electrolyte. When both condensation products and the organic compounds given in the table are present in the electrolyte, silvery dull coatings are obtained. Some sulfate electrolytes for plating lustrous tin coatings contain formaldehyde (I = 10.88 eV) along with luster-producing additives [1, 2]. Taking into account this fact, we performed the subsequent studies in electrolyte no. 2 containing 2 g l^{-1} Syntanol and 6 ml l^{-1} Formalin. Dull, semilustrous, and lustrous coatings were plated from these electrolyte in the presence of various organic additives. Depending on the electrolyte composition, lustrous coatings are formed at i_c = 1–12 A dm^{-2}.

The dependence of the luster L (%) of the coating plated from electrolyte no. 2 with mechanical stirring on I of organic additives is shown in Fig. 1. Two maxima in this curve correspond to formation of lustrous coating. The first maximum appears at I = 7.25 eV (diphenylamine). The second maximum is observed in a broader range of ionization potentials (I = 8.95– 10.43 V), i.e., lustrous coatings are plated in the presence of benzyl alcohol, coumarin, 2-butene-1,4-diol, acetic anhydride, benzenesulfonic acid, 2-butyne-1,4-diol, *p*-phenolsulfonic acid, propargyl

alcohol, or butane-1,4-diol [13, 14]. Lustrous coatings are also formed when these additives are present in combination with smoothing agents and formaldehyde. It should be noted that lustrous coatings are plated from electrolyte containing OP-7, OP-10, and OS-20 condensation products and luster-producing agents without addition of formaldehyde [15]. Formaldehyde addition is not required also when luster-producing agents, gelatin (glue), and cresol are present in the electrolyte [3].

Previously we found [16] that formaldehyde in an electrolyte containing gelatin (glue) and cresol starts to exhibit luster-producing properties itself, but only after plating for a definite time.

It should be noted that high-quality lustrous films are plated only from the stirred electrolyte. Without stirring, dull coatings are formed.

The study of cathodic polarization in the electrolyte for tin-plating (Fig. 2) showed that the condensation products inhibit electrodeposition (curves *1, 2*).

The polarization curves flatten out at the limiting current. The polarization ΔE_c decreases (curves *2–4*) in the presence of the condensation products, formaldehyde, and luster-producing agents in the electrolyte.

The polarization also decreases with stirring of the electrolyte (curves *4, 5*). However, when the electrolyte contains condensation products, formaldehyde, and benzyl alcohol, ΔE_c increases (curves *6, 7*).

Probably, organic compounds present in the electrolyte are adsorbed on the electrode surface, thus inhibiting tin-plating. The measured capacitance of the electrical double layer C confirms this assumption. As seen from Fig. 3, the capacitance of the electrical double layer decreases in the presence of the organic compounds in the electrolyte (curves *1–3*). In this case, the C–E curves pass through a minimum at E from –0.3 to –0.4 V. In this potential range, C = 6–10 μF cm^{-2}. At higher potentials, the continuity of the adsorption layer is broken owing to desorption of organic compounds from the cathode surface. As a result, the capacitance of the electrical double layer increases [17].

Thus, to obtain lustrous tin coating, the electrolyte should contain an inhibitor, formaldehyde, and a luster-producing agent or an inhibitor and a luster-producing agent.

An inhibitor decelerates tin-plating and provides formation of dull finely crystalline deposits. Condensation products (Syntanol DS-10, OP-7, OP-10, OS-20), VA-20 smoothing agent, gelatin, and glue

(*1*) Electrolyte no. 1; (*2*) 1 + Syntanol, 2 g l^{-1}; (*3*) *2* + Formalin, 6 ml l^{-1}; (*4*) *3* + propargyl alcohol, 10 ml l^{-1}; (*5*) *4* with stirring; (*6*) *3* + benzyl alcohol, 6 ml l^{-1}; and (*7*) *6* with stirring.

can be used as inhibitors. However, the two latter substances weakly inhibit tin-plating. In this case, cresols (I = 8.24–8.31 eV), phenols (I = 8.5 eV), and naphthols (I = 7.76–7.78 eV) should be added to the elec-

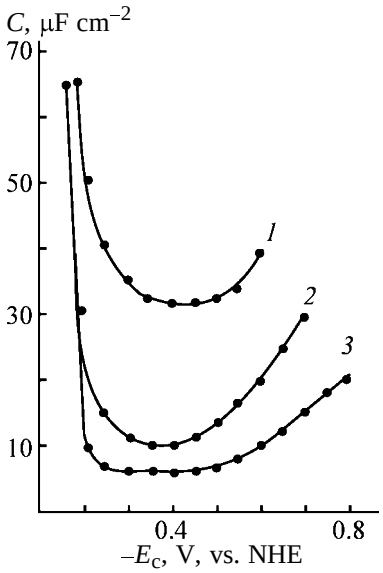

Fig. 3. Capacitance of the electrical double layer C as a function of the cathodic potential E_C: (*1*) electrolyte no. 1; (*2*) *1* + Syntanol, 2 g l^{-1} + Formalin, 6 ml l^{-1} + propargyl alcohol, 10 ml l^{-1}; (*3*) *1* + Syntanol, 2 g l^{-1} + Formalin, 6 ml l^{-1} + benzyl alcohol, 6 ml l^{-1}.

trolyte to obtain high-quality dull coatings [1, 2]. Formaldehyde (I = 10.88 eV) present in the electrolyte is a depolarizer of the process. Organic compounds with I = 7.25 and 8.95–10.43 eV exhibit lister-producing properties.

The fact that lustrous coating are formed only at a definite combination of organic compounds and stirring of the electrolyte suggests that sorption of organic compounds on the cathode surface is necessary but insufficient for obtaining such coatings. In this case, there are other factors affecting the luster of the coatings. Among them are complex physicochemical processes occurring in the catholyte layer [2] and the conditions of diffusion hydrodynamic feeding (or removal) of ions, which change the structure and properties of the absorption layer on the cathode surface [18].

Thus, the proposed approach affords a criterion of selection of organic compounds that, in combination with inhibitors, may provide formation of lustrous tin coatings. However, it does not warrant obtaining such coatings with particular additives *a priori*. Electrolytes for plating lustrous tin coatings are developed on the basis of this principle [13–16, 19, 20].

CONCLUSIONS

(1) Organic compounds promising for plating lustrous tin coatings were selected taking into account their first ionization potential. Lustrous tin coating were plated from the electrolyte containing an inhibitor, formaldehyde, and a luster-producing agent or an inhibitor and a luster-producing agent.

(2) Products of ethylene oxide condensation (Syntanol DS-10, OP-7, OP-10, and OS-20), VA-20 smoothing agent, as well as gelatin and glue in combinations with cresol, phenol, or naphthol can be used as inhibitors.

(3) Diphenylamine (I = 7.25 eV), benzyl alcohol (I = 8.95 eV), coumarin (I = 8.97 eV), 2-butene-1,4-diol (I = 9.13 eV), acetic anhydride (I = 9.5 eV), benzenesulfonic acid (I = 9.8 eV), 2-butyne-1,4-diol (I = 9.77 eV), *p*-phenolsulfonic acid (I = 9.8 eV), propargyl alcohol (I = 10.41 eV), and butane-1,4-diol (I = 10.43 eV) can be used as luster-producing additives to tin-plating electrolyte.

(4) The luster-producing additives allow plating of lustrous coatings from electrolyte containing or not containing formaldehyde, depending on the particular inhibitor. In the presence of gelatin, glue, and cresol, formaldehyde exhibits luster-producing properties.

(5) The proposed approach can be used to select organic compounds that may provide formation of lustrous tin coatings from electrolyte containing inhibitors.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Intensification of Fabrication of Nickel Oxide Metal–Ceramic Electrodes by Chloride Impregnation

T. E. Kuzina and A. A. Bachaev

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received November 27, 2001; in final form, August 2002

Abstract—The possibility of making shorter the time of fabrication of a nickel oxide electrode by impregnation of the metal–ceramic support with a nickel(II) solution and subsequent treatment with a solution of potassium hydroxide, containing potassium permanganate, was analyzed.

Electrodes on metal-ceramic (MC) supports for alkaline batteries have better specific characteristics than electrodes of other designs [1]. Nickel oxide electrodes (NOEs) of this kind are fabricated by high-temperature impregnation of an MC support in solutions of nickel(II) salts, most frequently nitrates, with high concentration. Several cycles are performed in order to introduce into the support a sufficient amount of nickel(II) compounds, with each cycle involving the entire process chain, including the alkaline treatment of the nickel(II) salts in pores of the support [1]. Fabrication of MC NOE is a time-, power-, and labor-consuming process.

The specific characteristics of MC electrodes are determined by the initial porosity and surface activity of the support, pore structure, concentration of the impregnating solution, activity of the forming nickel(II) hydroxide, and ability of nickel particles in the MC support to react with the impregnating solution to give additional electrochemically active nickel compounds in pores. The opening of blind pores, occurring in the process, is accompanied by development of the reaction surface. In some cases, industrial technologies envisage preliminary etching of supports in a hydrochloric acid solution to open pores and activate the surface of nickel supports [2].

The aim of this study was to analyze the possibility of replacing the commonly used impregnating solution of $Ni(NO_3)_2$ [1] by an $NiCl_2$ solution. The latter possesses a number of advantages over the nitrate solution [3]: the solubility in terms of nickel at 80°C increases from 320 to 380 g l^{-1}, the viscosity of a 30% solution at 80°C decreases from 1.3×10^{-3} to 1.2×10^{-3} Pa s, and the solution has higher corrosive activity. The last factor makes it possible to tackle with the problem of opening of blind pores in the support and activation of its surface in a single process cycle, with the stage of preliminary etching of supports in a hydrochloric acid solution eliminated.

EXPERIMENTAL

MC supports with dimensions of $34 \times 10 \times 0.75$ mm were used in corrosion tests, and those with dimensions of $40 \times 27 \times 1.6$ mm, for determining the change in mass and electrical characteristics. The volume porosity of the supports was 70–75%. The MC supports were filled with nickel(II) hydroxide by the following procedure (with no indication of occasionally used improving additives) [1, 4]: impregnation with $NiCl_2$ solution ($c_{Ni(II)}$ = 290–365 g l^{-1}, pH 3–4, temperature 60–80°C), crystallization in air (30 min), treatment with an alkali solution (c_{KOH} = 300–330 g l^{-1}, T = 60–80°C, τ = 1 h), washing to remove the alkali, and drying (T = 110°C). The content of residual chlorine (Cl^- ions) in the washing water after MC NOE treatment in an alkali solution was found using the procedure described in [5]. The mass gain of MC supports was determined from the difference of masses before impregnation and after drying. To find the amount of nickel oxidized in impregnation of an MC support, the method of selective dissolution of nickel(II) hydroxide from electrodes in a 30% solution of CH_3COOH was used. The difference of MC support masses before impregnation and after selective dissolution corresponded to the amount of oxidized nickel. The amount of nickel dissolved in CH_3COOH, found by complexometric titration [6], corresponded to the total amount of nickel(II) hydroxide formed via pore filling with the salt from the impregnating solution and nickel from the support, oxidized in the

1070-4272/02/7511-1804$27.00 © 2002 MAIK "Nauka/Interperiodica"

course of its impregnation. The optimal conditions for chloride impregnation were found by full factorial experimental design. The process of nickel etching was monitored on a prototype battery in the form of a voltaic cell with relatively large electrodes (S = 14 cm^2), with platinum as cathode and MC support as anode. The cathode and anode spaces in the cell were separated by a porous diaphragm (Khlorin fabric). The cathode space was filled with a solution under study, and the anode space, with an $NiCl_2$ solution. Both the solutions had the same ionic strength, for which purpose KNO_3 and NaCl, respectively, were added. The operation of a short-circuited voltaic cell Ni–Pt only qualitatively models the operation of real cells, since, in the course of nickel etching, microirregularities continuously move over the surface, and, what is more, platinum may exert electrocatalytic effect on the process.

The capacity characteristics of the electrodes fabricated were tested in cells with auxiliary electrodes made of perforated nickel foil with perforated polyvinyl chloride plastic as separator. As electrolyte served KOH solution with a density of 1.19–1.20 g cm^{-3}. In charging, 150% of the theoretical capacity was imparted to the electrodes at a current density of 4.4 mA cm^{-2} [4]. Discharge was done at the same current density until an abrupt change in the working potential.

Nickel dissolves in impregnation of MC supports by the electrochemical mechanism [1]. In $NiCl_2$ solutions, nickel oxidation occurs via reduction of dissolved oxygen and free hydrogen ions. The content of dissolved oxygen in $NiCl_2$ solutions is low (solubility of oxygen at 80°C in a 3–4.5 M $NiCl_2$ solution is 0.3–0.5 $cm^3\ l^{-1}$ [7]). The dissolution of nickel from the MC support (Fig. 1) proceeds with pronounced (96%) cathodic control over the process. Interaction of nickel with an acidic (pH 3–4) $NiCl_2$ solution leads to fast alkalization of the solution in the near-cathode layer with deposition of hydroxide films shielding the metal surface. This hinders the process of nickel dissolution and, presumably, is one of the reasons for lower use factors of MC electrodes in chloride impregnation, compared to electrodes subjected to treatment in a nitrate impregnating solution [4]. However, faster formation of solid products in the case of the chloride impregnation technique [1] must decrease the loss of dissolving nickel through its removal into the external volume of the electrolyte, which points to reserves of the capacitance characteristics of electrodes of this kind.

Up to 16–20% of nickel from the support passes

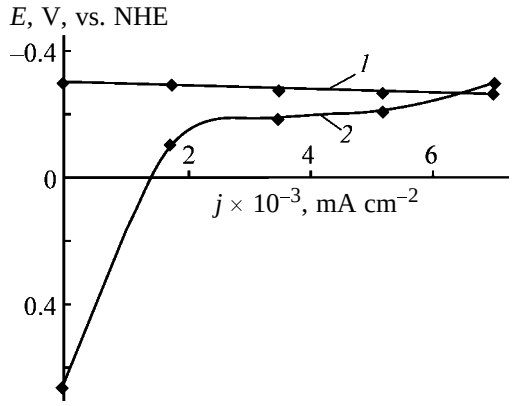

Fig. 1. Variation of the potential E of (*1*) MC support and (*2*) Pt electrode in cell operation in an $NiCl_2$ solution at T = 80°C, $c_{Ni(II)}$ = 360 g l^{-1}. (*j*) Current density.

into the active substance in impregnation of MC supports in an $NiCl_2$ solution containing 0.05–0.1 g l^{-1} $NaNO_2$, [4], and 11–15% in the case of a nitrate impregnating solution [8], which may be due to different oxidizing powers of the nitrate and nitrite ions [1, 4] (Fig. 2).

The forming nickel compounds hinder dissolution of the metal from the support. However, these compounds can be oxidized and act as oxidizing agents in subsequent oxidation.

For example, dry-charged NOE can be obtained using chemical oxidation of finished electrodes with hydrogen peroxide, hypochlorite, persulfate, or hypobromite [9]. The resulting formation of higher nickel hydroxides, which are in contact with nickel in the support, favors dissolution of the latter; in addition, the higher density of higher nickel hydroxides may give rise to porosity in the solid film [7].

Table 1. Relative mass loss, Δm, by MC supports after the first and second cycles of impregnation in an $NiCl_2$ solution and content of chlorine ions c_{Cl^-} in washing water for different types of treatment. $c_{Ni(II)}$ = 320 g l^{-1}, τ = 1 h, T = 60°C

Control	0.45	0.08	81.8
3% $KMnO_4$ (experiment)	0.45	4.0	24.3

In [6], readily available potassium permanganate $KMnO_4$ in an alkali solution was used as oxidizing agent. Reduction of MnO_4^- leads to formation of MnOOH-like structures, which are similar to NiOOH [10]. The close similarity of structures and ionic radii of Mn^{3+} and Ni^{3+} allows the former to be incorporated into the crystal lattice of NiOOH, making higher the concentration of electronic defects, which facilitates the charging of nickel oxide electrodes [10]. Permanganate treatment leads to formation of NiOOH in pores of MC supports, which acts in subsequent impregnation cycles as a depolarizer of nickel dissolution. In operation of an $NiOOH/Ni_{met}$ voltaic couple, the amount of nickel oxidized in MC supports in the second impregnation cycle increased 50-fold, compared to the control (Table 1). The forming nickel(III) oxide has a structure of β-NiOOH, which is indirectly confirmed by the oxidation state of nickel (equal to 3 for the β-NiOOH phase and 3.7 for γ-NiOOH) and by the potential of its reduction, which is more negative than the potential of γ-NiOOH reduction [11].

The most pronounced change in the electrode mass and the highest discharge capacity were achieved under the following conditions of MC support impregnation in $NiCl_2$ solution: $c_{Ni(II)}$ = 360–365 g l^{-1}, T = 65–70°C, and τ = 150 min.

After three impregnation cycles in nickel chloride solutions and subsequent intermediate oxidation, electrodes with perforated foil as current lead changed their mass by 0.76 g cm^{-3} and had the capacity Q = 0.19 A h cm^{-3} (Table 2).

The results obtained in measuring the change in mass and specific discharge capacity were also verified on 1.6-mm-thick MC supports with nickel mesh as current lead.

The change in mass of the electrodes under study after three impregnation cycles is approximately 1.4 times larger for 0.75-mm-thick supports, and 1.8 times larger for 1.6-mm-thick supports (Table 2). The amount of the active substance formed through oxidation of nickel from the support is 35% in the case of permanganate oxidation, and 7% in the control treatment. The change in mass after the first cycle of impregnation with intermediate oxidation is 1.4–2 times that in the control, possibly because of the presence of potassium permanganate reduction products (Table 2).

The electrical characteristics of compacted MC NOE fabricated with intermediate oxidation approach after three cycles of impregnation those of the elec-

* Q is the specific discharge capacity, and K_{use} is the use factor of the active paste.

trodes fabricated by the nitrate technology (0.32–0.37 A h cm^{-3} [8]). However, three cycles of nitrate impregnation take 20–24 h [8], whereas with the method being tested, MC NOE can be fabricated in 15 h, and this is achieved without preliminary etching of MC supports stored for several years.

Use of a $KMnO_4$ additive makes it possible to lower significantly the content of chlorine impurity in the electrodes. In subsequent impregnation of MC electrodes, MnO_2 contained in their pores can oxidize Cl^- ions in acid medium [10]:

$$2Cl^- + 4H^+ + MnO_2 \rightarrow Mn^{2+} + 2H_2O + Cl_2\uparrow.$$

As a result, the content of Cl^- ions in washing waters (serving as a criterion of their content in electrodes) decreased by a factor of approximately 3 (Table 1).

The recommended solution compositions and process modes are as follows: impregnation with $NiCl_2$ solution, $c_{Ni(II)}$ = 360–365 g l^{-1}, T = 65–70°C, τ = 150 min; treatment with alkali solution: c_{KOH} = 300–330 g l^{-1}, c_{KMnO_4} = 25–30 g l^{-1}, T = 60–80°C, τ = 1 h.

CONCLUSIONS

(1) The time required for fabrication of metal–ceramic nickel oxide electrodes is shortened by 25–40% in the case of intermediate oxidation of the active substance in an alkali solution containing $KMnO_4$.

(2) The duration of the process is decreased because of the intensification of anodic dissolution of nickel from metal–ceramic supports by the electrochemical mechanism with cathodic control.

(3) A procedure for chloride impregnation is proposed, which allows fabrication of electrodes of capacity 0.29 A h cm^{-3} without any additional activation of the support.

Abstract—The corrosion behavior at 25°C of tin plate, used for canning, in synthetic and natural brine solutions employed in storage of a number of food products (legumes) was studied.

Some kinds of foodstuff are stored in cans made of tin plate, in NaCl brine solutions. In the course of storage, the brine composition may change. For example, organic acids contained in the product may pass into brine and affect the corrosion of tin. In some cases, oxidizing agents and salts creating an alkaline medium are added to brine solutions.

Previously [1], it has been shown that tin is fairly corrosion-resistant in NaCl brine solutions. Addition of very small amounts of nitrates (up to 0.01 g) leads to acceleration of corrosion in storage of foodstuff with pH < 7. Under these conditions, corrosion processes may occur via reduction of nitrate ions with NH_4^+.

The composition of brine solutions depends on the temperature of product treatment, salt additives used to preserve the commercial value of the product, and storage time. Account should be taken of the influence exerted on the corrosion rate of tin plate by trace amounts of oxygen contained in brine solutions after can sealing.

This study is concerned with the corrosion behavior of electrolytic tin plate in synthetic and natural brine solutions used to store legumes (peas, kidney beans). Synthetic brine solutions were prepared from NaCl with and without addition of $NaNO_3$.

EXPERIMENTAL

The study was performed with samples of E-1 tin plate (manufactured by Sartid 1913 plant, Belye zhesti Joint-Stock Company, Sabac). Legume seeds were stored at 25°C in hermetically sealed containers made of unvarnished tin plate. During storage, natural brine was extracted after 1, 5, 12, and 18 months of storage and electrodes of area 1 cm^2 were cut out of the plate. The nonworking side of the electrodes was insulated with epoxy resin.

Synthetic brine solutions were prepared from chemically pure grade reagents and had concentration commonly used in storage of legumes [peas (I) and kidney beans (II)], namely, 25% NaCl, with and without addition of 0.015% $NaNO_3$.

The current and potential of corrosion were determined potentiometrically by the Evans–Hore galvanostatic technique [2–12] in an electrolytic cell with three electrodes: tin plate as working electrode, armco iron as auxiliary electrode, and calomel electrode as reference.

The measurements were carried out under natural aeration conditions and in an atmosphere of inert gas (nitrogen). To remove dissolved oxygen, nitrogen was passed through the solution. Preliminarily, nitrogen was passed (to remove trace amounts of oxygen) successively through a vessel containing an ammonium metavanadate solution, on whose bottom 25 g of zinc amalgam was placed [13], and through a column containing P_2O_5 with a 3 Å molecular sieve.

The currents and potentials were found graphically from the intersection of polarization curves. The corrosion currents i_{corr} ($\mu A\ cm^{-2}$) were recalculated into the corrosion depth factor V ($mm\ year^{-1}$) by the formula

$$V = \frac{mK}{\rho S \tau} = \frac{M i_{corr} 8.76 \times 10^4}{zF\rho}, \qquad (1)$$

where M is the molar mass of tin ($g\ mol^{-1}$); ρ, the density of tin plate ($g\ cm^{-3}$); F, the Faraday number ($C\ mol^{-1}$); S, the area (cm^2); τ, time (h); z, the num-

Table 1. pH of brine solutions studied

Brine solution	pH after tests for indicated time, months				
	1 day	2	7	12	18
Synthetic, %:					
NaCl, 2.5	5.92	–	–	–	–
NaCl, 2.5 + $NaNO_3$, 0.015	5.88	–	–	–	–
Natural:					
for product I	6.24	6.23	6.22	6.21	6.22
for product II	5.45	5.29	5.14	5.18	

ber of electrons; and *K*, the coefficient taking into account the dimension of area and time.

Table 1 presents the results obtained in determining the pH of brine solutions used for storage of products I and II in relation to the testing time.

As seen from Table 1, the pH of brine solutions used to store product I remains virtually unchanged during the time of testing. The high pH value of brines used in storage of product I is due to an increased amount of basic salts added to the solution in the course of product treatment to preserve its commercial value. The rise in the acidity of brine solutions used to store product II with increasing duration of testing may be due to the activity of the methylesterase enzyme, which leads to deesterification of carboxy groups and to their dissociation.

Figure 1 shows corrosion diagrams, which make it possible to find graphically the potential and current of corrosion in air of tin plate in synthetic and natural brine solutions extracted after the first day of tests. It can be seen that the highest current of tin plate corrosion is observed in natural brines used to store product I (curve *1*), and the lowest, in brine solutions used for storage of product II (curve *2*). The tin corrosion in the initial period of time, as a rule, occurs under cathodic control.

The corrosion diagrams reflecting dissolution of tin plate in synthetic and natural brine solutions in an inert atmosphere are presented in Fig. 2, curves *3* and *4*. It can be seen that, in both cases, removal of dissolved oxygen makes lower the current of tin plate corrosion.

Figure 3 shows how the current of tin corrosion in the solutions under study varies with time of testing (a) in air and (b) in an inert atmosphere. In all cases, a steep increase in corrosion current is observed during the first month of tests. Further, the dissolution of tin is hindered somewhat, with this phenomenon observed in both synthetic and natural brine solutions. Addition of $NaNO_3$ suppresses to some extent the corrosion of tin. Possibly this is due to inhibition under the given conditions of tin dissolution. In natural brines used to store product II, the rate of tin corrosion is higher than that in brines used in storage of product I. This is, in the first place, due to the higher temperature of treatment of product II and to introduction into the brine of additives aimed to preserve the commercial quality of the product. All these factors lead to a decrease in the brine pH during storage (Table 1) and to an increase in the rate of tin corrosion.

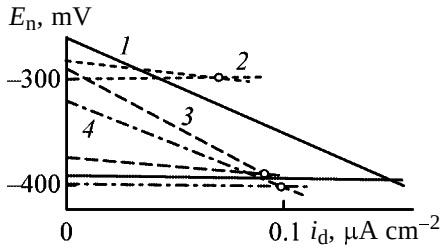

Fig. 1. Relationship between current i_d and potential E_n in polarization of tin plate in air after the first day of storage. (*1*) Liquid content of product I, (*2*) that of product II, (*3*) 2.5% solution of NaCl, and (*4*) 2.5% solution of NaCl + 0.015% Na_2CO_3; the same for Fig. 3.

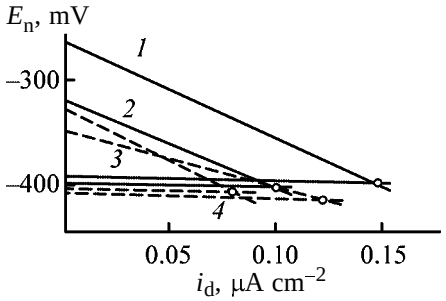

Fig. 2. Relationship between current i_d and potential E_n in polarization of tin plate in liquid content of products I and II in, respectively, (*1, 2*) air and (*3, 4*) nitrogen after the first day of storage.

	E, mV	–400	–418	–388	–402	–306	–407	–340	–348
	$V\times10^3$, mm year^{-1}	12.7	10.6	20.2	10.6	10.6	7.45	9.50	6.60

Table 2 presents corrosion potentials E, corrosion currents i_{corr}, and corrosion rates V in relation to test duration. It can be seen that, during 18 months of tests in all of the solutions studied, the corrosion rate of tin plate increases and the corrosion potential remains virtually unchanged. This indicates that, in the course of time, the corrosion of tin plate starts to proceed under mixed control conditions.

CONCLUSIONS

(1) Corrosion of tin plate in brine solutions becomes more pronounced with increasing test duration.

(2) Addition of $NaNO_3$ to brine solutions hinders the dissolution of tin plate.

(3) The rate of tin plate dissolution in an inert

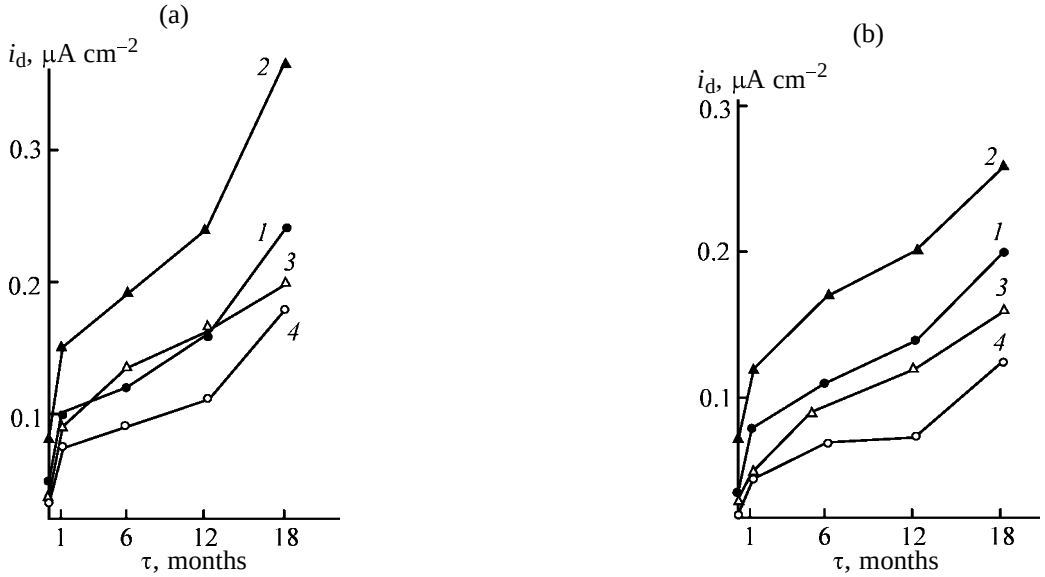

Fig. 3. Corrosion of tin plate vs. time of storage τ in (a) air and (b) nitrogen. (i_d) Corrosion current.

atmosphere is lower than that under natural aeration conditions.

CATALYSIS

Effect of Thermal Treatment on the Acidity and Catalytic Properties of Pentasil-Containing Catalysts

Received May 27, 2002

Abstract—The effect of thermal treatment of zeolite-containing catalysts on their acid and catalytic properties in aromatization of the long distillate of light hydrocarbons was studied.

One of application fields of Pentasil-containing catalysts is conversion of saturated hydrocarbons into aromatic compounds [1, 2]. These processes are carried out at 340–420 (aromatization of benzine fractions) or 500–600°C (conversion of C_3–C_4 alkanes), with the catalyst gradually deactivated by coking. To restore its catalytic properties, the catalyst is subjected to oxidizing regeneration at temperatures exceeding 550°C. During regeneration, zones with higher temperature may appear, and dehydroxylation, dealumination, and even disintegration of the crystalline framework of the zeolite are possible [3–5]. Therefore, one of the most important characteristics of catalysts is their thermal stability, which is largely determined by the SiO_2/Al_2O_3 molar ratio in the zeolite.

This study is concerned with the effect of thermal treatment on the acid and catalytic properties of catalysts synthesized on the basis of Pentasils of varied composition in aromatization of the long distillate of light hydrocarbons (LDLH).

EXPERIMENTAL

The starting zeolites of mixed structure, ZSM-5/11, with SiO_2/Al_2O_3 molar ratios of 30 and 60 were synthesized in the sodium form by crystallization of alkaline aluminosilicate hydrogels under hydrothermal conditions (pressure 5 atm, temperature 130–150°C, duration 94–96 h) using monoethanolamine as an organic template. The samples obtained were dried at 150°C for 3 h and calcined in air at 540°C for 16 h. The hydrogen form of Pentasils was obtained by treating the samples with NH_4NO_3 at 60°C to residual Na_2O content of 0.1 wt % and less, with subsequent conversion of the NH_4 form into the H form (thermal treatment in air flow at 540°C for 4 h). Catalyst samples were prepared by mixing 70 wt % Pentasils obtained with 30 wt % pseudoboehmite in a mixer and paste forming into sticks. It has been shown previously [2] that the presence of up to 40 wt % Al_2O_3 in catalysts of this kind has no noticeable effect on the activity and selectivity of a catalyst in aromatization of hydrocarbons.

To study the thermal stability, the catalyst samples were calcined in air at 600, 650, and 700°C for 6–24 h. The catalyst containing Pentasil with the molar ratio SiO_2/Al_2O_3 = 30 is denoted by TsSK, and that with SiO_2/Al_2O_3 = 60, by TsSK(M).

Transformations of LDLH were studied on a flow-through installation under atmospheric pressure in the temperature range 320–550°C and feed space velocity w of 0.5 h^{-1}. The working cycle comprised a 8-h experiment and 3-h catalyst regeneration with air at 550–580°C. The reaction products formed were analyzed by gas–liquid chromatography.

The LDLH characteristics are as follows: density at 20°C 0.675 g cm^{-3}, initial boiling point 27°C, final boiling point 185°C; content (wt %): *n*-paraffins 36.9, isoparaffins 43.8, naphthenes 16.8, and arenes 2.5.

The acid properties of the catalysts were studied by temperature-programmed desorption of ammonia on a Quarta Chrom instrument. The samples were heated in a helium flow to 600°C, kept at this temperature for 2 h, and then cooled to room temperature and saturated with ammonia. Thermal desorption of NH_3 was done at 100–575°C after removal of physically adsorbed ammonia.

The IR spectra were recorded on a UR-20 instrument. Samples for measurement of IR spectra of the

1070-4272/02/7511-1812$27.00 © 2002 MAIK "Nauka/Interperiodica"

zeolite framework (400–1300 cm^{-1}) were prepared by compaction into pellets with KBr; to study acid properties by adsorption of pyridine, catalyst pellets were pressed. The IR spectra of chemisorbed pyridine were recorded in the range 1400–3800 cm^{-1} after removal of weakly bound base molecules in a vacuum at 200°C.

X-ray diffraction analysis was performed on a DRON-3 diffractometer with monochromated CuK_α radiation (graphite monochromator in reflected beam).

According to the results of X-ray phase analysis, no changes in the crystallinity and pore structure of the catalysts occur after their thermal treatment at 550–700°C for 24 h and also upon 5 reaction–regeneration cycles. The IR spectra associated with framework vibrations of both the catalysts remained virtually unchanged after various treatments, which confirms that no disintegration of the crystal lattice of the zeolites occurs under the conditions studied.

It can be seen from Table 1 that, even after calcination at 700°C for 24 h, the specific surface area and pore volume do not decrease.

The nature of interaction between ammonia and the catalysts depends not only on their composition, but also on treatment conditions. As is known [6], ammonia is adsorbed onto decationized Pentasils in two forms: the peak at 100–350°C characterizes desorption of ammonia from "weak" acid centers, and that at 350–500°C, desorption from "strong" acid centers.

It can be seen from desorption patterns (Fig. 1) that raising the catalyst calcination temperature from 550 to 700°C makes lower the concentrations of both kinds of acid centers, especially that of strong centers. In the case of TsSK subjected to thermal treatment, the decrease in the total concentration of acid centers is much more pronounced compared to TsSK(M), and, as a result, the high-temperature peak characterizing strong acid centers is virtually absent in the desorption pattern of calcined TsSK.

Commonly, the decrease in the concentration of B centers in thermal treatment is related to zeolite dehydroxylation, during which one L center is formed from two B centers [7]. In this case, the IR spectra of pyridine adsorbed on the catalyst surface must show a decrease in the intensity of the absorption band associated with protonated pyridine (1550 cm^{-1}) and an increase in the intensity of the absorption band associated with coordination-bound pyridine (1450 cm^{-1}). However, it follows from the obtained IR spectra of adsorbed pyridine (Fig. 2) that, with increasing catalyst calcination temperature, the intensities of all absorption bands decrease, especially those of the bands at 1550 and 1491 cm^{-1} (at frequencies characterizing pyridine adsorption on both B and L centers, but to a greater extent related to that on B centers). In the spectrum of TsSK calcined at 700°C, these bands are virtually lacking at all. The simultaneous decrease in the intensity of the absorption band at 1450 cm^{-1}, i.e., in the concentration of L centers, suggests that the decrease in the concentration of strong B centers is due not only to dehydroxylation. Indeed, the IR spec-

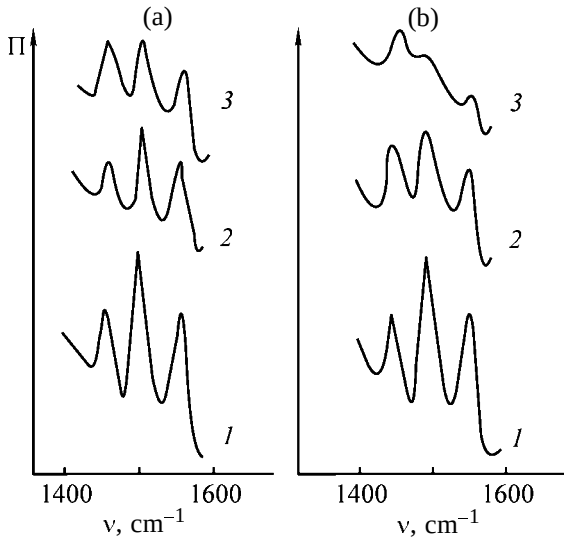

Fig. 2. IR spectra of pyridine adsorbed on TsSK samples calcined for (a) 1 and (b) 4 h. (∏) Absorption and (ν) wave number; the same for Fig. 3. Calcination temperature (°C): (*1*) 600, (*2*) 650, and (*3*) 700.

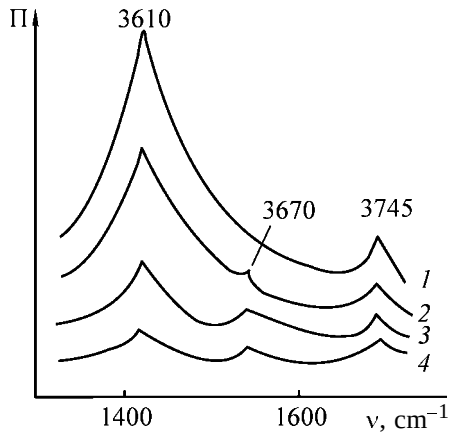

Fig. 3. IR spectra of fundamental vibrations of OH groups in calcined TsSK. Calcination temperature (°C): (*1*) 550, (*2*) 600, (*3*) 650, and (*4*) 700.

tra of catalysts subjected to thermal treatment contain (Fig. 3), together with the absorption bands peaked at 3610 (B centers, acidic bridging hydroxy groups, Si–OH–Al) and 3745 cm^{-1} (nonacidic terminal SiOH groups), also an additional absorption band at 3670 cm^{-1}, which can be assigned to OH groups bound to extra-framework aluminum appearing as a result of dealumination of the aluminosilicate lattice [8].

With increasing treatment temperature T_t, the intensities of the absorption bands at 3610 and 3745 cm^{-1}, associated with hydroxy groups, decrease and that of the band at 3670 cm^{-1} increases. Comparison of the IR spectra of the catalysts suggests that, in the case of TsSK, the extent of the dealumination process much exceeds that for TsSK(M).

Thus, the spectral data indicate that thermal treatment of the catalysts leads to surface rearrangement of the zeolite, during which the concentration and strength of acid centers change. The most typical is a dramatic change in the number of strong B centers. Since it is commonly believed that specifically B centers of Pentasils effect cracking of saturated hydrocarbons and the subsequent reactions with the forming olefins, it would be expected that the decrease in the acidity of thermally treated catalysts must change their catalytic activity in LDLH conversion.

Table 2 presents data on the effect of thermal treatment of the catalysts on the yield and composition of the reaction products obtained from LDLH at 360°C and $\omega = 0.5\ h^{-1}$. Raising the temperature T_t of thermal treatment of the catalysts changes their activity and selectivity: the amount of gaseous products decreases, the yield of the liquid catalyzate grows, and the conversion of paraffins and yield of aromatic hydrocarbons both decrease. In the composition of the gas phase, the content of olefins grows. At T_t = 600°C, TsSK is more active: a 1.6 times larger amount of aromatic hydrocarbons is formed on this catalyst, compared to TsSK(M). This is in agreement with the data on the catalyst acidity (Figs. 1a and 1b, curves *1*), whence follows that the number of strong acid centers on TsSK is 2 times that on TsSK(M).

In the case of TsSK, a noticeable decrease in the conversion of paraffins and in the content of arenes in the product formed is observed already at sample calcination temperature of 650°C, and on a sample calcined at 700°C, the concentration of aromatic hydrocarbons decreases twofold as compared to that at T_t = 600°C. TsSK(M) shows higher thermal stability: with a catalyst treated at 600 and 650°C, liquid products of close composition are obtained, whereas raising the treatment temperature to 700°C makes the conversion of paraffins lower, with the content of arenes decreasing by 5–10%.

CONCLUSIONS

(1) Thermal treatment of Pentasil-containing catalysts TsSK and TsSK(M) at 550–700°C strongly affects their acid and catalytic properties in conversion of the long distillate of light hydrocarbons.

(2) The number of strong B centers decreases to the greatest extent in high-temperature treatment of

CATALYSIS

Vanadium Catalysts Promoted with Magnesium Compounds for Production of Sulfuric Acid

S. M. Kuznetsova, E. I. Dobkina, L. A. Nefedova, and S. A. Lavrishcheva

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 6, 2002

Abstract—The feasibility and efficiency of promotion with magnesium compounds of supported and mixed catalysts for sulfuric acid production were studied.

Production of sulfuric acid based on catalytic oxidation of SO_2 on vanadium catalysts is one of the most large-tonnage processes in chemical industry. Efforts to make the production of sulfuric acid more efficient include development of new and improvement of existing processes and catalysts. The catalysts in the existing processes operate in a fairly broad range of temperatures and concentrations. To extend further this range, new flowsheets are developed, allowing gas conversion at a large concentration of sulfur dioxide under pressure. There is no universal catalyst exhibiting equally high performance under different reaction conditions [1–3]. To each range of temperatures corresponds its own optimal catalyst formulation.

Because the state of a catalyst essentially depends on reaction conditions, it should be expected that there should be certain optimal catalyst compositions ensuring the highest performance under different conditions.

For gas conversion at increased concentrations of sulfur (more than 10%), it is advisable to perform the process in a fluidized bed with a wear-resistant finely dispersed catalyst [2, 3].

In catalytic method of the sulfuric acid production, heterogeneous vanadium catalysts are used [3, 4]. Vanadium oxides dissolved in disulfates of alkali metals (promoters) containing more or less SO_3 are active components of all these catalysts [3, 4].

The most widely used promoter in industrial catalysts is readily available and cheap potassium. At the reaction temperature, the active component of the catalysts for sulfuric acid production exists as a molten mixture of the salts over the pore surface of a silicate support [4, 5].

The catalyst for oxidation of gases with increased concentration of SO_2 in a fluidized bed should exhibit activity in a wide temperature range, including $T \sim 380$°C, and low abradability during operation. The first condition is met by catalytic masses containing as promoters, along with alkali metal ions, also magnesium additives [1, 3].

The goal of this study was the development of promoted catalytic masses intended for production of sulfuric acid in fluidized and filtering beds.

EXPERIMENTAL

Because the catalysts in a fluidized bed should exhibit enhanced resistance, it is advisable to apply the active component onto appropriate support. The support should have the necessary strength and chemical composition, whose combination determines the catalyst activity and strength.

In various vanadium catalysts for sulfuric acid production, natural or artificial silicate materials serve as supports [2, 3, 6], in particular, spherical aluminosilicates with a low content of Al_2O_3 [3, 6].

In this study, aluminosilicate with a grain size of 0.4–1.2 mm, containing about 5.5% Al_2O_3, was the catalyst support. This material was subjected to hydrothermal treatment at 450–600°C for 6 h in a fluidized bed. The humidity of air fed for fluidizing ranged from 30 to 40%. The temperature was raised stepwise to 400, 500, 600, and 700°C; the heating time at each temperature was 2 h.

The heat treatment was done to enhance the water resistance of a support. As a result, we obtained aluminosilicates with the following structural characteristics: pore volume 0.6–0.7 $cm^3\,g^{-1}$ at the average pore radius of 5–6 nm and specific surface area of 210–250 $m^2\,g^{-1}$.

Table 1. Chemical composition of the catalyst samples

Sample no.	Composition of impregnating solution, g dm^{-3}			Catalyst composition, wt %			
	V_2O_5	K_2SO_4	$MgSO_4 \cdot 7H_2O$	V_2O_5	K_2O	MgO	K/V
1	40	120	–	6.4	12.1	–	3.64
2	60	120	–	9.6	13.1	–	2.64
3	80	120	–	10.0	13.4	–	2.58
4	100	120	–	11.6	13.1	–	2.20
5	50	130	–	7.3	12.6	–	3.35
6	40	120	30	6.6	11.8	0.6	3.46
7	50	130	40	7.3	12.0	0.65	3.20
8	50	130	30	6.8	12.1	0.55	3.41

The impregnation parameters were chosen based on the chemical composition characteristics that should ensure the conversion of concentrated gases, including those under pressure [1, 5, 6]. The amount of vanadium(V) oxide in the contact must be no less that 6 wt % at the ratio K/V > 2.5 and the magnesium oxide content of no more than 1 wt %.

Taking into account the porosity of the support used and data of the previous studies [3, 6], the concentration of the impregnating solution containing potassium vanadate and sulfate, as well as magnesium sulfate, was varied as follows (g dm^{-3}): V_2O_5 from 40 to 100, K_2SO_4 from 120 to 140, and $MgSO_4 \cdot 7H_2O$ from 30 to 40.

The impregnation was performed at the liquid-to-solid ratio of 1.5 for 2 h at 80°C. After the impregnating solution was decanted, granules were dried at 100–120°C and calcined for 2 h at 650°C. The characteristics of the chemical composition of the catalysts are presented in Table 1.

To adjust catalyst composition with respect to major components, i.e., potassium(I) and vanadium(V), sample nos. 1–5 were synthesized without addition of magnesium ions. Then, magnesium ions were added to sample nos. 1 and 5 chosen for further studies.

First, the activity of these samples was tested on a flow-through kinetic installation [3, 7] under standard conditions. In this case, the space velocity V was 4000 h^{-1}, the initial gas mixture contained 10 vol % SO_2 (the remainder was air), and the pressure was equal to atmospheric pressure. The conversion of SO_2 into SO_3 was 56–57% at 420°C and 91–92% at 485°C. At lower temperatures, this catalyst surpasses in activity the similar supported catalysts synthesized previously without addition of magnesium ions. Their activity at 420°C does not exceed 35%. The structural characteristics of the magnesium-containing catalyst (Fig. 1) are as follows:

Bulk density ρ_b, g cm^{-3}	0.74
True density ρ_t, g cm^{-3}	2.14
Apparent density ρ_{ap}, g cm^{-3}	1.1
Total pore volume ΣV, cm^3 g^{-1}	0.4–0.5
Specific surface area S_{sp}, m^2 g^{-1}	20–30
Average pore radius r, nm	80

The kinetic characteristics of sample nos. 5 and 8 were studied under conditions of SO_2 oxidation at elevated pressure (the study was performed at the Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Novosibirsk). The particle size was 0.180–0.315 mm, the gas mixture fed for oxidation contained (vol %) SO_2 12, O_2 12, and the remainder helium; the total gas pressure in a reactor was 8 atm. By varying the space velocity, we established how

the degree of sulfur dioxide conversion varies with contact time (s):

$$\tau = P/(\rho_b V_g),$$

where P is catalyst mass (g); ρ_b, bulk density, g cm^{-3}; V_g, space velocity of the gas mixture reduced to normal conditions, $ncm^3\ s^{-1}$.

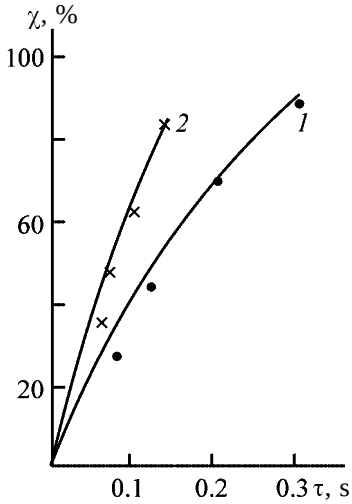

Fig. 2. Degree of SO_2 oxidation χ vs. contact time τ. T = 420°C and P = 8 atm. Gas mixture composition (vol %): SO_2 12, O_2 12, and the remainder helium. Sample: (*1*) no. 5 and (*2*) no. 8 (Table 1).

The results of the study are presented in Table 2 and Fig. 2.

As seen, the sample containing magnesium ions has the high kinetic characteristics over a wide temperature range. This makes it promising for SO_2 conversion at increased concentration and pressure [8].

Introduction of Mg(II) was also of interest in synthesis of filtering-bed catalysts prepared by another process. We chose a "mixed" process commonly used for preparing SVD catalysts for sulfuric acid production [3]. For this purpose, we used for the first time the silicate support containing (wt %) no more than 1–2 Al_2O_3, 0.2–0.3 MgO, and 0.8–1.2 K_2O + Na_2O [9]. This material is relatively cheap. Therefore, its use instead of diatomite seems appropriate. As noted above, in synthesis of the test sample with the new support, the main process parameters were fully reproduced.

The results of studying the kinetic characteristics under the given standard conditions, along with data on the heat resistance of the samples, are presented in Table 3.[1]

The heat resistance was determined by the method involving treatment for 10 h at 700°C with a gas mixture containing 15% SO_2 and 15.75% O_2 and subsequent measurement of the degree of deactivation.

The results obtained show that the catalyst on the new support containing magnesium(II) ions surpasses in activity and heat resistance the commercial SVD catalyst on diatomite. The degrees of the sulfur dioxide oxidation differ by 4–5% at 485°C and by about 15% at 420°C.

Apparently, this is explained by a unique combination of the oxides in both the initial support and the final catalyst. The simultaneous presence of certain amounts of potassium, sodium, and magnesium oxides ensures the strong promotion effect, especially at lower temperatures. This may be due to the lower melting point and lower viscosity of the active component, which are known [4] to facilitate promotion of sulfuric acid catalysts.

CONCLUSIONS

(1) It is appropriate to promote the catalysts of different types for production of sulfuric acid with magnesium compounds.

[1] The study was carried out at the Umpire Physicochemical Research Laboratory, Research Institute of Fertilizers and Insectofungicides (Moscow).

(2) The activity of the supported catalyst in conversion of gases with high concentration of sulfur dioxide was determined in a fluidized bed and at elevated pressure.

(3) It is appropriate to use the magnesium-containing silicate support instead of diatomite for the synthesis of the catalytic masses for SO_2 oxidation in a filtering bed.

(4) The introduction of Mg(II) enhanced the catalyst activity, especially in the low-temperature range.

CATALYSIS

Modification of Macrostructure of Silica Gels

E. I. Dobkina, S. M. Kuznetsova, L. A. Nefedova, and S. A. Lavrishcheva

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 18, 2002

Abstract—The possibility of physicochemical transformation of porous silica gels is studied.

The macrostructure of solid materials largely determines the intensity of a number of heterogeneous reactions, including catalysis and adsorption. For example, obtaining catalysts with a prescribed porosity is often a difficult problem [1–3]. The catalysts with the pore size considerably larger than that in standard commercial materials (active aluminum oxide, silica gels, and aluminosilicates) are frequently in demand. The structure considered to be macroporous as applied to sorbents may be extremely microporous and unsuitable as applied to many catalysts.

Transformation of aluminosilicate under the action of certain modifiers was considered and possible ways for controlling porosity within a wide range were demonstrated in [4, 5].

Owing to macro- and microstructural properties, aluminosilicates are widely used as sorbents and catalyst supports. Therefore, problems on controlling their porosity are of undoubted interest.

In this work, we used the method applied previously for modification of aluminosilicate in [5]. We pursued two goals: to check the versatility of the method and to transform the silica gel pore structure within a wide range.

EXPERIMENTAL

We used various silica gels: finely porous, medium-porous, and coarsely porous. All silica gels were impregnated with a potassium metavanadate solution and then dried and calcined. The treatment conditions were similar to those reported in [5]. The concentration of the potassium metavanadate solution was 120 g dm^{-3} V_2O_5; particle size, 1.5 mm; calcination temperature, 65°C; and time, 2 h.

The characteristics of the initial silica gels and modified samples are presented in Table 1. As seen, the molar ratio K_2O/V_2O_5 was above unity in all the systems, i.e., in the given case, as in impregnation of aluminosilicate, filling of pores with potassium metavanadate was accompanied by chemisorption of K^+ ions on accessible areas of the weakly acidic surface of the samples.

The integral structural curves for all the modified samples and two initial silica gels are shown in Fig. 1. As seen, all the silica gels undergo structural transformation under the action of potassium metavanadate. Only in the course of the calcination the modification is essential. Before high-temperature treatment, the initial and impregnated samples have very similar structures. The modification character is identical in all the silica gels: in the course of the treatment, the specific surface area decreases, the total pore volume decreases by 45–55%, and the average pore radius increases.

The extent of transformation is different in various silica gels. The most significant changes were ob-

served in coarsely porous and medium-porous samples (sample nos. 10 and 2, respectively). The structure of sample nos. 3 and 5 is transformed to a lesser extent. After treatment, their structure is multidispersed, and no pronounced maximum is observed. The pore size in the finest silica gel after modification is 150 Å on the average, i.e., it increased by only an order of magnitude.

Apparently, the structural transformation observed is due to the transformation of the silica gel skeleton, including size, shape, and mutual arrangement of globules [6]. Indeed, the electron-microscopic study of the impregnated and calcined silica gels revealed consolidation of the structural elements and transformation of the globular structure into quasi-globular structure (Fig. 2).

The structural similarity of aluminosilicates and silica gels and the close chemical compositions of the compounds obtained on their basis after impregnation with potassium metavanadate suggest that the mechanism of the porosity transformation in these materials under the action of vanadium(V) compounds at high temperatures is similar [2].

The content of the vanadium(V) compounds in silica gel can be varied by varying the number of impregnations, their time, and the concentration of the impregnating solution. In the tests, the potassium metavanadate concentration in terms of V_2O_5 was 50, 100, and 120 g cm^{-3}, which allowed introduction of different amounts of the modifier into the material. The heat-treatment conditions were always similar: 600°C and 2 h. As example we chose sample no. 1. As shown above, the structural transformations in it are more significant, and, consequently, the transformation pattern is more obvious. The results obtained are presented in Table 2 and Fig. 3.

The experimental data show that, with increasing modifier content in silica gel, the extent of the structural transformation also increases: the average pore radius increases, whereas the total porosity and the specific surface area decrease. Especially dramatic changes were observed in the sample containing 18 wt % V_2O_5 and 11 wt % K_2O (at a concentration of impregnating solution of 120 g dm^{-3} V_2O_5).

For the practice of catalysis, such a considerable increase in the pore radius accompanied by a dramatic decrease in the surface area is of little use. Therefore, it is appropriate to use solutions with a concentration less than 100 g dm^{-3}. Silica gel treated with less concentrated solutions (50 and 100 g dm^{-3} V_2O_5) contains less modifier and undergoes less considerable

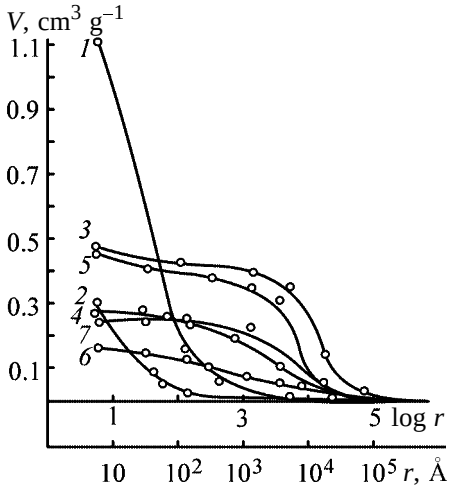

Fig. 1. Integral structural curves of the initial and modified silica gels (Table 1). (*V*) Total specific pore volume and (*r*) average pore radius; the same for Figs. 3–5. structural transformations. Thus, by varying the concentration of the potassium metavanadate impregnating solution, it is possible to finely modify the initial silica gel skeleton within a wide range.

The structural transformations as influenced by the calcination temperature were studied on a series of samples, which were impregnated with a KVO_3 aqueous solution containing 50 and 100 g dm^{-3} V_2O_5 and calcined at different temperatures from 400 to 700°C

600	54	2.24	0.89	0.67
700	6.2	2.25	0.93	0.64

for 2 h. The data for sample no. 1 are presented in Table 3 and Fig. 4. The pore structure of impregnated silica gel calcined at 400–500°C is similar to that of the initial material. As compared to the initial silica gel, the pore size, specific surface area, and total porosity slightly decrease. Apparently, the above structural transformation is due to deposition of the modifier in the pores of the initial support. As a result, the equivalent pore radius decreases, and a part of small pores becomes filled up.

The heat treatment of impregnated silica gels above 500°C results in dramatic changes in the pore-radius distribution. To each heat-treatment temperature corresponds a particular stable pore structure. With increasing temperature, the specific surface area decreases, but the total porosity varies insignificantly. In the 600–700°C range, the structural transformations are the most significant.

As in the case of aluminosilicate, the essence of the process observed is the formation of an eutectic mixture of the support (silica gel) and potassium vanadate. As the calcination temperature increases, the viscosity of the system decreases, and increasing amount of the support passes to the melt, i.e., the component ratio in the melt changes. The globules gradually increase in size owing to agglomeration. As a result, coarse pores are formed, whereas fine pores disappear.

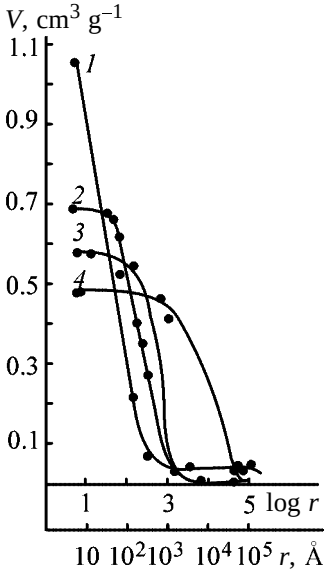

Fig. 3. Influence of the potassium metavanadate concentration on the extent of structural modification. Calcination temperature 600°C; τ = 2 h. (*1*) Initial silica gel; modified samples, V_2O_5 content in solution, g dm^{-3}: (*2*) 50, (*3*) 100, and (*4*) 120.

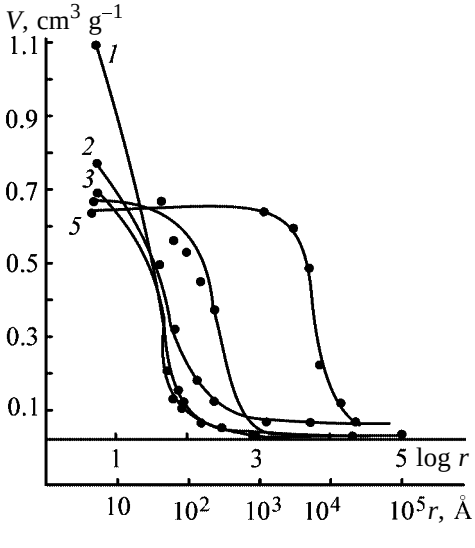

Fig. 4. Influence of the calcination temperture on the pore structure of silica gel (sample no. 1) impregnated with a potassium metavanadate solution. V_2O_5 concentration in solution 50 g dm^{-3}. (*1*) Initial silica gel; calcination temperature, °C: (*2*) 400, (*3*) 500, (*4*) 600, and (*5*) 700.

The irreversibility of transformation of the silica gel macrostructure under the influence of vanadium(V) compounds is the necessary condition for applying them as sorbents and catalyst supports. The second condition is that the content of the modifier in the transformed silica gels should be minimal and should not restrict their further use for catalyst support. The possibility of decreasing the modifier content was studied with sample no. 1 (Table 1), which was impregnated with a potassium metavanadate solution (50 g dm^{-3} V_2O_5) and calcined at 700°C for 2 h.

Based on many experiments, we chose the following conditions of washing off the modifier: liquid (H_2O)-to-solid ratio of 6, with the extractant replaced hourly. After 4 h of washing off, no potassium metavanadate was found in the wash water. The pore structure of the initial sample and that of the impregnated sample washed under the above conditions are characterized in Fig. 5. Washing of the modified silica gel removes about 60% of K_2O and 80% of V_2O_5 from the skeleton. However, the modifier is not removed from silica gel completely. In the wash water, the molar ratio of the extracted components, K_2O/V_2O_5, is 0.9, i.e., it is close to unity and corresponds to the water-soluble vanadium(V) compound KVO_3.

It should be noted that a minor amount of the modifier apparently remaining inside the silica gel globules is probably inactive and, therefore, "nontoxic" for sorbents and catalytically active substances deposited onto such a support.

Potassium oxide K_2O is removed from silica gel more actively than from aluminosilicates. This may be due to the fact that the surface of aluminosilicates is more acidic, and, as a consequence, it chemisorbs oxides, which therefore become difficultly extractable. The mutual influence of aluminum and silicon oxides in the aluminosilicate causes formation of strong acid centers [6, 7].

Treatment of silica gel with water does not noticeably alter the coarsely porous structure. At the same time, at the expense of a considerable amount of the extracted modifier, an additional pore volume is formed, and the specific surface area somewhat increases. Apparently, the increase in the surface area is also due to the fact that the surface of pore walls becomes rough owing to removal of crystals.

CONCLUSIONS

(1) The possibility of irreversible transformation of the pore structure of various silica gels was shown.

(2) The method of physicochemical structural transformation with KVO_3 modifier was chosen for silicate systems.

(3) The correlation of the modifier concentration and calcination temperature with the porosity characteristics was established.

(4) The data obtained can be used for forming the prescribed porosity of sorbents and supports intended for preparing certain catalytic masses.

CATALYSIS

Sorption and Catalytic Activity of Adsorbent–Catalyst Based on Montmorillonite Modified with Cr(III) and Cu(II) Mixed Oxides

Abstract—The sorption properties of mixed adsorbent–catalyst based on high-silica zeolite and montmorillonite modified with mixed oxides of Cr(III) and Cu(II) with respect to organic compounds of various classes were studied, and the optimal dynamic conditions of its operation were determined.

Utilization of organic solvents in industrial production poses a problem of minimization of their environmental hazard. The majority of common procedures of the exhaust treatment are unprofitable; they require special systems of the gas treatment, rather expensive catalysts, and complex equipment for their regeneration. Moreover, these methods are efficient only at fairly high concentration of organic compounds. At the same time, utilization of sorbent–catalysts in the first stage allows concentration of compounds occurring in amounts close to maximum permissible concentration, with their subsequent flameless catalytic oxidation to carbon dioxide and water. Hence, sorption-catalytic treatment of exhaust gases is rather promising due to the absence of regeneration stages, low temperature, and some other features of the process minimizing formation of by-products.

As seen from the published data, sorbent–catalysts based on high-silica zeolites (HSZs) are of particular interest. To perform exhaustive oxidation of organic compounds to CO_2 and water these materials should contain additional catalytic phase supported by layered montmorillonite commonly used as a binder in the zeolite granulation. Such layered materials undergo easy modification based on expansion of aluminosilicate layers at a certain distance by hydroxy complexes of polyvalent metal cations, which after calcination form oxide clusters fixing clay layers and acting as an active catalytic phase [1, 2]. The resulting interlayer spacing is determined by the nature of the metal cation as a complex-forming agent and by the procedure of hydroxy complex preparation. It can reach 2.5 nm, which allows utilization of this material in sorption of large organic molecules [3].

As shown in [4, 5], layered aluminosilicates modified with heteronuclear polyhydroxy complexes exhibit higher catalytic activity as compared to analogous minerals modified with homonuclear polyhydroxy complexes [6, 7]. Among catalys containing no expensive metals, mixed Cr–Cu oxide catalysts show high performance in exhaustive oxidation of organic compounds [8, 9]. This fact determined our choice of chromium–copper systems as intercalating agents.

In this work we studied the sorption and catalytic properties of composites based on high-silica zeolites and montmorillonite intercalated with polyhydroxy complexes of chromium and copper.

EXPERIMENTAL

The required layered-columnar material was prepared from montmorillonite clay from the Askan field. The heteronuclear polyhydroxy complexes were prepared by directed hydrolysis of chromium chloride; for this purpose a 0.2 M NaOH solution was added at a constant rate with stirring to a 0.2 M $CrCl_3$ solution until the OH^-/Cr^{3+} ratio (basicity degree) reached 2.0. The solution was aged for 24 h at 25°C and 0.2 M $CuCl_2$ solution was added in amounts providing equimolar (1 : 1) chromium–copper ratio. Then, after 3-day storage at 25°C, the montmorillonite suspension (3 wt %) was added to the solution of Cr–Cu polyhydroxy complexes to attain the concentration of Cr(III) of 10 mg-equiv per gram of montmorillonite. The mixture was stored for 2 h, and the resulting montmorillonite with fixed Cr–Cu polyhydroxy complexes (Cr : Cu-MM) was separated from the solution by centrifugation and washed with distilled water

1070-4272/02/7511-1824$27.00 © 2002 MAIK "Nauka/Interperiodica"

6–7 times. The resulting compound was thoroughly mixed with zeolite and A-175 brand Aerosil in 1 : 1 : 0.5 ratio. After drying, the resulting loose material was granulated on a tableting machine to obtain cylindrical granules 1–4 mm in diameter, which were dried in air and calcined at 500°C.

The specific surface area S_{sp} of the samples was evaluated from low-temperature sorption of nitrogen using a Micromeritics 2200 express analyzer. The value of the first basal deviation d_{200} of modified clays was determined on a Siemens 5000 diffractometer.

The sorption and catalytic properties of the resulting samples were measured using a gas mixture of the composition similar to that of the gas exhausts of the varnish-and-paint production. As seen from Table 1, the gas mixture prepared from chemically pure and analytically pure grade reagents contains various classes of organic compounds: saturated hydrocarbons, unsaturated hydrocarbons, alcohols, etc.

The concentrations of organic compounds were determined on a Tsvet-100 gas chromatograph equipped with a flame-ionization detector and a capillary column (d = 0.5 mm, l = 60 mm) coated with Carbowax-20; ultrapure grade nitrogen was used as a carrier gas. The content of CO in the waste gases was determined on an HP-5710A gas chromatograph equipped with a katharometer and a Teflon column (d = 3.5 mm, l = 2.5 m) packed with AG-3 activated carbon; carrier gas argon. The resulting chromatograms were interpreted using Multichrom 1.39 software.

The sorption and catalytic properties of the resulting samples were determined in both the static (in a desiccator) and dynamic modes on a pilot unit shown schematically in Fig. 1. Air is injected with blower *1* into a device *3* controlling the flow rate, which is equipped with vessel *2* warranting uniform gas flow. Then, the air passes chamber *5* containing a mixture of organic compounds and becomes saturated with its vapor, whose concentration was 80–100 mg m^{-3}. Organic compounds are sorbed from the air mixture in reactor *6* (d = 35 mm, l = 650 mm) packed with cylindrical granules of the sorbent–catalyst. The volume of this material was 100 ml.

The efficiency of sorption of organic compounds A (%) on the sorbent–catalyst under the dynamic conditions was calculated from the equation

$$A = \frac{c_i - c_o}{c_i} \times 100,$$

where c_i is the total content of organic compounds in the gas mixture at the reactor inlet and c_o is their content at the reactor outlet.

Table 1. Composition of the model gas mixture

Component	Content, wt %
n-Pentane	3.0
n-Decane	1.5
Ethylbenzene	12.0
p-Xylene	12.0
m-Xylene	41.0
o-Xylene	21.0
Isoamyl alcohol	7.0
Cellosolve	2.5

The sorption properties of the mixed sorbent–catalyst and initial compounds (Cr–Cu-MM and high-silica zeolite) with respect to some organic compounds determined under the static conditions are listed in Table 2. As seen, the sorption capacities of the initial compounds are similar. After calcination at 500°C, the sorption capacity for water of the Cr–Cu-MM sample strongly decreases from 7.50 to 4.62 mmol g^{-1}, which is due to the decrease in the volume of micropores [10]. After thermal treatment, the sorption capacity with respect to acetone and ethanol also decreases from 2.64 and 2.26 to 2.10 and 1.67 mmol g^{-1}, respectively. It should be noted that, after calcination, the sorption capacity of Cr–Cu-MM for benzene and toluene increases from 1.05 and 0.62 to 1.20 and 1.09 mmol g^{-1}, respectively. This is probably due to the increase in the average pore width in columnar clays after calcination [7]. This phenomenon

Table 2. Sorption of organic compounds and water on the sorbent–catalyst and initial compounds

Sample	Calcination temperature	Sorption, mmol g^{-1}				
		water	acetone	ethanol	benzene	toluene
Cr–Cu-MM	120	7.50	2.64 (35)*	2.26 (30)	1.05 (14)	0.62 (8)
	500	4.62	2.10 (45)	1.67 (36)	1.20 (26)	1.09 (24)
HSZ	200	7.80	2.62 (33)	2.30 (29)	1.16 (15)	0.70 (9)
HSZ–Aerosil–Cr–Cu-MM	500	4.46	2.66 (59)	2.54 (57)	1.75 (39)	1.24 (28)

* The ratio of the sorption capacity for the given substance to that for water (%) is given in parentheses.

was found previously at intercalation of montmorillonite with aluminum hydroxy cations, and it is probably a common property of columnar clays [11].

The sorption capacity of the composite sorbent–catalyst calcined at 500°C strongly differs from both Cr–Cu-MM and HSZ, especially with respect to aromatic compounds. For example, its sorption capacity for benzene and toluene is 1.75 and 1.24, whereas the respective sorption capacities of Cr–Cu-MM comprise 1.20 and 1,09 mmol g^{-1}, and those of HSZ, 1.16 and 0.70 mmol g^{-1}.

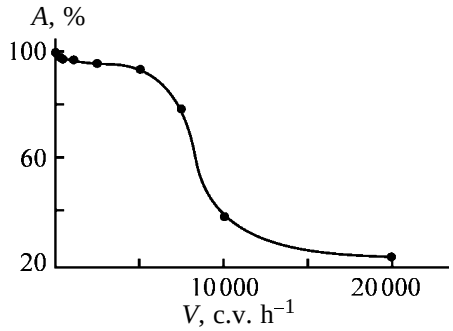

Fig. 2. Efficiency of sorption *A* of organic compounds from the gas mixture as a function of the space velocity *V* of the gas supply through the reactor packed with the sorbent–catalyst.

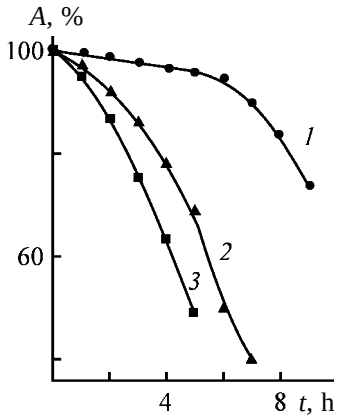

Fig. 3. Efficiency of sorption *A* of organic compounds from the gas mixture as a function of the operation time *t*. Temperature, °C: (*1*) 20, (*2*) 40, and (*3*) 70.

As seen from the ratio of sorption capacities for organic compounds and water (Table 2), the mixed sorbent–catalyst exhibits elevated affinity for organic molecules. This fact, indirectly confirming the selectivity of the sorbent in question, becomes important in sorption of organic compounds from humid air.

When studying the sorption capacity of the mixed sorbent–catalyst under the dynamic conditions, we varied the space velocity of the gas flow and its temperature.

The dependence of the efficiency of sorption of organic compounds *A* by the sorbent–catalyst on the inlet space velocity [column volumes per hour (c.v. h^{-1})] was measured at 20°C. The concentration of organic compounds at the reactor outlet was measured after passing 100 column volumes. As seen, at space velocity less than 500 c.v. h^{-1} the sorption efficiency reaches 95%. With increasing velocity of the gas supply to 10000 c.v. h^{-1}, *A* sharply decreases to 40, and then to 20% at 20000 c.v. h^{-1}.

Variations in the efficiency of sorption of organic compounds on the sorbent–catalyst in question as influenced by the operation time at different temperatures at V = 4800–5000 c.v. h^{-1} are illustrated in Fig. 3. As seen, with increasing temperature of the gas mixture, the operation life of the sorbent strongly decreases. For example, at 20°C the sorption efficiency decreases below 95% after 6 h operation, whereas at 30°C similar decrease in the sorption efficiency is observed in 2 h.

When the total concentration of organic compounds at the reactor outlet exceeded the limit of 5% as compared to the initial mixture, the gas supply was terminated, and the reactor was heated at a constant rate (30 deg min^{-1}) to 200–400°C with an electrical heater placed within the glass reactor. The temperature and the heating rate of the inner reactor volume were

Table 3. Content of organic compounds, a_o, and CO, a_{CO}, in the gas at the outlet from the reactor containing spent sorbent–catalyst after its heating

T, °C	No air supply		With air supply	
	a_o	a_{CO}	a_o	a_{CO}
	mg m^{-3}			
200	43	147	41	43
250	30	133	22	22
300	22	29	12	1
350	11	1	0	0
400	6	0	0	0

controlled with potentiometer *9* (Fig. 1). To monitor the real temperature changes in the reactor and to prevent the breakthrough of the contaminated gas mixture, the thermocouple was placed into a reference reactor *7* similar in size and design to reactor *6* (Fig. 1) and packed with a similar amount of the same sorbent–catalyst.

Heating was performed both with air supply into the reactor and without it. At certain temperatures, air samples were taken at the reactor outlet and analyzed for the content of CO and organic compounds.

As seen from the analytical data (Table 3), with increasing temperature the total amount of organic compounds including those partially oxidized on the catalyst decreases. High content of CO in the sample obtained at 200–250°C (147–133 mg m^{-3}) indicates incomplete oxidation of organic compounds at oxygen deficiency. Our catalyst is the most efficient at 300–400°C. However, even at so high temperatures the exhaust gas along with CO contains insignificant amounts of organic impurities. The air supply even at a low rate (1–2 l min^{-1}) provides exhaustive oxidation of organic compounds to CO_2 at 350°C, and no CO is detected in the outlet gas mixture.

CONCLUSION

A new sorbent–catalyst exhibiting high sorption capacity for organic compounds of various classes and efficient in exhaustive catalytic oxidation of organic compounds was developed. This sorbent–catalyst shows promise for neutralization of harmful impurities in exhaust gases from various branches of industry.

CATALYSIS

Promotion of Catalytic Properties of Sulfated Zirconium and Aluminum Oxides with Carbon Tetrachloride

A. V. Lavrenov, G. A. Urzhuntsev, E. A. Paukshtis, V. K. Duplyakin, and B. S. Bal'zhinimaev

Received July 2, 2002

Abstract— The promoting effect of minor amounts of carbon tetrachloride on the catalytic activity and working life of sulfated zirconium and aluminum oxides is considered for the example of isobutane alkylation with butenes.

Industrial processes for isobutane alkylation with olefins have been carried with sulfuric and hydrofluoric acids as catalysts for more than 60 years and fail to satisfy modern economical and environmental requirements. The development and improvement of technology for manufacture of alkylation gasoline largely rely upon changing to solid acid catalysts [1]. Attention has been rather long given to sulfated oxides of metals (zirconium, iron, titanium, tin, and aluminum) as the most promising catalysts for alkylation of isobutane with butenes. The strong acid properties of these oxides make it possible to carry out the reaction under the same conditions as in the case of the conventional liquid acids [2]. However, industrial use of these catalysts is hindered by the insufficient stability of their catalytic properties.

It is well known that presence of trace amounts of the so-called astoichiometric components in the reaction mixture [8] may exert positive influence on the activity, selectivity, and stability of various catalytic systems. Introduction of halogen-containing organic compounds into the raw material and their interaction with solid acid catalysts directly under the reaction conditions improve the rate and stability of numerous acid–base processes, including alkylation of isobutane with butenes on, e.g., a rare-earth form of the Y zeolite [4]. This approach has been used successfully to maintain the required acidity of aluminoplatinum chlorine-containing catalysts in industrial processes of reforming [5] and skeleton isomerization of paraffins [6].

In this work we performed a comparative study of the influence exerted by minor additions of CCl_4 on the catalytic properties of sulfated zirconium and aluminum oxides in alkylation of isobutane with butenes. The catalytic systems considered occupy extreme positions in the series of increasing activity of sulfated metal oxides in the alkylation [2]: SO_4^{2-}/ZrO_2 > SO_4^{2-}/TiO_2 > SO_4^{2-}/SnO_2 > SO_4^{2-}/Fe_2O_3 > SO_4^{2-}/Al_2O_3.

This will allow a clearer assessment of the extent and efficiency of the promoting effect of carbon tetrachloride.

EXPERIMENTAL

Sulfated zirconium oxide (henceforth SZ) was synthesized as follows: To 400 ml of an ammonia solution (28 wt % NH_3) we added at 80°C in the course of 2.5 h 300 ml of a 223 g l^{-1} (in terms of ZrO_2) solution of oxozirconium(IV) nitrate. The resulting precipitate of zirconium hydroxide was filtered off and washed with ammonia water (pH 9), and then dried in air at room temperature and calcined at 400°C for 4 h. Zirconium oxide was treated with 2 N H_2SO_4, dried at 150°C, and calcined in a flow of dry air at 550°C for 4 h. This yielded a sample with the specific surface area of 188 m^2 g^{-1} and SO_4^{2-} content of 5.8 wt %.

Sulfated aluminum oxide was prepared by adding to γ-Al_2O_3 with the specific surface area of 200 m^2 g^{-1} a 14% H_2SO_4 solution and drying the product obtained at 100°C. Calcination at 600 (sample SA-600) or 700°C (sample SA-700) yielded catalysts containing 8 and 6 wt % SO_4^{2-}, respectively.

The catalytic properties were studied in a 180-ml stainless steel autoclave. As raw material served industrial isobutane (IBF) and butane–butylene (BBF)

1070-4272/02/7511-1828$27.00 © 2002 MAIK "Nauka/Interperiodica"

fraction preliminarily purified over solid alkali and NaA zeolite. The composition of the fraction was as follows:

Component	IBF, wt %	BBF, wt %
Propane	0.01	0.55
Isobutane	99.81	42.64
1-Butene + isobutane	0.15	26.65
n-Butane	0.03	8.76
trans-2-Butene	0.00	12.54
cis-2-Butene	0.00	8.86

To carry out the reaction, the autoclave was charged with 2 g of a catalyst (with particle size of 0.4–1 mm) and 40 g of IBF. In experiments with promotion, the IBF contained 0.02 wt % CCl_4. In the course of the tests, BBF was fed into the autoclave with a syringe pump at a rate of 0.05 to 1 g h^{-1}.

The liquid reaction mixture and the catalyst were stirred with jolt-rammer on which the autoclave was mounted. The alkylation was done at a temperature of 40°C, maintained by passing hot water through the autoclave jacket.

The composition of the reaction mixture in the autoclave was determined every hour by gas–liquid chromatography using a syringe of special design for sampling liquid hydrocarbons under pressure and a Hewlett–Packard 5890 Series II chromatograph with a DB-1 capillary column and a flame-ionization detector. The chromatograms were recorded and processed using the Multikhrom computerized chromatographic system.

To characterize the course of the reaction on the basis of the autoclave tests, the following parameters were determined: conversion of butenes, mass yield of C_{5+} products and *n*-butane based on converted butenes, and their fractional composition. All the parameters were calculated on the basis of a material balance for each hour of the process, minus the starting compounds and reaction products accumulated in the autoclave.

The results of the experiments performed are shown in Figs. 1 and 2 and in the table. A sample of sulfated zirconium oxide is characterized by high initial activity (the yield of C_{5+} products is about 2 g g^{-1} at complete conversion of butenes), which decreases fast when 0.62 to 0.81 g of butenes is supplied per gram of catalyst. The alkylation of isobutane with butenes is nearly always accompanied by redistribution of carbon and hydrogen [7], which leads to formation of isoparaffin hydrocarbons with less than eight carbon atoms, *n*-butane, and high-molecular-weight unsaturated compounds as reaction products. In the case of sulfated zirconium oxide, these processes are the most pronounced during the initial stage of the reaction [8], and deposits of heavy unsaturated products on the

* L is the catalyst mass.

solid catalyst surface are one of the most probable reasons for fast loss of activity.

The working life of zirconium sulfate catalysts in alkylation (from several minutes to several hours) and, correspondingly, the extent and rate of side processes largely depend both on the preparation conditions of the catalyst and on the conditions and method of catalytic test [8, 10, 11]. The selectivity in alkylation, exhibited by the SZ sample obtained, proved to be satisfactory and was characterized by average-integral mass fraction of trimethylpentanes (TMP) in C_{5+} products equal to 54% and by fraction ratio of TMP to dimethylhexanes (DMH) of about 3.

The interaction of the SZ catalyst with the isobutane–butene raw materials in the presence of CCl_4 intensifies processes involving excessive (for alkylation) consumption of isobutane. With this behavior of the system, the conversion of butenes is not a parameter characterizing the catalyst activity. The depth of conversion of the starting hydrocarbons is in the first place determined by the yield of C_{5+} products, whose values exceed, during the initial stage of the reaction at 100% conversion of butenes, by a factor of 1.4–1.8 the value of 2.04 g g^{-1} corresponding to the stoichiometry of isobutane alkylation with butenes. The forming C_{5+} products are strongly enriched in isopentane, isohexanes, and isoheptanes. Simultaneously, substantial amounts of *n*-butane are formed. However, the average yield of target alkylation products proper, TMP, remains at the same level as that without a promoter, being equal to about 1 g g^{-1}.

In the presence of CCl_4, the working life of the SZ catalyst increases nearly twofold. For example, an SZ sample without promoting additive ensured conversion of 0.67 g of butenes per gram of catalyst, with the conversion decreasing from 100 to 38%. On adding the promoter, the conversion of 1.2 g of butenes per gram of catalyst was achieved, and the conversion was retained at a level of about 90%. However, the joint conversion of isobutane and butenes still remained unstable.

Commonly, the effect of chlorinated compounds on the course of acid–base reactions is attributed to chlorination of catalysts at temperatures exceeding 100°C. Depending on the interaction conditions, states with varied nature of the surface acidity, both Brønsted [12] and Lewis [13], may be generated. At low temperature, there is virtually no surface modification of oxide catalysts, since the chlorination rate turns out to be exceedingly low.

In the case of low-temperature alkylation, the promoting effect of CCl_4 is in all probability associated with intensified generation of active species, such as *tert*-butyl cation, which play a key part in the classical chain mechanism of the reaction [7]. Formally, the main pathway of formation of *tert*-butyl cations in the course of alkylation is detachment of hydride anion from an isobutane molecule, with its subsequent transfer to other positively charged species to give neutral products (*n*-butane and isoparaffins with varied number of carbon atoms). It is this process, the so-called hydride transfer, that determines the stages of chain initiation and transfer in the course of alkylation. In the case of solid acids, the course of the hydride transfer is presumably determined by the presence of Lewis acid centers as electron acceptors. As a rule, all solid catalytic systems exhibiting activity in isobutane alkylation (chlorinated aluminum oxide, zeolites, sulfated metal oxides) are characterized by the presence of both protic and aprotic acid centers.

The C_{sp^3}–Cl bond energy is 59 kJ mol^{-1} lower than the C_{sp^3}–H_{tert} bond energy (344.8 and 403.8 kJ mol^{-1}, respectively [14]). Therefore, it may be assumed that CCl_4 can be much easier, compared with isobutane, activated on the surface of sulfated zirconium oxide. An activated CCl_4 molecule may act as an intermediate in detachment of a hydride anion from the isobutane molecule:

$$[Zr^{\delta+}\cdots Cl^{\delta-}\cdots CCl_3^{\delta+}] + \textit{iso}\text{-}C_4H_{10} \rightarrow [Zr^{\delta+}\cdots Cl^{\delta-}] + CCl_3H + \textit{tert}\text{-}C_4H_9^+.$$

Thus, initiation of the alkylation reaction may also involve catalyst surface sites with weaker acidity, which formally increases the total number of centers responsible for joint conversion of isobutane and butenes, with the strength of these centers growing.

However, as seen from the data obtained, introduction of CCl_4, apparently, not only reduces the activation barriers for isobutane alkylation with butenes, but also leads to development of nonselective transformations in the form of intensive occurrence of the so-called self-alkylation (self-condensation) of isobutane.

In this case, *n*-butenes act as hydrogen acceptors, being converted into *n*-butane, and it is this fact that may account for its high yield, and molecules of C_{5+} products are mainly formed from isobutane. The role of CCl_4 may consist in initiation of multistage processes of hydrogen chloride exchange, with the starting butenes and isobutane involved and products formed, which are identical to those produced in alkylation. As an example may serve the following reactions:

$$\textit{iso}\text{-}C_4H_{10} + CCl_4 \rightarrow \textit{tert}\text{-}C_4H_9Cl + CCl_3H, \quad (1)$$

$$\textit{tert}\text{-}C_4H_9Cl + \textit{iso}\text{-}C_4H_{10} \rightarrow \textit{iso}\text{-}C_8H_{18} + HCl, \quad (2)$$

$$\textit{n}\text{-}C_4H_8 + HCl \rightarrow \textit{sec}\text{-}C_4H_9Cl, \quad (3)$$

$$\textit{sec}\text{-}C_4H_9Cl + \textit{iso}\text{-}C_4H_{10} \rightarrow \textit{tert}\text{-}C_4H_9Cl + \textit{n}\text{-}C_4H_{10}. \quad (4)$$

Indeed, special experiments with large amounts of CCl_4 revealed formation of both chloroform and *tert*- and *sec*-butyl chlorides. Thus, CCl_4 enters into the reaction in quantitative amounts, also playing a part of hydrogen acceptor and ensuring self-alkylation of isobutane, which was observed in [4] when carrying out alkylation on a zeolite catalyst.

As already noted, alkylation and self-alkylation of isobutane are not limited to formation of isoparaffins C_8, being a complex process of redistribution of carbon and hydrogen. The significant increase in the yield of isoparaffins C_5–C_7 (products of destructive processes), observed in the presence of CCl_4, is presumably caused by the surface acidity of the catalyst, which is induced by the promoter and is clearly excessive for the reaction considered here.

In the presence of CCl_4, sulfated aluminum oxide, exhibiting virtually zero inherent activity in alkylation, can be used in the reaction and yields as good results as those obtained in alkylation on sulfated zirconium oxide in the absence of promoter. The calcination temperature (samples SA-600 and SA-700) affects the initial acidity of the catalyst and governs the selectivity of conversion of isobutane and butenes in the presence of promoter. Sample SA-600 is characterized by noticeable superstoichiometric consumption of isobutane and formation of large amounts of *n*-butane, hydrocarbons C_5–C_7, and DMH. At the same time, sample SA-700 is characterized by amount and composition of products, corresponding to a greater extent just to isobutane alkylation. At butene conversion of 97%, the alkylate yield is 1.86 g g^{-1} at a mass fraction of TMP equal to 58% and TMP/DMH ratio of about 3.

The results obtained suggest that, with permanent dosing of minor amounts of CCl_4 into the raw material and the reaction carried out under flow-through conditions, alkylation of isobutane with butenes on common sulfated aluminum oxide may be efficient.

CONCLUSION

The influence of CCl_4 additions on the alkylation of isobutane with butenes on sulfated zirconium and

aluminum oxides is demonstrated. The observed strong promoting effect furnishes additional opportunities for control over industrial processes of alkylation on solid catalysts based on sulfated metal oxides.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Sensor Analysis of Gases Emitted in Basic Organic Synthesis

Ya. I. Korenman, Zh. Yu. Kochetova, and T. A. Kuchmenko

Voronezh State Technological Academy, Voronezh, Russia

Received October 11, 2001; in final form, May 2002

Abstract—A matrix comprised of eight different sensors based on piezoelectric-crystal resonators was used for analysis of multicomponent gas mixtures. The resonator electrodes were modified with both known and unconventional gas-chromatographic sorbents.

Gas emissions from basic organic synthesis consist of substances belonging to diverse classes, in particular, alcohols, amines, amides, ketones, aldehydes, ethers, esters, and aromatic compounds. Volatile anthropogenic pollutants are able of fast migration to residential areas; many of them are accumulated in the biosphere in concentrations posing hazard to human life. The content of these pollutants should be strictly controlled [1, 2].

Modern methods of analysis should be prompt, mobile, sensitive, cost-effective, and accurate. In this connection, particular attention is now paid to development of gas-analyzing sensors. The operation of these sensors is underlain by transformation of the analytical signal generated by interaction of the sample analyzed with the sensitive coating on the electrodes into a physical signal [3–5].

Sensor selectivity is governed by the nature of the sensitive coating (modifier) of the piezoelectric-crystal resonator. Modifiers should be selective to individual components or groups of related compounds, exhibit adhesion to the electrode surface, and afford accurate determination of pollutants at the levels of their maximum permissible concentrations (MPCs). Repeated use of sensors should not markedly affect the main physical and chemical properties of the modifiers.

The aim of this work was to optimize the detection of multicomponent gas mixtures emitted in basic organic synthesis using sensors based on piezoelectric-crystal resonators.

EXPERIMENTAL

The experimental setup for static determination of volatile organic compounds was assembled at the laboratory from inexpensive units (Fig. 1).

Standard gas mixtures were prepared in a generator, into which samples were injected under permanent stirring of the mixture components with a stirrer. The required amount of saturated vapors of the substances under study was injected into the generator with a syringe via a polyurethane gasket, where the sample was uniformly diluted to appropriate concentrations (MPC, 1/2 MPC, etc.).

The concentrations of the components c, $\mu g\ m^{-3}$, were calculated by the Mendeleev–Clapeyron equation [6]

$$c = 1.22 p_i M \times 10^7/(pT), \quad (1)$$

where 1.22 is the proportionality coefficient; p_i, the saturated vapor pressure, mm Hg; M, the molecular weight; p, atmospheric pressure, Pa; and T, temperature, K.

Table 1. Analytical signal for phenol sorption at different BW masses

$m \pm 2$, μg	ΔF, Hz	S, Hz m^3 mg^{-1}	a	τ, s	S_{rms}
5	24	8000	0.007	10	1.0
10	38	12 700	0.004	15	1.2
20	46	15 300	0.002	30	1.4
30	54	18 000	0.002	60	1.8
40	60	20 000	0.001	75	2.4
50	63	21 000	0.001	90	3.6

Note: $m \pm 2$ is the mass of the film being applied, measured with the accuracy of ±2 μg; and τ is the time of establishment of the equilibrium.

The air sample was introduced into a temperature-controlled detection cell at the sensor electrode height, which significantly decreases the loss of the compounds analyzed by adsorption on the cell walls. Interaction of the gas sample components with the modifier changes the sensor oscillation frequency by ΔF, Hz. The relationship between the analytical signal from the sensor based on a piezoelectric resonator of volume acoustic waves, on the one hand, and the mass of the film coating on the electrodes and the mass of the analytes adsorbed on its surface m_f, on the other hand, is described by the Sauerbrey equation [3]

$$\Delta F = -K_f m_f, \quad (2)$$

where K_f is the proportionality coefficient taking into account the intrinsic characteristics of the piezoelectric-crystal plate and electrodes.

As modifiers of the resonator electrodes we used standard stationary phases utilized in gas chromatography, namely, polyethylene glycol-2000 (PEG-2000), polyethylene glycol succinate (PEGS), polyethylene glycol sebacate (PEGSb), octylpolyethoxyphenol (Triton X-100), dinonyl phthalate (DP), beeswax (BW), and polystyrene (PS) [7]. Also we utilized an unconventional sorbent, bees glue, propolis (PP). The 1 μg μl^{-1} sorbent solutions were uniformly applied with a microsyringe onto the surface of two resonator electrodes. To evaporate the solvent (acetone, toluene, ethanol, chloroform), we kept the sensors for 30–40 min in an oven at 40–45°C. The degree of the solvent removal was estimated from the time stability of the oscillation frequency of the resonator with the coating applied (zero signal drift within 3 Hz min^{-1}).

The quantitative characteristics of the sorption, namely, the sorbent sensitivity to the compound being analyzed S, Hz m^3 mg^{-1}, and the sorption capacity of the modifier a (a dimensionless parameter) [8], were calculated by the equations

$$S = \Delta F/c, \quad (3)$$

$$a = \Delta F/(F_0 - F_f), \quad (4)$$

where F_0 and F_f are the intrinsic oscillation frequencies of the unmodified (10 MHz) and modified piezoelectric crystal-based resonator, respectively.

The root-mean-square deviation S_{rms} was calculated by the equation

$$S_{rms} = \left[\sum_{i=1}^{i=n}(x_1 - x)^2\right](n - 1)^{-1}, \quad (5)$$

where x_i is the result of a single run, and n is the number of replicate runs.

One of the major parameters governing the sensitivity, reliability, and stability of the operation of gas sensors based on mass-sensitive piezoelectric-crystal resonators is the optimal mass of the sorbent [Eq. (2)]. Taking interactions in the phenol–sorbent system as an example, we showed how the analytical signal of the sensor varies with increasing modifier mass (Table 1).

With the sorbent mass increasing to 20–30 μg, the parameter ΔF and, hence, the sensor sensitivity, tend to increase. At m = 30–50 μg the acoustic wave is quenched in the near-electrode sorbent layer, and the effective mass and the sorption capacity of the modifier tend to decrease [9, 10]. Also, increase in the modifier mass decreases the reproducibility of the results by increasing the proportion of the volume-acoustic wave quenching component in the total microweighing error. For all the sorbents studied in this work, the optimal mass is estimated at 20–30 μg.

Table 2 presents the sensitivities of the modifiers (m = 25–30 μg) with respect to the compounds studied at concentrations corresponding to their MPCs. Based on the maximal S value we identified the optimal sorbents for detecting individual compounds. The largest responses from the sensors were obtained with PEG-2000 sensitive film in sorption of ethanol, butyl acetate, and formamide, with PEGS and PEGSb films in the case of phenol and *n*-butanol, with Triton X-100 film in the case of butyl acetate, diethylamine, acetone, toluene, and nitrophenol, and dinitrophenols, and with PP film in the case of 1,4-dioxane.

For prompt and reliable identification of individual

Table 2. Sensitivity of the modifiers of different nature to the compounds under study

Compound	MPC, mg m^{-1}	S of indicated modifier, Hz m^3 mg^{-1}

Note: The dash means that the analytical signal is indistinguishable from the noise.

compounds, we proposed a graphical procedure which implies no complicated calculations. It consists in the following. The signals from different sensors based on sorbents with the preset properties are converted to a "visual image", namely, a petal diagram with ΔF, Hz, axes. Figure 2 shows the standard diagrams of sorption for the selected compounds. The diagram profile remains unchanged with varying concentrations of the substances in the sample. The content of each component was determined using the calibration plots $\Delta F = f(c)$.

The search for highly selective modifiers suitable for resonator electrodes in analyzing multicomponent gas mixtures using sensors still remains urgent. At the same time, active development of computational facilities for on-line processing of multiple-parameter information allows the use of a group (matrix) of nonselective sensors for analyzing complex mixtures. Multisensor devices provide information (with a certain accuracy) about the qualitative and quantitative composition of the mixture [11].

Sorption diagrams were plotted for multicomponent gas mixtures based on the total responses of the sensors for vapors of individual compounds (Fig. 3a) and mixtures of phenol, nitrophenol, and dinitrophenols (Fig. 3b). The diagram profiles are identical, though the ΔF parameters differ, thus confirming the previously revealed nonadditivity of sorption of the gas mixture components [12].

Data in Table 2 and the "visual images" of sorption make it possible to determine the composition of a gas

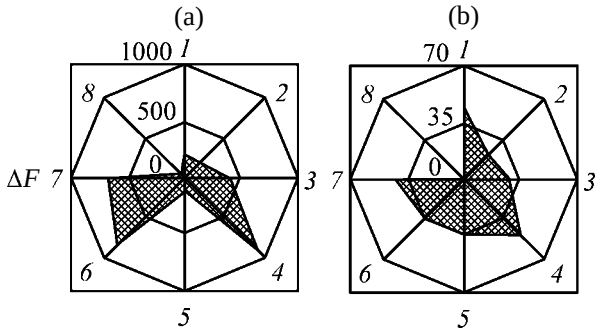

Fig. 2. Standard petal diagrams of sorption of (a) diethylamine and (b) 1,4-dioxane on (*1*) PEG-2000, (*2*) PEGS, (*3*) PEGSb, (*4*) Triton X-100, (*5*) BW, (6) PP, (*7*) DP, and (*8*) PS. (ΔF) Analytical signal from the sensor, Hz; the same for Figs. 3 and 4.

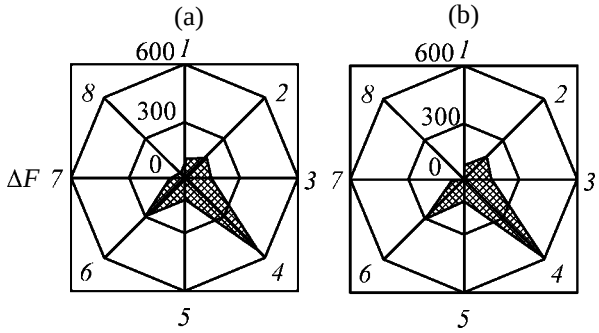

Fig. 3. (a) Calculated (from the sorption responses of individual compounds) and (b) experimental standard sorption diagrams of gas mixtures containing phenol, 2-nitro- and 2,4-, 2,5-, and 2,6-dinitrophenols.

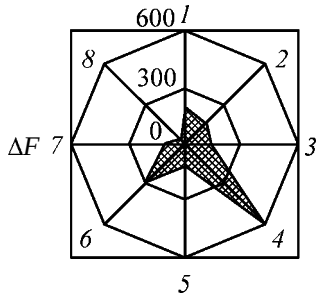

Fig. 4. Petal diagram of sorption of a mixture containing phenol, formamide, 2-nitrophenol, and 2,4-, 2,5-, and 2,6-dinitrophenol vapors.

mixture and the concentrations of its individual components. Increased ΔF parameter in axis *4* (Fig. 3) evidences the presence of nitro- and dinitrophenols in the mixture. The maximum permissible concentration of nitrophenol exceeds several times those of the other mixture components, as indicated in axis *6* (propolis). The ΔF value in axis *7* (DP) confirms the presence of phenol in the mixture. Increase of the content of any compound in the mixture tends to increase in ΔF in the corresponding axis.

The diagram profile changes with introduction into the mixture of concomitant components, e.g., formamide (Fig. 4). Enhanced sensitivity to formamide is exhibited by PEG-200 (axis *1*); in the other axes, ΔF varies insignificantly. By comparing the responses of the sensors to vapors of the mixtures of compounds with those on films with enhanced sensitivity to the individual substances, it is possible to determine the concentrations of individual components. For example, PEG-2000 and beeswax are insensitive to nitrophenol and dinitrophenols (Table 2), which allows determination of the formamide and phenol concentrations in axes *1* and *5*, respectively.

CONCLUSIONS

(1) The optimal masses of sorbents of different nature in determining volatile organic compounds, ensuring significant response, accuracy, and reliability of operation of the piezoelectric crystal-based sensor, were estimated at 20–30 μg.

(2) A new procedure was proposed for identifying the components of multicomponent gas mixtures. It is based on plotting standard petal diagrams of sorption for gas mixtures on different sorbents, electrode modifiers. Comparison of the experimental and standard diagrams allows determination of the composition and concentrations of individual components of multicomponent mixtures.

(3) An unconventional sorbent, propolis, was tested as modifier. It satisfies the requirements posed on modifiers and is suitable as sensitive coating for electrodes of piezoelectric-crystal resonator in detecting gases emitted in basic organic synthesis using sensors prepared therefrom.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

On the Possibility of Saving Chemicals in Salting-out Processes

A. I. Leont'eva, V. I. Konovalov, S. V. Karetnikov, and A. N. Utrobin

Tambov State Technical University, Tambov, Russia

Received September 10, 2001; in final form, August 2002

Abstract—A reagent charging mode is proposed to reduce the consumption of sodium chloride and water in manufacture of half-products of optical bleaching agents (Belofors).

Salting-out is used in chemical industry to isolate a number of organic substances from solutions [1, 2]. This method involves considerable consumption of sodium chloride (or some other salt) and formation of a large amount of wastewater enriched in this salt (up to 400 kg of NaCl per 1 m^3).

One of important half-products in manufacture of bleaching agents (Belofors) is 4,4'-dinitrostilbene-2,2'-disulfonic acid (DNS). DNS is produced industrially by oxidative dimerization of 4-nitrotoluene-2-sulfonic acid (NTSA) in the presence of atmospheric oxygen. Sodium chloride is used for isolating DNS in the stage of oxidation. To make lower the consumption of sodium chloride, it is necessary to analyze the salting-out mechanism based on the state of molecules and ions in solution.

The equilibria in protic solvents (H_2O and CH_3OH)

$$ArN< + H_3O^+ \underset{H_2O}{\rightleftarrows} ArN^+(H)< + H_2O, \quad (1)$$

$$ROH + H_3O^+ \underset{H_2O}{\rightleftarrows} R^+ + 2H_2O, \quad (2)$$

$$RH + CH_3O^- \underset{CH_3OH}{\rightleftarrows} R^- + CH_3OH, \quad (3)$$

$$ArOH + CH_3O^- \underset{CH_3OH}{\rightleftarrows} ArO^- + CH_3OH, \quad (4)$$

can be shifted to the right (toward larger ions) by adding alkali metal salts. This phenomenon is accounted for by the "drying" effect of salts [2] whose ions are characterized by high charge densities ("hard" anions and cations). Their solvation by protic solvents is very strong [3], and, therefore, the fraction of free solvent molecules decreases, which leads to the corresponding shift of the equilibrium. The magnitude of the effect depends not only on the concentration of a salt added, but also on the chemical composition of the ions constituting the salt. At the same concentration of salt additive in solution, the solvent vapor pressure corresponding to a decrease in the activity of water or methanol may be higher or lower, depending on the chemical composition of the salt. In addition to a decrease in the solvent activity, the drying effect is manifested in an increase in the degree of solvation of ions involved in the equilibria under study. In the reaction mixture, there exists competition between solvation processes for all of the ions present. Beginning with a certain concentration of an alkali metal salt in solution, ions involved in the equilibrium may be totally or partly desolvated:

$$OH \cdot nH_2O + X^-M^+ \rightleftarrows OH \cdot (n-m)H_2O + X^-M^+ \cdot mH_2O, \quad (5)$$

$$H_3O^+ \cdot nH_2O + X^-M^+ \rightleftarrows H_3O^+ \cdot (n-m)H_2O + X^-M^+ \cdot mH_2O. \quad (6)$$

The desolvation of ions is accompanied by an increase in their activity coefficients [2]. The energy of solvation of large ions by protic solvents, and especially that of organic ions with low charge density ("soft" ions) is markedly lower than the energy of solvation of small ions ("hard" ions) such as OH^-, CH_3O^-, and H_3O^+. The stability and, consequently, the activity of such large organic ions depend on desolvation to a lesser extent than the activity of small ions does. It should be noted that salt effects lowering the solvent activity are only clearly pronounced at a sufficiently large (≥ 0.1) salt : solvent ratio. In the existing production of bleaching agents with the use of sodium chloride, this ratio is 0.1875.

There also exists another approach to investigation

1070-4272/02/7511-1837$27.00 © 2002 MAIK "Nauka/Interperiodica"

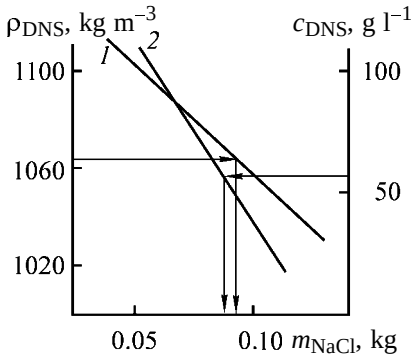

Fig. 1. (*1*) Density ρ_{DNS} and (*2*) concentration c_{DNS} vs. amount of NaCl, m_{NaCl}, to be added to salt-out DNS.

of electrolyte solutions. In this case, of particular importance is coordination in short- and long-range solvation of ions. It has been shown for cations with electronic configuration of noble gases that their coordination numbers are independent of the solvent nature and solution temperature and concentration [4, 5]. Experimental (NMR spectroscopy, gravimetry, X-ray and neutron diffraction analyses, IR spectroscopy, etc.) and calculational (Monte Carlo, molecular dynamics, quantum-chemical) investigation techniques yield information about the coordination of solvent molecules in the first solvation shell. A geometric analysis of the possible structural arrangements demonstrated that the number of solvent molecules directly bound to the ion must be limited. The most frequently occurring coordination numbers are 4, 6, and 8. For cations of small radius, e.g., Li^+, Be^{2+}, the maximum coordination number in a solvent is 4. In the case of large solvent molecules, the coordination number may decrease: e.g., Al^{3+} has 4 hexamethylphosphorotriamide molecules in the first coordination sphere. Cations of larger size, including Ln^{3+}, An^{3+}, may have in solution a coordination number exceeding 6, possibly in the range from 8 to 10 [6]. The coordination numbers in hydrate shells of ions, obtained by different methods, were reported in monograph [6].

The tentative scheme of DNS salting-out with NaCl can be represented as follows:

$$DNS \cdot nH_2O + NaCl \rightarrow DNS + NaCl \cdot nH_2O. \quad (7)$$

Scheme (7) may be valid in a wide range of DNS and NaCl concentrations in solution, since the heat of NaCl hydration is, in all probability, much higher than that of DNS hydration (large organic anion [2]). In this case, it would be expected that there exists a relationship between the amount of salt necessary for salting-out and the DNS concentration in solution.

This dependence was determined experimentally. A 1-l vessel was charged with 5×10^{-4} m^3 of a DNS solution of varied concentration, and then the necessary amount of NaCl was added to make the DNS solution density in the vessel 1150 kg m^{-3}. The precipitated DNS was filtered off, and the DNS content in the filtrate was determined. The amount of the salt necessary for salting-out the DNS was calculated from the material balance equation

$$5 \times 10^{-4}\rho + 2168V = (5 \times 10^{-4} + V) \times 1150, \quad (8)$$

where 5×10^{-4} is the DNS solution volume (m^3); ρ, the initial density of the DNS solution (kg m^{-3}); 2168, the NaCl density (kg m^{-3}) [7]; V, the NaCl volume (m^3); 1150, the final density of the DNS solution with the salt (kg m^{-3}).

As a result, linear relationships were obtained allowing the amount of NaCl required for salting-out DNS to be calculated from the density or concentration of the DNS solution (Fig. 1, straight lines *1* and *2*, respectively). For example, for a solution with a density of 1062 kg m^{-3} (which corresponds to the mass concentration of DNS equal to 54.45 g l^{-1}) the necessary amount of the salt (0.095 kg) is found on the abscissa. If account is taken of the fact that this amount is required for a solution with a volume of 5×10^{-4} m^3, then a value of 7.5 t is obtained for the reactor volume (40 m^3). Carrying out the same calculation procedure for an initial DNS concentration of 54.45 kg m^{-3} gives 7.4 t of sodium chloride.

The discrepancy (3%) between the amounts of NaCl salt to be added to the solution, found from the graphical dependences *1* and *2*, does not exceed the overall error of the methods. For practical purposes, it is simpler to determine the amount of sodium chloride required for salting-out by measuring the DNS solution density.

Analysis of the linear dependences shown in Fig. 1 shows that, with increasing concentration and density of the DNS solution, the amount of NaCl used to salt-out the same amount of DNS decreases. Under industrial conditions, the concentration and, correspondingly, density of the DNS solution can be raised by decreasing the amount of water fed into the reactor.

To check under laboratory conditions how a decrease in the amount of water affects oxidation of NTSA, we assembled a setup shown in Fig. 2. The setup comprises a vessel *1* with the reaction mass, placed in a thermostat *2*. The heating is done with boiler *3*. A blade stirrer is used to agitate the reaction mass. Air is fed through a bubbler integrated with the

bottom part of vessel *1*. The air flow rate is monitored with an RT-1 rotameter. The temperature is measured and controlled with a thermocouple and TR200 device *6*.

The dimerization of NTSA in the laboratory setup was carried out as follows. Vessel *1* was successively charged with water, soap (0.2 g), catalyst (0.08 g), defoaming agent (tributyl phosphate, 0.6 ml), and alkali (45% NaOH, 150 ml). With the stirrer *4* switched-on, air was fed through the bubbler 5 (Q = 0.6 $m^3 h^{-1}$), and a homogeneous NTSA solution (280 ml, density 1186 $kg\,m^{-3}$, acidity 179 $g\,l^{-1}$, concentration 298.5 $g\,l^{-1}$) was added. The alkalinity of the reaction mass was brought to 2% by adding NaOH in 2–5-ml portions. Samples were taken at 1-h intervals and the NTSA, DNS, and dye concentrations were determined spectrophotometrically from the optical densities measured on an SF-26 spectrophotometer.

Three sets of experiments on NTSA oxidation were carried out with the following amounts of water: 1200, 850, and 650 ml. It was found that, with the volume of fed water decreased, a precipitate [intermediate dinitrodibenzylsulfonic acid (DNDB)] is formed in the reaction medium 3–4 h after the beginning of oxidation. The amount of the precipitate depends on temperature and the NTSA and alkali concentrations in the reaction mass. The formal scheme of the reaction, with an intermediate formed, looks like

$$A \rightarrow B \rightarrow C$$

where A is the starting reagent, B is the intermediate, and C is the final product.

By varying the oxidation mode, a condition can be achieved when the DNDB concentration remains constant and does not exceed the saturation concentration in the reaction mass. This can be done by parallel charging of NTSA and NaOH into the apparatus over a long time (5–6 h).

The kinetics of oxidation, observed with the method of reagent charging used in manufacture of bleaching agents and the technique proposed here, is shown in Fig. 3. The parallel charging of NTSA and NaOH is done in five equal batches.

It can be seen from the dependences presented in Fig. 3 that, in the case of batch charging of the components, the maximum concentration of the intermediate (DNDB) (curve *5*) is lower than that with the charging mode used industrially in manufacture of bleaching agents (curve *4*).

To verify the efficiency of batch charging of components under laboratory conditions, experiments were carried out on a setup shown in Fig. 2, using the procedure described above.

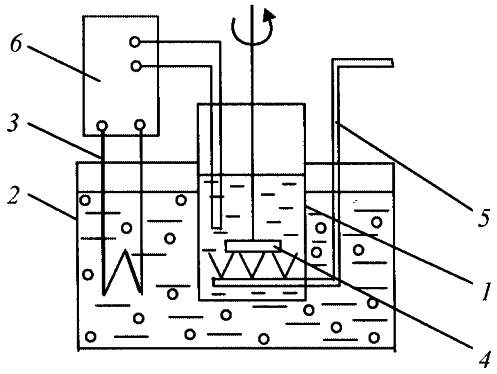

Fig. 2. Schematic of the experimental setup: (*1*) vessel, (*2*) thermostat, (*3*) boiler, (*4*) stirrer, (*5*) bubbler, and (*6*) TR-200 device.

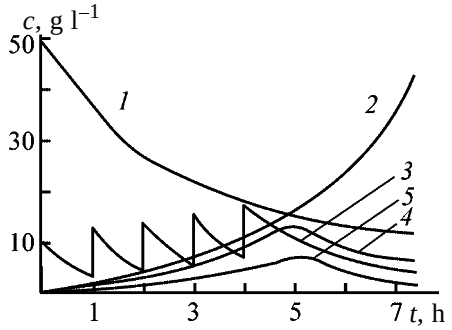

Fig. 3. Kinetics of oxidative dimerization of NTSA in DNS. (*c*) Concentration and (*t*) time. Variation of concentration: (*1*) NTSA with charging in a single portion, (*2*) DNS, (*3*) NTSA with charging extended over time, (*4*) intermediate (DNDB) with charging in a single portion, and (*5*) intermediate (DNDB) with charging extended over time.

The first set of experiments reproduced the process of oxidative dimerization of NTSA used industrially in manufacture of bleaching agents. The reactor was charged with 1200 ml of water, and then 250 ml of a homogeneous solution of NTSA and 100 ml of NaOH were introduced in a single portion.

The second set of experiments reproduced the process of oxidative dimerization of NTSA with batch charging of the components. To verify the assumption that the consumption of water and NaCl decreases in the case of batch charging, a smaller amount of water (850 ml) was fed into the reactor in the second set of experiments. A homogeneous NTSA solution (250 ml) and NaOH (100 ml) were charged as follows: 10 ml of NTSA and 3–4 ml of NaOH every 10 min. In the first charging, the alkalinity of the reac-

tion mass was brought to 2% by adding NaOH in 2–5-ml portions. The alkalinity and temperature were maintained constant (2%, 58°C) during the entire process (12 h).

After the oxidative dimerization of NTSA was complete, DNS was isolated and the amount of NaCl consumed was measured. Below are presented the results of the experimental studies:

V_{H_2O}, ml	m_{DNS}, g	m_{NaCl}, g
1200	54	432
1200	58	471
1200	61	455
850	57	254
850	53	250
850	59	263

It can be seen that, in the case of batch charging of the components, the consumption of water decreases by 30%, and that of the salt, by 40%, with the amount of DNS obtained in the experiment remaining virtually the same.

The proposed method of batch component charging was tested on an industrial installation. The industrial reactor was a 29 m^3 vessel with a jacket. The amount of water used in NTSA oxidation in the existing production of bleaching agents was 15 m^3. The total volume of the reaction mass was 19 m^3 (DNS concentration 54–55 g l^{-1}). This amount of the DNS solution requires 3.8 t of NaCl. With the batch charging of the components used, the reactor was charged with 10 m^3 of water. The total volume of the reaction mass was 14 m^3 (DNS concentration 72–74 g l^{-1}). This amount of the DNS solution required 2.3 t of NaCl.

CONCLUSION

A component charging method with which the consumption of water decreases by 30% and that of NaCl required for isolation of 4,4'-dinitrostilbene-2,2'-disulfonic acid, by 40% was developed experimentally and tested on an industrial installation.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Determining the Conditions of Preliminary Mixing in Stirred Vessels

O. A. Tishin and I. N. Dorokhov

Volzhskii Polytechnic Institute, Volgograd State Technical University, Volzhskii, Volgograd oblast, Russia
Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Abstract—The results of experimental and theoretical studies of the influence exerted by stirring on a chemical reaction are presented. A parameter is proposed for evaluating this influence. The values of this parameter at which the state of preliminary mixing of reactants is achieved are determined.

Stirring strongly affects the integral characteristics (conversion, selectivity, yield) of a chemical process. This influence was first studied by Danckwerts [1, 2] and Zwietering [3], who demonstrated that preliminary mixing of the fed reactants ensures guaranteed conversions. Therefore, conditions corresponding to the state of preliminary mixing are to be created at the reactor inlet in reactor design. However, reactants are fed into the reactor in separate flows, and their stoichiometric ratio is ensured for the entire volume of the medium fed into the reactor. The aim of mixing consists in that the reactants should be brought as fast as possible to a state for which the stoichiometric ratio is observed at any point of the medium, i.e., to the state of preliminary mixing. Of much interest in this context is defining the criteria that can be used to evaluate the state of the starting mixture as regards its mixing. This study makes an attempt to develop a criterion allowing evaluation of the condition of preliminary mixing.

The effect of mixing on the course of a chemical process is manifested, in the first place, in nonuniformity of the concentration of substances involved in the chemical reaction. The effect of concentration nonuniformity can be demonstrated for the example of a second-order reaction proceeding by the scheme

$$A + B \xrightarrow{k} P, \qquad (1)$$

where A, B, and P are reactants and reaction products; k is the rate constant of the chemical reaction ($m^3\ mol^{-1}\ s^{-1}$).

In the case of nonideal mixing, the concentration c ($mol\ m^{-3}$) of the substance can be represented as a sum of its mean value and concentration pulsation:

$$c = \bar{c} + \Delta c. \qquad (2)$$

The effect of stirring nonuniformity can be evaluated using an expansion of the function into a Taylor series. The rate of the chemical reaction, r ($mol\ m^{-3}\ s^{-1}$), in zones with positive and negative deviations of the concentration from its mean value is as follows:

$$\left.\begin{aligned} r(\bar{c} + \Delta c) &= r(\bar{c}) + \frac{dr}{dc}\Delta c + \frac{1}{2}\frac{d^2r}{dc^2}(\Delta c)^2, \\ r(\bar{c} - \Delta c) &= r(\bar{c}) - \frac{dr}{dc}\Delta c + \frac{1}{2}\frac{d^2r}{d^2c}(\Delta c)^2, \end{aligned}\right\} \qquad (3)$$

The volume-average rate of the chemical reaction is given by

$$r = r(\bar{c}) + \frac{1}{2}\frac{d^2r}{dc^2}(\Delta c)^2. \qquad (4)$$

The rate of chemical conversion at equal initial concentrations of the reactants is as follows:

$$r_A = -k\bar{c}_A^2 - k(\Delta c_A)^2. \qquad (5)$$

For a stirred vessel, the deviation of the concentration from its mean value is related to the degree of homogeneity of the mass being stirred by [4]

$$\Delta c_A = \bar{c}_A(1 - \eta). \qquad (6)$$

The dependence of the degree of homogeneity on the volume mass-transfer coefficient is described by the equation

$$1 - \eta = \exp(-k_m\tau), \qquad (7)$$

1070-4272/02/7511-1841$27.00 © 2002 MAIK "Nauka/Interperiodica"

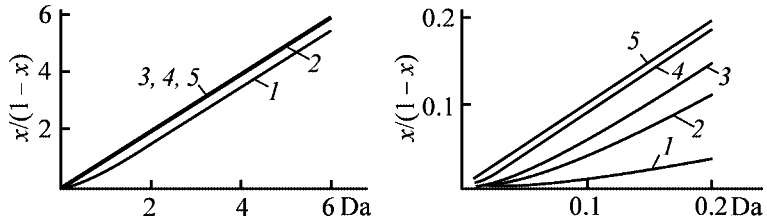

Fig. 1. Complex $x/(1 - x)$ vs. Dammköhler number Da for a batch reactor. *m*: (*1*) 1, (*2*) 5, (*3*) 10, (*4*) 50, and (*5*) ∞.

where k_m is the volume mass-transfer coefficient (s^{-1}), and τ is time (s).

Substitution of (6) and (7) into Eq. (5) gives an equation for calculating the average rate of the chemical reaction:

$$r_A = \frac{dc_A}{d\tau} = -k\bar{c}_A^2[1 + \exp(-2k_m\tau)]. \quad (8)$$

Integration of Eq. (8) with the initial conditions $\tau = 0$ and $c_A = c_{A_0}$ yields a relation for evaluating the reactant conversion in the course of the reaction:

$$\frac{x}{1 - x} = \mathrm{Da} + [\exp(-2m^2\,\mathrm{Da}) - 1]\frac{1}{2m^*}, \quad (9)$$

where $m^* = k_m/kc_{A_0}$ is the stirring parameter, c_{A_0} is the initial concentration of the reactant (mol m^{-3}), $\mathrm{Da} = kc_{A_0}\tau$ is the Dammköhler number, and x is the conversion.

An equation for calculating the conversion at unequal initial concentrations of the reactants can be derived similarly.

Figure 1, demonstrating the results of calculations by Eq. (9), shows that raising the complex m^* can create in the apparatus conditions close to the state of preliminary mixing of reagents. The complex m^* can be regarded as a characteristic of stirring. If the efficiency of mass transfer in the apparatus is high, i.e., $m^* \gg 1$, then stirring has no effect on the course of the chemical reaction; otherwise, the stirring starts to affect the chemical process.

The aim of this study was to determine experimentally the values of the parameter m^* at which the state of preliminary mixing of input flows in a srtirred vessel is ensured.

EXPERIMENTAL

The method of a model reaction was used in the experiments. As the model reaction served the second-order reaction of hydrogen peroxide with sodium thiosulfate [5]:

$$H_2O_2 + Na_2S_2O_3 \xrightarrow{k} \text{Products}, \quad (10)$$

with the rate constant $k = 6.853 \times 10^5 \times \exp(-18\,200/RT)$ l mol^{-1} s^{-1}.

The experiments were carried out on an installation described in [6–8]. As object of study served a 1-l flat-bottom cylindrical vessel 106 mm in diameter. The vessel casing was made of glass, which allowed visual inspection of the process. The reagents were fed into the vessel through standpipes directly to the surface of the reacting mass. The product formed was discharged through a pipe at the vessel bottom.

The conversion in the model reaction was determined as follows. The concentrations of reactant solutions in the feeding vessels were hydrogen peroxide 0.8 M and sodium thiosulfate 0.4 M. In all the experiments, the molar ratio of the reactant concentrations (peroxide : thiosulfate) in the reactor, provided that the substances were uniformly distributed over the entire volume of the apparatus, was 2 : 1, which corresponds to the reaction stoichiometry [5]. The solutions were fed into the reactor by dosing pumps, with the flow rates monitored with rotameters. The volumetric flow rates of the reactants were the same in all the experiments. All measurements were done in the steady state, the conditions for its attainment were established in [6–8]. The temperature was recorded with an electronic measuring and control system. The temperature probe was placed within the reactor outlet (at the reactor bottom). The accuracy of temperature measurements was 0.5°C. The temperature of the input flows was measured with mercury thermometers to within 0.1°C. The experiments were carried out at temperatures of the medium in the apparatus in the range 26–31°C. The heat effect of the reaction in this temperature range was 117 kcal mol^{-1}. The substance conversion was evaluated from the change in temperature within the reactor volume. The reactor operated under nearly adiabatic conditions since the heat removal through the side walls of the reactor did not

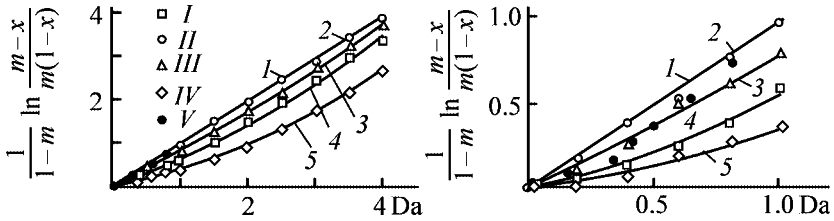

Fig. 2. Complex $(m-1)^{-1}\ln\{[(m-x)[m(1-x)]^{-1}\}$ vs. Dammköhler number Da for a batch reactor. m^*: (*1*) ∞, (*2*) 14, (*3*) 7.2, (*4*) 3.5, and (*5*) 1.75. Data from references: (*I–IV*) [10] and (*V*) [11] (m^* = 20.4).

exceed 1% of the heat carried away from the reactor by the output flow. The conversion of the reactants was calculated by the formula

$$x = \sum_{1}^{2}[\rho C_p(T_f - T_{in})](c_{A_0}\Delta H)^{-1}, \qquad (11)$$

where C_p is the specific heat of the substance (J kg^{-1} deg^{-1}); ΔH, the heat effect of the reaction (J mol^{-1}); T, the final and initial temperatures (deg); ρ, the density of the substance (kg m^{-3}).

The volume mass-transfer coefficient was calculated by the equation [9]

$$k_m = K\bar{V}^{-0.52}(\varepsilon/\nu)^{1/2}[\ln(Sc) - 1.27]^{-1}, \qquad (12)$$

where V is the vessel volume (m^3); Sc = ν/D, the Schmidt number; ε, the power expenditure for stirring of a unit mass of the liquid (m^2 s^{-3}); ν, the kinematic coefficient of viscosity (m^2 s^{-1}); D, the diffusion coefficient (m^2 s^{-1}); the coefficient K is 0.0016 for turbine-type agitators and 0.00047 for blade stirrers.

The numerical values of the coefficients and the dependence of the volume mass-transfer coefficient on the vessel volume were determined in experimental studies of the stirring rate in stirred vessels [10–12].

The distribution of the residence time (DRT) was studied using the tracer (KCl solution) and measuring variation of the electrical conductivity of the output flow. The DRT curves were obtained at varied process parameters (n = 120–625 rpm, τ = 90–200 s). Experimental data processing demonstrated that, in all process modes, the DRT of the vessel corresponds to the ideal mixing model.

The experimental conversion was compared with that possible theoretically, calculated by Eqs. (9) at m^* = ∞ and by the Danckwerts equation [1, 2] for continuous reactors:

$$x = 1 - \int \frac{\exp(-\theta)}{1 + Da\,\theta}d\theta, \qquad (13)$$

where $\theta = \tau/\bar{\tau}$ is the relative residence time; τ, the average residence time of the liquid in the apparatus (s); Da = $kc_{A_0}\bar{\tau}$, the Dammköhler number.

The results obtained in theoretical and experimental studies are shown in Figs. 2 and 3 for batch and continuous reactors, respectively. The results obtained in studying different reactions in vessels of different designs and dimensions are in good agreement. It can be seen from Figs. 2 and 3 that raising the parameter m^* makes it possible to increase the conversion in a reactor.

At $m^* \geq 30$, conditions are ensured at which the conversion achieved is close to the theoretical value under the given process conditions. When the parameter m^* reaches m^*_{cr}, the system passes into the state of preliminarily mixed flows. With the parameter increasing further, the conversion ceases to vary.

Thus, the parameter m^* can serve as a criterion characterizing the transition of the reagents to the preliminary mixing state. In apparatus for which $m^* \geq m^*_{cr}$, the integral characteristics of a chemical process can be calculated by the Danckwerts and Zwietering equations.

CONCLUSION

A theoretical analysis and experimental studies demonstrated that the state of preliminary mixing of

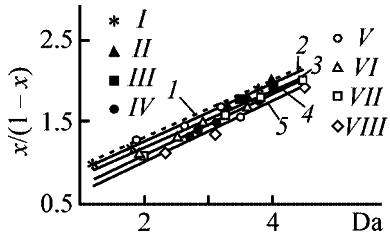

Fig. 3. Complex $x/(1-x)$ vs. Dammköhler number Da for a flow-through reactor. m^*: (*1*) ∞, (*2*) 54, (*3*) 25.4, (*4*) 14.2, and (*5*) 7.98. the input flows can be achieved at $m^* \geq 30$ in stirred vessels in the case when the flow structure corresponds to the ideal mixing model.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Multistage Mill with Flow-through Classification for Selective Comminution of Sylvinite Ore

A. E. Levdanskii, A. I. Vil'kotskii, and E. I. Levdanskii

Belarussian State Technological University, Minsk, Belarus

Received March 14, 2002

Abstract—The process of sylvinite ore comminution in a multistage flow-through mill is analyzed. The potential applications of the mill in preliminary treatment of the sylvinite ore to prepare it for flotation are considered.

In dressing of mineral ores, comminution occupies a prominent place. The efficiency of ore dressing is largely determined by the extent to which the components are accessible for agents used in dressing. Therefore, the ore is crushed to the required grain size, after which the valuable product is recovered. The flotation technique, based on differences in wettability between minerals, has gained the widest acceptance for recovery of components from ores.

The sylvinite ore contains three main components: potassium chloride, sodium chloride, and halopelite. The valuable recoverable mineral is potassium chloride, and the other two components are dumped. Halopelite contains various combinations of clayey minerals, carbonates, sulfates, chlorides, etc.

The potassium ores from the Starobinsk deposit contain an increased amount of halopelites, with the majority of these found in bands. The thickness of these bands in potassium horizons varies between fractions of a millimeter and several centimeters. In addition, a minor amount of halopelite is contained as microinclusions in rock salt and potassium minerals [1–4]. The composition of the potassium ore varies with the bed attitude, being not constant even within a single bed. In calculations, the following average component contents were adopted for the beds mined at the Starobinsk deposit (wt %): KCl 25, NaCl 69, and halopelite 8 [5].

The potassium ore extracted by plough machines in mines has lumps up to 150 mm in size, it is crushed in impact disintegrators to grain size of 10–15 mm. Since inclusions of potassium chloride in the sylvinite mineral are 0.5–3 mm in size, it is necessary to crush the ore to particle size of less than 3 mm to ensure total recovery of potassium chloride by flotation. For this purpose, the final comminution of the ore is done in rod mills by the wet method. A saturated aqueous solution of NaCl and KCl is used as liquid phase. The grinding is done using the closed system: the material ground in the rod mill is delivered for classification into an arch screen, wherefrom the undersize product is removed from the scheme, and the oversize product is returned into the mill for additional processing. The comminution by this scheme ensures the minimum possible overgrinding of the ore. However, water-insoluble impurities (halopelites) contained in the potassium ore and mainly represented by clayey–carbonate materials tend to swell in aqueous media and, when treated mechanically in a mill, are dispersed into fractions with grain size of less than 0.07 mm.

The presence in the milled ore of a finely dispersed clayey–carbonate sludge affects adversely the flotation of potassium salts [2]. This is accounted for by the fact that minute clay particles have large surface area onto which the flotation agents are adsorbed. The adverse influence of the clayey–carbonate sludge on the flotation is eliminated as follows: (1) mechanical rubbing-away of the sludges with subsequent removal of minute particles in hydrocyclones and hydroseparators; (2) flotation of sludges; (3) depression of sludges with depressing reagents, which, being adsorbed onto the surface of clayey–carbonate particles, preclude adsorption of collectors on these particles.

The scheme with preliminary removal of the major part of halopelite before delivering the ore into the drum mill for final comminution is more acceptable. It was noted in [3] that comminution of the sylvinite ore entails selective size distribution of KCl and halopelite: size grades larger than 3 mm are characterized

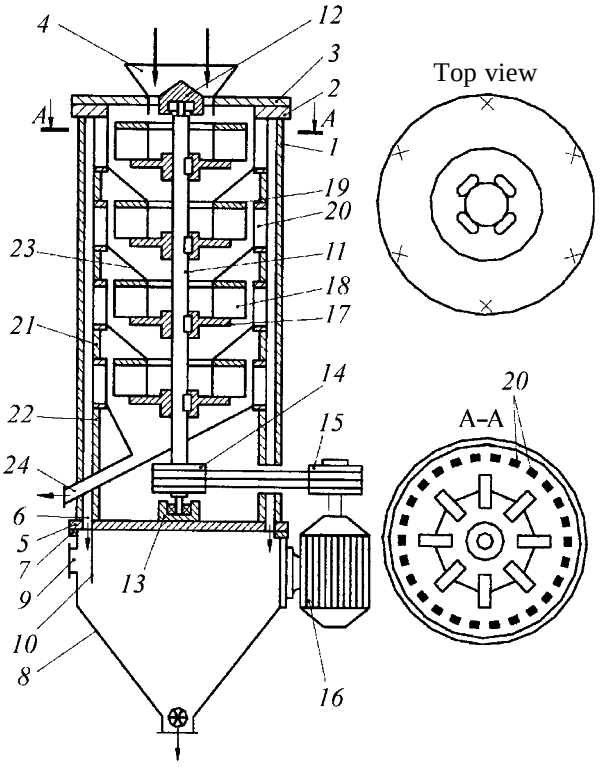

Fig. 1. Multistage rotary-centrifugal mill with flow-through classification of the material: (*1*) casing, (*2*, *7*) flanges, (*3*) cover plate, (*4*) funnel, (*5*) bottom plate, (*6*) annular slits, (*8*) bunker, (*9*) pipe, (*10*) bumper plate, (*11*) shaft, (*12*, *13*) bushing units, (*14*, *15*) pulleys, (*16*) electric motor, (*17*) discs, (*18*) blades, (*19*) rings, (*20*) baffler rods, (*21*) cylindrical collars, (*22*) bottom collar, (*23*) cones, and (*24*) pipe.

by lower content of KCl and higher content of halopelite, whereas fine grades are, conversely, characterized by high content of KCl and lower content of halopelite. It was proposed to process large-grain fractions containing increased amount of halopelite by means of halurgy, and fine fractions, by flotation, thus obtaining a high-quality concentrate. It was mentioned in the monograph [1] that, in dry grinding, the clayey admixtures having higher plasticity than salt minerals tend to accumulate in coarser fractions.

Of practical interest for the case of the potassium ore are the results obtained in tests on a pilot installation employing the dry method [5]. Based on the results obtained, the authors classed NaCl and KCl with easily milled components of the ore, and halopelite, with difficultly milled components. With the use of an installation comprising a unit for drying the material, impact mill, and air classifier, the content of halopelite in the ore can be lowered by 25–30%, with that in the clay–salt residue increasing to 40%. In the authors' opinion, this clay-salt residue can be used in various industries. To carry out investigations, a multistage rotary-centrifugal mill with continuous flow-through classification of the milled material has been developed. The mill design is shown in Fig. 1.

The mill comprises a vertical cylindrical vessel *1*, to whose upper part a cover plate *3* with a funnel *4* is attached with a flange *2*. A bottom plate *5* with annular slits *6* is attached to the lower part of the vessel. A flange *7* fixes a bunker *8* to the bottom. The bunker has on its side wall an outlet pipe *9* for air. To diminish the amount of the finely ground material carried away by air, a bumper plate *10* is mounted opposite the pipe *9*. A shaft *11* with ends fixed in bushings passes through the central part of the cylindrical casing of the mill. The upper bushing is attached to the bushing unit *12* of the upper cover *3*, and the lower, to the bushing unit *13* fixed to the bottom plate *5*. The shaft *11* is set in motion, via pulleys *14* and *15* and cone belts, by electric motor *16*. Coupling dowels and spacer sleeves fix discs *17* carrying blades *18*. The upper parts of the blades are attached to ring *19*. Baffler rods *20* with rectangular cross section are mounted opposite each disc with blades along the ring. The rods are mounted at a certain distance from one another, forming slits for passage of air and the milled material. The annular rows of rods are connected by cylindrical collars *21*. The bottom collar *22* is attached to the mill bottom *5*, so that the rings of baffler rods, collars *21* and *22*, and the shell of the casing *1* form an annular space communicating with the bunker through annular slits *6* in the bottom plate *5*. Cones *23* are mounted within the working space of the mill for delivery of the undermilled material from a higher stage to a lower one. The cone mounted below the last stage ends in a pipe *24* for removal of difficultly milled materials. A funnel *4* is attached to the upper cover for delivery of the material into the mill.

In an operating multistage rotary-centrifugal mill, the electric motor 16 sets in motion, via pulleys *14* and *15* and cone belts, the shaft *11* with discs *17* and blades *18*. The starting material is delivered into the funnel *4* and, passing through the annular slits in the upper cover plate, arrives at the upper disc *17* wherefrom its is thrown by blades *18* toward the baffler rods *20* at a high velocity. Upon impact on the rods, the material is crushed and its fine particles are carried by the air flow through slits between the rods into the annular space, and then move down within this space into the bunker. Coarse particles move down and,

passing through the cone *23*, arrive at the center of an underlying disc where additional comminution of the material occurs. Then the process is repeated. After the last stage, only those particles of the material remain which are difficultly milled, and these particles move within the cone and, further, through the pipe *24* out of the mill. Thus, there are no stagnant zones in the mill, accumulation of the material is ruled out, and the comminution process occurs repeatedly. It is the most appropriate to use this mill to carry out selective comminution based on the unequal extents of grinding of strong and soft rocks. Depending on physicomechanical properties of the minerals constituting the initial lumps, a certain degree of material dressing can be achieved at the outlet by selecting the necessary number of comminution stages and shaft rotation rate. Those components of the material which have low strength are crushed and, passing through slits between the rods, arrive at the bunker, and undermilled particles of a material with higher strength are removed from the mill via pipe *24*.

Thus, the multistage mill of the given design furnishes wider opportunities for carrying out selective comminution of sylvinite in order to recover halopelite to a fuller extent, with the minimum content of potassium chloride in the residue.

To test the working capacity of the new design and carry out preliminary investigations, a four-stage mill of this type with working wheel diameter (measured across the blade ends) of 400 mm was fabricated. The investigation demonstrated that this mill design can be used for selective comminution of multicomponent materials with different strengths of separate constituents. Preliminary studies revealed that the content of halopelite in enriched milled ore, and also the content of KCl and NaCl in the halopelite residue are affected by numerous factors, such as moisture content of the ore, speed of rotor rotation, width of slits between the baffler rods, number of stages in the mill, output capacity in terms of the starting ore, etc. Further, a single-stage mill with stage dimensions equal to those in the multistage mill was used. The unmilled residue, discharged from the bottom part of the mill, was again fed into the mill a necessary number of times. After each passage of the material through the mill, the amount of milled material, unmilled residue, and the content of halopelite in both of the flows were measured. The content of halopelite in the ore was determined by weighing the dry residue after dissolving an ore sample in water three times in succession. A 100-g portion of the ore was placed in a vessel and poured over with 1 l of water. The dissolution was

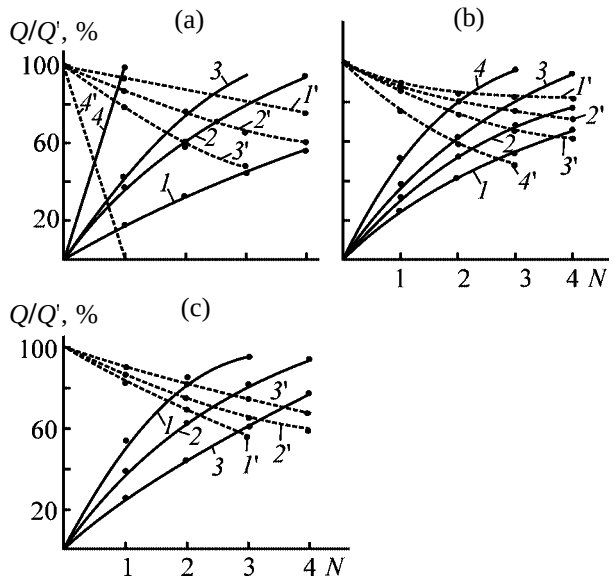

Fig. 2. Variation over stages *N* of (*1*–*4*) the amount *Q* of milled ore and (*1'*–*4'*) that of halopelite in the residue. (a) G = 960 kg h^{-1}, δ = 3 mm; (b) G = 960 kg h^{-1}, n = 1033 pm; and (c) n = 1033 rpm, δ = 3 mm. (a) Speed of rotor rotation, n (rpm): (*1*, *1'*) 710, (*2*, *2'*) 1033, (*3*, *3'*) 1500, and (*4*, *4'*) 3100. (b) Slit width between the rods, δ (mm): (*1*, *1'*) 1, (*2*, *2'*) 2, (*3*, *3'*) 3, and (*4*, *4'*) 4. (*c*) Load on the mill, G (kg h^{-1}): (*1*, *1'*) 480, (*2*, *2'*) 960, and (*3*, *3'*) 1030.

done under vigorous stirring, the sample was allowed to stay for 24 h, and then the aqueous salt solution was decanted. The procedure was repeated two times more, after which the insoluble residue was dried and weighed.

It should be noted that the content of halopelite in several samples taken from a small batch of sylvinite ore differed widely, and, therefore, three samples of each of the starting and milled ore and undermilled residue were taken. In data processing, the results of analysis were averaged over three samples. The experiments demonstrated that recovery of halopelite from the sylvinite ore by selective comminution can only be achieved at its moisture content not exceeding 1%. At moisture content of the ore exceeding 5%, no selective grinding of the ore was observed at all. Therefore, in further experiments, the ore was dried to moisture content of less than 1% and stored prior to experiments in tightly sealed polyethylene bags.

The principal results of the study are shown in Figs. 2a–2c. The solid lines represent the increase in the amount of milled ore (in percent of the initial amount) on its successive passage through the four stages of the mill, and the dashed lines show the decrease in the amount of halopelite (in percent of the initial amount) in the unmilled residue.

Figure 2a shows the results of experiments carried out at different rates of rotor rotation. The load on the mill in terms of the starting ore was 960 kg h^{-1}, and the spacing between the baffler rods, 3 mm. It can be seen that the largest amount of milled ore is removed from the mill in the first and second stages. This is due to the fact that the starting ore, mined with a plough machine and subjected to preliminary crushing, contains a large amount of the fine fraction, which is removed from the grinding zone in the first and second stages of the pilot mill. It can also be seen from Fig. 2a that the rotation speed of the rotor, n = 3100 rpm, which corresponds to a circumferential velocity of the blade ends of 65 m s^{-1}, is unacceptable since the ore comminution, including that of the difficultly milled halopelite, is complete already in the first stage (lines *4* and *4*'). At the same time, at n = 710 rpm, which corresponds to a circumferential velocity of blade ends of 15 m s^{-1}, the ore comminution is incomplete, and, even after the fourth stage, about 40% of the ore is removed from the mill in the form of an unmilled residue, which is economically and environmentally unacceptable. Thus, the acceptable circumferential velocity of blade ends in the rotary-centrifugal mill must be 20–30 m s^{-1}.

The influence exerted by the slits between the baffler rods on the degree of comminution was studied with the slit width varied between 1 and 4 mm. The granulometric composition of the grinding products was determined by sieving. Experiments demonstrated that the comminution product is composed of particles less than 3 mm in size at slit width δ = 4 mm, less than 2.2 mm at δ = 2 mm, and less than 0.6 mm at δ = 1 mm. Figure 2b shows the results of ore comminution for varied number of stages at different widths of slits between the baffler rods. For example, virtually complete ore comminution occurred in three stages at slit width δ = 4 mm. However, a considerable amount (>50%) of halopelite passed into the milled ore (curve *4*). At the same time, at slit widths of 1, and even 2 mm (curves *1* and *2*), the entire amount of the ore could be ground finely on passing four stages, and its considerable part (20 to 40%) was removed from the mill in the form of an unmilled residue. It should be noted that the major part of halopelite (curves *1*' and *2*') also remained in the unmilled part of the ore. The results presented in Fig. 2b demonstrate that, with account of the requirements to the granulometric composition of the ore delivered to flotation, the optimal width of slits between the baffler rods must be 3–3.5 mm.

The effect of the rate of supplying the starting ore, G, on the degree of its comminution over stages of the rotary-centrifugal mill can be seen from Fig. 2c, which shows for the same G how the content of halopelite in the residue decreases after multistage comminution. It follows from the figure that the optimal G value for the given mill dimensions is about 100 kg h^{-1}. In the pilot mill, the height of baffler rods was 70 mm. If these rods are made longer, the throughput will, naturally, increase. For industrial implementation of the mill, it is necessary to carry out industrial tests of a mill of similar design with output capacity of 8–10 t h^{-1}.

CONCLUSION

The study performed demonstrated that a multistage rotary-centrifugal mill can be successfully used instead of a rod mill in flotation manufacture of potassium fertilizers. In the process, more than half of the halopelite contained will be removed from the ore, which will markedly improve the flotation. In addition, impact comminution of the material in the given mill yields a much smaller amount of overmilled ore, which also exerts positive influence on the flotation process.

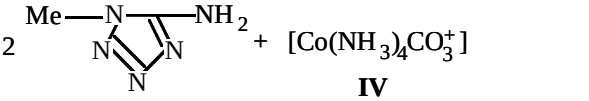
Abstract—Physicochemical and explosive properties of tetraamminebis(1-methyl-5-aminotetrazole-N^3, N^4) cobalt(III) perchlorate were studied. The possibility of using this compound as priming charge was demonstrated.

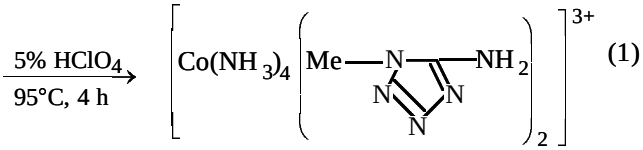
Previously we showed [1] that high-energy-capacity tetraammine-*cis*-bis(5-nitro-2*H*-tetrazolato-N^2)-cobalt(III) perchlorate (**I**) can be used instead of conventional primers in priming charges (PC). At present complex **I** is used in missile manufacture and mining industry. In this work we prepared and characterized tetraamminebis(1-methyl-5-aminotetrazole-N^3, N^4)cobalt(III) perchlorate (**II**) which has a combustion–detonation transition. The structure of this complex is similar to that of **I**. We studied structural features and detonating properties of **II**.

EXPERIMENTAL

Complex **II** was prepared as follows:



III **IV**



(1)

II

Carbonatotetraamminecobalt(III) perchlorate (IV) was prepared by the procedure in [2]. The yield of the dried compound was 77%. IR, cm^{-1}: 1596 s, 1560 m (C=O, NH_3), 1084 s (ClO_4). ^1H NMR (DMSO-d_6), δ, ppm: 4.40 (12 H, NH3).

Found, %: C 4.6, H 4.7, N 20.1
$CH_{12}ClCoN_4O_7$
Calculated, %: C 4.2, H 4.2, N 19.6

Tetraamminebis(1-methyl-5-aminotetrazole-N^3, N^4)cobalt(III) perchlorate (II). A solution of **IV** (0.5 g) in 5% perchloric acid (10 ml) was filtered. To the filtrate 1-methyl-5-aminotetrazole (**III**) prepared by the procedure in [3] was added. The reaction mixture was heated on a boiling water bath for 4 h and cooled to 15°C. The precipitate was filtered off, washed with ethanol (2 × 5 ml), and recrystallized from 1% perchloric acid. Yield 58%. IR, cm^{-1}: 3316 m, 1334 m 9NH_3, Tz), 1118 m (ClO_4), 1628 m (C=N), 3236 w, 1616 w (NH_2), 2830 w (CH_3). ^1H NMR (DMSO-d_6), δ, ppm: 3.85, 3.90 [9H, NH_3(*eq*)], 3.75, 3.80 [3H, NH_3(*ax*)], 7.12 [2H, NH_2-Tz(ax)], 7.52 [2H, NH_2-Tz(*eq*), 4.03 [3H, CH_3-Tz(*ax*)], 4.22 [3H, CH_3-Tz(*eq*)].

Found, %: C 7.8, H 3.3, N 31.9
$C_4H_{22}Cl_3CoN_{14}O_{12}$
Calculated, %: C 7.7, H 3.6, N 31.5

The IR spectrum of **II** in the form of thin film or Nujol mull was recorded on a Perkin–Elmer M-457 spectrometer; the electronic absorption spectrum was recorded on a Perkin–Elmer LAMBDA 40 spectrometer; the ^1H NMR spectra were recorded in DMSO-d_6 solution on a Bruker AC (300 MHz) spectrometer using hexamethyldisiloxane as internal reference.

Synthesis of **II** was monitored by thin-layer chromatography on Silufol UV-254 plates using 3% sodium perchlorate solution as the eluent.

Thermal gravimetric analysis was performed on an MOM derivatograph (Hungary) in the range 20–500°C with the heating rate of 5 deg min^{-1}. The onset temperature of intense decomposition T_0 was determined on a thermograph at the heating rate of

1070-4272/02/7511-1849$27.00 © 2002 MAIK "Nauka/Interperiodica"

5.3 deg min^{-1}. The sensitivity to shock and fire beam of fuse (SF) was determined by the pile-driving procedure performed in accordance with GOST (State Standard) 1944–80 and OST (Branch Standard) V-84-8892–72, respectively. The minimal primer charge (MPC) of the complexes was determined with respect to hexogen in the bulk of detonating cap (DC) no. 8 (compaction pressures P_p of the compound and hexogen were 121 and 363 kg cm^{-2}, respectively).

The X-ray reflection intensities were collected at room temperature on an Enraf–Nonius CAD-4 automatic diffractometer (graphite monochromator, MoK_α radiation, θ scanning, θ_{max} = 28°). A total of 5268 reflections were registered. The structural parameters were determined and refined using 3222 reflections with $I > 2\sigma(I)$. The calculations were performed with the aid of Shelx-93 software.

The structure of **II** was solved by the direct method and refined by the full-matrix least-squares techniques. Nonhydrogen atoms were refined anisotropically. Hydrogen atoms were located by difference maps and refined with the same thermal parameter (3.948 $Å^2$). The maximal and minimal densities of free electrons on the last *F* map were 0.92 and –0.77 e/$Å^3$, respectively. The structure was refined to *R* 0.048, R_w 0.136, and GOOF 1.119.

Complex **II** is a golden yellow powder soluble in water, DMSO, and DMF and poorly soluble in ethanol, isopropanol, and isobutanol. The physicochemical and explosion properties of **II** as as follows: density ρ_{exp} = 1.90 g cm^{-3}, detonation rate D^0_{calc} = 7.5 km s^{-1}, T_o 234°C, SF (the lower limit of 100% ignition) 2.0 cm, MPC 0.15 g, sensitivity to shock (height 25 cm, load 2 kg, weighted portion of the sample 20 mg) 8%.

To estimate the detonation rate of **II**, a molecule of the complex was separated into the active (perchlorate anion and ligands) and inert (metal cation) parts. The calculation was performed using increments of the structural fragments. The average error was ±140 m s^{-1} [4].

The study of thermolysis of **II** under dynamic conditions at a heating rate of 5 deg min^{-1} showed that this complex is relatively stable thermally (T_o > 230°C). The first step of thermolysis of Co(III) tetraamminetetrazolates is elimination of coordinated ammonia molecule with subsequent decomposition of the residual complex. Then tetrazole ligands are oxidized stepwise with perchlorate counterions [5]. In the case of complex **II**, all the steps overlap in time, and the thermogram contains a single exothermic peak with a maximum at 289°C. The kinetic parameters of thermolysis at T_o were calculated from the results of differential termogravimetry (DTG) and differential thermal analysis (DTA). The preexponential factor of the Arrhenius equation, activation energy (kJ mol^{-1}), and the reaction order are 18.5, 218.3, and 1.0, respectively. The first reaction order indicates that diffusion is not the rate-determining step of the degradation.

The IR spectrum of complex **II** contains the bands of coordinated ammonia, methyl and amino groups of the tetrazole ring, and perchlorate anions. The electronic absorption spectrum of an aqueous solution of this complex is typical for this type of coordination compounds and contains the band of *d–d* ($^1T_{1g} \leftarrow {}^1A_{1g}$) transition at 466 nm ($\varepsilon$ 77 l cm^{-1} mol^{-1}). The other strong band ($^1T_{2g} \leftarrow {}^1A_{1g}$) is obscured by the absorption of the tetrazole ligand. Clearly the molecule of the complex contains the octahedral CoN_6 chromophore. In the ^{1}H NMR spectrum of **II**, the signals of equatorial (downfield) and axial (upfield) ammonia ligands are present in the range 3.5–4.0 ppm. The difference in the location of the singals of equatorial (3.85 and 3.90 ppm) and axial (3.75 and 3.80 ppm) ammonia molecules is consistent with coordination of the heterocyclic ligands via the nitrogen atoms [7]. Spitting of these signals into doublets indicates that the ammine protons are nonequivalent. This spitting is due to coordination of N^3 and N^4 nitrogen atoms of the tetrazole rings.

As determined by single crystal X-ray diffraction, complex **II** crystallizes in the monoclinic system with space group $P2_1/c$, *a* = 13.664(3), *b* = 8.054(3), *c* = 19.880(4) Å, β = 95.07(3)°, *Z* = 4, *V* = 2179.3(9) $Å^3$, *M* = 623.64, ρ_{calc} = 1.90 g cm^{-3}, μ_{Mo} = 1.242 mm^{-1}, *F*(000) 1272.0.

The atomic coordinates and equivalent isotropic thermal parameters are deposited at the Cambridge Crystallographic Data Center. The crystal structure of **II** consists of $[Co(C_2H_5N_5)_2(NH_3)_4]^{3+}$ complex cations and "free" ClO_4^- anions. The octahedral coordination environment of Co is completed by four N atoms of ammonia molecules and two N atoms of 1-methyl-5-aminotetrazole molecules A and B. Molecules A and B are in the axial and equatorial positions, respectively, with the dihedral angle between the planes of the tetrazole rings being 60.2° (Fig. 1). It should be noted that the heterocyclic ligands are coordinated via different nitrogen atoms (N^3 and N^4), whereas in complexes containing several tetrazole molecules these ligands are usually coordinated by similar nitrogen atoms {e.g. complex **I** [8], [pentakis-(1-phenyltetrazole-N^4)-tetrafluoroborato]copper(II) [9]}. The CoN_6 octahedron is virtually undistorted:

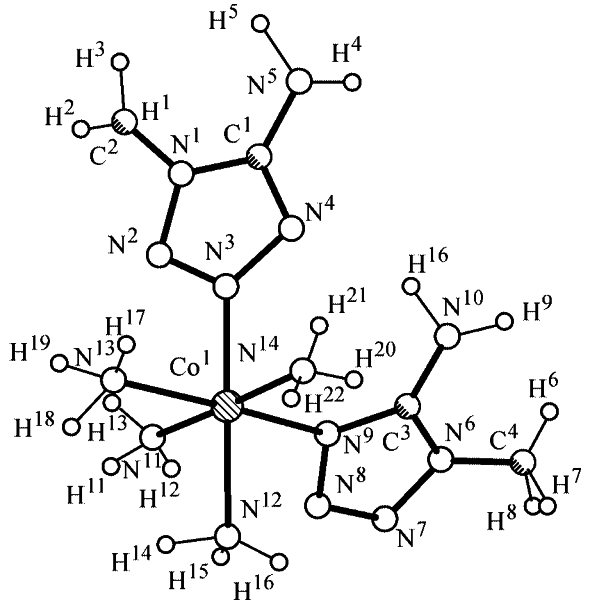


Fig. 1. Molecular structure of the $[Co(C_2H_5N_5)_2(NH_3)_4]^{3+}$ complex cation.

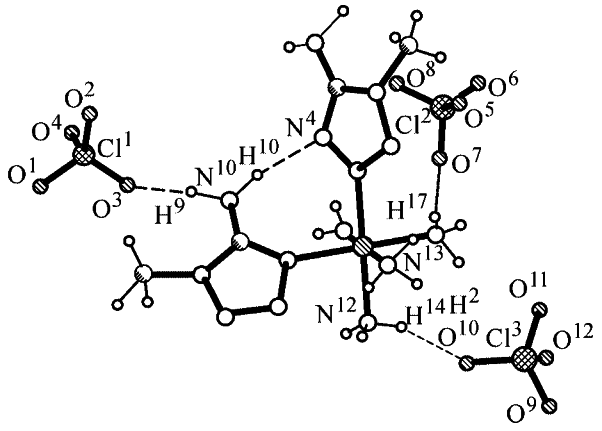

Fig. 2. Hydrogen bonding in the crystal structure of **II**.

the average deviation of nitrogen and cobalt atoms form the equatorial plane is 0.008 Å. The N^3N^{12} axial axis forms an 88.5° angle with this plane. The Co–N distances range from 1.929 to 1.9717 Å. The distance between Co and N^9 atom of the equatorial tetrazole ligand is the longest, and the distance between Co and N^3 of the axial tetrazole ligand is the shortest.

The tetrazole rings of the organic ligands are planar [the average deviation of the atoms form the least-squares plane in molecules A and B is 0.056 and 0.034 Å, respectively]. The interatomic distances and angles in molecules A and B are similar. The main differences are due to different orientation of the NH_2 groups and their hydrogen bonding. The amino group in molecule A is turned relative to the plane of the heterocyclic ring by 28.1°. The N^5 atom is in the flattened pyramidal surrounding (the sum of the bond angles at this atom is 344.1°) and does not form hydrogen bonds (Fig. 2). The NH_2 group of molecule B is almost coplanar with the plane of the heterocyclic ring. It is turned relative to the plane by 7.1°. The N^{10} atom is in trigonal planar surrounding (the sum of bond angles at this atom is 354.7°) and forms H bonds with the N atom of the heterocyclic ring of molecule A and ClO_4^- anion.

Coordinated ammonia molecules are nonequivalent: two of them form weak hydrogen bonds with ClO_4^- anion and two other do not (Fig. 2).

The perchlorate anions in the structure of **II** have typical interatomic distances and angles [10]. High thermal parameters of O atoms of these uncoordinated anions indicate their high mobility.

CONCLUSIONS

(1) 1-Methyl-5-aminotetrazole reacts with Co(III) tetraamminate in perchloric acid to form tetraammine-bis(1-methyl-5-aminotetrazole-N^3,N^4)cobalt(III) perchlorate. The heterocylic ligands are coordinated with the Co atom via different nitrogen atoms and occupy axial and equatorial positions in the coordination sphere.

(2) This complex shows promise as priming explosive which can be used in safe priming facilities operating from an incandescence bridge.

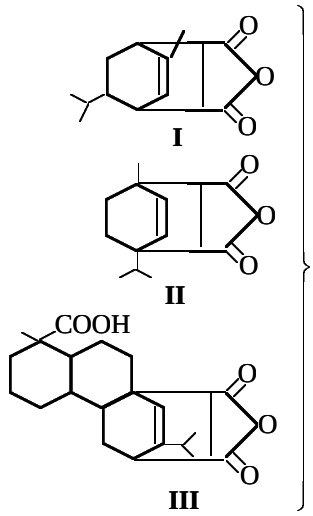
Abstract—Conditions were found for separation of a mixture of terpenoid–maleic adducts and maleic adduct of resin acids in the form of methyl esters by gas–liquid chromatography.

Terpenoid–maleic adducts (TMAs) prepared by the reaction of terpenoids with maleic anhydride, and also their derivatives (esters, imides, heavy metal salts) are used in electrical, paint-and-varnish, rubber, and pulp-and-paper industries [1]. TMAs are complex multicomponent mixtures whose composition is determined by the raw material and preparation conditions [2]. Group analysis of TMAs by physicochemical methods is difficult and labor-consuming. The use of a quicker analytical method, gas–liquid chromatography (GLC), for the analysis of TMAs was limited to chromatography of methyl esters of terpene–maleic adducts [3]; we found no data on the conditions for separation of TMAs containing, along with terpene–maleic adducts, also the resin acid adduct.

The goal of this study was to find conditions for GLC separation of a mixture of terpene–maleic adducts and the maleic adduct of resin acids (in the form of methyl esters).

EXPERIMENTAL

The procedure for preparing dimethyl esters of terpene–maleic adducts [3] is labor-consuming and involves synthesis and use of diazomethane, which is toxic and dangerously explosive [4]. With the aim to eliminate the use of diazomethane, we methylated adducts **I**–**III** by thermolysis of the tetramethylammonium salts of the adducts in the chromatograph vaporizer [5]:



$$+\ n[(CH_3)_4N]OH \xrightarrow{60^\circ C} R[COON(CH_3)_4]_n + n\,H_2O,$$

$$R[COON(CH_3)_4]_n \xrightarrow{250^\circ C} R(COOCH_3)_n + nCH_3)_3N,$$

where n = 2 (**I**, **II**), 3 (**III**); R is the hydrocarbon fragment of the adduct.

The methylation procedure proposed (method 1) involves titration of a sample of **I**–**III** (0.2 ml of a 10% alcoholic solution) with a 3% aqueous solution of tetramethylammonium hydroxide [5] in the presence of phenolphthalein (a drop of 0.1% alcoholic solution) at 60–70°C until appearance of stable pink

1070-4272/02/7511-1852$27.00 © 2002 MAIK "Nauka/Interperiodica"

color. The resulting solution was evaporated almost to dryness, and the residue was dissolved in alcohol (volume ratio from 1 : 1 to 1 : 3) and injected into the chromatograph vaporizer with a microsyringe (0.5 to 1.5 μl).

Compounds **I**–**III** were also methylated with diazomethane (method 2) [6]. A three-necked flask equipped with a dropping funnel, a reflux condenser, and a capillary for feeding inert gas (nitrogen) was charged with 8.4 g of KOH, 2.8 ml of hydrazine hydrate, and 30 ml of methanol; 10 ml of chloroform was placed in the dropping funnel. The flask was deaerated by passing nitrogen at a rate of 20 ml min^{-1}, with the gas outlet through the reflux condenser. After that, the outgoing gas from the flask was fed to a bubbler (25 ml) containing 0.2 g of **I**–**III** in 10 ml of ether–methanol (9 : 1 by volume). Chloroform was added dropwise from the dropping funnel. The evolving diazomethane was transferred with a nitrogen flow to the bubbler with the sample. After the reaction completion, the solvent was removed, and 2 ml of hexane was added. The crystals were separated and used for GLC experiments; their IR spectra were measured.

According to modern views, terpene–maleic adducts prepared from turpentines contain monoadducts consisting of α-phellandrene (**I**) and α-terpinene (**II**) adducts [7].[1]

Maleopimaric acid **III** was prepared from pine oleoresin. Oleoresin (16 g) was dissolved in 40 ml of hexane and kept at 2–3°C for 18 h, after which the solution was separated from the precipitated oxidized substances by decanting. The solution of resin acids in hexane was saponified with 2% aqueous NaOH (100 ml), and the aqueous phase was separated with a separatory funnel. Then the aqueous phase was acidified with 40 ml of 12.5% aqueous acetic acid, and the released acids were extracted with hexane (2 × 30 ml). The extract was dried over $CaCl_2$, and a solution of freshly distilled maleic anhydride (1.6 g) in acetone (2.5 ml) was added dropwise at 45–50°C over a period of 10 min. The mixture was stirred at 45–50°C for 4 h. The precipitated maleopimaric acid was washed with hexane (3 × 30 ml) and hot (60–70°C) water (4 × 125 ml) and dried in a vacuum desiccator over $CaCl_2$. The melting point of maleopimaric acid obtained was 224.5°C.

The IR spectra of adducts **I**–**III** (KBr, UR-20 spectrometer) contained absorption bands at 1784 and 1855 cm^{-1}, characteristic of carbonyl groups of maleic anhydride. The absence of these bands in the spectra of methyl esters of **I**–**III** and appearance of a band at 1750 cm^{-1}, characteristic of the ester carbonyl group, indicate that method 2 ensures exhaustive methylation of **I**–**III**.

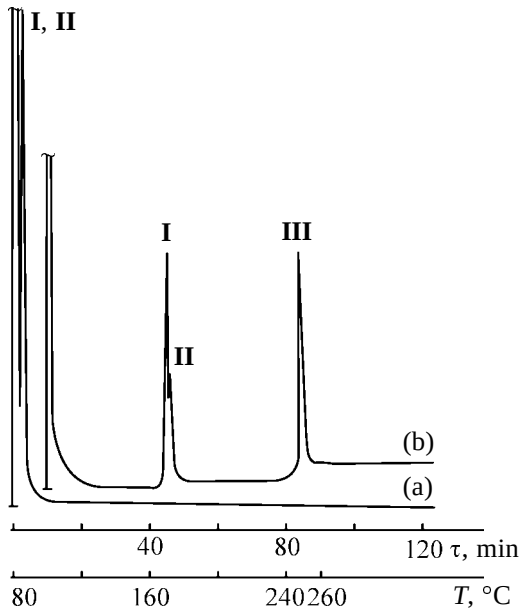


Fig. 1. GLC separation of a mixture of **I**–**III** methylated by method 1: (τ) time and (*T*) temperature; the same for Fig. 2. (a) Isothermal mode, column temperature 190°C, vaporizer temperature 245 ± 5°C, linear velocity of carrier gas (nitrogen) 11 cm s^{-1}; (b) programmed heating from 80 to 260°C at a rate of 2 deg min^{-1}.

GLC separation of **I**–**III** was performed with an LKhM-8MD-5 chromatograph equipped with a flame ionization detector; a stainless steel column (1000 mm long, 3 mm i.d.) was packed with Chromaton N-AW-DMCS + 5 wt % XE-60. With other high-temperature liquid phases (Apiezon L, Apiezon N, E-301, SE-30), separation of methyl esters of **I**–**III** was worse.

The column and vaporizer temperatures were chosen taking into account the fact that methyl esters of **I**–**III** and resin acid adducts tend to decompose at column temperatures higher than 190°C and vaporizer temperatures higher than 215°C [8, 9].

It should be noted that, in separation of methyl esters prepared by thermolysis of tetramethylammonium salts, the vaporizer temperature should be higher, 250°C [5].

Figures 1 and 2 show the chromatograms of the methyl esters of **I**–**III** obtained by methods 1 and 2, respectively.

[1] Samples of α-phellandrene and α-terpinene adducts were kindly submitted by A.I. Pronevich (Belarussian State Technological University).

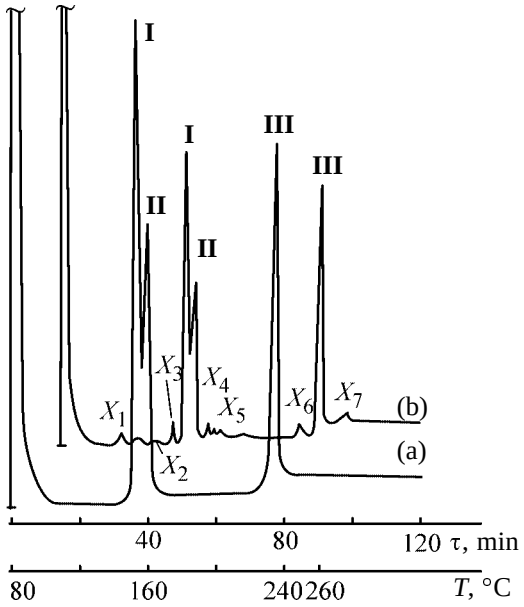

Fig. 2. GLC separation of a mixture of **I**–**III** methylated by method 2. Vaporizer temperature, °C: (a) 210 ± 5 and (b) 245 ± 5. (X_1–X_7) Peaks of decomposition products.

As seen from Fig. 1a, at a column temperature of 190°C in the isothermal mode the dimethyl esters of **I** and **II** are not separated, and the peak of the trimethyl ester of **III** is lacking. Programmed heating from 80 to 260°C at a rate of 2 deg min^{-1} and vaporizer temperature of 245 ± 5°C allowed satisfactory separation of **I** and **II** and elution of **III** as a narrow peak (Fig. 1b). These conditions ensure decomposition of tetramethylammonium salts of **I**–**III** and formation of the methyl esters without their subsequent thermolysis.

As seen from Fig. 2a, separation of a mixture of **I**–**III** methylated by method 2 should be performed at the vaporizer temperature of 210 ± 5°C, since at 245 ± 5°C (Fig. 2b) peaks of decomposition products X_1–X_7 appear in the chromatogram. The chromatograms of mixtures of **I**–**III** methylated by methods 2 (Fig. 2a) and 1 (Fig. 1b) were identical.

CONCLUSION

Conditions were found for separation by gas–liquid chromatography of not only dimethyl, but also trimethyl esters of adducts, with these esters being prepared without using diazomethane. The separation procedure proposed can be used for developing and optimizing processes of production of new terpene–maleic adducts, for revealing relationships between their composition and physicochemical properties, and for studying the mechanism of thermal degradation of terpene–maleic adducts by analysis of their decomposition products.

Received May 30, 2002

Abstract—Features of homogeneous radical copolymerization of sodium 2-acrylamido-2-methyl-2-propanesulfonate with *N*-vinyl-2-pyrrolidone in water and aqueous NaCl solutions at pH 9 and 50°C, initiated with the redox system potassium peroxomonosulfate K_2SO_5–sodium pyrosulfite $Na_2S_2O_5$ were studied dilatometrically.

Water-soluble copolymers of salts of 2-acrylamido-2-methyl-2-propanesulfonic acid (H-AMS) with *N*-vinyl-2-pyrrolidone (N-VP) exhibit high thickening, flocculating [1], adhesive, and antistatic activity [2] and complexing power, which makes them undoubtedly promising for medicine, pharmaceutical and cosmetic industry, etc. [3–5]. Data are available on copolymerization of N-VP with sodium salts of ethylenesulfonic acid [6], *p*-styrenesulfonic acid [7], and H-AMS [7, 8]; the effect of the cation on copolymerization of N-VP with Li, Na, K [9, 10], Mg, and Ca [10, 11] salts of H-AMS in aqueous solution was considered. A set of valuable properties and insufficient knowledge of the copolymerization processes make it necessary to study systematically the features of copolymerization of H-AMS salts with N-VP in various media with the aim to prepare copolymers with controllable molecular characteristics and properties. Here we report on features of radical copolymerization of Na-AMS with N-VP in water and aqueous salt solutions.

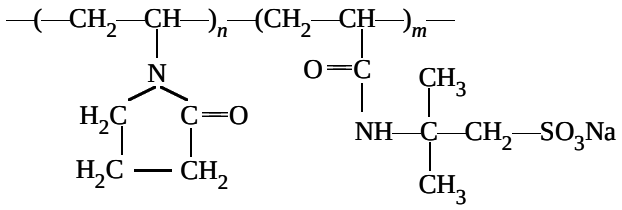
EXPERIMENTAL

Na-AMS was prepared by neutralization of aqueous solutions of H-AMS (Lubrizol, the United Kingdom; mp 185°C) with an aqueous solution of NaOH to pH 9; N-VP (Merck, Germany) was purified by double distillation in a vacuum from KOH (0.1%); n_D^{20} 1.5119. Potassium peroxomonosulfate (PP) was purified by double recrystallization from water; the main substance content determined by redox titration was 97.8%. All the solutions were prepared in distilled water. Other chemicals were of chemically pure or analytically pure grads.

Copolymerization of Na-AMS (M_1) with N-VP (M_2) was performed in 15% aqueous solutions in the presence of the redox initiating system PP–sodium pyrosulfite (SP) ([PP] = [SP] = 7.4×10^{-5} M) at 50°C for 2 h. All the experiments were performed at pH 9 at which the system PP–SP is effective [12], the initiation rate is independent of the solution ionic strength [13], and Na-AMS [4] and N-VP [5] are not hydrolyzed.

The reaction was performed in 7 cm^3 glass dilatometers and 25 cm^3 weighing bottles. The copolymerization procedure was similar to that described in [8]. The copolymers were reprecipitated from aqueous solurtions into acetone, washed with acetone, and dried in a vacuum oven at 50°C to constant weight.

The yield of the copolymers was determined gravimetrically. The content of ionic units in the N-VP–Na-AMS copolymer



was calculated from the sulfur content determined according to [14]. The molecular weight *M* of the copolymers was evaluated from the intrinsic viscosity

(x) Conversion and (τ) time. M_1: (*1*) 0.5, (*2*) 0.6, (*3*) 0.4, (*4*) 0.3, (*5*) 0.2, (*6*) 0.7, (*7*) 0.8, (*8*) 0.9, and (*9*) 0.1.

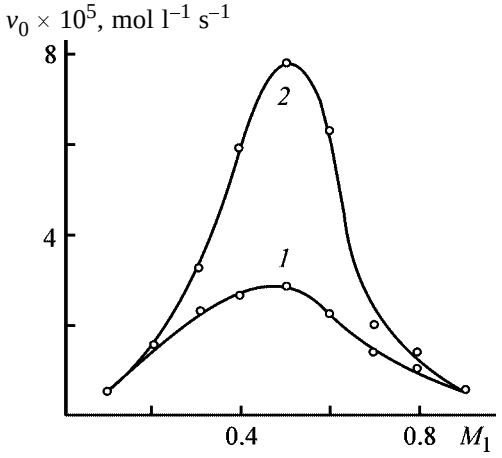

Fig. 2. Initial rate v_0 of copolymerization of Na-AMS with N-VP (*1*) in water and (*2*) in 1 M NaCl, as a function of the Na-AMS mole fraction M_1 in the initial monomer mixture.

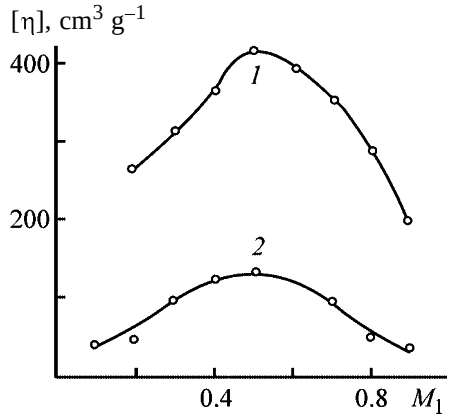

Fig. 3. Intrinsic viscosity [η] of copolymers as a function of Na-AMS mole fraction M_1 in the initial monomer mixture in copolymerization of Na-AMS with N-VP (*1*) in water and (*2*) in 1 M NaCl.

[η], determined with a VPZh-3 viscometer (d_c = 0.56 mm) by isoionic dilution in 0.5 M NaCl at 30°C.

The pH was measured with a pH-121 pH-millivoltmeter equipped with an ESL-63-07 glass working electrode and an EVL-1M3 auxiliary silver chloride electrode.

We found that, under the experimental conditions, the copolymerization of Na-AMS with N-VP occurred under homogeneous conditions, without spontaneous copolymerization. No unusual kinetic effects, characteristic of polymerization of N-VP in aqueous solutions at very high concentrations of the monomer [15], were revealed.

The effect of the composition of the initial monomeric mixture on the copolymerization was estimated at $[M_1 + M_2]$ = const and equal other conditions. Figure 1 shows as example the typical kinetic curves (dilatometric data) of the initial copolymerization stage at various compositions of the initial monomer mixture. In all the runs, the initial portions of the kinetic curves were linear, which allowed determination of the initial copolymerization rate v_0 at low conversions (x < 3%). From the data obtained, we constructed the dependences $v_0 = f(M_1)$, where M_1 is the mole fraction of Na-AMS in the initial monomer mixture (Fig. 2). As seen from Fig. 2, the dependence $v_0 = f(M_1)$ for copolymerization in both water (curve *1*) and 1 M NaCl (curve *2*) passes through a maximum.

The dependence $v_0 = f(M_1)$ is more pronounced in 1 M NaCl. The values of [η] in copolymerization in water (Fig. 3, curve *1*) and 1 M NaCl (Fig. 3, curve *2*) varied in parallel with v_0. Figures 2 and 3 show that the maximal values of v_0 and [η] are attained at the equimolar ratio of the monomers in the initial mixture ($[M_1] : [M_2] = 1 : 1$), which is nicely consistent with the data of [7, 8]. This fact confirms the occurrence of donor–acceptor interaction of Na-AMS with N-VP [16]. Comparison of the data for constant $[M_1]$ shows that, in going from water to 1 M NaCl, v_0 increases but [η] decreases (Fig. 3).

In copolymerization of Na-AMS with N-VP in water and in 1 M NaCl, the copolymer yield increases as the Na-AMS content in the initial monomer mixture is increased (see table). The table also shows that, in going from water to 1 M NaCl, the copolymer yield increases at any monomer ratio.

Figure 4 shows the dependence of the running composition of the Na-AMS–N-VP copolymer at low conversions (x < 3%) on the composition of the initial monomer mixture. For copolymerization in water, the dependence (curve *1*) corresponds to the relative activ-

ities of the monomers $r_1 < 1$ (for Na-AMS), $r_2 < 1$ (for N-VP), and $r_1 > r_2$. These data are nicely consistent with published data [7] ($r_1 = 0.66$ and $r_2 = 0.13$, $r_1 r_2 = 0.086$), confirming that the Na-AMS and N-VP units in the copolymer tend to alternate. According to Fig. 4 (curve *1*), the azeotropic composition of the copolymer is observed at the equimolar ratio of the monomers in the initial mixture ($[M_1] : [M_2] = 1 : 1$).

Comparison of data in Fig. 4 at $[M_1]$ = const shows that, in a wide range of compositions of the initial monomer mixture, the content of ionic units in the copolymer increases in going from water to 1 M NaCl (cf. curves *1* and *2*).

To explain the experimental data, let us consider the ionization equilibrium of the ionic groups in salt solutions:

$$\underset{\text{I}}{A^-X^+} \rightleftarrows \underset{\text{II}}{A^- \,||\, X^+} \rightleftarrows \underset{\text{III}}{A^- + X^+}.$$

where A^- is the anion of the monomer and macroradical; X^+ is the cation; I–III are the contact ion pairs, solvent-separated ion pairs, and free ions, respectively.

It is known that, in aqueous solutions, the sulfonate groups of the monomers and the corresponding units in the copolymers are fully ionized. The above-given ionization equilibrium is largely influenced by the ionic strength of solutions μ, which is determined by the concentration of Na-AMS in the initial mixture in the course of the copolymerization and also depends on the addition of NaCl. The reactivity of nonionic N-VP and of the corresponding propagating radical in polymerization is not affected by μ [17]. The nonisoionic conditions of Na-AMS copolymerization result in changes in the content of various ionic species of the monomer and macroradical in the reaction system. As a result, the intra- and intermolecular electrostatic interactions in the system change, causing variation of the copolymerization "constants" $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$, which does not allow the copolymerization to be described by the Mayo–Lewis equation.

An increase in μ in going from water to 1 M NaCl shifted the ionization equilibrium to the left, which weakened the electrostatic repulsion between the similarly charged Na-AMS monomer and the macroradical with the terminal Na-AMS unit, and also between the fixed charges of the macromolecules. This, in turn, affected the conformational state of the propagating chains, which was indirectly confirmed by viscometric data (Fig. 5). These factors affected the reactivity of Na-AMS and its macroradical in copolymerization and resulted in increased v_0; increase in only one of

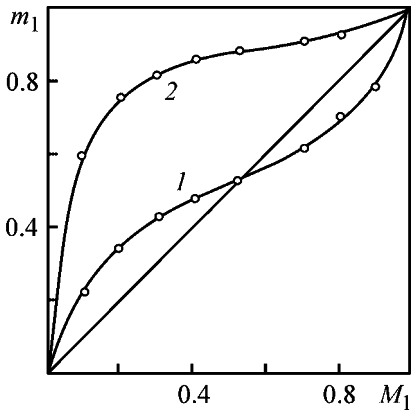

Fig. 4. Mole fraction of Na-AMS units in the copolymer, m_1, at the conversion $x < 3\%$ as a function of the Na-AMS mole fraction in the initial monomer mixture, M_1, in copolymerization of Na-AMS with N-VP (*1*) in water and (*2*) in 1 M NaCl.

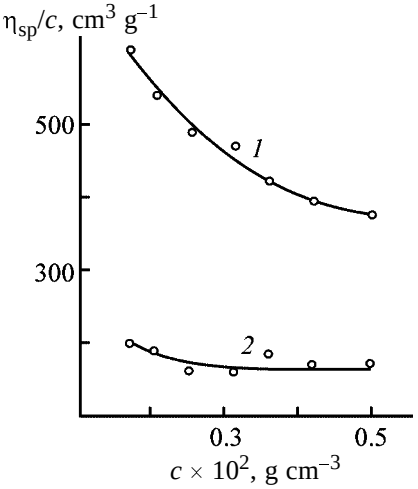

Fig. 5. Reduced viscosity η_{sp}/c of Na-AMS–N-VP copolymer as a function of copolymer concentration c (*1*) in water and (*2*) in 1 M NaCl. $[\eta] = 49$ cm^3 g^{-1}; content of Na-AMS units 34 mol %; $T = 30$°C.

Yield of Na-AMS–N-VP copolymer in copolymerization in various media as a function of the Na-AMS mole fraction M_1 in the initial monomer mixture

M_1	Copolymer yield	
	in water	in 1 M NaCl
0.1	36	64
0.2	47	71
0.3	60	68
0.5	70	98
0.6	70	–
0.7	–	96
0.8	87	98

the four elementary rate constants of chain propagation, k_{11}, describing addition of Na-AMS to the macroradial with the terminal Na-AMS unit, is apparently responsible for the increased content of the ionic units in the copolymer prepared in NaCl solution.

CONCLUSIONS

(1) In radical copolymerization of sodium 2-acrylamido-2-methyl-2-propanesulfonate with *N*-vinyl-2-pyrrolidone in water and 1 M NaCl, v_0 and [η] of the copolymer as functions of the $[M_1] : [M_2]$ ratio pass through a maximum at the equimolar ratio.

(2) The copolymer yield grows with increasing $[M_1] : [M_2]$ (both in water and in 1 M NaCl) and in going from water to 1 M NaCl.

(3) In going from water to 1 M NaCl, v_0 increases but [η] of the copolymer decreases.

Received April 25, 2002

Abstract—N-Monosubstituted tricyclodecenetetracarboxylic acid diimides with allyl- and vinyl-containing substituents, exhibiting antitumor activity, were prepared. Their copolymerization with *N*-vinylpyrrolidone yielded polymers with alicyclic diimide moieties in the pendant chain.

In the modern natural science, new lines of research often arise at the junction of different fields of knowledge. An example is the development of the chemistry of medicobiological polymers at the junction of macromolecular chemistry, medicine, pharmacology, and biochemistry. Its rapid progress resulted in the development of polymeric materials for surgery, public-health items, parts of medical apparatus and tools, dressings, organ and tissue prostheses, blood substitutes, packages, drug shells, etc. [1–5]. One of the important problems in this field was development of polymeric medicinals. Such medicinals create the therapeutic concentration of a drug in the body and maintain it at the required level for a long period, eliminating or reducing the side effects and decreasing the drug consumption for the therapeutic course owing to more complete utilization of the drug.

A number of high-performance polymeric and low-molecular-weight antiblastic agents have been developed; these agents are successfully used for treatment of some kinds of malignant tumors. However, the majority of such drugs oppress physiological regeneration of normal tissues, and tumors quickly become resistant to their effect [6, 7]. Therefore, it became necessary to develop a new generation of antitumor medicinals with increased selectivity, high therapeutic efficiency, and low toxicity.

Previously [8–12], we prepared diimides of alicyclic tetracarboxylic acids and demonstrated their high antitumor activity in the experiments on animals. Here we report on synthesis of N-monosubstituted tricyclodecenetetracarboxylic acid diimides with allyl- and vinyl-containing substituents, on their toxicity and antitumor activity, and on preparation of new polymeric forms of these agents.

EXPERIMENTAL

Tricyclo[4.2.2.0^{2,5}]dec-7-ene-3,4,7,8-tetracarboxylic acid dianhydride (AB) was purified by stirring for 1.5–2 h in hot acetone; the procedure was repeated three or four times, until acetone no longer got colored. The precipitate was filtered off and dried in air and then in a vacuum oven at 30–40°C. Then AB was additionally dehydrated by refluxing for 2–3 h in acetic or propionic anhydride. The dianhydride was filtered off, washed on the filter with acetone, and dried in air and then in a vacuum oven at 30–40°C to constant weight; equivalent weight 68.5 (calculated 68.5), mp 250–252°C (published data [13]: 252°C).

Allylamine was distilled at 56°C/692 mm Hg (reference data [14]: bp 58°C). 1-Vinyloxy-2-aminoethane (monoethanolamine vinyl ether) was distilled at 114°C/692 mm Hg (published data [15]: bp 114.5–115.5°C/710 mm Hg). *N*-Vinylpyrrolidone (VP), pure grade, stabilized with KOH, was distilled in a vacuum (bp 68°C/1.5 mm Hg); n_D^{20} 1.5116 [14]. Azobis(isobutyronitrile, pure grade, was recrystallized from ethanol; mp 103°C (published data [16]: mp 103°C).

Dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and *N*-methylpyrrolidone (MP) were dried over 4 Å molecular sieves and distilled; fractions with the boiling points consistent with reference data [14] were collected.

To prepare tricyclodecenetetracarboxylic acid

	2	2:1	140	5	20	79

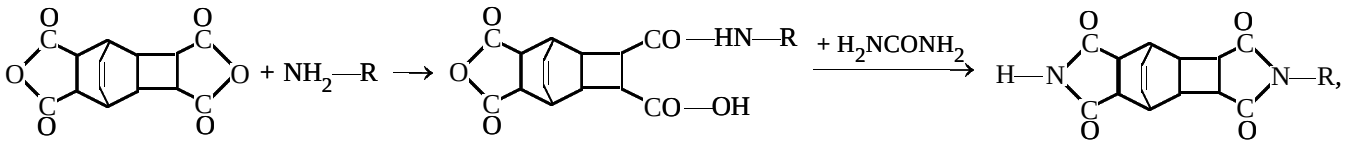
* (*c*) Reagent concentration.

N-monoallyldiimide (MADI), a three-necked flask equipped with a stirrer and a dropping funnel was charged with 24.66 g (0.09 mol) of AB, and 284 ml of DMF was added; the flask was submerged in a bath with an ice–salt mixture. To the cooled solution, 5.18 ml (0.09 mol) of allylamine was added dropwise in small portions; the residual amount of allylamine from the dropping funnel was washed into the flask with 20 ml of DMF. After the reaction completion, a part of the solvent (185 ml) was distilled off in a water-jet-pump vacuum, and 10.37 g (0.173 mol) of urea was added. The flask was submerged in a bath preheated to the required temperature. The product was precipitated by adding ethanol, filtered off, washed with diethyl ether, and dried at 30–40°C. Bromine number: found 51.29, calculated 51.22.

Tricyclodecenetetracarboxylic acid *N*-monovinyloxyethyldiimide (MVODI) was prepared similarly. Bromine number: calculated 46.84, found 46.73. The bromine number was determined by the procedure given in [16]. The IR spectra of the initial compounds and synthesized drugs were taken on a Jasco IR-810 spectrometer (Japan) in the range 4000–400 cm^{-1}; samples were prepared as KBr pellets (1 mg substance per 200 mg KBr). Pure KBr pellet was the reference.

Tricyclodecentetracarboxylic dianhydride has an asymmetrical structure, with different reactivity of the anhydride groups [17]. Therefore, it is feasible to involve in condensations either one anhydride group selectively or both anhydride groups [18, 19]. This fact was used for preparing N-monosubstituted diimides of alicyclic tetracarboxylic acids containing unsubstituted and substituted imide rings containing a terminal functional group or double bond, with the aim of subsequent preparation of polymers with pendant alicyclic diimide moieties.

Monosubstituted diimides of tricyclodecenetetracarboxylic acid, containing double bonds in the substituent, were prepared by the reaction



where R = CH_2–$CH=CH_2$, CH_2–CH_2–O–$CH=CH_2$.

Experiments performed to optimize the conditions for the synthesis of tricyclodecenetetracarboxylic acid diimides allowed us to abandon thermal imidization of anhydrido amido acid in a vacuum, described in [18, 19], and prepare N-monosubstituted tricyclodecenetetracarboxylic acid diimides by the reaction of anhydrido amido acid with urea at 130–150°C in amide solvents. The results are given in Table 1.

Monosubstituted tricyclodecenetetracarboxylic acid diimides are moderately (5–10%) soluble in organic solvents; consistent analytical data were obtained. The IR spectra of these compounds contain all the absorption bands characteristic of related substances (Table 2).

The synthesized diimides were tested for the toxicity and antitumor activity.[1] The toxicity data and high values of the maximum bearable dose indicate that these compounds are low-toxic and exhibit a wide range of therapeutic effect.

One of the ways to prepare polymeric medicinals is

[1] Tests were performed at the Kazakh Research Institute of Oncology and Radiology, Ministry of Public Health of the Kazakhstan Republic. The antitumor activity tests show that MADI exhibits moderate antitumor activity against Sarcoma 37 strain (53% at a treatment course dose of 5000 mg kg^{-1}).

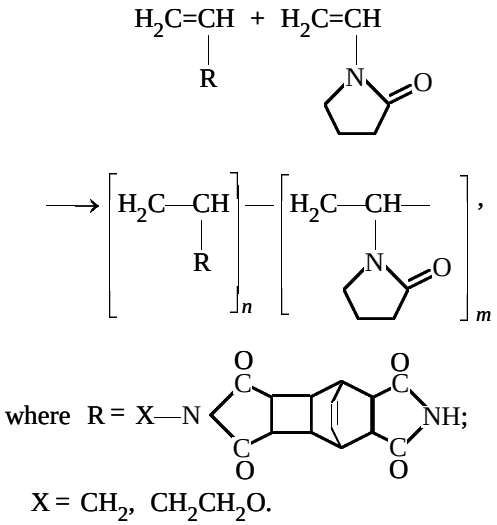
polycondensation or polymerization of a low-molecular-weight drug. Since tricyclodecenetetracarboxylic acid *N*-monoallyl- and *N*-mono-2-vinyloxyethyldiimides contain terminal functional unsaturated groups, their polymeric derivatives can be prepared by radical polymerization. A specific feature of such compounds in radical polymerizations is their tendency to degradation chain transfer; as a result, the compounds are low-reactive and form low-molecular-weight polymers [15, 20]. At the same time, vinyl ethers readily undergo radical copolymerization. As the second comonomer we took VP whose copolymers and polymers are widely used in medical practice and pharmacology.

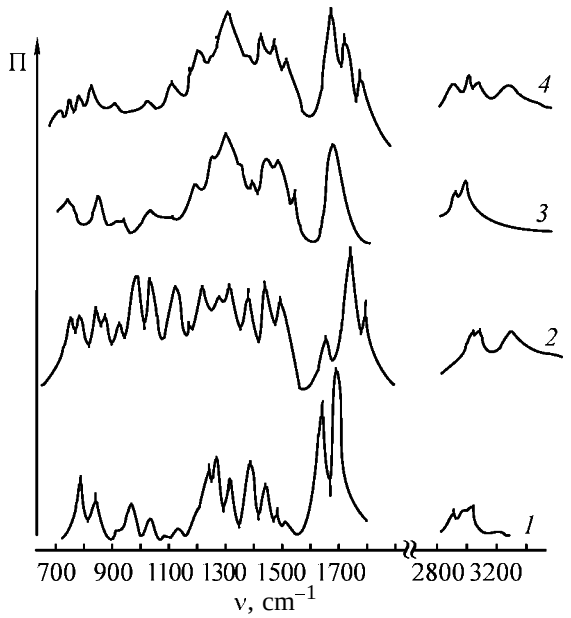
Copolymerization was performed in glass ampules at 1 : 1 ratio of the starting components in the presence of 2 mol % AIBN initiator in DMSO under nitrogen at 70°C for 8 h at the reactant concentration of 15 wt %. The reaction followed the scheme



The polymers were obtained as white powders soluble in DMSO and MP; yield 45–48%. The reduced viscosity of the polymers derived from MADI and MVODI was 0.19 and 0.16 dl g^{-1}, respectively.

Elemental analysis shows that the synthesized polymers are enriched iin VP; the content of the active substance is 25–30%. The results are listed in Table 3; the elemental composition of the homopolymers based on VP and N-monosubstituted diimides is given also for comparison.

The IR spectra of the starting compounds and their copolymer (with MADI as example) are shown in the figure. The spectrum of the copolymer contains no absorption bands at 1440 and 1635–1645 cm^{-1} (vibra-



IR absorption spectra: (*1*) VP, (*2*) MADI, (*3*) polyvinylpyrrolidone, and (*4*) VP–MADI copolymer. (П) Absorption and (ν) wave number.

tions of the C=C bond) and at about 980 cm^{-1} (vibrations of the vinyl CH bond), but contains the bands at 1720–1780, 1380, 1660, and 3200 cm^{-1}, assignable to the imide rings, amide group, and N–H-unsubstituted imide group.

CONCLUSIONS

(1) N-Monosubstituted tricyclodecenetetracarboxylic acid diimides containing a double bond in the substituent were prepared by the reaction of tricyclodecenetetracarboxylic acid with allylamine and 1-vinyloxy-2-aminoethane. Radical copolymerization of these diimides with *N*-vinylpyrrolidone in dimethyl sulfoxide yielded new polymers with alicyclic diimide moieties in the pendant chain. The compounds were identified by IR spectroscopy and elemental analysis.

(2) The copolymers are enriched in *N*-vinylpyrrolidone; the content of the active substance is 25–30%. Tests for the toxicity and maximum bearable dose show that the compounds are low-toxic and exhibit a wide range of therapeutic effect. Tricyclodecenetetracarboxylic acid *N*-monoallyldiimide inhibits by 53% the growth of Sarcoma 37.

Received July 3, 2002

Abstract—The kinetic parameters of hydrolysis of chitin–glucan complex of *Aspergillus niger* fungus with 85% phosphoric acid were studied at three temperatures. The activation energies of hydrolysis of chitin and glucan components of the complex were determined.

Chitin–glucan complex (CGC) is contained in the cell walls of mold fungus *Aspergillus niger*, producer of citric acid used in its industrial biochemical production. The mycelium of *Aspergillus niger* is a large-tonnage waste product of this production, and a search of ways to utilize mycelium or its components is extremely important for development of environmentally harmless and wasteless production. A high sorption power of CGC with respect to heavy metal ions [1] makes it promising for water treatment to remove some ions and also as an enterosorbent in the composition of baked and candy goods [2] for prophylactic food of staff subjected to possible impact of heavy metals.

The presence of chitin in the complex suggests the biological activity of CGC with respect to a number of diseases caused by weakening of the immunity. It is well known that the biological activity of polysaccharides increases with decreasing their molecular weight, and oligosaccharides most often give the maximum effect [3]. To decrease the molecular weight of polysaccharides, destructive methods such as oxidation, ultrasonic treatment, and mechanical and radiation degradation are used. Being highly efficient, these methods, however, involve side processes giving rise to new functional groups or causing cross-linking of macromolecule fragments owing to the arising radicals. Enzymatic methods are mild and selective, but they require certain bacterial cultures [4, 5]. Classic degradation method, acid hydrolysis, has no these drawbacks. However, the use of concentrated HCl and H_2SO_4 results in formation of oligosaccharides with a wide molecular-weight distribution or even in hydrolysis to monosaccharides. The use of 85% H_3PO_4, which is a milder hydrolyzing agent, for hydrolysis of chitosan under mild conditions (at room temperature) gives oligosaccharides with a degree of polymerization (DP) of 17 in 43% yield in 4 weeks or with DP 7 in 12.5% yield in 6 weeks [6]. The use of 85% H_3PO_4 in this work is also caused by the possibility of comparison of the hydrolysis rates of chitin and glucan components of CGC.

EXPERIMENTAL

In the study we used CGC recovered from *Aspergillus niger* mycelium [1]. The composition of CGC was as follows (wt %): chitin 81.6, glucan 15.1, and melanin 3.3.

CGC was hydrolyzed with 85% H_3PO_4 at 293, 323, and 353 K with sampling at certain intervals. In samples, we determined the solubility, absolute viscosity of hydrolyzate, and the amounts of glucose, *N*-acetylglucosamine, and glucosamine. Quantitative analysis of monosaccharides was carried out photocolorimetrically on an SF-46 spectrophotometer from the absorption of chromogens formed in the reactions of glucose with anthranone (absorption at λ = 620 nm) [7], glucosamine with salicylaldehyde (λ = 410 nm) [8], and *N*-acetylglucosamine with *N*,*N*-dimethyl-*p*-aminobenzaldehyde (λ = 585 nm) [9], using calibration curves preliminary plotted for each monosaccharide. The oligosaccharide composition was determined by exclusion gel chromatography with a TSK-PW support. Pullulan with the molecular weight of 1000 was used as a reference, and trifluoroacetate buffer solution, as an eluent.

CGC is dissolved in 85% H_3PO_4 within 5 days at 293 K. In the process, the hydrolyzate viscosity in-

1070-4272/02/7511-1864$27.00 © 2002 MAIK "Nauka/Interperiodica"

creases in the first 3 days owing to increasing solution concentration and then decreases as a result of predominance of the hydrolytic process. At 323 K, CGC passes into solution within 45 min, and at 353 K, within 30 min. In this case, the absolute viscosity of the solutions decreases asymptotically, tending to a constant value of approximately 10 cP (Fig. 1). Curves of this type are characteristic of hydrolysis of cellulose with trifluoroacetic acid: abrupt decrease takes place in the initial period and then the curves flatten out with the viscosity corresponding to the maximum degree of polymerization [10].

In CGC hydrolyzates produced at 293 K, the amount of glucose increases with time, reaching the maximum value, corresponding to the glucan content in CGC within 4 h. The amount of *N*-acetylglucosamine slowly increases, reaching only 2.5% of the amount of the initial polymer, despite the fact that CGC contains 81.6% of chitin. Glucosamine was not found in the samples (Fig. 2a).

At 323 K, the amount of glucose in the samples reaches the limiting value within 45 min, and the maximum amount of *N*-acetylglucosamine in the sample is 8%. Glucosamine was not found in the samples.

At 353 K, hydrolysis proceeds differently: The amount of glucose increases in the first 3 h. *N*-Acetylglucosamine is accumulated in the first 30 min, after which its amount decreases. Simultaneously, glucosamine appears in the samples and its amount increases to 60% by the end of the reaction (Fig. 2b). Glucosamine is formed by elimination of the *N*-acetyl group from *N*-acetylglucosamine, i.e., this is a secondary hydrolysis process occurring only at a high temperature.

Based on kinetic curves for accumulation of glucose and *N*-acetylglucosamine, we evaluated the initial rates of hydrolysis of chitin and glucan components of CGC (Table 1).

It is seen from Table 1 that the hydrolysis rate of the glucan component is higher than that of the chitin component by a factor of 5.3 at 293 K, 1.3 at 323 K, and 1.25 at 353 K. At 353 K, this value does not reflect the true hydrolysis rate of the chitin part, since it does not consider the simultaneous transformation of *N*-acetylglucosamine to glucosamine.

To evaluate the hydrolysis constants, the experimental data on the concentration of monosaccharides were expressed in mM and for 353 K the total concentration of *N*-acetylglucosamine and glucosamine was taken with the correction for molecular weight. Based on the data obtained, the dependences $\log[a/(a - x_i)] = f(\tau)$ were plotted. This dependence at 293 K is shown in Fig. 3. All the dependencies are linear, i.e., hydrolysis is described by a first-order reaction equation, which allows determination of the rate constants of

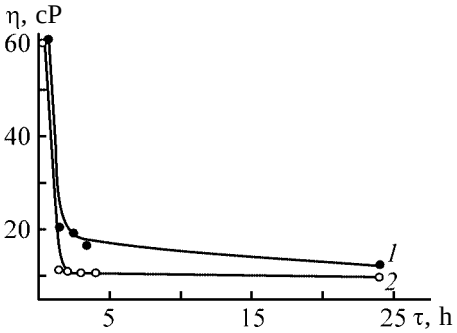

Fig. 1. Variation of the absolute viscosity of hydrolyzates η with time τ at (*1*) 323 and (*2*) 353 K.

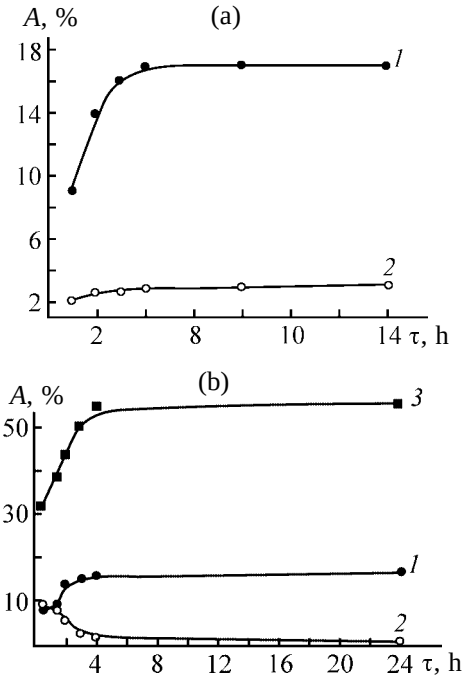

Fig. 2. Variation of the amount *A* of (*1*) glucose, (*2*) *N*-acetylglucosamine, and (*3*) glucosamine in the hydrolyzate in time τ at (a) 293 and (b) 353 K.

Table 1. Initial rate of hydrolysis of chitin and glucan components of CGC

CGC component	Initial rate of hydrolysis, % min^{-1}, at indicated *T*, K		
	293	323	353
Glucan	0.0083	0.1050	0.3000
Chitin	0.0016	0.0830	0.2400

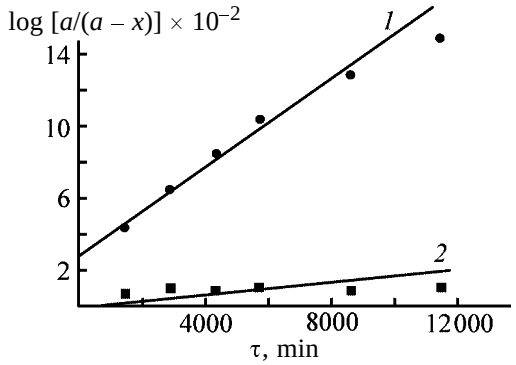

Fig. 3. Determination of the rate constants of hydrolysis of (*1*) glucan and (*2*) chitin components of CGC at 293 K. (τ) Time.

hydrolysis at the studied temperatures from the slopes of the straight lines. The results are listed in Table 2. From the rate constants, using the Arrhenius equation, we evaluated E_a for hydrolysis of chitin and glucan components of CGC.

The E_a values obtained for chitin and glucan components of CGC are significantly lower than those published for chitin, E_a = 106.22 kJ mol^{-1}, and laminarin having the structure of poly-β-1→3-glucopyranoside, i.e., the structure closest to that of glucan part of CGC, E_a = 110.82 kJ mol^{-1} [11]. It is believed that the activation energy of hydrolysis of the glucoside bond is almost independent of the molecular weight and structural features of polysaccharide [11]. However, the influence of supramolecular organization on the hydrolysis energy must not be ruled out. Contrary to chitin and laminarin having highly crystalline supramolecular organization, CGC has a disordered mesomorphic structure in which the system of intermolecular hydrogen bonds is strongly disturbed [12]. A fast change of hydrolysis conditions from heterogeneous to homogeneous relieves the influence of diffusion processes. It is likely that the accessibility of glucoside bond for the hydrolyzing agent is responsible for its low E_a values. In addition, it is not improbable that the branched structure of CGC, in which the main skeleton chain is chitin and the side short chains are 1→3 bonds of glucan, facilitates hydrolysis of both chitin and glucan components.

Table 2. Rate constants and activation energies of hydrolysis of glucan and chitin components of CGC

CGC component	*T*, K	$k \times 10^5$	E_a, kJ mol^{-1}
Glucan	293	1.1428	57.44
	323	100.0	
	353	794.3	
Chitin	293	0.107	89.99
	323	6.667	
	353	87.50	

The above data show that the composition of the hydrolyzed product strongly depends on the temperature and hydrolysis time. Considering the composition of the final hydrolysis products, we can conclude that at 293 K glucose and *N*-acetylglucosamine in the total amount of 20% of CGC taken for hydrolysis are present in the hydrolyzed product and, hence, 80% of CGC transforms into oligosaccharides. At 323 K, the hydrolyzed product contains the same monosaccharides in the amount of 25% of the initial CGC and 75% oligosaccharides. At 353 K, the hydrolyzed product contains 78.7% glucose, *N*-acetylglucosamine, and glucosamine (59.4%) and 21.3% oligosaccharides. Since oligosaccharides are not precipitated from hydrolyzed products with acetone, we can assume that their degree of polymerization does not exceed 10.

The gel-chromatographic analysis of the oligosaccharide composition in the final hydrolysis product at 323 K showed that the main part of oligosaccharides has the degree of polymerization of 5–6. Specifically at this degree of polymerization chitooligosaccharides have the highest biological activity [3].

CONCLUSIONS

(1) The hydrolysis of chitin–glucan complex with 85% phosphoric acid starts under heterophase conditions and passes to homogeneous conditions within a period depending on the process temperature.

(2) The glucan component of the complex is hydrolyzed first.

(3) The study of hydrolysis kinetics allows determination of the rate constants and activation energies of hydrolysis of chitin and glucan components of the complex. It was found that the glucan part is hydrolyzed first, and then the chitin chain is hydrolyzed to form *N*-acetylglucosamine with subsequent deacetylation to glucosamine.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymerization of Styrene in the Presence of Nitroxyl Radicals Generated Directly in the Course of the Polymer Synthesis (*in situ*)

M. V. Pavlovskaya, E. V. Kolyakina, V. V. Polyanskova, L. L. Semenycheva, and D. F. Grishin

Abstract—The features of radical polymerization of styrene in the presence of nitroxyl radicals generated directly in the course of the polymer synthesis (*in situ*) by irreversible reaction of stable organic compounds 2-methyl-2-nitrosopropane, *C*-phenyl-*N*-*tert*-butylnitrone, and nitrosodurene with propagating polymer radicals were studied.

The interest of the majority of researchers in radical polymerization substantially increased in late 1980s–early 1990s, with publication of papers on "pseudoliving" polymerization [1, 2]. Performing polymerization in the "living" chain mode allows control of the polymerization kinetics and molecular-weight characteristics of the macromolecules [3–6]. The mechanism of such a process is based on reversible reaction of stable radicals X$^{\bullet}$ with chain-leading macroradicals R$^{\bullet}$, yielding a labile adduct R–X which decomposes with regeneration of the same propagating macroradical:

$$R^{\bullet} + {}^{\bullet}X \rightleftarrows R\text{–}X \qquad (1)$$

The best studied is pseudoliving polymerization of styrene and its analogs in the presence of 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) and its derivatives [1, 3–7]. It is notable that, both with excess and deficiency of nitroxyl relative to the initiator, the process finally becomes steady-state, with constant concentrations of TEMPO and propagating macroradicals [7]. The major drawback of styrene polymerization in the presence of TEMPO is the low rate: At 120°C (optimal temperature for obtaining narrow-MWD polystyrene) the reaction takes more than two days [3, 6]. Several methods are used to shift the equilibrium of reaction (1) toward higher concentration of active radicals and to accelerate polymerization in the presence of TEMPO. In particular, special agents (e.g., organic acids, aldehydes, etc.) converting a part of nitroxyl radicals into the corresponding hydroxylamine are added [8–11]; high-temperature initiators (cumyl peroxide, *tert*-butyl hydroperoxide, etc.) generating additional radicals accelerating polymerization are introduced; TEMPO is replaced by more stable nitroxyl radicals [14–17] forming more labile adducts R–X. It should be noted that all these methods complicate the formulation and procedure and increase the production cost. Furthermore, the contribution of competing reactions considerably increases; as a result, the molecular-weight characteristics and physicochemical properties of the resulting polymers are appreciably deteriorated.

Here we propose to perform controlled radical polymerization of styrene, initiated with azobis(isobutyronitrile) (AIBN) or benzoyl peroxide (BP), at 70–100°C, in the presence of nitroso compounds, nitrones, and oxytriazenes, which were successfully used previously for controlled synthesis of polymers from (meth)acrylic monomers [18–24].

EXPERIMENTAL

2-Methyl-2-nitrosopropane (MNP), *C*-phenyl-*N*-*tert*-butylnitrone (PBN), *tert*-butyl-3-phenyl-1-oxytriazene (BPT), and nitrosodurene (ND) were prepared by the procedures described in [25–28]. Polymerization was performed at 70°C using AIBN as initiator and at 100°C with BP initiator. Styrene and solvents were purified by standard procedures. The polymerization kinetics was monitored gravimetrically, dilatometrically [29], and thermographically [30]. The molecular weight of the polymer M was determined by viscometry [31] and gel permeation chromatography

1070-4272/02/7511-1868$27.00 © 2002 MAIK "Nauka/Interperiodica"

(GPC); the chromatograph was equipped with a set of five styrogel columns with the pore diameter of 10^5, 3×10^4, 10^4, 10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector. The eluent was THF. Calibration was performed with close-cut polystyrene references [32].

As noted above, addition of nitroxyl radicals that form with propagating radicals [Eq. (1)] a more labile bond than TEMPO increases the rate of styrene polymerization. Among such nitroxyl radicals are phosphorus-substituted nitroxyls [33], diphenyldialkylpyrrolidone nitroxyl derivatives, etc. [7]. However, the synthesis of such derivatives is labor-consuming; the formulation and procedure are complicated, and the production cost of the polymer grows.

In our studies aimed at performing low-temperature pseudoliving polymerization of styrene at a high rate, we chose the strategy of approaching as much as possible the conditions of commercial synthesis, rather than complicating the process by introducing additional stages or expensive chemicals. In particular, we used traditional radical initiators (azo compounds and peroxides) and chose as chain propagation regulators such organic compounds as nitroso compounds, nitrones, and oxytriazenes, which are stable in storage and generate sterically hindered nitroxyl spin adducts directly in the polymerization system (*in situ*) [34].

Our experiments showed that addition of MNP or BPT in amounts comparable with that of BP initiator suppresses the gel effect in styrene polymerization at 100°C. It is interesting and important for practice that, in polymerization of styrene initiated with AIBN at 70°C, the gel effect is eliminated by additions of PBN and BPT in concentrations that are, respectively, ten and four times lower than the concentration of the initiator (Figs. 1a and 1b show as example the kinetic curves of styrene polymerization in the presence of MNP and ND, respectively). It should be noted that, when the gel effect is fully suppressed, the polymerization time increases, as compared to the process without the additive, by a factor of no more than 2, whereas polymerization of styrene in the presence of TEMPO at 100°C lasts for more than two days [7].

Thus, the additives proposed allow control of the kinetic parameters of styrene polymerization under conditions of radical initiation and eliminate gelation in the course of polystyrene synthesis.

As expected, nitroso compounds, PBN, and BPT strongly affect the molecular-weight characteristics of the polymer (see table). The viscosity-average and

number-average molecular weights of polystyrene prepared in the presence of the tested regulators uniformly grow with increasing styrene conversion. Without additives, under similar other conditions, the curve of M of the polymer vs. conversion is S-shaped, with uncontrollable growth of the molecular weight in the stage of the gel effect. Figures 2a and 2b show how the viscosity-average and number-average molecular weights of polystyrene prepared in the presence of MNP and PBN, respectively, vary with conversion.

Particular attention should be given to the polydispersity coefficients M_w/M_n of the synthesized polymers. In polymerization of styrene in the presence of MNP, the polydispersity coefficients do not change noticeably with conversion, amounting to 1.3–1.4 (see table, sample nos. 3–6). These values are somewhat higher than the similar characteristics of polystyrene prepared in the presence of TEMPO (~1.2) [5, 7]. The polydispersity coefficients of polystyrene prepared in

the presence of BPT, PBN, and ND are somewhat higher (1.4–1.6; see table, sample nos. 7–10, 13–17, and 18–20, respectively). Nevertheless, all these parameters are considerably lower than those of polystyrene prepared without additives in the presence of BP and AIBN initiators at 100 and 70°C, respectively (2.1 and 3.2; see table, sample nos. 1, 2, and 12).

The molecular-weight distribution (MWD) curves of polystyrene obtained at various conversions of the monomer in the presence of the above additives are unimodal; their maximum shifts toward higher molecular weights with increasing conversion (Figs. 3a, 3b). This pattern is typical of pseudoliving polymerization.

Thus, when styrene polymerization is performed in the presence of additives that are potential sources of stable radicals (MNP, BPT, PBN, ND), the main features of pseudoliving polymerization are observed: the lack of the gel effect, uniform increase in the molecular weight of the polymer, and shift of the unimodal MWD curves of polystyrene toward higher *M* with increasing conversion. The polymers have relatively low polydispersity coefficients. The polymerization time, compared to the process without addi-

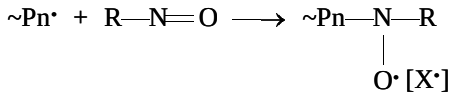
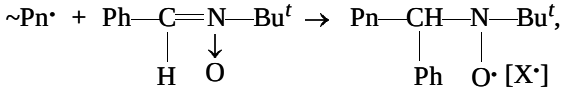
tives, increases insignificantly (by a factor of no more than 2).

Our experimental results, in combination with published data [18–24], suggest the following scheme of polymerization in the presence of the additives. Nitroso compounds and nitrones added to the polymerization system react with propagating radicals Pn$^{\bullet}$, generating stable nitroxyl spin adducts $^{\bullet}$X:





where R = *tert*-butyl and duryl.

Nitroxyl spin adducts, detected by ESR, react with propagating radicals by scheme (1), forming a labile R–X bond. After that, the chain propagation follows the traditional pattern of controlled radical polymerization in the presence of stable radicals [4–7, 18–20, 33].

The pattern of radical polymerization of styrene in the presence of BPT, which can also generate stable nitroxyl spin adducts directly in the polymerizing system [22], is similar to that described above for the synthesis of polymethyl methacrylate in the presence of this additive [23].

The somewhat higher polydispersity coefficients of polystyrene samples prepared in the presence of the above additives, as compared to the polymerization controlled by TEMPO, are probably due to the occurrence, along with the controlled process, of a common radical polymerization due to excess initiator, yielding the "dead" polymer by bimolecular termination.

CONCLUSION

Spin traps and oxytriazenes as sources of stable nitroxyl radicals effectively control chain propagation in styrene polymerization under the conditions maximally similar to those of the commercial process. The lower temperature of the controlled polymerization and relatively high polymerization rates are responsible for slightly higher polydispersity coefficients of the samples, compared to the process occurring in the living chain mode.

Abstract—The degree of hydrophilicity–oleophilicity of solid lignin recovered from cooking liquors of deciduous and coniferous wood at various pH and its influence on the aggregative stability of water–tall oil emulsion were estimated. The stabilizing effect of lignosulfonates on lignin suspension in aqueous electrolyte solution was studied. The values of absorption of lignosulfonates from aqueous solutions on kraft lignin were determined depending on the molecular weight of lignosulfonates and content of tall oil in the suspension.

Chemical treatment of plant materials in some cases involves formation of emulsions stabilized with a solid emulsifier. In particular, treatment of sulfate soap with an acid results in formation of a complex heterogeneous system oil–aqueous salt solution–lignin, which is an oil-in-water emulsion stabilized with solid lignin distributed at the interface in the form of a film preventing coalescence of emulsified oil droplets [1, 2].

In the practice of kraft cellulose production, coniferous and deciduous woods are usually processed in separate flows with the aim to produce cellulose of different quality. In so doing, the efficiency of recovery of sulfate soap and tall oil is different, which is apparently caused by the nature of lignin, the main component of spent cooking liquors, entrained into soap micelles with black liquor. Despite the fact that the optimization of these processes is a pressing problem in the pulp and paper industry, these aspects virtually were not considered in the literature. Therefore, in this work we studied one of the most important characteristics of kraft lignin as emulsion stabilizer: hydrophilic–oleophilic characteristics and adsorption capacity.

In the study, we used the lignin samples recovered by acidification of prederesined kraft black liquors of Solombal and Arkhangelsk pulp and paper combines (STsBK and ATsBK), in which coniferous and deciduous woods, respectively, predominate in the wood raw materials. After precipitation the lignin was washed with water on a filter cloth to neutral reaction, dried at 25–30°C, and ground to powder.

To characterize the recovered samples of lignins, we estimated their hydrophilic–oleophilic characteristics (Table 1) from the data obtained by the vacuum-static method from the adsorption of water vapor and a set of normal hydrocarbons on the lignin samples with subsequent evaluation of differential adsorption heats (with half-monolayer filling) [3].

For all these samples, the oleophilicity predominates over the hydrophilicity. However, the degrees of hydrophilicity and oleophilicity can be close (as, e.g., for sample no. 7) or can differ substantially (as, e.g., for sample no. 1 for which the degree of oleophilicity is 3.5 times greater than the degree of hydrophilicity). Table 1 reveals some correlation of hydrophilic–oleophilic characteristics of the recovered lignin samples with the type of wood raw materials. The balance of hydrophilic and oleophilic properties is characteristic of coniferous kraft lignin produced in cooking of pine wood, while the hydrophobic properties are clearly prevalent for lignins of deciduous wood (birch) and, to a greater extent, for spruce wood. This is apparently caused by saturation of these lignins with hydrogen bonds. The analysis of experimental data on the yield and composition of water–tall oil emulsion (Table 2) showed that the emulsion yield is affected by both the lignin origin and its content in sulfate soap, while the composition of the emulsion phase is predominantly governed by the lignin origin.

	6.40	18.9	38.8	37.1	17.1

* Recalculated to absolutely dry substance.

Based on the data presented in Tables 1 and 2, we can conclude that spruce and deciduous kraft lignins, being more hydrophobic, exhibit the affinity for the oil phase. This is responsible for their stronger stabilizing effect as compared to pine lignin. The hydrophilic–oleophilic characteristics of lignin also affect the phase ratio of the emulsion. In stabilization with deciduous kraft lignin, 31–54% of oil component remains in the emulsion, while in stabilization with coniferous lignin the oil fraction is somewhat lower (21–42%).

The positive effect of addition of lignosulfonates on production of tall oil was noted previously [4, 5]. In this case, the system behaved differently depending on the characteristics of the added agent [3]. Only high-polymeric fraction of lignosulfonates exerts a positive effect on the recovery of the oil phase, while nonfractionated and low-molecular-weight agents decrease the rate and efficiency of phase separation. At the same time, addition of any lignosulfonate sample to the system decreases the extent and rate of separation of the aqueous phase. It was also noted that addition of high-polymeric fraction of lignosulfonates exerts a positive effect only in the case of its addition to sulfate soap before acid treatment.

With the aim to elucidate the mechanism of the effect of lignosulfonates on the water–tall oil emulsion, we carried out a series of model experiments on the reaction of kraft lignins with fractionated and commercial lignosulfonates in aqueous medium.

As additives, we used commercial lignosulfonates (ILSs) of ATsBK and low- and high-molecular-weight fractions produced from them by separation on a polysulfonamide membrane (pressure 0.40 MPa, flow velocity 7.87×10^{-3} $m^3\,m^{-2}\,h^{-1}$, degree of selection

Table 3. Characteristics of lignosulfonates

Characteristic	Initial ILS	Fraction of ILS	
		I	II
Average molecular weight M_w	37 800	8400	73 000
Content of main substance,* %	80.1	68.2	86.9
Ash content,* %	15.3	25.7	9.4
Content of reducing substances,* %	4.6	6.1	3.7
Sulfur content in organosulfur compounds, %	7.3	7.3	4.5

* Recalculated to absolutely dry substance.

0.77, and retention coefficient 0.85) (Table 3). The gel chromatograms of these fractions in a buffer solution (pH 6.2) on Sephadex G-75 are shown in Fig. 1.

The molecular-weight distribution (MWD) of the commercial sample (Fig. 1, curve *1*) is clearly bimodal, while the fractions recovered from this sample are monomodal and correspond mainly to fairly well-resolved high- and low-molecular-weight peaks of the initial lignosulfonates. Along with gel chromatograms and the average molecular weights M_w, the efficiency of fractionation is indirectly confirmed by the contents of ash, reducing substances, and sulfur in organosulfur compounds (Table 3).

From the samples of air-dry lignin (Table 1) we prepared a 5% alkaline solution simulating black liquor of the industrial process and containing 20% of a mixture of sodium sulfate and sodium hydroxide whose ratio ensured the solution density of 1160 kg m^{-3} and pH 10.5. The samples were placed into cylinders and thermostated at 85 ± 1°C, and lignosulfonates were added. The mixtures were treated with sulfuric acid with vigorous stirring at pH 2.5.

Without lignosulfonates, lignin immediately formed a precipitate whose volume did not change in time. For all the lignin samples, on adding any of the studied samples of lignosulfonates both before and after acidification, a suspension stable for 3 days and more was formed. It may be suggested that, in the presence of lignosulfonates with various MWDs, the hydrophilic–oleophilic ratio of modified particles of kraft lignin in the polyelectrolyte solution varies noticeably, which results in stabilization of the suspension. The data obtained differ substantially from those observed in the above laboratory experiments close to the real processes. This suggests that hydrophobization of lignin with tall oil is of considerable importance in the reaction of kraft lignin with lignosulfonates.

To elucidate the possibility of variation of the hydrophilic–oleophilic ratio of lignin, we studied the adsorption of fractionated and industrial lignosulfonates on lignins, whose characteristics are listed in Table 1.

The amount of adsorbed lignosulfonates was determined from the difference in their concentrations in the solution before and after adsorption:

$$\Gamma = (c_0 - c_1)\frac{V}{m}, \quad (1)$$

where Γ is the amount of adsorbed lignosulfonates (kmol kg^{-1}); c_0, the initial concentration of lignosulfonates in the solution (kmol m^{-3}); c_1, the equilibrium concentration in the solution after adsorption (kmol m^{-3}); m, the weighed portion of the adsorbent (kg); and V, the volume of the solution of lignosulfonates (m^3).

The content of lignosulfonates in the solution was monitored by the surface tension technique [6], using the calibrating curve $\sigma = f(c)$ for the selected samples at a given temperature.

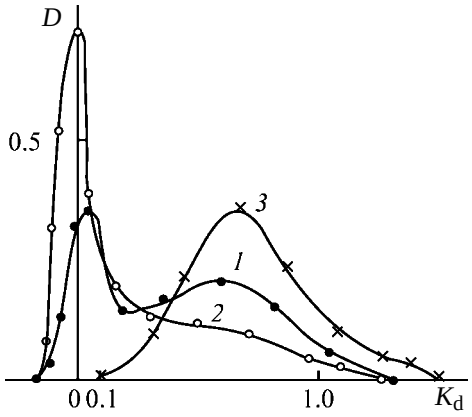

Fig. 1. Gel-chromatograms of lignosulfonates. (*D*) Optical density at λ = 280 nm and (K_d) distribution coefficient. (*1*) Industrial samples; fractions: (*2*) I and (3) II.

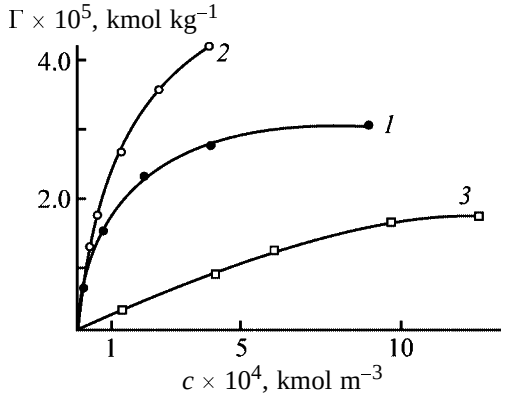

Fig. 2. Adsorption Γ on kraft lignin no. 3 as a function of concentration *c*: (*1*) commercial lignosulfonates (M_w = 37000); fraction: (*2*) I (M_w = 8400) and (*3*) II (M_w = 73000).

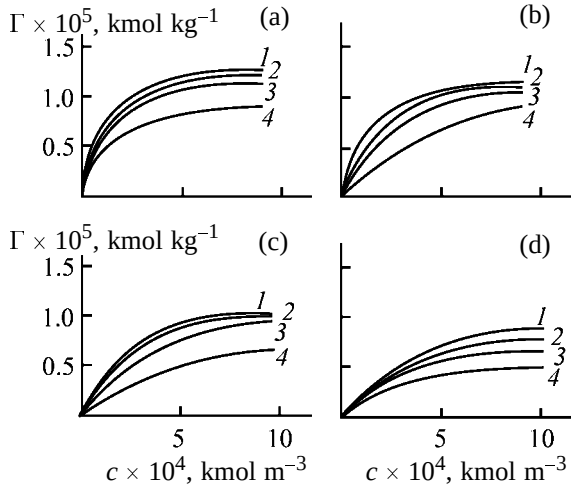

Fig. 3. Adsorption of lignosulfonates on kraft lignin Γ as a function of concentration *c* at pH 6.2: (a) before conditioning with tall oil; with conditioning at tall oil concentration of (b) 0.03, (c) 3, and (d) 30%. Kraft lignin sample no.: (*1*) 7, (*2*) 6, (*3*) 4, and (*4*) 3.

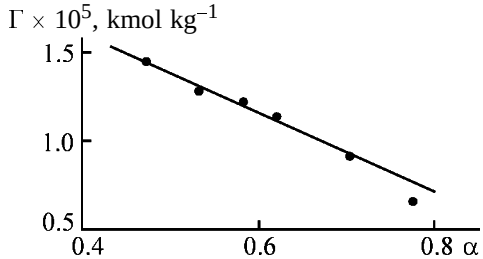

Fig. 4. Correlation between the degree of oleophilicity of kraft lignin α and the maximum adsorption of lignosulfonates on lignin Γ.

It follows from Fig. 2 that the adsorption on lignin no. 3 decreases with increasing molecular weight of lignosulfonates. Previous studies [7–11] showed an increase in the surface activity of lignosulfonates with increasing molecular weight. This is caused by the fact that high-molecular-weight lignosulfonates have more developed hydrophobic hydrocarbon part than low-molecular-weight lignosulfonates.

When dispersion of solid particles in the solution is considered in parallel with adsorption, it is characteristic [9] that dispersion of lignin suspension with lignosulfonates that have the highest molecular weight and surface activity begins with the first small additions of lignosulfonate and abruptly increases with their amount, reaching higher values in comparison with other samples. With respect to the ability of fractionated lignosolfonates to disperse a suspension, they can be ranked in the order corresponding to the increase in the molecular weight. This trend is well pronounced in adsorption on lignins with various degrees of oleophilicity.

Of the most interest for the industrial use is adsorption of industrial lignosulfonates on kraft lignin in the presence of the hydrophobic component of the emulsion layer, tall oil formed in decomposition of sulfate soap. Therefore, in further experiments we studied adsorption of commercial lignosulfonates on kraft lignin recovered at various pH from liquors formed in cooking of coniferous and deciduous wood (Table 1) before and after preconditioning of lignin suspension with tall oil of various concentrations.

In the absence of tall oil, the adsorption noticeably increases with increasing degree of hydrophilicity of kraft lignin (Fig. 3a). An increase of the amount of tall oil added to the suspension does not alter the shape of the adsorption isotherms (Figs. 3b–3d), but results in a significant decrease in adsorption of lignosulfonates on the lignin surface. Based on this fact, we can make a conclusion on additional hydrophobization of the lignin surface as a result of interaction with tall oil. This is also confirmed by the correlation between the degree of oleophilicity of the studied lignins and the maximum adsorption of lignosulfonates on these lignins (Fig. 4). This correlation shows how the lignin surface as an emulsion stabilizer is modified in the system tall oil–polyelectrolyte solution–lignin.

CONCLUSIONS

(1) Studies of the interphase interactions in the system tall oil–aqueous salt solution–lignin showed that the hydrophilic–oleophilic characteristics of lignin affect the stability and phase ratio of the emulsion: deciduous lignin, being more hydrophobic, exerts a stronger stabilizing effect than pine lignin.

(2) Addition of lignosulfonates with various molecular weight distributions noticeably affects the hydrophilic–oleophilic ratio of kraft lignin particles in the polyelectrolyte solution, which results in stabilization of the suspension.

Abstract—The features of pyrolysis of phenols from lignite semicoking tar were studied. The activation energy and order of the reactions of accumulation of methane, hydrogen, carbon monoxide and dioxide, naphthalene and its methyl homologs, phenols, and isomeric cresols and dimethylphenols were determined.

The goals of this work were to study the kinetic features of pyrolysis of phenols from lignite (near-Moscow fields) semicoking tar at 750–900°C, contact time of 0.5–6.0 s, and volume dilution with argon of 1 : 25, to determine the major pathways of pyrolysis, and to calculate the kinetic characteristics of accumulation of particular gaseous and liquid pyrolysis products. Pyrolysis of individual phenols has been extensively studied [1–21]; however, in some of these papers [1–7] data on the chemical group, qualitative, and quantitative component composition of the forming liquid products are virtually lacking, and no kinetic calculations are performed. To examine the feasibility of using the phenolic fraction of the lignite semicoking tar as a source of compounds whose production by other procedures is less profitable, it seemed interesting to study high-temperature pyrolysis of this fraction. Understanding of the behavior of this major (up to 40 wt %) component of the semicoking tar and knowledge of the kinetic parameters of accumulation of particular gaseous and liquid pyrolysis products are necessary for predicting the composition of "secondary" tars and for developing the mathematical model of tar pyrolysis as a whole.

Hypothetical structural formulas of compounds present in the phenolic fraction of lignite semicoking tar are shown in the scheme. According to [22–26], these include alicyclic (**1**–**7, 15, 24**), heterocyclic (**8**–**14, 16, 17, 26**), and aromatic (**17**–**23, 25**–**32**) compounds containing various alkyl and functional substituents. However, data on the kinetic features of high-temperature transformations of both individual phenols and phenolic fraction of the semicoking tar are virtually lacking.

In this connection, it is appropriate to study the kinetic features of high-tempertature pyrolysis of phenols from lignite semicoking tar and suggest possible pathways of formation of the identified liquid and gaseous products by thermal decomposition of particular components of phenols.

The kinetic parameters of accumulation of methane, hydrogen, carbon monoxide, carbon dioxide, and major liquid products are listed in the table.

Formation of methane follows a first-order equation; the activation energy E_a is 45.2 kJ mol^{-1}. The first order of the reaction is apparently due to the presence of various hydrocarbon substituents in the initial phenols which are cleaved to smaller fragments (and, finally, to methane) under the conditions of high pyrolysis temperatures and high concentrations of atomic hydrogen in the reaction zone.

Accumulation of hydrogen follows a 1.5-order equation; E_a = 66.1 kJ mol^{-1}.

Accumulation of CO follows a second-order equation; E_a = 42.8 kJ mol^{-1}. At lower temperatures, CO is formed by decomposition of quinoid rings and aromatic ketones; with increasing temperature, a growing contribution is made by processes involving pyrocarbon and water released in dehydration and pyrolysis:

$$C + H_2O \rightarrow CO + H_2, \quad (I)$$

$$C + CO_2 \rightarrow 2CO. \quad (II)$$

Thus, the overall reaction of CO accumulation is described by a second-order equation.

For the accumulation of CO_2, the reaction order is 1.5, and E_a = 81.8 kJ mol^{-1}. The noninteger reaction order is due to simultaneous occurrence of decarboxylation and reactions involving pyrocarbon:

$$C + 2H_2O \rightarrow CO_2 + 2H_2. \quad (III)$$

32

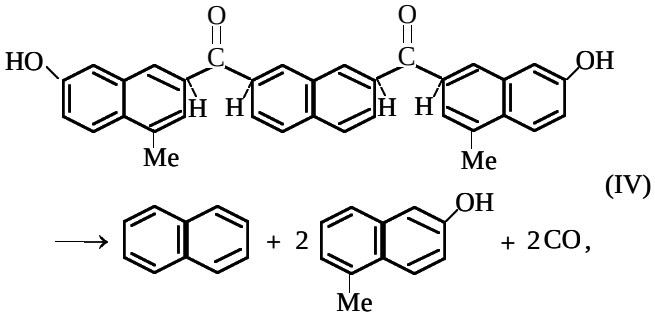
Accumulation of the liquid products is described by equations of orders 1 and 1.5. The first order of accumulation of particular components is due to the fact that the initial phenols contain compounds in which these components are structural fragments linked by carbonyl bridges or long hydrocarbon chains, unsubstituted or substituted with, e.g., phenolic and carboxy groups. Such bonds are the weakest and are cleaved first. Thus, these components are formed directly in pyrolysis of the initial phenols (1- and 2-methylnaphthalenes, *m*-cresol, 2,3-, 2,5-, and 3,4-dimethylphenols). The 1.5-order accumulation is characteristic of naphthalene, phenol, *o*- and *p*-cresols, and 2,6- and 3,5-dimethylphenols. These compounds, along with direct formation from the initial phenols, are products of cyclization, condensation, isomerization, and disproportionation; therefore, their accumulation is described by a more complex kinetic equation. The activation energy of accumulation is the highest for 1-methylnaphthalene (112 kJ mol^{-1}) and the lowest for 3,5-dimethylnaphthalene (19 kJ mol^{-1}). Among isomeric cresols, it is the highest for *o*-cresol (111 kJ mol^{-1}) and the lowest for *p*-cresol (47.2 kJ mol^{-1}).

Kinetic parameters of accumulation of particular gaseous and liquid pyrolysis products

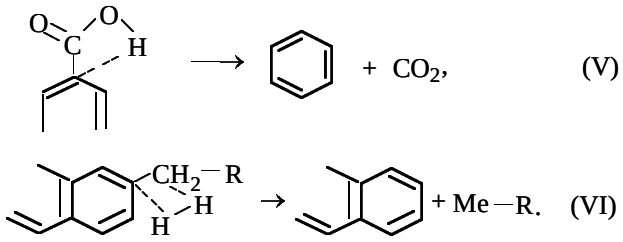
Components	Reaction order	Equation for the rate constant k
Hydrogen	1.5	$4.39 \times 10^{-2} \exp(-66.1/RT)$
Methane	1.0	$6.43 \times 10^{-4} \exp(-45.2/RT)$
Carbon monoxide	2.0	$9.99 \times 10^{6} \exp(-42.8/RT)$
Carbon dioxide	1.5	$4.68 \times 10^{5} \exp(-81.8/RT)$
Naphthalene	1.5	$3.66 \exp(-67.4/RT)$
1-Methylnaphthalene	1.0	$5.73 \times 10^{4} \exp(-112/RT)$
2-Methylnaphthalene	1.0	$2.41 \times 10^{2} \exp(-62.2/RT)$
Phenol	1.5	$1.91 \times 10^{-2} \exp(-97.8/RT)$
o-Cresol	1.5	$1.98 \times 10^{8} \exp(-111/RT)$
m-Cresol	1.0	$1.56 \times 10^{2} \exp(-56.3/RT)$
p-Cresol	1.5	$1.24 \times 10^{5} \exp(-47.2/RT)$
2,6-Dimethylphenol	1.5	$1.01 \times 10^{5} \exp(-43.5/RT)$
2,5-Dimethylphenol	1.0	$8.92 \times 10^{1} \exp(-49.3/RT)$
2,3-Dimethylphenol	1.0	$4.87 \exp(-90.6/RT)$
3,4-Dimethylphenol	1.0	$6.32 \exp(-28.6/RT)$
3,5-Dimethylphenol	1.5	$6.07 \times 10^{3} \exp(-19.0/RT)$

As for isomeric dimethylphenols, the activation energies for 2,5- and 2,6-dimethylphenols are close (49.3 and 43.5 kJ mol^{-1}, respectively), but for 2,3-dimethylphenol E_a is substantially higher, 90.6 kJ mol^{-1}.

In the first stages of pyrolysis, the main reactions responsible for formation of gaseous and liquid pyrolysis products are decarbonylation (IV), decarboxylation (V), and dealkylation (VI).

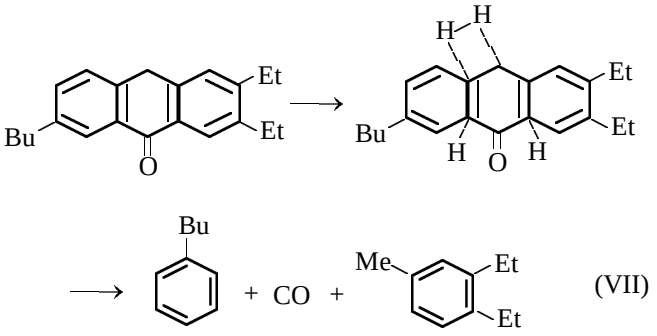


(IV)



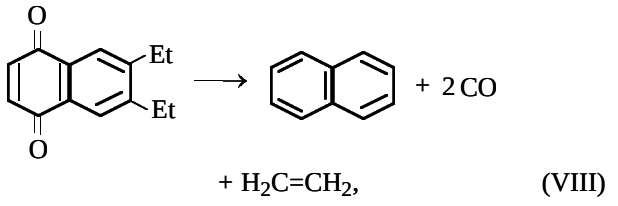
To confirm this assumption, we calculated for these reactions the activation energy, using the procedure in [27]. For example, for reaction (IV) E_a is 100.6 (taking into account release of 2 mol of CO), for (V), 121.5, and for (VI), 79.6 kJ mol^{-1}.

Specifically reactions (IV)–(VII) will occur first, determining the composition of pyrolysis products at low temperatures and short (0.5–1.5 s) contact times:

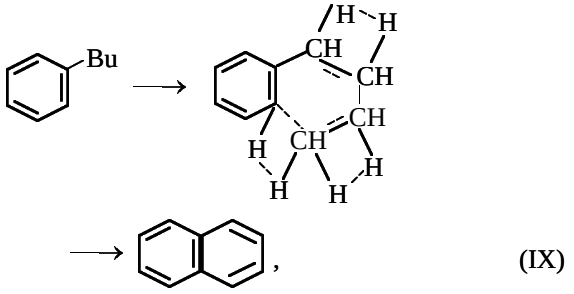


E_a = 146.7 kJ mol^{-1}.

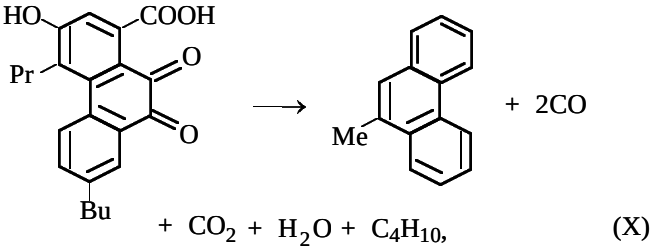
As the pyrolysis conditions become more rigorous, the contribution of condensations and cyclizations increases:



E_a = 280.7 kJ mol^{-1};



E_a = 632.7 kJ mol^{-1};



E_a = 972.1 kJ mol^{-1}.

The above calculations of E_a once again confirm the reaction sequence in pyrolysis of phenols: Less energy-consuming processes occur at lower temperatures and shorter (0.5–1.5 s) contact times, whereas under more rigorous conditions the contribution of reactions requiring more energy increases.

It should be noted that we are dealing with effective E_a of a rather complex process involving numerous branched successive and parallel reactions. According to the analysis results, phenols undergo both degradation and condensation to higher-molecular-weight products (neutral oxygen-containing compounds, asphaltenes). The final condensation product is pyrocarbon; its yield sharply increases in going to more rigorous pyrolysis conditions. Our special experiments (pyrolysis on pyrocarbon packing) confirmed the autocatalytic effect of pyrocarbon in pyrolysis.

The calculations show that homogeneous pyrolysis of phenols is a complex and multistage process, which is due to specific features of the chemical composition of the phenols and their degradation products.

CONCLUSIONS

(1) The kinetic features of pyrolysis of phenols from lignite (near-Moscow fields) semicoking tar were studied.

(2) The activation energies were calculated, and the reaction orders were determined for accumulation of methane, hydrogen, carbon monoxide and dioxide, naphthalene, 1- and 2-methylnaphthalenes, phenol, and isomeric cresols and dimethylphenols.

(3) Calculations of the activation energy by the additive scheme gave the results consistent with the bond energies in the activated complex. The sequence of reactions in pyrolysis of phenols was determined.

Abstract—A novel electrolytic method for preparing the catalyst (active aluminum oxide) for melamine synthesis and a process for catalytic synthesis of melamine from urea are proposed.

Melamine (1,3,5-triamino-2,4,6-triazine) is a valuable precursor in production of plastics, lacquers, and adhesives exhibiting high mechanical strength, stability in hot water and in organic solvents, low electrical conductivity, and high thermal stability. These materials based on melamine–formaldehyde resin are widely used in various branches of industry [1, 2].

To synthesize melamine from urea, we developed a catalyst, active aluminum oxide with the specific surface of about 300–400 $m^2 g^{-1}$.

A goal of this work was to develop a low-waste procedure for preparing the catalyst, by ensuring stable conditions of granule formation and improved quality of the target product.

We improved a process for production of $Al(OH)_3$ and γ-Al_2O_3 to increase the melamine content in the target product from 80 to 96–98%. Initially we took commercial aluminum hydroxide with the specific surface area of 80–120 $m^2 g^{-1}$. Impurities present in it (up to 0.1 wt % Na_2O, 0.1 SiO_2, and 0.4 Fe_2O_3) adversely affected the quality of the γ-Al_2O_3 obtained (the melamine yield was about 80%). To remove them, commercial aluminum hydroxide was reprecipitated from chemically pure grade HNO_3, washed to remove ammonia, molded, dried, and calcined. The thus prepared γ-Al_2O_3 provided the melamine yield of up to 88.5% and had the specific surface area of 160–170 $m^2 g^{-1}$, which is insufficient for commercial production of melamine.

Nevertheless, the above study showed that purification of alumina increases the process selectivity. However, the above purification procedure is unacceptable, because the increase in the number of reprecipitation stages complicates the technology and increases the washwater amount. Therefore, we developed a method for preparing $Al(OH)_3$ from pure metallic aluminum by electrolytic precipitation. The precipitate was molded in grains by a sol–gel process and then was thermally treated to obtain granulated γ-Al_2O_3 [3].

Two electrodes (200 × 120 × 15-mm plates) made from metallic aluminum (99.9 wt % Al) were placed parallel to each other at a distance of 10–15 cm in a glass vessel filled with distilled water containing 2–4 wt % NH_4NO_3 as an electrolyte; dc electrolysis was performed at I = 27 A and U = 65 V.

A gel-like $Al(OH)_3$ precipitate was formed on the anode. The pulp was separated at the solid : liquid ratio of 1 : 8 by centrifuging, and a substance with the solid : liquid ratio of 1 : 4 and pH 7 was obtained. Concentrated chemically pure grade HCl was added to decrease pH to 3–4. A transparent thixotropic colloid of basic aluminum chloride (BAC) was thus obtained by the reaction [4]

$$2Al(OH)_3 + HCl \rightarrow Al_2(OH)_5Cl + H_2O \qquad (1)$$

with the Al_2O_3 content of 50 g dm^{-3}; it was aged at room temperature for 12–24 h.

A drop-oil method was used to mold granules. A molding mass was poured in a cone-shaped vessel and fed through a pipette 1.5 mm in diameter at a rate of 2–3 drops s^{-1} into a molder, a cylinder filled with a two-phase liquid (3–4-cm layer of kerosene to form drops and 25% aqueous solution of urea to form three-dimensional gel structure; the layer thick was sufficient for neutralization of granules for 3–4 min). In the first stage, granules were dried for 1 day in air. In the second stage, they were dried in a vacuum drier for 2–3 days at 40°C. Then the temperature was elevated at a 10 deg h^{-1} rate to 150°C, and at this tem-

Scheme of the pilot setup for melamine production from urea: (*1*) melter, (*2*) catalytic reactor, (*3*) sublimer with packings for collecting product, (*4*) hatch for unloading the target product, (*5*) bubbler with ammonia water, (*6, 7*) rotameters, (*8, 9*) ammonia heaters, (*10–12*) valves, and (*13*) injector.

perature the granules were kept for 4 h. In the third stage, granules were calcined in a muffle furnace according to the following schedule: heating at a rate of 20 deg h^{-1} from 150 to 200°C, 50 deg h^{-1} from 200 to 500°C, 100 deg h^{-1} from 500 to 900°C; keeping at 900°C for 4 h; and gradual cooling and sampling. Production of the catalyst was tested in a pilot setup (see figure).[1]

The urea melt is fed from a melter *1* at 140–160°C under a pressure of 0.8 MPa into the reactor *2*. Ammonia heated to 350–500°C is also fed at the melt to gas wt ratio of 1 : (7–9). In the reactor, the melt is entrained with the gas and decomposes by the reaction

$$CO(NH_2)_2 \rightarrow HNCO + NH_3. \quad (2)$$

[1] The pilot setup was developed in Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering.

A mixture of cyanic acid and ammonia is fed to the catalyst bed, where melamine is formed by the reaction

$$6HNCO \rightarrow C_3H_6N_6 + 3CO_2 \quad (3)$$

at a pressure of 0.1–0.2 MPa.

The reaction products are sublimed in vessel *3* at 180–200°C. Melamine as a white finely dispersed powder is unloaded through hatch *4*. An NH_3 + CO gas mixture from the sublimer is bubbled through water in vessel *5*, where ammonia partially dissolves. The urea conversion amounts to 97–98%, and the yield of the target product is 98% [5].

CONCLUSION

The developed procedure for preparing granulated γ-Al_2O_3 provides high specific surface area of the catalyst (up to 300–400 $m^2\ g^{-1}$) and elevated selectivity with respect to the target product, melamine (yield 96–98%).

BRIEF COMMUNICATIONS

A Procedure for Isolating Desmotropic Forms of Tautomeric Compounds, with 5-Benzylidene-2-mercapto-Δ^2-thiazolin-4-one as Example

E. B. Aronova and A. I. Ginak

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 29, 2002

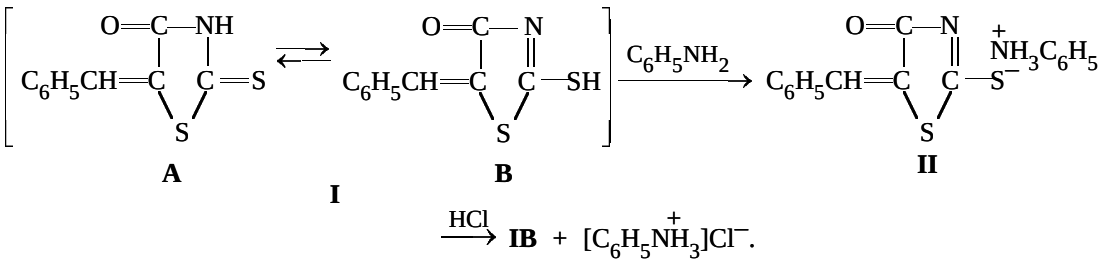
Abstract—Reaction of aniline with a mixture of tautomes of 3-benzylidene-4-oxothiazolidine-2-thione, followed by treatment with hydrogen chloride, allowed isolation of the pure desmotropic form of this compound, 5-benzylidene-2-mercapto-Δ^2-thiazolin-4-one.

It is known that different tautomers of synthetic and natural biologically active substances exhibit different activity [1]; therefore, isolation of pure desmotropic forms is an urgent problem. However, this is often difficult and even impossible, because tautomeric transformations are reversible, with the position of the equilibrium depending on numerous factors: polarity and basicity of the medium, acid–base properties of tautomers, nature of substituents, ionic strength of solution, and, finally, thermodynamic characterisitcs of crystallization of desmotropic forms, since specifically the desmotropic form with the lower crystallization energy is isolated as a solid [2, 3]. Therefore, in most cases, the tautomeric equilibrium in crystallization is shifted toward one of the forms [4, 5], with the other form being detectable only in solution; this prevents studying its biological and physicochemical properties relevant to practical applications (in medicine, agriculture, and microelectronics).

Sometimes tautomers crystallize in two forms simultaneously; the crystals can be distinguished with a microscope [6, 7] and even separated manually, but this procedure is unsuitable for practice.

To develop an efficient procedure for isolating pure desmotropic forms, we chose 5-benzylidine-2-mercapto-Δ^2-thiazolin-4-one **IB** whose tautomerism and reactivity are well studied [8, 9].

It was shown previously that mercaptothiazolidine **IB** exists in equilibrium with its thione form, 5-benzylidene-4-oxothiazolidine-2-thione **IA**; these forms crystallize from solutions in a 1 : 0.55 ratio, respectively. The tautomers are weak bases with $pK_{a_{eff}}$ 9.34; the equilibrium is shifted toward less acidic form **IA** (the acidity gradient of the tautomers is 0.17). Potentiometric and conductometric studies [10] showed that the tautomers form stable salts with alkali metals and amines, existing in solutions as equilibrium mixtures of contact ion pairs and free ions. The degree of dissociation of the salts is higher in more polar solvents; in low-polarity solvents (dioxane, chloroform), the salts are nonconducting, i.e., they exist in the nondissociated form. This fact suggests the possibility of isolating the more acidic tautomeric form by the reaction with a base (e.g., $C_6H_5NH_2$) in a basic solvent; in this case, it can be expected that the base would react primarily with the more acidic form **IB** to form the corresponding salt. This suggestion was confirmed previously [11].



$\xrightarrow{HCl}$ **IB** + $[C_6H_5\overset{+}{N}H_3]Cl^-$.

1070-4272/02/7511-1885$27.00 © 2002 MAIK "Nauka/Interperiodica"

After solvent evaporation, chromatographically pure salt **II** is obtained. Its treatment with gaseous HCl yields a mixture of pure desmotropic form **IB** and amine hydrochloride; the latter can be quantitatively washed out with water. The composition and structure of **IB** were confirmed by elemental analysis and IR spectroscopy [12].

The acidity gradient of the tautomers can also be used for isolating one of the desmotropic forms by crystallization from a medium with appropriate pH. Indeed, according to Kabachnik [2], in media with pH ≤ pK_a the tautomeric equilibrium will be stabilized, with the more basic species forming an ion pair with the acid, which is solvated more strongly, and the more acidic species precipitating when the solubility is decreased. To check this assumption, we attempted to isolate the more acidic form **IB** from solutions with pH ≤ p$K_{a_{SH}}$. To do this, we added water to an acidified alcoholic solution of **I** (pH 7.5) to decrease the solubility; in the process, needle-shaped crystals of **IB** precipitated. Their composition and structure were confirmed by elemental analysis, IR spectroscopy [12, 13], mixing test, and TLC [14].

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrometer.

TLC analysis was performed on standard Silufol-254 plates in the solvent system acetone : hexane : acetic acid, 1 : 2 : 0.01.

Compound **I** was prepared as described in [15] and purified by threefold recrystallization from ethanol; the product purity was checked by TLC (Al_2O_3).

Isolation of the thiol form. *a*. A 0.01-mol (2.21-g) portion of **I** was dissolved in 50 ml of aniline; the mixture was stirred for 10 min at room temperature and evaporated by half. Then dry HCl was passed for 30 min, 50 ml of chloroform was added, the mixture was evaporated to dryness, the solid residue was washed with 50 ml of water to remove aniline hydrochloride, and the precipitate was dried in a desiccator over phosphorus pentoxide. Yield 98%, mp 198°C. IR spectrum, ν, cm^{-1}: 1688 ($\nu_{C=O}$), 2515 ($\nu_{C=H}$), 860 (δ_{SH}).

Found, %: C 54.28, H 3.16, N 6.30, S 28.93.
$C_{16}H_{14}N_2OS_2$.
Calculated, %: C 54.30, H 3.17, N 6.33, S 28.96.

b. A 0.01-mol (2.21-g) portion of **I** was dissolved in 20 ml of ethanol, acetic acid was added to pH 7.5, the mixture was stirred for 20 min, the solution was evaporated by half, 20 ml of chloroform was added, and a small crystal of **I** was introduced. The precipitate that formed was filtered off, washed with water to neutral reaction, and dried in a desiccator over phosphorus pentoxide. Yield 97%, mp 198°C. The IR spectrum is identical to that of the sample prepared by method *a*.

Found, %: C 54.26, H 3.17, N 6.31, S 28.93.
$C_{16}H_{14}N_2OS_2$.
Calculated, %: C 54.30, H 3.17, N 6.33, S 28.96.

ANNIVERSARIES

Sergei Stepanovich Ivanchev (on 70th Anniversary of His Birthday)

On December 1, 2002, Sergei Stepanovich Ivanchev, one of the leading polymer scientists, doctor of chemical science, professor, corresponding member of the Russian Academy of Sciences, Honored Scientist and Technologist of the Russian Federation, winner of the Prize of the Council of Ministers of the USSR, awardee of the Academician Kargin Award, and director of the St. Petersburg Branch of the Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, is 70.

S.S. Ivanchev started his scientific and pedagogical activities at Lvov State University and continued these activities at Mechnikov State University in Odessa, where he defended his doctoral dissertation and made a career, from docent, acting head of a chair, to dean of the chemical faculty. In the 1970s, Ivanchev headed a department of exploratory research, organized by him at Plastpolimer Okhta Research and Production Association (St. Petersburg), where he was the first deputy general director for research from 1981 till 1998. At the end of 1998, he organized a branch of the Boreskov Institute of Catalysis, presently headed by him.

Ivanchev's scientific interests are in radical oligomerization and polymerization in homogeneous and heterogeneous systems (including emulsion polymerization, polymerization filling, and processes used to obtain polymeric formulations) and in catalysis of polymerization and oligomerization.

He substantiated scientifically and implemented pathways for synthesis of new classes of polyfunctional components used to obtain oligomers and reactive polymers and polymer systems (initiators, emulsifiers, monomers, fillers, etc.). In studying the polymerization initiated by polyfunctional initiators, he suggested for the first time and proved the polymerization–recombination nature of macromolecule formation and revealed conditions for its implementation. He formulated and implemented procedures for obtaining new polymers with complex structure and improved properties. Under Ivanchev's supervision, new methods for obtaining new latex systems with controllable morphology for coatings with a wide variety of properties, and also a number of filled formulations

for vibration-absorbing polymer systems and formulations for ship-building, electronic, and automobile industries were developed. In the field of Ziegler catalysis Ivanchev developed and put into practice a catalyst for ethylene dimerization into butene and developed new catalysts for polymerization and copolymerization of ethylene, based on components that had not been used for such purposes.

Ivanchev is the author or co-author of three monographs: *Emul'sionnaya polymerizatsiya* (Emulsion Polymerization) (Khimiya, 1978), *Radikal'naya polimerizatsiya* (Radical Polymerization) (Khimiya, 1985), and *Reaktsii v polimernykh sistemakh* (Reactions in Polymer Systems) (Khimiya, 1987). The first of these was republished in the United States in 1981. He published more than 300 review papers and papers in scientific journals and received more than 200 patents and inventor's certificates. He is actively working with young scientists: he has trained 43 candidates and 8 doctors of science.

Under Ivanchev's supervision, the research center for technology of polymerization plastics, Plastpolimer Okhta Research and Production Association, was designed, built, and put into operation at Tomsk Petro-

1070-4272/02/7511-1887$27.00© 2002 MAIK "Nauka/Interperiodica"

chemical Combine, and a technology of ethylene dimerization into α-butene was developed and the corresponding installation were put into operation. He also supervised the development, in the framework of an intergovernmental agreement with GDR, of a technology for ethylene synthesis.

Sergei Stepanovich is an Honorary Chemist of the Russian Federation; Honored Engineer of St. Petersburg (2002); member of the Higher Qualification Committee of the Council of Ministers of, first, USSR and then Russia; member (for 12 years) of the Editorial Board of *Vysokomolekulyarnye Soedineniya* (Macromolecular Compounds) journal and Editorial Boards of *Uspekhi Khimii* (Advances in Chemistry) and *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) journals. He is a member of the Scientific Council for Macromolecular Compounds at the Presidium of the Russian Academy of Sciences, Bureau of the Board of Directors of the Mendeleev Russian Chemical Society, and Scientific Council for Catalysts.

Ivanchev continues work on development of new postmetallocene catalysts for polymerization, improvement of the emulsion polymerization processes, control over the morphology of latex particles, synthesis of latexes with hollow particles, and modification of polyolefins, which was reflected in more than 30 publications in the last three years.

The Editorial Board and Editorial Office of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) heartily congratulate Sergei Stepanovich on his jubilee and wish him sound health and further success in his creative work.

Russian Journal of Applied Chemistry, Vol. 75, No. 11, 2002, pp. 1889–1892. Translated from Zhurnal Prikladnoi Khimii, Vol. 75, No. 11, 2002, pp. 1926–1929.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Marcellin Berthelot (on 175th Anniversary of His Birthday)

Pierre Eugene Marcellin Berthelot ranks among the most prominent chemists of the second half of the XIX century and early XX century. The great number of his works include fundamental investigations in virtually all branches of chemistry of that time, original studies in physics, biology, history of science and art, archeology, philosophy, pedagogics, linguistics, ethics, and esthetics. Works of the French scientist much promoted the transformation of organic chemistry into a separate kind of science, stimulated the development of the most important fields of physical chemistry, and enriched the history of chemistry.

M. Berthelot was born on October 25, 1827, in Paris into a doctor's family. In 1846, he graduated from a lyceum, having demonstrated substantial learning capability both in natural sciences and in humanities. Berthelot was aided in his diverse scientific activities by his knowledge of foreign languages, including Grecian and Sanskrit. Soon after graduating from the lyceum, he passed an examination to obtain bachelor's degree in philosophy and history (es lettres) and in mathematics and natural sciences (es sciences). Following the example of his father, Berthelot started his higher education from medicine and simultaneously attended lectures in chemistry and physics at College de France. In 1849, he obtained a degree of licentiate in physical sciences. By that time, the final choice of the main direction of research had been made, and this was chemistry. Berthelot mentioned among his teachers chemists J.B. Dumas (1800–1884), A.J. Balard (1802–1876), and T.J. Pelouze (1807–1867), and especially a physicist H.V. Regnault (1810–1878). All of them were known scientists and members of the Paris Academy of Sciences. In 1849, Berthelot started to work at Pelouze's private chemical laboratory, and in 1851, he became an assistant at Balard's laboratory at College de France.

In 1854, Berthelot defended his doctoral dissertation. His study was concerned with the reaction of glycerol with acids and artificial synthesis of natural fats. In 1858, he passed examinations and became a first-class pharmacist.

In 1859–1864, Berthelot was a professor at Ecole de Pharmacie in Paris. In 1863, the scientist was elected a member of the Academy of Medicine. From 1865 till 1906, he was a professor at College de France. Professors of this institution are not bound by any curricula and are free from taking part in examinations. Every year a scientist chooses the subject of his lectures himself, commonly in correspondence with the field of science he is currently interested in. In 1869, by proposition of J. Liebig (1803–1873), a known chemist, Berthelot was elected a member of the Bavarian Academy of Sciences. In 1873, he became a member of the Paris Academy of Sciences in physics. By recommendation of a group of academicians, including A.M. Butlerov (1826–1880), Berthelot was elected in 1876 a foreign corresponding member of the St. Petersburg Academy of Sciences. In 1877, the London Royal Society elected him a foreign member. Beginning in 1889, Berthelot was a permanent secretary of the Paris Academy of

1070-4272/02/7511-1889$27.00 © 2002 MAIK "Nauka/Interperiodica"

Sciences; in the same year he was elected a member of the French Academy of Literature and Fine Arts.

Together with being engaged in intensive and diverse scientific activities, Berthelot held a number of high state posts, he became a general supervisor of higher education in 1876 and was a minister of popular schooling in 1886–1887 and foreign minister of France in 1895–1896.

Berthelot was elected an honorary member of the German chemical society in 1894 and an honorary member of the French chemical society in 1900; in 1866, 1875, 1882, 1889, and 1901 he was elected the president of the French chemical society.

A lot of the credit for the development of various branches of chemistry and chemical technology must go to Berthelot; he made the most prominent contribution to the development of organic synthesis. This is quite understandable since organic chemistry dominated the development of chemistry in the middle of the XIX century.

Voluminous literature has been concerned with Berthelot's life and scientific activities; his works have been studied in detail. A prominent contribution to studies of this kind performed in Russia was made by Yu.S. Musabekov (1910–1970), a known historian of chemistry [1, 2]. Rather detailed reminiscences about his French colleague were published by K.A. Timiryazev (1843–1920), an outstanding natural scientist [3] who was well-acquainted with Berthelot and worked at his laboratory (1868–1870). In 1927, a collection of articles was published in connection with the centennial anniversary of Berthelot's birthday. The collection presented evidence about scientist's life (D.P. Konovalov) and his works in thermal chemistry (I.A. Kablukov), technology of explosives (S.P. Vukolov), and history of chemistry (B.N. Menshutkin). Materials on Berthelot can be found in numerous reference publications [5–8].

Berthelot was the first to synthesize by original methods from elements and simple substances a great number of new and known natural compounds. Berthelot's contribution to the development of the synthetic direction in organic chemistry was analyzed in [9–11]. In 1853–1854, the scientist was dealing with synthesis of fats by heating glycerol with palmitic, stearic, and oleic acids in sealed ampules. Berthelot proved that the substances synthesized by him form the basis of animal and vegetable fats and are composed of a combination of three parts of acids and one part of glycerol, with liberation of three parts of water. In 1855, he synthesized ethanol from ethylene and water mixed with sulfuric acid, and later (1882) obtained formic acid from carbon monoxide and water in an alkaline medium. Already in 1861, Berthelot wrote a two-volume book *Organic Chemistry Based on Synthesis*, which made its author famous.

Much later, in a three-volume publication *Hydrocarbons, Experimental Investigations*, 1851–1901, Berthelot summarized the results of an enormous number of syntheses of hydrocarbons and their derivatives from simple substances or elements.

He synthesized acetylene from carbon and hydrogen in an arc furnace, and acetylene could then be converted into quite a number of compounds: benzene, styrene, naphthalene, anthracene, etc. Berthelot then passed from acetylene to ethylene, methane, and other compounds of the aliphatic series, to numerous oxygen- and nitrogen-containing substances. The part played by acetylene in classical Berthelot's syntheses and the influence exerted by works of the French scientist on the subsequent development of the chemistry of acetylene were analyzed in detail in [12]. Berthelot proposed a versatile method for reduction of organic compounds with hydrogen iodide. This technique had been widely used before the discovery of the catalytic hydrogenation method.

Together with problems of organic synthesis, Berthelot had been intensively studying for more than 40 years, beginning in 1865, thermal chemistry and was, together with a Russian scientist G.I. Hess (1802–1850) and Danish physical chemist J. Thomsen (1826–1909), one of its founders. As noted by Solov'ev [13], Berthelot published in the field of thermal chemistry 152 works of his own, and 63, together with his numerous disciples. In particular, V.F. Luginin (1834–1911), a Russian physical chemist who organized at Moscow University the first Russian calorimetric laboratory (1892), took part in Berthelot's calorimetric studies. Berthelot paid much attention to improvement of techniques for calorimetric measurements. The manual of thermal chemistry, written by him, was translated in Russia (Odessa, 1894). As far back as 1881, Berthelot was the first to design a calorimetric bomb for determining the heat of formation of organic compounds. The bomb later found wide use in thermochemical laboratories all over the world. The advance in calorimetric measurements was much promoted by the invention by H. Le-Chatelier (1850–1936) of the platinum–rhodium thermocouple.

The basic idea in Berthelot's works, and also in investigations by Hess and Thomsen, was the concept of the heat effect of a chemical reaction as a measure of affinity of the reactants. In the final form, Berthelot

formulated the principle of maximum work as follows (1875): "Any chemical transformation occurring without any influence of a foreign external energy tends to produce bodies or systems of bodies whose formation is accompanied by liberation of the maximum amount of heat." In the subsequent years, the appropriateness of application of the maximum work principle was discussed by quite a number of scientists [13–15]. In particular, D.I. Mendeleev wrote in the fourth edition of *Osnovy khimii* (Fundamentals of Chemistry) (St. Petersburg, 1881, part 1): "...Although the principle of maximum work can well be applied to experimental data in numerous cases, it can be considered neither firmly established nor being in agreement with the whole body of chemical evidence."

The development of chemical thermodynamics in the end of the XIX century affected Berthelot's views and, as noted in [15], this principle is already not dominant in the two-volume publication of the French scientist, *Thermal Chemistry, Quantities and Numerical Laws* (1897). A constructive criticism of the Berthelot–Thomsen principle can be found in works by A.L. Potylitsyn (1845–1905), a Russian chemist, Mendeleev's disciple [15, 16].

Berthelot also worked in the field of chemical kinetics. Together with L. Pean de Saint-Gilles, he studied the rates of the reversible esterification–saponification and demonstrated that, at any given instant of time, the rate of ester formation is proportional to a product of reactant masses and described mathematically the reaction of acetic acid with ethanol. Having mentioned the relatively slow course of reactions of this kind, the authors predetermined for decades their being chosen as model reactions in studying the main kinetic laws. Berthelot was one of the first to pay attention in his book *Studies of Chemical Mechanics* (1879) to the role of time in the course of chemical reactions. Experimental studies by Berthelot and Saint-Gilles, carried out in 1862–1863, preceded classical works in chemical kinetics, performed in 1864–1867 by Norwegian scientists C.M. Guldberg (1836–1902) and P. Waage (1833–1900).

A prominent place in Berthelot's investigations was occupied by inflammation and explosion. According to Berthelot, two kinds of waves are generated in explosion: blast wave and sound wave. Berthelot was concerned with problems of explosion and chemistry and technology of explosives till the end of his life. This aspect of the activities of the French scientist was considered in detail by Vukolov [4]. The results obtained by Berthelot in studying explosives and explosions have been used for military purposes and in mining.

Much attention was paid by Berthelot to methodological and scientific-historical problems. The philosophical concepts of the scientist were summarized in quite a number of monographs: *Science and Philosophy* (1886), *Science and Morals* (1887), *Science and Education* (1901), and *Science and Free Thinking* (1905), and also in his correspondence with E. Renan (1898). E. Renan (1823–1892), professor of ancient Oriental languages at College de France, author of the multivolume publication *History of the Origin of Christianity*, was on very friendly terms with Berthelot from his teens till the end of his life. Berthelot imagined the beginning of the XXI century as the time of unprecedented flourishing and leading role of chemistry. Simultaneously, he suggested evolution of means of transportation, energetics, and communication. Unfortunately, Berthelot's predictions, and in the first place those concerning the structure of society and its morals and manners, proved to be unrealizable.

In 1869, Berthelot visited, as a member of the French delegation, Egypt in connection with the opening of the Suez channel. This trip much stimulated Berthelot's interest in the ancient culture of this country, and also in alchemy and astronomy. He studied the composition of ancient coins, decoration articles, and arms. Berthelot wrote 10 volumes directly concerned with history of chemistry, and he can be rightfully considered one of founders of archeological chemistry.

Marcellin Berthelot died on March 18, 1907, at the age of 79, several hours after his wife passed away. He was buried in the Pantheon, near other outstanding sons of France. As an exception, his wife was buried nearby.

Academician N.N. Beketov (1827–1911), a prominent Russian physical chemist, spoke of his French colleague as follows: "Markings of his activities will remain indelible in the intellectual development of the mankind." W. Nernst (1864–1941), an outstanding German physicist and physical chemist and Nobel Prize winner, named Berthelot "...one of the most prominent scientists of all times." And this is no overstatement. The already mentioned Timiryazev's reminiscences were named "Lavoisier of the XIX Century (Marcellin Berthelot, 1927–1907)."

In 1927, the centennial anniversary of Marcellin Berthelot's birthday was celebrated in France. A rather

representative Russian delegation, headed by A.V. Lunacharskii (1875–1933), a known statesman and public figure, people's commissar of education of the Russian Soviet Federative Socialistic Republic, took part in the celebration. Reminiscences of this celebration were published by V.E. Tishchenko [17] and Kablukov [18], members of this delegation.

INFORMATION

2nd International Conference on Polymer Modification, Degradation, and Stabilization

The 2nd International Conference on Polymer Modification, Degradation, and Stabilization (MoDeSt-2) was held from June 30 to July 4, 2002 in Budapest (Hungary).[1] The conference participants were more than 800 scientists from practically all the European Countries and also from the United States, Canada, Japan, China, Israel, and Brazil. The conference Chairman was Prof. Gy. Marosi (Hungary) and Co-chairman, Prof. Bela Pukanszky (Hungarian Academy of Sciences). The conference organizers were European Polymer Federation (EPF), Hungarian Academy of Sciences, and Polymer Degradation Discussion Group of the Macromolecular Group of the Royal Society of Chemistry, UK. The conference was held on the basis of the Budapest University of Technology and Economics (BUTE).

In the Opening session, Prof. Detrekoi (BUTE President), Prof. A.-C. Albertsson (EPF President), and Prof. F. La Mantia (MoDeSt-1 Chairman) outlined the topicality of the conference for fundamental and applied polymer research. The Conference Program included a plenary lecture and seven general lectures. The plenary lecture presented by W. Kaminsky was devoted to feedstock recycling of polymers by pyrolysis in a fluidized bed.

Seven general lectures covered the topical problems of the conference:

(1) W. Starnes: New Nonmetallic Additives for the Thermal Stabilization of PVC.

(2) F.E. Karasz: Electro-Optical Properties of Polymer Blends.

(3) F. La Mantia: Can Recycling Improve the Properties of Post-Consumer Plastic Materials?

(4) H. Höcker: Biomaterials—From Drug Release Systems to Surface Modified Implants with Enhanced Biocompatibility.

(5) G. Camino: Thermal Degradation and Combustion Behavior of Polymer–Layered Silicate Nanocomposites.

(6) M. Zrinyi: Smart Polymer Materials and Systems.

(7) N. Billingham: Surface Modification of Polyolefins by Migrating Additives.

Then the Conference was held in the form of a series of minisymposia on 6 dedicated topics. The first session (Thermal Degradation) covered 31 oral presentations. In this session, the problems of modeling random and end-chain scission (depolymerization), and of the use of modern instrumental methods, particularly ESR, for studying the kinetics and mechanisms of polymer thermal degradation were discussed. A special attention was paid to development and application of the chemiluminescence methods for studying thermooxidative degradation, and also of the isotopic methods including ^{18}O. Particular interest was aroused in the audience by the reports on "weak points" in the PVC structure sensitive to heating and thermal oxidation. A series of reports were devoted to natural and artificial aging of polymers and also to polymer degradation in the course of processing. The organizers, chairmen, and keynote lecturers in this section were K.S. Minsker, L. Rychla, F. Cataldo, J.E.J. Stagges, S. Seidler, J. Rychly, E. Pichett, N.C. Billingham, E. Foldes, B. Ivan, W. Habicher, A. Wegmann, D. Acierno, B. Balazs, S. Al-Malaika, M. Blazco, B. Pukanszky, and S. Schlick.

The second session (Aging, Irradiation, Stabilization) included 30 oral presentations on the problems of polymer aging, photo- and radiation degradation, and stabilization. A series of reports were devoted to the mechanisms of action of various types of stabilizers including new UV light absorbers and spatially hindered piperidines, synergism and antagonism with various chemical additives. Among the subjects of other reports were photodegradation of films and fibers, radiation-chemical and ozone-induced aging of polymers, and also development of methods for prediction of the lifetime of polymer goods. The organizers, chairmen, and keynote lecturers in this section were N.S. Allen, A.R. Horrocks, P. Staniek, M.P. Foulc, R. Todesco, C. Decker, J.L. Gardette, B. Mailhot, J. Pospisil, L. Audouin, W. Starnes, I. Stevenson, I. Rusznak, M. Stephan, Gy. Pokol, O. Figovsky, A. Vig, and L. Kravets.

The third session (Combustion and Fire Retard-

[1] MoDeSt-1 was held in September 2000 in Palermo (Italy).

1070-4272/02/7511-1893$27.00 © 2002 MAIK "Nauka/Interperiodica"

ance) included 32 lectures. Of primary concern were the problems of polymer burning and searching for the ways to decrease the flammability of polymer materials. Among the topics were changing halogen-containing fire retardants for non-halogen ones (particularly, nanocomposites), pyrolysis and degradation of polymers in burning, fire-retardant mechanisms, bloating and foaming in burning polymers, and development of new environmentally friendly fire retardants. The organizers, chairmen, and keynote lecturers in this section were T.R. Hull, J. Wang, M. Lewin, P. Anna, C.A. Wilkie, C. Jama, G. Camino, J.E.J. Staggs, S. Varma, I. Dekany, R. Kozlowsky, O. Grexa, S. Bourbigot, B. Schartel, P.R. Hornsby, and A. Kettrup.

The topic of the fourth session was Blends, Functionalization, and Reactive Processing (35 lectures). A particular attention was paid to cross-linking of polymer chains, control of the morphology of polymeric materials, modification of polymers by means of polymer-homologous transformation, phase transitions, and synthesis of special-purpose additives for polymers. The chairmen and keynote lecturers in this section were F.E. Karasz, A. Fainleib, R. Pfaendner, Gy. Bertalan, K. Ishizu, F. Fenouillot, J.E. Gerard, X. Xu, G. Ruggeri, Gy. Bunhegyi, B. Voit, J. Varga, A. Michel, E.V. Prut, T. Czigany, A. Murakami, M. van Duin, A. Toth, M. Zrinyi, and K.N. Chen.

The fifth session (Biodegradation, Biomaterials, Drug Release) included 28 oral presentations. Of primary concern were the problems of synthesis of biodegradable polymers, kinetics and mechanisms of their degradation in bioactive media, and performance of biodegradable materials for various purposes. A special emphasis was made on polyfunctional biomaterials, including their morphology, mechanical characteristics, and recycling. The chairmen and keynote lecturers in this section were H. Hocker, M. Zsuga, P.J. Lemstra, E. Csiszar, S. Slomkowsky, I. Tomka, A.J. Domb, J. Borza, J.E. Puskas, E. Polyanszky, R. Faust, S. Keki, J.P. Kennedy, S. Bronco, L. Costa, and K. Jacobson.

Finally, the sixth session (Recycling, Material and Energy Recovery) was devoted to recycling of post-consumer polymeric materials. The session covered 32 oral presentations. As the material and energy recovery methods, there were considered pyrolysis, hydrolysis, biodegradation of heterochain polymers, and recycling of polymers by, for example, reactive extrusion. The organizers, chairmen, and keynote lecturers in this section were U. Arena, W. Kaminsky, C. Papaspyrides, E. Takacs, A. Galeski, A. Jimenez, A. Okuwaki, J. Borda, P.J. Davis, T. Spychaj, J. Karger-Kocsis, Y. Sato, T. Czvikovszky, P. van Schijndel, F. La Mantia, I. Racz, J. Schoner, and E. Jakob.

Each of the minisymposia included poster presentations (a total of about 150 posters in all).

It was concluded that the problems discussed at the conference are topical from both the theoretical and practical standpoints. The next Conference (MoDeSt-3) is planned to be held in 2004.

BOOK REVIEWS

Naboichenko, S.S., Ni, L.P., Shneerson, Ya.M., and Chugaev, L.V., *Avtoklavnaya gidrometallurgiya tsvetnykh metallov* (Autoclave Hydrometallurgy of Nonferrous Metals)

Yekaterinburg: Ural'sk. Gos. Tekh. Univ.—Ural'sk. Politekh. Inst., 2002, 940 pp.

In recent decades, certain difficulties have been encountered in manufacture of a number of nonferrous metals. These difficulties are associated with deteriorating quality of raw materials, short supply of carbon fuels, and environmental problems. Also still important are mechanization and automation of industrial processes, possibility of remote control over these processes, and improvement of the safety of production. Of promise in solving these problems may be further extension of hydrometallurgical technologies and, in the first place, of their most intensive variety, autoclave processes (autoclave hydrometallurgy). The authors understand by the autoclave hydrometallurgy the processes employing hermetically sealed apparatus with intensive mass exchange at elevated temperature and pressure and those with the use of an external reaction gas.

The autoclave hydrometallurgy started to develop successfully in the second half of the XX century, when numerous publications and designs appeared, and a number of industrial installations of varied output capacity were constructed. The first book concerned with implementation of autoclave processes was the monograph *Avtoklavnye protsessy v tsvetnoi metallurgii* (Autoclave Processes in Nonferrous Metallurgy) (Maslenitskii, I.N., Dolivo-Dobrovol'skii, V.V., Dobrokhotov, G.N., *et al*., Moscow: Metallurgiya, 1969). During more than 30 years that have elapsed since that time, new results of investigations have accumulated and the scale of implementation of autoclave processes has increased, which required systematization, analysis, and generalization of the data obtained. In our opinion, the team of authors of the monograph, headed by S.S. Naboichenko, a corresponding member of the Russian Academy of Sciences, has successfully tackled with the problem.

The monograph considers physicochemical foundations of hydrometallurgical processes carried out at elevated temperatures and pressures and discusses their thermodynamics and kinetics. Examples of application of autoclave processes in manufacture of alumina, nickel, cobalt, zinc, copper, noble, and less-common metals are described. A special section is devoted to engineering implementation of the autoclave technologies.

The monograph comprises an introduction, twenty chapters grouped into five parts, and brief conclusion. Bibliography is given at the end of each chapter, with a total of about 1300 references to works by domestic and foreign authors given.

The introduction (pp. 10–29) contains evidence about a number of Russian scientists whose investigations much promoted the development of autoclave processes and application of high pressures in chemical technology. The introduction also discusses the history of development of autoclave processes at Russian plants and abroad.

The first part of the monograph (pp. 30–150, chapters 1–4) is concerned with specific features of equilibrium in a hydrothermal system including gas, solution, and solid. The first chapter considers general principles and concepts of the autoclave metallurgy. Typical solvents used in autoclave processes, reaction gases, oxidants, methods for preparing raw materials for autoclave leaching, various kinds of leaching of sulfide raw materials, and choice of optimal parameters of autoclave processes are discussed. The second chapter is concerned with thermodynamics of autoclave processes. Diagrams demonstrating the stability regions of separate compounds in metallurgical systems of interest for autoclave technologies are discussed. The third chapter contains data on solubility of oxygen and some other gases in aqueous solutions in a wide range of temperatures and pressures. The fourth chapter considers the influence exerted by a number of factors on the solubility of metal salts at elevated temperatures.

The second part of the book (pp. 151–318, chapters 5–8) covers a wide range of issues concerning dissolution of minerals, metals, and metal alloys under autoclave conditions. The fifth chapter is concerned with

1070-4272/02/7511-1895$27.00 © 2002 MAIK "Nauka/Interperiodica"

dissolution of chalcogenides, mainly sulfides, of quite a number of metals. The sixth chapter discusses side processes occurring in autoclave oxidation of sulfide concentrates. The seventh chapter is devoted to kinetics of dissolution of metals and alloys in various media. The eighth chapter discusses the kinetics and mechanism of dissolution of oxide minerals.

The third part of the monograph (pp. 319–670, chapters 9–14) considers processes of autoclave leaching in manufacture of alumina (chapter 9), metallurgy of nickel and cobalt (chapter 10), metallurgy of copper, zinc and lead, and noble metals (chapters 11–13), and processing of less-common-metal raw materials (chapter 14). The autoclave leaching, the leading operation in most of schemes for raw material processing, makes it possible to solve the whole set of technological problems.

The fourth part of the book (pp. 671–777, chapters 15 and 16) contains evidence concerning the autoclave precipitation of metals and their compounds. Chapter 15 considers autoclave methods for solution purification, which are based on hydrolysis of ions and precipitation of sulfides and end in formation of difficultly soluble compounds. Chapter 16 discusses the potentialities of the autoclave precipitation of metals.

The fifth part (pp. 778–935, chapters 17–20) is devoted to general engineering problems of autoclave hydrometallurgy. To these belong the apparatus implementation of autoclave processes (chapter 17), description of materials used in fabrication of autoclave apparatus (chapter 18), problems of safety in operation of autoclave installations (chapter 19), and mathematical modeling of autoclave processes (chapter 20).

The brief conclusion (pp. 936 and 937) points to advantages of autoclave processes and lists the most promising objects of their application. The authors also formulate the possible directions of improvement of the apparatus and technology of the autoclave hydrometallurgy.

The team of authors, comprising prominent specialists in autoclave processes, performed a vast amount of work, summarized and discussed numerous experimental studies and designs, and analyzed flowsheets and results of operation of industrial installations. However, it is impossible to envelop immensity. The book has a technological orientation, and this, probably, accounts for the fact that some sections of thermodynamic and electrochemical nature (e.g., chapter 2 and also paragraphs 3.2, 15.1, and 16.1) are presented without due clearness. Chapter 20 falls out of the general style of presentation. Probably, problems associated with modeling of autoclave processes should have been considered in more detail in a special-purpose monograph. The exceedingly brief description in the book of the models proposed raises too many questions.

The book is intended for engineers and research workers from plants and institutions concerned with problems of nonferrous metallurgy. Separate sections of the monograph may be of value for undergraduate students, masters, and postgraduate students specialized in nonferrous metallurgy or chemical technology.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Solid-Phase Conversion of Nonstoichiometric Hydroxoapatite into Two-Phase Calcium Phosphate

S. V. Dorozhkin

Nicol Hall, Mechanical Engineering, Queen's University, Kingston, Canada

Received June 25, 2000

Abstract—Two-phase and nonstoichiometric hydroxoapatites were synthesized and studied by X-ray phase and chemical analyses and by IR spectroscopy. A probable mechanism of solid-phase conversion of nonstoichiometric hydroxoapatite into two-phase calcium phosphate was considered on the basis of the model proposed and calculations.

Two-phase calcium phosphate (TCP), consisting of stoichiometric hydroxoapatite (SHA) $Ca_{10}(PO_4)_6(OH)_2$ and β-modification of calcium orthophosphate $Ca_3(PO_4)_2$, is widely used as a biomaterial owing to its chemical similarity to bone tissue [1, 2]. TCP is commonly obtained by calcination of nonstoichiometric hydroxoapatite (NHA) $Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$ ($0 < x < 1$) at 1000–1200°C for 1–4 h [3, 4]. Upon calcination, NHA is converted into TCP, but the mechanism of this process has not been elucidated as yet.

It is known that X-ray patterns of TCP are similar to those of a mechanical mixture of SHA and β-$Ca_3(PO_4)_2$ (Fig. 1). Therefore, TCP can be regarded as a mixture of SHA and β-$Ca_3(PO_4)_2$ crystals. However, no reports of successful separation of these phases could be found in the literature. Thorough studies of TCP in a scanning electron microscope at the highest possible magnifications of up to 100 000 failed to reveal two phases, and, consequently, TCP consists of phases with very fine crystals. According to [5], substances with very small-sized (less than 20–30 nm) crystals are characterized by broadened diffraction peaks in X-ray patterns. Furthermore, it is known that the majority of solid substances have so-called mosaic (or granular) structure and consist of crystallites (or blocks) with average size of 50–100 nm [5].

The aforesaid has also been established for calcium phosphates. For example, a block structure characterized by three levels of hierarchy has been suggested for crystals of fluoroapatite $Ca_{10}(PO_4)_6F_2$ [6]. The following data concerning the relation between crystallite sizes and width of diffraction peaks of calcium phosphates have been found.

(1) Crystallites of NHA enamel are 130 × 30 nm in size, similar crystallites of bones and tooth dentine have dimensions of 25 × 3 and 20 × 4 nm, respectively. Therefore, diffraction peaks of enamel are nar-

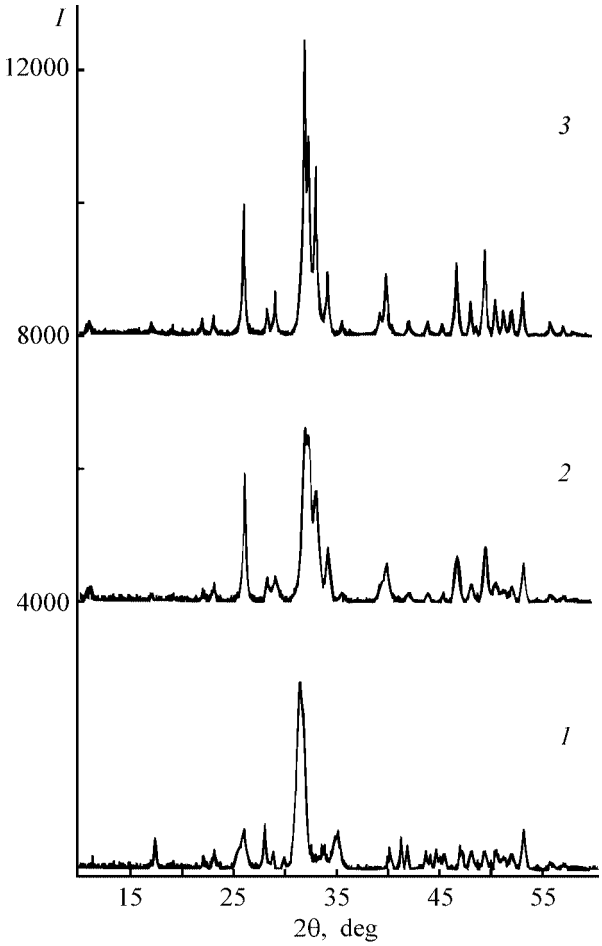

Fig. 2. X-ray patterns of uncalcined calcium phosphates. (*1*) $Ca_3(PO_4)_2$, (*2*) NHA, (*3*) SHA; the same for Fig. 4.

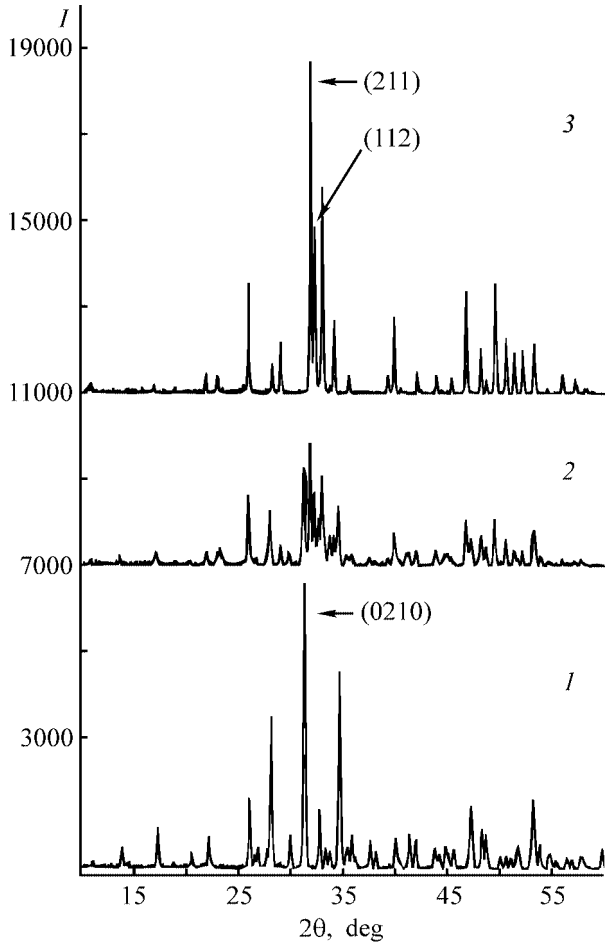

Fig. 3. X-ray patterns of calcined calcium phosphates. (*1*) β-$Ca_3(PO_4)_2$; (*2*) TCP consisting of 50% SHA + 50% β-$Ca_3(PO_4)_2$; (*3*) SHA; the same for Fig. 5. Peaks used to calculate the crystallite sizes are indicated.

row and intense, and the X-ray patterns of bone tissue and dentine have broad and low-intensity diffraction peaks, similar to X-ray patterns of amorphous substances [1].

(2) Coherent domains of size 50–60 nm, responsible for medium-width peaks in the X-ray patterns, have been found in natural fluoroapatite [7].

(3) X-ray patterns of SHA composed of 40–60-nm crystallites have broad low-intensity peaks, whereas X-ray patterns of SHA composed of 75-, 100-, and, especially, 130-nm crystallites have narrow and intense peaks [8, 9]. Even broader diffraction peaks have been detected in the case of SHA consisting of 20–50-nm crystallites [10].

(4) SHA calcined at 1200°C consists of crystallites 102 ± 2 nm in size, which is manifested in the presence of narrow and intense peaks in the X-ray patterns [11].

(5) A study of SHA, three types of bone tissue, and Endobone® biomaterial (Merck Biomaterial, Darmstadt, Germany) by X-ray phase analysis on a HASYLAB synchrotron (Hamburg) has shown that, depending on a selected crystallographic direction, the size of NHA crystallites in bone tissue is 8–23 nm, which is manifested as very broad diffraction peaks [12]. The SHA sample studied consisted of 22–34-nm crystallites characterized by rather broad, but narrower than in the case of NHA bone tissue, X-ray peaks. Only Endobone® (100% calcined SHA) gives intense and narrow diffraction peaks, since it consists of crystallites larger than 65 nm in size [12].

Thus, it may be suggested that the narrow and intense peaks of SHA and β-$Ca_3(PO_4)_2$, found in TCP (Fig. 1), indicate that TCP consists of two phases with crystallites (or blocks) of size 60 nm and larger. The aim of this study was to verify this assumption experimentally and to elucidate the mechanism of NHA conversion into TCP.

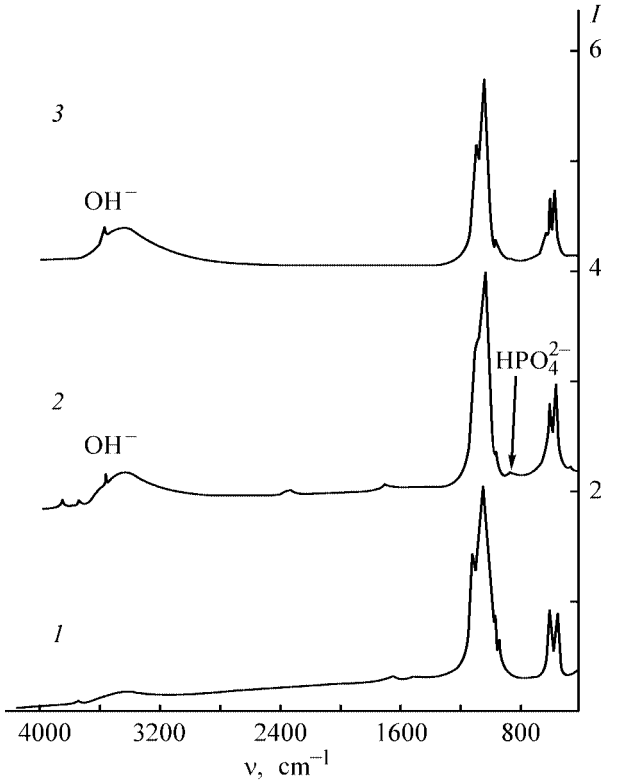

Fig. 4. IR spectra of uncalcined calcium phosphates. (*I*) intensity and (ν) wave number; the same for Fig. 5. Absorption bands of OH^- (3570 m^{-1}) and HPO_4^{2-} ions (875 cm^{-1}) are indicated.

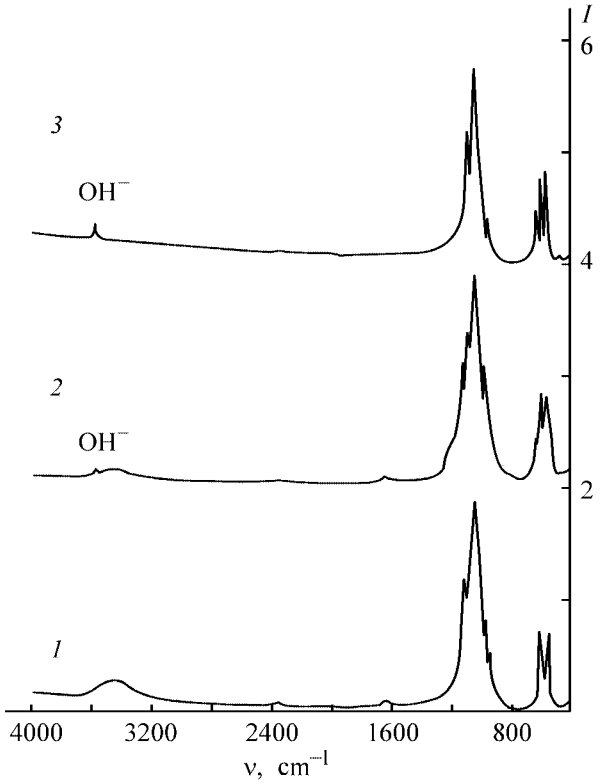

Fig. 5. IR spectra of calcined calcium phosphates. The absorption band of OH^- ion (3570 cm^{-1}) is indicated.

EXPERIMENTAL

TCP was synthesized by the method described in [3, 4, 11]. Chemically pure $CaHPO_4 \cdot 2H_2O$ and KOH were used as starting reagents. First, NHA was prepared by adding 36 g of solid KOH to 1 l of a $CaHPO_4 \cdot 2H_2O$ suspension (100 g l^{-1}) in distilled water. The suspension was heated to boiling and boiled for 4 h with constant stirring and pure nitrogen bubbled through. After cooling, the NHA precipitate was filtered off and washed with distilled water to absence of alkaline reaction with phenolphthalein. Then the precipitate was dried at 80°C for 24 h. To obtain TCP, the dry NHA precipitate was calcined at 1050°C for 4 h.

SHA and β-$Ca_3(PO_4)_2$ were prepared similarly, except that the amounts of KOH added were different. To obtain SHA, an excess amount of alkali (45 g KOH per 100 g of $CaHPO_4 \cdot 2H_2O$) is required, whereas for β-$Ca_3(PO_4)_2$, deficiency of alkali is necessary (31 g per 100 g of $CaHPO_4 \cdot 2H_2O$).

The chemical and phase composition of all the calcium phosphates prepared (whether calcined or not) was studied by X-ray phase analysis (XPA) (D8 Advance Bruker AXS diffractometer, 2θ angle variation range 10°–60°, Cu_{K_α} radiation), IR spectroscopy (1720X Perkin Elmer spectrometer) in the range 400–4000 cm^{-1}, and chemical analysis. In the last case, a 0.2-g weighed portion of calcium phosphate was dissolved in 10 ml of 0.5 M HCl, and the concentration of calcium (titration with Trilon B) and phosphate ions (photometric determination with ammonium molybdate) was determined by standard techniques [13].

XPA data for uncalcined and calcined calcium phosphates are shown in Figs. 2 and 3. As expected, diffraction peaks of calcined samples are more intense and narrower than similar peaks for uncalcined samples.

A similar conclusion about the width of absorption bands can be made on the basis of IR spectral data (Figs. 4 and 5). Moreover, the formation of TCP from NHA leads to disappearance of the characteristic absorption band of the HPO_4^{2-} ion (870 cm^{-1}) and to a decrease in the intensity of the absorption band of the OH^- ion (3570 cm^{-1}) [14].

Table 1. Average crystallite size τ calculated by formula (7)

Calcium phosphate	β,* deg	τ, nm
Uncalcined SHA	0.35	27
NHA	0.5	19
Uncalcined $Ca_3(PO_4)_2$	0.9	10
Calcined SHA	0.12	78
TCP: 50% SHA + 50% β-$Ca_3(PO_4)_2$	0.15	62
β-$Ca_3(PO_4)_2$	0.19	49

* Width of diffraction peaks in the range $2\theta = 31°–32°$ (it is in this range that most intense peaks are located in Figs. 2 and 3). In calculations by formula (7) these values should be expressed in radians.

Table 2. Time required for ions to diffuse over distance of 19 and 38 nm at 1000°C

Ion	Time, s	
	One crystallite (19 nm)	Two crystallites (38 nm)
OH^-	0.18	0.72
Ca^{2+}	3610 (~1 h)	14 400 (~4 h)
PO_4^{3-}	> 361 000 (> 4 days)	> 1 440 000 (>16 days)

The results of chemical analysis (molar ratio Ca/P) of all the calcium phosphates studied are presented below:

Calcium phosphate	Ca/P
Uncalcined SHA	1.66 ± 0.03
NHA	1.58 ± 0.03
Uncalcined $Ca_3(PO_4)_2$	1.49 ± 0.03
Calcined SHA	1.68 ± 0.02
TCP: 50% of SHA + 50% of β-$Ca_3(PO_4)_2$	1.59 ± 0.02
β-$Ca_3(PO_4)_2$	1.51 ± 0.02

The preparation of calcium phosphates is described by the following chemical reactions: (a) synthesis of SHA

$$10CaHPO_4 \cdot 2H_2O + 12KOH = Ca_{10}(PO_4)_6(OH)_2 + 4K_3PO_4 + 30H_2O, \quad (1)$$

(b) synthesis of $Ca_3(PO_4)_2$

$$3CaHPO_4 \cdot 2H_2O + 3KOH = Ca_3(PO_4)_2 + K_3PO_4 + 9H_2O, \quad (2)$$

(c) synthesis of NHA

$$CaHPO_4 \cdot 2H_2O + KOH \rightarrow Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x} + K_3PO_4 + H_2O, \quad (3)$$

where $0 < x < 1$.

In the case of $x = 0.5$, NHA is converted upon calcination into TCP consisting of 50% SHA and 50% β-$Ca_3(PO_4)_2$, and reaction (3) can be rewritten as

$$19CaHPO_4 \cdot 2H_2O + 21KOH = 2Ca_{9.5}(HPO_4)_{0.5}(PO_4)_{5.5}(OH)_{1.5} + 7K_3PO_4 + 56H_2O. \quad (4)$$

It is seen from the equations that the type of the final product is completely determined by the molar ratio of $CaHPO_4 \cdot 2H_2O$ and KOH being mixed.

The chemical reaction occurring in the course of calcination can only be written for NHA, whereas neither SHA nor $Ca_3(PO_4)_2$ undergo any chemical transformations in calcination (with only adsorbed water lost). The chemical transformation of NHA to TCP can be written as follows:

$$Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x} \rightarrow Ca_{10}(PO_4)_6(OH)_2 + \beta\text{-}Ca_3(PO_4)_2 + H_2O, \quad (5)$$

where $0 < x < 1$.

In the case of $x = 0.5$, NHA is converted upon calcination into TCP composed of 50% SHA and 50% β-$Ca_3(PO_4)_2$, and reaction (5) can be rewritten as follows:

$$2Ca_{9.5}(HPO_4)_{0.5}(PO_4)_{5.5}(OH)_{1.5} = Ca_{10}(PO_4)_6(OH)_2 + 3\beta\text{-}Ca_3(PO_4)_2 + H_2O. \quad (6)$$

The NHA structure has not been determined so far, mainly because of the inconstancy of its chemical composition. Nevertheless, chemical, spectroscopic, and X-ray studies of NHA give reason to maintain that, in all probability, NHA is SHA containing ionic vacancies at calcium and hydroxy sites and also a small number of protons in the form of HPO_4^{2-} ions [2]. In calcination, H^+ and OH^- ions present in the NHA crystal lattice diffuse and react to form water [reactions (5) and (6)] [1–4]. The formation of water is indirectly confirmed by IR spectral data. Comparison of NHA and TCP spectra (Figs. 4 and 5) shows that the intensity of the absorption band of the OH^- ion at 3570 cm^{-1} decreases and that of the absorption band of HPO_4^{2-} ion at 870 cm^{-1} disappears. In addition,

the IR spectral data point to an increase in the degree of ordering of calcium phosphates upon calcination. This follows from the fact that the absorption bands of phosphate groups at 500–600 and 950–1100 cm^{-1} become narrower and sharper [1, 2, 14].

According to the XPA data, calcination of calcium phosphates always results in upsizing of crystallites, which directly follows from the widths of diffraction peaks (Figs. 2 and 3). The average size of crystallites τ can be calculated by Scherrer's equation [15]:

$$\tau = K\lambda/(\beta \cos \theta). \quad (7)$$

Here β is the broadening (rad) of diffraction peaks, which is due to crystallites of small size; K, the form factor ($K \sim 0.9$ for most of substances [5]); λ = 1.54056 Å, the wavelength of Cu_{K_α} radiation; θ, the reflection angle corresponding to a diffraction peak.

The results of calculation by formula (7) are listed in Table 1.

It follows from Table 1 that, in the case of SHA and β-$Ca_3(PO_4)_2$, calcination only results in coarsening (agglomeration) of crystallites, without any change in their chemical composition. In the case of NHA, the agglomeration is complicated by chemical transformations resulting in the formation of new phases [reactions (5) and (6)]. Such transformations are impossible without ion diffusion, which can occur both in the bulk of the crystallites and along their boundaries.

Formally, SHA and $Ca_3(PO_4)_2$ are related by

$$3Ca_3(PO_4)_2 + Ca^{2+} + 2HO^- \rightleftarrows Ca_{10}(PO_4)_6(OH)_2. \quad (8)$$

In accordance with the calculated sizes of crystallites (Table 1), several small NHA crystallites transform upon calcination to a single large SHA or β-$Ca_3(PO_4)_2$ crystallite. This process is shown schematically in Fig. 6. In this case, calcium and hydroxy ions must diffuse over a distance approximately equal to the sizes of 1 or 2 small crystallites (19–38 nm). As follows from Eq. (8), phosphate ions are not involved in the diffusion. Now it is necessary to support these statements by calculations.

The numerical values of volume diffusion coefficients of ions in SHA at 1000°C are as follows ($cm^2\ s^{-1}$): OH^- 2×10^{-11}, Ca^{2+} 10^{-15}, and PO_4^{3-} $<10^{-17}$ [2]. Diffusion laws can be used to calculate the time required for these ions to diffuse over distances of 19 and 38 nm. The results of calculation are listed in Table 2. As seen from Table 2, calcination at 1050°C for 4 h is quite sufficient for diffusion of hydroxy and calcium ions over the distances specified, and, therefore, for NHA to be converted into TCP. The calculations demonstrate that phosphate ions virtually do not diffuse, and this is what was to be proved.

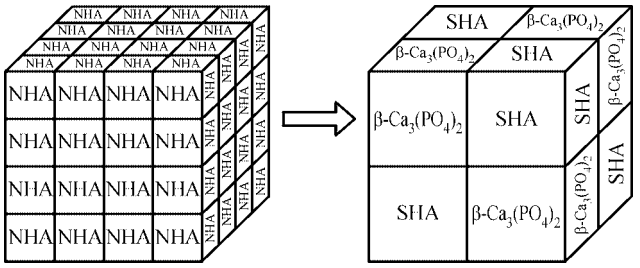

Fig. 6. Scheme of NHA conversion into TCP composed of 50% SHA + 50% β-$Ca_3(PO_4)_2$. The cubic structure is used for simplicity of drawing.

CONCLUSIONS

(1) Uncalcined and calcined calcium phosphates with varied initial Ca/P molar ratio were studied by IR spectroscopy, X-ray phase and chemical analyses. Published data indicating that no chemical transformations occur upon calcination of stoichiometric hydroxoapatite and $Ca_3(PO_4)_2$, whereas calcination of unstoichiometric hydroxoapatite results in its transformation to two-phase calcium phosphate, were confirmed. The sizes of crystallites of all the calcium phosphates studied were estimated on the basis of the widths of X-ray peaks, and a structure was suggested of two-phase calcium phosphate composed of stoichiometric hydroxoapatite and β-$Ca_3(PO_4)_2$ crystallites with average size about 62 nm. This value is in good agreement with the available published data.

(2) A mechanism of solid-phase conversion of nonstoichiometric hydroxoapatite into two-phase calcium phosphate was suggested. According to this mechanism, the transformation occurs via solid-phase diffusion of hydroxy and calcium ions over distances no longer than 38 nm. Phosphate ions virtually do not diffuse.

Abstract—Methods for concentrating hydrogen peroxide and obtaining this compound in anhydrous form, based on removal or binding of water from the surface of solution in an open vessel or in a closed volume and also on binding of water directly in a H_2O_2 solution, are described.

Methods for concentration of aqueous solutions of hydrogen peroxide in order to raise its concentration up to 90–99% H_2O_2 markedly differ from methods for obtaining anhydrous H_2O_2, containing no other impurities, suitable for measuring physical parameters of hydrogen peroxide. In the first case, water is removed from aqueous solutions of H_2O_2 by ordinary distillation or rectification [1]. This is done at moderate temperatures and pressures of about 20 mm Hg. A large number of old investigations in this field had been devoted to concentration of diluted H_2O_2 solutions obtained from solid peroxides, mainly BaO_2 [2]. These studies are of only historical interest.

Anhydrous, high-purity hydrogen peroxide to be used in physical measurements or in single-crystal growth is commonly obtained by multiple freezing of the solid phase from concentrated (95–99%) solution [3]. This method involves considerable loss of hydrogen peroxide and low yield of the target product. Anhydrous hydrogen peroxide can be obtained by extraction from a concentrated solution with ether dehydrated with $CaCl_2$ or P_2O_5 [4]. It should be noted that the problem of obtaining anhydrous H_2O_2 of high purity remains topical until now. This is so since numerous physical properties of hydrogen peroxide, reported in the literature, have been determined by extrapolation to the anhydrous state of the system H_2O–H_2O_2 at high hydrogen peroxide concentrations.

All the above techniques for concentration of H_2O_2 solutions involve gross energy expenditure, loss of substance, and explosion hazard. It is known that microimpurities of many solids, catalysts for decomposition of hydrogen peroxide, favor fast or explosive decomposition of this compound upon heating. Explosive mixtures with hydrogen peroxide are also formed in a wide range of compositions by numerous organic substances used as solvents.

The authors made an attempt to develop safe and energy-saving methods for concentrating and obtaining anhydrous hydrogen peroxide. The methods developed are based on a fundamentally new technique, specifically, removal or binding of water from the surface of solutions of hydrogen peroxide or directly in its solution. The methods require no heating, design of rectification apparatus, or use of organic solvents.

EXPERIMENTAL

It is known [2] that, on keeping hydrogen peroxide solutions in open state, their concentration increases since the pressure of water vapor exceeds by more than an order of magnitude the vapor pressure of hydrogen peroxide (17.5 against 1.36 mm Hg at 20°C). However, account should be taken of the fact that, simultaneously with an increase in the concentration of hydrogen peroxide, its decomposition is possible under the catalytic action of the surface of a vessel used or because of the ingress of catalytic impurities into the solution from the air. No quantitative characteristics of the process of H_2O_2 concentration by water evaporation have been reported in the literature.

* c_f H_2O_2 is the final concentration of H_2O_2; the same for Table 2.

Previously, the concentration of hydrogen peroxide solutions by means of natural evaporation of water at room temperature and humidity has been studied. A relationship between the degree of concentration and loss of H_2O_2, on the one hand, and height of solution layer and air flow velocity over the solution, on the other, has been established [5]. Experiments have been carried out in a laboratory compartment with forced ventilation, with 30% H_2O_2 solutions. The solutions were placed in polymeric cuvettes and kept at 20°C in the absence of airflow over solution or at 0.5 m s^{-1} flow velocity. The air humidity was varied between 35 and 45%. Every 24 h the solutions were stirred and, after the intervals of time τ, indicated in Table 1, were weighed and analyzed for the content of hydrogen peroxide by permanganatometric titration to within ±0.1%.

It was found that keeping a 30% solution of H_2O_2 in an open state is accompanied by a considerable increase in H_2O_2 concentration without pronounced loss of H_2O_2 (Table 1). The time necessary for obtaining a sufficiently concentrated, e.g., 60% solution of H_2O_2 strongly depends on the height of the solution layer, being equal to 7.5, 16, and 21 days for h 10, 21, and 37 mm, respectively. The yield A (%) of hydrogen peroxide was calculated by the formula

$$A = (m_f c_f)/(m_s c_s) \times 100,$$

where m_s, m_f is the mass of the starting and final solutions (g); c_s, c_f is the concentration of the starting and final H_2O_2 solution (wt %), respectively.

The yield of H_2O_2 in the form of a 60% solution is (%) 86 for h = 10 mm, 90 for h = 21 mm, and 87 for h = 37 mm. Attempts to obtain more concentrated solutions by making the exposure longer failed because of a considerable increase in the rate of H_2O_2 evaporation. At a cuvette area of 73.5 cm^2 the output capacity of the process for obtaining a 60% solution was (g day^{-1}) 1.9 for h = 10 mm, 3.2 for h = 21 mm, and 3.4 for h = 37 mm. Thus, raising the height of the solution layer leads, on the one hand, to an increase in the time necessary for a prescribed temperature to be reached and, on the other, to a rise in output capacity, with the loss of hydrogen peroxide varying only slightly. With an air flow over solution, the process of H_2O_2 concentration is much faster: a 60% solution can be obtained in 3.5–6.0 days at a flow velocity of 0.5 m s^{-1}, depending on the layer height. In this case, the yield of H_2O_2 is 86–87%.

Table 2. Process of concentration of H_2O_2 solutions in a closed vessel over H_2SO_4

30	4	67.7	81.0	99.7	–	21.1

* At the highest concentration.

The process of concentration of hydrogen peroxide solutions in a closed vessel over a desiccant is much faster than that in the case of natural evaporation of water [6]. H_2O_2 solutions were kept in a desiccator over sulfuric acid. The acid volume was 560 ml; acid surface area, 75 cm^2; concentration of the starting H_2O_2 solution, 31.7%. The process of concentration occurs at both reduced and atmospheric pressure. Solutions of any concentration can be obtained, including nearly anhydrous solutions (Table 2). Both under natural evaporation of water and with its absorption from the gas phase over solution in a closed

volume, the time in which a prescribed concentration of hydrogen peroxide is reached depends on the thickness of the solution layer. A concentration close to 50% H_2O_2 is reached in 3 days at h = 20 and 40 mm and in 1 day at h = 13 mm. A concentration close to 99% H_2O_2 is reached in 7 days at h = 20 mm and 5 days at h = 4 mm. The loss of H_2O_2 grows with increasing time of exposure and concentration, to become 70–79% at H_2O_2 solution concentration of 98–99%. A single example of H_2O_2 concentration by a similar method has been reported in the literature: an 88% solution was obtained in a vacuum desiccator over H_2SO_4 in 3 days, with hydrogen peroxide loss of 19% [7]. The method developed in the present study is a convenient laboratory technique for obtaining minor amounts of highly concentrated solutions and anhydrous hydrogen peroxide.

To significant disadvantages of the method based on removal of water from the gas phase over an H_2O_2 solution belong pronounced loss of hydrogen peroxide and preservation of all impurities present in the starting solution in the preparations obtained. The method in which water is bound directly in solution is devoid of these disadvantages [8]. This technique yields H_2O_2 solutions of any concentration and anhydrous hydrogen peroxide of high purity. It employs anhydrous magnesium perchlorate, capable of binding water to give hydrates $Mg(ClO_4)_2 \cdot nH_2O$ (n = 2, 4, 6), as drying agent. Anhydrous magnesium perchlorate was obtained by dehydration of a dihydrate $Mg(ClO_4)_2 \cdot 2H_2O$ in a vacuum with temperature gradually raised from 20 to 220°C.

The device for concentration comprised a vessel for reagent mixing, connected to a trap and, further, to a pumping system. To a H_2O_2 solution cooled to 0°C was added, in a "dry" box, anhydrous magnesium perchlorate. In most cases, viscous solutions were obtained because of the high solubility of $Mg(ClO_4)_2$ in water [9] and in hydrogen peroxide [6]; suspensions were obtained when large amount of magnesium perchlorate was added to a 30% solution of H_2O_2. Hydrogen peroxide was separated from the mixture obtained by vacuum distillation at 20°C into a trap cooled to –196°C. A single treatment of a 30% H_2O_2 solution with magnesium perchlorate taken in a ratio $Mg(ClO_4)_2 : H_2O$ close to 1 : 6 [which corresponds to formation of magnesium perchlorate hexahydrate (Table 3)] can bind most part of water present in solution, with 81–82% hydrogen peroxide obtained by keeping in a vacuum.

Solutions with higher concentrations (93–94% H_2O_2) can be prepared with molar ratio $Mg(ClO_4)_2 : H_2O$ = (1.2–1.4) : 6. Introduction of a greater amount of magnesium perchlorate into a 30% solution of H_2O_2 is inexpedient since a thick inhomogeneous suspension is formed in this case, with the process of hydrogen peroxide evaporation decelerated dramatically. Raising the concentration of the starting solution to 46–73% H_2O_2 at a constant ratio of 1 : 6 between magnesium perchlorate and water contained in solution does not make higher the concentration of the final solution. Apparently, the forming magnesium perchlorate hexahydrate is partly dehydrated in vacuum evaporation of hydrogen peroxide. Finding its way into the trap, water liberated in the process makes the concentration of hydrogen peroxide lower.

Table 3. Final H_2O_2 concentration c_f in relation to the concentration c_s of the starting H_2O_2 solution and to the molar ratio $Mg(ClO_4)_2 : H_2O$

c_s H_2O_2, %	$Mg(ClO_4)_2 : H_2O$, mol : mol	c_f H_2O_2, %
29.9	1.05 : 6	80.8
30.2	1.07 : 6	82.0
30.2	1.25 : 6	94.4
31.4	1.40 : 6	93.3
45.8	1.00 : 6	90.9
72.8	1.00 : 6	94.2
76.6	1.40 : 4	95.6
76.7	1.70 : 4	97.5
78.5	1.20 : 2	100.0
87.2	1.20 : 2	100.0
95.9	1.00 : 2	100.0
96.0	1.10 : 2	100.0

To obtain a 95–98% H_2O_2 solution, it is necessary to use a 70% starting solution and introduce magnesium perchlorate in an amount corresponding to the ratio $Mg(ClO_4)_2 : H_2O$ = (1.4–1.7) : 4, which leads to formation of a mixture of magnesium perchlorate tetra- and dihydrate. Anhydrous hydrogen peroxide is formed upon treatment with magnesium perchlorate of a H_2O_2 solution with initial concentration of 80% and more at a molar ratio $Mg(ClO_4)_2 : H_2O$ = (1.0–1.2) : 2, which exceeds somewhat the ratio required for $Mg(ClO_4)_2$ dihydrate to be formed. In all experiments, the loss of H_2O_2 does not exceed 1%.

To determine the stability of H_2O_2 during storage of solutions obtained using various concentration methods in unstabilized form and stabilized with various stabilizing additives known for hydrogen peroxide, the solutions were placed in nonhermetically closed glass vessels and stored under identical conditions (20 + 2°C). After the intervals of time indicated

Table 4. Stability of H_2O_2 solutions obtained by removal or binding of water

Concentration method	$c_{H_2O_2}$, %	Stabilization technique	Loss of H_2O_2 (%) in indicated time, days		
			10	19	50
With air flow	65.1	–	3.1	6.7	9.1
		$Na_4P_2O_7$, 0.1%	2.6	4.1	6.5
		$Sn(OH)_4$, 0.3%	3.7	5.0	7.4
		Vacuum evaporation	0.7	2.6	2.7
Over H_2SO_4	99.6	–	1.6	3.6	7.0
		Vacuum evaporation	0.5	1.7	2.1
Introduction of $Mg(ClO_4)_2$	100	The same	0.0	0.3	1.6

in Table 4 came to an end, the content of hydrogen peroxide in the solutions was determined. The stability was evaluated as loss of H_2O_2 (%) relative to the content of hydrogen peroxide in an initial solution placed in storage.

The stability of hydrogen peroxide solutions obtained by water evaporation with air flow is satisfactory. The loss of H_2O_2 in storage in a glass vessel is 3% in 10 days and 9% in 50 days. Such solutions can be used without additional stabilization. Introduction of sodium diphosphate or tin(IV) hydroxide as stabilizing additives improves their stability only slightly. The loss of H_2O_2 is much lower in the case of vacuum distillation of the solutions at 20°C into a receiver cooled to –196°C. The same procedure markedly improves the stability of solutions obtained in a closed volume (Table 4). Anhydrous hydrogen peroxide obtained by dehydration with magnesium perchlorate is distinguished by high stability. With account of the catalytic action of the glass surface on hydrogen peroxide [10], solutions of this kind have higher stability when stored in polymeric vessels and can be used to measure physical parameters of hydrogen peroxide.

CONCLUSION

The methods developed for concentrating hydrogen peroxide and obtaining it in anhydrous form are based on (i) evaporation of water from the solution surface in an open vessel with and without air flow, (ii) keeping a solution in a closed vessel over dehydrating agent, and (iii) binding of water directly in the H_2O_2 solution with anhydrous magnesium perchlorate and separation of hydrogen peroxide by vacuum evaporation at 20°C.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Reactions of *trans*-$[OsO_2Cl_2L_2]$ (L = PPh_3, $AsPh_3$, $SbPh_3$) with Acetic Acid

Abstract—The possibility of reactions between *trans*-$[OsO_2Cl_2L_2]$ (L = PPh_3, $AsPh_3$, $SbPh_3$) osmium(VI) complexes and glacial acetic acid to give osmium(IV) compounds of general formula $[Os_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ was studied.

Dissolution of platinum-containing raw materials is a labor-consuming and ecologically unsafe process [1–4]. The creation of safer and less expensive technologies for breaking-down such concentrates and the closely related problem of analytical monitoring of the efficiency of raw material processing can be regarded as one of important lines of development of modern chemical technologies for recovery of platinum metals.

At present, one of ways to dissolve osmium-containing concentrates consists in their fusion with sodium disulfate, leaching of the melt, and its treatment with chlorine for distilling-off OsO_4, which is absorbed successively, first by HCl solutions with methanol and then by an alcoholic solution of NaOH. Heating the latter with NH_4Cl allows osmium to be precipitated as $[OsO_2Cl_2(NH_3)_2$ [4].

The development of alternative procedures for dissolving osmium-containing concentrates is based on replacement of highly aggressive solutions with ethanol–acetate mixtures [5]. However, this requires a detailed study of the behavior of *trans*-$[OsO_2Cl_2L_2]$ complexes with ligands L of varied nature in acetic acid media.

Boiling of *trans*-$[OsO_2X_2L_2]$ (X = Cl, Br; L = PPh_3, PEt_2Ph, or Py) in a RCOOH-$(RCOO)_2O$ (R = CH_3, C_2H_5) mixture is known [6, 7] to give binuclear osmium acetates with a $Os_2(\mu\text{-}O)$ core.

X-ray structural data [6, 7] suggest that the formation of a linear or bent binuclear Os–O–Os fragment is affected by the nature of ligand (L) in the starting mononuclear *trans*-$[OsO_2X_2L_2]$ (X = Cl, Br) compound. If L is PPh_3 or PEt_2Ph, then $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ (R = CH_3, C_2H_5; X = Cl, Br) complexes are formed with bent metal-containing $Os_2(\mu\text{-}O)$ core and bidentate coordination of two bridging acetate groups [6]. If L is Py, then $[(Py)_2Cl_2(CH_3COO)Os(\mu\text{-}O)Os(Py)_2Cl_3]$ compound with a linear $Os_2(\mu\text{-}O)$ core and only one monodentately coordinated acetate group is formed [7].

The present study is concerned with the influence exerted by the nature of ligand L in *trans*-$[OsO_2Cl_2L_2]$ on the formation and spectral characteristics of osmium acetates $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)Cl_4(L)_2]$. PPh_3, $AsPh_3$, or $SbPh_3$ were selected as ligands L. Their choice was determined by the fact that, on the one hand, they behave as donors having a free electron pair and, on the other, they possess, unlike such a ligand as Py, free *d*-orbitals with rather low energies.

EXPERIMENTAL

The starting *trans*-$OsO_2Cl_2(PPh_3)_2$ was obtained using the procedure proposed in [8].

***trans*-$OsO_2Cl_2(AsPh_3)_2$.** A 2-g portion of OsO_4 was introduced into a mixture of 30 ml of ethanol and 5 ml of concentrated hydrochloric acid heated to approximately 90°C. Triphenylphosphine (4.5 g, or 14 mmol per 0.39 mmol of OsO_4) was dissolved in a minimal amount of boiling ethanol and poured into the first solution. The precipitated light beige complex was washed on a filter with ethanol and diethyl ether. Yield ~70%. IR spectrum, cm^{-1}: 471 s, 693 vs, 742 vs, 845 s, 1001 w, 1030 w, 1083 w, 1190 vs, 1460 s, 1510 w.

Found, %: Os 21.1; Cl 8.2.

$C_{36}H_{30}As_2Cl_2Os$.

Calculated, %: Os 21.0; Cl 7.8.

1070-4272/02/7512-1907 $27.00 © 2002 MAIK "Nauka/Interperiodica"

***trans*-$OsO_2Cl_2(SbPh_3)_2$.** The synthesis was similar to that of *trans*-$OsO_2Cl_2(AsPh_3)_2$. Owing to the low solubility of triphenylantimony in ethanol, the alcohol was replaced with an EtOH–Et_2O mixture (1 : 1 by volume). The precipitated light green complex was filtered off and carefully washed with ether, in which it is partially soluble. Slow evaporation of the filtrate gave an additional amount of the finely crystalline precipitate of the complex. Total yield ~80%. IR spectrum, cm^{-1}: 454 s, 683 vs, 729 vs, 836 s, 993 s, 1019 s, 1061 w, 1179 w, 1301 w, 1329 w, 1433 s, 1475 s, 1571 w, 1637 wide, 1871 wide.

Found, %: Os 18.9, Cl 7.2.

$C_{36}H_{30}Cl_2OsSb_2$.

Calculated, %: Os 19.0, Cl 7.1.

$[Os_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(PPh_3)_2Cl_4]$ (I). A suspension of 1 g of *trans*-$[OsO_2(PPh_3)_2Cl_2]$ in 20 ml of glacial acetic acid was boiled until the starting complex dissolved completely. In the process, the colorless solution turned dark brown. The dry residue formed upon evaporation of the solution on an air bath was dissolved in 40 ml of chloroform and a minor amount of pentane or hexane was added to the resulting solution. The precipitated complex was filtered off, washed with ether, and kept in a desiccator over KOH to constant weight.[1] Yield ~95%. IR spectrum, cm^{-1}: 443 w, 523 vs, 619 w, 691 vs, 720 s, 744 s, 997 w, 1028 w, 1091 s, 1159 w, 1220 w, 1408 w, 1435 vs, 1482 s, 1697 wide, 2927 w, 2964 w, 3059 w, 3440 wide.

Found, %: Os 32.0, Cl 12.5.

$C_{40}H_{36}Cl_4O_5Os_2P_2$.

Calculated, %: Os 32.2, Cl 12.0.

$[Os_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(AsPh_3)_2Cl_4]$ (II). The synthesis was similar to that of complex **I**. The yield of the dark brown complex was about 70%. IR spectrum, cm^{-1}: 472 s, 690 s, 740 s, 778 w, 860 wide, 1000 w, 1028 w, 1085 s, 1163 wide, 1187 wide, 1440 s, 1490 w, 1630 s, 3420 wide.

Found, %: Os 29.8, Cl 11.4.

$C_{40}H_{36}As_2Cl_4O_5Os_2$.

Calculated, %: Os 30.0, Cl 11.2.

[1] An X-ray structural analysis of a similar $[Os_2^{IV}(\mu\text{-}O)\cdot(\mu\text{-}O_2CCCl_2)_2Cl_4(PPh_3)_2]$ complex, obtained recently by the authors, confirmed the bent structure of the $Os_2(\mu\text{-}O)$ core and the presence of two bridging carboxylate ions.

Electronic absorption spectra of solutions of the complexes were recorded on an SF-56 spectrophotometer in the range 200–1100 nm in quartz cells with l = 1 cm. The IR spectra were recorded in the range 4000–400 cm^{-1} on a Nicolet FT-360 spectrophotometer in KBr pellets, and X-ray-photoelectron spectra (XPS), on a Perkin–Elmer PHI 5400 spectrophotometer with excitation by X-ray emission of Mg. Powdered samples were compacted with indium and placed, after preliminary evacuation of the chamber, on a manipulator cooled with liquid nitrogen. The working residual pressure in the spectrophotometer was 10^{-8} mm Hg.

The X-ray structural analysis was carried out on a SYNTEX P21 diffractometer with Cu_{K_α} emission (λ = 1.54178 Å) at 20 ± 1°C.

The experimental data obtained suggest that binuclear oxygen-bridged osmium acetates $[Os_2^{IV}(\mu\text{-}O)\cdot(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ (L = PPh_3 or $AsPh_3$) can be formed in the reaction of *trans*-$[OsO_2Cl_2L_2]$ with CH_3CO_2H in the absence of $(CH_3CO)_2O$, too. Heating of the *trans*-$[OsO_2Cl_2L_2]$ complexes with glacial acetic acid gives dark brown binuclear osmium(IV) compounds of general formula $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ in high yield. However, $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ complexes can only be isolated for L = PPh_3 (**I**) or $AsPh_3$ (**II**). According to XPS data, the Os ($4f7/2$) bond energies are 53.0 and 53.1 eV for complexes **I** and **II**, respectively, which corresponds to a formal oxidation state of osmium atoms in these compounds equal to +4, in good agreement with the data of [5].

Compounds **I** and **II** are stable in air, poorly soluble in water, ethanol, ether, and saturated hydrocarbons, but readily soluble in such solvents as chloroform, dichloromethane, or benzene.

The electronic absorption spectra of $[Os_2^{IV}(\mu\text{-}O)\cdot(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ solutions in chloroform contain absorption bands with λ_{max} = 456.0 nm (ε = 10134 l mol^{-1} cm^{-1}) for compound **I** and λ_{max} = 426.0 nm (ε = 7362 l mol^{-1} cm^{-1}), and a shoulder at 533.0 nm for complex **II** (Fig. 1). It is seen from Fig. 1 that the most intense band in the electronic absorption spectrum of complex **II**, which can be assigned to the $\pi^{unbonding} \rightarrow \pi^*$ transition within the $Os_2(\mu\text{-}O)$ [7], is shifted by 30 nm to higher energies. It is most likely that the shoulder in the low-energy region of the spectrum is related to charge transfer from the core to π^*-orbitals of $AsPh_3$.

The band related to the $\pi^{unbonding} \rightarrow \pi^*$ transition within the $Os_2(\mu\text{-}O)$ core shifts to higher energies

when osmium complexes react with $HClO_4$ (Fig. 2). The appearance of a shoulder with $\lambda_{max} \sim 580$ nm seems to be attributable to charge transfer from $d\pi$–$p\pi$ orbitals of the core to π^* orbitals of PPh_3. This process seems to be due to protonation of the bridging oxygen atom in the metal-containing core:

$$[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2] + H^+ \rightarrow [Os_2^{IV}(\mu\text{-}OH)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]^+.$$

It is necessary to note that protonation of bridging oxygen atoms in similar binuclear ruthenium complexes $Ru_2(\mu\text{-}O)(\mu\text{-}O_2\text{-}CCH_3)_2^{2+}$ is well known [9, 10].

The study demonstrated that the formation of complexes **I** and **II** can be described by the scheme:

$$2[OsO_2Cl_2L_2] + 2RCO_2H \rightarrow [Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CR)_2Cl_4L_2] + 2O = L + H_2O,$$

where L = PPh_3 or $AsPh_3$.

The presence of triphenylphosphinoxide ($POPh_3$) or triphenylarsinoxide ($AsOPh_3$) in the reaction products is indicated by the results of elemental analysis and also by IR spectral data and melting points of these compounds, which are in good agreement with published data [11, 12].

Found for $PO(C_6H_5)_3$, %: P 11.0, C 78.1, H 5.0.
Calculated for $C_{18}H_{15}OP$, %: P 11.1, C 77.7, H 5.43.

Found for $C_{18}H_{15}AsO$, %: C 67.0, H 3.2.
Calculated for $AsOC_{18}H_{15}$, %: C 67.1, H 4.7.

IR spectrum, cm^{-1}: 418 w, 461 s, 690 vs, 742 vs, 812 vs, 998 w, 1026 w, 1086 s (As=O), 1162 w, 1190 w, 1450 s, 1490 s; mp 184°C.

Triphenyldichloroantimony and a poorly soluble osmium-containing light brown compound are always formed in the reaction of *trans*-$[OsO_2Cl_2(SbPh_3)_2]$ with acetic acid. The composition of the osmium-containing product could not be determined; however, according to the elemental analysis it contains 59.2% Os and 16.4% C, and also trace amounts of chlorine. The Os : C ratio of about 1 : 4.4 shows that this product contains acetate ions $CH_3CO_2^-$. This is also indirectly confirmed by IR spectral data. Characteristic bands present in the frequency range 1400–1700 cm^{-1} are attributable to vibrations of acetate groups [8, 9, 11]. However, these bands are too broad and have too low intensity to be used in determining the coordination of the $CH_3CO_2^-$ ion.

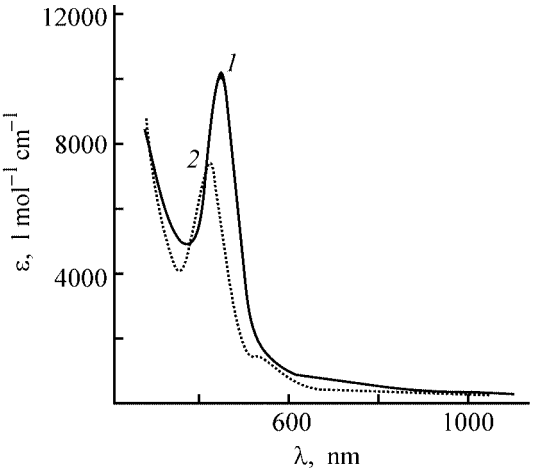

Fig. 1. Electronic absorption spectra of solutions of (*1*) $[Os_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(PPh_3)_2Cl_4]$ and (*2*) $[Os_2(\mu\text{-}O)\cdot(\mu\text{-}O_2CCH_3)_2(AsPh_3)_2Cl_4]$ complexes in $CHCl_3$. (ε) extinction coefficient related to 1 mol of a complex and (λ) wavelength.

The formation of $SbCl_2Ph_3$ is confirmed by the elemental and X-ray analyses[2] (Fig. 3).

Crystallographic data for $SbCl_2Ph_3$: the complex is crystallized from ether as colorless needles characterized by the orthorhombic space group *Pbca*, a = 13.122(2) Å, α = 90°, b = 23.885(3) Å, β = 90°,

[2] The X-ray structure analysis was carried out at the Karpov Physicochemical Institute (Moscow).

IR spectrum, cm^{-1}: 450 vs, 681 s, 727 s, 993 wide, 1018 w, 1055 w, 1430 s, 1480 s.

Since the starting *trans*-$[OsO_2Cl_2(SbPh_3)_2]$ complex is isolated from the reaction mixture containing hydrochloric acid, it is unlikely that its reaction with acetic acid may lead to an intramolecular redox reaction yielding $SbCl_2Ph_3$. Presumably, the first stage of the reaction between *trans*-$[OsO_2Cl_2(SbPh_3)_2]$ and acetic acid results in an unstable binuclear osmium acetate $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(SbPh_3)_2]$, which further decomposes to give $SbCl_2Ph_3$ and an osmium-containing compound, possibly of polymer composition.

In conclusion, it should be noted that the ionization energies I (eV) of ligands L increase in the order 7.85 (PPh_3) < 8.03 ($AsPh_3$) < 8.08 ($SbPh_3$). However, small differences between these energies suggest that the ligands have similar donor–acceptor properties. Therefore, it is most probable that the instability of the $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(SbPh_3)_2]$ complex is caused by steric effects: $SbPh_3$ is larger in size than PPh_3 or $AsPh_3$.

CONCLUSIONS

(1) Binuclear oxygen-bridged osmium acetates $[Os_2^{IV}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ (L = PPh_3 or $AsPh_3$) can be formed in high yield (95 to 70%) in the reaction of *trans*-$[OsO_2Cl_2L_2]$ complexes with glacial acetic acid.

(2) In glacial acetic acid, *trans*-$[OsO_2Cl_2(SbPh_3)_2]$ undergoes an intramolecular redox conversion to $SbCl_2Ph_3$.

(3) It is suggested that the increase in the size of ligands L in the order $SbPh_3$ > $AsPh_3$ > PPh_3 is one of the main reasons for the decrease in the stability of oxygen-bridged osmium acetates $[Os_2^{IV}(\mu\text{-}O)\cdot(\mu\text{-}O_2CCH_3)_2Cl_4(L)_2]$ in acetic acid medium.

Abstract—Iron-containing derivatives of arabinogalactan (ferroarabinogalactans) were subjected to X-ray diffraction analysis to determine the form and structure of bound iron. Crystal lattice parameters a of the iron-containing phase were measured and the average crystallite size was determined.

The problem of obtaining new iron-containing medicinal preparations is rather acute because of the wide occurrence of iron-deficiency anemia in the population. A promising way to create iron-containing preparations is to incorporate iron compounds into a polymer carrier [1]. As a carrier of this kind was used arabinogalactan distinguished from other polysaccharides by good water solubility and membranotropic properties. The concept of synthesis consisted in that a water-soluble iron-containing preparation should be created and delivered into a cell.

It is known that reaction of aqueous solutions of iron(II, III) salts with alkalis yields difficultly soluble hydrated iron(II, III) oxides. This reaction with a mixture of Fe^{3+} and Fe^{2+} salts in the presence of arabinogalactan has been used to obtain previously unknown iron derivatives of arabinogalactan, ferroarabinogalactans [2]. All ferroarabinogalactans are well soluble in water (up to 50%), whereas standard samples of the oxides FeO, Fe_2O_3, and Fe_3O_4 are water-insoluble. The characteristic viscosity of 1% aqueous solutions of the samples is 0.052–0.054 dl g^{-1}, which is close to the characteristic viscosity of the starting arabinogalactan (0.058 dl g^{-1}). This confirms that the reaction performed [2] yields hydrophilic and water-soluble kind of ferrites.

In order to establish the form and structure of bound iron, iron-containing derivatives of arabinogalactan were subjected to X-ray diffraction analysis in the present study.

EXPERIMENTAL

The starting arabinogalactan was isolated from an aqueous extract of larch wood and purified by reprecipitation into alcohol. Iron-containing polymers were synthesized as follows: aqueous solutions of iron salts ($FeSO_4 \cdot 4H_2O$ and $FeCl_3 \cdot 5H_2O$, sample nos. 1 and 2; $FeCl_3 \cdot 5H_2O$, sample no. 3) with iron content of 0.22–1.25 mmol were added to a concentrated (50%) aqueous solution of arabinogalactan under vigorous stirring and allowed to stay at room temperature for 15 min (all samples). Further, the resulting mixture was treated with 30% ammonium hydroxide to pH of reaction medium, 10–12. The mixture obtained was boiled on a water bath for 15 min and filtered, and ferroarabinogalactans was precipitated with alcohol.

The content of iron in the preparations obtained was found spectrophotometrically on an SF-26 instrument, with Trilon B as complexing agent, and by atomic-absorption analysis: 3.53% (sample no. 1), 5.01% (sample no. 2), and 4.50% (sample no. 3).

The X-ray analysis was carried out on a DRON-3.0 diffractometer with Cu_{K_α} (Ni filter) and $Fe_{K_{\alpha,\beta}}$ radiation, set of slits (2, 8 mm, Soller slit 1.5°, and 0.25 mm), scanning rate of 1 (phase analysis) and 0.25 deg min^{-1} (determination of parameters and halfwidths of reflections). The phase analysis was performed with Cu_{K_α} radiation, and the position and halfwidth of the (311) line was measured with $Fe_{K_{\alpha,\beta}}$ radiation. The lattice parameter was determined by the internal standard method for the (311) reflection, with quartz (a =

4.9126, b = 5.4044 Å) as standard. A correction for instrumental broadening of reflections was introduced using reflections from magnetite as reference.[1]

[1] As standard was used magnetite synthesized at the laboratory of experimental geochemistry, Institute of Geochemistry, Siberian Division, Russian Academy of Sciences.

Natural hemicelluloses may exist as amorphous or crystalline aggregates, with the forms and their ratio being individual for different types of polysaccharides. For example, xylan can be obtained in the crystalline form as hexagonal plates; galactoglucomannans are amorphous, but may contain fibrillar regions of molecule ordering [3]. It was of interest to find out what type of structure, crystalline or amorphous, is characteristic of arabinogalactan. For this purpose, an X-ray diffraction pattern of the starting arabinogalactan preparation isolated from larch wood was measured [2]. The X-ray diffraction pattern demonstrates in the range of angles 2θ = 8–40° an intense halo with peak intensity at d = 44 Å. No other reflections in the range of angles 2θ = 8–60° (Cu_{K_α}) are observed. This indicates that arabinogalactan is amorphous (Fig. 1a).

There exist several anhydrous iron oxides, occurring in nature as various minerals: hematite α-Fe_2O_3 (high-temperature form), maghemite γ-Fe_2O_3 (low-temperature form), magnetite Fe_3O_4, wustite FeO, and a number of ferrihydrites (which may be either crystalline or amorphous) [4].

Incorporation of iron into an arabinogalactan molecule changes the X-ray diffraction patterns of ferroarabinogalactan nos. 1 and 2 (Figs. 1b, 2a, and 2b). For example, several broad weak lines are observed on the background of a broad reflection from arabinogalactan in the range of angles 2θ = 28–75° (Cu_{K_α}), with the peak intensity of reflection from arabinogalactan remaining in the same position, at d = 4.4 Å.

X-ray diffraction data for sample nos. 1 and 2 are listed in the table. It can be seen that the interplanar spacings and line intensity distributions for sample nos. 1 and 2 are in good agreement with the X-ray diffraction pattern of magnetite (PDF, 19-629) and main lines of maghemite (PDF, 24-81). This confirms that iron is present in sample nos. 1 and 2 as magnetite and(or) maghemite.

Among important structural parameters are lattice constants. Magnetite is characterized by cubic symmetry, space group F*d3n*, and crystal structure of inverted spinel with lattice constant a = 8.396 Å (PDF, 19-629). Maghemite, having a structure of magnetite, differs from the latter in that only 21 1/3 out of 24 crystallographic positions of the metal are occupied, which leads to a decrease in a to 8.350 Å [5, PDF, 24-81]. Its X-ray diffraction pattern contains additional lines, absent in the case of minerals belonging to the spinel group. However, these lines are weak and cannot be seen in X-ray diffraction patterns of finely dispersed samples. In this case, the X-ray diffraction

pattern corresponds to that of magnetite, differing from it in only somewhat smaller interplanar spacings. In addition, phases of intermediate composition exist between magnetite and maghemite [5]. Studying these compounds, Basta [5] revealed a linear composition dependence of the lattice constant a, which enables evaluation of the Fe(II) to Fe(III) ratio from the lattice constant.

The lattice constant a was determined by the internal standard method for the preparations obtained. Only the (311) line was used in calculations, since the weak diffraction pattern and strongly broadened lines give no way of using lines at large angles 2θ, the accuracy of determining the lattice constant a being poor in this case. The position of the line was measured at 1/2 I for sample no. 1 and at 1/2 I and 2/3 I for sample no. 2, the profile of the (311) line being asymmetric in the latter case. The following values were obtained: $a = 8.39 \pm 0.01$ Å for sample no. 1 and $a = 8.36 \pm 0.01$ (with line position measured at half maximum) and $a = 8.346 \pm 0.007$ Å (with line position measured at 2/3 maximum) for sample no. 2. According to the plot of composition against lattice constant [5], the composition of sample no. 1 is close to that of magnetite. With account of the measurement error, the content of γ-Fe_2O_3 in its structure does not exceed 20–30%. Sample no. 2 is close in composition to maghemite, with a = 8.36 Å corresponding to approximately 80% γ-Fe_2O_3, and a = 8.350 Å characteristic of 100% γ-Fe_2O_3.

The information furnished by the X-ray diffraction pattern is not restricted to only the lattice metric. It is known that small dimensions of coherence domains, structural defects, presence of microstrains, and measurement conditions cause broadening of diffraction lines [6–8]. The existing analytical methods for revealing and evaluating the effect of one or another factor on the linewidth require precision measurements. However, even linewidths can yield, without any analysis of line profiles, a certain information about the fine structure of crystals. For example, presence of structural defects leads to broadening of only part of lines. Presence of microstrains causes broadening that is wavelength-independent, but depends on reflection indices; in addition, the linewidth is the larger at the same microstrain, the greater the absolute value of the angle θ [8, 9]. Line broadening associated with small dimensions of coherence domains, contrariwise, depends on the radiation wavelength, but is independent of reflection indices, and all lines are broadened to the same extent with account taken of the correction for radiation nonmonochromaticity.

The particle size, which can be determined from the broadening of X-ray diffraction lines, is limited to approximately the range from 10 to 10^3 Å [6–8]. The instrumental broadening of diffraction lines is taken into account in the simplest way, with the use of a standard. In the case when the line broadening is associated with only particle sizes, the average dimension of the coherence domains is calculated by the formula [7, 9]

$$L = 0.94\,\lambda / \left[(\sqrt{B_0^2 - B^2})\cos\theta\right],$$

where L is the particle size; λ, the wavelength; B_0, the line halfwidth for a sample under study (rad); B, the line halfwidth for the standard (rad).

The diffraction pattern of sample no. 2 made it possible to measure the halfwidths of (311), (220), and (440) reflections. The following 2θ values were obtained (deg): B_0 (220) = 1.08 ± 0.10, B_0 (311) = 1.00 ± 0.10, B_0 (440) = 1.15 ± 0.10. The halfwidth of the (311) line of standard magnetite, measured under the experimental conditions, is $(0.20 \pm 0.05)°$ (2θ). It can be seen from the data obtained that, within the experimental error, all lines are broadened to the same extent, irrespective of reflection indices and the absolute value of θ. Consequently, the main contribution to line broadening comes, in the case in question, from the small size of coherence domains. This made it possible to calculate L by the above formula. In addition, it is seen that the instrumental broadening is comparable with the measurement error. Therefore, it is unimportant in the given case whether magnetite or maghemite is used as a standard, since the differences between B_0 for standard lines is far less than the error in measurements of line halfwidths for the samples under study. For sample no. 1, only the halfwidth of the (311) reflection could be measured, the intensities of other lines being too low. However, with account of the nature of the object and of the method by which it is obtained, it may be assumed that the reason for line broadening is the same, specifically, the small size of coherent domains.

The (311) reflection was used to obtain the particle size $L \approx 160$–170 Å for sample no. 1 containing 3.53% iron, and $L \approx 250$ Å for sample no. 2 containing 5.01% iron. In addition, the profile of the (311) line for sample no. 2 was found to be somewhat asymmetric, looking like superposition of a wide and a narrow lines. This can be attributed to the presence in the sample of groups of crystallites with large and small average dimensions of coherent domains. The formation of phases with different crystal structures and of crystals with different sizes can be accounted for by dependence of crystal growth in aqueous solutions of iron salts and(or) suspensions of iron hydroxide on the process conditions.

The diffraction pattern of sample no. 3 contains only a halo of arabinogalactan, with lines of the iron-containing phase absent and no shift of the peak of reflection from arabinogalactan observed. This may mean that particles of the iron-containing phase are smaller in size than 10 Å or the phase is amorphous. This phase was identified as "ferrihydrite" on the basis of the results obtained in [10]. In the authors' opinion, ferrihydrite is characterized by empirical composition $Fe_2O_3 \cdot 1.8H_2O$. Iron in ferrihydrite is amorphous and exists in the form of δ-FeOOH and γ-FeOOH.

On the basis of the results of X-ray analysis performed in the present study, an assumption can be made that, similarly to dextranferrites [11], the ferroarabinogalactans synthesized are microspheroids with nuclei composed of either iron oxides with crystal structure of magnetite (maghemite), or amorphous ferrihydrites coated with a layer of arabinogalactan molecules.

CONCLUSIONS

(1) The starting natural polysaccharide arabinogalactan exists in the amorphous state, and preparations of ferroarabinogalactans have two-phase amorphous-crystalline structure.

(2) Iron is incorporated into ferroarabinogalactans in the form of an analogue of minerals of the magnetite-maghemite series or as ferrihydrite. The lattice constant a of the iron-containing phase varies within the range 8.35–8.39 Å, and the average size of crystallites, within 160–250 Å.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Determination of the Most Probable Route of High-Temperature Formation of β-Spodumene in Lithium–Alumina–Silica Mixtures

N. V. Trusov, Yu. D. Trusova, and L. P. Shchukina

Received March 5, 1999; in final form, September 2002

Abstract—The equilibrium composition of β-spodumene formed in high-temperature synthesis from lithium carbonate, metakaolinite, and silica was calculated thermodynamically. The extents of the thermodynamically possible reactions were determined in the range 400–1600K.

Studies of crystallization of a multiphase mixture from a heat-treated glaze glass required that the order of crystallization of separate phases should be determined, and, in the case of simultaneous phase formation, the conditions for formation of the maximal amount of β-spodumene $Li_2Al_2Si_4O_8$, responsible for the heat stability of the final complex of phases, should be elucidated. In particular, it was of certain interest to find the most energetically advantageous route β-$Li_2O \cdot Al_2O_3 \cdot 4SiO_2$ formation from lithium carbonate, metakaolinate $Al_2Si_2O_7$, β-SiO_2. This could provide a scientifically substantiated tool for optimization of the β-$Li_2O \cdot Al_2O_3 \cdot 4SiO_2$ production by the most thermodynamically probable route.

First, the thermodynamic parameters of thermal decomposition of the starting reagents

$$Li_2CO_3 = Li_2O + CO_2, \quad (1)$$

$$Al_2Si_2O_7 = \alpha\text{-}Al_2O_3 + 2\beta\text{-}SiO_2, \quad (2)$$

and of the reaction between them, resulting in the formation of the final product

$$Li_2CO_3 + 2Al_2Si_2O_7 = \beta\text{-}Li_2Al_2Si_4O_{12} + \alpha\text{-}Al_2O_3 + CO_2, \quad (3)$$

were determined.

The temperature dependence of the Gibbs energy in reactions (1)–(3) is illustrated in Table 1. The standard thermodynamic data for the reactants were taken from [1–8].

It follows from Table 1 that all the three reactions are highly probable thermodynamically. However, despite the predominance of reaction (3), which has the minimal ΔG_T^0 values in the temperature range studied, this gives no way of maintaining that β-spodumene is obtained by direct interaction, rather than via oxides preliminarily formed by reactions (1) and (2), the more so as the subsequent interaction of the oxides by the overall reaction

$$Li_2O + \alpha\text{-}Al_2O_3 + 4\beta\text{-}SiO_2 = \beta\text{-}Li_2Al_2Si_4O_{12} \quad (4)$$

is thermodynamically possible up to 1200 K. Therefore, it was necessary to calculate the equilibrium composition formed in parallel-consecutive reactions (1)–(3) [9]. Only calculations of this kind make it possible to determine the extent of all the reactions under consideration.

A graphical interpretation of the results of calculations, concerning the extent of reaction (3) on the background of the other two reactions, demonstrated that only reaction (3) proceeds at low temperature (600K). By contrast, β-spodumene is not formed by the reaction of lithium carbonate with metakaolinite at 1600 K. Varying simultaneously both the parameters (reaction temperature and initial molar ratio $Al_2Si_2O_7$: Li_2CO_3) within the range from minimal to maximal values leads to a complicated variation of the extent of β-spodumene formation by reaction (3).

Thus, the results of preliminary calculations show that the formation of the target product both by direct reaction between the reactants and via overall reac-

1070-4272/02/7512-1916 $27.00 © 2002 MAIK "Nauka/Interperiodica"

tion (4), which reflects the so-called oxide mechanism, cannot be ruled out. The latter assumption is confirmed by several facts.

First, if account is taken of only reaction (3), it is difficult to explain the experimental fact that, for β-spodumene to be formed, the starting raw mixture must contain silicon dioxide [10]. Second, there is no reasonable explanation for the presence of such highly active component as lithium oxide in the equilibrium mixture, which follows from the calculations of equilibrium composition formed in reactions (1)–(3).

Thus, it is impossible to solve the problem at hand without considering the thermodynamic possibility of occurrence of the reactions by the so-called oxide mechanism. Therefore, reactions between oxides in the Li_2O–Al_2O_3–SiO_2 system were studied. The system was divided into three binary systems: Li_2O–Al_2O_3, Li_2O–SiO_2, and Al_2O_3–SiO_2. The Gibbs energies were determined for each of the reactions resulting in the formation of the known binary oxides [10]:

$$Li_2O + \alpha\text{-}Al_2O_3 = Li_2Al_2O_4, \quad (5)$$

$$Li_2O + 5\alpha\text{-}Al_2O_3 = Li_2Al_{10}O_{16}, \quad (6)$$

$$Li_2O + \beta\text{-}SiO_2 = Li_2SiO_3, \quad (7)$$

$$Li_2O + 2\beta\text{-}SiO_2 = Li_2Si_2O_5, \quad (8)$$

$$2Li_2O + \beta\text{-}SiO_2 = Li_4SiO_4, \quad (9)$$

$$\alpha\text{-}Al_2O_3 + \beta\text{-}SiO_2 = Al_2SiO_5, \quad (10)$$

$$\alpha\text{-}Al_2O_3 + 2\beta\text{-}SiO_2 = Al_2Si_2O_7, \quad (11)$$

$$3\alpha\text{-}Al_2O_3 + 2\beta\text{-}SiO_2 = Al_6Si_2O_{13}. \quad (12)$$

It is necessary to note that only the last of three aluminum silicate modifications (andalusite, kyanite, and sillimanite) was considered, since it is its structure that is characterized by the strongest aluminum-oxygen bond [11], which forms a basis for further interactions yielding aluminosilicates.

The results of calculations are listed in Table 1, which shows that only reactions (7)–(9) are thermodynamically possible within the entire temperature range under consideration (400–1600 K). Reactions (5) and (11) do not occur, and the other reactions occur selectively, since the Gibbs energy changes its sign within this temperature range.

A system analysis of the reactions of newly formed compounds ($Li_2Al_{10}O_{16}$, Li_2SiO_3, $Li_2Si_2O_5$, Li_4SiO_4, Al_2SiO_5, and $Al_6Si_2O_{13}$) with an excess amount of oxides (Li_2O, α-Al_2O_3, and β-SiO_2), which yield β-spodumene and constitute the second stage of the oxide mechanism, revealed the following reactions:

$$Li_2Si_2O_5 + 2Al_2SiO_5 = \beta\text{-}Li_2Al_2Si_4O_{12} + \alpha\text{-}Al_2O_3, \quad (23)$$

$$2Li_2SiO_5 + 2Al_2SiO_5 = \beta\text{-}Li_2Al_2Si_4O_{12} + Li_2Al_2Si_4O_8, \quad (24)$$

$$Li_2Si_2O_5 + Al_6Si_2O_{13} = \beta\text{-}Li_2Al_2Si_4O_{12} + 2\alpha\text{-}Al_2O_3, \quad (25)$$

$$4Li_4SiO_4 + \alpha\text{-}Al_2O_3 = \beta\text{-}Li_2Al_2Si_4O_{12} + 7Li_2O, \quad (26)$$

$$3Li_4SiO_4 + Al_2SiO_5 = \beta\text{-}Li_2Al_2Si_4O_{12} + 5Li_2O, \quad (27)$$

$$4Al_2SiO_5 + Li_2O = \beta\text{-}Li_2Al_2Si_4O_{12} + 3\alpha\text{-}Al_2O_3, \quad (28)$$

$$2Al_6Si_2O_{13} + Li_2O = \beta\text{-}Li_2Al_2Si_4O_{12} + 5\alpha\text{-}Al_2O_3. \quad (29)$$

The Gibbs energies for these reactions at various temperatures are given in Table 1.

It can be seen that reactions (14), (15), (17), (18), (20), (21), (24), (26), and (27) are thermodynamically impossible within the entire temperature range under study. Other reactions occur selectively, i.e., their thermodynamic probability is temperature-dependent.

Even if the consideration is restricted to the base temperature (for which 1000K was taken), then, with account of the data of Table 1, 12 reactions for which $\Delta G_T^0 < 0$ should be considered in order to elucidate the mechanism of β-spodumene formation. Obviously, it is impossible to determine the extent of each reaction on the background of other reactions from a single Gibbs energy. Therefore, the equilibrium composition formed in the simultaneous parallel-consecutive course of all the above-mentioned reactions was calculated. The composition of the starting mixture, whose stoichiometry ensures β-spodumene formation (1 mol at the minimum) was selected as the variable parameter. The results obtained are listed in Table 2. In the entire range of variation of this parameter, Li_2CO_3, Li_2O, and $Li_2Si_2O_7$ are absent from the equilibrium mixture, and, therefore, these compounds are not listed in Table 2.

It is noteworthy that all the components of the equilibrium mixture fall into two groups: (a) compounds whose molar content exceeds 10% at least at a single temperature (β-SiO_2, α-Al_2O_3, Al_2SiO_5 and β-$Li_2Al_2Si_4O_{12}$) and (b) other compounds whose content does not exceed 6%. It is significant that the yield of β-spodumene depends on the initial mixture composition only slightly, whereas the equilibrium content of β-SiO_2 decreases by almost a factor of 2; the amount of Al_2SiO_5 aluminum silicate shows a small extremum at $Al_2Si_2O_{7\,in}$ = 1.8 and $\beta\text{-}SiO_{2\,in}$ = 0.4 mol.

Interesting conclusions can be reached in analysis of how the extent of the reactions under consideration depends on the initial composition of the stock. Thermodynamic calculations demonstrated that the distribution of lithium carbonate among reactions (1) and (3) is independent of the stock composition and constitutes about 0.5 of that possible theoretically. At the same time, the extent of reaction (2) increases linearly from 0 to 1. The extents of the other reactions do not exceed 0.15, but it is these reactions that determine the content of β-spodumene in the equilibrium mixture of the products.

CONCLUSION

A thermodynamic analysis of 29 stoichiometric reactions between lithium carbonate, metakaolinite, and silica, with the subsequent formation of β-spodumene, revealed 12 reactions to be taken into account in calculating the equilibrium composition. The molar content of β-$Li_2Al_2Si_4O_{12}$ in the equilibrium mixture of reaction products was found to be virtually independent of the composition of the starting stock mixture if its stoichiometry ensures formation of at least 1 mol of β-spodumene.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Diffusion of Aqueous Solutions of $CoCl_2$, $Co(NO_3)_2$, and $Cu(NO_3)_2$ in Porous Glass Membranes

Abstract—Diffusion coefficients of $CoCl_2$, $Co(NO_3)_2$, and $Cu(NO_3)_2$ salts, characterizing permeation of their aqueous solutions across glass membranes with predominant pore radius in the range from 70 to 4.5 nm are determined. With pores in the membranes becoming narrower, the diffusion mobility of the electrolytes decreases.

The possibility and efficiency of membrane purification of liquids and separation of solution components are determined by the diffusion coefficients D of substances in the corresponding porous media [1, 2]. It is known that, in the case of finely porous hydrophilic membranes, diffusion transport of a number of substances, including electrolytes, is characterized by lower D values, compared with diffusion in aqueous solutions [1–5]. This is due to the influence of pore walls, determining the formation of an electrical double layer, possibility of sorption, and specific properties of the near-wall layers of the liquid. The joint influence of the above factors makes difficult interpretation of diffusion processes and hinders prognostication of properties of particular systems. For example, the general concept that a decrease in pore radius r_p in a hydrophilic membrane must make smaller the diffusion coefficient of substances in it seems to be nearly obvious. Nevertheless, the importance and type of a D–r_p dependence can only be determined experimentally, and its analytical form has not been established for any particular system. A study [5] of NaCl diffusion in porous glasses demonstrated, in particular, that the expected decrease in D is weakly pronounced in a wide range of pore radii, being markedly manifested only at $r_p \leq 15$ nm. This fact was tentatively accounted for in terms of the structural-geometric model of the system constituted by a membrane and a pore solution.

Proceeding with previous investigations [5], the present study analyzes the diffusion transport of aqueous solutions of $CoCl_2$, $Co(NO_3)_2$, and $Cu(NO_3)_2$ in porous-glass membranes in order to determine the analytical dependence D–r_p. The existance of Co^{2+} and Cu^{2+} ions in aqueous solutions of the chosen salts in the form of stable aqua complexes, possibility of their direct photometric determination [6], and low adsorption on the silica surface in an acid medium [7], much simplify the formulation and solution of the problem, making it possible to distinguish the pore radius of membranes as the main potential factor exerting influence on the diffusion coefficient.

EXPERIMENTAL

Porous-glass membranes were fabricated in the form of thin (1-mm) disks 25 mm in diameter. The parameters of the porous structure of the membranes (see table) were preset by varying the modes of preliminary thermal treatment and conditions of subse-

quent leaching (and, in some cases, additional alkaline etching) of DV-1 sodium borosilicate glass [8–10]. The predominant pore radii r_p were found from the hysteresis loop parameters of water adsorption isotherms or from the gas permeability of the membranes by the Deryagin method, and the porosity δ, by triple weighing [10, 11]. In studying the diffusion, the membranes were fixed between two cells, with twice-distilled water poured into one of these (receiver), and an aqueous solution of a salt (with concentration of 0.1–0.5 M), into the other (feeding cell). The dynamics of the diffusion process was judged from the results of direct photometric determination of the amount of ions that passed into the receiver cell: Co^{2+} at a wavelength λ_{max} = 510 nm, and Cu^{2+} at λ_{max} = 800 nm [6]. In all cases, the profiles of absorption bands of solutions from the receiving and feeding cells were preserved, which indicates that the form of existence of cations remains invariable in the course of experiments carried out with temperature maintained constant at 25°C and continuous stirring of the solutions. It was established preliminarily that the difference between levels of liquid in the cells within 10–20 mm has virtually no effect on the rate of diffusion, which indicates that hydrostatic and osmotic pressures are not manifested in the experiments. A steady flow across the membranes was established after a certain delay, whose duration depended on the solution concentration and porous structure parameters r_p and δ. In special-purpose experiments, the membranes were preliminarily saturated with the working solution and then a receiving cell was connected. In these cases, a steady-state diffusion process, whose rate was the same as that in experiments without preliminary filling of the membranes, was attained already in 5–10 min.

Linear dependences of the amounts Q of substances transferred across the membranes on time τ give the diffusion rate as $dQ/d\tau$; a typical family of Q–τ straight lines is shown in Fig. 1. The first Fick law was considered to be valid for the stationary process. According to this law, the diffusion flux across the membrane is represented as

$$dQ/d\tau = Ds\delta\Delta c/h, \quad (1)$$

where D is the diffusion coefficient; $s\delta$, the free cross-section of a membrane, equal to its geometrical area with correction for the porosity δ (see table); $\Delta c/h$, the difference between the solution concentrations before and after a membrane of thickness h.

Since the solution concentration in the receiving cell, c_{out}, was much lower that that in the feeding

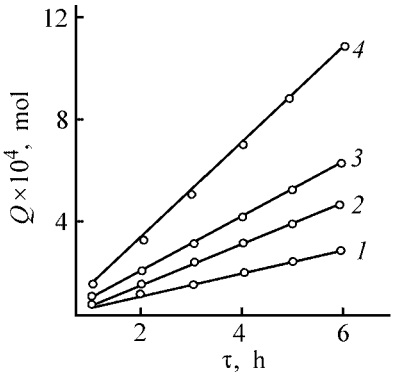

Fig. 1. Amount Q of $CoCl_2$ transferred across the membrane with pore radius r_p = 70 nm vs. time τ. Solution concentration (M): (*1*) 0.10, (*2*) 0.16, (*3*) 0.25, and (*4*) 0.50.

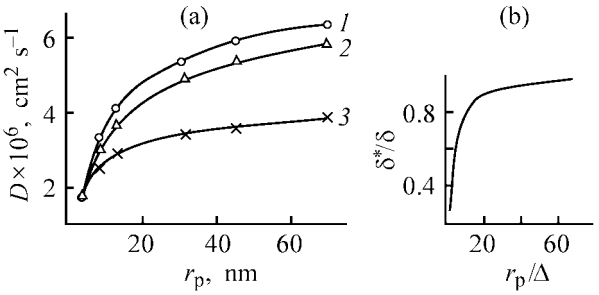

Fig. 2. (a) Diffusion coefficient D of (*1*) $CoCl_2$, (*2*) $Co(NO_3)_2$, and (*3*) $Cu(NO_3)_2$ in porous-glass membranes vs. pore radius r_p and (b) result of modeling of the system constituted by porous glass and pore solution on the basis of the structural-geometric approach. For explanations see text.

cell, c_{in}, in all experiments, the gradient was taken to be

$$\Delta c/h \simeq (c_{in} - c_{out})/h \simeq c_{in}/h. \quad (2)$$

A calculation of the diffusion coefficients from experimental data in accordance with Eqs. (1) and (2) demonstrated the lack of any regular variation of D in the salt concentration range 0.1–0.5 M, in agreement with the known fact of weak variation of D with concentration in aqueous solutions of electrolyte solutions [12, 13]. Correspondingly, the table lists averaged values of the diffusion coefficients, and Fig. 2 shows their graphical dependence on the pore radius of the membranes. A lower mobility of $Cu(NO_3)_2$, compared with that of cobalt(II) salts, is observed in a wide range of r_p, and a slight, but clearly noticeable decrease in D on passing from $CoCl_2$ to $Co(NO_3)_2$. The deficiency in reliable data on diffusion in solutions gives no way of comparing the coefficients obtained with the corresponding "bulk" values. However,

analysis of the data available for aqueous solutions of 1 : 1 electrolytes makes it possible to state with confidence that a systematic decrease in D values for nitrates, compared with those for chlorides of the same cations, is observed [12, 13].

As for the ratio of the diffusion coefficients in porous-glass membranes and in solutions, the run of the D–r_p dependences suggests that, even at large pore radii $r_p \geq 70$ nm, the mobility of ions within pores remains somewhat lower than that in free solution. With increasing r_p, the tendency for D to grow becomes increasingly less pronounced, which corresponds to weakening effect of the surface. However, at a distance of even tens of nanometers from pore walls the solutions still experiences their influence, which is indicated by the recorded increase in D (see table and Fig. 2). A decrease in the radii of membrane channels in the nanometer range results in that the diffusion coefficients of the salts studied fall considerably and, simultaneously, approach one another. It is not improbable that this is to a certain extent determined by an increase in tortuosity of narrow pores, which, when taken into account, may lead to higher h values in Eqs. (1) and (2). It is known [3, 14] that the tortuosity factor η depends on the method by which a porous glass is obtained; it is important that even in the case of pores with radii close to the smallest possible value, it exceeds unity only slightly ($\chi = 1.38$ at $r_p \approx 3$ nm [3]). It may be assumed that correction to the calculated D values is not very important in comparison with their pronounced variation between the membranes studied (see table).

The result obtained is apparently due to hindered diffusion of ions in the boundary layers of solutions in the membranes, changed with respect to the bulk. It is rather difficult to specify this general thesis, although it is clear that it is based on water structuring by the silica surface, which sets a limit on the mobility of hydrated ions. A transformation of the network of intermolecular hydrogen bonds under the action of surface forces predetermines, in particular, an increase in the viscosity of the boundary layers [1, 15–17]. There is good reason to believe that bound water is characterized by lowered dissolving ability [17, 18]. One of the reasons is a dramatic (caused by mobility restriction) decrease in its dielectric constant [19], with the result that it is less favorable energetically for ions dissolved in water to be in the boundary layer of water. All the aforesaid has to do with the decrease in the diffusion coefficient, observed in small-radius pores. In this context, the general appearance of the D–r_p dependences determined can be described, to a first approximation, in terms of the structural-geometric approach [5]. The limited involvement of the pore solution in diffusion will be modeled with a volume of a hypothetical near-wall layer of thickness Δ, entirely excluded from the transport process. With this assumption made, the effective pore space δ^* involved in diffusion can be determined, together with its fraction relative to the total porosity δ of the membrane. The total porosity is defined as the ratio of the pore volume V_p to the geometrical volume V of the membrane. The approximation of a cylindrical structure of pores in the porous glass gives for a flat disk of radius R, thickness h, and n pores on its cross section, the following

$$\delta = V_p/V = \frac{n(\pi r_p^2 h)}{\pi R^2 h} = \frac{n r_p^2}{R^2}, \quad (3)$$

$$\delta^* = n(r_p - \Delta)^2/R^2, \quad (4)$$

$$\delta^*/\delta = (r_p - \Delta)^2/r_p^2. \quad (5)$$

The dependence of the function (5) on the dimensionless parameter r_p/Δ, shown in Fig. 2, represents the general features of the experimentally established behavior of D, reflecting the manifestation of the structural-geometric factor in the series of the porous-glass membranes. The fraction of the free diffusion space of pores, δ^*/δ, decreases dramatically as their radius becomes comparable with Δ ($\delta^*/\delta \to 0$ at $r_p \to \Delta$); extrapolation to large radii gives $\delta^*/\delta \to 1$ at $r_p \to \infty$.

Despite the general agreement with experiment, the approach in question cannot be regarded as satisfactory. It is the assumption of a layer excluded from diffusion that is the weak point of the model, and attempts to evaluate its effective thickness [5] presumably have no strict physical meaning. Indeed, the structure-sensitive properties of water remain changed at a large distance from the silica surface [1, 15–19], exceeding the pore size of the membranes studied. In all probability, this is also valid in the case of aqueous solutions, whose properties must vary continuously with increasing distance from the surface, which corresponds to the type of variation of the diffusion coefficients in a wide range of pore radii of silica membranes (Fig. 2).

Thus, it seems important to determine the analytical approximation to the experimentally established D–r_p dependences. With the disjoining pressure considered to be a generalizing characteristic of the extent to which the properties of thin layers of liquids deviate from the bulk properties [1, 15–17], account will be taken of its exponential dependence on dimen-

sion parameters. This makes it possible to suggest, in the given case, a simple form

$$D = D_0 \exp(-K_p/r_p), \quad (6)$$

where D_0 is the diffusion coefficient in free solution, and K_p is the dimension constant.

In this case, the necessary physically grounded conditions are satisfied: $D \to D_0$ at $r_p \to \infty$ and $D \to 0$ at $r_p \to 0$. Figure 3 shows a good agreement between the experimental results and the exponential dependence (6); processing of the results by the least-squares method gives the following estimates for the parameters D_0 and K_p of Eq. (6):

Salt solution	$CoCl_2$	$Co(NO_3)_2$	$Cu(NO_3)_2$
$D_0 \times 10^6$, $cm^2\ s^{-1}$	6.78	6.09	3.89
K_p, nm	6.41	6.11	3.68

The dimension constants K_p obtained are characteristic, i.e., reflect the extent to which the silica surface affects the structure and properties of a particular solution. For example, it may presumably be assumed that the $Cu(NO_3)_2$ solution is structured by membrane pore walls to a much lesser extent (by a factor of ~1.7) than the $Co(NO_3)_2$ solution. This gives reason to believe that copper(II) cations cause stronger structuring of water, compared with cobalt(II) cations, and thereby partly "neutralize" the influence of the silica surface. In accordance with Eq. (6), the physical meaning of K_p is reduced to the observance of the rule: $D = 0.368 D_0$ at $r_p = K_p$. This means that the diffusion coefficient in pores of glass membranes with radius equal to the dimension constant K_p is approximately 2.7 times less than the "bulk" value.

The diffusion coefficients determined in a mesoporous membrane with r_p = 70 nm for three electrolytes constitute 94–99% of the D_0 values obtained by extrapolation $r_p \to \infty$. Thus, the concept of a compact near-wall layer of solution, which is totally or in part excluded from diffusion, should be considered incorrect. The structuring of the solutions studied by the silica surface, actually affecting the diffusion mobility of ions, decreases exponentially away from the wall and extends to layers with thickness of approximately 70 nm. The observance of the dependence (6) means, in addition, that even reducing the pore radius of porous-glass membranes to the maximum possible extent (limited by experimental capabilities), to $r_p \approx$ 1 nm, will not allow separation of water from dissolved salts "in a single run." The diffusion coefficient of, e.g., $Cu(NO_3)_2$, will be equal in this case to a finite value of about 10^{-7} $cm^2\ s^{-1}$.

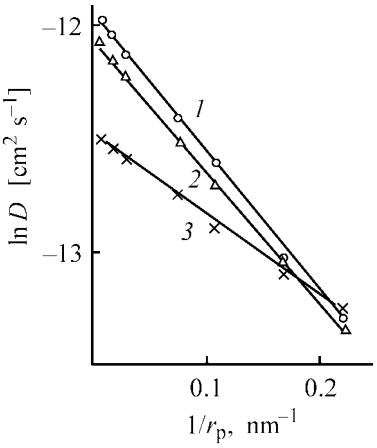

Fig. 3. Results obtained in measurements of diffusion of aqueous solutions of (*1*) $CoCl_2$, (*2*) $Co(NO_3)_2$, and (*3*) $Cu(NO_3)_2$ in porous glass and processed in accordance with Eq. (6). (*D*) Diffusion coefficient and (r_p) radius of pores in membranes.

CONCLUSIONS

(1) A study of transport of aqueous solutions of $CoCl_2$, $Co(NO_3)_2$, and $Cu(NO_3)_2$ across glass membranes revealed a substantial (by a factor of 2–4) decrease in the diffusion coefficients of salts with pore radii in porous glasses decreasing from 70 to 4.5 nm.

(2) The inadequacy of interpretation of the behavior of systems in terms of their structural-geometric models and concepts that a near-wall layer of solution is excluded from the diffusion process was demonstrated.

(3) It was established that the exponential dependence (6) fits experimental data. The following rule was formulated: The dimension constant characterizing the extent to which the silica surface affects the structure and properties of the pore solution is equal to the pore radius of a glass membrane in which the diffusion coefficient of the solute is approximately 2.7 times smaller than that in free solution.

(4) The structuring influence of the silica surface on the diffusion mobility of aqueous electrolyte solutions was shown to extend over an average boundary layer thickness of about 70 nm.

Abstract—The density of binary solutions methanol–*para*-xylene, methanol–*ortho*-xylene, and methanol–*meta*-xylene was measured on an installation for hydrostatic weighing in relation to pressure, temperature, and concentration. The experimental results are generalized using the equation of state.

Density is one of the most important physicochemical characteristics related to the structure of a substance. The thermal properties of binary solutions of methanol with aromatic hydrocarbons attract attention of not only researchers in various fields of science, but also engineers and designers in chemical, petrochemical, food, medical, and other industries. Studying the properties of these solutions is also of scientific interest for modernization of the theory of solutions.

An analysis of published data demonstrated that there is sufficient body of data on density of pure methanol and *para*-, *meta*-, and *ortho*-xylenes [1, 2], whereas for methanol–*para*-xylene, methanol–*ortho*-xylene, and methanol–*meta*-xylene solutions no data of this kind are available in the literature.

In this context, we studied experimentally the *P–V–T* dependence for these binary solutions in liquid phase at temperatures of 290–500 K in the pressure range 0.1–58.9 MPa at 25 wt % intervals.

The choice of the given systems is governed by the fact that the molecules of these substances contain even numbers of carbon atoms, have about the same ring structure, and, as shown by optical studies, these hydrocarbons and their solutions are characterized by intermolecular interaction varying with temperature, pressure, and concentration.

We chose the method of hydrostatic weighing for the experimental study. The piezometer used to determine the density of liquids operates on the principle that a solid submerged in a liquid experiences a buoyancy force, which depends on the density of a medium under study. Having determined the buoyancy force acting on the float (whose volume is known) and the mass of the float in empty space and in liquid, we can calculate the density of the medium [3, 4].

This method was proposed in [5, 6]. The experimental setup for measuring the *P–V–T* dependence for liquids is based on a variation of the hydrostatic weighing technique, which ensures high measurement accuracy and is comparatively simple in preparing for experiment and carrying out the procedure itself. In order to improve the sensitivity and to use heavier floats, the integrated circuit in the electronic servo system was replaced [7, 8].

Based on analysis of calibration data for elements of the suspension system, we obtained the following volumes and masses of the suspension system: m = 8.9650 g, V_f = 3.1212 cm^3, V_c = 0.2647 cm^3, V_t = 3.1212 cm^3, where subscript "f" corresponds to the float; "c" to core; "t" to thread. The measurement was done with maximum error of 0.1% in the entire range of parameters of state.

The purity of the substances studied was determined using a Tsvet chromatograph to be 99.87% for methanol and 99.96–99.98 wt % for *para*-, *meta*-, and *ortho*-xylenes.

Having determined on VLA-200g-M analytical balance to within 10^{-7} kg the mass of each component necessary for obtaining the required concentration of mixtures, we mixed the components in quartz vessels.

1070-4272/02/7512-1925 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The experimental temperature was measured with a standard PTS-10 platinum resistance thermometer with an accuracy of 0.01°C (thermometer parameters: R_0 = 10.1792 Ω, R_{100}/R_0 = 1.3940).

As controls were used densities of *n*-heptane and benzene, measured at temperatures of 290–520 K in the pressure range 0.1–58.9 MPa with temperature and pressure steps of, respectively, 20–25 K and 5–10 MPa. The measurement results demonstrated good agreement with the most reliable published data [4, 9], with discrepancy not exceeding 0.05%.

The experimental data on the density of methanol–*meta*-xylene, methanol–*ortho*-xylene, and methanol–*para*-xylene systems are listed in Table 1. A detailed analysis of the concentration dependence of *P*–*V*–*T*-data for all of the systems studied demonstrates that the concentration dependence of density deviates from the additivity line and changes with temperature and pressure.

In practice, empirical and semiempirical equations of state are widely used to compile tabulated data. The procedure for constructing equations of this kind assumes the existence of a sufficient body of high-precision experimental data, which is not always the case.

Analysis of our experimental data shows that, for all of the substances studied, the equation of state, proposed in [10], is valid:

$$\rho^4 = A + BP^{0.5} + CP, \quad (1)$$

where P is the pressure (MPa), ρ is the density of a substance (g cm^{-3}), and A, B, C are coefficients dependent on temperature T (K).

The coefficients A, B, C were determined for each isotherm by the least-squares method and described analytically as

$$A = \sum_{i=0}^{3} a_i T^i, \quad B = \sum_{i=0}^{3} b_i T^i, \quad C = \sum_{i=0}^{3} c_i T^i. \quad (2)$$

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Boiling Point of Tetraethyllead

I. B. Sladkov and M. S. Kokhatskaya

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received January 22, 2001; in final form, May 2002

Abstract—In view of the pronounced inconsistency of published data on the boiling point of tetraethyllead, its value was determined by several independent calculation procedures. Simultaneously, data on the molar volume of liquid tetraethyllead at the boiling point, lacking in the literature, were obtained.

The fields of practical application of tetraethyllead $Pb(C_2H_5)_4$ (TEL), which are rather diverse, are described in virtually the only Russia's monograph on TEL by Korshak and Kolesnikov [1]. References to later studies concerned with synthesis and use of TEL can be found in the monograph by Morachevskii and co-workers [2].

However, reliable data on such a fundamental constant of TEL as its boiling point are still lacking. This is largely determined by the impossibility of direct experimental determination of the boiling point because of the decomposition of TEL at temperatures close to its boiling point.

The present study was aimed to obtain missing data with the use of a number of independent calculation techniques. This task can be accomplished because experimental data on critical parameters are available for TEL. This allows application of methods developed on the basis of the theory of thermodynamic similarity, distinguished by high reliability of prognostication of physicochemical properties.

The experimental data on the physicochemical properties of TEL, available in the literature, give no way of producing an unambiguous answer to the question of its boiling point. For example, data on the boiling point can be obtained using the saturated vapor pressure (Table 1), but this gives rather contradictory results. In [9], the boiling point of TEL was given as 473 K, with the range 471–475 K reported in [10].

It can be seen that the information presented is rather contradictory: according to different sources, the boiling point of TEL is within 448.7–475 K. This is the probable reason why no evidence on the boiling point of TEL can be found in a fundamental reference book of thermodynamic properties of substances [11].

In the present study, the boiling point of TEL was determined as follows. The calculation procedure 1 is based on the temperature dependence of the density of the liquid. According to published data [12], the temperature dependence of the density (g cm^{-3}) of the liquid phase of TEL is described by the equation

Table 1. Boiling point of $Pb(C_2H_5)_4$, calculated from saturated vapor pressures

Temperature series of TEL saturated vapor pressure P, mm Hg	ΔT, K	Reference	T_b, K
$\log P = -2960/T + 9.4262$	351–423	[3]	452.2
$\log P = -2938/T + 9.428$	273–343	[4]	448.7
$\log P = -2908.43/T + 9.34286$	350–440	[5]	450.1
$\log P = -2535.84/T + 8.2724$	373–473	[6]	470.3
$\log P = -2899/T + 9.314$	350–450	[7]	450.6
$\log P = -2832/T + 9.122$	348–450	[7]	453.8
$\log P = -2184.6/(T - 43.2) + 8.1547$	345–455	[7]	457.4
$\ln P = -2063/(T - 43.2) + 11.576$	360–450	[8]	460.6
$\ln P = -1686/(T - 73.2) + 10.96355$	360–450	[8]	462.6

7	$Pb(CH_3)_4$	5.41	382.9	150.8	398.5	29.34	2.58
8	$Pb(C_2H_5)_4$	8.17	–	–	636	–	–

$$\rho = 2.118 - 0.00163T. \quad (1)$$

This temperature series was obtained up to 453 K, a temperature which is, presumably, rather close to the standard boiling point. From relation (1) follows that

$$T_b = (2.118 - \rho_b)/0.00163, \quad (2)$$

where ρ_b is the density of the liquid at its boiling point, which can be calculated from the corresponding molar volume ($\rho_b = M/V_b$).

Since data on the molar volume of liquid TEL at the boiling point are lacking, this volume was calculated using the following approximate relations

$$V_b = K_1\Pi, \quad (3)$$

$$V_b = V_{cr}/K_2, \quad (4)$$

where Π is the parachor; V_{cr}, the critical volume; K_1 and K_2, constants calculated from the properties of substances of the same type.

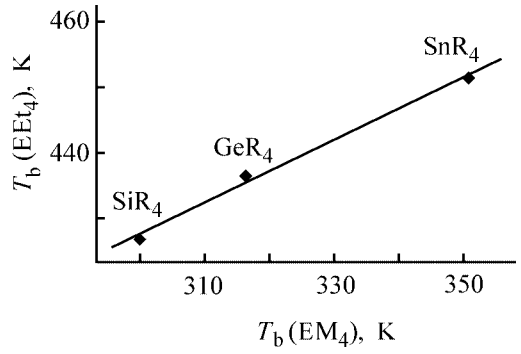

Fig. 1. Variation of the boiling point T_b in the series of ethyl and methyl compounds of Si, Ge, and Sn.

Calculation of the parachor for alkyl compounds was considered in detail in [13].

As substances of the same type were chosen alkyl compounds of elements belonging to Group IV of the periodic table, for which experimental values of the critical volume and the volume of the liquid at the boiling point are known [12, 14] (Table 2). The data listed in Table 2 were used to find the coefficients K_1 and K_2, equal to 29.05 and 2.66, respectively. Further, Eqs. (3) and (4) were applied to calculate the molar volume of TEL, which gave fairly consistent values of this parameter, 237.4 and 238.7 $cm^3\ mol^{-1}$.

Averaging of the data obtained gives the molar volume of liquid TEL at the boiling point of 238.1 $cm^3\ mol^{-1}$, which corresponds to ρ_b = 1.358 $g\ cm^{-3}$. Substitution of this value into Eq. (2) gives the boiling point of TEL, equal to 466.3 K.

The calculation procedure 2 is based on the Watson formula [15]

$$T_b = (T_b/T_{cr})\exp[2.77V_b^{0.18}/(T_b/T_{cr}) - 2.94]/V_b^{0.18}. \quad (5)$$

Substitution into formula (5) of the thus obtained molar volume of TEL liquid at the boiling point (238.1 $cm^3\ mol^{-1}$) and of its critical temperature (655 K [8]) yields a value T_b(TEL) = 466.8 K.

In the following stage of the study, the boiling point of TEL was determined using the method of comparative calculation, according to which a change in two properties in a single series of one-type substances or a single property in two series of one-type substances is described by a linear relation [16]. The existence of a linear relation was first verified by plotting the corresponding curve, with subsequent processing of the data by the least-squares method. The necessary experimental data are listed in Table 2.

Table 3. Verification of the reliability of the calculation procedure used to find the boiling point parameters

Substance	T_b, K		Δ, %	V_b, cm^3 mol^{-1}		Δ, %
	calculation	experiment		calculation	experiment	
$Si(C_2H_5)_4$	426.5	426.8	0.3	218.3	215.5	1.3
$Ge(C_2H_5)_4$	438.1	436.6	0.5	223.8	220.4	1.5
$Sn(C_2H_5)_4$	450.0	451.4	0.6	230.1	228.7	0.6

The following techniques were used in the present study for comparative calculation of the boiling point of TEL: procedure 3, based on comparison of boiling points in series of methyl and ethyl compounds of Si, Ge, and Sn (Fig. 1, correlation factor of the linear dependence R = 0.9968, rms error S = ±0.2%); procedure 4, comparing the boiling point and the parachor in a series of ethyl compounds of Si, Ge, and Sn (Fig. 2, R = 0.9997, S = ±0.1%); procedure 5, based on comparison of the quantity $\Pi^{3/2}/T_b^{1/2}$ and the critical volume in the series of methyl and ethyl compounds of Si and Ge, and also those of methyl compounds of Sn and Pb (Fig. 3, R = 0.9749, S = ±1.8%).

The results obtained in determining the boiling point of TEL by different methods are presented below:

Calculation technique	1	2	3	4	5
T_b, K	466.3	466.8	467.1	464.7	465.7
Average	466.1 K				

The boiling points obtained are in good agreement with one another and fall into the range established on the basis of experimental data on saturated vapor pressure. It may be assumed that averaging of the values obtained in this study will give a boiling point of TEL, close to the most reliable value of this parameter for $Pb(C_2H_5)_4$. This averaged value is 466.1 K.

Substitution of the thus obtained boiling point of TEL into Eq. (1) describing the temperature dependence of the density of the liquid yields the molar volume of the liquid at the boiling point (238.1 cm^3 mol^{-1}), coinciding with the value found above by other methods. This confirms once more the reliability of the molar volume of liquid TEL at the boiling point.

To confirm the reliability of the boiling point and molar volume at this temperature, the technique described above was applied to the closest analogues of TEL: $Si(C_2H_5)_4$, $Ge(C_2H_5)_4$, and $Sn(C_2H_5)_4$, for which experimental data on these properties are available in the literature (Table 2). The calculation results obtained, listed in Table 3, indicate the high reliability of the method used.

CONCLUSIONS

(1) T_b = 466.1 K and V_b = 238.1 cm^3 mol^{-1} were found using a number of independent calculation procedures.

(2) The good agreement between the results obtained using different methods and verification of the technique employed in the present study on compounds of the same type confirm the reliability of the data obtained.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Relationships in Dissolution and Solvation of Miconazole Nitrate in Binary and Ternary Solvents Based on Polyethylene Glycol-400

A. P. Krasnoperova, O. Yu. Sytnik, G. D. Yukhno, E. P. Bezuglaya, and N. P. Lyapunov

Karazin National University, Kharkov, Ukraine

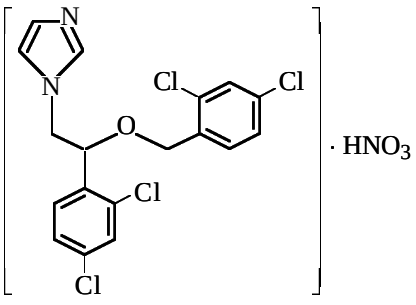
State Scientific Center of Medicinals, Kharkov, Ukraine

Received July 3, 2002

Abstract—The solubility of 1-[2,4-dichloro-β-(2,4-dichlorobenzyloxy)phenethyl]imidazole nitrate (miconazole nitrate) $C_{18}H_{14}Cl_4N_2O \cdot HNO_3$ in binary mixtures 1,2-propylene glycol–polyethelene glycol-400 and in ternary mixtures of these glycols with water at 293.15 K was studied. The correlation between the miconazole nitrate solubility and the dielectric constant of the solvents was discussed. The deviations of the miconazole nitrate solubility from additivity throughout the composition range of mixed solvents were calculated.

Imidazole derivatives are heterocyclic nitrogen-containing biologically active compounds widely used in modern pharmacology. Synthesis in solutions and development of the compositions of medicinals based on imidazole derivatives require knowledge of the solubility of these compounds in multicomponent solvents.

It is known that imidazole derivatives form with "rigid" acids complexes involving "pyridine"-type nitrogen atoms [1–3]. Among such compounds is 1-[2,4-dichloro-β-(2,4-dichlorobenzyloxy)phenethyl]imidazole nitrate (miconazole nitrate) used as microbiocide and fungicide



In this communication, we report on a study of the solubility of miconazole nitrate in a binary solvent, 1,2-propylene glycol–polyethylene glycol with the molecular weight 400 (1,2-PG–PEG-400), and in a ternary solvent, H_2O–1,2PG : PEG-400 (90 : 10 mol %), in the entire concentration range at 293.15 K.

EXPERIMENTAL

Mixed solvents, 1,2-PG – PEG-400 and H_2O – (1,2-PG – PEG-400), were prepared gravimetrically. To this end, we used double-distilled water, PEG-400 (Merck, Germany), and 1,2-PG preliminarily purified by double vacuum distillation [4]. The quality of 1,2-PG and PEG-400 was checked by measuring their density [$\rho^{25°C}$ (1,2-PG) = 1.0328 and $\rho^{25°C}$ (PEG-400) = 1.1250 kg m^{-3}] and dielectric constant [$\varepsilon^{25°C}$ (1,2-PG) = 29.0 and $\varepsilon^{25°C}$ (PEG-400) = 13.9]. Prior to being used, miconazole nitrate was dried at 105°C for 2 h, and its purity was checked by measuring the melting point (mp 454 K) and also chromatographically.

The solubility of miconazole nitrate was studied isothermally. To this end, an excess amount of the salt was placed in vessels with ground-glass stoppers, poured over with an appropriate solvent, and kept in a thermostat (temperature maintained constant to within 0.1 K) until the thermodynamic equilibrium was established. The saturation time was estimated experimentally to be 100 to 300 h, depending on the content of the nonaqueous component. The attainment of the thermodynamic equilibrium in miconazole nitrate solutions was judged from the invariance of the miconazole nitrate concentration in experiments with several successively taken samples. The concentration

* (x) Content of PEG-400 in the 1,2-PG–PEG-400 system and that of nonaqueous solvent in H_2O–(1,2-PG–PEG-400) system.

of the saturated solutions was determined by the spectral method. The optical density was measured on a Hitachi U3210 spectrophotometer in the UV spectral range at 280 nm. To this end, 2 ml of a transparent solution was diluted with ethanol to 100 ml so that the optical densities were within 0.3–0.7. Each solubility value was an average of those obtained in 3–4 runs. The maximal relative error in determining the solubility was 3% at a confidence level of 0.95. The results obtained are listed in the table.

Our data show that the solubility of miconazole nitrate varies widely depending on the solvent composition being a nonlinear function of the composition of mixed solvents.

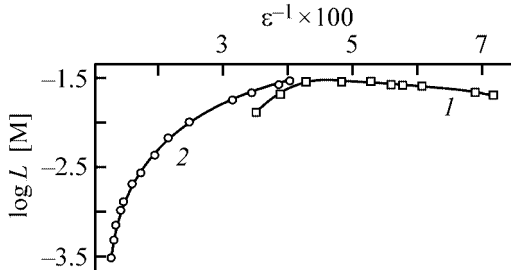

Fig. 1. Variation of $\log L$ of miconazole nitrate with the dielectric constant ε of (*1*) 1,2-PG–PEG-400 and (*2*) H_2O–(1,2-PG–PEG-400) systems at 293.15 K.

Izmailov *et al.* [5, 6] found that the solubility of substances in solvents of identical chemical nature is described by the equation

$$\log L = A + (\beta'\mu - \beta) \cdot 1/\varepsilon. \quad (1)$$

Here, L is the solubility, M; β' and β are empirical constants, μ is the dipole moment of the solvent, and ε is the dielectric constant of the solvent.

Equation (1) suggests that the solubility of miconazole nitrate in water must exceed that in PEG-400 and 1,2-PG, since the dielectric constant of water ($\varepsilon^{20°C} = 80.1$) significantly exceeds those of PEG-400 ($\varepsilon^{20°C} = 14.4$) and 1,2-PG ($\varepsilon^{20°C} = 30.8$). At the same time, the solubility of miconazole nitrate in these solvents varies in the reverse order: $L_{\text{PEG-400}} > L_{\text{1,2-PG}} > L_{H_2O}$. Hence, it is the specific solvation, rather than the dielectric constant, that governs the miconazole nitrate solubility.

A lower solubility of miconazole nitrate in water, compared to nonaqueous solvents, is typical of salts containing bulky hydrophobic ions. Bulky asymmetric hydrophobic ions exhibit a "structure-forming" effect in aqueous solutions by increasing the energies of the hydrogen bonds between the surrounding water molecules [7], thus hindering dissolution.

The higher solubility of miconazole nitrate in the studied glycols, compared to water, may also be due to the specific interactions between the π electrons of the phenyl groups of miconazole nitrate and hydrogen atoms in the solvents [8] and to the influence of the universal solvation via dipole–dipole and dispersion interactions [9].

Also, Eq. (1) suggests that, in contrast to the systems under study, the logarithm of the electrolyte solubility in mixed solvents with the same chemical nature depends linearly the reciprocal of the dielectric constant (Fig. 1). This once again confirms the leading role played by specific interactions in the systems studied.

The table shows that the solubility of miconazole nitrate in the 1,2-PG–PEG-400 binary solvent has a maximum at ~20 mol % PEG-400. This maximum can be attributed to the conformational changes in PEG-400 molecules, resulting from an increase in the content of 1,2-PG in the mixed solvent.

The conformation of the PEG chains, both in individual state and in solutions, has been studied extensively [10–14]. However, there is no consensus regarding the molecular structure of PEG. X-ray dif-

fraction studies [10] showed that the oxyethylene chain has a tortuous, rather than linear, structure. Beginning with nine oxyethylene groups (PEG-400), the tortuous chain forms a helix, and, with the number of units growing further, it can fold into a coil. Thus, steric hindrances in straight PEG-400 can make the oxyethyl groups insufficiently accessible to interactions with the substance being dissolved, and their interaction is accompanied by extra energy expenditure required for helix transformation. The interaction between the oxyethyl groups in PEG-400 and hydroxy groups in 1,2-PEG, evidently, results in helix unfolding. This makes the oxyethyl groups in PEG more easily accessible to miconazole nitrate solvation, which is responsible for the appearance of a solubility maximum.

We calculated the deviations of the solubility of miconazole nitrate from additivity throughout the composition range of the binary and ternary solvents by the formula [5]

$$L^E = L_{\text{exp}} - \Sigma L_i x_i. \quad (2)$$

Here, L^E is the deviation of the solubility from additivity; L_{exp} and L_i are the solubilities of miconazole nitrate in a mixed solvent and in straight ith solvent, respectively; and x_i is the mole fraction of ith straight solvent in a mixed solvent.

As seen from Fig. 2, the isotherm of deviations of the solubility from additivity in the 1,2-PG–PEG-400 system passes through a maximum at ~20 mol % PEG-400 in the mixture. The deviation exceeds 10%, which suggests that the solubility of miconazole nitrate is significantly influenced by the intermolecular interactions in the binary solvent.

In contrast to the binary solvent, the isotherm of deviations in the ternary solvent is more complex. With minor additions of the nonaqueous solvent to water, the solubility deviations are negative, and in the region rich in the nonaqueous solvent, positive. This suggests that the solubility of miconazole nitrate is affected by complex interactions in the mixed solvent H_2O–(1,2-PG–PEG-400). Numerous publications [11, 12, 16–19] suggest that minor additions of nonaqueous components to water are responsible for phenomena competing with dissolution of the third component. Physicochemical analysis and solubility studies with inert gases in the mixed solvent H_2O–1,2-PG showed [17, 18] that the methyl radical in 1,2-PG increases the hydrogen bonding energy in water, thus stabilizing the water structure. At the same time, in the H_2O–PEG-400 system with about 10 mol % PEG-400, oxonium compounds are formed

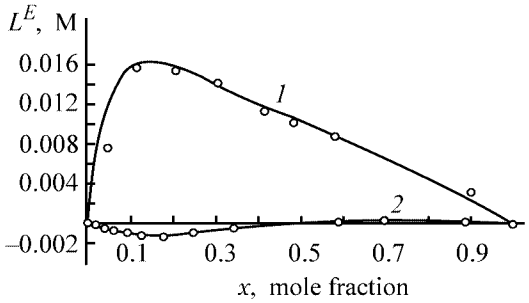

Fig. 2. Deviations of the solubility of miconazole nitrate from additivity, L^E, in (*1*) 1,2-PG–PEG-400 and (*2*) H_2O–1,2-PG–PEG-400 systems at 293.15 K. (x) Mole fraction of PEG-400 in 1,2-PG–PEG-400 system and the total mole fraction of the nonaqueous components in the H_2O–1,2-PG–PEG-400 system.

[19] via interaction of ether bridges in PEG with water molecules. This allows an assumption that, with minor additions of the nonaqueous solvent 1,2-PG–PEG-400 to water, both processes occur, and their competing influence is responsible for negative deviations of the solubility of miconazole nitrate from additivity.

CONCLUSION

Analysis of the correlation between the solubility of miconazole nitrate and the composition of a mixed solvent, dielectric constant, and deviations of the solubility from additivity showed that the solubility of miconazole nitrate is primarily determined by the specific interactions in the solvents under study and by conformational transformations in polyethylene glycol-400 molecules.

SORPTION AND ION-EXCHANGE PROCESSES

Acid–Base Properties and Structural Features of Composite Ion Exchangers Based on KU-23 and KM-2p Cation Exchangers and Hydrated Zirconium Oxide

Abstract—A method for introduction of hydrated zirconium oxide into macroporous cation exchangers KU-23 and KM-2p and the acid–base properties and structural features of the composite ion exchangers are described.

In contrast to anion-exchange resins, hydrated oxides (HOs) of multicharge metal ions exhibit increased selectivity with respect to certain oxygen-containing anions: phosphate, arsenate, and silicate [1–3]. Therefore, HOs show promise as sorbents for removal of their trace amounts from salt solutions. Unfortunately, inorganic ion exchangers, including HOs, are not commercially available because of difficulties encountered in their preparation in the form of mechanically strong spherical granules. A way to solve the problem of obtaining inorganic ion exchangers with satisfactory performance is to introduce them into an appropriate mechanically strong support and to use such a combined ion exchanger. Ion-exchange resins with porous structure are convenient supports for HOs. In [4, 5], we described methods for preparing composite ion exchangers consisting of macroporous KU-23 and KM-2p cation exchangers and hydrated zirconium oxide (HZO), one of the most efficient HO-based ion exchangers, and reported certain data on their ion-exchange properties.

In this study, we considered data on acid–base properties of the above composite ion exchangers, their pore structure, and distribution of the inorganic component in a sorbent.

EXPERIMENTAL

Commercial granulated macroporous sulfonic cation exchanger KU-23 and carboxylic cation exchanger KM-2p were used as supports. The cation exchangers were pretreated by the standard method [6]. Hydrated zirconium oxide was prepared by precipitation of hydroxide gel from 1 M zirconium nitrate solution with aqueous ammonia (pH 9.0–9.5). The gel was aged for 24 h, and the precipitate was separated from the mother liquor, washed with water by decantation, filtered, again washed with water, dried in air at 80°C, crushed, and sized. The 0.2–0.5-mm fraction was taken. The composite ion exchangers were prepared under dynamic conditions by saturation of cation exchangers with Zr(IV) from 0.1 M solution of zirconium nitrate at pH 1.0–1.2, washing with water, treatment with 1 M aqueous ammonia, and washing with water to remove excess ammonia [4, 5]. The composite ion exchangers thus obtained were unloaded from the column and dried in air at room temperature.

We prepared several batches of the composite ion exchangers on the basis of KU-23 and KM-2p cation exchagers and HZO. The scatter in the HZO content between different batches of the composite sorbents prepared with the same support was within 4.5 rel.% (Table 1), which indicates good reproducibility of the preparation procedure. Samples of the KU-23–HZO

(E_{Na^+}, $E_{NO_3^-}$) Ion exchanger capacities with respect to Na^+ and NO_3^-, respectively. Ion exchanger: (*1*) KM-2p, (*2*) KM-2p–HZO, (*3*) KU-23, (*4*) KU-23–HZO, and (*5*) HZO.

and KM-2p–HZO ion exchangers contained 29.0 and 22.5 wt % ZrO_2, respectively.

Before potentiometric titration (method of separate samples), the ion exchangers were transformed into the H form (titrated with NaOH solution) by treatment with 0.1 M HNO_3 or into the deprotonated form (titrated with HNO_3 solution) by treatment with 0.1 M NaOH, followed by washing with distilled water to neutral reaction. The pretreated ion exchangers were contacted under static conditions with solutions of NaOH or HNO_3 of various concentrations in the presence of a supporting electrolyte, 2 M $NaNO_3$. The contact time was 8–10 days.

The average size of prevailing pores and the specific surface area of the swollen ion exchangers were determined by small-angle X-ray scattering (SXS) [7, 8]. The intensity of SXS was measured within the range of angles 2–17' on a Kratky camera "Anton Paar" setup. The specific surface area of dried ion exchangers was determined by thermal desorption of argon [9]. The pore volume was estimated by adsorption of cyclohexane and toluene vapors [10]. The IR spectra of ion exchangers in a KBr matrix were recorded on a UR-20 spectrophotometer. An electron microscopic study of ion exchangers was performed on an REM-100U scanning electron microscope at an electron-accelerating voltage of 30 kV. The X-ray analysis of composite ion exchangers containing HZO was performed with characteristic zirconium radiation on a VDAR attachment to the electron microscope. The chemical stability of ion exchangers was estimated as the extent to which Zr(IV) passes into the solution at contact with solutions of various compositions. The Zr(IV) concentration in solution was determined photocolorimetrically with Alizarin Red S [11]. The Zr(IV) detection limit was 1 mg l^{-1}. The ZrO_2 content in the composite ion exchangers was determined gravimetrically after ashing at 800–850°C.

The curves of the potentiometric titration of KU-23–HZO, KM-2p–HZO, KU-23, KM-2p, and granulated HZO are shown in Fig. 1. Four inflections are observed in curves of KU-23–HZO and KM-2p–HZO titration with NaOH, corresponding to four stages of dissociation of functional groups by the acid mechanism. In the curve of HZO titration, there are three such inflections. The first inflection in the titration curves of composite ion exchangers corresponds to dissociation of functional groups of the support, and the other three inflections, to dissociation of OH groups of HZO by the acid mechanism. The exchange capacity of all the composite ion exchangers, corresponding to the first stage of dissociation of HZO OH groups by the acid mechanism, is virtually equal to that of the second stage of the dissociation. Because the capacities of ion exchangers corresponding to the first and second stages of dissociation of HZO OH groups are equal, we can identify these groups as $=Zr(OH)_2$, with the following dissociation scheme:

$$=Zr(OH)_2 + Na^+ \rightleftarrows =ZrO_2HNa + H^+, \quad (1)$$

$$=ZrO_2HNa + Na^+ \rightleftarrows =ZrO_2Na_2 + H^+. \quad (2)$$

The third inflection corresponds, most likely, to dissociation of isolated =Zr–OH groups. The titration curves of KU-23–HZO and HZO with HNO_3 exhibit a single inflection, whereas in the titration curve of KM-2p–HZO, clear inflections are absent. The anion-exchange power of the composite ion exchangers is due to dissociation of the HZO OH groups by the base mechanism only, since the supports (cation exchangers) have no anion exchange power. In principle, in titration of HZO with HNO_3, the isolated =Zr–OH groups must dissociate first, since this dissociation is facilitated as compared to that of $=Zr(OH)_2$ group. Inflections corresponding to particular steps of dissociation of $=Zr(OH)_2$ do not appear in the titration curves. Probably, the constants of the first and second steps

* The cation-exchange capacity due to HZO and support was calculated from the potentiometric titration curves.

of dissociation of this group are similar. The concentration constants of dissociation of ion exchangers by the acid and base mechanisms, calculated by least-squares fitting of the titration curves are listed in Table 2; the data on ion exchanger capacities are presented in Table 3.

The difference between the cation exchange capacity of composite sorbents and the capacity caused by dissociation of functional groups (sulfo or carboxy) of the support (i.e., the capacity corresponding to the first step in the titration curve) is the cation-exchange capacity of HZO incorporated in the sorbent. It follows from Table 3, that HZO belonging to KU-23–HZO has cation exchange capacity approximately three times, and that incorporated in KM-2p–HZO, four times higher than neat HZO (recalculated to ZrO_2). The anion-exchange capacity of the inorganic part of the composite ion exchangers is about four times the capacity of granulated HZO.

The difference in the cation and anion-exchange capacities of granulated and supported HZO is probably caused by better accessibility of the latter to ions being exchanged. In granulated HZO, only Zr atoms containing free OH groups are active. They are situated on the HZO surface, including the pore surface. A substantial fraction of Zr atoms are incorporated in the three-dimensional matrix. These atoms are bound with one another by oxide and hydroxide bridges and have no free (terminal) hydroxy groups. In HZO incorporated in the ion-exchange resin granules, the fraction of such a "ballast" must be smaller, which causes its higher ion-exchange power. It should be noted that the capacity of composite ion exchangers per unit mass of the supports for the first stage of the titration curves (corresponding to dissociation of functional groups of the support) is substantially lower than the capacity of the starting cation-exchange resins. This fact suggests that, after treatment of Zr(IV)-saturated cation exchangers with an ammonia solution, not all zirconium ions undergo complete hydrolysis, and part of them remain bound to functional groups of cation exchangers, which is confirmed by the IR spectra (Fig. 2). The spectra of both KU-23–HZO in the H^+ form and the support in the H^+ form (Fig. 2a) contain a broad band at 1140–1230 cm^{-1} with three peaks assigned to antisymmetric stretching vibrations of protonated sulfo groups, whereas the bands at 1370 and 920 cm^{-1} are absent. These bands are also absent in the spectrum of the support in the NH_4^+

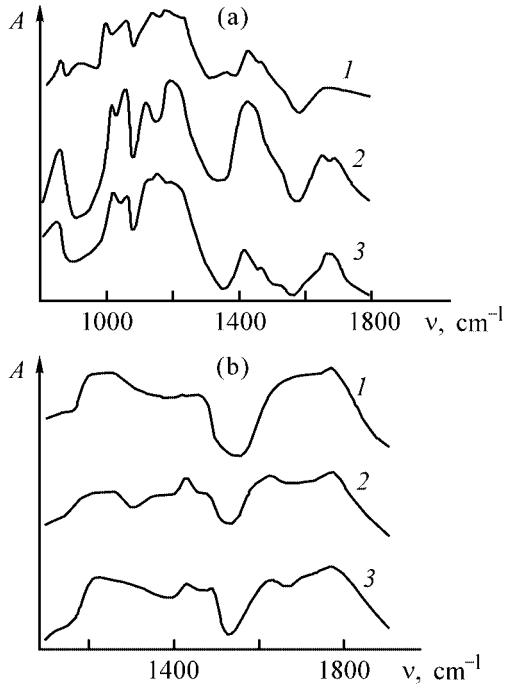

Fig. 2. IR spectra: (a) KU-23 cation exchanger in the (*1*) H^+ and (*2*) NH_4^+ form (*3*) KU-23–HZO in the H^+ form; (b) KM-2p in the (*1*) H^+ and (*2*) NH_4^+ form and (*3*) KM-2p–HZO in the H^+ form. (*A*) Absorption and (ν) wave number.

form. The first of them belongs to symmetrical stretching vibrations of the S=O bond in the $–SO_3H$ group, and the second, to stretching vibrations of the S–OH bond [12]. The spectrum of KM-2p–HZO in the H^+ form (Fig. 2b) contains, along with the band at 1760 cm^{-1} belonging to stretching vibrations of the protonated –COOH group, also the bands at 1620 and 1420 cm^{-1} belonging to antisymmetric and symmetrical stretching vibrations of the carboxylate ion, respectively. This indicates that, after treatment of composite ion exchangers with HCl (conversion into the H^+ form), part of functional groups of the support remain in the ionized form, which may be caused by preservation of the bond between SO_3H or COOH groups and hydrolyzed Zr(IV). At the same time, part of functional groups of the cation exchangers can be shielded with HZO particles.

The properties of ion exchangers (e.g., sorption kinetics) are determined not only by their sorption capacity but also by the pore structure. Introduction of HZO into the granules of macroporous cation exchangers may be accompanied by transformation of the support pore structure. However, as follows from Table 4, HZO introduced into KU-23 macroporous

Table 4. Characteristics of ion exchangers pore structure

* Parameters of pores and specific surface area of swollen ion-exchangers as determined by SXS.

cation exchanger does not decrease the effective radius of the support pores. This shows that HZO exists in the cation exchanger as finely dispersed inclusions. The specific surface area of the combined ion exchangers, both dry and swollen, and the total pore volume are larger than those in the support, which may be due to the own porous structure of HZO inside the ion exchanger granules and to an increase in the rigidity of resins after introduction of HZO into the support (the specific volume of dry combined ion exchangers is larger, and that of swollen ion exchangers, substantially smaller than that of the supports).

The virtually equal sizes of predominant pores in KU-23 and in the composite sorbent KU-23–HZO indirectly indicates that HZO introduced into the cation exchanger granules occurs in them in the finely dispersed state. Nevertheless, it was interesting to obtain direct information on the size of HZO particles and their depth distribution in the granules by electron microscopy. Cross-sectional electron micrographs of KU-23 and KU-23–HZO grains are shown in Fig. 3. No significant differences between them are seen. Taking into consideration the magnification, we can suggest that the composite ion exchanger contains no HZO particles of size larger than 100 nm. Figure 4 shows the results of X-ray microanalysis of a cross-section of a KU-23–HZO grain in the characteristic zirconium X-ray radiation. As seen, HZO is distributed in the depth of the ion exchanger grain fairly uniformly.

We also performed experiments to assess the chemical stability of composite ion exchangers. It was found that, in 1–2 M NaOH, 6 M NH_4NO_3, 6 M NH_4NO_3 + 3 M NH_3, and dilute solutions of HNO_3 (up to 0.5 M), both unsupported HZO and supported HZO are fairly stable. To estimate the mechanical wash-out of HZO from composite ion exchangers, distilled water was pumped through a column packed with KU-23–HZO (20–30 sp. vols.) at a linear velocity of 400–500 cm min^{-1}. Then, the ion-exchanger and water passed (after evaporation and acidification to dissolve the HZO particles that could be washed out from the composite ion exchanger) were analyzed. No zirconium was detected in the filtrate. Thus, the combined ion exchangers based on cation-exchange resins and HZO are fairly stable with respect to chemical and mechanical (under conditions of strong hydrodynamic load) impacts.

CONCLUSIONS

(1) The method proposed for introduction of HZO into macroporous cation exchangers KU-23 and KM-2p allows preparation of composite ion exchangers with stable content of the mineral constituent.

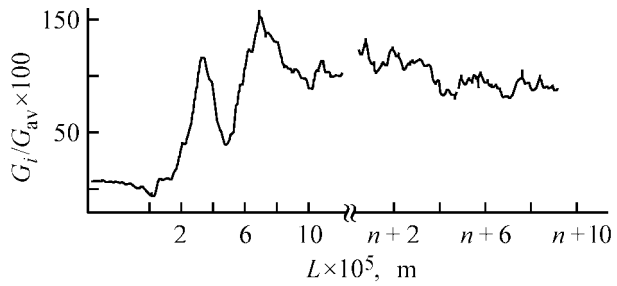

Fig. 4. Depth distribution of HZO in KU-23–HZO grains. (G_i) Running HZO concentration in the ion exchanger phase at a distance L from the grain surface of KU-23–HZO and (G_{av}) average HZO concentration in the ion exchanger phase. $L = 0 \ldots n \ldots (n + 10) \times 10^{-5}$ m.

(2) HZO is uniformly distributed throughout the depth of grains of the composite ion exchanger based on KU-23; particles of hydrated zirconium oxide with size exceeding 100 nm are absent.

(3) In the composite ion exchangers, hydrated zirconium oxide has greater ion-exchange power than neat HZO; part of functional groups of the support do not participate in the ion exchange.

SORPTION AND ION-EXCHANGE PROCESSES

Purification of Ammonium Molybdate and Tungstate Aqueous Solutions To Remove Phosphate, Arsenate, and Silicate Anions with a Composite Sorbent Based on KU-23 and KM-2p Cation Exchangers

Abstract—Selectivity sorption of phosphate, arsenate, and silicate anionic impurities from concentrated aqueous solutions of ammonium molybdate and tungstate by a composite sorbent consisting of macroporous KU-23 (or KM-2p) cation exchanger and hydrated zirconium oxide was studied.

It is known that phosphorus, arsenic, and silicon impurities deteriorate the properties of metallic molybdenum and tungsten [1–3]. These anionic impurities are distributed nonuniformly in the bulk of molybdenum and tungsten in the form of phosphide and silicide inclusions giving rise to structural strains increasing the brittleness of these refractory metals [2, 3].

Ammonium molybdate (AM) and tungstate (AT) used as starting compounds in production of metallic molybdenum and tungsten are recovered from weakly alkaline solutions. These solutions contain phosphorus, arsenic, and silicon impurities in the form of phosphate (HPO_4^{2-}), arsenate ($HAsO_4^{2-}$), and mononuclear and polymeric silicate anions [4]. One of the most efficient processes for purification of AM and AT solutions to remove phosphate, arsenate, and silicate impurities is based on treatment of solutions with hydrated multicharged metal oxides (HOs). There are two variations of this process. In the first of these, the impurities are coprecipitated and sorbed on HOs in the course of formation of these oxides [5–7]. In the second, the impurities are sorbed on a column packed with granulated HOs. The second version ensures more efficient purification of the solution to remove impurities because, in passing through a sorption column, the solution repeatedly contacts the sorbent. It has been reported previously that hydrated zirconium oxide (HZO), being one of the most efficient metal oxide ion exchangers, can be used as a component of a composite sorbent based on macroporous resin [8–10]. Certain properties of such composite sorbents and procedures for their preparation have been reported.

This study is concerned with purification of AM and AT aqueous solutions to remove phosphate, arsenate, and silicate impurities with a composite sorbent consisting of KU-23 (or KM-2p) cation exchanger and HZO.

EXPERIMENTAL

The composite sorbents and neat hydrated zirconium oxide were prepared by procedures reported in [8–10]. In sorption experiments, we used KU-23–HZO and KM-2p–HZO composite sorbents. The first of these consists of KU-23 cation exchanger and ZrO_2 (29.0 %) and the second, of KM-2p cation exchanger and ZrO_2 (22.5%). Granulated Fe(III) hydroxide (HIO) being the most available ion exchanger of the metal hydroxide type, and composite KU-23–HIO sorbent, consisting of KU-23 cation exchanger and Fe_2O_3 (13.5%), were also tested. Sorption was studied under both static and dynamic conditions. The ratio of the sorbent weight (g) to solution volume (ml) in static experiments was 1 : 1000. The contact time was 5–7 days. In dynamic experiments, the sorbents were fractionated and then packed in columns. The grain size of the air-dried composite sorbent and granulated zirconium and iron oxides was in the range 0.5–1 and 0.32–0.5 mm, respectively. These sorbents were loaded into identical fluoroplastic columns 10 mm in diam-

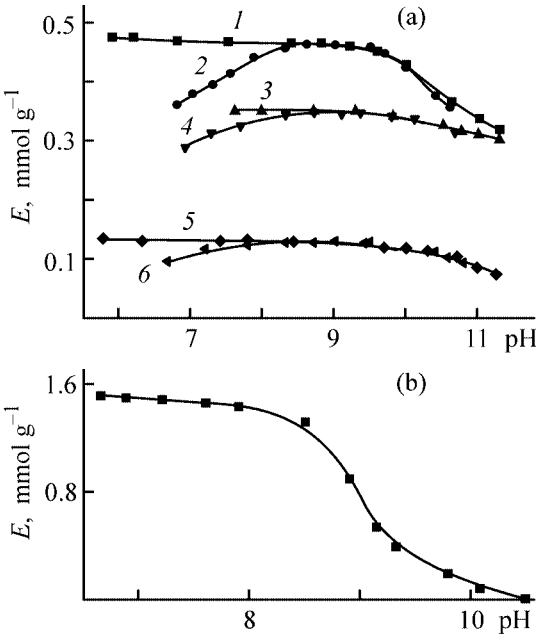

Fig. 1. (a) Sorption capacity E of KU-23–HZO for (*1*, *2*) phosphate, (*3*, *4*) silicate, (*5*, *6*) arsenate from (*1*, *3*, *5*) 2 M NH_4NO_3 and (*2*, *4*, *6*) 1M $(NH_4)_2MoO_4$ on KU-23–HZO vs. pH and (b) sorption E of molybenum(VI) from 1 M $(NH_4)_2MoO_4$ vs. pH. Initial concentration (mM): HPO_4^{2-} 4.8, $HSiO_4^{3-}$ 3.6, and $HAsO_4^{2-}$ 1.3.

eter. The cation exchanger bed height was 150 mm (ratio of the bed height to the column inner diameter $H : D = 15 : 1$). Molybdate and tungstate-containing solutions were passed through a column at a rate of one column volume per hour. Molybdenum(VI) and tungsten(VI) were determined gravimetrically or photocolorimetrically, depending on their content in solutions. Silicon(IV) and arsenic(V) were determined photocolorimetrically [11, 12]. pH was measured on an I-120 ionometer equipped with ESL-47-07 glass and EVP-AM-3 silver chloride electrodes. Phosphate anions were labeled with ^{32}P, and the specific β-activity of the isotope was measured on a KRK-1-01A setup equipped with a BDIB-01-1 counter and a PSO2-4 scaler.

It is known that hydrated zirconium and iron oxides exhibit high sorption power with respect to phosphate, arsenate, and silicate anions, which is due to formation of poorly soluble compounds in interaction of these anions with multicharged cations of the hydrated oxides [13–15]. At the same time, it is known that HOs efficiently sorb molybdate and tungstate anions [14, 15], which, present in solutions in microscopic amount, must interfere with their purification to remove phosphate, arsenate, and silicate anions. The state of molybdenum(VI) and tungsten(VI) in solutions, their affinity for ion-exchange resines, and, consequently, the extent to which anionic impurities affect sorption depend on the solution acidity. Solution acidity can also affect the anion-exchange sorption of the anionic impurities on HOs exhibiting weakly basic anion-exchange features. The state of phosphate, arsenate, and silicate impuritiesthemselves can also be influenced by acidity. Ammonium tungstate solutions are stable only at pH ≥ 9.6–9.7. In adjusting acidity of these solutions, pH must be not lower than these values but lower than ~10.5. Ammonium molybdate solutions are stable within a wider pH range. We studied the influence of pH on sorption of phosphate, arsenate, and silicate anions from AM solutions on composite sorbents containing HZO and HIO. To elucidate how anions of a macrocomponent affect the sorption of anionic impurities under consideration, we studied their sorption on HOs in the presence of NH_4NO_3 (2 M) at different pH. Ammonium nitrate was used in these experiments because nitrate anions are sorbed on HOs by the anion-exchange mechanism only.

Figure 1a shows typical patterns of sorption of the anionic impurities on the KU-23–HZO sorbent as influenced by pH. The pH dependence of sorption of these anions on other composite ion exchangers and also on neat HZO and HIO sorbents was found to be identical. These data show that phosphate, arsenate, and silicate anions are fairly well sorbed from AM solutions on KU-23–HZO within a wide pH range. The maximum sorption of these anions is reached at pH ~8.5–9.5. At higher and lower pH, their sorption on KU-23–HZO decreases.

We found that, in sorption on hydrated oxide sorbents of anionic impurities from solutions having the same ionic strength but free of molybdate ions, the pH dependence is different. In sorption of phosphate and arsenate anions from NH_4NO_3 solutions at pH (5.5–6.0)–9.5 and silicate anions within the pH range 7.5–9.5, sorption of these anionic impurities remains approximately constant or slightly decreases with increasing pH. At pH > 9.5, the decrease in sorption is more noticeable. Figure 1a shows that the right-hand parts of the sorption curves related to the similar anions and sorbents are identical, irrespective of the macrocomponent nature.

The decrease in sorption of the anionic impurities on KU-23–HZO, KM-2p–HZO, HZO, KU-23–HIO, and HIO with increasing pH is quite expected. This trend is caused by the fact that the sorbents used in our experiments are weakly basic anion exchangers whose sorption power decreases with increasing content of hydroxide ions in the solutions. Potentiometric titration of ion exchangers based on metal oxides shows [10] that they lose their capability to sorb an-

ions (e.g., nitrate anions) by the ion-exchange mechanism already at pH > 5. The high sorbability of phosphate, arsenate, and silicate anions on HOs from neutral and weakly alkaline solutions is consistent with the well-known fact that sorbents of this type exhibit high sorption power for multicharged anions. The noticeable decrease in sorption is only observed at pH > 9.5–10. The difference between the *E*-vs.-pH plots for anionic impurities in the presence and absence of molybdate anions at moderate pH is caused by sorption of molybdate ions on HOs (Fig. 1b). Hydrated metal oxides strongly sorb polymolybdate anions. In a 1 M molybdenum(VI) solution, the $Mo_7O_{24}^{6-}$ polymeric species are formed at pH < 7.5. It is possible that, in the bulk of the sorbents, these polymerized species are even formed at a lower acidity. With increasing pH, the fraction of $Mo_7O_{24}^{6-}$ species decreases, and, therefore, the sorption of molybdenum on the metal oxide sorbents decreases too. As a result, the sorption of phosphate, arsenate, and silicate anions grows with increasing pH, until the concentration of hydroxide anions becomes so high that they begin to displace anionic impurities from the sorbent.

Thus, in purification of AM solutions to remove anionic impurities with HZO- and HIO-containing composite sorbents, pH should be maintained within the range 8.5–9.5. Under these conditions, the sorption of anionic impurities changes only slightly in the presence of molybdenum(VI). This is demonstrated in Fig. 2 for the example of sorption of phosphate anions. Figure 2 shows that, in the presence of ammonium tungstate, which is stable at higher pH, sorption of phosphate decreases to a greater extent. With the AM concentration increasing from 0.1 to 2 M, sorption of phosphate anions decreases by 10–15%, and with the tungstate concentration increasing from 0.1 to 1M, sorption of phosphate anions decreases by 25–40%.

It was of interest to compare the sorption power of the composite sorbents and neat hydrated metal oxides contained in them. For this purpose, we obtained sorption isotherms of the anionic impurities on sorbents of both types (Fig. 3). These isotherms were constructed in the form of a plot of the sorption capacity *E* (mmol of anionic impurity/1 ml of sorbent) against the anionic impurity concentration in the solution (mM). The sorption capacity for anionic impurities was expressed in mmol/ml because this scale is the most frequently used in practice. Figure 3 shows that all of the sorbents tested, both composite and neat HZO and HIO, efficiently sorb phosphate, arsenate, and silicate impurities from concentrated solutions of ammonium molybdate and tungstate. The HZO-containing composite sorbents exhibit higher sorption power for anionic impurities than HIO-containing composite sorbents. Furthermore, the sorption capacity of HZO-containing composite sorbent for anionic impurities exceeds that of neat HZO in the whole range of equilibrium concentrations. The sorption power of neat HIO for the impurities is somewhat higher than that of KU-23–HZO composite ion exchanger. These data are consistent with the results on potentiometric titration of ion exchangers under consideration [10], which showed that HZO distributed throughout the bulk of macroporous cation exchangers has higher sorption power than neat HZO.

** (K_{pur}) Purification factor (ratio of the anionic impurity content in the initial solution to that in eluate).

In cotrast to zirconium hydroxide contained in the composite sorbents, zirconium atoms in a matrix of granulated HZO lack free hydroxide groups capable of exchanging anions or cations. We could expect that, with increasing surface area of granulated HZO, the number of its active sorbing sites and, hence, its sorption capacity must increase. Indeed, we found that, with the average HZO grain diameter decreasing from 0.75 to 0.1 mm, the sorption capacity of phosphate anions increases by a factor of 2.5. In these experiments, the sorbent was allowed to stand in a phosphate-containing solution for a long time (24 h) to exclude the kinetic effect on sorption. It was found that, for KU-23–HZO mesoporous composite sorbent in which HZO is uniformly distributed over the surface of cation exchanger pores, variation in the grain size and the corresponding variation in the surface area do not affect the sorption power.

The equilibrium sorption of phosphate impurities from 1 M AM and 2 M NH_4NO_3 on HZO, KU-23–HZO, and KM-2p–HZO was studied within the temperature range 0–60°C. We found that, with increasing temperature, the sorption of phosphate anions from both AM and NH_4NO_3 solutions becomes more pronounced, irrespective of the type of competing macrocomponent anions. The strengthening of sorption with increasing temperature shows that heat is consumed in this process, i.e., the enthalpy increases in sorption of phosphate. Therefore, the observed increase in sorption is due to the entropy factor.

We found that the sorption power of HZO-containing composite sorbent exceeds that of neat granulated HZO, irrespective of whether the sorption power of the composite sorbent is recalculated to zirconium oxide contained in the sorbent or to the total weight or volume of the composite sorbent. This experimental fact is somewhat unexpected if we take into account that the limiting cation and anion-exchange sorption capacity of zirconium oxide used in our experiments was typical of sorbents of this type [13–15]. Of course, we do not rule out the possibility that HZO used by us had lower sorption power than, e.g., the best sorbents of this type prepared by the sol–gel technique. However, we believe that this difference is mainly due to better kinetic characteristics of sorption on the composite sorbents as compared to granulated HZO, ensured by the developed porous structure of the cation-exchange matrix. This assumption is completely confirmed by the data on sorption kinetics of phosphate and arsenate anions from $(NH_4)_2MoO_4$ and NH_4NO_3 solutions, reported in [16]. The effective diffusion coefficients of anions in their sorption on HZO-containing composite sorbent are, on the average, an order of magnitude higher than those of neat HZO, and the corresponding activation energy of diffusion is lower by approximately a factor of 2 [16].

To quantitatively characterize the efficiency of purification of AM and AT solutions to remove anionic impurities with the composite sorbents (degree of purification, solution volume passed through a column till breakthrough of impurities, sorption capacity for impurities by the instant of breakthrough), the process should be studied in dynamic experiments. In these experiments, we used AM [c_{Mo} = 144 g l^{-1} (1.5 M); pH 8.7] and AT [c_{WO_3} = 174 g l^{-1} (0.75 M); pH 9.8] solutions prepared from ammonium para-

molybdate and tungstic acid of chemically pure grade, respectively. Anionic impurities were introduced into these solutions in the form of sodium silicate, disodium hydrogen phosphate, and disodium hydrogen arsenate in the following concentrations (mg l^{-1}): silicon and phosphorus 150, and arsenic 100. These anionic impurities were desorbed from the column with 2 M NaOH. The results of the desorption experiments are listed in the table and shown in Fig. 4. It is seen that the HZO- and HIO-containing composite sorbents, in spite of their larger grain size, sorb the anionic impurities more efficiently than neat granulated HZO and HIO and surpass the latter in the degree of purification, sorption capacity for impurities by the instant of breakthrough, total sorption capacity of anionic impurities under dynamic conditions, and easiness of desorption in sorbent regeneration. The reason for these advantages of the composite sorbents is their better kinetics features. We found that, on passing concentrated AM and AT solutions through a column packed with the composite sorbent, the content of anionic impurities in the eluate decreases by a factor of 50–100. Similarly to sorption of anionic impurities under static conditions, the HZO-containing composite sorbents exhibit better sorption characteristics in sorption under dynamic conditions than those containing HIO. The best purification of AT and AM solutions to remove anionic impurities was achieved with KU-23–HZO. This sorbent also surpasses the other sorbents in their sorption capacity for anionic impurities by the instant of breakthrough and in their total sorption capacity. The KM-2p–HZO sorbent is only slightly inferior to KU-23–HZO.

The possibility of reusing KU-23–HZO sorbent in the sorption-desorption cycles was studied by us in recovery of phosphate anions from AM solutions. The phosphate anions were desorbed with 2 M NaOH. The sodium anions were washed off from the sorbent with 2.5 M NH_4NO_3. We found that, after five sorption-desorption cycles, the purification factor and the sorption capacity for phosphate remained virtually unchanged.

KU-23–HZO and KU-23–HIO composite sorbents were successfully tested in large-scale laboratory experiments on purification of an AT-containing process solution to remove arsenic(V) impurities.[1]

KU-23–HZO was used in combination with ANKB-35 ampholyte and AN-106 anion exchanger for integrated purification of AM solutions to remove anionic impurities in preparation of several batches

of high-purity ammonium paramolybdate. The silicon and arsenic content (phosphorus was not determined) in two batches of single-crystal molybdenum prepared from high-purity ammonium paramolybdate was less than 3×10^{-5} and 1×10^{-5} wt %, respectively, which is lower than their detection limits by mass spectrometry.[2]

CONCLUSION

Composite sorbents consisting of KU-23 or KU-2p cation exchanger and zirconium or iron hydrated oxide exhibit high selectivity with respect to phosphate, arsenate, and silicate anions in their sorption from concentrated ammonium molybdate and ammonium

[1] The tests were carried out at Uzbek combine for production of refractory and heat-resistant metals.

[2] Single-crystal molybdenum samples were prepared by G.L. Klimenko (Institute for Technological Problems of Microelectronics and Ultrapure Materials, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia). Their mass-spectrometric analysis was carried out at the same institute.

tungstate aqueous solutions. These sorbents ensure purification of molybdate and tungstate to remove anionic impurities with purification factor of 50–100.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Hydrocarbons from Gas–Air Mixture on Polypropylene Stereoisomers

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received February 27, 2002

Abstract—Kinetics of absorption of a mixture of aliphatic, aromatic, and unsaturated hydrocarbons from the gas phase onto polypropylene containing 5, 18, and 40% atactic polymer in its molecular lattice was studied. The kinetic parameters, equilibrium constant, and Gibbs energy of adsorption–desorption of the hydrocarbons were determined by zero-, first-, and second-order optimization of the solution of the multiparameter equation. These parameters were correlated with the adsorbent composition and the number of sorption–desorption cycles.

To develop and improve industrial adsorption processes, new sorbents with high sorption capacity and selectivity are required. The main experimental efforts are aimed at overcome the internal diffusion hindering mass transfer in porous materials. Thermal treatment of graphite [1, 2] and silica gel [3], mechanical [4] and chemical [5, 6] deformation of internal surfaces of carbon materials, and chemical modification of silica [7, 8] were used for this purpose. The transport and functional properties of these sorbents can be changed, and adsorption and structural parameters of their surface, improved by varying duration and intensity of these treatments. The adsorption kinetics, rate of saturation of the sorption capacity, and relationship between the surface structure and the adsorption rate are of great importance for industrial processes, along with porosity (fractal dimensionality) of sorbents.

Previously we developed materials based on isotactic polypropylene with inclusions of an atactic polymer, to be used for sorption of hydrocarbons from gas–air flows. To improve the composition of the polymeric adsorbent, we studied the kinetics of cyclic adsorption and desorption of a mixture of aliphatic, aromatic, and unsaturated hydrocarbons from a gas–air mixture on the surface of polypropylene containing 5, 18, and 40 wt % atactic polymers (SP-5, SP-18, and SP-40, respectively).

EXPERIMENTAL

The adsorbents were prepared by suspension polymerization of propylene in heptane at 50–70°C in the presence of the MSC–$TiCl_3$–$Al(C_2H_5)_xCl_y$ catalytic system (MSC is a microspherical catalyst). The cocatalyst (ethylaluminum chloride) was prepared by mixing heptane solutions of AlC_3 and $Al(C_2H_5)_3$ in definite weight ratios. The polymers prepared in the presence of cocatalysts with Cl/Al weight ratio of 1.36, 1.24, and 1.18 contained 5, 18, and 40 wt %, respectively, atactic polypropylene (APP) in the molecular lattice of isotactic polypropylene (PP). As hydrocarbon mixture (HM) served a solvent used at Tomsk petrochemical plant in production of spherical catalysts for propylene polymerization. The solvent composition determined by GLC (solid phase Chromosorb P, liquid phase PFMS–4, carrier gas helium) is as follows, wt %: *n*-butane 0.03, 1-butene 0.02, 2-butene 0.01, isopentane 0.04, 1-pentene 0.01, 2-methylbutene 0.20, 2-methylpentene 0.04, 2-methylpentane 0.01, *n*-hexane 0.04, 2,2-dimethylbutane 0.38, 2-methyl-3-pentene 0.03, 2-methylhexane 8.75, 3-methylhexane 15.50, 2-hexene 1.12, cyclohexane 39.51, *n*-heptane 8.31, 2,3-dimethylhexane 1.11, heptene 0.46, benzene 19.93, *n*-octane 0.20, toluene 1.55, and *o*-xylene 2.76. Adsorption of HM from the gas–air mixture and regeneration of the adsorbent were performed on a unit consisting of a compressor, a Drechsel bottle, and a filter with continuous bed of the adsorbent. The gas–air flow was filtered through the sorbent bed. The flow rate of the gas–air flow was 6 $cm^3\ h^{-1}$. The weight of adsorbed and desorbed hydrocarbons was determined gravimetrically 15–20 min after attainment of equilibrium. Hydrocarbons adsorbed in the filter were desorbed with an air flow. The adsorption of hydrocarbons from the gas phase

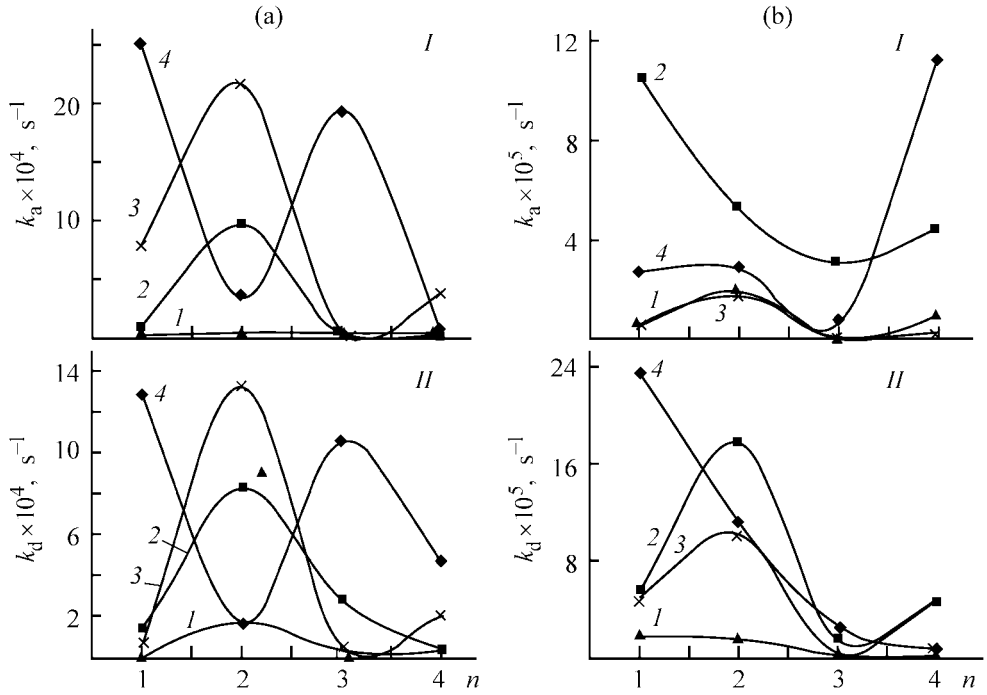

Fig. 1. Rate constants of (*I*) adsorption k_a and (*II*) desorption k_d of HM on (a) external and (b) internal surfaces of (*1*) SP-5, (*2*) SP-18, (*3*) PP, and (*4*) SP-40 adsorbents vs. the number of regeneration cycles *n*.

onto the surfaces of polypropylene (PP) and its stereoisomers (SP-5, SP-18, and SP-40) is an equilibrium nonlinear process described by the overall equation

$$\Delta m_\tau = \Delta m_1[1 - \exp(-k_1\tau)] + \Delta m_2[1 - \exp(-k_2\tau)], \quad (1)$$

where Δm_τ is the total weight of hydrocarbons adsorbed (g); Δm_1, the weight of hydrocarbons adsorbed on the external surface (sites of the first type) (g); Δm_2, the weight of hydrocarbons adsorbed on the internal surface (sites of the second type) (g); k_1, the rate constant of hydrocarbon adsorption on the external surface (s^{-1}); k_2, the rate constant of hydrocarbon adsorption on the internal surface (s^{-1}); τ, the sorption time (s) (independent variable).

Equation (1), containing five parameters, was solved by absolute optimization using OPTIM software. This method involves zero-order optimization by the Hook–Jeeves and Nelder–Mead procedures (direct calculation of the function being optimized), first-order optimization by generalized gradient procedure (calculation of the first derivative of the function being optimized), and second order optimization by the McCormick procedure (calculation of the first and second derivatives of the function being optimized) [9, 10].

The rate constants [k_a and k_d (s^{-1})], equilibrium constants (K_{eq}), and Gibbs energies (ΔG, kJ g^{-1} of sorbate) were calculated for four cycles of hydrocarbon adsorption–desorption on the external and internal surfaces of the sorbent by, respectively, Eq. (1) and the equations $K_{eq} = k_a/k_d$ and $\Delta G = -RT \ln K_{eq}$ with an accuracy of 0.1–0.3% (Fig. 1, 2).

The rate constants of sorption are close to those for a process controlled both kinetically and by diffusion, which is typical of spontaneous heterogeneous reactions. The rate constants of adsorption on the external surface are higher by 1–2 orders of magnitude than those of adsorption on the internal surface. The rate constants of equilibrium desorption from these polymer surfaces are close. The rate constants of HM desorption from the external surface of SP-18, determined in three cycles, are higher by approximately an order of magnitude than those of HM desorption from the internal surface. The total weight of hydrocarbons adsorbed in four cycles on the external polymer surface is higher than that on the internal surface. As the APP fraction in the PP structure increases, the rate constants of hydrocarbon adsorption–desorption on the external (sites of the first type) and internal (sites of the second type) surfaces grow (Figs. 1a, 1b). This behavior is the most pronounced for the sites of first type. The dependences of the rate of equilibrium sorption–desorption on both surfaces of all the

polymers examined on the number of the regeneration cycles pass through extrema. However, the shapes of these curves depend on the surface type and the polymer composition. The influence of the adsorbent composition and the number of sorption–desorption cycles on the sorption energy and the possibility of hydrocarbon sorption is illustrated by the dependence of the equilibrium constant and Gibbs energy of sorption, ΔG, on these parameters (Figs. 2a–2d). As seen from Fig. 2, the equilibrium constants of hydrocarbon sorption on the internal surface of SP-40 increase sharply after the third regeneration cycle and the Gibbs

Kinetic parameters of regeneration of the adsorbents at 293 K

	2	0.34	42.9	0.58	57.1
	3	0.59	42.0	0.80	58.0
PP	1	0.16	45.0	1.0	55.0
	2	0.41	49.5	0.80	50.5
	3	0.37	52.9	0.72	47.1

energy of adsorption becomes negative. At the same time, the parameters of sorption on the external surface change in the opposite direction (Fig. 2a). As a result, sorption on the internal, rather than external (as in the case of the first, second, and third sorption desorption cycles) surface becomes more energetically favorable. The dependences of the equilibrium constants and the sign of the Gibbs energy of adsorption on both surfaces of SP-18 and SP-5 sorbents (with lower APP content) on the number of adsorption cycles show oscillatory behavior (Figs. 2b, 2c).

Such a behavior of the equilibrium constant and of the Gibbs energy of hydrocarbon adsorption on SP-18 and SP-5 is clearly due to instability of the surface structure of these polymers under sorption conditions. An unusual compensation effect is observed in cyclic adsorption on SP-18 and SP-5. Three regions with similar energy states coexist on both surfaces in the adsorbent–adsorbate system. The sorption at the intersections of the dependences of K_{eq} and ΔG on the number of regeneration cycles is hindered as if it would occur on sites the first type. Small values of $-\Delta G$ for HM sorption on SP-18 and SP-5 indicate

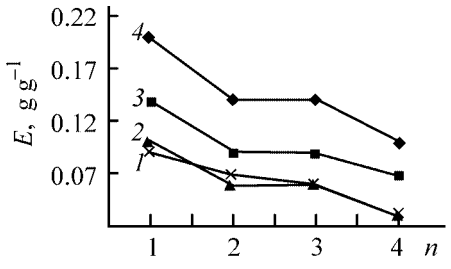

Fig. 3. Sorption capacity E of (*1*) PP, (*2*) SP-5, (*3*) SP-18, and (*4*) SP-40 vs. the number of regeneration cycles n of the adsorbent.

a negligible contribution of spontaneous adsorbent–adsorbate interactions to the sorption energy. The mechanism of HM sorption on PP differs fundamentally from that on SP-5, SP-18, and SP-40 (Fig. 2d). The energetically high absorption power of the external surface of PP remains constant in all the adsorption cycles. The structure of the PP surface, unlike that of SP-40 and especially SP-5 and CP-18, does not change during adsorption and desorption of hydrocarbons.

In contrast to the case of equilibrium adsorption of HM on PP, SP-5, SP-18, and SP-40, the dependence of the rate constants of nonequilibrium forced desorption of HM from the polymer surface on the number of desorption cycles is linear (see table). With increasing number of regeneration cycles, the kinetic parameters of equilibrium hydrocarbon adsorption on SP-18 and SP-40 (Figs. 1a, 2b) decrease and pass through extrema, whereas the rate constants of nonequilibrium forced desorption of HM from external (k_1) and internal (k_2) surfaces of these polymers increase linearly.

As the APP content in PP increases, the hydrocarbon desorption from the external surface increases, and that from the internal surface decreases. In each sorption–desorption cycle, hydrocarbon desorption from the external polymer surface decreases and that from the internal surface increases. Strongly sorbed hydrocarbons are accumulated on the internal surface (see table).

Thus, the mechanism of HM adsorption from the gas phase depends substantially on the APP content in the sorbent. Sorption of HM by polypropylene containing no APP in its molecular lattice is only enhanced on the external surface, whereas in the case of SP-5 and SP-18 the increase and decrease in sorption on external and internal surfaces alternate from cycle to cycle. In the case of SP-40, energetically favorable sorption on the external surface weakens after three cycles, whereas sorption on the internal surface strongly increases steeply in the fourth cycle. The dependence of K_{eq} and ΔG on the APP content and on the number of regeneration cycles indicates a gradual transformation of the heterogeneous process into a homogeneous process, i.e., mutual dissolution of hydrocarbons and gelatinous APP swollen in the PP structure after 3 sorption cycles on SP-40. Although HM sorption on the external PP surface is energetically favorable, the area of this surface is substantially smaller than that of the SP-40 surface. The influence of this parameter is clearly seen from the dependence of the sorption capacity (E) on the polymer composition and on the number of sorption–desorption cycles (Fig. 3). As the content of amorphous APP in the crys-

tal structure of PP increases, the sorption capacity of the adsorbent increases owing to an increase in its external surface area. The kinetic and thermodynamic parameters of equilibrium sorption of HM at 293 K on PP stereopolymers confirm the possibility of preparing adsorbents with required surface structure and surface area.

CONCLUSIONS

(1) Cyclic adsorption of a hydrocarbon mixture from the gas phase on the surface of polypropylene stereoisomers was studied. The sorption is an equilibrium and nonlinear process.

(2) To improve the sorbent composition, we determined the rate constants, equilibrium constants, and Gibbs energy of adsorption–desorption of a mixture of gaseous hydrocarbons on the external and internal surfaces of isotactic polypropylene containing 5, 18, and 40 wt % of atactic polymer in its molecular lattice.

(3) The rate constants of nonequilibrium desorption of hydrocarbons from the sorbents subjected to three equilibrium adsorption cycles were determined.

(4) The sorption capacity of the polymers for gaseous hydrocarbon increases with increasing content of the atactic polymer in polypropylene and decreases with increasing number of sorption–desorption cycles.

SORPTION AND ION-EXCHANGE PROCESSES

Comparison of Various Procedures for Regeneration of Activated Carbons Used for Recuperation of Ethyl Acetate

S. S. Stavitskaya, V. E. Goba, and N. N. Tsyba

Institute of Sorption and Endoecology Problems, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received November 15, 2001; in final form, October 2002

Abstract—The efficiency of various procedures (chemical, thermal, and electrochemical) for regeneration of activated carbons used for recuperation of ethyl acetate was studied. For each procedure, the optimal conditions were determined for complete regeneration of the sorption capacity of activated carbons without significant structural changes. The possibility of eliminating the interfering catalytic effect of carbon in its concomitant oxidation in the course of operation, causing loss of the target product, was evaluated.

Activated carbons (ACs) are widely used for deep purification and drying of various gases and liquids, for treatment of gas mixtures to isolate individual components, and in recuperation for recovering valuable products from industrial exhaust gases and liquids. Sorbents used in continuous processes, along with high sorption capacity and selectivity with respect to the target product, should be easily regenerated. Activated carbons belong to such type of sorbents.

Due to the expanding areas of AC application [1] and short supply of carbon sorbents, their regeneration is a topical problem.

Along with high sorption capacity and mechanical strength, activated carbons used for recuperation of vapors of organic solvents (benzine, ethanol, ethyl acetate, etc.) should have low retention power.

One of the main stages in regeneration of organic solvents by ACs is recovery of the sorbed material, usually performed by steam treatment [2]; simultaneously, the pores of sorbent are cleared, i.e., the sorbent is regenerated. A recuperation installation operates in such a mode (sorption-steam treatment) during many cycles, but, in the course of time, the sorption capacity of ACs decreases, especially due to filling of the sorbent pores with impurities contained in the target product and unremovable by steam treatment. Such a spent material should be substituted with fresh sorbent or regenerated. Hence, development of procedures for treatment of the spent ACs, providing complete regeneration of their sorption capacity, is very important. Despite considerable amount of published data on this problem [3–8], development of simple and efficient procedures for regeneration of spent carbons is still urgent, because they can provide significant economy of the resources, prolong the operation life of the deficient sorbents, and decrease the amount of waste.

EXPERIMENTAL

In this study, we analyzed the physicochemical properties and structural characteristics of the initial and spent Sorbon (Austria) and AR-V (Ukraine) carbons used in recuperation of ethyl acetate (common solvent used, e.g., in production of adhesive tapes) and the possibility of regeneration of these carbons by various procedures. The efficiency of various procedures (chemical, thermal, and electrochemical) [5–9] for regeneration of activated carbons used for ethyl acetate recuperation was compared. After a large number of operation cycles, the AC sorption capacity decreases by a factor of 2.5–3, and its further operation in the sorption-steam regeneration mode, with the regeneration performed directly in an adsorber, becomes inefficient. The experimental data show that the main contaminants, which block pores and decrease the sorption capacity, are varnishes, pigments, and other high-molecular-weight compounds and some volatile products.

The following desorbing agents were used: water, 0.05–3.00 M HCl, 1.00–5.00 M H_2SO_4, 1–5% ammonia, ethanol, acetone, and various mixtures of these.

The elution regeneration was performed under static conditions on bringing a 20-g potion of activated carbon in contact with a desorbing solution (100 ml) for 24 h, with intermittent stirring. After the treatment, the solid was separated from the solution, washed

1070-4272/02/7512-1956 $27.00 © 2002 MAIK "Nauka/Interperiodica"

with water, and dried. Then, the degree of regeneration of the sorption capacity was determined by measuring the limiting sorption volume W_s for benzene and ethyl acetate vapor [2]. Under similar conditions, solutions of oxidants ($KMnO_4$ and H_2O_2 in an acid medium) for chemical breakdown of sorbed compounds were studied. We also studied the procedure for electrochemical regeneration, presented in [7], which involves treatment of spent carbon with a mixture of sulfuric acid and hydrogen peroxide (3.5 : 0.5 wt % ratio) at 80°C for 2 h at anodic current density of 40 A m^{-2}. The silver chloride reference electrode and platinum anode and cathode were used. We also performed common thermal regeneration of spent carbons in a CO_2 flow; for this purpose, AC was placed in a quartz reactor and heated to 400–900°C for 1–5 h.

The data on regeneration of the spent activated carbon of Sorbon type by various procedures are listed in Table 1. As seen, elution regeneration does not fully restore the sorption capacity of carbon. Even triple treatment with water at the room temperature is virtually inefficient. Desorption grows with increasing temperature, especially so in the case of boiling. The W_s value for C_6H_6 increases from 0.2 to 0.5 $cm^3\ g^{-1}$. The highest efficiency of carbon boiling in water, compared with steam treatment in absorbers, is probably due to stirring and to other physical factors. The sorbent pores are also cleaned after treatment with acids, alkalis, and organic solvents. These data are in agreement with the existing concepts and with published data on the properties of ACs contaminated with organic impurities. It should be noted that, in our case, no significant difference was found in regeneration performance between compounds of varied nature. In all cases, W_s for benzene and ethyl acetate are about the same. Some mixtures, especially ethanol–acetone and ethanol–acetone–ammonia, are more efficient than the individual compounds. However, in general, all the eluents studied give similar results (Table 1), and each of them can be used for regeneration of spent activated carbon. Hence, selection of an appropriate reagent is determined by local requirements taking into account the possibility of further use (utilization) of the recovered compounds and permissible amount of industrial wastes.

When there is no need in complete recovery of the sorbed compounds, oxidative degradation procedures with breakdown of these compounds and their profound oxidation may be preferable. For this purpose, we studied the effect of oxidants (hydrogen peroxide and potassium permanganate in acid media). As seen from Table 1, after such a treatment the sorption capacity of activated carbons is restored by 30–75%.

Table 1. Regeneration of Sorbon activated carbons by various procedures

Regenerating agent	W_s, $cm^3\ g^{-1}$

400	0.44	0.43
500	0.45	0.44
600	0.46	0.44
700	0.46	0.45
800	0.48	0.47
900	0.53	0.47

To increase the regeneration efficiency, combined procedures should be probably used. For example, the highest, nearly quantitative regeneration was found after treatment with hydrogen peroxide in a sulfuric acid solution, with subsequent electrochemical treatment according to the procedure given above and in [7]. The same result was attained after thermal treatment at high temperatures in a CO_2 flow, when

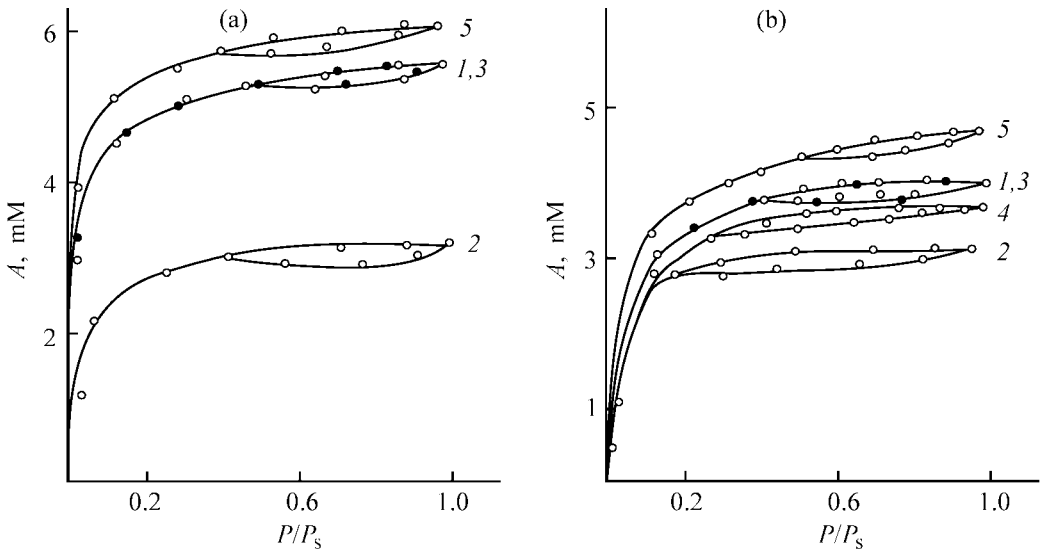

Fig. 1. Isotherms of sorption–desorption *A* of benzene on (a) Sorbon and (b) AR-V carbons: (*1*) initial carbons, (*2*) after regeneration with ethyl acetate, (*3*) after electrochemical treatment, and (*4, 5*) after thermal regeneration. (P/P_s) Relative pressure, where *P* is the equilibrium adsorbate pressure (mm Hg) and P_s is the pressure of the saturated adsorbate vapor (mm Hg). Thermal treatment conditions: (*4*) 440°C, 1 h; (*5*) 900°C, 5 h.

the sorbed compounds burned out (Table 1). We found in our experiments that the results of regeneration obtained for AR-V activated carbon are similar to those given in Table 1 for activated carbon of Sorbon type.

Using a vacuum-adsorption unit [2], we measured sorption–desorption isotherms of benzene on the initial, spent, and regenerated activated carbons to analyze possible changes in the structure of regenerated carbons (Figs. 1a, 1b). The isotherm of benzene sorption on the Sorbon activated carbon lies higher than that on AR-V carbon, indicating higher sorption capacity of this carbon, whereas the isotherms of the spent samples lie significantly lower. As seen, in some cases, the isotherms corresponding to the initial and regenerated samples are rather close, and, for high-temperature regeneration, the sorption capacity of regenerated carbons is even greater.

Comparison of the structural characteristics determined from these data (namely, total pore volume W_s, volume of micro- W_{mi} and mesopores W_{me}, and specific surface area S_{sp} [2]) shows that these values and their ratios vary only slightly, depending on the procedures and conditions of regeneration, indicating

	CO_2:				
	400°C	0.490	0.280	0.210	367
	900°C	0.555	0.308	0.247	389

no profound structural changes (Table 2). Upon high-temperature treatment (800–900°C), the total pore volume and the volumes of micro- and mesopores slightly increase, whereas the specific surface area of activated carbons treated at these temperatures is nearly 2 times higher as compared to spent carbons. If such an increase in S_{sp} is undesirable, thermal treatment can be performed at lower temperature but for longer time (Fig. 1b; Tables 1, 2). As seen, high-temperature treatment of Sorbon and AR-V carbons at 900°C in a CO_2 atmosphere restores completely their sorption capacity. Moreover, such a treatment causes additional activation, improving the structural properties of the sorbents.

Our experimental data show that activated carbons, especially Sorbon carbon, are oxidized in prolonged operation, and the concentration of the surface acidic groups reaches 0.6–1.2 mg-equiv g^{-1}. These groups can catalyze ethyl acetate hydrolysis [10], causing its undesirable loss. To eliminate this reaction, we studied the possibilities of inhibition of the carbon sorbent oxidation. It was found [11] that preliminary treatment of the carbon surface with certain additives can strongly affect carbon oxidation. For this purpose, carbons were impregnated with solutions of magnesium or calcium sulfates of various concentrations. Then, the impregnated carbon was subjected to common oxidation with atmospheric oxygen at 400–450°C [11].[1]

It was found that unmodified carbons can be easily oxidized, i.e., become catalytically active, whereas the carbons impregnated with even insignificant amounts of calcium or magnesium salts are stable to oxidation under the similar conditions. Thus, preliminarily impregnation of activated carbon containing surface acidic groups with calcium or magnesium salts is advisable to eliminate their interfering catalytic effect in the course of ethyl acetate sorption.

[1] Selection of a procedure for regeneration of carbon sorbents strongly depends on its required performance characteristics. The cost of the installation for chemical regeneration is rather low as compared to that of thermal treatment. Certain losses in sorption capacity after chemical regeneration are outweighed by its relative simplicity. Thermal regeneration requires more complex equipment. In our opinion, electrochemical regeneration is rather efficient and promising.

CONCLUSIONS

(1) Oxidative degradation procedure for regeneration almost completely restores the sorption capacity of activated carbons used in recuperation, without significant structural changes. The resulting regenerated carbon can be used for recharging the absorbers for subsequent many-cycle operation with current steam regeneration.

(2) The experimental data obtained allow selection of most appropriate regeneration procedure for specific production.

(3) Optimal procedures of sorbent regeneration improve the performance characteristics of absorption installations, in particular, in production of adhesive tapes.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation and Antimicrobial Properties of Chlorinated Carbon Materials

S. S. Stavitskaya, V. E. Goba, and N. T. Kartel'

Institute of Sorption and Endoecology Problems, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received March 25, 2002

Abstract—Antimicrobial preparations based on anthracite and carbon fabric and prepared by chlorination were studied as influenced by the moisture content of sorbent, its bulk weight, chlorination temperature, etc.

Preparation of efficient antimicrobial materials based on solid sorbents, polymers, and fibrous materials is an urgent problem. Such materials can be obtained as granules, powders, pellets, plates, etc. They are especially important for local water treatment and can be used in development of new procedures for the water treatment which would be more progressive than the reagent water treatment, etc.

Materials of this kinds both bactericidal,[1] ensuring death of bacteria upon contact, and bacteriostatic, hindering growth and reproduction of bacteria, antimicrobial composites are based on cellulose and some other fibers, polymers, and activated carbons [1–3]. The antimicrobial efficiency is imparted either by impregnation of appropriate materials with active chemical preparations or by chemical modification of the preparation, introduction of appropriate functional groups, cations, or anions into the sorbent (fiber) skeleton or surface. In the latter case, stronger grafting of antimicrobial material to the support is achieved.

Various antimicrobial modifying agents (silver, copper, and mercury salts, antibiotics, heteroorganic compounds, etc.) have been studied [1]. It has been found that the antimicrobial activity is largely determined by the type of bonding between the modifying agent and support, the highest antimicrobial activity being typical of composites with ionic, labile covalent, or coordination bonding, whereas in the case of strong covalent bonding no antibacterial activity is observed.

The aim of this study was to prepare water disinfectants based on charcoal and other carbon materials (activated carbons, carbon fibers) and to evaluate their antimicrobial effectiveness. It should be noted that the antibacterial activity has been observed previously for pure activated carbons [2, 3], which is probably due to sorption of bacteria onto the developed sorbent surface. To improve the antibacterial effect, activated carbon or carbon fiber was impregnated with drugs (e.g., antibiotics) or some other appropriate compounds [2, 4]. Activated carbon with silver additives is used in the known domestic Rodnik unit for additional purification and disinfection of water, in mobile compact installations, and in special-purpose filters; activated carbons impregnated with silver and other antimicrobial additives are widely used for water treatment on airplanes and ships [2]. The possibility of preparing antimicrobial materials by chlorination of anthracite and other coals has also been studied. As known [5], chlorination is the most widely used procedure for water disinfection. The disinfection effect of chlorine is based on oxidation and breakdown of compounds in the photocytoplasm of bacteria, which causes their death. Water is often treated with gaseous chlorine or compounds containing active chlorine, e.g., chloride lime, hypochlorite, chloramine, etc. Thus, it is believed that the chlorine sorbed or grafted on the carbon surface, or possibly incorporated in the surface compounds or skeleton would also exhibit antimicrobial activity. No published data on biological (bactericidal, bacteriostatic) activity of chlorinated carbon materials could be found. At the same time,

[1] According to "Regulations concerning Protection of Surface Waters from Pollution," water in sources of potable and public water consumption must contain no pathogenic organisms, and wastewaters should be disinfected after treatment. The permissible content of Saprophyte and Escherichia coli in potable water must not exceed 100 bacteria ml^{-1} and 3 bacteria l^{-1}, respectively [GOST (State Standard) 2374–73 "Potable Water"].

the high sorption capacity of activated carbons for chlorine is well known, and even during World War I these materials were used in respirators [2]. Moreover, it has been found [5] that the sorption capacity of carbon materials increases after their chlorination.

In our study, we analyzed for the first time activated anthracite; in our previous experiments we used charcoals commercial with varied surface nature, activated (BAU) and oxidized charcoal (DOU) [4], and AUT carbon fabric.

The chlorination was performed with gaseous chlorine obtained from a reaction of concentrated hydrochloric acid with crystalline potassium permanganate; in all the tests, 100 ml of HCl was added dropwise to 100 g of $KMnO_4$. The chlorine formed was passed through a carbon material (anthracite, charcoal, or fabric) placed in a standard vessel (column), when the experiment was performed at room temperature, or in a tubular reactor, when the experiments were performed on heating to 200–950°C with a furnace. The amount of carbon material was different for each treatment; it was determined by the reactor capacity and bulk weight of the material.

After being passed through a reactor, unchanged chlorine was fed into a vessel with ice-cooled 1 M NaOH. The amount of chlorine sorbed by the carbon material was evaluated from the difference of the concentrations of chlorine in the blank test (without carbon material) and after reaction with a weighed amount of a support. The initial concentration of chlorine was 0.62 mol l^{-1}; both weight and volume concentration of chlorine in the carbon material were estimated.

The time of chlorination varied because of the different reaction rates in each particular case; it was determined by the fact that equal amounts of chlorine were used in each experiment.

Along with chemical analysis, the increase in the coal weight after chlorination was also determined. These data were used only for tentative comparison of the results, because the increase in the material weight may be due to both sorbed chlorine and water vapor, especially when a preliminarily dried carbon material is used.

We prepared more than 20 samples of chlorinated carbons, with the type of carbon, sorbent moisture content (wet, air-dry, and dried at high temperature), and chlorination temperature (room, 200, 450, 650, and 950°C) varied. The preparation conditions of the samples are listed in Table 1.

* Conditions of sample preparation are listed in Table 1.

The data on the sorption capacity for chlorine, recalculated to the weight and volume of the carbon material, are listed in Tables 2 and 3. As seen, sorption of chlorine is rather high, but depends strongly on the experimental conditions. The smallest sorption (102 mg g^{-1}) is observed for carbon fabric; anthracite samples exhibited high sorption capacity (*A* = 300–550 mg g^{-1}), similar results were recorded for commercial charcoals.

As seen from Table 2, the amount of sorbed chlorine increases, (from about 300 to 350 mg g^{-1}) with increasing treatment temperature, which indicates chemical interaction of chlorine with carbons, and the mechanism of such an interaction may be rather complex [6, 7]. Various processes (e.g., chemical sorption, substitution reactions, addition reactions, etc.) may proceed simultaneously; the composition of the carbon material and chemical nature of the surface can also affect the process.

Taking into account the possible use of chlorinated carbons as antimicrobial materials, we evaluated (even if approximately) the strength of chlorine binding in the samples of carbon materials prepared. For this purpose, we determined the amount of active chlorine easily removed from the surface with water (Table 4); 1-g sample was shaken with distilled water (100 ml) for 1.5 h , then the solid phase was filtered off, and the concentration of chlorine in the filtrate was determined [8]. In some cases, we used 0.1-g samples and 50-ml water portions (conditions similar to those when the antimicrobial activity was determined). It should be noted that the amount of chlorine desorbed

Table 4. Desorption of chlorine from chlorinated carbons (carbon sample m = 1 g, water portion V = 100 ml, contact time τ = 1.5 h)

* Carbon sample m = 0.1 g, V = 150 ml.

from samples of chlorinated charcoals (BAU, DOU) and carbon fabric is 10–20 times smaller compared to that in the case of chlorinated anthracite (Table 4).

Moreover, we determined in some cases the rate of chlorine desorption from the carbons (see figure); the desorption was effected by triple treatment of a sample with distilled water (3×200 ml).

Our results showed that, under such conditions, only insignificant amount of chlorine is desorbed; however, the resulting concentration of chlorine in the solution is comparable with that used in at common water treatment. Actually, the initial concentration of chlorine for efficient water disinfection is 1–10 mg l^{-1} [8], and after the reaction with bacteria and impurities, the residual concentration decreases to 0.3–0.5 mg l^{-1}.

As seen from the figure, most of weakly bound chlorine is removed after first treatment with water, and then its amount decreases fast.

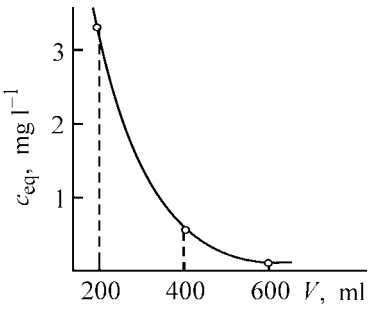
We also studied mixed samples of carbon materials, in which a chlorinated sample was diluted with pure anthracite in various ratios to decrease their activity and amount of desorbed chlorine (sample nos. 10, 11, etc; Table 1), and a sample three times washed with distilled water (sample no. 19).

The antimicrobial activity was evaluated with respect to *E.coli* K12, because the coli-index (content of bacteria per liter of water) is a standard characteristic of the water quality [2, 8].[2]

Data on the antimicrobial properties of the samples studied are listed in Table 3. As seen, unmodified activated anthracite exhibits zero antimicrobial activity; a similar behavior is observed for carbon fabric. At the same time, almost all samples of chlorinated anthracite and charcoals possess strong disinfection activity. Dilution of chlorinated samples with straight anthracite decreases the recovery of available chlorine into water (Table 4) and completely eliminates antimicrobial activity (Table 3).

Correlation of the disinfection effect with the amount of the sorbed and desorbed weakly bound chlorine (Table 4) shows no direct dependence between these parameters. In our opinion, sample nos. 2, 4, 7, 12 cannot be used in practice because of the strong smell of chlorine.

Some samples, including those chlorinated at high temperatures (e.g., sample nos. 3, 15 and charcoals BAU and DOU), possess the strongest disinfection activity and liberate insignificant amount of chlorine into solution.



Chlorine desorption after triple treatment with water (3×200 ml) of anthracite sample no. 16; m = 15 g and τ = 15 min. (c_{eq}) Equilibrium chlorine concentration and (V) distilled water volume.

[2] These tests were performed at the Kiev Research Institute of General and Public Hygiene, Kiev, Ukraine.

CONCLUSIONS

(1) Chlorinated carbon materials are promising antimicrobial agents. Several samples with strongly bound chlorine were prepared, which possess high antimicrobial activity with respect to *E.coli* K12 (bacteria commonly used in evaluation of hygienic requirements); the amount of chlorine desorbed from these materials into water is close to that satisfying sanitary requirements to potable water (GOST 2874–54).

(2) In some cases, chlorinated anthracene and charcoals can be used to replace water treatment with gaseous chlorine, which is especially important in water treatment at remote installations; their use does not require any special equipment, the necessary concentrations can be easily obtained, etc. Some of chlorinated anthracite samples exhibit acceptable (with respect to sorption capacity, stability, energy consumption, cost, antimicrobial activity, etc.) properties.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Cathodic Deposition of Copper–Indium Alloy from Trilonate–Tartrate Electrolyte

Abstract—The results obtained in studying the deposition of copper–indium alloys from a trilonate–tartrate electrolyte are presented. The conditions for joint discharge of copper and indium ions, the optimal composition of the electrolyte, and the electrolysis mode ensuring deposition of protective and decorative gold-colored coatings are determined.

It is known that the factors determining the possibility of joint electrochemical deposition of two metals at their certain ratio in the alloy are the following: equilibrium potentials of these metals and polarizations at discharge of the corresponding ions at the cathode from a given electrolyte, concentration ratio of ions of codeposited metals and their ability to form complex compounds, presence of surfactants in the electrolyte, overvoltage of hydrogen evolution at the alloy being deposited, electrolysis conditions (temperature, current density, stirring), etc.

The standard potentials of copper and indium (+0.337 and –0.34 V) differ to such an extent that mainly copper is deposited at the cathode from solutions of simple salts of these metals. With complex salts, e.g., trilonates or tartrates, used instead of simple salts, conditions can be chosen (modifier concentration, current density, electrolyzer potential, etc.), which ensure joint discharge of copper and indium ions.

It is known that Trilon B and potassium-sodium tartrate form with copper ions complex compounds $Na_2[CuR]$ (R is the acid residue of ethylenediaminetetraacetic acid) and $KNa[C_4O_6H_2Cu]$, whose instability constants are 1.38×10^{-19} and 7.3×10^{-20}, respectively [1]. The trilonate electrolyte enables electroplating of high-quality copper coatings. It has been established experimentally [2] that indium is mainly present in a solution of the Seignette salt, $NaK[C_4H_4O_6]$, in the form of an $In[C_4H_4O_6]^{2-}$ anion, whose instability constant is 3.2×10^{-8}.

Data on electroplating of copper, indium, and their alloys from a tartrate electrolyte were summarized in [3]. It was noted that the cathodic deposits obtained in this case contain a small amount of indium (up to 8%), have good antifriction properties, and their quality is high [3, 4].

This communication present the results obtained in studying the reduction of copper and indium ions from trilonate–tartrate electrolytes. The conditions for joint discharge of these metal ions, the optimal composition of the solution, and the electrolysis mode for electroplating of protective and decorative gold-colored coatings based on copper–indium alloys from the above complex electrolytes were determined.

EXPERIMENTAL

The reduction of copper(II) and indium(II) ions was studied by the potentiodynamic method in a YASE-1 standard electrochemical cell equipped with a magnetic stirrer. A copper plate served as the cathode. The anodes were fabricated from electrolytic copper or In-00 indium. The electrodes were polarized with a PI-50-1.1 potentiostat at 20–25°C. The potential sweep rate was 5×10^{-3} V s^{-1}. The cathode potential was recorded relative to a silver chloride reference electrode. Main components of the plating electrolyte (g l^{-1}): 32 NaOH, 25 Trilon B, 8 $CuSO_4 \cdot 5H_2O$, and 5 $In_2(SO_4)_3$. The content of the Seignette salt in the solution was varied within 0–320 g l^{-1}.

1070-4272/02/7512-1965 $27.00 © 2002 MAIK "Nauka/Interperiodica"

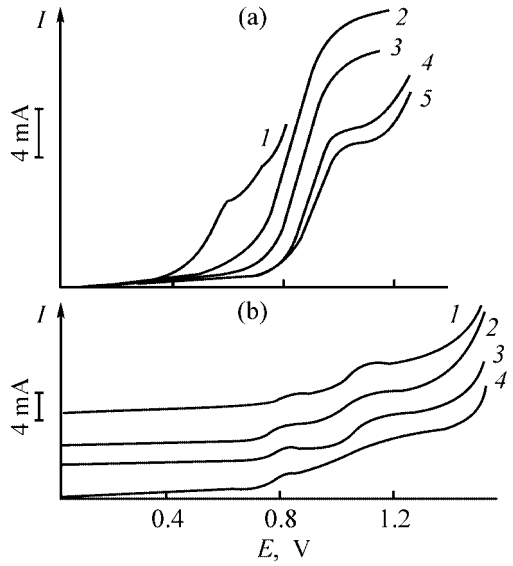

Fig. 1. Polarization curves for (a) copper and (b) indium deposition from electrolyte. (*I*) Current and (*E*) potential. $NaK[C_4H_4O_6]$ concentration (g l^{-1}): (*1*) 0.1, (*2*) 80, (*3*) 160, (*4*) 240, and (*5*) 320.

The voltammetric curves shown in Fig. 1a illustrate the cathodic reduction of copper ions. Curve *1* characterizes the discharge of trilonate complexes of this metal. A solution contained no indium sulfate and was agitated with a magnetic stirrer. It can be seen that the potential of copper reduction from the electrolyte of a given composition is 0.43 V.

Curves *2–5* in Fig. 1a were measured in a solution containing Seignette salt $NaK[C_4H_4O_6]$. It can be seen that the potential of copper reduction (0.68–0.8 V) shifts toward the electronegative region with increasing $NaK[C_4O_6H_4]$ concentration.

The polarization dependences measured in a solution containing (g l^{-1}): 5 $In_2(SO_4)_3$, 32 NaOH, 25 Trilon B, and 0–320 $NaK[C_4H_4O_6]$, are plotted in Fig. 1b. The data obtained suggest that tartrate complexes with indium(III) are less strong. The potential of indium reduction lies within 0.7–0.75 V. This range of potentials corresponds to joint deposition of copper and indium from a solution containing these metal ions and Trilon B and $NaK[C_4H_4O_6]$, simultaneously, as complexing agents.

Also, the influence of various factors on the quality of galvanic coatings was studied. The main parameter determining the color and quality of a deposit is the cathodic current density. Depending on its value, the color of the alloy deposited at the cathode varies from pinkish (at j_c = 0.05–0.2 A dm^{-2}) to golden-like (at j_c = 0.35–0.6 A dm^{-2}). Electrolysis at current densities exceeding 0.6 A dm^{-2} yielded a gray deposit turning darker in the course of time.

The anodic current density is also the important parameter of the process, which affects the deposit quality and the electrolyte efficiency. The dependence of the current efficiency by copper, η_a, on j_a is as follows:

j_a, A dm^{-2}	0.05	0.1	0.15	0.2	0.3
η_a, %	164	133.6	102	100.7	100.3
j_a, A dm^{-2}	0.4	0.5	0.6	0.8	1.0
η_a, %	100.7	42.5	7.7	1.9	0.73

At current densities in the range 0.15–0.40 A dm^{-2} the anodic current efficiency approaches 100%, which ensures stable dissolution of copper anodes. With j_a increasing further, η_a decreases drastically (to nearly zero). This indicates that, under these conditions of the electrolysis, the anode is virtually completely passivated and behaves as insoluble. At current densities lower than 0.15 A dm^{-2}, the current efficiency increases sharply. At j_a = 0.05 A dm^{-2}, η_a is as high as 164%, which points to formation of single-charged copper ions at the anode, which strongly affect the cathodic process. Galvanic coatings deposited under these conditions are matte pink, the anodes turn dark, and a red copper(I) oxide deposit is formed. According to the experimental data obtained, the optimal anodic current density is within 0.15–0.40 A dm^{-2}.

The $In_2(SO_4)_3$ concentration strongly affects the color and quality of a cathodic deposit. Under conditions of a stirred solution, the optimal $In_2(SO_4)_3$ concentration is within 2.5–5.0 g l^{-1}. Electrolysis of solutions containing more than 5 g l^{-1} of this salt yields are matte light yellow deposits. At $In_2(SO_4)_3$ concentration lower than 2.5 g l^{-1}, pinkish galvanic coatings are deposited on the cathode.

The concentration of $CuSO_4$ in the electrolyte affects the color of a cathodic deposit to a lesser extent; however, at concentrations lower than 8 g l^{-1}, the range of permissible cathodic current densities is narrowed to 0.1–0.2 A dm^{-2}, which makes the process unproductive. At $CuSO_4$ and $In_2(SO_4)_3$ concentrations higher than 12 and 3.5–5.0 g l^{-1}, respectively, the alloy deposited on the cathode has pink color.

The effect of $NaK[C_4H_4O_6]$ content in solution on joint deposition of copper–indium alloys was studied within the range 80–320 g l^{-1} of $NaK[C_4H_4O_6]$. It was found that at $NaK[C_4H_4O_6]$ concentrations lower than 100 g l^{-1}, a white deposit of basic indium salts was precipitated from the electrolyte. Raising the con-

centration of sodium-potassium tartrate to 160 g l^{-1} has no effect on the color and quality of the alloy deposited at the cathode. With the concentration of sodium-potassium tartrate increasing further, the range of current densities ensuring a prescribed coating composition and color becomes narrower.

The optimal Trilon B concentration, ensuring cathodic deposition of high-quality gold-colored coatings containing no less than 20% indium, is 25–30 g l^{-1}. Trilon B not only ensures joint discharge of indium and copper ions, but also hinders formation in the electrolyte of sparingly soluble compounds of these metals and concomitants, which appear in the course of prolonged electrolysis (e.g., as a result of exchange reactions between the support and the solution).

The NaOH concentration of 30–35 g l^{-1} leads to an electrolyte pH within 13.4–13.6 and ensures stability of indium compounds soluble in the electroyte. The pH of an electrolyte is the key parameter responsible for its stable operation and formation of a high-quality cathodic deposit.

It was found that the quality of a galvanic coating is largely dependent on the bulk current density. It was established that at a surface current density at the cathode, j_c = 0.5 A dm^{-2}, the bulk current density in a bath must not exceed 1.5–1.6 A l^{-1}. For the electrolyte to have higher electrical conductivity and throwing power, it must contain 15–30 g l^{-1} Na_2SO_4. Simultaneous introduction of glycerol (15–25 g l^{-1}) and gelatin (0.05–0.2 g l^{-1}) into the electrolyte ensures cathodic deposition of lustrous coatings.

The results of the study performed show that the optimal content of components in the electrolyte for deposition of lustrous gold-colored copper–indium alloy coatings is as follows (g l^{-1}): 8–12 $CuSO_4 \cdot 5H_2O$, 2.5–5.0 $In_2(SO_4)_3$, 100–160 $NaK[C_4H_4O_6] \cdot 4H_2O$, 25–30 Trilon B, 30–35 NaOH, 15–30 Na_2SO_4, 15–25 glycerol, and 0.05–0.2 gelatin.

Electrolysis mode: cathodic current density 0.4–0.6 A dm^{-2}, anodic current density 0.15–0.40 A dm^{-2}, temperature 20–25°C, and electrolyte pH 13.4–13.6. The electrolyte should be stirred during electroplating.

CONCLUSION

An electrolyte containing tartrate and trilonate complexes of indium and copper and ensuring formation of lustrous low-porosity gold-colored coatings strongly adherent to a carbon steel support was developed. The alloy deposited from the electrolyte contains 79–81% copper and 19–21% indium. The electrolyte is easy to prepare and stable during operation; it was tested in industrial conditions. It is recommended for deposition of protective decorative coatings.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Deposition of Vanadium(V) Oxide from Solutions in the Presence of Nickel Ions

V. M. Nagirnyi, R. D. Apostolova, A. S. Baskevich, and E. M. Shembel'

Ukrainian State University of Chemical Engineering, Dnepropetrovsk, Ukraine

Received May 13, 2002

Abstract—The preparation conditions, properties of the deposits obtained, and the nature of anodic processes occurring in the course of electrolytic deposition of vanadium oxide in the presence of nickel ions from solutions of oxovanadium and nickel sulfates were studied.

Electrolytic deposition of vanadium(V) oxide from acid solutions (pH ~2.0) of oxovanadium sulfate and $NiSO_4$ is of interest for studying the possibility of joint anodic deposition of vanadium and nickel oxides to obtain the corresponding V–Ni oxide system. Complex vanadium–nickel oxide systems with enhanced electrochemical activity are formed by anodic deposition of vanadium oxide from solutions of oxovanadium sulfate in the presence of nickel ions [1]. It is also essential that, unlike vanadium oxide, which is deposited on the anode from oxovanadium sulfate solution with current efficiency of about 40% [2], anodic oxidation of nickel(II) under the standard conditions does not give nickel oxide by itself in quantitative yield. At the same time, such a reaction is permissible thermodynamically in accordance with the equation [3]

$$2Ni^{2+} + 3H_2O - 2e \rightarrow Ni_2O_3 + 6H^+,\ E^0 = 1.84\ V. \quad (1)$$

Therefore, it would be expected that, if anodic oxidation by reaction (1) occurs in parallel with of oxidation of oxovanadium ions

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+,\ E^0 = 1.84\ V, \quad (2)$$

then more favorable energy conditions can be attained, at which reaction (1) proceeds irreversibly to give the corresponding modifying phase in a mixed anodic product.

This study is concerned with the nature of the anodic processes occurring in the course of electrolytic deposition of vanadium(V) oxide in the presence of nickel ions and the conditions for preparation of anodic deposits with properties (outward appearance, surface micro- and macrostructure, compactness) and composition close to those prescribed.

As objects of study served mixed solutions of oxovanadium and nickel sulfates with total concentration of 40–45 g l^{-1} at concentration ratios (hereinafter, V : Ni) of 5 : 1, 3 : 1, 1 : 1, 1 : 3, and 1 : 5 (the first digits stand for the main component, i.e., oxovanadium sulfate, and the second, for the modifying component). The solutions were prepared from reagents of pure and analytically pure grade and distilled water. Prior to use, the solutions were subjected to additional electrolytic treatment to remove metal impurities. The electrolysis was performed in a 200-ml temperature-controlled glass cell. Deposits were obtained in the form of compact coatings on two sides of smooth plate-like $10 \times 10 \times 0.3$-mm anodes made of 12Kh18N9T steel. For X-ray structural analysis, 0.15–0.20-g dispersed deposits were obtained on a smooth plate of technical-grade titanium with $S_a : S_c$ ratio of 1 : 5. The tests were performed at 85°C and pH 1.9–2.2, which were chosen on the basis of data from [2, 4]. The efficiency of the anodic process was estimated from the deposition rate V_{dep} (mg cm^{-2} h^{-1}) and conventional current efficiency CE_{con} (%) by the anodic product, on the assumption that the whole useful current is spent for formation of V_2O_5 vanadium oxide [electrochemical equivalent 3.4 g $(A\ h^-)^1$]. This assumption is justified in this case, since nickel oxide Ni_2O_3 has nearly the same electrochemical equivalent [3.02 g $(A\ h)^{-1}$]. Despite the incorrectness of the quantity thus defined, CE_{con} shows how the anodic process varies with electrolysis conditions with better reliability. The amount of the "modifying" phase (wt %) in the anodic deposits was estimated by a simplified procedure consisting in dissolution of a deposit in a H_2O_2 solution, alkalinization with NaOH to pH 9.0, settling, and subsequent washing, drying, and weighing of the $Ni(OH)_2$ sediment formed, with

1070-4272/02/7512-1968 $27.00 © 2002 MAIK "Nauka/Interperiodica"

the result recalculated to Ni_2O_3. Polarization curves were measured in a U-shaped cell with a 12Kh18N9T steel anode (S_a = 1 cm^2, $S_a : S_c$ = 1 : 5) under the above electrolysis conditions at I_a = 0.5–50 mA cm^{-2}. The potentials were measured relative to a silver chloride reference electrode (E = +0.225 V) with a ShCh-4315 digital voltmeter and then recalculated to the hydrogen scale. The phase composition of the deposits was determined qualitatively and approximately evaluated quantitatively (for selected samples) by comparing X-ray diffraction data (DRON-2 diffractometer) with the standard case, using a calibration plot [5]. The surface microstructure and morphology of the deposits were studied on 1.5–2.5-μm-thick films, using a digital nanoscope.

Figure 1 shows the deposition rate V_{dep} and the conventional current efficiency CE_{con} (%) by the anodic product as functions of the current density in anodic deposition of vanadium oxide in the presence of nickel ions from the above solutions with varied V : Ni concentration ratio. At V : Ni ≥ 1 these dependences are characterized by a pronounced rise in the deposition rate in the range I_a = 5–10 mA cm^{-2}, a limiting plateau at higher current densities, and only slight variation of the deposition rate with the current density increasing further. The last kind of behavior is also observed at V : Ni < 1 in the V_{dep}–I_a dependences over nearly the entire range of the current densities studied. The CE_{con}–I_a dependences are characterized by a pronounced fall in the CE_{con} by the anodic product in the range I_a = 5–15 mA cm^{-2}, with its subsequent gradual decrease to a certain minimum value with increasing current density. It can be seen that the efficiency of the anodic process decreases markedly in the presence of nickel ions. Even at their relatively low concentration in solution (V : Ni = 5 : 1), V_{dep} and CE_{con} are lower by approximately a factor of 1.5 than the corresponding values for a "straight" oxovanadium sulfate solution under comparable electrolysis conditions. This points to considerable energy hindrance to the concurrent reaction (1) of nickel ion oxidation in the anodic process occurring together with reaction (2), which makes higher the rate of the simultaneous oxygen evolution. The rise in the relative concentration of nickel ions in solution is not accompanied by any pronounced increase in the rates of codeposition of the modifying component and formation of the corresponding phase in the anodic deposit. This is confirmed by the weak dependence of the deposit formation rate on current density at V : Ni < 1 and by its relatively high values at V : Ni = 1 : 1, which is possibly due to predominant vanadium oxide deposition in the entire range of current densities studied. The same conclusion follows from the dependence of the concentration of the modifying nickel oxide phase in the anodic deposit on the V : Ni ratio in solution (Fig. 2). Comparative estimate shows that, even at V : Ni = 1 : 5, the limiting content of nickel oxide in the anodic deposits does not exceed 20 wt % (in terms of Ni_2O_3). The current efficiency by the anodic product, corresponding to the above V : Ni ratio, is the lowest (2.5%), and the deposits obtained under the corresponding conditions have unstable composition and quality. Probably, this is due to disturbance of the ion balance in the near-electrode layer, caused by the increasing influence of concurrent redox reactions.

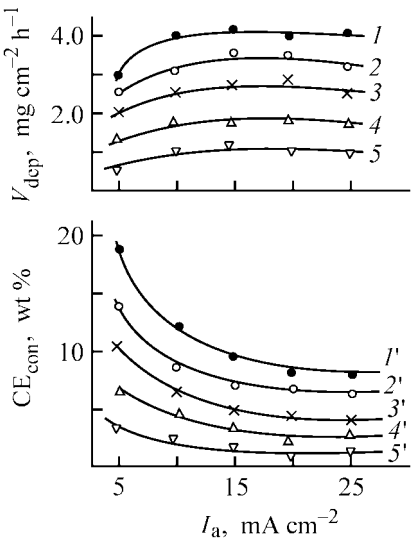

Fig. 1. Dependences of (*1*–*5*) deposition rate V_{dep} and (*1'*–*5'*) conventional current efficiency by the anodic product, CE_{con}, on the current density I_a in electrolysis of solutions of oxovanadium and nickel sulfates with total concentration of 40–45 g l^{-1}. Temperature 85°C, pH 2.0–2.2. V : Ni concentration ratio: (*1*, *1'*) 5 : 1, (*2*, *2'*) 3 : 1, (*3*, *3'*) 1 : 1, (*4*, *4'*) 1 : 3, and (*5*, *5'*) 1 : 5.

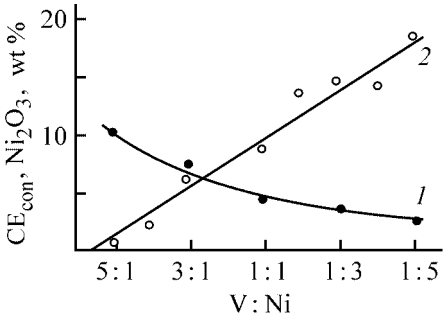

Fig. 2. Dependences of (*1*) conventional current efficiency by the anodic product, CE_{con}, and (*2*) the content of the Ni_2O_3 modifying phase in the anodic product on the ratio V : Ni of oxovanadium and nickel sulfate concentrations in electrolysis of solutions with total concentration of the sulfates of of 40–45 g l^{-1}. Temperature 85°C, pH 2.0–2.2, I_a = 10 mA cm^{-2}.

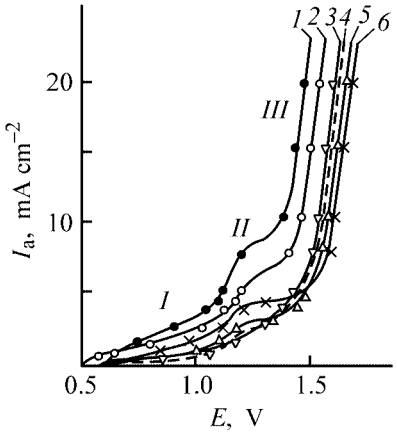

Fig. 3. I_a–E curve describing anodic deposition of vanadium oxide in the presence of nickel ions from solutions of oxovanadium and nickel sulfates. Temperature 85°C, pH 2.0, total sulfate concentration 40 g l^{-1}. V : Ni concentration ratio: (*1*) 5 : 1, (*2*) 3 : 1, (*3*) 0 : 1, (*4*) 1 : 5, (*5*) 1 : 3, and (*6*) 1 : 1.

The decrease in the rate of anodic deposit formation, occurring when the part played by the concurrent reaction (1) of nickel ion oxidation in the total anodic process becomes more pronounced, leads to higher rate of oxygen evolution, which markedly affects the kinetics of the anodic process. This is confirmed by analysis of the voltammetric I_a–E characteristics obtained for the processes studied at various V : Ni ratios in solution, whose appearance and relative positions are largely determined by the rate of jointly occurring discharge and oxygen evolution. The corresponding dependences are characterized by steplike curves with two ascending portions (*I*, *III*) and an intermediate portion (*II*) in between (Fig. 3). The only exception is curve *3* (Fig. 3) obtained in $NiSO_4$ solution, distinguished by a smooth transition from the lower gently sloping portion to the upper ascending portion. The lower portions of the curves (region *I*) are shifted with respect to one another toward more positive potentials in a sequence corresponding to increasing relative nickel ion concentration in solution. The same sequence is observed for the limiting current densities corresponding to the bends in the polarization curves (region *II*). The relative positions of the upper portions (region *III*) depends on the ratio of main component concentrations in solution (V : Ni) and corresponds to the above sequence of rise in the anodic potential at V : Ni > 1 (Fig. 3, curves *1*, *2*). At V : Ni ≤ 1 the corresponding portions of the curves are shifted toward positive potentials in the reverse order, starting from the curve describing the anodic polarization of nickel in pure $NiSO_4$ solution (Fig. 3, curves *3*–*6*).

The appearance and the relative positions of the curves (Fig. 3), considered with account of the above V_{dep}–I_a and CE_{con}–I_a dependences, suggest that their lower portions (region *I*) are due to predominant deposition of vanadium oxide and oxygen evolution at the anode. In this case, the overpotential of the total process grows with increasing nickel ion concentration in solution. The accumulation of nickel ions in the near-electrode layer hinders access of oxovanadium ions to anode, thus making lower the limiting current of their oxidation and enhancing the concentration polarization (region *II*). The relative positions of the upper ascending portions of the curves (region *III*) are determined by the ratio of the rates of the concurrent anodic reactions, i.e., oxidation of oxovanadium and nickel ions and oxygen discharge, which is established in solution at a given V : Ni ratio. At V : Ni > 1, the rate of nickel oxide deposition is close to zero because of the competing reactions of vanadium oxide deposition and oxygen evolution, which occur with lower energy expenditure. Nonetheless, the concurrent reaction of nickel oxidation decelerates the anodic process, thus enhancing the anodic polarization and leading to a shift of the corresponding portions of the curves to more positive potentials with increasing nickel ion concentration in solution (Fig. 3, curves *1*, *2*). At V : Ni ≤ 1, formation of nickel oxide and its codeposition with vanadium oxide become probable. However, this reaction is accompanied by a considerable deceleration of the total process and an increase in the anodic polarization (Fig. 3, curves *3*, *4*). This leads, at a still sufficient intensity of vanadium oxide deposition under the given conditions, to lower yield of the anodic product and higher rate of oxygen evolution. The latter grows with increasing nickel ion concentration in solution, which causes the corresponding decrease in the anodic potential because of the weaker screening of the anodic product by the forming film and the approach of the deposition conditions to those corresponding to oxygen evolution at the initial surface of the stainless steel anode. This conclusion is confirmed by the I_a–E dependence of the anodic polarization curve obtained in pure $NiSO_4$ solution (Fig. 3, curve *3*).

The formation of a complex binary oxide system during electrolysis of the mixed solutions studied is also confirmed by X-ray diffraction patterns of the anodic deposits obtained. The deposits formed under the optimal electrolysis conditions (85°C, pH 2.0, and I_a = 10 mA cm^{-2}) from solutions with V : Ni sulfate concentration ratios of 5 : 1, and 1 : 3 are systems, in which the V_2O_5 and NiV_3O_8 phases are identified (Figs. 4a, 4b). These phases are clearly resolved both

after drying at room temperature and after heat treatment in air at 300°C for 7–10 h. In this case, the deposits studied contain a single-phase compound of the NiV_3O_8 type. This compound is formed directly in the course of electrolysis and its content grows with increasing nickel ion concentration in solution (Fig. 4b). This may be a consequence of a complex multistage mechanism of formation of nickel oxide compounds at the anode, which undergo simultaneous structural and chemical interaction with vanadium oxide deposited in quantitative yield. Such a mechanism may be quite adequate if an assumption is made that NiV_3O_8 is a nonstoichiometric compound and can be, in principle, regarded as a structural formation of the $NiO \cdot VO_2 \cdot V_2O_5$ type, which reveals the relationship with the V–Ni oxide system formed in joint anodic deposition of vanadium and nickel oxides.

The surface microstructure and morphology of the deposits studied is to a certain extent dependent on the electrolysis conditions and the V : Ni ratio in solution. The deposits obtained at V : Ni = 5 : 1 have a rather developed surface and amorphous structure close to that typical of "pure" vanadium oxide. At the same time, already at V : Ni = 3 : 1, the deposits are more compact and the observed surface microstructure and microprofile confirm their crystalline structure characterized by disordered formation of chaotically oriented crystalline grains. At V : Ni ≤ 1, the anodic deposits have more ordered columnar crystalline structure, which shows that the concurrent reaction of nickel ion oxidation plays an important role in nucleation and formation of the V–Ni binary oxide system under the conditions studied. This is possibly related to the corresponding enhancement of the anodic polarization and to suppression of the random growth of vanadium oxide threads by the forming nickel oxide molecules.

Thus, the anodic deposition of vanadium oxide in the presence of nickel ions from mixed solutions of oxovanadium and nickel sulfates at a certain ratio of their concentrations and certain electrolysis parameters results in the formation of anodic deposits belonging to a complex binary oxide system V–Ni. This becomes possible owing to the fact that favorable energy conditions for quantitative transformation of nickel ion oxidation into a stage of nucleation and formation of the corresponding oxide are attained at a certain level of the anodic polarization.

CONCLUSION

It is established that, for anodic deposits to be obtained in the form of V–Ni binary systems containing 0.1–20 wt % modifying phase, the electrolysis should be performed in solutions of oxovanadium and nickel sulfates with a total concentration of 40–45 g l^{-1} at V : Ni concentration ratios of 3 : 1–1 : 3 at 80–85°C, pH 2.0–2.2, and I_a = 7.5–10 mA cm^{-2}. The maximum permissible concentration of nickel ions in solution (V : Ni = 1 : 3) is determined by the limiting conditions for electrolysis stability and by the sufficient current efficiency by the anodic product.

Abstract—The effect of sodium tungstate concentration in 0.4 M H_3BO_3 on the sparking voltage, thickness, and the phase and elemental composition of coatings formed on AMtsM aluminum alloy (~98% Al) by anodic-spark oxidation in a galvanostatic mode (i = 3 A dm^2) was studied.

The method of anodic-spark oxidation is commonly used to obtain coatings of various functional purposes: corrosion-resistant, heat-resistant, wear-resistant, etc. It was shown in [1, 2] that there exists a relationship between the formation of vanadium-phosphorus heteropolyoxo anions (HPA) in an aqueous solution and joint proportional incorporation of phosphorus and vanadium compounds into coatings formed on rectifying metals. The role of HPA consists in that it delivers necessary elements to the anode surface, which are then involved in high-temperature reactions at the anode. It is suggested that thermolysis of complexes contained in the deposit formed on the anode occurs in regions adjacent to electric breakdown channels, with only compounds and glass phases insoluble in the given electrolyte remaining in the coating. The number of presently known HPA is enormous: more than 65 elements can play the role of central elements in these anions [3, 4]. It is important to establish the relationship between the presence of HPA in an electrolyte and the composition of anodic-spark coatings formed on metals being treated in order to solve the problem of directed synthesis of coatings.

Tungstate-borate electrolytes are of interest because borotungstate HPA are formed in them at pH < 8, with the HPA hydrolyzed to borate and monotungstate anions at higher pH values [5].

The aim of the present study was to analyze the specific features of formation and composition of coatings formed on aluminum alloy in tungstate-borate electrolytes, including cases with pH higher and lower than this boundary value. It is noteworthy that the effect of the pH of borate, and the concentration of tungstate, electrolytes on the composition of anodic-spark coatings on aluminum alloy was studied preliminarily in [6, 7].

EXPERIMENTAL

The electrolytes were prepared from distilled water and the following reagents: $Na_2WO_4 \cdot 2H_2O$ and $(NH_4)_{10}[H_2W_{12}O_{42}] \cdot 10H_2O$ of analytically pure grade; H_3BO_3, $Na_2B_4O_7 \cdot 10H_2O$, $NaBO_2 \cdot 2H_2O$, H_2WO_4, and CH_3COOH of chemically pure grade. Potassium boroundetungstate $K_8[BW_{11}O_{39}H] \cdot 13H_2O$ was synthesized by a procedure described in [5]. Ammonium paratungstate was dissolved at 70°C. The electrolyte containing tungstic and boric acids and sodium tungstate was boiled for 1 h with stirring. All the other electrolytes were prepared by pouring solutions together at room temperature. The electrochemical cell employed and the pretreatment of aluminum samples have been described previously [6]. Oxide layers were formed on 40 × 10 × 1 mm AMtsM alloy samples in the galvanostatic mode at current densities of 3 A dm^{-2} in 10, 30, and 60 min. In the course of anodic-spark oxidation, the electrolyte temperature did not exceed 20°C. After treatment, samples with coatings were thoroughly washed with tap and distilled water and dried in air at room temperature.

The sparking voltage was evaluated from the appearance of the first visually observable sparks on the anode surface or by analysis of the forming curves $U = f(t)$ (from the onset of deviation from linearity of the time dependence of the voltage across the electrodes). As a measure of electrolyte development, Q^*, (C l^{-1}) was taken the quantity of electricity passed

* Coatings formed in 10 min: (1) in undeveloped electrolyte ($Q^* = 0$), (2) in developed electrolyte ($Q^* = 1400$ C l^{-1}), and (3) in developed electrolyte ($Q^* \geq 1800$ C l^{-1}) in 30–60 min; æ is the electrical conductivity.

through the electrochemical cell before oxidation of a given electrode, normalized to the solution volume.

The phase composition of the coatings was studied by X-ray phase analysis on a DRON-2.0 diffractometer (Cu_{K_α} radiation). The elemental composition of the coatings was determined using a JEDE JXA-5A X-ray fluorescence analyzer. The content of boron in the coatings was evaluated using an EMAL-2 laser mass spectrometer. The film thickness was measured with an MBI-15 microscope in reflected light on cross-sections of a coating as an average of 10–15 measurements with accuracy of ±2 μm. ^{11}B NMR spectra of aqueous solutions were recorded on a Bruker WP-80SY high-resolution spectrometer at a frequency of 25.705 MHz. The chemical shifts are given relative to 0.1 M NH_4BF_4.

With increasing concentration of Na_2WO_4 in 0.4 M H_3BO_3 solution, there occurs a gradual increase in pH values and electrical conductivity of the solutions, (changes of these parameters in the course of anodization being small) (Table 1). The decrease in the acidity of the medium is accompanied by formation of various forms of borate anions, with an equilibrium that maintains the pH value established between them. Colloids of tungstic acids start to form in all of the electrolytes in question, and those of Heteropoly Blue, in electrolytes with Na_2WO_4 concentrations in the range from 0.05 to 0.1 M, already 1 min after the onset of sparking. It should be noted that, 30–60 min after termination of electrolysis, the solutions turn colorless because of the oxidation of Heteropoly Blue by atmospheric oxygen.

The plots describing how the sparking voltage and final forming voltage, and also the thickness and elemental composition of the coatings obtained, depend on the sodium tungstate concentration (Fig. 1) show three ranges of concentrations c (M): (*I*) 0.005–0.05 (pH < 7.35), (*II*) 0.057–0.067 (7.35 ≤ pH ≤ 7.44), and (*III*) 0.07–0.4 (pH ≥ 7.55). An assumption can be made on the basis of the data of [5] that the change in the parameters is due to presence of borotungstate HPA at pH < 7.5 and their hydrolysis at pH > 7.5. However, in accordance with the outward appearance (Fig. 2) and phase and elemental composition of the coatings, a transition range 0.07 < c < 0.072 M

Fig. 1. Time of coating formation (min): (a, b) 10 and (c) 30. *Open symbols*: elemental composition and thickness of green coatings. The oxygen content was found from the difference.

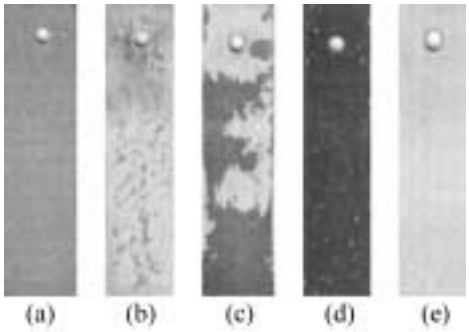

Fig. 2. Outward appearance of samples with coatings formed in tungstate-borate electrolytes in 10 min. Coating: (a) in range *I*, (b) in range *II*, (c) in transition range, (d) in range *III*, and (e) in 0.0091 M solution of $K_8[BW_{11}O_{39}H]$.

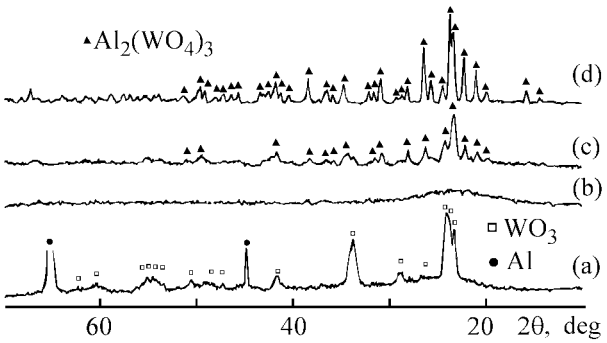

Fig. 3. X-ray diffraction patterns of (a) a sample with coating containing green islands and powders prepared from bluish black parts of the coatings (b) before and after annealing at (c) 760 and (d) 1000°C. Coatings formed in the course of 10 min in electrolyte no. 4. (2θ) Bragg angle.

(7.44 < pH < 7.55) should be additionally distinguished.

In range *I*, small islands of light green color, corresponding to tungsten oxides WO_3, are formed on the aluminum surface in undeveloped electrolytes ($Q^* < 45$ C l^{-1}) beginning with $c = 0.02$ M. They are formed by the mechanism of discharge propagation, following the spark front. Upon the development of the electrolyte, no WO_3 phase is formed, with thin (h = 3–4 μm) moire coatings appearing instead (Fig. 2a; dark gray and light gray islands are present). These coatings mainly contain aluminum oxides, predominantly in α and η modifications. At the same time, with the duration of anodic-spark oxidation increasing to 30–60 min, a $WO_{2.9}$ phase is crystallized. There is reason to believe that the existence of dark parts of the coatings is due to the presence of this phase. In range *I*, the content of tungsten in the coatings decreases, and that of aluminum increases, with growing Na_2WO_4 concentration.

In range *II*, the phase composition of the coatings is dependent on neither electrolyte development nor time of anodic-spark anodization. All the coatings are light green (Fig. 2b) and contain WO_3. The content of tungsten in the coatings is about 70 wt %, and that of aluminum does not exceed 0.4 wt %. The coating thickness grows with increasing oxidation time from 12–14 (10 min) to 60 μm (60 min).

In range *III*, bluish black layers of thickness ranging from 10 (10 min) to 30 μm (60 min) are formed, with raised green points of the WO_3 phase evenly distributed over the surface (Fig. 2d). The content of tungsten and aluminum in the bluish black layers is independent of the time of anodic-spark oxidation, being equal to, respectively, 45–60 and 4–8 wt %, with the Al/W ratio corresponding to aluminum tungstate. X-ray diffraction patterns of the green parts of the coating material and those of the coating material detached from the substrate contain an amorphous halo in the region characteristic of tungsten compounds. Upon annealing in air at 1000°C the powder changes its color from bluish black to white, and aluminum tungstate crystallizes in it (Fig. 3). XPA data indicate that, in addition to the amorphous

phase and WO_3, phases with W(V), such as tungsten bronzes $H_{0.1}WO_3$, $H_{0.33}WO_3$, Al_xWO_3 and nonstoichiometric oxides $WO_{2.9}$, $W_{20}O_{58}$, and $W_{18}O_{49}$, are possibly present in the initial coatings.

In the transition region (Fig. 2c), simultaneous formation of light green and dark blue-gray islands is observed. In this case, the green islands are formed by the mechanism of linear discharge following the spark front, whereas blue-gray layers are produced by uniform sparking on that part of the surface of the aluminum anode, which remained uncovered with green films.

Laser mass spectrometry enabled evaluation of the amount of boron in coatings obtained in electrolytes with sodium tungstate concentration $c \leq 0.1$ M. The content of boron is not too high (≤ 1 at.%, or 0.5 wt %). At the same time, coatings containing 1 to 9 at.% boron were obtained in the absence of sodium tungstate in borate electrolytes ($6.5 \leq pH \leq 10.2$) [6].

It is noteworthy that the manner in which the thickness and composition of coatings on aluminum depend on the concentration of Na_2WO_4 in electrolytes with and without boric acid [7] is about the same. In both cases, three ranges of Na_2WO_4 concentrations affecting the coating composition can be distinguished: ranges *I*, *II*, and *III*, in which, respectively, moire, green, and black layers are formed. The presence of H_3BO_3 leads to a shift of these concentration ranges, independence of the composition of coatings formed within range *II* from electrolyte development, and change in the coating color {the coatings turn bluish, instead of being green, which is possibly due to formation of compounds with W(V) [8]}. In addition, tungstate-borate electrolytes have, compared with tungstate electrolyte, lower pH value and possess buffer properties, which leads to formation of tungstic acid colloids. The existence of range *II* in tungstate solutions is due to the presence of isopolytungstates [7], and formation of borotungstates becomes possible in tungstate-borate electrolytes. Since the region of existence of borotungstate HPA is limited by the pH of the medium and concentrations of tungstate anions, the following may be assumed. In range *I*, the concentration of borotungstates in solution and their effect on coating formation are insignificant. In range *II*, their amount becomes sufficient for their predominant involvement in coating formation. In range *III*, the rise in pH leads to hydrolysis of borotungstate HPA to monotungstate and polyborate anions. The assumption that HPA are present in the electrolyte bulk is confirmed by the formation of Heteropoly Blue at Na_2WO_4 concentrations of 0.05 to 0.1 M ($7.35 \leq pH \cong 7.70$).

In order to additionally verify the effect of the electrolyte pH on the phase and elemental composition of coatings, solutions with constant total concentrations of boron (0.1 M) and tungsten (0.4 M) and varied pH value were prepared (Tables 2 and 3). The pH value

* Coatings formed in 10 min: (1) in undeveloped electrolyte ($Q^* = 0$), (2) in developed electrolyte ($Q^* = 1400$ C l^{-1}), and (3) in developed electrolyte ($Q^* \geq 1800$ C l^{-1}) in 30–60 min.

was varied by using different borate and tungstate anions (Table 2) or by acidifying electrolyte no. 4 (Table 2) with an acetic acid solution (Table 3).

Analysis of the data in Fig. 4 and Table 2 reveals two ranges of the pH of "acetate-free" electrolytes differing in their effect on the thickness and composition of coatings. At pH ≤ 7.5, green WO_3-containing coatings of thickness 12–14 μm (10 min) are formed. In anodic-spark oxidation of aluminum in electrolyte no. 1 (Table 2), green layers are formed on the background of a gray film. At pH > 7.5, the character of sparking changes, it becomes finer and more uniform, with the coating becoming thinner, 5–8 μm (10 min), and the content of tungsten and aluminum in the coatings, respectively, decreasing and increasing. The number of green islands (WO_3 phase) on the surface of the amorphous layer decreases. At pH 11.0 no WO_3 phase is formed.

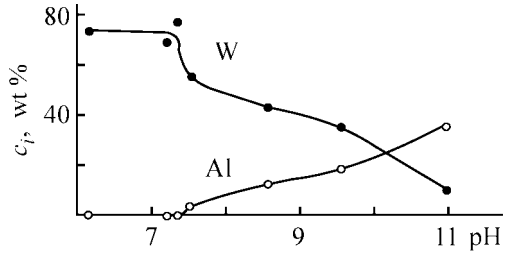

Fig. 4. Content c_i of main elements in coatings vs. pH of electrolytes containing 0.4 M B(III) and 0.1 M W(VI). Coatings formed in 10 min.

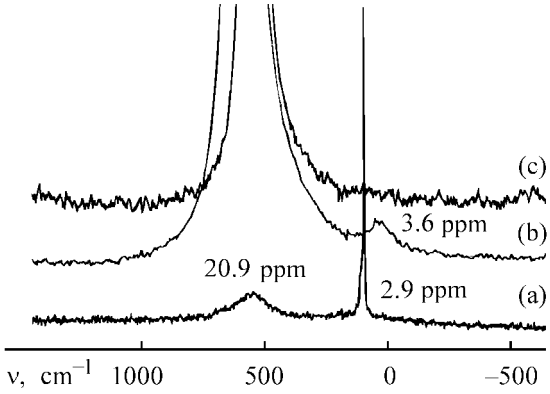

Fig. 5. ^{11}B NMR spectra of solutions containing B(III) and W(VI) in (a) 1 : 12 and (b, c) 4 : 1 ratios. Chemical shifts (ppm) refer to H_3BO_3 (20.9) and $[BW_{12}O_{40}]^{5-}$ (2.9 and 3.6) [3]. (ν) Frequency. (a) 0.2 M H_3BO_3 + 2.4 M Na_2WO_4 + HCl, pH 4; (b, c) electrolyte no. 1 (Table 2) pH 6.1 [(a) before and (c) after electrolysis).

It is noteworthy that, upon storage of electrolyte no. 1 for 1 month in a closed vessel, a precipitate is formed, which contains, according to XPA, $H_5[BW_{12}O_{40}] \cdot xH_2O$. After electrolysis, the precipitate formed in the electrolyte contains, in addition to borotungstic acid, products of its thermolysis, HBO_2 and WO_3. ^{11}B NMR spectra of solutions confirm the presence of a borododecatungstate peak in electrolyte no. 1 before electrolysis and a decrease in its intensity after electrolysis (Figs. 5b and 5c). In the other electrolytes (Tables 1–3), no ^{11}B NMR peaks characteristic of boron in tetrahedral environment are recorded, which is presumably due to hydrolysis of $[BW_{12}O_{40}]^{5-}$ at pH > 6.5. In the range 5 < pH < 8, the $[BW_{11}O_{39}H]^{8-}$ anion, characterized by a coordination intermediate between tetrahedral and triangular, is stable. It is noteworthy that coatings formed on aluminum alloy in a 0.0091 M $K_8[BW_{11}O_{39}H]$ solution [with W(VI) concentration equal to 0.1 M] are light green and contain the WO_3 phase (Fig. 2e).

Thus, there is reason to believe that borotungstic acids are formed as a result of acidification in the course of electrolysis in the near-anode region, and these acids decompose in the course of dehydration

to WO_3 [4]. It is noteworthy that the formation of ligt green coatings in a 0.0091 M $K_8[BW_{11}O_{39}H]$ solution is similar to that of oxide layers in vanadate-phosphate electrolytes [1, 2]. In both cases, nuclei of a new phase, which contains electrolyte components, precipitate after the onset of sparking. Further growth of coatings occurs via expansion of the region of the new phase, following the moving front of sparks at the perimeter of the nuclei.

Lowering the pH value by introducing acetic acid into a solution containing 0.4 M H_3BO_3 and 0.1 M Na_2WO_4 favors formation of intensely colored Heteropoly Blue on the cathode in the course of anodic-spark oxidation. The intensity of electrolyte coloration grows with decreasing pH, which indicates a rise in the concentration of borotungstate HPA. Formation of Heteropoly Blue in electrolysis of tungstate solutions containing 0.1 M Na_2WO_4 and acetic acid (pH 6) is only observed upon their boiling. At the same time, a decrease in the pH of tungstate-borate-acetate solutions affects neither the elemental composition nor the outward appearance of the coatings, which remain the same as in the case of an electrolyte containing no acetic acid (pH 7.6). The decrease in pH only favors crystallization of a $Al_2(WO_4)_3$ in the coatings (Table 3). The possible presence of the $?Na_{0.28}WO_3$ phase must be insignificant, since the content of sodium does not exceed 0.4 wt %.

It is known [9] that aluminum hydroxide has the lowest solubility in the pH range 6.5–7.5. Presence in an electrolyte of ions that can form soluble compounds or complexes with aluminum, including acetate ions, markedly raises the solubility of its oxide and hydroxide even in a neutral medium. As a result, first an amorphous phase and then $WO_{2.9}$ are formed on the surface of the anodic oxide film instead of tungsten(VI) oxide, whose formation is observed at the given pH values in the absence of acetate ions. At lower pH and longer anodic-spark oxidation, aluminum tungstate is formed.

In the absence of acetate ions in tungstate-borate electrolytes, the solubility of aluminum is controlled by the acidity of the medium. Aluminum ions are present in solution in the form of positively charged ions in an acid medium, and as negatively charged hydroxo complexes, in an alkaline medium. Thus, the coating formation involves both the elements contained in the initial components of the electrolyte and elements from an alloy being treated. It would be expected that, in neutral medium, aluminum ions from the electrolyte should be involved in the formation of anodic-spark layers to the minimum extent because of the low solubility of aluminum oxide and hydroxide, and just this is observed in range *II* (Fig. 1c) and at $6.1 < pH < 7.5$ (Table 2). The fact that the range of Na_2WO_4 concentrations (in 0.4 M H_3BO_3 solution) in which Heteropoly Blue is formed is wider than the range in which WO_3 is formed in the coatings confirms the assumption that the electrolyte pH affects not only HPA formation, but also the conditions of anode metal dissolution.

CONCLUSIONS

(1) Three ranges of Na_2WO_4 concentrations in 0.4 M H_3BO_3 solution, affecting the composition of anodic-spark layers on aluminum alloy, were established. In range *I*, thin layers mainly containing aluminum oxides are formed; in range *II*, solid layers containing WO_3 are produced; in range *III*, coatings are formed, which contain an amorphous phase approaching $Al_2(WO_4)_3$ in composition, with islands of the WO_3 phase uniformly distributed over its surface.

(2) At B : W = 4 : 1, solid WO_3 layers are formed on the surface of aluminum being anodized at $pH < 7.5$; at $pH > 7.5$ the content of aluminum in the coatings becomes higher, and that of tungsten, lower, and the coatings contain an amorphous phase and WO_3 in the form of islands.

(3) The data are obtained suggesting that the growth of WO_3 layers on the surface of the aluminum anode is related to formation in tungstate-borate electrolytes of borotungstate heteropolyoxo anions $[BW_{11}O_{39}H]^{8-}$ and(or) $[BW_{12}O_{40}]^{5-}$.

(4) It is shown that introduction of acetate ions chemically dissolving aluminum and its oxide into a borate-tungstate electrolyte favors crystallization of $WO_{2.9}$ and $Al_2(WO_4)_3$ phases.

(5) A correlation is observed between the influence of the electrolyte pH on the solubility of aluminum and its oxide and the phase and elemental composition of the anodic layers formed. At neutral pH values, when the solubility of Al_2O_3 is insignificant, the content of aluminum in coatings falls.

Abstract—The conversion of methanol and propane–butane fraction, taken separately and in combination, on Pentasil at 500–650°C was studied. The pathways and specific features of the occurring reactions were determined.

Today, one of the main processes for commercial production of lower olefins (ethylene, propylene) is pyrolysis of various straight-run oil fractions and oil distillates [1]. However, because of the short supply of petroleum raw materials, active efforts are made to develop processes for production of lower alkenes (C_2–C_4), arenes, motor fuels, and other valuable products from alternative raw materials: condensed gases, natural and casing-head gases. Utilization of natural and casing-head gases for chemical processing is impeded by the low reactivity of C_2–C_4 alkanes and, especially, of methane.

Of much promise in this context, is conjugate conversion of the propane–butane fraction (PBF) and methanol into lower olefins and arenes in the presence of high-silica catalysts like ZSM-5. Introduction into the reaction mixture of lower alkanes (C_2–C_4) and methanol in the presence of zeolite-containing catalysts allows the process to be performed at lower temperatures and without considerable heat effects, owing to conjugation of the endothermic cleavage of hydrocarbons and exothermic conversion of methanol [2].

The activity and selectivity of decationized high-silica zeolites (HSZs) in conversion of hydrocarbons are primarily governed by the composition of their framework and by the reaction conditions shifting the thermodynamic equilibrium toward formation of target products [3]. In conversion of methanol and C_2–C_4 alkanes on an HSZ, the primary products are lower olefins, which subsequently undergo dehydrocyclization and aromatization to give arenes; the yield of lower olefins can be increased by properly choosing the reaction conditions, modifying HSZ, etc.

In this study, we examined the influence of temperature, feed space velocity, methanol : PBF weight ratio, and time of Pentasil operation on its activity and selectivity in formation of C_2–C_4 olefins in the conjugate conversion of PBF and methanol.

EXPERIMENTAL

The initial samples of high-silica zeolites of the ZSM-5 type (silicate ratio 50) were prepared as described in [4]. The H form of the zeolite (H-HSZ) was prepared by decationization of the initial Na form (Na-HSZ) in 25% aqueous NH_4Cl, followed by thermolysis at 600°C for 8 h to remove ammonium ions. The residual content of Na_2O in H-HSZ did not exceed 0.05% (here and hereinafter, wt %). The degree of crystallinity of the zeolite sample, evaluated from the IR spectrum, was 93%.

The conversion of methanol and PBF, taken separately and in combination, was studied in a flow-through installation with fixed catalyst bed (reactor volume 3 cm^3) in the temperature range 450–700°C at atmospheric pressure. Methanol contained ≤0.02% water; the composition of PBF (%) was 0.9 ethane, 58.3 propane, 5.5 isobutane, and 35.3 butane.

The reaction mixture and products were analyzed by gas chromatography.

It is known that transformations of lower alkanes (C_2–C_4) on zeolite-containing catalysts start at temperatures above 500°C [3]; therefore, it was necessary to study transformations of methanol at these high temperatures.

Examination of the influence of temperature on the composition of products of methanol conversion on

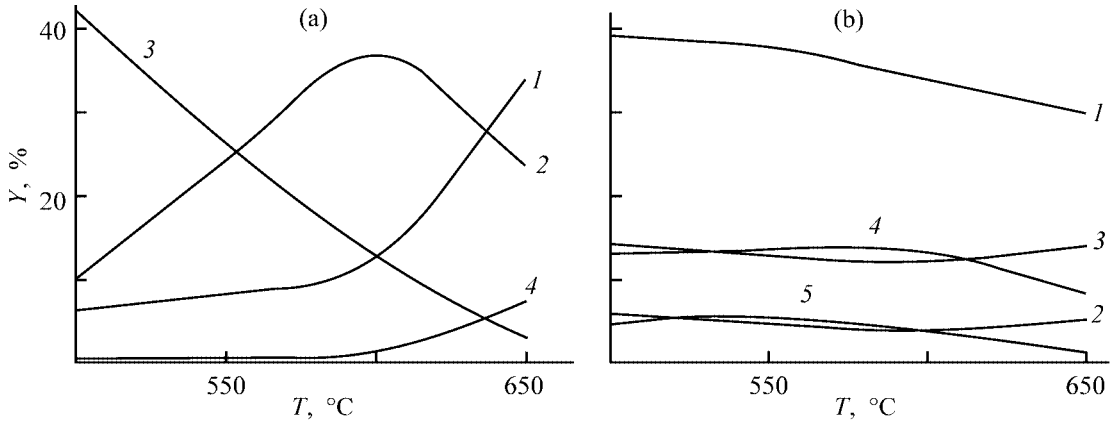

Fig. 1. Yields *Y* of methanol conversion products vs. temperature *T*. (a) (*1*) Methane, (*2*) C_2–C_4 olefins, (*3*) C_2–C_4 alkanes, and (*4*) CO; (b) (*1*) arenes, (*2*) benzene, (*3*) toluene, (*4*) xylenes, and (*5*) C_{9+} alkylbenzenes.

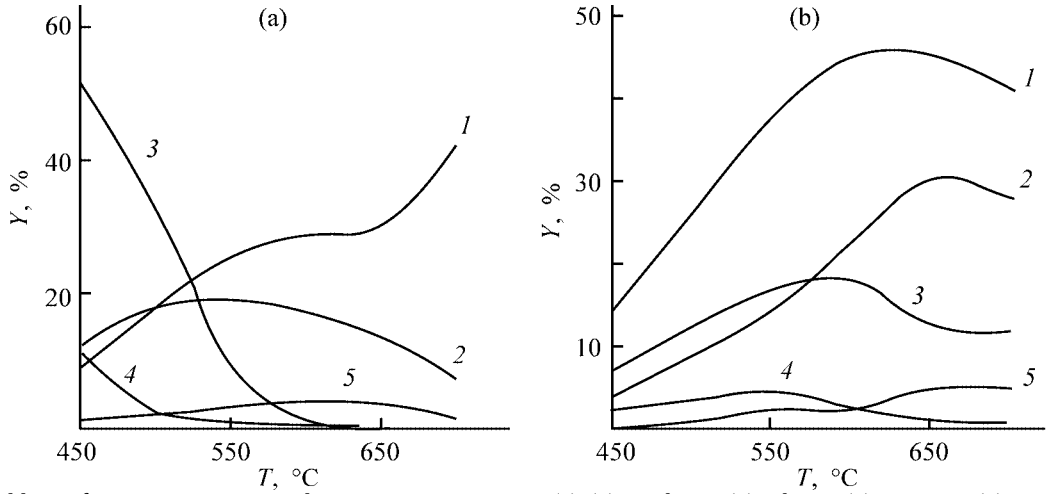

Fig. 2. Yields *Y* of PBF conversion products vs. temperature *T*. (a) (*1*) Methane, (*2*) ethane, (*3*) propane, (*4*) isomeric butanes, and (*5*) C_2–C_4 olefins; (b) (*1*) arenes, (*2*) benzene, (*3*) toluene, (*4*) xylene, and (*5*) naphthalenes.

HSZ at a space velocity of 2 h^{-1} showed that, with the temperature increasing from 500 to 650°C, the yields of CO and methane grow sharply, and the yield of C_2–C_4 olefins passes through a maximum at T_{max} = 600°C (Fig. 1a). The total yield of arenes in methanol conversion decreases monotonically with increasing temperature (Fig. 1b); the content of individual arenes varies insignificantly. The minimum (T_{min} = 600°C) in the temperature dependence of the benzene and toluene yields and the maximum (T_{max} = 550–600°C for the yields of xylenes and C_{9+} alkylbenzenes suggest the occurrence of dealkylation and disproportionation. The content of naphthalene in methanol conversion products was less than 0.5% at 500°C, and it also decreased with increasing temperature.

Transformations of propane in the presence of H-HSZ become noticeable at 500°C, i.e., at higher temperatures as compared to butanes (Fig. 2a). With the temperature increasing to 700°C, the content of PBF in the reaction mixture decreases drastically (to 0.3%). Nevertheless, the yield of C_2–C_4 olefins is low, as in conversion of methanol; their yield is the highest at 600°C. The high yield of arenes (up to 45%, Fig. 2b) indicates a high activity of Pentasil and high concentration on its surface of strong acid centers responsible for aromatization of alkenes. We should also note a high degree of methanation and high content of naphthalenes (up to 5%) in the liquid products. The shift of the reaction equilibrium toward formation of arenes may be due to plugging of zeolite channels and voids with coke deposits, which enhances the molecular-sieve properties of Pentasil [5]. The diffusion hindrance arising in the process shifts the reaction equilibrium toward formation of final products, specifically, arenes.

Thus, the increase in the CO yield with temperature in conversion of methanol and the high degree of methanation for both processes show that it is appropriate to perform conjugate conversion of PBF and methanol at temperatures above 650°C.

Preliminary experiments in the presence of Na-HSZ showed that the initial activity of the nondecationized zeolite is fairly high, but after operation for 3 h the catalyst loses its activity. The products contain propane (~50%), butane (~25%), methane (~13%), and no more than 5% lower olefins.

The composition of products formed in conjugate conversion of methanol and PBF in the presence of H-HSZ is given in Table 1. The major products are lower alkanes, olefins, and arenes. As seen from Table 1, with the reaction temperature increasing from 500 to 650°C, the content of propane and isomeric butanes in the products decreases by approximately a factor of 4, i.e., the Pentasil activity grows with temperature. The yield of C_2–C_4 olefins on H-HSZ as a function of temperature passes through a maximum, reaching 31%. It should be noted that ethylene and propylene are formed in about the same amounts. Below 600°C, the yield of propylene is somewhat higher, whereas above 600°C the yield of ethylene increases owing to larger contribution of cracking reactions.

The conversion of separately taken PBF (Fig. 2b) is characterized by an increase in the yield of arenes (especially benzene) with temperature, whereas in conjugate conversion of methanol and PBF on H-HSZ, the temperature rise has no appreciable effect on the total yield of arenes. The fraction of C_6–C_8 arenes contains 3–4 times less benzene than toluene; with increasing temperature, the yields of toluene and xylenes grow. The decrease in the content of xylenes in the reaction products at 650°C and the increase in the content of benzene and toluene suggest that alkylaromatic hydrocarbons undergo dealkylation. A similar pattern is characteristic of conversion on Pentasil of methanol taken alone, which is attributed to the occurrence of the carbocation mechanism of arene formation [6].

The calculated and experimental data given in [2] show that the heat effect of the conjugate process is close to zero when methanol and decane are taken in a weight ratio of (1.5–2) : 1; in this case, the conversion of methanol and decane is virtually complete, and the yield of lower olefins is as high as 35–40%. Conversion of PBF requires high temperatures than cleavage of decane; therefore, we took higher weight ratios of methanol to PBF. The composition of products formed at methanol : PBF weight ratios of 2 : 1, 4 : 1, and 6 : 1 is given in Table 2. Experiments were per-

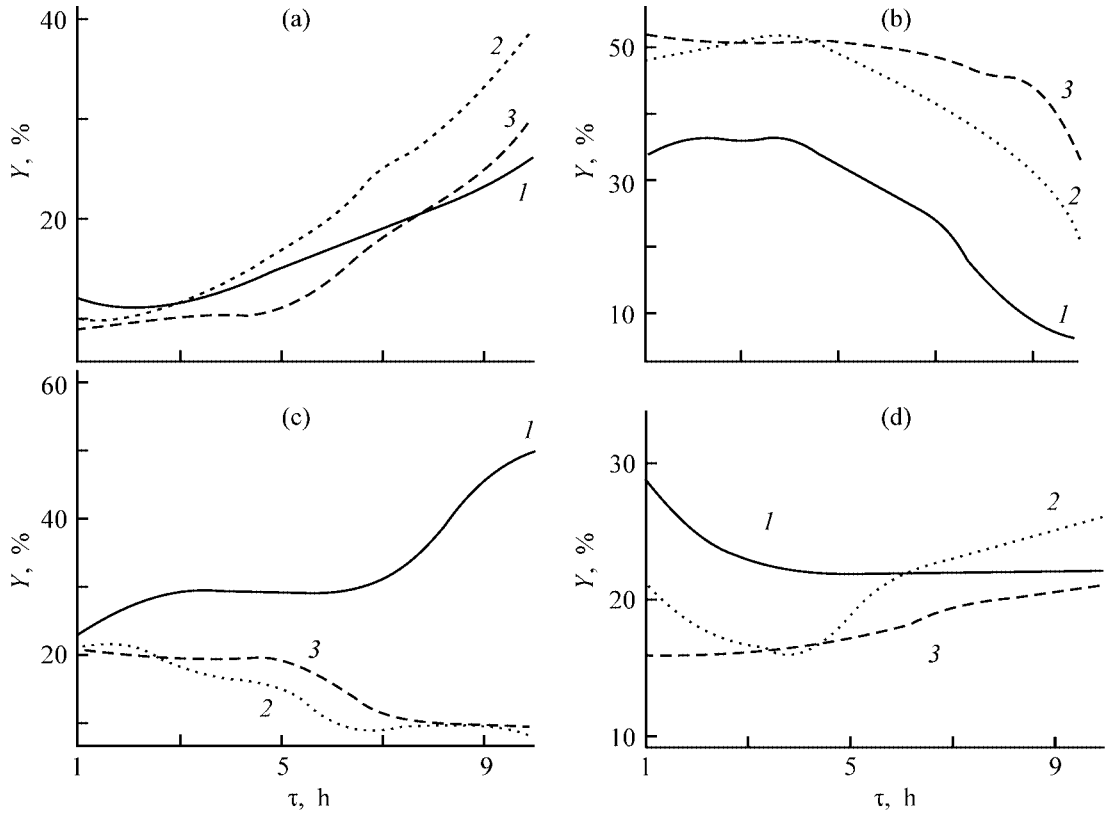

Fig. 3. Yields *Y* of products of conjugate conversion of methanol and PBF vs. time τ. Feed space velocity, h^{-1}: methanol 2 and PBF 200. *T* = 600°C. (a) Methane, (b) C_2–C_4 olefins, (c) C_2–C_4 alkanes, and (d) arenes. Yields: (*1*) before zeolite regeneration, (*2*) after first regeneration, and (*3*) after second regeneration.

formed at 600°C, since the yield of C_2–C_4 olefins is at a maximum at this temperature (Table 1) and the conversion of propane and isomeric butanes is fairly high. As seen from Table 2, the yield of methane grows with increasing content of methanol; hence, the contribution of methanol to methanation is higher under these conditions than that of PBF. The yield of olefins is the highest at methanol : PBF = 4 : 1; the yield of arenes grows with increasing content of methanol, mainly at the expense of formation of alkylsubstituted benzenes (toluene, xylenes, C_{9+} arenes).

It is known that, in conversion of methanol, the reaction equilibrium can be shifted toward formation of lower olefins by decreasing the partial pressure of methanol, for which purpose diluents are added [7]. In our system, on the one hand, methanol enhances the reactivity of lower alkanes, and, on the other, these alkanes act as diluents shifting the equilibrium toward formation of olefins. Therefore, the subsequent experiments were performed at 600°C and weight ratio methanol : PBF = 4 : 1.

Figure 3 illustrates the stability of H-HSZ functioning in conjugate conversion of methanol and PBF. Experiments showed that, in the first 10 h (before regeneration), the yield of C_2–C_4 olefins gradually decreases (Fig. 3b). The yield of methane increases by a factor of 2 in the course of the run (Fig. 3a); probably, gradual coking of the zeolite promotes additional methanation of coke [8]. One more evidence in favor of the gradual deactivation of the catalyst is the steady growth of the content of propane and isomeric butanes in the products (Fig. 3c, curve *1*).

The next 10-h run of the catalyst after regeneration is characterized by similar trends in the yield of lower olefins (Fig. 3b, curves *1*, *2*); however, the content of lower olefins in the reaction mixture increases, on the average, by 15%. The content of propane and isomeric butanes in the reaction products after 10-h run decreases, and the yield of arenes grows (Fig. 3d); that is, the catalyst activity remains high, but its selectivity with respect to formation of C_2–C_4 olefins decreases.

The second regeneration improves the stability of the catalyst functioning as compared to the first and second runs. These results can be accounted for by the influence exerted on zeolite by the water vapor released in methanol cleavage. Regeneration of the zeo-

lite at 550°C probably leads to escape of Al^{3+} ions from the zeolite lattice. Dealumination of the zeolite framework in the course of high-temperature treatment with water vapor decreases the total acidity of the zeolite, with replacement of strong acid centers with weaker centers [4, 9]. As a result, the zeolite selectivity changes: after Pentasil regeneration, the yield of olefins increases and the yield of arenes formed on strong Brønsted acid centers decreases.

CONCLUSIONS

(1) In conversion of methanol, the yields of CO and H_2 sharply grow with the temperature increasing from 500 to 650°C; the major contribution is made by dealkylation and disproportionation of alkylaromatic hydrocarbons.

(2) In conversion of the propane–butane fraction on Pentasil at 500°C and higher temperatures, the major products are aromatic hydrocarbons; methanation also occurs intensively. In conjugate conversion of methanol and propane–butane fraction on Pentasil, the major gaseous products are C_2–C_4 alkenes, and the major liquid products are arenes.

(3) In successive cycles of catalyst operation and regeneration, the yield of lower olefins increases, which is due to high-temperature effect on Pentasil of water formed in the process and to a decrease in the total acidity of the catalyst.

Abstract—A new method for heat exchange between dispersed flows and a unit for continuous selective heating, comprising a heater and a mass-exchange apparatus, was proposed. A mathematical model of the unit was developed for the cases of direct-flow and counterflow heaters. Analytical solutions to the model equations were obtained. The parameters affecting the result of continuous selective heating of the dispersion medium in the unit were determined.

Suspensions, gas-dispersed systems, or other dispersed systems are commonly heated by heat exchange in known apparatus with impermeable surface or in more complex apparatus with cleanable heat-exchange surface [1–3]. In apparatus of this kind, solid particles of material, contained in the dispersion medium, and the carrying continuous phase are subjected to a not-always-desirable identical direct action of the high-temperature heat-carrying agent.

For example, in the known thermochemical and power apparatus for thermal treatment of a flow of a gas-dispersed system containing pneumatically transported solid particles, both the gas and the particles themselves are subjected in the thermal treatment chamber to identical action of high temperature [1]. Dispersed particles or gas may undergo thermochemical decomposition or change irreversibly their properties. This may also occur in thermal treatment of a hydrodispersion, e.g., suspensions or sludges containing thermolabile phases, in fine chemical and foodstuff technologies, in which unacceptable overheating of solid particles of a product at the heat-exchange surface may affect its composition and quality [3].

Therefore, it is advisable to carry out, in some thermochemical, fine chemical, and foodstuff technologies, separate thermal treatment of the dispersed solid and continuous fluid or gas phases of the dispersion under conditions optimal for each phase. A technological scheme for such a treatment, e.g., for heating of the continuos phase of the dispersion involves three stages: separation of the dispersion into continuous and solid phases in a separator, transport of the solid phase from the separator to a mixer, heating of the continuous phase in a heat exchanger, and its mixing with the solid phase in the mixer. The multistage nature of this scheme and impossibility of performing the entire process in a continuous mode are apparent.

In the present study, we developed a process and a unit comprising a heater and a mass-exchange apparatus for continuous selective heating of the continuous phase of the dispersion on the basis of a new technique for mass exchange between dispersed flows across a convectively permeable surface, constructed a mathematical model of the process, and carried out calculations on its base.

We propose to use for selective heating of the continuous phase a continuous process according to which the separation of the dispersion into phases, the transport of the dispersed phase, and its mixing with the heated continuous phase are combined in the same continuous, valve-pulsatory mass-and-heat-exchange apparatus (VPMA) described in [4–6]. This method can be implemented in a unit (Fig. 1) comprising a heater (H) and VPMA (M) connected in a circuit with a circulatory pump. The VPMA contains two spaces *1* and *2*, separated by a porous semi-permeable partition *3*. The VPMA also includes a set

1070-4272/02/7512-1984 $27.00 © 2002 MAIK "Nauka/Interperiodica"

of valves *4–7*. The heater H contains a space for the continuous phase *8* being heated and for the heat-carrying agent *9*, separated by an impermeable partition *10*. The dispersion, containing the continuous phase being heated, with the initial temperature of the continuous phase equal to θ_L^{ini}, is delivered into channel *1* of VPMA through a valve *4*, and the heated continuous phase, coming out of the heater H, is delivered as a counterflow into the adjacent channel *2* through a valve *6* with temperature θ_L^{out}. The pulsatory system, including computer-controlled valves *4–7*, creates alternating pressure differences between the channels, with the result that the flows moving in VPMA repeatedly exchange portions of the continuous phase, without mixing their dispersed phases. In this case, counterflow convective mass-and-heat exchange results in that the cold continuous phase passes from channel *1* into channel *2*. The continuous phase being heated is delivered from channel *2* of VPMA through valve *5* with temperature θ_L^{in} to the inlet of the space *8* of the heater H. Hot heat-carrying agent with temperature θ_T^{in} is delivered to the inlet of the space *9* of the heater H. Heated continuous phase with temperature θ_L^{fin} is discharged, together with the dispersed phase, from channel *1* of VPMA through valve *7*.

The advantage of the given unit consists in that it enables continuous selective heating of the continuous phase of the dispersion. The dispersed phase does not penetrate into the heater and is not subjected to direct action of its hot wall.

The convective mass-and-heat exchange in VPMA was studied in [7–12].

The efficiency of a VPMA is characterized by the extent E of heat exchange, which is a constant parameter for a given VPMA [6, 9–12]. In the case in question, the parameter E is defined by:

$$E = \frac{\theta_L^{ini} - \theta_L^{fin}}{\theta_L^{ini} - \theta_L^{out}}. \quad (1)$$

Let us write down a heat balance equation for the VPMA:

$$\varepsilon\theta_L^{ini} + \theta_L^{out} = \varepsilon\theta_L^{fin} + \theta_L^{in}, \quad (2)$$

where ε is the porosity of the dispersion medium in the first channel of VPMA.

Equation (2) accounts for the fact that the volumetric flow rates in both channels of VPMA are the same. The heat balance for the heater can be represented as:

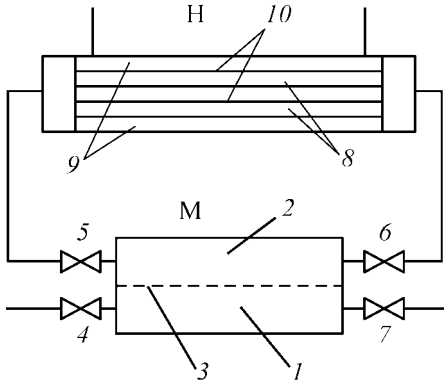

Fig. 1. Schematic of the unit comprising a heater H and mass-and-heat exchange apparatus M for permanent selective heating of the continuous phase of the dispersion: (*1*, *2*) channels of the mass-and-heat exchange apparatus, (*3*) permeable partition, (*4–7*) valves, (*8*) space for continuous phase being heated, (*9*) space for heat-carrying agent, and (*10*) impermeable partition.

$$|B|(\theta_L^{in} - \theta_L^{out}) + (\theta_T^{in} - \theta_T^{out}) = 0,$$

$$|B| = \frac{c_{pL}\rho_L|g_L|}{c_{pT}\rho_T g_T}, \quad (3)$$

where c_p is the specific heat under constant pressure, ρ is the density, the subscripts "L" and "T" make it possible to distinguish the continuous phase being heated and the heat carrying agent, the superscripts "in" and "out" refer to the inlet and outlet temperatures in the heater, and the superscripts "ini" and "fin" indicate the initial (at the unit inlet) and final (at the unit outlet) temperatures.

The volumetric flow rates of the continuous phase being heated, g_L, and of the heat-carrying agent, g_T, have the same signs for a direct-flow heater and opposite signs for a counterflow one. Equation (3) involves the absolute values of the volumetric flow rates.

Thus, six temperatures at the inlets and outlets of the VPMA and heater are related by three equations, (1)–(3). Having set three temperatures, we can determine the remaining three. Commonly, the following temperatures are known: temperature θ_L^{ini} of the continuous phase being heated, at the VPMA inlet (unit entry); temperature θ_T^{in} of the heat-carrying agent at the heater inlet; and temperature θ_L^{fin} of the continuous phase being heated, at the VMPA outlet (unit output). Then we can find from Eqs. (1)–(3) the temperatures θ_L^{in}, θ_L^{out}, and θ_T^{out}:

$$\theta_L^{out} = \theta_L^{ini} + \frac{1}{E}(\theta_L^{fin} - \theta_L^{ini}), \quad (4)$$

$$\theta_L^{in} = \theta_L^{ini} + \left(\frac{1}{E} - \varepsilon\right)(\theta_L^{fin} - \theta_L^{ini}), \quad (5)$$

$$\theta_T^{out} = \theta_T^{in} - \varepsilon|B|(\theta_L^{fin} - \theta_L^{ini}). \quad (6)$$

Thus, we find the temperatures of the continuous phase being heated and the heat-carrying agent at the inlets and outlets of the heater, which are necessary for a prescribed mode of unit operation. Further, we have to calculate the heater parameters ensuring the required temperatures of the continuous phase being heated and the heat-carrying agent.

Let us write the equation of convective heat exchange for the continuous phase (or heat-carrying agent) in the heater in the differential form [13]:

$$c_p\rho\left(\frac{\partial\theta}{\partial t} + \mathbf{w}\,\mathrm{grad}\,\theta\right) - \lambda\,\mathrm{div}(\mathrm{grad}\,\theta) = 0, \quad (7)$$

$$-\lambda\,\mathrm{grad}\,\theta = \alpha(\theta_w - \theta)\mathbf{e}, \quad (8)$$

where t is time; c_p, the specific heat at constant pressure; ρ, the density; $\theta = \theta(x, y, z, t)$, temperature; **w**, velocity; λ, the heat conductivity; θ_w, the temperature of the heat-exchange surface; α, the heat-transfer coefficient at heater walls; **e**, the unit vector of the external normal to the heater surface.

Equation (7) is a balance equation for the heat of the continuous phase, and Eq. (8) is the continuity equation for the flux of heat at the heater wall. Let us analyze the case when c_p, ρ, λ, and α can be considered temperature-independent. This assumption is commonly valid for a fluid, and, in the case of small variations of temperature and density, also for a gas.

Let us align the heater axis with the flow direction of the continuous medium being heated. We choose a small element of volume, $dV = s\,dx$, bounded by two closely spaced cross-sections s of the heater and a part of the lateral surface, $\pi_f\,dx$, between them. Here dx is the distance between the chosen cross-sections (infinitely small), and π_f is the perimeter of the cross-section s. Let us integrate Eq. (7) over the volume chosen, with account of the fact that, in the flow of the continuos phase along the heater, the velocity divergence of the continuous phase is zero, the flux of the velocity vector **w** across the lateral surface is zero, and the flux of heat across the lateral surface is determined by the condition (8). Dividing by the specific heat of the chosen volume, we obtain an equation for temperature averaged over the heater cross-section:

$$\frac{\partial\theta}{\partial t} + u\frac{\partial\theta}{\partial x} - \frac{\lambda}{c_p\rho}\frac{\partial^2\theta}{\partial x^2} - \frac{\alpha\pi_f}{c_p\rho s}(\theta_w - \theta) = 0, \quad (9)$$

where u is the x-component of the cross-section-average flow velocity of the continuous phase.

Let us now pass to dimensionless variables by the following rules:

$$T = \frac{ut}{l_0},\quad X = \frac{x}{l_0},\quad \Theta = \frac{\theta - \theta_L^{ini}}{\theta_T^{in} - \theta_L^{ini}}, \quad (10)$$

where l_0 is the heater length.

In a flow of the continuous phase along the heater, the following condition is commonly satisfied:

$$\frac{1}{\mathrm{Pe}} = \frac{\lambda}{c_p\rho u l_0} << 1. \quad (11)$$

With account of (11), Eq. (9) in dimensionless variables will take, for the steady-state case, the form:

$$\frac{\partial\Theta}{\partial X} - \frac{\alpha f}{c_p\rho g}(\Theta_w - \Theta) = 0, \quad (12)$$

where $g = us$ is the volumetric flow rate, and $f = \pi_f l_0$ is the total heat-exchange surface.

In the steady state, it follows from the heat flux continuity condition that:

$$\alpha_T(\theta_T - \theta_{wT}) = \frac{\lambda_w}{\delta_w}(\theta_{wT} - \theta_{wL})$$

$$= \alpha_L(\theta_{wL} - \theta_L) = K(\theta_T - \theta_L), \quad (13)$$

where θ_{wT} and θ_{wL} are the heater wall temperatures from the sides of, respectively, the heat-carrying agent and the continuous phase being heated; λ_w and δ_w are the heat conductivity and thickness of the heater wall; K is the coefficient of heat transfer between the flow of the heat-carrying agent and that of the continuous phase being heated.

Eliminating the wall temperatures θ_{wT} and θ_{wL} from Eq. (13), we obtain an expression for the heat-transfer coefficient:

$$\frac{1}{K} = \frac{1}{\alpha_T} + \frac{\delta_w}{\lambda_w} + \frac{1}{\alpha_L},$$

$$K = \frac{\alpha_T\alpha_L\lambda_w}{\alpha_T\lambda_w + \alpha_L\lambda_w + \alpha_T\delta_w}. \quad (14)$$

Then, having written Eq. (12) for the continuous phase being heated and for the heat-carrying agent, we obtain, with account of (13) and (14),

$$\frac{d\Theta_L}{dX} - A(\Theta_T - \Theta_L) = 0, \quad (15)$$

$$\frac{d\Theta_T}{dX} + AB(\Theta_T - \Theta_L) = 0, \quad (16)$$

$$A = \frac{K}{c_{pL}\rho_L g_L}, \quad B = \frac{c_{pL}\rho_L g_L}{c_{pT}\rho_T g_T}, \quad F(X) = \frac{\pi_f x}{f}. \quad (17)$$

For the direct flow, $g_L > 0$, $g_T > 0$, $A > 0$, and $B > 0$; for the counter flow, $g_L > 0$, $g_T < 0$, $A > 0$, and $B < 0$. Solutions to Eqs. (15) and (16) have the following form [13]:

$$\Theta_L(X) = \frac{\Theta_T(0) + B\Theta_L(0)}{1 + B} - \frac{1}{1 + B}[\Theta_T(0) - \Theta_L(0)]\exp[-A(1 + B)(X)], \quad (18)$$

$$\Theta_T(X) = \frac{\Theta_T(0) + B\Theta_L(0)}{1 + B} + \frac{B}{1 + B}[\Theta_T(0) - \Theta_L(0)]\exp[-A(1 + B)F(X)], \quad (19)$$

In a particular case, at $B = -1$

$$\Theta_L(X) = \Theta_L(0) + A[\Theta_T(0) - \Theta_L(0)]F(X), \quad (20)$$

$$\Theta_T(X) = \Theta_T(0) + A[\Theta_T(0) - \Theta_L(0)]F(X). \quad (21)$$

The heat balance equation (3) for the heater can be written in dimensionless form:

$$B[\Theta_L(0) - \Theta_L(1)] + \Theta_T(0) - \Theta_T(1) = 0. \quad (22)$$

From Eq. (18) we find the parameter A:

$$A = \frac{1}{1 + B}\ln\left[\frac{\Theta_T(0) - \Theta_L(0)}{\Theta_T(0) + B\Theta_L(0) - (1 + B)\Theta_L(1)}\right]. \quad (23)$$

With a knowledge of the dimensionless temperatures $\Theta_L(0)$, $\Theta_T(0)$, $\Theta_L(1)$, $\Theta_T(1)$, we can find the parameter A and the necessary heat-exchange surface area f from (23) and (17).

For a unit with a direct-flow heater ($B > 0$), we have

$$\Theta_L(0) = \Theta_L^{in}, \ \Theta_T(0) = \Theta_T^{in}, \quad \Theta_L(1) = \Theta_L^{out}, \ \Theta_T(1) = \Theta_T^{out}. \quad (24)$$

Then, we obtain from (23) with account of (4)–(6):

$$A = \frac{1}{1 + B}\ln\frac{E - (1 - \varepsilon E)\Theta_L^{fin}}{E - (1 + \varepsilon EB)\Theta_L^{fin}}. \quad (25)$$

From Eq. (25) follow the inequalities:

$$0 \le \Theta_L^{fin} \le \frac{E}{1 + \varepsilon E} \le \frac{E}{1 - \varepsilon E}. \quad (26)$$

Using (26), we can find the interval of possible values for one of the quantities ε, E, B, Θ_L^{fin}, if the other three are set. For example, at preset values of the parameters ε, E, and B, the maximum possible dimensionless temperature of the continuous phase being heated, at the outlet of a unit with direct-flow heater, can be calculated by the formula

$$\Theta_{L\,max}^{fin} = \frac{E}{1 + \varepsilon EB} \le E, \quad (27)$$

with the maximum only reached at $A \to \infty$.

For a unit with counterflow heater ($B < 0$), we have

$$\Theta_L(0) = \Theta_L^{in}, \ \Theta_T(0) = \Theta_T^{out}, \quad \Theta_L(0) = \Theta_L^{out}, \ \Theta_T(0) = \Theta_T^{in}. \quad (28)$$

Then we obtain from formulas (22) and (23), with account of (4)–(6),

$$A = \frac{1}{1 + B}\ln\left[\frac{1 + \left(\varepsilon + \varepsilon B - \frac{1}{E}\right)\Theta_L^{fin}}{1 - \frac{1}{E}\Theta_L^{fin}}\right]. \quad (29)$$

Using expression (29), we can find the limit at $B = -1$:

$$\lim_{B \to -1} A = \frac{\varepsilon E\Theta_L^{fin}}{E - \Theta_L^{fin}}. \quad (30)$$

Let us write the following possible intervals for the dimensionless temperature of the continuous phase being heated, at the outlet of a unit with a counterflow heater

$$0 \le \Theta_L^{fin} \le \Theta_{L\,max}^{fin}, \quad (31)$$

$$\Theta_{L\,max}^{fin} = \frac{E}{1 - \varepsilon E(1 + B)} \text{ at } 1 + B < 0, \quad (32)$$

$$\Theta_{L\,max}^{fin} = E \text{ at } 1 + B > 0, \quad (33)$$

with these maximum values only reached at $A \to \infty$.

Comparison of formula (27) with (32) and (33) shows that, all other conditions being the same,

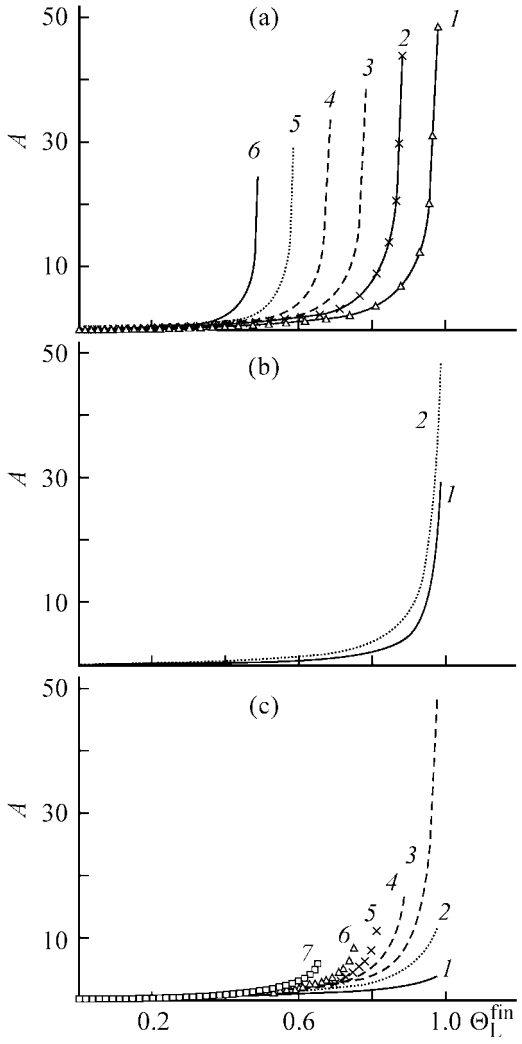

Fig. 2. Parameter A vs. preset dimensionless temperature Θ_L^{fin} of the continuous phase being heated, at the outlet of a unit with counterflow heater. (a) $\varepsilon = 1$, $B = -1$; (b) $E = 1$, $B = -1$; (c) $E = 1$, $\varepsilon = 1$. (a) Degree of heat exchange, E: (*1*) 1.0, (*2*) 0.9, (*3*) 0.8, (*4*) 0.7, (*5*) 0.6, and (*6*) 0.5. (b) Porosity: (*1*) 0.6 and (*2*) 1.0. (c) Parameter B: (*1*) 0, (*2*) 0.8, (*3*) 1.0, (*4*) 1.1, (*5*) 1.2, (*6*) 1.3, and (*7*) 1.5.

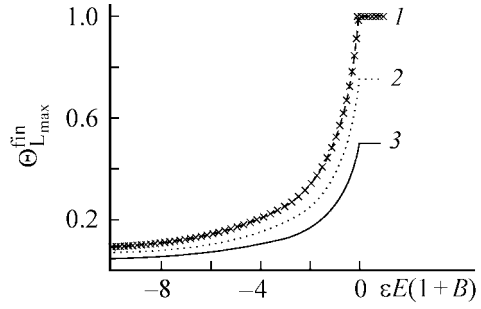

Fig. 3. Maximum dimensionless temperature of the continuous phase being heated, $\Theta_{L\,max}^{fin}$, at the outlet of a unit with counterflow heater vs. the product $\varepsilon E(1 + B)$. Degree of heat exchange E: (*1*) 1.0, (*2*) 0.75, and (*3*) 0.5.

the unit with counterflow heater is more efficient than that with a direct-flow heater. The efficiency of the unit can be characterized by the dimensionless temperature Θ_L^{fin}. The higher Θ_L^{fin}, the better the efficiency of the unit.

Let us calculate the final temperature of the dispersion medium in the outlet pipe of VPMA

$$\theta^{fin} = \frac{\varepsilon c_{pL}\rho_L\theta_L^{fin} - (1 + \varepsilon)c_p S\rho_S\theta_S^{ini}}{\varepsilon c_{pL}\rho_L - (1 + \varepsilon)c_p S\rho_S}, \qquad (34)$$

where the subscript "S" indicates the dispersed phase.

Figure 2 shows dependences of the parameter A on the preset dimensionless temperature Θ_L^{fin} of the continuous phase being heated, at the outlet of a unit with a counterflow heater, at different values of the degree E of heat exchange (Fig. 2a), porosity of the dispersion medium (Fig. 2b), and parameter B (Fig. 2c). Similar curves can also be calculated for a unit with directflow heater, using formula (25) with account of inequality (26).

With increasing absolute value of the parameter B and porosity ε of the dispersion medium and decreasing degree E of heat exchange, the value of the parameter A, necessary for prescribed Θ_L^{fin} to be obtained, grows. The increase in A at preset physical properties and flow rates of the continuous phase being heated and the heat-carrying agent means that the heat-exchange surface area, and, consequently, the heater length become greater.

It can be seen from Fig. 3 that the maximum dimensionless temperature of the continuous phase being heated, at the outlet of a unit with counterflow heater, calculated using formulas (32) and (33), decreases with increasing absolute value of $\varepsilon E(1 + B)$ and decreasing E.

CONCLUSIONS

(1) It was established that the process of continuous selective heating of the continuous phase of the dispersion in a unit comprising a heater and a mass-and-heat-exchange apparatus is affected by the following parameters: E, the degree of heat exchange in a valve-pulsatory mass-and-heat-exchange apparatus; ε, the porosity of the dispersion medium being heated; A, the ratio of the heat flux across the heat-exchange surface in the heater at unit temperature gradient to the specific heat of the continuous phase being heated, flowing through the heater in unit time; $|B|$, the ratio of the heat capacities of

the continuous phase being heated and the heat-carrying agent, flowing through the heater in unit time.

(2) It was found that, all other conditions being the same, a unit with counterflow heater has higher efficiency than that with direct-flow heater.

(3) It was established that the efficiency of the unit comprising a heater and a mass-and-heat-exchange apparatus is the higher, the greater E and A and the smaller ε and $|B|$.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Cleansing Action of Synergistic Mixtures of Surfactants in Pretreatment of Glass Fibers before Electroless Metal Plating

R. E. Skokina and L. I. Voronchikhina

Tver State University, Tver, Russia

Received January 8, 2002

Abstract—Cleansing action of synergistic mixtures of cationic and nonionic surfactants as influenced by their composition, temperature, and contact time is studied with the aim of developing detergents for pretreatment of thin glass fibers before electroless metal plating.

Applying thin (<1 μm) metallic (Cu, Ni, Co) coatings onto glass fibers by electroless metal plating solutions requires fiber surface pretreatment (degreasing), to remove paraffinic and dextrin-oil glass fiber sizers (the presence of such sizers on the fiber surface considerably decreases the wettability of glass fibers and the adhesion strength of coatings).

The procedure for fiber surface pretreatment largely controls extent the coating quality, adhesion to the support, continuity, and electrical conductivity (these characteristics are crucial in using metal-plated glass fibers in electronic countermeasure systems. There are two routine degreasing methods: treatment with organic solvents or special solutions and thermal treatment. Application of these traditional methods to thin (5–8 and 7–10 μm in diameter) glass fibers does not provide the desired result, since thermal treatment decreases the fiber strength (by up to 40%), and the use of chlorinated hydrocarbons requires their frequent regeneration to remove oils. Furthermore, these compounds are toxic, which makes necessary specially designed facilities.

Use of detergents containing phosphates, silicates, and alkali (commonly used in electroplating) also affects adversely the strength of thin glass fibers, since they have highly developed surface (compared to glass), failing faster in aggressive media. As a result, their strength decreases by 50–60% [1]. Therefore, the goal was to decrease the destructive effect of detergents on glass fibers in the course of their pretreatment before electroless metal plating. We studied synergistic mixtures of surfactants and recommended them for practical use in pretreatment of glass fibers before metal plating.

It is known that, on passing from individual surfactants to their mixtures, synergistic effects are often observed [2]. For example, the use of mixtures of surfactants with stepwise increasing polarity considerably improves removal of sizers. We found in the literature information on both synergistic and antagonistic effects of surfactant binary mixtures on such properties as micelle formation, solubility, cleansing action, etc. [3].

Widely used mixtures of ionic and nonionic surfactants demonstrate synergism in cleansing action [4, 5].

In this study, we used as cleaning fluids for pretreatment of glass fibers mixtures of cationic [cetyltriethylammonium bromide $C_{16}H_{33}N(C_2H_5)_3Br$, dodecyltriethylammonium bromide $C_{12}H_{25}N(C_2H_5)_3Br$, and decyltriethylammonium bromide $C_{10}H_{21}N(C_2H_5)_3Br$] and nonionic surfactants [Syntanol DS-10 (polyethylene glycol monoalkyl ether based on primary fatty alcohols, $C_nH_{2n+1}(C_2H_4O)_mH$, n = 10–18, m = 8–10) and OP-10 (polyethylene glycol monoalkylphenyl ether $C_nH_{2n+1}C_6H_4O(C_2H_4O)_mH$, n = 8–10, m = 10–12)]. We studied the effect of the detergent concentration and the degreasing temperature and time on the degreasing efficiency. The cleansing action (degree of degreasing) was estimated gravimetrically and also from the wetting angles of model glass surfaces pretreated by dressing. The detergent compositions were optimized by varying the surfactant mixture composition. The total surfactant content in the mixtures was constant (0.1 wt %). The cleansing action of synergistic mixtures as a function of their composition is illustrated in Fig. 1. In the $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 system, the maximal

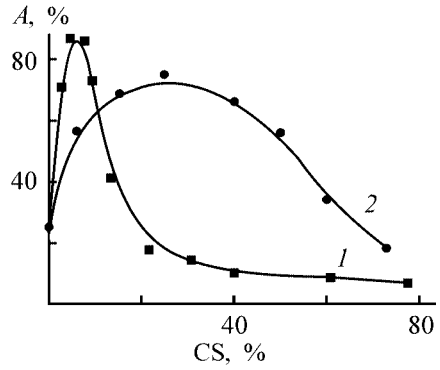

Fig. 1. Cleansing action *A* of synergistic mixtures vs. their composition. (CS) Fraction of the cationic surfactant in a mixture; the same for Fig. 4. Detergent: (*1*) $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 and (*2*) $C_{10}H_{21}N(C_2H_5)_3Br$–DS-10.

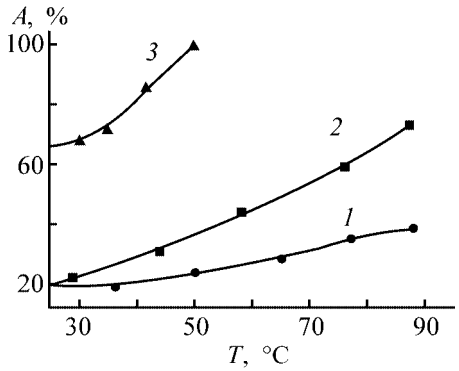

Fig. 3. Degree *A* of degreasing of the glass fiber surface vs. temperature *T*. Degreasing time 5 min. Detergent: (*1*) H_2O, (*2*) Syntanol DS-10, and (*3*) $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 (5 : 95).

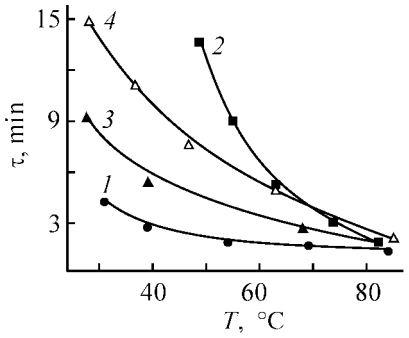

Fig. 2. Time of complete degreasing τ vs. temperature *T*. Detergent: (*1*) $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 (5 : 95), (*2*) Syntanol DS-10, (*3*) $C_{12}H_{25}N(C_2H_5)_3Br$–DS-10 (30 : 70), and (*4*) OP-10.

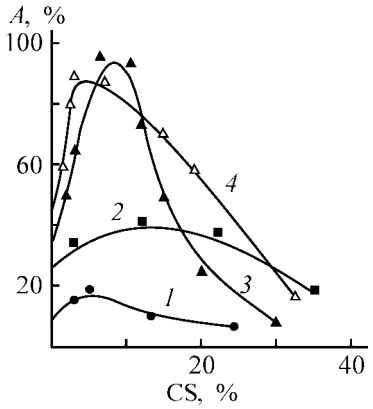

Fig. 4. Cleansing action *A* of $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 at various temperatures (°C): (*1*) 15, (*2*) 65, (*3*) 45, and (*4*) 35.

cleansing action is observed at a component ratio of 5 : 95. In the other systems, the maximum shifts toward higher concentrations of a cationic surfactant. In the system $C_{10}H_{21}N(C_2H_5)_3Br$–DS-10 it is observed at the 25 : 75 ratio (Fig. 1, curve *2*).

The results obtained show that the degreasing proceeds slowly at low temperatures, being accelerated on heating (Fig. 2), evidently, because of the increasing activity of the surfactants and decreasing viscosity of oils. Also, we observed the effect of the structure of a cationic surfactant on its degreasing efficiency: compounds with longer hydrocarbon chains (C_{16}) are more effective, which allows reduction of the degreasing time and temperature. At low temperatures the synergistic mixtures are more favorable, since the same degreasing effect is achieved at lower temperature (Fig. 3). The composition corresponding to the maximal cleansing action of the synergistic mixtures depends on temperature (Fig. 4). For the system $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 (5 : 95), the maximal cleansing action is observed at 35°C. The absolute maximum of the cleansing action in this system was observed for the composition 10 : 90 at 45°C. A study of how the cleansing action of a detergent depends on the liquor ratio showed that the synergistic mixtures are more efficient, whereas higher concentration of individual Syntanol DS-10 and OP-10 is required with increasing charge of fibers. However, addition of Syntanol above 0.1 wt % produces strong foaming (this is not the case with the synergistic mixtures).

There are several concepts of synergism in surfactant mixtures, their cleansing action, and other colloid-chemical properties. It is commonly accepted that the synergistic effect is associated with the formation of mixed micelles capable to sorb oil pollutants more effectively as compared to micelles formed with an individual surfactant [6]. In some cases, antagonism or synergism may be due to formation of heteroassociates [3] or interfacial adsorption of surfactants. It is known [7] that cationic surfactants demonstrate only

insignificant detergency; being adsorbed on negatively charged areas of the contaminated surface, they impart hydrophobic properties to it and impede wetting of the surface with water. At the same time, being a component of a synergistic mixture, a cationic surfactant facilitates adsorption of nonionic surfactants on the hydrophobized surface, decreasing the attraction between pollutant particles and the surface and also between separate pollutant particles. As a result, this facilitates detachment of the oil film from the fiber surface with the formation of an emulsion, i.e., the cleansing action of a detergent increases.

Finally, the results obtained on the synergistic mixtures of cationic and nonionic surfactants show that they can be recommended as components of cleaning solutions for pretreatment of glass fibers before electroless metal plating.

CONCLUSIONS

(1) Synergistic mixtures containing cationic surfactants with longer hydrocarbon chains ($C_{16}H_{33}$) demonstrate higher cleansing efficiency.

(2) In low-temperature degreasing of glass fibers, the cleansing action of synergistic mixtures of cationic and nonionic surfactants is considerably higher than that of individual components.

(3) Among the synergistic mixtures studied, the system $C_{16}H_{33}N(C_2H_5)_3Br$–DS-10 (5 : 95) demonstrates the highest cleansing effect in low-temperature degreasing of glass fibers.

Abstract—Influence exerted by salts with buffering action and by the initial pH of the reaction mixture on the polymerization kinetics, viscosity-average molecular weight, and amount and degree of surface carboxylation of polymethyl methacrylate particles formed in the course of emulsifier-free emulsion polymerization of methyl methacrylate initiated by 4,4'-azobis(4-cyanoisovaleric acid) was studied.

Synthesis of monodisperse polymethyl methacrylate (PMMA) particles with surface carboxy groups by emulsion polymerization of methyl methacrylate (MMA) with a carboxyl-containing azo initiator is complicated by partial hydrolysis of the monomer to methacrylic acid (MAA), which is especially pronounced at high initial pH of the reaction mixture [1]. In this case, MAA formed in the course of the synthesis copolymerizes with MMA, producing water-soluble oligomeric products and considerably reducing the size of the resulting particles. In this context, the method for directed control of the size of polymer particles by varying the initial pH of the reaction mixture, which provides good results in polymerization of styrene [2, 3], needs further modification in the case of MMA. The essence of the method indicated is that, in the course of polymerization, terminal carboxy groups of the initiator residues move toward the interface during formation of polymer-monomeric particles (PMPs). The surface charge formed as a result of ionization of these groups stabilizes PMPs through electrostatic repulsion.

Therefore, the degree of ionization of the initiator carboxy groups and carboxyl-containing styrene polymerization products strongly affects the size of the resulting particles, which allows its directed control by varying the initial pH of the reaction mixture. However, in the course of MMA polymerization started in an alkaline medium, the formation of MAA shifts pH to lower values, thus reducing the surface charge of PMPs and impairing the stability of the polymer dispersion. Furthermore, insertion of units of a carboxyl-containing comonomer into the oligomeric chains reduces their surface activity, thus changing the PMP formation conditions. To overcome these difficulties and to reveal factors controlling characteristics of the resulting PMMA particles, we studied the effect of salts, capable of stabilizing pH in weakly acidic or weakly alkaline medium, on the course of synthesis.

EXPERIMENTAL

Methyl methacrylate, isoamyl alcohol, and DMF were purified by distillation by the standard procedures. 4,4'-azobis(4-cyanoisovaleric acid) (CVA) was purified and characterized as in [1]. Suberic acid $HOOC(CH_2)_6COOH$ ("Ferak"), NaOH, HCl, NaCl,

* (S_{COOH}) Concentration of surface carboxy groups.

KH_2PO_4, and Na_2HPO_4 (analytically pure grade) were used without further purification. Double-distilled water was used as a dispersion medium.

The latexes were synthesized at 348 ± 1 K in the presence of 0.02 M NaCl or 0.01–0.02 M KH_2PO_4 or Na_2HPO_4 (initial pH 6.93–11.15) [1–3]. The amount of MMA in the reaction mixture was 10 wt %, and the CVA concentration, 7.14×10^{-3} M (2 wt % relative to MMA). The salt composition of the reaction mixtures is given in the table. The initial pH values of the reaction mixtures were determined by preliminary titration of the initiator [1] (run nos. are marked in Fig. 1). In the course of polymerization, samples of the reaction mixture were taken to determine the conversion of MMA, its surface tension, and current pH. The MMA concentration was determined by gas chromatography to within 5%, using isoamyl alcohol as internal reference. The surface tension at the interface between the reaction mixture and air was determined by the Du Noui method [4]. The pH was measured with a pH-121 instrument immediately after taking a sample and cooling it to 298 K.

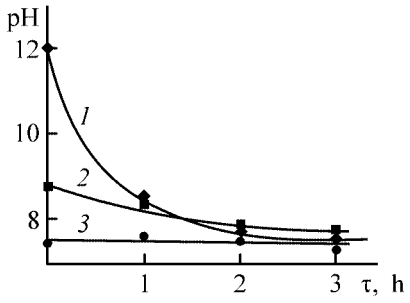

Fig. 2. pH of the reaction mixtures containing MMA, 0.01 M Na_2HPO_4, and suberic acid (instead of CVA) vs. the time τ at 348 K. pH_0: (*1*) 11.7, (*2*) 8.74, and (*3*) 7.47.

The diameter of latex particles D was found by electron microscopy (JEM 100 S, JEOL, Japan). After removal of water-soluble admixtures from latexes by centrifugation and redispersion in twice-distilled water, the surface carboxy groups were determined by conductometric titration [4]. The electrophoretic mobility of latex particles in 0.01 M NaCl was determined over a wide pH range (1.6–11.0) using the standard procedure [5]. The viscosity-average molecular weight (MW) of PMMA was found from the intrinsic viscosity measured at 20°C in DMF, using the Mark–Kuhn equation with $K = 1.73 \times 10^{-4}$ and $\alpha = 0.645$ [6].

The degree of MMA hydrolysis in synthesis of PMMA particles was estimated from data obtained with model reaction mixtures prepared with 0.01 M Na_2HPO_4, various amounts of NaOH, and suberic acid instead of CVA, to eliminate polymerization. pH was measured just after addition of MMA. Then the mixtures were allowed to stand at 348 K, and pH was measured at 3-h intervals (Fig. 2).

To study the effect of salt and pH value on CVA-initiated polymerization of MMA and characteristics of the resulting latex particles, we performed experiments with 0.01–0.02 M KH_2PO_4 and Na_2HPO_4, i.e., salts demonstrating buffer action in, respectively, weakly acidic and weakly alkaline solutions, and also with 0.02 M NaCl as an indifferent electrolyte, at varied initial pH of the reaction mixture. The compositions of the reaction mixtures and characteristics of

latexes obtained in these experiments and also in the experiments conducted without salt additives [1] are listed in the table. Experiments with the model reaction mixtures revealed (Fig. 2) that, even with salt additives, the high initial pH values decrease considerably during the first hour, i.e., hydrolysis of MMA occurs and MAA appears in the mixture. Furthermore, it has been demonstrated previously in the experiments on polymerization of styrene that pH may change by virtue of the formation of a highly developed interfacial surface [2, 3]. Therefore, only data obtained in titration of the reaction mixtures at room temperature allow reliable determination of the amount of NaOH needed for setting the initial pHs (pH_0) corresponding to various fixed degrees of ionization of the initiator carboxy groups (note that, in the experimental pH range, the initiator is totally soluble in water).

The MMA conversion and the surface tension and pH of the reaction mixtures with or without salt additives are shown in Figs. 3 and 4 as functions of the polymerization time. An important factor in CVA-initiated emulsifier-free emulsion polymerization is the degree of ionization of the terminal carboxy groups in surface-active oligomers and of growing radicals formed in the aqueous phase (on approaching the critical length of the chain, they form primary particles). At low pH_0, these nuclei of the new phase are mainly formed from oligomers bearing terminal carboxy groups in the H form, since their surface activity is higher as compared to the ionized form [1]. In this case, pH of the reaction mixture increases somewhat, since part of the carboxy groups become incorporated in the bulk of the primary particles. By contrast, at high pH_0, pH decreases through neutralization of the alkali by the reaction with the carboxy groups on the highly developed surface of newly formed particles. As a result, pH corresponding to the onset of polymerization (Figs. 3c, 4c) differs from pH_0. In the next stage of aggregation of the primary particles and their saturation with MMA, the displacement of the Na^+ cations from PMPs to the more polar aqueous phase via substitution with H^+ may result in a certain increase in pH of the reaction mixture (Fig. 3c, curves *1, 2*). The decrease in pH in the final stage of the

synthesis may be due to slow diffusion of the terminal polar carboxy groups of the polymer from the bulk of PMPs to the interface, as demonstrated for CVA-initiated polymerization of styrene [2, 3]. However, in the case of MMA, its partial hydrolysis causes polymerization in the stage of PMP growth even in weakly acidic medium. By contrast, salt additives make it possible to keep pH within the weakly alkaline range throughout the polymerization (Fig. 3c, curves *3*–*5*).

Figure 3 shows the results obtained at the lowest pH_0 (corresponding to the initial part of the abrupt change in the CVA titration curve) with and without salt additives (KH_2PO_4 and $NaHPO_4$). With NaCl additive, pH_0 was found to be 9.01, which corresponds to the central part of the abrupt change in the CVA titration curve. However, it appeared that, despite higher pH_0, raising the ionic strength by adding an indifferent electrolyte, NaCl, leads to the formation of a large amount of coagulum and also to polydispersity of the latex. We also observed deceleration of the polymerization after 75% conversion of MMA was attained, whereas in the absence of NaCl, at the same pH_0, the conversion was above 90% [1]. By contrast, in the presence of KH_2PO_4 and Na_2HPO_4, the MMA conversion was above 90% (Figs. 3, 4). In this case, polymerization of MMA was accompanied by the gel effect, as under the salt-free conditions [1]. In the stage of the synthesis, when a gel effect was observed, the surface tension of the reaction mixture considerably increased too, suggesting that the monomer and oligomeric reaction products are incorporated into growing PMPs. By contrast, we observed no gel effect with NaCl, and the surface tension of the reaction mixture remained rather low throughout the synthesis. This suggests the presence of a large amount of oligomers in the aqueous phase, which could provide formation of new particles and, as a result, of polydisperse latex. Therefore, compared to NaCl, addition of KH_2PO_4 and $NaHPO_4$ ensures higher aggregative stability of PMMA particles in the course of synthesis, thus favoring formation of monodisperse latexes. This is a result of stabilization of the surface charge of growing PMPs by virtue of keeping the pH of the reaction mixture within the weakly alkaline range regardless of pH_0 (Figs. 2–4). This constitutes the significant difference of CVA-initiated polymerization of MMA in the presence of salts with buffering effect from salt-free polymerization, when pH drifts steadily toward the acidic region (by virtue of hydrolysis of the monomer), the more so with increasing pH_0 [1]. In the presence of NaCl, we also observed a decrease in pH to 5.7. In this case, the reduction in the surface charge on PMMA particles resulted in latex agglomeration, which decelerated the polymerization.

The nature of a salt also considerably influences the dependences of the MMA conversion and the surface tension and pH of the reaction mixture on the polymerization time, and also on the size of the resulting PMMA particles and the carboxy group concentration on their surface. For example, in the presence of $NaHPO_4$ (run no. 2), considerably smaller monodisperse particles are formed, as compared to those obtained with KH_2PO_4 (run no. 7). The more developed interfacial surface in smaller particles formed with Na_2HPO_4 causes, evidently, a higher steady-state polymerization rate (see table and Fig. 3). A study of CVA-initiated polymerization of MMA in initially weakly acidic (run nos. 7 and 1-0) or weakly alkaline medium (no. 2) revealed temporary deceleration of the process at intermediate degrees of MMA conversion (Fig. 3). This period goes on until the gel effect onsets; its duration increases with salt composition of the reaction mixture changing in the order—no salt < 0.01 M Na_2HPO_4 < 0.02 M KH_2PO_4. In this case, the surface tension of the reaction mixture changes in time parallel to the conversion trend. In the presence of Na_2HPO_4, the gel effect is observed on reaching 30% conversion of MMA, being considerably more pronounced than that in the case of a more acidic buffer, KH_2PO_4, when the gel effect takes place only at 50% conversion.

The decrease in the polymerization rate at intermediate degrees of MMA conversion is probably due to a decrease in lifetime of the radical in PMP, which may occur on attaining a sufficiently low pH of the reaction mixture (6.7–7.5) corresponding to a small surface charge of PMP. In this case, the terminal carboxy groups of the oligoradicals occur essentially in the H form too, which increases their surface activity and, evidently, the rate of their capture by PMPs. At low pH, PMPs can also capture oligomers formed in the aqueous phase, as demonstrated by a certain increase in the surface tension of the reaction mixtures (Fig. 3).

The viscosity-average molecular weight of PMMA obtained in weakly acidic and neutral media (Fig. 5b) is remarkably lower if the reaction is performed in the presence of buffer salts. Raising the ionic strength of the dispersion medium stimulates the surface activity of oligomers and oligoradicals, favoring their capture by PMP and recombination of the radicals in the particle. In this case, MW of the resulting polymer and the polymerization rate decrease, and the gel effect is observed later, being less pronounced.

Exhaustion of the monomer in the aqueous phase must decrease the rates of oligoradical formation and capture by the particles, which may again increase the lifetime of the radicals in PMPs. As a result, the abrupt increase in the surface tension of the reaction mixture (Figs. 3b, 4b) coincides in time with the onset of the gel effect (Figs. 3a, 4a).

With increasing pH_0 of the reaction mixture, the inflections in the conversion curves at intermediate conversions of MMA disappear (Fig. 4). With the pH_0 increasing to the values corresponding to the central part of the abrupt change in the titration curve of CVA, the MW of PMMA increases too (Figs. 1, 5). This is caused by an increase in the degree of ionization of carboxy groups on the PMP surface and in oligoradicals, which decreases their surface activity and, therefore, makes lower the rate of their capture by the particles. Even at high pH_0 of the reaction mixtures, the decrease in MW of PMMA obtained in the presence of the buffer salts is not so pronounced as without them (Fig. 5). The reason is that hydrolysis of the monomer is suppressed in buffered weakly alkaline solutions.

In polymerization of MMA in salt-free media, the size of the resulting latex particles, carboxy group concentration on their surface, and steady-state polymerization rate decrease with increasing pH [1]. By contrast, in the presence of 0.01 M Na_2HPO_4 (run nos. 2–4), variation of pH over the range 7.47–11.15 has no remarkable effect on the particle size (see table and Fig. 5a). At the same time, the rise in ionic strength with Na_2HPO_4 concentration increasing from 0.01 to 0.02 M at the initial pH of the reaction mixture lying in the weakly alkaline range leads to coarsening of the resulting latex particles and to a noticeable decrease in the steady-state polymerization rate (run nos. 3, 5). This is probably due to contraction of the diffuse part of the electrical double layer and formation of $COO^{-1}Na^{+}$ ion pairs on the surface, which reduces the effective surface charge of the primary particles and promotes their aggregation into coarser PMPs. However, in strongly alkaline media (run nos. 4, 6), we observed no remarkable coarsening of the particles with increasing Na_2HPO_4 concentration, while the steady-state polymerization rate decreased as before. Evidently, incorporation of the hydrophilic MAA units into the polymeric chains results in the formation of water-soluble oligomeric products additionally stabilizing PMPs. With pH_0 shifted to the strongly alkaline region, the carboxy group concentration on the surface of the resulting PMMA particles increases (Fig. 5a), while in the absence of the salt additions, the reverse trend is observed [1]. Presumably, ion pairing on the PMMA surface reduces the lateral repulsion between the ionized carboxy groups, which allows higher degree of carboxylation to be attained. In this case, removal of water-soluble admixtures after synthesis does not provide a considerable reduction in the degree of carboxylation of the particle surface. Therefore, in CVA-initiated emulsifier-free polymerization of MMA, introduction of appropriate buffer salts allows formation of monodisperse submicrometer latex particles and also variation of the carboxy group concentration on their surface.

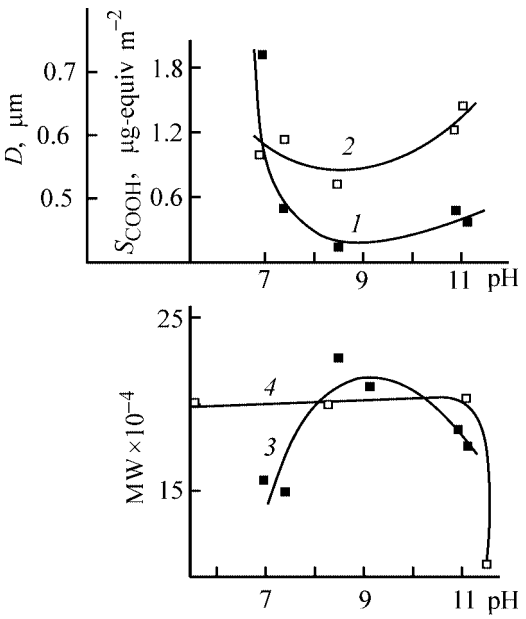

Fig. 5. (*1*) Particle size *D*, (*2*) concentration of the surface carboxy groups, S_{COOH}, and (*3*, *4*) viscosity-average molecular weight MW of PMMA in latex particles obtained with and without bufferring additives, respectively, vs. the initial pH of the reaction mixture.

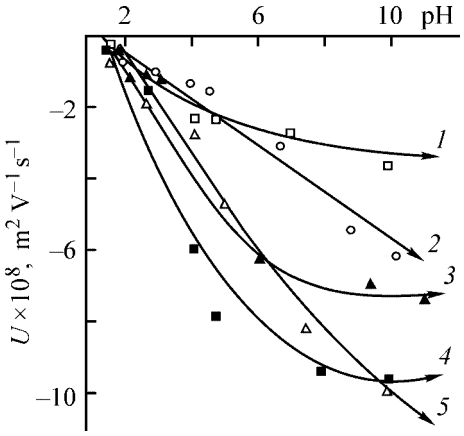

Fig. 6. Electrophoretic mobility of PMMA particles, *U*, in 0.01 M NaCl vs. pH. S_{COOH} (μg-equiv m^{-2}): (*1*) 0.73, (*2*) 0.96, (*3*) 1.05, (*4*) 1.41, and (*5*) 1.45.

A microelectrophoretic study of the surface electrical properties of PMMA particles obtained in the presence of buffer salt additions showed that their electrophoretic mobility *U* and, therefore, the surface charge grows both with increasing carboxy group concentration on the surface and with pH increasing, because of the rise in the degree of ionization of these groups (Fig. 6). Also, the electrophoretic mobility of the resulting PMMA particles exhibited the classical dependence on the ionic strength of the dispersion medium, i.e., decreased with increasing ionic strength as a result of compaction of the diffuse part of the electrical double layer. This points to a planar distribution of the carboxy groups and to weak conformational flexibility of the polymeric chains [7]. Therefore, the surface layer structure presumably remains unchanged when the salt composition of the dispersion medium is varied.

CONCLUSIONS

(1) In emulsifier-free emulsion polymerization of methyl methacrylate initiated by a carboxyl-containing azo initiator [4,4'-azobis(4-cyanoisovaleric acid)], addition of buffer salt (KH_2PO_4, $NaHPO_4$) eliminates the negative effect of hydrolysis of the monomer on the aggregative stability of the resulting polymethyl methacrylate particles.

(2) Raising the ionic strength of the reaction mixture by adding a buffer salt decreases the yield of water-soluble products of polymerization even at high initial pH and makes higher the yield of the polymer in the form of a monodisperse latex. Also, this leads to an increase in the size of PMMA particles formed in strongly alkaline medium and in the carboxy group concentration on their surface.

(3) A study of the surface electrical properties of the resulting latex particles demonstrated the possibility of controlling their surface charge over a wide range by varying the electrolytic composition and pH of the dispersion medium.

Abstract—The possibility of using H complexes of dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates and 4,4'-diaminodiphenyl ether and of polyimides prepared therefrom as polyimide foam materials, carbon-reinforced plastics, and foam composites was examined.

A number of such polyimide composite materials as polyimide foams [1], binders for carbon-reinforced plastics [2], and foam composites [3] have been prepared from dialkyl esters of 3,3',4,4'-benzophenonetetracarboxylic acid (BZP) and 4,4'-diaminodiphenylmethane (DADPM). However, DADPM is cancerogenic. Therefore, an urgent task is to replace DADPM with environmentally safer 4,4'-diaminodiphenyl ether (DADPE). As a rule, such a replacement impairs the properties of polyimide materials. The goal of this study was to find why the properties of DADPE-derived polyimides get worse and how this drawback can be overcome. To this end, we studied the features of thermal cyclization of H complexes of BZP diesters with DADPE and analyzed the supramolecular structure of the resulting polyimides.

EXPERIMENTAL

Dimethyl and diethyl BZP esters (BZPMe and BZPEt, respectively) were prepared by refluxing 0.03 mol of BZP dianhydride [TU (Technical Specifications) TSR 2159–69, purified by refluxing in acetone, mp 225°C) in 50 ml of an appropriate alcohol (anhydrous or containing 10 vol % water). To prepare the H complexes, DADPE (purified by distillation at 1–3 mm Hg, mp 150°C) or an equimolar mixture of DADPE and *m*-phenylenediamine (mPDA, purified by distillation at 1–3 mm Hg from zinc dust, mp 63°C) was dissolved (in the case of the mixture, the components were added successively) at room temperature in an alcoholic solution containing an equimolar amount of BZP diester. The solid H complexes were obtained by evaporating the alcohol at 20–30°C/1–3 mm Hg.

Samples for DSC were prepared by heating H complexes for 1 h at 220°C.

The viscosity of melts of H complexes was measured on a PIRSP rheometer with a cone–plane working unit (angle at the cone apex 1°, cone diameter 40 mm, shear rate $\gamma = 2 \times 10^{-2}$ s^{-1}) at 95 and 105°C [4].

Thermal gravimetric analysis (DTA, DTG, TG) of H complexes was performed with a C derivatograph (MOM, Hungary) in a ceramic crucible (50-mg sample, heating rate 5 deg min^{-1}).

The melting point of polyimides was measured with a Boetius heating stage.

The DSC studies were performed with a DSM-2M scanning microcalorimeter; heating rate 16 deg min^{-1}, threshold sensitivity 0.04 mW.

X-ray diffraction patterns of the H complexes and polyimides formed therefrom were obtained with a DRON-2 diffractometer (Ni-filtered Cu radiation).

The H complexes are formed spontaneously in the course of mixing of the reactants (dialkyl dihydrogen arenetetracarboxylates and aromatic diamines) in alcohols; after isolation from solution and drying, they may have different supramolecular structures and be amorphous or crystalline [5]. The supramolecular structure of H complexes appreciably affects the vis-

* The dash denotes no melting at the indicated temperature.

cosity of their melts. The more ordered the structure of H complexes, the higher the melt viscosity. In low-temperature impregnation of fibers to prepare prepregs of foam composites, it is desirable to use H complexes with low viscosity of the melt.

With DADPE, the viscosities of the melts of H complexes are considerably less reproducible as compared to the H complexes of DADPM; this fact may be responsible for problems arising when DADPM is replaced with DADPE. Let us take the H complexes with the highest and lowest viscosities of the melts and consider the differences in the structure and thermal behavior of these H complexes and of the polyimides therefrom.

Fig. 1. Diffraction patterns: (*1*) H complex BZPMe · DADPE, sample no. 1, initial; (*2*) the same, heated at 105°C for 20 min; (*3*) the same as 1, heated at 95°C for 90 min; and (*4*, *5*) final polyimides prepared from this H complex by heating at 220 and 275°C, respectively. (2θ) Bragg angle; the same for Fig. 2.

For analysis, we chose the H complexes obtained in methanol or ethanol with low viscosity of the melt, which is preserved for a long time at 95°C (sample nos. 1, 3) and the samples (nos. 2, 4) that do not melt at 95°C (Table 1).

Thermal treatment (220°C, 1 h) gives polyimides differing in the supramolecular structure. X-ray diffraction studies showed that the polyimides formed from sample nos. 2 and 4 are amorphous, and those formed from sample nos. 1 and 3, crystalline. The formation of the crystalline structure in sample nos. 1 and 3 was monitored in stages, from the initial H complex to the final polyimide, at various temperatures and times of heat treatment.

Naturally, the H complexes whose melts have low viscosity are amorphous (Figs. 1, 2, curves *1*). When a sample of the H complex BZPMe · DADPE is heated at 105°C for 20 min, a tendency toward formation of an ordered structure is revealed (Fig. 1, curve *2*). Heating at 95°C for 90 min gives a more ordered structure (Fig. 1, curve *3*). Previous rheological data for melts of H complexes suggest that, in the second case, the extent of imidization of the H complex is greater than in the first case despite the lower heating temperature [6]. Heating to 220°C yields a crystalline polyimide (Fig. 1, curve *4*).

8	117	154	227	265	475	520 (+)	587	98

* Temperatures of: ($T_{on.\ im}$) onset of imidization, ($T_{com.\ im}$) completion of imidization, (τ_0) onset of degradation, ($T_{max.\ im.\ rate}$) maximal imidization rate, ($T_{max.\ degr.\ rate}$) maximal degradation rate, and ($T_{max.\ degr}$) degradation peaks in DTA curves [(+) exothermic and (–) endothermic].

Similar structural changes were observed in heat treatment of the H complex BZPEt · DADPE (Fig. 2). Heating at 95°C for 1 h results in the appearance of weak reflections at 2θ ~22° and 25° (Fig. 2, curve *2*). Heating at 105°C for 30 min gives a more ordered structure (Fig. 2, curve *3*), and heating at 105°C for 1 h results in the appearance of well-defined peaks at 2θ ~19°, 23°, and 28° (Fig. 2, curve *4*). Thus, the sample structure becomes more perfect with the progress of imidization, and, finally, a crystalline polyimide is obtained (Fig. 2, curve *5*). By contrast, amorphous polyimides were obtained in all cases from crystalline H complexes [7].

Comparison of the positions of the main reflections in the diffraction patterns of BZPMe · DADPE (Fig. 1) and BZPEt · DADPE (Fig. 2) shows that the packing of polyimide chains in these samples (Fig. 1, curve *4*; Fig. 2, curve *5*) is about the same, with the structural motif being formed already in the course of heat treatment of the H complexes at 95–105°C.

Polyimide sample no. 1, heated to 220 or 275°C, has different crystal structures (Fig. 1, curves *4*, *5*), i.e., this sample exhibits polymorphism depending on the heat treatment temperature.

A thermal gravimetric analysis of H complexes revealed significant differences in behavior between sample nos. 1 and 3, compared to sample nos. 2 and 4, in all the stages from formation of the imide structure to degradation of the polyimide.

The DTG curves (Fig. 3) show that all the samples are characterized by two-step imidization with a slow second step; this is associated with the phase state of the substance: in the first step, imidization occurs in the melt, and in the second step, in the solid phase. For samples based on BZPMe (nos. 1, 2), according to the TG and DTA data, increase in the initial viscosity of the melts of the H complexes leads to extension of the temperature range of imidization and increase in the temperature of the maximal imidization rate. As a result, sample no. 2 transforms with almost 100% degree of imidization into a macromolecular polyimide exhibiting high heat resistance (Table 2). By contrast, at narrower temperature range

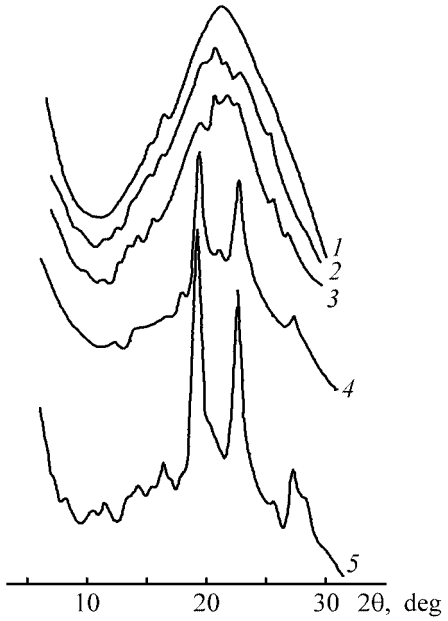

Fig. 2. Diffraction patterns: (*1*) H complex BZPEt · DADPE, sample no. 3, initial; (*2*) the same, heated at 95°C for 60 min; (*3*, *4*) the same as 1, heated at 105°C for 30 and 60 min, respectively; and (*5*) final polyimide prepared from this H complex by heating at 220°C.

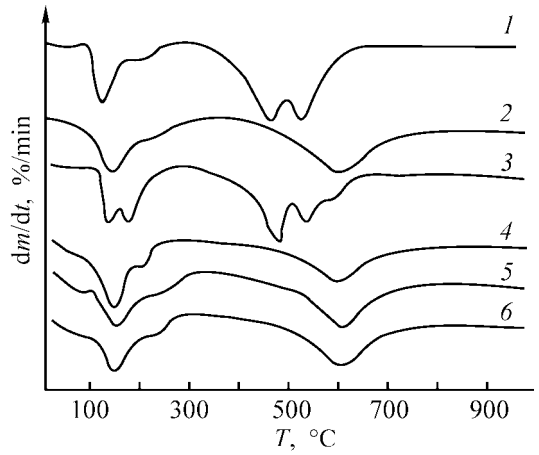

Fig. 3. DTG curves of H complexes: (*m*) weight, (*t*) time, and (*T*) temperature. *Curve nos*. are sample nos. in Table 1; the same for Fig. 4.

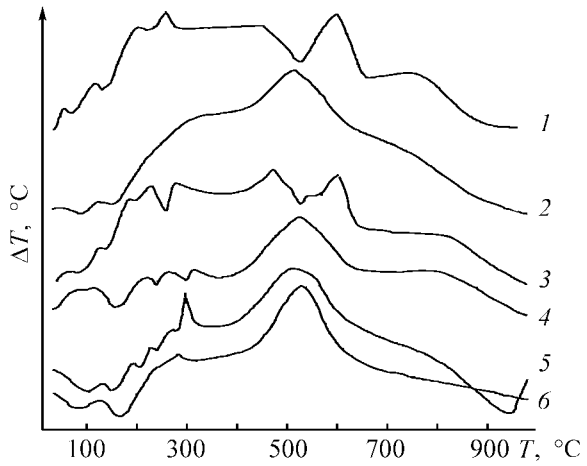

Fig. 4. DTA curves of H complexes. (*T*) Temperature; the same for Figs. 5 and 6.

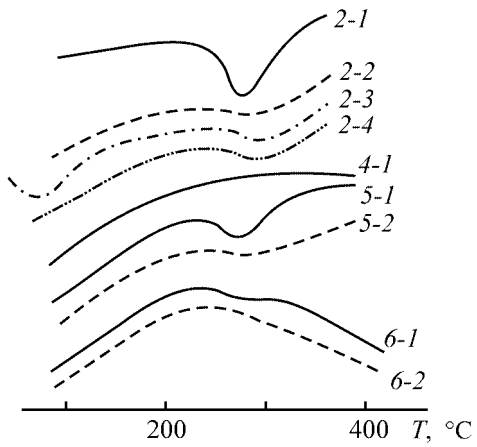

Fig. 5. DSC curves for samples of amorphous polyimides prepared by heating of H complexes at 220°C for 1 h. of imidization and lower temperature of the maximal imidization rate (sample no. 1), imidization is incomplete (degree of imidization 80%), and a crystalline polyimide is obtained. Similar results were obtained with sample nos. 3 and 4, prepared in ethanol.

Sample nos. 1 and 3 have low τ_0 values because of the incomplete imidization; furthermore, their degradation occurs in two steps, which is untypical of polyimides of this chemical composition (Fig. 3, Table 2). The degradation rate and the rate of the corresponding weight loss are appreciably higher than those for sample nos. 2 and 4. The two steps of degradation of sample nos. 1 and 3 are also seen in the DTA curves (Fig. 4).

Usually, the onset of degradation of polyimides is accompanied by an exothermic reaction; this was, indeed, observed with sample nos. 2 and 4. By the moment when the degradation rate reaches a maximum, the exothermic reaction is virtually complete. The difference between $T_{\text{max. degr}}$ of the exothermic peak and $T_{\text{max. degr. rate}}$ is 80–100°C. The DTA and DTG curves of sample nos. 1 and 3 (Figs. 3, 4) show that the temperature of the first maximum of the exothermic reaction virtually coincides with the temperature of maximal degradation rate in the first step, instead of the ~100°C difference. This is followed by an endothermic reaction corresponding to partial damping of degradation. The second degradation step occurs again with an exothermic effect, with the maximum virtually reached when the degradation is complete. Apparently, in these cases, the mechanism of thermal degradation differs from that observed in sample nos. 2 and 4.

In the range 220–350°C, the DTA curves for all the samples (Fig. 4) exhibit endo- and/or exothermic peaks of various intensities, not accompanied by any weight loss. These peaks might be assigned to softening, melting, and/or crystallization (for exothermic peaks) of the samples. However, visual examination shows that only samples of low-molecular-weight polyimides nos. 1 and 3 melt in the range 250–280°C. The other samples undergo no apparent changes in their aggregative state.

To reveal the nature of endo- and exothermic peaks in the DTA curves in the range 220–350°C, we studied by DSC the polyimide samples obtained by heating H complexes to 220°C. The results we obtained are shown in Fig. 5. In the case of amorphous polyimide prepared from the H complex based on BZPEt (no. 4), no noticeable thermal effects are detected in the range 220– 300°C (Fig. 5, curve *4*). The amorphous polyimide prepared from the H complex based on BZPMe (no. 2) shows a broad endothermic peak

(Fig. 5, curve *2-1*); the weight loss upon scanning to 310°C is about 1%. In a repeated scan (Fig. 5, curve *2-2*), the endothermic effect almost disappears, and no weight loss is observed. After keeping a sample for a day in a 100% humid atmosphere, an endothermic peak appears at 90°C, with the weak endothermic peak at 280°C remaining virtually unchanged. The weight loss is exclusively due to removal of sorbed moisture. Therefore, the endothermic peak under consideration may be assigned to softening and structural transformations of the polyimide, which do not occur at 220°C [at this temperature in the isothermal mode (1 h), imidization is complete in contrast to dynamic TGA].

The DSC curves of samples of crystalline polyimides (nos. 1 and 3; Fig. 6) strongly differ from the curves of amorphous polyimide samples. With crystalline polyimides, the endo- and exothermic effects above 220°C are preserved in repeated scans (Fig. 6). However, the temperatures of the peak maxima change, which is due, according to the X-ray diffraction data, to structural ordering and to polymorphism. The DSC data confirm that these samples have definite melting points.

The discrepancies between the temperatures of the exo- and endothermic peaks in the DTA and DSC curves may be due to different thermal histories of the initial samples (preliminary heating at 220°C for 1 h before DSC measurements and dynamic heating of H complexes to obtain polyimide in DTA measurements) and different heating rates.

Thus, with DADPE-based H complexes having the lowest viscosity of the melt, imidization in the course of heat treatment is incomplete, and low-molecular-weight crystalline polyimides are obtained. Therefore, in synthesizing prepregs for polyimide foam composites, low viscosity of melts of H complexes should not be sought for, because this may result in formation of brittle low-molecular-weight systems.

In this context, we studied H complexes formed from BZP diesters and DADPE in alcohols containing 10% water (sample nos. 5, 6) or from BZP diesters and an equimolar mixture of two diamines: DADPE and *m*-phenylenediamine (Tables 1 and 2, Figs. 3–5, sample nos. 7 and 8).

The H complexes prepared in alcohols with addition of water have relatively high viscosity of the melt, which complicates prepreg formation, but they yield exclusively high-molecular-weight amorphous polyimides. With mixtures of diamines, the viscosity of melts of H complexes at 95 and 105°C decreases. Therefore, it can be recommended to prepare DADPE-based H complexes in aqueous alcohol with addition of a second diamine as a comonomer.

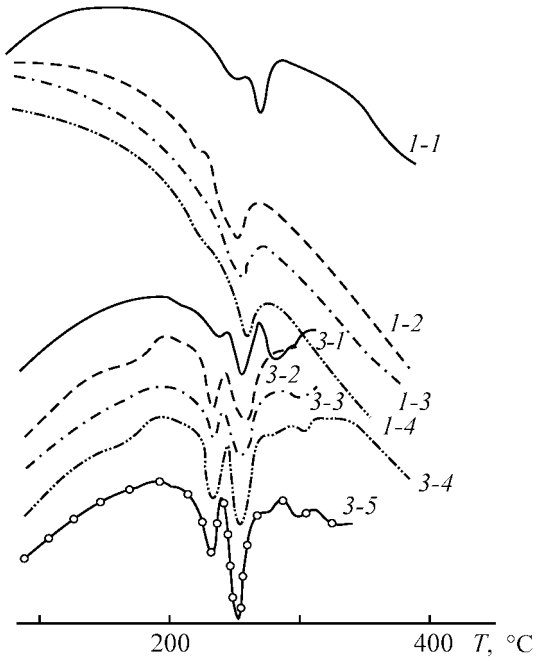

Fig. 6. DSC curves of samples of crystalline polyimides prepared by heating H complexes at 220°C for 1 h (repeated scans). *First digit*: H complex sample no.; *second digit*: number of scan.

CONCLUSIONS

(1) Factors impairing the performance characteristics of polyimides prepared from H complexes based on dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates and 4,4'-diaminodiphenyl ether were revealed. These factors are associated with the crystallinity of the polymer, which determines the viscosity of the process melt.

(2) The main features of thermal imidization of H complexes based on dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates and 4,4'-diaminodiphenyl ether, affecting the supramolecular structure of the forming polyimides, were determined.

(3) One of the components of the formulation for preparing a polyimide can be replaced with an environmentally safe product, 4,4'-diaminodiphenyl ether, provided that aqueous alcohols are used as solvents and 4,4'-diaminodiphenyl ether is taken as an equimolar mixture with another diamine (namely, *m*-phenylenediamine).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copper Tetra-4-Carboxyphthalocyanine as a Chemical Additive and Dye for Composites and Polycaproamide

V. E. Maizlish, G. P. Shaposhnikov, and Z. N. Zhukova

Ivanovo State Chemical Engineering University, Ivanovo, Russia

Received April 10, 2002

Abstract—Copper tetra-4-carboxyphthalocyanine was studied as a chemical additive and dye for a polymeric binder of fibrous composites and polycaproamide.

To make phthalocyanines (PC) soluble in aqueous alkaline solutions, carboxy and sulfonic groups are introduced into their structure. However, the solubility of carboxyphthalocyanines has been poorly studied. These compounds can be used in various fields of science and technology as dyes, catalysts for various reactions, photosensitizers for photodynamic cancer therapy, etc. [1–9]. Carboxyphthalocyanines are precursors for preparing thermally stable polymers and various phthalocyanine derivatives [10–20]. Copper tetra-4-carboxyphthalocyanine was studied as a component of a polymeric binder for composites and as a dye for polycaproamide (PCA).

Fibrous composites (FCs) have been recently regarded as a separate class of structural materials. They compete with conventional structural materials, such as metals, ceramics, and fiber glasses, and are widely used in various branches of science and industry [21].

Carbon fibers and high-strength high-modulus organic fibers composed of various linear aromatic polymers (SVM and ARMOS [21]), which show the most promise in this respect, are used to reinforce the composites.

Epoxy resins are used as curable polymeric matrices for organic plastics, being are one of the best binders for most of FCs [22]. This is due to the following: the adhesion of epoxy resins to many fillers, reinforcing components, and supports is high; the wide variety of available resins and curing agents allows preparation of materials with widely diverse properties under conditions meeting industrial requirements; no water and volatile compounds are formed in reaction of epoxy resins and curing agents, and shrinkage in the course of this process is lower than that in curing of phenol and polyester resins; cured epoxy resins are chemically stable and exhibit good insulating properties.

To further increase the production of FCss, their strength and resistance to light and heat should be improved. In addition, special demands are imposed on refractoriness of these materials and fire safety of articles therefrom.

A mixture of epoxy-4,4-isopropylidenediphenol and bromine-containing resins and a curing agent (a mixture of phenol-formaldehyde resin with aminophenol) is used as a binder for fireproof plastics [23].

In this study, we used ED-20 epoxy-4,4-isopropylidenediphenol resin [GOST (State Standard) 10487–84], AREM-2-20 epoxy-alkylresorcinol resin [TU (Technical Specification) 28.309.101–87] and Oksilin-6 epoxychloroaliphatic resin (TU 6-02-1376–87). SF 341A phenol-formaldehyde resin served as curing agent, and copper tetra-4-carboxyphthalocyanine $CuPc(4\text{-}COOH)_4$, as an additive to the polymeric binder [24]. Copper tetra-4-carboxyphthalocyanine enhances the heat resistance, with the refractoriness of the composite being preserved. In the presence of this compound, introduction of the bromine-containing epoxy resin used in the known procedure [23] is not required, which simplifies preparation of the composites.

The temperature of 0.8% weight loss by the modified binder based on ED-20 with and without $CuPc(4\text{-}COOH)_4$ is 258 and 265°C; fast weight loss is observed at 343.5 and 364.6°C, respectively.

The resistance of the coloration of SVM fiber and ARMOS containing $CuPc(4\text{-}COOH)_4$ to water, soap-sodium carbonate solution, organic solvents, UV radiation and daylight is evaluated as 5 points.

Properties of PCA

Property	Dye content, wt %	
	0.10	0.25
η_{rel}	2.38 ± 0.02	2.30 ± 0.01
Molecular weight	15600 ± 200	14700 ± 100
Content (wt %) of:		
LMWC*	10.13 ± 0.37	10.86 ± 0.21
caprolactam	7.53 ± 0.15	7.40 ± 0.28
mp, K	486 ± 1.0	482.5 ± 0.5

* LMWC denotes low-molecular-weight compounds.

The heat resistance of SMV fiber with and without CuPc(4-COOH)$_4$ additive is characterized by the following parameters:

Elongation, %	1.00/0.95
Preservation of elongation, %	71.4/95.0
Preservation of strength, %	82.05/97.7

The time of complete combustion of SVM fiber, ARMOS, and carbon fiber with/without CuPc(4-COOH)$_4$ is 5.4/10.3, 12/17, and 25/28 s, respectively.

Thus, introduction of the Pc in the composition of oligomeric binder improves the elastic, strength, thermal, and other properties of microplastics prepared from epoxy binders and reinforcing fiber, which extends the range of application of these FCs. Probably, in the presence of CuPc(4-COOH)$_4$ exhibiting mesomorphic properties [25], a more extended interface with improved structure is formed between the reinforcing filler and the polymeric matrix. In addition, in this case, blue-green composites with enhanced performances were prepared using SVM and ARMOS.

Among heterochain synthetic fibers, those based on caproamide polymers and copolymers (PCA) are of special interest. The world production of these fibers increases steadily. Having good consumer properties, these fibers are, however, difficultly colored. Preparation of colored and heat-resistant filaments and fibers is a topical problem. For the color of a composite to be most resistant to external effects, covalent bonds between the dye and polymer should be formed. Formation of these bonds is possible in the step of the polymer synthesis. Production of colored polymers is a kind of dyeing in the bulk and has all advantages of this process. In this case, the dye affects the process of fiber formation negligibly, the dye consumption decreases, and the resistance of the color to external effects is at a maximum.

Introduction of CuPc(4-COOH)$_4$ as a dye allowed us to abandon the use of acetic, benzoic, and adipic acids as chain-terminating agents. In addition, it is known that copper carboxyphthalocyanines are used to dye polyamides in the bulk.

We prepared PCA blocks with intense and uniform blue color. This color does not change after reprecipitation from sulfuric acid and 85% formic acid solutions, as well as after treatment with soap-sodium carbonate solutions, which indicates the formation of relatively strong chemical bonds between the phthalocyanine and the polymer.

The parameters of these polymers, listed in the table, meet the requirements to fiber-forming PCAs [26]. The fact that some macroheterocyclic compounds structurally similar to Pc are used as thermal and light stabilizers of PCAs suggests that the fibers prepared in the presence of CuPc(4-COOH)$_4$ must be resistant to heat and light [27].

EXPERIMENTAL

The tests of copper tetra-4-carboxyphthalocyanine as a chemical additive to a polymeric binder for composites were performed as follows. To prepare a polymeric binder, the epoxy resin, SF 341A phenol-formaldehyde resin, and copper tetra-4-carboxyphthalocyanine, taken in (95–105) : (65–75) : (0.9–1.1) weight ratio, were dissolved in 1 : 1 alcoholic–acetone mixture to obtain a 50% solution. The reinforcing fiber was impregnated with this solution on a bench impregnation unit and was air-dried for 15 min. The resulting composite was cured at 70°C for 30 min, 100°C for 60 min, 130°C for 60min, and 160°C for 120 min.

The heat resistance was estimated form the temperature of 0.8% weight loss, determined from TG curves.

Also, to evaluate the heat resistance, the samples were kept at 200°C for 12 h in a furnace. Then the strength and elongation were measured on a PM30-1 dynamometer at a clamping length of 10 cm and stretching rate of 300 mm min^{-1}.

The refractoriness was determined by the VIAM procedure in accordance with OST (Branch Standard) 190094–79.

To estimate the resistance of the composite coloration to external effects, the samples were treated with

cold and hot (100°C) water for 1 h, a solution of 5 g l^{-1} soap and 3 g l^{-1} sodium carbonate for 1.5 h, or organic solvents (acetone, 1 : 1 acetone–alcohol, DMF, DMSO), or were exposed to UV radiation of a PRK mercury lamp for 10 h or to daylight.

Polycaproamide. Caprolactam was polymerized in glass ampules in a special thermostat [28] maintaining temperature constant with an accuracy of ±0.3°C. A mixture of caprolactam with a definite amount of copper tetra-4-carboxyphthalocyanine and water was melted at 80°C, thoroughly stirred, and cast in thick-walled test tubes. The tubes were cooled with an ice-sodium chloride mixture, evacuated to a residual pressure of 66 Pa, and sealed. After the reaction was complete, the polymer obtained was cut in thin chips and analyzed.

Unreacted caprolactam was determined by vacuum sublimation. A weighted portion of PCA (0.2000 ± 0.0002 g) was placed in an open weighing bottle, dried in a vacuum desiccator over P_2O_5 at room temperature, and then sublimed at 150 ± 2°C for 150 min at a residual pressure of 66 Pa. The caprolactam content was determined from the weight loss after sublimation.

To determine the LMWC content, predried PCA (1 g) was poured over with distilled water (60 ml) and refluxed for 2 h with water replaced after 1 h. The polymer was filtered off and dried at 70°C under atmospheric pressure and for 6 h under reduced pressure (~66 Pa). The LMWC content was determined from the weight loss after extraction.

The relative viscosity η_{rel} of a polymer solution [1 g of the polymer in 100 ml of concentrated H_2SO_4 (ρ = 1.83 g cm^{-3})] was determined on a VPZh-2 viscometer at 20.00 ± 0.05°C.

The molecular weight was calculated by the equation

$$M = 113P_{av},$$

where P_{av} is the average degree of polymerization; 113 is the molecular weight of the polymer unit, $P_{av} = 100(\eta_{rel} - 1)$.

CONCLUSION

Fibrous composites with intense blue color and enhanced performance were prepared using a polymeric binder with copper tetra-4-carboxyphthalocyanine additive. Introduction of this complex allowed us to abandon conventional chain-terminating agents (carboxylic acids) in the polymerization.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Inorganic Electrolytes on the Stability and Structural and Rheological Properties of Emulsions Based on Rapeseed Oil

I. I. Goncharik and F. F. Mozheiko

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received May 14, 2002

Abstract—Formation conditions and structural and rheological properties were studied for emulsions based on rapeseed oil in the presence of aqueous solutions of sodium, potassium, and calcium chlorides and of sodium carbonate and sodium hydroxide.

At present, many branches of industry, such as paint-and-varnish, food, soap, and lubricant manufacturing, etc., utilize vegetable (linseed, hempseed, sunflowerseed, etc.) oils. In recent years, wide application has been enjoyed by rapeseed oil and emulsions on its base. Published data suggest that the formation conditions and structural and rheological properties of rapeseed oil emulsions, as well as the phase transformations in microemulsions and the influence of inorganic electrolytes on these properties, have been studied inadequately.

EXPERIMENTAL

We studied rapeseed oil containing, wt %: fat oils 38.1–45.3, essential oil 0.11–1.16, raw protein 25.0–29.8, P_2O_5 2.6, and other components [1]. The emulsions were prepared by the procedure from [1]. After a 15-min dispersing, a portion of the resulting emulsion was placed in calibrated test tubes, and the phase separation in the systems under study was monitored visually. As the measure of stability served the ratio (in per cent) of the volume of the separated aqueous or oil phase to that of the entire initially prepared emulsion. The remaining emulsion was used for structural and rheological, and electrical-conductivity studies. The structural and rheological properties of the emulsions were studied on a Rheotest 2 rotation viscometer in a coaxial-cylinder system at strain rates within 3.0–1312 s^{-1}. Based on the measured data, we calculated for each rate gradient D_r by standard procedures [2] the shear stress τ_r and the effective viscosity η. The procedure of studying the equilibrium shear stress as a function of the strain rate yielded full rheological curves.

First, we studied the emulsion formation in a system formed by water and rapeseed oil. We found that, whatever its concentration, rapeseed oil is able to forming emulsions in water without introdution of any emulsifying agent into the system (Table 1). The role of the emulsifying agent is, presumably, played by the impurities contained in rapeseed oil, such as phosphatides, soluble proteins, dyes, etc., as well as by oil hydrolysis products (in particular, monoglycerides), which are active emulsifiers [3]. The stability of the resulting emulsions varies with the oil phase concentration in the system. It was shown that, with increasing oil phase content, the emulsion stability increases to a maximum and then decreases. For example, the highest stability is observed at rapeseed oil concentrations of 50–60 wt %. Evidently, at these concentrations the adsorption layer at the liquid–liquid interface gets saturated with the emulsifier molecules, which is responsible for the high emulsion stability.

Table 1. Type, stability, and structural and rheological properties of rapeseed oil emulsions vs. the rapeseed oil concentration $c_{r.o.}$

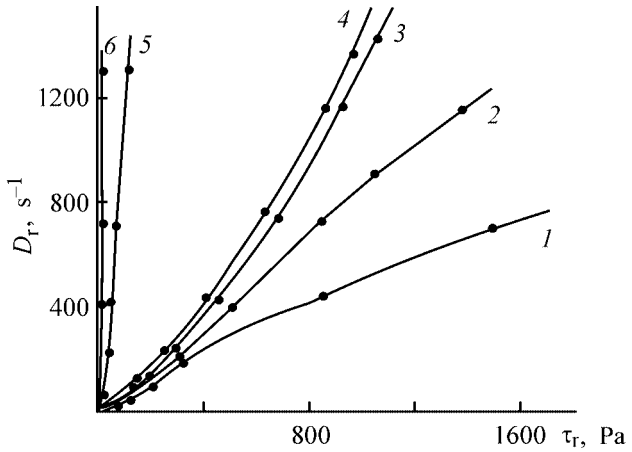

Fig. 1. Rheological flow curves of rapeseed oil-based emulsions at different rapeseed oil concentrations. (D_r) Velocity gradient and (τ_r) shear rate; the same for Fig. 2. Rapeseed oil content, wt %: (*1*) 60, (*2*) 75, (*3*) 90, (*4*) 100, (*5*) 50, and (*6*) 25.

Further increase in the rapeseed oil concentration in the system favors coalescence of the particles, which leads to emulsion breakdown. For example, at a rapeseed oil content of 75 and 90 wt % the resulting emulsions are characterized by significantly lower stability. They begin to break down already within 10–20 min, while at concentrations of 50–60 wt % only 32–16% breaks down even within 24 h.

Figure 1 shows how the structural and rheological properties of rapeseed oil emulsions vary with the oil concentration. It is seen that both individual rapeseed oil and emulsions on its base are structured liquid-like systems belonging to non-Newtonian liquids. For weakly structured liquids, the initial straight-line portion of the plot is typically short and virtually unidentifiable. With further increase in D_r and τ_r, the plots for these parameters get nonlinear. At the ultimate shear stress P_{c2} the system structure degrades completely. Our studies showed that, with increasing oil phase concentration, the emulsion structure gets somewhat stronger, as evidenced by an increase in the rheological characteristics P_{c2} and η. These parameters reach their maximal values, 80 Pa and 1.043 Pa s, respectively, with 60 wt % rapeseed oil in the system. With the rapeseed oil concentration increasing to 90 wt %, these parameters decrease to 80 Pa and 0.520 Pa s, respectively, thus evidencing a poorer structure strength.

Since many emulsification processes occur in the presence of inorganic electrolytes, it was of interest to elucidate how these electrolytes affect the stability and structural and rheological properties of the systems prepared from rapeseed oil. As known, inorganic electrolytes themselfes do not act as emulsion stabilizers because of the insufficient adsorption of their ions on the nonpolar hydrocarbon–water interface. However, in the presence of emulsifiers, the interphase activity of inorganic electrolytes may increase, thus making higher the packing density of the molecules in the surface layer at the liquid–liquid interface. Upon introduction of inorganic additions, the electrical double layer is compressed, the degree of hydration of the surfactant molecules decreases, and the structure of the solvent is modified. All this will affect the emulsion stability. In this study, we used sodium, potassium, and calcium chlorides, as well as sodium carbonate and sodium hydroxide [4, 5]. Our results (Tables 2, 3) suggest that the emulsion stability is determined by both the salt nature and concentration.

Our studies of the influence of cations on the stability of the emulsions prepared showed that, at minor cation concentrations, the emulsion stability is enhanced owing to the formation of a more stable adsoption layer at the liquid–liquid interface. For example, with $(0.02–0.3) \times 10^{-2}$ and $(0.03–0.05) \times 10^{-2}$ M of sodium and potassium chlorides, respectively, introduced into the rapeseed oil–water system, the resulting emulsions remain stable within 7 h, whereas without these additives they undergo 16% phase separation within 1 h (Table 2). With increasing concentrations of these salts, the emulsifier salting-out from the interface tends to enhance, facilitating breakdown of the emulsion. For example, with (0.04–0.14) and (0.12–0.24) M of sodium and potassium chlorides, respectively, introduced into a system formed by rapeseed oil and water, the emulsions undergo 12–80% phase separation within 4 h. With 0.09×10^{-2} M $CaCl_2$ introduced, these emulsions begin to break down, and, with 0.11 M $CaCl_2$, they completely break down within 1 h. According to the capability to form stable emulsions, the cations studied can be arranged in the lyotropic series $Na^+ > K^+ > Ca^{2+}$.

Sodium carbonate and sodium hydroxide exert a much stronger stabilizing effect on the system formed by rapeseed oil and water than the chlorides studied by us. It should be noted that, in the case of sodium hydroxide and sodium carbonate, the emulsion stability can be retained for longer time at concentrations much exceeding those of the chlorides. For example, at NaOH and Na_2CO_3 concentrations as high as 1.2 and 0.19 M, the emulsions remain stable for 1–3 days, respectively, whereas with 0.04 M NaCl, the 41% phase separation occurs already within 1 h. Thus, according to the effect on the emulsion stability, the anions can be ranked in the order $OH^- > CO_3^{2-} > Cl^-$.

Figure 2 presents the rheological curves obtained for rapeseed oil emulsions with varied content of NaOH and Na_2CO_3. The plots of the strain rate vs. shear stress are typical of pseudoplastic liquids. As expected, minor concentrations of the electrolytes much improve the rheological properties of the emulsions, most prominently in the case of sodium hydroxide. With 0.004–0.36 M NaOH, the ultimate shear stress is 240–290 Pa (Table 3) against 66 Pa

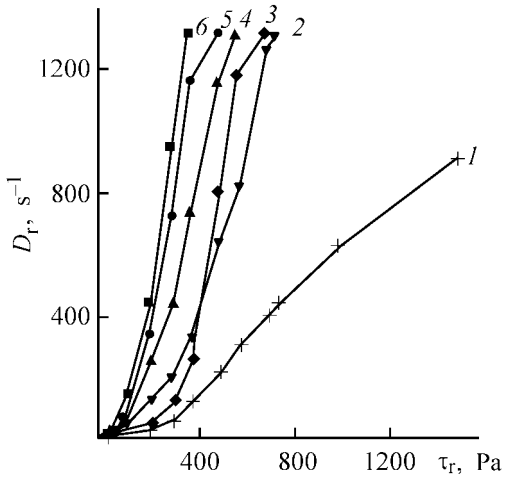

Fig. 2. Rheological flow curves for rapeseed oil emulsions (75 wt % rapeseed oil) at different concentrations of (*1–3*) NaOH and (*4–7*) Na_2CO_3 electrolytes. Electrolyte concentration, M: (*1*) 0.36, (*2*) 0.002, (*3*) 0.004, (*4*) 0.28, (*5*) 0.15, and (*6*) 0.075.

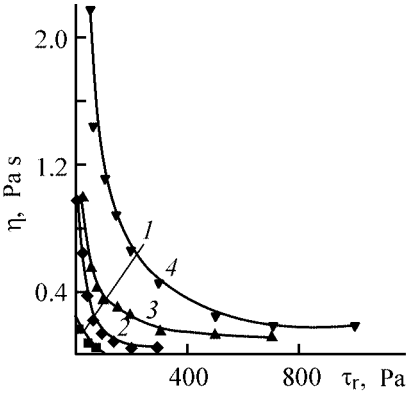

Fig. 3. Effective viscosity η, vs. shear stress τ_r, for rapeseed oil emulsions (75 wt % rapeseed oil) in the presence of (*2*) Na_2CO_3 and (*3*, *4*) NaOH. Electrolyte concentration, M: (*1*) 0, (*2*) 0.16, (*3*) 0.016, and (*4*) 0.36.

without NaOH. Na_2CO_3 tends to slightly decrease the ultimate shear stress P_{c2} to 80–180 Pa. With high concentrations of sodium hydroxide and carbonate (1.2–1.8 M), the structural and rheological properties decline dramatically, approaching those of the system formed by rapeseed oil and water. The ultimate shear stress in this case is 90–100 Pa.

An important characteristic of the structural and rheological properties of a system is its viscosity. Figure 3 shows the plots of the effective viscosity calculated from the flow rheograms against the shear stress for rapeseed oil emulsions containing inorganic electrolytes NaOH and Na_2CO_3. The $\eta = f(\tau_r)$ curves also suggest that these are non-Newtonian liquids, since their viscosity tends to decrease with increasing shear stress in the system. In this case, there is no region characterized by the highest Newtonian viscosity, where it is independent of the shear stress. The highest Newtonian viscosity of the system, probably, corresponds to very low shear stresses [6], which hinders measurements in view of the limited instrument capabilities. Our data suggest that, with NaOH (curves *3* and *4*) and Na_2CO_3 (curve *2*), both the initial and final viscosities increase relative to the emulsions without electrolytes. For example, with 0.36 and 0.16 M of sodium hydroxide and carbonate, respectively, the initial viscosities were equal to 2.0 and 1.1 Pa s, respectively, and the final viscosities, to 0.20 and 0.02 Pa s, the initial viscosity being 0.10, and the final, 0.01 Pa s, without electrolytes.

We identified the type of the resulting emulsions from the electrical conductivity. We found that formed by water, rapeseed oil, and potassium, sodium, and calcium chlorides yield type-2 (water-in-oil) emulsions, and those formed by water, rapeseed oil, and sodium carbonate or hydroxide, give both oil-in-water and water-in-oil emulsions (Tables 1 and 3). The electrical conductivity of the oil-in-water emulsions significantly exceeds that of the water-in-oil emulsions. With potassium, sodium, and calcium chlorides, it is independent of their concentrations, having a low value and remaining equal to that of rapeseed oil, i.e., 1.3×10^{-7} S cm^{-1}. In this case, the emulsifier dissolves in the oil phase, thus forming a type-2, i.e., water-in-oil, emulsion. With 0.2×10^{-2} and 0.8×10^{-2} M sodium hydroxide and sodium carbonate, the electrical conductivity increases to 8×10^{-4} and 1.2×10^{-5} S cm^{-1}, respectively, against 1.3×10^{-7} S cm^{-1} without additives. In this case, the phases invert. With further increase in the concentrations of these electrolytes, the specific electrical conductivity increases and only at 0.23 and 0.9 M Na_2CO_3 and NaOH, respectively, it declines to 1.3×10^{-7} S cm^{-1}, and the phases invert once again (Table 3). Evidently, with low concentrations of these electrolytes the emulsifier is accumulated at the interface and dissolves in the aqueous medium, thus forming type-1, i.e., oil-in water, emulsions. At high electrolyte concentrations, the emulsifier passes from the aqueous into the hydrocarbon phase, thus favoring formation of type-2 emulsions. In the system formed by water and rapeseed oil, with oil phase concentration of up to 60 wt %, type-1 emulsions are produced, and, with further increase in the oil phase concentration, type-2 emulsions (Table 1).

CONCLUSIONS

(1) Inorganic electrolytes introduced into a system formed by water and rapeseed oil modify its structural and rheological properties. The cation affects the emulsification of this system insignificantly, whereas the nature of the anion is of key importance.

(2) Sodium carbonate and sodium hydroxide affect the structural and rheological properties to a much extent than sodium, potassium, and calcium chlorides do. For example, introduction of sodium hydroxide or sodium carbonate into the system formed by water and rapeseed oil furnishes an opportunity of raising its thickening power, thus decreasing the amount of rapeseed oil to be spent for production of emulsions on this base and improving the quality of the structured dispersed systems.

(3) Phases invert under the action of inorganic electrolytes in the system formed by water and rapeseed oil: With alkali metal chlorides, type-2 emulsions are obtained in the system, and with sodium carbonate and hydroxide, both type-1 and type-2 emulsions, depending on the salt concentration.

Received April 24, 2002

Abstract—Homogeneous pyrolysis of 1,4-dimethoxynaphthalene was studied. The yield and group composition of liquid products and the component compositions of the gaseous products and hydrocarbons were determined; the asphaltenes and neutral oxygen-containing compounds were characterized. The kinetic parameters were determined, and possible mechanisms suggested, for decomposition of 1,4-dimethoxynaphthalene with the formation of CH_4, H_2, CO, and CO_2.

The need to study high-temperature transformations of compounds of strictly definite classes and, especially, of individual components corresponding to fragments of the organic matter of various caustobioliths and making the major contribution to formation of liquid products was convincingly substantiated in [1–16].

The goal of this study was to analyze the features of homogeneous pyrolysis of 1,4-dimethoxynaphthalene (DMN), determine the group composition of liquid products and the component compositions of the gaseous products and hydrocarbons, characterize asphaltenes and neutral oxygen-containing compounds (NOCs), and calculate the kinetic parameters of decomposition of 1,4-DMN and formation of CH_4, H_2, CO, and CO_2.

Pyrolysis of 1,4-DMN was performed on an installation described in [17]; the group composition of the liquid products was determined according to [18].

Data on the material balance of 1,4-DMN pyrolysis (Table 1) show that the thermal stability of this compound is relatively low. As the pyrolysis temperature was increased from 700 to 800°C and the pyrolysis time, from 1.5 to 4.5 s, the yield of liquid products decreased from 53.4 to 17.3 wt %, yield of gaseous products increased from 24.7 to 37.4 wt %, and yield of pyrocarbon increased from 21.2 to 44.3 wt % (based on the feed). The content of "crude benzene" was low and did not exceed 2.6 wt % (800°C, 3 s), which is apparently due to the lack of a simple route from a system of two fused aromatic rings to mononuclear aromatic hydrocarbons.

It should be noted that variation of temperature at fixed pyrolysis time affects the product yields less strongly than variation of the pyrolysis time. For example, as the pyrolysis temperature is raised from 750 to 800°C, at fixed pyrolysis times of 1.5 and 4.5 s, the yield of liquid products decreases by 8.5 and 8.8 wt %, respectively, whereas an increase in the pyrolysis time from 1.5 to 4.5 s causes a decrease in the yield of liquid products by 19.9 and 20.2 wt %, respectively.

Table 1 shows that, in the initial steps of 1,4-DMN pyrolysis (1.5 s), CO makes a half of the gaseous pyrolysis products (54.0 vol % at 700°C and 50.1 vol % at 750°C). Methane and CO_2 are formed in comparable amounts. As the pyrolysis temperature and time are increased, the content of CO decreases from 54.0 to 36.4 vol %, with the yield of hydrogen growing by a factor of 5 (from 4.6 to 23.2 vol %). Hence, with increasing temperature and time of pyrolysis, the relative contribution of condensation processes, occurring in parallel with the degradation to CO, CO_2, and CH_4, increases. The condensation processes can be monitored by formation of hydrogen and pyrocarbon. The yield of ethene decreases from 11.2 (700°C, 1.5 s) to 0.9 vol % (800°C, 4.5 s). This is apparently due to its participation in condensations by the Diels–Alder mechanism, more active under more severe conditions.

The tendency of 1,4-DMN to undergo condensations is confirmed by the high yield of asphaltenes, varying from 33.5 to 61.6 wt % based on the liquid products. The asphaletene structures are insufficiently

stable: With the pyrolysis time increasing from 1.5 to 4.5 s at 700–750°C, asphaltenes tend to accumulate, whereas at 800°C their relative content decreases from 61.6 to 52.1 wt %, with the yield of pyrocarbon growing simultaneously (Table 1).

The second most abundant group of liquid products is that of hydrocarbons. Their amount increases from 5.5 (700°C, 1.5 s) to 42.2 wt % (800°C, 4.5 s).

The yield of phenols is substantial only at 700 (1.5–3.0 s) and 750°C (1.5 s), amounting to 20.5, 16.3, and 14.2 wt %, respectively, but it decreases dramatically (to 1.3 wt %) at 800°C (4.5 s).

The content of NOCs, the main of which is unchanged 1,4-DMN, in liquid pyrolysis products is lower: Their yield decreases from 9.5 (700°C, 1.5 s) to 1.4 wt % (800°C, 4.5 s).

When studying thermochemical transformations of various compounds, it is important to obtain detailed data on the qualitative and quantitative composition of the products, in order to elucidate the main pyrolysis pathways, reveal its features, and find the best conditions for obtaining useful products in the highest yields.

The hydrocarbon fraction of liquid products of 1,4-DMN pyrolysis was studied by GLC. The yields of its components are listed in Table 2.

The major components of the hydrocarbon fraction are naphthalene, diphenyl, fluorene, and phenanthrene. The content of 2- and 1-methylnaphthalenes, pyrene, and chrysene is also high. A characteristic feature of the pyrolysis of 1,4-DMN is that the hydrocarbon fraction contains no anthracene.

The content of naphthalene, methylnaphthalenes, dimethylnaphthalenes, and acenaphthene decreases as the pyrolysis conditions are made more severe. At the same time, the content of more condensed components, such as phenanthrene, fluoranthene, pyrene, and chrysene, increases.

Table 2. Yields of components of the hydrocarbon fraction of liquid products formed in pyrolysis of 1,4-DMN

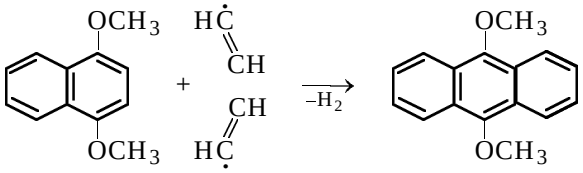
Note: (*M*) molecular weight; (C, H, O) content of carbon, hydrogen, and oxygen, respectively, wt % daf; (DA) degree of aromaticity, (PG) phenolic groups; (QG) quinoid groups; (AG) alkoxy groups; (O_c) oxygen in heterocycles; and (IN) iodine number, g-equiv mol^{-1}.

For asphaltenes, the molecular weight and elemental and quantitative functional compositions were determined (Table 3).

An increase in the molecular weight of asphaltenes from 250 to 326 in the examined range of parameters of 1,4-DMN pyrolysis indicates intensification of condensation processes. The high content of carbon (91.6–94.2%) and low content of hydrogen (5.44–5.65%) and oxygen (0.36–2.71%), in combination with the high molecular weight, point to the predominantly aromatic character and high degree of con-

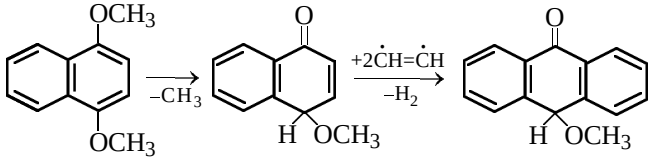
densation of asphaltenes and to the relatively low content of oxygen-containing functional groups in them. The major functional groups of asphaltenes are alkoxy, quinoid, and oxygen-containing heterocyclic groups. The content of methoxy groups increases from 0.03 to 0.72 g-equiv mol^{-1} as the time of pyrolysis at 750°C is increased from 1.5 to 4.5 s. At 800°C and pyrolysis time of 3 s, their content reaches a maximum (1.56 g-equiv mol^{-1}) and then decreases to 0.63 g-equiv mol^{-1} at pyrolysis time of 1.5 s. This may be due to attack on the 1,4-DMN molecule by radical fragments generated in the initial stage of degradation, which results in incorporation of methoxy groups in asphaltene structures:



As the residence time of the feed in the heated zone is increased, methoxy groups have time to decompose not only in 1,4-DMN, but also in asphaltenes, and their content decreases.

The content of quinoid groups tends to gradually decrease, which is due to their very high lability. It is important that quinoid groups, identified previously in asphaltenes formed by pyrolysis of a number of phenols [1–9] were also detected in asphaltenes formed by pyrolysis of 1,4-DMN, with the phenolic hydroxy groups being absent.

In view of this fact, we can suggest the following scheme of accumulation of quionid groups in asphaltenes in 1,4-DMN pyrolysis:



Heterocyclic oxygen can be formed as follows:

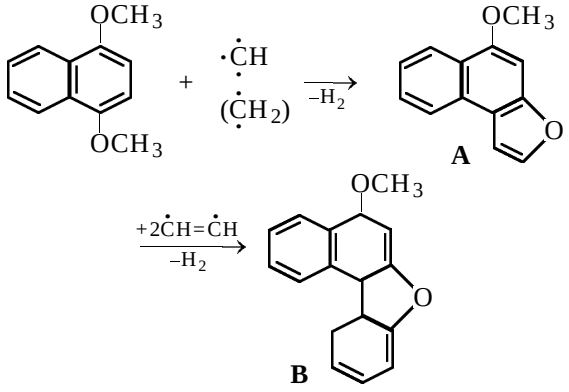


Table 4. Kinetic equations of overall decomposition of 1,4-DMN and formation of particular gaseous pyrolysis products*

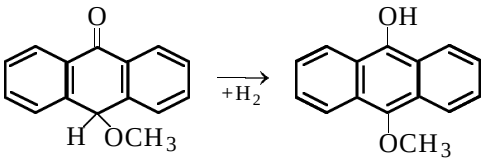
Process	K
Overall decomposition of 1,4-DMN	$1.10 \times 10^7 \exp(-123\,186/RT)$
Formation of:	
H_2	$2.63 \times 10^4 \exp(-79\,191/RT)$
CH_4	$3.31 \times 10^6 \exp(-52\,794/RT)$
CO	$2.58 \times 10^7 \exp(-159\,639/RT)$
CO_2	$2.94 \times 10^7 \exp(-162\,153/RT)$
C_2H_4	$2.36 \times 10^7 \exp(-27\,654/RT)$

* Reaction order 1.5, except the formation of CO_2 (reaction order 2.0).

The minimum in the content of heterocyclic oxygen, attained in 3 s and followed by its growth (4.5 s), is apparently due to easy transformation of unstable heterocycles of type **A** into more condensed and more stable structures of type **B**. Naturally, this multistage process must take certain time; therefore, the highest content of heterocyclic oxygen is reached in 4.5 s.

As compared to asphaltenes, NOCs have lower molecular weight (175–236). Their characteristic feature is the presence of small amounts of phenolic hydroxy groups (0.07–0.25 g-equiv mol^{-1}), reaching a maximum in 3 s. This is apparently due to their formation by reduction of the quinoid groups under the conditions when the concentration of these groups becomes high; in addition, increased concentrations of hydrogen are detected:



The content of the other functional groups is, on the whole, two times lower than that in asphaltenes.

The data on material balance, group composition, and component composition of the gaseous and liquid pyrolysis products were used to calculate the kinetic characteristics of the process (Table 4).

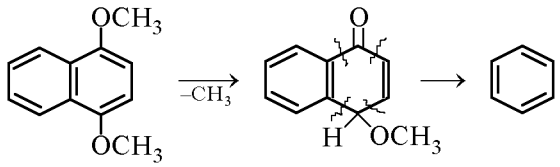
The overall decomposition of 1,4-DMN is described by an equation of the order of 1.5, with the activation energy E_a = 123.35 kJ mol^{-1}. The relatively low value of E_a of the overall decomposition process is apparently due to a significant contribution of radical reactions occurring with low energy barrier. The activation energy is considerably lower than that

of pyrolysis of naphthalene (278.64 kJ mol^{-1} [19]), α-naphthol (233.80 kJ mol^{-1} [7]), and 1,4-dimethylnaphthalene (159.09 kJ mol^{-1} [20]). Thus, methoxy groups destabilize the naphthalene core to a greater extent than phenolic hydroxyls and methyl groups do. The destabilizing effect of two methoxy groups is considerably stronger than that of a single methoxy group, so that E_a of 1,4-DMN decomposition is closer to that of 1,4-dimethylnaphthalene decomposition than to that of decomposition of compounds with a single functional group. The effect of oxygen atoms is stronger than that of methyl groups.

To elucidate the reaction mechanism and deduce the kinetic equations allowing control over formation of individual compounds with the use of an appropriate mathematical model of the process, it is of large interest to calculate the kinetic characteristics of particular pathways of the complex pyrolysis process.

Accumulation of CO follows a kinetic equation of order 1.5; E_a of this process is 159.64 kJ mol^{-1}. This activation barrier is two times lower compared to formation of CO from α-naphthol, which is probably due to a greater contribution of radical reactions to elimination of CO.

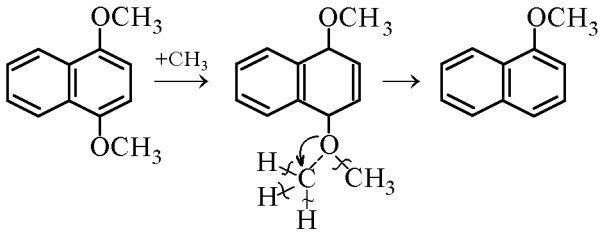
Transformation of 1,4-DMN into quinoid compounds must involve initiating demethylation. In this connection, we suggest the following scheme of CO formation. The first stage is initiation:



+ CO + $\dot{C}H{=}\dot{C}H$ + $H\dot{C}OCH_3$

This process generates a large number of radical products intensifying the cleavage of the 1,4-DMN molecule. The intermediate formation of the quinoid structure is confirmed by identification of quinoid groups in pyrolysis products, e.g., in asphaltenes and NOCs.

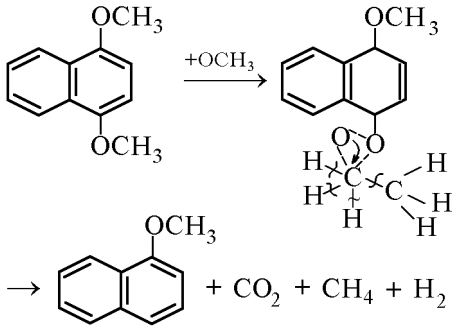
Second stage:



+ CO + CH_4 + H_2

A calculation of the theoretical E_a, assuming additivity of the bond energies in the activated complex [21], gave a value of 155.03 kJ mol^{-1}, in good agreement with the experimental value of 159.64 kJ mol^{-1}. This confirms the validity of the suggested scheme of the process. An additional evidence in favor of the presence of a second bimolecular initiating stage in the formation of CO is the reaction order of 1.5, since in the monomolecular cleavage of the ring in phenolic compounds it is equal to 1.0.

CO_2 formation is characterized by a similar activation energy (162.15 kJ mol^{-1}, Table 4), which suggest a kinetic relationship between these two processes, or similar mechanisms of formation of CO and CO_2. In this connection, we assume the following scheme: The first stage is initiation, similar to that in CO formation; the second stage is



→ + CO_2 + CH_4 + H_2

The calculated activation energy of CO_2 formation is 159.22 kJ mol^{-1}, which is nicely consistent with the experimental value of 162.15 kJ mol^{-1}; this fact supports the mechanism suggested. For anisole, E_a of CO_2 formation is 206.15 kJ mol^{-1}, i.e., it is higher than that for 1,4-DMN [8]. This is a manifestation of the destabilizing effect of two methoxy groups.

The relatively low energy barrier of methane formation (E_a 52.79 kJ mol^{-1}) is most probably due to the radical recombination mechanism of its formation, from both demethylation products and radical fragments of cleaved aromatic rings. This process is described by a kinetic equation of order 1.5.

The above schemes of CO and CO_2 formation involve formation of methane as a by-product. A calculation of the effective activation energy of methane formation by the method of additivity of the bond energies in the activated complex gave a value of 56.57 kJ mol^{-1} (with account taken of the demethylation stage); the experimental value is 52.79 kJ mol^{-1}. This indicates that the actual mechanism of methane formation is similar to that suggested here, with the only difference that the contribution of the less energy-consuming demethylation process is somewhat higher

(in calculations, it was assumed to be equal to the contribution of the ring cleavage).

In the case of naphthalene and α-naphthol, the activation energy of methane formation is higher by almost a factor of 5 (E_a 239.67 and 256.85 kJ mol^{-1}, respectively), which reflects the fact that, for these compounds, the only pathway of methane formation is energy-consuming cleavage of the aromatic ring.

Ethene is formed with a still lower activation energy (E_a 27.65 kJ mol^{-1}); the reaction order is 1.5. This is facilitated by the presence of C_2 radical fragments (e.g., $\dot{C}H=\dot{C}H$) in the stage of initiation of ring cleavage with the formation of CO. The C_2 radical fragments recombine with hydrogen present in the reaction zone to give ethene:

$$\dot{C}H=\dot{C}H + H_2(2H) \longrightarrow CH_2=CH_2$$

Such radical recombination reactions have zero activation energy, which is consistent with the low activation energy of the overall process of ethene accumulation in the pyrolysis zone. The very low preexponential term, equal to 2.36, supports the presumed formation of ethene from radical fragments like $\dot{C}H=\dot{C}H$ or by recombination of methyl radicals, followed by dehydrogenation, since the probability of radical recombination under conditions of dilution with an inert gas (1 : 25 by volume, neglecting additional dilution with gaseous and vaporous pyrolysis products) is very low. As a result, the concentration of ethene is low in most cases, although, in principle, it could be high.

Hydrogen can be formed by a number of pathways, including condensation of the initial 1,4-DMN molecules and radical fragments from degradation processes. The hydrogen formation is satisfactorily described by a kinetic equation of order 1.5, with E_a = 79.19 kJ mol^{-1} (Table 4). For 1,4-dimethylnaphthalene, this value is higher by almost a factor of 2 (159.22 kJ mol^{-1}), and for α-naphthol [7] and naphthalene [19] it is still higher (269.84 and 349.87 kJ mol^{-1}, respectively), which is indicative of the large contribution of molecular condensation reactions for these compounds.

The activation energy of hydrogen formation from anisole, 98.88 kJ mol^{-1} [8], proved to be the closest to that of hydrogen formation from 1,4-DMN.

CONCLUSIONS

(1) The thermal stability of 1,4-dimethoxynaphthalene is relatively low; its noticeable decomposition starts at 700°C. The major liquid products are asphaltenes and hydrocarbons. The major gaseous product is CO.

(2) The hydrocarbon fraction consists of naphthalene, methyl- and dimethylnaphthalenes, phenanthrene, fluoranthene, pyrene, and chrysene. The molecular weight of asphaltenes varies within 250–326, and that of neutral oxygen-containing compounds, within 175–236. The main functional groups are quinoid, alkoxy, and oxygen-containing heterocyclic groups.

(3) The kinetic parameters of overall decomposition of 1,4-dimethylnaphthalene and formation of particular gaseous products were calculated; the mechanisms of formation of these products were suggested.

Abstract—The structural-group composition of samples of organic matter of Chara sapropel and *Characeae* algae was studied by ^{1}H NMR.

In investigation of bioliths, high-resolution NMR spectroscopy was first used by Schnitzer and Barton [1] to analyze the functional composition of soil humus extracts. This allowed identification of methyl, polymethylene, phenolic, and carboxy groups in soil humus. By now, a great body of information on fragmentary structure of organic fractions of lignites, soils, shale oils, and bottom sediments has been derived from the ^{1}H NMR spectra [2–4].

However, studies concerning structural organization of various fragments of organic matter (OM) of saprpels are fragmentary and devoted to humic acids (HAs) only [3].

The aim of this work was to study the features of structural-group composition of OM of carbonate-chara sapropel and its main precursor, *Characeae* algae, using high-resolution ^{1}H NMR spectroscopy.

EXPERIMENTAL

Carbonate-chara sapropel samples for OM studies were taken from Lake Bezdonka (Tula oblast) and *Characeae* algae used by local balneal institutions. To obtain comparative data, we recorded ^{1}H NMR spectra of HA samples recovered from valley peat of the Yakhroma deposit (Moscow oblast) and macrophyt sapropel from Lake Glubokoe (Republic of Tatarstan).

Dry samples of HAs, fulvic acids (FAs), and nonhydrolyzable residue, humin (H), were produced from preliminary decalcified sapropel [5]. A set of "free" humic substances (FHSs) was recovered by extraction of dry sapropel with a solution of deuterated alkali immediately before recording the spectrum.

The hexane and alcoholic samples of macroalga, *Chara contraria L.*, were produced by extraction of dry native mass in a Soxhlet apparatus. All the extracts were dried in a vacuum at a temperature not exceeding 40°C.

The ^{1}H NMR spectra were recorded on a WP-80SY NMR spectrometer (Bruker, Germany) operating at 80 MHz with proton decoupling.

Samples for the ^{1}H NMR study were prepared by dissolution in chloroform-*d* or in a solution of deuterated alkali in heavy water. The samples were subjected to additional deuteration. For this purpose, the solutions of the samples were dried in a vacuum on a water bath at a temperature of approximately 90°C to remove heavy water, with subsequent dissolution of the dry residue in heavy water. The chemical shifts in the ^{1}H NMR spectra were measured relative to the signals of the residual protons of deuterated solvents: δ 7.25 ppm for chloroform and δ 5.00 ppm for water at pH > 2.

The signals in the ^{1}H NMR spectra of the samples were assigned according to [6].

The average length of alkyl radicals in the samples was evaluated by analysis of the integral intensities of the ^{1}H NMR signals from methyl and methylene groups. The average branching of alkyl radicals was estimated from the relative content of methine groups. The content of methylene and methine groups was

1070-4272/02/7512-2021 $27.00 © 2002 MAIK "Nauka/Interperiodica"

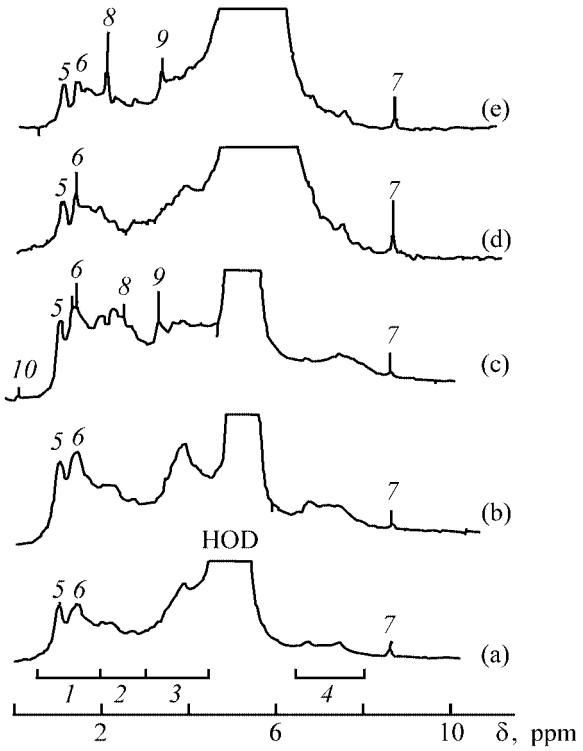

Fig. 1. ^{1}H NMR spectra of HSs of Chara sapropel of Lake Bezdonka. (δ) Chemical shift, the same for Figs. 2–4. (a) FHSs, (b) HA, (c) FA, (d) humin, and (e) humin after base hydrolysis. Assignment of proton signals in the spectra: (*1–4*) alkyl, carbonyl, polyols, and aromatic fragments, respectively; (*5*, *6*) methyl and methylene groups, respectively; (*7*) formyl group; (*8*) acyl methyl group; (*9*) *N*-methyl group; and (*10*) methyl group of silane.

calculated using the integral intensity of the signals from methyl groups as reference.

The samples of Chara sapropel are polyfunctional mixtures; therefore, for qualitative and quantitative comparative analysis, we used arbitrary division of the spectrum into ranges corresponding to the signals of the main proton-containing functional groups.

In particular, the spectrum range from 0.5 to 2.0 ppm was assigned to proton signals from the CH_3–, –CH_2–, and –CH= groups of the hydrocarbon radical. The range from 2.0 to 3.0 ppm was assigned to the proton signals from carbonyls (methyl, methylene, and methine groups in the α-position to the carbonyl carbon, i.e., ketones and carboxylic acids). The range from 3.0 to 4.5 ppm was assigned to the proton signals from polyols (methyl, methylene, and methine groups in the α-position to the OH group, i.e., alcohols and carbohydrates). The range from 4.0 to 6.0 ppm was assigned to the protons at double bonds, and the range from 6.0 to 8.0 ppm, to the protons of aromatic and heteroaromatic groups.

Ecosystematic studies of the deposit of sapropel in hand have shown [7] that its OM is produced under conditions of a medium strongly enriched in calcium ions (up to 400 mg l^{-1}) and unique type of the initial production of the pond, owing to predominant evolution of some species of *Characeae* algae, constituting 96.6% of OM and accumulating 95% of mineral substances of the lake ecosystem. In this case, the influence of terrigenous drainage on the lake ecosystem is at a minimum.

Hence follows that sapropel to be studied is of clearly pronounced carbonate-chara type, and the monodominant role of *Characeae* algae in the primary production and formation of the lake sediments makes it a convenient model object for studying the structure formation of OM of chara-type sapropels.[1]

The ^{1}H NMR spectra of humin samples (HSs) of Chara sapropel (Figs. 1a–1d) contain a set of broadened multiplets in the range 0.5–0.8 ppm and a singlet of formic acid at 8.6 ppm. The exception is the ^{1}H NMR spectrum of FA (Fig. 1c). In the range of FA spectrum characteristic of polyol protons, the signals show no pronounced polysaccharide pattern typical of other HSs. In addition, in the spectrum of FA narrow singlets were observed at 2.52 and 3.31 ppm against the background of broadened multiplets. These singlets were assigned to methyl groups of the acetate residue and *N*-methyl, respectively.

The functional composition of HSs of Chara sapropel from Lake Bezdonka according to ^{1}H NMR is presented in Table 1.

After boiling in strong alkali for 8 h, a narrow singlet appears at δ 2.08 ppm in the NMR spectrum of humin (Fig. 1e) on the background of broadened multiplets. This singlet is identified as the signal from the acetate methyl group. The appearance of an acetate group after severe alkaline treatment suggests that the sample contains *N*-acetylglucosamine, the main monomeric block of chitinic polyamino saccharides [9, 10].

This suggestion is confirmed by the appearance of a narrow singlet at δ 3.32 ppm in the ^{1}H NMR spectrum of the humin sample (Fig. 1b) after its severe alkaline treatment. This singlet was assigned to protons of the *N*-methyl group. This was also observed with the FA sample (Fig. 1b).

Hence follows that Chara sapropel contains chitinic polyamino saccharides. To prove more convincingly

[1] Vast resources of such Chara sapropels exist in Valdai, Issyk-Kul', Balkhash, and other lakes [8].

Table 1. Functional composition of Chara sapropel

Sample	Structure of aliphatic fragment	Relative content of stuctural fragments, %						
		aliphatic	carbonyl	polyols	aromatic	formyl	*N*-methyl	silane
FHA	$CH_3(CH_2)_3$–	26	20	45	8	0.6	0	0
FA	$CH_3(CH_2)_4$–	21	28	34	16	0.4	+	+
HA	$CH_3(CH_2)_4$–	27	19	36	17	0.4	0	0
H*	$CH_3(CH_2)_4$–	25	14	42	17	1.0	+	0

* Alkaline extract after boiling in concentrated alkali for 8 h.

this conclusion and also to obtain differential data on the structural organization of OM of Chara sapropel, we studied the functional composition of nonpolar (hexane) and polar (alcohol) extracts from sapropel in comparison with the composition of similar extracts from decalcified Chara.

According to the ^{1}H NMR spectrum (Fig. 2a), the hexane extract mainly consists of free unsaturated hydrocarbon of the hexadecene type.

It seems plausible that the source of this free hydrocarbon is chlorophyll, easily decomposing in an acidic or alkaline medium to phytol, chlorophyllin, and porphyrin core [9]. According to ^{1}H NMR analysis (Fig. 2b), the hexane extract from sapropel consists of free hydrocarbon, as in the case of Chara. However, the spectra of sapropel contain no clearly pronounced signals from protons at the double bond and protons of methylene groups in the α-position to the double bond in the range 1.8–2.3 ppm, present in the spectrum of the hexane extract of Chara (Fig. 2a). A relatively weak broadened multiplet observed in this range of the spectrum can be assigned to methylene groups at carbonyl, and the structure of the alkyl substituent as a whole, most likely, corresponds to the residue of hexylic acid (Fig. 2b).

This fact suggests that utilization of Chara to Chara sapropel is accompanied by degradation of free hydrocarbons (in particular, hexadecene) to hydrocarbons with lower molecular weight, proceeding by the exo mechanism.

According to the ^{1}H NMR spectrum (Fig. 3a), the polar extract from Chara consists of carbohydrates and bound hydrocarbons. A doublet of 1-α-proton of saccharide (δ 5.4 ppm) and a singlet in the region of δ 3.31 ppm, characteristic of *N*-methyl protons, suggest that the carbohydrate part of the polar extract from Chara is a polyaminosaccharide of the hyaluronic acid type, based on glucuronic acid and *N*-acetylglucosamine [1], or polyaminosaccharide of the chitin type with a monomeric unit incorporating glucosamine and its derivatives [9].

In biochemistry of algae, there are no published data on identity of polyaminosaccharides of *Characeae* algae. Only polysaccharides, starch and α-1,4-glucan, were described as reserve nutrients for *Characeae* algae [12]. These biopolymers occur in cells of many higher plants, algae, fungi, and bacteria in the form of polysaccharide exoskeleton [13].

As follows from the ^{1}H NMR spectra, the amino group of glucosamine in the Chara polysaccharide is methylated and/or acylated, and the carboxy or hy-

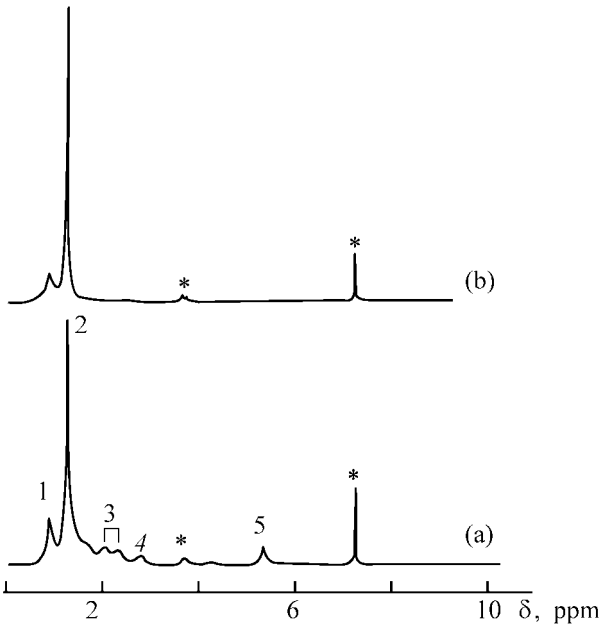

Fig. 2. ^{1}H NMR spectra of hexane extract from (a) Chara and (b) Chara sapropel of Lake Bezdonka. Assignment of proton signals in the spectra: (*1*, *2*) methyl and methylene groups, (*3*) methylene groups in the α-position to the double bond, (*4*) methylene groups in the α-position to carbonyl group, and (*5*) double bonds. The asterisks denote proton signals of the solvent and impurities in the solvent.

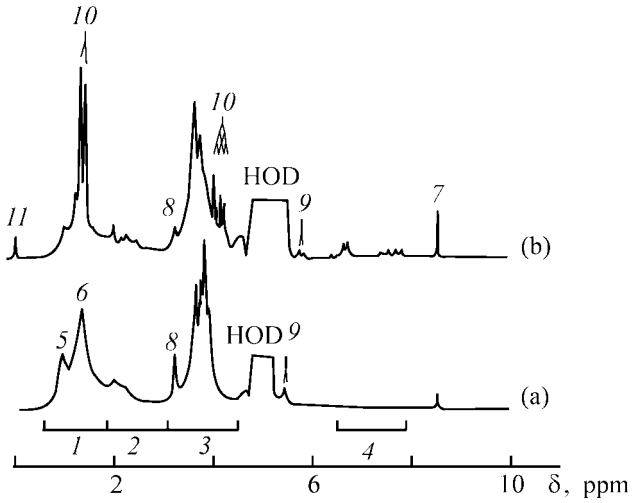

Fig. 3. ^{1}H NMR spectra of alcohol extracts from (a) Chara and (b) Chara sapropel of Lake Bezdonka. Assignment of proton signals in the spectra: (*1–4*) alkyl, carbonyl, polyols, and aromatic fragments, respectively; (*5*, *6*) methyl and methylene groups, respectively; (*7*) formyl group; (*8*) *N*-methyl; (*9*) α-H-1 residue of glucosides; (*10*) methyl and methylene groups of lactic acid; and (*11*) methyl groups of silane.

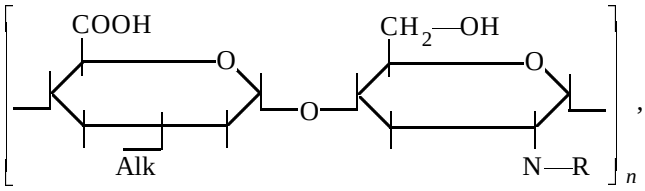
droxy group of glucuronic acid is probably alkylated, which follows from the structure of the alkyl radical of polar extract from Chara (Table 2). Based on these facts, we constructed a hypothetical structure of the polysaccharide skeleton of Chara:



where R is H, CH_3, and $CO–CH_3$.

The calculated content of the functional groups of the structure suggested is as follows (%): alkyl 42, polyols (carbohydrates) 46, and *N*-methyl and/or *N*-acyl 12.

The content of the functional groups of the polar extract from Chara, established on the basis of the ^{1}H NMR spectra (Table 2), appears to be close to that obtained for the hypothetical structure, except for the content of the *N*-methyl fragment, which is apparently caused by its alkaline hydrolytic elimination in preparation of Chara samples.

As in the case of Chara, the alcoholic extract from sapropel mostly consists, according to the ^{1}H NMR data (Fig. 3b), of polysaccharides and bound hydrocarbons (Table 2). The presence of a doublet at 5.4 ppm and a singlet at 3.2 ppm suggests that the structures of polysaccharides in Chara and in sapropel are similar. Hence follows that, in utilization of Chara to Chara sapropel, the structure of polysaccharide undergoes no noticeable transformations. It is likely that the degree of transformation of the carbohydrate skeleton of Chara is governed by the molecular weight of polysaccharide.

The presence of structures of the *N*-acetylglucosamine type and Chara origin in the humin fraction and in polar extract of the sapropel under study allows us to prognosticate a high physiological activity of sapropel and its individual fractions [13].

Along with bound hydrocarbons and polysaccharide fragment, the alcohol extract from Chara sapropel contains lactic acid, an insignificant amount of aromatic groups, formate, and silane group linked to the polymer matrix.

The absence of lactic acid and aromatic fragments in the alcohol extract from Chara (Fig. 3a) suggests

Table 2. Structural-group composition of hexane and alcohol extracts from sapropel and *Characeae* algae

Structure fragments	Relative content, %			
	hexane extract		alcohol extract	
	Chara $C_{14}H_3OCH=CH$	sapropel $CH_3(CH_2)_4–$	Chara $CH_3(CH_2)_4–$	sapropel $CH_3(CH_2)_4–$
Aliphatic	96	93	39	35
Carbonyl	4	5	14	9
Polyols	0	0	35	49
Aromatic	0	0	0	3
N-Methyl	0	0	5	3
Formyl	0	0	1	1
–HC=CH–	+	0	0	0

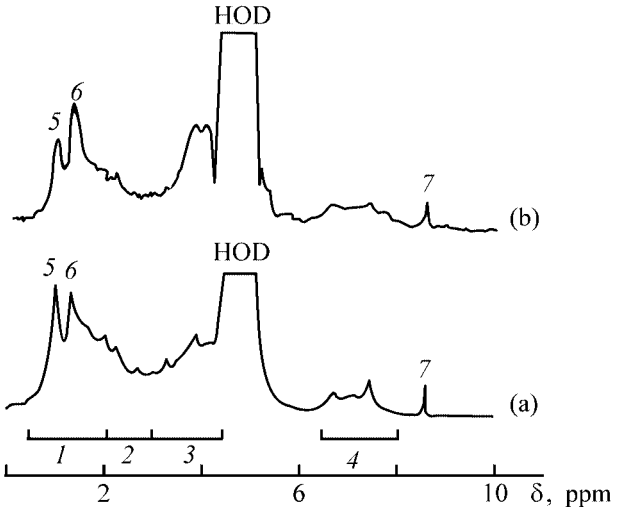


Fig. 4. ^{1}H NMR spectra of the HA samples of (a) macrophytic sapropel and (b) valley peat. Assignment of proton signals in the spectra: (*1–4*) alkyl, carbonyl, polyols, and aromatic fragments, respectively; (*5*, *6*) methyl and methylene groups, respectively; and (*7*) formyl group.

that these components are of secondary origin, i.e., they are exametabolites of microorganisms utilizing Chara.

It should be noted that the first conclusions concerning the structural organization of Chara and Chara sapropel are of limited nature, since the hexane and alcoholic extracts alone cannot reflect in full measure the overall structural organization of the substances in hand. A more detailed study of the structure of polysaccharide of *Characeae* algae and Chara sapropel requires appropriate experiments, which is the subject of our further work.

It is of interest to compare the functional compositions of Chara sapropel and bioliths of other nature. However, owing to the scarcity of data, this is only possible only for HAs of bioliths.

Data on fragmentary composition of HAs, obtained from the ^{1}H NMR spectra, are listed in Table 3 and shown in Fig. 4. For convenience of comparison, the functional groups of alkyl radicals and carbonyl-containing hydrocarbons are combined into aliphatic groups.

Table 3. Structural-group composition of HAs

Origin of HAs	Structural-group composition, %		
	aliphatic	polyols	aromatic
Chara sapropel	47	36	17
Macrophytic sapropel	58	29	13
Valley peat	49	38	11
South chernozem	66	11	23

Comparison of these formalized data shows that HAs of sapropels and peat are similar in the ratio of functional groups, being characterized by relatively high content of polyols (carbohydrates) and twice lower content of aromatic hydrocarbons.

The trend observed is accounted for by the fact that predominantly aquatic flora containing no lignin is the initial raw material for formation of these bioliths. This agrees with the conclusion about the secondary role of aromatic hydrocarbons and their derivatives in formation of Chara sapropel, made in this study.

In the case of HA samples recovered from chernozem, the opposite pattern is observed: relatively low content of the polyol fraction and a double amount of aromatic hydrocarbons. This is due to the nature of the surface plant materials forming soil humus containing lignin (phenolic derivative) [11].

Thus, analysis of the relative content of polyols and aromatic hydrocarbons in HA samples can be used to establish the origin of a biolith.

CONCLUSIONS

(1) The structural organization of Chara and Chara sapropel is based on polysaccharides of the type of hyaluronic acid or chitin, with the monomeric unit apparently incorporating glucuronic acid and derivatives of glucosamine. The amino group of glucosamine is methylated and/or acylated, and carboxy or hydroxy groups of glucuronic acid are apparently alkylated.

(2) Utilization of Chara to Chara sapropel is accompanied by degradation of unsaturated hydrocarbons of Chara to hydrocarbons with lower molecular weight, most likely by the exo mechanism.

(3) The structure of polysaccharide does not change significantly. Aromatic hydrocarbons and their derivatives (in particular, phenols) and also lactate found in the Chara sapropel are of secondary nature, being exo metabolites of microorganisms utilizing Chara.

(4) The relative content of the polyol fraction (carbohydrates) and aromatic hydrocarbons in the samples of humic acids of bioliths can be used for determining their origin.

Received January 28, 2002

Abstract—Graphite materials with coatings based on boron nitride and molybdenum disilicide were studied in order to find a way to prevent reaction of quartz glass with graphite members.

In quartz glass processing by extrusion, the equipment members are fabricated from finely dispersed MG graphite. The quality of extruded quartz glass articles, characterized by content of gas bubbles and capillaries, foreign inclusions, ribbing, and surface crystallization, depends on the intensity of the reaction between silica, SiO_2, and the forming graphite members at 1500–1750°C. Making this reaction slower is an important problem in manufacture of quartz glass tubes and rods. The reaction of silica with the graphite members occurs with intense gas evolution. The reaction products remaining within the closed space of the reactor are incorporated into the glass melt to form capillaries and bubbles in the articles. In addition, surface crystallization of the glass melt occurs under these conditions. As a result, extrusion is decelerated to the point of its complete stopping, and the quality of the article surface is deteriorated. The practice shows that the maximum permissible thickness of a cristobalite layer on the surface of an extruded quartz glass block must not exceed 350–450 μm.

Presently, a glass block is protected with a molybdenum sheath to prevent reaction of glass melt with graphite in the course of extrusion. To exclude the expensive molybdenum "shield" from the technological process, refractory materials that could prevent the reaction of the quartz glass melt with graphite members were selected.

Direct evidence concerning the behavior of refractories when in contact with quartz glass at temperatures of up to 1750°C in a vacuum is virtually lacking. The best materials, resistant to glass melts, were chosen on the basis of the available published data. These are materials based on zirconium, aluminum, hafnium, yttrium, and tin oxides, and also boron nitride and silicon oxynitride [1–6].

This study is concerned with the resistance of a quartz glass brought in contact with uncoated and coated graphite, and also with other materials, at 1600–1700°C in a vacuum. The equipment used gave no way of studying the effect of higher temperatures.

Quartz glass samples $1 \times 1 \times 0.5$ cm in size (or having the form of small pieces with flat surface) were

Results obtained with various materials brought in contact with a quartz glass at 1600–1700°C for 15 h in vacuum

placed onto the surface of a material under study and introduced into a furnace in molybdenum sheet containers. After the test was complete, the samples were subjected to visual inspection. The percentage loss of the glass mass was estimated, and the degree of its crystallization was monitored.

The results obtained in tests with different materials brought in contact with quartz glass at 1700°C for 15 h in a vacuum are listed in the table.

Dense samples of composition Al_2O_3–SiO_2–$ZrSiO_4$ and Al_2O_3–SiO_2 were compacted into pellets and tested at 1600°C for 24 h in a vacuum when in contact with a quartz glass. After the test, the glass was found to be crystallized completely.

The results of the experiments indicate that graphite with a BN coating is a promising refractory material to be used in contact with a quartz glass at 1600–1700°C. Graphite with $MoSi_2$-based coatings (composition nos. 11–13 in the table) is also of interest. The material of the coating acts as a barrier between the glass and the graphite members.

CONCLUSION

The study performed showed that $MoSi_2$-based and BN coatings are promising for preventing the reaction between graphite members and quartz glass.

Synthesis of New Sulfonic Acid Acrylamide Derivative from Acrylonitrile, Camphene, and Oleum

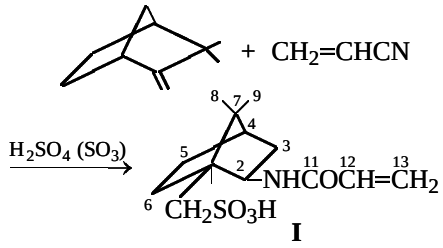
S. A. Kazakov, O. A. Kazantsev, and A. P. Malyshev

Dzerzhinsk Branch, Nizhnii Novgorod State Technical University, Dzerzhinsk, Nizhnii Novgorod oblast, Russia

Received June 28, 2002

Abstract—Synthesis of a new monomer, 2-acrylamido-7,7-dimethyl-1-sulfomethylbicyclo[2.2.1]heptane, is described.

Reaction of acrylonitrile with camphene in the presence of a sulfonating agent (oleum) yielded a new camphene derivative containing acrylamide and sulfonic acid moieties, 2-acrylamido-7,7-dimethyl-1-sulfomethylbicyclo[2.2.1]heptane **I**:



(1)

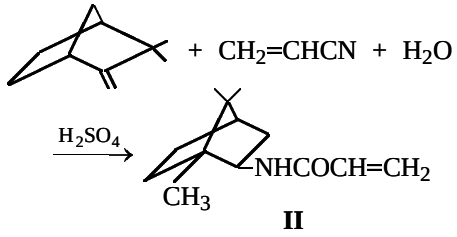
I

The initial reactant ratio, oleum concentration, and reaction temperature were chosen on the basis of published data on similar syntheses of *N*-substituted acrylamides, containing sulfo group, from other olefins [1, 2].

In the course of experiments, a precipitate formed. Product **I** can be purified by repeated washing of the crude precipitate with organic solvents (e.g., a mixture of acetone and chloroform) or by recrystallization from acetic acid. The second procedure affords the highest yield of **I**.

It is known [3] that acid-catalyzed transformations of camphene may be accompanied by its isomerization, yielding a large set of compounds. Comparison of the ^{13}C and ^{1}H NMR spectra of the purified product with the spectra of various camphene derivatives [3] allowed identification of this substance as pure **I**.

Analysis of the precipitate and mother liquor after the reaction revealed that, along with the main reaction, there occur the Ritter reaction yielding *N*-isobornylacrylamide **II** [Eq. (2)] and hydration of acrylonitrile to acrylamide [Eq. (3)]:



(2)

II

$$CH_2{=}CHCN + H_2O \xrightarrow{H_2SO_4} CH_2{=}CHCONH \quad (3)$$

The distribution of the products and unchanged reactants among the phases is illustrated in the table. It is seen that, when the reaction is performed at 40°C in the course of 6 h, the conversion of camphene reaches 93%, and the selectivity of its transformation into **I**, 47%; 88% of **I** occurs as precipitate.

EXPERIMENTAL

Syntheses were performed at 40°C in a temperature-controlled reactor equipped with a stirrer, a thermometer, and a reflux condenser. The initial molar ratio acrilonitrile : camphene : (H_2SO_4 + SO_3) was 1.0 : 7.0 : 1.2, and the oleum concentration, 15%.

Camphene was prepared according to [4]; its physicochemical characteristics were in agreement with published data.

In the reaction mixtures and isolated products, the concentrations of **I** and **II** were determined by liquid chromatography, the concentration of C=C bonds, by bromide–bromate titration, and the concentration of sulfo groups, by alkali titration. Liquid chromatography was performed on a Praha device equipped with a UV detector (λ = 254 nm) and a 150 × 3-mm glass column packed with Separon SCX C_{18}; eluent acetonitrile. The ^1H and ^{13}C NMR spectra were recorded on a Gemini-300 spectrometer (D_2O, internal reference DMSO). The IR spectrum was measured on a Specord M-80 spectrometer (KBr pellet).

Compound **I**. To a mixture of 27.3 g (0.515 mol) of acrylonitrile, 10 g (0.0735 mol) of camphene, and 0.1 g of hydroquinone, we added with stirring and cooling (temperature ≤10°C) 7.7 g of 15% oleum. The mixture was stirred for 6 h at 40°C. The precipitate was filtered off, recrystallized from acetic acid [1], and dried in a vacuum (40°C, 2 mm Hg) to constant weight. Yield 7.2 g (34.3%); white crystalline product readily soluble in water, lower alcohols, and DMSO and insoluble in nonpolar organic solvents.

Found, mg-equiv g^{-1}: C=C bonds 3.38, acid groups 3.62. Calculated, mg-equiv g^{-1}: C=C bonds 3.48, acid groups 3.48.

^1H NMR spectrum, δ, ppm: 5.90 s and 5.96 s (3H, CH_2=CH), 6.04–6.20 m (3H, CH=CH_2), 7.50–7.58 m (1H, NH), 3.80–3.88 m (2H, CH_2SO_3), 0.58 s and 0.75 s (3H, CH_3C), 0.90–1.80 m and 2.60–3.20 m (camphene core).

^{13}C NMR spectrum, δ_C, ppm: 48.98 (C^1) 49.81 (C^2), 38.95 (C^3), 44.42 (C^4), 26.74 (C^5), 32.91 (C^6), 48.54 (C^7), 19.75 (C^8), 19.60 (C^9), 55.75 (C^{10}), 130.40 (C^{11}), 55.86 (C^{12}), 127.00 (C^{13}).

Characteristic IR bands, ν, cm^{-1}: 1060 (SO_3H), 1165 (S=O), 1250 (amide III), 1590 (amide II), 1650 (C=C), 1720 (amide I).

CONCLUSION

2-Acrylamido-7,7-dimethyl-1-sulfomethylbicyclo-[2.2.1]heptane was prepared by reaction of acrylonitrile with camphene in the presence of a sulfonating agent (oleum); the by-products are acrylamide and *N*-isobornylacrylamide.

BOOK REVIEWS

Moiseev, G.K., Vyatkin, G.P., Barbin, N.N., and Kazantsev, G.F., *Primenenie termodinamicheskogo modelirovaniya dlya izucheniya vzaimodeistvii s uchastiem ionnykh rasplavov* (Thermodynamic Modeling in Studies of Interactions Involving Ionic Melts), Chelyabinsk, Yuzhn. Ural'sk. Gos. Univ., 2002, 165 pp.

Attention of readers is called to a monograph in which methods of thermodynamic modeling are applied to analysis of interactions occurring in systems containing ionic melts based on alkali metal carbonates and halides and more complex formulations. The general principles of thermodynamic modeling by means of the computer program used by the authors have been described in detail previously.

The book comprises a foreword, introduction, four chapters, conclusion, bibliography, and appendix. The foreword, having its own list of references (to 34 reports, mainly by the authors of the monograph), mentions the possibility of processing technological wastes containing heavy nonferrous metals and secondary raw materials (aluminum and aluminum alloy scrap, scrap lead from batteries) in ionic liquids, to which belong melts of halides, carbonates, and other oxygen-containing salts of, in the first place, alkali metals. A very brief introduction describes the software packages and databases used in thermodynamic modeling.

The first chapter (pp. 11–112) occupies the central place in the monograph, as regards its volume and nature of the problems discussed. It presents the results of thermodynamic modeling as applied to individual molten carbonates of alkali metals in the temperature range 1000–2000 K in various media (Ar, O_2, CO_2, CO). Also considered are mixtures of carbonates and more complex systems including compounds of lead and some other metals.

The second chapter (pp. 113–127) is devoted to more specific problems—possibility of synthesizing indium and gallium phosphides and gallium arsenide in complex ionic media. The authors carried out necessary thermodynamic calculations. As base melts served mixtures of metaphosphates, in one case, and those of sodium and potassium arsenates, in another.

The third chapter (pp. 128–136) applies the technique developed by the authors to evaluation of the content of cations in different oxidation states in molten halides. As specific objects of thermodynamic analysis served solutions of zirconium or titanium chloride in molten individual chlorides of sodium, potassium, or cesium in an atmosphere of argon.

The small fourth chapter (pp. 137–141) considers the interaction of silumin with ionic melts in the temperature range 300–1400 K under total pressure of 10^5 Pa in argon or in a model medium containing 20 wt % O_2 + 80 wt % Ar.

A number of important theoretical and practical problems related to ionic melts are discussed in the final part of the monograph (pp. 142–157). The authors, based on the models known for high-temperature phases of variable composition in liquid state, substantiate the validity of the model of "ideal solutions of interaction products," which is a variation of the model of ideal associated solutions, to thermodynamic analysis of complex systems. The main list of references (pp. 158–163) covers 90 reports, 30 of which belong to the authors of the monograph. An additional list includes references to 16 studies published in 2000–2002.

The book was written by known specialists in thermodynamic modeling and processing of secondary raw materials, working at the Southern-Ural State University (G.P. Vyatkin, corresponding member of the Russian Academy of Sciences), and Institutes of Metallurgy (G.K. Moiseev and G.F. Kazantsev) and

High-Temperature Electrochemistry (N.M. Barbin), Ural Division, Russian Academy of Sciences.

With the monograph, which is of interest and of use, highly appreciated, there is no escape from mentioning that it gives insufficient attention to comparison of the results of thermodynamic modeling with the data obtained in experimental studies of the systems and processes considered. Also, the atmosphere of argon is untypical of the technological practice and may hinder to a certain extent the use of the results of modeling in estimates and comparisons. The use of the model of ideal solutions of interaction products for describing some systems, e.g., Al–Si–Na–K solutions, can hardly be substantiated.

The monograph by G.K. Moiseev and co-authors may be of use for, in the first place, specialists in thermodynamic modeling of complex high- temperature systems.

BOOK REVIEWS

Mel'nichenko, E.I., *Ftoridnaya pererabotka redkometal'nykh rud Dal'nego Vostoka* (Fluoride Processing of Rare-Metal Ores from the Far East), Vladivostok: Dal'nauka, 2002, 268 pp.

The widely diverse existing technologies for processing of rare-metal ores are based on complicated hydro- and pyrometallurgical operations and have disadvantages related to ecological safety. In the Russian Far East, there are rather large deposits of such rare metals as tungsten, titanium, and zirconium, but no processing of these raw materials is done in the region. The monograph by E.I. Mel'nichenko summarizes the results obtained in scientific studies of scheelite, baddeleyite, ilmenite, sphene, and rutile processing to obtain oxides of rare metals, and considers a number of other technological problems. The book comprises a foreword, ten chapters, and a list of references, common to the monograph.

The brief foreword (pp. 5 and 6) notes the advisability of using widely a common reagent, ammonium bifluoride (hydrofluoride), in processing of various rare-metal raw materials. This recommendation is largely based on the presence in Primorskii krai of unique deposits of fluor-spar.[1]

The first chapter (pp. 7–13) presents evidence concerning the mineral resources of the Far East. This region is a part of the so-called Pacific ore belt. Quite a number of minerals from Primor'ye govern the balance of mineral resources of the country.

The second chapter (pp. 14–25) discusses the use of fluorinating agents in metallurgical processes ("fluoride metallurgy"). The author emphasizes that ammonium hydrofluoride is a serious rival to fluorine and hydrogen fluoride in fluoride metallurgy.

The third chapter (pp. 26–71) is concerned with problems associated with processing of tungsten concentrates. It describes the existing industrial technologies for manufacture of tungsten and physicochemical foundations of methods used in processing of scheelite concentrates with NH_4HF_2. Much attention is given to properties of ammonium oxofluorotungstates and tungsten oxyfluorides.

The fourth (pp. 72–110) and fifth (pp. 111–169) chapters contain data on processing of zirconium and titanium concentrates, possibility of using ammonium hydrofluoride in technological processes, and properties of fluoride compounds of zirconium and titanium.

The sixth chapter (pp. 170–193) discusses the behavior of molybdenum and chromium oxides heated with NH_4HF_2. The seventh chapter (pp. 194–200) summarizes results of original investigations into processing of gold- and silver-containing ores with the use of the fluoride technology. The eighth chapter (pp. 201–213) describes to other promising fields of application of ammonium hydrochloride (dressing of the fluorite concentrate, production of biocides). The ninth chapter (pp. 214–221) is concerned with thermodynamic substantiation of the use of NH_4HF_2 for processing of rare-metal ores. The tenth chapter (pp. 222–244) presents rather useful evidence concerning the corrosion resistance of construction materials in various fluorine-containing media in a wide range of temperatures. Also, the stability of high-nickel steels, nickel-based alloys, and fluoroplastics of domestic manufacture is considered.

The list of references (pp. 245–261) covers 308 original studies, inventor's certificates, patents, and other sources. The highly informative list gives titles of journal articles. A large number of works cited in the list have been carried out with participation of the author of the monograph.

The book has technological orientation and clear and logical structure; it is devoted to solution of a specific important problem and is well written. Some critical remarks may concern, in our opinion, the ninth

[1] The resources of fluor-spar ores are considered in more detail by V.I. Saenko, V.P. Yushkevich, V.V. Korshunov, *et al.* (*Tsvet. Metal.*, 1999, nos. 8–9, pp. 33–38).

chapter whose unwarranted brevity gives rise to a number of questions. In particular, it would be well to give, irrespective of temperature, the aggregative state of substances involved in a reaction in those cases when it may vary.

The monograph was recommended for publication by the Scientific Council of the Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences, and published with support from the Russian Foundation for Basic Research and administration of Primorskii krai. The book will be undoubtedly of interest to a wide audience of specialists working in research and design institutions dealing with technology of processing of various rare-metal raw materials. The simplicity and clarity of presentation make it possible to recommend the book for use as a textbook for students specialized in the corresponding branches of chemical technology and metallurgy.

BOOK REVIEWS

Yukhnin, Yu.M. and Mikhailov, Yu.I., *Khimiya vismutovykh soedinenii i materialov* (Chemistry of Bismuth Compounds and Materials), Novosibirsk: Sib. Otd. Ross. Akad. Nauk, 2001, 360 pp.

The keen interest in bismuth compounds and bismuth-containing materials is indicated by nearly simultaneous publication of two monographs, which have similar titles and well supplement each other.[1] The book by Yu.M. Yukhnin and Yu.I. Mikhailov pays much attention to chemistry of aqueous solutions of bismuth salts, hydrometallurgical operations involving compounds of bismuth, and properties of its salts. The book comprises five chapters and very brief introduction and conclusion.

The first chapter (pp. 5–22) considers the physical and chemical properties of bismuth, application fields of the metal and its compounds, and dynamics of prices on the world market. Probably, the authors used not quite consistent sources of information. According to Table 1.13, the world production of refined bismuth in 1993 was 4.39 thousand tons. At the same time, it is stated on page 15 that the world consumption of the metal in 1993 was 5.01 thousand tons. Such an excess of consumption over production is unlikely.

The second chapter (pp. 23–40) is concerned with chemistry of aqueous solutions of bismuth, hydrolysis of its ions, complexation, and effect of the anionic composition of solution on the stability of complex ions. According to the conventional concepts, the coordination number in formation of complex bismuth ions in aqueous solutions is 6, and the complexation reaction occurs in stages, with preliminary removal of water molecules from the first coordination sphere of the Bi^{3+} ion and formation of intraspheric complexes. At the same time, according to recent studies, formation of bismuth complexes with coordination number exceeding 6 is possible.

The third chapter (pp. 41–99) contains evidence concerning preparation of solutions of, mainly nitrate, bismuth salts and subsequent hydrometallurgical operations (hydrolytic precipitation, extractive recovery, ion-exchange processes) aimed to purify bismuth compounds.

The fourth chapter (pp. 100–235) describes chemical properties of the most widely occurring and frequently used bismuth compounds: oxides, nitrates, sulfates, perchlorates, chromates, carbonates, halides, and organobismuth compounds. In describing the properties of compounds, much attention is given to their structure and crystal-chemical characteristics.

The fifth chapter (pp. 236–354) analyzes publications of the last decade, concerned with chemical properties of various bismuth materials. Of particular interest among these materials are formulations with valuable electrical characteristics (superconductors; thermoelectric, magnetic, and optical materials; ferroelectrics; piezoelectrics), solid electrolytes with oxygen conduction, catalysts, light-sensitive materials, luminophores, pharmaceutical preparations, glasses and ceramics, and pigments.

Lists of references are given separately for each chapter of the monograph, with their total number equal to 1046. Particularly extensive is the list for the fifth chapter (521 references), with 95% of these published during the period from 1992 till 2000.

In the conclusion (pp. 355–357), the authors emphasize that the chemistry of bismuth materials has been successfully developing in the last 10–15 years in quite a number of directions. The monograph by Yukhin and Mikhailov is the most prominent summary of the chemical properties of bismuth, its compounds, and bismuth-containing materials. The informational value of the monograph is rather high.

The book is well written and contains a neatly presented graphical material. The monograph will be of interest for research workers and engineers engaged in studies or use of bismuth compounds or materials on their base.
