Sorption. Comparative data on the extent of lithium(I) recovery from brine indicate that this parameter depends on the sorbent grain size: the smaller the grain, the higher the sorption efficiency. For example, the extent of lithium recovery is 98% for brine passed through the fraction with grain size $0.63 < l < 1.0$ at flow rate of 0.5 l h^{-1} and is nearly 2 times lower for the fraction with $l > 2$ mm. The same is indicated by the output sorption curves (Fig. 1). According to these curves, the exchange capacity of the sorbent is low. Our results show that, in the best case (smallest grains, brine feed rate 2.6 l h^{-1}), only 2 brine volumes per 1 volume of sorbent can be passed before breakthrough. Table 1 shows the total dynamic exchange capacity (TDEC) and average extent of Li^+ recovery from the brine volume passed in relation to the rate of brine feed.

The data of Table 1 also indicate that the TDEC of a sorbent depends not only on its granulometric composition, but also on the brine feed rate. Achieving

Table 2. Physical properties of sorbent

Parameter	Fraction, mm		
	$0.63 < l < 1$	$1 < l < 2$	$l > 2$
Total pore volume, $cm^3\ g^{-1}$	0.18	0.23	0.28
Amount of micropores (diameter ≈2 nm)	5.4	1.3	2.3
Amount of macropores (diameter ≥1000 nm)	65.4	50.0	36.5
Specific surface area of starting material, $m^2\ g^{-1}$	1.6	1.6	2.0
Specific surface area after sorption–desorption cycle, $m^2\ g^{-1}$	27.1	27.0	28.6
Density of swollen sorbent, $g\ cm^{-3}$	1.495	1.424	1.506
Swelling factor	1.06	1.07	1.07

a high TDEC value requires a small sorbent grain size and low brine feed rate corresponding to long contact time. However, even under these conditions, the extent of recovery is not high. Such a dependence of TDEC on the specific load points to the slow sorption kinetics [26], caused by inner-diffusion hindrance to the transport of lithium ions inside the sorbent grains. However, it should be noted that, in accordance with the mercury porosimetry data, the grains have highly developed porosity appearing, in all probability, in solvent removal in the course of grain forming and drying. Table 2 presents data on the physical properties of various sorbent fractions.

The independence of the density from the grain size is presumably accounted for by the irregular shape of grains, their unstable packing, and inhomogeneity of the chemical composition of air-dry samples, since the chemical formula of the sorbent is $LiCl \cdot 2.3Al(OH)_3 \cdot 2.1H_2O$ for the $0.63 < l < 1.0$ fraction and $LiCl \cdot 2.7Al(OH)_3 \cdot mH_2O$ for the other fractions, with m varying from 1.9 for the $1.0 < l < 2.0$ fraction to 2.3 for that with $l > 2.0$.

The data in Table 2 also indicate that the sorbent fractions have a sufficient amount of macro- and intermediate transport pores, whose diameter is incommensurably larger than that of a hydrated lithium ion, equal to 0.107 nm [27], which would seemingly favor fast sorption. Moreover, it can be seen from Table 2 that the specific surface area of the sorbent markedly increases upon pretreatment and a sorption–desorption cycle. Probably, this can be accounted for by the fact that the sorbent synthesized always contains a minor admixture of unreacted LiCl (commonly up to 3–4 wt %), which is washed out in the course of sorbent pretreatment and acts as additional porophore. However, static studies show that, despite this circumstance, the equilibrium state in the system formed by the granular sorbent and strongly mineralized brine is attained rather slowly (in 24 h). It may be assumed that a significant contribution to the deceleration of inner diffusion is made by a film of PVC used as organic binder. The water permeability of such a film is extremely low [28].

Thus, the data obtained indicate that performing the sorption process in a flow-through mode is not optimal for a given sorbent. At the same time, analysis of how the sorbent capacity depends on the time of contact in initial stages of the sorption process ($t <$ 3 h) shows that a higher brine feed rate is preferable for achieving a higher capacity in the same time. Figure 2 presents these dependences for the fraction with $1.0 < l < 2.0$. This behavior is preserved for the other fractions, which indicates that it is advisable to perform sorption in a circulation mode.

The data obtained show that the largest gain in α and, consequently, in the sorbent capacity is ensured in the first 1–2 h of circulation. However, several cycles are necessary since complete recovery of Li^+ is not achieved under these conditions. Data on lithium sorption from brine in this mode at a circulation rate of $5.8\ l\ h^{-1}$ are presented in Table 3 for the fraction with $0.63 < l < 1.0$. The brine volume was 5 l. The brine obtained after completion of the first cycle served as the initial solution for a second cycle. Prior to each cycle, 3.5 mg of lithium per 1 g of sorbent was desorbed.

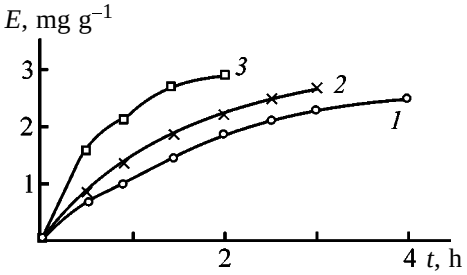

Fig. 2. Sorbent capacity E vs. time t. Fraction $1.0 < l < 2.0$ mm. Brine feed rate ($l\ h^{-1}$): (*1*) 0.93, (*2*) 2.55, and (*3*) 5.80.

Table 3. Li^+ sorption in the circulation mode

Cycle	Time, h	LiCl concentration, g l^{-1}	Extent of recovery		Capacity E, mg g^{-1}	
			in a cycle	total	in a cycle	total
First	0	2.30	0	0	0	0
	0.5	1.68	26.9	26.9	1.54	1.54
	1.0	1.44	37.4	37.4	2.14	2.14
	2.0	1.17	49.1	49.1	2.81	2.81
Second	0	1.17	0	0	0	0
	0.5	0.73	37.6	68.3	1.09	3.90
	1.0	0.52	55.5	77.4	1.62	4.43
	2.0	0.31	73.5	86.5	2.14	4.95
	3.0	0.21	82.0	90.9	2.39	5.20

Table 3 shows that the specified brine volume can be processed in two cycles, with the extent of Li^+ recovery equal to 91% at a total sorption time of 5 h. During this time, the total exchange capacity was 5.2 mg g^{-1}, which is close to the value found under static conditions. It was established experimentally that the optimal range of circulation rates is 5.8–14 l h^{-1} (linear flow velocities 11–27 m h^{-1}). With the circulation rate increasing further, the extent of lithium recovery from brine decreases somewhat.

Analysis of sorption operation parameters shows that the sorbent can recover Li^+ at its any concentration in brine. Figure 3a presents dependences of the sorbent capacity on the LiCl concentration (2.30–0.48 g l^{-1}) in brine. However, as would be expected, the lower the initial concentration of LiCl, the slower the sorption and the lower the sorbent capacity. Since the exchange capacity of the sorbent also decreases with increasing grain size, a greater number of cycles is necessary for complete lithium recovery from brine in the case when grains of the fraction with $l > 2.0$ are used. An extent of Li^+ recovery equal to 92.2% is achieved after four cycles (Fig. 3b).

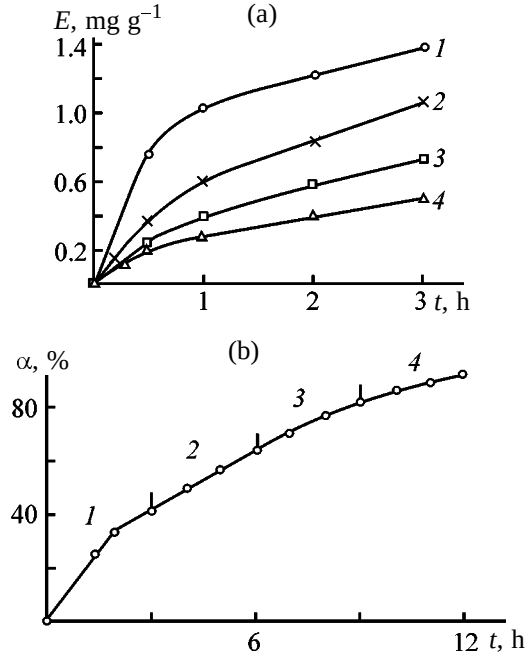

Fig. 3. (a) Sorbent capacity E and (b) extent of lithium(I) recovery from brine, α, vs. duration of sorption, t, in the cyclic mode. Brine volume 4 l. LiCl concentration in cycles *1–4* (g l^{-1}): (*1*) 2.30, (*2*) 1.49, (*3*) 0.86, and (*4*) 0.48.

Thus, dynamic tests of the sorbent demonstrated that the smaller the grain size, the higher the sorption efficiency. However, account should be taken of the fact that the resistance of the sorbent bed grows nearly twofold with decreasing grain size. Therefore, the optimal grain size is 1–2 mm.

Sorbent washing to remove brine. To obtain a purer eluate, it is necessary to wash the sorbent, prior to the desorption stage, to remove brine remaining on the grain surface and in the intergrain space. The study demonstrated that, the larger the sorbent grains, the larger the amount of water required for their washing. In the case of batch feed of water, 1.1–1.2 volumes of water per 1 volume of sorbent is necessary to remove approximately 90% of the remaining salts for the fraction with $0.63 < l < 1.0$. For the fraction with $l > 2.0$, this amount is already 2.2 volumes. With continuous feed of water, the consumption of water is approximately 30% larger than in the case of batch feed at the same process parameters.

In all cases, approximately 20% of sorbed lithium is lost in the washing stage. This is easily removable lithium localized in the surface layer of grains. Use of cooled water (3–5°C) makes it possible to reduce these parameters by 5–8%; however, it is impossible

to eliminate completely the washing loss. In a process cycle of brine treatment, washing water containing, on the average, 125 g l^{-1} of salts (in terms of $CaCl_2$) and 2.8–3.5 g l^{-1} of LiCl can be recycled.

Lithium desorption. It is known [10] that lithium desorption is governed by conditions of sorbent treatment with water and depends on temperature, amount of water used in desorption, and process duration. The desorption is carried out more effectively with water at elevated temperature; however, account should be taken of the fact that partial decomposition of the sorbent is possible at temperatures exceeding 50–60°C, and its sorption properties may be impaired [10]. In lithium desorption with dilute LiCl solutions under the same conditions, the achievable sorbent capacity decreases as compared with the value obtained in desorption with water.

We found that, under dynamic desorption conditions, the concentration of lithium chloride in the eluate depends of the rate of water feed. The lower this rate and, correspondingly, the longer the time of contact between the saturated sorbent and water, the higher the LiCl concentration at the same l : s ratio (Figs. 4a and 4b) and, consequently, the higher the exchange capacity of the sorbent. Figure 4 shows that, for an exchange capacity of about 3 mg g^{-1} to be achieved, the l : s ratio should exceed 5, with the LiCl concentration equal in this case to only 2–3 against 4.5 g l^{-1} at l : s = 2.

In order to obtain higher LiCl concentration in the eluate, we also examined the possibility of carrying out desorption in the circulation mode. We found that raising the linear flow velocity of circulation from 11 to 27 m h^{-1} affects desorption only slightly. After 15 min of water circulation through the sorbent of fraction $0.63 < l < 1.0$, the concentration of LiCl is approximately 3.5–3.7 g l^{-1}, and further lithium desorption is already performed with the resulting solution, which decelerates the desorption process. After 3 h of circulation at a solution flow velocity of 27 m h^{-1}, the LiCl concentration reaches a value of 4.5 g l^{-1}, with the sorbent capacity equal to 1.56 mg g^{-1}. Under these conditions, the capacity of 2.5 mg g^{-1} could be obtained after 10 h of circulation, which is technologically unfeasible. Moreover, this capacity can be achieved much faster by desorption of lithium with fresh portions of water after every 15 min of circulation. However, the LiCl concentration in the eluate decreases steadily in this case. Therefore, the possibility of successive sorbent treatment with portions of eluting solutions with different concentrations was considered with the purpose of

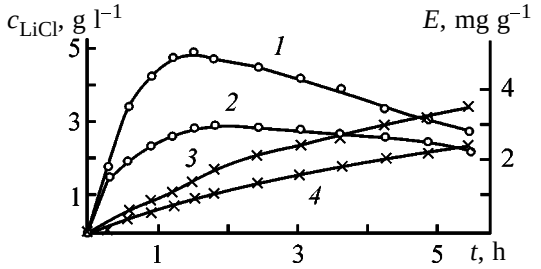

Fig. 4. (*1, 2*) LiCl concentration c_{LiCl} and (*3, 4*) exchange capacity E of the sorbent vs. sorption duration t. Fraction $0.63 < l < 1.0$ mm. Rate of water supply into the column (l h^{-1}): (*1, 3*) 0.64 and (*2, 4*) 1.3.

raising the LiCl concentration in the final eluate. The sorbent was treated with a solution containing about 5 g l^{-1} of LiCl in the first stage, about 3 g l^{-1} in the second, and with pure water in the third. Performing desorption in the circulation mode and lowering the l : s ratio make it possible to raise the content of LiCl in the first portion of the eluate to 9–10 g l^{-1} (Table 4). The first portion of the eluate is regarded as a desorption product, which is then purified to remove impurity salts and processed to obtain various lithium compounds [29]. The remaining portions of the eluate are used as recycle solutions in further desorption cycles.

By varying the l : s ratio and carrying out successive treatment of fresh sorbent portions with recycle LiCl solutions, the concentration of lithium chloride in the eluate can be raised to 12–15 g l^{-1}. At higher concentrations, lithium desorption from the sorbent is strongly suppressed [14]. Desorption from coarser fractions is characterized by the same pattern.

On the whole, it may be concluded that, despite having low dynamic exchange capacity, the sorbent is sufficiently stable in sorption–desorption cycles (i.e., in regeneration). A half-year operation of a column with sorbent of fraction $1.0 < l < 2.0$ demonstrated that the exchange capacity is not impaired, and the decrease in the mass of sorbent discharged from the

Table 4. Desorption of lithium in the circulation mode. Rate of solvent circulation 14.3 l h^{-1}, l : s = 1

Parameter	Treatment		
	first	second	third
c_{LiCl}, g l^{-1}:			
initial	6.00	3.81	0
final	8.77	7.25	4.47
c_{CaCl_2}, g l^{-1}	8.69	3.62	1.54
E, mg g^{-1}	0.45	0.56	0.74

column and dried was approximately 6%. It should be noted here that, in the case of sorbent abrasion in the course of operation, the washed out fine fraction (<0.25 mm) can be used after drying as an additional amount of stock in sorbent granulation and thus can be recycled. In the case of a decrease in the sorbent capacity, it can be easily restored by passing a concentrated LiCl solution (≥50 g l^{-1}) through the column.

CONCLUSIONS

(1) Large-scale laboratory tests of a sorbent based on $LiCl \cdot 2Al(OH)_3 \cdot mH_2O$ showed that it is advisable to perform the sorption–desorption process under dynamic conditions in a circulation mode at linear flow velocities of 10–27 m h^{-1}.

(2) The smaller the sorbent grain size, the higher the efficiency of the sorption–desorption processes. The optimal grain size is 1–2 mm. At the optimal sorption time of 3 h, the dynamic exchange capacity is about 3 mg g^{-1}.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Thin Lead–Tellurium Alloy Films from Fluoroborate Electrolyte

M. N. Mamedov

Institute of Inorganic and Physical Chemistry, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received October 23, 2001; in final form, March 2002

Abstract—Electrodeposition of lead–tellurium alloys from a fluoroborate electrolyte was studied. Cyclic voltammetry was applied to determine the range of potentials of joint electrodeposition of Pb and Te to form PbTe on the cathode.

Lead telluride, and also solid solutions on its base in the form of thin films are widely used in various fields of semiconductor industry to fabricate thermoelectric transducers, thermoelements, and IR detectors [1].

Thin films of metal chalcogenides, including PbTe, are commonly obtained by vacuum evaporation [2]. This technique is labor-consuming, requires intricate equipment, and involves use of high temperature. Moreover, PbTe dissociates in evaporation into the components, which commonly leads to its fractional distillation and to deposition of compositionally inhomogeneous films. Therefore, the electrochemical technique has been frequently used recently for obtaining thin chalcogenide films [3, 4]. This method is distinguished by simplicity, low material expenditure, and possibility of easily controlling the composition and thickness of the layers obtained.

The first electrochemical syntheses of lead telluride were carried out in [5–7]. The syntheses were based on cathodic dissolution of tellurium and anodic dissolution of the metal whose telluride is being obtained. In the process, interaction between Te^{2-} and Pb^{2+} present in the electrolyte results in the formation of PbTe powder on the electrolyzer bottom.

In [8], thin layers of lead–tellurium alloy were obtained by cathodic deposition from a simple nitrate electrolyte containing $Pb(NO_3)_2$ and TeO_2. However, it is known [9] that high-quality cathodic deposits cannot be always obtained from simple electrolytes, especially in those cases when the standard potentials of the metals being codeposited are strongly different.

The standard potential of the $Te/[TeOOH]^+$ couple in acid media is $+0.551$ V, and that of the Pb/Pb^{2+} couple is -0.126 V. The difference of the standard potentials is 0.677 V.

To make closer the potentials of tellurium and lead deposition, such complex electrolytes were used in which tellurium forms more stable complex ions than lead. In this study, as such an electrolyte we used a fluoroborate lead-plating solution of the composition (g l^{-1}): $Pb(BF_4)_2$ 180, HBF_4 40, H_3BO_3 12.6 and joiner's glue 1.0 (electrolyte no. 1) [10]. In electrolyte no. 1, lead deposition occurs without any noticeable hindrance, whereas in fluorine-containing media, tellurium is present as a complex anion $[Te(OH)_2F_4]^{2-}$ [11], with $Te(OH)_2^{2+}$ ions formed in its dissociation directly involved in the cathodic discharge. According to [11], the discharge of $Te(OH)_2^{2+}$ ions occurs in stages, with each stage of formation of intermediates characterized by a certain equilibrium potential, which becomes more negative in reduction processes. This may also make closer the deposition potentials of tellurium and lead.

EXPERIMENTAL

The electrolysis was performed and polarization curves were measured in a poly(methyl methacrylate) cell. Platinum electrodes coated with tellurium, lead, and tellurium–lead alloy (up to 5 μm) served as cathodes, and platinum plate, as anode. The polarization curves were measured in the potentiodynamic mode at a potential sweep rate of 8 mV s^{-1} with a P-5827M potentiostat and a PDP4-003 self-recorder. As reference served saturated silver chloride electrode. The potentials measured were recalculated to the hydrogen scale. TeO_2 to be added to the lead-plating electrolyte was preliminarily dissolved in HF, since TeO_2 is in-

soluble in HBF_4. X-ray studies were carried out on a DRON diffractometer (CuK_α radiation). The content of tellurium in an alloy was determined gravimetrically [12], and that of lead, from the difference of masses of the cathodic deposit and tellurium. The cathodic deposits were also analyzed using a Cameca MS-46 X-ray fluorescence analyzer. The outward appearance of the deposits was assessed visually; the type of conduction was determined using a hot probe.

Figure 1 presents the cathodic potentiodynamic curves obtained in fluoroborate electrolytes of various compositions (g l^{-1}): electrolyte no. 2: HBF_4 40, H_3BO_3 12.6, joiner's glue 1.0, and TeO_2 1.0; electrolyte no. 3: $Pb(BF_4)_2$ 180, HBF_4 40, H_3BO_3 12.6, joiner's glue 1.0, and TeO_2 1.0. The stationary potential of Te in electrolyte no. 2 is 0.5 V; deposition of Te is accompanied by high polarization, the deposition overvoltage is 0.34 V at i = 0.05 A dm^{-2} (Fig. 1, curve *2*). The stationary potential of lead in electrolyte no. 1 is –0.12 V, and the deposition overvoltage at i = 0.05 A dm^{-2}, 0.04 V (Fig. 1, curve *1*).

The codeposition of tellurium and lead from electrolyte no. 3 (Fig. 1, curve *3*) occurs at more positive potentials than separate deposition of these metals, i.e., both the components are deposited into the alloy via depolarization. Such an arrangement of polarization curves is observed in those cases when codeposition of components is accompanied by formation of a compound or a solid solution at the cathode [9]. Thus, it may be assumed that codeposition of tellurium and lead at the cathode can be accompanied by formation of PbTe.

To confirm this assumption and determine the potentials at which tellurium and lead are codeposited, cyclic voltammograms were measured on platinum electrode. In this case, it could be expected that current peaks associated with oxidation of products formed during the cathodic half-cycle may appear in the curves of the anodic half-cycle.

As seen from Fig. 2a, deposition of tellurium on the platinum electrode onsets at a potential of 0.18 V (curve *1*), and that of lead, at –0.13 V (curve *2*). The anodic half-cycle of the voltammograms obtained for the individual components shows a single peak of anode current. The current peak is observed at 0.6 V for tellurium and at about –0.1 V for lead. The codeposition curve shows three peaks of anode current (Fig. 2b). The current peaks at 0.6 and –0.1 V are due to oxidation of, respectively, tellurium and lead. The current peak observed at a potential of about 0.3 V may be due to dissolution of PbTe by the reaction

$$PbTe \rightarrow Pb^{2+} + Te + 2e. \quad (1)$$

The anodic half-cycle measured starting with a cathode potential of 0.15 V (Fig. 2b, curve *1*) shows only an anode current peak associated with oxidation of tellurium. Consequently, no codeposition of tellurium and lead occurs at the cathode up to a potential of 0.15 V, and elementary tellurium is the only cathodic product. Codeposition of tellurium and lead onsets at about 0.12 V, which is confirmed by the appearance in the anodic half-cycle (curve *2*) of a second anode current peak associated with PbTe dissolution. This is also confirmed by analysis of deposits obtained under potentiostatic conditions (see table).

The current in the PbTe dissolution peak mainly depends on the end potential, and increases when this potential is shifted to more negative values (curves *3*–*5*). In the anodic half-cycle curve measured on reaching the potential of lead deposition, a third current peak appears, associated with oxidation of lead as

a separate phase (curve *5*). Deposits obtained at potentials more negative than –0.15 V are composed of PbTe and Pb.

It is interesting that, as soon as the platinum electrode is coated with tellurium and a certain potential is reached (0.12 V in the given case), codeposition of lead and tellurium occurs. Tellurium "stimulates" deposition of lead at more positive potentials; the depolarization for lead is –0.25 V.

A similar phenomenon was also observed in codeposition of bismuth and tellurium from a chloride–fluoride electrolyte [13]. This phenomenon is due to the tendency of tellurium to form Te^{2-}. It should be noted that, in contrast to ions of other metals, quadruply charged tellurium tends to undergo six-electron reduction [14] by the reaction

$$Te^{4+} + 6e = Te^{2-}. \quad (2)$$

According to [14], this reaction is possible even at current densities lower than the limiting diffusion current density, with the occurrence of reaction (2) being the more probable, the lower the concentration of quadruply charged ions in solution. In solutions with higher tellurium concentrations, the main energetically favorable cathodic process is the four-electron reduction of Te^{4+} to Te. At low tellurium concentrations in the electrolyte, the region of limiting diffusion current is reached fast. In this case, the four-electron process is hindered through depletion of the near-cathode layer of Te^{4+} ions, and conditions favorable for six-electron reduction are created. Under these conditions, tellurium deposited at the cathode may undergo cathodic dissolution by the reaction

$$Te + 2e = Te^{2-}. \quad (3)$$

Pb^{2+} ions adsorbed on the electrode surface or present in the near-cathode layer may readily interact with the negatively charged surface, and the mechanism of PbTe formation can be described by the scheme

$$Te(OH)_2^{2+} + 4e = Te + 2OH^-, \quad (4)$$

$$Te + 2e + Pb^{2+} = PbTe. \quad (5)$$

To obtain additional data on the influence exerted by tellurium on the codeposition of Te and Pb, voltammetric curves were measured on a tellurium-coated platinum electrode in electrolyte no. 1. The curves were obtained in the potential range from 0.4 to –0.2 V, which ruled out anodic dissolution of tellurium deposited onto platinum. As seen from Fig. 3, deposition of lead on Te(Pt) electrode occurs at more positive potentials than that on Te and Pt electrodes. A noticeable current is seen in the polarization curve at a potential of about 0.1 V (Fig. 3, curve *1*), in good agreement with the onset potential of codeposition of Te and Pb (Fig. 2b). This is indicated by an anode current peak at 0.3 V, corresponding to anodic dissolution of PbTe obtained in codeposition of Te and Pb. When the end potential is shifted to negative potentials, a limiting current region is observed, extending as far as the onset potential of lead deposition (curve *4*). In repeated cycles, the limiting current decreases (curves *2*, *3*). The appearance of the limiting current may be due to either slow motion of charge carriers, i.e., the semiconducting properties of PbTe, or slow motion of tellurium or of lead ions across the PbTe film. At more negative potentials, lead is deposited as a separate phase. This is indicated by the appearance of an anode current peak at a potential of –0.12 V.

Thus, in codeposition of tellurium and lead, the primary part in alloying is played by the tendency

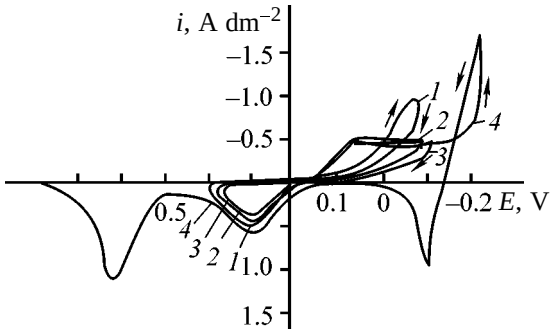

Fig. 3. Cyclic voltammograms obtained successively on a tellurium-coated platinum electrode in electrolyte no. 1. Potential sweep rate 40 mV s^{-1}.

of tellurium to undergo cathodic dissolution to form Te^{2-} ions. In this case, the depolarization in Te deposition into the alloy is associated with alloying (thermodynamic factor), and that in deposition of lead into the alloy, with the low overvoltage of lead deposition on tellurium (kinetic factor).

According to the results of X-ray phase analysis, films containing excess amount of tellurium and obtained at potentials more positive than –0.1 V are composed of two phases, PbTe and Te. The data obtained with a microprobe analyzer demonstrate that Te is mainly present in lower layers of the films (*p*-type conduction). The X-ray patterns of lead-rich films obtained at potentials more negative than –0.15 V contain, in addition to lines related to PbTe and Pb, also those associated with PbO and PbO_2 [15], with lead mainly present in upper layers of the films (*n*-type conduction). Films with composition very close to the compound PbTe are formed at potentials in the range 0.0–0.1 V.

CONCLUSIONS

(1) In electrodeposition of the Pb–Te alloy from a fluoroborate electrolyte, both the components are deposited into the alloy with depolarization due to a thermodynamic factor in deposition of tellurium and to a kinetic factor in that of lead. The range of potentials at which Te and Pb are codeposited was determined.

(2) Tellurium-rich films have *p*-type conduction, and lead-rich films, *n*-type conduction.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics of Copper(II) Electrodeposition from Dilute Electrolytes with a Bipolar Electrode

N. D. Ivanova, A. I. Gerasimchuk, and N. E. Vlasenko

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received December 11, 2001

Abstract—Results obtained in electrodeposition of copper(II) from sulfate solutions with a bipolar electrode are presented.

The principle of operation of the bipolar electrode and its industrial applications are known [1], but this electrode remains unconventional and its possibilities are far from being exhausted.

Noteworthy is the fact that the bipolar electrode allows very high current densities, occasionally exceeding by a factor of several tens those on monopolar electrodes [2]. The kinetics of the electrochemical process on the bipolar electrode has not been studied at all, and, therefore, the aim of this study is to analyze the mass transfer and its components.

The main distinction of the bipolar electrode from the monopolar one is that current is not fed directly to this electrode, being supplied to auxiliary electrodes (Fig. 1).

In studying the mass transfer, we measured stationary polarization curves (by points) with and without a supporting electrolyte (1 M Na_2SO_4 solution). The experimental error did not exceed 3%. As objects of study served dilute solutions which modeled washing water from the copper plating process. The concentration of copper ions was varied between 0.003 and 0.015 M. To our knowledge, the bipolar electrode has not been used in such cases previously, and, therefore, the investigations performed expand its application field.

Figure 2a presents typical stationary polarization curves for electrodeposition of copper. On introducing a supporting electrolyte, the curves virtually coincide in the limiting current range for monopolar and bi-

polar electrodes (curves *3* and *4*), characterizing the limiting diffusion current. Its value is in agreement with the limiting diffusion currents theoretically calculated for the given concentration of metal ions. In calculating the diffusion component, the thickness of the diffusion layer was taken to be 10^{-3}, which corresponds to vertical arrangement of electrodes with account taken of the natural convection [3]. In the absence of a supporting electrolyte, the limiting currents differ widely, with the currents on the bipolar electrode much exceeding those on the monopolar electrode. Hence follows that the migration component makes a major contribution to mass transfer. Under the experimental conditions, this difference of the limiting currents is about 2.8 mA cm^{-2}, or 30%.

When analyzing the polarization curves, we established that not only the limiting currents, but also the electrode potentials are different. All other conditions being the same, the potential of the bipolar electrode is shifted to the electronegative region by 100–150 mV as compared to the potentials of the monopolar electrode. This may serve as evidence in favor of a higher gradient of potential in the case of a bipolar electrode. Indeed, the migration current i_m is described by the equations [3]

$$i_m = -DC\frac{zF}{RT}\operatorname{grad}\varphi, \qquad i_m = -CU^0\operatorname{grad}\varphi,$$

$$U^0 = D\frac{zF}{RT},$$

where U^0 is the absolute velocity of ion motion at unit field strength **E** (V cm^{-1}).

Thus, $\mathbf{E} = -\operatorname{grad}\varphi$. All other conditions (metal ion concentration in solution, solution viscosity, ion mobility) being the same, the larger migration component in the case of a bipolar electrode may by due only to a rise in the electric field strength, i.e., in the potential gradient. This quantity is characterized by the ratio of the voltage applied to the cell to the interelectrode spacing: $\Delta U/L$ [4]. Finding the potential gradient is a complicated task even for the simplest electrochemical cell. In this study, we analyze cells of this kind with mono- and bipolar electrodes (Fig. 1), with the potential gradient determined experimentally and theoretically. In the cell with a bipolar electrode, platinum plates served as auxiliary electrodes, and a copper plate, as the working electrode. The interelectrode spacing L was 5, 7, and 9 cm. The potential difference across the electrodes was measured with a millivoltmeter with high input resistance [5].

The results of measurements are presented in Fig. 2. The $\Delta U/L$ ratio increases with decreasing interelectrode spacing. Hence follows that the matter concerns just the electric field strength, and not the voltage drop in electrolyte or electrode. Otherwise, an inverse relationship would be observed because of the increase in the resistance of the electrolyte and the electrode itself. Furthermore, it is known that the so-called ohmic polarization [6] does not affect the nature or rate of electrochemical processes. At the same time, as shown above, the rate of the process markedly increases in going from a monopolar to a bipolar electrode. The 50 mV cm^{-1} difference between the electric field strengths in the electrodes being compared leads to a rise in the limiting current by approximately 40%.

The electrode polarization results in the appearance in the cells of potential gradients directed perpendicularly to, and in parallel with the cathode (anode) [7]. This gives rise to longitudinal and transverse components of currents and voltages (Fig. 1).

The integral characteristics and estimates of these gradients (and, correspondingly, of the processes occurring in electrochemical cells) are currents and voltage drops in different parts of the cell, which is divided in two. The geometric parameters in the corresponding direction are halved. The electrolyte resistance in the transverse direction

$$R_{\perp} = \rho_e(I)h/(4ab),$$

and in the longitudinal direction,

$$R_{\parallel} = \rho_e(I)a/(2hb),$$

the resistance of the cathode material, which cannot be neglected,

$$R_c = \rho a/(2S_c),$$

where $\rho_e(I)$ is the electrolyte resistivity as a function of the current in the given part of the cell, $\rho = 1/æ$; æ, the electrical conductivity of the electrolyte; a and b, the electrode length and width, respectively; h, the cathode-to-anode distance; and S_c, the cathode cross-section area.

The electrolyte resistivity depends on the current density [8]; however, in the given case, the current density is expressed in terms of the cell parameters:

$$j_{\perp} = 2I_{\perp}/(ab), \qquad j_{\parallel} = I/(hb),$$

We studied the dependence of the average conductivity on current density, represented as a polynomial expression

$$æ_e(j) = (\rho j)^{-1} = \sum_{k=0}^{n} a_k j^k,$$

where j is the current density passing through the electrolyte.

A third-order polynomial was chosen for approximation with the least-squares procedure. It was found that $a_0 = 3.24$, $a_1 = 0.463$, $a_2 = 1.733$, and $a_3 = -0.25$.

The obtained polynomial expression for conductivity is the key formula in calculating a cell of any configuration. The equivalent circuits of the cells (Fig. 1) were used to construct matrices for all the currents I_1, ..., I_N. In the same way were constructed, in accordance with the Kirchhoff law, the matrices for voltages and resistances. Thus, finding the vector of the currents in the cell is reduced to solution of the matrix equation $[R][I] = [U]$.

The nonlinearity of the matrix equations is apparent, and, therefore, the solution is obtained by iteration processes $[I]_{N+1} = [Y]_N[U]$, where N is the number of iteration, and $[Y]$ is a matrix inverse to the matrix of resistances. The bipolar cell has geometric parameters similar to those of the monopolar cell, but with one more equivalent resistance, R_n, introduced. The quantity $I_eR_n(I_e)$ expresses the longitudinal component of the potential gradient between the two parts of the bipolar cell. The resistance R_n is analogous to $R_{\parallel}$ with a certain correction for the intermediate resistance, e.g., of the partition diaphragm. According to the equivalent circuit, the total current in the cells is given by $I = I_1 + I_2$. The resistances in the equivalent circuits, expressed in the matrix form $[R][I] = [U]$, yield the pattern of potential gradient distribution in the mono- and bipolar cells. In the latter case, the electric field strength and, consequently, the potential gradient are much higher. The results of calculation are in satisfactory agreement with the experimental data (Fig. 2b).

CONCLUSIONS

(1) The high rate of mass transfer in the case of a bipolar electrode is due to a major contribution of the migration component. This results from the higher potential gradient compared to the monopolar electrochemical cell. The method proposed for theoretical calculation takes into account the type of electrolyte, cell configuration, and nature of current leads, and well describes the difference in the potential gradients between the mono- and bipolar cells.

(2) The bipolar electrode can be used in electrodeposition of metal from dilute solutions modeling the washing water from electroplating shops.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic-Spark Deposition of P- and W (Mo)-Containing Coatings onto Aluminum and Titanium Alloys

V. S. Rudnev, I. V. Lukiyanchuk, V. V. Kon'shin, and P. S. Gordienko

Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Abstract—Data of ^{31}P NMR spectroscopy, conductometry, and pH-metry, and results of experiments on Na_2WO_4 replacement with $Na_2H[PW_{12}O_{42}]$ were used to study the relationship between the joint and proportional incorporation of P and W (Mo) into coatings, on the one hand, and the presence of heteropolyoxo anions in the electrolyte, on the other.

It has been shown previously [1] that simultaneous incorporation of phosphorus and vanadium into anodic-spark coatings on aluminum alloys from electrolytes containing $NaVO_3$ and $Na_6P_6O_{18}$ or NaH_2PO_4 is associated with the presence of heteropolyoxo anions (HPA) $[PV_{14}O_{42}]^{9-}$ in the solution bulk. The coatings formed, containing up to 22 wt % vanadium and 12 wt % phosphorus, possess a number of practically important properties. In particular, they decrease 10–100-fold the currents of the corrosion pairs aluminum/titanium, St.3/titanium, etc. in a 3% NaCl solution [2]. Vanadium-, and also tungsten- and molybdenum-containing anodic layers can be used not only in corrosion protection, but also for other purposes, e.g., in catalysis. A wide variety of tungsto- or molybdophosphate HPAs can be formed in aqueous tungstate– or molybdate–phosphate solutions, depending on the relative concentrations of the components, order of their introduction, pH value, and temperature [3]. By analogy with vanadate–phosphate electrolytes, it would be expected that phosphorus and W (Mo) are jointly incorporated into coatings as a result of the involvement of the forming HPA in high-temperature reactions initiated by electric discharges at the anode.

In this work, we studied the relationship between the ionic composition of aqueous electrolytes with PO_4^{3-}, WO_4^{2-}, and MoO_4^{2-} groups, on the one hand, and the elemental composition of coatings formed on anodes made of aluminum and titanium alloys at voltages of spark and microarc electric breakdowns.

EXPERIMENTAL

The electrolytes were prepared using distilled water and commercial chemicals: $NaH_2PO_4 \cdot 2H_2O$ and $Na_2HPO_4 \cdot 12H_2O$ of pure grade, $Na_2H[PW_{12}O_{42}] \cdot 9H_2O$ of chemically pure grade, and $Na_2WO_4 \cdot 2H_2O$ and $Na_2MoO_4 \cdot 2H_2O$ of analytically pure grade. As in phosphate–vanadate solutions [1], the concentration of NaH_2PO_4 in the electrolytes with sodium tungstate and molybdate was 0.3 M. First sodium dihydrogen phosphate, and then sodium tungstate and molybdate were dissolved, with their concentration raised gradually.

The anodic films were formed on electrodes made of technical-grade VT1-0 titanium and AMtsM aluminum alloy at current density of 0.05 A cm^{-2} in the course of 5 min, unless otherwise specified. As a current source served a TER-100/460R-2/2UKhL4 thyristor converter with unipolar pulse shape. Depending on the electrolyte composition, the first visible spark discharges appeared at the anodes 0.5–1.5 min after the beginning of the process.

The elemental composition of the films was determined on an EMAL-2 laser spectrometer and a JXA-5A X-ray fluorescence microprobe analyzer. X-ray phase analysis of coatings on substrates was made on a DRON-3.0 X-ray diffractometer (CuK_α radiation). The electrical conductivity of aqueous solutions was measured with a conductometer. The ^{31}P NMR spectra of aqueous solutions were recorded on a Bruker WP80SY high-resolution spectrometer at a frequency of 32.442 MHz. The chemical shifts are given on the δ scale (ppm) relative to 85% H_3PO_4.

Figure 1 shows the elemental composition of anodic coatings on titanium (Fig. 1a) and aluminum alloy (Fig. 1b) as a function of the Na_2WO_4 concentration in an electrolyte containing 0.3 M NaH_2PO_4. With increasing amount of sodium tungstate in solution,

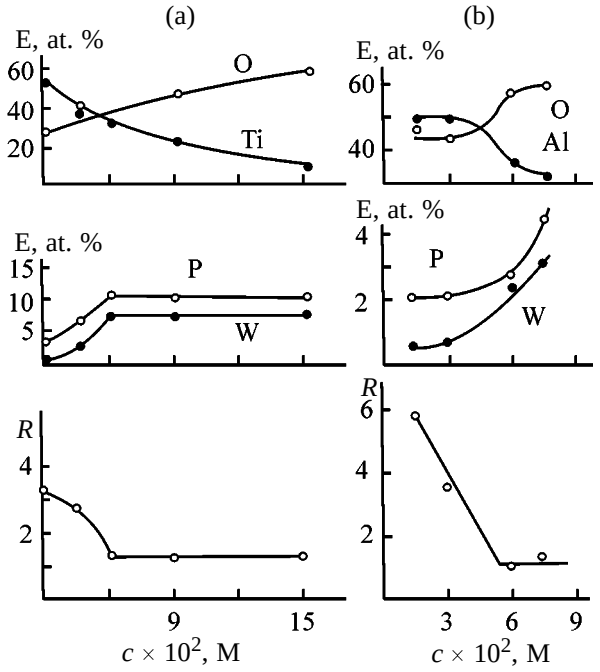

Fig. 1. Elemental composition E and the ratio R of atomic contents of phosphorus and tungsten for coatings on (a) titanium and (b) aluminum alloy vs. concentration c of Na_2WO_4 in 0.3 M aqueous NaH_2PO_4. The coatings were formed in 5 min at a current density of 0.05 A cm^{-2}.

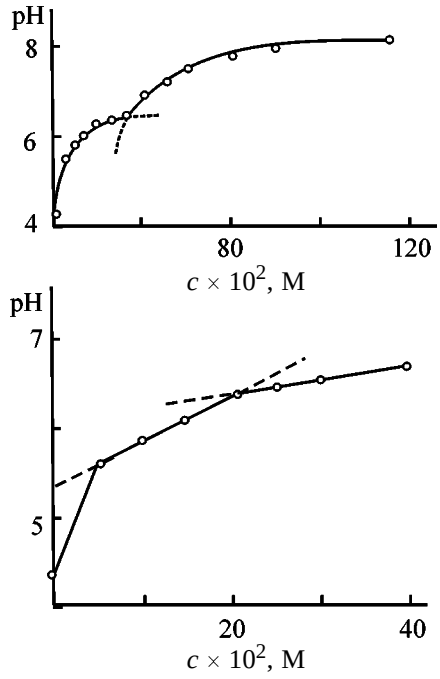

Fig. 2. pH of 0.3 M NaH_2PO_4 solution vs. Na_2WO_4 concentration c.

the content of titanium or aluminum in the coatings decreases, and that of oxygen grows. In the case of titanium, phosphorus and tungsten are incorporated into a film as follows: up to a concentration of 0.06 M, their content increases (phosphorus to 10 at. % and tungsten to 8 at. %) and then remains at this level when further amounts of sodium tungstate are added to the electrolyte. At Na_2WO_4 concentrations exceeding 0.06 M, the ratio of atomic contents of phosphorus and titanium is the same in coatings on both titanium and aluminum alloy and equal to about 1.3.

The sodium tungstate concentration affects the coloration of films formed on the aluminum alloy. At Na_2WO_4 concentrations $c \le 0.045$ M, the films are gray. At $c \ge 0.6$ M, the films are similar in coloration to marble or a kind of enamel, with darker broken lines or spots chaotically scattered on a gray background; the type of sparking at the anode (number per unit surface area, color and size of sparks) changes, and the voltage across the electrodes at a given instant of time decreases. At concentrations $c \ge 0.075$ M, formation of coatings on the AMtsM alloy is hindered. In this case, slow-moving electric discharges appear at the aluminum anode several minutes after the beginning of uniform sparking. These discharges occupy a large surface area and destroy the coating formed before their appearance to bare metal.

Thus, judging from the changes in characteristics of spark discharges and in the formation voltage, color, and elemental composition of the coatings, the concentration of 0.06 M Na_2WO_4 in an electrolyte with sodium dihydrogen phosphate is distinctive. At $c \ge 0.06$ M, the solution acquires yellowish coloration after electrolysis. The coloration becomes more intense with the content of sodium tungstate increasing further. The yellow coloration is characteristic of aqueous solutions of tungstophosphates [3]. The change in the ionic composition is confirmed by the data obtained in measuring the pH value and electrical conductivity (Figs. 2, 3). The curve describing the dependence of the electrical conductivity on concentration exhibits a bend at about 0.05 M, which indicates that the type of charge carriers in solution

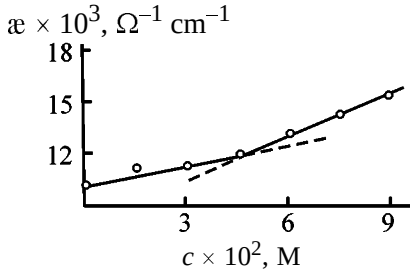

Fig. 3. Electrical conductivity æ of NaH_2PO_4 vs. $Na_2WO_4 \cdot 2H_2O$ concentration c.

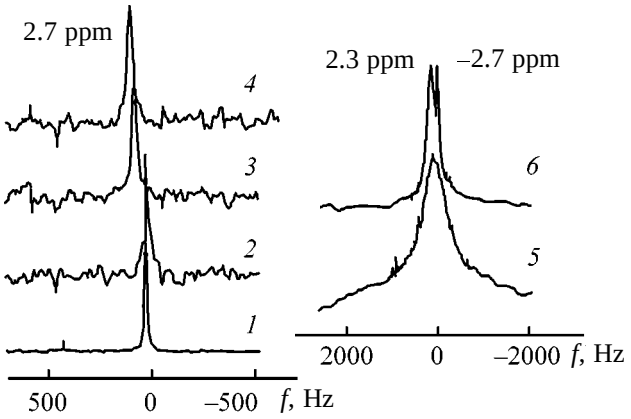

Fig. 4. ^{31}P NMR spectra of aqueous solutions containing 0.03 M NaH_2PO_4. (*f*) Frequency. Na_2WO_4 concentration (M): (*1*) 0, (*2*, *5*) 0.03, (*3*, *6*) 0.15, and (*4*) 0.24. (*1–4*) Before and (*5*, *6*) after formation of anodic-spark coatings.

changes. The variation of all the parameters points to the occurrence of complexation in solution.

Figure 4 presents the ^{31}P NMR spectra of aqueous tungstate–phosphate solutions before and after deposition of anodic-spark coatings onto aluminum alloy. In solutions that were not used for coating formation, addition of Na_2WO_4 in amounts exceeding 0.03 M shifts the ^{31}P resonance line from 0.2 to 2.2–2.7 ppm. This shift may be due to a change in the concentration of the $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-} ions in solution with increasing pH value. After electrolysis, the spectra change. In an electrolyte containing 0.03 M Na_2WO_4, the resonance line is broadened, which indicates that the phosphorus(V) speciation in solution is altered. At an Na_2WO_4 concentration of 0.15 M, the resonance line is split in two, with chemical shifts of 2.3 and –2.1 ppm. The resonance line with the chemical shift δ = –2.1 ppm can be assigned to tungstophosphates $[P_2W_5O_{23}]^{6-}$ and $[P_4W_8O_{40}]^{12-}$ [3]. The changes in the ^{31}P NMR spectra upon coating formation presumably result from both electric-breakdown phenomena, accompanied by electrolysis of water [4], and an increase in the content of aluminum and titanium ions in the electrolyte bulk [5] and from a change in the electrolyte parameters in the near-anode and near-cathode spaces. For example, this may be due to acidification and warming-up of the near-anode region of the electrolyte, which creates favorable conditions for formation of HPA differing in structure and composition from those forming in weakly alkaline, neutral, or weakly acidic solutions at room temperature. It is noteworthy that the solutions used are characterized by a significant excess of PO_4^{3-} ions with respect to WO_4^{2-}.

Thus, in phosphate–tungstate electrolytes, as also in phosphate–vanadate electrolytes [1], there is a correlation between complexation processes in the solution bulk (solution color, conductometric and pH-metric measurements, ^{31}P NMR spectra) and changes in the elemental composition of the forming films. As in the case of electrolytes with vanadophosphates, the content of aluminum or titanium in the anodic-spark films decreases, and that of oxygen, phosphorus, and tungsten increases, with the formation of tungstophosphates in solution. The independence of the P/W atomic ratio in the coatings (Fig. 1) from the concentration of sodium tungstate at $c \geq 0.6$ M must be associated with a certain chemical composition of the films formed.

It is noteworthy that coatings containing the crystalline phases of $Al_2(WO_4)_3$, WO_3, and $W_{18}O_{49}$ are formed in a 0.1 M aqueous solution of Na_2WO_4 on an aluminum anode under the action of spark and microarc discharges [6]. In this case, the phase composition depends on the mode of film formation and electrolyte development. In the course of the development (successive formation of coatings on a number of samples), the electrolyte becomes colloidal, and then a precipitate containing $WO_3 \cdot H_2O$ is formed. The coatings obtained on the aluminum alloy in electrolytes containing NaH_2PO_4 and Na_2WO_4 are X-ray amorphous. Such electrolytes are stable and do not change their aggregative state when in use. The sequential processing of a batch of samples results in that the yellow coloration of the solution becomes more intense, which indicates an increase in the concentration of tungstophosphates.

The elemental composition of anodic films obtained on titanium in an electrolyte containing 0.3 M of NaH_2PO_4 and 0.17 M of sodium molybdate is given below (deposition mode: i = 0.05 A cm^{-2}, t = 10 min):

Element	Content, at. %	Element	Content, at. %
C	2.7	P	13.0
N	0.3	Ti	17.7
O	60.1	Mo	5.4

Comparison of the above data with those in Fig. 1 shows that the element contents are virtually the same in Mo- and W-containing coatings. At the same time, the content of carbon is an order of magnitude higher in coatings with phosphorus and molybdenum. The presence of carbon in the coatings is associated with

carbon dioxide dissolved in the electrolyte. It may be suggested that synthesis of carbon-containing compounds is caused by the catalytic effect of the whole set of molybdenum and tungsten oxides in high-temperature reactions initiated by electric breakdowns. Carbon is firmly fixed in the coatings, since it remains in the coating subjected to a vacuum with residual pressure of down to 10^{-6} mm Hg in the vacuum chamber of the laser mass spectrometer.

To verify the assumption that HPAs affect the coating composition, an electrolyte containing 0.3 M NaH_2PO_4 and 0.075 M Na_2WO_4 (see table, electrolyte no. 4) was modeled. Sodium tungstate was replaced with $Na_2H[PW_{12}O_{42}]$. Electrolytes of the following compositions were used (M): no. 1: $Na_2H \cdot [PW_{12}O_{42}]$ 0.006; no. 2: $Na_2H[PW_{12}O_{42}]$ 0.006 and NaH_2PO_4 0.29; and no. 3: $Na_2H[PW_{12}O_{42}]$ 0.006, NaH_2PO_4 0.22, and Na_2HPO_4 0.07.

The concentrations of tungsten are the same in electrolyte nos. 1–4, and those of tungsten and phosphorus, in electrolyte nos. 2–4; the pH values are close in electrolyte nos. 3 and 4. Heteropoly blues are formed during anodic-spark oxidation of aluminum and titanium in electrolyte nos. 1–3, with the solutions remaining true. At the same time, the interaction with atmospheric oxygen leads to solution decoloration in the absence of electrolysis. In electrolyte no. 3, formation of reduced forms of HPAs is less pronounced, presumably, because of the higher pH value. During electrolysis, this electrolyte acquires first light blue and then yellowish-greenish color, which is characteristic of electrolyte no. 4.

The coatings formed on the aluminum alloy in electrolyte no. 1 contain the largest amount of tungsten, and the smallest, of phosphorus. X-ray phase analysis shows the presence of tungsten oxide $WO_{2.9}$ in their composition. In anodization of titanium in this electrolyte, the sparking mode cannot be attained in 5 min. As a result, very thin coatings of temper coloration are formed. The coatings formed in electrolyte nos. 2–4 are X-ray amorphous and contain an order of magnitude greater amount of phosphorus. Formation of coatings on the aluminum alloy is hindered in electrolyte no. 2. After 5 min of treatment, aluminum anodes are covered with partly gray anodic-spark film and partly with light gray anodic film. Rough light gray anodic-spark layers are formed on titanium anodes.

Electrolyte no. 3 is the closest in composition and pH value to electrolyte no. 4 being modeled. These electrolytes have close formation parameters (final voltage across the electrodes) and coating compositions on both aluminum and titanium. Thus, model experiments confirm the assumption that the presence of tungstophosphate HPAs in the electrolyte bulk affects the composition of coatings obtained by anodic-spark deposition.

One of the most important stages of an electrochemical process is adsorption. Tungstate ions can protect metals from corrosion by forming a film of isopoly compounds on their surface [7]. In the given case, the incorporation of HPA components into the coatings may result from formation on the oxide surface of an adsorbed HPA layer involved in reactions occurring at, and around, electric breakdowns.

Thus, it follows from the results presented here and data of [1] that the quantitative changes in the elemental composition of anodic-spark layers formed in phosphate–vanadate, phosphate–tungstate, and phosphate–molybdate electrolytes, simultaneous and proportional incorporation of phosphorus and M (M = W, Mo, or V) into coatings, and the decreasing

content of the anode metal correlate with the change in the ionic composition of the electrolytes and the formation of vanado-, tungsto-, and molybdophosphates in them.

The incorporation of the electrolyte components into anodic-spark coatings results from the occurrence of high-temperature reactions on the anode surface, including thermolysis of deposits from the electrolyte in regions adjacent to the breakdown channels. Here, account should be taken of the fact that only those of the compounds synthesized on the anode remain in the coating, which are insoluble in a given electrolyte. The following sequence of stages in which anodic-spark layers are formed in electrolytes with HPAs can be suggested. A layer of oxide of the anode metal is formed in the prespark region. Electrolyte anions are adsorbed on this layer. Sparking is accompanied by additional deposition on the anodes of the salts contained in the electrolyte. Thermolysis of heteropoly compounds results, in certain electric breakdown modes, in the formation of oxides of the constituent elements and products of interaction with the substrate material. If the compounds formed are insoluble in the electrolyte, then and "island" ("nucleus") of the new phase remains in the vicinity of a breakdown.

The results presented here, as well as the data of [1, 2], give reason to believe that, by creating in the electrolyte bulk favorable conditions for formation of HPA of a known composition, one can introduce necessary elements into anodic-spark layers, i.e., purposefully change the composition of the anodic coatings.

CONCLUSIONS

(1) Joint incorporation of phosphorus and tungsten into anodic layers formed on an aluminum alloy and titanium under the action of electric breakdowns from electrolytes containing 0.3 M of NaH_2PO_4 and Na_2WO_4 is due to the presence in the electrolyte of tungstophosphate heteropolyoxo anions.

(2) The P/W atomic ratio in coatings formed on both titanium and aluminum is 1.2–1.6 at an Na_2WO_4 concentration of 0.06 M and more in an electrolyte containing 0.3 M NaH_2PO_4.

(3) Electrolytes containing NaH_2PO_4 and Na_2WO_4 are stable and do not change their aggregative state in electrolysis and coating formation.

(4) The amount of carbon in coatings obtained in anodic-spark deposition on titanium from molybdate–phosphate electrolytes exceeds by an order of magnitude that in the case of tungstate–phosphate electrolytes.

ACKNOWLEDGMENTS

The authors thank A.S. Rudnev (Far-Eastern State University) for assistance in determining the elemental composition of the coatings.

Abstract—Electrolytic mixtures of vanadium(V) oxide and β-$Na_xV_2O_5$ bronze were synthesized and studied by X-ray diffraction and thermal analyses, step galvanostatic titration, IR absorption spectroscopy, mass spectroscopy, and electrochemical methods.

Vanadium oxide compounds (VOCs) obtained by electrolysis of aqueous solutions are used for preparing ballastless cathodes of thin-film lithium batteries [1–3]. Oxovanadium(V) sulfate solutions containing 20 g l^{-1} sodium ions were used to synthesize a monoclinic sodium–vanadium oxide bronze β-$Na_xV_2O_5$ (x = 0.22–0.40) [4–6]. In thin-film cathodes of lithium battery, it provides enhanced discharge characteristics. Since sodium ions increase adhesion of vanadium deposits to a substrate, we continued a study of the electrolytic sodium-containing VOCs (NaVOCs). Some physicochemical and electrochemical characteristics of 5NaVOCs synthesized from solutions of $VOSO_4$ containing 5 g l^{-1} sodium ions were reported in [7].

Here we report new data on electrolytic 5NaVOCs, which show promise as cathode materials for lithium batteries.

EXPERIMENTAL

Electrolytic 5NaVOCs were synthesized by the method [4, 5] developed for β-$Na_xV_2O_5$ bronze, except that the concentration of sodium ions in the electrolyte was decreased to $c \le 5$ g l^{-1}.

The test objects were thin-film "ballastless" cathodes (1–40 mg cm^{-2}) and 5NaVOC composite electrodes prepared with addition of carbon black and fluoroplastic binder (10 wt % each) [2, 4].

The X-ray diffraction analysis and IR absorption study of 5NaVOC samples were performed as described in [4, 5]. Thermal analysis and mass-spectroscopic study were done with a Mettler Toledo Star^C System on 13-mg powdered 5NaVOC samples heated at a rate of 10 deg min^{-1}.

The reversible electrochemical intercalation of lithium ions into the compounds synthesized was studied in the electrolytes containing (i) propylene carbonate (PC), dimethoxyethane (DME) [PC : DME = 2 : 1 (by volume)], and 1 M $LiClO_4$, and (ii) ethylene carbonate (EC), dimethyl carbonate (DMC) [EC : DMC = 1 : 3 (by volume)], and 1 M $LiAsF_6$ [5, 6].

The chemical coefficient of the lithium ion diffusion in the course of electrochemical intercalation was determined by step galvanostatic titration [8], which, as applied to vanadium oxides, was described in detail in [2, 4].

The electrolytic 5NaVOC samples obtained in the form of finely dispersed powder or as compact deposit on stainless steel gauze are finely crystalline black formations of brown shades. They were studied in various heat-treatment modes.

According to the X-ray diffraction analysis, the non-heat-treated 5NaVOC deposits dried at room temperature are a mixture of orthorhombic vanadium(V) oxide and $V_2O_4 \cdot H_2O$. The presence of sodium–vanadium oxide compound in these deposits was confirmed by weak diffuse reflections of NaV_6O_{15}, also present in the diffraction pattern.

The thermal analysis and mass spectrometry of the 5NaVOC powder revealed the presence of water and of impurities of carbonate and sulfate ions. The mass spectrum contains peaks at m/z 16, 18, 39, 44, and 64, probably corresponding to O_2, H_2O, an unidentified compound, CO_2, and SO_2, respectively, released on heating. These compounds are formed by decom-

position of the vanadium oxide compound, water evaporation, and decomposition of carbonate and sulfate impurity ions.

The presence of carbonates on the surface of 5NaVOCs was established previously by IR Fourier reflection spectroscopy [7]. The carbonates are formed by reaction of 5NaVOCs with atmospheric CO_2. The SO_2 evolution can result from the decomposition of impurity sulfates captured by the electrolytic deposit from the sulfate electrolyte.

The thermogravimetric (TG) curves show that the mass loss of the 5NaVOC sample on heating occurs in two stages in the range 50–400°C. The mass loss in the first stage (50–140°C) is due to evaporation of weakly bound water (0.91 mol mol^{-1} V_2O_5). The mass loss is maximal at 110°C. The second stage (140–400°C) is the evaporation of strongly bound water (0.23 mol mol^{-1} V_2O_5). The total content of water in 5NaVOC was 1.14 mol mol^{-1} V_2O_5. The content of sulfates, as judged from the negligible mass change in the corresponding temperature range (above 500°C), does not exceed trace amounts.

The 5NaVOC deposits heat-treated at high temperature (500°C, 7 h) acquire a light brown color imparted by a mixture of orange orthorhombic vanadium(V) oxide and black β-$Na_xV_2O_5$ bronze. The reflection intensities of these oxide compounds were found in the diffraction pattern of the 5NaVOC powder annealed at 500°C (Fig. 1).

The open-circuit voltage (OCV) of the thin-film ballastless 5NaVOC samples lies within 3.55–3.73 V depending on the heat treatment conditions.

The cyclic voltammograms of 5NaVOC depend on the deposit mass, annealing temperature T_{an}, and potential sweep rate. The voltammograms in the range from OCV to 2.40 V differ in the number of maxima, their positions, and currents.

The maxima for the 5NaVOC electrodes with a deposit mass of 3–4 mg cm^{-2} are more pronounced than for those with a mass of 20–40 mg cm^{-2}. As the potential sweep rate decreases, the current maxima become better resolved. For example, the cyclovoltammograms taken at a potential sweep rate of 10.5×10^{-4} V s^{-1} with the samples annealed at T_{an} = 300°C for 2.5 h have three cathodic current waves and three corresponding anodic current waves. At the lower sweep rate (1×10^{-4} V s^{-1}), the maximum close to 2.80–2.90 V is split in two. As a result, four maxima reflecting phase transitions in 5NaVOC are revealed in the cyclovoltammogram in the course of both intercalation and deintercalation of lithium ions. At lower

sweep rates, the potentials of the anode and cathode maxima become closer, i.e., the lithium ion intercalation becomes more reversible.

At similar values of the deposit mass (4 mg cm^{-2}) and sweep rate (5×10^{-4} V s^{-1}), the voltammograms are determined by the efficiency of the thermal action on the electrolytic deposit. In the cyclovoltammograms obtained with the 5NaVOC electrodes annealed at various temperatures, three current waves corresponding to phase transitions accompanying intercalation of lithium ions are always present: those near 3.20, 2.90, and 2.50 V (Fig. 3). The intensity of the current waves varies down to zero depending on the annealing temperature. As a result, three essentially different cyclovoltammograms are observed (Fig. 3). For example, the nonannealed deposits are characterized by one pronounced cathodic wave and one corresponding anodic wave. The potentials of the cathodic and anodic current maxima are 2.90 and 3.13 V, respectively (Fig. 3*a*). For the nonannealed sample, the second current wave (2.72 V) is weak and not always revealed in the anodic region. As shown above (Fig. 2, curve *3*), the cyclovoltammogram of the deposits annealed at T_{an} = 300°C for 2.5 h (Fig. 3*c*) has three current waves corresponding to intercalation and 3–4 waves corresponding to deintercalation of lithium ions. Increasing annealing temperature to 500°C changes the position of the current maxima and decreases the current value (Fig. 3*b*).

The current decrease can be explained by the crystallization of vanadium oxide compounds incorporated in 5NaVOCs, vanadium(V) oxide and β-bronze, during high-temperature annealing. After crystallization, the morphology of the deposits changes. According to the data of electron microscopy, the electrolytic deposits have a rather rough surface [2, 4]. The 0.5–3.0-μm ordered microformations were observed in the electron micrographs of the oxide compounds annealed at high temperatures. Annealing of the deposits increased their compactness, decreased the tortuosity and relief, and, as a consequence, decreased the specific surface area. Thus, to provide high specific discharge characteristics for 5NaVOC thin-film electrolytic compounds, it is necessary to optimize the thermal treatment conditions with the aim to prepare the cathode material with prescribed compactness, relief, adhesion to the substrate, and chemical composition. Attaining the crystallization and melting temperatures of the synthesized compounds in ballastless electrodes is undesirable. For such electrodes, the optimal annealing temperature is 300°C. The 5NaVOC deposits in the form of thin layers, annealed at 300°C for 2.5–7 h, have high specific discharge characteristics and high Coulombic efficiency of cycling (Fig. 4).

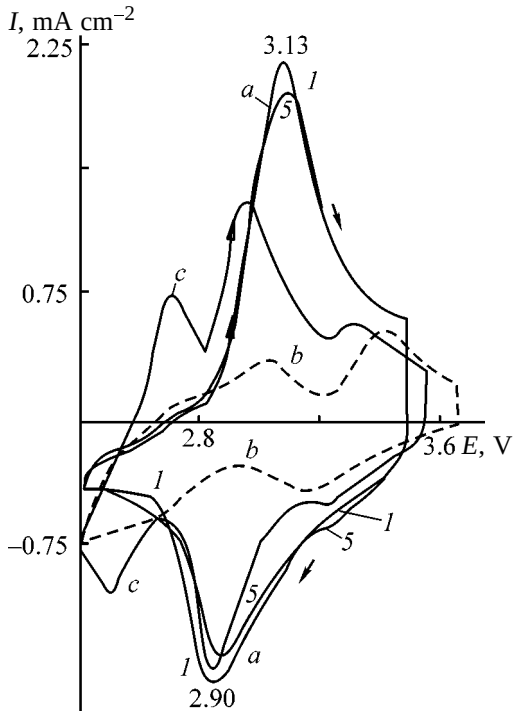

Fig. 3. Cyclic voltammograms of 5NaVOC ballastless electrodes. Potential sweep rate 5×10^{-4} V s^{-1}; Electrolyte: PC, DME, and 1 M $LiClO_4$. Annealing temperature (°C): (*a*) no annealing, (*b*) 500, and (*c*) 300. (*1*, *5*) Number of cycles at room temperature.

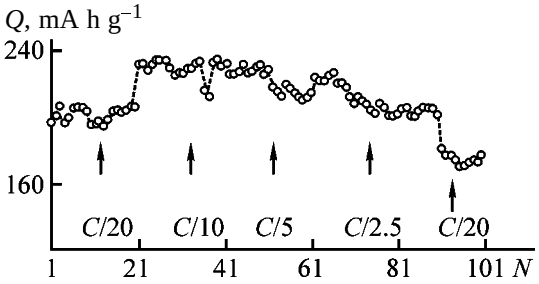

Fig. 4. Discharge capacity Q of the NaVOC ballastless electrode vs. the number of cycles N. T_{an} = 300°C; 2.5 h; electrolyte: EC, DMC, and 1 M $LiAsF_6$; electrode mass 1.1 mg cm^{-2}. $C/20$, $C/10$, $C/5$, and $C/2.5$ are capacities after 20, 10, 5, 2.5 h of discharge, respectively.

The galvanostatic discharge curve of the 5NaVOC electrodes annealed at T_{an} = 300°C depends on the deposit mass. This is due to the kinetic features of intercalation of the sodium ions into the deposit. In the course of electrolysis, sodium ions are intercalated into electrolytic vanadium oxide via the ion-exchange process [9]. For deposits with the 5NaVOC mass equal to or less than 1 mg cm^{-2}, the number of intercalated ions is less than that for the electrodes with

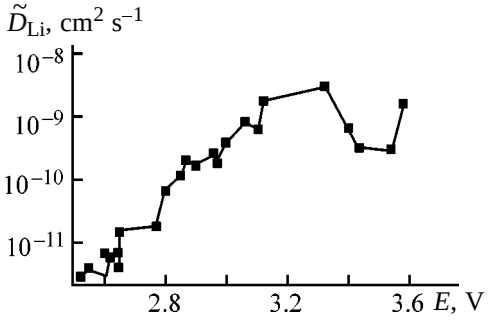

Fig. 5. Chemical coefficient of diffusion $\tilde{D}_{Li}$ for 5NaVOC ballastless electrode vs. electrode potential *E*. Electrolyte: PC, DME, and 1 M $LiClO_4$; electrode mass 1.1 mg cm^{-2}.

the deposit mass equal to or greater than 4 mg cm^{-2}. The galvanostatic discharge curve of the latter compounds is similar to that of electrolytic $Na_xV_2O_5$ β-bronze (three potential plateaus at 3.20, 2.90, and 2.60 V) [4, 5]. However, the potential plateaus for 5NaVOC are weakly pronounced. The discharge curve of the 5NaVOC electrodes with the deposit mass equal to or less than 1 mg cm^{-2} resembles to a greater extent that obtained with electrolytic vanadium(V) oxide [3], whose content exceeds the content of bronze in the 5NaVOC deposit.

Since 5NaVOC is a mixture of vanadium(V) oxide and bronze, the kinetics of intercalation of lithium ions is determined by lithium diffusion and phase formation in this complex system. Some insight into the variations of kinetics in the course of the lithium intercalation into 5NaVOC is given by the dependence of the chemical diffusion coefficient of lithium ions $\tilde{D}_{Li}$ on the electrode potential (Fig. 5). This dependence, obtained by step galvanostatic titration, does not noticeably differ from that obtained by pulsed potentiostatic titration and impedance spectroscopy [7]. The degree of intercalation of lithium ions into 5NaVOC decreases by two–three orders of magnitude after attaining the potential of 2.60 V (the coefficient of the lithium diffusion changes from approximately 10^{-9} to 10^{-12} cm^2 s^{-1}).

The discharge curves of the Li–5NaVOC composite electrodes (T_{an} = 300°C, 2.5 h) operating in the current source 2325 show that, in the course of the intercalation of lithium ions, the potential varies without sharp changes, with smoothly sloping potential plateaus near 3.20, 2.90, and 2.60 V. The smooth run of the discharge curve is well reproduced during the 73rd–100th galvanostatic cycles. The initial discharge capacity Q_1 was 190 mA·h·g^{-1} at the final potential E = 2.50 V and the capacity on the 73rd cycle, Q_{73} = 220 mA h g^{-1} (E = 2.30 V); I_{dis} = 100 μA cm^{-2}.

The high specific discharge characteristics of electrolytic 5NaVOC compounds make them promising as cathode materials for lithium batteries.

CONCLUSIONS

(1) Electrolytic deposits of sodium–vanadium oxide compounds show promise as ballastless electrodes for thin-film lithium batteries, the demand for which is fairly high.

(2) Sodium–vanadium oxide compounds in the form of dispersed powder are new heterogeneous electrode materials and, as composite paste electrodes of lithium batteries, compare well with vanadim(V) oxide.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Possibility of Improving Lead Dioxide Electrode of Lead Battery

G. A. Kolikova and M. M. Barsukova

Istochnik Research Institute of Batteries, Joint-Stock Company, St. Petersburg, Russia

Received January 8, 2002

Abstract—The influence exerted by a reinforcing additive, an aqueous suspension of 4D fluoroplastic (Teflon), on the structural, physicochemical, and service characteristics of the positive electrode of the lead battery was studied. A paste with polymer and carbon additives, extending the service life of the lead dioxide electrode, was developed for industrial use.

Presently, lead batteries constitute about 85% of the entire amount of chemical power cells, and, therefore, further improvement of their service characteristics remains a topical task. One of the most important service characteristics of a lead battery is its service life, which largely depends on the service life of the positive electrode. The failure of a positive electrode is mainly due to corrosion of current leads (grids) and sagging of the active paste, with the shares of these factors being approximately equal.

The problems and methods of improvement of the positive electrode in a lead acid battery were reviewed in considerable detail in [1]. An analysis of the causes and mechanisms of disintegration of the active paste in the lead dioxide electrode revealed their fundamental nature, much hindering the possibility of eliminating this phenomenon [2].

One of ways to extend the service life of lead batteries is to use as a binder in the positive active paste an aqueous suspension of 4D fluoroplastic (Teflon) (VSF4D) [1]. This additive shows high chemical stability with respect to sulfuric acid and resistance to electrochemical oxidation at high anode potentials, which occur at the positive electrode.

However, despite the positive effect of this additive on the service life of lead batteries, it has not found practical use. The reason is that the results obtained are inadequate since no systematic study of the influence exerted by the VSF4D additive on the electrical and physicochemical properties of the lead dioxide electrode has been performed; furthermore, the additive exerts a negative effect on the application characteristics of the paste and the formation process.

To solve these problems, we examined in this work the influence exerted by the VSF4D additive on the structural, physicochemical, and service characteristics of the lead dioxide electrode.

The aqueous suspension of 4D fluoroplastic contained fluoroplastic particles 0.3 μm in diameter, which are in the suspended state because of the addition of a surfactant, have a spherical shape, and are stretched into elastic fibers under mechanical action (in the process of application). The content of fluoroplastic in the suspension is 50–60 wt %. In accordance with the technology developed, the amount of VSF4D introduced into the paste is 0.05–0.15% (in terms of dry substance). Simultaneously, one more additive, a carbon-chain polymeric fiber, can be introduced into the paste in amount of 0.01–0.4 wt % to enhance its strength in electrode fabrication [1].

The present study is concerned with the effect of the reinforcing VSF4D additive and Khlorin fiber on the structure of the positive active paste (porosity, pore tortuosity factor), electrical resistance, and capacity characteristics of the electrode in various modes of its discharge and on its service life.

EXPERIMENTAL

The study was carried out on electrodes of the MT type with the dimensions $62 \times 74 \times 2.65$ mm. Current leads were fabricated from a lead–antimony alloy with antimony content of 6 wt %; the mass of the leads was 35 ± 1 g. Positive pastes were prepared from powdered lead produced with a Chloride mill (PbO content 68.4%, moisture capacity 136 ml kg^{-1}, apparent density 1.48 g cm^{-3}) and sulfuric acid with addition of

a VSF4D solution and Khlorin thread with fiber length of 4–5 mm. The content of sulfuric acid monohydrate in the paste was 36.1 g per gram of powdered lead. The parameters of the pastes studied are listed in Table 1.

Plates with equal dry paste masses of 41 ± 1 g were used in experiments. The plates were formed in a sulfuric acid solution with a density of 1.07 g cm^{-3} (at 15°C), with 0.39 A h of electricity spent per 1 g of paste. The composition of the formed active paste is given in Table 2.

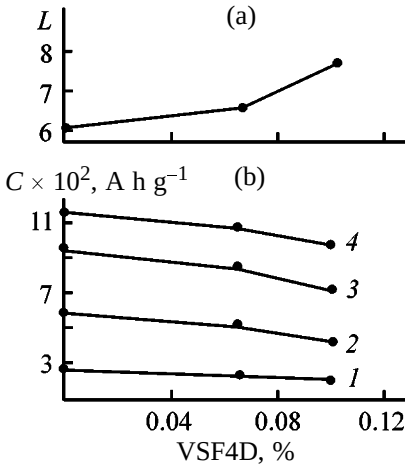

Fig. 1. (a) Relative electrical resistance *L* and (b) specific capacity *C* of lead dioxide electrode in various discharge modes vs. VSF4D content in the active paste. Discharge current density (A dm^{-2}): (*1*) 13.1, (*2*) 2.44, (*3*) 0.74, and (*4*) 0.44.

The relative electrical resistance *L* was measured on a dc setup by the technique proposed by Zhivotinskii [3].

The volume porosity (fraction units) was determined from the difference of masses of dry electrodes and those impregnated for 1 h under vacuum with sulfuric acid with a density of 1.280 g cm^{-3} at 20°C.

The tortuosity factor β, characterizing the pores in the active paste, was calculated from the relative electrical resistance *L* of the electrode and the volume porosity *P* of the active paste by the formula

$$\beta = (LP)^{1/2}.$$

The average values of the pore tortuosity factor of the formed active paste are presented in Table 2.

The capacity characteristics of the electrodes and their service life in cycling were found on prototype batteries comprising one positive and two negative electrodes.

The data in Tables 1 and 2 indicate that introduction of organic additives does not affect noticeably the parameters of the positive and active pastes. Only an insignificant (by 2.5%) increase in the paste density and a minor change in the pore tortuosity factor of the active paste are observed: introduction of VSF4D somewhat raises the pore tortuosity, whereas addition of Khlorin fibers to a VSF4D-containing paste straightens the pores.

Figure 1 presents the relative electrical resistances and capacity characteristics of the electrodes at different discharge currents, which indicate that addition of VSF4D to the positive paste also makes higher the relative electrical resistance of the electrode. With increasing amount of the additive, *L* grows, which leads to a decrease in the electrode capacity. This decrease is particularly noticeable at small discharge rates, when deep layers of the active paste are involved in the process.

Of interest is the fact that addition of Khlorin fiber to the paste changes both the structural parameters of the active paste (porosity, pore tortuosity factor) and the electrical resistance of the electrodes, which affects their capacity characteristics during the initial cycles. For example, the porosity of an active paste with addition of VSF4D and fiber increases in comparison not only with the VSF4D-containing paste, but also with the active paste of the control electrode (Fig. 2). Upon introduction of fiber, the relative elec-

trical resistance of the electrode with VSF4D additive decreases, with its value virtually coinciding with that of the control electrode.

As seen from Fig. 2, the capacity of an electrode with VSF4D and fiber additives occupies an intermediate position between the corresponding values for the control electrode and an electrode with VSF4D additive. Presumably, this is due to the increasing porosity of the active paste and its decreasing relative resistance. It may be assumed that the porosity of the active paste grows because of the formation of more straightened pores oriented along the fibers (Table 2).

As seen from the curves in Fig. 3, describing the variation of the specific capacity of positive electrodes, the capacity of all the electrodes studied grows in the course of cycling. As would be expected, the control electrodes have the highest capacity during the first 40 cycles. After the 70th cycle, the capacity decreases abruptly because of the sag of the active paste. The service life of the control electrodes was 93 cycles. The introduction of the VSF4D additive allowed an increase in this parameter by 20% under free assembly conditions (Fig. 3), which confirms the previously obtained data. Joint introduction of VSF4D and Khlorin fiber into the positive paste raised the discharge capacity of the lead dioxide electrode and lengthened by 40% its service life.

All the batteries failed because of short-circuit at lower edges, caused by sagging of the active paste. The outward appearance of the positive electrodes with VSF4D additive after exhaustion of their service life indicates that more intensive sagging of the active paste is observed without adding the fiber. The totality of elastic adhesive fluoroplastic fibers and rigid carbon-chain polymer fibers forms a three-dimensional skeleton, which keeps the active paste from sagging more reliably.

Thus, the results obtained in studying the structural parameters and electrical characteristics of a positive electrode with organic additives in its active paste revealed the effect of these additives on the operation of the lead dioxide electrode and confirmed the effectiveness of their use to prolong the service life of the lead battery.

Introduction of polymeric additives, which are insulators, impairs the initial capacity characteristics of the electrodes (Figs. 2, 3) and hinders the formation process: a surface layer of lead sulfate is observed on the positive electrodes. Since only the current lead is electrically conducting in the initial stage of formation and the resistance of the paste composed of lead sulfates is very high (10^7–10^{10} Ω), the presence of nonconducting components in the paste complicates the process. Introduction of the electrically conducting additive into the paste must make lower its resistance and improve the process of its formation.

It is known that some carbon materials exhibit high electrical conductivity. Presently, much attention is given to experimental and theoretical studies of recently discovered forms of carbon. These materials possess unique beneficial properties [4] which can be used to compensate for the negative influence of the above-mentioned organic additives.

In this study, we examined the possibility of lowering the electrical resistance of the VSF4D-containing paste and improving its application properties through addition of activated carbon obtained by thermal treatment of graphite of the GL-1 brand. Our study showed

that introduction of 0.01–0.5% activated carbon into the paste with VSF4D additive improves the formation of the lead dioxide electrode, which is indicated by the decrease in the average electrode potential in formation and by the absence of the surface lead sulfate layer.

A study of the electrode microstructure on a JEOL JSM-840A electron microscope (Japan) demonstrated that the active paste with addition of VSF4D and activated carbon has more uniform structure ensuring more stable discharge characteristics of lead dioxide electrodes in cycling.

In addition, it was established that addition of activated carbon, which possesses plasticizing properties, improves the application properties of a paste with VSF4D, i.e., ensures its processability.

Thus, a comprehensive study of the influence exerted by polymer and carbon additives on the physicochemical and electrical characteristics of the lead dioxide electrode allowed a directed modification of its properties, i.e., not only prolonged its service life, but also ensured its stable capacity characteristics and fabricability.

The paste for the positive electrode of a lead battery is protected by a patent [5].

CONCLUSIONS

(1) A study of the structural, physicochemical, and electrical characteristics of a lead dioxide electrode with reinforcing additives in the active paste revealed the effect of these additives on the operation of the electrode and confirmed the effectiveness of their use for extending the service life of the lead battery.

(2) Introduction of activated carbon into the paste with reinforcing VSF4D additive positively addects the structure of the active paste and improves the process of electrode formation.

Abstract—Electrochemical fluorination of some unsaturated sulfides and sulfones and their reactions with anhydrous HF were studied.

Electrochemical fluorination (ECF) of organosulfur compounds in anhydrous HF was studied with saturated or aromatic sulfides, disulfides [1–3], thiols [4–6], sulfoxides [1], and sulfones [7]. On the whole, ECF of S(II) derivativres involves cleavage of one or both S–C bonds. The C–S(O)–C moiety in sulfoxides is not preserved in ECF [1], whereas ECF of sulfones yielded, along with perfluoroalkylsulfonyl fluorides R_fSO_2F, also the corresponding sulfones $R_fSO_2R_f$ [7]. Virtually no data are available, except a single paper [9], on ECF of unsaturated aliphatic or alkenylaromatic sulfides and sulfones.

In this work, we studied ECF of ethyl vinyl sulfide $C_2H_5SCH{=}CH_2$ (**I**), di(1-propenyl) sulfide $(CH_3{-}CH{=}CH)_2S$ (**II**), phenyl vinyl sulfide $C_6H_5SCH{=}CH_2$ (**III**), and phenyl vinyl sulfone $C_6H_5SO_2CH{=}CH_2$ (**IV**), and also reactions of anhydrous HF with **III**, **IV**, and divinyl sulfide $(CH_2{=}CH)_2S$ (**V**). We failed to perform ECF of dichlorovinyl aryl sulfones $ArSO_2{-}CH{=}CCl_2$ (Ar = Ph, *m*-ClC_6H_4, *m*-$NO_2C_6H_4$) because of their insolubility in HF. The compositions and structures of liquid ECF products were determined by GLC, GC–MS, elemental analysis, IR spectroscopy, and ^1H, ^{13}C, and ^{19}F NMR spectroscopy. Gaseous ECF products were analyzed by IR spectroscopy and gas chromatography (GC).

Electrochemical fluorination of sulfide **I** yields gaseous products among which we identified by GC and IR spectroscopy CF_4, C_2F_6, C_3F_8, C_4F_{10}, SF_4, SF_6, SO_2F_2, F_2O, and also liquid low-boiling products (bp 30–35°C) exhibiting no IR absorption in the range above 1350 cm^{-1}, which indicates that these products contain no C=C and C–H bonds. The ^{13}C NMR spectra of liquid ECF products of **I** contain a quartet of triplets at 116 ppm corresponding to the C_2F_5 group. As judged from the boiling points, the major products of ECF of **I** are dodecafluoropentane C_5F_{12} (bp 29.3°C [10]) and pentafluoro(1,1,2,2,2-pentafluoroethyl)-λ^6-sulfane $C_2F_5SF_5$ (the boiling point of the closest homolog, $C_3F_7SF_5$, is 43°C [6]). Formation of dodecafluoropentane was confirmed by the fact that the intensity of ^{19}F NMR signal at –84.2 ppm (CF_3) was equal to the sum of the intensities of the signals at –125.3 (C^3F_2) and –128.9 ppm ($C^{2,4}F_2$), by its refractive index, which was close to the reference value [10], and by the IR spectrum of the distilled product, which coincided with the reference spectrum [11]. The presence of pentafluoro(1,1,2,2,2-pentafluoroethyl)-λ^6-sulfane is confirmed by the substantial (>6%) sulfur content in the liquid products and by the presence in the ^{19}F NMR spectrum of downfield signals at δ_F 46.53 and 64.15 ppm with the intensity ratio of 4 : 1 and J_{FF} 143 Hz. According to [12], the downfield signal belongs to the axial fluorine, and the upfield signal, to equatorial fluorine atoms of the SF_5 group. On the whole, ECF can be described by the equation

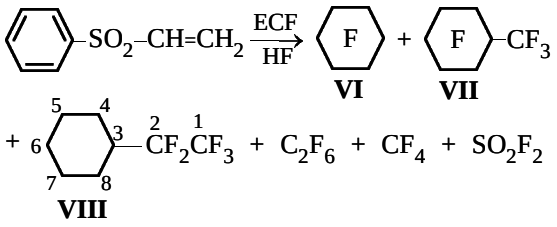
$$C_2H_5SCH{=}CH_2 \xrightarrow[HF]{ECF} C_nF_{2n+2}\ (n = 1{-}5) + C_2F_5SF_5 + SF_4 + SF_6 + SO_2F_2 + F_2O. \quad (1)$$

The gaseous products of ECF of sulfide **II** include HF, CF_4, C_2F_6, CO, CO_2, F_2O, and SO_2F_2. CO, CO_2, and SO_2F_2 are formed by electrochemical fluorination of oxygen-containing organic impurities present in the initial compound. Oxygen difluoride OF_2 is the product of electrochemical fluorination of water

1070-4272/02/7507-1095$27.00 © 2002 MAIK "Nauka/Interperiodica"

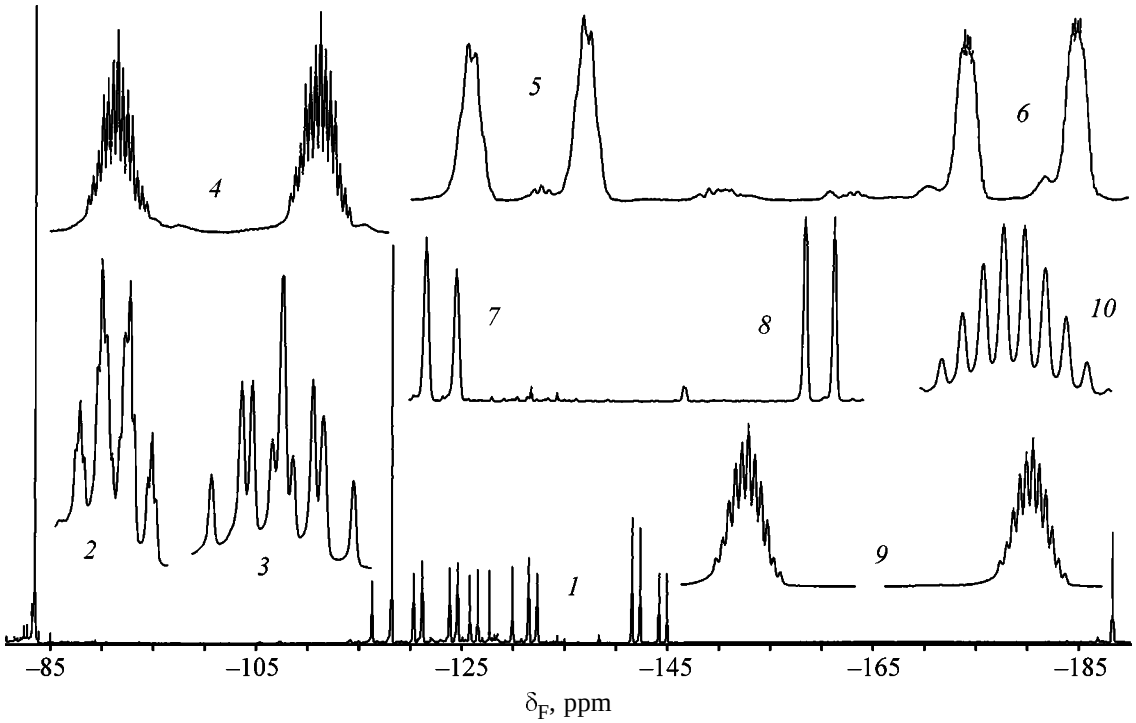
present in small amounts in liquid HF and in the substrate. The content of sulfur in liquid ECF products is about 2%, and that of hydrogen, about 0.5% (at the level of the determination error); the absence of absorption bands above 1350 cm^{-1} indicates that C=C and C–H bonds are absent. This means that ECF involves substitution of all hydrogen atoms, addition of fluorine to all double bonds, and noticeable removal of sulfur. A GC–MS analysis revealed formation of four products, For all of them, the base peak is that of the CF_3^+ ion, and the other peaks (5–20%) are those of C_bF_m ions (n = 1–6, m = 3–13, odd m). Since perfluorocarbons typically give in the mass spectra the $[M - F]^-$ ion and ions corresponding to successive loss of CF_2 up to formation of CF_3^+, our mass spectra confirm formation of perfluorohexanes. Liquid products were fractionated at 50–86°C. The ^{19}F NMR spectra of all the fractions show signals at –75 to –85 (CF_3), –110 to –130 (CF_2), and –185 to –190 ppm (CF). The presence of several CF_3 signals suggests formation of both linear (CF_3CF_2, δ_{CF_3} –80 to –85 ppm) and branched [$(CF_3)_2CF$, δ_{CF_3} –70 to –75 ppm] perfluoroalkanes; the presence of branched perfluoroalkanes is also confirmed by the CF signal at –185 to –190 ppm. As judged from the boiling points, the major ECF products of **II** are linear and branched perfluoroalkanes C_6–C_7. The downfield region of the ^{19}F NMR spectrum of the fraction with bp 80–85°C contains signals at δ_F 46.62 and 61.20 ppm (intensity ratio 4 : 1, J_{FF} 138.8 Hz) belonging, apparently, to pentafluoro(1,1,2,2,3,3,3-heptafluoropropyl)-λ^6-sulfane $C_3F_7SF_5$. The ^{19}F NMR spectrum of the fraction with bp 100°C contains signals at δ_F 42.82 and 61 ppm (J_{FF} 137.7 Hz), belonging, apparently, to equatorial and axial fluorine atoms of the SF_5 group in $C_5F_{11}SF_5$. The signal at δ_F = 28.09 ppm, characteristic of the SF_4 group [12], belongs, apparently, to tetrafluoro[bis(1,1,2,2,3,3,3-heptafluoropropyl)]-λ^6-sulfane $(CF_3CF_2CF_2)_2SF_4$. These data indicate that ECF involved desulfuration with formation of linear and branched C_6–C_8 perfluorocarbons, and also oxidation of sulfur.

In the experiment on ECF of **III**, we analyzed only the gaseous products by IR spectroscopy. Similar to ECF of **I** and **II**, HF, CF_4, SF_4, SF_6, SOF_2, and SO_2F_2 are formed, i.e., the reaction involves oxidation of sulfur and cleavage of the C–S bonds. Electrochemical fluorination of **IV** occurs with complete saturation and desulfuration and is accompanied by fragmentation, yielding perfluorocarbons of the cyclohexane series:



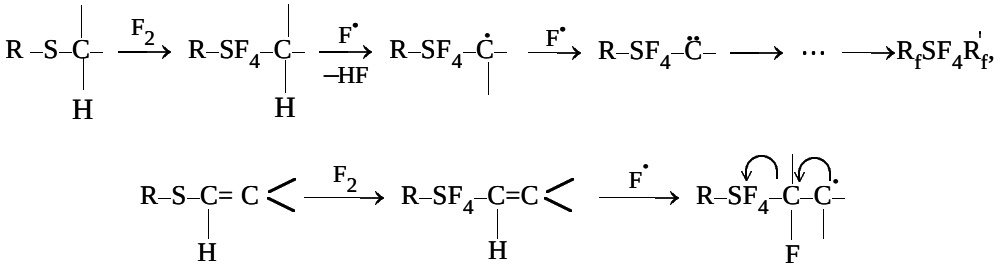
$$+ C_2F_6 + CF_4 + SO_2F_2 + SF_4 + SF_6. \quad (2)$$

Along with the compounds indicated in the scheme, we identified in the gas phase HF, CO, CO_2, and F_2O. The sulfur content in the liquid products is less than 3%, and the hydrogen content, less than 1%. A GC–MS analysis revealed three major products with the fragmentation pattenrs similar to that given for **II**. The ^{19}F NMR spectrum of the products before distillation contained downfield signals at δ_F 65.8 and 61.4 ppm, suggesting formation of R_fSF_5 derivatives, as in ECF of **I** and **II**. The low-boiling (48°C) fraction from distillation of liquid ECF products of **IV** solidifies; its ^{19}F NMR spectrum contains a very broad signal at δ_F –134 ppm. These data confirm formation of perfluorocyclohexane **VI** (mp 51°C, bp 52°C [13]; δ_F –133.25 ppm [14]). The large width of the signal is due to mutual transformations of conformers of **VI** [15]; the signal width varies by two orders of magnitude with temperature [13]. Perfluorocyclohexane **VI** is formed by ECF of various aromatic compounds, including thiophenol [16]. Formation of perfluoroalkylperfluorocyclohexanes **VII** and **VIII** is confirmed by the presence of CF in the ^{13}C NMR spectrum (doublets of multiplets at 96 ppm for **VII** and at 88 ppm for **VIII**) and, in the case of **VIII**, of a quartet of triplets at 116.6 ppm belonging to the CF_3 gorup. The presence of perfluoroethylperfluorocyclohexane **VIII** was confirmed by GLC and by comparison of the ^{13}C and ^{19}F NMR spectra with those of an authentic sample. The content of **VIII** in the product mixture is 19.3%. The ^{19}F NMR spectrum is a complex set of multiplets (see figure). Consideration of the chemical shifts, multiplicities, and integral intensities of signals and comparison with the ^{19}F NMR spectrum of **VII** [17] lead to the following assignments, δ_F, ppm: CF_3 –83.51 d.t.t, 3F, ^2J 2.3, ^3J 14.0, ^3J 12.8 Hz; CF_2 –118.13 t.t, 2F, ^3J 15.8, ^4J 21.5 Hz; CF –187.97 m, 1F, ^3J 15.0 Hz; C^4F_{eq}, C^8F_{eq} –120.67 d.m, 2F, ^2J 303.0 Hz; C^5F_{eq}, C^7F_{eq} –124.11 d.m, 2F, ^2J 288.5 Hz; C^6F_{eq} –126.05 d.m, 1F, ^2J 289.4, ^3J 7.0 Hz; C^4F_{ax}, C^8F_{ax} –131.78 d.m, 2F, ^2J 303.0 Hz; C^5F_{ax}, C^7F_{ax} –141.7 d.m, 2F, ^2J 288.5 Hz; C^6F_{ax} –144.37 d.m, 1F, ^2J 289.4, ^3J 7.0 Hz.



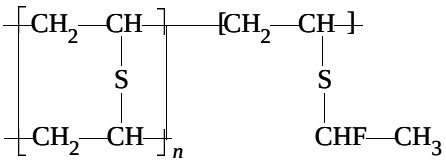
^{19}F NMR spectrum of perfluoroethylperfluorocyclohexane: (*1*) total, (*2*) CF_3, (*3*) CF_2, (*4*) C^6F_{eq}, (*5*) $C^{4(8)}F_{eq}$, (*6*) $C^{5(7)}F_{eq}$, (*7*) $C^{4(8)}F_{ax}$, (*8*) $C^{5(7)}F_{ax}$, (*9*) C^6F_{ax}, and (*10*) CF.

The compounds studied in this work differ from the previously studied alkanethiols, dialkyl sulfides, and dialkyl sulfones in that, in ECF of unsaturated sulfides and sulfones, the yield of sulfur-containing organic compounds is extremely low. For example, in ECF of vinyl sulfides, perfluoroalkyl derivatives of sulfur hexafluoride R_fSF_5 and $R_fSF_4R_f$, which are typical products of ECF of saturated S(II) derivatives [1–6], are formed in minor amounts. As for S(VI) derivatives, it is noted in the literature that the S=O bonds show very high stability in the process, which opens up possibilities for commercial synthesis of trifluoromethanesulfofluoride and, starting from this compound, of the whole class of triflates. However, this is true only for the lower representatives of this series. The yield of perfluoroalkanesulfonyl fluorides R_fSO_2F in ECF oof sulfonyl chlorides RSO_2Cl decreases in the order R = C_1–C_8 from 87 to 25% [18]. In unsaturated sulfones, as shown by the example of **IV**, the ECF products contain virtually no organic sulfonyl detivatives. An increased tendency of unsaturated sulfides and sulfones to undergo desulfuration in ECF is probably due to the fact that the C=C bond is fluorinated more readily than the C–H bond. In the first stage of ECF of S(II) derivatives, S(II) is oxidized to S(VI) [5]. Then, in the case of saturated sulfides, an α-centered radical is formed, and, in the case of unsaturated sulfides, the fluorine atom can add to the α-C atom with subsequent β-scission, which increases the probability of formation of desulfuration products. The general scheme of the process can be represented as follows:



$$\xrightarrow{\beta\text{-Scission}} \dot{R}SF_4 \xrightarrow{F^\cdot} RSF_5 \xrightarrow{F^\cdot} \cdots \rightarrow R_fF + R_fR_f + SF_6,$$
$$\dot{R}SF_4 \xrightarrow{-SF_4} R^\cdot \xrightarrow{F^\cdot} \cdots\rightarrow R_fF + R_fR_f. \qquad (3)$$

To examine the possibility of fluorination of vinyl sulfides and vinyl sulfones on dissolution in HF prior to ECF, compounds **III**–**V** were treated with anhydrous HF. We found that sulfone **IV** in which the vinyl group shows a decreased reactivity toward electrophilic agents due to the electron-withdrawing effect of the sulfonyl group does not react with HF even at 90°C (4 h). At the same time, sulfides **III** and **V**, when brought in contact with anhydrous HF, undergo transformations, probably due to the catalytic effect of HF as acid. For example, divinyl sulfide, when kept in HF at room temperature for several hours, polymerizes to give a light creamy powdered polymer containing 36% sulfur and 5% fluorine; prolonged heating does not change the chemical composition of the polymer, which indicates that the polymer contains chemically bound fluorine rather than adsorbed HF. The polymer is insoluble in organic solvents (benzene, methanol, dichloroethane, CCl_4, DMSO, DMF) and decomposes on heating above 290°C, which suggests its cross-linked structure. We propose the following structure of the polymers (n = 3 on the average):



Under similar conditions, phenyl vinyl sulfide gives products containing no vinyl group. After treatment of the reaction mixture with chloroform, removal of excess HF with NaF, distillation of the solvent, and evacuation, we obtained a blue-green viscous oil, from which we isolated by distillation thiophenol, which is probably formed by addition of HF, followed by protonation of sulfur and scission of the C–S bond with the release of volatile fluorocarbons:

$$PhS{-}CH{=}CH_2 \xrightarrow{HF} [PhSCHF{-}CH_3]$$
$$\xrightarrow{H^+} PhS^+(H){-}CHF{-}CH_3 \xrightarrow{F^-} PhSH + [CH_3CHF_2].$$

The residue is a complex mixture; its ^{1}H NMR spectrum contains no signals from vinyl proton of the initial compound but contains complex multiplets in the range of aromatic (7.1–7.8 ppm) and aliphatic (1.0–3.5 ppm) protons, intensity ratio 5 : 4. According to elemental analysis, the product contains no fluorine. These facts suggest oligomerization of the initially formed $[PhSCHCH_3]^+$ ion with the formation of oligomers of the composition close to $(PhSC_2H_4)_n$. We failed to isolate or identify any individual products.

EXPERIMENTAL

The IR spectra of the products in the liquid phase were taken on an IKS-29 spectrometer in a thin film. The ^{1}H, ^{13}C, and ^{19}F NMR spectra were measured on a Bruker DPX 400 spectrometer (400, 100, and 376 MHz, respectively) with neat samples, external reference DMSO-d_6; the chemical shifts are given relative to TMS (^{1}H, ^{13}C) and $CFCl_3$ (^{19}F). The GC–MS analysis was performed with an LKB 2091 device (EI, 70 eV), and GLC analysis, on a Tsvet-100 chromatograph [thermal conductivity detector, carrier gas helium, 3000 × 3-mm columns, stationary phase 20% α,α,α-tris(β-cyanoethyl)acetophenone on Silochrom-80 (France)].

The IR spectra of gaseous electrolysis products were recorded on a Specord-20M spectrometer in a 10-cm Monel metal cell with AgCl windows. The GC analysis was performed with an LKhM-80 chromatograph (thermal conductivity detector, carrier gas helium, 3000 × 3-mm columns, sorbent MgF_2-17, particle diameter 0.25–0.5 mm).

Electrochemical fluorination was performed in a 150 cm^3 cylindrical cell made from St.3 steel and equipped with a reflux condenser and with stopcocks for supplying HF and removing liquid fluorination products; surface area of the nickel anode 54 cm^2. The reflux condenser was kept at –35°C with HCFC 22 as coolant.

Electrochemical fluorination of **I**–**IV** was performed as follows.

Ethyl vinyl sulfide I. An electrochemical cell was filled with 125 ml of anhydrous HF, and 10 g of divinyl sulfide was added. Electrolysis was performed at 14–16°C for 38 h (38 A h) at the anodic current density of 2 A dm^{-2} and cell voltage of 4.4–4.8 V. Electrolysis gases from the reflux condenser were

sampled into an IR cell. IR spectrum of the gas, ν, cm^{-1}: 3700–4000 (HF); 1502, 1269, 848, 885, 925 (O_2F_2); 1300, 1290, 1250, 1120, 715 (C_2F_6); 900, 830, 610 (SF_4, SF_6); 828, 930 (F_2O). Gaseous samples for GC analysis were passed through aqueous KI. The following products were identified by GC: CF_4, C_2F_6, C_3F_8, C_4F_{10}, SO_2F_2, and SF_6. High-boiling fluorination products (1.6 g) were removed through the stopcock on the electrolyzer bottom into a polyethylene vessel filled with water. Found, %: C 19.46, H 0.58, F 70.86, S 6.24. By distillaiton, we isolated a fraction with bp 30–35°C, consisting mainly of dodecafluoropentane, n_D^{20} 1.2805 (bp 29.3°C, n_D^{15} 1.2411 [9]). The IR spectrum is in agreement with published data [10]. ^{19}F NMR spectrum, δ_F, ppm: –84.2 (CF_3), –125.3 ($CF_2CF_2CF_2$), *–128.9 (CF_3CF_2)*. ^{13}C NMR spectrum, δ_C, ppm: 116.2 q.t (*C*F_3CF_2, $^1J_{CF}$ 286.5, $^2J_{CF}$ 34.0 Hz), 109.4 m ($CF_2CF_2CF_2$). The fraction contains a minor amount of pentafluoro(1,1,2,2,2-pentafluoroethyl)-λ^6-sulfane. ^{19}F NMR spectrum, δ_F, ppm: –83.54 [CF_3, J(CF_3–SF_4) 9 Hz], –100.1 [CF_2, J(CF_2–F_{eq}) 13 Hz], 46.53 d (SF_4), 64.15 quintet [J(F_{ax}–F_{eq}) 143 Hz].

Di(propen-1-yl) sulfide II was treated similarly to **I**. Electrolysis was performed with a 30-g portion of **II** at 14–16°C for 122 h (122 A h) at the anodic current density of 2 A dm^{-2} and cell voltage of 5.3–6.8 V. IR spectrum of gaseous electrolysis products, ν, cm^{-1}: 3700–4000 (HF); 1502, 1269, 848, 885, 925 (SO_2F_2); 1300, 1290, 1250, 1120, 715 (C_2F_6); 828, 930 (F_2O); 900, 830, 610 (SF_4, SF_6). CF_4, C_2F_6, CO_2, and SO_2F_2 were identified by GC. Heavy fluorination products (7.35 g) were discharged into a polyethylene vessel filled with water. Found, %: C 21.2, H 0.76, F 62.65, S 2.10. The mixture of liquid products was fractionated. Fraction with bp 50–60°C. ^{19}F NMR spectrum, δ_F, ppm (the most intense signals are given): –74.96, –75.17 (*iso*-CF_3), –83.80, –84.17 (*n*-CF_3), –108.54, –127.64, –128.79 (CF_2), –185.66, –188.70 (CF). Fraction with bp 84–86°C. ^{19}F NMR spectrum, δ_F, ppm: 46.62, 61.20 (SF_5), –73.00, –74.86, –75.09 (*iso*-CF_3), –83.85, –84.07, –84.15 (*n*-CF_3), –114.06, –114.90, –122.75, –124.97, –126.58, –128.39 (CF_2), –184.87, –185.18, –187.46, –188.40 (CF). The ^{13}C NMR spectra of all the fractions contain doublets of multiplets in the range 90–92 ppm (CF), multiplets in the range 104–112 ppm (CF_2), and signals of two types of CF_3 groups: 118.11 q.d [*C*F_3CF, $^1J_{CF}$ 288.8, $^2J_{CF}$ 22.5 Hz] and 116.61 q.t [*C*F_3CF_2, $^1J_{CF}$ 286.5, $^2J_{CF}$ 34.4 Hz].

Phenyl vinyl sulfide III was treated similarly. Electrolysis was performed with a 18-g portion of **III** at 14–16°C for 45 h (45 A h) at the anodic current density of 2 A dm^{-2} and cell voltage of 5.7–7.6 V. IR spectrum of gaseous electrolysis products, ν, cm^{-1}: 3700–4000 (HF); 1502, 1269, 848, 885, 925 (SO_2F_2); 1300, 1290, 1250, 1120, 715 (C_2F_6); 828, 930 (F_2O); 900, 830, 610 (SF_4, SF_6).

Phenyl vinyl sulfone IV. A 20-g portion of phenyl vinyl sulfone was placed in an electrochemical cell, and 125 ml of anhydrous HF was added. Electrolysis was performed at 14–16°C for 64 h (64 A h) at the anodic current density of 2 A dm^{-2} and cell voltage of 5.5–6.6 V. IR spectrum of gaseous electrolysis products, ν, cm^{-1}: 3700–400 (HF); 2320, 2350 (CO, CO_2); 1502, 1269, 848, 885, 925 (SO_2F_2); 1300, 1290, 1250, 1120, 715 (C_2F_6); 828, 930 (F_2O). CF_4, C_2F_6, CO_2, and SO_2F_2 were identified by GC. The heavy fluorination products (8.74 g) were discharged into a polyethylene vessel filled with water. Found, %: C 17.2, H 0.80, F 66.41, S 2.92.

The mixture was separated by fractional distillation. The fraction with bp 38–48°C solidifies on cooling and mainly consists of perfluorocyclohexane **VI**. ^{19}F NMR spectrum, δ_F, ppm: –134 br.s. The fraction with bp 50–70°C contains perfluoromethylperfluorocyclohexane **VII**. ^{19}F NMR spectrum, δ_F, ppm: –188.7 m (CF), ^3J(CF_2–CF) 14.7 Hz. The fraction with bp 68–80°C mainly consists of perfluoroethylperfluorocyclohexane **VIII**. ^{13}C NMR spectrum (DMSO-d_6, δ_C, ppm: 116.26 q.t, CF_3, ^1J 287.12, ^2J 33.17 Hz; 103–112 m, CF_2; 87.42 d.sept, ^2J 218.93, ^3J 25.8 Hz.

Reactions of **III**–**V** with HF were performed as follows.

Phenyl vinyl sulfide III. Into a 100 cm^3 stainless steel autoclave, 3–5 ml of HF was condensed, and 3.0 g of **III** was added. The autoclave was kept at room temperature for 5 h. The mixture was diluted with 50 ml of chloroform and purged with air, after which NaF was added to pH 7.0. The solution was filtered and evaporated. From the resulting green viscous oil, 0.5 g of thiophenol was isolated by vacuum distillation (bp 50°C/23 mm Hg). ^1H NMR spectrum, δ, ppm: 3.54 s (SH, 1H), 7.21 m (*p*-CH, 1H), 7.29 m (*m*-CH, 2H), 7.33 m (*o*-CH, 2H). ^{13}C NMR spectrum, δ_C, ppm: 125.16 (C_p), 128.99 (C_o), 130.44 (C_1). The blue-green residue was analyzed by NMR. Found, %: C 73.10, H 6.74, S 20.66.

Phenyl vinyl sulfone IV. *a.* Similarly to the above procedure, 1.1 g of **IV** was added to HF. The autoclave was heated at 90°C for 4 h. Then 50 ml of chloroform was added, the mixture was purged with air,

and NaF was added to pH 7.0. The solution was filtered and evaporated to dryness, and the residue was vacuum-dried (1 mm Hg). The initial sulfone **IV** (0.8 g) was recovered; its melting point and the ^{1}H and ^{13}C NMR spectra coincided with those of an authentic sample.

b. Gaseous HF was passed for 1.5 h through a solution of 0.84 g of **IV** in 30 ml of dry benzene, cooled with ice to 12–16°C. The mixture was purged with air under stirring, and NaF was added to pH 7.0. The solution was filtered and evaporated to dryness. The initial sulfone **IV** (0.5 g) was recovered; its melting point and the ^{1}H and ^{13}C NMR spectra coincided with those of an authentic sample.

Divinyl sulfide V. Into a stainless steel autoclave, 3–5 ml of HF was condensed, and 4.44 g of cooled sulfide **V** was added. The mixture was kept at room temperature for 24 h. A light creamy powdered polymer (4.48 g) was obtained. Found, %: C 51.35, H 6.72, F 5.90, S 36.02. Found after heating at 50°C for 24 h, %: C 50.33, H 6.52, F 5.10, S 36.34.

CONCLUSIONS

(1) Electrochemical fluorination of vinyl sulfides and sulfones occurs with complete substitution of all the hydrogen atoms by fluorine, addition of fluorine to the double bonds and benzene ring, and considerable desulfuration, yielding perfluorocarbons as major products, and also perfluoroalkyl derivatives of sulfur hexafluoride and fragmentation products.

(2) With no current applied, vinyl sulfones do not react with anhydrous HF even on prolonged heating, whereas vinyl sulfides take up HF (electrophilic addition to the double bond) with the subsequent scission of the C–S bond or polymerization.

CATALYSIS

Straight and Modified Copper Catalysts for Stereoselective Hydrogenation of 5,17-Docosadiyne

Received February 12, 2001; in final form, March 2002

Abstract—Modified copper catalysts providing high rate of 5,17-docosadiyne hydrogenation with 100% yield of *cis,cis*-5,17-docosadiene (gypsy moth attractant) were developed.

Stereoselective hydrogenation of high-molecular-weight acetylene derivatives to corresponding *cis*- or *trans*-olefins is the most complex and the finest stage in the synthesis of attractants and pheromones.[1] Stringent requirements are placed upon hydrogenation products, since even 1% impurities of positional or geometric isomers present in an attractant or pheromone decrease or fully eliminate its biological activity.

It is known that, in hydrogenation of acetylene derivatives, copper catalysts exhibit high selectivity [2–4] and stereospecificity [5, 6] but low activity. The goal of this study was to develop modified copper catalysts for sufficiently fast and stereoselective hydrogenation of diacetylene hydrocarbon 5,17-docosadiyne,[2] with the aim to ensure its complete conversion and quantitative yield of *cis,cis*-diene and fairly high hydrogenation rate.

EXPRERIMENTAL

Copper catalysts (10% Cu) modified with europium and yttrium oxides were prepared by impregnating a support with metal salt solutions [6]. The europium and yttrium content was varied from 1 to 10%.

The catalyst precursors were thermally treated in air at 473 K for 2 h and then reduced in a hydrogen flow in a tubular furnace at 623 K for 3 h.

Hydrogenation was performed in a high-pressure kinetic device (HPKD) by a common procedure. The temperature was varied from 373 to 423 K, and pressure, from 6 to 10 MPa. Hexane was used as a diluent. Hydrogenation was performed until hydrogen uptake ceased after complete conversion of diacetylene derivative into the *cis,cis*-ethylene compound.

The products of 5,17-docosadiyne hydrogenation were analyzed on a Tsvet-500 chromatograph equipped with a $50\,000 \times 0.25$-mm capillary column coated with OV-101 phase. Chromatograms were treated using an internal reference.

The catalysts were studied by X-ray phase analysis on a DRON-4 diffractometer with filtered CuK_α radiation. The catalyst surface area was determined on an Accusorb-2100 device by the BET method from physical adsorption of nitrogen. Temperature-programmed desorption of hydrogen was also performed.

It was found that all catalysts contain metallic copper lattice without any extrinsic atoms. At the same time, no sharp diffraction maxima of the modifier were observed. This may be due to the fact that rare-earth compounds form thin surface films on aluminum and copper oxides, or X-ray amorphous compounds are formed by a solid-phase reaction of the modifier, copper oxide, and aluminum oxide on heating in an air flow. Both the above processes can proceed simultaneously. These suggestions are indirectly confirmed by a decrease in the surface area on introduction of europium and yttrium oxides into the catalyst. Introduction of 1 to 10% europium decreases the catalyst surface area from 68 to 48 $m^2\,g^{-1}$. For the catalyst 10% Cu/γ-Al_2O_3, the surface area is 90 $m^2\,g^{-1}$. With the yttrium content increasing from 1 to 10%, the surface area decreases from 75 to 38 $m^2\,g^{-1}$. The largest amount of hydrogen (2.2 cm^3) is desorbed from the catalyst modified with 5% Eu

[1] Attractants and pheromones of harmful insects allows opportune and efficient use of insecticides, which substantially decreases contamination of the environment [1].

[2] The hydrogenation product of this compound, *cis,cis*-5,17-docosadiene is the hypsy moth attractant.

Hydrogenation of 5,17-docosadiyne in hexane on Cu/γ-Al_2O_3 catalysts

Copper content in catalyst, wt %	*P*, MPa	*T*, K	τ, min	Catalyzate composition, %	
				Z,Z-5,17-docosadiene	5,17-docosadiyne
10	4	393	300	–	100
10	6	393	200	86	14
10	8	393	175	100	–
10	4	423	300	–	100
10	6	423	140	100	–
10	8	423	120	100	–
20	4	423	300	–	100
20	6	423	200	100	–
20	8	423	180	100	–
30	4	423	300	–	100
30	6	423	210	100	–
30	8	423	180	100	–

(this catalyst is the most active); it is 2.4 times greater than the amount of hydrogen (0.9 cm^3) desorbed from 10% Cu/γ-Al_2O_3. The increased amount of desorbed hydrogen is probably due to increased hydrogen spillover in copper modified with a rare-earth metal oxide [7]. It is believed [8] that, in some cases, rare-earth metal oxides themselves can generate atomic hydrogen.

In samples modified with yttrium oxide (1% Y), the maximal hydrogen content (1.1 cm^3) is slightly larger than in 10% Cu/γ-Al_2O_3 (0.9 cm^3).

Diacetylene hydrocarbon, 5,17-docosadiyne, is converted into *cis,cis*-5,17-docosadiene with 100% yield on 10% Cu/γ-Al_2O_3 at 393 K and hydrogen pressure of 8 MPa (see table). At a lower pressure (6 MPa), conversion of acetylene hydrocarbon is incomplete at 393 K but becomes complete at 423 K. On 20–30% Cu/γ-Al_2O_3 catalysts at 423 K and hydrogen pressure 6–8 MPa, the initial 5,17-docosadiyne is also completely converted into the single product, *Z,Z*-5,17-docosadiene, after which the reaction stops.

An XPES study showed that mainly metallic copper occurs on the surface of the Cu/γ-Al_2O_3 catalyst; only 5% of Cu occurs as Cu^{2+}. The phase composition of catalysts was refined by X-ray and electron diffraction. It was shown that catalysts consist of metallic copper and a small amount of nonstoichiometric spinel, Cu/γ-Al_2O_3. This conclusion was confirmed by ESR spectroscopy: a weak signal of Cu^{2+} is observed in the spectrum of 10% Cu/γ-Al_2O_3. Electron-microscopic measurements showed that both finely divided (40–60 Å) and dense particles (they are usually 2000–3000 Å in diameter, but sometimes reach microns) occur in all catalyst samples irrespective of the copper content.

The 100% yield of *cis*-olefins in hydrogenation of acetylene derivatives on copper catalysts is attained under appropriate conditions [9–11], but the reaction time is very long. To enhance the activity, modifying additives were introduced into the copper catalysts. It was shown in [12] that, as the donor power of the catalyst increases, the dative electron transfer at adsorption of acetylene derivatives becomes stronger, which loosens the triple bond and increases the selectivity of its hydrogenation.

Rare-earth metal oxides (Eu_2O_3, Y_2O_3), which are strong donors (electronegativity EN: Y 1.2, Eu 1.1) [13], were taken as modifiers.

The most active copper catalyst, 10% Cu/γ-Al_2O_3, was modified at 393 K and hydrogen pressure of 8 MPa. Hydrogenation of 5,17-docosadiyne on the catalyst modified with europium oxide gives 100% yield of *cis,cis*-5,17-docosadiene (GLC). The reaction stops after complete conversion of diacetylene hydrocarbon into *Z,Z*-5,17-docosadiene:

Eu content in the catalyst, wt %	0	1	3	5	7	10
Reaction time τ, min	175	30	40	15	50	50

As seen, the activity of copper catalyst increases after modification. The catalyst containing 5% Eu en-

sures the highest hydrogenation rate and the shortest reaction time. The reaction time decreases by a factor of 11 as compared to Cu/γ-Al_2O_3. For catalysts with 1–3% Eu, the reaction time decreases by a factor of 3.3, and with 7–10% Eu, by a factor of 2.

Hydrogenation of 5,17-docosadiyne at 393 K and hydrogen pressure of 8 MPa on the catalyst 10% Cu/γ-Al_2O_3 modified with 1–10% yttrium oxide proceed with 100% yield of *cis,cis*-5,17-docosadiene (GLC). The reaction stops when formation of *Z,Z*-diene hydrocarbon is complete:

Y content in the catalyst, wt %	0	1	3	5	7	10
Reaction time τ, min	175	40	45	48	50	55

As seen, catalysts containing Y accelerate hydrogenation and correspondingly decrease the reaction time. The shortest reaction time is observed for the catalyst with 1% Y (by a factor of 4.3 shorter than with the yttrium-free catalyst), while for the catalyst with 10% Y this factor is 3.2, e.g., the reaction time increases with increasing yttrium content.

Thus, the developed catalysts 10% Cu + Eu_2O_3/γ-Al_2O_3 and 10% Cu + Y_2O_3/γ-Al_2O_3 not only keep all advantages of copper catalysts (complete conversion of diacetylene derivative, 100% yield of *cis,cis*-diene, reaction completion after dialkyne conversion into *cis,cis*-diene), but also are characterized by higher activity than unmodified catalysts. High selectivity of copper catalysts in dialkyne hydrogenation is mainly caused by low heat of adsorption of ethylene bond on copper, insufficient for its activation [14]. It is known [15] that the limiting stage of hydrogenation on copper catalysts is the dissociative hydrogen chemisorption. Therefore, all factors increasing the amount of sorbed atomic hydrogen should enhance the catalyst activity.

High stereospecificity of copper catalysts is caused by the ability of copper to form dihydride complexes HCuH [16] providing a possibility of simultaneous addition of two hydrogen atoms to a triple bond with formation of a *cis*-olefin.

cis,cis-5,17-Docosadiene obtained by stereoselective hydrogenation of the acetylene derivative was tested as gypsy moth attractant. In an arboretum with a very low population of harmful insects, 5–7 gypsy moth butterflies were found in each catcher with a dispenser containing *cis,cis*-5,17-docosadiene after 7 days.

CONCLUSION

Copper catalysts, both straight and modified with rare-earth metal oxides, can be used in synthesis of gypsy moth attractant.

CATALYSIS

Effect of Reaction Medium on the Composition of Vanadium–Titanium Catalyst in Oxidative Ammonolysis of Alkylpyridines

L. I. Saurambaeva and D. Kh. Sembaev

Bekturov Institute of Chemical Sciences, Almaty, Kazakhstan

Received July 25, 2001; in final form, January 2002

Abstract—The influence exerted by the concentration of alkylpyridines on the chemical composition of a vanadium–titanium catalyst under oxidative ammonolysis conditions was subjected to a comparative study.

In the course of catalysis, a catalyst undergoes transformations as a result of its interaction with reactants. The steady-state composition of the catalyst, which determines its activity and selectivity, is formed under the influence of the reaction medium. Under the conditions of oxidative ammonolysis, as also in other reactions, the extent to which the medium affects the catalyst depends on numerous factors, among which the relative amounts of air (oxidizing agent) and an organic compound are important. The change in the composition of a catalyst and, in particular, of a vanadium oxide catalyst modified with oxides of titanium(IV), tin(IV), and other metals is due to reduction of vanadium(V) oxide. For example, it has been shown [1–5] that vanadium(V) oxide in a vanadium–titanium catalyst is reduced under the action of the reaction medium, with the result that the ratio of V_2O_5 to the VO_2–TiO_2 solid solution, which determines the activity and selectivity of the catalyst, also changes.

The extent to which the reaction medium affects a catalyst depends on the degree of conversion of an organic substance, which is determined by the nature of this substance [6]. Therefore, in selecting a catalyst and determining the optimal conditions of the oxidative process, account should be taken of the catalyst composition, which is formed in the course of catalysis under the influence of the reaction medium and ensures the stability of the catalyst operation [7].

This study was aimed to reveal how the structure of alkylpyridines affects the composition and, consequently, catalytic properties of the vanadium–titanium oxide catalyst.

EXPERIMENTAL

The starting 2-methyl-5-ethylpyridine (MEP) and β-picoline of pure grade contained no less than 98% main substance.

Experiments on oxidative ammonolysis of alkylpyridines were performed on a flow-through installation with the reaction tube (length 130 mm, diameter 20 mm) made of quartz glass. The reaction products were absorbed with water and analyzed chromatographically with a flame-ionization detector on a column packed with 15% Carbowax 20M on Chromaton N-AW (0.16–0.20 mm). The analytical procedure with programmed heating from 100 to 180°C at a rate of 10 deg min^{-1} enabled determination of pyridine, 3-methylpyridine, 2-methyl-5-ethyl-, 2-methyl-5-vinyl-, 3-cyano-, 2-cyano-5-ethyl-, and 2-cyano-5-vinylpyridines. 2,5-Dicyanopyridine was determined polarographically after its conversion to isocinchomeronic acid by base hydrolysis.

Carbon oxides were analyzed chromatographically with a heat conductivity detector.

The vanadium–titanium catalysts were prepared by mixing vanadium(V) and titanium(IV) oxides of analytically pure grade with subsequent compaction of the stock into pellets and calcination at 800°C in air flow for 2 h.

X-ray phase analysis of the catalysts was carried out on a DRON-0.5 diffractometer with CuK_α radiation. The content of vanadium(V) oxide in the catalysts was determined by IR spectroscopy [8]. Samples for analysis were prepared as KBr pellets.

The oxidative ammonolysis of MEP on a vanadium–titanium oxide catalyst with the molar ratio

1070-4272/02/7507-1104$27.00 © 2002 MAIK "Nauka/Interperiodica"

$V_2O_5 : TiO_2 = 1 : 16$ at $MEP : O_2 : NH_3 : H_2O = 1 : 42 : 25 : 124$, temperature of 380°C, contact time of 0.83 s, and load of 15 g of MEP per 1 l of catalyst per hour (henceforth, g l^{-1} cat. h^{-1}) proceeded to give virtually a single product of partial conversion, 3-cyanopyridine, in 70 mol % yield (Fig. 1, points *a*). Under these conditions, the catalyst operated efficiently and stably for a long time (1200 h). The content of V_2O_5 in the catalyst decreased, compared to that in the initial catalyst, by 51.6 wt %. According to the results of X-ray phase and IR analyses, the catalyst had the form of an oxide system composed of V_2O_5 and a VO_2–TiO_2 solid solution.

Raising the load (MEP) to 27 g l^{-1} cat. h^{-1} caused a minor decrease in the content of vanadium(V) oxide in the catalyst (Fig. 1, point *b*, curve *6*). This led to a decrease in the selectivity of nicotinonitrile formation to 58.6% (curve *4*) and to the appearance in the catalyst of nitriles of 5-ethyl- and 5-vinylpicolinic and pyridine-2,5-dicarboxylic acids (Fig. 1, points *b*, curves *1–3*).

Raising the concentration of dialkylpyridine in the reaction zone further caused an even more significant decrease in the V_2O_5 content and enrichment of the solid solution with the forming vanadium(IV) oxide. As a result, the conversion of the starting compound decreased and the selectivity of formation of 5-ethyl- and 5-vinylpicolinonitriles and 2,5-dicyanopyridine increased to a total of 55% for MEP feed of 68 g l^{-1} cat. h^{-1} (Fig. 1, points *d*).

With a feed of 92 g l^{-1} cat. h^{-1} of MEP, the entire amount of V_2O_5 contained in the catalyst was reduced. On a catalyst in the form of a V_2O_5–TiO_2 solid solution, the conversion of the pyridine base did not exceed 68%, and the major reaction products were nitriles of 5-ethyl- and 5-vinylpicolinic and pyridine-2.5-dicarboxylic acids (Fig. 1, points *e*, curves *1–3*). The intensity of deep oxidation processes decreased dramatically: the selectivity with respect to carbon dioxide did not exceed 3%.

The experimental data presented in Fig. 1 indicate strong changes in the composition of the vanadium-containing catalyst under the influence of the composition of the reaction medium. In the course of vanadium(V) reduction, both the $V_2O_5/(VO_2–TiO_2)$ ratio and the composition of the solid solution changed. At high MEP concentration in the reaction medium, the catalyst was a solid solution. To each composition of the reaction mixture corresponded a certain chemical composition of the catalyst, which determined its activity and selectivity. As a result, the conversion of MEP decreased and the direction

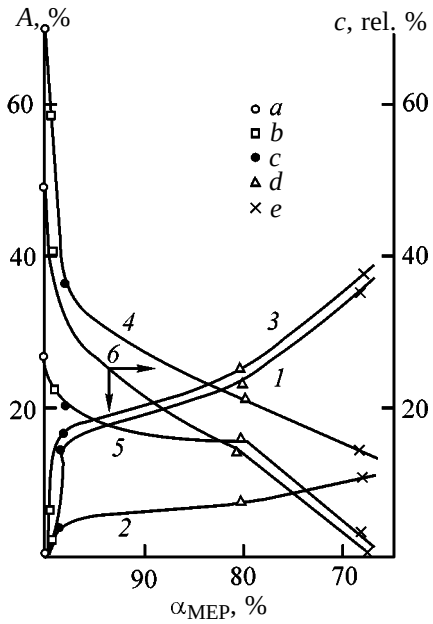

Fig. 1. Effect of conversion α_{MEP} on the selectivity *A* and V_2O_5 content *c* of the catalyst with $V_2O_5 : TiO_2 = 1 : 16$. Temperature 380°C, contact time 0.83 s. MEP feed rate (g l^{-1} cat. h^{-1}): (*a*) 15, (*b*) 27, (*c*) 40, (*d*) 68, and (*e*) 92. Product: (*1*) 2-cyano-5-ethylpyridine, (*2*) 2-cyano-5-vinylpyridine, (*3*) 2,5-dicyanopyridine, (*5*) CO_2, and (*6*) V_2O_5.

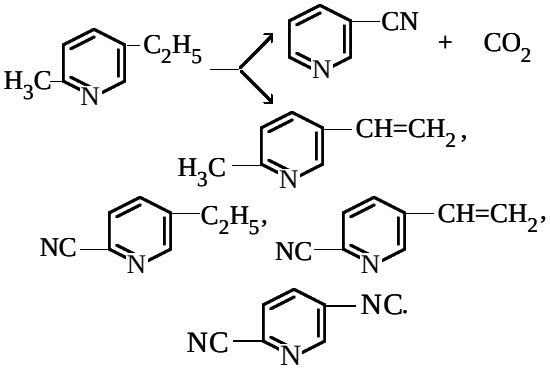
of oxidative transformations changed fundamentally:



On a catalyst rich in vanadium(V) oxide, oxidative ammonolysis proceeded with oxidative elimination of the methyl group of MEP, and 3-cyanopyridine was the major reaction product. On a catalyst containing a small amount of V_2O_5 (with solid solution the rest), the yield of products with two carbon atoms retained at the pyridine ring increased. These compounds were the major products of the reaction occurring on a catalyst containing minor amounts of V_2O_5 and solid solution.

The results obtained in studying the effect of operation time of a freshly prepared vanadium–titanium

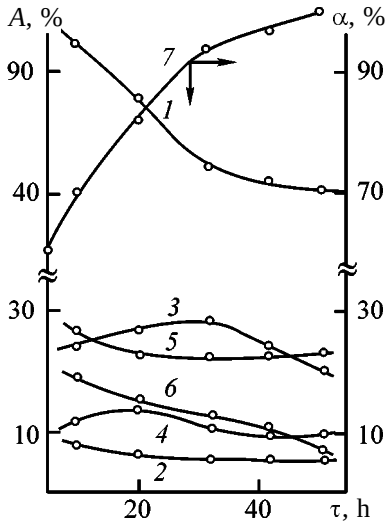


Fig. 2. Effect of the operation time τ of catalyst with $V_2O_5 : TiO_2 = 1 : 16$ on the conversion α of V_2O_5 in the catalyst and on the conversion of MEP and yield of products formed in oxidative ammonolysis of 2-methyl-5-ethylpyridine, *A*. Feed rate: MEP 92, air 1980 l, ammonia 100 g, and water 590 g l^{-1} cat. h^{-1}; temperature 380°C; contact time 0.27 s. (*1*) MEP conversion; yield of products: (*2*) 2-methyl-5-vinylpyridine, (*3*) 2-cyano-5-ethylpyridine, (*4*) 2-cyano-5-vinylpyridine, (*5*) 2,5-dicyanopyridine, and (*6*) 3-cyanopyridine; (*7*) V_2O_5 conversion.

catalyst at high load (MEP) are presented in Fig. 2. An analysis of the catalyzate after 10 h of operation demonstrated that a minor decrease in the V_2O_5 content of the catalyst changed the reaction direction. In this case, 2-methyl-5-vinyl- and 2-cyano-5-ethylpyridines, and also 2-cyano-5-vinyl- and 2,5-ethylpyridines, whose total yield is as high as 70%, became the major reaction products of oxidative ammonolysis of MEP. 3-Cyanopyridine was obtained in a yield as low as 18 mol %.

In prolonged operation of the catalyst (>50 h) under these conditions, the yield of the above-mentioned products changed only slightly. The main reaction products were 2-cyano-5-ethyl- and 2,5-dicyanopyridines. The yield of 3-cyanopyridine was not higher than 7 mol %. The main direction of the oxidative ammonolysis of MEP on a catalyst in the form of a VO_2–TiO_2 solid solution is associated with conversion of one or both alkyl groups into nitrile groups. The share of oxidative elimination of alkyl substituents is low on a catalyst of this kind, which is indicated by the low selectivity of 3-cyanopyridine formation and virtually total absence of CO_2 in the catalyzate.

Effect of 3-methylpyridine load on the yield of products formed in oxidative ammonolysis on catalyst with $V_2O_5 : TiO_2 = 1 : 16$

β-Picoline load, g l^{-1} cat. h^{-1}	β-Picoline conversion	Yield, mol %	
		3-cyanopyridine	CO_2
27.5	98.0	95.0	3.0
49.9	97.8	94.2	3.0
60.0	97.7	94.8	2.8
82.0	97.8	93.8	2.7
100.0	97.7	93.6	2.6

A comparative study of the influence exerted by the reaction medium with varied 3-methylpyridine concentration on the composition of the vanadium–titanium oxide catalyst and on the yield of products formed in oxidative ammonolysis was carried out. The feed rate of the pyridine base was varied between 27.5 and 100 g l^{-1} cat. h^{-1} at constant molar ratio of β-picoline, oxygen, ammonia, and water, equal to 1 : 37 : 8 : 47. The reaction temperature was 380°C, and the contact time, 0.47 s.

The experimental results presented in the table indicate that the reaction medium with widely varied β-picoline feed rate exerts no significant influence on the chemical composition of the catalyst and catalyzate. At a feed of the picoline base at a rate of 100 g l^{-1} cat. h^{-1} for 60 h, the amount of V_2O_5 in the catalyst decreased by 1–2% relative to the initial content, with the conversion of β-picoline decreasing by only 0.2–0.3%, and the yield of 3-cyanopyridine and CO_2, by 1.4 and 0.4%, respectively. Prolonged operation of the catalyst (>200 h) under these conditions did not lead to any new changes in the steady state of the catalyst or in the catalyzate composition.

The data obtained are in agreement with the results of previous experiments on *o*-xylene oxidation into phthalic anhydride on the same catalyst at hydrocarbon load exceeding 100 g l^{-1} cat. h^{-1} [1].

The stronger influence of MEP on the chemical composition of the vanadium–titanium oxide catalyst, compared with that of 3-methylpyridine and *o*-xylene [1, 9], is due to the presence in the molecule of an ethyl group subjected to dehydrogenation, which can be judged from the composition of products formed in oxidative ammonolysis (Figs. 1, 2). The appearance of hydrogen in the catalytic system causes intensive reduction of V_2O_5 to VO_2, which becomes a component of the continuous series of substitutional VO_2–TiO_2 solid solutions [1].

Thus, we found that the extent to which the reac-

tion medium affects the composition of the vanadium–titanium oxide catalyst under the conditions of oxidation reaction depends not only on the reactant ratio, but also on the structure of the organic compound. Therefore, when selecting an effective catalyst and choosing conditions for a particular oxidation reaction, it is necessary to obtain the information about the extent to which the catalyst composition changes under the action of the reaction medium.

CONCLUSIONS

(1) In contrast to 3-methylpyridine, 2-methyl-5-ethylpyridine strongly affects the chemical composition of the vanadium–titanium oxide catalyst, which changes the direction of the dialkylpyridine conversion.

(2) The strong influence of 2-methyl-5-ethylpyridine on the composition of the vanadium–titanium oxide catalyst is due to the presence at the pyridine ring of an ethyl group subjected to dehydrogenation on the catalyst surface.

CATALYSIS

Trifluoroacetic Acid as a New Effective Catalyst for Preparing Monolithic Silica Gel by the Sol–Gel Process

N. N. Khimich, B. I. Venzel', I. A. Drozdova, and L. A. Koptelova

Received November 12, 2001

Abstract—Trifluoroacetic acid was proposed as a new effective catalyst for organic sol–gel synthesis. The influence of the solvent (polar or nonpolar, protic or aprotic) on the sol–gel process was studied.

Synthesis of glassy materials by organic sol–gel process involving hydrolysis of silicon alkoxides, polycondensation of the products, drying of the samples, and sintering of the resulting xerogels was extensively studied [1, 2]. These transformations can be described by the following scheme:

$$\equiv Si{-}OR + H_2O \underset{\text{Etherification}}{\overset{\text{Hydrolysis}}{\rightleftharpoons}} \equiv Si{-}OH + ROH, \quad (1)$$

(2)

$$\equiv Si{-}OR + HO{-}Si\equiv \underset{\text{Alcoholysis}}{\overset{\text{Condensation}}{\rightleftharpoons}} \equiv Si{-}O{-}Si\equiv + ROH, \quad (3)$$

(4)

$$\equiv Si{-}OH + HO{-}Si\equiv \underset{\text{Hydrolysis}}{\overset{\text{Condensation}}{\rightleftharpoons}} \equiv Si{-}O{-}Si\equiv + H_2O, \quad (5)$$

(6)

Silicon alkoxides are hydrolyzed to form silanols (1) which can be condensed by two ways [reactions (3) and (5)]. In acidic media, silanols polymerize to form three-dimensionally cross-linked silica gel [3].

As the sol–gel process occurs, the contribution of reverse reactions, silanol etherifications (2) and rupture of siloxane bonds by alcoholysis (4) and hydrolysis (6), increases, which results in degradation of the gel matrix [3]. Therefore, monolithic samples usually crack in the course of their drying.

There are two ways to prevent cracking. The first is controlled drying, i.e., removal of dispersion media from the gel matrix by capillary forces transferring the liquid to the gel surface. Strong stresses arising after gel shrinkage can be decreased by several ways. The simplest but not the best is performing the process for a longer time. Monolithic samples with excellent physicochemical properties were obtained by drying gels for many months (better years) [4]. We will not consider supercritical drying since it is mainly used for preparing aerogels [3]. Optimization of drying by addition of fine SiO_2 powder or treatment of porous articles in a fluidized bed of ceramic powder [5] deserve attention.

The second approach to prepare monolithic silica is introduction of drying control chemical additives (DCCAs) [6, 7] into the sol–gel system. These compounds optimize hydrolysis of silicon alkoxides and polycondensation of the hydrolysis products.

Indeed, the main function of DCCA (in this case, an organic acid amide) in acid hydrolysis of tetramethoxysilane (TMOS) consists in partial neutralization of acid used as catalyst in the sol–gel system [8]. It is known [9] that hydrolysis and polycondensation of TMOS occur at pH < 1 and pH 4–5, respectively. Hence, neutralization of the reaction mixture from pH 0.7–0.9 to pH 1.8–4.5 owing to reaction of the amides with acid protons provides the best conditions for hydrolysis–polycondensation processes and strengthening of the resulting gels, i.e., promotes polycondensation reactions (3) and (5) and suppresses the reverse reactions (4) and (6) of hydrolysis and alcoholysis of the siloxane chain. Under these conditions, the maximal number of siloxane bonds in a unit volume is formed, which prevents cracking of a gel on drying [10].

A substantial disadvantage of xerogels thus prepared is the presence of difficultly volatile organic impurities (5–10% of the SiO_2 weight) in their pores [10]. These impurities are not removed from the gel matrix at 120–150°C, and their pyrolysis at temperatures above 300–400°C is one of the factors causing cracking of monolithic xerogels on sintering. A search for additives to a sol–gel system, which, on the one hand, provide the best conditions for hydrolysis–polycondensation processes and, on the other hand, are

readily removed on drying, is an urgent problem. One of the ways of its solution is the use of trifluoroacetic acid instead of a strong inorganic acid. Formation of volatile methyl trifluoroacetate provides, on the one hand, the required pH and, on the other hand, the absence of difficultly volatile organic impurities in the gel matrix. Preliminary data on the catalysis with trifluoroacetic acid are briefly reported in [11].

In this work, we studied in detail the influence of the solvent on preparation of monolithic silica gel by the sol–gel process. A solvent is the necessary component of the organic sol–gel system, since alkoxysilane is insoluble in water. In most works, only alcohols (ethanol, methanol, and sometimes 2-methoxyethanol) were used as solvents. Other organic solvents were not studied in this respect. However, the type of the solvent (protic or aprotic, polar or nonpolar) should undoubtedly affect the physicochemical properties of xerogels.

EXPERIMENTAL

TMOS gelation in the presence of various solvents was studied as follows. TMOS (1 equiv) was mixed with a solvent (1 equiv) and then with water (4 equiv). To the resulting solution, on cooling, trifluoroacetic acid (0.1 equiv) was added with vigorous stirring. The solvent-free sol–gel system was prepared by adding dropwise a solution of trifluoroacetic acid (0.1 equiv) in water (4 equiv) to TMOS (1 equiv) with vigorous stirring. Each subsequent drop of the acid solution was added after complete homogenization of the reaction mixture.

The solvents studied in this work were thermally stable under gelation conditions, and their boiling points were close (except for acetic acid). The properties of these solvents are summarized in Table 1.

We studied six solutions. The solutions were placed in hermetically sealed Teflon cylinders 20 mm in diameter (four samples of each system, layer thickness 8–10 mm) and heated for 2 days. Then the hermetic cylinder lids were replaced by lids with 1-mm holes, and samples were dried under the following conditions: heating to 80°C over a period of 2 h, keeping at 80°C for 20 h, heating to 100°C over a period of 4 h, keeping at 100°C for 40 h, heating to 120°C over a period of 4 h, keeping at 120°C for 20 h, heating to 150°C over a period of 3 h, and keeping at 150°C for 20 h.

Six gels were thus prepared. Their numbers correspond to those of the solvent (gel no. 6 was prepared by the solvent-free sol–gel process). Gel no. 7 was prepared from TMOS (1 equiv)–H_2O (4 equiv) mixture containing HCl (0.1 equiv) as catalyst.

The open, W_{open}, and total, W_{tot}, porosities of the samples were determined. The apparent, d_{app}, and true, d_{true}, densities were determined by the Archimede's procedure using toluene and water as saturating and working liquids, respectively. The gel point t (h) was determined as a time required for the sol to become stagnant. The hardness was measured on a PMT-3 microhardness gage. Thermogravimetric analysis was performed on a Q-1500D derivatograph (Hungary) by heating to 1000°C with a rate of 20 deg min^{-1}. The SiO_2 content in the gels was determined thermogravimetrically; the carbon content, from the electrical conductivity of barium hydroxide solutions that absorbed carbon dioxide liberated after combustion of the sample in oxygen; and fluorine content, by a spectrophotometric procedure based on breakdown of the zirconium complex with xylenol orange. The NMR spectra were recorded on a Bruker DPX-300 spectrometer using $CDCl_3$ as the solvent and tetramethylsilane as the internal reference. Electron-microscopic study of the gels was performed on an EM-125 microscope with the accelerating voltage

Table 2. Physicochemical properties of the gels

of 5 kV. For this purpose, cellulose–carbon replicas of fresh chips of the gels were prepared.

Tetramethoxysilane and solvents were purified by distillation on a 10-TP column. The fractions in the range 0.3–0.5°C were collected.

The gels were monolithic transparent disks except for sample nos. 4, 6, and 7 which were partiallty cracked. The physicochemical properties of the gels are given in Table 2.

Trifluoroacetic acid is a strong (pH 0.3) thermally stable organic acid. It forms strong complexes with water and methanol, which complicates its removal from the reaction mixture. Very low fluorine content in the matrix of gel nos. 1–6 dried at 150°C can be only due to chemical transformation of this acid into a more volatile compound. Indeed, the ^{1}H NMR spectrum of the volatile fraction obtained by condensation in a cooled trap of vapor formed on drying of gel no. 6 contains the signals of water (δ = 4.85 ppm), methanol (δ = 3.34 ppm), and methyl trifluoroacetate (δ = 3.98 ppm). To confirm the assignment of the latter signal, methyl trifluoroacetate was prepared from trifluoroacetic acid and methanol in the presence of sulfuric acid [12].

Analysis of the dispersion media of gel nos. 1 and 5 gave the similar results. The spectrum of the condensate contained, along with signals of the solvents (δ = 1.22 and δ = 2.45 ppm for propionitrile and δ = 1.97 ppm for acetic acid), the signals of methanol and methyl trifluoroacetate.

It is interesting that the dispersion medium of the sol–gel process performed in the presence of acetic acid contains one more volatile product, methyl acetate. This is unambiguously indicated by the presence of signals at 3.56 and 1.95 ppm (cf. ethanol).

Thus, the sol–gel process of formation of gel no. 1 involves the reaction

$$CF_3COOH + CH_3OH \rightleftarrows CF_3COOCH_3 + H_2O.$$

In the first steps of the sol–gel synthesis performed in hermetically sealed vessels, this equilibrium is strongly shifted to the left. As a result, the pH of the reaction mixture is ~1, which favors hydrolysis. When the dispersion media is vaporized on drying of the gel matrix, the equilibrium is shifted to the right owing to removal of low-polar highly volatile (bp 43.0–43.5°C) methyl trifluoroacetate. As a results, the acidity of the sol–gel system appreciably decreases, which favors polycondensation of silanol groups [9].

Table 2 demonstrates the influence of the solvent on preparation of monolithic silica gel by sol–gel process. The samples prepared with aprotic nonpolar dioxane are cracked.

When the gelation is performed in the presence of hydrochloric acid, the reaction mixture is constantly acidic (pH < 1). The hardness and density of gel nos. 6 prepared in the presence of trifluoroacetic acid are appreciably higher than those of gel no. 7 prepared in the presence of HCl (Table 2). The structural differences are clearly seen on electron micrographs (Fig. 1). Ordered and uniform structure of gel no. 6 (Fig. 1b) strongly differs from porous and channeled structure of gel no. 7 (Fig. 1a).

However, it is difficult to perform sol–gel process in the absence of solvent, since TMOS is very sparingly soluble in water.

The influence of the solvent on the sol–gel process of formation of monolithic silica gel can be revealed by comparing the physicochemical properties of the samples (Table 2), their electron micrographs (Fig. 1), and the results of thermogravimetric analysis (Fig. 2). Cracked samples with the minimal silica content are formed in the presence of aprotic nonpolar dioxane.

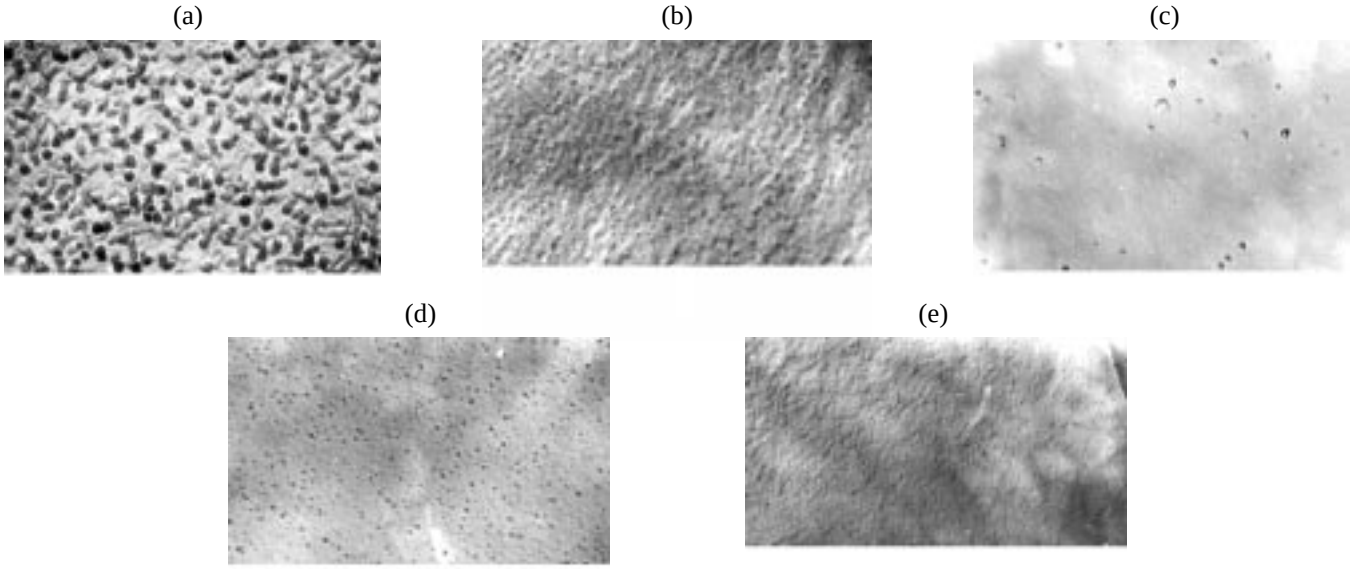

Fig. 1. Electron micrographs of gel nos. (a) 7, (b) 6, (c) 4, (d) 2, and (e) 1. Magnification: (a, b) 60 000 and (c–e) 80 000.

High hardness and density of the gels are due to increased filling of pores with the dispersion media but not to formation of a strong gel skeleton.

The use of alcohols as solvents for the sol–gel synthesis is ineffective. The increased carbon content in the matrix of gel no. 3 prepared with propanol can be due to etherification of silanols formed by TMOS hydrolysis and alcoholysis of the siloxane bonds [13] [Eqs. (2) and (4), respectively]. In *tert*-amyl alcohol, these reactions are sterically hindered. However, although the matrices of the resulting gels are uniform, their density and hardness are low (Fig. 1d).

Acetic acid and propionitrile are promising solvents for the sol–gel process. The density and hardness (Table 2) of the gels prepared with these solvents are the highest. These gels have uniform and microporous structure (Fig. 1e; the structure of gel no. 5 is similar).

As noted above, the reaction of acetic acid with residual methanol suppresses alcoholysis (Eq. 4), thus promoting condensation [Eqs. (3), (5)]. At the same time, transformation of low-volatile acetic acid into the volatile ester reduces the carbon content in the matrix of gel no. 1.

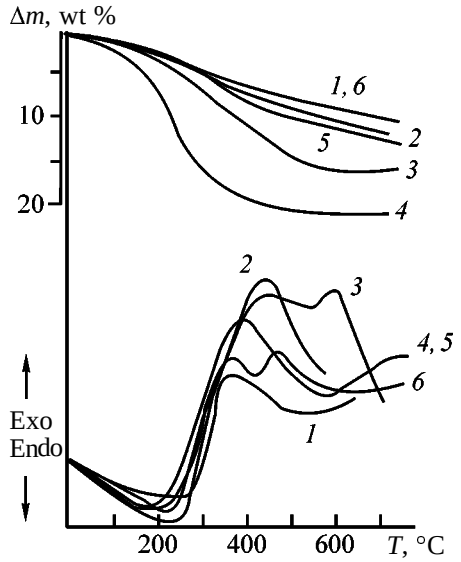

Fig. 2. DTA and TG curves of gel nos. 1–6 (*1–6*, respectively). (Δ*m*) Weight loss and (*T*) temperature.

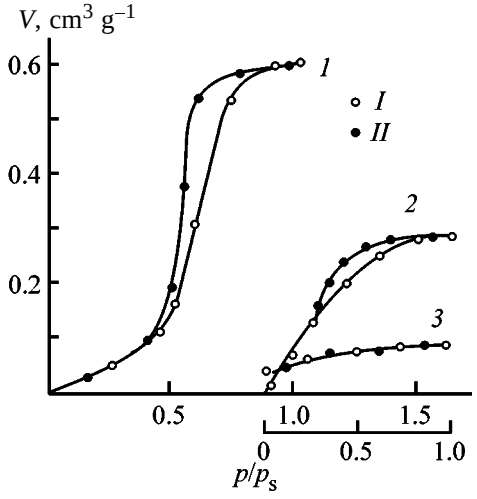

Fig. 3. Adsorption (*I*)–desorption (*II*) isotherms of ethanol on gel nos. (*1*) 7, (*2*) 6, and (*3*) 1 at 18°C. (*V*) Pore volume and (p/p_s) ratio of the ethanol vapor pressure to its saturated vapor pressure.

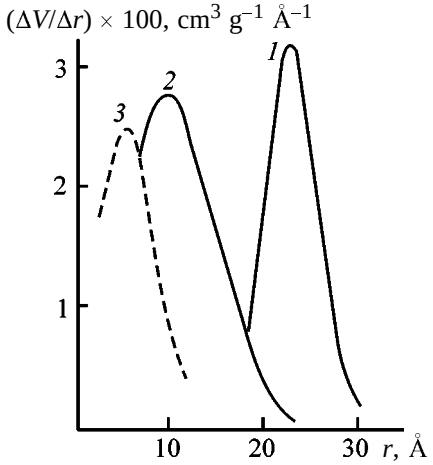

Fig. 4. Distribution of pore volume *V* with respect to pore radius *r* for gel nos. (*1*) 7, (*2*) 6, and (*3*) 1.

It should be noted than macropores of gel nos. 1 and 7 (10–15 and 40–50 nm in diameter, respectively) are not empty. The isotherms of ethanol sorption on gels prepared without solvent (*1*, *2*) and with acetic acid (*3*) are shown in Fig. 3. The size of fine particles filling gel macropores can be estimated from these isotherms. The distribution of pore volume with respect to pore radius is shown in Fig. 4. Since no hysteresis is observed in isotherm *3* for gel no. 1, the volume of pores (smaller than 10 Å) cannot be determined, and curve *1* is shown as dashed line.

Thus, macropores of the gels are filled with more finely divided SiO_2 powder. Although the fact that there are two types of porosity of microporous silica glasses is well known [14], this phenomenon for silica gels is not understood.

CONCLUSIONS

(1) Hydrolysis of tetramethoxysilane and polycondensation of the hydrolysis products were optimized by replacing a strong inorganic acid used as the catalyst by trifluoroacetic acid. The use of trifluoroacetic acid allows the pH of the reaction mixture to be increased from ~1 to almost neutral values owing to removal of trifluoroacetic acid in the form of its volatile methyl ester.

(2) This optimization allows preparation of monolithic gels which do not crack on drying and have high density and hardness.

(3) Difficultly volatile organic impurities formed in the presence of conventional drying control chemical additives are not accumulated in the presence of trifluoroacetic acid, since it is removed from the gel matrix in the form of volatile methyl ester.

(4) The use of propionitrile and acetic acid as solvents for sol–gel process should simplify preparation of gels with the highest hardness and density.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Coagulation and Flocculation Purification of Fat- and Protein-Containing Disperse Systems

Received July 13, 2001; in final form, December 2002

Abstract—Procedure for treatment of wastewater with a coagulant (aluminum sulfate) and anionic flocculants to remove fats and proteins was studied The purification efficiency was evaluated from the flocculation parameters.

Wastewater from dairy, meat-processing, mayonnaise, and other plants of food industry is often a complex disperse mixture of various compounds, among which the most typical are fats and proteins. The parameters of such systems and, in particular, their aggregation and sedimentation stability are determined by the structure of the electrical double layer (DLVO theory) [1, 2], properties of the surrounding boundary layers, and presence of a structural-mechanical barrier (according to Rebinder [3]).

Colloidal-chemical methods involving, in particular, flocculation and coagulation can disturb the aggregation and sedimentation stability of these disperse systems. The mechanisms of particle aggregation occurring in this case were analyzed in detail in [4, 5].

In this work we studied the effect of various factors on the transition of highly dispersed fat- and protein-containing wastewater from the stable into the aggregation-unstable state under the action of a coagulant or its mixture with flocculants.[1]

EXPERIMENTAL

The composition of the product and wastewater characteristics are listed in Tables 1 and 2. First, the wastewater was stored for several hours, then the top layer and precipitate were separated, and the layer containing dispersed proteins, fats, and other impurities was studied.

In our work we used pure grade aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ [GOST 3758–65] as coagulant, and DKS F40 T1 (Japan Chemical Department) and Praestols 2530TR and 2540TR (Stockhausen GmbH and Co.CG) as flocculants. The characteristics of flocculants are given in Table 3.

The granulometric composition of the untreated

[1] The wastewater from washing of mixers for preparing a crude emulsion of Provansal' mayonnaise was used.

Table 1. Product composition

Praestol 2540 TR	1600	4.4	72	28

disperse system was studied by optical microscopy (Biolam microscope). Since the disperse phase particles are often of irregular shape, their statistical average radius (R) was evaluated.

To plot the differential curves of the particle size distribution in the dQ_n/dR–R coordinates (Q_n is the particle number in the fraction), 20 series of measurements were carried out. The number of particles in each fraction was calculated at least six times in different sections of the micrometer network. In our calculations we assumed that the radius range in each fraction is equal and comprises a half of the scale factor ($\Delta R = x/2$). For each fraction, the average particle radius was calculated from the following equation:

$$R_i = x(m + 0.5)/2, \quad (1)$$

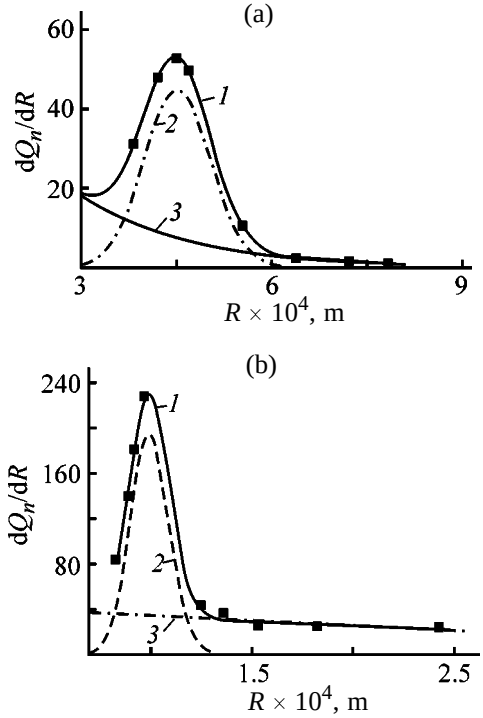

Fig. 1. (*1*) Differential distribution curve of the particle size R in the (a) initial and (b) purified disperse system, and (*2*) normal and (*3*) exponential distributions.

where x is the micrometer scale factor and m is the integer number of the scale factors in the particle diameter for a given fraction.

For each disperse system, we determined (1) the average particle radius

$$R_n = \Sigma N_i R_i / \Sigma N_i, \quad (2)$$

where N_i is the number of particles with radius R_i and ΣN_i is the total number of particles in the system, and (2) weight-average radius

$$R_m = \Sigma N_i R_i^4 / \Sigma N_i R_i^3. \quad (3)$$

The coefficient for polydisperse system $k = R_n/R_m$ was 0.84.

The particle size distribution in the initial disperse system is illustrated in Fig. 1a (curve *1*); the average particle size is 4.6×10^{-6} m.

The differential curve of the particle size distribution is asymmetric and deviates from the normal Gaussian distribution (Fig. 1, curve *2*). Since the system analyzed is multicomponent, we assumed that the total distribution function is a sum of distribution functions of different types. The best approximation is a sum of the normal and exponential distribution functions:

$$dQ_n/dR = A\exp[(R - R_0)^2/\sigma^2] + B\exp(-KR). \quad (4)$$

The parameters A, B, σ, R_0, and K can be calculated from the experimental results using a procedure of nonlinear distribution of the regression analysis [6].

Published data [5, 7] on the aggregation stability of real and model systems suggest the possibility of their destabilization by adding coagulants. Treatment of the disperse system under consideration with coagulants (alumina, aluminum chloride, calcium hydroxide) showed that alumina at pH 6.5–8.0 exhibits the highest coagulation power. The kinetics of the wastewater clarification as influenced by the coagulant

content is illustrated in Fig. 2. The results of 20 experimental series showed that the optimal coagulant concentration is 0.05%.

Data on the optical density and turbidity of the wastewater before purification and after treatment with the optimal dose of alumina indicate that additional treatment with flocculants is required (water turbidity before and after treatment was 3.1 and 2.3 mg l^{-1}, respectively [8]).

The kinetic curves of precipitation of disperse particles on adding optimal doses of the coagulant and its mixtures with flocculants were obtained by sedimentation analysis; they are shown in Fig. 3.

The size distribution curve of the flocculated particles (Fig. 1a), determined by sedimentation analysis using the Stokes equation, suggests the prevalence of coarse particles and essential change in the effective size of the particles as compared to the initial system (from 4.6×10^{-6} to nearly 1.1×10^{-4} m).

Evaluation of the flocculation power of polymers allows us to predict formation of either flocculated or stable colloidal system.

The flocculating power of polymers can be quantitatively evaluated using the dimensionless parameter D [10]:

$$D = V/V_0 - 1 = \tau_{1/2(c=0)}/\tau_{1/2(c)} - 1, \qquad (5)$$

where V and V_0 are the sedimentation rates of the disperse phase in the presence of the polymeric flocculant and without it; $\tau_{1/2(c)}$ and $\tau_{1/2(c=0)}$ are the times of 50% sedimentation of the disperse phase in the presence of flocculant (c) and without it ($c = 0$).

For comparison, we calculated the flocculating activity λ of each additive:

$$\lambda = (\tau_{1/2(c=0)}/\tau_{1/2(c)} - 1)/c_i = D/c_i, \qquad (6)$$

where c_i is the concentration of the polymeric additive.

The flocculation parameters and the size of the resulting aggregates in the presence of various flocculants are shown in Fig. 4 and Table 4.

Our results show that the flocculation power of Praestols 2530 TR and 2540 TR is similar. In the case of DKS, the flocculation activity is two times greater, which is probably due to its higher molecular weight and, thus, larger effective size of macromolecules in solution. This allows efficient use of the DKS flocculant for wastewater treatment at significantly smaller doses as compared to Praestols.

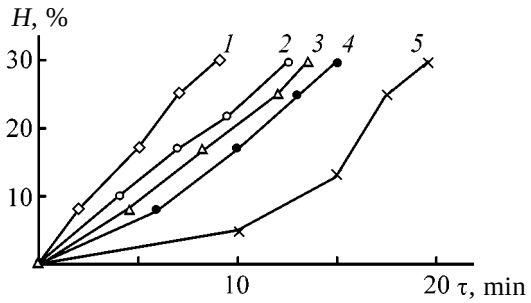

Fig. 2. Clarification degree H in the presence of alumina coagulant as a function of time τ. Alumina content, %: (*1*) 0.05, (*2*) 0.1, (*3*) 0.03, (*4*) 0.15, and (*5*) 0.2.

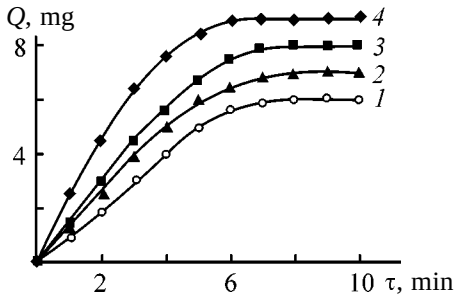

Fig. 3. Kinetic curves of sedimentation of dispersed particles Q at (*1*) optimal dose of coagulant and (*2–4*) in the presence of coagulant and various flocculants. Flocculant content, %: (*2*) Praestol 2540 TR, 2×10^{-4}; (*3*) Praestol 2530 TR, 2×10^{-4}; and (*4*) DKS F40 T1, 4×10^{-6}.

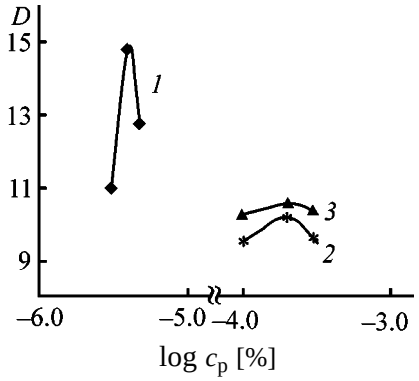

Fig. 4. Flocculation parameter D as a function of the flocculant concentration c_p. Flocculant: (*1*) DKS F40 T1, (*2*) Praestol 2530 TR, and (*3*) Praestol 2540 TR.

It should be noted that the D–$\log c_p$ dependences (Fig. 4) pass through a maximum, the most pronounced in the case of DKS. This is due to the fact [5] that, at low polymer concentrations, the flocculation proceeds through interaction of a single molecule with several particles of the disperse phase ("bridging" flocculation). With increasing polymer concentration, the disperse particles are stabilized by their complete coating with an adsorption layer of the polymer. This

Table 4. Characteristics of the resulting aggregates

Flocculant	c_p, %	D	$\lambda = D/c_p$, $m^3\ kg^{-1}$	$R \times 10^4$, m
DKS F40 T1	3×10^{-6}	11.0	3.7×10^5	1.0
	4×10^{-6}	14.8	3.7×10^5	
	5×10^{-6}	12.6	2.5×10^5	
Praestol 2530 TR	1×10^{-4}	10.2	10.2×10^3	1.2
	2×10^{-4}	10.5	5.3×10^3	
	3×10^{-4}	10.3	3.4×10^3	
Praestol 2540 TR	1×10^{-4}	9.5	9.5×10^3	1.2
	2×10^{-4}	10.1	5.0×10^3	
	3×10^{-4}	9.5	3.2×10^3	

fact should be taken into account when choosing the optimal flocculant dose.

CONCLUSIONS

(1) Fat- and protein-containing disperse system of wastewaters from mayonnaise production contains emulsion particles of the fat with solid inclusions and without them. The average size of the particles is 4.6×10^{-6} m.

(2) Addition of a coagulant or its mixture with flocculants causes flocculation of the particles, with their average size increasing to 1×10^{-4} m.

(3) The flocculating power of the flocculants added at optimal concentration of the coagulant increases in the series Praestol 2540 TR ≈ Praestol 2530 TR < DKS.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Synthesis of a Copper-Containing Catalyst for Electrocatalytic Oxidation of Volatile Organic Compounds

Yu. V. Tsarev, A. E. Dmitriev, and V. V. Kostrov

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received December 11, 2001; in final form, April 2002

Abstract—The synthesis of a copper-containing catalyst for electrocatalytic oxidation of acetone in exhaust gases was studied. Data on the electrocatalytic oxidation of acetone were analyzed in relation to the CuO content.

Treatment of waste gases to remove volatile organic compounds (VOCs) is an urgent problem of environmental protection. The largest amounts of exhaust VOCs are discharged by oil refining and oil production plants (502 and 202 thousand tons annually), chemical plants, and machine-building plants (89.45 and 43.28 thousand tons annually) [1]. The traditional methods for treatment of waste gases to remove VOCs are thermal afterburning, catalytic oxidation, sorption, and sorption-catalytic treatment [2]. Along with traditional methods, the oxidation of VOCs in barrier discharge plasma became a common method [3]. The thermal afterburning and sorption treatment of VOCs are rather expensive processes. Sorption-catalytic and catalytic treatment (including VOC oxidation) in the non-steady-state mode [4] involve smaller service expenditures. Platinum or less expensive oxide catalysts are used in oxidation. As oxide catalysts are used copper(II) and manganese(IV) oxides [5], and as supports, alumina, titania, and other oxides. In some studies [6, 7], the support was activated carbon. In this study, the main attention is given to the electrocatalytic treatment of hydrocarbon-containing gases on a copper oxide catalyst supported by carbon black.

As support we used PM-750 carbon black. The catalysts were obtained from a mixture of carbon black and copper hydroxycarbonate, to which a plasticizer (10% polyvinyl alcohol solution) was subsequently added. The mixture with the optimal moisture content was pressed into 0.5–1-mm granules, which were then calcined in a CO_2 flow at 350°C. The model gas mixture contained air and acetone (the concentration of the latter was 1–2 g m^{-3}). The acetone concentration in a gas–air mixture was determined nephelometrically on a KFK-2MP photoelectrocolorimeter at λ = 320 nm [8]. The degree of the acetone conversion in the catalyst samples synthesized was determined in an isothermal plug-flow reactor. An ac voltage was applied to the catalyst bed.

The total specific surface area of the catalyst was measured on a Tsvet-211 sorption meter [9]. The surface area of the catalysts was determined by selective low-temperature sorption of helium in pulsed mode at –136°C. The X-ray phase analysis of the catalyst samples was done on a DRON–UM1 diffractometer using a CuK_α X-ray tube (λ = 0.154 nm). The interplanar spacings were calculated on a PC. The compounds were identified by comparison of the interplanar spacings with the reference data [10]. The phase composition of the catalyst samples as influenced by the preparation conditions was evaluated from the intensity of the strongest reflections. The diffraction angle 2θ was calculated from the relation $\lambda = 2d\cos\theta$. The electrocatalytic oxidation products were absorbed with hexane and analyzed on a Saturn-2000R gas chromatograph–mass spectrometer.

The contribution of the acetone sorption on a catalyst to the total process of the electrocatalytic treatment was estimated from the dependence of the degree of the acetone adsorption on time (Fig. 1). It was shown that, at saturations longer than 15 min, the degree of adsorption is virtually zero. Therefore, in determining the degree of acetone oxidation on a catalyst, after the acetone-containing gas is passed through a catalyst bed for 1 h, the sorption can be neglected.

The optimal content of copper oxide in the catalyst samples was determined from the plots of the catalytic activity vs. the CuO percentage in the catalyst for

1070-4272/02/7507-1117$27.00 © 2002 MAIK "Nauka/Interperiodica"

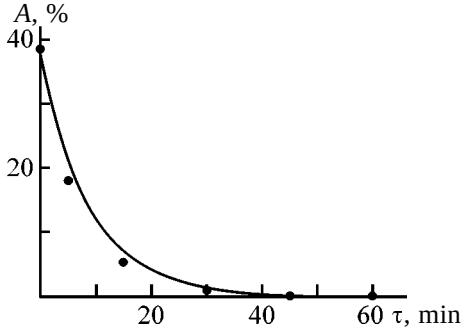

Fig. 1. Degree *A* of acetone adsorption on the catalyst vs. time τ.

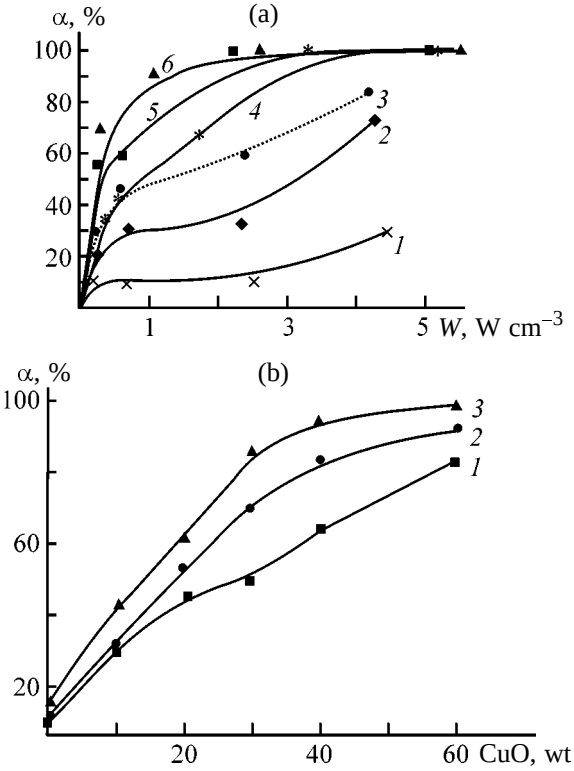

Fig. 2. Degree α of acetone conversion vs. (a) the supplied specific power of electric current *W* and (b) CuO content. (a) CuO content (wt %): (*1*) 0, (*2*) 10, (*3*) 20, (*4*) 30, (*5*) 40, and (*6*) 60. (b) *W* (W cm^{-3}): (*1*) 1.0, (*2*) 2.0, and (*3*) 3.0.

different specific loads of the electric current (Figs. 2a, 2b). The experimental data show that, with the specific load on the catalyst bed increased from 0.6 to 3 W cm^{-3}, the maximal degree of acetone conversion is observed for catalysts containing 40 and 60% copper oxide, respectively. At high specific loads of the electric current (more than 4 W cm^{-3}), the content of the active component in the catalyst only slightly affects the degree of acetone conversion.

The specific surface area of the catalyst samples was determined in the course of the experiment (28–35 $m^2 g^{-1}$). The experimental data show that the specific surface areas of the sample calcined at 350°C and of that calcined at 700°C are similar (28 $m^2 g^{-1}$), i.e., factors other than sintering of the catalyst are responsible for the decreased catalytic activity of the samples calcined at high temperatures. Most probably, the high specific surface area of the catalyst sample containing 60% CuO develops owing to decomposition of $(CuOH)_2CO_3$ whose content in the catalyst is large. The specific surface area of the catalyst sample without copper oxide is equal to that of the initial carbon black (35 $m^2 g^{-1}$), i.e., it is affected by mixing insignificantly.

The experimental data show that, for the specific powers of the supplied electric current less than 2 W cm^{-3}, the degree of acetone conversion on the catalyst decreases with increasing calcination temperature (Fig. 3). Thus, we can conclude that the CuO and Cu_2O phases enhance the effect of the electric current power on the electrocatalytic oxidation of acetone. The metallic copper phase does not affect electrocatalytic oxidation of acetone. At the powers of the supplied electric current higher than 2 W cm^{-3}, the calcination temperature does not affect the degree of acetone conversion on a catalyst. This may be due to the fact that, at high specific powers of supplied electric current, the electrical contribution is dominating.

The phase composition of the catalyst samples was determined by X-ray phase analysis. The test samples containing 20% active component were calcined at 350, 500, and 700°C. The diffraction pattern is shown in Fig. 4. A comparison of the experimental diffraction patterns with the reference data for various compounds revealed crystalline CuO (2θ = 62°) or Cu_2O (2θ = 36°) in the samples synthesized. With increasing calcination temperature, the amount of the crystalline phase decreases, which is manifested as a decrease in the intensity of the strongest reflections attributable to these compounds. Copper oxides undergo reduction, which occurs on the catalyst at high temperature and results in the formation of phase C of metallic copper (2θ 43°, 51°). The diffraction patterns show that the reflections of metallic copper grow in intensity with temperature. The catalyst support, carbon black A, exists in the catalysts in amorphous or weakly crystalline state, which is revealed as a halo corresponding to the diffraction angle 2θ = 25°.

CONCLUSIONS

(1) A study of the conversion of acetone-containing gas in relation to the content of copper(II) oxide

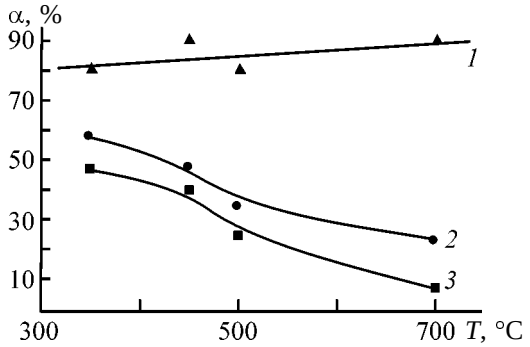

Fig. 3. Degree of acetone conversion α vs. calcination temperature *T*. *W* (W cm^{-3}): (*1*) 4.0, (*2*) 2.0, and (*3*) 0.6.

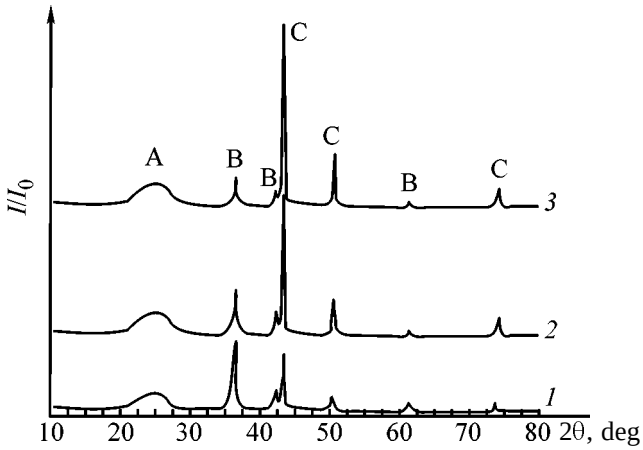

Fig. 4. Diffraction patterns of the catalyst sample containing 20% CuO and calcined at different temperatures. (I/I_0) Relative intensity and (2θ) Bragg angle. Calcination temperature (°C): (*1*) 350, (*2*) 500, and (*3*) 700. (A) Carbon black, (B) CuO (Cu_2O), and (C) metallic copper.

in the catalyst samples showed that the catalyst containing 40–60% copper oxide is the most efficient in electrocatalytic oxidation of acetone.

(2) The X-ray phase analysis showed that the decrease in the catalytic activity of samples with increasing calcination temperature is due to the reduction processes, which occur on the catalyst at high temperatures and result in the formation of metallic copper, inactive in acetone oxidation.

(3) The calcination temperature does not affect the specific surface area of the catalyst samples.

Received December 19, 2001; in final form, March 2002

Abstract—Liquid-phase oxidation of cyclic acetals and 2,2-disubstituted 1,3-dioxacyclanes with dimethyldioxirane, Caro salt, potassium persulfate, and complex of potassium chlorodiperoxochromate with 15-crown-5 was studied.

Liquid-phase oxidation of cyclic acetals receives much attention as a route to hydroperoxides, peroxides, glycol monoesters, and other valuable organic compounds [1]. Such oxidants as oxygen, ozone, organic hydroperoxides, and nitrogen(II) and (IV) oxides were used [2]; however, search for agents ensuring high selectivity of acetal oxidation remains an urgent problem.

In this work, we studied transformations of cyclic acetals and 2,2-disubstituted 1,3-dioxacyclanes under the action of dimethyldioxirane, Caro salt $K_2SO_4 \cdot 2KHSO_5 \cdot KHSO_4$, potassium persulfate, and complex of potassium chlorodiperoxochromate with 15-crown-5.

EXPERIMENTAL

The initial 1,3-dioxacycloalkanes **I**–**VII** [3, 4], dimethyldioxirane [5], Caro salt [6], and complex of potassium chlorodiperoxochromate with 15-crown-5 [7] were prepared by published procedures. Stable nitroxyl radical, 2,2,5,5-tetramethyl-4-phenyl-3-imidazoline-3-oxide-1-oxyl, was prepared according to [8]. Oxidation with dimethyldioxiane was performed as described in [9].

Oxidation with Caro salt was performed in a 30-ml temperature-controlled glass vessel stirred with a magnetic stirrer. To a solution of 1 mmol of a substrate in 10 ml of chloroform, 3 g of wet alumina was added, and the mixture was heated to 50°C. Caro salt (3 mmol) was added in portions over a period of 1 h, and stirring was continued for 2–5 h. The resulting mixture was cooled to room temperature and filtered. The solvent was removed on a rotary evaporator, and the products were analyzed. Oxidation in the presence of nitroxyl radical was performed similarly.

Oxidation with potassium persulfate and complex of potassium chlorodiperoxochromate with 15-crown-5 was performed in acetonitrile at 60°C for 7 h, molar ratio substrate : oxidant 1 : 3.

The reaction products were identified and analyzed by ^1H and ^{13}C NMR spectroscopy (Bruker 300 spectrometer, 300 and 75 MHz, respectively; reference TMS, solvent $CDCl_3$), GC–MS (Finnigan), and GLC (Chrom-5, 1200 × 3-mm column, stationary phase SE-30), using authentic samples of the monoesters and ketones.

We found that cyclic acetals **I**–**VII** react with dimethyldioxirane with quantitative formation of the corresponding glycol monoesters **VIII**–**XVI**:

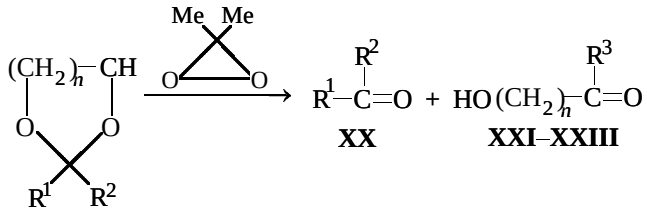
where n = 0, R^1 = *i*-Pr (**I**, **VIII**), Ph (**II**, **IX**), R^2 = R^3 = R^4 = H (**I**, **II**, **VIII**, **IX**); n = 1, R^1 = *i*-Pr (**III**, **X**), Ph (**IV**, **XI**), R^2 = R^3 = R^4 = H (**III**, **IV**, **X**, **XI**); R^1 = *i*-Pr (**V**, **XII**, **XV**), Ph (**VI**, **XIII**, **XVI**), R^2 = Me, R^3 = R^4 = H (**V**, **VI**, **XII**, **XIII**, **XV**, **XVI**); R^1 = Ph (**VIII**, **XIV**), R^2 = H, R^3 = R^4 = Me (**VII**, **XIV**).

From **V** and **VI**, both isomeric esters **XII** and **XV**, **XIII** and **XVI** are formed, since the C^2–O^1 and C^2–O^3 bonds are cleaved concurrently. According to the ^{1}H and ^{13}C NMR data, under conditions of our experiments, esters **XII** and **XIII** with the secondary hydroxy group are the major products.

2,2-Disubstituted 1,3-dioxacyclanes **XVII**–**XIX** under the action of dimethyldioxirane decompose to the corresponding ketones **XX**:



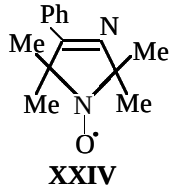
XVII–**XIX** **XX** **XXI**–**XXIII**

where n = 1, R^1 = R^2 = Me, R^3 = H (**XVII**, **XX**, **XXI**); R^1 = R^2 = Me, R^3 = CH_2OH (**XVIII**); n = 2, R^1 = R^2 = R^3 = Me (**XIX**, **XXII**, **XXIII**).

Apparently, in the first stage compounds **XVII**–**XIX** give the corresponding unstable 4-hydroxy-1,3-dioxacyclanes, subsequently decomposing to give ketones **XX**.

It is known [5] that dimethyldioxirane is prepared using Caro salt. We found that this agent oxidizes 2-alkyl-1,3-dioxacyclanes **I** and **III** in the presence of alumina to the corresponding monoesters **VIII** and **X**. However, benzaldehyde derivatives **II** and **VI** under these conditions, along with monoesters **IX** and **XI**, give also benzaldehyde (Table 1).

We found that oxidation of cyclic acetals with Caro salt in the presence of stable nitroxyl radical 2,2,5,5-tetramethyl-4-phenyl-3-imidazoline-3-oxide-1-oxyl **XXIV**



XXIV

allows preparation of monoesters **VIII**–**XI** in quantitative yield (Table 1). The catalytic effect of nitroxyl radicals was noted previously in [10].

Table 1. Oxidation of acetals **I**–**IV** with Caro salt in the presence of alumina (A) or radical **XXIV** (B). Solvent $CHCl_3$, 50°C, 2 h

Acetal	Monoester	Yield of monoester, A (B), %
I	**VIII**	40 (99)
II	**IX**	76* (97)
III	**X**	38 (94)
IV	**XI**	45** (96)

* 13% benzaldehyde. ** 25% benzaldehyde.

Table 2. Oxidation of dioxacycloalkanes **I**–**IV** with the complex $KCrO_5Cl \cdot 2C_{10}H_{20}O_5$ in the absence (A) and in the presence (B) of the radical. Solvent MeCN, 60°C, 2 h; molar ratio substrate : oxidant 1 : 3, substrate : radical 1 : 0.01

Substrate	Product	Product yield, A (B), %
I	**VIII**	55 (≥99)
II	PhCHO	88 (≥99)
III	**X**	≤1 (≥99)
IV	PhCHO	65 (≥99)

In the series of 1,3-dioxacycloalkanes **I**–**VI**, only compounds **I** and **II** are oxidized with potassium persulfate $K_2S_2O_8$ to form, in the first case, ethylene glycol monoisobutyrate **VIII** (yield 45%) and, in the second case, benzaldehyde (yield 25%). In the presence of catalytic amounts of **XXIV**, compounds **I**–**VI** afford esters **VIII**–**XIII** in quantitative yield.

We also studied oxidation of cyclic acetals **I**–**IV** with the complex of potassium chlorodiperoxochromate $KCrO_5Cl$ with 15-crown-5 $C_{10}H_{20}O_5$. We found that acetals **I** and **III** are oxidized with this complex to the corresponding monoesters **VIII** and **X**. At the same time, 2-phenyl derivatives **II** and **IV** are selectively oxidized to benzaldehyde (Table 2). Catalytic amounts of nitroxyl radical **XXIV** provide complete conversions of acetals even in 2 h (Table 2).

Thus, complex of potassium chlorodiperoxochromate with 15-crown-5 can be successfully used for removing acetal protective groups from aromatic aldehydes.

CONCLUSION

Dimethyldioxirane, Caro salt, and complex of potassium chlorodiperoxochromate with 15-crown-5 efficiently oxidize polycyclic acetals to the corre-

sponding glycol moonoesters. 2,2-Disubstituted 1,3-dioxacyclanes under these conditions decompose to the corresponding ketones. Additions of catalytic amounts of the nitroxyl radical increase the reaction yield.

Abstract—Liquid-phase oxidation of crotonaldehyde in ethyl acetate at 285–309 K and oxygen pressure of 1–16 atm was studied. Kinetic equations satisfactorily describing the oxidation kinetics of crotonaldehyde were obtained.

Crotonic acid (CA) and its esters form polymers, which are used in various branches of industry (specialty rubbers, latexes, adhesives, plastics, rubber-modifying agents, etc.). Some CA esters are biologically active compounds exhibiting insecticidal, ascaricidal, and herbicidal properties. Crotonic acid is often prepared by oxidation of crotonaldehyde (CAl) with molecular oxygen at atmospheric pressure. It was found [1, 2] that this process is intensified with increasing pressure. As the partial oxygen pressure is increased from 0.2 to 1 atm, the CAl oxidation accelerates [3], whereas the selectivity of a formation of crotonic and percrotonic (PCA) acids remains virtually constant. The data on the effect of higher oxygen pressures on the CAl oxidation are lacking. In this work, we studied the kinetics of crotonaldehyde oxidation at an oxygen pressure of 1–16 atm.

EXPERIMENTAL

A solution of crotonaldehyde (45 cm^3) in ethyl acetate was placed into a 70-cm^3 stainless steel reactor. Previously we found [4] that ethyl acetate is the best solvent for CAl oxidation. The reactor was sealed and purged with argon (3 atm) three times to remove oxygen. Then the reactor was placed in a water bath temperature-controlled with a thermocouple and a KSP-4 potentiometer. When the required temperature was attained, the excess argon pressure was relieved, and the required oxygen flow of 3.5 $l\,h^{-1}$ through the reactor was set. The reaction mixture was stirred with a magnetic stirrer; it was found that at 1200 rpm the CAl oxidation is kinetically controlled. The reaction products were analyzed by chromatography and IR spectroscopy [5]. Along with the main products of CAl oxidation (CA and PCA), the reaction mixture contained propionic aldehyde, formic and propionic acids, propenyl formate, and epoxypropenyl formate; the total content of by-products did not exceed 15% with respect to reacted CAl. Since the concentration of these by-products in the reaction mixture is low, kinetic study of their formation is rather difficult; thus, we studied only the kinetics of CAl consumption and CA and PCA formation.

The effect of oxygen pressure on the CAl oxidation was studied in the 285–309 K range using ethyl acetate solvent. The kinetic curves of CAl consumption at 309 K at different oxygen pressures (from 1 to 16 atm) are shown as example in Fig. 1. As seen,

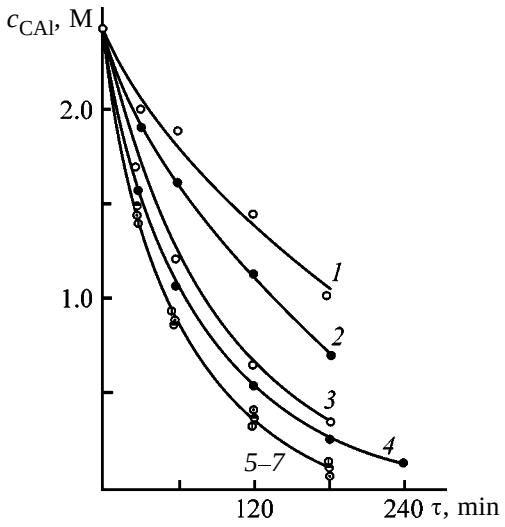

Fig. 1. Kinetics of CAl oxidation at 309 K as a function of the oxygen partial pressure. (C_{CAl}) Concentration of crotonaldehyde and (τ) time. p_{O_2}, atm: (*1*) 1, (*2*) 2, (*3*) 3, (*4*) 4, (*5*) 7, (*6*) 11, and (*7*) 16.

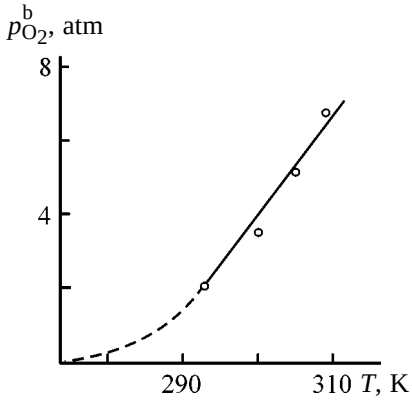

Fig. 2. Boundary oxygen pressure $p^b_{O_2}$ as a function of temperature *T*.

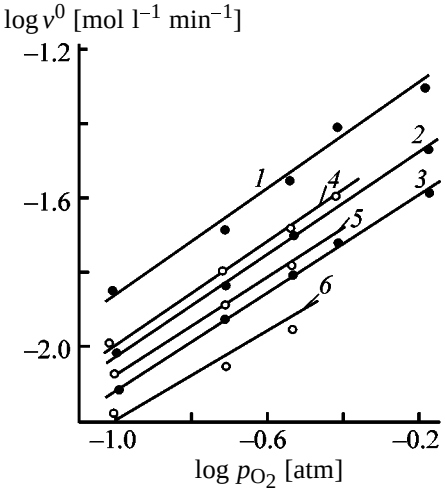

Fig. 3. Initial rate v^0 of (*1*, *4*) CAl oxidation, (*2*, *5*) PCA + CA formation, and (*3*, *6*) PCA formation as a function of the oxygen partial pressure p_{O_2}. C^0_{CAl} = 2.46 M. Temperature, K: (*1*–*3*) 309 and (*4*–*6*) 300.

with increasing pressure to 7 atm, the CAl oxidation is intensified, whereas further increase in p_{O_2} does not noticeably affect the process. Similar phenomenon was observed at the other temperatures studied: at each temperature, above certain boundary pressure of oxygen $p^b_{O_2}$, the oxidation rate becomes independent of the oxygen pressure. Analysis of our experimental data showed that $p^b_{O_2}$ linearly increases with temperature (Fig. 2). Such a trend is probably due to the solubility of oxygen in the reaction medium. With increasing pressure and decreasing temperature, the solubility of gases in liquids increases. Hence, the lower the temperature, the smaller pressure is required to provide certain boundary concentration of dissolved oxygen above which the oxidation rate is independent of its concentration, because the rate of the elementary stages involving dissolved oxygen becomes so high that it does not longer affect the overall reaction rate.

By numerical differentiation, the kinetic dependences $c = f(\tau)$ at 285, 293, 300, and 309 K were transformed into the $v = \varphi(\tau)$ functions. Since the initial CAl concentration in these tests was similar (2.46 M) and in the initial moment there were no by-products in the reaction mixture to affect the process rate, we can determine the kinetic order of reaction with respect to oxygen from the dependences $v = f(p_{O_2})$. Such dependences for the rates of CAl consumption and PCA and PCA + CA accumulation are shown in Fig. 3. Analysis of the experimental data showed that at $p_{O_2} < p^b_{O_2}$ the reaction order with respect to oxygen is similar: 0.6 ± 0.05.

The effect of CAl concentration on the rate of its oxidation and formation of the reaction products was studied at 295 K and p_{O_2} = 2 atm. The experimental results are listed in Table 1. The initial rates of CAl oxidation v^0_{CAl}, PCA formation v^0_{PCA}, and PCA + CA formation $v_{\Sigma A}$ at different initial concentrations of crotonaldehyde were determined by numerical differentiation of the functions $c_i = f(\tau)$. The linear run of the $v^0_i = f(c^0_{CAl})$ curves suggests that the consumption of CAl and formation of PCA and CA are first-order with respect to CAl.

Thus, under the experimental conditions studied, the kinetics of CAl oxidation and PCA and CA formation can be described by the following equations:

$$v_{CAl} = k^{ef}_{CAl} c_{CAl} p^{0.6}_{O_2}, \quad (1)$$

$$v_{PCA} = k^{ef}_{PCA} c_{CAl} p^{0.6}_{O_2}, \quad (2)$$

$$v_{\Sigma A} = k^{ef}_{\Sigma A} c_{CAl} p^{0.6}_{O_2}, \quad (3)$$

where v_{CAl}, v_{PCA}, and $v_{\Sigma A}$ are the rates of CAl consumption and PCA and PCA + CA accumulation, respectively; k^{ef}_{CAl}, k^{ef}_{PCA}, and $k^{ef}_{\Sigma A}$ are the effective rate constants of these reactions.

To analyze the temperature dependences of the reaction rates, we used only the initial rates, which are negligibly affected by the by-product accumulation. Using the initial reaction rates (Table 2) and Eqs. (1)–(3), we calculated the effective rate constants at different temperatures and, using the least-squares procedure, the Arrhenius dependences for the rates of CAl consumption and PCA + CA and CA accumulation:

$$k^{ef}_{CAl} = (1.43 \pm 0.14) \times 10^8 \exp(-60.9 \pm 1.2) \times 10^3/RT, \quad (4)$$

$$k^{ef}_{PCA} = (3.97 \pm 0.59) \times 10^5 \exp(-47.1 \pm 1.2) \times 10^3/RT, \quad (5)$$

$$k^{ef}_{\Sigma A} = (6.34 \pm 0.63) \times 10^7 \exp(-58.6 \pm 1.2) \times 10^3/RT. \quad (6)$$

* 120 min after the reaction start.

The validity of Eqs. (1)–(6) is confirmed by satisfactory agreement of the experimental rate constants determined at various temperatures and partial pressures of oxygen and calculated by Eqs. (1)–(3) with the theoretical values determined from the Arrhenius dependences (4)–(6) (Table 2). The activation energies of CAl oxidation and PCA + CA formation are close: 61.5 and 58.6 kJ mol^{-1}, respectively. The activation energy of PCA accumulation is significantly lower (47.1 kJ mol^{-1}), and with increasing temperature

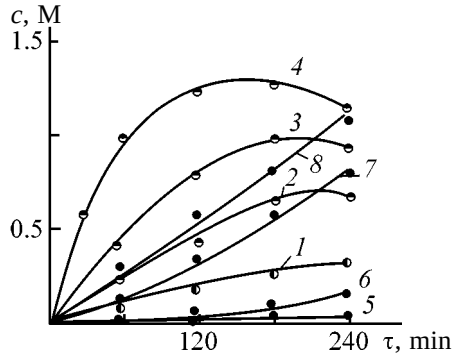

Fig. 4. Kinetics of formation of (*1–4*) PCA and (*5–8*) CA at different temperatures, p_{O_2} 4 atm, c^0_{CAl} 2.46 M. (*c*) Concentration of PCA or CA and (τ) time. Temperature, K: (*1, 5*) 285, (*2, 6*) 293, (*3, 7*) 300, and (*4, 8*) 309.

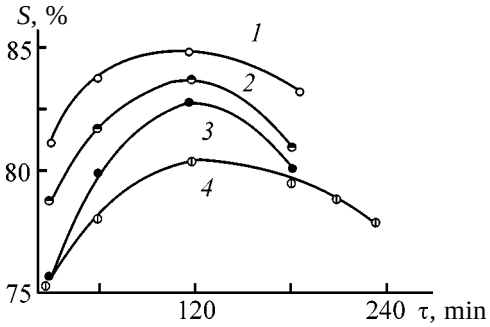

Fig. 5. Total selectivity of PCA + CA formation *S* as influenced by (*1–3*) pressure and (*1, 4*) temperature; c^0_{CAl} 2.46 M. (τ) Time. Temperature, K: (*1–3*) 309 and (*4*) 318. p_{O_2}, atm: (*1, 4*) 1, (*2*) 4, and (*3*) 16.

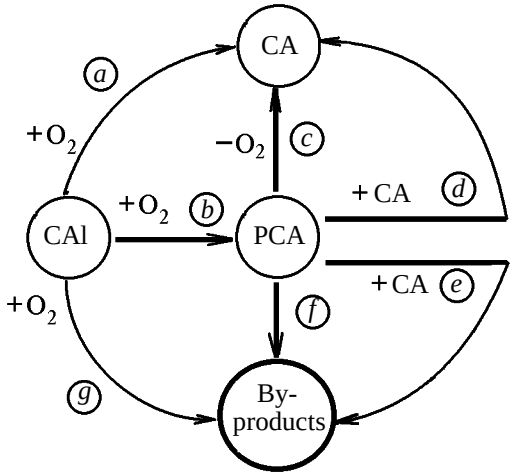
the selectivity of PCA formation decreases (Table 2).

According to published data [6, 7], oxidation of CAl can be presented by a series of successive and parallel radical and molecular reactions:



Reactions (1), (2), (6), and (7) are radical reactions and reactions (3)–(5), molecular. As seen from the above scheme, CA can be formed via PCA (reactions *c*, *d*) and directly from CAl (reaction *a*). The kinetic curves of accumulation of CAl oxidation products at different temperatures are similar (Fig. 4). With time, the rate of PCA accumulation decreases and that of CA accumulation grows. Successive formation of CA via PCA is obviously the main process in the kinetic scheme. At low temperatures (285, 293 K), the initial rate of CA formation is close to zero. This suggests that, at $c_{PCA} = 0$, CA is virtually absent in the reaction mixture, and the successive route is the only pathway of CA formation. As seen from Fig. 4, at higher temperatures (300, 309 K), the initial rate of CA formation becomes nonzero and significantly increases with temperature, suggesting that the contribution of the parallel reaction *a* becomes pronounced. This fact is confirmed by decreased selectivity of PCA + CA formation at increased temperature (Table 2).

Thus, PCA is the main intermediate in CA formation. Percrotonic acid is fairly stable, it accumulates in the reaction mixtures in concentrations comparable with the content of crotonic acid and transforms into CA with a high selectivity. Thus, it is advisable to estimate the selectivity of CA formation in the course of oxidation taking into account the total content of PCA and CA and the individual concentration of each acid. While the reaction mixture contains PCA, the selectivity of CA formation will change with time. In most of the published papers, this phenomenon was not taken into account.

Our experimental results show that the total selectivity of PCA + CA formation is independent of the oxygen pressure. As seen from Fig. 5, with increasing oxygen pressure from 1 to 16 atm the selectivity changes by only 2–3%. It should be noted that, in the initial period before accumulation of significant amounts of PCA, the selectivity of PCA + CA formation is lower than in the course of the further process. We believe that, in the initial period, less selective (compared to CA formation) radical reaction *a* is more pronounced, and only with time more selective reaction *d* of CA formation via PCA becomes predominant.

Data on the effect of CAl concentration on the selectivity of its oxidation to acids listed in Table 1 show that, as the initial concentration of CA in ethyl acetate is increased from 1.5 to 4.9 M, the selectivity of CA + PCA formation decreases by 6–8%.

Since the effective activation energy of PCA accumulation is lower as compared to PCA + CA formation, with increasing temperature reactions *e* and *f*

become important, and the selectivity of PCA + CA formation decreases by 8–10% in going from 285 to 309 K (Fig. 5).

The data on the CAl oxidation kinetics were used to optimize CA production. The main optimization factor was the product of CAl conversion X (%) and the selectivity of formation of the target products S (%), i.e., the total yield of crotonic and percrotonic acids B (%). We found that, to attain the maximal yield of the target product at a given temperature, it is advisable to increase the oxygen pressure to $p^{b}_{O_2}$, which allows the oxidation temperature to be decreased and thus the selectivity of formation and yields of PCA and CA to be increased.

CONCLUSION

In oxidation of crotonaldehyde in ethyl acetate, the highest total yield (80%) of crotonic and percrotonic acids is attained at initial crotonaldehyde concentration of 2.5–3.7 M, temperature of 300–309 K, and oxygen pressure of 3–7 atm.

These experimental results were used in the development of a process for production of crotonic acid.

Abstract—Temperature dependence of the detergency of one of the basic components of synthetic detergents, sodium alkylbenzenesulfonate, and compositions thereof was studied. The influence of the temperature on the detergency equation parameters was elucidated.

The experience of application of synthetic detergents (SDs) shows that the detergency of solutions is temperature-dependent [1, 2]. The temperature affects the solubility of the detergent components and contaminants. The kinetics of diffusion of surfactants to the contaminated surface and of emulsification of the washed off contaminants in a synthetic detergent solution are also temperature-dependent [3]. Rising temperature decreases the viscosity of liquid contaminants and promotes saponification of fat contaminants. In selected cases, however, increased temperatures can exert adverse affect, namely, decrease the surface activity of certain detergents, increase the degree of hydrolysis of soaps, and reduce the stability of emulsions [2]. The temperature dependence of individual properties (solubility, viscosity, surface tension, critical micelle concentration) of surfactants and other components of detergents are widely covered in reference literature and monographs. The quantitative temperature dependence of the detergency of substances is, however, studied inadequately.

Earlier [4, 5] we studied how the qualitative composition of synthetic detergent solutions and concentrations of individual components affect the detergency. For isothermal conditions, the detergency equation was derived:

$$M = \frac{M_{\max} c}{\alpha + c}, \qquad (1)$$

where M is detergency; $M_{\max}$, the maximal detergency; c, the detergent concentration; and α, the coefficient measured in the concentration units, which is a function of the energy parameters of the process. Equation (1) holds for both individual components of synthetic detergents and complex detergents.

The aim of this wirk is to establish the quantitative dependence of the parameters of Eq. (1), $M_{\max}$ and α, on the temperature T and to collect systematized experimental data for developing a physicochemical model of detergency. Also, such data are useful practically, in particular, for optimizing the conditions of using specific synthetic detergents.

We studied the basic component of synthetic detergents, namely, linear sodium alkylbenzenesulfonate C_{10-14}–(C_6H_4)–SO_3Na (SABS), a binary mixture of 30 wt % SABS and 70 wt % inorganic addition, sodium carbonate Na_2CO_3 (for preparing alkaline solution), as well as a complex composition MS-1 comprised of organic and inorganic components, close in composition to commercial synthetic detergents. The MS-1 composition contains, wt %: SABS 20, sodium tripolyphospahte $Na_5P_3O_{10}$ (STPP) 10, sodium hydrosilicate $2SiO_2 \cdot Na_2O \cdot 2H_2O$ 15, sodium sulfate 20, sodium carbonate 14, and sodium salt of carboxymethyl cellulose $[C_6H_7O_2(OH)_{3-x}^-(OCH_2COONa)_x]_n$ 1.

The detergency was studied with white cotton (coarse calico) fabric samples of two types: with dense (for the binary mixture) and loose (for SABS and MS-1) structure. We used solutions of detergents with the practically important concentrations in the range 0.5–10 g l^{-1}.

The detergency was estimated by the accepted [OST (Branch Standard) 6-15-1574–87] method by which we determined the whiteness of 5 × 5 cm fabric samples: initial, contaminated with a standard formulation, and cleansed.

We fixed the rotation rate of the framework stirrer with a fabric sample (200 rpm) and the time of contact

1070-4272/02/7507-1128$27.00 © 2002 MAIK "Nauka/Interperiodica"

with the synthetic detergent (20 min) [4, 5]. The studies were carried out at four temperatures of the detergent solution (30, 50, 70, and 85°C). The lowest temperature corresponds to conditions of careful (manual) washing with thermally unstable biological additions, enzymes. The regime in which the detergent temperature is 50°C is most often used in activator-type washing machines, that with 85°C, in automatic washing machines, and that with 70°C is intermediate.

The degree of whiteness of the fabric samples was estimated with a computer and a scanner, which allowed the error in determining the detergency to be significantly lowered (to 3%).[1]

The detergency, %, was determined by the formula

$$M = \frac{X_3 - X_2}{X_1 - X_2} \times 100, \qquad (2)$$

where X_1, X_2, and X_3 are the whitenesses of the initial (artificially aged), contaminated, and cleansed fabrics, respectively.

Figure 1 presents the plots of the detergency vs. concentration, $1/M$ vs. $1/c$, at various temperatures for all the three investigation objects. The M_{max} and α values obtained by processing these plots are presented in Table 1. It is seen that, for all the systems studied, M_{max} tends to increase with temperature, and α remains virtually unchanged, namely, 1.48 ± 0.02, 0.51 ± 0.04, and 1.78 ± 0.06 for SABS, binary mixture, and MS-1, respectively.

Thus, we found that α is temperature-independent. This can be explained as follows. In [5], we showed that $\alpha = M_{max} \tan\beta$, where β is the slope of the $1/M$ vs. $1/c$ plot. With rising temperature, M_{max} tends to increase, and α remains unchanged (Table 1). Therefore, the growth of M_{max} with temperature is compensated by a decrease in $\tan\beta$, i.e., decrease in the rate of detergency growth with increasing concentration (Fig. 1). The mutual compensation of these two factors may be due to thermodynamic factors. Of all the detergency factors studied [4, 5], the parameter α is affected only by the qualitative composition of the detergent formulation (chemical nature and structure of the detergent components), while M_{max} is affected by the mixture composition and temperature as well.

The detergencies estimated were compared with that of the standard solution M_{st} estimated under identical conditions for a fabric with dense and loose structures. The standard solution satisfied the above-mentioned OST and contained linear SABS (1 g l^{-1}) and sodium tripolyphosphate (2 g l^{-1}).

$\overline{M}$ values obtained in the experiment at different concentrations and temperatures are presented in Table 2.

Figure 2 presents the plots of the reciprocal $\overline{M}$ vs. reciprocal concentration at different temperatures for SABS, binary mixture, and MS-1 composition. It is seen that, in the temperature range studied, the plots for each of the objects are straight lines with the correlation coefficients of 0.99, 0.96, and 0.98 for SABS, binary mixture, and MS-1, respectively. The $\overline{M}_{max}$ and α values determined in the $1/\overline{M}$–$1/c$ coordinates from the section cut on the ordinate and the product of $\overline{M}_{max}$ and the slope of the correlation dependence [4], respectively, proved to be constant for a particular washing composition. Thus, $\overline{M}_{max}$ and α are independent of temperature and reflect only the relative detergency of a specific substance of composition. This, in turn, means that the equation of the relative detergency in the form

$$\overline{M} = \frac{\overline{M}_{max} c}{\alpha + c}, \qquad (3)$$

($\overline{M}_{max}$ is the maximal relative detergency) derived by us in [4] for a fixed temperature (80°C) is a general equation for a wide temperature range. Equation (1) is, essentially, the detergency isotherm.

The influence of the temperature on the washing efficiency is illustrated by Fig. 3 showing the temperature dependence of the maximal detergency at a given temperature as referenced to the maximal detergency at a fixed temperature (30°C), M^T_{max}/M^{30}_{max}, for five objects: SABS, SABS + Na_2CO_3, MS-1, and standard solution (1 g l^{-1} SABS + 2 g l^{-1} STPP) for dense and loose cotton fabrics. Mathematical processing of the results presented in Fig. 3 showed that all the

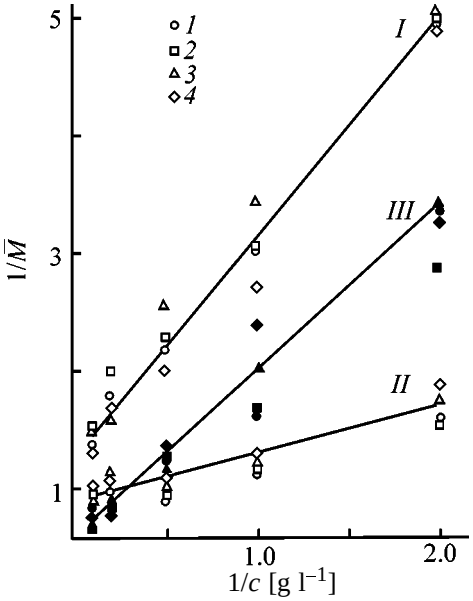

Fig. 2. Relative detergency $\overline{M}$ as a function of the detergent concentration c: (*I*) SABS, (*II*) binary mixture, and (*III*) MS-1 composition.

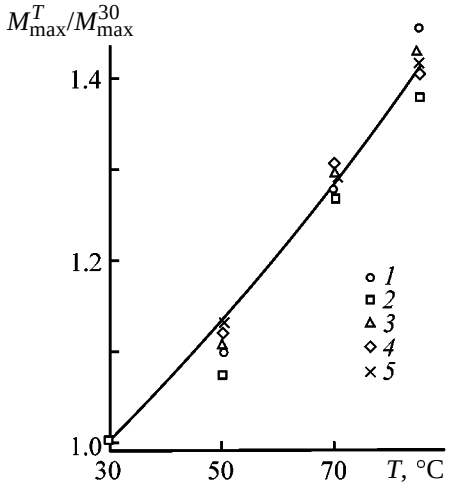

Fig. 3. Maximal detergency M^T_{max} as referenced to the maximal detergency at 30°C M^{30}_{max} as a function of temperature T for (*1*) SABS and (*2–5*) compositions thereof. (*2*) SABS + Na_2CO_3, (*3*) MS-1, and (*4, 5*) standard solution with dense and loose cotton fabrics, respectively.

M^T_{max}/M^{30}_{max} values correspond to the exponential correlation dependence with a correlation coefficient of 0.99:

$$M^T_{max}/M^{30}_{max} = 0.83e^{0.006T}, \quad (4)$$

where T is temperature.

Such an exponential form of equation is characteristic of the temperature dependence of the parameters of various processes: chemical potential, reaction rate constant, solubility, viscosity, etc. Rewriting Eq.(4) in the form

$$M^T_{max} = 0.83M^{30}_{max}e^{0.006T},$$

and analyzing the equation at the boundary conditions $T \to 0$°C and $T \to 100$°C, we obtain for the SABS-based systems studied the maximal detergency varying from $M^0_{max} = 0.83M^{30}_{max}$ to $M^{100}_{max} = 1.52M^{30}_{max}$.

Our results suggest the existence of a common temperature dependence of M_{max} for the basic component of detergents, SABS, and compositions thereof, which is unaffected by the structure of the contaminated fabric. This makes it possible, using formula (5) obtained by substituting the modified equation (4) into Eq. (1), to predict the detergency of such formulations as dependent on both the concentration [4, 5] and temperature of solutions:

$$M^T = \frac{0.83M^{30}_{max}e^{0.006T}c}{\alpha + c}, \quad (5)$$

CONCLUSIONS

(1) The temperature dependence of the detergency was studied for linear sodium alkylbenzenesulfonate and compositions thereof in practically important temperature 30–85°C and concentration 0.5–10 g l^{-1} ranges. For a particular substance or composition, the parameter α in the detergency equation is temperature-independent.

(2) Linear sodium alkylbenzenesulfonate and compositions thereof exhibit a common exponential dependence of the maximal detergency on the temperature. This dependence is unaffected by the structure of the contaminated fabric.

(3) Based on analysis of the experimental data, an equation was proposed for predicting the detergency as dependent on the concentration of the composition and the temperature of the solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Molecular Structure of H Complexes of Dialkyl Dihydrogen Benzophenonetetracarboxylates with Aromatic Diamines on the Viscosity of Their Melts

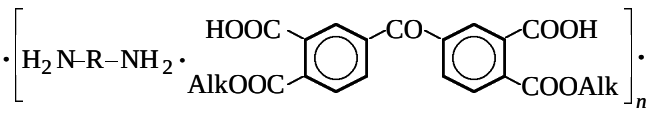
Abstract—The possibility of preparing from dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates and 4,4'-diaminodiphenylmethane or 4,4'-diaminodiphenyl ether H complexes of both amorphous and crystalline structures was elucidated. Methods were proposed for disordering the supramolecular structure of the H complexes, which is technologically essential for reducing the melt viscosity when preparing polyimide carbon-filled plastics and foamed composites.

When aromatic diamines are dissolved in solution of dialkyl dihydrogen tetracarboxylates in alcohol (methanol or ethanol) or in a water–alcohol mixture, complexes with hydrogen bond (H complexes) are formed spontaneously between the amino group of diamine and the ester and carboxy groups of dialkyl dihydrogen carboxylate [1, 2]. Despite high polarity of the solvents used, hydrogen bonds are formed even in solutions with a low concentration of the initial components (0.01% solutions) [1]. In 7–8% solutions, H complexes occur as di- and trimers (n = 2, 3) [3]:



At higher solution concentrations, the n-size of the H complexes increases (n > 5, 6), and the solution gets anisotropic owing to formation of fluctuation domains [3], i.e., an ordered supramolecular packing of such supramolecular structures as H complexes. Even insignificant changes in the concentrations of such solutions cause fluctuations of the orientation ordering factor characterizing the ordering of the H complexes inside the fluctuation domains [4].

Under virtually identical conditions, it is possible to obtain H complexes with different supramolecular structures because of fluctuations of ambient temperature and humidity, solvent purity, etc.

The above-mentioned supramolecular structures can yield polyimide materials such as EPPI foamed polyimides [5], carbon-filled plastics [6], and foamed composites [7] promising for modern aviation and space technology, as well as for ship-building applications. Since all the above-listed materials can be prepared from molten H complexes with low viscosity only, of special importance are data on how the melt viscosity is influenced by the structure of the initial H complexes.

In this work, we proved experimentally that H complexes with amorphous and crystalline supramolecular structures can be obtained by slightly modifying the conditions of their preparation. Also, we studied how the melt viscosity is influenced by the crystallization of H complexes and suggested a method for directed modification of the supramolecular structure of H complexes.

EXPERIMENTAL

Dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates (BZPMe and BZPEt, respectively) were prepared by refluxing 0.03 mol of 3,3',4,4'-benzophenonetetracarboxylic dianhydride [TU (Technical Specifications) TSR 2159–69; purified by refluxing in acetone; mp 225°C] in 50 ml of the appropriate alcohol or alcohol with addition of 6 vol % water. The H complexes were prepared by dissolving at room temperature equimolar (with respect to BZPMe or BZPEt) amounts of 4,4'-diaminodiphenylmethane (DADPM) or 4,4'-diaminodiphenyl ether (DADPE) (purified by distillation at 1–3 mm Hg; mp 90–92

1070-4272/02/7507-1132$27.00 © 2002 MAIK "Nauka/Interperiodica"

and 190°C, respectively) in solutions of BZPMe or BZPEt in the appropriate alcohol. Solid H complexes were recovered by alcohol evaporation at 1–3 mm Hg and 20–30°C.

X-ray studies of the samples of H complexes were carried out on a DRON-2 diffractometer (nickel-filtered copper radiation). The viscosity of molten H complexes was measured on a PIRSP rheometer (cone–plane working unit; angle at the cone vertex 1°, cone diameter 40 mm) at 95 and 105°C at a shear rate of 0.02 s^{-1} [8].

In most cases, mixing dialkyl dihydrogen benzenetetracarboxylates with aromatic diamines yields H complexes with amorphous structure. Preparation of crystalline H complexes, though practically unpredictable, is rather common. Essential for preparing ordered structures are, typically, seasonal fluctuations of ambient temperature and humidity, uncontrollable changes in the solvent quality, or minor fluctuations of the stoichiometry or concentration of the initial components. Virtually any H complex of any chemical composition can be prepared with amorphous or differently ordered structures.

Figure 1 presents as an example the X-ray diffraction patterns of selected H complexes of various chemical compositions formed in alcohols or aqueous alcohols. It is seen that H complexes with identical compositions BZPEt–DADPE prepared in ethanolic solution (Fig. 1, curves *1*, *1*') can have both amorphous (curve *1*) and low-crystalline structures (curve *1*'). In the case of BZPMe–DADPE H complexes prepared in aqueous methanol, it is possible to obtain supramolecular structures with various degrees of crystallinity (curves *2*, *2*'). With DADPM as amino component, the degree of ordering of the H complexes is also diverse (curves *3*, *3*').

In this connection, it was of interest to elucidate how the crystalline structure of the H complexes affects their viscosity, which governs the preparation of polyimide materials.

Figure 2 shows how the viscosity of molten H complexes with different structures varies with time. Curves *1* and *1*' characterize the variation with time of the viscosity of molten BZPEt–DADPE H complexes, isolated from ethanolic solution, with amorphous (Fig. 1, curve *1*) and low-crystalline (Fig. 1, curve *1*') structures. It is seen that the viscosity of the more highly ordered H complex in the melt is two orders of magnitude higher than that of the amorphous H complex. Curve *2* refers to the BZPMe–DADPE H complex with low-crystalline structure (Fig. 1, curve *2*)

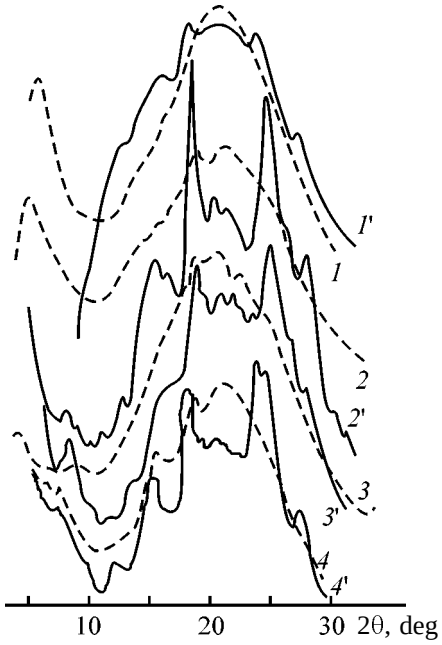


Fig. 1. X-ray diffraction patterns of H complexes (*1*, *1*') BZPEt–DADPE prepared in ethanol, (*2*, *2*') BZPMe–DADPE prepared in aqueous methanol, (*3*, *3*') BZPMe–DADPM prepared in methanol, and (*4*, *4*') BZPEt–DADPM prepared in aqueous ethanol with and without benzimidazole addition, respectively. (2θ) Bragg's angle; the same for Figs. 3 and 4.

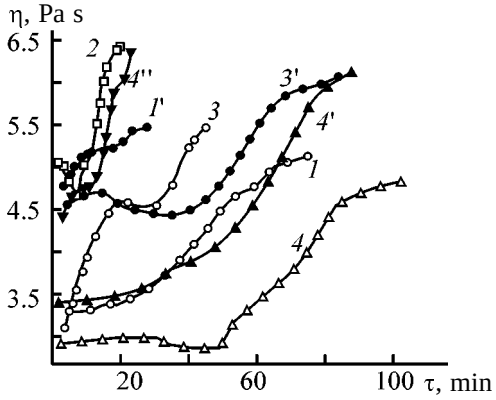

Fig. 2. Variation of the viscosity η with time τ of molten H complexes (*1*, *1*') BZPEt–DADPE prepared in ethanol, (*2*) BZPMe–DADPE prepared in aqueous methanol, (*3*, *3*') BZPEt–DADPM prepared in aqueous ethanol with and without benzimidazole addition, respectively, and (*4*, *4*', *4*'') BZPMe–DADPE prepared in methanol. Temperature, °C: (*1*, *1*', *2*, *3*, *3*', *4*'') 105 and (*4*, *4*') 95.

isolated from aqueous methanol. The BZPMe–DADPE H complex with a high degree of crystallinity (Fig. 1, curve *2*') does not melt at all at 105°C. Thus, the more highly ordered the supramolecular structure of the initial H complex, the higher the melting point

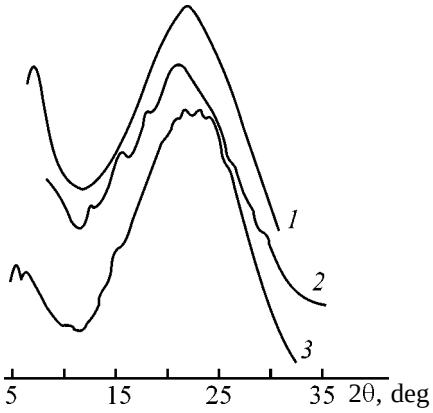

Fig. 3. X-ray diffraction patterns of BZPMe–DADPE H complexes prepared in methanol. Sample nos.: (*1*) 1, (*2*) 2, and (*3*) 3.

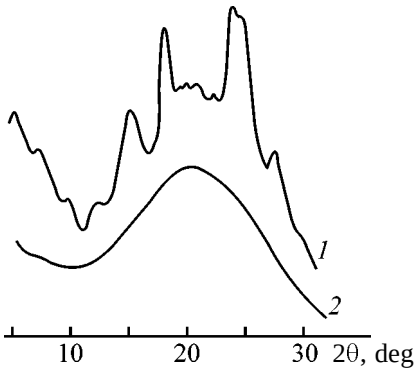

Fig. 4. X-ray diffraction patterns of the BZPEt–DADPM H complex prepared in aqueous ethanol: (*1*) initial and (*2*) after melting at 105°C.

of the H complex and the higher the viscosity of its melt.

As known, in preparing foamed polyamides EPPIs, samples of H complexes are foamed at temperatures above 180°C [5]. Therefore, high viscosities of molten crystalline H complexes at 100±5°C are of no importance for foam formation. However, prepregs for carbon-filled plastics and foamed composites are obtained at temperatures close to 100°C [6, 7]. This makes undesirable the use of crystalline H complexes for these purposes.

In this connection, we suggest a method for disordering the supramolecular structure of H complexes. It was found that adding minor amounts of benzimidazole (3 wt % with respect to dialkyl dihydrogen carboxylate) to the initial reaction mixture yields H complexes with less highly ordered structure, all other conditions being the same. For example, the degree of ordering of the crystalline BZPEt–DADPM H complex prepared from aqueous ethanol (Fig. 1, curve *4*') significantly decreases on adding benzimidazole (Fig. 1, curve *4*). The viscosity of the molten complex decreases, as expected, by two orders of magnitude relative to the crystalline sample (Fig. 2, curves *3*, *3*').

In the case of BZPMe–DADPE H complex isolated from methanolic solution, we succeeded in preparing samples with significantly differing viscosities of melts. Curves *4* and *4*' (Fig. 2) show how the viscosities of melts of these H complexes, as measured at 95°C (sample nos. 1 and 2), vary with time. Curve *4*" refers to sample no. 3 of this H complex at 105°C. At 95°C sample no. 3 does not melt.

The X-ray diffraction patterns of these samples (Fig. 3) show that none of them has highly ordered crystalline structure. Unlike amorphous sample no. 1, however, the X-ray diffraction pattern of sample no. 2 in the region of 2θ = 10°–20° exhibits clear reflections which evidence formation a more ordered structure in it. Sample no. 3 exhibits in the 2θ ~ 18°–27° region low-intensity reflections against the background of an amorphous halo. This suggests formation of ordered domains, similar to crystalline domains in the BZPMe–DADPE sample prepared from aqueous methanol (Fig. 1, curve *2*').

The diffraction patterns (Fig. 3, curves *2* and *3*) suggest that the samples can contain various ordered domains responsible for formation at a later time of both low-crystalline (Fig. 1, curve *1*') and highly ordered crystalline (Fig. 1, curves *2*'–*4*') structures.

Figure 4 presents the X-ray diffraction patterns of the BZPEt–DADPM H complex isolated from aqueous ethanolic solution (curve *1*) and of the sample obtained on melting this H complex at 105°C (curve *2*). It is seen that the initial sample has a crystalline structure. On melting and subsequent cooling, the sample gets amorphous. Similar structural changes were also observed for crystalline H complexes of other compositions.

CONCLUSIONS

(1) The H complexes prepared from dialkyl dihydrogen 3,3',4,4'-benzophenonetetracarboxylates and 4,4'-diaminodiphenylmethane or 4,4'-diaminodiphenyl ether can have both amorphous and crystalline structures. With growing degree of ordering of the H complex, the initial viscosity of its melt tends to increase. The viscosity of molten crystalline H complex exceeds by two orders of magnitude that of amorphous or low-crystalline H complexes with identical chemical compositions.

(2) To obtain low-viscosity melts required for successfully preparing prepregs, it is recommended that minor amounts of benzimidazole, which exerts a disordering effect on the supramolecular structure of the forming H complex, be added to the initial reactant mixture.

Received March 4, 2002

Abstract—Rheological properties of concentrated aqueous solutions of lemon pectin, polyvinylpyrrolidone, polyvinyl alcohol, and 1 : 1 blends of lemon pictin with these polymers were studied at 25–70°C.

Among polymeric materials with complex composition, growing attention is given to blends of polymers whose specific mechanical and structural features make them suitable for obtaining materials with new properties. Understanding of the mechanism of structure formation in concentrated solutions based on mixtures of linear polymers of different nature, as well as of the factors responsible for the specific complex of properties exhibited by these systems, requires a detailed study of their rheological behavior [1, 2].

Rheological characteristics in certain cases prove to be the most sensitive to changes in the structural parameters of polymers. Molding of almost a half of all polymeric articles proceeds via dissolution. In this case, the relationships in molding are governed by the rheological behavior of concentrated polymer solutions, and the properties of articles originate from the solution proper [3, 4].

In this work, we studied the rheological properties exhibited by concentrated aqueous solutions of blends of linear polymers of different nature: rigid-chain (Kuhn segment 300 Å) polysaccharide lemon pectin (PC) and flexible-chain polymers, polyvinyl alcohol (PVA) and polyvinylpyrrolidone (PVP). These polymers are used in food industry [5] and agriculture. Our studies furnish information about the structure of concentrated solutions of polymers themselves and their blends, as well as about the structural changes in flow.

EXPERIMENTAL

We studied (1) citrus PC prepared from peel and seeds of lemons of the Yalongoch sort, obtained by local selection following the procedure in [6], with molecular weight (MW) of 8.9×10^4 (seeds) and 1.5×10^5 (peel); (2) PVA with MW of 2.2×10^4 containing 1.2 wt % acetate groups and 0.5 wt % sodium acetate (commercial sample); and (3) PVP with MW 10^4 (commercial sample). We studied the rheological properties of concentrated (5%) solutions of polymers and their blends on a Rheotest-2 rotation visometer with a working unit comprised of coaxial cylinders at stresses within 2–380 Pa and shear rates of $(1.5–1.3) \times 10^3$ s^{-1} at 25, 40, 55, and 70°C.

Using the data obtained, we calculated the thermodynamic parameters of the system, namely, enthalpy ΔH_v, entropy ΔS_v, and Gibbs energy ΔG_v of activation of viscous flow [7].

The macromolecules of the PC base, α-*D*-galacturonic acid, are nonuniform in the composition and molecular weight and differ in the degree of esterification of carboxy groups and in the distribution pattern of the methyl groups [8, 9].

The PC macromolecules (α-*D*-galacturonic acid with *D*-rhamnose inclusions) can contain minor amounts of *D*-galactose, *L*-arabinose, and other monosaccharides [10]. Pectin dissolves in water and under certain conditions forms dense gels, which indicates that its macromolecules strongly tend to associate.

The structure of the macromolecules governs the structure of concentrated PC solutions. Aqueous 5% solutions of PC are characterized by higher degrees of structure formation and aggregation of macromolecules than equiconcentrated aqueous solutions of PVA and PVP. When the regular structure of high-molecular-weight associates in concentrated solutions of polymers of different nature is disturbed by mixing,

1070-4272/02/7507-1136$27.00 © 2002 MAIK "Nauka/Interperiodica"

this modifies the structure of solutions, which affects, above all, their viscosity.

The viscosity of solutions of the polymers and their 1 : 1 blends was determined as a function of the shear stress (flow curves) (Figs. 1a, 1b).

The shape of the curves suggests a pseudoplastic non-Newtonian flow. The abnormal viscosity of concentrated polymer solutions is mainly caused by the progressive degradation of the structure with growing shear stress. In concentrated polymer solutions, with their complex system of interacting macromolecules, small shear stresses do not cause deviation from Newtonian flow. This means that the structure of solutions does not change significantly or that flow affects only the bond elements characterized by very short relaxation (restoration) times. At higher shear stresses, the structure of the solutions degrades more profoundly, which disturbs the interchain contacts with relatively long restoration times. This makes the viscosity dependent on τ.

The highest viscosity is exhibited by those aqueous PC solutions whose viscosity anomaly in the flow curves is more pronounced than in the case of solutions of PC–PVA and PC–PVP blends. PVA and PVP solutions themselves exhibit weakly pronounced anomalies of the flow viscosity. Incorporation of these flexible-chain polymers into more structurized systems of aqueous PC solutions reduces the viscosity, but at the PC content in mixtures of 50% the rheological behavior of the systems is the most similar to that of PC solutions.

In the case of associated structures, the kinetic units migrating in flow are chain aggregates, whose size depends on the nature of the solvent, concentration, and temperature, rather than the chains or chain segments [11]. The character of packing of macromolecules into associates and their contacts with each other are determined by the chemical structure of the chains, the ratio between the amounts of different macromolecules in these associates, and the nature of the polymer matrix [12, 13]. With polymer blends, the onset of intensive degradation of the solution structure at different temperatures, as estimated from the flow curves obtained, shifts to lower shear stresses. The reason is that the uniformity of the network of intermolecular contacts is disturbed and decreased by a flexible-chain polymer incorporated into PC associates. It should be noted that PVA macromolecules have a stronger structure-making power than PVP macromolecules, which is explained by a higher molecular weight of the former. The temperature dependence of the viscosity of the studied solutions in the 25–70°C range is described by the Arrhenius–Frenkel relation $\eta = Ae^{\Delta E/RT}$ [3, 4], where ΔE is the viscous flow activation energy.

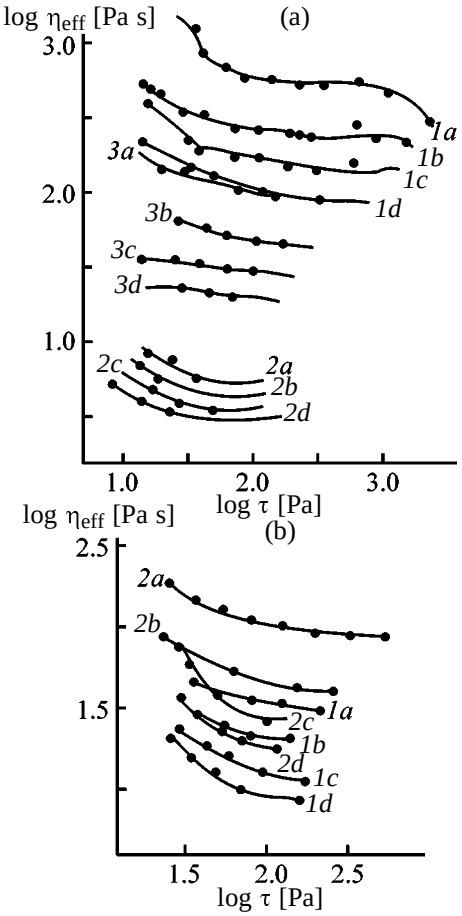

Fig. 1. Flow curves for concentrated (5%) solutions of (*1*) PC, (*2*) vinyl polymer, and (*3*) their blends. (η_{eff}) Viscosity and (τ) stress. Temperature, °C: (*a*) 25, (*b*) 40, (*c*) 55, and (*d*) 70. Polymer: (a) PVP and (b) PVA.

The effective activation energy of viscous flow ΔE is a measure of intensity of intermolecular interaction of macromolecules in solutions (Table 1).

Concentrated aqueous PC solutions are characterized by the highest ΔE values and, hence, the highest stability of the solution structure. When a PC solution is mixed with solutions of flexible-chain polymers, ΔE changes insignificantly. The activation heat of viscous flow is determined by the strength of intermolecular interaction and stability of structural formations in solutions [11, 14]. Thus, formation of more stable structural domains in solution should affect the activation energy more profoundly than formation of a fluctuation network. Presumably, such relationships for ΔE in the case of solutions of PC blends with flexible-chain polymers are explained

Table 1. Effective activation energy of viscous flow ΔE

by formation of relatively stable structures of intermolecular PC associates with PVA and PVP macromolecules and their associates.

Basing on the rheological data obtained, we estimated the "viscous volumes" V^*, or statistical mean sizes of the kinetic units [15]. The parameter V^* is a qualitative characteristic suitable for estimating the mobility of the structural elements and their sizes for concentrated solutions of PC, PVA, and PVP and their blends (Table 2).

With rising temperature, V^* tends to increase for solutions of PC, PVA, and PVP and their blends, which is explained by unfolding of the macromolecules and facilitation of intermolecular interactions yielding associates. With increasing shear stresses the structural associates gradually degrade for all the systems studied (Table 2).

In the series studied, the smallest V^* is exhibited by PVP solutions, suggesting higher mobility of the structural associates in them. The PVA solution is characterized by a lower mobility of the structural formations owing to higher molecular weights. The structural elements formed in PC solutions are the least mobile and the largest in size.

Interesting V^* data were obtained in going to polymer blends. The V^* parameters (Table 2) for blend solutions exceed those for solutions of PC and flexible-chain polymers, taken separately. Presumably, solutions of PC–PVA and PC–PVP blends undergo rearrangement of the macromolecular associates of PC with flexible-chain polymers and formation of structural elements larger than those in PC solutions and significantly larger than those in PVP solutions. This may be due to the fact that, in the case of blends, the macromolecules (or macromolecular associates) of PC and PVP, as well as those of PC and PVA, form stronger bonds than in the PC : PC, PVP : PVP, and PVA : PVA associates. This yields formations comprised of macromolecular associates of PC surrounded (as if they were enveloped) by macromolecules and macromolecular formations of PVA and PVP. In the case of the PC–PVP blend, this effect is due to hydrogen bonding between the carbonyl (proton-accepting) groups of vinylpyrrolidone and the carboxy (proton-donating) groups of *D*-galacturonic acid >C=O···HOOC–. In the case of PC–PVA blend, hydrogen-bonded are hydroxy groups of *D*-galacturonic acid and PVA (>HC–OH···OH–CH<) or carboxy groups of *D*-galacturonic acid and hydroxy groups of PVA (>HC–OH···HOOC). The occurrence of proton-donating and proton-accepting groups in these polymers governs the nature of the intermolecular bonds responsible for formation of associates between mac-

romolecules of polymers of different nature. Our results suggest that the specific features of the structure of concentrated solutions of polymers significantly differing in the nature (MW, chain flexibility, structure of the monomer unit, etc.) in a strongly polar solvent such as water will affect the patterns of variation of the thermodynamic functions of systems with varying shear stress and temperature.

We calculated the Gibbs energy ΔG_v, characterizing the stability of the structures, and the activation entropy of viscous flow ΔS_v, characterizing the degree of ordering of the structures [7].

The parameters ΔS_v and ΔH_v are temperature-dependent. The temperature coefficient of these parameters is the greater, the more highly associated are the systems and the greater is the energy of intermolecular interaction. In this case, the work required for making a "hole" in the liquid is supplemented by the work required for breaking strong intermolecular bonds. With rising temperature, these bonds are degraded by the thermal motion, which causes ΔH_v to decrease [12, 13].

Figures 2a and 2b show that, for systems with pronounced structure formation, the parameters ΔH_v at ordinary temperatures are very high. The reason is the energy spent for degrading the structure of the solution; $\Delta S_v < 0$ suggests a higher degree of ordering in the state characterized by dominating orientation processes owing to unfolding of the macromolecules in a flow. Fairly high ΔH_v and ΔS_v parameters at elevated temperatures suggest fairly stable and ordered structural formations occurring in the initial system in the case of non-Newtonian flow.

High shear stresses radically change the initial structure of the material (Fig. 4). Each stress value corresponds to a particular initial structure of the material. If, after applying an external mechanical field, the initial structure of a concentrated solution gets more highly ordered and more stable, the activation entropy ΔS_v and activation heat ΔH_v should exceed those for small shear stresses. This is the case for aqueous PVA solutions (Fig. 2b). On the contrary, if the structure of the system degrades under shear stress, ΔS_v and ΔH_v tend to decrease. Therefore, decreases in the activation heat and activation entropy with increasing shear stress (Fig. 2b) for solutions of PC, PVA, and PC–PVP and PC–PVA blends suggest that structure degradation processes dominate in flow. For the processes in flow, be they ordering or disordering, the shear stress causes the activation free energy to decrease (Fig. 2b), thereby decreasing the system viscosity.

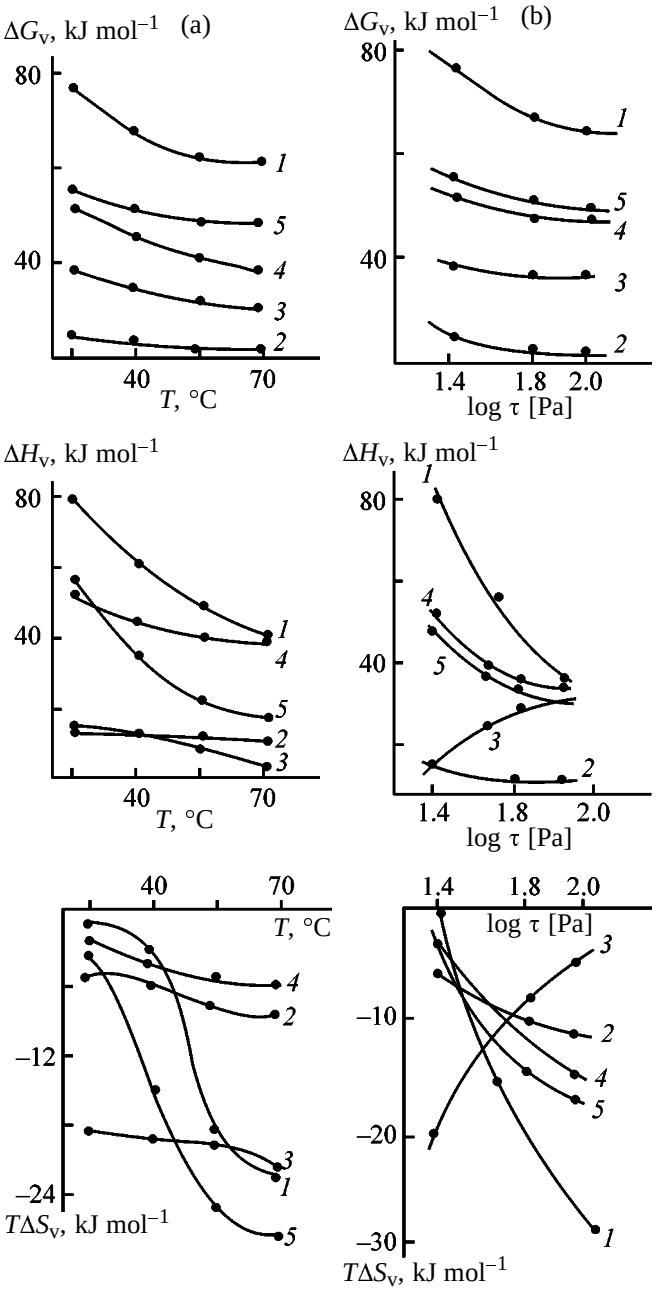

Fig. 2. Gibbs energy ΔG_v, activation heat of viscous flow ΔH_v, and activation entropy of viscous flow $T\Delta S_v$ as functions of (a) temperature T and (b) shear stress τ at 25°C, for solutions of (*1*) PC, (*2*) PVP, (*3*) PVA, (*4*) PC–PVP blends, and (*5*) PC–PVA blends.

Thus, our study of the thermodynamic parameters shows that, for blends of PC with flexible-chain polymers, structure degradation processes dominate in a flow.

Our results can be of importance for developing biodegradable polymeric systems promising for food and other industrial applications. In agriculture, such systems can be used for encapsulating seeds of diverse agricultural crops.

CONCLUSION

Study of the rheological behavior of concentrated solutions and thermodynamic analysis of the properties of PC, PVA, PVP, and their blends shows that these systems are pseudoplastic liquids for which the anomaly of viscous flow is determined by the structure of the associates formed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Partially Degraded Copolymers of Acrylamide with (Acrylamidopropyl)trimethylammonium Chloride in the Presence of Radical Initiators

Abstract—Chain degradation of copolymers of acrylamide with (acrylamidopropyl)trimethylammonium chloride at 25–50°C in aqueous solutions under the action of radical degradative agents was studied viscometrically. The effiency of controlling the molecular weight of the copolymers was evaluated.

Water-soluble cationic acrylamide (AA) copolymers Praestols (Moscow–Stockhausen–Perm Russian–German Private Company) are successfully used for treating natural and waste waters and for concenrtating and dehydrating sludges. These copolymers have high molecular weight (MW); they are produced as powders and have certain commercial advantages over the analogs produced in other countries. However, in some cases, the MWs of commercial cationic Praestol samples are not optimal for particular applications. This primarily concerns low-molecular-weight cationic copolymers, which can be used as organic coagulants in water treatment with the aim to partially or fully replace mineral coagulants. A promising way to decrease the MW of water-soluble polymers is degradation [1]. Previously we studied some features of degradation of polyacrylamide [2, 3] and its anionic derivatives in aqueous solutions [4, 5] in the presence of various additives [6]. In this work, we studied degradation of high-molecular-weight cationic AA copolymers (Praestols) in aqueous solution under the action of radical degradative agents, with the aim to examine the possibility of preparing low-molecular-weight copolymers with controllable MW.

EXPERIMENTAL

We used commercial samples of cationic Praestols, which are copolymers of AA with (acrylamidopropyl)-trimethylammonium chloride (APTMAC). The sample characteristics are given in the table. The content of APTMAC units in the copolymers was determined mercurimetrically from the concentration of chloride ions [7]. The MW of the copolymers was estimated from their intrinsic viscosity [η] in 0.5 M NaCl at 25°C, using the Mark–Kuhn–Houwink equation.

The radical degradation initiators were potassium persulfate (PP), hydrogen peroxide (HP), and the redox system PP–sodium bisulfite (SB); all chemicals were of chemically pure grade. All the solutions were prepared in double-distilled water.

Degradation experiments were performed in a glass reactor ewuipped with a temperature-control jacket, a magnetic stirrer, a thermometer, a sampling nipple, and a VPZh-3 capillary viscometer (d = 0.56 mm) with which the viscosity of the aqueous solution of the copolymer was monitored in the course of degradation [8]. The viscometer was temperature-controlled with water from a thermostat, flowing through the jacket.

The reactor was charged with an aqueous solution

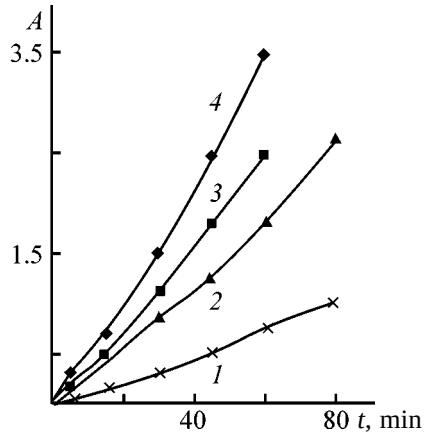

Fig. 2. Number of scissions A per macromolecule as a function of the time t of degradation of cationic Praestol 655 at various PP concentrations. [PP] (% in water): (*1*) 0.01, (*2*) 0.02, (*3*) 0.04, and (*4*) 0.06.

of the copolymer, the required temperature was adjusted, and a radical initiator was added; this moment was considered as the start of degradation. In the course of degradation, the reaction mixture was sampled at regular intervals with a syringe to determine [η]. To do this, NaCl was added to the sample in an amount required to obtain 0.5 M NaCl solution, which was followed by isoionic dilution with 0.5 M NaCl. The viscosity was measured with a VPZh-3 viscometer (d = 0.56 mm) at 25°C. The correction for the kinetic energy did not exceed 2%, and in determinations of the reduced viscosity η_{sp}/c_p it was neglected. The experimental linear dependence $\eta_{sp}/c_p = f(c_p)$ was extrapolated to $c_p = 0$ to determine [η].

Initially, we examined the possibility of degradation of AA–APTMAC copolymer (Praestol 655) under the action of radical degradative agents. Degradation was performed in 0.1% aqueous solutions of the copolymers in the presence of water-soluble initiators PP and HP at 50°C. The results are shown in Fig. 1. It is seen that [η] does not change in time in the absence of an initiator, i.e., the copolymer undergoes no noticeable degradation (Fig. 1a, curve *1*). In the presence of PP (Fig. 1a) and HP (Fig. 1b), [η] decreases with time; this decrease, indicating the occurrence of degradation, is the more pronounced, the higher the initiator concentration.

From data in Fig. 1a, we determined the number of scissions per macromolecule A:

$$A = ([\eta]_0 - [\eta]_t)^{1/\alpha},$$

where $\alpha \approx 1$ for the copolymers in hand, and $[\eta]_0$ and $[\eta]_t$ are the initial (time t = 0) and running intrinsic viscosities, respectively.

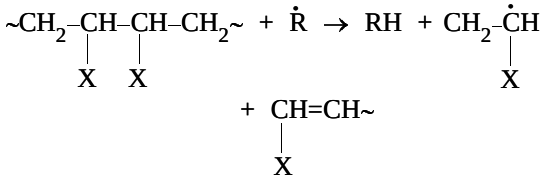
The calculated values of A of Praestol 655 are plotted in Fig. 2 vs. degradation time. It is seen that A grows with time; this trend is more pronounced at higher concentrations of a degradative agent (cf. curves *1–4*). The highest value of A attained in 1 h does not exceed 3.5, which excludes formation of low-molecular-weight products under the experimental conditions.

Degradation of AA–APTMAC copolymers is effected by radicals $R^{\bullet}$ generated by decomposition of initiators; the process occurs randomly without depolymerization. Radicals $R^{\bullet}$ abstract a hydrogen atom from the backbone at the initiation centers; at low concentrations of the copolymer in solution, this was followed by scission of abnormally (head-to-head) linked units which had formed by recombination of propagating macroradicals under the copolymerization

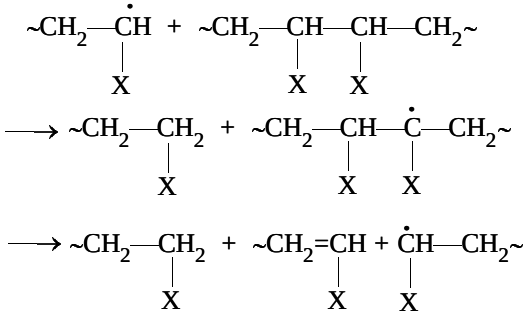
conditions. The presence of these structural anomalies in polyacrylamide macromolecules is confirmed in [11]; similar anomalies can apparently be present in macromolecules of AA–APTMAC copolymer. Therefore, the scission of C–C bonds in the backbones of the copolymer macromolecules between the AA and APTMAC units is not excluded.

The degradation of AA–APTMAC copolymer effected by free radicals $R^{\bullet}$ can be described by the following scheme:

Initiation:

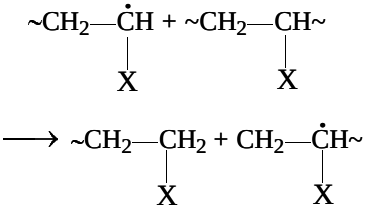


Chain propagation:

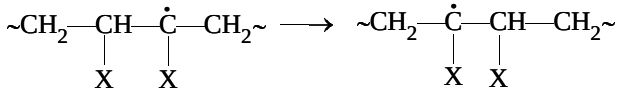


Chain transfer:

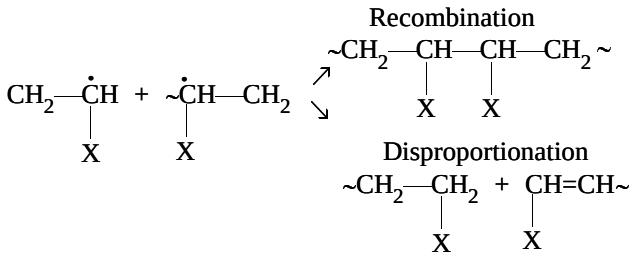
Intermolecular



Intramolecular



Chain termination:



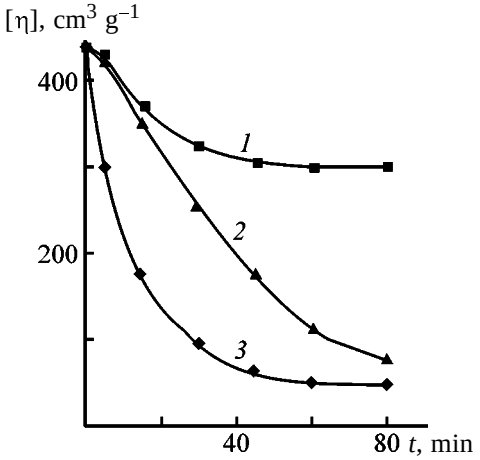


Fig. 3. Plot of [η] of cationic Praestol 655 vs. degradation time t in the presence of various degradative agents. c_p = 0.1%. Degradative agent: (*1*) HP, (*2*) PP + SB, 2 : 1 (by weight), and (*3*) PP. T, °C: (*1*, *3*) 50 and (*2*) 25.

X = $CONH_2$ or $-(CH_2)_3\overset{+}{N}(CH_3)_3Cl^-$.

This scheme is simplified and suggests that various radicals can be involved in initiation of the copolymer degradation (e.g., sulfate radical ions $SO_4^{\bullet-}$ or $HO^{\bullet}$ radicals formed by decomposition of PP in water); it does not exclude participation of these low-molecular-weight radicals in chain termination reactions.

Figure 3 shows how [η] of AA–APTMAC copolymer (Praestol 655) varies with time in the course of degradation effected by various agents: PP, HP, and PP–SB redox system. It is seen that, at 50°C, the initial rate and extent of degradation grow in going from PP to HP (curves *1*, *3*). Figure 5 also demonstrates that the PP–SB redox system ensures efficient degradation of Praestol 655 even at 25°C (curve *2*) when the components taken separately cause no degradation.

We also studied how the degradation of AA–APTMAC copolymer (Praestol 655) is influenced by the copolymer concentration, which was varied in the range 0.1–0.5% (in water). Experiments were performed in the presence of PP at 50°C (Fig. 4). Under these conditions, as seen from Fig. 4, the [η] values noticeably decrease in the course of degradation. Figure 4 also shows that the degradation becomes less intense at increased polymer concentrations. This may be due to increased viscosity of the reaction medium and hence to slower diffusion of the degradative agent and macromolecules in the reaction medium.

We also examined the influence of the MW of AA–APTMAC copolymer on the degradation efficiency. Experiments were performed with samples of Praestols 644 and 655, having similar chemical composi-

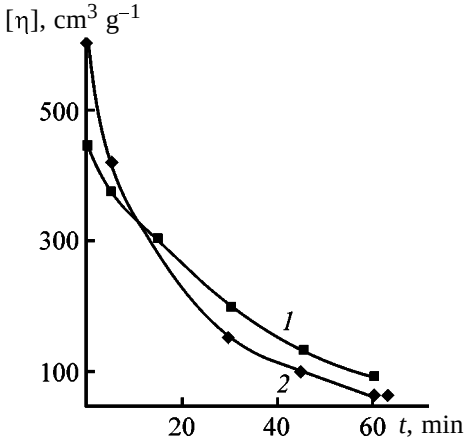

Fig. 4. Plot of [η] of cationic Praestols (*1*) 655 and (*2*) 644 vs. degradation time *t*. T = 50°C, c_p = 0.1%, [PP] = 0.04% (in water).

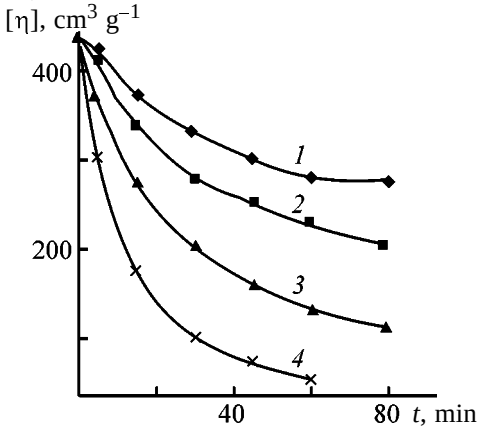

Fig. 5. Plot of [η] of cationic Praestol 655 vs. degradation time t at various concentrations of the copolymer c_p. T = 50°C, [PP] = 0.06% (in water). c_p, % (in water): (*1*) 0.5, (*2*) 0.4, (*3*) 0.3, and (*4*) 0.1.

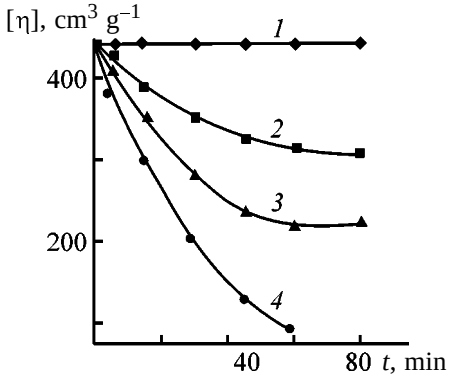

Fig. 6. Plot of [η] of cationic Praestol 655 vs. degradation time t at various temperatures. c_p = 0.1%, [PP] = 0.04% (in water). T, °C: (*1*) 25, (*2*) 30, (*3*) 40, and (*4*) 50.

tion (see table) but differing in the intrinsic viscosity. The reaction was performed under identical conditions; the results are shown in Fig. 5. It is seen that both Praestol samples appreciably degrade under the experimental conditions, with the extent of degradation (variation of [η]) being more pronounced for Praestol 644 whose initial [η] (and hence initial MW, see table) is higher. This trend is due to the fact that the number of probable scission sites is larger in longer macromolecules, which is consistent with the general relationships of the chain degradation of polymers [12]. Furthermore, in higher-molecular-weight samples, [η] should decrease to a greater extent even at the equal number of scission events.

The influence of temperature on degradation of AA–APTMAC copolymer (Praestol 655) in aqueous solutions was estimated in the range 25–50°C and equal other conditions. The results are shown in Fig. 6. At 25°C, no degradation occurs (curve *1*); at higher temperatures, the degradation accelerates (cf. curves *1–4*) owing to faster decomposition of the initiator and accumulation of radicals, causing degradation of the copolymer, in higher effective concentration. As a result, [η] and hence the MW of the copolymer appreciably decrease.

CONCLUSIONS

(1) The molecular weight of the acrylamide–(acrylamidopropyl)trimethylammonium chloride can be varied in a wide range (covering an order of magnitude) by partial degradation of the copolymer in aqueous solutions under the action of radical initiators at 25–50°C.

(2) In the course of degradation, the molecular weight of the copolymer decreases with time. This trend becomes more pronounced with increasing temperature, initiator concentration, and molecular weight of the initial copolymer, decreasing concentration of the copolymer, and in going from hydrogen peroxide to potassium persulfate.

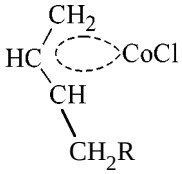
Abstract—Based on experimental results and reference data, the main elementary stages of butadiene polymerization on a cobalt-containing catalyst were determined and a mathematical model of the polymerization was developed. The following characteristics of the process were studied using this model: number-average, weight-average, and sedimentation-average degrees of polymerization and branching factor.

SKDK rubber is 1,4-*cis*-polybutadiene prepared with a cobalt-containing catalyst. This rubber, along with titanium (SKD) and rare-earth (SV-22, SV-23) rubbers, is used in production of tires, industrial rubber, industrial asbestos ware, shock-resistant polystyrene, and other items.

To develop a mathematical model of SKDK synthesis, the molecular-kinetic scheme considering the main reactions in the system is required. The synthesis mechanism can be formulated, and its main elementary stages determined, on the basis of reference data and various experimental dependences [1–6], although the structure of active centers of cobalt-containing catalytic systems and their reactivity are not yet clearly understood.

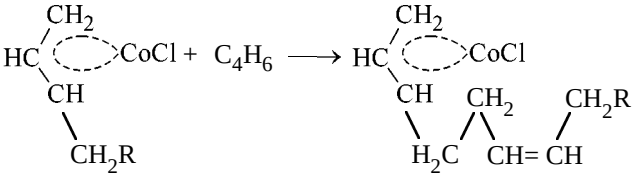
Butadiene polymerization includes some stages. The first of them is initiation, when a catalytic complex with active centers is formed: in the presence of a monomer, it is a π-allyl complex of the transition metal, and in the absence of the monomer, cobalt is reduced to metal [1]:

$$R_3Al + CoCl_2 \rightarrow R_2AlCl + [RCoCl] \rightarrow R_{-H} \downarrow C_4H_6$$



$$+ R_{+H} + Co^0 + CoCl_2.$$

The next stage is chain propagation



$\rightleftarrows$ $RCH_2–CH=CH–CH_2–CH_2–CH=CH–CH_2CoCl$ etc.

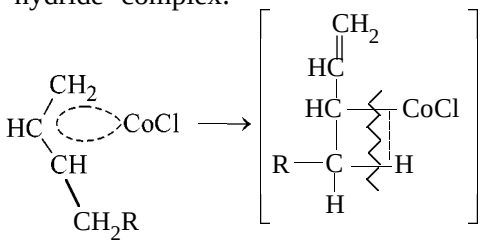
Either *cis* or *trans*- polymers can be formed depending on reaction conditions and composition of the catalytic system.

The chain propagation has certain specific features [1]: the reaction is first-order with respect to the concentration of the monomer and catalyst (cobalt); the overall activation energy amounts to 8.2 kcal mol^{-1}; one active center (per cobalt atom) produces a number of polymeric molecules due to chain transfer to the monomer.

Chain transfer to the monomer and polymer, spontaneous transfer, polymer cross-linking, and chain termination (deactivation) occur simultaneously with chain propagation.

It is believed [1–7] that chain transfer to the monomer consists of two successive spontaneous reactions.

(1) Decomposition of active center and formation of a hydride complex:



1070-4272/02/7507-1146$27.00 © 2002 MAIK "Nauka/Interperiodica"

$$\rightarrow \text{RCH=CH–CH=CH}_2 + \text{HCoX}.$$

In the process, conjugated double bonds are formed on chain ends [8]. The same bonds are formed by migration of double bonds within molecular chain.

(2) Regeneration of active center, i.e., propagation of a new polymer chain:

$$\text{HCoCl} + \text{C}_4\text{H}_6 \rightarrow \pi\text{-C}_4\text{H}_7\text{CoCl}.$$

In the process, the hydride complex can be deactivated. The same hydride complex can add to a propagating chain with formation of an additional active center, which results in chain branching. Molecules slowly cross-link by reaction of conjugated double bonds with active centers of another molecule. This gives branched polymeric species of various structures. The propagation rate grows with increasing number of active centers in the macromolecule. In turn, the number of centers increases with growth of the macromolecule [8].

In addition, appearance of branched macromolecules is the necessary but insufficient condition for gelation. It is also probable that all monomer molecules polymerize before the formation of macroscopic polymeric three-dimensional network. Gelation is caused by pronounced nonuniformity in the growth of various polymeric chains. As a result, separate strongly branched molecules can grow to macroscopic dimensions even at a low conversion. To determine the gelation conditions, it is necessary to monitor how statistical characteristics of the molecular-mass distribution (MMD) of polymeric chains vary over time. The mechanism of cross-linking of polymeric chains for the case of radical polymerization is described [8]. For anionic polymerization, a particular case of cross-linking of "living" and "dead" macromolecules was considered [9]. Let us consider additionally branching (cross-linking):

$$R(i,l) + R(j,n) \xrightarrow{k_c(in+jl)} R(i+j,\ l+n),$$

where $R(i,l)$ is the concentration of macromolecules with i active centers and l monomeric units, $R(j, n)$ is the concentration of macromolecules with j active centers and n monomeric units, and k_c is the rate constant of macromolecule cross-linking.

The double and conjugated double bonds present in diene polymers can enter into secondary reactions under the action of the components of catalytic systems and catalytic complexes themselves.

The $CoX_2 \cdot H_2O–R_2AlCl$ system contains the components $R_2AlCl–H_2O$ and $RAlCl_2–H_2O$ capable to initiate cationic polymerization. In addition to the above catalysts, hydrogen chloride can be formed in the system as a result of catalyst hydrolysis with a water impurity. For instance, high-molecular-weight *cis*-polybutadiene is comparatively rapidly converted into a gel under the action of $RAlCl_2 \cdot H_2O$. The contribution of the intermolecular reaction will strongly increase with increasing polymer concentration. Organometallic complexes can react with both conjugated and olefin bonds of the polymeric chains.

Taking the above into consideration, we can suggest the following kinetic scheme of polymerization on the cobalt-containing catalyst:

initiation

$$I + M \xrightarrow{k_i} R(1,1);$$

chain propagation

$$R(i,l) + M \xrightarrow{k_p} R(i, l+1);$$

spontaneous chain transfer (in two stages)

(a) transfer proper

$$R(i,l) \xrightarrow{k_{sp}} R(i-1,\ l) + S^*,$$

(b) reinitiation

$$S^* + M \xrightarrow{k_{ri}} R(1,1);$$

chain transfer to monomer

$$R(i,\ l) + M \xrightarrow{k_{tm}} R(i-1,\ l) + R(1,1);$$

chain transfer to polymer

$$R(i,\ l) + R(i',\ l') \begin{cases} \xrightarrow{k_{tp}i'l} R(i+1,\ l) + R(i'-1,\ l'), \\ \xrightarrow{k_{tp}il'} R(i-1,\ l) + R(i'+1,\ l'); \end{cases}$$

polymer cross-linking

$$R(i,l) + R(i',l') \xrightarrow{k_c(il'+i'l)} R(i+i',\ l+l');$$

chain termination

$$R(i,\ l) \xrightarrow{k_t} R(i-1,\ l),$$

where I is the initiator concentration; M, the monomer concentration; S^*, the concentration of the intermediate generated by transfer (probably HCoX); $R(i, l)$, the concentration of macromolecules with i active centers and l monomeric links; k_p, the propagation rate constant; k_i, the initiation rate constant; k_{tm}, the rate constant of chain transfer to monomer; k_{sp}, the rate constant of spontaneous chain transfer; k_{tp}, the rate constant of chain transfer to polymer; k_{ri}, the rate constant of reinitiation; and k_c, the rate constant of macromolecule cross-linking.

The rate of macromolecule cross-linking is proportional to $k_c(in + jl)$, e.g., it depends on the number of the active centers in the reacting molecules and on their length.

In accordance with the kinetic scheme, the system of the equations describing the variation in time of the concentrations of monomer M, active centers R, and propagating chains for a batch process is as follows:

$$dM/dt = -k_p MR, \quad (1)$$

at $t = 0$ $M = M_0$, $R(1, 1) = I_0$, $R(0, 0) = 0$;

$$dR/dt = -k_t R; \quad (2)$$

$$\partial R(i, l)/\partial t = -ik_p M[\partial R(i, l)/\partial l] + [k_{sp} + (k_{tm}M + k_t)][(i + 1)R(i + 1, l) - iR(i, l)] + k_c/2 \sum_{i=0}^{i} \int_0^l [j(l - n) + n(i - j)]R(j, n)R(i - j, l - n)dn - k_c R(i, l) \sum_{i=0}^{\infty} \int_0^{\infty} (in + jl)R(j, n)dn + k_{tp} \sum_{i=0}^{\infty} lj \int_0^{\infty} R(j, n)dn[R(i - 1, l) - R(i, l)] + k_{tp} \sum_{i=0}^{\infty} \int_0^{\infty} nR(j, n)dn[(i + 1)R(i + 1, l) - iR(i, l)] + (k_{sp} + k_{tm}M) I_0 \delta_{i,1} \delta(l), \quad i = 0, 2, \ldots, 0 \le l \le \infty. \quad (3)$$

At $i = 0$ $R(i - 1, l) = 0$.

It is assumed that the initiation and reinitiation proceed instantaneously. Since k_{tm}/k and k_{sp}/k are always much less than unity, the monomer consumption in chain transfer and reinitiation [Eq. (1)] can be neglected. In Eq. (3), the first term of the right-hand part describes the variation of $R(i, l)$ due to propagation; the next five terms describe the variation of $R(i, l)$ due to chain transfer, cross-linking, and termination; and the last term describes the appearance of new short propagating chains at reinitiation.

Equation (3) is wrote for the case of long chains. Equation (2) describes the decay rate of active centers $R = \sum_{i,l}^{\infty} R(i, l)$. It is readily integrated. Using the initial condition, we obtain

$$R = I_0 \exp(-k_t t). \quad (4)$$

After substitution of Eq. (4) in (1), we find the time dependence of monomer conversion $x = (M_0 - M)M_0$:

$$-\ln(1 - x) = \frac{k_p I_0}{k_t}(1 - e^{-k_t t}). \quad (5)$$

In accordance with Eq. (5), at first-order termination the monomer does not transform into the polymer completely. The limiting conversion is

$$x_\infty = 1 - \exp(-k_p I_0/k_t).$$

Thus, if the polymerization kinetics is known, we can determine the propagation rate constant from the initial slope of the first-order dependence of $-\ln(1 - x)$ on time and the termination rate constant from the limiting conversion. It should be noted, however, that, along with deactivation of the active centers by β-elimination, a substantial role can be played by termination on uncontrollable impurities. When there is no deactivation in the system ($k_t = 0$), the number of active centers in the system is constant throughout the process ($R = I_0 e^0 = I_0$). Then, it follows from Eq. (1) that

$$dM/dt = -k_p M I_0,$$

and the equation

$$x = 1 - e^{-k_p I_0 t} \quad (6)$$

is obtained for conversion.

According to preliminary data obtained in the experiments with thoroughly prepared systems, the limiting conversion was close to 100%, although in the other experiments at the same concentrations of cobalt and water the polymerization fully ceased at 50% conversion, which suggests the effect of impurities rather than spontaneous deactivation. Therefore, in this step, when the reliable experimental data are lacking, we will neglect the deactivation reaction

and analyze how chain transfer and cross-linking of macromolecules affect MMD. It follows from the conversion equation that

$$\frac{\partial}{\partial t} = k_p I_0(1 - x)\frac{\partial}{\partial x}, \qquad M = M_0(1 - x).$$

Then, Eqs. (3) can be presented as

$$\partial R(i, l)/\partial x = i\beta[\partial R(i, l)/\partial l] + [\gamma_{sp}/(1 + x) + \gamma_m][(i + 1) \times R(i + 1, l) - iR(i, l)] + [\gamma_{sp}/(1 + x) + \gamma_m] I_0 \delta_{i,1}\delta(l) + 0.5\gamma_c(1 - x)^{-1}\sum_{i=0}^{i}\int_0^l [j(l - n) + n(i - j)]R(j, n) \times R(i - j, l - n)dn + \gamma_c(1 - x)^{-1}[i R(i, l) M_0 x + lR(i, l)I_0] - \gamma_p l[\beta(1 - x)]^{-1}[R(i - 1, l) - R(i, l)] + \gamma_p x(1 - x)^{-1} \times [(i + 1)R(i + 1, l) - iR(i, l)], \quad i = 0, 2, \ldots, \quad (7)$$

where $\beta = M_0/I_0$ is the calculated degree of polymerization, and the parameters $\gamma_m = k_{tm}M_0/k_pI_0$, $\gamma_p = k_{tp}M_0/k_pI_0$, $\gamma_{sp} = k_{sp}/k_pI_0$, and $\gamma_c = k_c/k_pI_0$ characterize the rate of chain transfer to the monomer and polymer, the rate of spontaneous transfer, and the rate of macromolecule cross-linking, respectively.

The system of Eqs. (7) can be combined in one equation by the function $f = \sum_{i=0}^{\infty} s^i \int_0^{\infty} e^{-pl} R(i, l)dl$, which is usually named as producing function:

$$\partial f/\partial x = -\beta sp\,\partial f/\partial x + [\gamma_{sp}/(1 - x) + \gamma_m](s - 1)\partial f/\partial x + [\gamma_{sp}/(1 + x) + \gamma_m]I_0 s - \tilde{\gamma}_c s[(1 - x)\beta I_0]^{-1}(\partial f/\partial s)(\partial f/\partial p) - \tilde{\gamma}_c(1 - x)^{-1}[(xs\partial f/\partial s) - \beta^{-1}(\partial f/\partial p)] + \tilde{\gamma}_p(s - 1)(1 - x)^{-1} \times [\beta^{-1}(\partial f/\partial p) + x(\partial f/\partial s)], \quad (8)$$

where γ_{sp} is the intensity of spontaneous transfer, γ_p is the intensity of chain transfer to polymer, and $\gamma_c = \gamma_c M_0$ is the intensity of cross-linking.

After differentiating Eq. (8) the required number of times with respect to s and p, we obtain the equations for calculating statistical moments of macromolecule distribution with respect to the degree of polymerization l and the number of active centers i. Let us introduce the following designations: $J_{ij} = \left.\frac{\partial^{i+j} f}{\partial s^4 i \partial p^j}\right|_{\substack{s=1,\\ p=0}}$; by definition of MMD moments, $J_{00} = \left. f \right|_{\substack{s=1,\\ p=0}} = \mu_0$ is the total concentration (number) of polymeric chains at the instant t; $J_{10} = \left.\partial f/\partial s\right|_{\substack{s=1,\\ p=0}} = I_0$ is the total concentration (number) of active centers at the instant t; $J_{01} = \left.\partial f/\partial p\right|_{\substack{s=1,\\ p=0}} = -\mu_1 = -M_0 x$ is the concentration of the polymer formed to the instant t (with the opposite sign); and $J_{02} = \left.\partial^2 f/\partial p^2\right|_{\substack{s=1,\\ p=0}} = \mu_2$ and $J_{03} = \left.\partial^3 f/\partial p^3\right|_{\substack{s=1,\\ p=0}} = -\mu_3$ are second- and third-order moments. The system of equations for calculating MMD is as follows:

$$d\mu_0/dx = I_0[\gamma_{sp}/(1 + x) + \gamma_m] - I_0\mu_1[\gamma_c/(1 - x)],$$

$$\mu_1 = M_0 x,$$

$$d\mu_2/dx = -2\beta J_{11} - 2\gamma_c\mu_2 J_{11}/(1 - x),$$

$$dJ_{11}/dx = -\beta I_0 - \beta J_{20} - J_{11}[\gamma_{sp}/(1 - x) + \gamma_m] - [\gamma_c(I_0\mu_2 + J_{11}^2 + J_{20}\mu_2)/(1 - x)] - [\gamma_p(\mu_2\beta^{-1} + xJ_{11})]/(1 - x),$$

$$dJ_{20}/dx = -2J_{20}[\gamma_{sp}/(1 - x) + \gamma_m] - [2\gamma_c(I_0 J_{11} + J_{20}J_{11})/(1 - x)] - [2\gamma_p(J_{11}\beta^{-1} + xJ_{20})/(1 - x)],$$

$$d\mu_2/dx = -3\beta J_{12} - [\gamma_c(3J_{12}\mu_2 - 3J_{11}\mu_3)/(1 - x)],$$

$$dJ_{12}/dx = -2\beta(J_{11} + J_{21}) - J_{12}[\gamma_{sp}/(1 - x) + \gamma_m] - [\gamma_c(2J_{11}\mu_2 - I_0\mu_3)/(1 - x)] - [\gamma_c(2J_{21}\mu_2 + 3J_{11}J_{12} - I_{20}\mu_3)/(1 - x)] - [\gamma_p(\mu_3\beta^{-1} + xJ_{12})]/(1 - x),$$

$$dJ_{30}/dx = -3J_{30}[\gamma_{sp}/(1 - x) + \gamma_m] - [\gamma_c(2J_0 J_{11} + 3J_0 J_{21} + 3J_{30}J_{11} + 3J_{20}J_{21})/(1 - x)] - [3\gamma_p(J_{21}\beta^{-1} + xJ_{30})]/(1 - x).$$

$$dJ_{21}/dx = -2J_{20} - J_{30} - 2J_{21}[\gamma_{sp}/(1 + x) + \gamma_m] - [\gamma_c(6J_{20}\mu_2 + 2I_{12}I_0 + 2J_{30}\mu_2 + 2J_{11} + 3I_{21}J_{11} + 2J_{20}J_{12})/(1 - x)] - [2\gamma_p(J_{12}\beta^{-1} + xJ_{21})]/(1 - x),$$

Initial conditions: $\mu_0 = I_0$ ant $x = 0$, $\mu_1 = \mu_2 = \mu_3 = J_{11} = J_{12} = J_{10} = J_{21} = J_{20} = 0$, $\bar{P}_n = \mu_1/\mu_0$, $\bar{P}_w = \mu_2/\mu_1$, and $\bar{P}_z = \mu_3/\mu_2$.

The results of calculations by the mathematical model proposed are shown in Figs. 1–3.

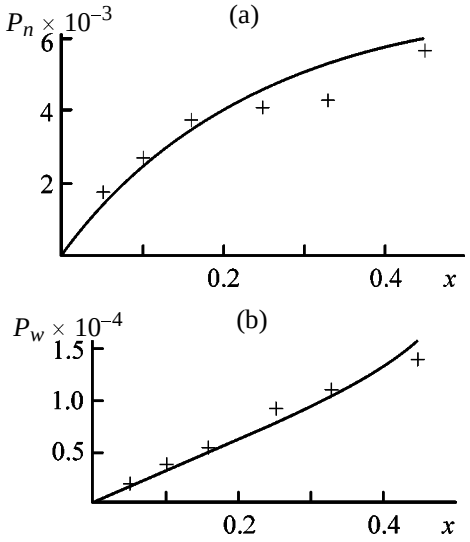


Fig. 1. Comparison of experimental data (points) and calculated curve of (a) number-average, P_n, and (b) weight-average, P_w, degrees of polymerization. k_{sp} = 0.048, k_c = 0.016, k_{tm} = 0, k_p = 297.2, k_{tp} = 0.032, and I_0 = 0.00006; M_0 = 1.85; the same for Figs. 2 and 3. (*x*) Monomer conversion; the same for Figs. 2 and 3.

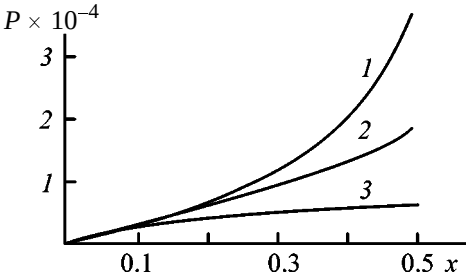

Fig. 2. Comparison of (*1*) sedimentation-average, P_z, (*2*) weight-average, P_w, and (*3*) number-average, P_n, degrees of polymerization.

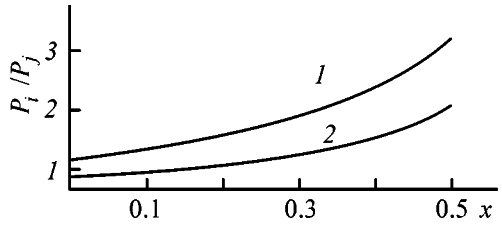

Fig. 3. Polydispersity coefficients (*1*) P_w/P_n and (*2*) P_z/P_w.

The deviation of the calculated data from the experiment amounted to 18.6%, which confirms the proposed mechanism of butadiene polymerization on the cobalt catalyst. The comparison with the experiment showed that the best fitting is attained with k_m = 0, suggesting small contribution of the transfer to the monomer. Probably, spontaneous transfer is sufficient to form conjugated double bonds. In addition, the difference between the chain transfer to the monomer and the spontaneous transfer is manifested only at monomer conversion greater than 30–40%.

Consideration of branching reactions (transfer to polymer and cross-linking) improves agreement between the calculated and experimental data. Figure 3 shows how branching varies with conversion. The polydispersity factor P_w/P_n changes from 1.3 to 3.2, and P_z/P_w, from 0.8 to 2.1, which indicates strong branching at monomer conversion higher than 40%.

CONCLUSIONS

(1) Based on reference and experimental data, the kinetic scheme and mathematical model of SKDK rubber polymerization were developed. The importance of branching reactions, chain transfer to polymer, and cross-linking of macromolecules was demonstrated. Modeling was performed for the case of cross-linking of the "living with living" type.

(2) The model proposed can be used to improve the butadiene polymerization process and optimize properties of SKDK rubber.

Abstract—The conditions and products of oxidative polycondensation of 2-(*p*-tolyliminomethyl)phenol in alkaline aqueous solution in the presence of sodium hypochlorite or atmospheric oxygen were studied. The optimal conditions were found, and procedures for preparing oligo(*p*-tolyliminomethyl)phenols were developed. The composition and structure of the products were determined by chemical and spectroscopic methods.

Thanks to the presence of a system of polyconjugated bonds and of reactive hydroxy groups, oligophenols exhibit a number of specific useful properties: paramagnetism, semiconductor behavior, resistance to radiation, plasma, and high temperatures, reactivity, inhibiting activity, etc. Therefore, they are successfully used for preparing heat-resistant epoxy oligomers and compounds [1, 2], adhesives [3], thermal stabilizing agents [4], plasma-resistant photoresists [5], and antistatic additives [6]. Introduction into oligophenols of additional ionic groups allows preparation of radiation-resistant cation exchangers [7] and high-performance expanding surfactants [8] for pretreatment of lead electrodes.

In this context, we prepared and studied a new oligophenol, oligo(*p*-tolyliminomethyl)phenol, containing a system of conjugated bonds. The structural features of this substance and the presence of two reactive functional groups may make this oligomer suitable not only for the above-mentioned applications, but also for preparation of metal–polymer chain complexes [9], analytical [10, 11] and environmental [12] chemistry, and treatment of industrial wastewater to remove toxic heavy metals [13]. Owing to the presence of radiation-resistant polyconjugated bonds and of active functional groups, oligo(*p*-tolyliminomethyl)phenol can also be used for recovery of radionuclides [14].

The desired product was prepared by oxidative polycondensation of 2-(*p*-tolyliminomethyl)phenol (TIMP) in alkaline aqueous solution in the presence of sodium hypochlorite or atmospheric oxygen, and the properties of the resulting oligomer, OTIMP, were studied.

Under ambient conditions in neutral organic and aqueous solutions, TIMP is not noticeably oxidized with atmospheric oxygen, NaOCl, and H_2O_2. However, addition of an alkali immediately causes red-brown coloration, suggesting oxidation of TIMP to the corresponding phenoxyl radical.

The reaction of 0.8 M of TIMP potassium salt with an equivalent amount of NaOCl in aqueous solution at 50°C for 6 h gives oligomeric products in 42.8% yield (Table 1). With increasing temperature, the conversion of TIMP grows to 47.6% at 60°C, 53.9% at 70°C, 73.1% at 80°C, and 85.0% at 90°C. However, under these conditions, the yield of fractions 2 and 3 (2.8–7.2%) is considerably lower than the yield of fraction 1 (36.9–73.3%). Addition of a double amount of the oxidant under similar conditions results in 97.9% conversion of the monomer, with 25.3% yield of OTIMP-2. At 80°C, $[TIMP]_0 = [KOH]_0 = 0.8$ M, $[NaOCl]_0 = 1.6$ M, and longer (13 h) reaction time, the total yield of reaction products increased to 98.7%, and the yield of OTIMP-2, to 27.9%. In any case, the yield of OTIMP-3 is the lowest (2.8–8.2%). The highest yield of OTIMP-2 (29.3%) is attained with air bubbling (8.5 l h^{-1}, run no. 9).

Replacement of NaOCl with atmospheric oxygen, under equal other conditions, somewhat decreases the TIMP conversion. For example, at 50°C, with air bubbling at a rate of 8.5 l h^{-1}, the conversion in 7 h is 26.9% (with NaOCl, 42.8% in 6 h). At 80°C, the monomer conversion in 17 h is 90.5%, whereas in the presence of NaOCl it reaches 97.9% in 6 h (Table 2).

Oxidative polycondensation of OTIMP-1 with atmospheric oxygen at 80°C for 7 h in alkaline aqueous solution yields 35.1% OTIMP-2 and 19.8% OTIMP-3.

OTIMP-1 is a light brown solid (mp 81°C) solu-

* OTIMP-1 was taken instead of the monomer.

ble in hot heptane, in chlorinated, aromatic, and polar organic solvents, and also in aqueous alkali and H_2SO_4. OTIMP-2 is a dark brown solid; it does not melt up to 220°C but is soluble in DMF, concentrated H_2SO_4, and aqueous alkali and partially soluble in THF, acetone, and dioxane. OTIMP-3 is a black or dark brown nonmelting solid soluble only in aqueous alkali, concentrated H_2SO_4, and partially in DMSO. Heating of OTIMP-3 in aqueous sodium carbonate solution results in CO_2 evolution, suggesting the presence of acidic groups. Determination of the molecular weight (MW) and molecular-weight distribution (MWD) of TIMP oxidative polycondensation products showed that OTIMP-1 consists of di- and trimers (Fig. 1, Table 3); OTIMP-2, of oligomers with the number-average MW $\overline{M}_n$ = 690–1320 and weight-average MW $\overline{M}_w$ = 1580–1860. The MWD of this fraction has two maxima: the first at $\overline{M}_n$ = 615–620 and $\overline{M}_w$ = 650–760, and the second, weaker peak, at $\overline{M}_n$ = 6610–6780 and $\overline{M}_w$ = 7640–7660. The amounts of the low- and high-molecular-weight fractions are 80–90 and 10–20%, respectively. The MW and MWD of OTIMP-3 are similar to those of OTIMP-2, except that the content of the high-molecular-weight fraction in OTIMP-3 prepared in the presence of NaOCl is higher (26%) than in OTIMP-2 (18%), and the polydispersity of this OTIMP-3 sample is high (3.26).

Table 3. Molecular-weight distribution of products obtained by oxidative polycondensation of TIMP with atmospheric oxygen (run nos. 1–3) and NaOCl (run nos. 4–6)

The elemental compositions of OTIMP-1 (C 79.49%, N 6.27%) and OTIMP-2 (C 78.13%, N 6.38%) are similar and close to the calculated elemental composition of TIMP (C 80.38%, N 6.69%). This means that the oxidative polycondensation leaves the monomer core intact. The IR spectra of the monomer (Fig. 2) and OTIMP-1 are similar, differing only in the band intensities. Both spectra contain broad absorption bands of OH groups at 3450 and 3427 cm^{-1}, aromatic C–H groups, and aliphatic C–H groups at 2920 and 2865 cm^{-1}. The azomethine groups absorb at 1618–1620 cm^{-1}, and benzene rings give strong bands at 1598, 1568, 1510, and 1496 cm^{-1}. The C–N and C–O stretching vibrations are observed at 1278–1282 and 1182–1184 cm^{-1}, respectively. The bending vibrations of the aromatic C–H groups of TIMP and OTIMP-1 are observed at 850 (weak), 817 (strong), and 758 cm^{-1} (strong). The band at 817 cm^{-1} is due to vicinal C–H bonds in the toluene ring; that at 850 cm^{-1}, to the vicinal C–H bonds in the phenol ring; and that at 758 cm^{-1}, to three adjacent C–H bonds in OTIMP-1 terminal units. Note that the IR spectra of OTIMP-1 samples prepared in the presence of NaOCl and O_2 differ insignificantly. Therefore, the main pathway of TIMP oxidative polycondensation does not depend on the kind of the oxidant.

In the IR spectra of OTIMP-2 and OTIMP-3, some absorption bands overlap owing to the bond conjugation (Fig. 2). Nevertheless, in the range 3200–3600 cm^{-1} we identified the majority of bands characteristic of stretching vibrations of polymer-associated OH groups in OTIMP-2 (maximum at 3387 cm^{-1}). The stretching vibrations of aromatic, azomethine, and methyl C–H bonds give rise to bands at 3033, 2862, and 2920 cm^{-1}, respectively. A number of strong bands are observed at 1618 (azomethine groups),

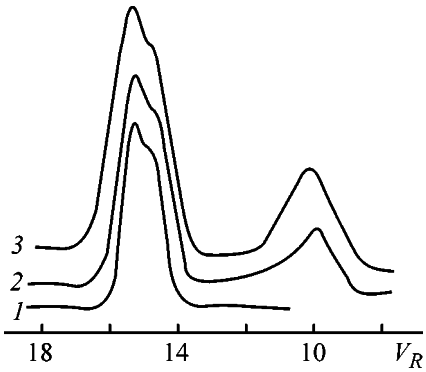

Fig. 1. Molecular-weight distribution of TIMP oxidative polycondensation products. (V_R) Retention volume. (*1*) OTIMP-1, (*2*) OTIMP-2, and (*3*) OTIMP-3.

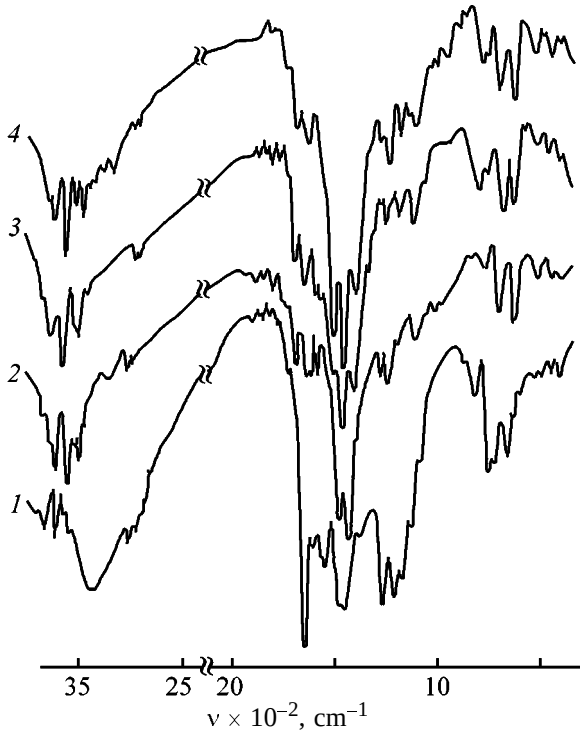

Fig. 2. IR spectra of TIMP and its oxidative polycondensation products. (ν) Wave number. (*1*) TIMP, (*2*) OTIMP-1, (*3*) OTIMP-2, and (*4*) OTIMP-3.

Table 4. ^{1}H NMR spectra of TIMP oxidative polycondensation products

Protons	δ, ppm		
	OTIMP-1	OTIMP-2	OTIMP-3
OH	13.0–13.3 s (1H)	13.1–13.2 s (1H)	13.1–13.3 s (1H)
CH=N	8.8–9.1 s (1H)	8.9–9.1 s (1H)	8.7–8.8 s (1H)
Ar–H	6.9–7.7 m (5H)	6.9–7.7 m (5H)	6.8–7.7 m (5H)
CH_3	2.0–2.6 s (3H)	2.0–2.6 s (3H)	2.0–2.4 s (3H)

1600, 1575, 1512, and 1456 cm^{-1} (aromatic rings and C=C bonds). The C–N and C–O vibrations in OTIMP-2 give rise to bands at 1379 and 1220 cm^{-1}. In the IR spectrum of OTIMP-2, the absorption bands of three (756 cm^{-1}) and two (818 cm^{-1}) adjacent aromatic C–H bonds belong, apparently, to the terminal units and *p*-tolyl saubstituents; a weak band at 857 cm^{-1} is probably due to structural fragments of the oligomer.

In the spectrum of OTIMP-3, as compared to OTIMP-2, the OH absorption bands are stronger and broader, and additional bands appear, originating from vibrations of aldehyde (1653 cm^{-1}) and carboxy (1682–1702 cm^{-1}) groups. These groups are apparently formed in the water-soluble fraction of the oligomer by partial hydrolysis and oxidation of the azomethine groups during the synthesis.

The ^{1}H NMR spectra confirm the structural data derived from the IR spectra. As seen from Table 4, the ^{1}H NMR spectra contain a singlet at 8.7–9.1 ppm belonging to the CH=N proton, a signal of the phenolic OH proton at 13.0–13.3 ppm, singlets of CH_3 protons at 2.0–2.6 ppm, and multiplets of aromatic protons at 6.8–7.7 ppm. The ^{1}H NMR spectrum of OTIMP-3 also contains CHO and COOH proton signals at 12.6 ppm.

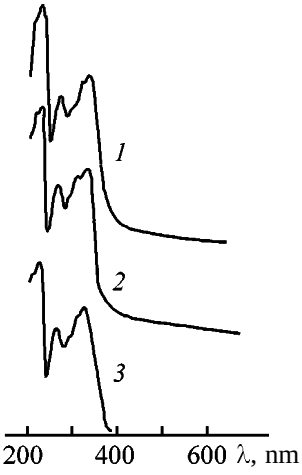

Fig. 3. UV spectra of TIMP and its oxidative polycondensation products. (λ) Wavelength. (*1*) TIMP, (*2*) OTIMP-1, and (*3*) OTIMP-2.

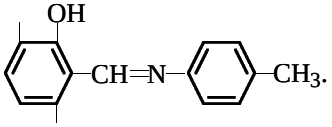
The IR and electronic absorption spectra of TIMP and OTIMP-1 are very similar (Fig. 3). The UV spectrum of the monomer contains the *K* band of phenol rings at 209 nm and a band of the $–C_6H_4N=$ group at 227 nm; in the spectrum of OTIMP-1, these bands coalesce, and an absorption appears at 225 nm. The benzene ring in both substances absorbs at 270 nm. The *R* band, which can be assigned to azomethine groups, is observed at 341 nm. The monomer is fully transparent at $\lambda > 360$ nm, whereas the absorption tail of the di- and trimers extends to 600 nm. Also, the absorption spectrum of OTIMP-1 is noticeably more intense than that of TIMP. This may be due to the longer conjugation system in OTIMP-1.

In the spectra of OTIMP-2 and OTIMP-3, which are very similar, the *K* band is observed at 225–227 nm. Strong bands with peaks at 320 (OTIMP-2) and 307 nm (OTIMP-3) start at 284 nm and extend to 900 nm. These bands are apparently due to interaction of the electronic systems of pendant CH=N groups with the polyconjugated system of the oligophenol macromolecules. Such interaction is also responsible for the brown or black color of these samples.

Thus, our data on the composition, structure, and chemical properties of TIMP oligomers, in combination with published data on the mechanism and products of oxidative polycondensation of hydroaromatic compounds [15–17], suggest that oligophenols prepared by oxidative polycondensation of TIMP mainly consist of the following units:



with fraction 3 also containing salicylaldehyde and salicylic acid fragments.

Oligo(*p*-tolyliminomethyl)phenols react under ambient conditions with acetates of some metals (Zn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Pb^{2+}) to form partially soluble metal–polymer complexes.

The TGA data (Table 5) show that oxidative degradation of OTIMP-2 and OTIMP-3 starts at 130–134°C, with 5 and 50% weight loss occurring at 200–239 and 639–757°C, respectively. Owing to the presence of the polyconjugated systems, the oligomers are considerably more heat-resistant than TIMP. Thermal oxidative degradation of oligo(*p*-tolyliminomethyl)-phenols is a multistage process. This may be due to formation at elevated temperatures of stable macromolecular networks by recombination of phenoxy macroradicals. This suggestion is consistent with formation of a coke residue at high temperatures.

Because of the low stability of COOH groups, OTIMP-3 is less heat-resistant than OTIMP-2. Nevertheless, even this oligomer forms at 1120°C a coke residue (15.9%). In contrast to monomeric TIMP, whose antimicrobial activity is weak, its oligomers, especially their phenolates and onium salts, actively inhibit the growth of 13 test microcultures.

Thus, TIMP reacts with atmospheric oxygen or sodium hypochlorite in alkaline aqueous solutions to form di-, tri-, and oligomers with $\overline{M}_n$ = 615–690 and $\overline{M}_w$ = 650–1860. At equimolar ratios of the reactants, the TIMP conversion at 50–90°C in 6 h is 42.8–85.0%. Increased amount of the oxidant and longer reaction time ensure virtually complete conversion of the monomer. Despite relatively low activity of atmospheric oxygen, compared to NaOCl, in oxidative polycondensation of TIMP, under optimal parameters it also ensures almost complete (90.5%) conversion of the monomer.

The products of TIMP oxidative polycondensation with both oxidants contain (*p*-tolyliminomethyl)-phenol units linked via *o*- and *m*-positions of the phenol ring. A certain fraction of the oligomers also contains minor amounts of CHO and COOH groups originating from partial oxidation and hydrolysis of the azomethine groups.

Oligo(*p*-tolyliminomethyl)phenols show fairly high resistance to thermal oxidation. They decompose by half at 488–757°C and form up to 15.9% coke residue at 1120°C.

The synthesized oligophenols actively react with Zn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, and Pb^{2+} acetates to form partially soluble metal–polymer complexes. Oligo(*p*-tolyliminomethyl)phenols, especially their alcoholates and onium salts, actively inhibit the growth of 13 test microcultures.

Table 5. Parameters of thermal oxidative degradation of TIMP and oligomerization products*

Substance	T_{on}	$T_{5\%}$	$T_{50\%}$	Coke residue, %
	°C			
TIMP	184	243	306	0.3
OTIMP-2	130	239	757	2.9

* (T_{on}) Degradation onset temperature; ($T_{5\%}$, $T_{50\%}$) temperatures of 5 and 50% weight loss, respectively.

EXPERIMENTAL

In experiments and analyses, we used salicylaldehyde, toluidine, KOH, 35% NaOCl solution, 37% HCl, heptane, THF, ethanol, methanol, DMF, and 1,4-dioxane (Merck, Carlo Erba, Analar BDH Chem).

2-(*p*-Tolyliminomethyl)phenol was prepared by condensation of salicylaldehyde with *p*-toluidine in refluxing ethanol [18]; mp 93°C (from ethanol).

Before use in oxidative polycondensation, air was passed through 20% aqueous KOH to remove CO_2.

Oxidative polycondensation of TIMP was performed in a 100-ml three-necked glass flask equipped with a magnetic stirrer, a temperature control unit, a thermometer, and a reflux condenser. In experiments on oxidative polycondensation of phenol with atmospheric oxygen, an air inlet tube was attached.

The flask was charged under stirring with 40 ml of distilled water, 2.24 g (0.04 mol) of KOH, and 8.44 g (0.04 mol) TIMP and was heated to the required temperature. Then air was bubbled at a rate of 8.5 l h^{-1}. After reaction completion, the mixture was neutralized with 37% HCl. The precipitate was separated from water-soluble products (OTIMP-3) on a glass frit, thoroughly washed with hot distilled water to remove inorganic salts, thoroughly washed with heptane to remove unchanged TIMP, and dried at 105°C. Then this product was treated with refluxing heptane to separate the soluble (OTIMP-1) and insoluble (OTIMP-2) fractions and dried at 105°C.

The aqueous solution of the water-soluble products (OTIMP-3) was evaporated to dryness on a water bath and then dried at 105°C for 6 h in an oven. After such a treatment, the major fraction (80–85%) of this product (similar to other oligomers with a system

of conjugated bonds [19]) became water-insoluble. Therefore, it was thoroughly washed with distilled water to remove mineral salts and dried at 105°C to constant weight.

The conversion of TIMP in the course of oxidative polycondensation was monitored by paper chromatography.

Oxidative polycondensation of TIMP with 35% aqueous NaOCl and the subsequent work-up were performed similarly.

The UV and IR spectra were measured in THF solutions and KBr pellets on Shimadzu UV-160A and FT-IR-8300 spectrophotometers. The ^{1}H NMR spectra were recorded on a Varian XL-200 spectrometer (200 MHz) in DMSO-d_6, internal reference TMS.

The molecular weight and MWD of TIMP oligomerization products were determined by exclusion chromatography on a Kovo high-performance liquid chromatograph (Czechia) equipped with a refractometric detector. Two 3.3×150-mm columns were packed with Separon-SGX (particle size 7 μm, porosity 100 Å); eluent DMF, flow rate 0.2 ml min^{-1}.

The thermal analysis was performed on a HiGeH RG 2/5 device at a heating rate of 2 deg min^{-1}.

CONCLUSIONS

(1) Procedures for preparing oligo(*p*-tolyliminomethyl)phenols by oxidative polycondensation of 2-(*p*-tolyliminomethyl)phenol with sodium hypochlorite and atmospheric oxygen were developed and optimized.

(2) The reaction products mainly consist of (*p*-tolyliminomethyl)phenol units linked via *o*- and *m*-positions.

(3) The products consist of low- and high-molecular-weight fractions whose content, depending on the reaction conditions, is about 80 and 20%, respectively. The molecular weight of the oligomers ranges from approximately 600 to 7500.

(4) Oligo(*p*-tolyliminomethyl)phenols show high resistance to thermal oxidation and high inhibiting activity with respect to the growth of 13 test microcultures; these products readily react with transition and heavy metal acetates to form partially soluble metal–polymer complexes exhibiting high heat resistance and high antimicrobial activity.

Received September 17, 2001

Abstract—Preparation of protecting fluoroplastic coatings at varied composition of the reaction mixture was studied. Introduction of quarternary pyridinium poly salt and various pigments into the polytrifluorochloroethylene composition allows variation of the process parameters of coating deposition on the cathode and preparation of modified fluoroplastic coatings with good anticorrosive properties.

The most common way to protect metals against corrosion is application of polymeric coatings, with fluoroplastic being the most stable to aggressive media. The properties of polymeric coatings are known [1] to strongly depend on the presence of pigments and fillers. Introduction of pigments in the course of electrodeposition of coatings not only changes the appearance and properties of the coatings but also affects the deposition process, nominal current efficiency, throwing power, and stability of the system as a whole. It is important to determine the protecting properties of electrodeposited coating as influenced by the type of pigment.

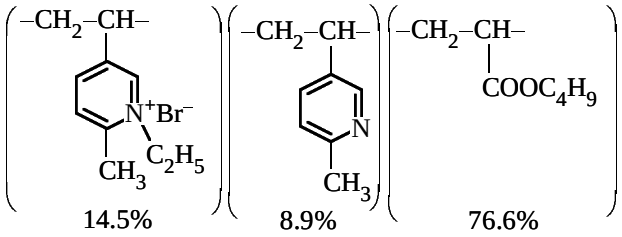
EXPERIMENTAL

By the mechanism of protecting action, pigments can be divided into three groups [2]: (1) passivating the metal (Cr_2O_3, ZnO); (2) forming difficultly soluble compounds on the metal surface ($CaHPO_4 \cdot 2H_2O$); and (3) cathodically protecting the metal (Al and Zn powders).

The physicochemical properties of pigments used in electrodeposition are presented in Table 1. The particle size was determined by sedimentometric analysis, and the particle charge, by electroosmosis.

The protecting coatings were deposited from multicomponent dimethylformamide dispersion containing polytrifluorochloroethylene (F-3) and copolymer of quaternary pyridinium salt (CPS) specially synthesized for this purpose (see below).

A CPS macromolecule contains 14.5% *N*-ethyl-2-methyl-5-vinylpyridinium bromide, 8.9% 2-methyl-5-vinylpyridine, and 76.6% butyl acrylate units. The butyl acrylate units make the polymer elastic and enhance adhesion of the polymeric coating to the cathode. Pyridinium functional groups behave as inhibitor. They are converted to 14.5% into pyridiniomethyl bromide groups which readily dissociate in dimethylformamide (DMF) to form polycations. Positively charged pyridinium groups of CPS are sorbed on fluoroplastic particles which become positively charged and are deposited on the cathode [4].



The composition for electrodeposition was prepared as follows. The solid copolymeric salt (0.35 g) was dissolved in DMF (50 ml). The resulting solution (1 ml) was added to fluoroplastic powder wetted with a small amount of DMF (5 ml). The mixture was stirred for a long time with a magnetic stirrer. Then an additional portion of the solvent was added to obtain 7% dispersion. The content of the polymeric salt in the dispersion was 7×10^{-3} g/100 ml.

The deposition process was controlled by varying the dispersion composition, electric parameters, deposition time, and heat treatment conditions. The dispersion composition and electrodeposition conditions are presented in Table 2.

To determine the best pigment concentration, we studied the dependence of the deposit weight on the dispersion composition. The deposit weight was

maximal at 5–7% pigment content in the dispersion. The thickest coatings with the best properties were formed in the presence of chromium(III) oxide, and the thinnest, in the presence of calcium hydrogen phosphate.

As determined by IR spectroscopy, the pigment content in the deposit differs from that in the electrolytic bath. The pigment : film-forming agent ratio in the deposit is higher than that in the dispersion.

Pigments promote formation of more uniform coating, thus decreasing its electrochemical heterogeneity.

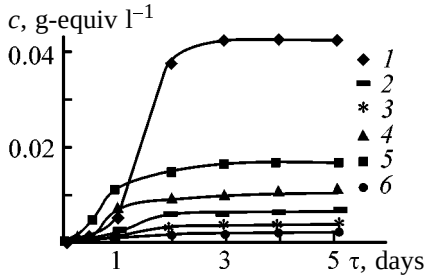

Fig. 1. Concentration c of chloride ions that have diffused through the film as a function of time τ. The figures at the curves correspond to the coating number in Table 2; the same for Figs. 2 and 3.

They increase the electrical resistivity, decelerate the cathodic and anodic processes on passivated support, and plug the channel pores, thus preventing ion diffusion [5].

In this work, we studied the permeability of fluoroplastic coatings filled with various pigments. As seen from Fig. 1, the transfer rate of chloride ions changes with time. Within the first day, the ions transfer is difficult owing to hydrophobic properties of the fluoroplastic. Then the dependence becomes linear, i.e., chloride ions penetrate through the film only by diffusion. In 2–3 days, the ion transfer stops. This is due to both formation of the electrical double layer in film capillaries and the negative film potential appearing owing to the difference in the transference numbers of Na^+ and Cl^-. In the simplest case, the liquid-phase potential can be calculated by the equation

$$\Delta\varphi_z = RT/(zF)(t_{Na^+} - t_{Cl^-}) \ln (c_0/c),$$

where R is the gas constant (J mol^{-1} K^{-1}); T, the temperature (K); F, the Faraday number (C mol^{-1}); z, the charge of the chloride ion; c_0 and c, the concentration of the initial solution and solution in the chamber to which the ions have diffused, respectively (M);

Table 3. Physicochemical properties of chloride ion transfer in the coatings

Coating (Table 1)	Thickness δ, μm	$D \times 10^9$, $m^2\ s^{-1}$	V, g-equiv $l^{-1}\ s^{-1}$	P, $g\ cm^{-2}$	$-\Delta\varphi_z$, V

5	35–40	2.73	8.1×10^{-8}	0.0830	0.0200
6	45–50	1.85	6.3×10^{-9}	0.0028	0.0299

and $t_{Na^+} = 0.382$, $t_{Cl^-} = 0.618$, the transference numbers.

The liquid-phase potential correlates with the transfer rate v and diffusion coefficients of chloride ions D calculated from the kinetic data (Fig. 1) by the Fick's law.

The film permeability was calculated by the equation [6]

$$P = c\mu V/S,$$

where c is the concentration of diffused chloride ions (g-equiv l^{-1}), determined by titration at time τ (s); μ, the atomic weight of chloride ion; V, the cell volume (l); and S, the surface area of the film.

As seen from Table 3, the liquid-phase potential, diffusion coefficient, transfer rate, and permeability depend on the type of the composite coating. The unfilled fluoroplastic coatings are the most permeable. Introduction of pigments appreciably decreases the film permeability. Finely divided pigment fills the interparticle space of the fluoroplastic matrix. As a result, the coating thickness becomes more uniform and the porosity and hence permeability of the coatings decrease. The coatings filled with Al powder are the least permeable. The diffusion coefficient in these films is 5 times lower than that in the fluoroplastic coatings without the filler.

Polymeric coatings restrict access of reactive compounds to the support surface and affect the electrode processes at the metal–polymer interface, thus protecting the support.

The time dependences of the potential of a coated electrode were measured by chronopotentiometry (Fig. 2). Among the examined coatings, that containing chromium(III) oxide is characterized by the most positive final potential and the smallest difference between the initial and final potentials Δφ.

The rate of chemical reactions occurring on the metal–coating interface cannot be measured directly. However, it can be indirectly estimated from the polarization resistance [7]. The cathodic and anodic polarization curves without the ohmic component are shown in Fig. 3. It should be noted that good anticorrosive properties are determined by high polarization resistance. Among the filled fluoroplastic coatings, the polarizability of the coating with Cr_2O_3 filler is the highest. Polarization of these coatings at low currents indicates the absence of side corrosion processes. The polarizability of all the coatings at cathodic polarization is higher than that at the anodic polarization, i.e., the coatings suppress to a greater extent the cathodic process at the metal–polymer interface. The occurrence of corrosion processes under the film can be also determined by the corrosion currents and their variation with time. The lower the corrosion current, the better the protecting function of the coating. Pigments passivating the metal (Cr_2O_3, ZnO) and forming difficultly soluble compounds ($CaHPO_4 \cdot 2H_2O$) decelerate the cathodic processes, as is indicated by low current, which does not noticeably change with time.

Zinc and aluminum powders plug the channel pores and decrease the permeability. However, corrosion processes are promoted and the corrosion currents increase owing a contact potential difference between iron and the metal powder.

Thus, the type of the pigment strongly affects both

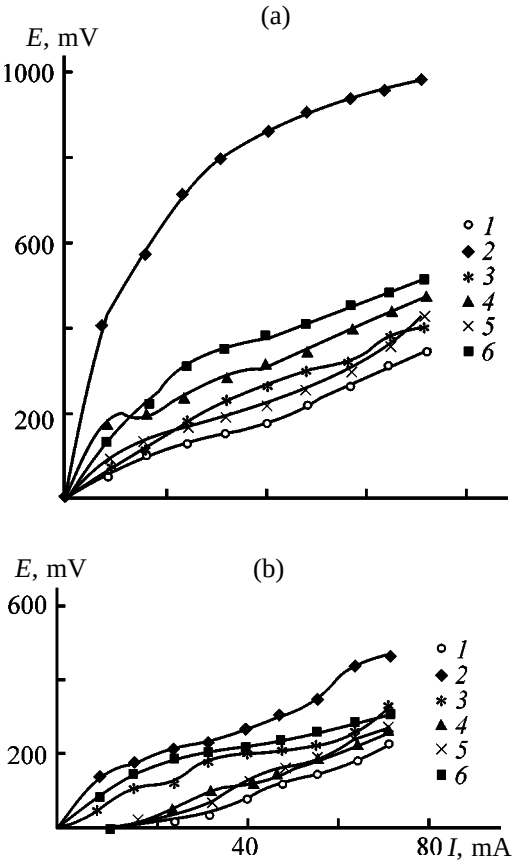

Fig. 3. (a) Cathodic and (b) anodic polarization curves of a coated electrode in 0.5 M NaCl. (*E*) Potential and (*I*) current. (a) $2H^+ + 2e \rightarrow H_2$; (b) $Fe - 2e \rightarrow Fe^{2+}$.

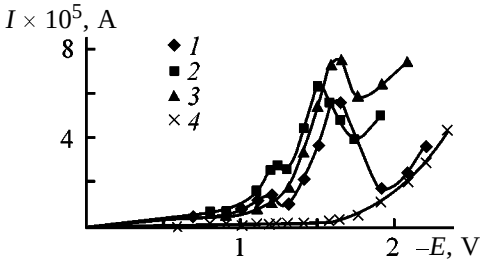

Fig. 4. Voltammogram of reduction of (*1*) poly-NEt2Me5VPBr, (*2*) poly-NEt2Me5VPBr–2Me5VP–BuAcr, (*3*) NEt2Me5VPBr, and (*4*) 0.1 M $NaClO_4$. Concentration 1×10^{-4}, sweeping rate 80 mV s^{-1}; (*I*) current and (*E*) potential.

the electrodeposition and the protecting properties of fluoroplastic coatings. All electrochemical methods used in this work show that cathodic processes are inhibited to a greater extent than anodic processes.

Good protecting properties of the composite coatings are determined mainly by their strong adhesion to the support, which, in its turn, is provided by formation of the first microlayer on the molecular level by electrochemical reduction of pyridinium polyanion sorbed on fluoroplastic and pigment particles.

As determined by chronovoltammetry, pyridinium polycations as well as their monomeric analogs have electroactive centers reducible at cathodic polarization from –0.6 to –1.7 V (Fig. 4). The voltammogram of 2-methyl-5-vinylpyridinium bromide 2Me5VPBr contains only a single current peak due to reduction of the pyridinium ring. In the polycation voltammograms, the current peak splits in two peaks. Along with a strong peak at the potentials close to the potential of monomer reduction, a weak peak or ascending current plateau appears at more positive potentials. The value of the capacitance indicates strong adsorption of the polymeric salt at these potentials [6].

As seen from Fig. 4, the peak potentials of the copolymer salt are shifted to the anodic region as compared to those of the homopolymeric salt. This is due to readier discharge owing to accessibility of the electrode surface to charged chains.

A composite coating is formed by colloid-chemical and electrochemical reactions which make the electrodeposit denser and strengthen the adhesion interaction owing to formation of intermetallic bonds with the metal surface.

The composite fluoroplastic coatings can be used to protect metallic articles from the atmospheric action and as priming coatings protecting from humid and sea atmosphere and saline media.

CONCLUSIONS

(1) The type of the pigment strongly affects electrodeposition and protecting properties of fluoroplastic coatings.

(2) Introduction of aluminum powder into the coatings decreases their permeability and decelerates diffusion of corrosive agents to the support.

(3) Electrochemical studies show that the cathodic processes under the coating are inhibited to a greater extent as compared to the anodic processes.

(4) The electrodeposition mechanism was determined by chronovoltammetry.

Abstract—The interaction of polyfluorinated alcohols with triethylamine and the kinetics of the reaction of the resulting triethylamine complexes with thionyl chloride were studied, the mechanism of formation of polyfluoroalkyl chlorosulfites was considered, and the optimal reaction conditions were found. The alkylating power of polyfluoroalkyl chlorosulfites was studied in reactions with alkali metal halides (to obtain polyfluorohaloalkanes), in synthesis of acrylic and methacrylic acid esters, and in synthesis of polyfluoroalkyl ethers (with polyfluoroalkyl 1-adamantyl ethers as example).

Polyfluoroalkyl chlorosulfites have been studied poorly. These compounds were prepared by the reaction of perfluoroalkyl hypochlorites with thionyl chloride [1–5]

$$R_FOCl + SOCl_2 \rightarrow R_FOS(O)Cl + Cl_2.$$

In a later study [6], these compounds were prepared by the reaction of polyfluoro alcohols with thionyl chloride in the presence of triethylamine:

$$R_FOH + SOCl_2 \rightarrow R_FOSOCl.$$

In contrast to alkyl chlorosulfites, which are intermediates in reactions of alcohols with thionyl chloride and readily eliminate SO_2 to form chloroalkanes, polyfluoroalkyl chlorosulfites are stable compounds distillable without decomposition.

In this work, we studied the interaction of polyfluorinated alcohols with triethylamine and the reaction of the resulting complexes with thionyl chloride, with the aim to optimize the preparation of polyfluoroalkyl sulfites, which are of interest as polyfluorinating agents in syntheses of polyfluorohaloalkanes and of esters and ethers containing polyfluoroalkyl groups.

EXPERIMENTAL

Calorimetric studies were performed with a DAK-1-2M isothermal differential calorimeter. An ampule-in-ampule glass microreactor was placed in a calorimetric cell equipped with a device for breaking the inner ampule (a thin-walled sphere). After the required temperature was attained, the thin-walled sphere was broken, and the thermokinetic curve was recorded with an LKS 4003 device; this curve was processed to calculate the heat release rate and to determine the rate constants using the kinetic model. The heat of formation of the alcohol–triethylamine complex was determined in the bulk at 30°C and equimolar ratio of the alcohol and amine. Three replicate runs were performed, and the thermokinetic curves were processed by the trapezium method. The error of the calorimetric measurements was 3–5%.

The kinetics of formation of polyfluoroalkyl chlorosulfites was studied at 25, 30, and 35°C. The initial concentrations of the alcohol–amine complex and thionyl chloride were 0.18 M.

Procedures for synthesis and identification of polyfluoroalkyl chlorosulfites are reported elsewhere [7]. The reaction was performed in chloroform; the complex of a polyfluorinated alcohol (0.05 mol) with triethylamine (0.05 mol) was added to a solution of 0.075 mol of thionyl chloride, cooled to –40°C; in the process, the mixture was not allowed to warm up above –15°C. After adding the whole amount of the complex, the mixture was warmed up to 20°C. The precipitate of triethylamine hydrochloride was filtered off, excess thionyl chloride was distilled off at atmospheric pressure, and the residue was vacuum-distilled. The yields and constants of polyfluoroalkyl chlorosulfites obtained by the reaction

$$H(CF_2CF_2)_nCH_2OH\cdot N(C_2H_5)_3 + SOCl_2$$

$$\rightarrow H(CF_2CF_2)_nCH_2OSOCl + (C_2H_5)_3N\cdot HCl, \quad n = 1\text{–}3,$$

are listed in Table 1.

Polyfluorinated alcohols virtually do not react with thionyl chloride in the absence of triethylamine. If triethylamine is added to a mixture of alcohol and thionyl chloride, the yield of alkyl chlorosulfite does not exceed 15%. The highest yield (80–84%) is attained when the complex of a polyfluorinated alcohol with triethylamine, prepared in advance, is added to thionyl chloride. Therefore, using microcalorimetry and IR and ^{1}H NMR spectroscopy, we studied the interaction of polyfluorinated alcohols with triethylamine.

The thermal effect of the interaction of polyfluorinated alcohols with triethylamine was estimated microcalorimetrically. The heat of interaction with triethylamine is 19.9 kJ mol^{-1} for 2,2,3,3-tetrafluoro-1-propanol (FA1) and 20.7 kJ mol^{-1} for 2,2,3,3,4,4,5,5-octafluoro-1-pentanol (FA2).

Complexation causes significant changes in the IR spectra of polyfluorinated alcohols. The stretching vibration band of the OH group at 3620 cm^{-1} sharply decreases in intensity, and a new medium-intensity band appears at 2600–2700 cm^{-1}, which is split in several bands (Fig. 1). These changes are due to formation of a salt, $H(CF_2CF_2)_nCH_2O^-\,{}^+NH(C_2H_5)_3$.

The conclusions made from the IR spectra are confirmed by the ^{1}H NMR spectra of FA2 solutions in CCl_4. Interaction of FA2 with triethylamine causes a downfield shift of the hydroxyl proton signal by 2.49 ppm. Triethylamine is a stronger proton acceptor than acetone, as with acetone, under similar conditions, the OH proton signal is shifted downfield by only 1.86 ppm. Thus, the complexation is favored by the acid properties of polyfluorinated alcohols and high basicity of triethylamine.

Based on the data on complexation with triethylamine, we optimized the conditions for preparing polyfluoroalkyl chlorosulfite. We suggest the following mechanism of nucleophilic substitution of chlorine in the thionyl chloride molecule:

$$SOCl_2 + R_FO^-[NHEt_3]^+$$

$$\rightleftharpoons \left[R_FO\text{---}\overset{\displaystyle O}{\overset{\|}{S}}\text{---}Cl\right][NHEt_3]^+$$

$$\longrightarrow R_FOS(O)Cl + [NHEt_3]^+Cl^-.$$

This mechanism is confirmed by the kinetic data. Using the kinetic model, we processed experimental heat release curves [8] and determined the rate constants and the effective activation energy of the reaction. For the reaction of thionyl chloride with FA1–triethylamine, the second-order rate constants are as follows (l mol^{-1} s^{-1}): 0.020 at 25°C, 0.025 at 30°C, and 0.027 at 35°C. The effective activation energy is 31.77 kJ mol^{-1}.

We have studied the alkylating power of polyfluo-

* Numerator: found; denominator: calculated.

roalkyl chlorosulfites in the reactions with alkali metal halides, carboxylic acid salts, and alcohols.

Polyfluoroalkyl chlorosulfites react with alkali metal halides (KF, LiCl, KBr, KI) in diethylene glycol to form the corresponding polyfluorohaloalkanes in 75–90% yield:

$$H(CF_2CF_2)_nCH_2OS(O)Cl + MX \rightarrow H(CF_2CF_2)_nCH_2X + MCl + SO_2,$$

where n = 1, 2, 3; X = F, Cl, Br, I; M = K, Li, Na.

The advantages of the synthesis of polyfluorohaloalkanes by substitution of the chlorosulfite group in alkyl chlorosulfites are the use of low-toxic chemicals, versatility, and high yield of the reaction products.

By the reaction of alkyl chlorosulfites with potassium (meth)acrylate, we prepared the corresponding polyfluoroalkyl (meth)acrylates:

$$CH_2=C(R)COOH + H(CF_2CF_2)_nCH_2OS(O)Cl \longrightarrow CH_2=C(R)COOCH_2–(CF_2CF_2)_nH,$$

where n = 1, 2, 3; R = H, CH_3.

The yield of acrylates and methacrylates in this case is appreciably higher than in the known procedure [9] (Table 2).

Polyfluoroalkyl chlorosulfites readily react with alcohols in dioxane to form the corresponding ethers. For example, previously unknown polyfluoroalkyl 1-adamantyl ethers were prepared by the reaction of 1-adamantol with polyfluoroalkyl chlorosulfites:

$$Ad–OH + H(CF_2CF_2)_nCH_2OS(O)Cl \longrightarrow Ad–OCH_2(CF_2CF_2)_nH,$$

where n = 1, 2.

Adamantyl polyfluoroalkyl ethers are colorless liquids readily distillable in a vacuum (Table 3). The composition and structure of these compounds were determined by elemental analysis and by IR and ^{1}H NMR spectroscopy.

The IR spectra of the ethers exhibit a very strong absorption at about 2916 cm^{-1} assigned to the stretching vibrations of the methylene and methine groups and at about 1124 cm^{-1} assigned to the ether C–O stretching vibrations.

The ^{1}H NMR data for 1-adamantyl alkyl ethers are given in Table 4.

The ^{1}H NMR spectra of 1-[2,2,3,3-tetrafluoropropoxy]adamantane and 1-[2,2,3,3,4,4,5,5-octafluoropentoxy]adamantane contain characteristic proton signals of the adamantane moiety [10]. The β- (δ 1.56 ppm) and δ-protons (δ 1.68 ppm) give narrow signals. The signal of the γ-protons is broad (δ 2.12 ppm). The signal of the methylene protons in the polyfluoroalkyl moiety is a triplet with a coupling constant of 12 Hz. The proton signal of the hydrofluoromethyl group is a triplet of triplets with a coupling constant of 6 Hz.

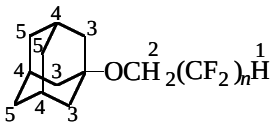
According to the predictions of the medicobiological activity, perfluoroalkyl 1-adamantyl ethers show promise as antidepressants and tranquilizers.

CONCLUSIONS

(1) A procedure was developed for synthesis of polyfluoroalkyl chlorosulfites by the reaction of thionyl chloride with complexes of polyfluorinated alcohols with triethylamine.

(2) Complexation in the system polyfluorinated alcohol–triethylamine was studied by microcalorimetry and IR and ^{1}H NMR spectroscopy, and the salt-like structures of the complexes were suggested.

Table 4. ^{1}H NMR spectra of 1-adamantyl alkyl ethers



n	Chemical shift δ, ppm					Coupling constant, Hz		
	1	2	3	4	5	J_{HCF}	J_{HCCF}	J_{2HCH}
2	5.78 t.t	3.64 t	1.56 s	2.12 s	1.66 s	52	6	12
4	5.84 t.t	3.74 t	1.56 s	2.12 s	1.68 s	52	6	12

(3) A mechanism of formation of polyfluoroalkyl chlorosulfites was suggested, involving bimolecular nucleophilic substitution of chlorine by the polyfluoroalkoxy group in thionyl chloride in its reaction with the polyfluorinated alcohol–triethylamine complex.

(4) Polyfluoroalkyl chlorosulfites efficiently alkylate carboxylic acid salts (alkyl acrylates and methacrylates were obtained) and alcohols (with 1-adamantol as example); they can also be used for preparing polyfluorohaloalkanes by the reactions with metal halides.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Kraft Lignin Concentration on the Efficiency of Its Coagulation Recovery from Aqueous Electrolyte Solutions

Yu. M. Chernoberezhskii, A. B. Dyagileva, A. A. Atanesyan, and T. V. Leshchenko

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received February 26, 2002

Abstract—The dependence of the aggregation stability of aqueous suspension of kraft lignin on its concentration in the system was studied spectrophotometrically in wide ranges of pH and sodium chloride concentrations.

At present, the main procedure of production of commercial cellulose is kraft cooking of wood [1, 2]. This procedure allows processing of virtually all types of plant raw materials and production of cellulose with high strength characteristics. In addition, kraft cooking has a number of environmental and process advantages. First, this process provides perfect regeneration of chemicals, allowing the use of wood components passing into the cooking liquor as a source of energy. Second, this process allows the most exhaustive treatment of liquor-containing wastewater flows with arrangement of local water-treatment systems at the sites of formation of these concentrated flows. This will decrease the load on the biological treatment plant by preliminary removal of poorly soluble organic impurities and reduction of the color index of wastewaters. These problems cannot be solved by traditional procedures of biological treatment.

High color index and chemical oxygen demand (COD) of this wastewater are caused by a significant concentration of kraft lignin (KL), which is an aromatic compound that is difficult to oxidize biochemically at the wastewater treatment facilities existing at virtually all paper and pulp plants. Therefore, development of procedures of removal of KL from wastewater is an urgent problem. Coagulation recovery of KL can be one of such procedures.

Practically any procedure of wastewater treatment, among them coagulation, includes separation of a phase to be recovered from wastewater so as to prevent secondary contamination of surface and underground water. Therefore, decrease in the amount of the resulting precipitates and their utilization can be of practical interest.

The choice and substantiation of regimes for recovery of poorly soluble part of wastewater (KL) require detailed studies in this field. The results reported here present a part of complex studies of colloid-chemical behavior of KL in aqueous systems.

EXPERIMENTAL

In this work, the aggregation stability of the system water–lignin–electrolyte was studied spectrophotometrically in a wide range of KL and NaCl concentrations and pH. Characteristics of KL, its colloid-chemical properties, and procedures of experiments with "instant mixing" of components were described in [3–5]. The systems for studies with KL concentration from 25 to 1000 mg l^{-1} were prepared from weighed portions of KL by their dissolution in 0.1 M NaOH, dilution with distilled water, and subsequent addition of required amounts of HCl and NaCl. The efficiency of coagulation recovery of KL was determined after settling for 120 min from the residual KL concentration in the solution over the separated phase c_s and in the filtrate c_f. Filtration was carried out through a "blue band" filter. The residual concentration was determined spectrophotometrically (λ = 280 and 480 nm) on an SF-46 spectrophotometer from the optical density of the solution alkalized to pH 11, using the calibrating plot. The residual concentrations of KL in the solution and filtrate were plotted vs. pH of the system.

The pH dependences of the residual concentrations of KL in the solution (Fig. 1a) and filtrate (Fig. 1b) at ionic strength of 10^{-2} M are shown in Fig. 1. Figure 1a showes that at a KL concentration of 25 mg l^{-1} the solution is stable with respect to sedimentation throughout the studied range of pH down to pH 1.5.

1070-4272/02/7507-1166$27.00 © 2002 MAIK "Nauka/Interperiodica"

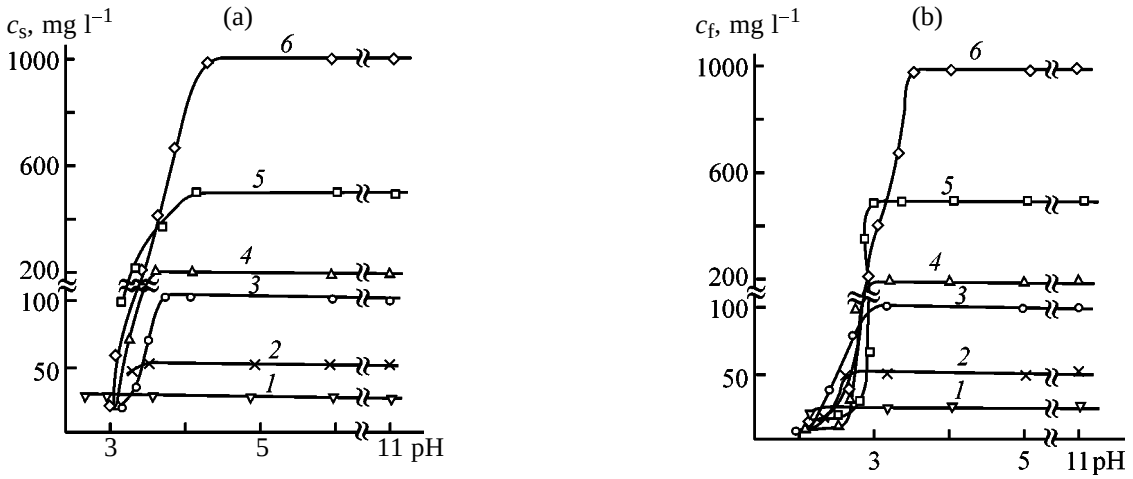

Fig. 1. Residual concentration of KL c (a) in the solution, c_s, and (b) in the filtrate, c_f, as a function of pH. Ionic strength 10^{-2}. Initial concentration of KL (mg l^{-1}): (*1*) 20, (*2*) 50, (*3*) 100, (*4*) 200, (*5*) 500, and (*6*) 1000.

An increase in the initial KL concentration results in the loss of the sedimentation stability of KL. In this case, with increasing the initial KL concentration, pH of the onset of sedimentation is shifted to the less acidic range: from pH 2.5 (50 mg l^{-1}) to 3.2 (1000 mg l^{-1}). A similar pattern is observed with filtered samples (Fig. 1b); however, pH values corresponding to the onset of retention of KL on the filter are somewhat higher (2.6 and 3.3 at KL concentration of 50 and 1000 mg ml^{-1}, respectively), because, in the initial stages of coagulation, finely dispersed slowly sedimending KL aggregates are formed, which, however, can be retained by the filter. Thus, $c_s - c_f$ (the difference between the ordinates of the respective curves in Figs. 1a and 1b) at a certain pH corresponds to the concentration of sedimentation-stable coagulated KL.

The dependences presented in Fig. 1b and also the similar dependences obtained for KL solutions in 0.1 and 1 M NaCl were used to determine the conditions of the onset of KL retention on the filter, corresponding to pH values at which c_f starts to decrease (Fig. 2). As seen from Fig. 2, an increase in KL concentration and ionic strength of the supporting electrolyte results in increased pH value of the onset of KL retention on the filter.

The resulting dependences can be explained as follows. An increase in KL concentration results in increased frequency of particle collisions. Therefore, at a higher concentration of KL, the same coagulation rate should be observed at a higher energy barrier caused, according to the DLVO theory, by the ion–ion electrostatic repulsion forces. Considering the fact that the zero-charge point of KL is at pH 2 [3, 4], at pH > 2 KL particles are negatively charged and their charge and, hence, the ion–ion electrostatic component of the particle interaction energy increases with increasing pH. This should result in a shift of coagulation pH toward lower acidities with increasing KL concentration. The similar effect should be observed with increasing ionic strength of the supporting electrolyte, resulting in weakened ion–ion electrostatic repulsion of KL particles.

Based on the experimental data on the residual KL concentrations after coagulation of the systems under "rigorous conditions" of phase separation (pH 2, zero-charge point of KL), we plotted the concentration dependences of the efficiency of KL recovery by sedimentation (Fig. 3a) and filtration (Fig. 3b) in the absence and in the presence of the supporting electrolyte NaCl. In all cases, an increase in KL concentration results in significant increase in the efficiency of KL recovery. For example, the efficiency of KL recovery (without filtration) in the absence of additional electrolyte increases from approximately zero to

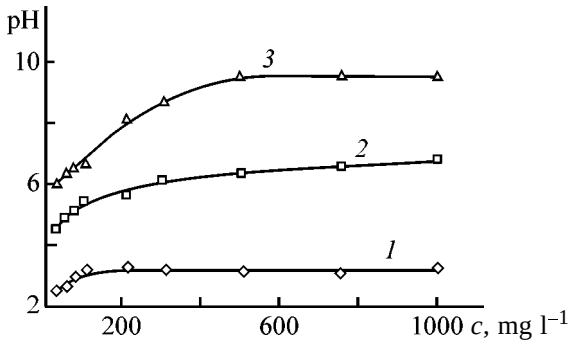

Fig. 2. pH of the onset of lignin retention on the filter as a function of lignin concentration c. NaCl concentration (M): (*1*) 0, (*2*) 0.1, and (*3*) 1.0; the same for Fig. 3.

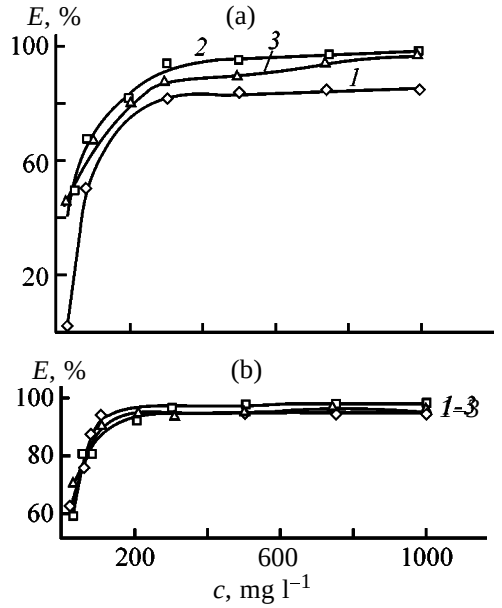

Fig. 3. Efficiency of KL recovery E (a) without filtration and (b) after filtration as a function of KL concentration c at pH 2.0.

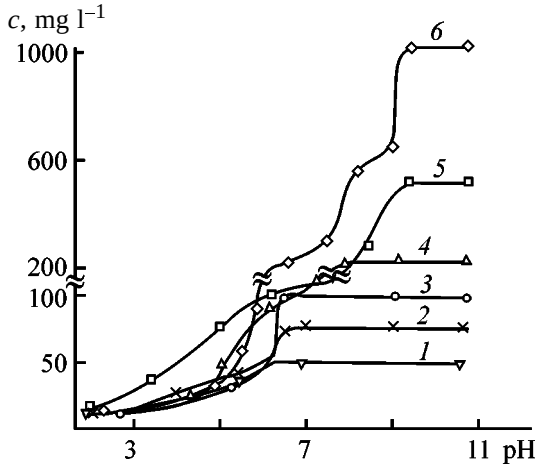

Fig. 4. Residual concentration of KL c as a function of pH after filtration. NaCl concentration 1 M. Initial concentration of KL (mg l^{-1}): (*1*) 50, (*2*) 75, (*3*) 100, (*4*) 200, (*5*) 500, and (*6*) 1000.

85% with the KL concentration increasing from 25 to 1000 mg l^{-1}.

An increase in the concentration of supporting electrolyte in the system also results in significant increase in the efficiency of KL recovery, which reaches 97.5% in 0.1 M NaCl solution at a KL concentration of 1000 mg l^{-1} (Fig. 3a). With separation of coagulated particles by filtration, the efficiency of KL recovery can reach 97–98% (Fig. 3b). It should be noted that in this case addition of supporting electrolyte does not noticeably affect the efficiency of KL recovery. The fact that 2–3% of KL remains in the solution is apparently due to the presence of a low-molecular-weight fraction in KL. This fraction remains aggregation-stable and cannot be recovered by coagulation even at the zero-charge point (pH 2) and high supporting electrolyte concentration.

The pH dependences of the residual concentration of KL (after filtration) at various initial concentrations of KL in the presence of supporting electrolyte NaCl (1 M) are presented in Fig. 4. These data show that, at the initial concentration of KL in the system of 500–1000 mg l^{-1}, in the range of pH 4.5–5.0, the residual concentrations of KL are 25–30 mg l^{-1}, i.e., the degree of its removal from the system is high. The results obtained can be of practical significance.

The natural suppoting electrolyte in the liquors from the kraft process of production of KL-containing cellulose is Na_2SO_4. Washing of cellulose to remove spent cooking liquor is an important process governing proper operation of the main shops and also the amount and degree of contamination of wastewater supplied to a treatment facility. The results of washing are usually estimated from the amount of alkali recalculated to the weight of sodium sulfate or from the degree of withdrawal of dry substances of black liquor from washing to regeneration. Therefore, local recovery of KL from the wastewater of a cooking and washing shop and return of KL in the form of precipitate to the total process flow for regeneration is environmentally and economically attractive.

Since the coagulating powers of NaCl and Na_2SO_4 for negatively charged particles (in our case, KL particles) differ insignificantly, data in Fig. 4 suggest that, with local treatment systems, KL can be recovered to a high degree from liquor-containing flows by their acidification. The higher the concentrations of KL and sodium sulfate, the higher is pH of coagulation recovery of KL. The KL precipitate recovered by this procedure can be supplied to soda-regeneration boilers together with evaporated black liquor, and clarified water with a minimal content of low-molecular-weight fraction of KL from the system of local treatment, to washing of cellulose or to the biological treatment station. After biological treatment, with consideration of dilution and purification, the concentration of organic substances in wastewater will be substantially decreased and will become lower than MPC.

CONCLUSIONS

(1) The pH of coagulation recovery of kraft lignin in filtration of its aqueous solution depends on the concentrations of kraft lignin and supporting electrolyte in the system. An increase in the concentrations

of kraft lignin and NaCl (and, hence, of other Na-containing salts) shifts pH of recovery of kraft lignin to higher values.

(2) Irrespective of the concentrations of kraft lignin and supporting electrolyte NaCl in the initial solution, approximately 2% of the initial amount of kraft lignin remains in the solution after its coagulation treatment. This is due to the presence of low-molecular-weight fraction of kraft lignin unaffected by coagulation recovery.

(3) The results obtained can be used for design of closed-loop systems for water supply in kraft procedure of cellulose production.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Colloid-Chemical Characteristics of Aqueous Alkaline Solutions of Organic Components of Pine and Birch Wood

E. Yu. Dem'yantseva and N. P. Lysogorskaya

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received October 15, 2001; in final form, March 2002

Abstract—The surface activity and sedimentation stability of organic substances passing into solution in kraft cooking of pine wood were studied. The data obtained were compared with the corresponding data characteristic of organic components of birch wood.

In kraft cooking of cellulose, resin and fatty acids contained in wood are saponified and pass into solution, black liquor, in the form of sodium salts. Recovery of the resulting sulfate soap from black liquors is governed by its salting-out and settling. Despite the growth of production of sulfate soap and tall oil, the coefficients of their recovery remain low (approximately 50%) [1]. Knowledge of the composition of solutions of wood organic substances passing into the liquor during cooking, their surface activity, and its dependence on the solution temperature can facilitate development of scientific principles of radically new efficient processes for recovery of secondary products formed in kraft cooking. Previously we proved that solutions of organic substances of birch wood in aqueous alkaline medium from kraft cooking are heterogeneous [2, 3]. In this connection, it was of interest to study the sedimentation stability, surface tension, and surface activity of solutions of organic substances of pine wood as a typical coniferous wood and birch as a typical deciduous wood, used in kraft cooking.

Solutions of wood organic substances had pH 12.7, which corresponds to pH of real liquors in kraft cooking. The selected temperature interval (363–293 K) and cooling time (40 min) corresponded to the stage of completion of kraft cooking and separation of black liquor. Precisely this stage is responsible for problems brought about by resins in pulp and paper production [4].

The initial samples of kraft lignin, resinous components, and carbohydrate derivatives were prepared by extraction from wood with various solvents. Lignin was extracted with dioxane, and resin, with diethyl ether. To prepare solutions for the study, the above substances were subjected to the traditional kraft cooking for 1 h at 443 K (liquor ratio 4 : 1). The solution of carbohydrate derivatives was prepared by kraft cooking of holocellulose preliminarily recovered from deresined wood by thorough delignification with peracetic acid. In addition to the solutions of individual components, we used the black liquor (a mixture of organic substances under consideration) recovered after kraft cooking of wood chips. The sedimentation stability of the systems at various temperatures was studied gravimetrically by monitoring of the residual concentration of the substances in the solution during cooling.

The concentration of organic substances of pine and birch wood in aqueous alkaline solution as a function of temperature is plotted in Fig. 1. As seen from Fig. 1a, the amount of dissolved pine wood resin decreases with temperature (curve *1*), which is due to a decrease in the resin solubility and formation of a sedimentation-unstable system. It also follows from Fig. 1 that the rate of sedimentation of the resin particles formed is low. This is due to small difference in the densities of resin particles and liquor, which are 0.95 and 1.15 g cm^{-3}, respectively.

The solutions of kraft lignin and carbohydrate derivatives are sedimentation-unstable. In the case of pine wood, the solutions are somewhat less stable than in the case of birch wood (Figs. 1a and 1b, curves *2* and *3*). The highest sedimentation instability is observed in the solutions of the mixture of organic substances. This is due to a larger size of their particles in comparison with the particle size of individual components [3]. The previously found aggregation instability of the mixture of substances is apparently caused by formation of adsorption ligno-

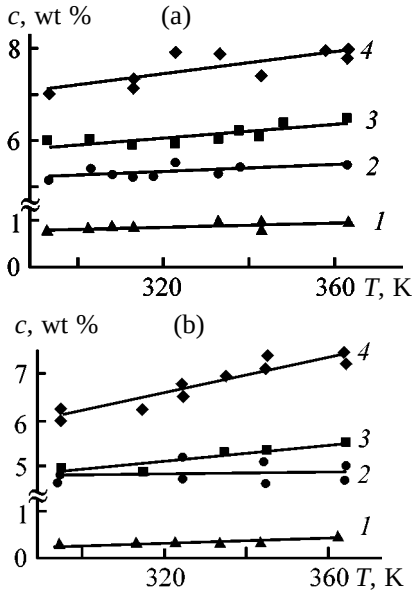

Fig. 1. Concentration of organic substances of (a) pine wood and (b) birch wood in aqueous alkaline solution c as a function of temperature T. (*1*) Resinous substances, (*2*) kraft lignin, (*3*) derivatives of carbohydrate fraction, and (*4*) mixture of organic substances; the same for Fig. 3.

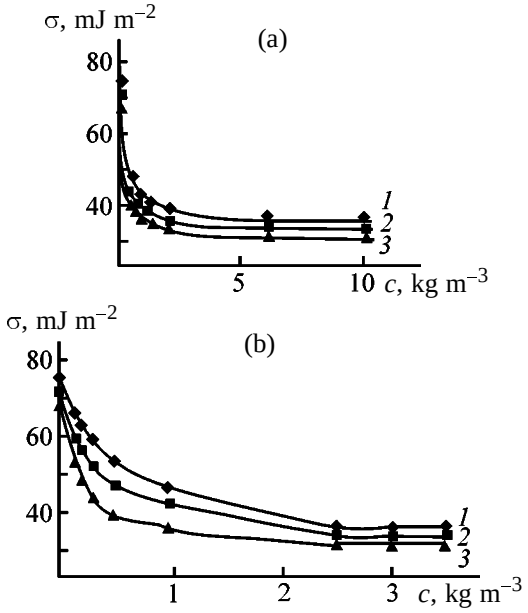

Fig. 2. Surface tension σ of solutions of resinous substances of (a) pine wood and (b) birch wood as a function of solution concentration c at various temperatures T. Temperature (K): (*1*) 293, (*2*) 313, and (*3*) 333.

carbohydrate complexes with resin in cooling of the solutions. It should be noted that the sedimentation instability of the mixture of organic components of birch wood is higher than that of pine wood.

To explain the data obtained, we measured the surface tension of the systems by the ring detachment method [5] at 293, 313, and 333 K, plotted the surface tension isotherms, and evaluated the surface activity G (mJ m kg^{-1}) of the substances by the formula [6]

$$G = \lim \partial\sigma/\partial c, \text{ at } c \to 0,$$

where σ is the surface tension (mJ m^{-2}), and c is the solution concentration (kg m^{-3}).

The surface tension isotherms of the solutions of resinous components of pine and birch wood are shown in Fig. 2. The shapes of the isothermal curves are similar to those of traditional surfactants. With increasing concentration, the surface tension decreases, and in this concentration range the solutions are homogeneous. From a certain concentration of the solutions, the surface tension does not vary noticeably (as for traditional surfactants), which suggests micelle formation and heterogeneity of the solutions. This allows evaluation of the fractions of the homogeneously and heterogeneously dissolved substance. In solutions of resinous substances of birch wood at the initial concentration of the substances of 0.5% and critical micelle concentration c_{CMC} 0.1%, the homogeneously dissolved fraction is 20%. For resinous substances of pine wood at the initial concentration of 1% and c_{CMC} 0.32%, it is 32%.

The surface activities evaluated from the surface tension isotherms are listed in the table.

The table shows that birch extractives are more surface-active. This may be due to high content of fatty acids and phenolic compounds (including sterols) having high surface activity. The surface activities of

Surface activity G of resinous components and kraft lignin in aqueous–alkaline solutions

T, K	G, mJ m kg^{-1}	
	resinous substances	kraft lignin
	Pine wood	
293	11.9	4.8
313	18.6	5.0
333	19.1	5.1
	Birch wood	
293	40.0	3.5
313	74.0	4.3
333	84.0	4.3

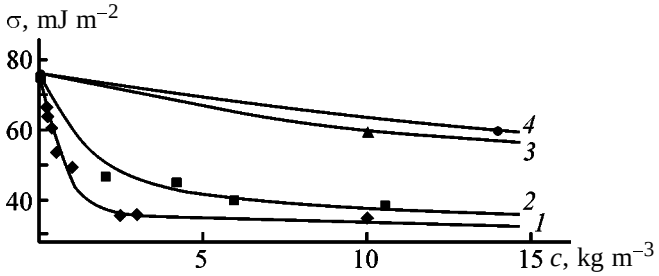

Fig. 3. Surface tension σ of solutions of organic substances of birch wood at 293 K as a function of solution concentration *c*.

pine wood extractives are lower by a factor of 3–4, which is due to lower surface activity of resinous acids mainly contained in the extractive components of pine wood [1]. High surface activity of resinous substances of birch wood suggests their higher hydrophobicity and, hence, higher tendency to aggregate in aqueous solutions. This can explain their higher sedimentation instability described above.

The surface tension isotherms of the other studied solutions of pine wood and birch wood substances are similar. Therefore, Fig. 3 presents the surface tension isotherms only for solutions of organic substances of birch wood. From the surface tension isotherms of kraft lignin solution (curve *2*), the fraction of homogeneously dissolved substance was estimated to be 28% for kraft lignin of birch (substance concentration 5.3%, c_{CMC} 1.5%) and 17% for kraft lignin of pine (substance concentration 6%, c_{KCM} 1%). According to data in the table, the surface activity of solution of kraft birch lignin is lower than that of pine wood, which suggests its higher hydrophilicity and, hence, higher sedimentation stability, as mentioned above.

A comparison of the surface tension isotherms of solutions of resinous components (Fig. 3, curve *1*) and kraft lignin (curve *2*) with the isotherm of the mixture of components (curve *4*) shows that, in the latter case, surface tension does not noticeably decrease. This may be due to the absence of free homogeneously dissolved fraction of resin and lignin, which can be adsorbed at the solution–air interface and decrease the surface tension. Hence, the molecular-dispersed soluble fractions of lignin and resinous substances, found when the individual components are dissolved (Figs. 2, 3), apparently, are not in the free state but are bonded to dispersed particles to form an adsorption complex. This confirms the presumed formation of an adsorption lignocarbohydrate complex with resin in aqueous alkaline solutions of the mixture of organic components.

CONCLUSIONS

(1) The mixture of organic substances of birch and pine wood is less sedimentation-stable in aqueous alkaline solutions than solutions of components of this mixture taken separately.

(2) The fractions of homogeneously and heterogeneously dissolved components in aqueous alkaline solutions were estimated to be 28 and 72% for kraft birch lignin, 17 and 83% for pine lignin, 20 and 80% for resinous substances of birch wood, and 32 and 68% for those of pine wood, respectively.

(3) The surface tension isotherms of solutions of the mixture of organic substances suggest their practical inactivity and possible formation of an adsorption lignocarbohydrate complex with the resin.

Received January 31, 2002

Abstract—The degree of aromaticity of petroleum tars, bitumens, and their fractions is characterized by infrared spectroscopy and X-ray diffraction.

Resinous-asphaltenic matter (RAM) of petroleum tars of West Siberian industrial oil occurs in the substrate as particles with a discrete size distribution [1]. However, their major amount (91%) forms aggregates 2.6–3.2 nm in size. There is only limited information on the supramolecular structure of RAM of bitumens of the indicated oil [2]. It was demonstrated that more structured quality bitumens are characterized by not only more compact chain-packed structure of asphaltenes, but also by closer packing of malthenes around the asphaltenic cores as a result of their higher aromaticity as compared to less thermostable (substandard) bitumens. Malthenes of petroleum tars and bitumens contain a broad spectrum of chemical compounds with different molecular weights, with the structures based on naphthene–aromatic cores with various alkyl substituents. Note that the major amounts of heteroatoms and metal complexes of the petroleum are concentrated in RAM.

Chromatographic group analysis [3] allows separation of petroleum tars and bitumens into cleaner cuts differing in their polarity [naphthenoparaffinic compounds (NPCs), monocycloaromatic compounds (MCACs), bicycloaromatic compounds (BCACs), toluene (TRs) and alcohol–toluene resins (ATRs)]. The supramolecular structure of tars is formed in the course of genesis of the crude oil, and that of bitumens, in the course of oxidation of tars and in the subsequent aging.

After fabrication of bitumen, its structured colloidal system gradually reaches the thermodynamic equilibrium characterized by the fixed distribution of RAM between the dispersed phase (asphaltenes) and the dispersion medium (malthenes). Malthenes of petroleum tars and bitumens contain polar (PCs) and nonpolar components (NPCs). The degree of their structurization is different. In this work we studied the supramolecular structure of the dispersed phase and dispersion medium in petroleum tars and related bitumens (quality and substandard), using chemical analysis, IR spectroscopy, and X-ray diffraction.

EXPERIMENTAL

In the work we studied two samples of petroleum tars (from AVT-6 unit of the KINEF Limited Liability Company) and two samples of bitumens obtained by oxidation of the indicated tar samples. The characteristics of the samples are given in Table 1. It is interesting that the bitumens obtained from the tar samples with a close relative viscosity demonstrate a considerably different thermal stability. One of them (BDUS 70/100) was classified with quality bitumens, as totally meeting the requirements of the technical specifications for bitumens with respect to the softening point, penetration Π_{25}, and elasticity before and after heating in a thin layer at 160°C for 5 h (this test simulates aging of bitumen). The second sample of bitumen (BDUS 60/90) is characterized by a lower thermal stability reflected in an intolerably low penetration and ductility after heat treatment.

Petroleum tars and bitumens were deasphalted by the cool and Holde's hot methods [4, 5] in a Soxhlet apparatus.

Polar components were extracted from malthenes of the tars and bitumens with DMF [6].

Group separation of polar and nonpolar components was performed on silica gel according to the

procedure described in [3]. The boundaries of chromatographic zones of the fractions (NPCs, MCACs, BCACs, TRs, and ATRs) were determined by the characteristic luminescence under UV light.

The infrared spectra were recorded on an IKS-29 instrument over the ranges 1100–1800 and 2600–3100 cm^{-1}. The samples were prepared as thin layers or 5% solutions in $CHCl_3$. We analyzed the bending and stretching vibration bands of C–H and C–C bonds in the CH_3 and CH_2 groups and aromatic fragments: the methylene groups in paraffin and six-membered naphthene structures were determined by the bands at 2850 and 2930 cm^{-1}; the bands at 1590 and 3050 cm^{-1} were assigned to the C–C and C–H vibrations in aromatic fragments, respectively; and also we monitored the intensities of the bands at 1378 and 1460 cm^{-1}, to estimate the content of the C–H bonds in the methyl and methylene groups, respectively.

Asphaltenes extracted from petroleum tars and bitumens, the tars and bitumens themselves, and their polar and nonpolar components were also studied by X-ray diffraction using a DRON-2 diffractometer (CuK_α, V = 8.9 kV, λ = 1.544 Å, T = 22°C). We used samples in the form of fine powders (no solvent), to prevent degradation of supramolecular structures. The X-ray diffraction patterns were processed as in [2].

Table 1 shows that the yields of malthenes from both tar samples are very close (88.62 and 89.55%). The same is true for the yields of polar and nonpolar components. After oxidation of the tars into bitumens BDUS 70/100 and BDUS 60/90, the yield of malthenes decreased to 79–80.7%, and the yield of asphaltenes increased.

While the asphaltene content in the initial tars was 10.45–11.38%, that in the corresponding bitumens ranged from 19.3 to 21%. The yield of polar components from the bitumens is higher by 4.3–6.3% than that from the corresponding tars. In this case, the oxidative conversion of the tar with the initial penetration of 390 mm × 0.1 and relative viscosity of 92 s was higher (sp 48°C) as compared to the sample with the initial penetration of 305 mm × 0.1 and relative viscosity of 89 s. The content of polar components in the bitumen having higher softening point increased by 1.8%. Bitumen BDUS 70/100 appeared to be thermostable, and BDUS 60/90, having lower thermal stability, appeared to be substandard (penetration and ductility of this bitumen considerably decreased after heat treatment of a thin layer at 160°C for 5 h).

The typical IR spectra of group components of the tars and bitumens studied are given in Figs. 1a–1e, and their parameters, in Table 2.

For nonpolar and polar components of the tar and bitumen, the ratios I_{1590}/I_{2930} and I_{3050}/I_{2930} increase

Asphaltenes of polar components of tar ($\prod_{25}$ = 390 mm × 0.1)	0.37	0.615	1.162	0.877	0.45	3.37	Native

on passing from MCACs to BCACs and then to TRs, suggesting increase in the degree of aromaticity in this series. Somewhat lower intensity ratio of the indicated bands in the IR spectra of ATRs is consistent with the results of direct determination of the contents of aromatic hydrogen and carbon by ^1H and ^{13}C NMR.

The interplanar spacings d_m in asphaltene blocks and micelles of bitumens, tars, and polar and nonpolar components were estimated according to the procedure described in [7]:

$$d_m = 0.5\lambda/\sin\theta_{002},$$

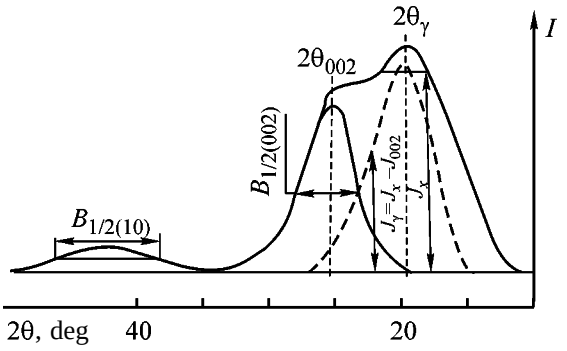

Fig. 2. Typical X-ray diffraction pattern of asphaltenes from bitumen BDUS 70/100 (sp 46°C). (*I*) Peak intensity and (2θ) Bragg angle.

where λ is the wavelength (Å) of the X-ray radiation used.

We analyzed the peak of amorphous carbon at $2\theta_\gamma$ = 18° (Fig. 2). This peak is due to scattering on spatially disordered carbon atoms and heteroatoms. Asphaltene and resin particles forming the ordered stack structure [8] give two broad peaks in the X-ray diffraction patter: a weak peak (10) at $2\theta_{10}$ = 42° due to reflection from planar aromatic layers and also a peak (002) at $2\theta_{002}$ = 21.5°–24°.

From the X-ray diffraction patterns, we estimated [7] the regular spacings between paraffin fragments of the molecules $d_\gamma = 0.625\lambda/\sin\theta_\gamma$ and also the interplanar spacing d_m, size of the condensed aromatic layers L_a, thickness of the stack of aromatic layers L_s, and number of the aromatic layers in the stack M.

From the measured peak halfwidths $B_{1/2}(10)$ and $B_{1/2}(002)$, expressed in the $\sin\theta/\lambda$ units, using the Scherrer equations, we estimated the mean diameter of planar molecular fragments in the stack $L_a = 0.92\,B_{1/2}(10)$ and the mean thickness of the stack $L_c = 0.45\,B_{1/2}(002)$. The mean number of the layers in the stack was estimated as

$$M = (L_c/d_m) + 1.$$

Also we measured the areas under individual peaks (002) and γ (A_{002} and A_γ, respectively) and estimated the aromaticity factor f_{ar} as $f_{ar} = A_{002}/(A_{002} + A_\gamma)$.

The estimated results are summarized in Table 3. It is seen that all the samples studied are considerably different in the parameters of the asphaltene stacks. Asphaltenes, malthenes, and bitumen with sp 46°C appeared to be the most ordered. It is the latter sample that demonstrates the maximal cohesion, which is reflected in the minimal change in its ductility after heat treatment.

CONCLUSIONS

(1) Infrared spectroscopy was used to quantitatively estimate the degree of aromaticity of various polar and nonpolar fractions of malthenes in petroleum tar and quality thermostable bitumen (KINEF Limited Liability Company). The aromaticity increases in the order monocycloaromatic compounds < bicycloaromatic compounds < toluene resins < alcohol–toluene resins.

(2) Parameters of the supramolecular structure of asphaltenes, tars, bitumens, and polar and nonpolar fractions of malthenes were obtained from the X-ray diffraction data. The samples studied are distinguished by parameters of the stack structure of asphaltenes. Asphaltenes, malthenes, and quality bitumen having the maximal cohesion and high thermal stability (minimal change in $\prod_{25}$ and D_{25} after heating under standard conditions) have the most ordered structure.

Abstract—Distribution of C, H, N, S, and O among polar and nonpolar components of malthenes and asphaltenes of initial tars and quality and substandard bitumens obtained from them is studied by chemical and elemental analyses and ^{1}H and ^{13}C NMR.

Improving quality of road asphalts is a topical problem [1]. The heaviest supplier of this material in the Russian Northwest is the KINEF Limited Liability Company refining West Siberian industrial oil. At present, this company manufactures BDUS road bitumens having higher quality as compared to BND tars. However, along with thermostable quality road tars, substandard products are sometimes obtained from particular batches of petroleum tars, which do not meet the requirements of the technical specifications with respect to the thermal stability [ductility of a thin layer of the product after heating at 160°C for 5 h decreases to an intolerably low value ($D_{a.h.}$<100 cm)].

Therefore, the goal of this work was to reveal what characteristics of the initial petroleum tars and resulting road bitumens and their fractions (polar and nonpolar components of malthenes and asphaltenes) may be responsible for the observed differences in the quality of the products.

EXPERIMENTAL

Elemental (C, H, N) analysis was carried out on a Perkin–Elmer-240 analyzer. Sulfur was determined by the Schoeniger microanalysis method.

The ^{1}H NMR spectra were recorded on a Tesla BS-497 instrument (working frequency 100 MHz) against internal HMDS.

Distribution of carbon and hydrogen among fractions of petroleum and road asphalts and polar and nonpolar components of malthenes was studied by ^{1}H and ^{13}C NMR using a Bruker AM-500 instrument (working frequencies 500 and 125 MHz, respectively) at room temperature. In recording ^{1}H NMR spectra, we used 5-μs pulses (30°) (relaxation delay between pulses 15 s; number of scans 32).

The ^{13}C NMR spectra were recorded with inverse gated proton decoupling [to reduce the nuclear Overhauser effect, we used 5-μs pulses (60°) and relaxation delay of 10 s (number of scans 6000)].

In the work, we studied two samples of petroleum tars (from AVT-6 unit of the KINEF Limited Liability Company) and two samples of bitumens obtained by oxidation of the indicated tar samples. In addition, four BDUS samples (two quality and two substandard) were studied by ^{1}H and ^{13}C NMR. The differences between the bitumen samples were that substandard bitumens did not meet the requirements of the technical specifications for bitumens with respect to the ductility after heating in a thin layer at 160°C for 5 h (this test simulates aging of bitumen).

Characteristics of the samples studied were as follows: tar, penetration Π_{25} = 305 mm × 0.1, relative viscosity 89 s; tar, Π_{25} = 390 mm × 0.1, relative viscosity 92 s; BDUS 70/100, Π_{25} = 84 mm × 0.1, sp* 46°C, D_{25} = 140 cm; BDUS 60/90, Π_{25} = 78 mm × 0.1, sp 48°C, D_{25} >150 cm; quality BDUS 70/100, sp 45°C, D_{25} = 147 cm, Π_{25} = 97 mm × 0.1, Π_{25ah}** = 74% of the initial Π_{25}, D_{25ah} = 125 cm; quality BDUS 100/130, sp 43°C, D_{25} = 148 cm, Π_{25} = 103 mm × 0.1, Π_{25ah} = 68% of the initial Π_{25}, D_{25ah} = 140 cm; substandard BDUS 70/100, sp 47°C, D_{25} = 131 cm, Π_{25} = 100 mm × 0.1, Π_{25ah} = 60% of the initial Π_{25}, D_{25ah} = 55 cm; and substandard BDUS 100/130, sp 45°C, D_{25} = 146 cm, Π_{25} =

* Ring-and-ball softening point.
** After heating in a thin layer at 160°C for 5 h.

Asphaltenes of nonpolar components of tar (Π_{25} = 390 mm × 0.1)	85.54	7.74	0.75	2.62	3.35	1.06

103 mm × 0.1, Π_{25ah} = 67% of the initial Π_{25}, D_{25ah} = 49 cm.

Asphaltenes were separated from the tar and bitumen samples by two methods: exhaustive cool precipitation with petroleum ether and the Holde's hot method in a Soxhlet apparatus [2].

After precipitation of asphaltenes, malthenes of tars and bitumens were separated into polar and nonpolar fractions using DMF [3].

Group separation of malthenes of tars and of the corresponding bitumens into naphtheno–paraffinic compounds (NPCs), monocycloaromatic compounds (MCACs), bicycloaromatic compounds (BCACs) or polycycloaromatic compounds (PCACs), and toluene (TRs) and alcohol–toluene resins (ATRs) was carried out by the procedure described in [4]. The boundaries of chromatographic zones of the indicated fractions were determined by the characteristic luminescence under UV light.

Table 1 shows that the H/C atomic ratio regularly decreases in the order nonpolar components of bitumen (or tar) > tar (or bitumen) > polar components of tar (or bitumen) > asphaltenes. Both tar samples and the corresponding bitumens are characterized by close contents of sulfur and oxygen, but considerably different nitrogen content.

The maximal content of heteroatoms (S, N, O) was found in native asphaltenes extracted from tar or bitumen, and also in heavy fractions of the polar and nonpolar components of the bitumens and tars. It is worth noting that the distribution of the heteroatoms in the polar and nonpolar components of tars and bitumens differs from that in the initial products. The structuring components (asphaltenes) of BDUS 70/100 thermostable bitumen are characterized by the maximal oxygen content (5.68%) and increased contents of sulfur (2.8%) and nitrogen (0.94%) (Table 1).

Table 2 shows that the elemental composition of asphaltenes extracted from the polar and nonpolar components of tars and bitumens differs essentially in the content of heteroatoms (content of heteroatoms in the polar components is higher than that in the nonpolar components).

It is seen that various group components of the tars

and bitumens differ in the content of not only the base elements (C and H), but also heteroatoms (O, S, N). The H/C atomic ratio regularly decreases in the order NPCs > MCACs > BCACs > TRs ~ ATRs for both the tars and bitumens. Sulfur and oxygen are distributed among all the group components of the tars and bitumens. The sulfur and oxygen contents in the polar components of the tars and the corresponding bitumens are higher than those in the nonpolar components. The oxygen content in resins (TRs and ATRs) is always higher than that in the oil fractions (NPCs, MCACs, and BCACs).

Nitrogen is concentrated essentially in the polar and nonpolar components (BCAs, TRs, and ATRs).

We found some differences in the elemental composition of particular fractions of the polar and nonpolar components of the thermostable (BDUS 70/100) and less thermostable bitumens (BDUS 60/90). In particular, NPCs of BDUS 70/100 contain no oxygen. They contain more sulfur than NPCs of BDUS 60/90. Naphthenoparaffinic compounds of the nonpolar components of BDUS 60/90, on the contrary, contain 2.83% oxygen. Furthermore, the H/C atomic ratios in NPCs of BDUS 70/100 and BDUS 60/90 is also different (1.63 and 1.53, respectively).

MCACs of the nonpolar components of the bitumens under comparison are characterized by similar sulfur and oxygen contents, but different H/C.

The H and O contents in TRs and ATRs of the polar components of the bitumens are comparable (Table 2).

Comparison of the group components of the polar compounds of the bitumens in hand also demonstrates differences not only in the H/C atomic ratio for MCACs, BCACs, and ATRs, but also in the distribution of nitrogen, sulfur, and oxygen among these components. Therefore, we observed differences in the elemental composition not only for particular fractions of the polar and nonpolar components of the initial tars, but also for the bitumens obtained from them. Without question, when interpreting data on the stability of colloidal structures of tars and bitumens, it is necessary to take into account the donor–acceptor power of heteroatoms and microelements as well as the contribution of this factor to the formation of thermostable structures in addition to the aromaticity of asphaltenes, resins, and oils.

In bitumens and tars having close chemical compositions, the course of structurization is governed by such specific features of their structure as the amount, location, and length of alkyl chains; the content of aromatic and naphthenic fragments; the type of condensation of the rings (*peri* or *cata* condensation); the arrangement of heteroatoms and their bonding to microelements (metals); etc.

The colloidal stability of bitumens and their physicochemical properties are controlled not only by the proportion of oils, resins, and asphaltenes in them, but also by their chemical nature. The presence of a fairly large amount of the oil fraction characterized by high carbon content in cyclic structures and aromaticity imparts the colloidal stability and desirable physicochemical characteristics to bitumens. However, in this case they demonstrate relatively higher temperature sensitivity and low elasticity. In the case of an insufficient content of the oil fraction, or when this fraction is of essentially naphtheno paraffinic nature, the colloidal stability of bitumen decreases as well as its ductility and mechanical characteristics.

The condition of the bituminous colloidal system depends not only on the asphaltene to malthene ratio, but also on the aromaticity of asphaltenes (C/H ratio) and solvency of malthenes K_s:

$$K_s = C_{ar} + 1/3\,C_n,$$

where C_{ar} and C_n are the carbon contents (%) in the aromatic and naphthenic structures, respectively.

The stability of the bitumen structure decreases with increasing K_s of the oil fraction and decreasing asphaltene/resin ratio.

The chemical features of the dispersion medium and dispersed phase are characterized by the degree of dispersion D:

$$D = (B + C)/(A + E),$$

where A, E, B, and C are the contents (%) of asphaltenes, saturated and cyclic hydrocarbons, and resins, respectively.

It follows from this relationship that, the higher the asphaltene content in the system (to certain limit), the more ordered the system. In aging initiated by thermal effects, the colloidal state of bitumen changes through aggregation of dispersed particles (free energy of the system decreases). The evolution occurs from a sol with random distribution of particles via a structured sol to a gel. In this case, the orientation ordering of colloid particles increases, and the free energy at the interface decreases. As aging proceeds, micellar aggregates become more compact, the interparticle interaction increases, the volume of the system de-

Table 3. Intensity of signals in the ^{1}H NMR spectra of nonpolar and polar components of bitumens and tars

	ATRs	9.0	23.6	45.8	21.6

creases, and the bitumen hardness increases; the elasticity passes through a maximum.

Carbon and hydrogen are the base elements of tars and bitumens, forming the skeletons of their structural fragments (oils, resins, and asphaltenes).

The ^{1}H and ^{13}C NMR data are given in Tables 3–5. In the ^{1}H NMR spectra of tar, bitumen, polar and nonpolar components of asphaltenes, and particular fractions of the polar and nonpolar components, we observed four groups of signals assigned to hydrogen atoms of the aromatic rings (H_{ar}, 6.8–9.2 ppm); hydrogen atoms of CH, CH_2, and CH_3 groups located in the α-position against the aromatic ring (H_α, 2–3.2 ppm); hydrogen atoms in CH_2 and CH groups of the alkyl chains and naphthenic rings located in positions more distant than H_α (H_β, 1.05–2 ppm); and finally, hydrogen atoms in CH_3 groups located in positions more distant than H_α and H_β (H_γ, 0.5–1.0 ppm).

As seen, the quality bitumens and the corresponding tars are characterized by higher degree of aromaticity, as demonstrated by both H_{ar} and the parameter H_{ar}/H_{al}, which is also consistent with data on C_{ar}/C_{al}. Table 4 shows that the quality of bitumen correlates with that of the initial tar. For example, the aromatic hydrogen contents in BDUS 70/100 (sp 46°C) and the initial tar were determined to be 5.9 and 5.5%, respectively. The aromatic hydrogen content in BDUS 60/90 [second after BDUS 70/100 in performance characteristics (thermal stability)] is 5.35%; and that in the initial tar, 3.6%, i.e., the degree of aromaticity of the tar and bitumen is lower in the second case. The nonpolar components of the tar and bitumen are characterized by lower H_{ar} (Table 4). On the contrary, the polar components and asphaltenes are characterized by the highest hydrogen content in the aromatic structures. Comparison of H/C in asphaltenes of the tars and bitumens shows that data on the aromatic hydrogen obtained from the ^{1}H NMR spectra (Table 3) are overestimated. This also follows from results of direct determination of the aromatic carbon in asphaltenes by ^{13}C NMR.

Table 4. Distribution of hydrogen and carbon among structural groups by ^{1}H NMR data

Evidently, in the ^{1}H NMR spectra (Fig. 1a), the broad signal of the aromatic hydrogen H_{ar} in the polar components and asphaltenes is overlapped with the signal of hydrogen atoms in heteroatomic fragments (pyrrole rings, metal porphyrin complexes, etc.). In the ^{13}C NMR spectra of the tars and bitumens (Fig. 1b), we observed two groups of signals assigned to carbon atoms of aromatic rings (110–155 ppm) and carbon atoms of methylene groups of six-membered naphthenes with one or two alkyl substituents or condensed with aromatic (heteroaromatic) or naphthenic rings (31.94–32.07 ppm). The range 29.4–30.13 ppm

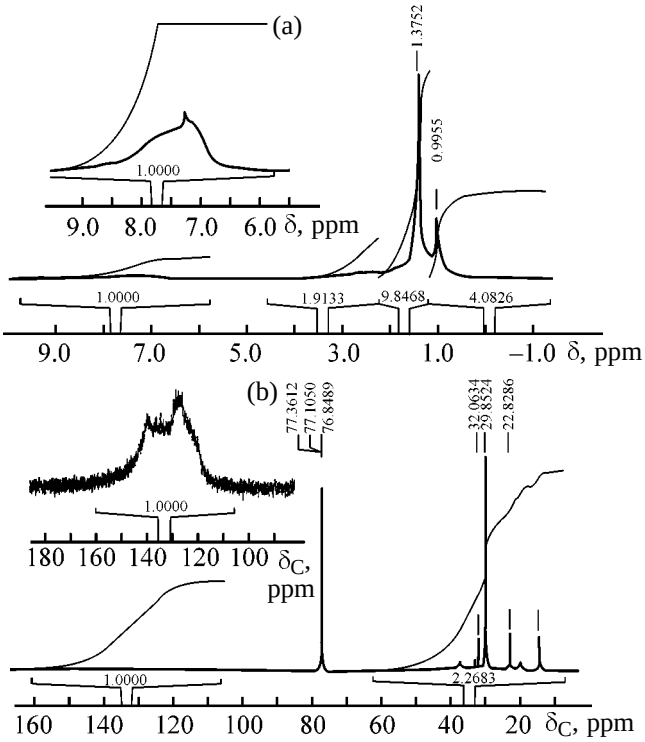

Fig. 1. Typical (a) ^{1}H and (b) ^{13}C NMR spectra of quality bitumen BDUS 70/100 (sp 46°C).

corresponds to the resonance of ^{13}C in the methylene groups of six-membered naphthene rings and distant (at least γ) CH_3 groups of long aliphatic chains. Signals of the methylene groups of aliphatic chains are found at 22.69–22.82 ppm, and those of methyl groups, at 14.11–14.22 ppm. These signals can overlap with signals of the methylene groups at the tertiary C–H bonds in hydroaromatic rings.

The carbon distribution among the structural groups is given in Table 5. The fact that BDUS 60/90 is inferior in quality is due to its lower aromaticity (C_{ar} = 29.2%) as compared to BDUS 70/100 (C_{ar} = 31.1%). Furthermore, the initial tar from which BDUS 60/90 was obtained is characterized by higher oil/resin ratio in both the polar and nonpolar components, and also by lower content of TRs relative to ATRs. It should be pointed out that we observed some differences in the degree of aromaticity of the polar and nonpolar components of the tars and bitumens in all the fractions (MCACs, BCACs, TRs, and ATRs). Also some differences were found in the NPC content in the polar and nonpolar components of both the tars and bitumens studied.

CONCLUSIONS

(1) Various group components of the tars and bitumens differ in the content of not only the base elements (C and H), but also heteroatoms (O, N, S). The H/C atomic ratio decreases in the order naphthenoparaffinic compounds > monocycloaromatic compounds > bicycloaromatic compounds > toluene resins > alcohol–toluene resins for both the tars and bitumens.

(2) The contents of sulfur and oxygen in the polar components of tars and the corresponding bitumens are higher than those in the nonpolar components. The oxygen content in the resinous fraction (toluene and alcohol–toluene resins) is always higher as compared to the oil fractions (naphthenoparaffinic, monocycloaromatic, and bicycloaromatic compounds).

(3) Nitrogen is concentrated essentially in the polar and nonpolar components of bicycloaromatic compounds and alcohol–toluene resins.

(4) Monocycloaromatic compounds of the nonpolar components of BDUS 70/100 quality bitumen and BDUS 60/90 substandard bitumen are characterized by similar sulfur and oxygen contents, but different H/C.

(5) The degree of aromaticity of BDUS quality bitumens and the tars from which these bitumens were obtained is higher than that of substandard (less thermostable) products.

(6) The fact that BDUS 60/90 is inferior in quality to BDUS 70/100 is due to its lower aromaticity (C_{ar} = 29.2 and 31.1%, respectively). The initial tar from which BDUS 60/90 was obtained is characterized by higher oil/resin ratio in both the polar and nonpolar components, and also by lower content of toluene resins relative to alcohol–toluene resins.

(7) Some differences were found in the degree of aromaticity in all the fractions (MCACs, BCACs, TRs, and ATRs) of the polar and nonpolar components of the tars and bitumens. Also some differences were observed in the content of naphthenoparaffinic compounds in the polar and nonpolar components of both the initial tars and resulting quality and substandard bitumens.

Abstract—X-ray phase analysis was applied to study the phase composition of products formed in reaction between components of silicophosphate solutions obtained on the basis of potassium water glass. The temperature ranges of phase transformations of chemical compounds, occurring in thermal treatment of gels of various compositions, were established.

Low-melting systems containing lead oxide are used in most cases in manufacture of decorative coatings [1, 2]. However, the high toxicity and cost of lead make necessary a search for other glass-forming systems, among which the silicophosphate system shows the most promise [3].

The sol–gel method based on the use of organosilicon compounds is widely used for obtaining glassy coatings [4, 5]. Much fewer papers have been concerned with synthesis of glassy coatings based on soluble silicates or silicic acid sols [6, 7].

The primary stage in using the sol–gel method for obtaining glasses is preparation of a homogeneous solution capable of gel formation. In doing so, it is very important that the forming gels and powders obtained from them should contain low-melting compounds, which do not raise the temperature of melt formation.

The aim of this study was to analyze the processes occurring in formulating a silicate colloid solution based on potassium water glass and to determine the composition of the gel powder used for obtaining decorative coatings in the system K_2O–Al_2O_3–B_2O_3–SiO_2–P_2O_5 and phase transformations of this powder upon heating.

As solution components we used potassium water glass with the silicate ratio M = 3.5, potassium aluminate solution, ammonium hydrogen phosphate $(NH_4)_2 \cdot HPO_4$, boric acid H_3BO_3 of pure grade, and potassium hydroxide KOH of analytically pure grade. The potassium aluminate solution was prepared by dissolving powdered aluminum in an alkali solution.

The products of possible chemical reactions between the solution components were identified by X-ray phase analysis (XPA) on a DRON-3 diffractometer with CuK_α radiation.

Thermal analysis of the powders was made on an MOM Q-1500D derivatograph (Hungary).

The dried water glass is X-ray amorphous. In heating of a powder prepared from the water glass, an exothermic effect is observed, peaked at 180°C (Fig. 1, curve *1*). The X-ray pattern of the resulting product (Fig. 2, curve *1*) and the data of [8] allow its identification as $K_2O \cdot 4SiO_2 \cdot H_2O$ ($KHSi_2O_5$). At 220°C, an intense endothermic effect is observed, which is related to release of adsorbed and molecular water [7, 8].

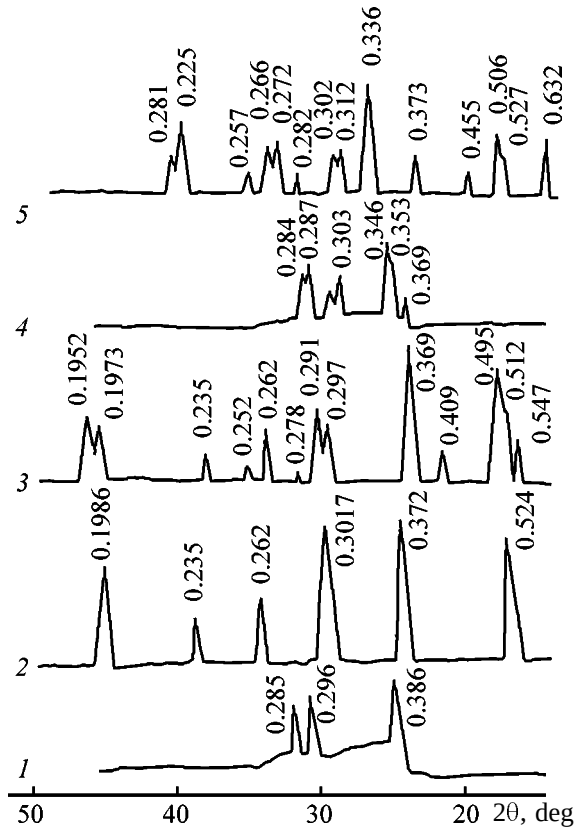

Fig. 2. X-ray diffraction patterns of gel powders. (2θ) Bragg angle. System: (*1*) K_2O–SiO_2, (*2*) K_2O–SiO_2–P_2O_5, (*3*, *4*) K_2O–SiO_2–P_2O_5–Al_2O_3, and (*5*) K_2O–SiO_2–P_2O_5–B_2O_3. Thermal treatment temperature (°C): (*1*) 180, (*2*, *3*) 50, (*4*) 280, and (*5*) 380.

On adding an diammonium hydrogen phosphate solution to water glass, a gel is formed, in agreement with the results of [8]. PO_4^{3-}, K^+, and NH_4^+ ions remain in solution. A crystalline phase is formed in gel drying. This phase is presumably the compound $(0.73NH_4H_2PO_4)\cdot(0.27KH_2PO_4)$ (*d*/*n* 0.524, 0.372, 0.3017, 0.262, 0.235, 0.1986 nm; Fig. 2, curve *2*). Similar lines, characteristic of this compound, are presented in [9]. The presence of potassium dihydrogen phosphate indicates that water glass reacts with $(NH_4)_2HPO_4$. The change in the degree of protonation of phosphate ions in the final products can be accounted for by the occurrence at 50°C of the reaction $(NH_4)_2HPO_4 \rightleftarrows NH_{3(gas)} + NH_4H_2PO_{4(cryst)}$ [10, 11]. No crystalline silicates were found.

To adjust the content of potassium oxide in the system formed by water glass and diammonium hydrogen phosphate, a KOH solution was added. As a result, NH_3 and KH_2PO_4 were formed. In heating (Fig. 1, curve *2*), two endothermic effects are observed at 260 and 640°C, and also an exothermic effect at 490°C. The possible reason for the appearance of the endothermic effect at 260°C is dehydration of the gel powder, and also melting of KH_2PO_4 (T_m = 252.8°C) to give dihydrogen pyrophosphate $K_2H_2P_2O_7$. In further heating of the powder, further dehydration $K_2H_2P_2O_7 \rightarrow 2KPO_3 + H_2O$ occurs at 320–340°C. The $(0.73NH_4H_2PO_4)\cdot(0.27KH_2PO_4)$ phase melts in the range 170–240°C. A minor exothermic effect peaked at 490°C is probably due to partial crystallization of ammonium polyphosphates [12]. The endothermic effect at 640°C can be accounted for by a polymorphic transition of Kurrol's salt KPO_3, melting at 800°C.

Addition of an H_3BO_3 solution to the system $K_2O\cdot 3.5SiO_2$–KOH–$(NH_4)_2HPO_4$ does not change the situation significantly. A single crystalline compound was found in the powder of the mixture obtained. Thermal treatment leads to the appearance in the DTA curve (Fig. 1, curve *3*) of peaks corresponding to an endothermic effect at 275°C and exothermic effect at 380°C. The endothermic effect is due to dehydration processes. Also, H_3BO_3 present in the powder decomposes at 185°C [13]. The appearance of the exothermic effect can be attributed to the formation of BPO_4, confirmed by XPA data (Fig. 2, curve *5*; *d*/*n* 0.632, 0.527, 0.506, 0.455, 0.373, 0.336, 0.312, 0.302, 0.272, 0.266, 0.225, 0.221 nm).

To enhance the chemical stability of the coatings, aluminum ions were introduced into the system $K_2O\cdot 3.5SiO_2$–KOH–$(NH_4)_2HPO_4$. It is known [8] that aluminum salts are completely hydrolyzed in an excess of an alkaline silicate. These reagents form flaky precipitates, composed, in all probability, of aluminum hydroxide. To prevent precipitation, it has been proposed to introduce aluminum in the form of an alkali metal aluminate, which is stable in a strongly alkaline medium [6]. That is why $Al(OH)_3$ additionally precipitates, in accordance with the reaction $K[Al(OH)_4] \rightarrow KOH + Al(OH)_3\downarrow$, after precipitation of H_4SiO_4 and introduction of potassium aluminate. Two crystalline phases, KH_2PO_4 and $AlPO_4\cdot(1.1–1.3)H_2O$ (Fig. 2, curve *3*; *d*/*n* 0.547, 0.512, 0.495, 0.369, 0.278 nm) were identified in a dried gel. In the course of thermal treatment (Fig. 1, curve *4*), an endothermic effect is observed at 280°C, which is due to the same processes as those in the three-component system. A crystalline phase of the composition $3Al_2O_3\cdot 2SiO_2$ (Fig. 2, curve *4*; *d*/*n* 0.369, 0.353, 0.346, 0.297, 0.284 nm) was identified at this temperature.

In industrial manufacture of coatings, account should be taken of both the process parameters of their formation (melt appearance temperature, adhe-

sion) and service characteristics (chemical stability, thermal coefficient of linear expansion).

Of particular interest in this regard is the system $K_2O \cdot 3.5SiO_2$–KOH–$(NH_4)_2HPO_4$–H_3BO_3–$K[Al(OH)_4]$. The chemical reactions occurring in this system in the course of its preparation are similar to those considered above. Only a single crystalline phase, $(0.73NH_4H_2PO_4) \cdot (0.27KH_2PO_4)$, was found in dried gel powder. The DTA curve (Fig. 1, curve *5*) shows exothermic peaks at 140 and 470°C and an intense endothermic peak at 270°C. An X-ray phase analysis confirmed that $(0.73NH_4H_2PO_4) \cdot (0.27KH_2PO_4)$ and KH_2PO_4 are present in the powder at 140°C, with the latter compound crystallized in heating of the starting powder. On raising temperature to above 270°C, the powder becomes totally X-ray amorphous.

Thus, we found that compounds melting below 270°C are formed in the prepared gels of the three-component system in drying. In four-component systems including boric acid and potassium aluminate, high-melting compounds $(0.73NH_4H_2PO_4) \cdot (0.27KH_2PO_4)$ and KH_2PO_4 are formed. In the system K_2O–Al_2O_3–B_2O_3–SiO_2–P_2O_5, low-melting compounds are formed, which favor appearance of the liquid phase at 300°C. The results obtained demonstrate that it is advisable to use solutions of this system for preparing low-melting decorative glassy coatings.

Description of the Boiling Curve on the Basis of State Parameters of a Single Point

A. I. Vitvitskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 28, 2002

Abstract—It is shown for the example of 40 substances that the normal boiling point can be used for approximately describing the entire boiling curve from the triple to critical point.

Data on the equilibrium in single-component two-phase systems gas–liquid are commonly represented in phase diagrams as a boiling curve in the coordinates temperature T (K)–pressure P (Pa) [1, 2]. For all substances, the boiling curve is limited, on the one hand, by the critical state parameters, T_c and P_c, beyond which the two-phase system becomes a single-phase one, and, on the other, by the triple point parameters, T_t and P_t, at which a third phase (crystalline) appears, since boiling, sublimation, and melting curves all run into the triple point. The boiling curve characterizes the temperature dependence of the saturated vapor pressure P_{sv} (Pa) of a substance or the dependence of the boiling point of a substance $T = T_b$ on external pressure P, equal to P_{sv}.

As a rule (except in the case of As, CO_2, C_2H_2, and some other substances [2]), the boiling curve has a point with parameters $P = P_{sv} = P_{st}$ and $T = T_b = T_{b.st}$ (P_{st} is the standard pressure equal to 101 325 Pa; $T_{b.st}$ is the boiling point under standard pressure or normal boiling point), which lies between the triple point (with the parameters $T = T_b = T_t$ and $P = P_{sv} = P_t$) and the critical point ($T = T_b = T_{cr}$ and $P = P_{sv} = P_{cr}$). In a phase diagram plotted in the $\ln P$–$1/T$ coordinates, the boiling, sublimation, and melting curves are virtually straight lines running into the triple point.

The aim of this paper is to demonstrate the possibility of using the point with the parameters $T = T_{b.st}$ and $P = P_{st}$ for describing the entire boiling curve.

It is noteworthy that there is no zero for the parameters P and T in the $\ln P$ and $1/T$ scales. Therefore, it is appropriate to introduce certain constant (initial, standard) state parameters, e.g., P_{st} = 101 325 Pa and T_0 = 298.15 K. Then, representing the temperature dependence of the saturated vapor pressure as an equation of the type

$$\ln(P_{sv}/P_{st}) = A - \Delta H_b/RT \quad (1)$$

[where the dimensionless coefficient A and the heat of boiling ΔH_b (J mol^{-1}) are constant over the entire range of state parameters, from the triple to the critical point; and R is the universal gas constant equal to 8.315 J mol^{-1} K^{-1}], we obtain that, at $\ln(P_{sv}/P_{st}) = 0$ ($P_{sv} = P_{st}$), the heat of boiling (J mol^{-1}) is related for many substances to the normal boiling temperature by the equation

$$\Delta H_b = RT_{b.st}[10.36 + \ln(T_{b.st}/T_0)]. \quad (2)$$

Table 1 lists the results obtained in calculating by Eq. (2) the ΔH_b value for 40 substances differing by a factor of more than 100 in normal boiling points and heats of boiling (e.g., Ne and Au) and by a factor of 62 in the number of atoms in a molecule (from monoatomic molecules to $C_{20}H_{42}$). The average calculation error was 2.3% (for 40 substances) at the maximum error of 6.4% for CH_4.

Using Eq. (2), we can eliminate the heat of boiling in equation of the type (1):

$$\ln(P_{sv}/P_{st}) = [10.36 + \ln(T_{b.st}/T_0)](1 - T_{b.st}/T). \quad (3)$$

Solving Eq. (3) for T, we can obtain the dependence of the boiling point $T_b = T$ on the external pressure P, equal to P_{sv}:

$$T_b = T_{b.st}\left(1 - \frac{\ln(P/P_{st})}{10.36 + \ln(T_{b.st}/T_0)}\right)^{-1}. \quad (4)$$

Table 2 presents the results obtained in calculating by

* State parameters below the critical point according to [4].

Eq. (4) the T_b values at extreme points of the boiling curve (at $P = P_t$ and $P = P_{cr}$), at which the calculation error must be the highest. The average calculation error for 20 substances ($T_{b.st}$ value is presented in Table 1) was 1.8% (for 40 values) at the maximum error of 6.2% for HF at the critical point. The average error of the values in Table 2 can be diminished by virtually a factor of 2 by taking the dimensionless coefficient in Eq. (4) to be 10.6, instead of 10.36.

CONCLUSION

The normal boiling point of substances can be used to describe approximately the entire boiling curve in the range of state parameters from the triple to the critical point.

Abstract—The features of sorption of ethanol, isopropanol, butanol, isobutanol, and *tert*-butanol with activated charcoals under static conditions were studied.

Lower alcohols are widely used in paint and varnish industry, as chemicals, in production of phenylsiloxanes, photographic films, ascorbic acid, and in other branches [1, 2]. Butanol, isobutanol, *tert*-butanol, and isopropanol are environmental pollutants.

Here we report on the sorption of lower alcohols on activated charcoals produced from birch wood and from a blend of oak and beech wood (Kabardino-Balkar charcoal).[1] The main characteristics of the charcoals were determined previously [3] and are listed in the table.

The characteristics of the sorbents listed in the table demonstrate advantages of birch charcoal. It has lower moisture content, larger pore volume, and higher sorption capacity for iodine. However, in subsequent experiments it was noted that birch charcoal has lower mechanical strength than charcoal produced from a blend of oak and beech wood.

In this work, we studied sorption of butanol, *tert*-butanol, isopropanol, isobutanol, and ethanol from aqueous solutions with the above charcoals. To determine the time required to attain the static sorption capacity of the adsorbent, we studied the alcohol sorption kinetics and sorption isotherms.

The concentrations of aqueous solutions were measured by gas–liquid chromatography on an LKhM-8 MD chromatograph equipped with a heat conductivity detector. Porokhrom was used as a support. Polyethylene glycols with molecular weights of 1000 and 2000 (PEG-1000 and PEG-2000) were used as stationary phases. The mixture composition was calculated using internal reference [4].

Since the solubility limit of butanol, which is the least soluble in water, does not exceed 5.5 wt % (hereinafter, %), to plot the kinetic curves, weighed portions of activated charcoal (1 g) and 100 ml of aqueous solutions (0.8 and 5.5%) of the above alcohols were shaken for 3 h at 20°C. The samples were withdrawn at certain intervals. The results are presented in Fig. 1.

Analysis of the curves shows that the sorption capacity of birch charcoal for practically all alcohols is higher than that of the charcoal produced from a blend of oak and beech wood. Butanol is the most actively sorbed from solutions (0.8 and 5.5%), and the second sorbable is isobutanol. Ethanol is the least actively sorbed from solutions (Figs. 1a, 1b). This is apparently due to this fact that substances readily soluble in water are sorbed on charcoals less efficiently [3].

In sorption from 0.8% solution with charcoal produced from a blend of oak and beech wood, the sorp-

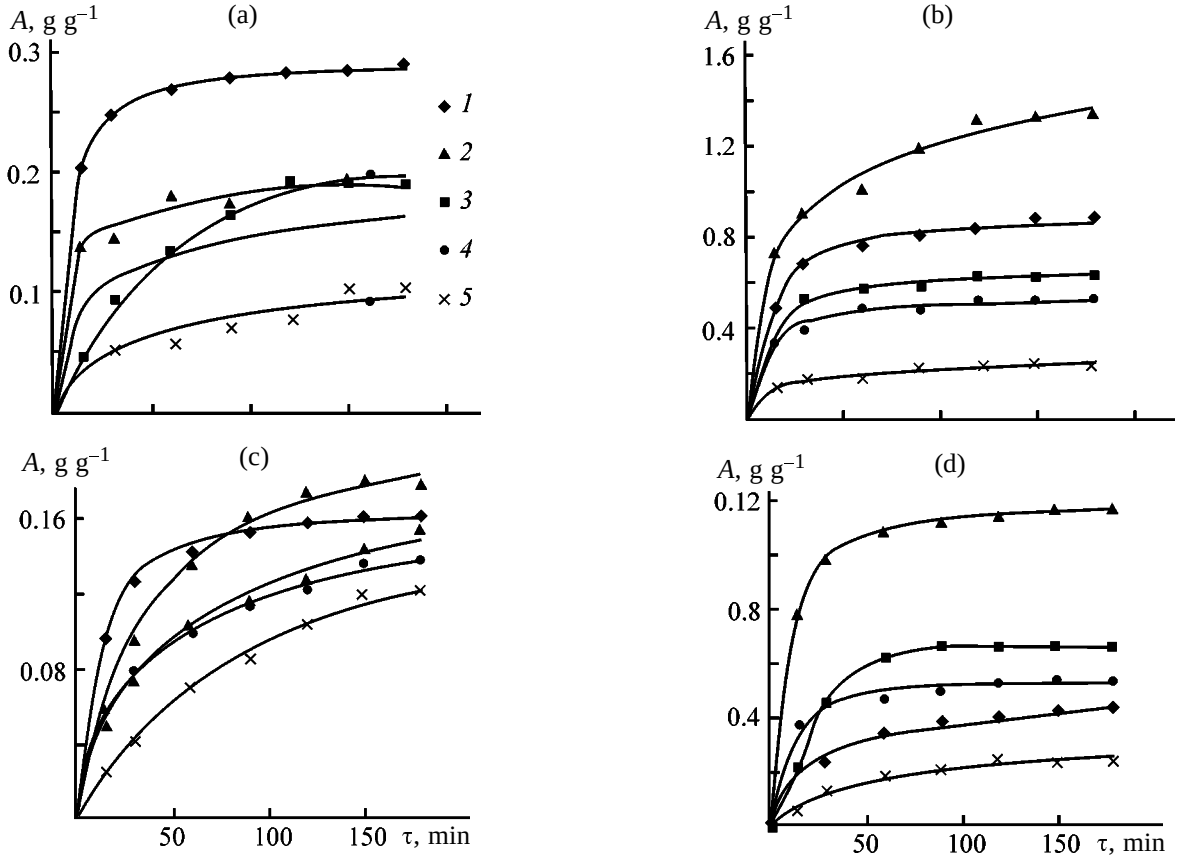

Fig. 1. Kinetic curves of sorption of alcohols with charcoal produced from (a, b) birch wood and (c, d) a blend of oak and beech wood. (*A*) Sorption capacity and (τ) time. (*1*) Butanol, (*2*) isobutanol, (*3*) *tert*-butanol, (*4*) isopropanol, and (*5*) ethanol; the same for Fig. 2. Aqueous solution of alcohol: (a, b) 0.8 and (c, d) 5.5 wt %.

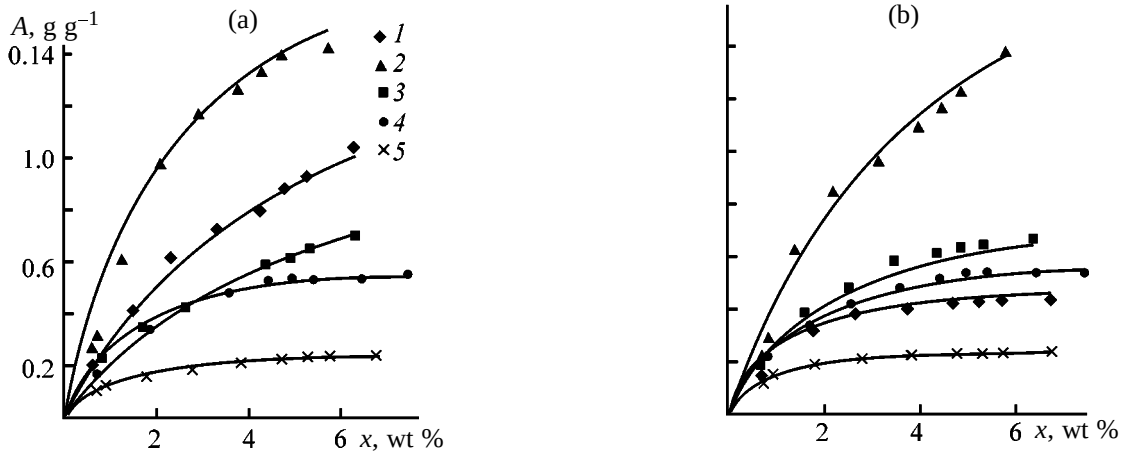

Fig. 2. Isotherms of sorption of alcohols from aqueous solutions with (a) birch charcoal and (b) charcoal produced from a blend of oak and beech wood. (*A*) Sorption capacity and (*x*) equilibrium concentration.

tion efficiency decreases in the order *tert*-butanol > butanol > isobutanol > isopropanol > ethanol. The sorption capacity of these charcoals for the same substances in sorption from 5.5% solutions decreases in the order isobutanol > *tert*-butanol > isopropanol > butanol > ethanol (Figs. 1c, 1d).

The maximal sorption capacity of birch charcoal is reached in 120–180 min for 0.8% solutions of alcohol and in 90–180 min for 5.5% solutions. The maximal sorption capacity of charcoals produced from a blend of oak and beech wood is reached in 150–180 min for solutions of both concentrations.

In study of the sorption isotherms, we used the same procedure as in the study of the kinetic curves, but the concentration was varied from 0.5 to 8%. The analysis was carried out after the equilibrium was reached. The results are shown in Fig. 2. As seen from these data, the absorption capacity of both kinds of charcoal reaches a maximum at a concentration of 5.5–8%.

In preliminary studies of sorption of *tert*-butanol from aqueous solutions (0.4 and 0.8%) with charcoals under dynamic conditions, 99.87% purification was reached. It was found that, in treatment of 0.4% solution, the breakthrough concentration is reached in a shorter time. In addition, charcoal produced from a blend of oak and beech woods has lower dynamic sorption capacity.

From the data obtained, we can conclude that both kinds of charcoal can be used for treatment of wastewater to remove alcohol impurities. Birch charcoal has a higher sorption capacity for alcohol.

BRIEF COMMUNICATIONS

Inhibitor of Acid Corrosion

S. Sh. Idrisova

Sumgait State University, Sumgait, Azerbaijan

Received July 31, 2001; in final form, January 2002

Abstract—A new inhibitor for steel protection in sulfuric acid solutions, 2,4,6-tribromo-*m*-phenylenediamine, was studied.

It is known that *p*-phenylenediamine is used as inhibitor of acid corrosion of steel. It was of interest to study in this respect 2,4,6-tribromo-*m*-phenylenediamine.

2,4,6-Tribromo-*m*-phenylenediamine was synthesized by oxidative bromination of *m*-phenylenediamine with a mixture of 40% hydrobromic acid and 28% solution of hydrogen peroxide with *m*-phenylenediamine : HBr : H_2O_2 molar ratio of 1 : 3 : 3 at 0–5°C and vigorous stirring for 2 h [2]; yield 99.5%, mp 157°C. Tribromo-*m*-phenylenediamine is a yellow-brown crystalline product identified by IR spectra, in which absorption bands at 650–720 cm^{-1}, characteristic of the C–Br bond, and at 3450 cm^{-1}, characteristic of NH_2 groups, were found.

The inhibiting properties were studied on $30 \times 20 \times$ 2-mm plates made of St.3 low-carbon steel. Prior to experiments, the steel samples were cleaned on a polishing machine to uniform shine of the surface, which was degreased with acetone and then kept in a corrosive medium (0.5, 2.5, or 4 M sulfuric acid solution) at 25–80°C for 1–2 h. The solutions were inhibited immediately before the experiments.

The protection efficiency was evaluated gravimetrically from the weight loss by a steel sample subjected to corrosion for the same period of time in inhibited and uninhibited solutions. The calculations were done on the basis of the results of three replicate runs. The extent of protection of a sample from acid corrosion, *Z*, is presented in the table, whence it is seen that *p*-phenylenediamine exhibits a satisfactory protecting effect.

Introduction of three bromine atoms into the *m*-phenylenediamine molecule much improves the inhibitor performance, presumably by enhancing the adsorption action because of the presence of the Br^- ion.

For comparison, 2,4,6-tribromoaniline was studied as acid corrosion inhibitor under similar conditions.

Protecting properties of 2,4,6-tribromo-*m*-phenylenediamine inhibitor and rate *V* of in-depth corrosion. Inhibitor content 0.2 wt %

It was found that its inhibiting action is also lower than that of 2,4,6-tribromo-*m*-phenylenediamine.

Thus, the composition of substituents strongly affects the inhibitor performance.

The protecting effect of 2,4,6-tribromo-*m*-phenylenediamine is also indicated by the fact that samples remain unchanged at 25°C at H_2SO_4 concentrations of 0.5, 2.5, and 4 M, and the steel surface becomes somewhat dull only at 80°C in a 4 M solution.

Solvent Regeneration in Direct Synthesis of Alkoxysilanes

A. S. Gorshkov, V. M. Kopylov, A. A. Markacheva, and A. N. Polivanov

State Research Institute of Chemistry and Technology of Organoelement Compounds, State Scientific Center of the Russian Federation, Moscow, Russia

Received July 6, 2001; in final form, April 2002

Abstract—A procedure was developed for regeneration of Termolan, solvent used in synthesis of alkoxysilanes, involving its treatment with ethanol to remove alkoxysilanes.

Alkoxysilanes are synthetic precursors of various organosilicon products. They are used for preparing organosilicon oligomers, carbofunctional products, compounds, high-purity silicon dioxide for fiber optics, etc. Triethoxysilane is also used for producing monosilane and semiconductor-grade silicon. Tetraethoxysilane and ethyl silicate prepared from it are used as binders in fabrication of molds for precision casting [1, 2].

Direct synthesis of alkoxysilanes is based on the reaction of silicon with alcohols. With copper chloride as catalyst, the major products are trialkoxysilanes [3, 4]:

$$Si + 3ROH \rightarrow SiH(OR)_3 + H_2. \quad (1)$$

With base catalysts and with copper or silver salts as cocatalysts, tetraalkoxysilanes $Si(OR)_4$ are formed [5] (R is an alkyl group).

The reaction is performed in a high-boiling solvent, e.g., in polyaromatic oils, alkylbenzene, etc. [6, 7]. In this work, direct synthesis of triethoxysilane was performed in alkylated naphthalene (Termolan [8], an analog of Therminol 59 and Therminol 60 [6, 9]).

Direct synthesis of alkoxysilanes is accompanied by side processes yielding water, which inhibits the main reactions and hydrolyzes alkoxysilanes:

$$(n + 1)Si(OR)_4 + nH_2O \rightarrow Si_{n+1}O_n(OR)_{n+2} + 2nROH, \quad (2)$$

where $n > 1$.

The occurrence of reaction (2) results in the accumulation of oligoethoxysiloxanes. They should be removed from the solvent at regular intervals for its regeneration and reuse.

Procedures are known for the solvent regeneration by treatment with boron derivatives [9, 10] or organic acids [11]. However, in this procedure, oligoethoxysiloxanes decompose to form solid silicon compounds.

Here we propose an extraction procedure for solvent regeneration to remove ethoxysiloxanes after the direct synthesis. The siloxanes were extracted with ethanol. The procedure was optimized using model systems alcohol–ethoxysiloxanes–Termolan. As a source of ethoxysiloxanes we used ethyl silicate from which the low-boiling fraction was preliminarily removed by distillation. The silicon content in the initial ethoxysiloxanes was 14–22%.

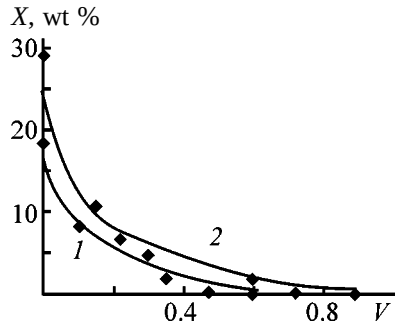
First, we prepared a solution of siloxanes in the solvent, and then added alcohol. The contents were thoroughly mixed, with the subsequent phase separation. The siloxanes passed to the alcohol fraction. Experiments were performed at 20°C.

The results are shown in the figure. It is seen that, at the initial concentration of ethoxysilanes in Termolan of up to 30%, the alcohol/Termolan volume ratio of 0.6–0.8 is sufficient to virtually completely remove the siloxanes from the solvent by extraction.

The density of siloxanes is higher than that of the initial Termolan, and at low amounts of alcohol added for extraction the concentration of siloxanes in the alcohol becomes fairly high, with the density of the alcohol phase becoming higher than the density of the solvent phase. In this case, the lower layer was an alcoholic solution of siloxanes, and the upper layer was the regenerated solvent. With a larger amount of alcohol taken for extraction, the concentration of siloxanes in the alcohol phase was lower, and the alcohol phase having lower density formed the upper layer, and the regenerated solvent, the lower layer.

The suggested regeneration procedure was tested

1070-4272/02/7507-1196$27.00 © 2002 MAIK "Nauka/Interperiodica"



Concentration of ethoxysilozanes in Termolan *X* as a function of the volume ratio of the extractant (alcohol) to Termolan *V*. Initial concentration of ethoxysilanes in Termolan X_0, wt %: (*1*) 18.5 and (*2*) 30.

with the solvent after the direct synthesis of triethoxysilane. It was shown that oligoethoxysiloxanes are recovered by extraction, and the solvent becomes suitable for further syntheses. This procedure can be efficiently used in commercial production of alkoxysilanes. Oligoalkoxysiloxanes recovered from the solvent can be used as components of plugging formulations and for other purposes.

Prediction of Properties of Asphalt Oil in Asphaltic Concrete

D. A. Rozental' and E. S. Ivanova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 26, 2002

Abstract—Evolution of characteristics of asphalt oil in contact with mineral ballast in the course of long-term storage of asphaltic concrete at room temperature is studied. Data on the effect of the preparation time of mix asphalt on the structure and properties of asphalt oil in asphaltic concrete are analyzed.

Asphalt oils are widely used in road construction as materials for asphaltic concrete pavement. Asphalt oils in asphaltic concrete play a role of an organic binder for the mineral fraction. When manufacturing asphaltic concrete, asphalt oil is mixed with mineral ballast at 160°C for 20 min. Physical interaction of asphalt oil with the mineral filler is accompanied by formation of adsorption layers of the binder on the filler grains. This process includes many adsorption–desorption stages, until reaching the equilibrium. This is a selective process, resulting in extraction of the most readily adsorbed components from asphalt oil, which, in its turn, distorts the thermodynamic equilibrium in the colloidal system of asphalt oil. As a result, the system is transformed, approaching new equilibrium state corresponding to given conditions. Finally, transformation of the asphalt oil structure changes its characteristics.

The factors influencing adsorption of asphalt oil on the mineral filler surface are as follows [1–3]: heating temperature, heating time τ, the kinds of mineral ballast and asphalt binder, and, finally, the ballast grading.

The goal of this work was to predict the evolution of characteristics of asphalt oil in asphaltic concrete. Therefore, we studied the effect of the time of heating of mix asphalt at 160°C on the adherence of asphalt oil to mineral ballast. As mineral ballast we used granite with a grading of 3–5 mm. The heating time was varied from 20 min to 4 h. In experiments we used BND 40/60 asphalt oil produced by the KINEF Production Association, Limited Liability Company from a mixture of West Siberian oils. The adhesion was measured by the hot centrifugation method [4], followed by determination of the performance characteristics of the extracted product.

With increasing heating time, the amount of asphalt oil retained on the mineral ballast surface increases, saturating at τ = 3 h (see figure).

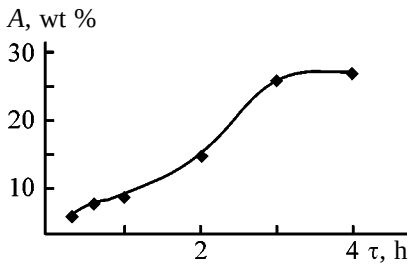
Evolution of the performance characteristics (penetration Π_{25} and softening point T_s) of asphalt oil extracted from mix asphalt by centrifugation is given below.

τ, h	0	1/3	2/3	1	2	3	4
Π_{25}, mm × 0.1	59	58	55	34	32	30	28
T_s, °C	51	54	56	67	70	72	73

With increasing τ, the softening point considerably increases, and the penetration abruptly decreases. At τ = 3 h these parameters approach their saturated values.

The observed evolution of the softening point and penetration is well consistent with data on the adhesion of asphalt oil to the mineral ballast, suggesting that establishment of the adsorption equilibrium in mix asphalt takes about 3 h.

In asphaltic concrete in service, asphalt oil occurs in the cold state. Our results obtained at room temperature allow prediction of the behavior of asphalt oil in asphaltic concrete pavements.



Effect of the heating time τ of mix asphalt at 160°C on the adherence of asphalt oil to mineral ballast *A*.

1070-4272/02/7507-1198$27.00 © 2002 MAIK "Nauka/Interperiodica"

Evolution of characteristics of asphalt oil in storage after heating of mix asphalt for 1 h

Storage time	Adherence, wt %	T_s, °C	Π_{25}, mm × 0.1
0	(27)*	67 (72)	34 (30)
1/3	12 (9)	49 (51)	54 (52)
2/3	12 (9)	51 (55)	52 (42)
1	12 (9)	52 (55)	48 (36)
2	10 (10)	55 (56)	42 (34)
3	8 (10)	56 (57)	39 (33)
4	8 (25)	57 (59)	38 (33)
5	8 (25)	57 (61)	37 (32)
6	8 (25)	58 (63)	37 (32)
7	8 (25)	58 (63)	37 (32)

* Data for mix asphalt after 3-h heating are given in parentheses.

We studied the evolution of characteristics of asphalt oil separated by hot centrifugation from mix asphalt after long-term storage (from 10 days to 7 months) at room temperature (18°C). The results are given in the table.

Initially mix asphalt was heated at 160°C for 1 and 3 h. The results show that establishment of the adsorption equilibrium requires at least 3-h heating. Thus, it is seen how the initial heating time influences the characteristics of asphalt oil in asphaltic concrete.

The temperature drop from 160 to 18°C in mix asphalt initiates a considerable change in the structure and characteristics of asphalt oil (see table). However, in the course of subsequent storage of mix asphalt in the cold state, these changes decay as a result of a large number of adsorption–desorption events. It follows from the table that the equilibrium established after heating for a fixed time is practically identical to that after the subsequent storage at room temperature. Therefore, data on evolution of characteristics of asphalt oil in the course of heating in contact with mineral ballast allows prediction of the behavior of this material in asphaltic concrete.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Academician German Ivanovich Hess (on the 200th Anniversary of His Birthday)

Academician German Ivanovich Hess (Germain Henri Hess) made an outstanding contribution to the development of chemical science and teaching of chemistry in higher school institutions of St. Petersburg in the first half of the XIX century. He carried out comprehensive studies in inorganic and organic chemistry, chemical technology, and mineralogy, and was the first to formulate fundamental concepts of thermochemistry, one of the most important branches of physical chemistry.

G.I. Hess was born on July 26 (August 7), 1802, in Geneva. However, soon after his father, and then the whole family, moved to Russia (1805), where G.I. Hess's parents worked as family tutors. German Hess was well educated at home. His Swiss-born mother, who had a perfect command of German and French, paid much attention to bringing up her son. In 1817, Hess moved to Derpt (Tartu), where he went to a private school for two years, and then to Derpt Gymnasium, which he finished in 1822. In autumn of the same year he became a student of the Faculty of Medicine at Derpt University. One of the largest not only in Russia, but in Europe, too, this oldest university was again opened, after a long break, in 1802, and in the 1820s–1830s, up to 600 students were taught at the university, with, however, no specialists in chemistry trained there till 1850. The chair of chemistry, organized in 1804, satisfied the needs of medicine and pharmacy only. The teaching was in German. During the time when Hess was a student, chemistry (inorganic, organic, and analytical) was taught by Professor G.W. Osann (1797–1866), later (since 1828) a professor at Würzburg University in Germany, a versatile scientist, author of investigations in various fields of chemistry and chemical technology and physics. He studied, in particular, Ural platinum ore and wrote the first volume of a manual of theoretical chemistry (1827). Under Osann's supervision, Hess carried out chemical analyses. Hess was much interested in lectures delivered by Professor of Physics G.F. Parrot (1767–1852), the first rector of the university and academician of the St. Petersburg Academy of Sciences (since 1826), and also lectures given by Professor of Mineralogy M. Engelhardt (1779–1842).

Hess graduated with honors from Derpt University and, having defended the dissertation "Something about Curative Waters, Especially Those in Russia," received the degree of a doctor of medicine. By application of Professors Osann and Engelhardt, Hess was sent on a business trip abroad, to Sweden, to visit one of the best-known chemists of that time, J.J. Berzelius (1779–1848), professor of the Medical-Surgery Institute in Stockholm, member of the Royal Swedish Academy of Sciences (since 1808), and honored member of the St. Petersburg Academy of Sciences (since 1820). Berzelius was a prominent specialist in chemical analysis; he determined the atomic weights of 45 chemical elements and discovered cerium (1803), selenium (1817), and thorium (1828). He was the first to obtain in free state silicon, titanium, tantalum, and zirconium; he studied the phenomenon of catalysis and introduced the notion of allotropy. Berzelius and Hess became good friends. Berzelius highly appreciated the gifted nature and potentialities of his disciple, and was in correspondence with him for many years [2, 3].

After four months in Stockholm, Hess returned to

1070-4272/02/7507-1200$27.00 © 2002 MAIK "Nauka/Interperiodica"

Russia and took part in Professor Engelhardt's expedition to the Urals. When being a student, Hess received a stipend and, according to the regulations of that time, had to serve after having graduated from the University. He was appointed a doctor at Irkutsk and came there in August 1826. In addition to his direct duties, Hess paid much attention, when in Irkutsk, to chemical investigations and studies of the nature of this richest territory. He analyzed local hot mineral waters, a number of minerals, studied impurities in common salt mined in Irkutsk guberniya, recommended a method for impurity removal, and launched several expeditions during which he conducted geological surveys. Later, Hess composed a geological review of a part of Transbaikalia.

In October 1828, by recommendation of Academician Parrot and (by letter) Berzelius and Osann, Hess was elected, at the age of 26, an adjunct in chemistry of the St. Petersburg Academy of Sciences. By that time, the Academy lost such well-known chemists and natural scientists as E. Laksman (1737–1796), T.E. Lovits (1757–1804), and V.M. Severgin (1765–1826), and there was no chemical laboratory any more.

In the late March 1829, Hess came to St. Petersburg from Irkutsk and immediately commenced active work. First, he equipped a laboratory in a room of his flat, and later the Academy of Sciences satisfied Hess's request for organization of a chemical laboratory of the Academy, and this laboratory was opened on February 10, 1830, in a house situated near the main building of the Academy on the Neva River embankment.

German Ivanovich continued his investigations of natural waters and minerals. His works became increasingly known and impressed everybody with the diversity of objects studied. He was elected extraordinary academician in 1830, and ordinary academician in 1834. In these years, Hess started intensive teaching activities. In October 1831, the St. Petersburg Practical Technological Institute was opened in order to "train people having sufficient theoretical and practical knowledge to manage plants or parts of these" [4]. The course of training was intended to be three years. Hess accepted an invitation to become an inspector of classes (deputy director) at this institute. He composed curricula and invited the best specialists from other civilian and military educational institutes of St. Petersburg to teach the basic disciplines. A chemical laboratory was organized in accordance with Hess's recommendations and under his supervision. The fulfillment of the curricula at the institute was checked both by Hess himself and by the specially organized Technical Committee, also serving to control all practical studies.

In 1832, Hess was elected an ordinary professor of chemistry and technology of the Chief Pedagogical Institute (1832–1847). Hess also delivered lectures at the Institute of Ways of Communications and Artillery Mikhail College. Particularly intensive were pedagogical activities of German Ivanovich at the Mining Institute (1832–1849). He organized there a chemical laboratory, introduced practical training in chemistry for students, and paid much attention to studying the analytical chemistry and qualitative and quantitative analyses. Hess emphasized the importance of teaching the students to carry out experimental work. Owing to Hess's efforts, the chemical laboratory of the Mining Institute became a prominent scientific and pedagogical center in the field of analytical chemistry in Russia.

In 1831, Hess published his fundamental work *Osnovaniya chistoi khimii* (Foundations of Pure Chemistry). In the book, practical evidence and theoretical concepts are closely interconnected, and the Russian chemical terminology is introduced for the first time. As experiments are described, their theoretical substantiation, possible at that time, is given. The book was approved by the Academy of Sciences and ran into 7 editions in 18 years. The book was the basic textbook in chemistry in the 1830s–1840s and exerted a strong influence on the formation of scientific outlook in subsequent generations of Russian chemists, among which were such well-known scientists as A.A. Voskresenskii (1809–1880), N.N. Zinin (1812–1880), N.N. Beketov (1827–1911), A.M. Butlerov (1828–1886), and D.I. Mendeleev (1834–1907). Voskresenskii, who graduated from the Chief Pedagogical Institute in 1836, attended Hess's lectures. In his turn, Mendeleev entered the Chief Pedagogical Institute in 1850 and was taught chemistry by Professor Voskresenskii.

Much success was achieved by A.I. Khodnev (1818–1883), Hess's disciple at the Chief Pedagogical Institute. His pedagogical and scientific activities were considered in detail by Figurovskii and Solov'ev in [5] and in monograph [6]. To representatives of Hess's school formed at the Mining Institute belong P.I. Evreinov, N.A. Ivanov, P.P. Shubin, and K.I. Raevskii [7, 8].

Hess's scientific investigations carried out in St. Petersburg were still concerned with mineral resources and practically important processes. He was the first to describe and analyze four minerals, named

vertite (1830), uvarovite (1832), hydroboracite (1833), and volborthite (1834). German Ivanovich also studied the mineral, silver telluride, named hessite after him, and proposed a method for recovering tellurium from this mineral.

In a practical study, Hess came to a conclusion that use of hot blast in blast furnaces must "save a lot of combustible materials." He studied comprehensively the technique for processing of raw platinum and proposed methods for its analysis. Hess was among the first to study the ability of platinum black to accelerate the reaction between oxygen and hydrogen.

German Ivanovich also carried out a number of investigations in the field of organic chemistry. He studied the composition of gas from oil fields near Baku and the process of pyrolysis of oil and wood tars. In one of his studies, Hess isolated a new acid, named "saccharic" by him, and determined its composition.

Despite the great number of various investigations in the field of applied chemistry, technological analysis, and metallurgy, Hess expressed in his public lectures and letters to colleagues, beginning already in 1830, a desire to contribute to solution of the fundamental problem of chemistry, the problem of chemical affinity. German Ivanovich started from the presumption that any chemical addition event is accompanied by heat release. He started experimental determinations of heat effects in 1834, using a specially constructed calorimeter. However, Hess wrote as far back as in the first edition of his book *Osnovaniya chistoi khimii* that "It may be assumed that the stronger the mutual affinity, the larger the amount of heat released." After the beginning of his own calorimetric measurements, he wrote in a letter to Berzelius more categorically: "...I have no doubt concerning the fundamental issue: the heat released is a measure of affinity... My aim is to demonstrate to the scientific community the large amount of work required by this new standpoint and thereby to induce the possibly greater number of researchers to take part in the development of thermochemistry" [6, 9].

In 1840, based on a vast body of experimental data, Hess formulated the thermoneutrality law: in mixing of two salt solutions having the same temperature and forming two new salts through exchange decomposition, the temperature of the mixture remains unchanged. This law was exhaustively substantiated only by the theory of electrolytic dissociation developed by S. Arrhenius (1859–1927) in 1887 and served as one of its verifications. German Ivanovich was also the first to observe that strong acids and strong bases always release the same amount of heat when neutralized in equivalent amounts.

Simultaneously (in 1840), Hess formulated a fundamental law of thermochemistry, named after him, the law of constant heat summation: "The heat evolved in the formation of a chemical compound is the same whether the compound is formed in one or in several steps." This law and other thermochemical investigations of Hess were analyzed in detail in [3, 6, 9, 10].

Germam Ivanovich Hess, state counselor of the 4th class, ordinary academician, member of the Scientific Committee of the Corps of mining engineers, and bearer of other honorary titles died of severe illness on November 30 (December 12), 1850 in St. Petersburg. He was only 48. Hess was buried at Smolenskoe Lutheran cemetery.

The life and pedagogical and scientific activities of Hess have been the subject of a great number of publications. Among these, particular mention should be made of the monograph by Yu.I. Solov'ev [3], paper by A.F. Kapustinskii "German Ivanovich Hess and His Role in the Creation and Development of Thermochemistry" [9], and articles [11, 12]. Biographic information about Hess was included in books [13, 14].

Hess's works, his pedagogical activities were exceedingly important for training of highly educated chemists in Russia. We have every reason to mention his name among the names of other Russian chemists known all over the world.

BOOK REVIEWS

Bulanova, M.V., Buyanov, Yu.I., and Sidorko, V.R., *Vzaimodeistvie redkozemel'nykh metallov so svintsom* (Interaction of Rare-Earth Metals with Lead)

Kiev: Inst. Problem Materialovedeniya im. I.N. Frantsevicha, Nats. Akad. Nauk Ukrainy, 2001, 107 pp.

In continuation of previous publications concerning the interaction of Group IV elements with rare-earth metals,[1] the reference book under consideration discusses alloys of rare-earth metals (REMs) with lead.

In a brief introduction, the authors mention that compounds of REMs with lead, plumbides, have been studied to a lesser extent compared to their Group IV analogs: silicides, germanides, and stannides. This may be due both to the lack among plumbides of compounds with any practically important properties and to severe experimental difficulties encountered in studying the rather reactive R–Pb alloys (where R is a rare-earth metal). Compounds of rare-earth metals with lead are insufficiently stable against the action of atmospheric moisture and oxygen, possess increased brittleness, and therefore can be, probably, used only in multicomponent formulations. In accordance with the position of lead in the periodic table, its alloys with REMs must be closer in their structural, physical, and chemical properties to REM alloys with tin, than to alloys with silicon and germanium. Comparison of the properties of stannides and plumbides confirms this conclusion.

The book by M.V. Bulanova, Yu.I. Buyanov, and V.R. Sidorko presents, with varied extent of completeness and reliability, data on phase diagrams and crystal structure of compounds, and thermodynamic properties of alloys with lead of scandium, yttrium, lanthanum, and all lanthanides, from cerium to lutetium. Of the 17 possible R–Pb phase diagrams, relatively reliable evidence based on experimental studies is available for nine systems (alloys of lead with Sc, Y, La, Pr, Eu, Gd, Dy, Yb, Lu). Less reliable are data on phase diagrams and compositions of compounds in the systems Ce–Pb and Sm–Pb. For the remaining 6 systems (alloys of lead with Nd, Pm, Tb, Ho, Er, Tm) hypothetical phase diagrams are constructed using mathematical simulation. The method is based on various correlations, which allow the authors to evaluate the composition of compounds, their melting and decomposition points, composition and temperature of eutectic mixtures, and position of the liquidus line.

The thermodynamic properties of the R–Pb alloys were studied using various kinds of the emf method, calorimetric measurements, and, in some cases, by measuring the saturated vapor pressure. The emf method was applied to study, to a greater or lesser extent, 15 systems (data are lacking only for the systems Pm–Pb and Tm–Pb). However, evidence on the thermodynamic properties of liquid alloys is, as a rule, lacking. The emf measurements were used in many systems to evaluate the thermodynamic properties of plumbides with the general formula RPb_3 and to determine the solubility of rare-earth elements in liquid lead. To evaluate the enthalpies of compound formation, model concepts were used together with the results of experimental determinations.

The refereed publication is very convenient in use. The material is presented in the book successively for all the systems considered in order of increasing REM number in the periodic table. Data on crystallographic characteristics of intermediate phases, nonvariant equilibria, thermodynamic properties, and, in some cases, liquid phases are presented in the form of tables, and the phase diagrams, in the form of figures. For some systems, data on the specific heat of compounds, REM solubility in liquid lead, and limiting thermodynamic characteristics (partial molar excess Gibbs energies and enthalpies of REM mixing at infinite dilution) are available. In all cases, references to relevant publications are given, with a total of 132 published sources used. There is no escape from mentioning that specialists in thermodynamics of alloys, working at the Institute of Materials Science Problems, National Academy of Sciences of the Ukraine, possess a vast experience in expert assess-

[1] For reviews, see *Zh. Prikl. Khim.*, 1998, vol. 71, no. 7, p. 1229 and *Zh. Prikl. Khim.*, 1999, vol. 72, no. 10, p. 1757.

1070-4272/02/7507-1204$27.00 © 2002 MAIK "Nauka/Interperiodica"

ment of various kinds of experimental studies and in analysis and prognostication of phase diagrams.

Based on the material presented, the authors revealed a number of fundamental aspects of the interaction between rare-earth metals and lead. Intermetallic compounds, whose number varies between 2 for the Sc–Pb system and 7 for Pr–Pb, are formed in all the R–Pb systems. All the compounds can be conditionally classed with constant-composition phases, with narrow homogeneity regions (up to 2 at. %) found only for the compounds Y_5Pb_3, Gd_5Pb_3, and Dy_5Pb_3. The highest-melting compounds in all the R–Pb systems are those of the type R_5Pb_3. Certain patterns are revealed regarding the structural types of compounds in the R–Pb systems.

The book by Bulanova and co-authors contains extensive and useful reference data. It is, undoubtedly, of interest to a wide audience of specialists working in the field of inorganic materials science and chemistry of rare-earth metals.

INFORMATION

X Korshak Symposium

X Korshak Symposium was held on February 13, 2002 at the Nesmeyanov Institute of Organoelement Compounds (INEOS), Russian Academy of Sciences (RAS) (Moscow). The symposium was organized by the Russian Academy of Science (Scientific Council on Macromolecular Compounds at the Department of General and Technical Chemistry), INEOS, and the Mendeleev Russian University of Chemical Engineering (Moscow).

The symposium was opened by Yu.N. Bubnov (Moscow) who outlined that Academician V.V. Korshak (1909–1988) was one of the pioneers in the polymer chemistry of the XX century, and that his school is one of the largest in the world.

The symposium participants were 150 scientists from 25 institutions of RAS, universities of the Ministry of Higher Education of the Russian Federation, and applied research institutions.

The symposium program included five plenary lectures under the general topic *The Korshak's Concepts are Alive and Flourishing*. The lectures emphasized that the Korshak's concepts are developed at present, being realized in new scientific lines and significant practical applications.

The first lecture given by E.M. Sul'man (Tver) was devoted to nano-scale metal–polymer catalysts in hydrogenation and oxidation. The reported results were obtained by INEOS in cooperation with some German research centers.

The second lecture on polymerization with atom transfer and also on synthesis of amphiphilic block copolymers was given by Yu.A. Kabachii (Moscow). The background of this line was founded by Cristoff Matisevski (Poland). Then his works were successfully developed by Korshak's disciples.

V.I. Sidorenko and I.I. Ponomareva (Moscow) in their lecture reported on a new generation of polyheteroarylene-based binders for highly heat-resistant composite materials. The authors obtained unique polymeric materials for aircraft industry, which are stable to 400–450°C. Such materials are used, in particular, in construction of skin of extrasupersonic airplanes and in manufacture of engines (e.g., turbine blades). Note that the preparation procedure of the binder proposed by the authors is very simple.

The lecture given by A.P. Petrova and P.M. Valetskii (Moscow) was devoted to development of special polymeric materials based on carborane derivatives, suitable for exploitation at temperatures of up to 1000°C. Under such conditions, polymers based on carborane-containing compounds degrade with formation of a coke with good mechanical characteristics. The authors successfully used novolac resins as binders for composites with good mechanical properties. Phenol–rubber and polyurethane adhesives found wide application as binders also. The resulting materials can be exploited not only at very high, but also at very low temperatures (to –200°C).

The composites proposed can operate without deterioration of their performance characteristics for 10000 h at 600°C (for example, they were used to seal joints on the skin of the Soviet shuttle Buran).

The last lecture entitled *The Lessons of V.V. Korshak* was given by P.M. Valetskii. He outlined the Korshak's scientific activities. A special emphasis was made on the fact that he easily entrusted young researchers with important pieces of theoretical and practical works, including those by request of the USSR Defense Ministry.

All the lectures were followed by lively discussions. Particularly, Academician N.A. Plate, vice-president of RAS, and Academician V.A. Kabanov, the Secretary of the Department of General and Technical Chemistry of RAS, participated in the discussions.

The next XI Korshak Symposium will be held at INEOS RAS in 2004.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetic Parameters of Dissolution of Iron(III) Oxides of Varied Thermal and Chemical Prehistory in Hydrochloric Acid

N. V. Dvoretskii, L. G. Anikanova, Z. G. Malysheva, and G. N. Koshel'

Yaroslavl State Technical University, Yaroslavl, Russia

Received November 1, 2001; in final form, February 2002

Abstract—The kinetic parameters of dissolution in hydrochloric acid of Fe_2O_3 (hematite) samples of varied thermal and chemical prehistory are calculated in terms of Delmon's model of instantaneous nucleation on the surface of a solid reagent.

A finely crystalline structure (FCS) is one of the major structural characteristics of a sample, determining its activity in reactions (ferrite formation, dissolution in acids, etc.) [1]. It is characterized by such parameters as the coherent domain size, level of residual microdistortions, and possibility of stacking fault formation.

The aim of the study was to establish a correlation between the kinetic parameters of dissolution in hydrochloric acid and the FCS characteristics of Fe_2O_3 samples of varied thermal and chemical prehistory.

EXPERIMENTAL

"Carbonate" iron(III) oxide was obtained by thermal decomposition of iron(II) carbonate at 830–850 and 870–890 K for 180 min; "sulfate" iron(III) oxide, by thermal decomposition of iron(II) sulfate at 920–940 and 940–960 K for 180 min; and Fe_2O_3, by thermal decomposition of Mohr's salt, $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$, at 960–980 K for 120 min.

X-ray diffraction analysis data were used to calculate the FCS parameters by the method of the fourth central moments [2]. The kinetics of dissolution was studied on homogeneous fractions of Fe_2O_3 samples, with particle size R_0 = 140–150 μm. A 0.5-g portion of the oxide was introduced into a temperature-controlled reactor containing 2 l of a 1 M aqueous solution of hydrochloric acid. The diffusion hindrance was avoided by stirring the water–dispersion mixture at a rate of 400–500 rpm. The tests were performed at temperatures of 300, 310, and 320 K maintained within (±1 K). Systems deoxygenated by bubbling nitrogen through the reactor for 1.5 h before sample introduction were used in the study. The concentration of Fe^{3+} ions in filtrate samples taken at regular intervals from the reactor through a Schott filter was determined by photocolorimetry [3].

The rate of dissolution of metal oxides is determined by the number of active centers on their surface [4, 5]. The kinetics of formation and dissolution of active centers of iron(III) oxide samples of varied thermal and chemical prehistory, brought in contact with an aqueous solution of hydrogen chloride was studied using Delmon's model of nucleation on the surface of a solid reagent [6].

We used in experiments Fe_2O_3 samples obtained by thermal decomposition of various iron(II) salts. Thermolysis followed by quenching is a method for sample treatment, which differs from the reaction under study and creates potential nuclei before the beginning of dissolution. Hence, the nucleation is localized at strictly specified points. The creation of nuclei before the start of the process studied is named artificial nucleation. Processes of artificial nucleation belong to reactions caused by instantaneous nucleation [6]. For this reason, the mathematical analysis of dissolution, performed here, is based on the model of instantaneous nucleation.

To describe the instantaneous nucleation mathematically, it is necessary to assume the existence of a function, $g_{t''}(\theta, \nu_0)$, that expresses the nucleation rate at different instants of time, θ, close to the start time. This function, which is nonzero only during a very

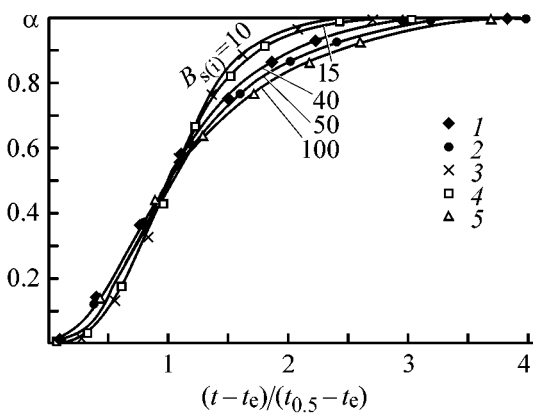

Fig. 1. Degree of Fe_2O_3 transformation, α, vs. reduced time $(t - t_e)/(t_{0.5} - t_e)$. Digits *1*–*5* correspond to sample numbers in Table 1.

short time interval t'', is chosen so that the sum of $g_{t''}(\theta, \nu_0)d\theta$, equal to the number of nuclei appearing during a time dθ, is equal to the concentration of nuclei at the initial instant of time.

In the case when the nucleation occurs at the potential nuclei, the concentration of nuclei at the initial instant time is equal to the initial concentration ν_0 of active centers.

The model of instantaneous nucleation can be conveniently described using the following reduced parameters:

$$B_{s(i)} = \pi \nu_0 a_0^2, \quad (1)$$

$$\tau = (k_i/a_0)t, \quad (2)$$

$$\varepsilon = x/a_0, \quad (3)$$

where $B_{s(i)}$ is a parameter characterizing reactions initiated on samples consisting of spherical grains (subscript "s") by instantaneous nucleation (subscript "i"); τ is reduced time; a_0 is the initial radius of a spherical grain; and x is the distance between the surface of the spherical layer and the grain surface (layer depth).

$B_{s(i)}$ is a dimensionless parameter equal to a quarter of the average number of nuclei on each sphere. The reduced time τ changes from zero to unity within a time necessary for an initial nucleus to reach the center of the sphere corresponding to a solid particle. The τ value becomes equal to 2 when the growth of the given nucleus leads to complete transformation of the entire grain.

According to Delmon's model [6], the dissolution rate is determined by the kinetic parameter k_i, which is the velocity of interface motion or the rate of nucleus growth. The degree of transformation α (or the extent of the reaction) is related to the reduced time τ by the equations:

$$\alpha = 1 - (1-\tau)^3 - 3\int_0^{\tau}(1-\varepsilon)^2 \exp\left(-B_{s(i)}\frac{\tau^2-\varepsilon^2}{1-\varepsilon}\right)d\varepsilon, \quad (4)$$

$$0 \le \tau \le 1;$$

$$\alpha = 1 - (1-\tau)^3\exp(-4B_{s(i)}) - 3\int_0^{2-\tau}(1-\varepsilon)^2\exp\left(-B_{s(i)}\frac{\tau^2-\varepsilon^2}{1-\varepsilon}\right)d\varepsilon,$$

$$1 \le \tau \le 2; \quad (5)$$

$$\alpha = 1 - \exp(-4B_{s(i)}), \quad \tau \ge 2. \quad (6)$$

The kinetic parameters were calculated from the tabulated values of the $B_{s(i)}$ function. The k_i value was determined by superimposing the experimental data plotted in the coordinates α–$(t - t_e)/(t_{0.5} - t_e)$ ($t_{0.5}$ is time necessary for the degree of transformation to become 50%, and t_e is the induction period) on a grid of theoretical curves plotted in the same coordinates at different $B_{s(i)}$ values. Figure 1 shows kinetic curves of dissolution of Fe_2O_3 samples in hydrochloric acid. Points represent the experimental data on dissolution of samples of different prehistories, and solid lines, the graphical solution to the equation.

Comparison of the experimental data and the results of theoretical calculations shows that $B_{s(i)}$ is within 10–100, depending on the sample prehistory. The induction period was calculated in terms of the instantaneous nucleation model by the formula:

$$\alpha^{1/3} = \text{const} \times (t - t_e). \quad (7)$$

In the case of artificial nucleation the induction period t_e is commonly negative (Table 1) and corresponds to the time necessary for natural nuclei to reach the size of the artificial nuclei. Thus, the artificial nuclei have a considerable size even at zero time, i.e., at the beginning of dissolution.

The rate constant of interface motion or nucleus growth at each active center was determined from the relation:

$$\alpha = 2B_{s(i)}\frac{k_i^3}{a_0^3}(t - t_e)^3. \quad (8)$$

The parameters obtained are presented in Table 1.

The rate of dissolution of various samples of dispersed solid phases with the same chemical composition and crystal structure depends on their dispersity and pore structure, on the area of the reaction surface formed by various crystal faces, and on the type and extent of defectiveness of their lattice defects, i.e., on the real structure of the phases. In the course of dissolution, the initial particle-size and particle-shape distributions undergo changes that virtually cannot be predicted, as also the corresponding changes in the dissolution rates. It was shown that at stirrer rotation rates exceeding 400 rpm the stirring intensity does not affect the dissolution rate, which means that the process passes to the kinetic region in which the interaction at the interface is the rate-determining stage. It was found that the samples of dispersed phases with the same composition and crystal structure, but different prehistories, are always characterized by more or less different curves. Any curve of this kind can be represented as a sum of kinetic curves characterizing the dissolution of separate particles forming a sample. Analysis of the dissolution pattern of various iron(III) oxide samples shows that the run of a kinetic curve varies depending on the sample prehistory. The parameters determining the shape of the kinetic curve (Table 1) are directly related to the FCS of the sample (Table 2).

The fact that the highest rate of nucleus growth is observed in dissolution of "carbonate" Fe_2O_3 results from the large value of root-mean-square microdistortions and presence of exceedingly small mosaic blocks, being also, possibly, associated with the high probability of propagation of quaternary and half-dislocations (Tables 1, 2). Raising the temperature of sample preparation makes the coherent domains larger and the amount of microdistortions lower, which is due to deceleration of nucleus growth.

Hematite obtained from Fe(II) sulfate has low k_i value. Samples of this iron(III) oxide contain rather large mosaic blocks and only high-temperature stacking faults. With increasing temperature, the coherent domains grow in size dramatically and the microdistortions are rather intensively annealed out, which accounts for the very low k_i value and the long period of half-transformation. The Fe_2O_3 sample obtained from Morh's salt contains few defects and large mosaic blocks, being, therefore, characterized by low k_i value.

Thus, the data on the hematite FCS are in agreement with the results obtained in dissolution in hy-

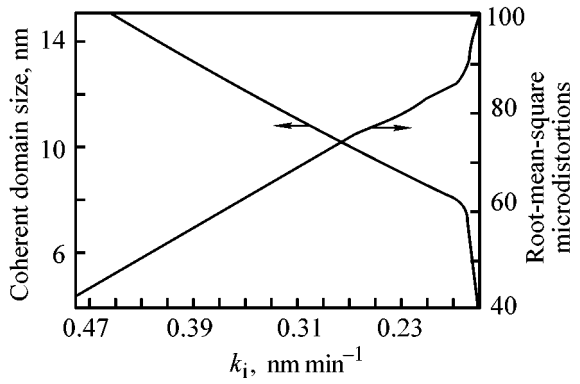

Fig. 2. Relation between the coherent domain size, root-mean-square microdistortions, and kinetic parameter k_i.

drochloric acid of Fe_2O_3 samples of different thermal and chemical prehistories. The relationship between the FCS characteristics and the kinetic parameter k_i for hematite samples is shown in Fig. 2.

CONCLUSIONS

(1) The size of coherent domains and the root-mean-square microdistortions can be determined graphically from the revealed kinetic dependences of dissolution in hydrochloric acid of iron(III) oxide samples.

(2) The kinetics of dissolution in acids can be recommended as a method for evaluating the parameters of finely crystalline structure of hematite samples.

Received December 21, 2001

Abstract—The influence exerted by the dispersity and composition of the starting powder and by the temperature and time of treatment on the properties of Al_2O_3–TiC powder formulation was studied.

Al_2O_3–TiC formulations find wide application in cutting tools and heaters and can be used to manufacture abrasives [1, 2]. Studies concerned with joint reduction of titanium and aluminum oxides for obtaining an Al_2O_3–TiC composite powder are few in number [3]. This process can give an active powdered formulation with high degree of homogeneity, which allows intensification of sintering and compaction of oxide–carbide formulations and enables synthesis of a material with high mechanical characteristics without the expensive stage of hot pressing.

To obtain high-strength pore-free composites with a ceramic matrix, powders of high dispersity and purity are necessary. The use of chemical methods for preparing powders of this kind, e.g., joint precipitation of the components in the form of hydroxides or salts, enables application of inexpensive and accessible reagents and simple apparatus. The technique mentioned is employed by numerous researchers for obtaining Al_2O_3-based compounds. Methods for precipitation of individual hydrated aluminum and titanium oxides have been described in the literature [4]; however, carrying out joint precipitation of the hydroxides requires special investigations and choice of optimal conditions. Compared with the conventional technique used in stock preparation by mechanical grinding, namely, mixing of the components, chemical methods ensure formation of particles much less than 1 μm in size. Moreover, the structure-forming phases of the materials are synthesized at much lower temperatures.

Morrow and co-authors [5] were the first to report a method for obtaining an ultrafine Al_2O_3–TiO_2 powder (surface area by BET 330 $m^2 g^{-1}$) from titanium and aluminum isopropoxides in a benzene solution. By now, tens of studies have been published, part of which were analyzed in a review [6] concerned with the development of this method. However, the high cost of the starting organic derivatives of titanium and aluminum necessitates a search for new, less expensive techniques. A scheme closely similar to that employed in the present study was described in [7]. According to this scheme, an Al_2O_3–TiO_2 powder is also prepared from an aqueous solution of a mixture of aluminum and titanium sulfates, but by direct evaporation of water in a vacuum evaporator (without precipitation of hydroxides) with the subsequent calcination of the residue to oxides.

To achieve a high homogeneity of finely dispersed powder formulations, conditions are chosen, ensuring simultaneous precipitation of all the necessary components from solution, e.g., in the form of hydroxides.

Thus, the aims of the present study were as follows: (1) to obtain powdered mixtures of titanium and aluminum oxides with strongly different degrees of dispersity by joint precipitation of the corresponding hydroxides (JPH) from solutions of inorganic salts of these elements (oxide products with specific surface area $S_{sp} > 100$ $m^2 g^{-1}$) and mechanical grinding (MG) of the oxides ($S_{sp} < 5$ $m^2 g^{-1}$); (2) to carry out carbothermic reduction of titanium oxides with different prehistories to titanium carbide in the presence of aluminum oxide; and (3) to determine the influence exerted by the dispersity and composition of the starting powder and by the temperature and time of treatment on the properties of an Al_2O_3–TiC powder formulation.

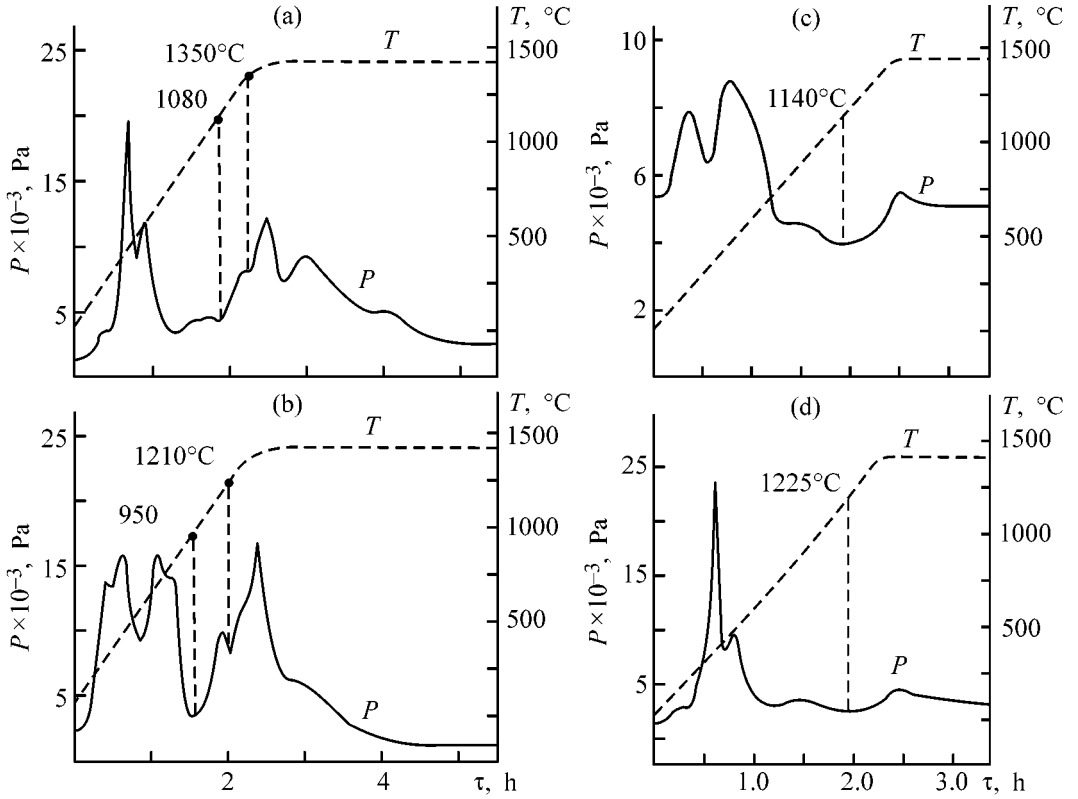

Fig. 1. Thermal treatment mode and curves describing the variation of pressure P in the vacuum chamber for samples prepared (a) by MG, (b) by JPH, (c) via stage of hydroxide precipitation from a solution of an Al(III) salt, and (d) on the basis of standard Al_2O_3 of chemically pure grade. (T) Temperature and (τ) time. Sample composition: (a, b) Al_2O_3–TiO_2–3C and (c, d) Al_2O_3–C.

According to X-ray diffraction analysis data [8], the uncalcined powder of hydrated aluminum and titanium oxides prepared by coprecipitation is X-ray-amorphous. After its isothermal treatment at 1000°C for 2 h, reflections corresponding to corundum and rutile appear in its X-ray diffraction pattern. Beginning with 1300°C, these materials enter into the following solid-state reaction:

$$Al_2O_3 + TiO_2(\text{rutile}) = \beta\text{-}Al_2TiO_5(\text{thialite}). \quad (1)$$

The reaction rate is relatively low at the given temperature: after isothermal treatment for 2 h the reaction is incomplete and X-ray diffraction patterns of the samples contain reflections of thialite and those of corundum with rutile. Raising the temperature to 1500°C results in that the process of aluminotitanate phase formation is complete in 2 h. According to the results of differential-thermal analysis [8], loss of adsorbed and crystal water is observed upon heating to 400°C. Rutile crystallization from coprecipitated hydroxides starts at 800°C, and corundum phase formation, at 1000°C. An endothermic peak corresponding to the reaction of aluminotitanate formation is observed in the interval 1350–1450°C. It should be noted for comparison that, in the case of a mechanically ground Al_2O_3–TiO_2 powder, the temperature of this reaction is shifted to 1450–1500°C.

The specific surface area of the powder obtained by calcination (at 500°C) of coprecipitated aluminum and titanium hydroxides is 130 $m^2\,g^{-1}$ (according to BET), which corresponds to an average equivalent particle radius of about 20 nm. After calcination at 1000°C (surface area by BET 9 $m^2\,g^{-1}$), the average equivalent particle radius increases to 130 nm. Mechanically ground Al_2O_3–TiO_2 powders are characterized by specific surface area of 2 $m^2\,g^{-1}$ and average equivalent particle size of more than 500 nm.

The reduction processes in the system Al_2O_3–TiO_2–nC ($0 \le n \le 4$) are accompanied by release of a large amount of gaseous products. The reduction of titanium dioxide by carbon occurs via formation of lower titanium oxides, with titanium oxocarbide TiO_xC_y or titanium carbide TiC_x being the final products of TiO_2 reduction, depending on temperature, pressure, and composition of the gas phase [9–11]. The intensity of gas formation was monitored by changes in the pressure in the vacuum chamber. Figure 1 shows, in the pressure–time–temperature coordinates, dynamic

curves describing the reduction processes for Al_2O_3–TiO_2–3C samples prepared by MG + carbon (Fig. 1a) and JPH + carbon (Fig. 1b). The observed increase in pressure in the vacuum chamber at low temperatures (below 900°C) is due to liberation of gaseous products formed in pyrolysis of the binder (polyvinyl alcohol) and in degassing of activated carbon. Noticeable reduction onsets at above 950°C, with two peaks of pressure build-up observed in the barograms: peak of medium intensity at 950–1210 (JPH + carbon) and 1080–1350°C (MG + carbon) and a very strong peak at above 1210–1450 (JPH + carbon) and 1350–1450°C (MG + carbon (Figs. 1a and 1b). In the given ranges, the pressure increases until the maximum temperature of isothermal ?keeping is reached and then gradually decreases to the initial values.

According to X-ray phase analysis (XPA) data, reduction of TiO_2 by carbon begins already at 950°C for highly dispersed oxide powders of composition Al_2O_3–TiO_2–3C (JPH + carbon) and at 1080°C for the MG + carbon powder. Carbidization of titanium oxide starts at 1210°C for the JPH + carbon powder and at 1350°C for the MG + carbon powder. Isothermal calcination at 1350°C for 6 h of Al_2O_3–TiO_2–3C powders prepared by both the techniques yields a composite mixture of α-Al_2O_3 and TiO_xC_y. Carbidization of a highly dispersed oxide TiO_2 (JPH + carbon) leads to the formation of a TiC lattice with unit lattice constant ($a = 4.327 \pm 0.004$ Å) virtually coinciding with those of nearly stoichiometric titanium carbide (a = 4.330 Å) [12]. At the same time, treatment of a more coarsely dispersed TiO_2 under the same conditions (MG + carbon) yields TiO_xC_y with lattice constant $a = 4.253 \pm 0.005$ Å. More complete carbidization requires in this case a calcination at higher temperature for a longer time.

Simultaneously with carbothermic reduction of titanium oxide, reduction of aluminum oxide is also observed at temperatures below 1100°C. In carbothermic reduction of aluminum oxide obtained from the hydroxide, this processes begins at a temperature lower by 85°C, which indicates an increase in pressure in the vacuum chamber already at 1140°C (Fig. 1c); for samples containing Al_2O_3 of pure grade and carbon, the onset temperature of gas-forming reactions is 1225°C (Fig. 1d). Although the gas phase composition was not studied, it can be stated on the basis of published data [13, 14] that CO is formed in reduction of metal oxides by carbon in a vacuum. In addition, the gaseous components present at 1140°C in the system studied are Al_2O(g), AlO(g), and also Al(g), which condense to form a loose gray deposit. The condensate contains (according to XPA data) the following phases: Al_2O_3, Al_4O_4C, Al_4C_3, C, and, occasionally, trace amounts of elementary aluminum. The solid residue formed after calcination of the samples at 1600°C for 1 h is only composed of α-Al_2O_3.

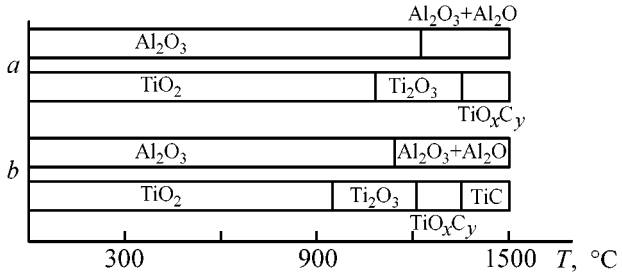

Fig. 2. Changes in the phase composition at various reduction temperatures T for Al_2O_3–TiO_2–3C samples in relation to treatment temperature and prehistory of starting oxides. (*a*) Mechanical grinding of standard oxides with carbon and (*b*) coprecipitation of hydroxides, calcination, and mixing of the oxides with carbon.

To compare the processes of phase formation in Al_2O_3–TiO_2–3C samples obtained using the two methods proposed, Fig. 2 presents histograms of changes in the phase composition at various reduction temperatures in relation to treatment temperature and prehistory of preparation of the oxides. It can be seen that, with coprecipitation of derivative oxides of aluminum and titanium used, the temperature of Ti_2O_3 phase formation can be lowered by 100°C, that of aluminum oxide reduction, by 85°C, and that at which the carbide phase is formed in the oxide system, by 150°C.

Sedimentation analysis shows that a composite micropowder containing α-Al_2O_3–TiC is formed from nanosize precursors (JPH + carbon) of Al_2O_3–TiO_2–3C composition, with the fine fraction (1–3 μm) predominant (>80%) in this micropowder. At the same time, the MG powder is characterized by a broad particle size distribution (5–40 μm).

Also, the nature of phase formation in the system in question was studied in relation to the content of carbon. Figures 3 and 4 present data on the phase composition and mass loss of samples of the Al_2O_3–TiO_2–nC system with carbon content in the range $0 \le n \le 4$ at 1600°C and time of isothermal treatment of 1 h. The amount of gaseous products formed was determined from the difference between the mass of

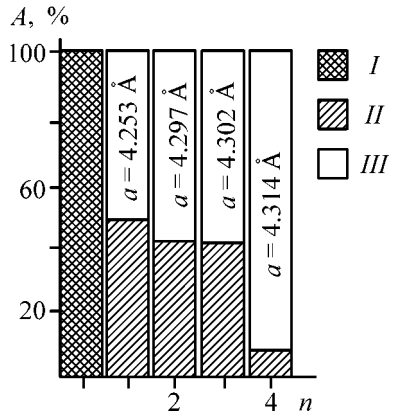

Fig. 3. Phase composition A of solid products of Al_2O_3–TiO_2–nC reduction vs. initial carbon content. T = 1600°C, calcination time 1 h; the same for Fig. 4. (*a*) Lattice constants of titanium oxocarbide TiO_xC_y. (*I*) Al_2TiO_5, (*II*) TiO_xC_y, and (*III*) Al_2O_3.

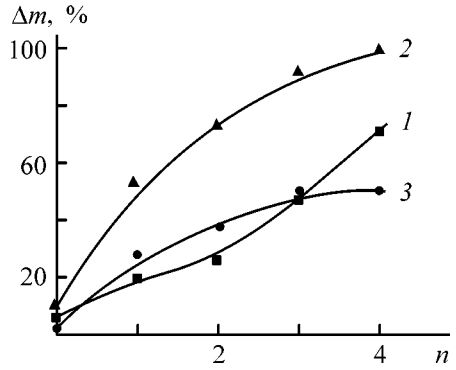

Fig. 4. Mass loss Δm in carbothermic reduction of (*1*) Al_2O_3–TiO_2–nC, (*2*) Al_2O_3–nC, and (*3*) TiO_2–nC systems vs. carbon content of the stock.

the initial reaction mixture and mass of solid reduction products. In the initial portion (carbon content of up to 6 wt % at $n \le 1$), rutile is reduced to TiO_xC_y with lattice constant a = 4.253 Å. The mass loss values recorded can be accounted for by the formation of only CO, since they coincide with experimental loss measured for TiO_2–nC samples containing no aluminum oxide. With 16.5 wt % carbon introduced (n = 3), titanium oxocarbide TiO_xC_y with larger lattice constant a = 4.302 Å is one more reduction product. In the range 6–16.5 wt % C ($1 \le n \le 3$), the mass loss constitutes about 51%, which is mainly due to CO formation. Upon introduction of more than 16.5 wt % C, the loss of mass increases to 70% because of the partial reduction of aluminum oxide to gaseous aluminum suboxides and elementary aluminum [13, 14]. After calcination of the Al_2O_3–TiO_2–4C stock at 1600°C for 1 h, the reduction products contain 10% Al_2O_3 and 90% TiO_xC_y with lattice constant a = 4.314 Å.

EXPERIMENTAL

Joint precipitation of aluminum and titanium hydroxides was carried out with the use of oxotitanium sulfate $TiOSO_4 \cdot 2H_2O$ and aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$, both of pure grade, taken in Al : Ti = 2 : 1 ratio. The precipitation was achieved by adding an equimolar mixture of aluminum and titanium salt solutions to an ammonia solution, taken in excess amount with pH maintained at 7–8 [8].

After drying, hydrated powders of aluminum and titanium oxides were calcined at 1000°C for 2 h in air. As a result, oxides were formed in crystalline state and the specific surface area of the powders decreased. In obtaining Al_2O_3–TiO_2–nC samples ($0 \le n \le 4$), carbon was introduced by mechanical mixing (JPH + carbon).

To reveal the effect of dispersity on the reduction of aluminum and titanium oxides, the starting stocks were also prepared by mechanical grinding. Powdered mechanically ground Al_2O_3–TiO_2–nC samples ($0 \le n \le 4$) were prepared by mixing powdered corundum Al_2O_3 of pure grade and rutile TiO_2 of special-purity grade, taken in a Al : Ti = 2 : 1 ratio, with carbon C of BAU-A grade. The grinding was carried out under wet conditions for 6 h, the aqueous dross was passed through a sieve no. 0050 and then dried at 120°C to constant weight.

Precipitation and mechanical mixing was used to prepare Al_2O_3–C samples from the reagents described above.

The specific surface area of powder samples was measured by BET.

Mixtures for high-temperature treatment were prepared by semidry compaction under pressure of 150 MPa, with 10% aqueous solution of polyvinyl alcohol used as binder. The slugs had the shape of pellets 20 mm in diameter and 5 mm high; the density of compacted samples was 2.0 g cm^{-3}. The thermal treatment of the samples was carried out under dynamic vacuum conditions (P = 10^{-3}–10^{-1} Pa) in an SNVE-1.3.1/16-IZ vacuum electric shaft furnace.

The phase composition of the thermally treated samples was studied by X-ray powder diffractometry on a DRON-3M installation with Cu_{K_α} radiation. The unit cell parameters of TiC were found by the least-squares method for all the unambiguously assigned lines at 2θ reflection angles ranging from 10 to 80°. The error in determining the lattice constants did

not exceed 0.001 Å for titanium carbide and oxocarbide crystallizing in the cubic crystal system.

The powder particle sizes were determined using a Polam R-113 optical polarization microscope at magnification of 400–1100 and JSM-6400 scanning electron microscope at magnification of 2000–10 000 [15].

CONCLUSION

Use of coprecipitation for synthesizing aluminum and titanium oxides makes it possible to lower the onset temperature of their reduction by 100°C and diminish the duration of the high-temperature process in which titanium carbide phases are formed. The reduction of TiO_2 to Ti_2O_3 begins at 950°C for highly dispersed coprecipitated oxide powders and at 1080°C for a powder obtained by mechanical grinding. The final stage of titanium carbidization starts at 1210°C for a powder mixture obtained by coprecipitation and at 1350°C for a powder prepared by mechanical grinding. Further carbidization of highly dispersed mixtures at 1600°C gives TiC with lattice constant $a = 4.327 \pm 0.004$ Å close to that in stoichiometric titanium carbide. Under the same conditions, TiO_xC_y with lattice constant $a = 4.302 \pm 0.005$ Å was obtained from coarser TiO_2. This indicates that the activity of the powders obtained by coprecipitation is retained at high temperature, up to 1600°C.

Processing of nanosize precursors of Al_2O_3–TiO_2–3C composition yields a composite micropowder containing α-Al_2O_3–TiC with predominant (>80%) fine fraction (1–3 μm), whereas the MG powder is characterized by broad particle size distribution (5–40 μm).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Vanadium(V) Complexes in Hydrochloric Acid Solutions

L. D. Kurbatova, T. I. Polupanova, and D. I. Kurbatov

Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received April 19, 2002

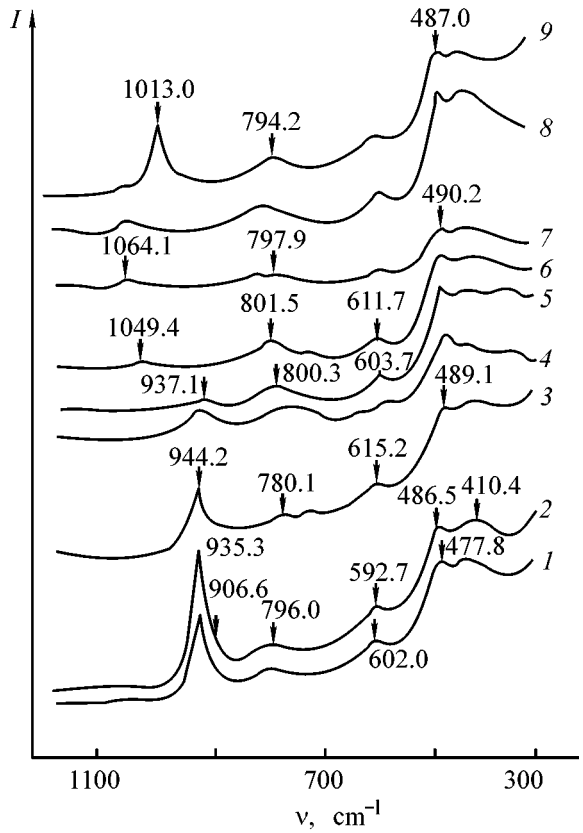
Abstract—^{51}V NMR, electronic, and vibrational spectroscopies were applied to study the ionic state of vanadium(V) in hydrochloric acid solutions at c_{HCl} = 1.0–11.3 M and vanadium(V) concentration of 1 M.

In extraction of vanadium(V) with neutral extracting agents (tributyl phosphate and alcohols) from concentrated hydrochloric acid solutions, co-extraction of the mineral acid is possible. Therefore, in selecting the optimal extraction conditions, a knowledge is necessary of the ionic state of vanadium(V) in concentrated hydrochloric acid solutions. It follows from a review of published data that the ionic state of vanadium(V) in concentrated solutions of mineral acids has been studied insufficiently. Previously, the ionic state of vanadium has been studied [1] at $c_V = 2 \times 10^{-4}$ M in concentrated solutions of hydrochloric acid and its mixtures with lithium chloride. Since more concentrated solutions (c_V = 0.1 M), in which vanadium(V) polymerization is possible, are commonly used in extractive recovery of vanadium(V), it is of interest to study the ionic state of vanadium(V) in a wide range of hydrochloric acid concentrations c_{HCl} = 1.0–11.3 M.

The study was carried out using ^{51}V NMR, electronic, and vibrational (IR, Raman) spectroscopies. The working solutions were prepared from chemically pure reagents. ^{51}V NMR spectra were measured on a Bruker MSL-400 spectrometer at a frequency of 105.24 MHz. The chemical shifts were determined relative to $VOCl_3$ (external standard). IR spectra of vanadium(V) solutions in hydrochloric acid were recorded on a Specord IR-75 spectrometer in the range 400–4000 cm^{-1}. The solutions studied were placed between KRS-6 plates. Raman spectra were recorded on an LTN-402 spectrometer (λ = 532 nm). The acid concentration was varied between 1.0 and 11.3 M at a step of 1 M. The concentration range 8–9 M, in which vanadium(V) dioxocation was assumed to be converted into an oxocation, was studied with a step of 0.1 M.

The figure shows selected Raman spectra of vanadium(V) solutions in hydrochloric acid. A Raman spectrum of a chloride solution of vanadium(IV) at a concentration of 0.506 M is shown for comparison.

The Raman spectra of vanadium(V) solutions in hydrochloric acid, presented in the figure, can be divided into two groups. The high-frequency band ν_1 lies at 930–940 cm^{-1} in the first of these and at 1040–1050 cm^{-1} in the second. In the first group of



Raman spectra of (*1*–*8*) solutions of the system V(V)–HCl–H_2O and (*9*) $VOCl_2$ complex. (*I*) Intensity and (ν) wave number. c_{HCl} (M): (*1*) 1.0, (*2*) 3.0, (*3*) 7.0, (*4*) 8.0, (*5*) 8.6, (*6*) 8.7, (*7*) 9.5, and (*8*) 11.3.

1070-4272/02/7508-1216 $27.00 © 2002 MAIK "Nauka/Interperiodica"

spectra, the ν_1 band is shifted somewhat to higher frequencies (by up to 10 cm^{-1}) with the acid concentration increasing from 1.0 to 8.6 M and its intensity decreases to the point of its complete disappearance. This is presumably due to a decrease in the concentration of dioxocations VO^{2+} with increasing HCl concentration, similarly to the case of low vanadium(V) concentrations [1]. Three bands were found in the IR and Raman spectra of the first group: 930 [$\nu_s(VO_2)$], 900 [$\nu_{as}(VO_2)$], and 300 [$\delta(VO_2)$] cm^{-1}, characteristic of complexes $VO_2Cl_4^{3-}$ of *cis*-configuration [2]. This suggests that vanadium(V) is present in hydrochloric acid solutions with concentration in the range from 1.0 to 8.6 M in the form of chloride complexes of the vanadium(V) dioxocation. The ^{51}V NMR spectra of vanadium(V) solutions in hydrochloric acid with $c_{HCl} \le 8.6$ M contain a singlet signal with a chemical shift of –(526–540) ppm ($\Delta 1/2$ = 300 Hz), which can be attributed, in accordance with the results of investigations described above, to $VO_2Cl_4^{3-}$ in *cis*-configuration. This is also confirmed by published data. It was shown in [3] that at pH ≤ 1 vanadium(V) exists in solutions as a dioxocation and has, according to Raman studies, a *cis*-dioxo structure and pseudo-octahedral structure of $[VO_2(OH_2)_4]^+$. ^{51}V NMR spectra of vanadium(V) in nitric and chloric acids contain a single broad line with chemical shift of -545 ± 2 ppm ($\Delta 1/2$ = 400 Hz). In acid sulfate and phosphate solutions, the band is markedly broadened ($\Delta 1/2$ = 600–1500 Hz) and has a chemical shift of –(520–580) ppm. It can be seen that the broad lines with chemical shifts within –(520–580) ppm in the ^{51}V NMR spectra of vanadium(V) solutions in chloric, nitric, and sulfuric acids suggest that vanadium(V) also presumably has at $c_{HCl} \le 8.6$ M a pseudo-octahedral structure with a *cis*-dioxo group.

At $c_{HCl} > 8.6$ M the ^{51}V NMR spectra of vanadium(V) solutions show a singlet signal with a chemical shift of –326 ppm ($\Delta 1/2$ = 600 Hz). The strongly differing chemical shift of the ^{51}V signal (by more than 200 ppm) in vanadium(V) solutions at high hydrochloric acid concentrations points to changes in the ligand environment of the first coordination sphere of vanadium(V). The downfield shift of the ^{51}V NMR signal, compared with published data [4], indicates that additional chloride ligands are introduced into the inner coordination sphere of vanadium(V), and the Cl/V(V) ratio increases.

The changes occurring in the inner coordination sphere of vanadium(V) at high hydrochloric acid concentrations ($c_{HCl} \ge 8.6$ M) are also confirmed by Raman spectra. At a hydrochloric acid concentration exceeding 8.60 M (second group of solutions) a low-intensity high-frequency band appears at 1040–1050 cm^{-1}. This band can be assigned [5] to stretching vibrations of the type ν_1 of the oxovanadium(V) cation. If the coordination number of vanadium(V) is preserved equal to six, then further increase in the number of chloride ligands in the inner coordination sphere becomes possible if a pentachloride complex of oxovanadium(V) cation $[VOCl_5]^{2-}$ is formed. In this case, the Cl/V(V) ratio corresponds to 5, which exceeds the value for the $[VO_2Cl_4]^{3-}$ complex.

However, a Raman spectrum of the pentachloride complex of the oxovanadium(V) cation, $(VOCl_5]^{2-}$, different from the Raman spectra of vanadium(V) solutions at high hydrochloric acid concentrations, was described in [6]. This means that complexes of composition $[VOCl_5]^{2-}$ are not formed in concentrated hydrochloric acid solutions. Presumably, at high hydrochloric acid concentrations, not only the vanadium(V) dioxocation is converted into the oxovanadium(V) cation, but also the coordination number of vanadium changes to 5, or even 4, with the formation of complexes of the type $[VOCl_4]^-$ or $[VOCl_3]$. For example, to the stretching vibration ν_1 of the V=O double bond in the complex $[VOCl_3]$ having the coordination number of 4 corresponds the frequency of 1035 cm^{-1} [7].

Comparison of the Raman spectra of vanadium(V) solutions at high hydrochloric acid concentrations (see figure, curves *7* and *8*) with the Raman spectrum of the complex $[VOCl_3]$, presented in [7], reveals their significant difference. This suggests that no complexes of the type $[VOCl_3]$ are formed at high hydrochloric acid concentrations. Under these conditions, vanadium(V) forms complexes of composition $[VOCl_4]^-$ in which the Cl/V(V) ratio exceeds that in the tetrachloride complex of the vanadium(V) dioxocation, $[VO_2Cl_4]^{3-}$. It is this circumstance that leads to a downfield shift of the ^{51}V signal. An identical change in the coordination number with increasing hydrochloric acid concentration was noted in [4] for gallium(III) complexes. A single signal with chemical shift of 0 ppm was observed in ^{71}Ga NMR spectra at c_{HCL} in the range from 0.2 to 5.2 M. At $c_{HCl} \ge 7.0$ M the ^{71}Ga NMR spectrum contains a narrow line with a chemical shift of 248 ppm. The shift of the ^{71}Ga signal was attributed in [4] to conversion of the gallium hexa aqua complex $[Ga(H_2O)_6]^{3+}$ into a tetrachloride complex $[GaCl_4]^-$.

An additional study was carried out to confirm these conclusions. In [8], calculations by the MO

method were performed and an electronic spectrum of a tetrachloride complex of oxovanadium(V) cation, $[VOCl_4]^-$ was presented. Comparison of the electronic spectrum of a vanadium(V) solution with c_{HCl} = 11.3 M, measured in the present study, with the spectrum from [8] shows that both these spectra contain a strong band at 21 500 cm^{-1}, which can be assigned to $b_1(a_2) \rightarrow e\pi^*$ or $e\pi(e) \rightarrow b_2^*$ $(A_1 \rightarrow E)$ transitions. This indicates that, presumably, not only the vanadium(V) dioxocation is converted into the monooxocation at high hydrochloric acid concentrations, but also the coordination number of vanadium(V) changes to 5, with the result that vanadium(V) forms tetrachloride complexes of the oxovanadium(V) cation, $[VOVCl_4]^-$.

A comparative analysis of Raman spectra of vanadium(V) solutions belonging to the first and second groups and hydrochloric acid solutions with the corresponding concentrations was made in the spectral range $\nu < 900$ cm^{-1} where the characteristic vibration frequencies of V–O–V and V–Cl bonds lie. No bands associated with symmetric and asymmetric vibrations of the bridge bonds V–O–V [9, 10] were found in the ranges 750–800 and 480–490 cm^{-1}. This indicates that no polymerization of vanadium(V) polyhedra occurs at high concentrations of vanadium(V) and hydrochloric acid.

Unfortunately, it is impossible to analyze the lowest-frequency range, in which the V–Cl vibrations lie ($\nu < 480$ cm^{-1}), since these vibrations are overlapped by the deformation vibrations of the V–O bond [10].

CONCLUSION

A study of the ionic state of vanadium(V) at c_V = 0.1 M in hydrochloric acid solutions established that the composition of the complexes depends on the hydrochloric acid concentration. Tetrachloride complexes of the vanadium(V) oxocation, $[VO_2Cl_4]^{3-}$, are formed at $c_{HCl} \le 8.6$ M, whereas at $c_{HCl} > 8.6$ M vanadium(V) exists in the form of tetrachloride complexes of the oxovanadium(V) cation, $[VOCl_4]^-$.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Stability of Polymeric-Salt Gels Used To Synthesize Complex-Oxide Materials

A. A. Ostroushko, D. S. Mikhalev, and N. V. Reshetnikova

Ural State University, Yekaterinburg, Russia

Received October 16, 2000; in final form, November 2001

Abstract—The conditions for stability of polymeric-salt systems based on polyvinyl alcohol, used to synthesize complex-oxide materials containing rare-earth, alkaline-earth, and *d* metals, were studied.

Formulations containing nonionogenic water-soluble polymers of the type of polyvinyl alcohol (PVA) or polyvinyl pyrrolidone and methyl cellulose, and also metal salts (nitrates, acetates, formates, etc.) are used to obtain various complex-oxide materials in the form of powders or coatings [1].

The use of the given method for synthesizing complex oxides containing Mo(VI), W(VI), V(V), rare-earth (REM), alkaline-earth (AEM), and other metals is characterized by a number of specific features associated with the ability of *d* metals contained in these oxides to form oxygen-containing anionic forms. The conventional coprecipitation of components in the form of aqua polycompounds with their subsequent separation from the mother liquor and thermal treatment is frequently hindered by complicated control over the composition of the products being precipitated [2, 3], especially in those cases when two or three different cations are to be introduced into a complex oxide simultaneously.

In the presence of polymers, salts (nitrates, in particular) of REM and AEM can be mixed in solutions with ammonium molybdates, tungstates, and vanadates in such a way that stable dispersed systems (gels or jellies) appear, with homogeneously distributed components. This occurs because of the appearance of three-dimensional (3D) networks in which REM and AEM cations serve as cross-linking agents for fragments of molecular complexes formed by polyanions [4, 5]. Such a method yields homogeneous starting formulations for synthesis of complex oxides of prescribed composition, with the results of synthesis directly dependent on the stability of the corresponding dispersed systems. In the present study, factors determining the stability of dispersed structures are considered and the limits of existence of some of these factors are determined.

EXPERIMENTAL

As starting inorganic reagents served ammonium heptamolybdate tetrahydrate $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, ammonium vanadate NH_4VO_3, ammonium *para*-dodecatungstate hydrate $(NH_4)_{10}W_{12}O_{41} \cdot nH_2O$, lanthanum trinitrate hexahydrate $La(NO_3)_3 \cdot 6H_2O$, strontium dinitrate tetrahydrate $Sr(NO_3)_2 \cdot 4H_2O$, $RbNO_3$, $(NH_4)_3PO_4$, NH_4HF_2, and HNO_3, all of no less than analytically pure grade. As polymeric component was used PVA with molecular weight M_r 15 000 and 31 000–50 000 (Aldrich Chemical).

The salt and polymeric components were dissolved in distilled water, with heating on water bath when necessary. Then a PVA solution was mixed with solutions of individual salts. The order in which the solutions were poured together was varied depending on the composition of a complex-oxide product to be obtained. Solutions of like components, e.g., those of nitrates of various metals or ammonium vanadate and phosphate were preliminarily mixed, or the components were subjected to joint dissolution in water. Gels or jellies obtained after mixing of the working solutions were allowed to stay in closed tubes for visual inspection of the stability. These formulations were used to obtain by casting and subsequent drying films of thickness ranging from 30 μm to 1 mm on substrates of K8 optical glass. In the case of fluorine-containing compositions, polyethylene substrates were used. The films served for visual inspection under an MIM-7 microscope in reflected light at magnification of up to 100. Films separated from sub-

strates were subjected to pyrolysis in a muffle furnace and final annealing in air at 600–900°C for 2–24 h. The complex-oxide materials obtained were identified using X-ray phase analysis on a DRON-3M diffractometer with Cu_{K_α} radiation.

The stability of the gels or jellies obtained was assessed by three main criteria: by the absence of (i) stratification with liquid separation in the upper part of the tubes; (ii) compact solid deposits; and (iii) macroscopic separation in the films, with the appearance of nonuniform distribution density of gel or particles discernible under microscope. The requirements to stability were satisfied by gel-forming systems in which the uniformity was not disturbed for any of the characters for at least three weeks. X-ray diffraction analysis of ground films obtained in systems of this kind demonstrated that they contain no individual salt components [4]; complex oxides were most frequently synthesized in thermal treatment directly from the amorphized mass, without intermediate formulation of individual oxides [6, 7].

The stability of dispersed structures is determined by a number of factors and, in particular, by the concentration of a polymer and its molecular weight (see table). The stability of gels is higher for a polymer with larger molecular weight, which forms starting solutions with higher viscosity. Raising the polymer concentration, all other conditions being the same, also stabilizes dispersed systems (Fig. 1). An important factor is the concentration ratio of salts containing cations [lanthanum(III), in particular] and ox-

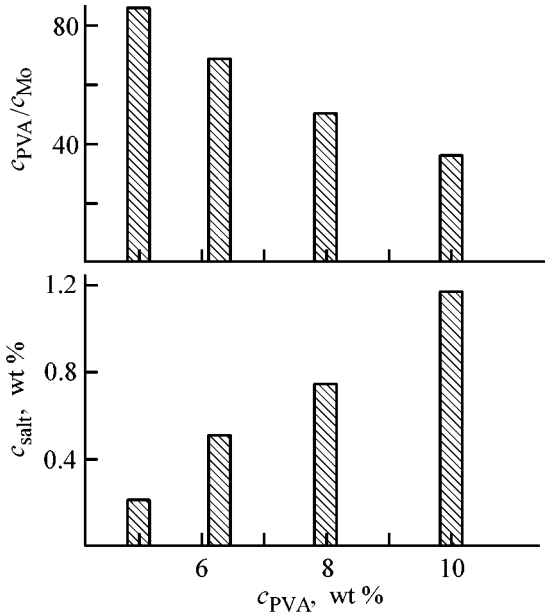

Fig. 1. Concentration dependences of stability of polymeric-salt gels in a system formed by ammonium heptamolybdate and lathanum trinitrate. Atomic ratio La_2O_3 : MoO_3 = 1 : 3. (c_{PVA}/c_{Mo}) Ratio of molar concentrations of PVA (per monomeric unit) and Mo(VI) (in terms of MoO_4^{2-}); (c_{salt}, c_{PVA}) concentrations of salts (total) and PVA (wt %). The region of stable gels is shaded; the same for Fig. 2.

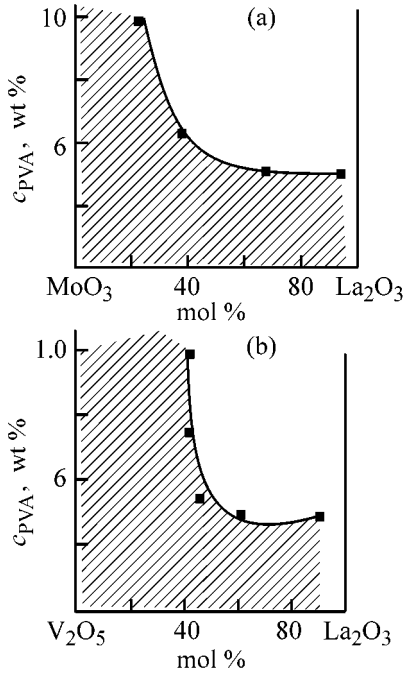

Fig. 2. Stability diagrams of polymeric-salt gels at total salt content of 0.35 wt % in systems formed by (a) ammonium heptamolybdate and lanthanum trinitrate and (b) ammonium vanadate and lanthanum trinitrate. (c_{PVA}) PVA concentration.

ygen-containing anionic forms of *d* metals [molybdenum(VI) and vanadium(V)]. This can be accounted for by the existence, in mixing of polymer-containing salt solutions, of ratios (equivalence points of precipitation titration) corresponding to their maximum binding [4]. For example, in the system comprising ammonium heptamolybdate and lanthanum trinitrate, such a point lies at lanthanum(III) content close to 25 mol % (in terms of La_2O_3). Just at this concentration there occurs a transition from more to less stable gels with higher content of ammonium molybdate (in terms of MoO_3), with the corresponding bend observed in the curve in Fig. 2a. The same circumstance accounts for the dependence of gel stability on the order in which the components are poured together: when this order is changed, the equivalence point is shifted [4]. In particular, for obtaining a stable gel with composition corresponding to that of the compound $LaVO_4$ ($La_2O_3 : V_2O_5 = 1 : 1$), it is necessary to add the ammonium vanadate solution to that of lanthanum trinitrate. In this case, the equivalence point is close to the above ratio, whereas at the inverse order of pouring together it approaches the ratio $La_2O_3 : V_2O_5 = 1 : 3$. It should be noted that use of polymer-containing solutions enables preparation of stable gels in a sufficiently wide concentration range with increasing concentration and molecular weight of the polymer. This circumstance expands the range of applicability of the method, compared with purely salt systems, for synthesizing complex oxides containing the components in amounts differing from their ratios at the equivalence point.

Introduction, together with of REM ions, of AEM or alkaline metal ions impairs the stability of gels because of the higher solubility of the corresponding molybdates, tungstates, and vanadates [4, 8]. In mixed formulations, salts with higher solubility are in the dispersed medium and pass into a liquid that separated from the gel. To prevent stratification of such gels, it is necessary to raise the concentration of a polymer or its molecular weight. One more factor impairing the stability of dispersed systems is the lower charge of AEM ions as compared with REM ions; hence follows their decreased ability to act as cross-linking agents in formation of 3D networks. Nevertheless, it is possible to obtain stable gels by dosing the starting solutions in prescribed proportions (see table). Stable formulations with atomic ratios of the components La(III) : Sr(II) : W(VI), equal to 4 : 1 : 7, 2 : 1 : 1, 2 : 3 : 2, and 2 : 9 : 4, which corresponds to complex oxides or solid solutions $SrLa_4(WO_4)_7$, $SrLa_2WO_7$, $Sr_3La_2W_2O_{12}$, and $Sr_9La_2W_2O_{24}$. Conversely, difficultly soluble aqua polycompounds are occasionally precipitated from gels (see table); in this case, the gel is acidified with nitric acid to improve the stability of dispersed systems. The presence of H^+ ions lowers the concentration of oxygen-containing anionic forms of *d* metals because of their transition to neutral or cationic oxygen-containing forms [2, 4], with their capacity for complexation with the polymer preserved.

Replacing part of vanadium(V) in the system composed of ammonium vanadate and lanthanum trinitrate with phosphorus(V) (which corresponds to $LaV_{1-x}P_xO_4$ solid solutions with x of up to 0.5 [9]) by introduction of ammonium phosphate much improves the stability of gels, to the point of formation of resin-like jellies. These jellies possess a characteristic property of such formations, thixotropy, i.e., the ability to restore geometric shape after removal of mechanical stresses applied. They are even stable upon heating to 80–90°C. In this case, the strength of cross-linking of fragments of molecular complexes into a 3D network is very high, which suggests the influence of the effective charge of the anion per atom of a *d* metal or its substituent, P(V). Vanadate, molybdate, and tungstate anions in solution and in the solid state tend to form strongly condensed polyanions [2, 10] with 4, 7, 12, and more coordination polyhedra of *d* metals associated into a complex polyanion. The bonding between the polyhedra (commonly, distorted octahedra) is effected by common oxygen(II) ions simultaneously belonging to two or three *d* metal atoms. The effective charge per *d* metal atom is equal to, or somewhat greater than unity, e.g., for $V_4O_{12}^{4-}$, $Mo_7O_{24}^{6-}$, and $W_{12}O_{41}^{10-}$ anions. Phosphate ions PO_4^{3-} show less pronounced tendency toward condensation [11], which makes higher the charge state of the formula unit and its capability to be cross-linked into 3D networks by the cations introduced.

The experiments performed yielded gels stable within 1 to several days, corresponding to $La_{1-x}Ca_xVF_yO_{4-y}$ solid solutions (with x of up to 0.7 and $0 \le y \le 0.3$) [9]. The following solid solutions were synthesized: solid solution with monazite structure, $LaV_{1-x}P_xO_4$ (annealing at 700°C for 6 h); $La_{1-x}Rb_xVO_{4-y}$ with x from 0 to 0.5 (4 h at 700°C); $SrWO_4$-based solid solution containing 40 mol % $La_2(WO_4)_3$, with scheelite structure; and $SrLa_4(WO_4)_7$ with perovskite structure (annealing at 800°C for 9 h).

CONCLUSIONS

(1) The stability of polymeric-salt gels and jellies used to synthesize complex-oxide materials containing *d* metals, Mo(VI), W(VI), and V(V), is determined by a number of factors, the most important of which is the nature of the constituents.

(2) The stability of dispersed system is markedly improved by an increase in the effective charge of anions and cations. Presence of cations forming soluble compounds with *d* metals in the anionic form impairs the stability of gels and leads to separation of the liquid part; formation of aqua polycompounds with low solubility product causes precipitation.

(3) All other conditions being the same, higher stability is observed for gels whose composition is close to the equivalence point of precipitation titration of the corresponding salt systems and those with high content of polymer or in the presence of a polymer with high molecular weight.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Inorganic Phosphate Curing Agents for Epoxy Composite Materials

P. V. Nikolaev and L. N. Lebedeva

Ivanovo State Academy of Chemical Technology, Ivanovo, Russia

Received March 20, 2002

Abstract—Fundamental aspects of how epoxy polymeric materials are formed on the basis of phosphate curing systems undergoing homopolycondensation were studied. The advisability of using phosphate curing agents in a microheterogeneous colloid-dispersed state was demonstrated.

The wide use of epoxy composite materials (ECM) containing no organic solvents has shown that they have, together with numerous advantages and, occasionally, unique properties, also disadvantages associated with the toxicity of the volatile components (epichlorohydrin, toluene) contained in epoxy oligomers (EO). The assortment of curing agents used in ECM containing no organic solvents is rather narrow. The most widely used at present are aliphatic amines, which allow deposition of polymeric epoxy coatings without heating. As a rule, the amines used are toxic. Important disadvantages of epoxy polymeric systems obtained with the use of most of amine curing agents is their poor thermal stability and high combustibility. In this connection, development of new ecologically safe curing agents improving the thermal stability and lowering the combustibility of epoxy polymeric materials is an urgent task.

Particularly noteworthy is the use of orthophosphoric acid as a curing agent for ECM, since one of the best fire retardants, phosphorus, and an environmentally pure fire retardant, water, are introduced into the material in this case. However, investigations of the systems ⟨epoxy oligomer ED-20⟩–H_3PO_4–H_2O demonstrated that the lifetime of the composites is short, and the degree of their curing strongly depends on the content of water in the acid [1].

In order to make lower the activity of H_3PO_4, to improve the technological properties of the systems being cured, and to enhance their thermal stability and diminish combustibility, a technique for obtaining new phosphate curing agents (PCA) of inorganic origin was developed.

As a raw material for their preparation served large-tonnage commercial products: H_3PO_4, red iron oxide pigment, and talc. The components of phosphate pastes (PP) were mixed without heating. The relative contents of the solid and liquid phases, as a rule, corresponded to acid capacity of the first degree. In the initial state, PCAs are pastes that can spontaneously undergo homopolycondensation without heating of the system. Owing to this circumstance, it is possible not to perform precise dosage of the components in formulating an epoxy composite.

The reactions in which condensed phosphates (PCA prepolymers) are formed in curing agents (homopolycondensation) occur in stages. It is known that H_3PO_4 forms with iron(III) oxide three types of salts: $2Fe(H_2PO_4)_3 \cdot 3H_2O$ (dihydrophosphate), $Fe_2(HPO_4)_3 \cdot 3H_2O$ (hydrophosphate), and $2FePO_4 \cdot 3H_2O$ (orthophosphate). Curing of PPs and their polycondensation yields polymeric phosphate stone.

The intermediate products of homopolycondensation, iron dihydro- and hydrophosphates, are reactive toward EOs and can cure them. The functionality of incomplete phosphates with respect to EO, following from their structure, is 6 and 3 for, respectively, dihydro- and hydrophosphates. This ensures preparation of an epoxy-phosphate organo-inorganic polymeric material with three-dimensional network structure, which may contain $-Fe-O-\underset{|}{P}=O$, $O=\underset{|}{P}-O-CH_2-$. fragments. The final products of homopolycondensation, iron orthophosphate and polymeric inorganic phosphate [2], are inert toward the EO.

In their aggregation state, the curing agents are phosphate pastes of color determined by the presence

of a mixture of iron oxide and talc. It should be noted that such a technological property as the viscosity of PPs prepared from iron oxide and talc first decreases and then, in the course of time, EO turns solid. The time during which this transformation occurs is determined by the concentration of the acid and by the acid/oxide ratio. With decreasing concentration of the acid employed, the "lifetime" of a curing agent becomes shorter. For example, the lifetime of a PP prepared from a 37% solution of H_3PO_4 is only 24 h, and that with a 77% solution, about 1 month.

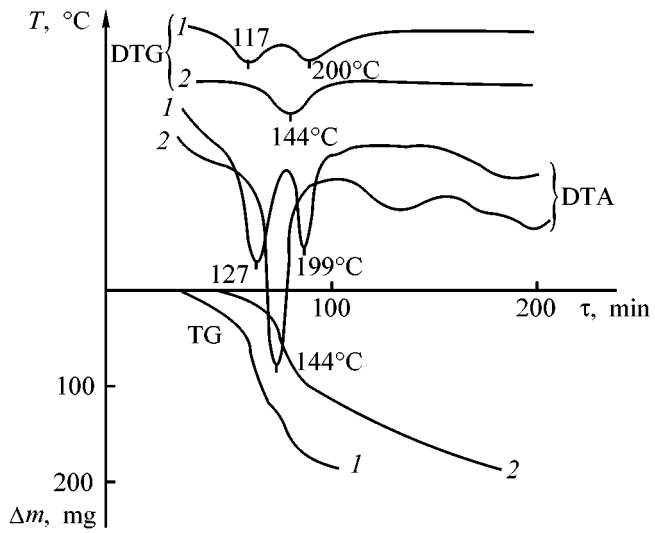

Fig. 1. Thermograms of PCA samples containing 77 wt % H_3PO_4 and red iron oxide pigment. (*T*) Temperature, (Δ*m*) loss of mass, and τ time; the same for Fig. 2. Time of aging of curing agent: (*1*) 30 min and (*2*) 900 h. Rate of temperature rise 5 deg min^{-1} up to 500°C.

The density of the curing agents is 1.29–2.74 g cm^{-3}, with acid number (AN) equal to 150–600 mg KOH/g. The phosphate curing agents are well compatible with liquid EOs or mixtures of these, and also with ECMs, e.g., with EP-0010 epoxy filling and EP-1155 and BEP-1264s epoxy enamels.

To elucidate the nature of the processes occurring in a mixture of a red iron oxide pigment with H_3PO_4 of various concentrations, which ensure a spontaneous conversion of a heterogeneous coarsely dispersed system obtained on mixing powdered oxide with H_3PO_4 into a microheterogeneous colloid-dispersed system, and then into a monolithic solid, the variation of the dispersity *D* of the system, AN, and the content of iron ions, $c_{Fe^{3+}}$, and free H_3PO_4, $c_{H_3PO_4(fr)}$, with the aging time τ of a curing agent was studied (see table).

It can be seen from the table that both the H_3PO_4 content and the AN in the system decrease. This indicates that the acid interacts chemically with the α-oxide of iron(III), with the interaction the more intensive, the lower the acid concentration. However, such characteristics as the content of iron ions and the dispersity vary nonlinearly, which indicates that there occurs homocondensation of the components of the system, and, first, acid iron phosphates and then orthophosphate and polymeric phosphate stone are formed [3].

The phosphate pastes prepared from iron(III) oxide and 77 wt % H_3PO_4 were subjected to thermogravimetric (TG) and differential-thermal (DTA) analyses. Figure 1 presents the results obtained in analysis

of PPs after varied time of aging. It can be seen from the DTA curves that the processes occur in PCAs at moderate temperatures. Two pronounced endothermic peaks in the DTA curves and two regions of mass loss in the TG curves are observed in the temperature interval 120–200°C for a freshly prepared curing agent. These features indicate that the system contains bound and constitution water [4], each removed in a certain temperature range. With increasing time of curing agent aging, the composition of the formulation changes, which is due to the occurrence of a complex physicochemical process accompanied by, e.g., evaporation of the constitution water. The presence of a single endothermic peak and of the corresponding region of mass loss characterizes the loss of the crystal hydrate water by the reaction

$$FePO_4 \cdot 2H_2O \xrightarrow{140–210°C} FePO_4 + 2H_2O\uparrow.$$

A significant difference is also observed in studying the curing of EO with PPs with varied conversion of their components (Fig. 2). The DTA curves exhibit a clear-cut distinction consisting in a strongly pronounced endothermic peak (T_{max} = 408°C) in the case of an aged curing agent, which, in the authors' opinion, indicates a thermal destruction of the organo-inorganic three-dimensional structure formed in curing in the isothermal mode without heating, which does not appear at short aging time. The TG curves show two portions of mass loss. With increasing time of PCA aging, the maximum rate of mass loss is shifted to higher temperatures (from 314 to 372°C), which indicates that the thermal stability of composites with aged curing agents is high. This conclusion is also confirmed by the $T_{0.25}$ values (332 and 362°C for, respectively, the systems with freshly prepared and aged curing agents).

Depending on the H_3PO_4 concentration and time of aging of PP, the content of the curing agent can be varied between 4 and 400 wt % relative to EO. Therefore, the dependence of the relative hardness and degree of curing on the time of aging of phosphate pastes was studied. A decrease in their activity, i.e., an increase in the lifetime of the EO–PCA system, was observed.

The dependences of the content of the gel fraction GF on the time of PP aging are presented in Fig. 3a. The difference in the observed types of behavior is due to the content of acid in the initial PP. The phosphate pastes based on aqueous H_3PO_4 solutions are converted from a heterogeneous coarsely dispersed system of the starting components, by the interaction of these components,

into a microheterogeneous colloid-dispersed system [4, 5], which contains, together with H_3PO_4 and iron(III) oxides, also products of their reaction, iron phosphates. The pastes based on anhydrous H_3PO_4 become thinner in the course of time and strat-

ify, with no microheterogeneous colloid-dispersed system formed.

The curing agents developed exhibit latent behavior, similarly to H_3PO_4. At moderate temperatures (~140°C) there occurs additional curing of systems formed without heating. The GF content is as high as 98 wt % in some cases (Fig. 3b). For formulations based on anhydrous H_3PO_4, no extremal behavior of the dependences is observed.

It is not impossible, either, that, similarly to the case of ordinary cements, structuring occurs in the system after mixing of PP components and formation of a primary layer of hydrates, owing to molecular interparticle interaction. The resulting iron phosphates are centers of crystallization, and crystals grow through material deposition onto primary miniscule particles, named nuclei [6]. In this case, water plays the part of a component that favors dissolution of the pigment iron(III) oxide and of the forming molecules of iron phosphates, i.e., promotes adhesion of the appearing particles and formation of a solid phosphate stone.

The GF content of cured coatings decreases if the aging time of the curing agent (PP) obtained on the basis of anhydrous H_3PO_4 increases. Chemisorption of the acid on the α-oxide of iron(III) and their chemical reaction in the system containing anhydrous acid also occur. However, these processes are hindered since the surface of iron(III) oxide is more hydrophilic than acidophilic. As a result, a polymer with the maximum GF content is formed at short time of PP aging, when the content of free H_3PO_4 in the PP is high and the amount of iron phosphates and water, as reaction products, is low. The lifetime of the PCA–EO system is at a minimum. In the course of time, the content of free acid in the PP decreases; however, the forming incomplete iron phosphates can only be hydrated by the reaction water whose amount is insufficient to cause dissociation and ionization of salts in the system.

For this reason the intermediate reaction products, incomplete iron phosphates, do not react in the given system with EO without heating and the content of the gel fraction decreases. However, additional curing of ECM occurs at elevated temperature. The content of the gel fraction in the system EO–PCA increases by 5–35%. The effect of additional curing is the most pronounced with PP aged for up 7 days. At 140°C incomplete iron phosphates react, in the first place, with one another and with iron(III) oxide to form an inorganic polymeric phosphate, with reactions involving the epoxy binder being not improbable, either.

The reaction water forms crystal hydrates with iron salts or evaporates, which also favors an increase in the content of the gel fraction, since hydrolysis of tri- and diphosphate esters become less probable.

These features are accounted for by differences between the changes occurring in PPs obtained with diluted and anhydrous H_3PO_4. The presence of water in the acid, and in the PP obtained on its base, favors formation of an organo-inorganic polymeric structure with high degree of cross-linking. It should be noted that the composite obtained contains a substantial amount of unreacted iron(III) oxide and its hydrophosphate.

CONCLUSIONS

(1) Formulas of phosphate curing agents (phosphate pastes) that undergo homopolycondensation and the technology of their use in epoxy composite materials were developed. It was shown that water contained in the starting acid exerts decisive influence on the process of prepolymerization of the system ⟨orthophosphoric acid⟩–Fe_2O_3. This water determines the structure of prepolymers and the lifetime of phosphate curing agents and epoxy composites, and also affects the degree of curing of the polymeric material obtained.

(2) It was shown that phosphate curing agents in microheterogeneous colloid-dispersed state are to be used to obtain an organo-inorganic epoxy polymeric material with high content of the gel fraction.

SORPTION AND ION-EXCHANGE PROCESSES

Chromatomembrane Gas-Extraction Water Purification To Remove Dissolved Oxygen

L. N. Moskvin, O. V. Rodinkov, G. L. Grigor'ev, and I. A. Zykin

St. Petersburg State University, St. Petersburg, Russia

Received October 8, 2001; in final form February, 2002

Abstract—Fundamental aspects of the process of continuous chromatomembrane gas-extraction purification of water to remove dissolved oxygen are considered. An adequate physicochemical model and mathematical description of the process are proposed. The advantages of the chromatomembrane technology of water deaeration over the conventional methods for removing dissolved oxygen are demonstrated and substantiated.

The problem of effective removal of gas impurities, and dissolved oxygen in the first place, from water is encountered both in various branches of industry, such as nuclear and thermal power engineering, organic synthesis, and manufacture of semiconducting materials, and in laboratory practice, e.g., in carrying out biochemical and electrochemical studies and, in particular, in preparing standard aqueous solutions with prescribed concentrations of these impurities in the stage of calibration of analytical instruments. The efficiency of the most widely used techniques for removing gaseous impurities from aqueous solutions, based on the conventional mass–exchange processes in the gas–liquid system (boiling, bubbling), proves to be insufficient in many cases. Even with the optimal designs of deaerating installations the residual content of oxygen in water exceeds that required by regulations [1]. Membrane methods for extraction of volatile impurities across porous hydrophobic membranes are characterized by relatively low output capacity, which results from hindrances to diffusion processes in membranes [2]. Chemical techniques for removal of dissolved oxygen change the composition of the water medium and, therefore, are not always acceptable for water deaeration.

More promising for deep purification of water to remove volatile impurities and, in particular, dissolved oxygen is the chromatomembrane method for performing mass-exchange processes in the liquid–gas system, proposed by Moskvin [3, 4]. This method combines advantages of chromatographic (high mass-exchange efficiency) and membrane (continuous process mode) techniques of substance separation.

The aim of the present study was to reveal the fundamental aspects of the process of continuous chromatomembrane gas extraction and to evaluate its efficiency in deep purification of water to remove dissolved oxygen.

EXPERIMENTAL

The scheme of the process of continuous chromatomembrane gas extraction is shown in Fig. 1. The mass-exchange between the flows of liquid and gas, leading to gas-extraction removal of dissolved oxygen, occurs in a capillary-biporous medium formed by particles of porous polytetrafluoroethylene (PTFE), which are bound together in sintering. The spaces between the particles form a system of open macropores of arbitrary configuration, through which moves water

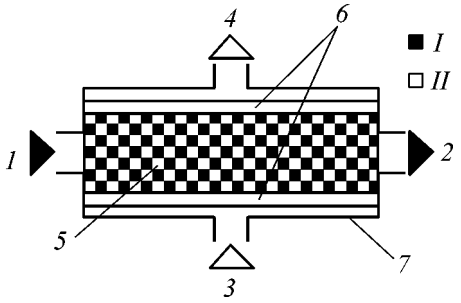

Fig. 1. Scheme of chromatomembrane gas extraction: (*1, 2*) inlet and outlet for liquid, (*3, 4*) inlet and outlet for extracting gas, (*5*) mass-exchange bed of hydrophobic biporous material, (*6*) membranes, and (*7*) case of the chromatomembrane unit. Space in the mass-exchange bed occupied by (*I*) macropores and (*II*) micropores.

being purified to remove dissolved oxygen. The sizes of PTFE particles and, correspondingly, the macropore sizes are set arbitrarily by the technique used to obtain biporous PTFE. The particles themselves contain open pores of micrometer and submicrometer sizes: micropores through which moves extracting gas, whose part was played in the given case by high-purity nitrogen containing less than 0.001 vol % oxygen. Biporous mass-exchange bed is limited from above and below by water-impermeable PTFE membranes through which the flow of the extracting gas is supplied and withdrawn. The inflow of water into micropores of the membranes and the mass-exchange bed is prevented by the negative capillary pressure appearing in the micropores because of the nonwettability of PTFE by water. In its turn, the inflow of the extracting gas into the macropores, in which the capillary pressure is negligibly small, is hindered by the pressure of the liquid, which is maintained higher than the gas pressure according to the experimental conditions. More evidence about the physicochemical essence of chromatomembrane mass-exchange processes and the conditions under which they are to be carried out can be found in [3, 4].

We performed the study on prototype chromatomembrane units (CMU) of our own manufacture, with a mass-exchange bed in the form of a parallelepiped. We analyzed the influence exerted by the ratio of flow rates of water and extracting gas, macropore size in the mass-exchange bed, and bed length on the efficiency of chromatomembrane purification of water to remove dissolved oxygen. For the bed length was taken the extension of the mass-exchange bed in the direction of motion of the liquid being deoxygenated, and for the bed height, the extension of the bed in the direction perpendicular to that of the fluid flow (Fig. 1). The length L of the mass-exchange bed in the CMU prototypes studied was varied within 1–10 cm at constant height and width of 0.8 cm. The macropore diameter, for which was taken the average size of PTFE particles forming the mass-exchange layer, was varied within 0.25–1.5 mm.

A flow of distilled water saturated with atmospheric oxygen was fed into the inlet of a CMU under study. To evaluate the efficiency of the chromatomembrane purification and determine the residual concentration of dissolved oxygen, the flow of water from the CMU under study was directed into a chromatomembrane cell (CMC) of similar design and smaller size, which ensured, as shown by results of independent tests, at least 99% deoxygenation oxygen because of the higher flow rate of the extracting gas. The flow of the extracting agent outflowing from the analytical CMC was directed through a drier with indicator silica gel into the dosing loop of an LKhM-80 gas chromatograph equipped with heat conductivity detector and a column packed with CaA zeolite, and analyzed for the content of oxygen. As carrier gas in gas-chromatographic analysis served helium of B brand, containing less than 0.001 vol % oxygen. The oxygen content in the carrier gas was determined using the method of absolute calibration against standard gas mixtures of oxygen in nitrogen. The residual mass concentration of oxygen, c, in air after chromatomembrane purification was calculated using the formula [4]

$$c = c_g W_g^*/W_l,$$

where c_g is the mass concentration of oxygen in the flow of the extracting gas at the CMC outlet, found by gas-chromatographic analysis; W_g^* and W_l are the volumetric flow rates of the extracting gas and water through the CMC (ml min^{-1}).

The gas-chromatographic technique described allows determination of the residual concentration of dissolved oxygen beginning with 15 μg l^{-1}, with relative error not exceeding 20%.

The admissible pressure gradients in fluid and gas phases and, correspondingly, the maximum velocities of motion of these phases across the mass-exchange bed in carrying out chromatomembrane processes are determined by the capillary pressure, which is inversely proportional to the radius of micropores in the capillary-porous medium [4]. However, the decrease in the micropore radius makes lower the permeability of the porous medium. As shown previously [4], there exists the optimal range of micropore radii (1–10 μm), which ensures the maximum flow velocity of the extracting agent and thereby creates necessary prerequisites for raising the degree of fluid purification to remove volatile substances.

Another opportunity for raising the total flow rate of the extracting gas through a CMU consists in making larger the cross-sectional area of the mass-exchange bed in the direction perpendicular to the gas flow and lowering its height. In this regard, the most appropriate scheme of the extraction process is two-dimensional, with the flows of the fluid and the extracting agent moving at an angle of 90°. The two-dimensional scheme of chromatomembrane gas extraction allows, all other conditions being the same, variation of the flow rate of the extracting gas in much wider range, compared with the counterflow scheme in which the flows of fluid and gas move in opposite directions.

Taking into account the fact that the mass-exchange bed is elongated along the direction of the fluid flow, which is necessary for ensuring the maximum flow rates of the extracting gas through the unit, we can assume that the pattern of the extraction process corresponds in the given case to the model of the so-called cross-extraction [5, 6]. According to this model, the mass-exchange bed of the CMU can be represented as a number of in-series connected identical stages (equivalent theoretical plates), through which passes a fluid flow, with a flow of pure gas passed through each stage in the perpendicular direction. In this case, the flow rate of the extracting agent through each plate is W_g/n, where W_g is the flow rate of the extracting agent through the CMU and n is the number of equivalent theoretical plates in the unit. The relationship between the component concentration in the aqueous phase at the inlet, c_0, and outlet, c, of the cross-extraction system was established in [5, 6]. In terms of the accepted notation system, this relationship is reflected by the equation

$$c = \frac{c_0}{(1 + KW_g/nW_l)^n}, \quad (1)$$

where K is the distribution coefficient of a component between the gas and liquid phases, equal to the ratio of the mass or molar concentration of the component in the gas phase to its concentration in the liquid phase in equilibrium.

As follows from Eq. (1), the main factors affecting the efficiency of gas-extraction purification are the component distribution coefficient, ratio of volumetric flow rates of the extracting gas and the liquid phase, and the efficiency of the mass-exchange process, characterized by the number of equivalent theoretical plates existing within the mass-exchange bed.

The table lists the oxygen distribution coefficients in the gas–liquid system in relation to temperature. The K values presented in the table were calculated by the procedure described in [7] from the known data on oxygen solubility in water [8]. The relatively low solubility of oxygen in water and the correspondingly high K values enable high-efficiency gas-extraction purification of water to remove dissolved oxygen. Raising the number of theoretical plates by improving the efficiency of the exchangeprocess itself or by making longer the mass-exchange bed must lead to a significant decrease in the residual content of the component being extracted.

Comparison of experimentally established dependences of the relative residual content of oxygen dissolved in water on the ratio of flow rates of the extracting gas and water with those calculated by Eq. (1) (Fig. 2) indicates a high level of adequacy of the cross-extraction model to the real process at small W_g/W_l ratios. In this case, the height of the equivalent theoretical plate is 2–3 cm. At the same time, at $W_g/W_l > 1$ the experimental dependence significantly differs from the theoretical one. The decrease in the efficiency of the chromatomembrane process in this range can be accounted for by a substantial decrease in the ratio of the geometric volumes of the liquid and gas phases in the mass-exchange bed with increasing flow rate of the extracting gas, which necessarily entails raising the pressure of the extracting gas [9].

Coefficients of oxygen distribution between the gas and water phases in relation to temperature

20	33.1		

At one and the same ratio of flow rates of the extracting gas and water being purified, raising the absolute values of these flow rates leads to a decrease in the residual concentration of oxygen dissolved in water (Fig. 3). The possible reason is that the ratio of the geometric volumes of phases in the mass-exchange bed changes as a result of the compressibility of the extracting gas. Since, at one and the same W_g/W_l ratio, the efficiency of chromatomembrane water purification to remove oxygen is the higher, the greater the flow rate of the liquid being purified, it becomes possible to develop high-throughput instal-

lations for continuous chromatomembrane purification of water to remove gaseous impurities and, in particular, dissolved oxygen.

The effect of the mass-exchange bed length on the efficiency of chromatomembrane removal of oxygen is reflected by Fig. 4. It can be seen that making the bed longer than 5 cm has no practical importance since the residual concentration of dissolved oxygen changes only slightly at lengths exceeding this value. This fact can be well accounted for in terms of the plate theory of chromatography and follows from Eq. (1).

Our study of the influence exerted by the size of pores in the mass-exchange bed on the efficiency of chromatomembrane gas extraction (Fig. 5) makes it possible to state that this parameter affects the efficiency of this process only slightly. Presumably, this can be attributed to the key influence exerted by longitudinal diffusion in the gas phase, which is known to be weakly dependent on the pore size [10], to the broadening of the zone corresponding to the substance being extracted [4]. This circumstance makes appropriate use of CMUs with coarser macropores, which ensure higher permeability of the mass-exchange bed to the liquid phase, in chromatomembrane purification of water to remove dissolved oxygen.

CONCLUSION

It was established that chromatomembrane gas extraction enables continuous purification of water to remove dissolved oxygen to residual concentrations of less than 50 μg l^{-1} at 1 : 1 ratio of the volumetric flow rates of water being purified and extracting gas. The output capacity of the technique can be estimated at about 0.6 l h^{-1} per 1 cm^3 of the volume of the mass-exchange unit.

SORPTION AND ION-EXCHANGE PROCESSES

Fe–Ethylenediamine Tetraacetate Complexes Immobilized on Fibrous Anionite and Their Catalytic Activity in H_2S Oxidation

Abstract—The effect of the complexonate solution pH on the nature and amount of ethylenediamine tetraacetate complexes of iron, immobilized on a FIBAN A-5 fibrous anionite, and their catalytic activity in H_2S oxidation by molecular oxygen was studied.

Purification of gas mixtures to remove hydrogen sulfide is commonly carried out by sorption or oxidation techniques with the use of solid or liquid sorbents and catalysts. High activity in liquid-phase oxidation of H_2S by molecular oxygen to sulfur is exhibited by ethylenediamine tetraacetate complexes of iron (Fe–EDTA) [1–4].

Previously (5–7), catalytic systems with Fe–EDTA complexes immobilized on some fibrous anionites have been synthesized and the effect of various factors on their activity has been studied. The catalysts were prepared using a complexonate solution obtained by mixing solutions containing stoichiometric amounts of an iron salt and a disodium salt of ethylenediamine tetraacetic acid (Trilon B). The complexonate solution was strongly acidic (pH ~0.5) and contained, together with complex anions, NO_3^- or Cl^- anions. All other conditions being the same, the presence of competing anions in the system puts limitation on the content of complexes immobilized on the fibrous anionite, which is associated with the ion-exchange equilibrium. Therefore, it was of interest to obtain a solution of iron complexonate without foreign ions and to study the effect of the complexonate solution pH on the content and nature of Fe–EDTA complexes immobilized on the ionite and also on the catalytic activity of the samples obtained.

EXPERIMENTAL

Iron(III) hydroxide and iron(III) complexonate were prepared using conventional procedures. An iron(III) chloride solution was prepared by dissolving 24.3 g of $FeCl_3 \cdot 6H_2O$ in 50 ml of H_2O. The resulting solution was acidified with 2 ml of conc. HCl and heated to 80–90°C, with 30 ml of a 25% NH_4OH solution added dropwise under constant stirring. Then 50 ml of hot water was added to the $Fe(OH)_3$ precipitate formed, the mixture was stirred and allowed to stay for 1 h for particle coagulation to occur, and the precipitate was separated by filtration.

To obtain iron complexonate, 32 g of Trilon B was placed in a beaker, 150 ml of water was added, and the mixture was heated on a water bath, with $Fe(OH)_3$ paste gradually added at 80–90°C. The obtained complexonate solution (of brown color) was filtered to remove a minor amount of unreacted hydroxide and then a complex salt was precipitated. For this purpose, dimethylacetamide was added to the complexonate solution (1 : 2 : 5 by volume) and the mixture was heated on a water bath. The dark yellow crystals precipitated at 60–90°C were separated by filtration and dried in air. The yield of the product was 90% of the theoretically calculated value (~30 g).

The complexonate synthesized was used to prepare a 0.1 M solution for treatment of ionite samples: 11.6 g of complexonate in 300 ml of solution, pH 6–6.5. To vary the solution pH within the prescribed limits (2.5–10.5), concentrated NH_4OH or HCl solutions were added.

The catalysts were prepared from the chloride form of the FIBAN A-5 anionite, which is an ionite with weakly basic tertiary amino groups and low content of carboxy groups (exchange capacity 4.3 mg-equiv g^{-1}, that of carboxy groups 0.6 mg-equiv g^{-1}). The an-

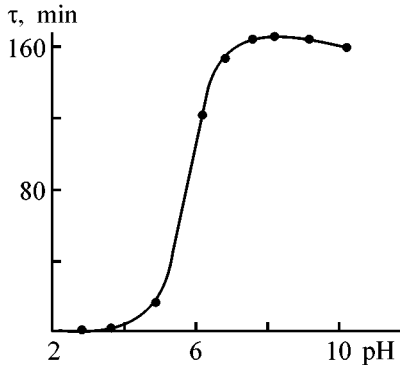

Fig. 2. Working life of samples, τ, vs. complexonate solution pH.

ionite was obtained on the basis of a polyacrylonitrile fiber with *N*,*N*-dimethylaminopropylamine used as aminating agent. Approximately 2 g of anionite swollen in water and squeezed on filter paper (~0.8 g of air-dry fiber) was poured over with 15 ml of a solution with prescribed pH value, kept for 30 min, and then removed from the solution and squeezed on filter paper. The treatment was repeated several-fold, until the ionite was saturated with the complex. The amount of the complex in the fiber was determined gravimetrically: by burning a weighed portion of the sample (1000°C, 1 h) and weighing the Fe_2O_3 formed.

Experiments on oxidation of hydrogen sulfide with molecular oxygen were carried out in a flow-through reactor at room temperature. Composition of the reaction mixture (vol %): H_2S 0.4, O_2 12.2, and N_2 the rest. The sample weight in swollen state was 0.21 g (cross-sectional area of the catalyst bed 0.6 cm^2, bed height 1 cm), and the flow rate of the gas mixture, 27 ml min^{-1}. To evaluate the efficiency of a catalytic system (relative activity), the working life of the samples till H_2S breakthrough, which was recorded chromatographically, was determined.

It can be seen that the dependence of the amount of the complex immobilized on the samples (wt %) on the solution pH is complex: with increasing pH, the amount of the complex decreases from 21 to 13 wt % in the pH interval 3–5, then increases steeply at pH 6–8, and again decreases at pH > 8 (Fig. 1).

The working life till H_2S breakthrough of the catalysts synthesized also depends on the pH of the complexonate solution (Fig. 2). It can be seen that samples obtained from a sufficiently acid solution (pH 3–4) are low-active: H_2S breakthrough is observed in the very first minutes of experiment. Higher catalytic activity is exhibited by samples obtained at pH > 5, and the highest activity, by those prepared at solution pH 7–8.5. With the pH increasing further, to 10, the sample activity decreases somewhat. Noteworthy is the fact that a sample obtained at complexonate solution pH equal to 3 shows low activity despite the relatively high content of the complex (21 wt %).

It should be kept in mind in interpreting the results obtained that the complexonate solution pH simultaneously affects the following factors: composition and degree of ionization of the functional groups of the anionite, composition and charge of ethylenediamine tetraacetate complexes with iron and their quantitative relationship, and the degree of dissociation of hydrogen sulfide molecules.

The known constants of the acid-base equilibria [8, 9] allow calculation of the fractions of various forms of the starting reagents at 20°C:

$$\text{Fe–HEDTA} + OH^- \rightleftarrows [\text{Fe–EDTA}(H_2O)]^-,$$
$$K_1 = 0.5 \times 10^{13}\ M^{-1};$$

$$[\text{Fe–EDTA}(H_2O)]^- \rightleftarrows [\text{Fe–EDTA(OH)}]^{2-} + H^+,$$
$$K_2 = 2.88 \times 10^{-8}\ M;$$

$$[\text{Fe–EDTA(OH)}]^{2-} + OH^- \rightleftarrows [\text{Fe–EDTA}(OH)_2]^{3-},$$
$$K_3 = 3.47 \times 10^{4}\ M^{-1};$$

$$H_2S \rightleftarrows HS^- + H^+, \quad K_4 = 0.91 \times 10^{-7}\ M;$$

$$HS^- \rightleftarrows H^+ + S^{2-}, \quad K_5 = 0.11 \times 10^{-11}\ M.$$

The results of the calculations were used to plot the dependences of the fraction of acid-base forms of the reagents on the pH of the medium (Fig. 3). It can be seen that the degree of hydroxylation of the complexes and their charge grow with increasing pH. At pH equal to 4, 8.5, and 12, the solution contains the maximum amounts of, respectively, single-, double-, and triple-charged anions of iron ethylenediamine tet-

raacetate. According to the electroselectivity rule, an increase in the charge of the complex favors a rise in its content in the anionite. At the same time, the degree of ionization of the functional groups decreases with increasing complexonate solution pH. As a result, the absorption of the complex anion decreases.

In the pH range 3–5, only a hydrated single-charged complex $[Fe–EDTA(H_2O)]^-$ is present in solution (Fig. 3), and the decrease in the content of the complex introduced by ion exchange (Fig. 1) is apparently due to a decrease in the degree of ionization of the functional groups of the ionite. At pH 6–8.5, an increase in the content of the supported complex is observed, which correlates with the increase in the fraction of the hydroxylated double-charged complex ion $[Fe–EDTA(OH)]^{2-}$, and at solution pH 8.5–10.5 the content of the complex in the anionite decreases. Apparently, the charge of the counter ion affects more strongly the ion-exchange equilibrium in the first case (region of transition from weakly acid to weakly alkaline medium), whereas in the second case (strongly alkaline medium) stronger influence is exerted, conversely, by the decrease in the content of ionized functional groups of the anionite, which results from the increase in the concentration of OH^- ions.

Hydrogen sulfide virtually does not dissociate in the acid medium (pH 3–5), and, therefore, the system is low-active, irrespective of the amount and composition of the complex introduced into the anionite. With increasing pH, the H_2S dissociation becomes more pronounced (Fig. 3, curves 5 and 6) and, correspondingly, the activity of the catalytic system grows. It is noteworthy that the content of the complex anion in the ionite falls markedly (from 30 to 13 wt %, Fig. 1) at pH 8.5–10.5, whereas the working life of the samples to H_2S breakthrough decreases only slightly (Fig. 2). The latter indicates that the activity of the $[Fe–EDTA(OH)]^{2-}$ and $[Fe–EDTA(OH)_2]^{3-}$ hydroxo complexes in oxidation of hydrogen sulfide is sufficiently high and dissociation of hydrogen sulfide, rather than HS^- oxidation on active centers of the catalyst, is the rate-limiting stage of the process.

CONCLUSIONS

(1) The amount of Fe–EDTA complexes immobilized on a fibrous anionite depends on the charge of the complex anion and the degree of ionization of the functional groups.

(2) Catalytic activity in oxidation of H_2S by molecular oxygen is exhibited by the complex anions $[Fe–EDTA(OH)]^{2-}$ and $[Fe–EDTA(OH)_2]^{3-}$.

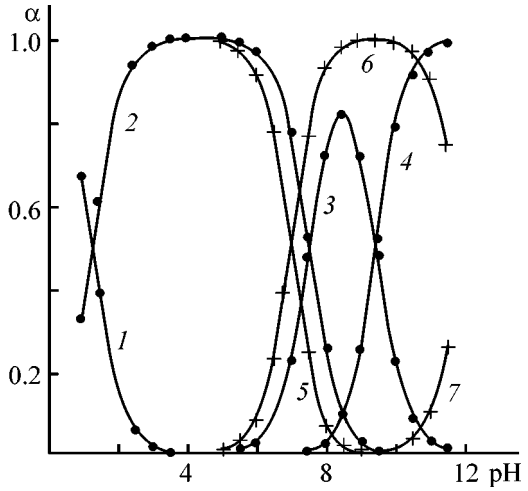

Fig. 3. Fraction of acid-base forms of the reagents, α, vs. the pH of the medium. (*1*) HFe–EDTA, (*2*) $[Fe–EDTA(H_2O)]^-$, (*3*) $[Fe–EDTA(OH)]^{2-}$, (*4*) $[Fe–EDTA(OH)_2]^{3-}$, (*5*) H_2S, (*6*) HS^-, and (*7*) S^{2-}.

(3) The necessary condition for effective operation of the catalytic systems studied is high degree of H_2S dissociation to form the hydrosulfide ion, which can be achieved at pH 8–10.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of the Kinetics of Tin Electrodeposition from Sulfate Electrolyte with Organic Additives

G. I. Medvedev and N. A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Technology, Novomoskovsk, Tula oblast, Russia

Received January 15, 2002

Abstract—The method of Faraday impedance was applied to study the kinetics of tin electrodeposition from a sulfate electrolyte in the simultaneous presence of syntanol DS-10, formalin (37% solution), and benzyl alcohol.

Previously, the kinetics of tin electrodeposition from a sulfate electrolyte in the presence of syntanol DS-10 has been studied [1]. Dull tin coatings have been obtained in this electrolyte. It has been shown that the kinetics of tin electrodeposition depends on the electrode potential and is gaverned by a heterogeneous and a homogeneous chemical reactions.

In [2], the electrodeposition of tin from a sulfate electrolyte in the presence of syntanol, formalin (37% solution), and benzyl alcohol was studied. It was shown that that, with these organic substances present simultaneously in an electrolyte subjected to stirring, shining coatings are formed at i_c = 4–12 A dm^{-2}.

It was of interest to study the kinetics of tin electrodeposition in the presence of these organic substances. This was done, as in [1], using the Faraday impedance method. The differential capacitance was measured during electrolysis with an R-5021 ac bridge at frequencies in the range 200 Hz–20 kHz on an electrode made of tin-coated platinum wire (S = 0.126 cm^2), placed at the center of a platinum-black-coated platinum cylinder. Electrochemical measurements were carried out using a P-5878 potentiostat in an electrolyte stirred with a magnetic stirrer.

A tin layer 10 μm thick was deposited onto the surface of the working electrode. The electrode surface was refreshed before making a measurement at each potential. The discrepancy between the results of measurements in different series did not exceed 5%. The potentials are given relative to a standard hydrogen electrode. The differential capacitances in electrolytes with organic additives are given with account of the roughness factor f. The procedure for determining f was described in [3].

The results obtained in measurements of the differential capacitance C at different electrode potentials show that C decreases with increasing frequency and is constant in the range 30–50 kHz. It was assumed on the basis of this fact that the differential capacitance measured at these frequencies is the capacitance of the electrical double layer (EDL).

The measurements were done using a series equivalent circuit. The C_b and R_b values obtained with an ac bridge were recalculated to C_s and R_s values [4]. The equivalence of the circuit was verified using the procedure described in [5]. The electrode impedance components R_s and $1/\omega C_s$ were studied in relation to $\omega^{-1/2}$.

The results obtained in measuring the cathode current density and EDL capacitance as functions of the electrode potential demonstrate that organic additives inhibit tin electrodeposition (Fig. 1, curves *1* and *2*). At potentials in the range –0.3…–0.4 V the EDL

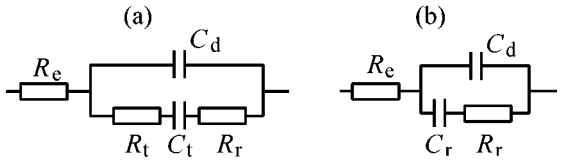

Fig. 4. Equivalent electric circuits of the process of tin deposition from a sulfate electrolyte with organic additives at different potentials. R_e is the electrolyte resistance; C_d, capacitance of the electrical double layer; R_t, the transition resistance; and C_r and R_r, the capacitance and resistance of a heterogeneous chemical reaction. Potential (V): (a) –0.3, –0.4, and –0.8; (b) –0.7 and –0.8.

capacitance is 5.9–6.1 μF cm^{-2}. At $E < -0.54$ V the EDL capacitance and the electrodeposition rate increase. The inhibition of the process in the electrolyte with organic substances is due to their adsorption and formation on the electrode surface of a dense adsorption layer, which starts to disintegrate at $E < -0.4$ owing to desorption of molecules of the organic substances [6]. Dull coatings are obtained at potentials in the range –0.2…–0.6 V, and shining coatings, at –0.7…–0.83 V. With account of these data, the Faraday impedance was measured at potentials of –0.3, –0.4, –0.6, –0.7, and –0.8 V. The dependences of R_s and $1/\omega C_s$ on $\omega^{-1/2}$ are presented in Figs. 2 and 3, curves *1* and *2*, whence it can be seen that R_s at 200 Hz varies within the interval 1–10 Ω cm^2 at all the potentials studied. At –0.3, –0.4, and –0.6 V, R_s grows gradually with increasing frequency and passes through a maximum to reach a constant value after that at a frequency of 20 kHz (Fig. 2, curves *1*, *2*, and *5*). At $E = -0.8$ V, R_s varies in the range 0.9–1.2 Ω cm^2 with frequency increasing in the interval 200–3000 Hz; at higher frequencies R_s increases to 1.6 Ω cm^2 (Fig. 3, curve *1*). Extrapolation of R_s values to higher frequencies yields the ?transition resistance R_t. At E equal to –0.3, –0.4, and –0.6 V, R_t is, respectively, 8.5, 4, and 3 Ω cm^2 (Fig. 2, curves *1*, *2*, and *5*). At a potential of –0.7 V, R_s passes through a maximum with increasing frequency and then tends to zero (Fig. 2, curve *6*). The capacitive components of the impedance, $1/\omega C_s$, much exceed R_s. At a frequency of 200 Hz and potentials equal to –0.3, –0.4, –0.6, and –0.7 V, $1/\omega C_s$ varies in the interval 16–40 Ω cm^2 (Fig. 2, curves *3*, *4*, *7*, and *8*). With increasing frequency, $1/\omega C_s$ decreases, passes through a maximum at a certain frequency, and then tends to zero. The only exception is the potential of –0.8 V at which the $1/\omega C_s$–$\omega^{-1/2}$ dependence shows a decrease from 4.2 to 2.5 Ω cm^2 after the maximum (Fig. 3, curve *2*).

Analysis of the results of impedance measurements suggests that the impedance dependences correspond to equivalent electric circuits with in-series connection of the transition resistance R_t, capacitance C_t and resistance R_r of a heterogeneous chemical reaction at $E = -0.3$, –0.4, and –0.8 V (Fig. 4a); and to in-series connection of the capacitance C_r and resistance R_r of a heterogeneous chemical reaction at $E = -0.7$ and –0.8 V (Fig. 4b).

Thus, it may be concluded that the process kinetics is governed by a transition reaction and a heterogeneous chemical reaction in obtaining dull coatings,

and by a heterogeneous chemical reaction in depositing shining coatings. The transition resistance at $E = -0.3$, -0.4, and -0.6 V is due to the hindered stage of discharge of tin ions. The heterogeneous chemical reaction is of varied nature, depending on the electrode potential.

At the potential of maximum adsorption, $E = -0.3$ and -0.4 V) the heterogeneous chemical reaction is determined by the stage of tin ion penetration to the electrode surface across the adsorption layer. In this case, the process kinetics is governed by the so-called "penetration overvoltage" [7].

At $E = -0.6$ and -0.7 V, when the adsorption layer starts to disintegrate because of the desorption of organic substances from the electrode surface, the heterogeneous reaction is the chemical reaction of tin atoms adsorbed on the electrode surface with organic substances or products of their reduction. The heterogeneous chemical process occurring at $E = -0.8$ V is crystallization, with the transition resistance $R_t = R_{cr}$ (crystallization resistance), $R_{cr} = 2\ \Omega\ cm^2$.

As already noted, at $E = -0.8$ V the capacitive component of the impedance reaches a constant value after passing through a maximum. Extrapolation of $1/\omega C_s$ to higher frequencies yields a value $1/\omega C_{cr}$, where C_{cr} is the crystallization capacitance. According to the data of [5]

$$C_{cr} = z^2F^2C_{ad}/RT,$$

where C_{ad} is the concentration of adatoms on the electrode surface, z is the charge of tin cations, and F is the Faraday number.

The calculations performed demonstrate that $C_{ad} = 2.6 \times 10^{-14}$ mol cm^{-2} for tin. The assumption that heterogeneous reactions occur depending on the electrode potential is also confirmed by measurements of the phase shift δ. The phase shift was calculated in accordance with [5]. With account of the ω_{max} value found from the dependence $1/\omega C_s$–$\omega^{-1/2}$, the reaction rate constant k was determined. For a heterogeneous reaction, $\omega_{max} = k$ and $\tan\delta = -\omega/k$, $\delta \to -90°$. The results of calculations are presented in Fig. 3, curves *3* and *4*. It can be seen that the phase shift does approach –90° at potentials of $-0.3\ldots-0.8$ V.

To conclude, it should be noted that the experimental data on the kinetics of tin electrodeposition from sulfate electrolytes with organic additives, obtained in [1] and in the present study, indicate that, in depositing dull coatings, the rate of the process is determined by a transition reaction and a heterogeneous and homogeneous chemical reactions. At the same time, when shining coatings are deposited, the kinetics of the electrodeposition process is determined by a heterogeneous chemical reaction, which has varied nature depending on the electrode potential.

CONCLUSIONS

(1) A study of the kinetics of tin electrodeposition from a sulfate electrolyte in the presence of syntanol DS-10, formalin (37% solution), and benzyl alcohol by the method of the Faraday impedance established that the kinetics of the process in the range of potentials at which dull tin coatings are formed is determined by a transition reaction and a heterogeneous chemical reaction.

(2) In the range of potentials at which shining coatings are formed, the process rate is determined by a heterogeneous chemical reaction.

(3) It was shown that the part of the transition reaction is played by the hindered reaction of discharge of tin ions, and the heterogeneous reaction has varied nature, depending on the electrode potential. At potentials of -0.3 and -0.4 V, when a dense adsorption layer is formed on the electrode surface, the hindered stage of the process is penetration of tin ions across the adsorption layer.

(4) At more electronegative potentials (E = –0.6, –0.7 V), when the adsorption layer starts to disintegrate as a result of desorption of organic substances from the electrode surface, the role of the heterogeneous reaction is played by the interaction of metal atoms adsorbed on the electrode surface with organic substances or products of their reduction, and at E = –0.8 V, by crystallization.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Synthesis of Arsenic Acid

V. V. Turygin, A. V. Smetanin, A. V. Khudenko, and A. P. Tomilov

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received November 26, 2001

Abstract—The possibility of oxidizing arsenic(III) oxide to arsenic acid in quantitative yield in the presence of hydrochloric or hydrobromic acid as a catalyst was studied.

Arsenic acid and arsenic(V) oxide are used to synthesize dyes and pharmaceuticals, to manufacture optical glass, etc. Commonly, arsenic acid is prepared by oxidation of As_2O_3 with nitric acid [1]. A shortcoming of the method is that toxic wastes are formed. Of interest in this connection is the possibility of performing this process electrochemically. As is known, As_2O_3 oxidizes on a rotating platinum electrode in acid medium at a potential of about 1.3 V [2, 3]. The oxidation rate is the highest in a sulfate solution at pH < 1 [4].

A procedure for preparing arsenic acid by oxidation of As_2O_3 suspension on a tin dioxide anode in a 1% sulfuric acid solution containing 1% Na_2SO_4 was described in [5]. However, this technique fails to yield pure, impurity-free arsenic acid.

Much more attention has been given to oxidation of As_2O_3 in an alkaline solution to obtain reagent-grade arsenates, e.g., those of sodium [6] and lithium [7].

The aim of this study was to develop a method for synthesis of pure arsenic acid.

EXPERIMENTAL

We used in the study reagent-grade arsenic(III) oxide containing 99% main substance. Other reagents were of chemically pure grade.

The experiments were performed in a filter-press electrolyzer with platinum or ruthenium oxide anode and a tungsten or titanium plate as a cathode. The anode and cathode spaces were separated by a MF–4SK or Nafion cation-exchange membrane. The anolyte was circulated at a rate sufficient for maintaining As_2O_3 in the form of a suspension with a centrifugal pump. The working area of the anode was 30 cm^2.

In a typical run, 0.5M HCL solution (60 ml) was fed into the cathode chamber of the filter-press electrolyzer equipped with tungsten cathode and ruthenium oxide anode, and 0.5 M HCL solution (70 ml) and 15 g As_2O_3 (0.15 mole As), into the anode chamber. The electrolysis was performed with a current of 6.0 A (current density i = 0.2 A cm^{-2}) for 1.5 h (110% of the theoretically necessary quantity of electricity, Q). In the course of the experiment, the anolyte temperature increased from 20 to 45°C. The catholyte volume increased by 18 ml owing to electrophoresis. H_3AsO_4 was found in the catholyte in amount of 0.0012 mol, i.e., 0.8% of the initial As_2O_3.

The anolyte was evaporated until dry, together with the wash water from the anode chamber, and calcined at 250°C. The resulting dry residue (18.2 g) contained 92.7% As_2O_5. Arsenic acid was obtained by dissolving the residue in water. The yield of the arsenic acid by substance was 97%, and the current efficiency by the acid, 88%.

First, we checked the possibility of oxidizing an aqueous suspension of As_2O_3 on platinum or graphite without addition of any supporting electrolytes. As is known, arsenic(III) oxide is poorly soluble in water and is present in aqueous solutions in the form of a weak arsenous acid, responsible for low electrical conductivity of the solution. The results of these experiments are presented in Table 1.

It can be seen that the voltage across the electrolyzer is high at the beginning of the process and then gradually decreases owing to accumulation of the stronger arsenic acid, which raises the electrical conductivity of the solution. The oxidation is slow, and a nearly sixfold current excess is necessary for oxidizing only half the feed at the Pt anode.

0.20	7.9–8.6	20–27	110	~100	90

In view of the aforesaid, we performed runs with introduction of electrically conducting additives, such as arsenic, sulfuric, hydrochloric, and hydrobromic acids. The results obtained in this series of experiments are presented in Table 2.

It can be seen that As(III) oxidation is slow in solutions of arsenic and sulfuric acid, and much faster in the presence of hydrohalic acids. Probably, the increase in rate of anodic oxidation is due to the fact that free halogens liberated at the anode in this case act as catalysts and transporting agents, namely: free halogen released at the anode

$$2Hal^- - 2e \rightarrow Hal_2,$$

oxidizes As_2O_3 by the reaction

$$As_2O_3 + 2Hal_2 + 5H_2O \rightarrow 2H_3AsO_4 + 4HHal.$$

Since the results obtained for HCl and HBr were about the same, further experiments were done with the cheaper and more readily available hydrochloric acid. Runs were performed with a 0.5 M HCl solution at different current densities. The results obtained demonstrated that the oxidation is fast and can be performed at current densities of up to 0.2 A cm^{-2} (Table 3). It is appropriate, however, for economical reasons, to perform oxidation at current densities not exceeding 0.1 A cm^{-2}, since at higher densities the electrolyzer voltage increases essentially.

The control runs showed that the efficiency of arsenic(III) oxidation is about the same for ruthenium oxide and platinum anodes. Therefore, further experiments on the influence exerted by the hydrochloric acid concentration were performed with a ruthenium oxide anode (Table 4). It was found that raising the hydrochloric acid concentration to 4.0 M has virtually

Table 4. Influence of HCl concentration on As_2O_3 oxidation (Ag cathode, ruthenium oxide anode; Nafion membrane; 10 g As_2O_3; current density 0.1 A cm^{-2})

c_{HCl}, M	Electrolysis conditions		Q, % of theoretical value	H_3AsO_4 yield, %	Current efficiency by H_3AsO_4 %	As transfer into catholyte %	Current efficiency by O_2 %
	U, V	T, °C					
0.5	5.3–5.6	22–23	110	94	85	2.2	9.6
1.0	5.0–5.2	22–27	102	98	96	1.7	3.4
2.0	4.5	23–27	102	98	98	1.4	1.5
3.0	4.3	24–26	102	93	91	1.0	0.7
4.0	4.0–4.3	23–27	102	99	97	0.7	0.8

no effect on the oxidation, but diminishes somewhat the loss of arsenic for its migration into the cathode space. However, it is inappropriate, for technological reasons, to make the concentration of hydrochloric acid in the anolyte higher than 1.0 M.

Finally, we studied the possibility of preparing a concentrated solution of arsenic acid in a single run. For this purpose, we carried out an experiment in which fresh portions of arsenic(III) oxide were fed into the anodic space at regular intervals. The test was performed at a current density of 0.2 A cm^{-2} in a 0.5 M HCl solution, to which As_2O_3 (50 g) was gradually added. As a result, a 5.0 M H_3AsO_4 solution was obtained in 96% yield at a current efficiency of 81%. The loss of arsenic for its migration into the cathode space was 3.7%.

CONCLUSIONS

(1) The study yielded a simple and efficient method for oxidation of arsenic(III) oxide to arsenic acid. The advantage of this technique is the feasibility of preparing sufficiently pure arsenic acid in a single stage.

(2) Hydrogen chloride present in the anolyte is completely removed upon solution evaporation. The HCl-containing distillate is used for preparing a fresh portion of the anolyte. This opens up the possibility of organizing a nearly waste-free production.

Abstract—The steady-state electrical conductivity and microhardness of glasses in the system Na_2O–B_2O_3 was studied. IR spectroscopy was applied to determine the content of impurity hydrogen in the glasses studied.

Inorganic materials find wide application in various fields of science and technology: as highly conducting ("superionic") solid electrolytes in chemical power cells, in fabrication of electrochemical energy storage units (ionistors), in highly sensitive ion-selective chemical sensors, etc. [1–5].

It has been noted in the literature that the electrical conductivity of glassy solid electrolytes exceeds the conductivity of crystalline solids of the same composition by 1–2 orders of magnitude, with the following postulated: the electrical conductivity of both crystalline and glassy solid electrolytes is due to migration of ions of the same sign. Owing to their high chemical stability, simplicity of fabrication of articles of varied complexity by the conventional glass technology, low sensitivity to impurities, and high ionic conductivity, solid electrolytes attract researchers' attention and more and more frequently find use in various electrochemical devices.

It should be noted that publications concerned with rigorous determination of the nature of charge carriers and mechanisms of their migration in various classes of inorganic solid glasses are scarce in both the domestic and the foreign literature. There is no unified standpoint in the literature, concerning the nature of effects associated with migration of charged particles even in the best-studied borate and silicate glasses. According to common theoretical concepts, anions, cations, electrons, or various combinations of these may be electric current carriers in a solid. At present, there are, presumably, no published results of systematic investigations of migration processes in glasses, which are characterized by a change of the type and nature of a charge carrier.

With account of the aforesaid, we studied the concentration dependence of the electrical conductivity and determined the nature of charge carriers and the dependence of their transport numbers on the composition of glasses in the system Na_2O–B_2O_3.

EXPERIMENTAL

The glasses were synthesized in crucibles made of SU-2000 glassy carbon in a laboratory electric furnace in an atmosphere of argon. As starting reagents were used boric acid and sodium carbonate of analytically pure grade. Boric acid was preliminarily dehydrated at about 450°C to constant weight by a procedure described in [6]. However, it should be noted that removal of chemically bound hydrogen, which can be present in the glass structure in various forms, e.g., $>B–O^{\delta-}\cdots H^{\delta+}$, $\geq B–O^{-}H^{+}$, etc., is difficult, and, therefore, only crystallization water can be removed by calcination at 450°C.

The stock was poured in preheated crucibles at the synthesis temperature. Molten glass was cast into preheated metallic molds and then the billets were placed in a muffle furnace for annealing and kept there for about 60 min at a temperature lower than T_g by 10–15°. Then the samples were allowed to cool together with the muffle furnace to room temperature. The quality of annealing was checked by the polarization-optical method on a PKS-500 polariscope. The billets obtained were used to fabricate samples for further investigation. Selective chemical analysis demonstrated that the content of boron and sodium in the glasses corresponded to the calculated values to within ±1%. The analytical procedure was described in [7].

The electrical conductivity and density were measured on disc-shaped samples 20 mm in diameter and 1.5 mm thick. The samples were plane-parallel to within 0.01 mm. The surface and roughness of the samples corresponded to class 8 according to GOST (State Standard) 2789–79. The surface of the samples for transport number and microhardness measurements was polished. The quality of surface processing corresponded in this case to class 14, and the surface finish to R1-10, with the total error not exceeding two interference rings. The high quality of surface processing enabled optical contact and gave rise to intermolecular interaction forces over the entire surface of contacting samples and thereby ensured unhindered passage of migrating ions across the interface in the course of electrolysis.

We measured in the present study the steady-state dc electrical conductivity with the use of active electrodes. The voltage applied to the samples corresponded to an electric field strength not exceeding 10 kV cm^{-1}, which ensured that the Ohm law was observed. According to [8], glasses in the system $Na_2O–B_2O_3$ show electrolytic conduction, and, therefore, use of active electrodes (sodium amalgam) in dc electrical conductivity measurements prevents electrochemical polarization. An ED-05M dc electrodynamic amplifier was used as measuring instrument. The voltage was supplied from a PI-50-1.1 potentiostat. The measurements were done in heating and cooling modes, with no hysteresis detected. A linear dependence, $\log\sigma = f(1/T)$, where σ is the electrical conductivity, was observed in the range from room temperature to 350°C. The measurement error was about 7%. The activation energy of electrical conductivity, E_σ, was calculated using the equation $\sigma = \sigma_0\exp(E_\sigma/2kT)$.

The density of the glasses was determined by hydrostatic weighing both with samples from the same melting [with the results reproduced to within $(1–5)\times10^{-3}$ g cm^{-3}] and with samples from parallel meltings (reproducibility $\pm1\times10^{-2}$ g cm^{-3}).

The microhardness was measured on PMT-3 and PMT-5 instruments by impressing a diamond pyramid with square base (angle formed by pyramid faces 136° ± 30') into a polished glass surface (Vickers method).

The nature of charge carriers and their transport numbers were determined using the Hittorf method, for which purpose a complete chemical analysis of near-electrode and middle glass samples was made before and after electrolysis. An experiment was considered correct if the composition of the middle glass sample remained unchanged during electrolysis. The nature of species involved in charge transport was determined from changes in the composition of glasses subjected to electrolysis. Tubandt proposed that changes in glass composition are to be judged from a change in their mass as a result of electrolysis, instead of using a complicated chemical analysis. The Tubandt technique is only correct if the nature of charge carriers is established experimentally. The electrolytic nature of conduction in the glasses studied was evaluated by the observance of the Faraday law, by comparing the amount of sodium deposited at the cathode with the amount that should have been deposited in accordance with the Faraday law. A coincidence of the amount of sodium deposited at the cathode as a result of electrolysis with the theoretical value was regarded as evidence in favor of a unipolar conduction associated with migration of sodium cations, and discrepancy of these values, as an indication that some other positively charged species or electrons are involved in transport processes.

The quantity of electricity passed in the course of electrolysis through samples of the glasses under study was measured with in-series connected silver-thallium coulometer and Kh-603 electric-current integrator.

The samples were weighed on VLAO-100/1 semimicroanalytical balance with accuracy of $\pm5\times10^{-5}$ g.

In addition to verifying the observance of the Faraday law, the electronic component of conductivity was evaluated with the use of the Liang–Wagner polarization method [9–11]. This technique also enables evaluation of the contribution of the electronic component to the total electrical conductivity. The electronic component of conductivity is found from current–voltage characteristics of the electrochemical cell M | solid electrolyte | E in which one of the electrodes is reversible (M) and the other is ideally polarizable (E); the solid electrolyte is, in our case, a sample of a glass under study. The cell is polarized in such a way that no Faraday processes occur at the inert electrode. Then the cell is blocked with respect to the ionic current and the current passing through the cell is due to migration of electrons or holes in the solid electrolyte. In the general case, the current strength is given by the equation

$$I = I_n + I_p = \frac{RT}{lF}\left\{\sigma_n^0\left[1-\exp\left(-\frac{EF}{RT}\right)\right] + \sigma_p^0\left[\exp\left(-\frac{EF}{RT}\right)-1\right]\right\},$$

where σ_n^0 and σ_p^0 are, respectively, the electron or hole conductivity of the solid electrolyte, E is applied voltage, and l is the sample thickness.

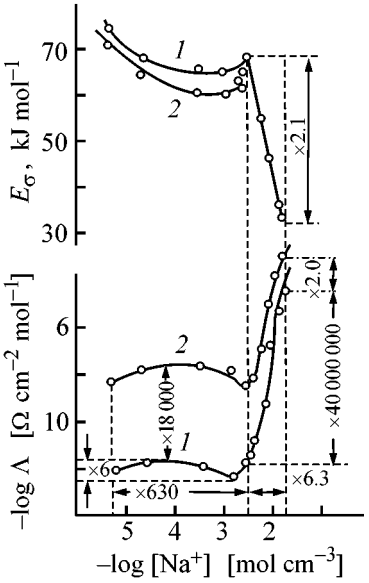

Fig. 1. Dependences of the equivalent electrical conductivity $\Lambda = \sigma/C$ and activation energy E_σ on the concentration of sodium ions in glass, plotted in the $\log \Lambda = f(\log [Na^+])$ and $E_\sigma = \varphi(\log [Na^+])$ coordinates. Temperature (°C): (*1*) 200 and (*2*) 300 [24].

Analysis of this equation shows that, in the case of $\sigma_n^0 > \sigma_p^0$, the current–voltage characteristic levels off at

$$I = I_n = \frac{RT}{lF}\sigma_n^0.$$

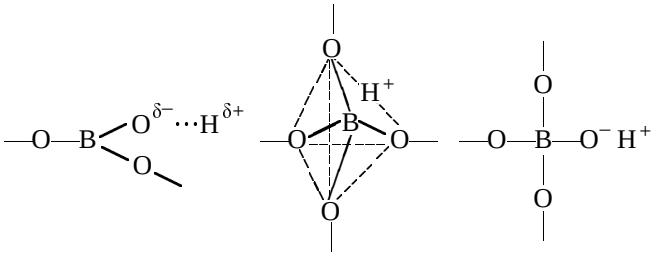
At $\sigma_n^0 < \sigma_p^0$, an exponential dependence of the current density on applied voltage is observed:

$$I = I_p = \frac{RT}{lF}\sigma_p^0\left[\exp\left(-\frac{EF}{RT}\right) - 1\right]\Bigg\}.$$

The applied voltage should be lower than the decomposition potential of the solid electrolyte. Analysis of the experimental dependence of the current strength on voltage allows evaluation of the sign and concentration of charge carriers (electrons or holes) in the solid electrolyte. For example, at a temperature of about 320°C the electronic component of the electrical conductivity of glassy borax ($33.3Na_2O \cdot 66.7B_2O_3$, mol %) does not exceed $(1–3) \times 10^{-10}$ Ω^{-1} cm^{-1}, which constitutes less than 10^{-3}% of the total electrical conductivity.

As is known, structurally bound hydrogen is always present in the glass bulk as an impurity. The position of hydrogen ("water") in the glass structure was considered in [12]. The content of structurally bound hydrogen in glass samples of the system Na_2O–B_2O_3 was determined by IR spectroscopy from the absorption band of OH groups at 2.8–2.9 μm by the procedure described in [13, 14]. The absorption spectra were measured with a Specord IR-75 instrument on plane-parallel polished samples about 1.5 mm thick. The extinction coefficients reported in these papers were used in our calculations.

The structure of boron oxide in glassy state and glasses on its base has been studied in detail [15, 16]. Despite certain discrepancies in minute details, most of the authors regard the structure of glassy B_2O_3 as a continuous three-dimensional skeleton composed of tetra- and tricoordinated boron [17–19]. Tetracoordinated boron forms polar $[BO_{4/2}]^-$, and tricoordinated boron, nonpolar $[BO_{3/2}]$ structural-chemical units. Hydrogen is always present as impurity in glassy boron oxide and glasses on its base. It was shown in [20, 21] that crystal hydrate water contained in crystalline borax can be removed by heating. However, hydrogen incorporated into the glass structure in the form



and similar fragments is retained in the melt and cannot be removed by heating. The firmness of hydrogen fixation in structural-chemical fragments of this kind varies, and hydrogen itself strongly affects the coordination of boron.

In [22], a review of studies concerned with the electrical conductivity and other physicochemical properties of alkali-rich oxide glasses was presented. Also considered were experimental data on their electrolysis. Warburg was, presumably, the first to prove that the amount of sodium transferred during electrolysis from anode to cathode through a glass with high content of M_2O obeys the Faraday law with high precision. These data served as a basis for the conclusion that alkaline oxide glasses are electrolytes with unipolar alkali conduction, irrespective of the M_2O concentration, and their electrical conductivity is determined by the concentration of alkali metal ions.

It was shown in [23] that introduction of an alkali oxide into boron oxide is accompanied by a change in the coordination number of boron from 3 to 4, with the number of bridging oxygen atoms also increasing:

$$BO_{3/2} + Na_2O + BO_{3/2} \rightarrow 2[BO_{4/2}]^-Na^+.$$

The stability of the structure increases because of the incorporation into the newly formed borate tetra-

hedron of one more bridging atom of oxygen. Thus, the structural-chemical network of glasses belonging to the system $Na_2O–B_2O_3$ is mainly composed of polar $Na^+[BO_{4/2}]^-$ and nonpolar $[BO_{3/2}]$ structural-chemical units. It is the ratio of these concentrations and also the concentration of polar structural-chemical units that determine the physicochemical properties of glasses in this system.

In [23, 24], it was demonstrated that the concentration dependences of the electrical conductivity of alkali oxide glasses are similar. Figure 1 presents the results obtained in studying the concentration dependence of the electrical conductivity of glasses belonging to the system $Na_2O–B_2O_3$, according to [24].

It is commonly accepted that charge is carried by alkali metal ions in the entire range of sodium oxide concentrations. As seen from the experimental data presented in Fig. 1, with the sodium ion concentration increasing from 0 to 8×10^{-3} mol cm^{-3} ($\log [Na^+] = -2.09$, the molar electrical conductivity remains virtually unchanged. With the concentration of Na^+ ions increasing further (from 8×10^{-3} to 24×10^{-3} mol cm^{-3}; $-1.62 \geq \log[Na^+] \geq -2.09$), the molar electrical conductivity grows exponentially (by more than 7 orders of magnitude). In Muller's opinion [23, 24], such an increase in conductivity is due to the E_σ value. It can be seen from Fig. 1 that there are two clearly delimited portions in the $E_\sigma = f(\log Na^+])$ dependence: at low concentrations of alkali ions E_σ is relatively high, whereas at $[Na^+] > 8 \times 10^{-3}$ its value decreases dramatically. Such a behavior of the $E_\sigma = f(\log Na^+])$ dependence can be accounted for as follows. In the first region, the electrical conductivity is limited by the fact that alkali ions formed in dissociation of polar structural-chemical units have to migrate in the medium of nonpolar chemical-structural units. In the second region, sodium ions migrate in the medium of polar structural-chemical units $Na^+[BO_{4/2}]^-$. This circumstance enabled Muller to suggest that the dissociation energy of alkali ions exceeds the energy of activated displacement: $E_{dis} > E_a$, whence follows that $E_\sigma \sim E_{dis}$. Figure 2 shows schematically the relationship between these quantities.

To characterize the critical concentration of polar chemical-structural units, at which occurs their merging and, consequently, migration of dissociated sodium ions passes from the nonpolar medium ($[BO_{3/2}]$ chemical-structural units) to the polar medium ($Na^+[BO_{4/2}]^-$ structural-chemical units), Muller introduced the function γ equal to the concentration ratio of nonpolar and polar structural-chemical units:

$$\gamma = \frac{[\text{Nonpolar structural-chemical units}]}{[\text{Polar structural-chemical units}]}.$$

At concentration of sodium ions, equal to, or exceeding 8×10^{-3} mol cm^{-3}, the blocking of polar structural units by nonpolar units is disrupted and migration of alkali ions, which are charge carriers, occurs in the medium of polar structural-chemical units, with the degree of blocking $\gamma \leq 6$.

The experimental results obtained in studying the dependence of the electrical conductivity of glasses in the system $Na_2O–B_2O_3$ on temperature and concentration, presented in Fig. 3 and Table 1, are in satisfactory agreement with published data [15]. The differences in the activation energies of electrical con-

* According to chemical analysis data, the content of Na_2O in the glass is 34.2 mol % (31.5 mol %).

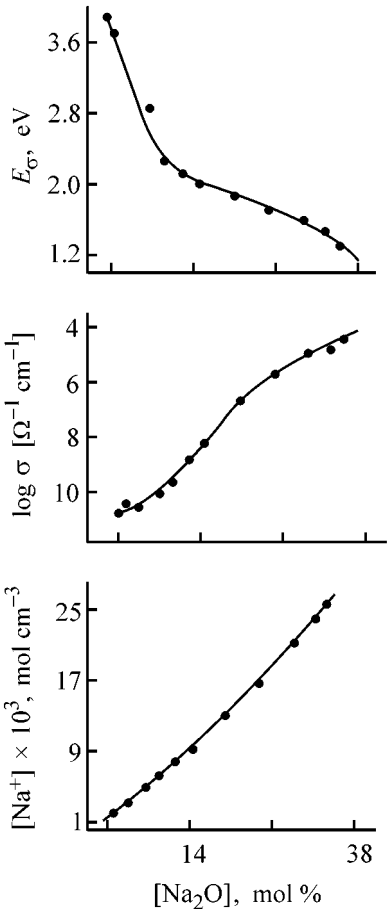

Fig. 3. Activation energy E_σ of electrical conductivity, electrical conductivity σ at 300°C, and volume concentration $[Na^+]$ of sodium ions in glasses of the system $Na_2O–B_2O_3$ vs. the content of sodium oxide, $[Na_2O]$.

ductivity and the conductivity itself at low concentration of Na^+ ions are due to differences in synthesis conditions (compare Figs. 1 and 3).

As already mentioned, the structure and physicochemical properties of borate glasses have been studied in detail. However, studies concerned with the nature of charge carriers are virtually lacking. Conclusions about the type of charge carriers in alkali-free borate glasses were made on the basis of circumstantial evidence [25], and those concerning alkali-borate glasses, on the basis of results obtained in studying electrolysis of alkali-rich glasses [22]. Based on the results of electrolysis, Ostroumov postulated that charge carriers in sodium borax glasses are sodium ions [8]. Using Tubandt's technique he demonstrated that the true sodium ion transport numbers are close to unity ($\eta_{Na^+} \to 1$).

Some researchers believe, on the basis of circumstantial evidence, that charge carriers in alkali-free glasses are either impurity alkali ions or ions of alkaline-earth metals, or electrons [26–28]. In some publications, attention is drawn to the effect of impurity water on the physicochemical properties of glasses. In [25], it was, presumably for the first time, confirmed experimentally that charge carriers in alkali-free, including borate glasses are ions (mainly protons) formed in dissociation of structural-chemical fragments including impurity hydrogen. Therefore, it would be expected that introduction of alkali metal oxides into glassy B_2O_3 is accompanied by a change from protonic conduction to that associated with migration of alkali ions.

92	24.3	66.5	45.1
87.5	31.0		

Table 2 lists the results obtained in a study of the nature of charge carriers and their transport numbers in glasses of the system $Na_2O–B_2O_3$. It can be seen that unipolar sodium conduction is achieved in glasses of this system at $[Na_2O] > 15$ mol % ($\eta_{Na^+} = 1.01 \pm 0.02$), in good agreement with the data of [8], with, however, a discrepancy going beyond the experimental error observed for the glass $0.15Na_2O–0.85B_2O_3$.

The content of impurity hydrogen incorporated into the structure of glasses belonging to the system $Na_2O–B_2O_3$ is given in Table 3. As seen from these data, 1.5–1.7 mol % H_2O is contained in the structure of glasses in the region with low sodium oxide content. With the concentration of sodium oxide increasing to approximately 12 mol % and more, the content of "water" stabilizes at the level of 0.7–0.9 mol % H_2O. The volume concentration of hydrogen is, in this case, about 4.4×10^{-3} mol cm^{-3}, with the degree of blocking of hydrogen-containing structural fragments $\gamma \approx 9$. Therefore, it would be expected that impurity hydrogen exerts strong influence on the physicochemical properties of borate glasses. The hydrogen incorporated into the structure of glasses affects the coordination of boron, as also metal cations do, and is in thermodynamic equilibrium with atmospheric moisture:

$$H^+[BO_{4/2}]^- \rightleftarrows [BO_{3/2}] + H_2O.$$

As already mentioned, it is impossible to remove thermally the hydrogen incorporated into the glass structure. However, thermal treatment combined with, e.g., bubbling of dried oxygen through the melt, leads to changes in the physicochemical properties of glasses. Table 4 presents the results of microhardness measurements for glassy B_2O_3 and $Na_2B_4O_7$. The microhardness was measured on a fire-polished surface. It can be seen that the microhardness of the glasses grows with increasing time of oxygen bubbling (at T = const). The most probable reason for the rise in microhardness is that the position of hydrogen changes as a result of a change in boron coordination, $B^{III} \rightarrow B^{IV}$, by the scheme

$$>B–O^{\delta-}\cdots H^{\delta+} + 1/2\,O_2 \rightarrow H^+[BO_{4/2}]^-.$$

This assumption is supported by the results obtained in studying the concentration dependence of the microhardness of glasses in the system $Na_2O–B_2O_3$ (Table 5).

Hydrogen forms in the structure of glassy boron oxide, together with other structural-chemical units, also polar fragments of the type $H^+[BO_{4/2}]^-$. Therefore, it would be expected that introduction of alkali oxides into B_2O_3 is accompanied by reactions of the type

$$2H^+[BO_{4/2}]^- + Na_2O \rightleftarrows 2Na^+[BO_{4/2}]^- + H_2O\uparrow.$$

This assumption is supported by the data in Table 3. Indeed, the content of hydrogen decreases with increasing content of alkali ions (to ~10 mol %) and then levels off at 0.7–0.9 mol %.

Comparison of the concentration dependence of sodium ion transport numbers with the content of impurity hydrogen indicates that unipolar alkali conduction is achieved in Na_2O–B_2O_3 glasses at Na_2O content in the glasses of 17–20 mol %, with the content of impurity water equal to 0.8–0.9 mol %. At sodium oxide content lower than 17 mol %, protons are involved in charge transport together with sodium cations.

CONCLUSIONS

(1) A study of the nature of charge carriers in glasses of the system Na_2O–B_2O_3 revealed that protons are involved in charge transport together with sodium ions, at low content of sodium oxide.

(2) It was shown that the contribution of the electronic component to the total conductivity is at the level of sensitivity of the Liang–Wagner method and does not exceed 10^{-3}%.

(3) A study of true transport numbers of sodium ions, η_{Na^+}, demonstrated that unipolar alkali conduction is observed in glasses of this system only at $[Na_2O] > 17$ mol %. At $0 \le [Na_2O] \le 17$ mol %, protons are involved in charge transport together with Na^+ ions.

(4) The dependence of the electrical conductivity on temperature and concentration was interpreted in terms of a microheterogeneous glass structure.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Synthesis and Corrosion-Protecting Power of Quaternary Ammonium Salts Based on 2-Acetylallyl Chloride

D. A. Pisanenko and I. S. Pogrebova

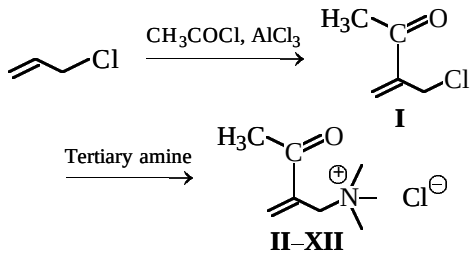
Kiev Polytechnic Institute, Ukrainian National Technical University, Kiev, Ukraine

Received July 18, 2001; in final form, March 2002

Abstract—Quaternary ammonium salts were synthesized at a 62.5–98% yield by quaternization with 2-acetylallyl chloride of pyridine and its α-methyl and γ-benzoyl derivatives; tributyl-, triethanol-, and dimethylbenzylamines; *N*-methylpiperidine; quinoline; *N,N*-dimethylaniline and its *p*-bromo and *p*-methyl derivatives. The inhibiting activity of these salts against corrosion of 08 KP steel and TsO zinc in sulfuric acid solution was studied.

It is well known that a number of industrial inhibitors of acid corrosion of metals are based on aromatic amine salts, whose protective action is due both to the positive charge on the nitrogen atom and to the π-electron interaction of the aromatic system with a metal [1]. The inhibiting activity is also demonstrated by some carbonyl compounds and ammonium salts with alkenyl radicals [2, 3], whose adsorption on the metal surface involves electrons of the oxygen atom and multiple bonds. It would be expected that simultaneous presence of all the indicated adsorption centers in an ammonium salt could enhance the protective effect of a corrosion inhibitor in acid solutions.

To study the inhibiting activity of compounds of this type, we synthesized a series of quaternary ammonium salts by the reaction



where N is the nitrogen atom of the tertiary amine molecule (Table 1).

As an alkylating agent for quaternization of tertiary amines we used 2-acetylallyl chloride (**I**) obtained by acylation of allyl chloride [4]. The yield of the ammonium salts was 62.5–98% (Table 1). To characterize the corrosion resistance of salts **II**–**XII**, we studied their action against corrosion of 08 KP steel and TsO zinc in sulfuric acid solutions. We determined the inhibition coefficient γ, protective efficiency Z, and free-corrosion potential shift in the presence of inhibitors ΔE_f.

EXPERIMENTAL

2-Acetylallyl chloride was obtained by acylation of allyl chloride with acetyl chloride in CCl_4 in the presence of $AlCl_3$ [4]. The tertiary amines used were of chemically pure grade.

Quaternary ammonium salts II–XII. A mixture of halide **I** (0.05 mol), acetonitrile (25 ml), and a tertiary amine (0.05 mol) was refluxed with stirring for 10–12 h. Then the solvent and unreacted compounds were removed in a vacuum (residual pressure 20 mm Hg) using a rotary evaporator, and chloride in the residue was determined by argentometric titration. The resulting salts were viscous hygroscopic liquids or crystals. Their yields and properties are summarized in Table 1.

Corrosion tests were carried out by the gravimetric method with 08 KP steel and TsO zinc foil (working surface areas 7.2×10^{-4} and 8.4×10^{-4} m^2, respectively). The testing times for the steel were 24 h (20°C), 2 h (40°C), and 0.5 h (50 and 70°C), and for zinc, 1 h (20°C). The polarization curves were registered in the potentiodynamic mode at a scan rate of 2 mV s^{-1} with a steel electrode in the initial and inhibited sulfuric acid solutions.

The results showed that salts **III** and **VII**, having aliphatic radicals in their structure, are low-efficient corrosion inhibitors for 08 KP steel in 0.5 M H_2SO_4 at 20°C (Table 2). Compounds with aromatic radicals and nitrogen-containing heterocycles demonstrate higher performance (with the exception of **IV**), with salts **II**, **V**, and **XII** containing unsaturated heterocycles being the best. These salts, taken in a concentration of 1 g l^{-1}, provide an inhibition coefficient of 3.0–5.7 for the steel in 0.5 M H_2SO_4 at 20°C (Table 2). In the presence of 2 g l^{-1} of the salts (3 M H_2SO_4, 20°C), the inhibition coefficient was found to be 5.4–9.5 (Table 3). With increasing temperature, the performance of **VII** containing aliphatic radicals decreases steadily, while salts **V** and **XII** with unsaturated heterocycles preserve their high performance

up to 40°C (it decreases only at 50–70°C) (Fig. 1). This is consistent with the known concept of specific π-electron interaction of unsaturated heterocycles with a corroded metal surface [2].

The presence of the 2-acetylallyl radical in a quaternary ammonium salt molecule has a considerable

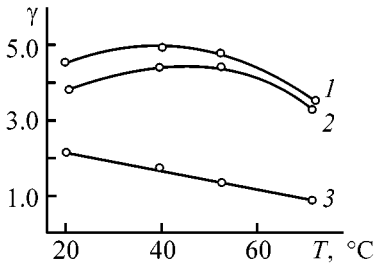

Fig. 1. Inhibition coefficient γ vs. the temperature in corrosion of 08 KP steel in 0.5 M H_2SO_4 in the presence of (*1*) **V**, (*2*) **XII**, and (*3*) **VII**. Salt concentration 0.5 g l^{-1}.

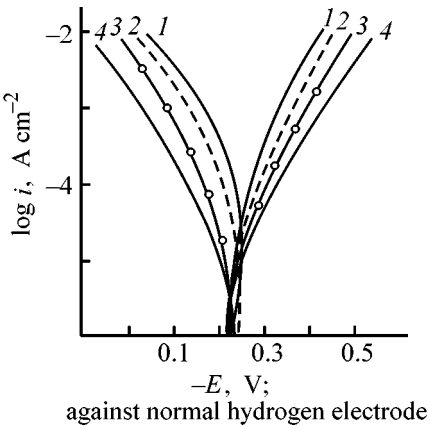

Fig. 2. Polarization curves of the steel electrode in 0.5 M H_2SO_4 at 20°C in the presence of the salts synthesized. Salt concentration 2 g l^{-1}. (*i*) Current density and (*E*) potential. (*1*) Supporting electrolyte solution, (*2*) **VII**, (*3*) **II**, and (*4*) **V**.

effect on the corrosion inhibition of steel. With temperature increasing from 20 to 40°C, the inhibiting coefficient for 08 KP steel in 3 M H_2SO_4 in the presence of 0.01 M pyridinium chloride (**XIII**) decreased from 9.6 to 2.2, and the protective efficiency, from 89.5 to 54.5%, while in the presence of the same concentration of *N*-(2-acetylallyl)pyridinium chloride (**II**), γ increases from 9.5 to 13.7, and *Z*, from 89.4 to 92.7 (Table 3) This is probably due to specific interaction of the steel surface with the C=C bond and carbonyl group of the 2-acetylallyl radical, which increases with the solution temperature.

It is known that the presence of multiple bonds and active π electrons favors adsorption of organic compounds on transition metals, thus enhancing the corrosion resistance [2]. For nontransition metals this effect is considerably less pronounced. In our case, this is manifested in relatively low inhibiting activity of the salts obtained with respect to corrosion of zinc in 0.5 M H_2SO_4 at 20°C (Table 4). Addition of KI in amount of 2 g l^{-1} to the salt solutions enhances their inhibiting activity, which is particularly pronounced in the case of zinc. The inhibition coefficients γ determined in the presence of such mixtures for corrosion of zinc exceed the product of the γ values estimated for their individual components, suggesting occurrence of the synergistic effect [5].

The voltammetric results showed that the salts obtained are corrosion inhibitors of a mixed type. They inhibit both cathodic and anodic corrosion of steel, the anodic process being more strongly affected. The slopes of the cathodic and anodic polarization curves are only slightly sensitive to the presence of these salts (Fig. 2), and the free corrosion potential shifts toward more positive values, i.e., $\Delta E_f > 0$ (Table 2).

The corrosion inhibition coefficients estimated on the basis of Antropov's formalism [6, 7] from γ and

ΔE_f (Table 2) on assumption that $\theta = 0$ are close to the experimental values obtained in the presence of the salts studied. This suggests an energy-related mechanism of the inhibiting action of the salts studied, as well as an insignificant contribution of the blocking effect to inhibition of corrosion. Such a mechanism of inhibiting action of the salts in hand is caused by the positive charge on the nitrogen atom, which results in the formation of a positive adsorption jump of potential in their presence.

CATALYSIS

Zeolite Modification with Aluminum and Efficiency of Gas Purification

V. N. Shchurin, A. K. Baev, and V. I. Tishevich

Minsk Research Institute of Materials for Radio Engineering, Minsk, Belarus
Belarussian State Technological University, Minsk, Belarus

Received May 24, 2001; in final form, December 2001

Abstract—A method for modifying the NaX zeolite with aluminum via decomposition of an organoelement compound at low temperature was developed. The basic parameters of gas purification with the modified zeolite were determined.

Efffective methods for gas purification to remove water vapor and oxygen rely upon heterogeneous reactions characterized by high reactivity of the reactants and by an endothermic reverse reaction. Therefore, particular importance in a search for new techniques for gas purification to remove oxygen and water vapor impurities is acquired by zeolites modified with metals. Since zeolite contains aluminum oxide, which is a good dehumidifier of gas mixtures [1] to remove the drop moisture, and the enthalpy of dissociation of the zeolite is extremely high, aluminum is particularly important in zeolite modification. However, this problem has not emerged previously because, in the case of modification with aluminum, the possibility of using the conventional techniques seems to be unrealistic owing to the difficult reduction of its oxide. This issue is complicated by the fact that aluminum melts at relatively low temperature, and, therefore, even implementation of the process of Al_2O_3 reduction fails to yield highly reactive aluminum with developed surface on porous materials.

The most promising is modification of the zeolite surface with aluminum by decomposing an organoelement compound with high volatility and low decomposition temperature. Since Al(III) is present on the surface of a zeolite treated at above 673 K, the decomposition of the organoelement compound must result in good adhesion of aluminum to the surface. To compounds promising in the gas-phase method of aluminum film preparation belong alkyl compounds. Our investigations of the kinetics of thermal decomposition of trimethylaluminum [2] confirmed the formation of aluminum on zeolite and made it possible to choose conditions of zeolite modification. NaX-TB-1235 synthetic zeolite was chosen as adsorbent.

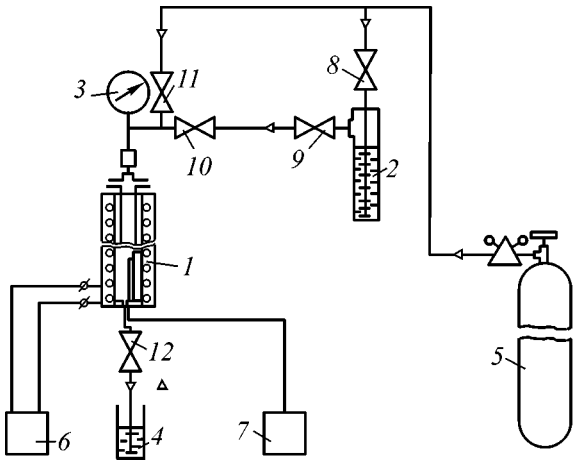
The installation for depositing aluminum onto the adsorbent and its activation is shown schematically in the figure. The installation comprises a device with adsorbent *1*, feeder *2*, manometer *3*, hydroseal *4*, cylinder *5* with argon, laboratory autotransformer *6*, instrument *7* for monitoring the temperature in the device, and cocks *8–12*. The device with adsorbent is also intended for activating the adsorbent with the deposited aluminum. The design of the device is identical to that described previously [3]. It is equipped with a 0.5-kW electric heater. The hydroseal serves to control the flow rate of the carrier gas and to neutralize vapors of organoelement compounds. The feeder is used to obtain a gas-and-vapor mixture of the carrier gas and the vapor of an organoelement compound. Since the process of zeolite modification with aluminum is based on decomposition of an organoelement compound at elevated temperature and occurs with metal formation on the surface, the zeolite was preliminarily thoroughly treated to remove adsorbed moisture and OH functional groups. With account of the fact that the adsorbed moisture is removed at lower temperature than OH groups, the device with zeolite was initially heated to 400 K in an argon flow (1 h) and then kept at 773 K for 6–8 h. The zeolite was modified in a flow of argon under atmospheric pressure, and, therefore, the temperature of the evaporator with trimethylaluminum and the flow rate of the inert gas were maintained constant. The amounts of trimethylaluminum passed through the zeolite and the metal formed were determined from the volume of inert gas, which contained the organoelement compound in a constant concentration, passed through the zeolite and from the change in the zeolite mass. The forming volatile organic products of trimethylaluminum decomposition were removed from the re-

1070-4272/02/7508-1252 $27.00 © 2002 MAIK "Nauka/Interperiodica"

action zone together with argon. After being cooled to room temperature, the device with modified zeolite was connected to the experimental setup described in [3], without letting-in gas and air with excess pressure of 0.1 MPa.

Argon was purified to remove water vapor and oxygen with a zeolite modified with aluminum at a gas flow rate of 30 l h^{-1} at an excess pressure of 0.105–0.115 MPa. The argon used in the study contained (vol %): O_2 1.0×10^{-3} and H_2O 2.5×10^{-4}. The content of water vapor was determined with a G-2-72 condensation hygrometer, and the content of oxygen in the gas, with KhTM-73NL automated chromatograph. The chromatograph operates on the adsorption in an accumulation column at liquid nitrogen temperature and of the impurities to be monitored their subsequent desorption in the stationary gas-chromatographic mode. The results of analysis and measurement errors were calculated using the procedure recommended by the instrument manufacturer. The oxygen detection limit was 0.56×10^{-7} vol %, the total measurement error did not exceed 25 rel. % in the concentration range 1×10^{-5}–1×10^{-7} vol %.

The results of the investigations performed are presented in Table 1. It can be seen that passing the gas leads initially to a gradual depression of the dew point, with the lowest dew point (–100°C) only achieved after passing 1 m^3 of argon. Passing of additional 3 m^3 of argon does not lead to any changes in the dew point. Consequently, the capacity of the zeolite modified with aluminum is not exhausted. The achieved degree of purification exceeds the level corresponding to the first grade. Similar data have been obtained for a zeolite modified with iron, nickel, and palladium [4]. Thus, the given experimental fact is due to the zeolite, rather than to the behavior of metal on the adsorbent. Since the silica gel component of the zeolite loses its OH groups at above 673 K, activation of the zeolite above this temperature makes lower the number of these groups per unit surface area. Therefore, passing the carrier gas initially equilibrates the zeolite with respect to OH groups which favor more complete absorption of water vapor. Naturally, the saturation of the zeolite with OH groups is accompanied by purification of the carrier gas. However, the effective operation of the zeolite is only achieved after passing 1 m^3 of gas with initial water vapor content of 1×10^{-3} vol %. At higher content of water vapor in the gas to be purified its volume that can saturate the zeolite with OH groups decreases. By contrast, lowering the content of water vapor in the carrier gas leads to an increase in its volume capable of saturating the initial zeolite with OH groups and thereby makes the zeolite more efficient, with the result that the extent of purification becomes higher. At the outlet of an adsorber packed with aluminum-modified zeolite the content of oxygen in argon does not exceed 5×10^{-7} vol %. The dynamic capacity for moisture of such a zeolite containing 115 g of aluminum is 18 g/100 g under the given adsorbent activation conditions. In the case of hydrogen purification to remove oxygen and moisture, the content of impurity oxygen becomes 1×10^{-6} vol % the dynamic capacity for moisture 1.5 g/100 g, and the dew point –85°C



Schematic of installation for zeolite modification with aluminum.

under similar conditions of purification. Consequently, the zeolite modified with aluminum is characterized by high dynamic capacity for moisture, purification to remove oxygen to a level as low as 5×10^{-6} vol %, and low dew point (–100°C). This allows its use for gas purification to a level better than that corresponding to first-grade purity.

The results [3, 4] obtained in studying purification of hydrogen, nitrogen, and argon to remove water vapor and oxygen impurities with a NaX zeolite modified with iron, aluminum, nickel, or palladium allow evaluation of their efficiency. The essence of purification of hydrogen and inert gases to remove oxygen consists in fundamentally different processes occurring on metals. The results obtained in studying hydrogen and nitrogen purification to remove water vapor and oxygen impurities with a zeolite modified with various metals and gallium-based liquid solutions of metals (gallam) are presented in Table 2. It can be seen that the methods developed for purification of the gases under consideration allow higher depth of purification, compared with the first-grade requirements. The commercial diffusion installations of the ODV type can yield hydrogen with oxygen and water vapor content of, respectively, 1×10^{-4} and 5×10^{-4} vol %, whereas OST (All-Union Standard) 11.050.003–83 MEP requires that the volume fraction of impurities in technological gases should not exceed 1×10^{-5} vol %. The data obtained not only satisfy these requirements, but also indicate that the technique we developed markedly outperforms all the previously known methods for purification of hydrogen, nitrogen, and argon.

Indeed, the metal hydride method yields gas with residual pressure of water vapor of up to 5×10^{-5} vol %. This requires 35 kg of a $Ti \cdot Fe \cdot Cr$ alloy or 50 kg of $Ti \cdot Fe_{0.86} \cdot Mn_{0.14}$ [5–8]. In the case of a gallium alloy Ga (100 g)–In (10 g)–Al (12 g), hydrogen and nitrogen of volume 1.5 m^3, containing 0.1 vol % water, were purified to humidity level of 5×10^{-5} vol % [9]. Catalytic hydrogenation on platinum or palladium yields hydrogen with oxygen content of 1×10^{-4} vol %. Such a purification level cannot be always achieved. The content of water is 5×10^{-4} vol % upon purification on $7Al_2O_3 \cdot 3H_2O$ alumogel, and 1×10^{-4} and 1×10^{-5} vol % on silica gel [1, 10]. With 3A zeolite used, moisture content as low as 3.5×10^{-5} vol % can be obtained. However, gas could not be purified to this level in practice. In the case of molecular sieves, a gas with moisture content as low as 1×10^{-4} vol % can be obtained in the first two days of purification. Then the content of moisture in the gas being purified levels-off [11].

It follows from the data in Table 2 that the maximum depth of hydrogen purification to remove oxygen, to 5.0×10^{-6} vol %, is achieved with alloy of composition Ga (300 g)–In (30 g)–Al (8.1 g)–Ca (3.4 g), whereas NaX zeolite modified with aluminum ensures purification to 5.0×10^{-6} vol %. The level to which the alloy removes water vapor from hydrogen is an order of magnitude poorer (5.0×10^{-5} instead of 6.0×10^{-6} vol %). The maximum depth of purification to remove impurities at equal, but somewhat higher initial content was achieved on a zeolite modified with aluminum by means of gas-phase decomposition of an organoelement compound of aluminum. The given adsorbent is the most effective. This method yielded hydrogen with oxygen content of 3×10^{-7} vol %, instead of 6.0×10^{-6} vol % on a zeolite modified with palladium at enhanced depth

of purification to remove water vapor (dew point –101°C). The depth of nitrogen purification to remove water vapor and oxygen by the methods developed, with the use of zeolites modified with iron, nickel, or palladium, is in the range 1×10^{-5}–1×10^{-6} vol % for each of these impurities, which has not been achieved previously, either. However, the NaX zeolite modified with aluminum with the use of organoaluminum compounds ensures purification of inert gases to remove oxygen to 5×10^{-7} and water vapor to 1.3×10^{-6} vol % (dew point –102°C). This opens up prospects for obtaining a titanium-modified zeolite with the use of an organoelement compound, which will ensure deeper purification to remove oxygen.

CONCLUSIONS

(1) A method was developed for modifying NaX zeolite with aluminum by thermal decomposition of an organoelement compound in a flow of nitrogen. The method is characterized by high efficiency and depth of purification to remove oxygen (5×10^{-6} vol %) and moisture (dew point –100°C). In purification of 29400 dm^3 of hydrogen, the level of purification to remove oxygen is 3×10^{-7} vol % at dew point of –100°C.

(2) Ga–In–Al–Ca alloy and NaX zeolite modified with iron, nickel, palladium, or aluminum, and conditions of zeolite activation, are characterized by high dynamic capacity and depth of purification of inert gases to remove water vapor and oxygen impurities, which cannot be achieved with other techniques described in the literature.

Received December 17, 2001; in final form, April 2002

Abstract—The kinetics of oxidative dehydrodisproportionation of methylcyclohexane in the presence of H-TsVM zeolite ($SiO_2 : Al_2O_3 = 30$) modified with gallium and gadolinium oxides was studied. A kinetic model fairly adequately describing this process in a wide temperature range was proposed. The kinetic constants of some oxidation reactions were determined.

In contrast to dehydrogenation, proceeding without changes in the number of carbon atoms in the molecule, oxidative dehydrodisproportionation of alicyclic hydrocarbons is a poorly studied catalytic process involving heterogeneously bound oxygen atoms [1–4]. This reaction allows polyalkylbenzenes and naphthenic hydrocarbons, whose content in straight-run naphtha is fairly high, to be involved in basic organic synthesis along with low-molecular-weight aromatic hydrocarbons [5–9].

Single-stage oxidative dehydrodisproportionation of methyl- and ethylcyclohexane in polyalkylbenzenes is thermodynamically feasible and yields a limited number of products [10, 11]. The kinetic data on these reactions are important for mathematical simulation and optimization of the process.

In this work, we studied the kinetics of oxidative dehydrodisproportionation of methylcyclohexane (MCH) to form xylene isomers in the presence of H-TsVM zeolite modified with gallium and gadolinium oxides.

EXPERIMENTAL

The initial MCH was prepared by hydrogenation of chemically pure toluene; according to gas–liquid chromatography (GLC), its purity was 99.3–99.5%, bp 100–101°C, $n_D^{20} = 1.4244$, $d_4^{20} = 0.7720$.

To prepare the required catalyst, the H-TsVM zeolite ($SiO_2 : Al_2O_3 = 30$) was modified with gallium and gadolinium oxides [10]; the content of metal oxides was 3 wt %.

The experiments were performed in a laboratory unit with a nongradient reactor at 773–813 K and MCH space velocity of 108–432 h^{-1}; the initial partial pressures of MCH and oxygen were 11.8–33.2 and 12.3–17.5 kPa, respectively. The gas mixture was diluted with nitrogen or water vapor. The size of catalysis grains was varied within 0.5–0.8 mm; the plunge pulsation frequency in the reactor was 25 and 50 Hz. Such experimental conditions eliminate the effect of the outer- and pore-diffusion hindrance on the reaction rate.

The liquid and gaseous reaction products were analyzed on Tsvet-31 and KhL-3 chromatographic units using bis(-2-cyanoethyl) sulfide (12 wt %) on Chromosorb W for liquid products or triethylene glycol butyrate (TEGB, 15 wt %) on INZ–600 brick for gaseous products.

The reaction products mainly consisted of xylene isomers, toluene, benzene, cyclohexane, CO_2, water vapor, and minor amounts of C_2–C_5 aliphatic hydrocarbons. In some runs, isomers of tri- and tetramethylbenzene, methylcyclohexene, cyclopentadiene, CO, and hydrogen were identified. However, due to the low concentration of these compounds in the catalyzate, their correct quantitative analysis was impossible and thus they were disregarded in the kinetic simulation of the process. In the catalyzate residue (after distillation of liquid reaction products and condensed water; 0.5–0.8% of the total product weight), we identified by GLC and IR spectroscopy oxygen-containing compounds, such as saturated and unsaturated ketones, aldehydes, and acids [12].

The main experimental results obtained with a catalyst of steady-state activity are listed in Table 1. As seen from these data, under the above conditions, MCH is predominantly involved in oxidative dehy-

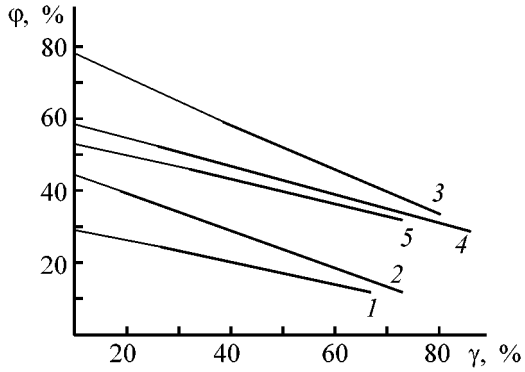

Fig. 1. Selectivity φ of the reaction with respect to xylene isomers vs. MCH conversion γ. Temperature, °C: (*1*) 753, (*2*) 773, (*3*) 803, (*4*) 823, and (*5*) 873.

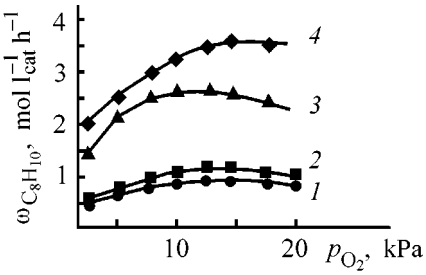

Fig. 2. Rate of oxidative dehydrodisproportionation of MCH vs. the oxygen partial pressure p_{O_2}. p_{MCH} = 33.2 kPa, v_{MCH} = 432 h^{-1}. ($\omega_{C_8H_{10}}$) Rate of accumulation of xylene isomers. Temperature, °C: (*1*) 773, (*2*) 793, (*3*) 813, and (*4*) 843.

drodisproportionation, dehydrogenation, dehydrodemethylation, and destructive oxidation. The oxidative dehydrodisproportionation of MCH leads to accumulation of benzene and xylene isomers in the catalyzate; benzene is also formed in oxidative dehydrodemethylation. The "conversion curves" (dependences of the process selectivity on MCH conversion) at various temperatures (Fig. 1) show that, at MCH conversion close to zero, the selectivity of the process with respect to xylene isomers is lower that 100%, which suggests a parallel-consecutive reaction pattern.

Based on the experimental data, we included in our model the following series of independent reaction pathways:

$$2C_7H_{14} + 3O_2 \rightarrow C_6H_6 + C_8H_{10} + 6H_2O, \quad (1)$$

$$C_7H_{14} + 1.5O_2 \rightarrow C_7H_8 + 3H_2O, \quad (2)$$

$$C_7H_{14} + 3O_2 \rightarrow C_6H_6 + CO_2 + 4H_2O, \quad (3)$$

$$C_7H_{14} + 1.5O_2 \rightarrow C_4H_8 + C_2H_4 + CO_2 + H_2O, \quad (4)$$

$$C_7H_8 + 1.5O_2 \rightarrow C_6H_6 + CO_2 + H_2O, \quad (5)$$

$$C_8H_{10} + 1.5O_2 \rightarrow C_7H_8 + CO_2 + H_2O. \quad (6)$$

Reaction (1) describes oxidative dehydrodisproportionation of MCH into benzene and xylene isomers; reaction (2) is dehydrogenation of MCH into toluene; reactions (3), (5), and (6) correspond to oxidative dehydrodemethylation of the initial hydrocarbon and resulting alkylaromatic compounds, and reaction (4) describes destructive oxidation of MCH. These parallel-consecutive transformations of the initial hydrocarbon and products of its primary conversion proceed at different active centers of the catalyst [13]. The effect of the surface heterogeneity of oxide-modified zeolite catalysts was studied previously in [14].

The above model does not include the reactions of deep oxidation of MCH and coke formation, because our calculations showed that the contribution of these processes is negligibly small.

To determine the formal reaction orders with respect to MCH and oxygen, we plotted the rate of oxidative dehydrodisproportionation of MCH against the partial pressures of hydrocarbon (p_{O_2} = 12.3 kPa) and oxygen (p_{MCH} = 33.2 kPa). The results obtained show that the formal reaction orders with respect to MCH and O_2 are about 2 and 1, respectively. Hence, the rate of the main reaction (1) can be given as follows:

$$r_{C_8H_{10}} = Kp_{C_7H_{14}}^2 p_{O_2}, \quad (7)$$

where $r_{C_8H_{10}}$ is the rate of reaction (1) and $p_{C_7H_{14}}$ and p_{O_2} are the partial pressures of MCH and O_2, respectively.

With account taken of the stage scheme, in the steady state, the sum of the active centers with different oxidation states is 1:

$$Z + ZO + ZO_2 = 1, \quad (8)$$

where ZO and ZO_2 are represented, in accordance with the stage scheme (Table 2), the by equations

$$ZO_2 = K_\beta [Z] p_{O_2}, \quad (9)$$

$$ZO = K_\alpha [ZO_2]^{0.5} [Z]^{0.5} = K_\beta K_\alpha [Z] p_{O_2}^{0.5}, \quad (10)$$

where K_α is the constant of dissociative adsorption of O_2 and K_β is the equilibrium constant of O_2 adsorption.

According to the kinetic data (Figs. 2, 3), at partial pressures of oxygen and water vapor of 2.0–17.5 and 0.1–10 kPa, respectively, the rate of formation of xylene isomers decreases with increasing concentration of both oxygen and water vapor, and this dependence is rather complex. At low partial pressures of oxygen and water vapor, the rate of formation of

Table 2. Stage scheme of oxidative dehydrodisproportionation of MCH

$Z + O_2 \rightarrow ZO_2$	3	1.5	2	0.5	0.5	0.5
$Z + ZO_2 \rightarrow 2ZO$	3	1.5	2	0.5	0.5	0.5

xylene isomers increases. However, with increasing volume fraction of oxygen and water vapor, the rate of xylene formation sharply decreases. Thus, stoichiometric amounts of oxygen and water vapor are probably effective agents restoring the active centers which provide dehydrogenation of the initial hydrocarbon and disproportionation of the intermediate carbanions. Taking into account the above considerations and substituting Eqs. (8)–(10) in Eq. (7), we obtain the following kinetic equation:

$$r_{C_8H_{10}} = \frac{k_1 p_{C_7H_{14}}^2 p_{O_2}}{1 + K_\alpha^{0.5} p_{O_2}^{0.5} + K_\beta p_{O_2} + K_\gamma p_{H_2O}}, \quad (11)$$

where $r_{C_8H_{10}}$ is the rate of reaction (1), k_1 is the rate constant of reaction (1) in the steady state, and K_γ is the equilibrium constant of H_2O adsorption.

The kinetic constants were determined by least-squares method, using the random search procedure and taking into account the main and side reactions of hydrocarbon conversion [schemes (1)–(6)]. Our experimental values are fairly adequately described by the following kinetic equations.

$$r_1 = \frac{k_1 [p_{C_7H_{14}}]^2 [p_{O_2}]}{1 + K_\alpha [p_{O_2}]^{0.5} + K_\beta [p_{O_2}] + K_\gamma [p_{H_2O}]}, \quad (12)$$

$$r_2 = \frac{[k_2 p_{C_7H_{14}} + k_6 p_{C_8H_{10}}][p_{O_2}]}{1 + K_\alpha [p_{O_2}^{0.5}] + K_\beta [p_{O_2}] + K_\gamma [p_{H_2O}]}, \quad (13)$$

$$r_3 = \frac{[k_1 [p_{C_7H_{14}}] + k_3][p_{C_7H_{14}}][p_{O_2}^{0.5}]}{[1 + K_\alpha p_{O_2}^{0.5} + K_\beta p_{O_2} + K_\gamma p_{H_2O}]}, \quad (14)$$

$$r_4 = \frac{k_4 [p_{C_7H_{14}}][p_{O_2}]}{1 + K_\alpha [p_{O_2}^{0.5}] + K_\beta [p_{O_2}] + K_\gamma [p_{H_2O}]}, \quad (15)$$

where k_1–k_6 are the rate constants of the corresponding reactions and r_1–r_4 are the rates of hydrocarbon accumulation ($r_1 = r_{C_8H_{10}}$, $r_2 = r_{C_7H_8}$, $r_3 = r_{C_6H_6}$, and $r_4 = r_{C_4H_8}$) in stoichiometric reactions (1)–(4).

Based on the data of additional experiments and analysis of the reaction products, the rates of oxidative demethylation of xylene isomers into toluene and of toluene into benzene were assumed to be zero.

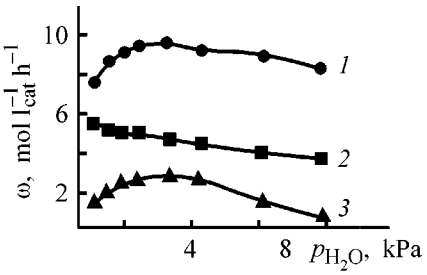

Fig. 3. Rates ω of (*1*) MCH conversion and of accumulation of (*2*) toluene and (*3*) xylene isomers vs. the water vapor partial pressure p_{H_2O}. p_{MCH} = 33.2 kPa, T = 813 K.

The rates of conversion of the initial hydrocarbon and accumulation of the reaction products by the above pathways were calculated using the following expressions:

$$\omega_{C_7H_{14}} = -2r_1 - r_2 - r_3 - r_4, \quad (16)$$

$$\omega_{C_8H_{10}} = r_1 - r_6, \quad (17)$$

$$\omega_{C_6H_6} = r_1 + r_3 + r_5, \quad (18)$$

$$\omega_{C_7H_8} = r_2 - r_5 + r_6, \quad (19)$$

$$\omega_{C_2-C_4} = 2r_4, \quad (20)$$

$$\omega_{CO_2} = r_3 + r_4 + r_5 + r_6, \quad (21)$$

where $\omega_{C_7H_{14}}$, $\omega_{C_8H_{10}}$, $\omega_{C_6H_6}$, $\omega_{C_7H_8}$, $\omega_{C_2-C_4}$, and ω_{CO_2} are the experimental reaction rates given in Table 1.

The best agreement between the rates of oxidative dehydrodisproportionation of MCH and experimental values was obtained with the following rate constants for reactions (1)–(6):

$$k_1 = 5.94 \times 10^3 \exp(-97453.146/RT),$$

$$k_2 = 3.4572 \times 10^4 \exp(-62211.432/RT),$$

$$k_3 = 4.275 \times 10^3 \exp(-70818.8/RT),$$

$$k_4 = 7.18 \times 10^8 \exp(-158352.43/RT),$$

$$k_5 = k_6 = 0,$$

$$K_\alpha = 5.21 \times 10^3 \exp(-164450/RT),$$

$$K_\beta = 9.04 \times 10^{-11} \exp(135523.98/RT),$$

$$K_\gamma = 4.21 \times 10^{-7} \exp(119199.546/RT)$$

(R is the universal gas constant, 8.3144 J mol^{-1} K^{-1}). The root-mean-square deviations of the calculated rates [Eqs. (6)–(21)] from the experiment were 14.5% for main reaction (1), 18–22% for reactions (2)–(4), and 21–25% for reactions (5) and (6). Zero values of k_5 and k_6 suggest that toluene and benzene are predominantly formed by reactions (1)–(3).

The second order of the reaction with respect to MCH and the maximum in the dependence of the disproportionation rate on the partial pressure of water vapor indicate that the limiting stage is the reaction of two intermediate radicals, followed by their disproportionation, whereas adsorption of MCH and elimination of the hydrogen atom with nucleophilic surface oxygen are fast. In this stage, electron passes from the hydrocarbon to the catalyst. The carbocations formed are converted in two competitive reactions to form toluene (dehydrogenation) and xylene isomers (dehydrodisproportionation). The first reaction order with respect to MCH in stage (2) suggests that the dehydrogenation rate is rather high.

The destructive oxidation of MCH can proceed by two independent pathways: (1) by heterogeneous–homogeneous conversion of hydrocarbons to form cycloalkyl radicals and carbocations (after electron transfer from the radical to the catalyst) on the catalyst surface, their subsequent passing into the gas phase, and oxidation with molecular oxygen, and (2) heterogeneous conversion of MCH at the active centers of the catalyst providing oxidative dehydrodisproportionation (strong acid–base centers). In this case, the destructive oxidation on the surface proceeds by the separate interaction mechanism through dissociative adsorption of hydrocarbons, accompanied by the formation of strongly bound hydroxy group from the oxygen ion with localized negative charge, stabilization of hydrocarbon radical on the metal cation linked with oxygen, and reactions of the oxygen molecule from the gas phase with a surface radical. Both mechanisms of oxidative degradation can operate simultaneously.

In the analysis of the reaction mechanism, we used the stage scheme given in Table 2, involving a number of stoichiometric reactions whose sequence determines the rates of realization of independent runs.

According to the stage scheme (Table 2), the stage of reaction of oxygen from the gas phase with the reduced center of the catalyst ($Z + O_2 \rightarrow ZO_2$) is assumed to be irreversible, and the stage of dissociative adsorption of oxygen ($Z + ZO_2 \rightarrow 2ZO$), reversible. Hence, the rate of oxidative dehydrodisproportionation strongly depends on the partial pressure of MCH ($r_{C_7H_{14}} \approx p^2_{MHC}$) and is inhibited by oxygen at its content exceeding the stoichiometric amount.

Our kinetic model of oxidative dehydrodisproportionation of MCH fairly adequately describes the system of chemical transformations proceeding in the reaction scheme in a wide range of experimental parameters and can be used for mathematical simulation of the process.

CONCLUSIONS

(1) The kinetic features of oxidative dehydrodisproportionation of methylcyclohexane in benzene and xylene isomers in the presence of H-TsVM zeolite modified with gallium and gadolinium oxides were studied.

(2) At 773–813 K, methylcyclohexane is involved in oxidative dehydrogenation, dehydrodisproportionation, and dehydrodemethylation. The kinetic model of the process, fairly adequately describing the experimental results in a wide temperature range, was proposed. The rate constants for some reaction pathways were calculated.

(3) Reaction of the products of partial dehydrogenation of methylcyclohexane (namely, methylcyclohexyl and methylcyclohexenyl radicals), with their subsequent disproportionation and dehydrogenation into benzene and xylene isomers, is the limiting stage of the process.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Catalytic Purification of Gases to Remove Vinyl Chloride

V. M. Vlasenko and V. L. Chernobrivets

Institute of Sorption and Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received March 13, 2002

Abstract—The catalytic purification on spinel-like catalysts containing no noble metals of ventilation exhaust gases formed in manufacture of PVC film was studied in the thermal and sorption modes.

Ventilation exhaust gases from numerous industrial plants manufacturing or reprocessing polyvinylchloride are contaminated with a considerable amount of vinyl chloride (C_2H_3Cl). The high toxicity of this substance, whose maximum permissible concentration (MPC) in the atmosphere is strictly limited by pollution control regulations, requires that efficient and reliable methods for its removal from exhaust gases should be developed. A promising method for removal of chlorinated organic compounds, including vinyl chloride, from gas mixtures is based on deep catalytic oxidation of these compounds to nontoxic compounds (CO_2 and H_2O) and neutralization of chlorine and hydrogen chloride formed in the process. The high output capacity, continuity, and simplicity of heterogeneous-catalytic processes constitute a pronounced advantage of catalytic purification methods over other techniques.

The catalytic purification can be implemented in a number of variants, depending on the concentration of an impurity to be removed.

Heating the reaction mixture on a catalyst to temperatures at which the impurity oxidation is complete is appropriate at C_2H_3Cl concentrations of a few percent. The sorption-catalytic purification is more efficient for ventilation exhaust gases containing no more than 20 mg cm^{-3} of vinyl chloride. This method consists in sorption of a contaminant on a catalyst at room temperature and, after the catalyst is saturated, removal of the sorbate by deep oxidation under short heating [1].

The catalysts for oxidation of organochlorine substances commonly contain noble metals. Deep oxidation of vinyl chloride is achieved on catalysts containing platinum-group metals [2]. Ruthenium [3] and platinum–ruthenium [4] catalysts have been proposed for this purpose. Recently, efficient catalysts without noble metals have also been developed. They are based on binary oxide systems of spinel structure, possess high chemical and thermal resistance, and ensure complete oxidation of organochlorine compounds at moderate temperatures. A catalyst ensuring efficient oxidation of chlorinated hydrocarbons to CO_2, H_2O, HCl, and Cl_2 at temperatures below 400°C has been developed on the basis of copper(II) and cobalt(II) chromites on γ-Al_2O_3 support [5]. It has been established that high catalytic properties are also exhibited by catalysts based on chromium(III) oxides.

All the above-mentioned catalysts, both with and without noble metals, cannot be used for sorption-catalytic purification of gases because of their poor sorption capacity for substances to be removed. Catalysts-sorbents that can be recommended for use in sorption-catalytic purification have only been obtained after the development of methods for preparing oxide catalysts with enhanced sorption capacity for chlorinated hydrocarbons. The highest efficiency was achieved with a γ-Al_2O_3-supported catalyst based on chromium(III) oxides, treated with 0.5 vol % HCl. This catalyst exhibits high sorption capacity for vinyl chloride and is sufficiently active in its oxidation [6].

Laboratory studies carried out with a mixture containing 2.6 vol % C_2H_3Cl in air demonstrated that oxidation of vinyl chloride on a catalyst containing 35 wt % Cr_2O_3 on γ-Al_2O_3 support is complete even at 350°C volumetric flow rate not exceeding 1000 h^{-1}. A similar effect is observed on a catalyst containing 20 wt % copper chromite and an equal amount of cobalt chromite on the same support. The sorption

1070-4272/02/7508-1262 $27.00 © 2002 MAIK "Nauka/Interperiodica"

capacity of the chromium oxide catalyst for C_2H_3Cl at 70–75°C does not exceed 10 mg m^{-3}. Regeneration of this catalyst at 350–400°C in an air flow restores completely its sorption capacity.

It is known that, under real conditions, waste gases may contain, in addition to vinyl chloride, other contaminants, such as hydrogen chloride, carbon(II) oxide, etc. In the case of manufacture of PVC articles, waste gases also contain plasticizers (dibutyl phthalate). The presence of these substances in gases may strongly complicate the purification process. To evaluate the efficiency of oxide catalysts containing no noble metals and of methods for gas purification, developed on their basis, the catalysts were tested with ventilation exhaust gases discharged from industrial plants manufacturing the PVC film. The results obtained are presented in this communication.

The purification processes were studied in both thermal-catalytic and sorption-catalytic modes. The average composition of the contaminating impurities was as follows (mg m^{-3}): vinyl chloride up to 5, dibutyl phthalate up to 4, and carbon(II) oxide 1.6–1.8. The study was performed in a flow-through glass reactor of diameter 18 mm, with external heating. The reactor was charged with 40 cm^3 of a catalyst in the form of 5-mm irregular grains.

The content of vinyl chloride in the mixture was determined by its burning on an incandescent platinum coil of a PSU device, followed by absorption of the combustion products with alkaline solution and nephelometric determination of chloride ions in a reaction with silver nitrate [7]. The analysis for dibutyl phthalate was based on hydrolyzing this compound with sulfuric acid to butyl alcohol and determining the alcohol colorimetrically from the product of its condensation with paradimethylaminobenzaldehyde [8]. The CO content in the gas mixture was found by oxidizing it with I_2O_5 to CO_2 and absorbing the latter with barium hydroxide [7].

In the thermal-catalytic mode of purification, two types of catalysts were tested: copper–cobalt–chromium catalyst (20 wt % $CoCl_2O_4$ and $CoCl_2O_4$ each on γ-Al_2O_3) and chromium oxide catalyst (35 wt % Cr_2O_3 on γ-Al_2O_3). In the course of the study, the reactor with the catalyst was heated to 400°C at a volumetric flow rate of waste gases of 1000 h^{-1}. After the prescribed mode was attained, it was maintained for 1 h, and the mixture was analyzed at the inlet and outlet of the reactor. The installation was maintained in the working state for 24 h. The next day, samples were taken for analysis 60 min after the process conditions were stabilized. The results obtained in a continuous test of the copper–cobalt–chromium catalyst for 50 h are presented in Table 1 (c_{VC} and c_{DBPh} are, respectively, the concentrations of vinyl chloride and dibutyl phthalate, and τ is the experiment duration).

Table 1. Degree of oxidation, X, of vinyl chloride and dibutyl phthalate on copper–cobalt–chromium catalyst at volumetric flow rate of 1000 h^{-1}

T, °C	τ, h	c_{VC}, at inlet,* mg m^{-3}	c_{DBPh}, mg m^{-3}		X_{DBPh}, %

* The concentration c_{VC} is zero at the outlet, and X_{VC} is 100%, in all runs.

It can be seen that, when present together in a gas mixture, vinyl chloride and dibutyl phthalate are oxidized on this catalyst at 400–423°C. The oxidation of vinyl chloride is complete under any of the above conditions, and that of dibutyl phthalate, only above 420°C.

The chromium oxide catalyst was tested with industrial ventilation exhaust gases by a similar procedure at 425°C and volumetric flow rate of 1000 h^{-1}. Since waste gases contained CO in this case, we first checked the possibility of carbon(II) oxide oxidation on the catalyst in question. It was found that, under the given conditions, the oxidation of CO at its concentrations of up to 10 mg m^{-3} is complete even at 300°C. A study of waste gase purification to remove vinyl chloride, dibutyl phthalate, and CO on the chromium oxide catalyst at 425°C and volumetric flow rate of 1000 h^{-1} showed that, under the given conditions, the oxidation is complete for all the abovementioned toxic substances, present in waste gases formed in manufacture of the PVC film.

74	145	0.6	–	76	337	0.5	–				

* The concentrations c_{VC} and c_{DBPh} at the outlet are zero, and X_{VC} and X_{DBPh}, 100%, in all runs.

The concentrations c_{VC}, c_{DBPh}, and c_{CO} at the outlet were zero, and the degrees of purification X_{VC}, X_{DBPh}, and X_{CO} were 100%, in all tests.

The sorption-catalytic purification was studied on a chromium oxide catalyst composed of 35 wt % Cr_2O_3 supported on γ-Al_2O_3 and treated with 0.5 vol % HCl. According to the results of a laboratory study, this catalyst exhibits high sorption capacity for C_2H_3Cl. The tests were performed at a temperature of 70–75°C, ensuring chemisorption of vinyl chloride at a gas flow rate of 1000 h^{-1}. In the course of the study, the catalyst was preheated in air at 350°C for 2 h. After that the temperature was lowered to 75°C, and the reaction mixture was fed into the reactor. The results of these tests are presented in Table 2.

It can be seen that at 72–76°C and volumetric flow rate of 1000 h^{-1} the chromium oxide catalyst-sorbent effectively sorbed both vinyl chloride and dibutyl phthalate for 337 h, thus ensuring the absence of toxic impurities in the gas mixture at the reactor outlet.

The catalyst was regenerated in an air flow on heating to 400°C for 2 h, with CO_2 determined at the reactor outlet. After regeneration, the temperature in the reactor was lowered to 75°C, and the study of purification was continued. The data characterizing the operation of a regenerated catalyst are also presented in Table 2. These data confirm the efficiency of operation of the regenerated catalyst-sorbent in the sorption-catalytic mode. With a gas mixture containing up to 1 mg m^{-3} of vinyl chloride and up to 6.5 mg m^{-3} of dibutyl phthalate, these impurities were completely removed from the gas.

CONCLUSIONS

(1) The thermal-catalytic and sorption-catalytic methods for purification of ventilation exhaust gases formed in manufacture of the PVC film were studied on spinel-type catalysts containing no noble metals.

(2) The treatment of gases to remove vinyl chloride, dibutyl phthalate, and CO by oxidation on chromium(III) oxide catalysts is efficient at 400–425°C and volumetric flow rate of 1000 h^{-1}. For catalysts composed of copper(II) and cobalt(II) chromites the purification conditions are similar.

(3) In the chemisorption mode, gases are effectively purified to remove vinyl chloride and dibutyl phthalate at 70–75°C on a chromium oxide catalyst composed of 35 wt % Cr_2O_3 supported on γ-Al_2O_3 and treated with 0.5 vol % HCl solution.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Purification of Wastewater Containing Color Developers and Silver Ions under Conditions of Low-Temperature Plasma Electrolysis

Received July 25, 2001; in final form, November 2001

Abstract—The action of glow discharge on aqueous solutions containing color developers and silver ions was studied. The influence of the main processing parameters, such as treatment time, current efficiency, current density, reaction zone pressure, and cathode material, was considered.

Some types of plasma, generated in glow discharge and other kinds of discharge, initiate, while acting upon aqueous solutions, various reactions whose main active agents are hydroxy and hydrogen radicals formed upon decay of water molecules. Plasma-induced oxidation is especially strong and occurs without any additional oxidizing agents. Unlike plasma reactions in the gas phase, these plasma-initiated reactions are reliably controllable. Chemical reactions caused by glow discharge plasma in aqueous solutions cannot be carried out by conventional methods.

Previously, the influence of glow discharge on liquid-phase systems containing silver and thiosulfate ions has been studied [1]. The main kinetic relationships for recovery of silver ions and decomposition of sodium thiosulfate in wastewater have been obtained. It has been shown [2, 3] that the glow discharge plasma efficiently affects decomposition of nonionic surfactants in solutions. It was of interest to consider the efficiency of glow discharge in decomposition of color developers contained in wastewater of photographic and motion-picture production.

EXPERIMENTAL

We used in the study a glow-discharge setup described in [1–3]. As objects of study served aqueous solutions containing 50 or 10 mg l^{-1} of color developer and 500 mg l^{-1} of Ag^+, modeling the real sewage.

Figure 1 shows how the color developer concentration varies with the time of glow discharge treatment. It can be seen that the concentration for the most part decreases at the beginning of the process. After a certain period of time the decomposition rate decreases dramatically.

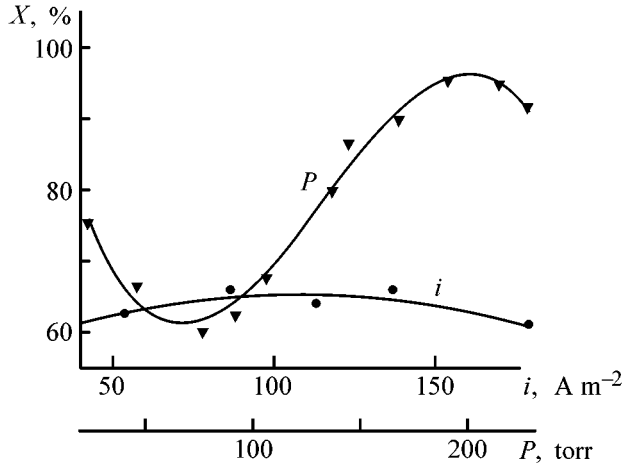

Fig. 2. The degree of purification, *X*, of aqueous solutions to remove color developers vs. current density *i* and pressure *P* in the reaction zone.

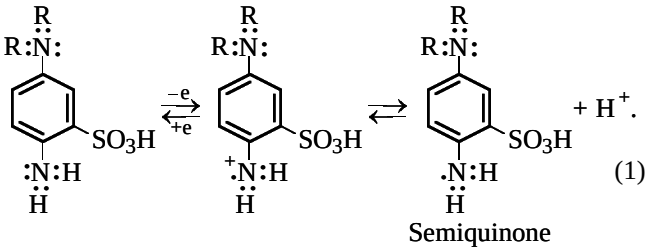
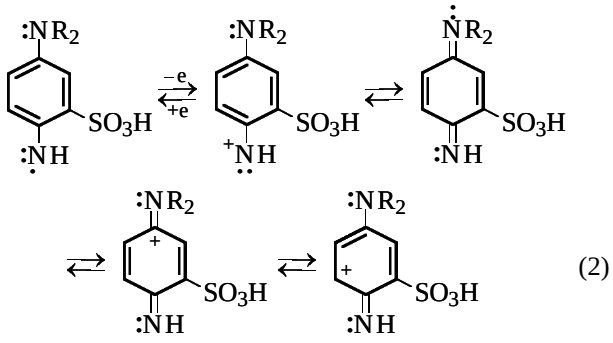
It should be noted that treatment with glow discharge changes the color of solutions containing color developers. This suggests that the reaction yields a colored intermediate. In the process, the colorless solution turns pink and then again colorless. This indicates that the oxidation is complicated by a number of subsequent chemical reactions, which was considered in detail for phenylenediamines in [4–5].

Published data and the experimental results obtained suggest that the initial substance, *p*-aminodiethylaniline sulfate, interacts with free electrons at the interface between the liquid and the ionized gas in the anode region (R = C_2H_5–):



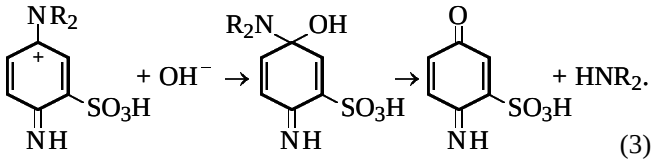
(1)

Then, loosing one more electron, semiquinone can be oxidized further to quinonediimine [6]:



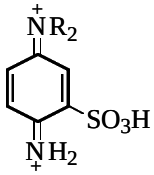
(2)

Reactions (1) and (2) are fast and cannot be the rate-determining stages. The limiting stage is transformation of quinonediimine into quinonemonoimine:



(3)

The initial imine group can be eliminated solely in an acid medium, since a doubly charged quinonediimine cation is the active species in the given reaction.



(4)

The qualitative analysis presented indicates the considerable potentialities of the method under consideration. These data are, however, insufficient for substantiating the choice of reactor. They can serve solely as a criterion for qualitative assessment of the systems presented. To describe the processes of nonequilibrium plasmochemical treatment in more detail, it is necessary to determine the dependence of the efficiency of these transformations on the reaction mass temperature, height at which the anode is placed over the liquid surface, discharge current, and pressure in the reaction zone.

Because all the reactions considered occur at the electrode–solution and electrode–gas phase interfaces, the process rate may depend on the current density per cathode area at constant current in the circuit and residual pressure in the reaction zone.

The results obtained in the study are presented in Fig. 2. It can be seen that variation of the current density within the permissible limits affects the degree of solution purification to remove color developers only slightly. The optimal current density is within 10–130 A m^{-2}. Beyond this range, the degree of purification decreases. Figure 2 also illustrates the influence exerted by the reaction zone pressure on the degree of color developer decomposition. The degree of solution purification is at a maximum at a pressure of 150–200 torr. With the pressure decreasing to 70 torr, the purification efficiency decreases, and

then increases upon further decrease in pressure. Apparently, such an unambiguous effect of pressure is due to concurrent reactions of dissipative absorption of the glow discharge energy by the gas phase and formation in it of active radicals captured by the liquid and initiating chemical reactions there.

Because the purification efficiency depends not only on the processes occurring at the gas–liquid interface, but is also affected by processes occurring on the cathode submerged in the solution, it was of interest to study the effect of the cathode material on the degree of purification. In this case, the choice of the cathode material may strongly affect the final result in purification of wastewater from motion-picture and photographic production. Figure 3 demonstrates the influence of the cathode material on the purification efficiency. Analysis of the data in Fig. 3 shows that the most acceptable cathode materials in decomposition of color developers are tin, braze, and steel.

As already mentioned, we studied the recovery of silver ions from wastewater formed in motion-picture and photographic production. The degree of Ag^+ recovery from aqueous solutions is presented in Fig. 4a as a function of the reaction zone pressure. It can be seen that the degree of purification grows markedly with pressure increasing to a certain value (110 torr) and then the process of silver ion deposition becomes slower. It is believed that the increasing pressure activates physicochemical effects associated with the growing amount of elementary events in both the gas phase and the liquid. At pressures above 110 torr the normal glow discharge transforms first into an abnormal glow discharge and then into an arc discharge. The potential distribution between the surface of the aqueous solution and the anode becomes uniform, which adversely affects the purification efficiency because of the considerable increase in the voltage across the electrodes. Below we show how the separation L between the liquid surface and the anode and the pressure P in the reaction zone affect the electrode voltage in recovery of silver ions from aqueous solutions:

P, torr	7.6	38	76	114	152
U, V	600	680	780	890	960
$L \times 10^3$, m	4	9	15	19	25
U, V	600	630	700	800	900

The distance through which the anode is raised above the reagent in deposition of silver ions from solution produces a similar effect (Fig. 4b), with, however, the working voltage across the discharge gap being somewhat lower. The dependence of the rate of nonequilibrium plasmochemical processes on interelectrode spacing is accounted for by the fact that this parameter is responsible for the forming anode and

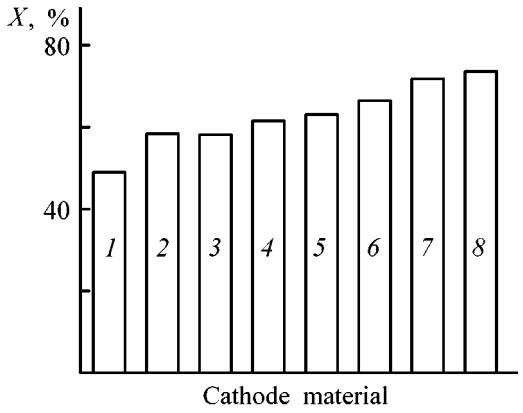


Fig. 3. Dependence of the degree of purification, X, on cathode material. Cathode: (*1*) copper, (*2*) carbon, (*3*) titanium, (*4*) aluminum, (*5*) lead, (*6*) steel, (*7*) brass, and (*8*) tin.

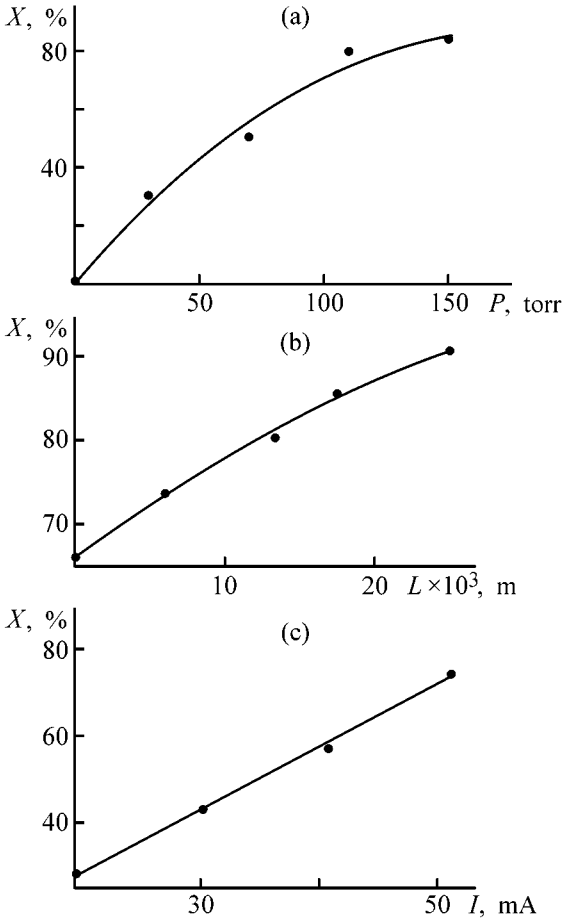

Fig. 4. Degree of purification, X, of solutions to remove silver ions vs. (a) reaction zone pressure P, (b) distance L between the anode and the liquid surface, and (c) current I.

cathode zones and determines their dimensions. The space charge is mainly located near the cathode, where the charge particle concentration is also at a maximum [7]. Consequently, the efficiency of the processes considered is determined by chemical transformations in this region. As the anode is moved away from the solution surface, the above-mentioned discharge zone is formed and the chemical processes associated with the contact action of glow discharge on the liquid are accelerated.

The main parameter ensuring deposition of heavy metal ions in plasmochemical treatment of waste-water, is the current strength in the glow discharge region. The dependence of the rate of the chemical reactions on the discharge current is shown in Fig. 4c. It can be seen that the degree of purification of the liquid also increases linearly with the current. It should be noted that the current can only be raised to 150 mA. Further increase in current results in the appearance of an arc and a drastic decrease in the process efficiency.

A sedimentation analysis of inhomogeneous liquid systems was made to determine the dispersity of the deposits obtained. A weighed portion of the deposit was dissolved in 0.1×10^{-3} m^3 of water. When necessary, the solution was dispersed with ultrasound in a UZDN-2T device and then poured into a FES-112 cuvette. The minimal fraction that can be detected by the device was 5–10 μm. The number of particles was recorded by a photosensitive element. In the given case, the size distribution of the particles was as follows (%): 5–10 μm 44, 10–25 μm 53, and >100 μm 3. Consequently, the recovered silver and its compounds mainly have particles 5–25 μm in size, and only their minor amount exceeds 100 μm or is less than 5 μm. The data presented here show convincingly that the dispersity of particles of the deposits formed exceeds somewhat that of deposits recovered from wastewater by the known technologies and qualified as "compressible."

It should be noted that the deposits formed in the course of the tests have composition and properties inviting additional theoretical and experimental investigation. In this communication, only some characteristics of the recovered solid phase are presented.

CONCLUSIONS

(1) The efficiency of low-temperature plasma electrolysis for purification of wastewater formed in photographic production is demonstrated.

(2) The main technological parameters determining the process intensity are the treatment time, reaction zone pressure, and distance from the anode to the phase boundary.

(3) It is suggested that the decomposition of color developers proceeds via formation of quinonemonoimines.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Production of Fluorinated Ethanes Using Elemental Fluorine[1]

D. S. Pashkevich, D. A. Mukhortov, Yu. I. Alekseev, and V. S. Asovich

Prikladnaya Khimiya, Russian Research Center, St. Petersburg, Russia

Received January 17, 2002

Abstract—Scientific principles of industrial gas-phase fluorination of fluoroethanes with elemental fluorine were developed. Conditions for fluorination of low-fluorinated ethanes without rupture of the C–C bond were determined.

Fluorinated ethanes (FEs), such as 1,1-difluoroethane (1,1-DFE), 1,1,2-trifluoroethane (1,1,2-TFE), 1,1,1,2-tetrafluoroethane (1,1,1-2-TFE), pentafluoroethane (PFE), and hexafluoroethane (HFE), are widely used in modern industry as refrigerants, propellants, fire-extinguishing agents, gaseous insulators, reagents for plasmochemical preparation of very large-scale integrated circuits, etc. [1]. The annual consumption of these compounds by the world industry is about tens thousand tons.

Modern industrial production of FEs is based on catalytic fluorination of fluorochloroethanes and fluorochloroethylenes with HF. This process involves chlorine-containing ozone-infriendly compounds whose manufacture should be stropped in accordance with the Montreal protocol. In addition, this process yields large amounts of hydrogen chloride waste and requires replacement of environmentally hazardous chromium-magnesium fluoride catalyst at regular intervals, followed by its utilization. Hence, development of new procedures for producing fluoroethanes is an urgent problem. One of these procedures is gas-phase fluorination of low-fluorinated enthanes with molecular fluorine.

Fluorine is a commercially available product and can be used for production of fluorine-containing compounds.

The first experiments on gas-phase fluorination of ethane with molecular fluorine were performed by Prof. Bigelow's group in 1940–1950 [2–5]. In particular, the possibility of preparing HFE was demonstrated. However, this method has not been used for industrial production.

Production of highly fluorinated ethanes, such as PFE and HFE, by the conventional procedure is the most difficult. Hence, to develope a process for industrial production of highly fluorinated ethanes by fluorination with elemental fluorine of fluoroethanes with lower fluorine content we studied first the kinetics of 1,1,1,2-TFE fluorination. We found that this is a degenerate branched chain reaction terminated by the surface. The reaction order with respect to fluorine is 0.8. The activation energy and the pre-exponential factor in the Arrhenius equation are 50 kJ mol^{-1} and 2.8×10^5 s^{-1}, respectively [6, 7].

The thermal parameters of 1,1,1,2-TFE-F_2 system, calculated from these kinetic data by equation of the combustion theory, show that the steady-state thermal conditions are unsuitable for industrial synthesis [8].

These results stimulated us to study 1,1,1,2-TFE fluorination under non-steady-state thermal conditions, when the reaction temperature is close to the adiabatic temperature. To estimate the fluoroethane stability, we performed a number of experiments under conditions of thermal explosion. The results are presented in Table 1. At fluorine concentration lower than 30 vol %, the major reaction product is PFE and the yield of fluoromethanes is very low. At higher fluorine concentration the C–C bond is ruptured, with fluoromethanes formed.

To provide continuous production, the synthesis should be performed under the conditions of a steady-state self-propagating thermal wave.

In bench experiment, the reactant mixture was fed from a mixer into a reactor equipped with an elec-

tric heater. As determined from the temperature of the gas flow, a steady-state self-propagating reaction front is formed at the fluorine concentration exceeding 20 vol %. This wave is initiated by the heated wall, rises along the flow, and is stabilized in the zone of reverse flows at the reactor inlet [8].

The composition of the reaction products is shown in Fig. 1a. At fluorine concentration lower than 30 vol %, the main product is PFE, and the 1,1,1,2-TFE conversion is 35%. At fluorine concentration exceeding 40 vol %, the content of fluoromethanes becomes high [9, 10].

Among FEs, production of HFE by the conventional procedure is the most difficult. In this work we studied formation of HFE from PFE in the wave fluorination mode. The composition of the reaction products is shown in Fig. 1b. At fluorine concentration of up to 30 vol %, the yield of fluoromethanes is very low and the main product is HFE [8–10].

In addition, we studied gas-phase fluorination of 1,1-DFE in the wave mode; the results are presented in Table 2.

Tables 1, 2 and Fig. 1a–1d show that rupture of the C–C bond of fluoroethane molecules (1,1,1,2-TFE, 1,1-DFE, and PFE) in the wave fluorination mode becomes appreciable at fluorine concentration exceeding 25–30 vol % [11].

The kinetic study of gas-phase fluorination of 1,1,1,2-TFE showed that this reaction is autocatalytic, with liberated HF being the catalyst [7].

* FM the total content of fluoromethanes in the reaction products.

We studied 1,1,1,2-TFE fluorination in the wave mode in the presence of 5–10 vol % HF [11]. In these experiments, the features of wave fluorination were similar to those observed with pure fluorine [11]. As seen from Fig. 1c, introduction of 5–10 vol % of HF has no effect on the composition of the products of the wave synthesis. Hence, the crude gas from electrolytic fluorine production can be used for the fluorination in the wave mode without additional purification.

To develop the process for industrial fluorination of fluoroethanes, the scaling principles for gas-phase fluorination in the wave mode should be determined. One of the features of combustion process is that the thickness of the reaction front in the laminar flare is tenths of a millimeter. In a turbulent flare of a tunnel burner, 80% conversion is reached within the length of five crater diameters [12]. This suggests that the compound is converted mainly at the temperature close to the adiabatic temperature. Then the composition of wave-mode fluorination products must be independent of the diameter of the reaction unit and of the gas flow rate in it.

To confirm the assumption that the composition of wave-mode fluorination products is independent of the reactor diameter, we performed the fluorination in reactors 10, 4, 3, and 2 mm in diameter at such a flow rate of the cold mixture which provides the same linear velocity of the gas [13]. The conditions of these experiments (reactor diameter d, flow rate of cold gas mixture u_m, Re number, and the coefficient of convective heat transfer from the reaction zone to the wall α) and the composition of the reaction products are presented in Table 3. The fluorine concentration in all the experiments was 30 vol %.

The composition of the products of wave-mode fluorination is independent of the coefficient of convective heat transfer α in the range 25–130 W m^{-2} K^{-1}, which confirms the absence of heat exchange in the reaction zone of fluorine with 1,1,1,2-TFE and allows prediction of the the synthesis results upon changing reactor size at the same initial fluorine concentration.

Thus, the fluorine concentration is the only parameter affecting the composition of wave-mode fluorination products, which simplifies construction and operation of the reactor [13].

The ignition parameters of 1,1,1,2-TFE-F2 mixture were calculated by the equations of the thermal theory of ignition in a gas flow [12]. These equations allow calculation of the wall temperature providing formation of self-propagating thermal wave from the kinetic

parameters of the reaction and the parameters of the gas flow. At Re ~10^5 the temperature of the reactor wall should be 150–200°C. Under these conditions, a stable thermal wave is formed and detonation processes are ruled out. In addition, permissible flow rates not exceeding the rate of the thermal wave were calculated for different reactor diameters and Re = 35 000. These calculation show that 100 t of PFE can be annually produced from 1,1,1,2-TFE in a reactor 100 mm in diameter [8].

The predicted operation parameters were checked on a pilot unit with a reactor 20 mm in diameter. The fluorine concentration ranged from 22 to 28 vol %. The main reaction product of the wave synthesis was PFE [8].

One of the disadvantages of the wave mode is that synthesis should be performed at substoichiometric fluorine concentration. As noted above, for the content of fluoromethanes in the reaction products to be not higher than 1–2%, the maximal permissible fluorine concentration should be about 30%. Under these conditions, the conversion is relatively low.

To increase the conversion, the following operations should be performed. First, the sabstance to be fluorinated can be partially replaced by HFE, which is not involved noticeably in the reaction at the fluorine concentration lower than 30 vol %, or by other inert compound. Second, a sequence of series-connected wave reactors with intermediate cooling of the reaction products can be used. Third, intermediate fluorination products can be separated from the reaction products and recycled [12].

To illustrate the first approach, we studied fluorination of 1,1-DFE to trifluoroethanes in the wave mode (Table 4). Hexafluoroethane was used as the inert compound. The 1,1-DFE concentration in the initial mixture was 14%. This compound was contaminated with 0.35% CHF_3 and 0.49% CF_3CH_3. The 1,1-DFE conversion was as high as 80%; the selectivity of trifluoroethane formation was 50%. However, at the fluorine concentration exceeding 20 vol %, the TFM yield was relatively high. This is probably due to rupture of the C–C bond in the HFE molecule under the conditions of fluorination in the wave mode.

The first approach was also illustrated by wave-mode fluorination of 1,1,1,2-TFE to HFE, with argon used as a diluent of the reaction mixture. The conditions of these experiments and the composition of the reaction products are summarized in Table 5. In

the presence of argon diluent and at a fluorine excess, the conversion of the initial compound was almost quantitative and the selectivity of HFE formation was about 97%. The yield of fluoromethanes was low. It should be noted that the temperature of the reactor wall was 200–250°C. We failed to generate a thermal wave of gas-phase fluorination at the temperature of the reactor wall of 10°C.

To simulate the operation of a sequence of two series-connected wave reactors, we studied the synthesis of PFE from 1,1,1,2-TFE by fluorination of a PFE (32 vol %)-1,1,1,2-TFE (68 vol %) mixture in the wave mode (Fig. 1b).

The content of PFE formed under these conditions is maximal (43 vol %) at the fluorine concentration of 27 vol %. The HFE content is 6 vol % and fluoromethanes are virtually absent.

The ratio of the rate constants of fluorination of 1,1,1,2-TFE and PFE was estimated from the data presented in Fig. 1 b. At the fluorine concentration of 25 vol % (adiabatic temperature in the reaction zone 1000 K) the rate constant of 1,1,1,2-TFE fluorination is higher than that of PFE by a factor of 1.5. In this calculation, we assumed that 1,1,1,2-TFE is converted only into PFE, and PFE only into HFE. The activation energy of PFE fluorination was estimated to be 53 kJ mol^{-1}. We assumed that the activation energy of 1,1,1,2-TFE fluorination is 50 kJ mol^{-1} [7].

The activation energy of high-temperature fluorination of 1,1-DFE, estimated from the data presented in Table 2, is 44 kJ mol^{-1}. In this calculation, we assumed that 1,1-DFE is converted only into 1,1,1-TFE, 1,1,2-TFE, 1,1,1,2-TFE, and 1,1,2,2-TFE, and 1,1,1,2-TFE, only into PFE and HFE [11].

Based on the experimental data on wave-mode fluorination of 1,1,1,2-TFE, PFE, and their mixtures, we proposed a kinetic model of this process. Formation of both the substitution products and fluoromethanes is taken into account in this model. We suggested that the ratio of the activation energies of hydrogen substitution and degradative fluorination is equal to the ratio of the energies of the C–H and C–C bonds [14, 15].

Parameters of 1,1-DFE fluorination to a mixture of PFE and HFE in the ratio 3 : 1 in two-step and three-step wave reactors were calculated by this model, refined using the experimental data on 1,1-DFE fluorination. The fluorine concentration in each step was 23 vol %. Intermediate tetra- and trifluoroethanes were recycled.

Our calculations show that 1,1-DFE conversion in a series of three wave reactors with recycling of intermediate fluorination products can reach 90% [11].

EXPERIMENTAL

In the bench experiments were used the following chemicals: commercial 1,1,1,2-TFE (ICI company, UK); PFE, HFE, and 1,1-DFE produced by Prikladnaya Khimiya Russian Research Center on a pilot installation for enthylene fluorination with cobalt trifluoride; commercial hydrogen fluoride (Khimprom Joint-Stock Company); and commercial argon (Lentekhgaz plant).

To determine the kinetic parameters of 1,1,1,2-TFE fluorination under the steady-state thermal conditions, a mixture of 1,1,1,2-TFE and fluorine was passed through a 2-mm copper tube thermostat in which the temperature was maintained in the range from 105 to 148°C. The reaction time was controlled by varying the flow rate of the initial mixture and the tube length. The fluorine concentration in the initial mixture was 4–10 vol %, which provided fluorination under the isothermal conditions. Gas samples were taken at the tube outlet, neutralized, and analyzed chromatographically. The reactor scheme and experimental procedure were described in detail in [7].

Fluorination of 1,1,1,2-TFE was performed in a 25-mm steel ampule 150 mm long under the conditions of thermal explosion. An ampule was purged with a 1,1,1,2-TFE–F_2 mixture so as to provide tenfold gas exchange. Then the inlet and outlet valves were closed and the ampule was immersed in a heat-transfer agent heated to 100°C. The thermal explosion was monitored with the aid of a 200 μm Chromel–Copel thermocouple fixed inside the ampule without protective covers. The gaseous samples for chromatographic analysis were taken with a medical syringe.

The bench experiments on wave-mode fluorination of fluoroethanes were performed as follows. A fluoroethane-fluorine mixture was fed in a reactor, which was, unless otherwise noted, a steel tube 300 mm long and 10 mm in diameter. An electric heater initiating the wave process was fixed on the reactor surface in the vicinity of the outlet. A thermal wave rose from the heated region counter to the flow and was stabilized in the region of reverse flows at the reactor inlet. The reactor surface in this region was cooled with water to 10°C. Three Chromel–Copel thermocouples 200 μm in diameter were fixed without protective covers inside the reactors. The thermocouple junctions

were in line with the reactor axis. propagation of the thermal wave counter to the flow and its stabilization in the region of reverse flows was monitored, and the gas temperature in the reaction zone measured with the aid of the thermocouples. Gas samples for chromatographic analysis were taken at the reactor outlet and neutralized with chemical lime absorbent. The laboratory unit was also described in [8, 10].

The initial gaseous mixtures and neutralized reaction products were analyzed chromatographically on an LKhM-80 gas chromatograph (thermal conductivity detector, flow rate of the carrier gas, helium, 30 $cm^3\ min^{-1}$) at 50°C. A 6-m column was packed with Polisorb-10.

CONCLUSIONS

(1) The kinetics of gas-phase fluorination of fluoroethanes with molecular fluorine was studied.

(2) Our calculations demonstrated that the steady-state thermal conditions of gas-phase fluorination of fluoroethanes with fluorine are unsuitable for industrial synthesis.

(3) Gas-phase fluorination of fluoroethanes with fluorine under non-steady-state thermal conditions (thermal explosion and self-propagating thermal wave) was studied. The main process parameters were determined. This process can be industrially used.

(4) Based on the fact that the wave reaction zone is adiabatic, the principles for scaling of the gas-phase wave reactor were developed.

(5) The methods for increasing both conversion of the initial compounds and selectivity of formation of the target product formed in the wave reactor were proposed and the process parameters were calculated and studied experimentally.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Photolysis of Perfluoropropylene-Methanol Mixture in Vacuum Ultraviolet[1]

Abstract—The products of reaction of C_3F_6 with CH_3OH, initiated by vacuum ultraviolet, were determined. The kinetics scheme of the process was proposed. The parameters of the kinetic processes were calculated. The feasibility of photochemical preparation of 2,2,3,4,4,4-hexafluoro-1-butanol was analyzed.

One of methods for introducing perfluoroalkyl groups in molecules of organic compounds is addition of these groups to unsaturated hydrocarbons in the course of radical telomerization [1, 2]. Many fluorinated organic compounds exhibit absorption only in the range of vacuum ultraviolet (VUV). A great number of compounds with required properties can be prepared by photoreactions of fluorinated organic compounds under exposure to VUV. In this work, we examined a new route to polyfluorinated 1-butanol: irradiation of a C_3F_6–CH_3OH mixture with 185-nm light.

Perfluoroolefins, as well as lower alcohols, do not absorb in the range above 200 nm. Photolysis of C_2F_4 in VUV was studied in [3, 4]. Continuous absorption of C_3F_6 in VUV, determined in our works, suggests radical photolysis of this compound. Reactions of fluoroolefins with alcohols, usually initiated by peroxides or γ-radiation, yield telomers [5]. Photochemical initiation, unlike these methods, allows control of the process owing to selective activation of definite bonds. The aim of this study was do develop a new photochemical synthesis procedure. In particular, we studied possible reaction pathways, determined the yield of the reaction products and the irradiation efficiency, and constructed a mathematical model of the photolysis.

EXPERIMENTAL

Photochemical studies were performed in a cylindrical quartz reactor. A 70 W low-pressure mercury lamp [6] 0.9 m long was fixed at the reactor axis. The power of this lamp, measured at 185 and 254 nm, was 1 and 20 W, respectively. The photoreactor was equipped with a vacuum system used to fill the reactor with the initial reagents and to sample the reaction mixture. The photolysis products were analyzed on an HP5972 chromato–mass spectrometer with an HP-PLOT capillary column coated with Al_2O_3. The mass spectra were assigned with the aid of WILEY.138.L library.

To understand the kinetics of synthesis of polyfluorinated 1-butanol, we studied perfluoropropylene photolysis. Initially we studied C_3F_6 photolysis at a pressure of 4 kPa and exposure time of 15 min. Under these conditions, C_3F_6 is quantitatively converted into perfluorocyclobutane derivatives (up to 45%) and perfluoroparaffin isomers.

Formation of perfluoromethylcyclobutane, 1,2-, and 1,3-bisperfluoromethylcyclobutane (in the ratio 1.6 : 1.4 : 1) can be described by the following scheme:

$$C_3F_6 + h\nu \rightarrow C_3F_6^*(+M) \rightarrow :CF_2 + CF_3CF:,$$

$$C_3F_6^* + (M) \rightarrow C_3F_6,\ 2:CF_2 \rightarrow C_2F_4,$$

$$CF_3CF: + (M) \rightarrow C_2F_4,$$

$$C_2F_4 + h\nu \rightarrow C_2F_4^*(+M) \rightarrow 2:CF_2,$$

$$C_2F_4^* + (M) \rightarrow 2:C_2F_4,$$

$$C_2F_4 + C_3F_6^* \rightarrow C_5F_{10}\ \text{(perfluoromethylcyclobutane)},$$

$$C_2F_4^* + C_3F_6 \rightarrow C_5F_{10},$$

$$C_3F_6 + C_3F_6^* \rightarrow C_6F_{12}\ \text{(perfluorodimethylcyclobutane isomers)},$$

where perfluoropropylene in the electronically excited state is marked with an asterisk. This is probably the

triplet state that is involved in deactivation, predissociation degradation into radicals, and reactions with other molecules, ultimately resulting in cyclodimerization.

The presence of trace amounts of perfluoro-2-butene (~0.01%) and C_2F_4 (<1%) in the reaction mixture agrees with the reaction scheme, since C_2F_4 is converted incompletely and the perfluoro-2-butene formation by recombination of methylcarbene radical is considerably slower than the C_2F_4 formation. "Biradical" formation was detected in C_3F_6 pyrolysis [7], i.e., at significantly lower excitation energy of perfluoropropylene. Although cyclodimerization proceeds mainly by degradation of compounds containing a double bond to form saturated compounds and is typical of C_3F_6 pyrolysis (*T* ~200°C), it occurs in the course of C_3F_6 photolysis too.

Photolysis of C_2F_4 under the same conditions occurs simslarly. The main product, perfluorocyclobutane, is formed after irradiation of perfluoroethylene for 3 min (the C_2F_4 conversion is ~15%). The process can be described by the above kinetic scheme, since, in both cases, predissociation degradation yields difluorocarbene. However, C_3F_6 photolysis is a more complex process and yields a series of paraffin isomers, from perfluoropropane to perfluorononane. This process involves an additional pathway initiated by the $:CF_2$ biradical and atomic fluorine formed in the primary photolysis step.

The weakest bonds of a molecule excited by a VUV quantum are ruptured owing to energy redistribution after molecular collisions. Several pathways of $C_3F_6^*$ dissociation are possible. The excess energy of photodissociation products was estimated on the basis of the energy balance and analysis of fluorocarbon fragments of saturated polyfluorinated products of C_3F_6 photolysis performed at a large excess of hydrocarbon. Based on the results of this estimation, we suggest the following scheme of $C_3F_6^*$ dissociation:

$$C_3F_6^* + (M) \rightarrow \cdot CF{=}CFCF_3 + \cdot F,\ E_{exc}\ 22 \text{ and } 158 \text{ kJ mol}^{-1}, \text{ respectively,}$$

$$C_3F_6^* + (M) \rightarrow \cdot CF{=}CF_2 + \cdot CF_3,\ E_{exc}\ 31 \text{ and } 36 \text{ kJ mol}^{-1}, \text{ respectively.}$$

The secondary processes can involve reactions with "hot" radicals $\cdot CF_3'$ and $\cdot F'$, with subsequent photodegradation of the fragments formed. The first photolysis step can be described by a superposition of the above reactions:

$$C_3F_6 + h\nu \rightarrow C_3F_6^*(+M) \rightarrow \cdot CF_3 + \cdot F + C_2F_2,$$

which agrees well with the kinetic scheme of formation of fluoroparaffin isomers presented in Table 1.

Subsequent transformations involve addition of fluorine atom to double bonds to form $\cdot R_F$ radicals ($\cdot R_F$, $\cdot C_3F_7$, $\cdot C_2F_5$, and $\cdot CF_3$) recombining to give a series of paraffin isomers. The rate constants of radical recombination decrease appreciably in going from linear to branched structures and with increasing number of carbon atoms [8]. Therefore, recombination of branched radicals, $\cdot C_4F_9$ and higher, was disregarded in the kinetic scheme. The C_7–C_9 isomers may arise in the photolysis products in the step of formation of methylcyclobutanes, when $\cdot R_F$ radicals recombine with the $:C_6F_{12}$ biradical, which has no time to form a four-membered ring.

Photolysis of C_3F_6 to form detectable products is initiated to the same extent by difluorocarbene and atomic fluorine generated in primary photolysis steps. Generally C_3F_6 is photolyzed under the conditions when the rate of reactions of excited $C_3F_6^*$ molecules is comparable with that of predissociation degradation followed by secondary and tertiary radical reactions, which strongly complicates the photolysis mechanism. To understand the photolysis mechanism, mathematical modeling can be used.

A mathematical model of C_3F_6 photolysis was developed by comparing experimental and calculated data on the composition of the reaction products. The kinetics scheme includes 50 reactions whose constants were taken from the literature or were estimated by extrapolation of the known rate constants of homologs, taking into account the steric factors. A system of differential kinetic equations of these reactions was constructed and integrated by the Gear procedure [9].

The time dependeces of the concentration of the photolysis products are adequately described by the kinetic model (Table 1). The calculations show that C_3F_6 is completely decomposed after 100s of irradiation. The convergence of the calculated and experimental concentrations can be improved by varying the rate constants of the reactions and quantum yields of the products and by recording more exactly the absorption spectra of the radical products. A model calculation confirmed the occurrence of the main reactions of C_3F_6 photodissociation.

Synthesis of polyfluorinated 1-butanol by continuous irradiation of a C_3F_6–CH_3OH mixture with VUV for 15 min was studied. Synthesis was performed at three ratios of the partial pressures of the components C_3F_6 : CF_3OH = 4 : 0.8, 4 : 4, and 0.8 : 4. Under these conditions, the ratio of the absorption coefficients of C_3F_6 and CH_3OH at 185 nm are 75, 15, and 3, respectively. This allows evaluation of the effect of the CH_3OH photolysis on the formation of the target product.

The fact that the chromatograms of the photolysis products of C_3F_6 and the initial mixture C_3F_6 : CH_3OH = 4 : 0.8 are similar indicates that CH_3OH is not involved appreciably in the radical process and is converted mainly by addition to the double bond

$$C_3F_6^* + CH_3OH \rightarrow CF_3CHFCF_2CH_2OH.$$

The yield of 2,2,3,4,4,4-hexafluoro-1-butanol is 20%. This reaction is responsible for formation of about 90% of the photolysis products. Telomerization of $C_3F_6^*$ with CH_3OH is more intense than C_3F_6 dimerization. Side recombination reactions yield up to 1.5% fluorinated ethers [$(C_3F_6 + \cdot F) + CH_3O\cdot \rightarrow C_3F_7OCH_3$, $(C_3F_6 + \cdot CF_3) + CH_3O\cdot \rightarrow C_4F_9OCH_3$] and up to 6.2% R_FH ($\cdot R_F = \cdot CF_3$, $\cdot C_4F_9$, $\cdot C_5F_{11}$, $\cdot C_6F_{13}$). Compounds R_FH are formed mainly by recombination with the $\cdot CHF_2$ radical

$$\cdot CHF_2 + (C_3F_6 + \cdot F) \rightarrow C_4HF_9,$$

$$\cdot CHF_2 + (C_3F_6 + \cdot CF_3) \rightarrow C_5HF_{11},$$

$$\cdot CHF_2 + (C_3F_6 + \cdot C_2F_5) \rightarrow C_6HF_{13},$$

$$(C_3F_6 + \cdot H) + (C_3F_6 + \cdot F) \rightarrow C_6HF_{13}.$$

This system of three-step consecutive reactions accounts for the absence of C_2HF_5 and C_3HF_7 in the photolysis products. The radical $\cdot CHF_2$ is effectively formed by the reactions $:CF_2 + \cdot H \rightarrow \cdot CHF_2$, $:CF_2 + CH_3O\cdot \rightarrow \cdot CHF_2 + CH_2O$. Formation of C_2HF_3 traces is due to the reactions $C_2F_2 + \cdot F \rightarrow \cdot C_2F_3$, $\cdot C_2F_3 + CH_3OH \rightarrow C_2HF_3 + CH_3O\cdot$, or $\cdot CF_3' + CH_3O\cdot \rightarrow C_2HF_3 + H_2O$. CH_3CF_3 is formed by the reactions $\cdot CF_3 + \cdot CH_3 \rightarrow CH_3CF_3$ or $\cdot CF_3' + CH_3O\cdot \rightarrow CH_3CF_3 + O:$ ($\cdot CF_3'$ is "hot" radical). Methanol is involved in photolysis and in reactions with fluorine radicals:

$$CH_3OH + h\nu \rightarrow \cdot H + CH_3O\cdot \ (79\%),$$

$$CH_3OH + h\nu \rightarrow CH_2O\ H_2 \ (20\%),$$

$$CH_3OH + h\nu \rightarrow \cdot CH_3 + \cdot OH \ (1\%) \ [10],$$

$$\cdot R_F + CH_3OH \rightarrow R_FH + CH_3O\cdot \ (85\%),$$

$$\cdot R_F + CH_3OH \rightarrow R_FH + \cdot CH_2OH \ (15\%) \ [11].$$

The main reactions competing with the formation of the fluornated alcohol are cyclodimerization of C_3F_6 and predissociation decomposition of C_3F_6. Photolysis of CH_3OH has virtually no effect on the synthesis. Chromatograms of the products formed in photolysis of the C_3F_6–CH_3OH system are presented in Table 2 in order of increasing retention time.

The yield of 2,2,3,4,4,4-hexafluoro-1-butanol decreases to 11.5% with increasing CH_3OH content in the initial mixture (C_3F_6 : CH_3OH = 4 : 4). The total content of the products of chemical reactions of the photolysis products increases to 60%, and the selectivity of the alcohol formation decreases from 90 to 19%. Among the photolysis products, 2,2,3,4,4,4-

hexafluorobutanal is characterized by the maximal yield (30%). As the temperature increases, this compound can be formed by the reaction

$$C_3F_6^* + CH_3OH \rightarrow CF_3CHFCF_2C(O)H + H_2$$

or the secondary reaction

$$C_3F_6^* + CH_2O \rightarrow CF_3CHFCF_2C(O)H.$$

The number of the products of radical reactions increases by approximately a factor of 5. The total content of R_FH compounds increases to 24%. New compounds R_FCH_3 with total content of up to 12% are formed instead of ethers by recombination $\cdot R_F + \cdot CH_3 \rightarrow R_FCH_3$, where $\cdot CH_3$ is generated by the reaction $\cdot H + CH_3OH \rightarrow \cdot CH_3 + H_2O$. These compounds can also be formed by reactions $\cdot R_F + CH_3O\cdot \rightarrow R_FCH_3 + O{:}$. The contribution of these reactions increases with temperature. The heating of the reaction mixture is due to a stronger absorption in the system owing to an increase in its optical density. The increase to approximately 10% in the content of polyolefins ($CF_2=CFCHF_2$, $CH_2=CFCF_3$, $C_2H_2F_2$, C_2HF_3 formed in reactions like $\cdot CF_3 + CH_3 \rightarrow C_2H_2F_2 + HF$) that were not subjected to photolysis is due to intensification of the pyrolytic processes. The kinetic model of the process becomes severely complicated, since CH_3OH photolysis and some temperature-dependent reactions should be taken into account.

No products of addition to the double bond of C_3F_6 were detected in the reaction mixture of photolysis at C_3F_6 : CH_3OH = 0.8 : 4. All the products of the reaction of C_3F_6 with CH_3OH are formed by radical reactions initiated by the photolysis products of C_3F_6 and CH_3OH. The content of R_FH and R_FCH_3 increases to 31 and 32%, respectively. The other products are polyfluorinated paraffins and olefins. Trace amounts of CH_2O, CO_2, HF, H_2O, CF_3OCF_3, etc. are also formed. The chromatograms of the main reaction products are presented in Table 2.

CONCLUSIONS

(1) Photolysis of perfluoropropylene by vacuum ultraviolet was studied. The photolysis products were determined. The kinetic scheme of the process was proposed.

(2) Irradiation of a C_3F_6 : CH_3OH mixture (4 : 0.8) with vacuum ultraviolet yields 2,2,3,4,4,4-hexafluoro-1-butanol in 20% yield. The yield of this compound decreases with increasing CH_3OH content in the mixture. The calculated composition of photolysis prod-

ucts agrees well with the composition of the products formed in the photochemical reactor.

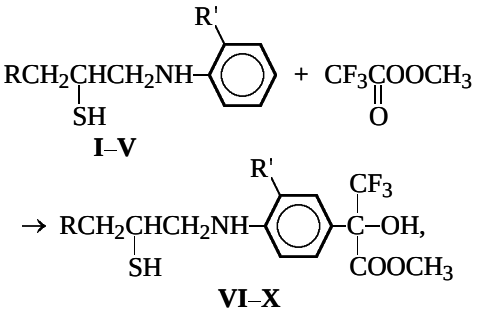
Abstract—Reactions of 1,2-aminopropanethiols with methyl trifluoropyruvate were studied, and the antibacterial and fungicidal activity of the resulting trifluoromethyl derivatives as additives to lubricants was examined.

Proceeding with investigations on synthesis of 1,2-aminopropanethiols and their derivatives [1–7], we performed in this study the reactions of 1,2-aminopropanethiols with methyl trifluoropyruvate with the aim to prepare the corresponding trifluoromethyl derivatives. The reaction of various aromatic amines with methyl trifluoropyruvate was comprehensively studied in [8–10]. The reaction involves alkylation of the aromatic ring of the amines and yields the corresponding trifluoromethyl derivatives. However, this reaction has not been performed previously with *N*-aryl-substituted 1,2-aminopropanethiols. Owing to the presence of the reactive NH and SH groups in their molecules, several reaction pathways may be possible along with C-alkylation, such as S-alkylation and cyclization under the action of strongly electrophilic methyl trifluoropyruvate.

We found that 1,2-aminopropanethiols **I**–**V** react with methyl trifluoropyruvate along a single pathway, alkylation of the aromatic ring at the *p*-position relative to the NH group:



I–**V** → **VI**–**X**

where R = H, R' = H (**VI**), CH_3 (**VII**), CH_3O (**VIII**); R = CH_3O, R' = CH_3 (**IX**), CH_3O (**X**).

The initial aminopropanethiols **I**–**V** were prepared by the reactions of 1,2-epithiopropane and 1,2-epithio-3-methoxypropane with appropriate aromatic amines.

The physicochemical constants of **VI**–**X** are listed in Table 1.

The structure of **VI**–**X** was proved by IR and ^{1}H NMR spectroscopy, and the purity, by elemental analysis and thin-layer chromatography.

The IR spectra of **VI**–**X** contain a strong band at 1730–1740 cm^{-1}, characteristic of esters. A very weak SH band is observed at 2530–2570 cm^{-1}. The overlapping bands of the OH and NH groups are observed at 3350–3370 cm^{-1}. The bands at 1140 and 970 cm^{-1} correspond to stretching vibrations of the C–F bonds in the CF_3 group.

The ^{1}H NMR spectra of **VI**–**X** contain signals of methyl (1.25–1.30 ppm), NCH_2, and methine (3–4 ppm) protons. The CH_3Ar protons give a singlet at about 2.3 ppm, and the ester methyl protons, a singlet at 3.7–3.8 ppm.

The CH_3OAr protons in **VIII** and **X** give signals at 3.65 ppm. The downfield multiplets at 6.2–7.1 ppm in the spectra of all the compounds correspond to nonequivalent protons of the benzene ring.

Fluorinated 1,2-aminopropanethiols **VI**–**X** were tested as antimicrobial additives to Vaseline oil according to GOSTs (State Standards) 9.052–88 and 9.085–78. Tests were performed with *Pseudomonas aeruginosa* bacteria and *Aspergillus niger* and *Candida tragicalic* fungi.

The results of the tests are listed in Table 2. Straight Vaseline oil shows poor biological resistance and degrades under the action of these microorganisms.

Compounds **VI**–**X** exhibit pronounced fungicidal and antibacterial activity at low concentrations (0.1–1.3%); they are readily soluble in Vaseline oil and do not stimulate corrosion. Compounds **VI**–**X** are more effective than a commercial antimicrobial additive, butyl salicylate, used as reference. As seen from Table 2, compounds **VIII** and **X** are the most active. With these compounds, the suppression zone width for fungi is 2.4 cm, whereas with butyl salicylate it is considerably smaller: 0.7 cm.

EXPERIMENTAL

The IR spectra of 1,2-aminopropanethiols **I**–**V** and their derivatives **VI**–**X** were taken on a Specord 75-IR spectrophotometer (3600–400 cm^{-1}, liquid films, KBr and NaCl prisms) under standard conditions. The frequencies were determined with an accuracy of ±5 cm^{-1}.

The ^{1}H NMR spectra were recorded on a Varian T-60 spectrometer (60 MHz, internal reference TMS, solvent CCl_4). The chemical shifts δ were measured with an accuracy of ±0.03 ppm.

The purity of the compounds was determined by gas–liquid chromatography on a Tsvet-104 instrument equipped with a 200 × 0.3-cm column. The column temperature was 210°C. The moisture content of the carrier gas was P_{H_2O} = 0.2 mg cm^{-2}. The sample volume was 0.1 μl. The stationary phase was SE-301, 5% on Chromaton N-A, 0.5–0.15 mm.

Thin-layer chromatography was performed on Silufol UV-254 plates, with ethanol–hexane (1 : 5) as eluent. In all cases, development with iodine vapor revealed a single spot.

1-[4-(1-hydroxy-1-methoxycarbonyl-2,2,2-trifluoroethyl)phenyl]aminopropane-2-thiol VI. A three-necked flask was charged with 3.3 g (0.02 mol) of 1-(phenylamino)propane-2-thiol **I**, 20 ml of anhydrous tetrachloromethane, and 3.1 g (0.02 mol) of methyl trifluoropyruvate. The mixture was vigorously stirred for 16 h at room temperature. Then the solvent was distilled off, and the product was isolated by column chromatography (alumina, Brockmann grade II, eluent CCl_4–acetone, 10 : 1). A viscous yellow liquid

was obtained; yield 3.3 g (51%), n_D^{20} = 1.4950, R_f = 0.20.

Found, %: C 48.48, H 5.19, N 4.13, F 17.84, S 10.07.

$C_{13}H_{16}NO_3F_3S$.

Calculated, %: C 48.29, H 4.99, N 4.33, F 17.63, S 9.92.

Compounds **VII**–**X** were prepared similarly; the physicochemical constants of **VI**–**X** are listed in Table 1.

CONCLUSIONS

(1) Methyl trifluoropyruvate alkylates 1,2-aminopropanethiols exclusively at the aromatic ring.

(2) Trifluoromethyl derivatives of 1,2-aminopropanethiols added to lubricants exhibit antibacterial and fungicidal activity.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Extractive Power of Polycyclic Pyrimidine Derivatives

V. P. Krivonogov, N. G. Afzaletdinova, G. A. Sivkova, G. G. Kozlova, Yu. I. Murinov, and I. B. Abdrakhmanov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

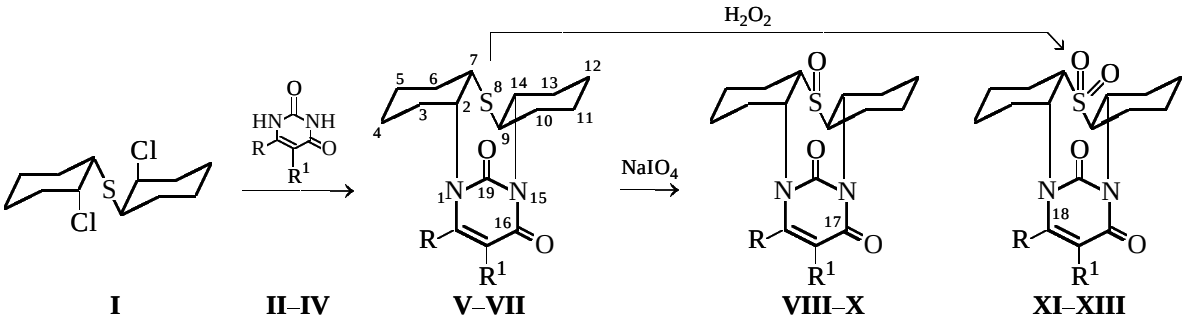
Received December 19, 2001; in final form, February 2002

Abstract—A procedure was developed for synthesis of polycyclic pyrimidine derivatives by the reaction of 2,2'-dichlorodicyclohexyl sulfide with uracil, 6-methyluracil, or 5-fluorouracil in the presence of K_2CO_3, followed by oxidation of the resulting products with sodium metaperiodate and hydrogen peroxide. Two of the synthesized compounds were tested in extraction of Ir(IV) from hydrochloric acid solutions.

Functionally substituted acyclic and cyclic sulfides and their oxidized derivatives are valuable as immunostimulants and antiphlogistics [1–6], and also as metal extractants and complexing agents [7].

Previously, a new class of low-toxic nonsteroid antiphogistics has been prepared by the reactions of SCl_2 with cyclohexene [3], cyclooctadiene [4], and cyclododecatriene [5], followed by treatment of the resulting 2,2'-dichlorodicyclohexyl sulfide, 2,6-dichloro-9-thiabicyclo[3.3.1]nonane, and 2,9-dichloro-13-thiabicyclo[8.2.1]-*cis*-tridec-5-ene with secondary amines: morpholine and piperidine. The resulting amino derivatives of dicyclohexyl sulfide, 9-thiabicyclo[3.3.1]nonane, and 13-thiabicyclo[8.2.1]-*cis*-tridec-5-ene showed high antiphlogistic activity in inflammations caused by carragenin and Formalin. The extractive power of amino sulfides has been studied, and fast recovery of iridium with these agents containing N,S-functionalities was reported [8].

In this study, we prepared polycyclic pyrimidine derivatives and tested them in extraction of iridium from hydrochloric acid solutions. As a continuation of our studies concerned with synthesis of potential immunotropic, antiphogistic, membrane-stabilizing, and antiradical agents, and also of extractants for noble metals, we developed a route to previously unknown polycyclic pyrimidine derivatives, involving the reactions of *trans*-2,2'-dichlorodicyclohexyl sulfide with pyrimidine derivatives (uracil, 6-methyluracil, 5-fluorouracil):



I **II–IV** **V–VII** **VIII–X** **XI–XIII**

R = R' = H (**II**, **V**, **VIII**, **XI**); R = CH_3, R' = H (**III**, **VI**, **IX**, **XII**); R = H, R' = F (**IV**, **VII**, **X**, **XIII**).

It is known that the reaction of SCl_2 with cyclohexene initially yields the *a,e*-dichloro sulfide, which irreversibly isomerizes into stable *e,e,e,e*-dichloro sulfide **I** [8].

1070-4272/02/7508-1283 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The reactions of **I** with uracil **II**, 6-methyluracil **III**, and 5-fluorouracil **IV** in the presence of K_2CO_3 occurred at 80°C within 5 h, yielding sulfur-containing polycyclic pyrimidine derivatives **V**–**VII**. Oxidation of **V**–**VII** with sodium metaperiodate in aqueous alcohol at room temperature for 4 h yielded sulfoxides **VIII**–**X**, which were isolated by extraction with chloroform. Oxidation of **V**–**VII** with hydrogen peroxide gave sulfones **XI**–**XIII**. These products are readily soluble in water, chloroform, alcohol, benzene, acetone, and ether and insoluble in hexane.

The purity and structure of the products were confirmed by IR, UV, and ^{1}H and ^{13}C NMR spectroscopies, and also by elemental analysis. IR spectra of all the compounds contain absorption bands in the ranges 1620–1730 cm^{-1}, characteristic of the pyrimidine moiety [ν(C=O, =NC=O)], 640–690 cm^{-1}, belonging to the C–S bons, and, in the case of **VIII**–**X**, also 1060–1080 cm^{-1} (SO stretching vibrations). The SO_2 group gives bands at about 1175, 1220, and 1320 cm^{-1}. The spectra of **V**–**XIII** also contain absorption bands in the ranges 1120–1200 cm^{-1}, typical of tertiary nitrogen (–N=) derivatives, and 3320–3400 cm^{-1}, belonging to OH stretching vibrations.

In the ^{1}H NMR spectra of sulfoxides VIII–X, the signals of protons of the α-carbon atoms ($C^{7,9}$) are shifted downfield by 0.1 ppm relative to the sulfides, whereas the signals of protons of the β-carbon atoms ($C^{6,10}$) are shifted downfield by 0.8 ppm, and those of protons of $C^{2,14}$, by 1–1.5 ppm. In the spectra of **II**, **V**, **VIII**, and **X**, the signals of protons in 5- and 6-positions of uracil are doublets with *J* 7–7.1 Hz.

In the ^{13}C NMR spectra of sulfoxides **VIII**–**X** and sulfones **XI**–**XIII**, the signals of the α-carbon atoms ($C^{7,9}$) are shifted downfield by 20–23 ppm, whereas the signals of the β-carbon atoms ($C^{6,10,2,14}$) are shifted upfield by 10–15 ppm.

The ^{1}H and ^{13}C NMR spectra were recorded with 1% (^{1}H) or 10–20% (^{13}C) solutions in $CDCl_3$ on a Bruker AM 3000 spectrometer (^{1}H, 300 MHz; ^{13}C, 75.7 MHz). The proton chemical shifts are given relative to TMS (δ, ppm). The IR spectra were recorded on a UR-20 spectrophotometer with NaCl and LiF prisms. The melting point was measured with a Boetius device. The analytical data are consistent with the suggested compositions. The UV spectra (1×10^{-5}% solutions in DMSO) were measured with a Specord M-400 spectrophotometer.

Iridium(IV) was taken in the form of K_2IrCl_6. The working solutions were prepared by diluting the initial solution of Ir(IV) in 2 M HCl with the acid of appropriate concentration. It should be noted that, in the examined range of HCl concentrations, Ir(IV) occurs in the form of the anions $[Ir(OH)Cl_5]^{2-}$, $[IrCl_5(H_2O)]^-$, and $[IrCl_6]^{2-}$ [9]. The total Ir(IV) content in solutions was determined spectrophotometrically [10]. The extraction was performed at room temperature and 1 : 1 ratio of the aqueous and organic phases. Stirring was performed with an R-3 magnetic stirrer. The electronic absorption spectra were taken on a Specord M-40 spectrophotometer with glass and quartz cells.

8-Thia-1,15-diazatetracyclo[13.3.1.$0^{2,7}$.$0^{9,14}$]nonadec-17-ene-16,19-dione V. To a solution of 8.2 g (0.031 mol) of **I** in 100 ml of dimethyl sulfoxide, we added 8.6 g (0.062 mol) of K_2CO_3, 3.47 g (0.031 mol) of uracil **II**, and 2.3 g of the catalyst (tetrabutylammonium bromide, TBAB). The mixture was stirred at 40–70°C for 4 h and left overnight. The next day, 50 ml of water was added, and the mixture was extracted with chloroform (3 × 50 ml). After solvent evaporation, the residue (9.5 g) was dissolved in a minimal amount of acetone (50 ml) and purified by column chromatography (silica gel, 40/100 mesh). Yield of **V** 8 g (84%). The compound is soluble in methanol, acetone, and chloroform and insoluble in hexane and water. TLC: R_f 0.61. IR spectrum, ν, cm^{-1}: 640, 800 (C–S); 1120–1200 (=N–); 1660–1700 [ν(C=O,=NC=O)]; 3400 [ν(OH)]. 18-Methyl-8-thia-1,15-diazatetracyclo[13.3.1.-$0^{2,7}$.$0^{9,14}$]nonadec-17-ene-16,19-dione VI. A flask was charged with 12.6 g (0.1 mol) of 6-methyluracil **III**, 30 g (0.2 mol) of K_2CO_3, 10 g of the catalyst, and 300 ml of DMF. The mixture was stirred at room temperature for 2 h and left overnight. The next day, 26.7 g (0.1 mol) of 2,2'-dichlorodicyclohexyl sulfide

I was added. The mixture was stirred on a boiling water bath for 5 h. After cooling, 200 ml of water was added to dissolve the crystals, and the mixture was extracted with chloroform (3 × 70 ml). The extract was washed with water (50 ml), and the solvent was distilled off. Compound **VI** was obtained (37.9 g) as a viscous liquid readily soluble in chloroform, ethanol, and methanol and insoluble in hexane and water. IR spectrum, ν, cm^{-1}: 640, 800 (C–S); 1120–1200 (=N–); 1660–1700 [ν(C=O, =NC=O)]; 3400 [ν(OH)]. UV spectrum: λ_{max} 262.5 nm (DMSO). ^1H NMR spectrum ($CDCl_3$), δ, ppm: 1.5–2.0 m (16H, $C^{3,4,5,6,10,11,12,13}H_2$), 2.05 s (3H, $C^{18}CH_3$), 2.35–2.76 m (2H, $C^{7,9}H$), 3.48–4.08 m (2H, $C^{2,14}H$), 5.68 s (1H, $C^{17}H$). ^{13}C NMR spectrum ($CDCl_3$), δ_C, ppm: 15.06 (C^{18}–CH_3), 21.93 (C^{12}), 25.00 ($C^{5,11}$), 25.04 (C^4), 26.79 (C^{10}), 28.71 (C^{13}), 29.90 (C^6), 30.10 (C^3), 54.92 (C^9), 60.01 (C^2), 60.16 (C^{14}), 68.93 (C^7), 99.15 (C^{17}), 147.97 (C^{18}), 159.24 (C^{19}), 161.93 (C^{16}).

17-Fluoro-8-thia-1,15-diazatetracyclo[13.3.1.-$0^{2,7}$.$0^{9,14}$]nonadec-17-ene-16,19-dione VII. To a solution of 8.5 g (0.032 mol) of **I** in 100 ml of dimethyl sulfoxide, we added 9 g (0.065 mol) of K_2CO_3, 4.2 g (0.031 mol) of fluorouracil **IV**, and 1 g of the catalyst. The mixture was heated to 70°C, stirred at the same temperature for 8 h, and left overnight. The next day, 100 ml of water was added, and the mixture was extracted with chloroform (3 × 50 ml). After evaporation of the solvent the residue (11.6 g) was dissolved in acetone and refluxed with activated carbon. The product, however, remained dark; therefore, it was dissolved in a minimal amount of acetone (50 ml) and purified by column chromatography (silica gel, 40/100 mesh). Yield of **VII** 6.4 g (61.7%); the product is soluble in methanol and acetone and insoluble in hexane and water. TLC: R_f 0.69; mp 129–131°C. IR spectrum, ν, cm^{-1}: 990, 1010 [ν(C=C)]; 1150–1250 (=N–); 1590, 1660–1715 [ν(C=O,=NC=O)]; 3400 [ν(OH)]. UV spectrum: λ_{max} 272.3 nm (DMSO). ^1H NMR spectrum ($CDCl_3$), δ, ppm: 1.35–1.9 m (16H, $C^{3,4,5,6,10,11,12,13}H_2$), 2.2 m (1H, C^7H), 2.63 s (1H, C^9H), 3.45 m (1H, C^2H), 4.2 m (1H, $C^{14}H$), 7.3 d (1H, $C^{18}H$, J_{HF} 9.0 Hz). ^{13}C NMR spectrum ($CDCl_3$), δ_C, ppm: 21.93 (C^{12}), 25.00 ($C^{5,11}$), 26.79 (C^{10}), 27.84 (C^4), 28.70 (C^{13}), 29.63 (C^3), 32.21 (C^6), 61.16 (C^{14}), 61.41 (C^2), 64.23 ($C^{7,9}$), 134.15 d (C^{18}, J_{CF} 26 Hz), 139.70 (C^{17}, J_{CF} 238 Hz), 147.77 (C^{19}), 159.27 d (C^{16}, J_{CF} 32 Hz).

Compounds **VI** and **IX** were tested in extraction of Ir(IV) from hydrochloric acid solutions. First, we examined how the recovery of Ir(IV) with **VI** and **IX** depends on the phase contact time τ_c. We found that, with solutions of Ir(IV) in 0.2 and 1.0 M HCl, the extraction equilibrium is attained within 5 min. Therefore, further experiments were mostly performed with this contact time (Fig. 1). Below are given the Ir(IV) distribution factors *D* obtained at various contact times [aqueous phase: c_{HCl} 0.2 and $c_{Ir(IV)}$ 4×10^{-4} M; organic phase (chloroform): $c_{\mathbf{VI}}$ 0.06 or $c_{\mathbf{IX}}$ 0.05 M]:

τ_c, min	5	10	15	20	30
$D^*_{\mathbf{IX}}$	2.4	2.4	2.4	2.4	2.4
$D^{**}_{\mathbf{VI}}$	3.3	3.3	3.3	3.3	3.3

* Reagent **IX**. ** Reagent **VI**.

We studied how the Ir(IV) distribution factor is influenced by the HCl concentration. When calculating the distribution factor, we took into account the formation of Ir(III) in the aqueous phase. The Ir(IV) recovery decreases with increasing HCl concentration.

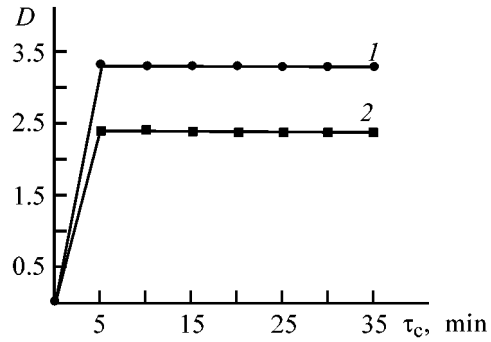

Fig. 1. Iridium(IV) distribution factor *D* vs. contact time τ_c. $c_{\mathbf{VI}}$ or $c_{\mathbf{IX}}$ 0.06 (in chloroform), $c_{Ir(IV)}$ 0.00032, c_{HCl} 0.2 M. (*1*) **VI** and (*2*) **IX**; the same for Fig. 2.

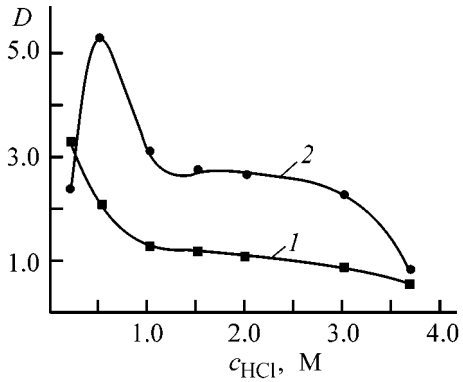

Fig. 2. Iridium(IV) distribution factor *D* vs. HCl concentration c_{HCl}. $c_{\mathbf{IX}}$ 0.06 or $c_{\mathbf{VI}}$ 0.05 M (in chloroform); $c_{Ir(IV)}$ 4×10^{-4} M.

The experimental results [$c_{\mathbf{IX}}$ 0.06 or $c_{\mathbf{VI}}$ 0.05 M in chloroform; $c_{Ir(IV)}$ 4×10^{-4} M] are listed below:

c_{HCl}, M	0.2	0.5	1.0	1.5	2.0	3.0	3.7
$D_{\mathbf{IX}}$	2.4	5.3	3.1	2.9	2.7	2.3	0.9
$D_{\mathbf{VI}}$	3.3	2.1	1.3	1.2	1.1	0.9	0.6

With **IX**, the maximal recovery is observed from 0.5 M HCl. The decreased iridium recovery at increased HCl concentration may be due to the prevalence of the nonextractable iridium species $[IrCl_6]^{2-}$ and to suppression of the extraction by similarly charged chloride ions (Fig. 2).

We also studied how the Ir(IV) recovery with **VI** and **IX** is influenced by the chloride ion concentration, at fixed c_{HCl} = 0.2 M. With increasing chloride ion concentration, the extraction is suppressed.

To confirm the mechanism of iridium extractive recovery, we examined the influence of hydrogen ion concentration at [NaCl] + [HCl] = 1 M. The slope of the plot $\log D = f(c_{H^+})$ is close to zero (0.3), which suggests that the extractable species are neutral.

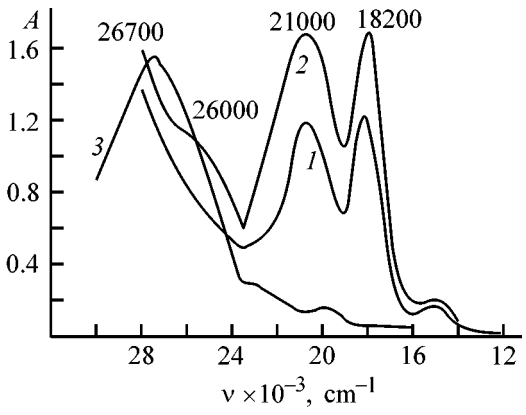

Fig. 3. Electronic absorption spectra of Ir(IV) extracts obtained with **VI**: (*A*) extinction coefficient and (ν) wave number; the same for Fig. 4. Phase contact time, min: (*1*) 1, (*2*) 5, and (*3*) 10.

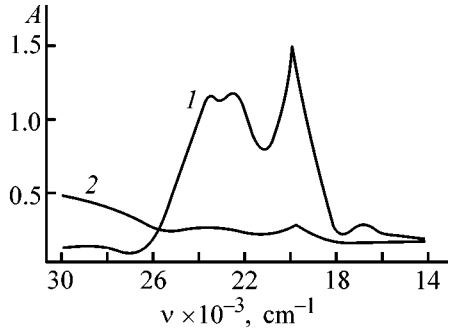

Fig. 4. Electronic absorption spectra of the aqueous phase after extraction of iridium with **VI**. Phase contact time, min: (*1*) 1 and (*2*) 5.

Apparently, in acid solutions, the extractants are protonated at the amide groups. Therefore, initially Ir(IV) is probably recovered from acid solutions in the form of ionic associates (interphase anion exchange). However, this reaction is very fast, and its kinetics cannot be monitored, probably owing to the labilizing effect of the amide nitrogen atoms. It has been shown previously [8, 11] that the amine nitrogen atoms in amino sulfides and amino keto sulfides exert a labilizing effect in recovery of Ir(IV) from acid solutions. It is known that sulfides and sulfoxides recover Ir(IV) only upon prolonged phase contact with heating. The compounds studied here recover Ir(IV) fast and without heating.

Figure 3 shows the electronic absorption spectra of Ir(IV) extracts with **VI**, obtained at various phase contact times: from 1 (curve *1*) to 10 min (curves *2*, *3*). The electronic absorption spectra show that, at longer phase contact times, the extraction occurs by the complexation mechanism: sulfur atoms of the ligands replace chloride ions from Ir(IV) acido complexes. Figure 4 shows the electronic absorption spectra of the aqueous phase after extraction of Ir(IV) with **VI** for 1 and 5 min. It is seen that the extraction is accompanied by gradual accumulation of Ir(III) in the aqueous phase. Reduction was also observed in extraction of Ir(IV) with amino sulfides.

In extraction of Ir(IV) with **IX**, the electronic absorption spectra of the aqueous and organic phases vary with time similarly, suggesting that, in this case, the extraction is also accompanied by redox reactions.

In the course of extraction, sulfide sulfur is probably oxidized to sulfoxide, and sulfoxide, to sulfone. It is yet unclear whether iridium is reduced in the organic or aqueous phase.

Our experimental results suggest that iridium is extracted with VI and IX in the form of the complexes $IrCl_4 \cdot 2L$.

The coordination of iridium by the sulfur atoms of the ligands is also confirmed by the fact that the largest coordination shift in the ^1H NMR spectra is observed for protons of the methylene groups bound to sulfur ($\Delta\delta$ 1.3 ppm).

CONCLUSIONS

(1) Previously unknown polycyclic pyrimidine derivatives were prepared by reactions of 2,2'-dichlorodicyclohexyl sulfide with uracil, 6-methyluracil, and 5-fluorouracil. The resulting products **V**–**VII** were oxidized with sodium metaperiodate to sulfoxides **VIII**–**X** and with hydrogen peroxide to sulfones **XI**–**XIII**, respectively.

(2) Compounds **VI** and **IX** were tested in extraction of Ir(IV) from hydrochloric acid solutions. The optimal conditions of iridium recovery (contact time 5 min, HCl concentration 0.2–0.5 M) were found. The iridium recovery decreases with increasing HCl concentration.

Abstract—The kinetic features of dehydration of maleic acid during preparation of a copolymer based on the styrene distillation bottoms from joint production of styrene and propylene oxide were studied. The potential application fields for the copolymer synthesized were analyzed.

Processing and utilization of waste and by-products from chemical, petrochemical, and other industries receive now much attention both in Russia and abroad. These allow both mitigation of the environmental pollution and preparation of new materials with a set of valuable properties. Of the greatest importance among the wide variety of waste products are those from styrene production, namely, styrene distillation bottoms (SDB). One of the best ways of SDB utilization is processing into polymeric products by copolymerization with other monomers, most often, maleic anhydride (MA).

Reactions of styrene and its oligomers with maleic anhydride and widely covered in literature [1–5]. It has been shown that this copolymer can yield good paint and varnish materials. Application of maleic anhydride is, however, not always advisable because of its short supply and high price. At the same time, it should be noted that maleic anhydride production yields large amounts of maleic acid (MAc) as by-product, which is suitable for copolymerization with styrene instead of maleic anhydride. This, undoubtedly good alternative allows integrated processing of the waste. However, the behavior of maleic acid in copolymerization still remains to be understood. The use of this waste requires extensive studies of both the copolymerization process and its mechanism and the quality of the resulting polymeric product and its behavior in various composite materials.

Therefore, elucidation of the kinetic features of dehydration of maleic acid in the course of copolymer preparation is of both theoretical and applied importance.

The kinetics of the maleic acid dehydration by the reaction

$$\mathrm{MAc} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{MA} + \mathrm{H_2O}$$

can be described by the following mathematical model:

$$dc_{MAc}/dt = -k_1 c_{MAc} + k_{-1} c_{MA} c_W. \qquad (1)$$

Here, c_{MAc}, c_{MA}, and c_W are the concentrations of maleic acid, maleic anhydride, and water at instant of time t, respectively, and k_1 and k_{-1} are the rate constants of the forward and back reactions, respectively.

In our experiments, dehydration of maleic acid involved permanent removal of water from the reaction mixture. Thus, c_W can be regarded as a function slowly varying with time. For theoretical analysis, c_W = const and, hence, $k_{-1W} = k_{-1} c_W$ = const was taken.

According to the stoichiometry of the reaction, $c_{MA} = c_{MAc0} - c_{MAc}$, where c_{MAc0} is the maleic acid concentration at the initial moment, and $c_{MAc0} = c_{MAc}$ at $t = 0$.

With the new parameters substituted, Eq. (1) takes the form

$$dc_{MAc}/dt + (k_1 + k_{-1W}) c_{MAc} = k_{-1W} c_{MAc0}. \qquad (2)$$

Differential equation (2) can be solved analytically

1070-4272/02/7508-1290 $27.00 © 2002 MAIK "Nauka/Interperiodica"

$$c_{MAc} = \left(c_{MAc0} - \frac{k_{-1W}c_{MAc0}}{k_{-1} + k_{-1W}}\right)e^{-(k_1 + k_{-1W})t} + \frac{k_{-1W}c_{MAc0}}{k_{-1} + k_{-1W}}. \quad (3)$$

Equation (3) represents the mathematical model of the maleic acid dehydration kinetics. To check the suitability of the model for both theoretical and practical applications, it is necessary to solve the inverse kinetic problem on determining k_1 and k_{-1}.

We studied dehydration of maleic acid at 110, 130, and 150°C in acetophenone at initial maleic acid concentration of 0.442 M by monitoring the variation of the maleic anhydride content in the process by IR spectroscopy.

To determine the kinetic constants k_1 and k_{-1}, we used Eq. (2) in the integral form

$$Y = A_0 + A_1X_1 + A_2X_2, \quad (4)$$

where $Y = c_{MAc}$, $A_0 = c_{MAc0}$, $A_1 = -(k_1 + k_{-1W})$,

$$A_2 = k_{-1}c_{MAc0}c_W = k_{-1W}c_{MAc0}, \quad (5)$$

$$X_1 = \int_0^t c_{MAc}\,dt, \quad X_2 = t. \quad (6)$$

The X_1 parameter was calculated by a numerical procedure from the experimental data. The results are presented in Table 1, along with the maleic acid concentrations (designated as Y).

The coefficients A_0, A_1, and A_2 were determined by solving the problem by the least-squares method for the equation in the matrix form

$$XA = Y, \quad (7)$$

where X is a matrix, and A and Y are vectors.

The matrix X is constructed using the X_1 and X_2 parameters for different instants of time. Using the experimental data from Table 1 for 110, 130, and 150°C, we obtained

$$X = \begin{vmatrix} 1 & 0 & 0 \\ 1 & 6.29 & 15 \\ 1 & 11.8 & 30 \\ 1 & 16.7 & 45 \\ 1 & 21.4 & 60 \\ 1 & 25.6 & 75 \\ 1 & 29.3 & 90 \\ 1 & 32.55 & 105 \end{vmatrix}, \quad X = \begin{vmatrix} 1 & 0 & 0 \\ 1 & 3.74 & 10 \\ 1 & 6.66 & 20 \\ 1 & 9.03 & 30 \\ 1 & 10.8 & 40 \\ 1 & 12.2 & 10 \\ 1 & 13.3 & 60 \end{vmatrix}, \quad X = \begin{vmatrix} 1 & 0 & 0 \\ 1 & 0.83 & 2 \\ 1 & 1.55 & 4 \\ 1 & 2.17 & 6 \\ 1 & 2.75 & 8 \\ 1 & 3.29 & 10 \\ 1 & 3.83 & 12 \end{vmatrix},$$

For the same temperatures,

$$Y = [0.442\ \ 0.396\ \ 0.336\ \ 0.318\ \ 0.314\ \ 0.248\ \ 0.239\ \ 0.195]^T,$$

$$Y = [0.442\ \ 0.305\ \ 0.280\ \ 0.195\ \ 0.158\ \ 0.127\ \ 0.097]^T,$$

$$Y = [0.442\ \ 0.388\ \ 0.330\ \ 0.296\ \ 0.277\ \ 0.268\ \ 0.264]^T.$$

The vector $A = [A_0A_1A_2]^T$, whose elements are coefficients including the kinetic constants, is to be determined. Using formulas (5), we calculated $k_{-1W} = A_2$ and $k_1 = -(A_1 + A_2)$. The results are presented in Table 2. It is seen that the experimental and calculated kinetic data are in good agreement. Thus, the model proposed is adequate to the real system.

The equilibrium pseudoconstant for maleic acid dehydration was calculated by the formula

Table 1. Experimental data on maleic acid dehydration

T, °C	t, min	c_{MAc}, M	$X = \int_0^t c_{MAc}\,dt$

	10	0.268	3.292
	12	0.264	3.827

Table 2. Kinetic constants k_1 and k_{-1W} and equilibrium constants K_{eq}

T, °C	k_1, min^{-1}	k_{-1W}, $dm^3\ mol^{-1}\ min^{-1}$	K_{eq}, M
110	5.57×10^{-3}	0	∞
130	2.75×10^{-2}	7.54×10^{-4}	36.5
150	1.54×10^{-1}	4.90×10^{-2}	3.14

$$K_{eq} = k_1/k_{-1W}. \quad (8)$$

The results are presented in Table 2 as well. The pseudoconstant tends to decrease with rising temperature, which suggests heat evolution in the reaction [6, 7]. In view of the shift to maleic anhydride formation with lowering temperature, $k_1 >> k_{-1W}$ holds at a certain temperature. Equation (3) suggests that, in a certain time period,

$$c_{MAc} = c_{MAc0}e^{-k_1t}$$

or, in the differential form,

$$dc_{MAc}/dt = -k_1c_{MAc}.$$

This means that maleic acid dehydration can be regarded as an irreversible first-order reaction.

Our data suggest that maleic acid is 90% converted to maleic anhydride within 5.5 and 2 h at 110 and 130°C, respectively. At 150°C, equilibrium is attained within 0.3 h at 50% conversion.

The content of maleic anhydride in the reqaction mixture was determined with an IKS-22 spectrophotometer. To this end, we developed a procedure for quantitative determination of maleic anhydride from the IR absorption spectra. Maleic anhydride is characterized by an intense absorption band near 1840 cm^{-1}, due to stretching vibration of anhydride groups ν(CO–O–CO). This band does not overlap with those of other components and, hence, was chosen for determining the content of maleic anhydride [8].

Thus, we studied the kinetics of maleic acid dehydration into maleic anhydride and showed that, in the initial stage of the combined processing of acetophenone SDB and maleic acid, the temperature should not exceed 130°C, as under these conditions the whole of maleic acid is converted to maleic anhydride, and formation of the product (styrene copolymer with maleic anhydride) is highly probable. Since preparation of a film-forming copolymer at 120–170°C takes no less than 10 h, chemical conversion of acetophenone SDB below 150°C predominantly involves the reaction with maleic anhydride. With temperature increasing at the beginning of the reaction to above 150°C, the equilibrium of maleic acid dehydration shifts to the left, and the content of maleic anhydride participating in the copolymerization tends to decrease. These results are important both from the technological standpoint and for assessing the end product quality (at elevated temperatures maleic acid can directly participate in the chemical process).

At the same time, the most promising line of application of polymeric materials prepared from petrochemical waste and by-products still remains to be chosen. This is due, above all, to essential drawbacks of these polymeric materials, such as low stability of the polymer composition governing the structure and properties of macromolecules, high chromaticity, opalescence, etc., which significantly limits their application field.

The aforesaid suggests that the most promising application line is that posing not very strict requirements on the properties of the resulting polymeric materials and allowing their use despite the above-listed drawbacks. One line can be protection of wood and wood articles against unfavorable factors. Modifying compositions intended for wood protection should satisfy a number of requirements, namely, be available and nontoxic, not deteriorate the principal properties of the material, and easily penetrate into it. Expensive protective agents significantly increase the cost of wood articles, which makes reasonable the use of readily available cheap petrochemical waste and by-products and materials thereof. Also, the SDB-based copolymer contains a large amount of carboxy and anhydride groups which can react with wood components to form chemical bonds.

The available gel-chromatographic data show that the SDB copolymer has a relatively low molecular weight ($\overline{M}_n$ = 1900, $\overline{M}_v$ = 17000, $\overline{M}_w$ = 26500, $\overline{M}_z$ = 252000, $\overline{M}_w/\overline{M}_n$ = 13.8, $\overline{M}_z/\overline{M}_w$ = 9.5). Evidently, polymer molecules with low molecular weights are small in size and, hence, can easily penetrate into the wood structure [9, 10].

We studied the protective properties of the SDB copolymer with 10 × 10 × 20-mm birch wood samples dried to 8–10% moisture content.

The samples were weighed, immersed in a solution of SDB copolymer, and kept there for appropriate time. The impregnated birch samples were taken from the bath, dried, quenched, and weighed. The copolymer content in the samples was estimated gravimetrically, from the mass gain.

The penetrability of a SDB copolymer solution is strongly dependent on its concentration and impregnation temperature. The influence exerted by these factors deserves consideration, as at low tem-

peratures (10–30°C) and high concentrations (over 60 wt %) the impregnating solution based on SDB copolymer is highly viscous, which complicates its use. Raising the temperature decreases the viscosity and significantly improves the penetrability of impregnating solutions into the wood structure. However, at SDB copolymer concentrations above 80%, even elevated temperatures do not afford high impregnation efficiency. The SDB copolymer solution was prepared using a mixed 4 : 1 xylene–acetone solvent. The optimal concentration of the SDB copolymer solution is not higher than 60 wt % [11]. This affords favorable properties of the impregnating solutions and their penetration into wood via diffusion. In view of the aforesaid, we fixed the SDB copolymer concentration at 43 wt % and varied the impregnation temperature from 20 to 80°C. The main relationships in impregnation of the birch wood samples were studied by the fouth-order Greek–Latin square design [12]. As the principal factors most strongly affecting the properties of the resulting modified wood we chose impregnation time, min (factor A); impregnation temperature, °C (factor B); heat treatment time, h (factor C); and heat treatment temperature, °C (factor D) of the samples being impregnated. The above-cited factors are presented in Table 3.

After computer processing of the experimental data, we obtained the regression equations (9)–(14) describing the water resistance of the birch samples treated with the SDB copolymer solutions as influenced by the main process parameters of impregnation. The regression equations for the response functions y, y', and y'', %, have the following form: after a 1-day period

for water resistance

$$y = 3.726 \times 10^{-5}(36.9 - 0.638a)(43.9 - 0.254b) \times (38.9 - 1.98c)(18.0 + 0.0913d), \quad (9)$$

for radial swelling

$$y' = 5.278 \times 10^{-3}(6.78 - 0.0958a)(6.06 - 0.00605b) \times (6.79 - 0.254c)(5.34 + 0.003d), \quad (10)$$

for tangential swelling

$$y'' = 2.262 \times 10^{-3}(8.64 - 0.0952a)(8.62 - 0.0192b) \times (8.51 - 0.217c)(8.35 - 0.054d), \quad (11)$$

and after a 30-day period,

$$y = 2.868 \times 10^{-6}(73.6 - 0.306a)(71.2 - 0.0156b) \times (72.0 - 0.399c)(73.7 + 0.0246d), \quad (12)$$

$$y' = 1.656 \times 10^{-3}(9.38 - 0.087a)(8.53 - 0.0016b) \times (9.47 - 0.249c)(8.49 + 0.0003d), \quad (13)$$

$$y'' = 8.267 \times 10^{-4}(12.2 - 0.144a)(10.7 - 0.0007b) \times (10.7 + 0.0005c)(11.4 - 0.0055d). \quad (14)$$

The calculated and experimental data for the modified birch wood samples are presented in Table 4.

Our results show that the optimal conditions for birch wood modification are as follows: impregnation

time 18 min, impregnation temperature 80°C, and heat treatment temperature and time 150°C and 7 h, respectively.

CONCLUSIONS

(1) A study of the kinetics of the reactions between styrene distillation bottoms and maleic acid showed that, in the examined temperature range, dehydration of maleic acid into maleic anhydride dominates. The resulting maleic anhydride participates in copolymerization.

(2) With the copolymer as impregnating composition, wood can be efficiently protected against moisture and water, since most of the macromolecules con-

tained in the copolymer have significantly smaller sizes than wood micropores and easily penetrate into the wood structure during impregnation.

Abstract—A mathematical model of cyclohexane ozonolysis was developed. The reaction rate constants were found experimentally or by fitting.

Experiments on reactions of ozone with saturated hydrocarbons revealed a nonlinear dependence of the rate constant on the hydrocarbon concentration [1]. At substrate concentrations less than 0.1 M, the reaction was bimolecular.

These results were rationalized [2] by assuming the formation of an intermediate complex RH···O_3. At the same time, Korotkova [3] denies formation of ozone–hydrocarbon complexes under these conditions.

Experiments on ozonolysis of cyclohexane and methylcyclohexane show (Figs. 1–3) that, with increasing substrate concentration, the apparent rate constant decreases.

For ozonolysis of cyclohexane under static conditions, Galimova [4] found the following empirical relationship between the rate constant and the ozone and substrate concentrations:

$$k_{app} = 3.2 \times 10^{-3} + 0.3\sqrt{[O_3]_0/[RH]} = k_0 + bK_0'. \quad (I)$$

According to [4], at oxygen content in the reaction solution of 4.4×10^{-2}, $[O_3] = (4.3–6.0) \times 10^{-4}$, and [RH] = 9.25 M, $k_{app} = 9.5 \times 10^{-3}$ l mol^{-1} s^{-1}.

In contrast to [5], it was shown in [4, 6, 7] that the rate constant of hydrocarbon ozonolysis is an apparent quantity taking into account the consumption of ozone in nonchain and chain reactions:

$$-d[O_3]/dt = k_0[RH][O_3] + b[RH]^{1/2}[O_3]^{3/2} = W_0 + W_0'. \quad (II)$$

The experimental data (Fig. 2) show that the expression for the ozone consumption rate must include not only terms corresponding to nonchain and chain reactions of ozone with the initial hydrocarbon, but also those corresponding to further ozonolysis of the reaction products such as cyclohexyl hydroperoxide, cyclohexanol, hydroxycyclohexyl peroxide, cyclohexanone, and ε-caprolactone. The reactivities of neat hydrocarbons, alcohols, and ketones toward ozone are comparable (Table 1).

In nonassociated dilute solutions in CCl_4 and cyclohexane, alcohols react with ozone considerably faster than hydrocarbons [8].

It should be noted that the mechanism of ozonolysis of organic compounds appreciably depends on the concentrations of the substrate, ozone, and oxygen, on the extent of the reaction (effect of reaction products), and on the hydrodynamic conditions (mass exchange).

According to [9, 10], for slow reactions of ozonolysis of saturated compounds (k 10^{-3}–10 l mol^{-1} s^{-1}), performed in a bubbled vessel, the rate of ozone bubbling is not rate-determining, i.e., the reactions are kinetically controlled.

The ozonolysis of cyclohexane to small conversions was studied in [11]. It was shown that cyclohexanol, cyclohexanone, organic peroxides, and cyclohexene are accumulated in parallel. The $RO_2^{\bullet}$ radicals not only recombine but also react with ozone. No less than 70% of $R^{\bullet}$ and $OH^{\bullet}$ radicals formed in the initiation event recombine to give an alcohol.

The initial steps in reactions of ozone with saturated hydrocarbons (*n*-alkanes, cycloalkanes), generating radical species, may be different:

$$RH + O_3 \rightarrow RO^{\bullet} + HO^{\bullet} + 91\ \text{kJ mol}^{-1}, \quad \text{(III)}$$

$$RH + O_3 \rightarrow [R^{\bullet} + HO_3^{\bullet}]_{cl} \rightarrow R^{\bullet} + HO_3^{\bullet}$$
$$\rightarrow R^{\bullet} + HO^{\bullet} + O_2 - 127\ \text{kJ mol}^{-1}, \quad \text{(IV)}$$

$$RH + O_3 \rightarrow R^{\bullet} + HO^{\bullet} + O_2 - 75\ \text{kJ mol}^{-1}. \quad \text{(V)}$$

An alternative pathway is a molecular reaction yielding unstable hydrotrioxide:

$$RH + O_3 \rightarrow ROOOH - 19\ \text{kJ mol}^{-1}. \quad \text{(VI)}$$

Reaction (III) is strongly exothermic, but it does not account for the actual composition of cycloalkane oxidation products. With this reaction, the major products must be alcohols and hydrogen peroxide, whereas actually only insignificant amounts of hydrogen peroxide (Table 2) were detected in reaction mixtures from ozonolysis of cyclohexane and methylcyclohexane [12].

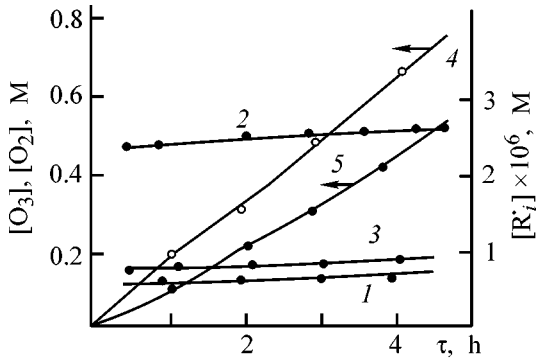

Fig. 3. Kinetic curves of (*1*–*3*) variation of radical concentration [$R_i^{\bullet}$] [(*1*) $HO_2^{\bullet}$, (*2*) $RO_2^{\bullet}$, and (*3*) ], (*4*) consumption of ozone, and (*5*) accumulation of oxygen in ozonolysis of cyclohexane (20°C).

The major product accumulated in ozonolysis of cyclohexane is the ketone rather than alcohol. As for hydrotrioxide, it is unstable and its analytical detection is only possible at low temperatures.

Comparison of the thermal effects of the possible endothermic radical reactions of hydrotrioxide decomposition suggests that reaction (V)

$$ROOOH \rightarrow RO^{\bullet} + HO_2^{\bullet} - 83.5\ \text{kJ mol}^{-1} \quad \text{(VII)}$$

is preferable. Assuming that the preexponential factor in the expression for the rate constant of this reaction is 10^{14}, we obtain for the rate constant of hydrotrioxide decomposition into radicals a value of 6.3×10^{-2} s^{-1} (22°C).

* Including hydroxycyclohexyl hydroperoxide.

** Including hydroxycyclohexyl hydroperoxide and hydrogen peroxide.

The relative stabilities of secondary and tertiary hydroperoxides formed by oxidation of, respectively, cyclohexane and methylcyclohexane suggest that detection of 1-methylcyclohexyl hydrotrioxide is more probable than that of cyclohexyl hydrotrioxide. The activation energy of the overall ozonolysis reaction is 60 ± 2 kJ mol^{-1} for cyclohexane and 53.7 ± 2.8 kJ mol^{-1} for methylcyclohexane [12].

These energy parameters are considerably lower than the values expected for thermal decomposition of hydrotrioxide into radicals. In ozonolysis of saturated hydrocarbons, hydrotrioxide can form only in low amounts, which was subsequently confirmed by calculations:

$$\mathrm{ROOOH} \rightarrow \mathrm{RO}^{\bullet} + \mathrm{HO}_2^{\bullet} - 83.5\ \mathrm{kJ\ mol}^{-1}, \quad \text{(VIII)}$$

$$\mathrm{ROOOH} \rightarrow \mathrm{RO}_2^{\bullet} + \mathrm{HO}^{\bullet} - 117\ \mathrm{kJ\ mol}^{-1}, \quad \text{(IX)}$$

$$\mathrm{ROOOH} \rightarrow \mathrm{R}^{\bullet} + \mathrm{HO}_3^{\bullet} - 280\ \mathrm{kJ\ mol}^{-1}. \quad \text{(X)}$$

By contrast, in ozonolysis of polar oxygen-containing substrates (alcohols, ketones), the occurrence of the reaction via hydrotrioxide is more probable. The reaction of hydrotrioxide with ozone (XI) is exothermic, whereas reaction (XII) and the reaction with hydrocarbon (XIII) are endothermic:

$$\mathrm{ROOOH} + \mathrm{O_3} \rightarrow \mathrm{RO}^{\bullet} + \mathrm{HO}_3^{\bullet} + \mathrm{O_2} + 80\ \mathrm{kJ\ mol}^{-1}, \quad \text{(XI)}$$

$$\mathrm{ROOOH} + \mathrm{O_3} \rightarrow \mathrm{RO}_2^{\bullet} + \mathrm{HO}_2^{\bullet} + \mathrm{O_2} - 25\ \mathrm{kJ\ mol}^{-1}, \quad \text{(XII)}$$

$$\mathrm{ROOOH} + \mathrm{RH} \rightarrow \mathrm{RO}^{\bullet} + \mathrm{H_2O} + \mathrm{R}^{\bullet} - 22\ \mathrm{kJ\ mol}^{-1}. \quad \text{(XIII)}$$

It is not improbable also that ozone reacts with hydrotrioxide to form ketone and $HO_2^{\bullet}$ and $HO_3^{\bullet}$ radicals. Even experimental detection of hydrotrioxide among the reaction products cannot be considered an evidence of the single-stage process [13] [reaction (IV)].

In view of the composition of the reaction products and ESR data [1, 11, 14], the primary initiation, most probably, occurs by schemes (IV) and (V), yielding $R^{\bullet}$ and $HO^{\bullet}$ radicals and molecular oxygen. Oxygen-containing products are accumulated by the reactions of ozone with hydrocarbons and radicals; the radicals can also react with oxygen. The contribution of the chain reaction can be judged from the ratio of the oxygen content in oxidation products of a hydrocarbon (cyclohexane, methylcyclohexane) to the amount of the ozone consumed.

As shown in [13, 15], in developed ozonolysis of methylcyclohexane and cyclohexane, oxygen is involved in the process along with ozone. For ozonolysis of cyclohexane, the initiation rate W_i at 20°C was estimated to be 1.318×10^{-5} mol l^{-1} s^{-1}. The chain

length is 3.6 units, which is consistent with published data [2, 16, 17].

Previous studies [6, 16] have shown that, under the conditions of low-temperature ozonolysis of cyclohexane, the reaction of $RO_2^{\bullet}$ with the substrate can be neglected. A significant part of alcohols and ketones are formed by recombination of peroxy radicals. The whole set of the experimental data [18–26] and reference information [27] allow us to propose a mechanism of cyclohexane ozonolysis to large (10%) conversions.

The initial events are radical (generating $R^{\bullet}$, $OH^{\bullet}$) and molecular reactions yielding unstable hydroperoxide (ROOOH), alcohol (ROH), and oxygen.

We took into account the possible formation of an intermediate hydrocarbon–ozone complex, consistent with the experimentally observed decrease in the apparent rate constant with increasing concentration of the saturated substrate [28].

The possible transformation pathways of intermediates (cyclohexyl hydroperoxide, ROOH; cyclohexanol, R–OH; cyclohexanone, R=O; hydroxycyclohexyl hydroperoxide; ε-caprolactam) under these conditions were confirmed by experiments in a bubbled vessel, allowing the reaction to be performed to large conversions, with reliable quantitative determination of the products.

In the fitting procedure, we used the constants determined spectrophotometrically [12] and the estimated values based on published data for related reactions [11, 27]. Then these constants were refined by comparing the experimental and calculated concentrations of products in the course of ozonolysis. Fitting was performed until the deviations of the calculated concentrations from the experiment became lower than the chosen level.

We included the following initial substances A_1–A_3 and final products A_4–A_{13}:

A_1, ; A_2, O_3; A_3, O_2; A_4,  ; A_5,  ;

A_6, H_2O_2; A_7, H_2O; A_8, ozonide;

A_9,  ; A_{11},  ; A_{12},  ; A_{13}, adipic acid.

The following intermediates were included:

X_1, ROOOH; X_2, ; X_3, $^{\bullet}OH$; X_4, $HO_2^{\bullet}$; X_5, $HO_3^{\bullet}$;

X_6,  ; X_7,  ; X_8,  ; X_9,  ;

X_{10},  ; X_{11},  ; X_{12}, $\dot{C}H_2(CH_2)_4C(=O)O^{\bullet}$;

X_{13}, $\dot{C}H_2(CH_2)_4COOH$; A_{14}, $H-\underset{\underset{O}{\|}}{C}-(CH_2)_4C(=O)OH$;

A_{10}, .

The concentrations of the intermediates can be determined from the Bodenstein–Semenov principle of steady state [29, 30]:

(28)

Along with the recombination of peroxy radicals, we took into account transformations of the alcohol,

ketone, cyclohexyl hydroperoxide, cyclohexene, hydroxycyclohexyl hydroperoxide, and hydrotrioxide. These compounds are very reactive (Table 1). We also took into account the recombination of hydroxyperoxy radicals, formation of a biradical, and its transformation into acids with ring opening, and also the most probable reactions of lactone ozonolysis and reactions of the $HO_2^{\cdot}$, $HO_3^{\cdot}$, $HO^{\cdot}$, and radicals with the reaction medium.

For the rates R_i of ith reactions, we can write

$R_0 = K_0[A_1][A_2]$, $R'_0 = [X_{11}]k'_0$, $R_{04} = [X_{11}][A_1]k_{04}$, $R_{05} = k_{05}[X_1]$, $R_{06} = k_{06}[X_1][A_2]$, $R_{07} = k_{07}[X_1][A_2]$, $R_{08} = k_{08}[X_5][A_2]$, $R_{09} = k_{09}[X_5]$, $R_{010} = k_{010}[X_4]^2$, $R_1 = k_1[X_8][A_1]$, $R_2 = k_2[A_2][A_4]$, $R_3 = k_3[X_2][A_3]$, $R_4 = k_4[X_7]^2$, $R_5 = k_5[A_2][A_{10}]$, $R_6 = k_6[X_7][A_2]$, $R_7 = k_7[X_9][A_3]$, $R_8 = k_8[X_{10}][A_2]$, $R_9 = k_9[X_{10}]^2$, $R_{11} = k_{11}[A_5][A_2]$, $R_{12} = k_{12}[X_3][A_1]$, $R_{13} = k_{13}[X_7][A_{11}]$, $R_{14} = k_{14}[X_7][A_2]$, $R_{15} = k_{15}[X_6]$, $R_{16} = k_{16}[X_{12}][A_1]$, $R_{17} = k_{17}[X_{13}][A_2]$, $R_{18} = k_{18}[A_9][A_2]$, $R_{19} = k_{19}[A_{14}][A_3]$, $R_{20} = k_{20}[X_{14}][A_{11}]$, $R_{21} = k_{21}[A_{12}][A_2]$.

The concentrations of radicals X_i of cyclohexene and adipic acid monoaldehyde can be determined from the steady-state condition $d[X_i]/dt = 0$. Let us introduce the following designations:

$k_{04}/k'_0 = Z_1$, $k_{08}/k_{09} = Z_2$, $k_{06}/k_{05} = Z_3$, $k_{07}/k_{06} = Z_4$, $l = y_1$, $y_2 = 1/(1 + Z_1[A_1])$, $Z_5 = y_1y_2/\{1 + [A_2](Z_3 + Z_4)\}$, $Z_6 = Z_5[A_2]Z_3$, $Z_7 = Z_5[A_2]Z_4$, $y_3 = Z_1[A_1]y_2R_0$.

Then, we take into account that

$R_{14} = R_{15} = R_{16} = R_{17}$, $R_7 = dR_2$, $R'_0 = R_0/(1 + Z_1[A_1])$, $R_{04} = R_0Z_1[A_1]/(1 + Z_1[A_1]$, $R_{05} = Z_5R_0$, $R_{06} = Z_6R_0$, $R_{07} = Z_7R_0$, $R_5 = (1 - f)R_4$, $R_{19} = (1 - i)R_5$.

From the steady-state condition for each kind of radicals, it follows that

$R_1 = R_{05} + R_{06} + R_6 + R_{13}$, $R_{09} = (R_{06} + R_{07})/(1 + Z_2[A_2])$, $R_{08} = (R_{06} + R_{07})Z_2[A_2]/(1 + Z_2[A_2])$, $R_{010} = 0.5(R_{05} + R_{07})$, $R_1 = (Z_5 + Z_6)R_0 + R_6R_{13}$, $R_{010} = 0.5R_0(Z_5 + Z_7)$, $R_{09} = (Z_6 + Z_7)R_0/(1 + Z_2[A_2])$, $R_{08} = (Z_6 + Z_7)RZ_2[A_2]/(1 + Z_2[A_2])$, $R_{12} = bR_0/(1 + Z_1[A_1]) + dR_2 + 2R_{11} + (Z_6 + Z_7)R_0 + R_8 + 2R_{14}$, $R_3 = (Z_5 + 2Z_6 + Z_7)R_0 + R_6 + dR_2 + 2bR_0/(1 + Z_1[A_1]) + 2R_{11} + R_8 + 3R_{14} + R_{13}$, $d[X_7]/dt = (Z_5 + 2Z_6 + Z_7)R_0 + dR_2 + 2bR_0/(1 + Z_1[A_1]) + R_8 - R_{13} + 2R_{14} - 2k_4[X_7]^2 = 0$, $d[X_{10}]/dt = dR_2 - R_8 - 2k_9[X_{10}]^2 = 0$.

In the equation for $d[X_7]/dt$ and the corresponding equations for consumption and accumulation of the initial and final products, the rates R_8, R_{13}, and R_{14} are considerably lower than the other rates and can be neglected. For the same reason, the rate R_8 can be neglected in the equation for $d[X_{10}]/dt$.

For the rates of consumption and accumulation of the initial and final products of cyclohexane ozonolysis, we obtain first-order differential equations:

$d[A_1]/dt = (-by_2 - 1 - Z_5 - Z_7 - 2Z_6)R_0 + y_3 - k_6[A_2][X_7] - dR_2 - R_8 - 2R_{11} - R_{13}\ 3R_{14}$, $d[A_4]/dt = (ay_2 + Z_5 + Z_6)R_0 - R_2 + k_6[A_2][X_7] + f[X_7]^2k_4 - R_{14}$, $d[A_5]/dt = (1 - f) \times [X_7]^2k_4 - R_{11}$, $d[A_6]/dt = 0.5(Z_6 + Z_7)R_0 + (1 - k)0.5dR_2$, $d[A_7]/dt = (Z_6 + Z_7 + by_2)R_0 + R_2 + R_8 + 2R_{11} + 2R_{14} + R_{18}$, $d[A_8]/dt = iR_5$, $d[A_9]/dt = 0.5kdR_2 - R_{18}$, $d[A_{11}]/dt = Z_7R_0 + [f(2 - i) + (1 - i)][X_7]^2k_4 + (1 - 0.5kd)R_2 + R_8 + R_{11} + R_{13}$, $d[A_{12}]/dt = (1 - i)(1 - f)[X_7]^2k_4 + R_{13} - R_{21}$, $d[A_{13}]/dt = (1 - i)(1 - f)[X_7]^2k_4 + R_{14} + R_{18} + R_{21}$.

The rate of ozone consumption[1]

$$-W_{O_3} = Z_9R_0 + (1 + d - fd)R_2 + (3 - 2f)R_{11} + k_6[A_2][X_7] + 2R_{14} + R_{18} + R_{21},$$

where $Z_9 = (1 - Z_1[A_1])/(1 - Z_1[A_1]) + (Z_6 + Z_7) \times \{1 + 1/(1 + Z_2[A_2])\} + (1 - f)(Z_5 + 2Z_6 + Z_7 + 2by_2)$.

The rate of oxygen accumulation

$$W_{O_2} = Z_{10}R_0 + (1 - 2d - kd/2)R_2 + (2.5 + k/2)R_8 + R_6 - 1.5R_{13} - R_{14} + 0.5(R_{18} + R_{21}),$$

where $Z_{10} = ay_2 + \{(Z_6 + Z_7)/(1 + Z_2[A_2])\}(1 + 2.5Z_2[A_2])$.

Thus, the problem is reduced to a search for adequate values of the constants k_0, k_2, k_{11}, k_6, k_{18}, and k_{21}, ratios of the constants Z_1–Z_4, and stoichiometric coefficients a, l, d, f, i, and k. The constant $k_4 = 1.6 \times 10^6$ l mol^{-1} s^{-1} was taken from the literature [31].

This system of differential equations was integrated numerially by the modified Euler method [32] with an ES-10 22 computer. The calculated, c_{calc}, and experimental, c_{exp}, running concentrations of the cyclohex-

[1] In most cases, only one of the three oxygen atoms in the ozone molecule is involved in the reaction (see the scheme of the mechanism).

* Numerator: experiment; denominator: calculation.

ane ozonolysis products were compared, and the target function F was minimized:

$$F = \sqrt{\left\{\sum_{j=1}^{m}\sum_{i=1}^{n}[(c_{i\,\mathrm{exp}} - c_{i\,\mathrm{calc}})/\varepsilon_i]^2\right\}/mn} \times 100,$$

where n is the number of components monitored, m is the number of experimental points for each component, and ε_i is the absolute error of the experimental determination of the concentration of ith component.

The rate constants and the corresponding coefficients were refined using the complex method [32, 33]. The results are listed in Table 3 and in the scheme of the cyclohexane ozonolysis mechanism.

Table 3 shows that the calculated running concentrations of the reaction participants reasonably agree with the experiment. Hence, the above scheme of differential equations can be considered a mathematical model of cyclohexane ozonolysis, and the calculated constants describe adequately the whole set of the experimental data.

The calculated reaction selectivity with respect to the target product, cyclohexanone, is 70.8%, at hydrocarbon conversion of 9%. We found that the contribution from formation and transformation of the ozone–cyclohexane adduct is insignificant ($Z_1 = 0.00895$). At the same time, a significant role is played by formation and transformation of hydrotrioxide ($L = 0.12$, $Z_3 = 7.1$, $Z_4 = 137.8$). The reaction occurs by the radical chain mechanism. However, 78% of the R$^\bullet$ and OH$^\bullet$ radicals generated in the primary initiation stage [reaction (1)] recombine in a cage to form cyclohexanol. Alkyl radicals are generated in reactions (1), (9), (19), and (23) with rate constants k_0, k_1, k_{12}, and k_{16}, involving ozone and the radicals RO$^\bullet$, $^\bullet$OH, and $^\bullet CH_2(CH_2)_4COO$. Peroxy radicals are consumed by recombination and reactions with ozone and cyclohexanone.

Alkoxy radicals are fairly active and react with the initial hydrocarbon with rate constants of 10^{-4}–10^5 l mol^{-1} s^{-1}. The $^\bullet$OH radical is also characterized by high rate constants of hydrogen abstraction from the substrates. The parallel formation of acids and neutral oxidatiomn products (20°C) from the very beginning of the process is, most probably, due to reaction of the peroxy radical to form a biradical, with the subsequent ring opening. As the hydrocarbon conversion increases, new precursors of adipic acid appear, such as hydroxycyclohexyl hydroperoxide, adipic acid monoaldehyde, or ε-caprolactam. We performed special experiments on ozonolysis of these compounds.

The high selectivity with respect to cyclohexanone is due to its formation by reactions (5), (10), (12), and (16)–(18), characterized by the rates R_{07}, R_2, R_4, R_8, R_9, and R_{11}. The rates R_2, R_4, R_9, R_{11} are determining. Cyclohexanone is relatively slowly (rates R_{13} and R_{20}) consumed by reactions (20) and (27). A significant role in the cyclohexane ozonolysis mechanism is played by such fast reactions as selective oxidation of cyclohexanol to the ketone ($k_2 = 0.432$ l mol^{-1} s^{-1}) and reaction of peroxy radical with ozone ($k_6 = 1.385 \times 10^3$ l mol^{-1} s^{-1}).

The kinetic model proposed ensures good agreement with the experiment for all the products of cyclohexane ozonolysis.

CONCLUSIONS

(1) A mathematical model was developed for low-temperature ozonolysis of cyclohexane in a bubbled vessel to large conversions.

(2) The high efficiency of chemical systems for selective low-temperature ozonolysis of saturated hydrocarbons with equivalent C–H bonds into carbonyl compounds is mainly determined by fast oxidation of secondary alcohols and hydroperoxides with ozone, recombination of secondary radicals $RO_2^{\bullet}$, their destructive disproportionation in reaction with ozone to give alkoxy radicals, and relatively slow consumption of ketones by reactions with ozone. The $RO^{\bullet}$ radical can also be generated from hydrotrioxide.

Received April 4, 2002

Abstract—The resistance to thermal oxidative degradation of paraform-modified rosin and its derivatives (esters and salts) was studied. The modified rosin esters can be used as components of thermoplastic formulations, and modified salts, as heat-resistant additives to cutting fluids.

Rosin and its derivatives are widely used as components of formulations prepared or applied in a wide temperature range, from 50 to 300°C and higher. At high temperatures, rosin products undergo thermal oxidative degradation, which deteriorates the performance of the material. Therefore, data on heat resistance of secondary rosin products are necessary for the development of new formulations.

In this work, which continues our previous studies [1–3], we evaluated the resistance to thermal oxidative degradation of paraform-modified oleoresin rosin and its derivartives (esters and salts).

EXPERIMENTAL

For the experiments, we took commercial pine oleoresin rosin (POR) containing 96.0 wt % resin acids and 4.0 wt % high-boiling unsaponifiable substances. The resin fraction of POR contained 75.0% resin acids with conjugated double bonds (abietic levopimaric, palustric, neoabietic) and 25.0% pimaric-type acids (pimaric, isopimaric, sandaracopimaric), and also saturated and aromatic acids (dehydroabietic, dihydroabietic).

Modification of POR with paraform (PF) was performed at 140–180°C for 1.5–4 h with the subsequent vacuum distillation of residual PF and unsaponifiable substances [PF = $(CH_2O)_n$, n = 6–12, mp 64°C]. The PF-modified rosin (FPOR) was esterified with ethylene glycol (bp 198–200°C, d_4^{20} 1.1088), diethylene glycol (bp 244.6°C, d_4^{20} 1.1177), *d*-sorbitol (mp 89–93°C), glycerol (bp 290°C, d_4^{20} 1.2604), and pentaerythritol (mp 260.5°C).

Rosin esters were prepared by treatment of FPOR at 265–290°C with alcohols, followed by vacuum evaporation of residual alcohols, water formed in the reaction, and unsaponifiable substances. The alcohol was taken in the amount of one hydroxyl equivalent per mole of resin acid. The reaction progress was monitored by variation of the acid number (AN) of the reaction mixture. The reaction was stopped when AN did not change further for 1 h. The softening point T_s and AN were determined as described in [4]. The group composition of POR, FPOR, and its esters was determined according to [4, 5]. The qualitative and quantitative composition of POR and FPOR and its esters was determined by NMR spectroscopy and GLC. The ^{1}H NMR spectra were measured by standard procedures with a BS-567A spectrometer, using 10% solutions in $CDCl_3$ and TMS as internal reference. The ^{13}C NMR spectra were measured with a BS-587A spectrometer using 20% solutions in $CDCl_3$ and standard 10-mm ampules. The procedures allowed quantitative analysis of the samples. Chromium tris-acetylacetonate was used as relaxant.

The physicochemical properties and compositions of the products are listed in Table 1.

FPOR salts (sodium, ethanolammonium, diethanolammonium, triethanolammonium) were prepared in aqueous solutions by treatment of FPOR with the corresponding bases under heating, followed by evaporation.

* $FPOR_i$, POR modified with i wt % PF; esters of PF-modified POR: DEFPOR, diethylene glycol ester; EEFPOR, ethylene glycol ester; SEFPOR, sorbitol ester; GEFPOR, glycerol ester; and PEFPOR, pentaerythritol ester.

The bases were added in amounts necessary for full neutralization of all the carboxy groups in FPOR.

The parameters of thermal oxidative degradation of rosin products were determined by dynamic and isothermal thermogravimetry [6]. Since FPOR esters, except resin esters and resin acids that remained unchanged after esterification with polyhydric alcohols, contained physically bound water, residual alcohol, and unsaponifiable substances (boiling in the range 100–220°C), the weight loss started at relatively low temperatures. Therefore, the heat resistance was judged from the temperature of degradation onset T_d^{DTG} and T_d^{DTA}, rather than from the temperatures of 5% weight loss $T_{5\%}$ [7].

To fully characterize the stability of FPOR and its esters, we used isothermal TG. Samples of FPOR or its esters (0.5–1.3 g each) were heated at 240°C for 4, 8, and 12 h in a muffle furnace in air. The initial POR was used as reference. The weight loss was determined with an analytical balance.

Data on thermal oxidative degradation of FPOR and of its esters and salts are listed in Tables 2 and 3. The names and abbreviations of FPOR esters are given in Table 1.

As seen from Table 1, as the extent of rosin modification with PF is increased (from 2 to 10 wt %), the softening point increases from 72.5 to 87.0°C, and the AN decreases from 165 to 154 mg KOH g^{-1}. The best results are attained with 6–8 wt % PF: T_s 89.0°C, AN 158–155 mg KOH g^{-1}. At a higher (10 wt % PF) degree of POR modification, the rosin quality decreases: T_s 87.0°C, AN 154 mg KOH g^{-1}.

The $FPOR_6$ sample was esterified with polyhydric alcohols. As seen from Table 1, PEFPOR has the highest (130°C), and DEFPOR, the lowest (85.6°C) softening point. The physicochemical characteristics of the esters depend on the alcohol used. All the FPOR esters, except the corresponding resin acid esters, contain free resin acids and unsaponificable substances. The higher T_s of PEFPOR, compared to the other FPOR esters, may be due to higher reactivity of pentaerythritol. Comparison with our previous data [2] shows that T_s of FPOR esters considerably exceeds T_s of POR esters.

The quantitative and qualitative composition of the main POR components was determined by ^1H and ^{13}C NMR. Oleoresin rosin contains the following acids (%): abietic 39, levopimaric 17, palustric 10, neoabietic 9, dehydroabietic 6, dihydroabietic 1, pimaric 7, isopimaric 9, and sandaracopimaric 2.

The ^1H and ^{13}C NMR data are nicely consistent with the results of the GLC analysis.

The spectra of FPOR show that it is a mixture of organic compounds with resin acids as major components, as judged from the high intensity of the signals of carboxyl hydrogen (δ 9.4 ppm) in the ^1H NMR spectrum and carboxyl carbon (δ_C 185.5 ppm) in the ^{13}C NMR spectrum. The PF-modified rosin samples appreciably differ in quantitative and qualitative composition. After treatment of POR with para-

form, the content of the major component, abietic acid, does not change noticeably, whereas the content of levopimaric acid decreases from 17 to 3%. It is logical to assume that levopimaric acid reacts with formaldehyde by the scheme given in [8], with isomerization of conjugated double bonds and addition of the formaldehyde molecule to form the CH_2OH group. The formation of this group is confirmed by the appearance of the ^1H NMR signals at δ 4.2–3.2 ppm, absent in the spectra of POR. In the ^{13}C NMR spectrum, a broad maximum appears at about 65 ppm.

The treated product contains no neoabietic acid. Dehydroabietic and pimaric acid, similarly to abietic acid, do not react with paraform, and their content remains unchanged. Isopimaric acid is, by contrast, completely converted to other substances.

The ^1H and ^{13}C data suggest that some of the resin acids become linked via the $–CH_2–$ group [9]. This is indicated by the appearance of signals attributable to a methylene group located between double bonds (^1H, δ 2.9 ppm; ^{13}C, δ_C 26 ppm). This is consistent with an appreciable growth of T_s of modified rosins: from 72.5 to 89°C. Also, a ^{13}C NMR signal appearing at about 178 ppm suggests the presence in modified rosin of esters (~15%) along with the acids.

Thus, the NMR spectra show that modified rosin is mainly a mixture of resin acids, some of which additionally contain the $–CH_2OH$ group and some are linked via the $–CH_2–$ group. However, additional studies are required to fully understand the reaction of PF with rosin.

The NMR spectra of products formed in reactions of polyhydric alcohols with FPOR suggest that these products are mixtures of esters. In particular, the ^{13}C NMR signal at 178 ppm is characteristic of carboxy groups.

Table 2 shows that, as judged from all the criterial parameters (T_d^{DTG}, T_d^{DTA}, T_d^{av}, $T_{5\%}$, $T_{10\%}$, $T_{50\%}$), the resistance to thermal oxidative degradation increases upon modification with FP, with the $FPOR_6$ sample being the most stable (T_d^{av} 309°C). The activation energy of thermal oxidative degradation of FPOR samples, calculated from the dynamic TG data by the Broido method [10], increases from 86 to 98 kJ mol^{-1} in going from $FPOR_2$ to $FPOR_8$.

Treatment of $FPOR_6$ with alcohols enhances its resistance to thermal oxidative degradation. For example, the T_d^{av} values increase, on the average, by 11, 25, 29, 35, and 37°C in going from $FPOR_6$ to SEFPOR, DEFPOR, EEFPOR, GEFPOR, and PEFPOR, respec-

tively. The most resistant is PEFPOR (T_d^{av} 346°C), and the least resistant, SEFPOR (T_d^{av} 320°C). The activation energy E_d in the series SEFPOR–PEFPOR increases from 86 to 110 kJ mol^{-1}. FPOR esters are more resistant to thermal oxidative degradation than their analogues prepared from the initial POR [2].

For FPOR esters, a linear correlation is observed between the parameters characterizing the onset of thermal oxidative degradation and T_s: these temperatures vary in the same direction.

As seen from the isothermal TG data (Table 3), the largest weight loss in 4–12 h at 240°C is observed with SEFPOR and DEFPOR, and the smallest weight loss, with PEFPOR, GEFPOR, and EEFPOR.

Our dynamic and isothermal TG studies revealed the general trends in the resistance of FPOR esters to thermal oxidative degradation. The lower the molecular weight of a monohydric alcohol and the larger the number of hydroxy groups in it, the higher the resistance of FPOR ester to thermal oxidative degradation. With respect to this characteristic, FPOR esters can be ranked in the following order: PEFPOR > GEFPOR > EEFPOR > DEFPOR > SEFPOR.

The FPOR esters can be recommended as components of new thermoplastic formulations instead of the less thermostable esters of the initial POR.

The high heat resistance of FPOR opens up possibilities for preparing heat-resistant additives to cutting fluids instead of the traditionally used sodium and ethanolammonium salts of oleoresin rosin.

Therefore, we prepared from $FPOR_6$ its ethanolammonium, diethanolammonium, triethanolammonium, and sodium salts and examined their resistance to thermal oxidative degradation by dynamic TG.

Table 2 shows that, as judged from all the criterial parameters (T_d^{DTG}, T_d^{DTA}, T_d^{av}), the resistance to thermal oxidative degradation grows in going from EAFPOR to NaFPOR. Treatment of FPOR with ethanolamine, diethanolamine, triethanolamine, or NaOH enhances its heat resistance. For example, T_d^{av} increases, on the average, by 11, 21, 31, and 71°C in going from $FPOR_6$ to EAFPOR, DAFPOR, TAFPOR, and NaFPOR, respectively. The T_d^{av} of FPOR salts increases with approximately equal increments in going from monoethanolamine (molecular weight 61.08) to di- and then to triethanolamine (149.18), and the sodium salts are still more stable. All these substances are more heat-resistant than their analogues prepared from the initial POR and can therefore be recommended as heat-resistant additives to cutting fluids.

Table 3. Weight loss Δm of rosin products on isothermal heating at 240°C

Sample	Δm, wt %, in indicated time, h		
	4	8	12
POR	24.3	41.2	46.4
$FPOR_6$	15.0	30.0	35.0
SEFPOR	10.0	14.0	16.0
DEFPOR	7.5	9.0	12.0
EEFPOR	1.2	2.8	3.0
GEFPOR	1.0	2.6	2.8
PEFPOR	0.9	2.4	2.6

CONCLUSION

The heat resistance of rosin is considerably enhanced by its treatment with paraform. The process is simple and waste-free; its product, paraform-modified pine oleoresin rosin, can be converted to more heat-resistant products, in particular, esters and salts.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Hydrodynamic Conformation Properties of Poly(1-Trimethylsilylpropyne) Molecules Obtained on $NbCl_5$ Catalyst

Received January 28, 2002

Abstract—Hydrodynamic properties of 10 samples of poly(1-trimethylsilylpropyne) of various molecular weights, obtained with $NbCl_5$ catalyst and containing 60–70% *cis* C=C bonds, were studied by sedimentation, translation diffusion, and viscometry techniques. The equilibrium rigidity of the polymer molecules was estimated from the viscometric data using the formalism of the intrinsic viscosity theory as applied to the worm-like coil model with excluded-volume effects. For the polymer macromolecules, the Kuhn segment length, thermodynamic parameter ε, and hydrodynamic diameter of the chain *d* were estimated.

A study of molecular properties of disubstituted polyacetylenes [1] and aromatic polyamides [2] revealed that even insignificant differences in the monomeric unit structure, including those in the alternation of double bonds in the backbone chain [1] or side substituents, can have a considerable effect on properties of the polymer molecule as a whole. Also of vital importance for properties of a polymer can be the arrangement (regular or random) of *cis* and *trans* C=C bonds in the backbone chain [3].

Presently, disubstituted silicon-containing polyacetylenes are intensively studied as promising materials for gas-separating membranes [1, 4, 5].

In this connection, a study of properties of polymers of this class at the molecular level is a topical task [1–3, 5]. It is known that, depending on the synthetic procedure, macromolecules of the disubstituted polyacetylene, poly(1-trimethylsilylpropyne) (PTMSP), can have different relative amounts of the *cis* and *trans* C=C bonds in the backbone chain. It was demonstrated that PTMSP obtained with a $TaCl_5$-based catalyst is characterized by a *cis*/*trans* ratio of 40/60. This polymer is readily soluble in a number of solvents, and its molecular conformation has an increased equilibrium rigidity [1, 5].

To elucidate the effect of the *cis*/*trans* ratio in the backbone chain on the conformation features of the macromolecules, we studied in this work such hydrodynamic parameters as the intrinsic viscosity [η], translation diffusion coefficient *D*, and flotation coefficient (–*s*) of the PTMSP samples obtained on the $NbCl_5$ catalyst, which are characterized by increased *cis*/*trans* ratios (60/40 and 70/30).

EXPERIMENTAL

In the work we used PTMSP synthesized with $NbCl_5$ as a catalyst [4]. Depending on the synthesis conditions, PTMSP samples of various molecular weights were obtained. First, the samples were characterized by gel permeation chromatography (GPC) on a Waters chromatograph with two HP PL columns (particle size 10 μm, pore size 10^4–10^5 Å, 50°C). To obtain initial data on the molecular weight of the samples, we used 0.2 wt % solutions of the polymers in toluene. The flow rate was 1 ml min^{-1}. The PTMSP samples obtained with $NbCl_5$ demonstrated a narrow molecular-weight distribution, which allowed their use without further fractionation.

The *cis*-*trans* microstructure of the polymer macromolecules was studied by ^{13}C NMR in $CDCl_3$ used as internal reference. The spectra were registered on a Bruker MSh-300 instrument (75.47 MHz, solution concentration 20%, integration time 12 h). The spectra of PTMSP show four characteristic doublets corre-

1070-4272/02/7508-1308 $27.00 © 2002 MAIK "Nauka/Interperiodica"

sponding to the four carbon atoms of the monomeric unit $-[C(-Me)=C(-Si(-Me)_3]_n-$ of the macromolecule. The doublet structure of the signals of the carbon atoms suggests the presence of the *cis* and *trans* C=C bonds in the backbone chain of the polymer. The relative intensities of the peaks in the doublets reflect the *cis*/*trans* ratio. The spectra were processed using the ACD:CNMR version 1.1 program pack (product from the ACD Inc. Company). The mean content of the *cis* C=C bonds was estimated to be $65 \pm 5\%$.

For PTMSP **I** we determined the intrinsic viscosity [η], translation diffusion coefficient *D*, and flotation coefficient (–*s*).

We used the Swedberg method to determine the absolute molecular weights of PTMSP **I** samples with [η] ranging from 48.6 to 10^4 cm^3 g^{-1}. For this purpose, we measured the flotation coefficients (–*s*) of five samples of PTMSP **I** in chloroform as a good solvent for ultracentrifugation (viscosity $\eta_0 = 0.542 \times 10^{-2}$ P, density $\rho_0 = 1.485$ g cm^{-3}, 25°C). Centrifugation was carried out with an MOM Model 3170/B ultracentrifuge (Hungary) equipped with a polarization–interferometric unit with 0.3-mm spar split) [3]; rotor speed 40 000 rpm; solution concentration $c \leq (0.1–0.2) \times 10^{-2}$ g cm^{-3}. The time dependence of ln *x* (*x* is the abscissa of the maximum of the sedimentation curve) is presented in Fig. 1. The flotation coefficient was estimated from the slope of this dependence for each of the five PTMSP samples by the equation $(-s) = \omega^{-2}\,\Delta(\ln x)/\Delta t$, where ω is the rotor speed.

The translation diffusion coefficients *D* in chloroform at 25°C were determined with a polarization diffusometer [3] at solution concentrations below 0.1×10^{-2} g cm^{-3}. The diffusion curves were processed using data on the areas under the curves and on the peak ordinates [3]. Fifure 2 shows the variance of the diffusion curves $\langle\Delta^2\rangle$ as a function of the diffusion time *t*.

The absolute molecular weights M_{sD} were estimated by the Swedberg equation (1).

$$M_{sD} = (s/D)RT/(1 - \bar{\nu}\rho_0), \qquad (1)$$

where $\bar{\nu} = 0.94$ cm^3 g^{-1} is the partial specific volume of the polymer determined by the bottle method in chloroform at 25°C; and $(1 - \bar{\nu}\rho_0) = 0.392$ is the flotation factor.

The [η], *D*, (–*s*), and M_{sD} of the PTMSP samples are given in the table.

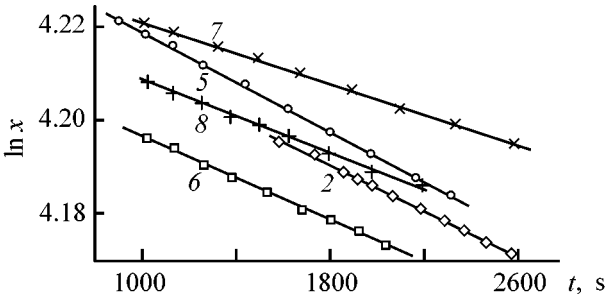

Fig. 1. ln *x* vs. time *t*. The numbers at the curves correspond to the PTMSP sample numbers; the same for Fig. 2.

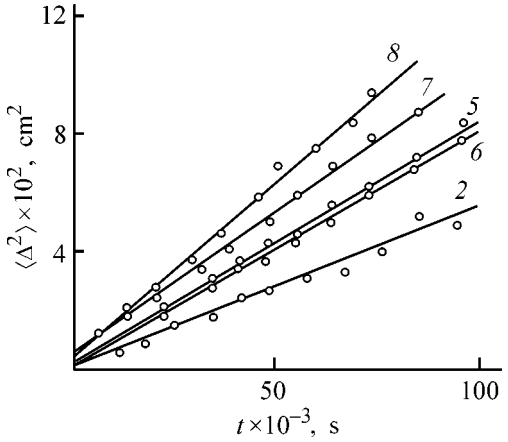

Fig. 2. Variance of the diffusion curves $\langle\Delta^2\rangle$ vs. the diffusion time *t*.

The logarithmic dependence of the intrinsic viscosity [η] of the PTMSP **I** samples, measured in toluene at 21°C, on M_{sD} is given in Fig. 3. This de-

* Estimated from [η] in toluene by Eq. (3).

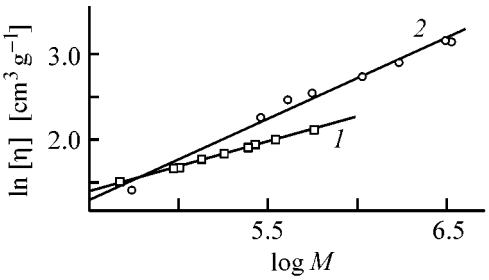

Fig. 3. log [η] vs. log *M*: (*1*) PTMSP **I** fractions in toluene and (*2*) PTMSP **II** fractions in heptane. Temperature 21°C.

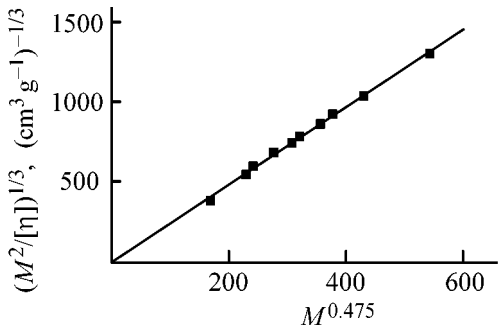

Fig. 4. $(M^2/[\eta])^{1/3}$ vs. $M^{(1-\varepsilon)/2}$ at $\varepsilon = 0.05$.

pendence was approximated by the Mark–Kuhn–Houwink equation (2) (MKH) (Fig. 3, curve *1*).

$$[\eta] = 5.7 \times 10^{-2} M_{sD}^{0.59}. \quad (2)$$

Slight increase in the exponent *a* in Eq. (2) (0.59 against the theoretical value of 0.5) is due to the bulk swelling effect, as for the previously studied PTMSP **II** synthesized on $TaCl_5$/BuLi [1], whose swelling was studied in heptane. At the same time, [η] of PTMSP **II** (Fig. 3, curve *2*) exceeds that of PTMSP **I** at the same *M* (curve *2* in Fig. 1 lies above curve *1*). This suggests that, at any molecular weight, the statistical size of the PTMSP **II** molecules is larger than that of PTMSP **I**, which indirectly suggests the lower equilibrium rigidity of PTMSP **I**.

The molecular weights of the other PTMSP **I** samples were estimated by Eq. (3).

$$M = ([\eta]/0.057)^{1.7}. \quad (3)$$

The estimated results are given in the table.

The equilibrium rigidity of the PTMSP **I** molecules was estimated from the viscometric data using the formalism of the intrinsic viscosity theory as applied to the worm-like coil model with excluded-volume effects. The solvent effect on the dependence of [η] on *M* can be accounted for using Eq. (4) [6–9].

$$(M^2/[\eta])^{1/3} = \Phi_\infty^{-1/3}\left[(1-\varepsilon)(1-\varepsilon/3)\right]^{-1}\left[M_L^{(1+\varepsilon)/2}/A^{(1-\varepsilon)/2}\right] M^{(1-\varepsilon)/2} + M_L P_\infty (3\pi\Phi)^{-1}[\ln(A/d) + 1 + \Psi(\varepsilon)], \quad (4)$$

where ε is the parameter characterizing the thermodynamic quality of the system polymer–solvent; $\Phi_\infty = 2.2 \times 10^{23}$ mol^{-1}, the Flory constant [8]; $P_\infty = 5.11$, the translation friction theory constant [9]; *A*, the Kuhn segment length; *d*, the hydrodynamic diameter of the chain; and Ψ(ε), the tabulated function [9].

The weight of the unit length of the outstretched molecular chain $M_L = M_0/\lambda$, where $M_0 = 112$ is the molecular weight of the monomeric unit and λ is the length of the monomeric unit projection along the direction of the outstretched molecular chain. The λ values are close for the *cis* and *trans* conformations of the monomeric unit (2.32×10^{-8} and 2.12×10^{-8} cm, respectively) [5]. Using Eq. (5),

$$\lambda = 2.321 \times 10^{-8} p + 2.12 \times 10^{-8}(1 - p), \quad (5)$$

we obtained the mean $\lambda = 2.18 \times 10^{-8}$ cm (for *trans*/*cis* = 30/70).

The experimental dependence $(M^2/[\eta])^{1/3}$ vs. $M^{(1-\varepsilon)/2}$ is presented in Fig. 4 at $\varepsilon = 0.05$, close to that obtained previously for PTMSP **II** [5]. The dependence was approximated by a straight line using Eq. (4). From the slope of this dependence, equal to

$$\Phi_\infty^{-1/3}\left[(1-\varepsilon)(1-\varepsilon/3)\right]^{-1}\left[M_L^{(1+\varepsilon)/2}/A^{(1-\varepsilon)/2}\right] = 2.44, \quad (6)$$

we obtained the Kuhn segment length $A = 33 \times 10^{-8}$ cm. This value is half that for PTMSP **II**, determined from hydrodynamic data ($A = 70 \times 10^{-8}$ cm) [2, 5]. Note that the *trans*/*cis* ratio is higher in PTMSP **II** than that in PTMS **I** (60/40 and 40/60, respectively). The difference in the *cis*/*trans* ratio at strongly different equilibrium rigidity suggests a different organization of the *cis* and *trans* structures in the polymers obtained with different catalysts, specifically, different extension of continuous sequences of units having the same conformation (*cis* or *trans*). The higher equilibrium flexibility of PTMSP **I** is caused by the longer flexible *cis* sequences or the shorter *trans* sequences.

The absolute term in Eq. (4), estimated from the position of the approximating straight line (Fig. 4) to be

$$M_L P_\infty (3\pi\Phi)^{-1}[\ln(A/d) + 1 + \Psi(\varepsilon)] = -3.701, \quad (7)$$

gives us the hydrodynamic diameter of the chain $d = 10 \times 10^{-8}$ cm at $\Psi(\varepsilon) = -2.58$ ($\varepsilon = 0.05$). This value is consistent with the chemical structure of the polymer, being virtually coincident with that obtained previously for PTMSP **II** [5].

CONCLUSIONS

(1) Comparison of the hydrodynamic parameters of poly(1-trimethylsilylpropyne) (polymers **I** and **II**) shows that, at the same molecular weight, the molecular size of polymer **I** synthesized with $NbCl_5$ as a catalyst is smaller that that of polymer **II** obtained with $TaCl_5$/BuLi.

(2) The Kuhn segment length of polymer **I** is half that of **II**, suggesting a higher flexibility of the macrochains of **I**.

(3) The higher equilibrium flexibility of PTMSP **I** is caused by the longer flexible *cis* sequences or the shorter *trans* sequences.

ACKNOWLEDGMENTS

The work was financially supported by the Integration Federal Target Program (project AO147).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thiouretane Formation from Polyoxyalkylene Oligomers

A. D. Elchueva and A. A. Tabachkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received January 14, 2002

Abstract—Thiouretane formation in compounds based on polyoxyalkylenethiols and polyoxyalkylene isocyanates in the presence of catalysts was considered.

At present, polysulfide (PSO) and isocyanate-containing oligomers (ICO) and their mixtures with other reactive oligomers (ROs) are cured by the ionic mechanism in the presence of amine catalysts [1].

EXPERIMENTAL

The developed thiourethane polymer compounds TURELAST are prepared from ROs in the presence of phenolic Mannich bases; they combine advantages of Thiokol and polyurethane materials. Stabilized polyoxyalkylene isocyanate (POAI), the adduct of isocyanate and polyoxyalkylened polyol (POAP), synthesized in the presence of acidic stabilizing agents [2], was used as ICO. Data on variation of the content of isocyanate group in the synthesized prepolymers, depending on the type of the stabilizing agent, are listed in Table 1.

Both catalyzed and uncatalyzed thiouretane formation (TUF) reactions are described by a second-order kinetic equation with respect to concentrations of thiol and isocyanate groups. In this case, the rate constant of the reaction is determined by graphical solution of the equation

$$\frac{1}{x_0 - y_0} \log \frac{y_0}{x_0} \frac{x}{y} = -k\tau, \qquad (1)$$

where x_0 and y_0 are the initial, and x and y, the current concentrations of the reacting groups (M); τ is time.

At the equimolar ratio of ROs, the rate constant of the reaction [3] was determined from Eq. (2):

$$\frac{1}{x} \frac{1}{x_0} = -k\tau, \qquad (2)$$

The kinetic curves of consumption of terminal groups of Thiokol and oligoisocyanate in uncatalyzed TUF and the results of their linearization are shown in Fig. 1.

The efficiency of thiourethane cross-linking is affected by the structure of oligothiol. Comparison of the curing kinetic curves for compounds containing PSO (Thiokol) and polyoxyalkylenethiol (POAT), a thiopolyether, shows that the rates of the reaction of oligothiols with toluylene isocyanate, determined by pulse NMR at room temperature, are almost the same, while the final relaxation time T_2 for the compound based on Thiokol is significantly shorter (Fig. 2). The transverse nuclear magnetic relaxation time T_2 was measured by the Hahn method on a relaxometer operating at 17.5 MHz with restoration time of the transmitting-receiving unit of 50 μs. Thus, with more polar Thiokol of molecular weight 3000, the forming polymer is denser than with thiopolyether of molecular weight 4500.

It has been established previously [4] that phenolic hydroxyl in 2-(methylaminomethyl)phenol (**I**) (MAP) is usually involved in intramolecular or intermolecular hydrogen bonds (**A**) and (**B**), respectively:

Table 1. Variation of the content of isocyanate group in prepolymers in relation to the type of the stabilizing agent

Stabilizing agent	Content of isocyanate group, M	
	immediately after synthesis, x_0	after 3 years, x
Acetylacetone	2.28	1.94
Dinonyl phosphite-chloridite	2.57	1.79
Hydrochloric acid	2.28	1.96

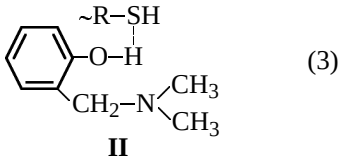
A **B**

I

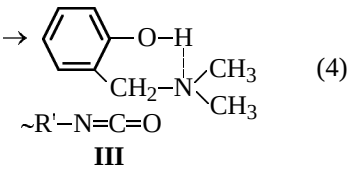
The terminal thiol group is more acidic than the hydroxy group of aminophenlol **I**. This results in activation of aminophenol **I** by the scheme



(3)

II

The lone electron pair of the nitrogen atom of the isocyanate group facilitates the attack of the methylene group of the catalyst **II** to give **III**):



(4)

III

According to the kinetic curves for the reaction of oligoisocyanate with the catalyst (Fig. 3), with the concentration of 2-(dimethylaminomethyl)phenol **I** increasing by a factor of 2, the rate constant of the reaction increases from 8.7×10^{-4} to 23.8×10^{-4} l mol^{-1} s^{-1}, i.e., when aminophenlol **I** molecule adds to oligocyanate, its catalytic activity decreases. The results obtained were used for forecasting the storage life of the prepolymer–catalyst mixture:

$$\frac{d[OH]}{d\tau} = k_{OH}[NCO][OH]^2 = 8.7 \times 10^{-3} \times 1.4[OH]^2 = 1.21 \times 10^{-2}[OH]^2, \quad (5)$$

$$\frac{1}{[OH]} - \frac{1}{[OH]_0} = 1.21 \times 10^{-2}\tau. \quad (6)$$

In sealing compounds, the catalyst is used in an amount of 1.7×10^{-3} mol kg^{-1}. For 90% consumption of hydroxy groups, we can determine the time in which the catalyst loses its activity:

$$\frac{1}{0.1[OH]_0} - \frac{1}{[OH]_0} = \frac{10-1}{[OH]_0} = \frac{9}{[OH]_0} = 1.21 \times 10^{-2}\tau, \quad (7)$$

$$\tau = \frac{9}{1.21 \times 10^{-2} \times 1.7 \times 10^{-3}} = 130 \text{ h} \approx 5.5 \text{ days}. \quad (8)$$

Table 2. Degree of conversion of oligomers with various catalysts

Catalyst	Degree of conversion, wt %, with indicated catalyst in indicated amount, wt %							
	Thiokol				thiopolyether			
	20	30	40	50	20	30	40	50
–	27.4	37.6	45.6	50.4	13.5	17.5	21.6	25.0
2-(Dimethylaminomethyl)phenol	64.8	67.2	68.7	70.4	61.7	65.6	68.0	69.6
2,4-Bis(dimethylaminomethyl)phenol	66.0	69.6	72.0	74.4	62.8	69.2	72.0	73.0
2,4,6-Tri(dimethylaminomethyl)phenol	67.5	72.7	75.0	79.5	64.0	72.0	76.0	79.2

Table 3. Physicomechanical characteristics of Thiokol-prepolymer and thiopolyether–prepolymer compounds

Characteristic	Catalyst content recalculated to Thiokol or thiopolyether, wt %							
	Thiokol–prepolymer				Thiopolyether–prepolymer			
	0.2	0.4	0.6	0.8	0.2	0.4	0.6	0.8
Working life, h	4	3	2	1	3	2	2	0.5
Nominal tensile strength, MPa	1.5	2.4	2.2	2.0	1.8	1.7	1.6	1.5
Relative elongation, %	150	210	200	180	440	500	600	700

The working life of the compound increases from 2 to 18 h.

The higher nucleophilicity of the sulfur atom in the oligothiol in comparison with the nitrogen atom in isocyanate group favors predominance of TUF over cyclotrimerization of the prepolymer.

The degree of conversion of oligomers grows with increasing basicity of (dimethylaminomethyl)phenols (Table 2). Irrespective of the catalyst type, the rate constants of the reaction of the oligocyanate with the thiopolyether are higher.

Based on the above data, we considered how the catalyst structure affects the main characteristics of filled compounds at the ratio Thiokol : prepolymer = 1.0 : 0.8. When the optimal amount of the catalyst is exceeded (0.4 wt parts), the deformation characteristics are deteriorated, which suggests the prevalance of oligocyanate cyclization over its copolymerization with Thiokol.

With polar thiopolyether, the elastic characteristics of the composites are significantly better, while the nominal strength is approximately the same (Table 3). This is caused by additional cross-linking of oligomers in the reaction of intramolecular hydroxy groups of oligothiol with isocyanate groups of the prepolymer along with the terminal mercaptan groups.

CONCLUSION

Thiourethane compounds TURELAST based on polyoxyalkylenethiol and stabilized polyoxyalkylene isocyanate (produced by Nizhnekamskneftekhim Joint-Stock Company) can be recommended for industrial use. A combination of elasticity, cohesion strength, impact resistance, and adhesion to various substrates make these materials extremely promising for use as elastic, corrosion-resistant, and sealing coatings and as impregnating agents.

Abstract—Binary blends of segmented polyetherurethanes were prepared from oligooxytetramethylene glycol, toluylene diisocyanate, and a chain extender (*p*-hydroxybenzoic acid magnesium salt or *N*-methyldiethanolamine). The nature of intermolecular interactions in the blends of various compositions was studied by IR spectroscopy. Depending on the formulation of the blends, various kinds of microstructural organization exist (as demonstrated by low-angle X-ray scattering data), strongly influencing the mechanical characteristics of polyurethane blends.

Ionomers and their blends attract researcher's attention in view of the possibility of development on their basis of new adhesives, coatings, binders, membranes, and other materials having high performance characteristics [1–5]. By now, a series of binary blends and interpenetrating polymer networks containing ionic groups in one or both components of the blend have been obtained and characterized [6–10]. Polyurethane ionomers and their blends have been studied to a lesser extent [11–14]. At the same time, introduction of ionic groups in polyurethanes, which have a highly developed physically bonded network, forms an additional ionic network, considerably influencing the structural features and other properties of these systems. It was demonstrated that introduction of ionic groups in one of the components of polyurethane–polyurethane systems has a considerable effect on the microphase structure [15] as well as on the thermodynamic and adhesion properties [16].

In this work, we studied binary blends of polyurethanes in which one of the component contains ionic groups, and another component, tertiary amino groups. Study of the intermolecular interactions and phase structure of these systems is a necessary step on the way to directed synthesis of composite materials on their basis.

EXPERIMENTAL

We prepared polymer blends of a linear polyurethane ionomer (LPI) and a linear polyaminourethane (PAU).

The individual LPI and PAU were synthesized in two steps, using the standard procedure described in [12]. Initially we obtained a prepolymer by the reaction of oligooxytetramethylene glycol (MW 1000) with 2,4(or 2,6)-toluylenediisocyanate at a molar ratio of the reacting groups OH/NCO = 1/2. Then the prepolymer was extended by using *p*-hydroxybenzoic acid magnesium salt (for LPI) or *N*-methyldiethanoleamine (for PAU). The molecular weight M_η of LPI was 40 000, and that of PAU, 50 000.

The blends were prepared at room temperature by the method of chemical mixing of the two polymers [6]. To a PAU solution in DMF, the initial prepolymer and chain extender for LPI were added, so that LPI was formed in the PAU solution. The films were formed by casting on Teflon supports with subsequent removal of the solvent and drying at 85°C for 5–7 days. As a result, we obtained a series of samples of polyurethane blend films at various component ratios (from 1 to 95% PAU).

The samples were studied by IR spectroscopy and low-angle X-ray scattering. Also the samples were characterized by the strength and elongation at break.

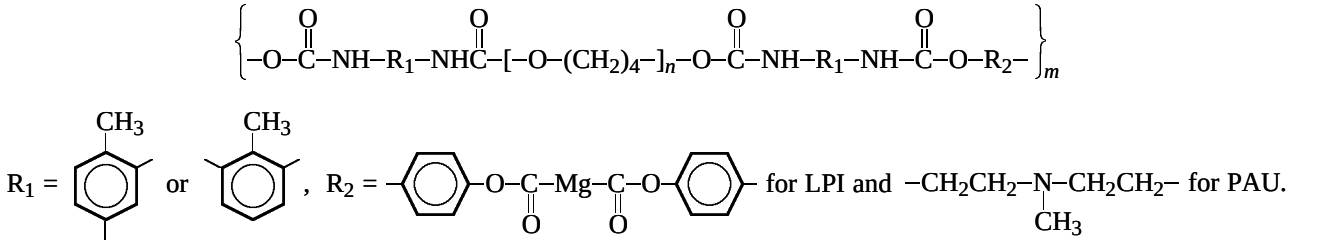
IR spectra were recorded on a Specord M-80 spectrometer in the range 600 – 4000 cm^{-1}, using the KBr technique.

X-ray diffraction study was made with a KRM-1 low-angle X-ray camera (Cu_{K_α} radiation monochromated using a Ni filter; slit collimation of the initial X-ray beam was performed by Kratky's method

1070-4272/02/7508-1315 $27.00 © 2002 MAIK "Nauka/Interperiodica"

[17]). The experimental X-ray scattering curves were normalized to the scattering volume of the samples, taking into account the attenuation of the initial beam.

LPI and PAU are segmented polyetherurethanes, whose flexible segments (or blocks) are formed by the same oligoether, oligooxytetramethylene glycol, and rigid blocks are formed by the reaction of the terminal isocyanate groups of the prepolymer with the chain extender. In this case, the backbone chains of the polyurethanes contain the Mg-dicarboxylate groups (LPI) or tertiary amino groups (PAU). The general formula of the polyurethanes obtained can be represented as



The structure of the molecular chains of the individual polyurethanes used allows various types of intermolecular interactions, including hydrogen bonding and ion–molecule interaction, which control to a considerable extent the properties of polyurethanes [13, 18–20]. These interactions can be studied by IR spectroscopy [3, 13, 21, 22].

A comparison of the IR spectra of LPI, PAU, and their blends showed noticeable differences in the range of stretching vibrations of carbonyl groups in various moieties (urethane, ester, and ionic) of the backbone chains. The IR spectra of the individual polyurethanes and several blends in the range 1800–1500 cm^{-1} are shown in Figs. 1 and 2.

The spectrum of PAU (Fig. 2, spectrum *1*) shows a distinct band at 1730 cm^{-1}, due to vibrations of free C=O groups, and a shoulder at 1710 cm^{-1}, assigned to carbonyl groups involved in H bonding with the NH groups of the urethane fragments. This suggests that a network of intermolecular bonds between the urethane groups exists in the PAU structure, which is typical of segmented polyurethanes [13, 19, 20].

In the range of stretching vibrations of carbonyl groups, the spectrum of LPI (Fig. 1, spectrum *1*) shows the bands of H-bonded carbonyls of the urethane groups and, additionally, the bands at 1675 and 1630 cm^{-1}. It is known that, in polymers, metal cations having high effective charge and polarizability

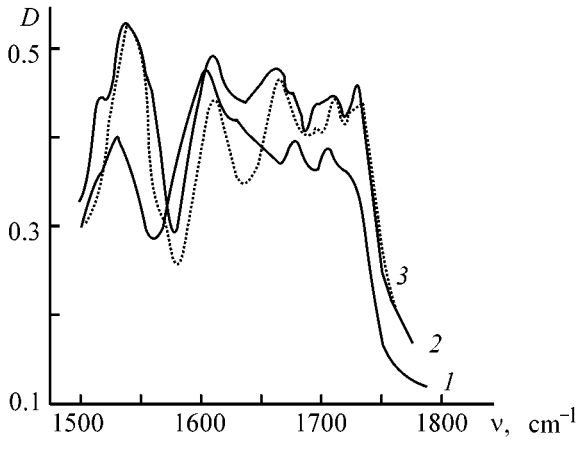


Fig. 1. IR spectra of (*1*) LPI, (*2*) LPI + 10% PAU, and (*3*) LPI + 30% PAU. (*D*) Optical density and (ν) wave number; the same for Fig. 2.

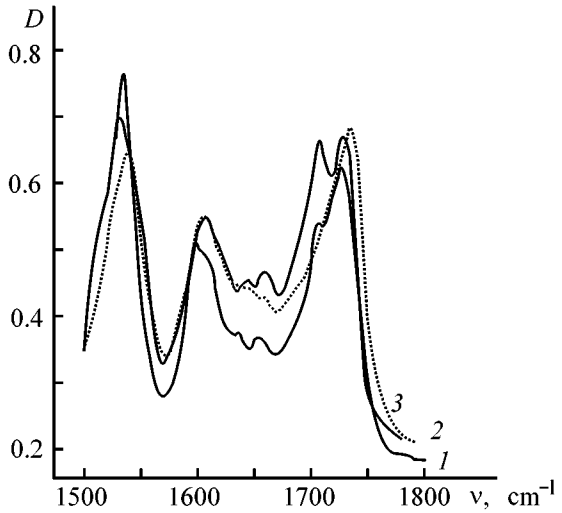

Fig. 2. IR spectra of (*1*) PAU, (*2*) LPI + 70% PAU, and (*3*) LPI + 50% PAU.

can form ion–molecule bonds with the carbonyl groups, resulting in a low-frequency shift of the carbonyl bands [23]. Presumably, the band at 1675 cm^{-1} characterizes the ion–molecule bonds of the carbonyls of the urethane groups with magnesium cations of the ionic fragments $C{=}O\cdots Mg^{2+}$. The shoulder at 1630 cm^{-1} is assigned to vibrations of the carboxylate groups $RCOO^-$ coordinated to the metal [22]. The observed noticeable increase in the relative intensity of the bands in the range 1600–1610 cm^{-1} in the spectrum of LPI, compared to PAU, is due to the absorption of nonassociated $RCOO^-$ groups.

Comparison of the IR spectra of the polyurethane blends studied shows that the nature of absorption of the carbonyl groups strongly depends on the component ratio (Figs. 1, 2). For example, in the spectrum of a blend containing 10% PAU (Fig. 1, spectrum *2*), the intensity of the band at 1730 cm^{-1} increases as compared to that in the spectrum of LPI; a new band is found at 1664 cm^{-1}; and the intensities of the bands at 1610 and 1630 cm^{-1} considerably decrease. This fact suggests that the nature of the intermolecular interactions changes on passing from one system to another. Specifically, the fraction of the nonassociated and metal-coordinated $RCOO^-$ groups decreases, and there occur ion–molecule interactions of the $COO^-\cdots NH$ type involving the protons of the urethane groups of PAU and carboxylate anions of LPI. Such ion–molecule interactions in polyurethanes are more energetically favorable (by a factor of 1.4) as compared to H bonding between the urethane groups [13]. Evidently, small concentration of PAU (up to 20%) in a polyurethane blend initiates reorganization of the intermolecular bonds with preferential realization of ion–molecule interactions between the LPI and PAU macromolecules.

An increase in the PAU concentration to 30% is accompanied by the appearance of a band at 1675 cm^{-1} ($C{=}O\cdots Mg^{2+}$), which is found as a shoulder at the band 1664 cm^{-1} ($COO^-\cdots NH$). In this case, the intensity of the band at 1664 cm^{-1} decreases (Fig. 1, spectrum *3*) and the intensity of absorption bands of H-bonded carbonyls in the urethane groups increases. These facts suggest that ion–molecule bonds between the LPI and PAU polymer chains partly break down, and the contribution of the hydrogen and ion–molecule bonds formed by only the individual LPI and PAU molecules increases. In the spectrum of a blend containing 50% PAU, we found no absorptions at 1664 and 1675 cm^{-1}, as well as in the range of absorption of the H-bonded carbonyls of the urethane groups (Fig. 2, spectrum *3*). Therefore, specific interactions between LPI and PAU do not occur in a blend of this composition.

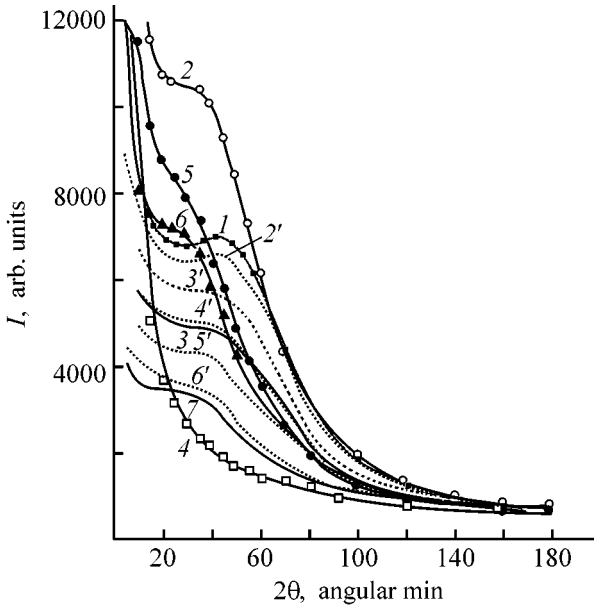

Fig. 3. Low-angle scattering curves of (*1*) LPI, (*2*) LPI + 10% PAU, (*3*) LPI + 30% PAU, (*4*) LPI + 50% PAU, (*5*) LPI + 70% PAU, (*6*) LPI + 90% PAU, and (*7*) PAU. (*I*) Intensity and (2θ) scattering angle. (*2*′–*6*′) Additive curves.

In the IR spectra of the blends with high PAU concentration (70% and more) (Fig. 2, spectrum *2*), we mainly observed the absorption bands of carbonyls of the urethane groups at 1710–1730 cm^{-1} (the band at 1664 cm^{-1} is very weak). It should be suggested that, in this case, the intermolecular interactions are occur primarily via the urethane groups of the polymeric components.

The interrelation between the nature of intermolecular interactions and the microphase structure in the polyurethane blends investigated can be elucidated by analysis of the low-angle X-ray scattering data. Figure 3 shows such data obtained for the initial polyurethanes and their blends.

The results (Fig. 3, curves *1*, *7*) suggest that the individual LPI and PAU both have the rigid-block domain structure, but of different degrees of perfection. A distinct interference peak in curve *1* is an indication of the occurrence in the LPI structure of a three-dimensional macroscopic lattice formed by uniformly sized rigid domains (major domain period L is equal to 105 Å). The presence of ionic groups, actively participating in formation of intermolecular bonds, in the rigid blocks of LPI favors association of these blocks [14], resulting in fairly high degree of their segregation ($\alpha_{seg} = 0.60$). The estimate for this parameter was made by Bonart's method [24]. Curve *7* in Fig. 3 demonstrates a broad peak,

5	95	25.2	540	3.9	11

reflecting a distorted structure of the rigid-domain superlattice ($L \approx 160$ Å), as well as a relatively low level of block segregation ($\alpha_{seg} = 0.27$). The low scattering intensity near the interference peak in curve *7* is an indication of a small density of packing of the rigid blocks in domains, which is a result of the effect of the side bulky substituents at the nitrogen atom [14]. Therefore, the highly developed network of intermolecular bonds in LPI (concluded from the IR spectra) implies the formation of a perfect domain structure. PAU has a domain structure, characterized by low degree of segregation of blocks and low density of their packing.

Let us consider the microstructure of LPI–PAU binary blends. In addition to the experimental curves, Fig. 3 also shows the theoretical additive curves (curves *2*'–*6*') estimated for the polyurethane blends, assuming the physical ideality. Significant deviation of the experimental curves from the ideality gives additional evidence in favor of the existence of a system of intermolecular interactions between the polymers in their blends, which is consistent with the IR data.

In the composition range 10–20% PAU, the X-ray scattering curves show distinct interference peaks and, simultaneously, the highest scattering intensities (see, e.g., curve *2*). It follows from the IR spectra that, in this composition range, more energetically favorable ionmolecule bonds are formed between the polymeric components. The low-angle X-ray scattering data demonstrate that formation of these bonds controls the microstructure in polyurethane blends, providing high ordering of the domain structure in the bulk of the polymers with high level of segregation of flexible and rigid blocks and density of their packing into the domains.

With the PAU content in a blend increasing to 30 wt %, the scattering intensity near the interference peak decreases and the peak shifts toward the primary X-ray beam (curve *3* in Fig. 3). According to the IR spectrum, the fractions of ion–molecule bonds and associated anionic groups in this sample are decreased, which results in disordering of the rigid-block domain structure, as demonstrated by the scattering data. In this case, a tendency is observed toward extension of the superlattice formed by these domains ($L = 117$ Å) and decrease in the degree of segregation of rigid blocks ($\alpha_{seg} = 0.37$) and in the density of packing of these blocks into domains.

The lack of the interference peak in the scattering curve of the sample with 50% PAU (Fig. 3, curve *4*) implies total breakdown of the rigid domains and existence of a quasihomogeneous structure, which is consistent with the IR spectroscopic data showing the lack of intermolecular interaction in this blend.

Raising the percentage of PAU to 70 wt % is accompanied by the appearance of an interference peak in the scattering curve (curve *5*), suggesting that the superlattice formed in the bulk of this polymer blend contains rigid domains nonuniform in size. Furthermore, the high intensity of scattering on this sample reflects an increased packing density of the rigid blocks in the domains. With the percentage of PAU increasing further to 90% (curve *6*), the interference peak in the scattering curve becomes more distinctly pronounced, which is accompanied by certain decrease in the scattering intensity. Evidently, in PAU-rich blends, when PAU becomes a matrix-forming component, especially at an LPI content of 5–10 wt %, the ionic group concentration in the system is insufficient to formation realization of a highly developed network of ion-ion and ion–molecule bonds. Nevertheless, small addition of the ion-containing polyurethane plays a significant role, as providing conditions for formation of the domain structure (as demonstrated by the low-angle X-ray scattering data), typical of segmented polyurethanes with high degree of segregation and packing density of rigid blocks [14].

The nature of intermolecular interactions controlling the microphase structure in the polyurethane

blends directly influences their mechanical characteristics. Mechanical properties of the polyurethane blends of various compositions are given in the table.

The results show that the strength properties pass through a maximum at a PAU content of 5–20 wt %, i.e., in the composition range where, as demonstrated above, the system of ion–molecule bonds between LPI and PAU is the most developed, providing formation of a perfect domain structure in the polymer blends.

Raising the PAU content to 30 wt % makes worse the mechanical characteristics of the polymer blends. Only the modulus of elasticity of the blends remains relatively high, compared to that of the individual polymers.

In the polymer blends containing 50–5 wt % LPI, the strength properties pass through a maximum at low LPI contents (10–20%). However, their absolute values are lower than those in the blends with low PAU content. The plausible reason is that H bonds between the urethane groups, similar to those in ordinary segmented polyurethanes, rather than ion–molecule interactions, are preferentially formed in this composition range, as supported by the IR spectra.

Polyurethane blend samples of the intermediate composition (50/50), in which, as follows from the IR spectrum and low-angle X-ray scattering curve, a network of intermolecular bonds cannot be formed and the domain structure is not formed, demonstrate the worst mechanical characteristics.

CONCLUSIONS

(1) A network of intermolecular bonds is formed in binary blends of polyurethanes, which is typical of segmented and ion-containing polyurethanes.

(2) In the range of high concentrations (95–80%) of the linear polyurethane ionomer, where a system of essentially ion–molecule bonds is formed to give a quite perfect domain structure, the polyurethane blends demonstrate the best strength parameters.

(3) With small additions (10–20%) of the linear polyurethane ionomer, a network is formed in polyurethane blends mainly via H bonding, which is accompanied by formation of a less perfect domain structure. In this case, the blend samples are inferior in quality.

(4) Polyurethane blend samples in which a network of intermolecular bonds is not formed and the domain structure cannot be formed (at intermediate concentration of the linear polyurethane ionomer of 50%) demonstrate the worst mechanical characteristics.

Abstract—The effect of various factors on preparation of carboxy starch nitrate esters was examined. The ester samples were characterized by IR spectroscopy and chemical analysis.

Growing efforts in the modern carbohydrate chemistry are aimed at development of synthetic routes to biologically active polymers and of new materials for medicine, based on modified polysaccharides [1].

Although certain data are available on nitration of carboxyl-containing polysaccharides [2], the effect of various factors on this reaction has not been studied systematically. Carboxy starch nitrate ester (CSN) prepared by successive polymer-analogous transformations of starch (oxidation with NO_2 in an inert solvent and *O*-nitration) is essentially a random copolymer containing units of different structures. The sodium salt of CSN exhibits appreciable antiaggregation, anticoagulation, and antiarythmic activity [3].

In this work, we studied the effect of various factors (temperature, reaction time, bath ratio, nitrating mixture composition, carboxy group content in oxidized starch) on the esterification of carboxy starch. The modification products were also studied by IR spectroscopy.

EXPERIMENTAL

The characteristics of potato starch used in this study were as follows: amylose content 23.8 wt %, degree of polymerization $\overline{P}_w$ 1760, ash residue 0.31%, phosphorus content 0.22%, moisture content 12.5%, and acidity 15.5 (determined according to [4]). Phosphoric acid (87.6%) and phosphoric anhydride were of pure grade. Fuming (98–99%) nitric acid was prepared by distillation of 61.7% nitric acid mixed (1 : 1 by volume) with concentrated sulfuric acid; the fraction with $T_b \le 94$°C was collected. Oxidation of starch to attain varied content of carboxy groups was performed as described in [5]. *O*-Nitration of carboxy starch was performed with a mixture of nitric acid, phosphoric acid, and phosphoric anhydride at various component ratios by the following procedure. A prescribed volume of the nitrating mixture preliminarily thermostated at 0, 18, or 35°C was added to a sample of carboxy starch, preliminarily pulverized and dried to constant weight. The mixture was kept at a prescribed temperature for a prescribed time. After that, CSN was separated from the nitrating mixture by squeezing on a glass frit and washed with large amount of cold distilled water to neutral reaction; then it was dried in a vacuum oven at 50°C over phosphoric anhydride. The extent of chemical modification of starch was qualitatively monitored by IR spectroscopy (Specord IR-75 spectrometer, 400–4000 cm^{-1}, KBr pellets). The content of nitrogen in nitrate ester groups and of carboxy groups in CSN was determined by the modified Devarda method [6] and with barium acetate [7], respectively. The degree of substitution (DS) with COOH and ONO_2 groups in CSN was calculated by the formulas

$$DS_{COOH} = \frac{162.15\,c_{COOH}}{4500 - 14\,c_{COOH} - 144.64\,c_N},$$

$$DS_{ONO_2} = \frac{162.15\,c_N}{1400 - 4.36\,c_{COOH} - 45\,c_N},$$

where 162.15 is the molecular weight of the anhydroglucopyranose unit, c_{COOH} is the content of carboxy groups (wt %), and c_N is the content of nitrogen in nitrate ester groups (wt %).

To choose the optimal conditions for preparing water-soluble salts of highly substituted nitrate esters of carboxy starch, we examined the effect of *O*-nitration conditions on the composition and properties of the resulting products. As seen from Fig. 1, nitration occurs more slowly at low temperatures. For example, the maximal nitrogen content is attained

1070-4272/02/7508-1320 $27.00 © 2002 MAIK "Nauka/Interperiodica"

at 35°C already in 2–3 min, whereas at 0°C this takes 20–30 min. However, reaction temperatures of 20°C and higher cannot be recommended because of the significant degradation. The highest content of nitrogen in the products obtained by nitration of carboxy starch (DS_{COOH} 0.51) with a mixture of HNO_3, H_3PO_4, and P_2O_5 is 8.50–9.45% (DS_{ONO_2} 1.40–1.64). The relatively low degree of nitration may be due to several factors: steric hindrance produced by bulky carboxy groups, decreased content of primary hydroxy groups in carboxy starch (and, correspondingly, decreased total content of OH groups, which are the most reactive in acid solutions), and also the presence in the glucopyranose unit of a certain amount of carbonyl groups formed by oxidation of starch with NO_2. Furthermore, a part of reactive hydroxy groups in carboxy starch react with carboxy groups to form lactone rings and ester cross-links [8], which also decreases the possible content of nitrate ester groups. The formation of lactone rings and ester cross-links is suggested by the effect exerted on the properties of nitrate esters by carboxy groups, even in small amounts. For example, the solubility of all the carboxy starch nitrate esters with low content of carboxy groups (0.5–3 wt %) is considerably decreased, and the nitrate esters derived from starch with 6–15% substitution of hydroxy groups by carboxy groups are insoluble in organic solvents commonly used for dissolving carbohydrate nitrate esters (amyl acetate, acetone, alcohol–ether mixture, etc.). Owing to the formation of a fairly strong three-dimensional network of ester bonds, these products show only limited swelling in the above solvents at –20 to 60°C.

The influence of the content of COOH groups in carboxy starch on the degree of nitration is shown in Fig. 2. It is seen that, as the content of carboxy groups in the polysaccharide is increased, the content of nitrate ester nitrogen decreases steadily. It should be noted that the total degree of substitution, DS_{tot}, with ONO_2 and COOH groups decreases also (from 2.40 to 1.73) with increasing content of carboxy groups, which confirms the assumption that COOH and OH groups react to form ester bonds, decreasing the amount of OH groups subject to nitration.

A kinetic study of the nitration (Fig. 3) showed that the nitration rate is different with carboxy starch samples differing in the content of carboxy groups, which may be due to different accessibilities of OH groups to the nitrating agent. The highest esterification rate is observed in the samples with high content of COOH groups (DS_{COOH} 0.74), whose grains underwent profound structural transformations, with significant breakdown of ordered regions and of the hydrogen bond system in the course of oxidation. With this sample, the limiting degree of nitration is attained within 3–5 min. By contrast, in low-oxidized samples, the limiting stage is the diffusion of the nitrating agent to active centers, and the reaction is complete in much longer time (~2.5 h). Carboxy starch samples with low content of COOH groups get strongly hardened after oxidation and drying in air, which also considerably decreases their reactivity.

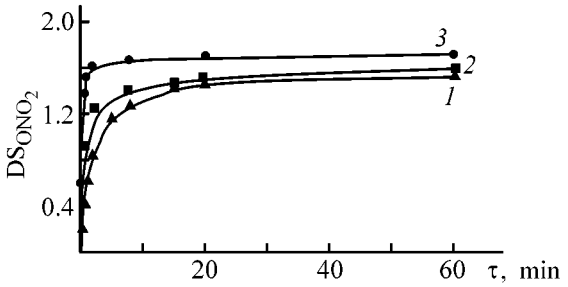

Fig. 1. Accumulation of nitrate ester groups, DS_{ONO_2}, with time τ of esterification of carboxy starch (DS_{COOH} 0.51) with the nitrating mixture $HNO_3 : H_3PO_4 : P_2O_5$ 66.8 : 28.2 : 5; bath ratio 1 : 5; the same for Figs. 2 and 3. *T*, °C: (*1*) 0, (*2*) 18, and (*3*) 35.

66.8 : 18.2 : 15	1 : 50	3.84	0.53	12.84	76.3

Table 1 shows how the degree of nitration and the product yield and properties are influenced by the composition of the nitrating mixture and the bath ratio. It is known that the major factor governing the degree of nitration is the water content in a nitrating mixture. Table 1 shows that, with increasing water content, the nitrogen content in the product decreases. The presence of water in the nitrating mixture affects not only the degree of nitration of carboxy starch, but also its other properties. At increased water content, more soluble nitration products are formed, but their yields are lower. This is due to the increased hydrolytic and oxidative effect produced on starch by water-rich nitrating mixtures. A decrease in the HNO_3 content from 66.8 to 40 wt % has virtually no effect on the content of nitrate ester nitrogen; the degree of nitration considerably decreases only when nitration is performed with mixtures containing 20 wt % HNO_3 (both anhydrous and aqueous). This may be due to insufficient swelling of modified starch in viscous phosphoric acid and slow diffusion of the nitrating mixture inside the polysaccharide grains. Furthermore, experiments showed that the nitration is the more active, the higher the HNO_3 content in the bath. As seen from Table 1, the best bath ratio is 1 : 50; it ensures high degree of substitution and saving of chemicals. It should be noted that, under any nitration conditions tested, phosphorylation of carboxy starch was insignificant: the phosphorus content in the final products did not exceed 0.15%.

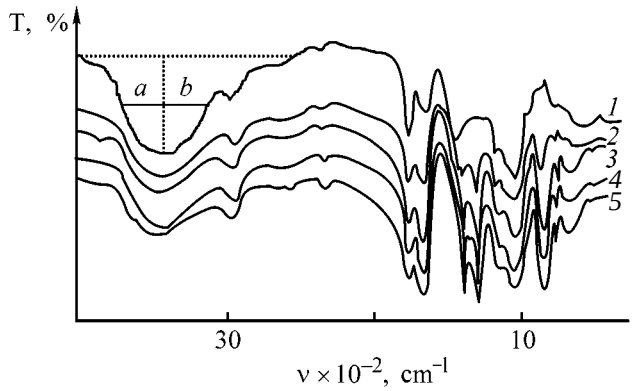

Fig. 4. IR spectra (400–4000 cm^{-1}) of (*1*) carboxy starch with DS_{COOH} 0.51 and (*2*–*5*) its nitration products with varied content of nitrato groups. (T) Transmission and (ν) wave number. DS_{ONO_2}: (*2*) 0.54, (*3*) 1.08, (*4*) 1.32, and (*5*) 1.64.

Figure 4 shows IR spectra of carboxy starch and its nitrate esters with varied content of nitrato groups. The most significant changes in the IR spectrum of CSN, compared to carboxy starch, are due to vibrations of nitrato groups manifested at 1700–1600, 1260–1310, 800–900, and 600–750 cm^{-1}. The IR spectra of all the nitrated samples contain a strong band of antisymmetric stretching vibrations ν_a(N=O) at 1650 cm^{-1} and a band of the symmetric mode ν_s(N=O) at 1280 cm^{-1}. These bands are highly characteristic and are independent of the localization of nitro groups and of the degree of substitution. A broad strong band at 838 cm^{-1} is mainly due to N–O stretching vibrations, with a certain contribution of O–N=O bending vibrations. Also, the IR spectra of CSN contain bands at 747, 675, and 827 cm^{-1}, belonging to the bending modes of the CCO, CON, and O–N=O groups. The IR spectra of CSN samples with any content of nitrogen and carboxy groups contain a band at 1375 cm^{-1}, absent in the spectra of nitro starch. Its intensity grows with increasing degree of nitration. Ivanova *et al.* [9] believe that this band is due to

vibrations of free NO_2 groups. It is quite probable that this band originates from vibrations of the NO_3^- ion (1350–1390 cm^{-1}), since one of the decomposition products of the nitrate esters is nitric acid. Presumably, all the CSN samples contain certain amounts of free or weakly bound NO_2 and HNO_3 molecules. This is, most probably, due to gradual local acid hydrolysis of nitrato groups, promoted by carboxy groups of the polysaccharide; their acidity in air-dry samples is sufficient to cause slow saponification of the nitrato groups. Experiments showed that, the higher the content of COOH and ONO_2 groups in the modified starch macromolecule, the faster the hydrolysis with the release of decomposition products and the greater its extent. Prolonged storage of such samples results in complete degradation of the polysaccharide with the formation of water-soluble oligomeric products. Therefore, for the subsequent biological activity tests, the samples were converted to salts by dissolution in 5% $NaHCO_3$ (pH 8.2), followed by dialysis against distilled water and isolation of the product by lyophilic drying. The sodium salt of CSN can be stored for a long time without noticeable changes.

In the range 3100–3700 cm^{-1}, the IR spectra contain broad bands of irregular shape, belonging to ν(OH) stretching vibrations. These bands are due to H-bonded hydroxy groups in modified starch. The most probable proton acceptors are nitrato groups, other OH groups, COOH groups, and O(5) oxygen atoms of pyranose rings. As seen from Fig. 4, the OH band with a peak at 3400 cm^{-1} decreases in intensity upon esterification of carboxy starch, as the content of nitrato groups increases. In the IR spectrum of CNS (DS_{ONO_2} 1.64), an additional band appears with a maximum at about 3650 cm^{-1}, characteristic of free hydroxy groups.

Carboxy starch should be considered a mixture of granules differing in accessibility to reactive agents. In the course of a heterogeneous reaction, the accessible regions of the modified polysaccharide grains are esterified first. Hence, as the reaction proceeds, the distribution of hydroxy groups with respect to hydrogen bonding energy must change. In heterogeneous nitration of carboxy starch, the most accessible hydroxy groups involved in the weakest hydrogen bonds react first. As these groups are consumed, the relative amount of OH groups involved in stronger hydrogen bonds increases. In this case, the symmetry index a/b (Fig. 4) must decrease, since the relative absorption from the low-frequency side (associated with the parameter b) must increase. At the same time, the progress of substitution and introduction of nitrato groups in place of hydroxy groups must cause the strength of hydrogen bonds between the remaining groups to decrease, owing to steric hindrance. This, in turn, must shift the OH absorption maximum in the IR spectrum [ν(OH)] toward higher frequencies.

Table 2. Absorption frequency of OH groups and the band symmetry at various degrees of nitration of carboxy starch (DS_{COOH} 0.51)

c_N, wt %	DS_{ONO_2}	Symmetry index of OH band, a/b	ν_{OH}^{max}, cm^{-1}
Carboxy starch (DS_{COOH} 0.51)	–	0.87	3385
3.90	0.54	0.83	3415
6.94	1.08	0.81	3415
8.11	1.32	0.78	3430
9.45	1.64	0.50	3485

The parameters of the OH band in the IR spectra of nitrated carboxy starch samples are listed in Table 2. It is seen that, with increasing degree of substitution, the absorption peak shifts toward higher wave numbers, which was previously interpreted as a gradual increase in the content of hydroxyls involved in weak hydrogen bonds. Along with this trend, the OH band becomes more asymmetric (up to DS_{ONO_2} 1.64), which suggests existence of hydroxy groups that are involved in strong hydrogen bonds and remain intact in the reaction. This is quite natural, in view of the above reasoning.

Thus, carboxy starch is structurally nonuniform, and this nonuniformity affects the course of *O*-nitration and the composition of the resulting products.

CONCLUSIONS

(1) The *O*-nitration rate can be considerably increased by raising the temperature from 0 to 35°C. A decrease in the COOH content in the initial carboxy starch and an increase (to 40 wt %) in the nitric acid concentration (in both anhydrous and aqueous nitrating mixtures) result in appreciably higher content of nitrato groups in the final product.

(2) The results of this work allow prediction of conditions necessary for obtaining carboxy starch nitrate esters with prescribed composition in high yield.

(3) The nitrated carboxy starch samples were characterized by IR spectroscopy; free NO_2 and/or NO_3^- species were detected, originating from acid hydrolysis of ONO_2 groups, promoted by carboxy groups of

the polysaccharide. The content of these groups grows with increasing content of ONO_2 groups in nitrated carboxy starch samples.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

New Effective Binary Formulations for Inhibiting Thermal Polymerization of Styrene

A. F. Gogotov, M. V. Parilova, and A. K. Khaliullin

Received February 6, 2002

Abstract—Synthesis of effective formulations for inhibiting thermal polymerization of styrene, based on sterically hindered phenols, is reported.

Styrene, like many other commercially significant monomers, extremely readily polymerizes upon heating; therefore, its distillation should be performed with addition of inhibitors. Undesirable polymerization in the course of distillation impairs the economical parameters of the process and results in frequent interruptions of the process to remove polymer deposits. In Russia, the most widely used inhibitor of styrene thermal polymerization is *p*-quinone dioxime (QDO) [1, 2], a typical scavenger of alkyl radicals, in combination with various synergistic additives. In the US, Europe, and Japan, have long been using, styrene-producing plants use soluble inhibiting systems based on more effective inhibitors, including inhibitors of the latest generation, nitroxyl radicals [3]. In particular, Nalco Exxon (the US) and Kurita (Japan) produce a wide range of inhibiting formulations containing nitroxyl radicals. In Russia, unfortunately, components of many modern inhibiting systems are not produced commercially (there are only a few patents on this matter [4, 5]); therefore, efforts are still being made to improve commercially used formulations based on QDO with the aim to enhance their performance and decrease the consumption of the main inhibitors. The well-known drawbacks of QDO are low solubility in aromatic hydrocarbons and high toxicity. Therefore, development of effective QDO-free inhibiting formulations is an urgent problem.

The goal of this study is to extend the range of soluble QDO-free inhibiting formulations and enhance their inhibiting effect on thermal polymerization of styrene in the course of its distillation from process solutions.

EXPERIMENTAL

The performance of the inhibiting formulations was evaluated under laboratory conditions with pure freshly distilled styrene or with styrene-containing process solutions, with access of air (no purging with inert gas). The testing procedure consisted in determination of the polystyrene yield after heating of the freshly vacuum-distilled monomer at 120°C for 2–7 h, because polymerization of styrene is considerably slower at temperatures lower than 115–118°C.

Styrene (100 cm^3, 90.6 g) was placed in an autoclave, and weighed portions of the inhibiting formulation components were added. The autoclave was sealed and placed in a thermostat heated to 119 ± 1.5°C. After the first 2 h of heating, samples were taken every hour. The samples were distilled on a boiling water bath at 20 mm Hg. The inhibition efficiency was judged from the amount of the polymeric residue (% of the sample weight). With styrene-containing process solutions, the inhibiting components were taken in proportions corresponding to the styrene content in these solutions.

One of the ways to enhance the performance of inhibiting formulations is to use, in combibation with QDO, various phenolic coinhibitors acting as synergistic additives [6]. Experiments show that, when taken in larger amounts, the coinhibitors can be sufficiently effective not only in combination with QDO but also without it. As examples can serve systems QDO + Ionol + TBPC [7] and Ionol + TBPC [8]; QDO + MB + PNP [2] and MB + PNP [9]; QDO + MB + PCF [10] and MB + PCF [11] {MB, Mannich

Isomeric methyl-1,3-dihydroxybenzenes	14.8
Isomeric dimethylethyl-1,3-dihydroxybenzenes	13.7

Based on these results, we attempted to develop a binary inhibiting formulation consisting of MB and a known phenolic inhibitor, TBPC, instead of PNP, which showed poor performance in other formulations. Along with TBPC, we tested as a dihydric phenolic coinhibitor the so-called pyrocatechol fraction of dihydric phenols from the coal-tar plant of the Angarsk Petrochemical Company. The formulations of MB with PCF and TBPC show similar performance, as suggested by the results of laboratory tests (Table 1).

Table 1 shows that the proposed inhibiting formulation (MB + dihydric phenols; run nos. 2, 7) is considerably more effective than the known formulation (run no. 3) [12]. Partial replacement of stearic acid with a dihydric phenol (run no. 4) decreases the formation of the polymer, and full replacement of the aliphatic acid with a pyrocatechol derivative (run nos. 2, 5) sharply (by a factor of about 20) suppresses the formation of the polymer under similar conditions.

Partial decrease in the MB content (by 25%, run no. 6, or 50%, run nos. 7, 10), compared to run no. 3 [12], does not impair the performance. A decrease in

* At 100°C. ** At 90°C.

the content of dihydric phenols by a factor of 2 impairs somewhat the performance (run no. 9). Change in the OM : PCF ratio from 1 : 1 (run no. 2) to 1 : 2 (run no. 10) enhances somewhat the inhibiting activity of the formulation.

An individual dihydric phenol, TBPC (run no. 5), shows somewhat higher performance than a mixture of phenols (PCF, by-products from coal-tar plants, run no. 2; for the composition of PCF, see Table 2; the sample used contained ~45% pyrocatechol and hydroquinone derivatives and ~30% resorcinol derivatives).

At lower heat-treatment temperatures (100°C, run nos. 11, 12; 90°C, run no. 13), the inhibiting power of the formulation proposed remained high, and the polymerization was almost fully suppressed.

In industry, styrene is distilled from a mixture consisting approximatelly by half of alkyl-substituted aromatic hydrocarbons (for the composition, see Table 3). The inhibiting formulations based on dihydric phenols and MB were tested with this crude mixture and efficiently inhibited thermal polymerization of styrene in the course of its distillation (run nos. 14–17).

It has been noted previously that the inhibiting effect of MB-containing formulations is associated with the acid–base interaction of protons of an organic acid with the lone electron pair of the nitrogen atom of benzylamine [13]. It is quite probable that pyrocatechols, in which phenolic hydroxyl protons are fairly labile, can efficiently replace organic acids in MB-containing formulations; however, such acid–base interactions are typical of aqueous, rather than hydrocarbon solutions. Apparently, the longer inhibiting effect of the binary formulation, compared to its components taken separately, may be due to regeneration of MB by the reaction of the phenoxyl radical formed from it with TBPC. In the process, TBPC transforms into monoradical and then *o*-quinone; furthermore, in the quinoid form it scavenges alkyl radicals. It is quite possible that, as noted in [14], the pyrocatechol derivative and MB form an activated complex which deactivates variable-valence metals in rubbers and radical species in our system.

Along with the systems MB–TBPC and MB–PCF [11], we also tested formulations consisting of a monohydric phenol (Agidol-1) or bisphenol (Agidol-2) and TBPC (1 : 1.5 or 1 : 2 ratio; Tables 4, 5).

Tables 4 and 5 indicate that bisphenols (by the example of Agidol-2) show higher inhibiting power than mononuclear phenols (Ionol) [15].

Thus, virtually any inhibiting formulation containing QDO can be reformulated with elimination of QDO. This preliminary conclusion can be illustrated by the following example. Previously, we proposed an effective formulation for inhibiting thermal polymerization of styrene, consisting of QDO and vanillin barbiturate (VB) [16]. As noted in [17], VB taken separately possesses no inhibiting properties. However, a QDO-free mixture of VB with TBPC effectively inhibits thermal polymerization of styrene in the course of its heating at 120°C for several hours (Table 6).

Table 6 shows that the 1 : (1.5–2.0) ratio of mono- and dihydric phenols in inhibiting formulations for thermal polymerization of styrene, which proved to be optimal for sterically hindered phenols (Ionol, Agidol-2, MB), is also appropriate with methoxylated phenols such as VB (run nos. 34, 35 and 43, 44). Run nos. 39 and 41 also gave satisfactory results,

Table 7. Comparison of various inhibiting formulations

Formulation no.	Composition	Inhibitor content, wt %	*T*, °C	Heating time, h	Polymer yield, wt %
1	Sinoms-5	0.11	120	6	1.1
		0.082	120	6.5	2.88
2	Sinoms-6	0.11	120	6.5	0.74
		0.082	120	6	1.2
3	QDO + hydroquinone	0.05	120	6.5	1.3
4	QDO + PNP	0.05	120	6	2.5
5	MB + PNP	0.1	120	6	3.88
		0.075	100	6	1.1
6	Naugard 1-5	0.1	120	6	1.6
7	Naugard 1-31	0.1	120	6	0.49
8	MB + TBPC	0.075	120	6	0.54
9	MB + PCF	0.105	120	6	0.45
10	MB + TBPC	0.090	100	6	0.30

despite the fact that the component ratios in the inhibiting formulation were not optimal.

Our results are a step forward in the development of effective inhibitors based on 4-*tert*-butylpyrocatechol [18–20]. The proposed formulations MB + PCF and MB + TBPC (Table 7) were compared in performance and total consumption of the inhibitor with the previously tested systems inhibiting thermal polymerization of styrene.

As seen from Table 7, the inhibiting formulations proposed (nos. 8–10) well compete in performance with actively advertised formulations like Naugard (nos. 6, 7) and contain no toxic components.

Thus, we have developed fairly effective soluble inhibiting formulations for styrene production, based on mixtures of mono- and dihydric sterically hindered phenol derivatives.

CONCLUSIONS

(1) A series of hydrocarbon-soluble formulations for inhibiting thermal polymerization of styrene, based on mono- and dihydric sterically hindered phenols and containing no *p*-quinone dioxime, were developed.

(2) Coinhibitors used in combination with *p*-quinone dioxime can also be used in dioxime-free formulations; however, to preserve the high inhibiting power, these compounds should be taken in larger amounts.

Abstract—The protective film (≤1000 Å thick) formed on the copper foil surface upon friction of a steel roller lubricated with industrial oil containing 5% fullerene C_{60} was studied by optical and electron microscopy, X-ray diffraction (XRD) analysis, hardness measurements, and mass spectrometry. This protective film is probably a fullerene-polymer network formed by fullerene C_{60} and covalently bound fragments of hydrocarbon chains released in the course of mechanochemical degradation of the lubricating oil. The film exhibits elevated hardness and antiwear properties, and increases the load-carrying power of the tribotechnical unit. Chemical mechanisms of tribopolymerization were analyzed.

Even the first data on the antiwear properties of fullerenes [1–3] showed that this material is promising for tribotechnical applications. At the same time, fullerenes and their modifications did not decrease significantly the friction coefficient in the case of dry and boundary sliding friction of solids. However, systematic study of tribological properties of fullerenes and materials based on them was continued in [4–6]. It was found that the addition of fullerene-containing materials to lubricating oils significantly improves the antiwear and antiscuff properties of tribotechnical units and expands the allowable pressure range by a factor of 1.5–2. Boundary sliding friction of a steel roller on a copper foil lubricated with an oil containing 5% C_{60} gives almost smooth shining friction surface. It was assumed that, during friction treatment, a thin antiwear film is formed on the copper surface. The effect of fullerene additives on I-40A industrial oil was studied by mass-spectrometric thermal analysis (MTA) in [7]. The results showed that fullerene C_{60} reacts with naphthene and paraffin components of the oil in the course of heating or friction; samples of the copper foil after their friction treatment with I-40A oil containing C_{60} were also analyzed [7]. In the presence of fullerene, the major peaks in the mass spectra were shifted toward lower temperatures, which was attributed to covalent linking of hydrocarbon radicals to fullerenes with the formation of a weak β-bond. Such an interpretation was based on published data for fullerene C_{60} with grafted polymeric chains [8]. Hence, it was suggested that the antiwear structure on the copper surface is a tribopolymeric hydrocarbon network in which the fullerene molecules occur predominantly at the network points. It was also concluded [7] that, in the course of friction and thermal treatment, fullerene acts as a trap for free radicals arising from mechanochemical degradation of naphthene and paraffin molecules and initiates polymerization of the fragments of the above hydrocarbons.

In this work, we studied the friction surface structure of the copper foil formed in the presence of fullerene C_{60} and analyzed possible chemical mechanisms of formation of the tribopolymeric network with the participation of C_{60} and atmospheric oxygen contacting the friction surfaces.

We used fullerene C_{60} (99.7%)[1] and I-40A industrial oil. To prepare the required 5% lubrication compositions, finely dispersed fullerene was added to the oil and stirred.

The tribological properties were tested on a 2070 SMT-1 friction machine according to the roller–shoe scheme. A mobile roller (46 mm diameter, 16 mm width) was prepared from 18Kh2N4MA chromium-

[1] Khromotron project, Russian Scientific and Technical Program "Fullerenes and Atomic Clusters," 1994.

1070-4272/02/7508-1330 $27.00 © 2002 MAIK "Nauka/Interperiodica"

nickel-molybdenum wear-resistant steel; the speed of rotation was 400 min^{-1} (1 m s^{-1} linear velocity). The shoe was crimped with a 200-μm commercial copper foil (10 mm width, 2 cm^2 nominal contact area). An oil drop (0.5 g) was placed on the foil surface, and the pressure on the tribotechnical system was increased stepwise to 4–6 MPa.

The XRD patterns were registered on a Dmax-RC (Rigaku) single-crystal diffractometer (Cu_{K_α} radiation, Ni filter). The friction surfaces were studied using a CamScan 4-88DV-1000 scanning electron microscope (accelerating voltage 15 kV), an EM-420 transmission electron microscope (accelerating voltage of up to 100 kV), and an MIM-8 metallographic microscope.

In our experiments, we analyzed copper foils (1) before their treatment; (2) after friction treatment with I-40A lubricant, including the mode of elevated wear resistance [9] attained by slowly increasing the pressure on the tribotechnical unit; and (3) after treatment in the presence of the lubricant containing 5% C_{60}. The surfaces of failure of the copper foils, obtained in the course of stretching in liquid nitrogen of preliminarily notched samples, were also studied. Owing to low temperature of stretching, structural distortions due to plastic deformations were eliminated.

Tribological tests. Two most typical dependences of the friction momentum on time are shown in Fig. 1. Curve *1* is observed for straight I-40A oil in which the friction momentum, providing scuffing, starts to increase at rather small loads (300–600 N), whereas the tribotechnical unit with the lubricant containing C_{60} (curve *2*) operates for a long time in the 800–1200 N load range. In the latter case, the friction coefficient is as low as 0.015–0.030; this level is not attained with straight oil or its mixtures with other carbon additives (graphite, carbon black, and fullerene black after extraction of the main fullerene fraction). In the presence of C_{60} in the lubricating oil, almost entire friction surface of copper becomes smooth and bright, and no copper traces and wear particles are observed on the steel roller, in the lubricant, and on the friction surface. Further rubbing of the roller or substitution of the modified lubricant with straight oil does not affect stable operation of the tribotechnical unit, and the friction coefficient remains as low as in the presence of C_{60}. This suggests the formation of the antifriction antiwear structure on the copper friction surface.

Optical microscopy. The surface of the initial foil exhibits grooves oriented in the rolling direction (Fig. 2a). After friction with the lubricating oil, these

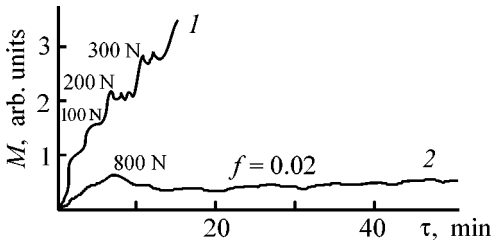

Fig. 1. Friction momentum of the steel roller on the copper foil with (*1*) I-40A lubricant and (*2*) I-40A + 5% C_{60} at stepwise loading of the friction system. (*M*) Friction momentum, (τ) time, and (*f*) friction coefficient.

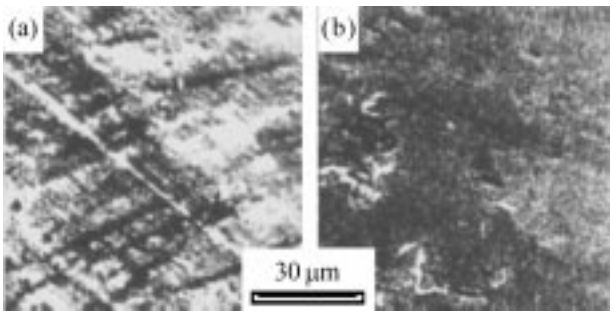

Fig. 2. Photomicrographs of the copper foil surface (a) in the initial state and after treatment with lubricant I-40A + 5% C_{60} and (b) after friction treatment with straight I-40A oil.

groves disappear, the surface becomes fairly uniform, and visual determination of the directions of rolling and even friction becomes impossible (Fig. 2b). After friction with the lubricant containing fullerene C_{60}, the initial grooves are retained, but a protective film is formed on the surface (Fig. 2a).

Scanning electron microscopy (SEM). The SEM data on the surface relief of the copper film are similar to those of yielded by optical microscopy: in the presence of fullerene, the initial surface relief is retained and the surface is coated with a thin film, whereas operation in the straight lubricating oil (even in the elevated wear resistance mode) significantly modifies the material structure.

Additional data on the structure of surface layers were obtained with the samples ruptured in liquid nitrogen. After the fullerene-free friction, the area near the foil rupture exhibits fragments of the surface layer with changed structure, and, as seen at large magnifications (Fig. 3a), the surface layer consists of spherical submicrometer particles (region A). It should be noted that no analogous surface layers were observed in the initial copper samples ruptured in liquid nitrogen, i.e., it is formed in the course of friction treatment. In the case analyzed, the thickness of this layer reaches nearly 3 μm, and its structure signi-

ficantly differs from the structure of the deeper lying coarse-grained material. Moreover, there are no grooves formed during rolling or friction treatment of the surface, which is coated with very thin smooth layer (region B) with the thickness ≤100 nm. This confirms our conclusion that the surface structure of the copper foil changes after its operation with the straight lubricating oil.

After friction in the presence of C_{60} we found no fragment of the surface layer whose structure differed from the initial structure. As seen (Fig. 3b), the friction surface near the foil rupture zone exhibits micrometer surface irregularities whose surface is coated with a film worsening the micrograph contrast. The resulting surface differs from the friction surface formed during treatment in the presence of straight I-40A oil. The layer formed on the copper surface looks like a polymeric film, it is broken in the rupture area and often dangles from the fracture edge; no structural modifications of the surface copper layers or formation of dispersed particles are observed (cf. Fig. 3a).

XRD data. The protective properties of the resulting film are confirmed by wide-angle X-ray diffraction analysis (Fig. 4). The initial structure of the foil (curve *1*) remains unchanged after friction treatment for several hours in the presence of a lubricating oil containing C_{60} (curve *2*). After treatment with the straight lubricant, the surface structure changes sharply (curve *3*): peak 111 increases, and peaks 200 and 400 decrease in relative intensity, with peak 200 becoming smaller than peak 220 (in the initial samples, the pattern was inverse).

Due to the small thickness, the resulting film itself does not noticeably affect the X-ray diffraction; we failed to exfoliate the protective film from the foil and directly study its structure. This film did not dissolve in toluene and other organic solvents. Hence, we used another approach.

Transmission electron microscopy (TEM). The direct confirmation of the presence of a protective film and some data on its structure were obtained by TEM. The foil was treated by ion etching (from the back side) until formation of a hole with a shape of truncated cone (Fig. 5a). Different sections of the material profile formed in this procedure were studied against dark and light background in combination with electron diffraction. The direction of the electron beam coincided with that of the etching ion beam. The pattern of the hole edge in the foil operating with fullerene-free lubricant in the wear-resistant mode [9] is shown in Fig. 5b. In this case, a protective film, which is observed at the hole edge, is formed too. This film has an amorphous structure (no reflections on the corresponding electron diffraction patterns are observed), it thickness reaches 100 Å, and it is fairly resistant to the electron beam. The surface layer has fine structure with crystallite size of 0.1 μm, which agrees with the SEM

data [9]. As seen from Fig. 5b', this layer consists of copper crystallites with admixture of Cu_2O particles.

After friction treatment in the presence of C_{60}, no fragmentation of the surface copper layer was found (Fig. 5c). The resulting surface film is also amorphous and its thickness is an order of magnitude thicker (1000 Å) than in the case of fullerene-free friction and thus is revealed in the electron diffraction patterns. This may be due to the reduced energy of β-bonds in the hydrocarbon chains covalently bound to C_{60} [7] and to decreased heat transfer through the thicker film. The electron diffraction pattern of the film and surface layer corresponds to a textured lattice of Cu_2O [111] with interlayer spacing of 2.45 Å. In the dark-background pattern of the film in the light of reflections 200 [copper(I) oxide] and 111 (metallic copper), nearly overlapping with each other, particle inclusions of 100–1000 Å size are seen, which are obviously the wear particles formed in the initial moment from the oxidized surface material. There are no reflections of crystalline fullerene C_{60} and its derivatives in the diffraction patterns. This fact does not mean that fullerene does not participate in the film formation. The results of tribological studies and the data on the surface structures registered in the case of straight fullerene and its 5% additives to the lubrication oil are the same. Nearly equal positive effect of small fullerene additives (0.5–0.75%) confirms our assumption that C_{60} initiates tribochemical polymerization of hydrocarbons present in petroleum oils, which promotes formation of a protective film of increased thickness.

Chemical mechanisms of tribopolymerization. First of all, we should determine whether the concentration of C_{60} is enough to a form continuous layer on the friction surface. The area of the friction surfaces of the samples in question was nearly 2 cm^2, and the real gap between them was 1 μm. At 5% concentration of fullerene in the lubricating oil, the total amount of the molecules in the gap is 0.8×10^{16}. At hexagonal close packing of fullerene, each C_{60} molecule occupies 100 $Å^2$, and thus the molecules present in the gap can form 40 monolayers with compact packing of the molecules in them over the entire friction surface. The thickness of 40 monolayers reaches nearly 400 Å and reasonably agrees with electron-microscopic data on the protective film thickness (≤1000 Å). Thus, the concentration of fullerene C_{60} is enough to form a continuous film. The resulting film is insoluble in toluene; hence it consists of components other than unmodified molecular fullerene.

(b') Diffraction pattern of the block structure, which is a superposition of the diffraction patterns typical of Cu and Cu_2O crystal lattices. (c) the same as in Fig. 5b, but after treatment in the presence of I-40A + 5% C_{60} lubricant: (O) through hole, (A) 1000-Å surface film, and (B) surface copper layer with no block structure. (d) Dark-background patterns of film A in the light of reflections 200 (Cu_2O) and 111 (Cu); (D) wear particle inclusions.

Let us consider possible differences in the chemical mechanisms of tribochemical polymerization of industrial oil components in the presence and absence of

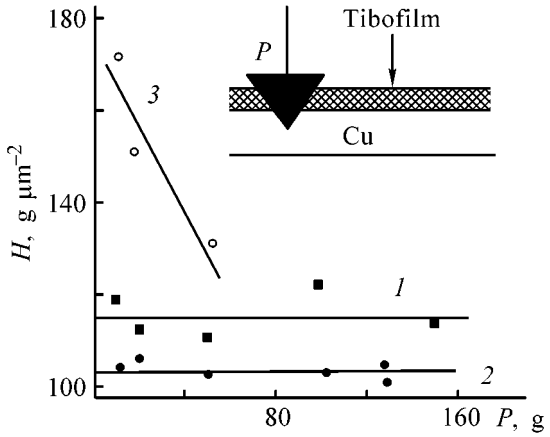

Fig. 6. Microhardness *H* of the copper foil surface vs. the indentor load *P*. The scheme of experiment is shown in the inset. Foil surface: (*1*) initial and after friction treatment in the presence of (*2*) I-40A and (*3*) I-40A + 5% C_{60} lubricants.

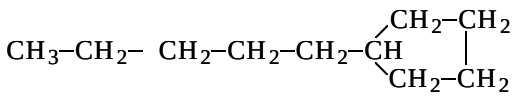
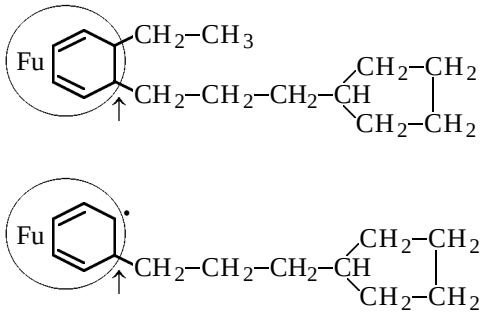
C_{60}. Fullerene is an effective scavenger of free organic radicals. This suggests its activity with respect to the radicals formed in the course of mechanochemical degradation of naphthene and paraffin molecules present in the oil. Each fullerene C_{60}, molecule can add up to 6 macroradical chains [10] forming a point of a three-dimensional tribopolymeric network. At the same time, in the absence of C_{60} analogous network points are formed in the course of multiple bond scission, chain transfer, and recombination of several radicals in a small volume, which requires considerably longer time.

It is known that, at elevated temperatures and pressures, C_{60} can from polymeric chains [11, 12]. The shear deformation activates various chemical processes in the region of mechanical contact [13], which suggests that it would promote polymerization of fullerene C_{60} at lower temperatures and pressures. Oil components can act as agents promoting formation of polyfullerenes. Let us analyze this mechanism for the example of naphthene molecules (molecular weight 140). In the course of friction, this molecule can degrade (energy of the C–C bond 260–270 kJ mol^{-1}), e.g., according to the following scheme:

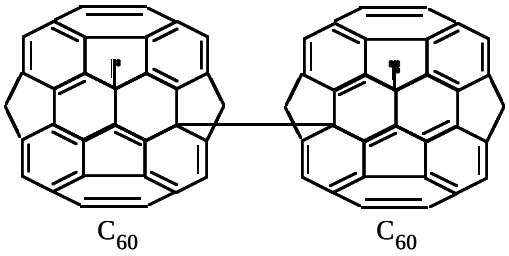


The resulting two radicals can react with a fullerene molecule by the following reactions with low activation energy (≈12–20 kJ mol^{-1}):



or

The β-bond denoted by an arrow has a dissociation energy 40 kJ mol^{-1} lower than that in the ordinary C–C bond and thus it can be broken at lower temperature and smaller mechanical impact. The scission of β-bonds results in the formation and accumulation of fullerene C_{60} radicals. Two such radicals can recombine [14] (with nearly zero activation energy) to form a dimer:



Formation of oligomeric or polymeric fullerene chains and also of two- or three-dimensional fullerene or fullerene-polymeric networks can be described similarly. The capability of C_{60} molecules to react with several macroradical chains obviously ensures accelerated self-restoration of the polymeric tribofilm damaged in the course of mechanochemical degradation. It should be noted that friction can change the density of points in the network and its mechanical and adhesion properties. Since friction treatment proceeds in air, oxygen must play a significant role in tribopolymerization. According to thermogravimetry, thermal oxidation of C_{60} proceeds at the highest rate at 400–600°C [15]. Oxygen reacts with fullerene at lower temperatures, and with the fullerene radical at the same temperature as in the case of the organic radical. For example, the reaction of alkyl radicals with oxygen at 20°C proceeds with nearly zero activation energy [16]:

$$R^{\bullet} + O_2 \rightarrow ROO^{\bullet} \begin{cases} + H \rightarrow ROOH \rightarrow RO^{\bullet} + {}^{\bullet}OH \\ + R_1 \rightarrow ROOR_1 \rightarrow 2RO^{\bullet} \end{cases}$$

$$R^{\bullet} + C_{60} \rightarrow RC_{60}^{\bullet} \begin{cases} + RO^{\bullet} \rightarrow RC_{60}OR \\ + O_2 \rightarrow RC_{60}OO^{\bullet} \begin{cases} + H \rightarrow RC_{60}OOH \\ + R \rightarrow RC_{60}OOR \end{cases} \end{cases}$$

etc.

The tribofilm obviously contains some oxygen. However, due to high reactivity of oxygen with respect to fullerene, the thermal-oxidation stability of the tribopolymeric film increases owing to extra-chain inhibition of the oxidation of the hydrocarbon film [17], which prolongs its operation life. Thus, the presence of C_{60} in the lubricating oil significantly affects the mechanism of chemical processes occurring under the conditions of tribopolymerization and thus changes the mechanical properties of the tribofilm.

Microhardness data. In the analysis of changes in the microhardness of the friction surface of a copper foil, we should note two main factors (Fig. 6). First, the microhardness of the surface layer after friction treatment in the presence of C_{60} is significantly higher (curve *3*) as compared to the initial sample or to the foil after its treatment with straight lubricating oil (curve *2*). Second, after the friction treatment in the presence of C_{60}, the dependence of the microhardness on the load (i.e., in the course of indentor penetration into the material bulk) is descending, showing that the surface layer is harder than the bulk of the material.

It is known that, at elevated temperatures and pressures and/or under the conditions of shear deformation, fullerene can yield several compounds with high hardness: diamond, amorphous carbon (amorphous diamond), and various polyfullerenes with two- and three-dimensional networks. Fragments of the above compounds are probably formed on the friction surface, which, in combination with tribopolymers bound with fullerenes and its modifications, causes its elevated hardness.

CONCLUSIONS

At boundary sliding friction of a steel roller over a copper rider in the presence of small additives of fullerene C_{60} in the lubricating oil, a film (≤1000 Å thick) is formed on the copper foil surface, which exhibits antiwear properties, enhances the bearing strength of the tribotechnical unit, and stabilizes its operation at fairly low friction coefficient. The data of physical and physicochemical methods suggest that this film is a fullerene-polymer network, which is formed by fullerene C_{60} and fragments of the hydrocarbon chains of the oil released during mechanochemical degradation.

Abstract—The possibility of combining an inorganic polymer, silicon dioxide sol, with urea-formaldehyde resins, was studied with the aim to prepare a binding agent for producing nontoxic chip boards. The kinetic characteristics of formaldehyde binding with silicon dioxide during complex binder curing were determined.

Urea-formaldehyde (UF) resins are widely used in chip board production. At present, the application of chip boards is, however, limited by the rather high emission of formaldehyde CH_2O. Formaldehyde can be bound with sorbents compatible with UF polymer, in particular, with silicon dioxide SiO_2 sol having large specific surface area [1]. As shown in [2], SiO_2 sol can be used as part of urea-formaldehyde binder (UF adhesive) in production of chip boards widely applied in furniture production, interior finishing, and construction. Stringent requirements imposed on the free formaldehyde content in chip boards make reasonable introducing SiO_2 sol into the UF adhesive formulation as a sorbent. For example, CH_2O emission from class E1 chip board should not exceed 10 mg per 100 g of the chip board.

The approach we took to preparing nontoxic efficient adhesive based on UF resin and SiO_2 sol is underlain by the physicochemical properties of silicon-containing compounds and the specific features of interaction of polymeric silicon dioxide with other polymers. We had to take advantage of combining the two mutually complementing components of the adhesive in chip board production.

Our study was concerned with 65% aqueous UF oligomer (UF resin) and SiO_2 sol. Sol characterization: $SiO_{2\,total}$ 21.02, Na_2O 0.51, and α-SiO_2 (relative to $SiO_{2\,total}$) 0.305 wt %; specific surface area 256 $m^2\,g^{-1}$; and particle diameter 10.7 nm.

It is found that, in the course of cross-linking, SiO_2 sorbs and strongly retains up to 15 wt % CH_2O. Therefore, the sorbing power of the sol can be utilized in absorption of CH_2O evolving during UF oligomer curing. The sorption of CH_2O was studied with a combined adhesive containing 85% UF resin and 15 wt % sol (in terms of dry substance). The UF resin containing no sol served as reference. The UF resin was cured in the presence of a catalyst and free CH_2O contained in the resin [3]. We monitored variation of the CH_2O content in the cured adhesive during its heat treatment simulating the hot pressing of boards. The rate constants for various stages of the CH_2O binding were determined using the formal-kinetics method.

The plot showing how the temperature in the reaction mixture varies in the course of curing of the UF resin–sol system, combined with the independently obtained plot showing how the CH_2O content varies in the course of curing under identical conditions revealed three stages corresponding primarily to the following processes: (a) reaction of the CH_2O contained in the resin and yielded by condensation of hyrdoxymethyl groups, as well as by breakdown of methylene ether bonds, with unsubstituted hydrogen atoms in amino groups of the oligomer; (b) sorption of CH_2O with SiO_2 sol during gelation; and (c) reaction between the residual CH_2O in the system and unsubstituted hydrogen atoms in amino groups of the polymer.

Table 1 presents the temperature ranges of the processes studied. These data are supplemented with the results of thermogravimetric (TG) and differential thermal (DTA) analyses, which also evidenced three stages of the process in the temperature ranges in-

* Curing temperature 100°C, curing time 5 min.

dicated. This allowed quantitative estimation of the contribution from SiO_2 sol to CH_2O binding in the course of curing: 30% of free CH_2O occurring in the system is sorbed by the sol.

The degree of formaldehyde binding in the course of curing of the initial resin was estimated at 0.21 wt %, and that in the course of curing of the combined binder, at 0.30 wt %, of which almost one-third of free CH_2O (0.10 wt %) is bound with the sol.

Taken together, these data allowed the rate constants for various stages of CH_2O binding and the contribution from the SiO_2 sol to the CH_2O binding reaction in the course of curing to be estimated by the formal-kinetics method. The rate of the CH_2O binding reaction for the sol significantly differs from that for the reference resin: 0.55 against 0.23 $dm^3\ mol^{-1}\ s^{-1}$.

Our results (Table 2) show that the SiO_2 sol in the cured adhesive tends to decrease the content of free CH_2O and of the water-soluble substances characterizing the degree of curing of the UF oligomer. The minimal effect corresponds to 15% SiO_2 sol; at this concentration the gelation time slightly increases, evidently, due to the system dilution with water making about 78.5 wt % of the sol.

The amount of free CH_2O contained in the combined adhesive is reduced by its sorption by colloidal SiO_2 particles, which significantly reduces the CH_2O emission as estimated under standard condition by the Brunner method [4], namely, 1.0 against 3.0 μg g^{-1} in the reference UF resin. This also reduces the CH_2O emission from chip boards based on the cured adhesive to 6–8 mg per 100 g of board against 15–20 for the reference sample.

The SiO_2 sol improves the glueing power of the adhesive under comparable conditions (Table 3). Pre-

Table 3. Influence of SiO_2 sol on the shear strength of adhesive joints, σ_{shear}, of the initial wood and that pretreated with sol

Sol in adhesive, wt %	σ_{shear} (MPa) at indicated glueing temperature, °C

30	6.1	6.5	9.0	8.0
No sol (reference)	4.6	6.0	5.3	6.4

treatment of the wood surface with SiO_2 sol, followed by glueing of the treated surfaces with UF resin, additionally increases the adhesive strength. The data in Table 3 refer to 0.5 g m^2 of the sol spent, which must afford a monolayer of SiO_2 particles coating the wood sample. This is due to the fact that the formation of siloxane bonds between the colloidal SiO_2 particles of the combined adhesive involves the SiO_2 particles occurring on the wood surface, which, in turn, participate in hydrogen bonding with hydroxy groups of the wood components.

The enhanced strength of the adhesive joint with the combined adhesive is also due to increased cohesion strength of the adhesive proper. This is evidenced by the rupture tests with model samples of filter paper as adhesive carrier, whose intrinsic strength is 8 MPa. After curing at 105°C, the strength of the samples of the filter paper impregnated with sol-containing UF adhesive increased, compared to the samples impregnated with UF resin, from 34.1 to 44.0 MPa. This evidences the cross-linking effect of the SiO_2 sol on the UF oligomer. It can be assumed that simultaneous curing of UF resin and SiO_2 sol yields a composite with a different, stronger supramolecular structure with interpenetrating networks [5].

Thus, we substantiated the beneficial effect of the SiO_2 sol on the properties of UF adhesive and its suitability for producing wood boards characterized by the class E1 formaldehyde emission.

EXPERIMENTAL

We studied colloidal silicon dioxide (SiO_2 sol) available from the Cherepovets Metallurgy Combine (TI 105-ST.PS–0.1.89) and UF resin of the KF-MT-15 [GOST (State Standard) 14231–86] brand.

The total content of $(SiO_2)_n$ in the sol was estimated spectrophotometrically, and the Na_2O content, by titration with 0.1 M HCl solution [6]. The fraction of monomeric α-SiO_2 was estimated from the reaction with molybdic acid. The average particle size for $(SiO_2)_n$ was calculated from the specific surface area of the sol, which was estimated by the Sears method [6].

The UF resin was analyzed by the procedure from [7]. The amount of the CH_2O bound with the sol was determined after keeping the sol in 10% Formalin at 100°C for 2 h, as the difference between the initial and final CH_2O concentrations (estimated by potentiometric titration with hydroxylamine).

The CH_2O biding kinetics in curing of UF adhesive with and without sol were monitored by the CH_2O content in the samples taken in curing the adhesive at 100°C with 10-min intervals. The glueing power of the adhesive was estimated from the ultimate shear strength of adhesive joints for birch samples; the amount of the adhesive spent was 25 g m^{-2}.

Thermal analysis was carried out on an MOM derivatograph (Hungary).

CONCLUSIONS

(1) Inorganic polymer, silicon dioxide sol, can be combined with urea-formaldehyde resins with the aim to produce nontoxic boards (medium-density chip and wood-fiber boards). The silicon dioxide sol converts to gel and thus can bind the formaldehyde contained in the resin and evolving in the course of curing.

(2) The kinetic characteristics of the formaldehyde binding in the course of curing of the combined adhesive were determined. The rate constant of formaldehyde sorption by silicon dioxide sol was estimated at 0.55 dm^3 mol^{-1} s^{-1}.

(3) Silicon dioxide sol significantly improves the glueing power of the adhesive, compared to the reference, urea-formaldehyde resin, especially when the wood sufrace being glued is additionally treated with the sol.

Abstract—Copper(II) complexes formed in the interphase area between Thiokol–epoxy adhesive and brass support were studied using the method of the envelope of modulation of the electron spin echo.

Brass plating is a well-known and widely used method of strengthening adhesive joints between a metal and a rubber. High strength of rubber–brass adhesive joints is due to the interaction of macromolecules with a sulfide (Cu_xS, Zn_xS) film formed at the brass surface owing to chemisorption of sulfur added either as a vulcanizer or as an adhesive additive. The nature of this interaction is not yet fully understood. Some researches assume that the high adhesive strength is mainly caused by chemical bonds formed between rubber and surface sulfides, whereas others assume adsorption bonding, facilitated by the high specific surface of the sulfide film [1, 2]. In any case, the necessary component of the rubber stock is sulfur, since without sulfur the adhesion of rubber to the brass surface is poor.

Here we consider one of the factors governing the adhesion strength of such systems, namely, complex formation at the interface of brass and sealant based on polysulfide oligomer (liquid Thiokol). Previous studies have shown that, in contact of Thiokol sealant with the brass surface, paramagnetic copper(II) complexes are formed, and their concentration varies in parallel with the content of free sulfur added as an adhesive additive to the mixture [3, 4]. It has been suggested [3] that the ligands are organic and are coordinated via sulfur atom.

A more detailed study of the forming copper complexes is required in view of the established relationship between their concentration and the adhesion (Fig. 1). Additional data on the structure of ligands would give a possibility of directed control over adhesion characteristics of a sealant by varying its formula. In addition, these data are useful for development of theoretical concepts of the adhesion mechanism.

EXPERIMENTAL

The sealant composition was based on liquid Thiokol of the LP-977 brand (100 wt parts)

$$\begin{array}{l} CH_2{-}R_n{-}SH \\ | \\ CH{-}R_m{-}SH \\ | \\ CH_2{-}R_k{-}SH \end{array}$$

where $k + n + m = 12–14$ and R is $SSC_2H_4OCH_2OC_2H_4–$, and epoxy resin of E-40 brand (20 wt parts).

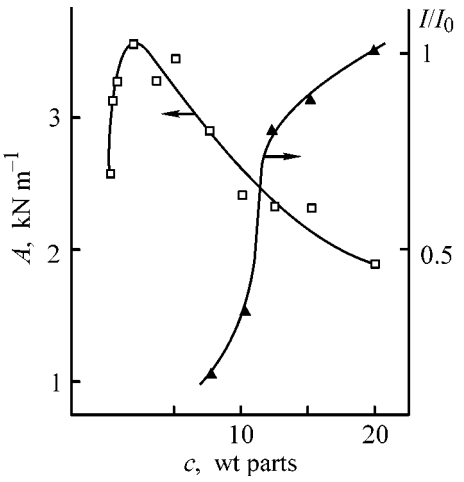

Fig. 1. Adhesion A and relative intensity I/I_0 of the ESR signal vs. sulfur content c.

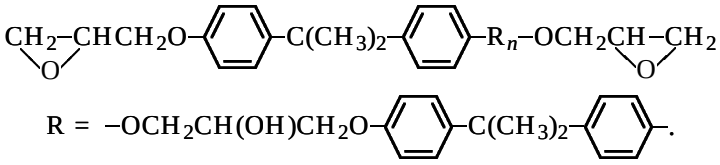
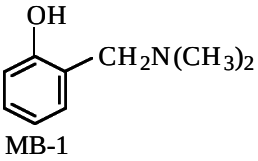
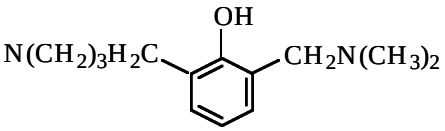
1070-4272/02/7508-1339 $27.00 © 2002 MAIK "Nauka/Interperiodica"



The copolymerization was initiated with a mixture of 2- and 2,6-dimethylaminomethylphenol (phenol Mannich bases, MB-1 and MB-2, respectively; 1.5 wt parts):



MB-1



MB-2

The mechanism of copolymerization of Thiokol and epoxy resin in the presence of MB has been discussed previously [5]. Polymeric sulfur S_8 (α-form) in the amount of 0 to 30 wt parts was used as an adhesive additive. Brass plates with relative copper content of 52.6% were used as supports. A mixture applied to the support was cured for 24 h under heating with hot air (80°C) [GOST (State Standard) 12.812–80)].

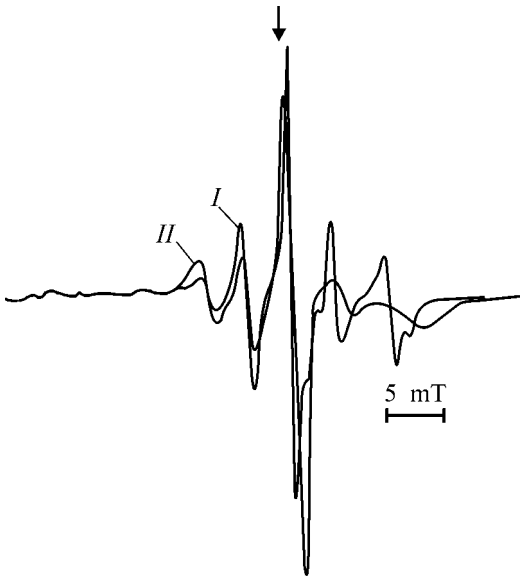


Fig. 2. (*I*) ESR spectrum of the copper complex in a sample containing 20 wt parts of sulfur. The arrow indicates the component excited in the experiments with ESE. (*II*) Spectrum of copper(II) dibutyldithiocarbamate $Cu(Budtc)_2$ in $Zn(Budtc)_2$.

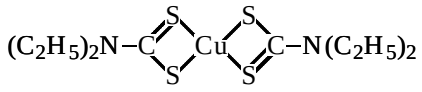
ESR measurements were performed with thin sealant layers (<0.5 mm) cut close to the brass surface. The ESR spectra were recorded on a Bruker ESP 300E spectrometer at room temperature. The experiments on electron spin echo (ESE) were carried out on a Bruker ESP 380 spectrometer at 18 K, using the two-pulse technique (primary ESE) [5].

The ESR spectrum of the sample is shown in Fig. 2 (spectrum *I*). The sample was a thin layer of the sealant in direct contact with the brass surface. The sealant bulk gave no ESR signal. The spin Hamiltonian

$$h = g_{\|}\beta H_z S_z + g_{\perp}\beta(H_x S_x + H_y S_y) + A_{\|} I_z S_z + A_{\perp}(I_x S_x + I_y S_y),$$

corresponding to this spectrum has the following parameters: spin $S = 1/2$; nuclear spin $I = 3/2$ (copper); components of the hyperfine coupling (HFC) tensor $|A_{\|}| = 15.67$ mT, $|A_{\perp}| = 3.77$ mT, $|a| = (|A_{\|}| + 2|A_{\perp}|)/3 = 7.74$ mT; components of the *g*-factor tensor: $|g_{\|}| = 2.086$, $|g_{\perp}| = 2.027$, $g = (|g_{\|}| + 2|g_{\perp}|)/3 = 2.047$.

The coordination of the complex is difficult to elucidate from this spectrum, since broad components of the ESR lines bear little information on ligands. To identify the complex, we recorded the ESR spectra of copper(II) dibutyldithiocarbamate $Cu(Budtc)_2$, a paramagnetic chelate of the following structure



In ether solution, $Cu(Budtc)_2$ gives a spectrum consisting of four lines due to isotropic HFC of unpaired electron with the copper nucleus ($I = 3/2$) with the parameters $|a| = 8.43$ mT and $|g| = 2.046$, which are close to the parameters of the complex in hand. In addition, according to published data [7], the components of the anisotropic HFC tensor for copper(II) thiocarbamates meet the conditions $T_{\|} < 0$ and $T_{\perp} < 0$, which is also in good agreement with the parameters of our complex at appropriate choice of signs of the HFC tensor components ($A_{\|} < 0$, $A_{\perp} > 0$). In a diamagnetic matrix [with addition of diamagnetic $Zn(Budtc)_2$ with subsequent removal of the solvent], $Cu(Budtc)_2$ gives the spectrum practically identical to the spectrum of our complex (Fig. 2, spectrum *II*).

The identity of the spectra and especially the correspondence of their magnetic resonance parameters suggest that the nearest environment of the copper ion consists of four sulfur atoms with the square planar geometry. In terms of the valence bond theory, this configuration is formed when hydridized dsp^2 orbitals of the copper(II) ion overlap with the σ orbitals of the sulfur atom [in the case of $Cu(Budtc)_2$ these are sp^2-hybrids]. Furthermore, there is good reason to believe that, similarly to copper(II) dithiocarbamate, the resulting species is a chelate compound. In particular, this follows from the equality of *g*-factors, whose values are extremely sensitive to the ligand charges.

More detailed data on the environment of copper(II) ion were obtained from analysis of the modulation of ESE envelope, due to HFC of unpaired electron with the magnetic nuclei of ligands [6]. According to [8], the envelope of the initial ESE $\langle V(\tau)\rangle$, averaged over the ensemble of systems containing one electron and one nuclear spin $I = 1/2$, has the form

$$\langle V(\tau)\rangle = 1 - \frac{3T_\perp}{10\nu^2} \times [2 - 4F(T_\perp\tau)\cos(2\pi\nu\tau) + \cos(4\pi\nu\tau) + F(2T_\perp\tau)], \quad (1)$$

$$F(T_\perp\tau) = \frac{15}{4}\int_0^\pi \{\cos^2\theta \sin^2\theta \cos[\pi T_\perp\tau(1-3\cos^2\theta)]\sin\theta\}\, d\theta,$$

where $T_\perp$ is the perpendicular component of the anisotropic HFC tensor; ν is the NMR frequency; τ is the time interval between pulses exciting ESE; θ is the angle between the magnetic field direction and *z* axis in the molecular coordinate system.

It is seen from expression (1) that, in disordered systems, HFC results in oscillation of the ESE envelope at frequencies ν and 2ν.

For quantitative description of modulation of the ESE envelope, we selected the dimensionless parameter

$$\lambda(\tau) = \frac{V_{max}(\tau) - V_{min}(\tau)}{V_{max}(\tau)},$$

where $V_{max}(\tau)$ and $V_{min}(\tau)$ are the extremum values of the ESE envelope.

This parameter is the degree of modulation and can be easily determined from experimental data. For low values of $T_\perp\tau$, expansion of $\lambda(\tau)$ in a series shows a linear dependence of $\lambda(\tau)$ on τ^2 [9]. When an electron interacts with *N* nuclei, the modulation of the ESE signal $V^N(\tau)$ is governed by the product of modulations $V^N(\tau)$ due to HFC with each particular nucleus. In this case, we can write the following equation for the parameter $\lambda(\tau)$:

$$1 - \lambda^{(N)} = \prod_{i=1}^{N}\left[1 - \lambda_i^{(1)}\right],$$

where $\lambda^{(N)}$ and $\lambda^{(1)}$ are the degrees of modulation due to HFC with *N* nuclei and one nucleus, respectively.

When nuclei are nonequivalent and form different coordination spheres containing N_j nuclei each, one can expect that several linear portions would be observed in the experimental dependence of λ on τ^2 according to the number of these coordination spheres. Commonly, nuclei localized in no more than two coordination spheres are distinguished, and more distant nuclei are considered matrix nuclei. By subtracting the contribution of matrix nuclei, as well as the component at the combination frequency 2ν, from the experimental dependence $\lambda(\tau)$, we can determine the dependence $\lambda_j^{(N)}(\tau)$ for neighboring coordination spheres. Then, using the expression obtained from the expansion of $\lambda(\tau^2)$ in terms of $\tau T_\perp$ [9]:

$$\lambda_j^{(1)}(0) = \frac{2\lambda_j'}{2a\nu^2\delta\lambda_j(\ln\delta\lambda_j) + \lambda_j'}, \quad (2)$$

we determine the degree of modulation $\lambda_j^{(1)}$ due to HFC with each nucleus of *j*th individual coordination sphere. In expression (2),

$$\lambda_j' = \frac{d}{d\tau^2}\lambda_j^{(N)}\Big|_{\tau=0}, \quad \delta\lambda = 1 - \lambda_j^{(N)}(0), \quad a = \frac{5\pi^2}{42}.$$

Knowing $\lambda_j^{(1)}$, it is possible to determine the number of nuclei N_j entering into *j*th coordination sphere:

$$N_j = \frac{\ln[1 - \lambda_j^{(N)}(0)]}{\ln[1 - \lambda_j^{(1)}(0)]}, \quad (3)$$

and the transverse component of the anisotropic HFC

$$T_\perp = \sqrt{\frac{5\nu^2\lambda_j^{(1)}(0)}{12}}, \quad (4)$$

which, in turn, allows determination of the distance *r* from the ion to nuclei of the coordination sphere, using approximation for interaction of point dipoles

$$T_\perp = \frac{\mu_0}{4\pi}\frac{g_e g_n \beta_e \beta_n}{r^3 h}, \quad (5)$$

where g_e and g_n are electron and nuclear *g*-factors, β_e is Bohr's magneton, β_n is the nuclear magneton, and *h* is the Planck constant.

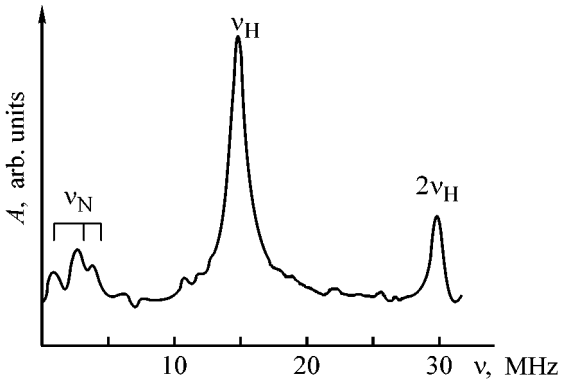


Fig. 3. Fourier image of the ESE envelope $V(\tau)$. (A) Amplitude and (ν) frequency.

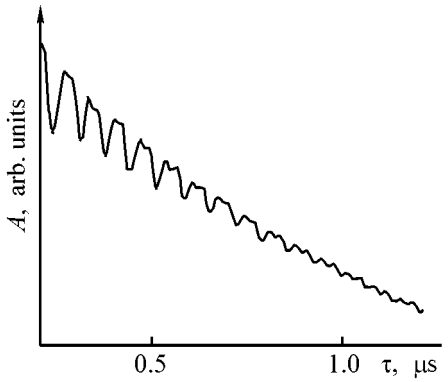

Fig. 4. ESE envelope restored after subtraction of the component at the frequency $2\nu_H$. (A) Amplitude and (τ) time interval between exciting pulses.

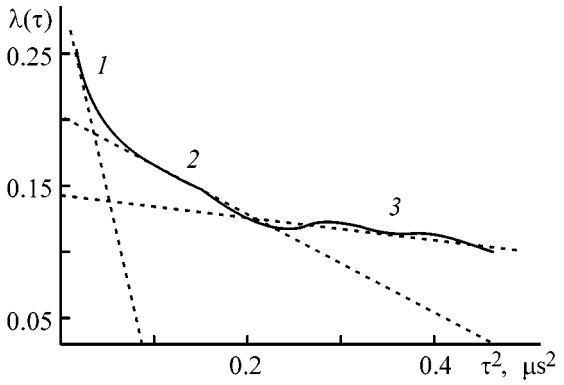

Fig. 5. Degree of modulation $\lambda(\tau)$ vs. τ^2. (τ) Time interval between exciting pulses.

The Fourier image of the envelope of the initial ESE $V(\tau)$, obtained in excitation of the strongest component of the ESR spectrum of the complex (Fig. 2), is shown in Fig. 3. It contains two peaks at the frequencies $\nu_H = 15$ and $2\nu_H = 30$ MHz corresponding to the Zeeman proton frequency and its doubled value, respectively, and three lines in the low-frequency range. After subtraction of the peak at 30 MHz and reverse Fourier transform, the envelope $V(\tau)$ takes the form shown in Fig. 4. The dependence $\lambda(\tau^2)$ found from this envelope (Fig. 5, *solid line*) is a superposition of three contributions, which, based on the preceding, can be referred to HFC with protons of the first and second coordination spheres and matrix (Fig. 5, *dashed lines 1–3*). Using this dependence and formulas (2)–(5), we found $N \approx 2$ and $r \approx 0.3$ nm for the first sphere and $N \approx 4$ and $r \approx 0.4$ nm for the second sphere.

The lines at $\nu_0 = 0.980$, $\nu_- = 2.696$, and $\nu_+ = 3.676$ MHz (Fig. 3) are assigned to ^{14}N nuclei in initiator molecules participating in copolymerization of Thiokol and epoxy resin [7]. With large distance between ^{14}N nucleus and copper ion assumed, the observed frequencies can be assigned to the ^{14}N NQR frequencies.

$$\nu_- = 2K\eta,\ \nu_0 = K(3 - \eta),\ \nu_+ = K(3 + \eta)$$

with the quadrupole coupling constant $K \approx 1.06$ MHz and asymmetry parameter $\eta \approx 0.461$.

The results obtained prove that the ligands in the complex are organic; apparently, these are sulfur-containing fragments of macromolecular chains of the Thiokol–epoxy copolymer. Formation of these complexes can be regarded as including three successive stages: (1) breakdown of the crystal lattice of brass, (2) successive ionization of copper atoms, and (3) coordination of copper ion with ligands incorporated in the polymer matrix. Extraction of copper from iodide and copper-chloride aqueous solutions with organic sulfides and sulfoxides is a classic example demonstrating this scheme [10]. For this process to occur, the matrix should contain, firstly, components acting as acceptor of electrons released in ionization of metal (oxidizing agent), and, secondly, ligands capable of formation of strong coordination bonds. Apparently, disulfide fragments in the main chain of Thiokol can serve as such ligands. These fragments are more reactive with respect to copper than sulfides, since the activity of sulfur-containing compounds with respect to copper decreases in the order elemental sulfur > thiols > disulfides > sulfides [11]. It is evident that free sulfur used as adhesive additive acts in this case as oxidizing agent withdrawing electrons from the metal, which is required for metal–ligand coordination bonding. This can be represented as the scheme

$$xCu + S \rightarrow Cu_xS,$$

$$Cu_xS + S \rightarrow 2Cu_{x/2}S,$$

$$Cu_2S + S \rightarrow 2CuS,$$

$$CuS + 4L \rightarrow [CuL_4] + S,$$

where 2L is RSSR'.

It is assumed that, with increasing concentration of sulfur in the interphase layer, the formal oxidation state of copper grows to +1 or even +2 at a fairly high amount of sulfur. This is quite possible, since, as shown previously [12], the appreciable chemisorption effect of sulfur at the brass surface must result in enrichment of the surface layer of brass with sulfur. The final stage of the reaction in this scheme is coordination of Cu^{2+} ions with sulfur-containing fragments of Thiokol molecules as a result of nucleophilic cleavage of disulfide bonds –S–S– in Thiokol under the action of forming sulfides [13, 14].

The proposed mechanism of formation of copper(II) organic complexes explains adequately the dependence of the intensity of the ESR signal of complexes on the sulfur content, presented in Fig. 1. Addition of more than 5 wt parts of sulfur results in an abrupt increase in the content of paramagnetic copper (II) complexes owing to the formation of the required amount of CuS. At the same time, an excess of CuS (and ZnS) not bound to metallic support must exert a negative effect on the adhesion strength (Fig. 1).

Thus, we believe that the complexes under consideration serve as a peculiar indicator of formation of copper(II) sulfides and do not apparently play any significant role in the formation of the adhesion bond proper, which, as in the case of natural rubber, is governed predominantly by adsorption of macromolecules on the sulfide film having a large specific surface area. However, it is evident that the presence of such metals as copper or zinc, in the form of complex ions or inorganic sulfides, in transition layers of an adhesive joint significantly affects the course of chemical reactions governing the structure and physicochemical characteristics of transition layers. In this relation, mention should be made of a paper [15] concerning Thiokol sealant filled with carbon black. In that work, the concentration of carbon free radicals on the filler surface was found as a function of the distance from the brass support. It was assumed that their decreased concentration directly at the brass surface is due to the presence of copper and zinc cations promoting binding of Thiokol with the filler surface, which results in strengthening of the transition layer and contributes to the adhesion.

CONCLUSION

With respect to magnetic resonance parameters, the copper(II) complex under consideration is similar to copper(II) dibutyldithiocarbamate, with the nearest environment consisting of four sulfur atoms. The presence of protons in the coordination sphere suggests that the ligands are organic, namely, sulfur-containing fragments of Thiokol. Based on the dependence of the intensity of the ESR signal on the concentration of elementary sulfur and also on the correlation of the concentration with the adhesion; a mechanism of formation of the complexes was proposed. This mechanism includes three stages: chemisorption of elemental sulfur at brass surface with the formation of surface copper sulfides, successive ionization of copper atoms, and their coordination with sulfur-containing fragments of Thiokol. The potentialities of electron spin echo as a method for studying these systems were demonstrated.

CHEMISTRY OF FOSSIL FUEL

IR-Spectroscopic Determination of the Maceral Composition of Coal

T. G. Gladun and S. G. Gagarin

Institute of Fossil Fuels, Moscow, Russia

Received March 28, 2002

Abstract—The maceral composition of coal was determined from the IR spectra by factor analysis. Simulated spectra were obtained.

The mathematical and statistical method of factor analysis is successfully used in computer processing of the IR spectra of polymer substances [1]. It operates with eigenvalues and eigenvectors of matrices of the coefficients of correlation between the intensities of spectra of various polymer samples. For example, Kim *et al.* [2] applied this method to estimating the amounts of the crystalline and amorphous phases in vinylidene fluoride and trifluoroethylene. We used this method for estimating the quality of chitin-based biopolymer sorbents [3].

In this study, we analyzed the suitability of factor analysis for estimating the amounts of the main groups of macerals (high-molecular-weight organic microcomponents) in fossil coals on the basis of IR spectra of coal samples with varied maceral (petrographic) composition. This was paralelled by simulating the model spectra of selected groups of macerals. This allows subsequent decomposition of the IR spectra of new coal samples, aimed at determining their maceral composition. Our study was concerned with low-metamorphized long-flame coal from Vesta site (Canada), which was characterized in [4, 5].

EXPERIMENTAL

Photoacoustic IR spectra of nine coal fractions of varied density were recorded without fillers at the Coal Research Centre, Devon, on a Bruker IFS 88 FTIR spectrophotometer in the 4000–400 cm^{-1} range (MTEC-200 PA cell, resolution 2 cm^{-1}). For each sample we performed two runs with 100 scannings each. The primary processing of the spectra, carried out on an interfaced PC, involved averaging of the scans, making corrections for the dependence of the intensity on the excitation frequency, and accounting for the background and electronic light absorption [6].

Coal fractions of varied density were isolated both manually and by flotation and density gradient methods. This allowed the maceral composition to be widely varied within 0–76, 5–98, and 0–95% ranges for the major groups, liptinite (L), vitrinite (Vt), and inertinite (I), respectively (Table 1). The reliability of the calculation procedure was assessed using the available petrographic characteristics.

As known [7], the content of hydrogen decreases steadily and the degree of aromaticity of the macromolecules of the organic matter increases in the maceral group order L, Vt, I. Therefore, the IR spectra of

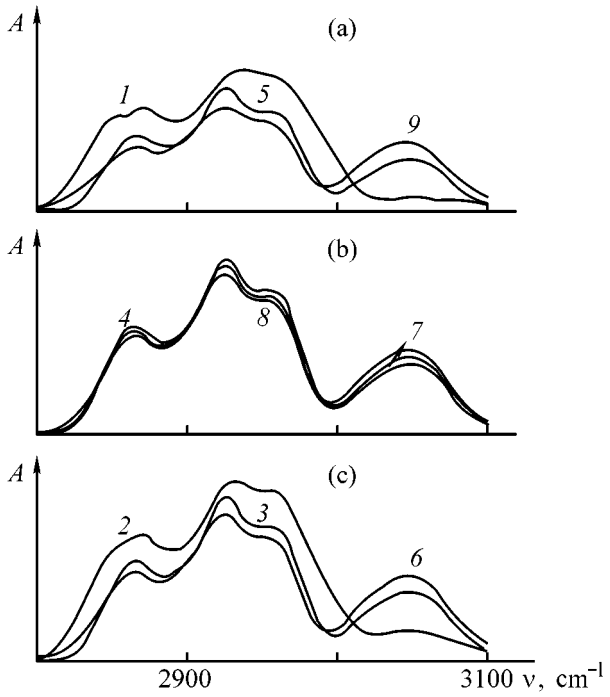

Fig. 1. IR spectra of the coal fractions isolated (a) manually, (b) by flotation, and (c) by the density gradient method. (*A*) Absorption intensity and (ν) wave number; the same for Figs. 2 and 3. Figures at curves correspond to fraction nos. in Table 1.

the maceral groups differ to the greatest extent in the 2800–3100 cm^{-1} region corresponding to the stretching vibrations of the C–H bonds in the aliphatic and naphthene moieties of the organic matter of coal (with the contribution from the stretching vibrations of hydroxy groups subtracted [5, 8]). Therefore, this region was chosen for subsequent computer analysis. The corresponding IR spectra of the nine fractions are shown in Fig. 1.

When represented in the point-by-point manner (with a step $\Delta\nu = 2$ cm^{-1}), the spectra are described by the matrix $A(i, j)$; $i = 1, ..., m$; $j = 1, ..., n$; where $m = 9$ and $n = 151$. When factor analysis is used, these data are utilized for constructing a symmetric quadratic matrix of the correlation coefficients R (with the dimensionality $m \times m$) between the spectra of individual coal fractions. The matrix R is presented in Table 2 (here and hereinafter, the values obtained by computer processing are rounded). Naturally, the largest correlation coefficients are typical of the spectra of the fractions with close petrographic compositions (e.g., sample nos. 3 and 5), and the smallest, of the spectra of the fractions significantly differing in the maceral content (e.g., sample nos. 1 and 9).

Similar to [3], the eigenvalues λ and eigenvectors **V** of the matrix of the correlation coefficients governing the structure of the integrated factors were calculated by the Jacobi method. The parameters λ and the variances corresponding to these factors are presented in Table 3. This table also contains the Fisher *F*-statistics, which, along with total variance, were used for determining the number of the statistically significant factors, and also the components of eigenvectors for factors 1–3. The parameters F are the ratios of the variances corresponding to the given factor, k, to the sum of the variances corresponding to less significant factors $k + 1, ..., m$.

Table 3 shows that factors 1–3 are the key ones, since specifically these factors virtually fully determine the total variance and, unlike other factors, are statistically significant according to the Fisher test F (at significance level $\alpha = 0.01$ [9]). The existence of only three key factors evidences that the IR spectra of coal are determined by three main maceral groups.

In the next stage of data processing, the IR spectra of these maceral groups are constructed, and the maceral composition of each coal fraction is determined. This requires determining the quasi-spectra of the key

statistical factors ("eigenspectra" of the problem Λ) which can be written in the matrix form as

$$\Lambda^t = A^t(\mathbf{V}^*)^t, \quad (1)$$

here, t is the transposition sign; A is the total spectral matrix; and $\mathbf{V}^*$ is the submatrix of eigenvectors corresponding to factors 1–3.

The matrix dimensionalities in (1) are as follows: Λ^t, $(n \times 3)$; A^t, $(n \times m)$; and $(\mathbf{V}^*)^t$, $(m \times 3)$. Figure 2 presents graphically the eigenspectra. The quasispectra of insignificant factors are at the "noise" level (e.g., that of factor 4 in Fig. 2).

As known [1], factors are certain linear combinations of the sought-for variables, which are in our case, the fractions of the macerals in the coal composition. Therefore, the rows in the matrix Λ can be regarded as linear combinations of the IR spectra of individual macerals. In other words, the sought-for spectra M $(3 \times n)$ are bound to Λ $(3 \times n)$ by the matrix relation

$$M\mathrm{t} = \Lambda^t T, \quad (2)$$

where T (3×3) is the transformation matrix.

The numerical values of the matrix T elements were determined by the iteration algorithm, with the initial approximations chosen according to a certain information known *a priori* [2]. In this study, we used as such information the well-known fact that light coal fractions are usually enriched in liptinite, those with intermediate densities, in vitrinite, and the heaviest ones, in inertinite [7]. This can, undoubtedly, be supported by the data in Table 1, but the actual composition of the fractions is taken as unknown in solving the actual problem. Nevertheless, we can take as the initial approximation the *a priori* known fact that the fractions with densities of 1.19, 1.31, and 1.71 g dm^{-3} correspond to maceral groups L, Vt, and I, respectively. Finally, the iteration process yields

$$T = \begin{bmatrix} 0.2838 & 0.3476 & 0.3305 \\ -0.9309 & 0.0466 & 0.3899 \\ 0.4924 & -0.4326 & 0.6584 \end{bmatrix}$$

The IR spectra of the macerals calculated by formula (2) are shown in Fig. 3. Through matrix inversion by transformation, we can also determine the maceral composition of each coal fraction. It will be represented as a matrix X $(3 \times m)$ with rows corresponding to coal fractions and columns, to

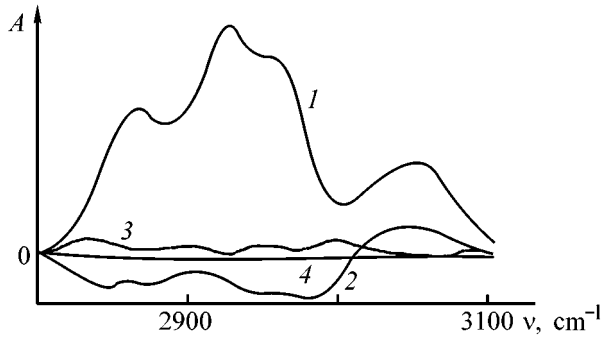

Fig. 2. IR spectra characterizing statistical factors 1–4.

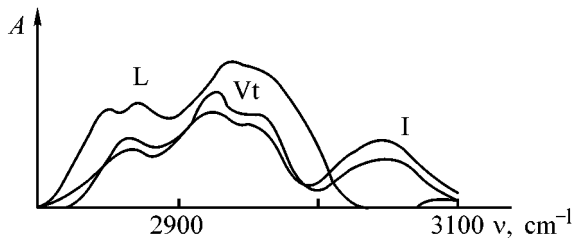

Fig. 3. Calculated IR spectra of the main groups of coal macerals: (L) liptinite, (Vt) vitrinite, and (I) inertinite.

Table 4. Maceral composition of coal as determined from the IR spectra of coal and macerals

Sample	Maceral	Given, %	Found, %		
			range	average	σ
1	L	15	14.75–16.04	14.98	0.16
	Vt	65	59.29–65.97	64.93	0.77
	I	20	19.24–24.67	20.09	0.63
2	L	11	10.84–11.20	11.02	0.09
	Vt	82	81.08–82.68	81.86	0.34
	I	7	6.46–7.98	7.12	0.27
3	L	6	5.92–6.11	6.00	0.05
	Vt	40	39.70–40.30	39.36	0.15
	I	54	53.78–54.25	54.04	0.12

the maceral proportions in their composition. This matrix is given by the equation

$$X = T^{-1}\mathbf{V}^{*}. \quad (3)$$

Since the calculations by formulas (1)–(3) utilize a truncated matrix of eigenvectors of the general problem, the columns in the matrix X need to be normalized to unity for retaining the physical meaning (the possible minor negative values of the fractions of any maceral are replaced by zeros). The corresponding solution of the problem is demonstrated in Table 1, with the calculated data compared with the actual maceral composition determined independently by the coal petrographic method.

The IR spectra of the individual maceral groups, obtained by factor analysis, were used for constructing the spectra of model mixtures with different maceral compositions:

$$A_{M}(\nu) = A_{L}(\nu)x_{L} + A_{Vt}(\nu)x_{Vt} + A_{I}(\nu)x_{I}, \quad (4)$$

where $A_{M}(\nu)$ is the intensity as a function of the wave number ν for a maceral group M (M = L, Vt, I), and x_{M} is the fraction of the group M in the composition of the coal organic matter.

Next, we determined x_{M} by least-squares fitting of the given spectrum $A(\nu)$.

Table 4 presents the starting and found x_{M} values for the three model mixtures. The search followed the Monte-Carlo scheme with randomly chosen initial composition in 100 versions of the calculation for each mixture. Table 4 shows that, with IR spectra of macerals available, it is possible to determine with sufficient precision the maceral composition of coal from its IR spectrum. With data for macerals lacking, elucidating the composition and predicting the individual IR spectra of the components require a factor analysis.

CONCLUSION

The maceral composition of various coal samples was determined from their IR spectra by factor analysis, which allows the amounts of macerals in individual samples to be determined and the model spectra of selected macerals to be obtained. The spectra of macerals, in turn, afford reliable evaluation of their content in coals of any petrographic composition.

Received February 7, 2001

Abstract—Several fractions of diesel fuel recovered from Arlan crude oil were treated with hydrogen peroxide, and the sulfoxides formed by oxidation of petroleum sulfides were isolated with aqueous sulfuric acid. The water solubility of these sulfoxides and their limiting extraction capacity with respect to neodymium nitrate were determined. Correlations between several characteristics of the petroleum sulfoxides [water solubility, limiting extraction capacity with respect to neodymium(III) nitrate, phase separation time under standard conditions, and viscosity] and the boiling range of corresponding petroleum fractions were analyzed.

As noted in [1], sulfoxides find growing application as extractants in hydrometallurgy. The most important parameters of extractants used for recovery of metals from aqueous solutions are their water solubility R, limiting extraction capacity [in particular, with respect to neodymium(III) nitrate] E_{lim}, phase separation time τ_{sep} under standard conditions, and viscosity η [2].

In this work, we studied the correlation between the properties of petroleum sulfoxides and the boiling ranges of the petroleum fractions used for their preparation.

EXPERIMENTAL

The sulfoxides were prepared from a diesel fraction of the Arlan crude oil. The initial and final boiling points of this fuel were 211 and 360°C, respectively. The total sulfur content was 2.2 wt %, including 1.15% sulfide sulfur. The composition of sulfides contained in the diesel fuel was determined on an Finnigan-402 gas chromatograph-mass spectrometer [3]. The sulfide sulfur content S_s was determined iodometrically [4]. The sulfides mainly include monocyclic and bicyclic thiaalkanes.

The initial diesel fuel was fractionated on a high-performance distillation tower at 4–5 torr and the reflux ratio equal to 5. To prepare sulfoxides, these petroleum fractions were oxidized with 30% hydrogen peroxide [GOST (State Standard) 177–88].

The oxidative conversion of sulfides to sulfoxides was performed by the technique described in [5]. The resulting sulfoxides were isolated by extraction with 62% aqueous sulfuric acid [6]. This aqueous sulfuric acid containing sulfoxides was neutralized with aqueous sodium carbonate, washed with aqueous sodium sulfate, and then kept under reduced pressure (80–100 torr) to remove emulsified and dissolved water. The following characteristics of dehydrated sulfoxides RR'SO were determined: the sulfoxide sulfur content S_{SO}, by potentiometric titration [7]; molecular weight $M_{RR'SO}$, cryoscopically [8]; and water solubility R, by a technique developed by us. Namely, a sulfoxide sample (10 ml) was added to distilled water (60 ml) placed in a separatory funnel and this mixture was shaken for 15 min. The resulting emulsion was centrifuged (3000 rpm) for 20 min. The centrifuged aqueous solution (25 ml) was sampled, and petroleum sulfoxides were extracted by successive threefold contact with fresh portions of chloroform (20 ml).

All chloroform extracts were collected in a 100-ml round-bottomed flask. This flask was heated on a water bath to remove chloroform and trace amounts of water. Chloroform was removed at atmospheric pressure, and water, under 100–200 torr. The nonvolatile

1070-4272/02/7508-1349 $27.00 © 2002 MAIK "Nauka/Interperiodica"

bottoms were dissolved in *m*-xylene (or any other high-boiling organic solvent), the resulting organic solution was quanitatively transferred into a 25-ml volumetric flask, and then the organic solvent was added to make the total volume equal to 25 ml. The sulfoxide sulfur content S_{SO} in this solution was determined by potentiometric titration. Based on these data, the water solubility of sulfoxides R (g l^{-1}) was calculated by the equation

$$R = \frac{S_{SO} V d M_{RR'SO} \times 1000}{32 \times 100 \times 25},$$

where d is the solvent (*m*-xylene) density (g cm^{-3}), is the sulfur atomic weight of 32, 25 is the volume of the equilibrium aqueous phase taken for analysis (ml), and V is the volume of sulfoxide solution in *m*-xylene (ml).

The accuracy and sensitivity of sulfoxide analysis were evaluated using organic solutions containing known amounts of thoroughly recrystallized diisobutyl and diamyl sulfoxides.

The sensitivity of sulfoxide determination in our experiments was 0.1 g l^{-1}. The accuracy of determination of sulfoxides in mixtures containing diisobutyl or diamyl sulfoxides taken in amount of 1.0 to 4.0 g l^{-1} did not exceed 5%. This accuracy was accepted by us as the actual accuracy in determination of the water solubility of petroleum sulfoxides.

As the result of analysis was taken the arithmetic mean of two parallel determinations at a standard deviation less than 5% and confidence probability of 0.95.

Apart from the water solubility, we determined the phase separation time τ_{sep} and the limiting extraction capacity E. For this purpose, a mixture consisting of *m*-xylene (5 ml), petroleum sulfoxides (5 ml), and aqueous neodymium(III) nitrate solution (10 ml) was placed in a separatory funnel (100 ml). The separatory funnel was shaken for 5 min, and the phase separation time was registered with a stopwatch. After complete phase separation, the aqueous phase was poured into a beaker and pH was measured with a pH meter. If pH was beyond the range 3.0 ± 0.1, it was adjusted to 3 ± 0.1 by adding aqueous NH_4OH or HNO_3 and then the contact with the organic phase was repeated until pH remained at the level of 2.9–3.1. All contacts were carried out under similar conditions. The phase separation time τ_{sep} was determined as the time within which a distinct interface between the organic and aqueous phases appeared at pH 3.0 ± 0.1. After pH adjustment, the equilibrium aqueous and organic phases were analyzed for neodymium. Prior to analysis, the aqueous phase was diluted in a volumetric flask and its aliquot was analyzed. The organic phase was poured into a centrifuge test tube and centrifuged for 10–15 min at 2500–3000 rpm. The centrifuged organic solution (3 ml) was placed in a separatory funnel and neodymium was backwashed by threefold treatment with 0.1 M HNO_3. The resulting aqueous solutions were collected in a beaker. The neodymium(III) content in the backwash was determined complexometrically with Na_2EDTA. An aliquot of the backwash was placed in a 200-ml beaker and distilled water was added to a volume sufficient for immersing pH meter electrodes. While stirring this solution with a magnetic stirrer, pyridine (8 drops) was added, pH was adjusted to 6.2–6.25 by adding aqueous HNO_3 and NH_4OH, xylenol orange (6–8 drops) was added, and then neodymium was titrated with 0.05 M Na_2EDTA until the initial violetblue color changed to yellow. The neodymium concentration C was calculated by the equation

$$C = \frac{VM \times 168.3n}{a},$$

where C is the neodymium nitrate concentration in the organic or aqueous phase, recalculated to $NdO_{1.5}$, g l^{-1}; V is the Na_2EDTA volume consumed in titration (ml); M is the Na_2EDTA molar concentration determined by titration of standard aqueous yttrium nitrate prepared from a precisely weighed portion of Y_2O_3; 168.3 is the $NdO_{1.5}$ formula weight; a is the volume of organic or aqueous phases taken for analysis (ml); and n is the dilution factor.

The neodymium nitrate content (g l^{-1}, recalculated to $NdO_{1.5}$) in the organic phase is the extraction capacity E of sulfoxides. At the working solution concentration of 400 ± 10 g l^{-1} (recalculated to $NdO_{1.5}$) and pH 3.0 ± 0.1, petroleum sulfoxides exhibit the maximal (limiting) extraction capacity E_{lim}. We found that the sum of the neodymium nitrate content in the organic and aqueous phases is equal to the neodymium nitrate amount taken for extraction, i.e., in our systems a balance with respect to neodymium is observed.

Several characteristics of sulfoxides prepared by oxidation of different petroleum fractions are listed in Table 1.

These results show that the water solubility of petroleum sulfoxides noticeably depends on the boiling range of the petroleum fractions taken for oxidation. For example, the water solubility of sulfoxide prepared from the petroleum fraction 211–360°C with the lowest initial boiling point is 10.6 g l^{-1}. In passing

Table 1. Characteristics of sulfoxides* prepared from petroleum fractions with different boiling ranges

* The limiting extraction capacity of sulfoxides with respect to neodymium(III) E_{lim} was determined with 50% sulfoxide solution in *m*-xylene. For comparison, E_{lim} of neat TBP with respect to neodymium nitrate is 144.4 g l^{-1}.

to fractions with higher initial boiling point (for example, to fractions 275–360 and 300–360°C), the water solubility decreases to 7.1 and 5.6 g l^{-1}, respectively. Figure 1 shows that the water solubility of the sulfoxides prepared from the petroleum fractions with similar final boiling points, linearly decreases with increasing initial boiling point. Thus, to prepare poorly water-soluble sulfoxides, the high-boiling petroleum fractions should be used.

To estimate possible losses of sulfoxides in the course of extraction under industrial conditions, we studied changes in the water solubility of sulfoxides on repeated contact of the organic phase with fresh portions of water. In these experiments, equal volumes of the organic and aqueous phases were placed in a separatory funnel and vigorously shaken for 15 min. The resulting emulsion was centrifuged. After phase separation, samples of the organic and aqueous phases were taken for analysis. The remaining volume of the organic phase was measured and contacted with an equal volume of fresh water ($V_{org} : V_{aq} = 1$). After several repeated contacts (third, sixth, tenth, etc.), the equilibrium organic and aqueous phases were analyzed. All sulfoxides used in our experiments were prepared from the diesel fraction of Arlan crude oil (boiling range 260–360°C). Distilled water acidified to pH 3 was used as an aqueous phase.

Figure 2 shows that, with increasing number of repeated contacts, the water solubility of sulfoxides gradually decreases. The largest decrease in the water solubility occurs in the first contacts. In further contacts, the water solubility curve flattens out. We believe that this is caused by multicomponent composition of the petroleum sulfoxides. On contact with water, the most water-soluble low-molecular-weight sulfoxides dissolve first. The remaining higher-molecular-weight are less soluble.

After 24 successive contacts for six hours in total, the sulfoxide content in the organic phase decreases

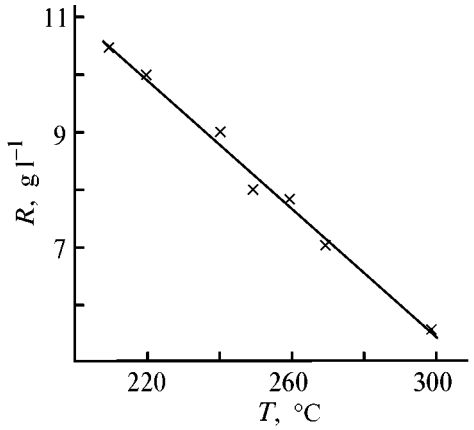

Fig. 1. Water solubility of petroleum sulfoxides R vs. the initial boiling point of the petroleum fractions T.

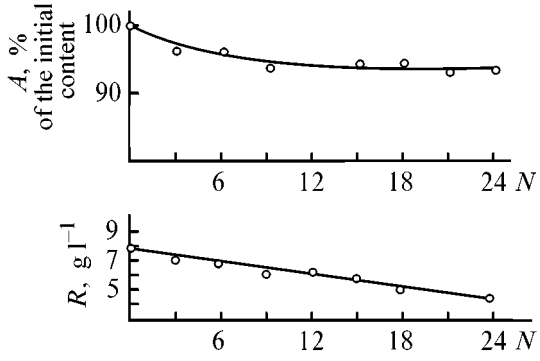

Fig. 2. (A) Sulfoxide content in the organic phase and (R) sulfoxide solubility in acidified water vs. the number N of repeated contacts of the organic and aqueous phases.

* (S_{SO_2}) Sulfone content.

by 7.5% of the initial amount, and the water solubility of sulfoxides decreases from 7.8 to 4.6 $g\ l^{-1}$.

The limiting extraction capacity of the sulfoxides decreases with increasing initial boiling point of the petroleum fraction. For example, in passing from sulfoxide prepared from the petroleum fraction 211–360°C to that prepared from the fraction 300–360°C, the limiting extraction capacity decreases from 86.9 to 77.6 $g\ l^{-1}$.

In determination of the extraction capacity, the phase separation time was approximately similar for all sulfoxides studied (1.5–2.1 min). The extraction capacity of sulfoxides suitable for hydrometallurgy should be no less than 50–55 $g\ l^{-1}$, and the phase separation time, no more than 3 min [9].

In our experiments, the limiting extraction capacity of sulfoxides with respect to neodymium nitrate was determined for 50% sulfoxide solution in *m*-xylene. Data for neat tributyl phosphate are given in Table 1 for comparison.

The extraction capacity of sulfoxides prepared from different petroleum fractions correlates with the sulfoxide sulfur content in these reagents. For the sulfoxides prepared from the petroleum fraction 211–360°C, the sulfoxide number is 10.7 wt %. In passing to sulfoxides prepared from the petroleum fractions with higher initial boiling point, 275–360 and 300–360°C, the sulfoxide number decreases to 10.1 and 9.5 wt %, respectively. We believe that this is caused by the fact that, with increasing molecular weight of the oxidized products, the content of the extraction-active >S=O functional groups decreases. Our further studies showed that the extraction capacity of sulfoxides is in direct proportion to the sulfoxide sulfur content in them. For all the sulfoxides, the average ratio of the limiting extraction capacity to the sulfoxide sulfur content E_{lim}/S_{SO} is 8.0. This ratio varies from 7.9 to 8.1, i.e., within the limits of the error in determination of both the extraction capacity and the sulfoxide sulfur content. Therefore, in some cases, the content of sulfoxide sulfur, being the simpler determinable factor, can be used instead of the limiting extraction capacity.

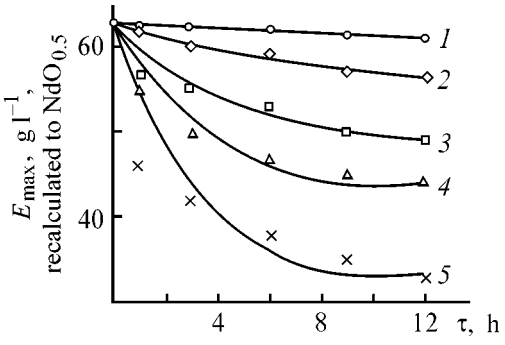

Fig. 3. Limiting extraction capacity of petroleum sulfoxides with respect to $Nd(NO_3)_3$ E_{lim} vs. heating time τ. Temperature (°C): (*1*) 90, (*2*) 110, (*3*) 130, (*4*) 150, and (*5*) 170.

To meet the requirements to extractants suitable for a hydrometallurgical processes, the sulfoxide viscosity η must be no more than 200 $mm^2\ s^{-1}$ at 20°C. Table 1 shows that, with increasing initial boiling point of the petroleum fraction, the sulfoxide viscosity grows. In passing from sulfoxides prepared from the petroleum fraction 220–360°C to those prepared from fractions with higher initial boiling points (275–360°C and 300–360°C), the viscosity increases from 78.7 to 119.7 and 158.8 $mm^2\ s^{-1}$, respectively.

We also studied how the degree of petroleum sulfide oxidation affects the quality of the resulting sulfoxides. Experiments were performed with the petroleum fraction 260–360°C. To vary the degree of sulfide conversion to sulfoxide, hydrogen peroxide was added in different amounts corresponding to 60, 80, 100, and 120% of the stoichiometry. As seen from Table 2, the increase in the degree of conversion from 39.1 to 68.7 % does not affect appreciably the limiting

Table 3. Thermal stability of sulfoxides

extraction capacity of sulfoxide, i.e., the main parameter of the sulfoxide quality. Table 2 shows also that, with increasing degree of conversion, the sulfone content increases to 1.42%. The minor variations in viscosity and extraction capacity of sulfoxides under these conditions are within the limits of the determination accuracy.

To elucidate whether the petroleum sulfoxides can be used as extractants in high-temperature hydrometallurgical processes, we studied the thermal stability of these reagents. For this purpose, a sulfoxide sample was placed in a temperature-controlled three-necked flask equipped with stirrer, thermometer, and reflux condenser. The sulfoxide was kept at a prescribed temperature for 1, 3, 6, or 9 h, and, after each temperature interval, a portion of sulfoxide was taken from a flask for analysis. The remaining amount was also analyzed after heating for 12 h. Portions of sulfoxide were treated with sodium chloride, filtered and analyzed for sulfoxide sulfur. The viscosity of sulfoxides at 20°C and their extraction capacity were also determined. The remaining amount was analyzed for sulfoxides and sulfones and its elemental composition was determined (Table 3). We found that, with increasing temperature and time of heating, the content of sulfoxide sulfur and, as a consequence, the extraction capacity decrease (Fig. 3). Heating to above 130°C causes liberation of sulfur dioxide and hydrogen sulfide. At 150°C and higher temperatures, SO_2 predominates in the gas phase, while the H_2S content is minor. The influence of the heating time on sulfoxide viscosity is governed by thermal degradation of sulfoxides. On heating to 150°C and higher temperatures, the sulfoxide viscosity sharply decreases. Our results showed that, at temperatures higher than 100°C, the petroleum sulfoxides are unstable. Thus, both high temperature and prolonged heating deteriorate the performance of sulfoxides.

CONCLUSIONS

(1) The petroleum sulfoxides prepared from several fractions of diesel fuel with different boiling ranges considerably differ in water solubility, limiting extraction capacity with respect to neodymium(III) nitrate, and viscosity.

(2) Correlations between the boiling ranges of the petroleum fractions used for sulfoxide preparation and some performance characteristics of the resulting sulfoxides allow approximate prediction of the sulfoxide loss in extraction under industrial conditions and enable a choice of best crude oil for production of sulfoxide extractants suitable for hydrometallurgy.

Abstract—The behavior of zinc sulfide in the system HNO_3–$Fe(NO_3)_3$–H_2O at 25, 55, and 80°C was studied using the simplex-lattice design method.

Data on reactions of certain metal sulfides with mineral acids are well known; however, the range of systems under study is rather narrow. The system HNO_3–$Fe(NO_3)_3$–H_2O has been studied insufficiently [1].

This system was studied to analyze reactions of zinc sulfide in the ternary system HNO_3–$Fe(NO_3)_3$–H_2O at various HNO_3 and $Fe(NO_3)_3$ concentrations and to obtain data on the composition of precipitates formed in redox reactions at 25, 55, and 80°C.

EXPERIMENTAL

Zinc sulfide was synthesized by the technique described in [2] and identified by X-ray phase analysis; its specific surface area S_{sp} = 4.1 $m^2 g^{-1}$ was determined by BET. Chemically pure iron(III) nitrate and nitric acid, and also distilled water, were used in the study. The experiments were carried out in a temperature-controlled system (the accuracy of temperature measurements was ±0.1°C) in the course of 2 h (preliminary experiments showed that the concentration of Zn^{2+} ions in solution remains unchanged after 2-h contact of zinc sulfide with the solution) with permanent stirring and initial s : l ratio of 1 : 5.

The concentration of Zn^{2+} ions in the liquid phase was determined by titrimetry and atomic-absorption spectrophotometry [3, 4], and that of nitric acid, by titrimetry [4]. After filtration, the solid phase was washed with water and ethanol to remove the solution, dried, and subjected to X-ray phase analysis.

The results obtained were processed by means of the simplex-lattice design [5]. The following components were the vertices of the concentration triangle: X_1, H_2O (55.56 M); X_2, $Fe(NO_3)_3$ (1.8 M); and X_3, HNO_3 (3.2 M). As functions served the extents to which Zn^{2+} passes from ZnS into solution.

A simplex-lattice design for the incomplete cubic model used to describe the system under study is presented in the table. These data were used to calculate the regression equations for 25, 55, and 80°C:

$$Y_{25} = 0.05X_1 + 21.79X_2 = 49.44X_3 + 30.95X_1X_2 + 24.16X_1X_3 + 96.34X_2X_3 + 113.09X_1X_2X_3,$$

$$Y_{55} = 0.08X_1 + 12.46X_2 + 37.31X_3 + 74.42X_1X_2 + 37.16X_1X_3 + 49.70X_2X_3 - 176.91X_1X_2X_3,$$

$$Y_{80} = 0.07X_1 + 50.00X_2 + 55.22X_3 + 22.53X_1X_2 - 98.05X_1X_3 - 19.40X_2X_3 + 237.98X_1X_2X_3.$$

The root-mean-square error was 3%. It was found that these equations describe adequately the data obtained in control experiments nos. 8–10, with 97% probability. The equations were used to construct phase diagrams for the temperatures under study (Figs. 1a–1c).

The increase in the degree of Zn^{2+} leaching is directed toward the HNO_3–$Fe(NO_3)_3$ system in all the diagrams, with the most complete extraction of about 62% achieved at 25°C. The same behavior is observed at 55 and 80%, but the degree of leaching of zinc ions is lower (40 and 55%, respectively). Addition of nitric acid to the solution promotes the oxidation reaction, with an increase in acidity favoring sulfide break-

* Y_{e25}, Y_{e55}, Y_{e80}, Y_{c25}, Y_{c55}, and Y_{c80} are the experimental and calculated degrees of zinc extraction at 25, 55, and 80°C.

down, as seen from the figures. At 80°C, the concentrations of Fe^{3+} and HNO_3 ions hardly affect the degree of leaching, which falls within the range 50–55%. When temperature is lowered, the oxidation process is shifted to higher nitric acid concentrations, although the highest degree of zinc extraction is observed in the concentration ranges 1.92–2.4 M of HNO_3 and 0.72–0.45 M of $Fe(NO_3)_3$.

According to X-ray phase analysis data, undecomposed ZnS and elementary sulfur are present in the solid phases. As shown by an analysis of the precipitates after breakdown, the content of elementary sulfur at 25°C is much lower than that at elevated temperatures. This suggests that S(–2) → S(0) → S(+6) conversion occurs in the course of the reaction of nitric acid and iron(III) nitrate with ZnS. Raising the temperature results in faster ZnS oxidation and evolution of gaseous reaction products (evolution of NO and NO_2). Such a behavior of the system under study seems to be related to the screening of the reaction surface of the material by elementary sulfur, which is the reason for the poorer extraction of zinc ions at elevated temperatures.

The reaction of ZnS with the oxidizing system $Fe(NO_3)_3$–H_2O depends only on the concentration of the reactants in virtually the entire temperature range under study. Such a behavior suggests that the presence of Fe^{3+} ions in solution promotes zinc sulfide oxidation, and further increase in the concentration of nitric acid results in faster oxidation of the sulfide sulfur to elementary sulfur and in the screening of the reaction surface. By varying the dispersity, one can pass from leaching to complete dissolution of zinc sulfide.

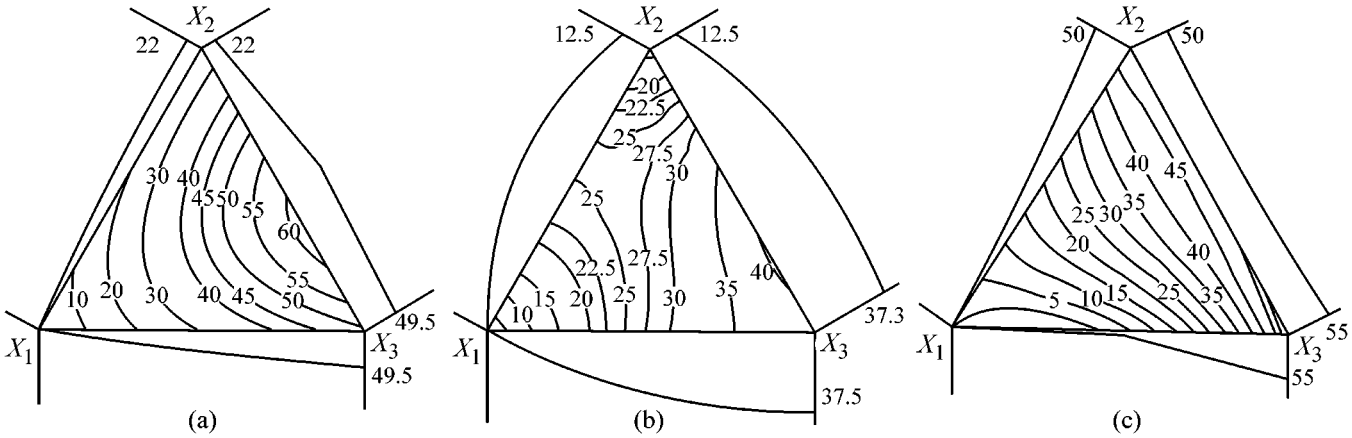

Fig. 1. Zn^{2+} extraction from ZnS (%) at (a) 25, (b) 55, and (c) 80°C.

CONCLUSIONS

(1) The degree of Zn^{2+} leaching grows with increasing concentrations of nitric acid and iron(III) nitrate, and an increase in temperature hardly affects the leaching.

(2) At 25°C the solid phase contains a lesser amount of elementary sulfur than that at elevated temperatures.

(3) In the course of the ZnS reaction with nitric acid and iron(III) nitrate a $S(-2) \rightarrow S(0) \rightarrow S(+6)$ conversion takes place.

(4) Equations describing the degree of Zn^{2+} extraction at 25, 55, and 80°C were obtained, and the corresponding diagrams were constructed on their basis.

On Production of Cerium Dioxide

V. N. Lebedev and A. V. Rudenko

Tananaev Institute of Chemistry and Technology of Rare Elements and Minerals, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received March 11, 2002

Abstract—The possibility of obtaining cerium dioxide by recovery of Ce(IV) phosphate from acid nitrate solutions with subsequent conversion of Ce(IV) phosphate to Ce(III) oxalate was studied.

Cerium is the most widespread and demanded representative of rare-earth elements (REE). Its content in most of the concentrates being refined exceeds 50 wt %. As a rule, Ce(III) is isolated from an REE mixture through its oxidation to Ce(IV) and subsequent separation by extraction or precipitation with account of differences in the pH of precipitation of mixture components [1, 2].

It is impossible to completely separate cerium(IV) from other REEs by precipitation techniques owing to the close pH values of their precipitation and the considerable adsorptivity of the resulting precipitates. Purer cerium compounds can be obtained by precipitation of Ce(IV) phosphate, which is precipitated at higher acidity than triply charged REEs. Processes of this kind have been proposed for recovery of cerium from monazite [3] and a phosphate concentrate from apatite [4]. A drawback of the phosphate procedure is the complexity of phosphorus(V) removal.

A procedure for processing REE phosphates, based on their conversion to oxalates, has been proposed earlier [5, 6]. Its applicability to the production of cerium dioxide was assessed in the present study.

EXPERIMENTAL

Cerium was oxidized in an acid nitrate medium on a platinum anode. A solution prepared from loparite was used for oxidation. It contained 300 g l^{-1} of Ln_2O_3 and 164 g l^{-1} of Ce_2O_3. After the oxidation the solution contained Ce(IV) in the form of CeO_2 (42 g l^{-1}). The cerium(IV) content in solutions was determined by titration with Mohr's salt $(NH_4)_2Fe(SO_4)_2$. Cerium(IV) phosphate was precipitated from 2–3 N HNO_3 solution by addition of ammonium hydrophosphate $(NH_4)_2HPO_4$. Almost complete precipitation was attained by addition of one mole of PO_4^{3-} per one mole of CeO_2, which corresponds to precipitation of basic phosphate $CeOHPO_4$. This precipitate was filtered off, washed by repulping in 1 N HNO_3 at a solid-to-liquid phase ratio (s : l) of 1 : 3 and treated with oxalic acid in 1.5 N HNO_3 at 80°C for 1 h (s : l = 1 : 3). The conversion to the oxalate occurs by the following reaction:

$$2Ce(OH)PO_4 \cdot nH_2O(s) + 4H_2C_2O_4(l) \rightarrow Ce_2(C_2O_4)_3 \cdot 10H_2O(s) + 2H_3PO_4 + 2H_2O + 2CO_2.$$

Precipitated oxalates were isolated, washed with 1 N HNO_3, and calcined at 900°C. The impurities in cerium dioxide were determined by X-ray fluorescent analysis. The results of the experiments are presented in the table.

As a rule, 75–90% concentrates are produced by single-stage precipitation of Ce(IV) hydroxide, carbonate, or basic nitrate [3]. Cerium samples obtained by precipitation of Ce(IV) phosphate are significantly

purer and can be used in various fields of technology. A required purity of cerium phosphate can be achieved by its reprecipitation, which can be used for recovery of cerium(IV) from acid solutions after its electrolytic oxidation, since the precipitation procedures involve solution neutralization. At the same time, the extraction recovery entails a considerable loss of the extractant because of its decomposition by Ce(IV), which is a strong oxidizing agent, and by hydrogen peroxide used for the reextraction.

It was found that oxalates obtained from Ce(IV) phosphate differ from those prepared by conversion of Ce(III) orthophosphate in their thermal behavior. Samples of Ce(III) oxalates were synthesized under similar conditions. The content of P_2O_5 in the samples under study was not greater than 0.1%. Although both kinds of oxalate samples have identical X-ray diffraction patterns (Fig. 1a) and thermogravimetric characteristics (Fig. 2), the oxalate obtained from Ce(IV) phosphate is converted to bright yellow cerium dioxide under heating at 250°C for 3 h, whereas the oxalate obtained from Ce(III) phosphate only loses water and becomes X-ray-amorphous (Fig. 1b) under the same conditions. It is converted to dioxide only at 410°C [7], and cerium(III) oxide is shown to form at 370°C [8].

Low-temperature forms of cerium dioxide are likely to be of practical importance, e.g., in catalysis [9, 10]. On the whole, the technology of cerium dioxide production with preliminary recovery of Ce(IV) phosphate is well applicable, because phosphate ions and most of oxalic acid can be recycled. Naturally, treatment of bulk precipitates of Ce(IV) phosphate presents difficulty, but advantages of the method are also obvious.

CONCLUSION

It was shown that cerium dioxide can be produced through preliminary recovery of Ce(IV) phosphate from acid nitrate solutions and its subsequent conversion to Ce(III) oxalate.

Differences in thermal behavior between cerium oxalates obtained by conversion of Ce(IV) and Ce(III) phosphates were found. In the first case, the product decomposes at low temperature (250°C) to form CeO_2.

Synthesis of Mordenite with the Use of Aluminum Sulfate Solutions

M. L. Pavlov, R. A. Makhamatkhanov, B. I. Kutepov, F. Kh. Kudasheva, and Yu. A. Lebedev

Institute of Petrochemistry and Catalysis, Academy of Sciences of Bashkortostan Republic and Ufa Scientific Center of Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received October 15, 2001; in final form, January 2002

Abstract—A procedure has been developed for synthesis of a mordenite-type zeolite with high phase purity and high dispersity of crystals. The procedure is based on hydrothermal crystallization of aluminum-silicon hydrogels prepared from aluminum sulfate solutions serving as a source of Al(III).

Commonly, a mordenite-type zeolite is obtained using sodium aluminate solutions with Al_2O_3 and Na_2O concentrations of 150–200 and 200–230 g l^{-1}, respectively, as aluminum-containing reagents. However, the metastability of these solutins results in that the desired results are not always obtained. The composition of the reaction mixture can be disturbed in storage or upon dilution with water owing to the precipitation of aluminum hydroxide [1]. Coarse grains of aluminum hydroxide can play the part of foreign heterogeneous crystallization centers, which deteriorates the phase purity and the dispersion composition of the resulting zeolite. Furthermore, a separate unit for preparation of sodium aluminate solutions is required in commercial production of the zeolite.

In this communication, an industrially promising version of mordenite-type zeolite synthesis, with aluminum sulfate solutions as aluminum-containing raw material, is proposed.

EXPERIMENTAL

The synthesis was carried out in an autoclave with a stirrer and a sampler. The degree of crystallization and the type of the resulting zeolite were determined by X-ray phase analysis. The procedure for obtaining and studying zeolites is described in [2] in more detail.

Preliminary experiments have shown that mordenite-type zeolite can be synthesized from reaction mixtures containing (mol): $(1.8–7.1)Na_2O \cdot Al_2O_3 \times (12–30)SiO_2 \cdot (250–600)H_2O$, which were prepared by mixing aqueous solutions of sodium silicate and hydroxide, and also aluminum sulfate. The kinetics of solid phase crystallization was studied for this range of reaction mixture compositions at 125–170°C.

Kinetic curves describing mordenite crystallization at 130°C are presented in Fig. 1. They are S-shaped, which is characteristic of kinetic curves describing the crystallization of zeolites.

Approximately 35 h is necessary for mordenite with high degree (~100%) of crystallinity to be formed (Fig. 1, curve *1*). Raising the Na_2O/Al_2O_3 ratio (mol : mol) in the reaction mixture from 1.8 to 3.0 leads to

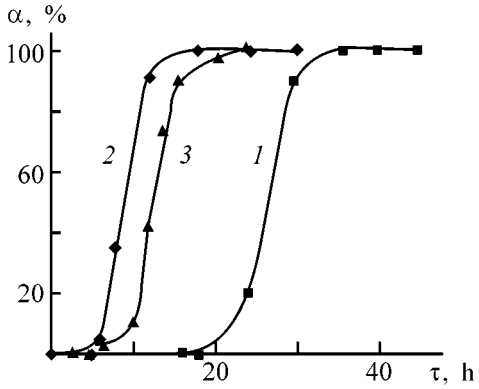

Fig. 1. Dependence of the degree of sample crystallinity, α, on the time τ of crystallization at 130°C of reaction mixtures obtained with the use of aluminum sulfate solution. Reaction mixture (mol): (*1*, *2*) $xNa_2O \cdot Al_2O_3 \cdot 12SiO_2 \times 250H_2O$ and (*3*) $7.1Na_2O \cdot Al_2O_3 \cdot 30SiO_2 \cdot 600H_2O$. *x*: (*1*) 1.8, (*2*) 3.0.

1070-4272/02/7508-1360 $27.00 © 2002 MAIK "Nauka/Interperiodica"

a twofold decrease in the duration of the induction period and in the total duration of the mordenite synthesis (Fig. 1, curve *2*).

A higher degree of dispersion is characteristic of mordenite crystals formed with the use of aluminum sulfate solutions, compared with those obtained using of sodium aluminate solutions. In the first case, the predominant crystal size is 4–5 μm, compared with 6–8 μm in the second [2].

An electron micrograph of mordenite crystals synthesized with the use of aluminum sulfate solutions is shown in Fig. 2. It is evident that the crystals are close in size, which seems to be associated with the formation of the main amount of crystallization centers in the nucleation stage, owing to the use of a true aluminum sulfate solution, instead of a colloidal sodium aluminate solution. This assumption is also confirmed by higher rate of mordenite formation. For example, the duration of synthesis of a mordenite with nearly 100% crystallinity from a $3Na_2O \cdot Al_2O_3 \cdot 12SiO_2 \cdot 300H_2O$ alumina-silica gel prepared using a sodium aluminate solution, is about 40 h at 135°C [2]. When mordenite is crystallized from an alumina-silica hydrogel with similar composition, prepared using an aluminum sulfate solution, the time of synthessis decreases to 18 h (Fig. 1, curve *2*), although the temperature of synthesis is 5°C lower in the second case.

The mordenite-type zeolite obtained using this method has an adsorption capacity of 0.14–0.15 and 0.08–0.09 $cm^3\ g^{-1}$ for, respectively, water and heptane vapor. Close values are characteristic of the mordenites described in [2].

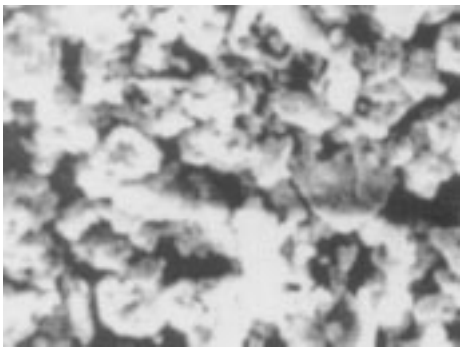

Fig. 2. Electron micrograph of a mordenite-type zeolite. (Magnification 1500).

CONCLUSION

A procedure has been developed for synthesis of finely dispersed mordenite with high phase purity and high degree of crystallinity (close to 100%). The procedure is based on crystallization at 125–170°C of an alumina-silica hydrogel prepared by mixing of gel-forming solutions of sodium silicate, sodium hydroxide, and aluminum sulfate in the ratio (mol) $(1.8–7.1)Na_2O \cdot Al_2O_3 \cdot (12–30)SiO_2 \cdot (250–600)H_2O$.

Radio-Frequency Method for Measuring the Water Content of Liquids

V. A. Bannyi, A. V. Makarevich, L. S. Pinchuk, and B. G. An

Abstract—The method for radio-frequency measurements of water content in nonaqueous liquids is improved, and a procedure for measuring the concentration of water emulsified in oils and diesel fuels is described. Correlations between the composition of emulsions studied and the attenuation of the energy of electromagnetic radiation passing through the emulsions are revealed.

Emulsified water admixtures contained in nonaqueous technological liquids and fuels for machinery impair their service characteristics. For example, presence of water in transformer oil causes electric breakdown of the dielectric medium (oil) and short-circuiting of transformer windings. Water accumulated in motor oils in engine operation affects the functional properties of oils: their lubricating ability decreases, tendency toward sludge formation grows, etc. [1]. When minor amounts of water find their way into diesel fuels, the throughput capacity of fuel filters decreases and the corrosion rate of fuel tanks and lines increases. Determining quantitatively the content of water in nonaqueous technological liquids is an important task, which poses a serious technological problem.

Various methods are used in technology for measuring the water content. These methods differ in complexity, sensitivity, precision, and cost. Some techniques for determining the water content of liquid working media employ electromagnetic fields [2–6]. In particular, the radio-frequency (RF) method [5] relies upon the influence exerted by electromagnetic radiation (ER) of the microwave range with nonthermal intensity upon a liquid sample placed in the waveguide of a measuring instrument. The parameter measured in this case is the ER reflection coefficient for the surface of the liquid at its interface with air.

The aim of the present study was to improve the existing methods for RF water content measurements and to reveal and explain in terms of physical chemistry correlations between the water content of liquids and attenuation of the energy of ER passed through the liquids. The point is that the attenuation of the energy of ER passed through a liquid layer is used as the main recorded parameter, instead of the reflection coefficient. This makes it possible to reduce the volume of a sample being analyzed, with the sensitivity of the method preserved, and to use it for media with high content of water. For this purpose, a special cell for small-volume liquid samples and an original system for its fixation in the waveguide were designed.

As objects of study served nonaqueous technological liquids: diesel fuel, automotive ($M6_312G_1$) and transformer oils containing emulsified water. The emulsions were obtained by intensive mechanical dispersion of water in oil media. The content of water in the emulsions was determined using R2-61 standing-wave and ER-attenuation meter assembled in accordance with the attenuation measurement scheme (Fig. 1). Cell *1* was filled with the liquid under study

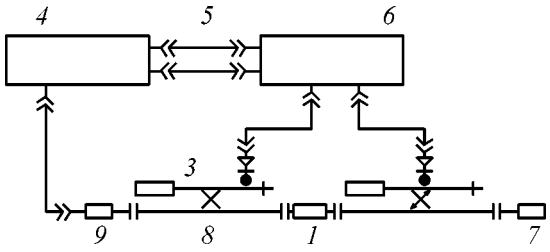

Fig. 1. Setup for measuring the attenuation of the energy of ER passing through a liquid being analyzed. (layer thickness 3 cm) and placed between the detectors *2* and *3* of incident and passed ER. The parameter *S* of ER attenuation was measured at a fixed frequency and the water content was found from the calibration concentration dependences *S*–*c* for reference liquids.

Analysis of the data in Figs. 2a and 2b shows that the intensity of ER interaction with the dispersed liquid–liquid systems under study depends on, at least, several factors. Of fundamental importance is the dielectric constant of the dispersed medium, which is higher in diesel fuel, compared with oils [7]. Other important factors changing the conditions of absorption and scattering of the ER energy are the concentration *c* and particle size of the dispersed phase (water).

The dependences of *S* on *c* are exponential (Fig. 2b). At concentration *c* in the range from 3 to 20 vol % they are virtually linear and have high slope, which predetermines the high sensitivity of the method. The main contribution to the attenuation of the energy of the passing ER comes in this case from dielectric losses, which markedly grow with increasing content of water, which is characterized by high dielectric constant. The measurement results are also affected by the energy loss for ER scattering at the interface between the dispersed phase and dispersion medium. With the concentration of water increasing to above 20 vol %, the run of the *S*–*c* curves changes, with only a small rise in *S* corresponding to large increments Δc. It is believed that, at high content of water in oil emulsions, ER mainly interacts with the dispersed (aqueous) phase whose particles become coarser as a result of coagulation.

The resolving power of the proposed RF method for measuring the water content of liquids is 0.5–1.0 vol %.

CONCLUSIONS

(1) A radio-frequency technique for water content measurements is proposed. This technique belongs to physicochemical methods for studying colloid systems with the use of microwave electromagnetic radiation and is based on the difference between the dielectric properties of the components of the systems under study.

(2) The technique proposed ensures simplicity, accessibility, and reliability analysis of liquids for water content and can be used to study coagulation processes in colloid systems.

Influence of the Solution Acidity and pK_a of the Amine on the Reaction of Dextran Polyaldehyde with Amines

O. B. Suvorova, E. V. Tishchenko, A. A. Iozep, and B. V. Passet

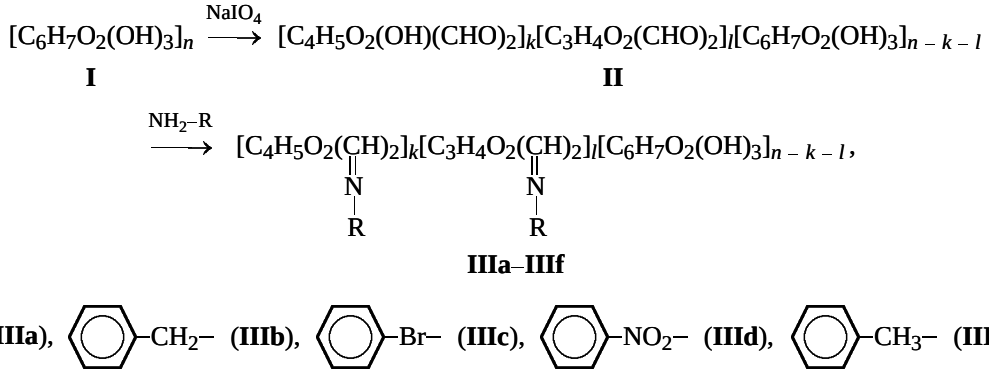
St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received March 7, 2002

Abstract—The influence exerted by the solution pH and pK_a of the amine on the reaction of dextran polyaldehyde with aromatic and aliphatic amines was studied.

As shown previously [1], the solution pH strongly influences the reactions of polysaccharide aldehydes with amines; the pH values at which the maximal degrees of substitution are attained correlate with the acidity constants of the amines. In this context, our goal was to study the influence exerted by the solution acidity on the yield of the target product in the reaction of dextran polyaldehyde (DPA) with aromatic and aliphatic amines.

The chemical modification of DPA was performed by the scheme



R = ⬡– (**IIIa**), ⬡–CH_2– (**IIIb**), ⬡–Br– (**IIIc**), ⬡–NO_2– (**IIId**), ⬡–CH_3– (**IIIe**), OH (**IIIf**).

Dextran **I** was activated by periodate oxidation in an acetate buffer solution (pH 4.1). The metaperiodate consumption was monitored spectrophotometrically at 222.5 nm, and the amount of the formic acid released was determined by volumetric titration. After oxidation completion, the reaction mixture was dialyzed to remove low-molecular-weight substances, and the polyaldehyde was precipitated with ethanol after concentrating the solution in a vacuum at 60°C.

DPA samples were characterized by the degree of substitution C_{sa} (number of aldehyde groups per monosaccharide unit of the polymer), which was determined by the oxime and hydroxamic procedures [2]. In the samples used, C_{sa} varied from 0.73 to 1.

The reactions of DPA with amines were performed for 2 h at 18–20°C; the reactant ratio was 3 mol of aromatic or 2 mol of aliphatic amine per mole of aldehyde groups. The solution pH was varied from 0.5 to 10. After reaction completion, the mixture was diluted with 10 volumes of alcohol, and the precipitated products were filtered off, washed with alcohol and ether, and vacuum-dried (60°C, 20–25 mm Hg) for 2 h. The absence of low-molecular-weight impurities in the samples was confirmed by thin-layer chromatography.

The polymeric azomethines synthesized were characterized by the degree of substitution C_s (number of amine fragments per monosaccharide unit), which was

1070-4272/02/7508-1364 $27.00 © 2002 MAIK "Nauka/Interperiodica"

calculated from the analytical data and results of conductometric titration of the samples hydrolyzed with 0.1 N HCl; the extent of the reaction with amines was characterized by the degree of conversion of aldehyde groups C_{ca} (%), defined as $C_{ca} = (C_s/C_{sa}) \times 100$.

The samples are white, light creamy, yellow, or orange amorphous powders insoluble in water, alcohol, ether, acetone, and most of other organic solvents.

The IR spectra of the reaction products contain absorption bands at 1600, 690, and 750 cm^{-1}, characteristic of monosubstituted benzene, at 1640–1660 cm^{-1}, belonging to C=N stretching vibrations, and (for *p*-substituted benzene derivatives) also at 810 cm^{-1}. The product of the reaction of DPA with *p*-nitroaniline also exhibits absorption at 1560 cm^{-1}, characteristic of the NO_2 stretching vibrations.

In accordance with the reaction mechanism, the rate of transformation of the aldehyde groups into azomethine groups depends on the nucleophilicity of the amine. There is no common nucleophilicity scale, and we assume the nucleophilicity of primary amines to be proportional to the quantity pK_a, characterizing their basicity.

Indeed, if the reactions with primary amines are performed under similar conditions at the same pH, there is a linear correlation between the degree of conversion of DPA aldehyde groups into azomethines and the pK_a value of the amine (Table 1):

$$C_{ca(pH\ 7)} = 20.5\,pK_a - 13.16\ (n = 5,\ R^2 = 0.986).$$

Also, C_{ca} linearly correlates with the σ_p constants of substituents in the aromatic ring (Table 1). This fact shows that C_{ca} correlates with the reaction rate. For *p*-substituted amines, the correlation between C_{ca} and the Hammett constants is as follows: $C_{ca} = -87.14\sigma_p + 79.06$ ($n = 5$, $R^2 = 0.996$). Electron-withdrawing substituents decrease, and electron-donor substituents enhance the reactivity of amines toward DPA.

As expected, the acidity of the reaction mixture strongly affects the yield of the products in reactions of DPA with amines. The optimal pH at which the degree of conversion of DPA aldehyde groups reaches a maximum correlates with pK_a of the amine (Fig. 1, Table 2).

For each amine, there is a certain pH at which the rate of its reaction with DPA is the highest. With strong (benzylamine) and very weak (*p*-nitroaniline) nucleophiles, the yield of the target product decreases by a factor of 1.5–2 when the pH of the reaction mixture differs from the optimum by ±1.5 units; with aniline and *p*-bromoaniline, the pH dependence of the conversion of DPA aldehyde groups is less pronounced. With less nucleophilic amines (*p*-nitroaniline, *p*-bromoaniline, aniline), a catalytic effect of the acid is required for the reaction to occur. Stronger bases (*p*-toluidine, hydroxylamine, benzylamine), by contrast, better react with DPA in neutral and alkaline solutions.

Table 1. Degree of conversion of aldehyde groups into azomethine groups in reactions of DPA with aromatic amines in relation to pK_a of the amine and the Hammett constant σ_p (pH 7, 20°C, 3 mol of amine per mole of aldehyde groups)

Amine	pK_a	σ_p	C_{ca}, %
p-Nitroaniline	1.02	0.778	10
p-Bromoaniline	3.91	0.232	61
Aniline	4.63	0	81
p-Toluidine	5.12	–0.170	91
p-Phenetidine	5.25	–0.268	100

Table 2. pH values at which the conversion of DPA aldehyde groups in reactions with amines reaches a maximum (15–20°C, 2 h, 3 mol of amine per mole of aldehyde groups)

Amine	pK_a of amine	pH
p-Nitroaniline	1.02	1.03
p-Bromoaniline	3.91	4.6
Aniline	4.63	5.88
p-Toluidine	5.12	6.6
Hydroxylamine	5.97	7.45
Benzylamine	9.33	10.45

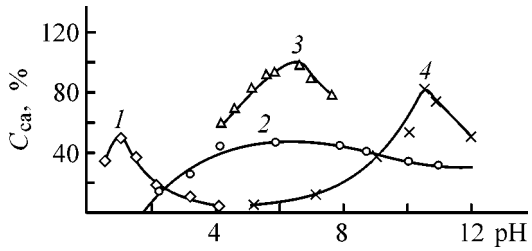


Fig. 1. Degree of conversion, C_{ca}, of DPA aldehyde groups in reactions with (*1*) *p*-nitroaniline, (*2*) aniline, (*3*) *p*-toluidine, and (*4*) benzylamine vs. pH.

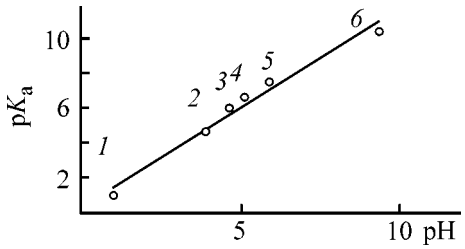

Fig. 2. Correlation of the optimal pH for the reactions of DPA with (*1*) *p*-nitroaniline, (*2*) *p*-bromoaniline, (*3*) aniline, (*4*) *p*-toluidine, (*5*) hydroxylamine, and (*6*) benzylamine with pK_a of the amine.

Based on these data, we plotted the optimal pH values against the basicity (pK_a) of the amine (Fig. 2).

We found that the correlation between these quantities is linear: pH = 1.47 pK_a + 0.28 (n = 6, R^2 = 0.9822). That is, the more basic the amine, the higher the optimal pH value.

Using this correlation, we can estimate *a priori* the optimal pH values for the reactions of DPA aldehyde groups with other amines, which will significantly simplify development of procedures for modification of polyaldehydes with biologically active substances.

CONCLUSION

In reactions of dextran polyaldehyde with amines, the highest rate is attained at certain optimal pH values, which correlate with pK_a of the amine: pH = 1.47 pK_a + 0.28. This correlation allows the *a priori* estimation of the optimal reaction conditions.

Reaction of Chlorine in Aqueous Solution with Hydrolysis Lignin under Elevated Pressure

A. R. Aliskerov, Z. M. Aliev, and T. A. Kharlamova

Dagestan State University, Makhachkala, Dagestan, Russia
Moscow State University of Food Industry, Moscow, Russia

Abstract—Chlorination and oxidation of hydrolysis lignin with chlorine in aqueous solution under elevated pressure was studied with the aim to intensify the process.

Chlorination is one of promising ways to modify technical-grade lignins, a large-tonnage waste from hydrolysis, pulp-and-paper, and sulfite-and-alcohol industry. Chemical chlorination of hydrolysis lignin has been studied in sufficient detail [1–3]. Chlorination involves substantial activation of lignin macromolecules owing to incorporation of chlorine and oxidation, accompanied by an increase in the content of carbonyl and carboxy groups.

The goal of this study was to prepare chlorinated lignins with high content of chlorine and other functional groups under elevated pressure.

EXPERIMENTAL

Experiments were performed with coniferous hydrolysis lignin. Chlorination of lignin saturated with chlorine under elevated pressure (0.1 to 0.6 MPa) was performed in an autoclave made of a titanium alloy and lined with fluoroplastic. Gaseous chlorine from a cylinder was purified by passing through distilled water in an intermediate vessel and then was fed into the autoclave containing 50 g of hydrolysis lignin suspended in 0.5 l of distilled water. The contents were stirred for 2–3 h on a laboratory magnetic stirrer to attain the phase equilibrium (monitored with a manometer). Chlorination was performed at approximately 20°C for 3 h. The experimentally determined solubility of Cl_2 is 0.72 g per 100 g of water (with increasing temperature, it decreases to 0.56 g of Cl_2 per 100 g of water). The resulting chlorinated lignin was filtered through a paper filter, washed to negative reaction for chloride ions, and dried first in air and then at 40°C in a vacuum desiccator to constant weight. The content of functional groups was determined as described in [4], and that of chlorine, according to [5]. The UV spectra were taken with a Specord UV VIS spectrophotometer [6].

Data on the content of chlorine and functional groups in chlorinated lignins prepared under various pressures are listed in the table.

It is seen that, with increasing pressure, the content of chlorine and of carbonyl and carboxy groups increases, and the content of methoxy and hydroxy groups decreases.

Elevated pressures favor chlorination of lignin because of the increased content in solution of the chlorinating agent, molecular chlorine. Its solubility grows, and the degree of its hydrolysis decreases [7–9].

The aromatic rings in lignin macromolecules are chlorinated first. This is confirmed by the fact that the chlorine content in chlorinated lignins does not noticeably decrease after their saponification with 5% NaOH. The generally accepted mechanism of

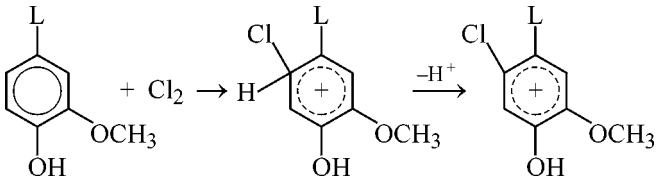
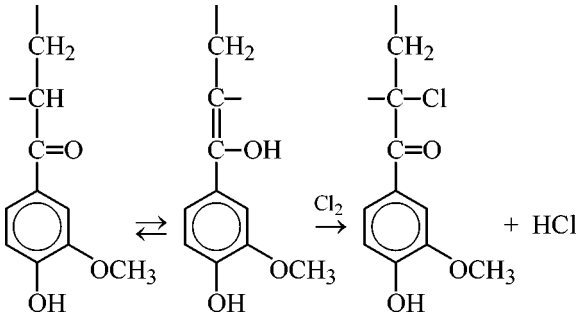
UV spectra of solutions of (*1*) initial hydrolysis lignin and (*2*–*4*) chlorinated lignin prepared at pressures of (*2*) 0.1, (*3*) 0.5, and (*4*) 0.6 MPa. (*D*) Optical density and (λ) wavelength.

chlorination of aromatic rings in lignin is shown below:



Further chlorination involves side chains of lignin macromolecules:



It is known [1] that chlorination under atmospheric pressure decreases the content of methoxy groups; since the chlorine content in lignin increases with chlorine pressure, elevated pressures apparently favor demethoxylation.

The demethoxylation usually yields phenolic groups. However, our experiments show that the content of phenolic hydroxyls in chlorinated lignin prepared under elevated pressure is lower than that in the initial lignin. Probably, chlorination under elevated pressure is accompanied by oxidation of hydroxy derivatives to carbonyl compounds. *o*-Benzoquinones are formed, which are oxidized further, as indicated by the increased content of carboxy groups originating from degradation of lignin with breakdown of aromatic rings to dicarboxylic acids. The breakdown of the aromatic rings is clearly seen in the UV spectra of chlorinated lignins (see figure): A clear maximum at 280 nm, characteristic of hydrolysis lignin, transforms into an ill-defined shoulder even at low pressures. In the spectra of chlorinated lignins prepared under higher pressures (0.5, 0.6 MPa), this peak is virtually lacking, which suggests decreased content of guaiacyl and syringyl structures.

CONCLUSION

With increasing chlorine pressure, the chlorine content in chlorinated lignins grows, with the extent of oxidation and degradation of lignin macromolecules increasing.

Effect of Acetylacetone on the Residual Content of Formaldehyde in Urea–Formaldehyde Resin

V. Z. Maslosh, V. V. Kotova, and O. V. Maslosh

Institute of Applied Chemistry, Ministry of Education and Science of Ukraine, Rubezhnoe, Lugansk oblast, Ukraine

Received March 25, 2002

Abstract—The effect of small additions of acetylacetone and ammonia to urea–formaldehyde resin is considered. The occurring processes, involving the formation of 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine and condensation of this compound and acetylacetone with terminal methylol groups of the resin, are discussed.

Stringent environmental requirements are imposed upon the quality of urea–formaldehyde resins (UFRs), which are widely used as binders and are produced on large scale in many countries.

The major drawback of UFRs is their toxicity, resulting from the presence of free formaldehyde. The toxicity can be decreased by improving the production process or introducing special additives that bind free formaldehyde. Numerous additives have been patented for this purpose [1–7], such as urea, thiourea, melamine, higher aldehydes and ketones, aliphatic amines, some inorganic compounds, etc. However, the problem of decreasing the content of free formaldehyde in UFRs remains topical.

The poor performance of the majority of additives may be due to the fact that they react with formaldehyde relatively slowly and reversibly. Thus, the following requirements to the additives can be formulated *a priori*: They should react with formaldehyde fast and irreversibly in the absence of strong acids, bases, and oxidants degrading UFRs or causing their premature curing. Furthermore, the additives and products of their reactions with formaldehyde should be well compatible with UFRs.

Despite the fact that the formaldehyde chemistry has been extensively studied [8, 9], there are only a few reactions meeting these requirements. One of them is the reaction of formaldehyde with β-diketones and ammonia, yielding pyridine derivatives [10]. This reaction is fast at room temperature, even at very low concentration of formaldehyde.

In this study, we examined the possibility of using this reaction to decrease the content of free formaldehyde in UFR.

EXPERIMENTAL

We used a commercial sample of KFMP-15 resin containing 0.5% free formaldehyde; 99% pure acetylacetone; and 25% aqueous ammonia, pure grade.

A glass beaker was charged with 100 g of the resin, and 3.36 g of acetylacetone and aqueous ammonia containing 0.57 g of NH_3 were added. The mixture was stirred at room temperature for 30 min, after which the content of free formaldehyde and the conventional viscosity (VZ-4 viscometer) were determined. Samples were placed in a hermetically sealed vessel, and their viscosity and free formaldehyde content were determiend daily [11, 12].

Experiments were performed with the simplest β-diketone, acetylacetone. Addition to UFR of a mixture of acetylacetone and ammonia (molar ratio 2 : 1) in amount of about 3 wt % fully eliminates free formaldehyde. Monitoring of the sample for 9 days showed that no free formaldehyde appeared in UFR. In a control sample (without addition of acetylacetone and ammonia), the content of free formaldehyde varied within 0.3–0.7%. After adding acetylacetone and ammonia, the resin appearance changed: Within 30 min, the resin became orange-yellow, and the color grew in intensity in the course of 9-day storage at room temperature. Three days after preparing the mixture, the characteristic acetylacetone odor disap-

Conventional viscosity η of urea–formaldehyde resin vs. storage time τ. Acetylacetone : ammonia molar ratio: (*I*) 1 : 0.5, (*II*) 1 : 1, and (*III*) 1 : 1.5; (*IV*) control sample without additives.

peared. In the course of 9-day storage, the resin viscosity rapidly increased (to 150 s), after which the resin became unsuitable for use (see figure), whereas the viscosity of the control sample remained virtually constant within this period. The rapid growth of the viscosity can be avoided by increasing the amount of ammonia added from 0.5 to 1.3 mol per mole of acetylacetone. Such a concentration increases the working life of the resin to 29 days (see figure); throughout this period, no free formaldehyde was detected in the resin.

Let us discuss the possible mechanism of formaldehyde binding. It is known that acetylacetone reacts with acetone and formaldehyde (Hansch reaction [10]) to give 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine.

$$CH_3COCH_2COCH_3 + CH_2O + NH_4OH$$

$$\xrightarrow[-H_2O]{} \begin{array}{l} H_3C{=}COCH_3 \\ HN \\ H_3C{=}COCH_3 \end{array}$$

The formation of this product is confirmed by the appearance of a characteristic yellow-orange color (λ_{max} = 410 nm). However, the role of acetylacetone is not limited to this reaction. The disappearance of the acetylacetone odor and the growth of the viscosity suggest a reaction of acetylacetone with reactive groups of the resin and incorporation of acetylacetone into the polymer chain. The most probable pathway of acetylacetone binding may be its reaction with terminal *N*-methylol groups of the resin (Mannich reaction [13]):

$$-CO-NHCH_2OH + CH_3COCH_2COCH_3$$

$$\rightarrow -CO-NH-CH_2-\underset{\displaystyle COCH_3}{\overset{\displaystyle COCH_3}{CH}} + H_2O.$$

Acetylacetone is very reactive in Mannich reactions [14]. Since it contains several active hydrogen atoms in the methylene and methyl groups, it can react as a polyfunctional monomer.

2,6-Dimethyl-3,5-diacetyl-1,4-dihydropyridine can also enter the Mannich reaction via methyl groups bound to the heteroring and carbonyl carbon atoms; it can react as a polyfunctional monomer also. Therefore, the increase in the resin viscosity may be due to the presence of polyfunctional monomers capable of forming cross-linked structures. Indeed, heating of the resin with the additives to 100°C in the absence of acid catalysts causes formation of a solid nonmelting polymer within several minutes. The control sample of the resin is not cured in the absence of acid catalysts.

Our results demonstrate that UFR containing no free formaldehyde can be prepared by adding acetylacetone and ammonia.

Synthesis of Diperoxy Acetals and Their Use in Production of Latexes for Textile Finishing

I. Yu. Kovalets, T. P. Aleinikova, and V. E. Derbisher

Volgograd State Technical University, Volgograd, Russia

Received February 14, 2002

Abstract—Conditions of synthesis of hydroxyl-containing mono- and diperoxy acetals by the reactions of α-chloroethyl *tert*-butyl peroxide with triethylene glycol and glycerol were determined. These compounds were used for preparing latexes.

The diversity of existing and new requirements to peroxides used in polymer synthesis and processing makes it necessary to extend their assortment and functionality, improve preparation processes, study comprehensively their physicochemical properties, optimize conditions for radical generation, and find conditions of their use in polymer synthesis.

Dialkyl peroxides and their derivatives are of interest in this respect, especially from the viewpoint of their functionality, since these compounds, when decomposing, generate not only alkoxy but also alkyl radicals, which actively initiate radical polymerization. Among such peroxides are, in particular, peroxy acetals containing peroxy and alkoxy groups separated by a carbon atom. Experiments on vulcanization of siloxane, ethylene–propylene, and liquid carboxyl-containing rubbers with functionally substituted peroxy acetals demonstrated their high performance, e.g., in cross-linking of saturated elastomers [1]. These compounds also show promise as initiators of high-temperature radical additions across C=C bonds [2]. Owing to their high thermal stability, low sensitivity to shocks and friction, and low toxicity, peroxy acetals can be widely used to initiate not only polymerization, but also some high-temperature radical processes in various branches of chemical industry.

It should be noted that the available data on synthesis of peroxy acetals are insufficient for setting up their commercial production. In this study, we prepared peroxy acetals by the reactions of α-chloroethyl *tert*-butyl peroxide (α-CETBP) with triethylene glycol (TEG) and glycerol (GL):

$$\begin{array}{l} CH_2{-}OH \\ | \\ R_1 \\ | \\ CH_2{-}OH \end{array} + Cl{-}CH(CH_3){-}O{-}O{-}C(CH_3)_3$$

$$\xrightarrow{-HCl} \begin{array}{l} CH_2{-}O{-}CH(CH_3){-}O{-}O{-}C(CH_3)_3 \\ | \\ R_1 \\ | \\ CH_2{-}OH \end{array} \quad (1)$$

$$\begin{array}{l} CH_2{-}OH \\ | \\ CH{-}OH \\ | \\ CH_2{-}OH \end{array} + 2Cl{-}CH(CH_3){-}O{-}O{-}C(CH_3)_3$$

$$\xrightarrow{-2HCl} \begin{array}{l} CH_2{-}O{-}CH(CH_3){-}O{-}O{-}C(CH_3)_3 \\ | \\ CH{-}O{-}CH(CH_3){-}O{-}O{-}C(CH_3)_3 \\ | \\ CH_2{-}OH \end{array} \quad (2)$$

where $R_1 = (CH_2{-}O{-}CH_2)_2$.

In view of the fact that the initial chloro peroxides are readily hydrolyzed, the chemicals used in the synthesis were thoroughly dried.

Hydrogen chloride was removed from the reaction mixture by purging the reactor with dry nitrogen or argon. It is advisable to perform the reaction at 65°C for 2.5 h. Higher temperatures or longer reaction times are not appropriate, as leading to a decreased content of available oxygen. The diperoxy acetals synthesized were purified by common procedures and analyzed.

The structure of the products was confirmed by IR spectroscopy, titrations, and elemental analysis (see table), and their purity, also by thin-layer chromatography. The ether groups give an absorption band in the range 1000–1300 cm^{-1}; the peroxy groups, a broad band at 820–890 cm^{-1}; also, absorption is observed in the range 2500–3600 cm^{-1}. A broad band at 1160–1190 cm^{-1} is due to C–O vibrations. Broad bands originating from stretching vibrations of alkyl-substituted hydroxy groups are observed at about 3400 cm^{-1}.

Experimental and calculated characteristics of peroxy acetals

Product	Available oxygen content		Hydroxyl number		Found		Calculated	
	%							
	experiment	calculation	experiment	calculation	C	H	C	H
Monoperoxy acetal	5.97	6.02	6.10	6.39	56.3	9.43	56.5	9.9
Diperoxy acetal	9.73	9.85	4.95	5.26	43.5	9.5	43.7	9.7

Peroxy acetals were tested without isolation as initiators for preparing butadiene–styrene, butadiene–acrylonitrile, polyvinyl chloride, polyacrylate, and polystyrene latexes. In the last case, sodium dibutylnaphthalenesulfonate (Nekal') mixed (1 : 1) with nonionic surfactant OP-10 (6.5 wt parts per 100 wt parts of the monomer) was used as emulsifier. The concentrations of the polymers in the latexes were 16–18%.

The latexes prepared were used for impregnation of various textile fabrics (polymer content on the fiber 1.6–1.8%) containing natural and manmade fibers by the procedure accepted in textile finishing [3]. The most interesting results were obtained with polyacrylate and butadiene–styrene latexes: The durability, strength, and resistance to wet-heat treatments of the finished textile materials increased by 90–170%.

EXPERIMENTAL

α-Chloroethyl *tert*-butyl peroxide. Technical-grade *tert*-butyl hydroperoxide was purified by treatment with sodium carbonate, followed by vacuum distillation. Chloroform used as solvent was purified according to [4]. A reactor equipped with a stirrer, a thermometer, and a bubbler was charged with a solution of 9.6 g (0.23 mol) of acetaldehyde in 50 ml of chloroform and 18 g (0.20 mol) of *tert*-butyl hydroperoxide. Dry hydrogen chloride (8.0–8.5 g, 0.22–0.24 mol) was passed at 263–268 K. After phase separation, the aqueous layer was removed, and the organic layer was dried over sodium sulfate. The product was isolated by vacuum distillation (bp 298–299 K at 3 mm Hg). Yield of α-CETBP 21.4 g (70%); n_D^{20} 1.4194.

Monoperoxy acetals. A reactor equipped with a stirrer, a thermometer, and a reflux condenser was charged with 0.2 mol of α-CETBP, to which 40 ml of dry chloroform and 15 g (0.1 mol) of TEG were added. The HCl released was removed with a flow of a dry inert gas and absorbed with an NaOH solution placed in a stirred bubbler. Then the reaction mixture was washed with 15% aqueous $NaHCO_3$ and water to neutral reaction. The resulting solution was dried over sodium sulfate. After removal of the solvent, the product was analyzed. Yield 53% based on the initial chloro peroxide; n_D^{20} 1.4278, d^{20} 1.4938.

Diperoxy acetals were prepared similarly using glycerol instead of TEG. A reactor was charged with 40 ml of chloroform, 6.2 g (0.07 mol) of glycerol, and 30.5 g (0.21 mol) of α-CETBP. The mixture was worked up as described above. Yield 67% based on the initial chloro peroxide; n_D^{20} 1.4465, d^{20} 1.3389.

The IR spectra were taken on a Specord M82 spectrophotometer.

Active oxygen was determined by iodometric titration [5], and hydroxyl number, according to [6].

CONCLUSIONS

(1) Hydroxyl-containing peroxy acetals were prepared by reactions of α-chloroethyl *tert*-butyl peroxide with polyhydric alcohols.

(2) Peroxy acetals were successfully tested as initiators of radical polymerization in preparation of latexes for textile finishing.

BOOK REVIEWS

Chernov, Ya.B., Afinogenov, A.I., and Shurov, N.I., *Borirovanie stalei v ionnykh rasplavakh* (Boronizing of Steels in Ionic Melts), Yekaterinburg: Ur. Otd. Ross. Akad. Nauk, 2001, 223 pp.

Systematic studies of steel boronizing with the use of ionic melts have been carried out at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, since 1965. The investigations were commenced by professor N.G. Ilyushchenko and are continued now by his pupils. The primary attention has been given to deposition of boride coatings on steels by liquid electroless diffusion boronizing. The monograph presents the physicochemical foundations of this method and the technology of coating deposition, and discusses the properties of boride coatings and promising fields of their use. The book comprises an introduction, seven chapters, and list of references.

The introduction (pp. 3–7) notes that the diffusion boronizing is one of the most effective and promising methods for surface strengthening of machinery and tools. This procedure improves their wear resistance, surface hardness, and fatigue strength. The authors give a classification of the boronizing methods. The first chapter (pp. 8–23) is concerned with the physicochemical foundations of the liquid boronizing technique. Various viewpoints concerning the mechanism of electroless boron transfer in ionic melts are analyzed. The authors note that boron transfer processes are based on the same electrochemical reactions involving boron ions in lower oxidation states. The very small second chapter (pp. 24–28) considers boronizing in halide and halide-oxide melts. Their main disadvantage is the relatively high volatility of boron halides and oxyhalides. The third chapter (pp. 29–63) discusses boronizing in oxide melts. The main component of the electrolyte is sodium tetraborate, to which various compounds and, in particular, boron carbide B_4C are added. The material presented in the chapter is predominantly of formulation nature.

The fourth chapter (pp. 54–79) summarizes evidence concerning the influence of various factors on the boronizing kinetics, formation of the surface boride layer, and its thickness. It is, in particular, mentioned that raising the content of carbon and alloying elements in steels hinders the diffusion of boron and leads to its accumulation in the surface layer. Some alloying elements are incorporated into the composition of borides, which makes higher their hardness and wear resistance; however, alloying, as a rule, lowers the rate of boronizing, leads to build-up of internal stresses, and enhances the tendency toward flaking-off of the boronized layer. The fifth chapter (pp. 80–113) describes the technology of liquid boronizing, developed at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, with the participation of the authors of the monograph. The electrolyte contains (wt %): sodium tetraborate 79, sodium chloride 15, amorphous boron 6. The process temperature lies within 850–950°C. Data on how the thickness of the diffusion layer on steels of various brands depends on temperature and time of boronizing are presented.

The sixth chapter (pp. 132–180) is devoted to the properties of boride coatings: their structure, microhardness, residual stresses, wear resistance, and corrosion resistance. The seventh chapter (pp. 181–205) lists plants employing the technology of liquid boronizing. The bibliography (pp. 206–221) contains references to 270 publications and patents, mainly by domestic authors.

On the whole, the monograph has a technological orientation. It includes various kinds of evidence concerning processes of boronizing and, in the first place, the results of the studies performed at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences. In our opinion, the book pays insufficient attention to the theory of electroless boronizing, to which were devoted comprehensive and original investigations of Ilyushchenko and co-workers, among whom were the authors of the monograph. Thermodynamic analysis of the process virtually escaped the attention of the authors. Nevertheless, there is good reason to believe that the book will promote wider use of boronizing techniques at machine-building plants of the country. The authors present the technology of the process with exhaustive completeness.

BOOK REVIEWS

Moiseev, G.K. and Vatolin, N.A., *Nekotorye zakonomernosti izmeneniya i metody rascheta termokhimicheskikh svoistv neorganicheskikh soedinenii* (Some Patterns of Variation and Methods for Calculation of Thermochemical Properties of Inorganic Compounds), Yekaterinburg: Inst. Metall. Ur. Otd. Ross. Akad. Nauk, 2001, 136 pp.

In the last two decades, much attention has been given to compiling and supplementing of databases of thermodynamic quantities for inorganic compounds. Among important sources furnishing new information and allowing revision of the existing data are various calculation methods. Investigations in this field have been carried out at the Institute of Metallurgy, Ural Division, Russian Academy of Sciences, under general supervision of V.A. Vatolin, academician of the Russian Academy of Sciences, for quite a number of years. These investigations were aimed to reveal patterns of variation of the thermodynamic properties of various groups of inorganic compounds, establish the corresponding correlations, and develop methods for evaluation of the basic thermodynamic characteristics of the compounds: standard enthalpy of formation, ΔH^0_{298}; standard entropy, S^0_{298}; specific heat, $C^0_{p,298}$; and temperature of congruent melting, T_m.

The book presents new evidence concerning the thermochemical properties of several tens of inorganic substances of varied complexity, which allowed the authors to substantially supplement the previously compiled database[1] and carry out various computer simulations. The arrays of reference data were analyzed and correlations were revealed using the method of thermodynamic modeling, developed in previous works of the same authors. It should be particularly emphasized that the given publication presents information concerning exclusively the studies of its authors and does not pretend to give a complete review of methods for calculating the quantities in question.

[1] Moiseev, G.K., Vatolin, N.A., Marshuk, L.A., and Il'inykh, N.I., *Temperaturnye zavisimosti privedennoi energii Gibbsa nekotorykh neorganicheskikh veshchestv: Al'ternativnyi bank dannykh ASTRA, OWN* (Temperature Dependences of Reduced Gibbs Energy of Some Inorganic Substances: Alternative Database Astra, OWN), Yekaterinburg: Ur. Otd. Ross. Akad. Nauk, 1997.

The book comprises six chapters, conclusion, and a common bibliographic list for the entire monograph. The first chapter (pp. 5–38) discusses fundamental aspects of how ΔH^0_{298} varies for related substances in binary and quasi-binary inorganic systems. The possibility of evaluating the standard enthalpies of formation of oxides, double oxides, intermetallic compounds, carbides, phosphides, borides, and chlorides are considered.

The second chapter (pp. 39–53) is devoted to application of the model of ideal solutions of reaction products to evaluation of the standard thermodynamic characteristics of copper-containing ceramic semiconductors. The third chapter (pp. 54–57) presents an analysis of the variation pattern of the standard entropy S^0_{298} in some classes of inorganic compounds. The numerical equations proposed by the authors on the basis of the pattern revealed can be used to revise the known, and find unknown S^0_{298} values for binary compounds. Data on standard entropy are analyzed for 380 compounds: phosphides, arsenides, selenides, tellurides, and bismuthides, and their reliability is assessed.

The fourth chapter (pp. 68–92) is concerned with calculation of the standard thermodynamic characteristics of double oxides. The authors demonstrate that the procedure proposed is applicable to calculation of ΔH^0_{298}, S^0_{298}, and $C^0_{p,298}$ for binary oxides, with precision achieved in physical experiments, from the results of a single computer simulation in terms of the model of ideal solution of reaction products. The fifth chapter (pp. 93–117) analyzes the dependences of the standard enthalpies of formation of intermetallic compounds on the atomic radius of one of components and on the numbers of the constituent elements in the periodic table. In the sixth chapter (pp. 118–125), the authors summarize the results of their studies concerned with evaluation of the standard thermo-

dynamic characteristics of inorganic compounds of various classes.

In a brief conclusion (pp. 126, 127), it is, in particular, noted that the known data on ΔH^0_{298}, S^0_{298}, and $C^0_{p,298}$ for approximately 1335 binary and quasi-binary compounds are subjected in the book to a critical review with the use of the numerical evaluation methods proposed. For 20–25% of the substances the deviations of the calculated values from the known data are found to exceed 15%. Based on this fact, the authors conclude that only 75–80% of the reference and previously accepted data on the thermodynamic properties of inorganic compounds are reliable and can be used in calculations.

The bibliographic list contains references to 166 publications, of which about 30% belong to the authors of the book.

The monograph was published with the financial support of the Russian Foundation for Basic Research. It is of indubitable interest, although its manner of presentation is intended for rather advanced readers. In our opinion, the authors use, when not absolutely necessary, too large a number of various abbreviations, without giving their meaning in a single place. The book is very well printed.

Ufa State University of Petroleum Engineering, Ufa, Bashkortostan, Russia

Abstract—The use of microwave techniques in scientific research is reviewed. Also some semicommercial-scale microwave units are examined.

The microwave range of the electromagnetic spectrum covers the ultrahigh frequencies from 30 GGz to 300 MHz [1]. Radiation from this range is used in radiolocation, satellite TV communication systems, radio navigation, biology, chemistry, and medicine. For the unification sake, the working frequencies of 915, 2450, 5800, and 22 125 MHz were accepted by the International Agreement as the working frequencies for industrial and scientific microwave facilities [2, 3]. The frequency of 2450 MHz (working frequency of home microwave ovens) is most often used in research practice.

At present the term microwave radiation (MWR) is commonly used in Western literature, and the term ultrahigh frequency (UHF), in the Russian-language literature.

The first device for generation of microwaves was invented in the Birmingham University in the Second World War time in the framework of the program on development of radar systems. This device called magnetron was manufactured in large amounts in the wartime in collaboration with the United States [3, 4]. It was known even at that time that microwaves can heat up water very rapidly.

In the middle 1950s, microwave heating became the custom with microwave ovens, and later it was used in food industry for drying of macaroni foods [5], corn [6], fruits and berries [7], etc.

At present, microwave heating is more and more frequently used for drying industrial goods. For example, the Ford Motors uses a microwave unit for drying ceramic molds used in manufacture of automotive engines [8]. International Standard Electric Co. and Special Metals Co. use MWR in production of refractory and ceramic products [9]. Microwave units were developed for drying and splicing of wood and for acceleration of hardening of concrete [10]. The Institute of Mines of the Russian North and the St. Petersburg Mining Institute developed microwave units for softening of frozen grounds [11]. Also microwave radiation finds use for drying processed films [12, 13].

After 1986, when the first works were published on the use of MWR in organic synthesis [14, 15], great interest has been expressed by chemists in this method, since many reactions proceed considerably more rapidly in the MWR field, providing higher yields of the products as compared to the traditional heating methods. Although the effect of MWR on the reaction mechanism has not been demonstrated in these first works, such indisputable advantages of the method as high heating rate, power control without inertia, and the possibility of bulk heating gave impetus to further investigations in this field.

Despite active research performed in recent years in Russia [16–21] and other countries [22–30] in the reviewed area, the progress in the microwave chemistry is somewhat limited by hardware implementation problems.

The most researchers conducted their experiments in home microwave ovens equipped, if necessary, with a stirrer and also a reflux condenser arranged outside the irradiation zone [3, 16, 21, 24]. In such a system, it is needed to avoid escape of the radiation at the joints between the reaction flask with a stirrer and a pipe for withdrawal of the reagent vapor. Mingos [3] in his experiments protected the withdrawal pipes at the outlet from the case using copper pipes at least 12 cm long, which should have good contact with the case. In any case, a microwave unit should be equipped with an escaping radiation detector. According to the existing Sanitary Regulations, the radiation power density should not exceed 1 mW cm^{-2} at a distance of 5 cm from the oven (ANSI US Standard) and 0.01 mW cm^{-2} at a distance of 50 cm from the

radiation source (European and Russian Standards) [31].

A home microwave oven is of little use for chemical experimentation. It is not designed to be operated under conditions of explosions and action of aggressive media. Rotary tables and bottoms of home ovens are unsuitable for chemical reaction vessels. The known information about explosions of reaction vessels in the MWR field [15, 22] demonstrate the necessity in installation of a temperature and pressure control and regulation system, which appears to be rather difficult with a home oven.

This and other problems arising with home microwave ovens initiated the researchers to begin development of microwave systems specially designed for chemical experiments [32, 33]. For example, Cablewski *et al*. [32] developed a laboratory microwave continuous reactor (MCR) (Fig. 1) with a power of 600–800 W. In this reactor, the reaction mixture is fed under pressure to a coil pipe arranged in the microwave heating zone and then through a heat exchanger to the product receiver. The setup is equipped with temperature and pressure control devices, a pressure regulating valve, and a microprocessor-based controller for setting such process parameters as the reagent feed rate and heating and cooling temperatures, which can be varied in the course of the process. The coil is made from perfluoroalkoxy Teflon. The system can operate at temperature of up to 200°C and pressure of up to 1400 kPa. Cablewski *et al*. [32] reported the results for 26 reactions, whose rates were higher by a factor of 3 on the average as compared to the reference data. Among these reactions were nucleophilic substitution, esterification, ester interchange, acetylation, acid and base hydrolysis, isomerization, decarboxylation, and elimination. However, MCR is not a universal setup. It cannot be used in the cases of solid or highly viscous substances and also of microwave-incompatible substances (metals and compounds having no dipole moment).

Strauss and Trainor in their review [33] described a 1200-W microwave batch reactor (MBR) (Fig. 2). Its performance characteristics are as follows: volume 20–100 ml, temperature up to 260°C, and pressure up to 10 MPa. The reactor is equipped with a device for determination of the absorbed and reflected energy, a load control system providing the optimal heating, a system for direct measurement of the temperature and pressure, a stirrer, and a system for feeding and withdrawal of the reaction mixture in the course of heating. The reactor has chemically inert walls. It is designed so as to provide the possibility of conducting a reaction at atmospheric pressure in air or under inert gas.

To prevent back irradiation of the magnetron, the reflected microwave power is controlled. With increasing reflected power, the input power is decreased through the load control system. Continuous control of the temperature, pressure, and radiation power, stirring, and the presence of cooling pipe and emergency valve—all these provide safe and efficient operation of the system.

With an example of heating of a 100-ml sample of 1,3-propanediol, Strauss and Trainor demonstrated the high rate of establishment of the desired temperature in MBR: bp 214°C was reached in 2 min, whereas that in an autoclave, only in 14 min [33].

An additional advantage of microwave heating over the traditional methods is in exclusion of the effect of vessel walls. However, the most of the reaction vessels for conducting microwave-stimulated reactions

Table 1. Characteristics of microwave digests

Characteristic	Closed multimode system	Monomode system	
		open	closed
Type	Floyd ovens	Digests 301, A301, 401, MX 350, MX 4350	Superdigests
Operation under pressure	Yes	No	Yes
Automated addition of reactants	No	Yes	No
Mineralization mode	Up to 12 samples simultaneously	From 4 to 16 samples simultaneously, depending on the model	Up to 4 samples simultaneously
Use of acids with bp above 200°C	No	Yes	No
Use of acids with bp below 200°C	Yes	Yes	Yes
Reaction vessel material	PTFE*	PTFE, quartz, borosilicate glass	Quartz

Bringing to dry residue	No	Yes	No
Main fields of application	Dissolution of biological and geological samples (nonexplosive)	Analysis of plastic materials, petroleum products, composites, environmental objects, mineral samples, and agricultural, food, and sea products; determination of COD** in water (MX 4350 Model only)	Determination of trace amounts of volatiles, hydrolysis, and dissolution of ceramic materials

* Poly(tetrafluoroethylene).
** Chemical oxygen demand.

under pressure are made from heat-insulating materials, so that cooling after completion of the reaction takes a long time. In CMR the problem of rapid cooling is solved by arranging the heat exchanger just at the outlet of the radiation zone, i.e., the reaction mixture is cooled under pressure, to prevent loss of volatiles and decomposition of thermally unstable compounds.

In MBR, a cooling pipe filled with a coolant is used, whose end is arranged immediately in the reaction mixture, thus increasing the cooling efficiency. Furthermore, cooling can be started, if needed, even in the course of irradiation. It is also important that, in the course of heating and cooling, the reaction vessel is inside the microwave reactor, so that there is no access to it until its content is under pressure. Therefore, MBR and CMR are particularly efficient in synthesis of thermally unstable compounds.

The energy distribution throughout the microwave chamber can be both multi- and monomode. In a multimode reactor, as a home microwave oven is, the energy is randomly distributed as a result of multiple reflections from the oven walls.

Microwave digests provide an example of a monomode reactor. They are designed for sample preparation for atomic absorption spectroscopy, spectrocalorimetry, ICP, ion-exchange chromatography, polarography, and also for nitrogen determination by the Kjeldahl method. In these reactors, MWR is input as a focused beam to the bottom of the reaction vessel. The performance characteristics of Prolabo digests (France) are given in Table 1 [34].

The digest units are equipped with a reagent feed pump and a programming block for control of the process parameters (reagent feed rate, temperature, and irradiation power and time). The unit can include several digest modules.

Other manufacturers of microwave facilities for analysis are Milestone Inc. and CEM Corp. Among their products one may find open- and closed-vessel systems, moisture analyzers, microwave extraction systems, and accessories and vessels for microwave systems [35].

Loupy [36] proposed to use a Maxidigest MX-350 microwave analyzer (Prolabo) for chemical syntheses. The advantage of this instrument over a home oven is

Table 2. Comparative data on heating of diethyl benzylmalonate in decarboxylation

Heating mode	Power, temperature	Reaction time	Yield, %
Reactor:			
multimode	600 W	10 min	50
monomode	60 W	10 min	90
Thermal heating	160°C	4 h	90

in the single-mode microwave type characterized by high output power at decreased power consumption and also in excellent reproducibility of the results. Particularly, the author made a comparative analysis of the efficiency of the two types of reactors (Table 2) with an example of decarboxylation.

$$PhCH_2CH(CO_2Et)_2 \xrightarrow[-CO_2]{} PhCH_2CH_2CO_2Et.$$

In performing chemical syntheses under elevated pressure in the microwave zone, the reaction vessels should be chemically inert, transparent for microwaves, and thermally and barostable. Researchers most frequently used sealed pressure tubes of borosilicate or Pyrex glass, placed into a heat-insulating medium (vermiculite) [15, 37] or into a Parr bomb [3] for the safety sake in the case of explosion or failure of the vessel. Pyrex tubes were also used for conducting reactions at the atmospheric pressure [16–20]. Parr [38] and the CEM Corp. [39] developed specially designed acid-proof screw-top vessels.

Temperature monitoring is a difficult problem in microwave experiments, since the traditional methods are unsuitable under conditions of high-frequency electric field. Giguere [15] measured the temperature in sealed tubes using capillaries filled with reference compounds (with known mp) attached to the reaction vessel. This method is not universal. It provides no information about the temperature evolution in the course of the process. It is more reliable to use fiber-optic devices [33, 40, 41]. Abramovitch [22] monitored the temperature of the closed-vessel system using a gold-coated thermocouple in a thick quartz casing, but he did not describe technical details. Daminev [42] improved the temperature monitoring capabilities by eliminating undesired arcing at temperatures near 500°C in the thermocouple quartz well by isolation of this unit and shielding of the thermocouple. The shield was a metal well of corrosion-resistant steel, isolated from the case via ceramics or fluoroplastic and grounded.

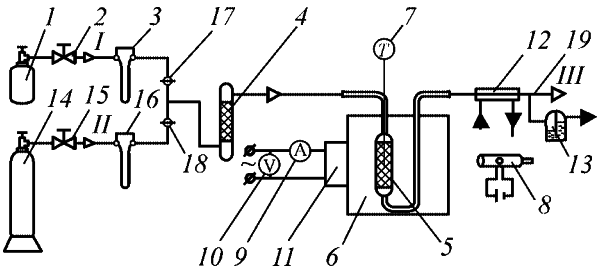

Fig. 3. Schematic of a laboratory microwave dehydrogenation unit: (*1, 14*) cylinders with butenes and nitrogen, respectively, (*2, 15*) fine control reducers, (*3, 16*) rheometers, (*4*) dehumidifier, (*5*) reactor, (*6*) cavity, (*7*) thermocouple, (*8*) optical pyrometer, (*9*) ammeter, (*10*) voltmeter, (*11*) microwave generator, (*12*) cooler, (*13*) safety valve, (*17, 18*) cocks, and (*19*) gas withdrawal to the gasometer. (*I*) Raw material (butenes), (*II*) diluent (nitrogen), and (*III*) contact gas.

Several microwave units of various purposes were developed at the Ufa State University of Petroleum Engineering [42–46].

Daminev *et al*. [42, 43] studied the effect of microwave radiation on catalytic dehydrogenation of 1- and 2-butenes into 1,3-butadiene. A microwave reactor for performing heterophase endothermic reactions and a laboratory unit for dehydrogenation of butanes were designed on the basis of the results obtained. The essence of the technique proposed is that the cold raw material (1- and 2-butenes) is passed through a catalyst, which, in its turn, is an absorber of microwave radiation. Therefore, the catalyst serves as a thermal energy source for dehydrogenation, preserving, however, the function of the ordinary heterogeneous catalyst in the gas-phase process.

In the laboratory dehydrogenation unit (Fig. 3), a gas mixture of the butenes and nitrogen (gas-diluent) is fed via a dehumidifier to the reactor partly filled with the catalyst. The reactor is arranged in the cavity of the microwave generator. The temperature of the reaction zone is monitored using a thermocouple, and the temperature of the outer side of the reactor, by a pyrometer. The power consumed by the microwave generator is controlled with an ammeter and a voltmeter.

The microwave generator (1300 W) consists of a power supply, a waveguide, a ventilation unit, and a control station. The magnetron transforms electric current into electromagnetic radiation (2450 MHz), which passes to the cavity through the waveguide. The control station provides the magnetron switch on and switch off and the time control using an automatic timer. The cavity represents a case made from sheet steel with a door at one side and process holes at

the other side. To prevent escape of the microwave radiation, copper tubes are fixed to the holes from the outside. In the top of the cavity, a scatterer (device for uniform dissipation of the electromagnetic energy throughout the bulk) is arranged. The reactor (quartz tube 170 cm long and 30 mm i.d.) is equipped with a quartz well for the thermocouple and a quartz net for arranging the catalyst.

The reactor of the setup for conducting thermocatalytic reactions serves as a resonator of the microwave generator (Fig. 4) [42]. Its upper cover plays a role of an emitting antenna. The raw material is fed to the top of the reactor, and the contact gas is taken off from the bottom. The coupling chamber in the outlet unit is meant for utilization of the residual radiation which is absorbed by water. The circulator is arranged in the waveguide to prevent the entry of the reflected radiation to the magnetron.

Bikbulatov *et al*. [43] optimized the process with K-16u industrial catalyst: temperature 600°C, raw material to nitrogen volume ratio 1 : 10, and raw material space velocity 800 h^{-1}. With these conditions and at a catalyst bed of 73 mm, the radiation at the bottom of the reactor is practically lacking.

Shulaev [44] proposed thermodynamic methods for designing a reactor for heterophase catalytic processes with the use of a new mode of heat supply to the reaction zone. The mathematical relationship between the MWR parameters and reactor characteristics obtained in this work provides the possibility of optimizing and controlling the operation mode of electrodynamic reactors.

Energy calculations made for the microwave reactor demonstrated that its efficiency is more than twice that of an industrial adiabatic reactor [42]. The use of microwaves eliminates the need in water vapor as a heat carrier, which, in its turn, eliminates atmospheric pollution with toxic materials formed as a result of firing in superheaters, and water is used only for absorption of the excess radiation in the closed line. Therefore, the new method for heat supply to the reaction zone shows promise in the economic and environmental respects.

In [45] one can find a description of Elektronika KIE-501 laboratory microwave unit (2.5 kW, 2450 MHz) designed for thermal treatment of dielectric materials, particularly grounds, and for research purposes. Also stationary (industrial) and portable (for field works) semicommercial-scale microwave units for heat strengthening of grounds were described. Heat treatment with these units involves three stages:

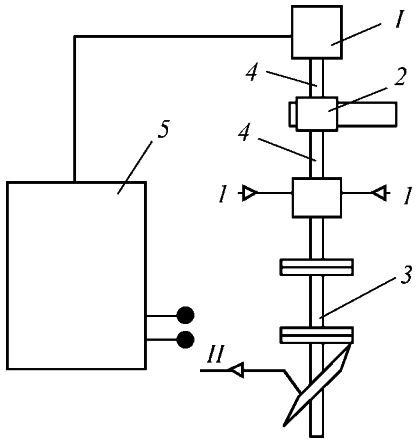

Fig. 4. Laboratory unit for performing thermocatalytic reactions in the microwave field: (*1*) microwave generator, (*2*) microwave circulator, (*3*) reactor, (*4*) waveguide, and (*5*) power supply. (*I*) Raw material (butenes) and (*II*) contact gas.

heating (supplied heat entirely goes to heating of ground to 100°C); drying; and roasting (heating to 1100°C).

The laboratory microwave unit is assembled on a specially designed elevating platform on a laboratory table. It includes an MWR source, waveguide system, working chamber, control system (direct and reflected power wattmeters and thermocouple), and ventilation and cooling systems.

Two versions of the stationary units were designed: one for one-side treatment of ground blocks and another, for two-side treatment. The first version includes an electric heating unit, since in one-side treatment it is impossible to ensure uniform warming of the entire body of ground. In the second version, only microwave heating is used.

The stationary units include three basic blocks: energy, working, and safe (for protection of the personnel against stray radiation). The energy block includes a microwave generator, waveguide system, power dividers, transmitters, and a medium for absorbing excess radiation. It is arranged on a mobile platform, which moves by a sinusoidal trajectory along the ground block surface, to provide the estimated energy density. The base element of the working block is a kiln. Protection of the personnel against radiation is provided by a heat-retention lagging, metallic shield of the kiln, and airtight doors.

A ground block on a small cart goes from the molding shop to the first channel, moving in the direction of the transmitters. It is heated to 950–1100°C, and then it goes to the second channel, to be further

Table 3. Characteristics of semicommercial-scale microwave units for thermal strengthening of grounds

Characteristic	Unit			
	stationary one-side	stationary two-side	mobile	mobile unit for operation just at deposition site
Maximal total output power of MWR sources, kW	500	1000	500	500
Unit capacity, m^3 $year^{-1}$	7500	12 100	6500	3500
Specific power consumption, MJ m^{-3}	2637	2513	2012	3668
Application area	Manufacture of heavers for stabilization of pipelines			Manufacture of anchor stabilizers for pipelines; construction of foundations

heated with the electric heaters. At the final section of the second channel, the block is cooled.

The two-side stationary unit has two energy blocks and a Z-shaped kiln. In the first channel, a ground block is heated to 500–600°C, in the initial section of the second channel, to 950–1100°C, and in the end section, it is cooled.

The mobile microwave unit for manufacture of heat-treated ground blocks is intended for the pipe run conditions. It includes a molding machine and a kiln, which are arranged on mobile platforms. The unit is equipped with power and movement facilities, automatic control system, and a radiation protection block. A molded ground block goes to a roll-table of the kiln, where it is dried and heated to 950–1100°C, and then to a receiver.

The mobile microwave unit for heat treatment of grounds just at their deposition site is based on KrAZ-250 truck. Its energy block includes an MWR source, waveguide and transmitter systems, and also a rotating gear for the waveguide sections to revolve on their axis. Characteristics of the semicommercial-scale units are given in Table 3.

The strengthening of grounds with microwaves, compared with other methods (chemical and physicochemical), provides better mechanical characteristics of grounds after treatment and reduces the transport charges. The temperature distribution across the ground body with firing in a well is close to that with microwave heating at 915 MHz. However, the heating time in the first case is 40 h, and in the second case, only 8 h [46].

Finally, the use of microwaves shows promise for improving technical, cost, and environmental parameters of the most important physicochemical processes, particularly, for accelerating chemical reaction and increasing yields of target products in organic synthesis. By now, techniques are developed for microwave enhancement of various processes under both laboratory and industrial conditions.

Abstract—Transformations of hydrargillite γ-$Al(OH)_3$ during mechanochemical activation in various grinding mills and further calcination of activated samples at 200–1300°C were studied. The effects of mechanochemical activation and additions of iron(III) oxide compounds on the temperature of corundum formation and on its crystal size distribution were studied.

Finely crystalline corundum α-Al_2O_3 with the crystal size less than 1 μm is a promising polishing material [1]. One of procedures for preparing corundum is heat treatment of γ-$Al(OH)_3$ (hydrargillite) in air. The sequence of transformations in the course of its calcination, the temperatures of formation of intermediate and equilibrium phases, and the size distribution and habit of corundum crystals depend on a number of factors, e.g., on the chemical composition and particle size distribution of the initial aluminum hydroxide [1, 2], its purity [2–5], presence of structure defects [6–8], etc. The formation of α-Al_2O_3 is preceded by the formation of a number of intermediates, and, according to [2, 7–10], the general scheme of the transformations can be presented as follows:

$$\gamma\text{-}Al(OH)_3 \begin{cases} \xrightarrow{300^\circ C} \text{X-ray amorphous } Al_2O_3 \xrightarrow{500-800^\circ C} æ\text{-}Al_2O_3 \xrightarrow{1200^\circ C} \alpha\text{-}Al_2O_3 \\ \xrightarrow{180^\circ C} \gamma\text{-AlOOH} \xrightarrow{300-500^\circ C} \gamma\text{-}Al_2O_3 \xrightarrow{850-1000^\circ C} \theta\text{-}Al_2O_3 \xrightarrow{1200^\circ C} \alpha\text{-}Al_2O_3 \end{cases} \quad (1)$$

As believed in [2, 8], the existence of two directions of phase and chemical transformations results from the fact that X-ray amorphous Al_2O_3 is always formed along with the γ-AlOOH (boehmite) phase in the thermolysis of γ-$Al(OH)_3$ in air, with further phase transitions of X-ray amorphous Al_2O_3 occurring independently. The consequence of this fact is high polydispersity of α-Al_2O_3, which makes it unsuitable as a polishing material. It is known [11–14] that mechanochemical activation of hydrated oxides promotes the formation of finely dispersed powders on calcination, and admixtures of oxides isostructural with α-Al_2O_3 reduce the temperature of the corundum formation.

In this work we studied phase and chemical transformations of hydrargillite in the course of mechanochemical activation in grinding mills of various types and of the further calcination in air at 200–300°C. Also, we examined the effect of mechanochemical activation and additions of iron(III) oxides on the temperature of formation and crystal size distribution of corundum.

EXPERIMENTAL

We used technical-grade aluminum hydroxide (irregular-shaped platelike crystals 1–5 μm in diameter and 10–15 nm thick). According to the data of X-ray phase and thermogravimetric analyses, the sample was single-phase γ-$Al(OH)_3$; its empirical composition $Al_2O_3 \cdot 3.1H_2O$ was close to the stoichiometric composition. As additions we used Fe(II) or Fe(III) com-

1070-4272/02/7509-1384$27.00 © 2002 MAIK "Nauka/Interperiodica"

pounds in the form of $FeSO_4 \cdot 7H_2O$, α-FeOOH, and α-Fe_2O_3 in amounts of 1–10 wt % (recalculated on Fe_2O_3), which were added to hydrargillite before mechanochemical activation and uniformly distributied by stirring. Hydrargillite samples mixed with iron compounds (e.g., α-FeOOH) were mechanochemically activated in laboratory grinding mills under various energy conditions. The duration of the activation was 2–10 min in planetary mills; 15, 30, and 60 min in vibratory mills; and 0.5–3 h in ball mills. Isothermal calcination of samples was carried out at 200–300°C for 2 h.

The phase composition and particle size distribution of samples were evaluated by X-ray phase analysis (DRON-3 diffractometer, filtered CoK_α radiation) and by transmission electron microscopy (UEMV-100K), and the chemical composition, by volumetric chemical analysis and thermogravimetry (MOM derivatograph, Hungary; heating rate 10 deg min^{-1}). The unit cell parameters *a* and *c* of compounds with the corundum structure were determined by the standard technique [15] from the reflections (226) and $10\bar{1}0$). The average crystal size *d* was calculated from physical broadening $\Delta 2\theta$ of diffraction peaks [15].

According to the thermogravimetric data, the weight loss in the initial hydrargillite sample occurs within a broad temperature range, 200–500°C (Fig. 1, curve *a*). The DTA curve contains three endothermic peaks at 215, 310, 480°C and one exothermic peak at 850°C. According to the published data [2, 3] and the data of X-ray phase analysis (Fig. 2) for samples subjected to isothermal calcination at the above-mentioned temperatures, the first endothermic effect results from chemical transformation of a part (~15 wt % by the thermogravimetric data) of γ-$Al(OH)_3$ to the γ-AlOOH (boehmite) phase; the second (310°C), from chemical transformation of the remaining hydrargillite to X-ray amorphous Al_2O_3; and the third (480°C), from chemical transformation of γ-AlOOH to γ-Al_2O_3. The exothermic effect at 850°C results from the crystallization of X-ray amorphous alumina into finely crystalline (~7 nm) θ-Al_2O_3. The formation of the equilibrium corundum phase during the isothermal calcination in air is macroscopically manifested starting from 1100°C (Fig. 2, curve *e*). According to the electron microscopic data, the single-phase sample of α-Al_2O_3 obtained by calcination of γ-$Al(OH)_3$ at 1300°C is polydisperse and consists of isometric or oval corundum crystals of size from 0.2 to 6.0 μm, sintered into larger aggregates of size 2–5 μm (Fig. 3a).

The mechanochemical activation of the initial hydragillite resulted in changes in its structure and chemical composition, with the extent of these changes being proportional to the energy of the mechanochemical action. Thus, redistribution of the relative intensities of the diffraction peaks was observed in the X-ray patterns of a sample subjected to mechanochemical activation in a ball mill for 3 h. For example, the ratio of intensities of reflections β with Miller indices (002) and (110) ($\beta = I_{002}/I_{110}$, where I_i are the integral intensities of the corresponding reflections) increases from 3 [initial γ-$Al(OH)_3$] to 10. Also, hydrargillite samples became moist after milling. No changes in the shape and size of γ-$Al(OH)_3$ crystals

were observed after mechanochemical activation in a ball mill.

In addition to the redistribution of the relative intensities of reflections in the X-ray patterns of hydrargillite samples mechanochemically activated in a vibratory mill, the half-widths of the reflections increased with the grinding time τ. In particular, when τ increased from 0 to 1 h, the half-width $\Delta 2\theta$ of the (002) reflection of hydrargillite increased approximately twice. As compared to the mechanochemical activation in a ball mill, moistening of samples was more pronounced. When γ-$Al(OH)_3$ was ground in a planetary mill, which exerts the strongest mechanochemical effect on samples as compared to the other mills [11], along with strong moistening observed alreay within 10 min, the crystalline structure of hydrargillite was completely destroyed. This is proved by the absence of γ-$Al(OH)_3$ reflections in the X-ray patterns. However, diffuse diffraction maxima were detected, assignable to the boehmite phase in accordance with the data of [16] and Fig. 2 (curve *c*).

There are two maxima and one minimum at 105, 410, and 520°C, respectively, in the DTA curve of a hydrargillite sample activated in a planetary mill (Fig. 1, curve *c*). Comparison of the data [1, 7, 10] on the boehmite dehydration with the results of the X-ray phase analysis of samples subjected to isothermal calcination at the above-mentioned temperatures shows that the endothermic effect at 105°C is due to the removal of approximately 11 wt % of physically adsorbed water (Fig. 1, curve *d*); the second endothermic effect (410°C), to the chemical transformation of finely crystalline γ-AlOOH to γ-Al_2O_3 accompanied by the removal of the remaining (~15 wt %) constitutional water; and the exothermic effect at 510°C, apparently, to crystallization of γ-Al_2O_3. The presence of a considerable amount (~11 wt %) of physically adsorbed water in the mechanochemically activated hydrargillite sample shows that the crystal structure of the γ-$Al(OH)_3$ phase is partially (in ball and vibratory mills) or completely (in planetary mill) destroyed during the activation. As a result, a part of constitutional water (OH^- groups in hydrargillite) is released (activated hydrargillite dehydration), which results in moistening of the sample during the activation. The highest degree of γ-$Al(OH)_3$ dehydration is reached in a planetary mill as compared to the other mills and is probably responsible for the formation of the γ-AlOOH phase. We emphasize that the conversion of compounds based on hydrated oxides of various metals to the amorphous state and their phase and chemical transformations in the course of mechanochemical activation were mentioned in numerous pub-

lications [6, 11–13], where the possibility of the transformation of crystallization water into adsorbed water was confirmed. If adsorbed water is not taken into account, the composition of the hydrargillite sample mechanochemically activated in a planetary mill corresponds to the formula $Al_2O_3 \cdot 1.1H_2O$, which is close to the boehmite stoichiometric composition.

The X-ray phase analysis shows that, in calcination of mechanochemically activated hydrargillite samples, corundum starts to form from at about 1100°C. Its content reaches 100 wt % in samples calcined at 1200°C. According to the electron microscopy data, α-Al_2O_3 samples obtained by calcination of activated hydrargillite at 1200°C are characterized by narrow particle size distribution and consist of isometric or oval crystals of size 0.3–0.5 μm (Fig. 3b). When the temperature of heat treatment is increased to 1300°C, separate corundum crystals are sintered to form aggregates.

Heat treatment of activated γ-$Al(OH)_3$ in a mixture with Fe(II) or Fe(III) compounds results in a decrease in the temperature of corundum formation to approximately 900°C; however, apart from a set of reflections characteristic of the α-Al_2O_3 phase (their half-width $\Delta 2\theta$ is 0.3°), weak maxima are observed in the X-ray patterns, which, according to [16], should be assigned to the α-Fe_2O_3 phase. The relative intensity of these reflections changes in parallel with the weight fraction of iron(III) oxide added to hydrargillite. The pink color of samples calcined at 900°C, characteristic of hematite, also suggests the existence of the individual α-Fe_2O_3 phase. The increase in the calcination temperature to 1100°C results in the formation of single-phase samples with the corundum structure. Their color depends on the weight fraction C of added iron(III) compounds and changes from white ($C \leq$ 1 wt %) to light yellow. As the weight fraction of Fe_2O_3 in samples increases, the unit cell parameters a and c of the phase with the corundum structure increase from $a = 0.4760 \pm 0.0002$ and $c = 1.2987 \pm 0.0005$ nm ($C = 0$) to $a = 0.4790 \pm 0.0002$ and $c = 1.3025 \pm 0.0005$ nm ($C = 10$ wt %). This suggests formation of a solid solution of Fe_2O_3 in α-Al_2O_3 under these conditions.

According to the electron microscopic data, the size of corundum crystals depends on the amount of added Fe_2O_3. In particular, the corundum sample obtained at 1200°C and containing 1 wt % Fe_2O_3 is monodisperse and consists of crystals 0.3–0.4 μm in size with approximately hexagonal faces (Fig. 3c). At the Fe_2O_3 content in samples increased to 5 wt %, larger corundum crystals are formed (approximately 1 μm, Fig. 3d), and the crystal size in samples containing more than 5 wt % Fe_2O_3 can reach 2 μm (Fig. 3e).

Let us examine possible causes of the formation of monodisperse corundum samples upon the heat treatment of hydrargillite. As already noted, the chemical transformations of hydrargillite in the range 200–400°C can occur by two independent pathways shown in scheme (1). Therefore, along with γ-AlOOH, X-ray amorphous aluminum oxide is always formed by dehydration of γ-$Al(OH)_3$. At higher temperatures, phase and chemical transformations of boehmite and X-ray amorphous Al_2O_3 give rise to various nonequilibrium forms of aluminum oxide differing in the crystal structure and temperature ranges of their existence, which is the main cause of the polydispersity of the final product of hydrargillite phase and chemical transformations, namely, α-Al_2O_3. In this case, most probably, large (up to 5 μm) aggregates are formed from finely crystalline α-Al_2O_3, i.e., from the product of phase transformation of amorphous aluminum oxide, owing to activation of sintering and coalescence processes in the finely crystalline system upon heat treatment, whereas isometric corundum crystals are formed by the second pathway via γ-Al_2O_3. During mechanochemical activation, hydrargillite completely or partially transforms into boehmite (in the latter case, formation of nuclei of the γ-AlOOH phase should be assumed), which promotes phase and chemical transformations during calcination of activated hydrargillite predominantly (or completely) by the pathway involving formation of the γ-Al_2O_3 phase and its further transformations. This ultimately results in formation of monodisperse α-Al_2O_3 samples.

The effect of added iron oxides on the temperature of corundum formation and its particle size distribution is probably due to the following facts. On the one hand, small α-Fe_2O_3 crystals formed at relatively low (~700°C) temperatures play the role of corundum crystal seed, as they are isostructural with α-Al_2O_3, which decreases the temperature of α-Al_2O_3 formation. On the other hand, an increase in the calcination temperature leads to the formation of a Fe_2O_3 solid solution in α-Al_2O_3, which, according to the phase diagram of the Fe_2O_3–Al_2O_3 system [17], decreases the melting point of the solid solution $\alpha(Fe_xAl_{1-x})_2O_3$ from 2044 ($x = 0$) to 1700°C ($x = 0.1$). Therefore, the intensity of mass transfer in the finely crystalline system varies in parallel with x, which is manifested as an increase in the average size of crystals and as formation of crystal faces.

CONCLUSIONS

(1) In the course of mechanochemical activation, depending on its energy, γ-$Al(OH)_3$ is partially or completely dehydrated to form the γ-AlOOH phase, which subsequently promotes the formation of monodisperse finely crystalline α-Al_2O_3 on calcination.

(2) The presence of an α-Fe_2O_3 admixture, which is isostructural with α-Al_2O_3, reduces the temperature of corundum formation approximately by 100°C and affects the average size of its crystals. The factors responsible for a decrease in the temperature of formation of corundum crystals and for the formation of their faces were revealed.

Abstract—Fine purification of niobium(V) to remove tantalum(V) by extraction was studied at various compositions of solutions and ratios of phase volumes. Washing of tantalum(V) and niobium(V) extracts with aqueous solutions of their fluorides was considered.

Preparation of niobium(V) compounds with a minimal content of tantalum(V) is a complicated problem in the extraction technology of tantalum(V) and niobium(V). Such a problem arises in processing of rare-metal raw materials with high Nb(V)/Ta(V) ratios (e.g., pyrochlore*) or in extraction flowsheets based on joint revovery of tantalum(V) and niobium(V) with their subsequent separation in the backwashing stage. In the latter case, as a rule, the niobium backwash is contaminated with tantalum(V). Whereas in pyrochlore processing addition of sulfuric acid to the extraction system for improving tantalum(V) and niobium(V) separation [2] is possible (though undesirable because of complicated utilization of spent fluoride solutions), in refining of the niobium backwash introduction of an additional reagent is unacceptable, as the backwash purified to remove tantalum(V) is immediately directed to the precipitation of niobium hydroxide. This limitation imposed on the extraction system composition additionally complicates separation of Ta from Nb. If the content of tantalum(V) is sufficiently high and commercial production of tantalum products is economically feasible, a necessity arises in treating the tantalum-containing organic phase (after processing of niobium solutions) to remove niobium(V).

We studied earlier [1, 3] the removal of tantalum(V) impurities from niobium(V) using tributyl phosphate (TBP) as extractant. Conditions were found for efficient separation of these elements at low volume ratios of the organic and aqueous phases $V_o : V_a$ both in the absence and in the presence of sulfuric acid. However, a significant drawback of TBP is its hydrolysis in contact with process solutions, which leads to contamination of niobium–tantalum products with phosphorus(V) and other elements [2]. Additional drawbacks of TBP are its toxicity and high density, which impedes phase separation of emulsions and increases the size and cost of the equipment.

Octanol is a promising extractant finding growing application in the extraction technology of tantalum(V) and niobium(V) [4–11]. It was used in production of high-purity tantalum(V) and niobium(V) compounds by processing tantalite–columbite concentrates [5–9] and in the isolation of pure pentoxides of these elements from titanium fluoride solutions containing up to 500 g l^{-1} TiO_2, according to one of versions of processing loparite (rare-earth titanoniobate) [4, 10]. It was shown in [5] that, in extraction power, octanol compares well with methyl isobutyl ketone, which is usually used in other countries to extract tantalum(V) and niobium(V); however, in contrast to octanol, methyl isobutyl ketone is dangerously explosive and noticeably soluble in aqueous solutions.

In this work we used 1-octanol $CH_3(CH_2)_6CH_2OH$ (OCL). We found previously that OCL and other octanol isomers (2-octanol and 2-ethylhexanol) have similar extraction properties; these extractants are commercially available and relatively cheap. 1-Octanol is resistant to prolonged action of fluoride–sulfate solutions; for example, after a contact with a solution of 4 M HF and 5 M H_2SO_4 for 280 days ($V_o : V_a$ = 1 : 1), OCL remains usable. Under the same conditions, TBP forms a homogeneous solution in 70 days, which determines the stability limit of this extractant [8, 12]. The physicochemical properties of OCL are

described in [8, 12], and the techniques of operation with aggressive fluoride solutions and the corresponding analytical control are given in detail in [13].

The distribution of tantalum(V) and niobium(V) extracted from solutions of these elements taken separately is shown in Table 1 in relation to the phase volume ratio $V_o : V_a$ and HF_{free} content. Here and hereinafter, HF_{free} is the calculated nominal HF content in excess of its content in the complexes $HTa(Nb)F_6$, H_2TiOF_4, H_2SiF_6, etc. (according to [13, 14], these complexes dominate in the extraction system under study). It should be noted that, as opposed to tantalum(V), niobium(V) is relatively poorly extracted from solutions containing HF only, even at high $V_o : V_a$ ratios. This drawback of OCL is attributable to its low basicity. Furthermore, it follows from the obtained data that the best separation of Ta(V) and Nb(V) can be achieved for solutions with low $c_{HF_{free}}$.

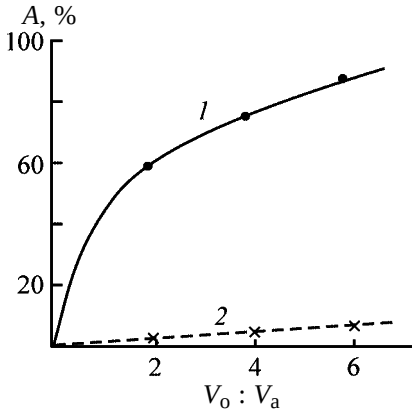

Fig. 1. Influence of the $V_o : V_a$ ratio on the extraction of (*1*) Ta(V) and (*2*) Nb(V) from a solution containing 0.3 M Ta(V) and 0.5 M Nb(V). (*A*) Recovery; the same for Fig. 2.

We have studied the effect of the $V_o : V_a$ ratio on the separation of tantalum(V) and niobium(V) from mixed solutions of these elements with low HF_{free} content (Fig. 1) and found that tantalum(V) is extracted much better in the presence of niobium(V). It is known [2] that neutral organic solvents, including OCL, extract tantalum(V) and niobium(V) from fluoride-containing solutions as complexes of fluorometallic acids HMF_6 whose extraction increases with the H^+ concentration in the system. In the case of HF deficiency, niobium(V), as opposed to tantalum(V), is not noticeably extracted; however, the presence of the readily dissociating acid $HNbF_6$ increases the acidity of the system and promotes the tantalum(V) extraction. Under the experimental conditions (Fig. 1), the extraction of Ta(V) in one stage is 80–90, and that of Nb(V), only 5–8%. A calculation by Cremser's formula [14] shows that, when the Ta(V) recovery in one stage is 90% ($V_o : V_a \approx 7 : 1$), only six equilibrium steps are sufficient to obtain Nb_2O_5 containing less than 0.001 wt % Ta_2O_5 in a continuous counterflow process.

The above-found conditions for the extraction and separation of tantalum(V) and niobium(V) from solutions containing HF without additions of other inorganic acids were used to find conditions for the removal of tantalum(V) impurity, which may be as large as several weight percents of Ta_2O_5 in Nb_2O_5 [2], from niobium(V) backwash. The data on the influence of the Nb(V) content on its purification to remove Ta(V) are given in Table 2. As the Nb(V) concentration (i.e., the content of $HNbF_6$) increases, the extraction of both Nb(V) and Ta(V) into the organic phase grows. However, at high Nb(V) contents (more than 2.7 M), the extraction of Ta(V) decreases, apparently owing to competition with Nb(V) for the organic phase. In the examined range of process conditions, the optimal Nb(V) concentration ensuring fairly complete extraction of Ta(V) with relatively low coextraction of Nb(V) is about 2.2 M.

Table 3. Removal of niobium(V) impurities from tantalum(V) extract ($V_o : V_a = 10 : 1$, $c_{HF_{free}} \approx 0$ M)

Molar ratio Ta(V) : Nb(V) in extract	Ta(V) concentration in scrubbing solution, M	Degree of Nb(V) washout, %	Total extraction of Ta(V) to scrubbed extract, %
1 : 110	0.18	86.1	92.4
1 : 110	0.36	72.7	117.2
1 : 10	0.18	87.3	96.0
1 : 10	0.36	84.4	109.4
1 : 1.1	0.18	74.1	94.8
1 : 1.1	0.36	64.9	114.3

We studied in detail the effect of various process parameters on the extraction of Ta(V) impurities from solutions containing 2.2 M Nb(V) (Fig. 2). The extraction of Ta(V) only weakly depends on the Ta(V) : Nb(V) ratio, which suggests the possibility of fine purification of Nb(V) to remove Ta(V) in a continuous counterflow process. As expected, the extraction weakly increases with increasing $V_o : V_a$ ratio and decreases with increasing HF_{free} content. These data suggest that niobium backwashes should be purified at $c_{HF_{free}} \geq 0$ M and $V_o : V_a \geq 1.8 : 1$. A calculation by Cremser's formula [14] shows that, when about 80% of Ta(V) is extracted in one stage, four equilibrium steps are necessary to decrease the content of Ta_2O_5 in Nb_2O_5 from 3 to 0.01 wt %, and six steps, to decrease it to 0.001 wt %.

The niobium backwash purified to remove tantalum(V) is sent to the precipitation of niobium hydroxide, whereas the organic phase should be treated to recover both Nb(V) and Ta(V), with Ta(V) being in the form of a commercial product. The Ta(V) extract can be scrubbed to remove Nb(V) with water or (Table 3) with a Ta(V) solution. In the latter case, addition of Ta(V) to a scrubbing solution increases its content in the extraction system and, correspondingly, promotes displacement of impurities from the organic phase into the aqueous phase. The introduction of one of components to be separated into a scrubbing solution is successfully used, e.g., in separation of cobalt(II) and nickel(II) [15]. The backwash or a solution obtained by dissolving Ta(V) oxide in HF can be used as such scrubbing solution. A solution containing 0.18 M Ta(V) appeared to be efficient for Nb(V) purification at Nb(V) : Ta(V) ratios in the extract varying a wide range (Table 3). The increase in the Ta(V) content to 0.36 M leads to an increase in the acidity of the scrubbing solution (owing to $HTaF_6$ dissociation) and, correspondingly, to less complete removal of Nb(V). In a continuous counterflow scrubbing process with 6–8 equilibrium steps, the Nb_2O_5 content in Ta_2O_5 is reduced to values less than 0.001–0.01 wt %. Tantalum(V) is readily backwashed with water from the scrubbed extract at $V_o : V_a \approx 3 : 1$ [9], and OCL is returned to the extraction of Ta(V) impurity.

The scheme of extraction treatment of niobium(V) to remove tantalum(V) is shown in Fig. 3. The initial solution, e.g., niobium(V) backwash, is evaporated to the Nb(V) concentration of about 2.2 M, which is the best for the efficient extraction of Ta(V) impurities. The evaporation also makes it possible to reduce as much as possible the HF_{free} content and the volume of process streams. The spent solution after scrubbing the tantalum(V) extract is combined with the initial solution to prevent losses of rare metals. Using main process stages of this scheme, we have prepared niobium(V) oxide containing less than 0.005 wt % Ta_2O_5, as shown by mass spectrometry.

We have considered niobium(V) treatment to remove tantalum(V) without adding other inorganic acids, e.g., sulfuric acid, into the extraction system. Of great practical interest is the recovery of tantalum(V)

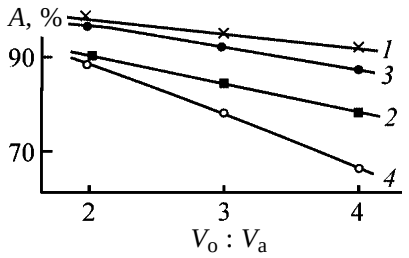

Fig. 4. Influence of the $V_o : V_a$ ratio on Nb(V) backwashing from extracts by water. (*A*) Degree of backwashing. Composition of extracts (M): Nb(V) (*1, 2*) 0.3 and (*3, 4*) 0.75; HF_{free} (*1, 3*) 0 and (*2, 4*) 1.5.

and niobium(V) from solutions obtained in pyrochlore processing, which have a high Nb(V) : Ta(V) ratio close to that in niobium backwash. When pyrochlore is broken down with hydrofluoric acid without adding other acids [2, 3], pure tantalum(V) is readily recovered by a scheme similar to that shown in Fig. 3, and niobium(V) can be utilized for obtaining ferroniobium. However, if production of pure niobium(V) compounds is intended, a necessity arises in its transfer into the organic phase to remove concomitant impurities. With OCL as extractant, niobium(V) is efficiently extracted only on adding other inorganic acids. According to [9], when niobium(V) is extracted with OCL, the concentration of H_2SO_4 should be 5–6 M. Our experiments showed that fluoride solutions of niobium(V) can be successfully used to remove impurities from its extracts. When an extract [0.7 M Nb(V)] is scrubbed with an 1.9 M Nb(V) solution [$c_{HF_{free}} \approx 0$ M, $V_o : V_a = (6–8) : 1$], the degree of titanium(IV) removal (the most difficult-to-remove impurity [2]) is more than 90% in one step. Niobium(V) is readily backwashed with water from the scrubbed organic phase (Fig. 4): at $V_o : V_a = 4 : 1$, 66–92% of Nb(V) passes into the aqueous phase in one step depending on the Nb(V) and HF_{free} contents in the extract. The best parameters of niobium(V) backwashing were obtained, as expected, at low Nb(V) and HF_{free} concentrations (Fig. 4): in this case, backwashing can be performed at a ratio $V_o : V_a \geq 5 : 1$. Thus, our study has confirmed the efficiency of using octanol as extractant in tantalum(V) and niobium(V) hydrometallurgy.

CONCLUSIONS

(1) The optimal conditions for the removal of tantalum(V) impurity from niobium(V) backwash are as follows: Nb(V) content in the initial solution 2.2 M and low $c_{HF_{free}}$.

(2) The applicability of the developed technology to pyrochlore processing was demonstrated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Globular Zirconium(IV) Hydroxide by Sol–Gel Process

L. M. Sharygin

Termoksid Production and Research Company, Zarechnyi, Sverdlovsk oblast, Russia

Received January 25, 2001; in final form, February 2002

Abstract—The sol–gel process of the preparation of globular zirconium(IV) hydroxide is described, which involves formation of zirconium(IV) hydroxide sol by electrolysis of zirconium(IV) chloride solution in a one-compartment cell to a Cl/Zr atomic ratio of less than 0.6, gelation of sol droplets in aqueous ammonia, treatment of gel spheres to remove electrolytes, and drying.

Zirconium(IV) hydroxide is used as inorganic sorbent in radiochemistry for concentrating and separating radionuclides, in chemical industry for preparing ultrapure substances, in medicine, and in other fields.

Zirconium(IV) hydroxide is an amphoteric ion exchanger; its properties have been studied by many researchers [1–4]. It is a cation exchanger in neutral and alkaline solutions and an anion exchanger in acid solutions. With multiple-charged anions and cations, ion exchange is complicated by chemical interaction between the sorbate and sorbent, yielding sparingly soluble surface compounds. Therefore, zirconium hydroxide in neutral solutions is selective to multiple-charged anions (phosphates, silicates, molybdates, arsenates, and other anions) and cations [lead(II), copper(II), cobalt(II), and other cations].

The requirements to the content of toxic impurities in tap water become at present more and more stringent. For example, the maximum permissible concentration of silicon is 10 mg dm^{-3}. The high chemical stability of zirconium(IV) hydroxide in neutral aqueous solutions and the high selectivity to multiple-charged anions and cations make this compound promising as a sorbent for local systems of tap water treatment.

Also, zirconium(IV) hydroxide is used for preparing zirconium(IV) oxide powders, which, in turn, are used for the manufacture of ceramics, refractory materials, and catalysts [5].

Globular zirconium(IV) hydroxide is prepared by gel or sol–gel process [1–10]. The gel process involves precipitation of zirconium(IV) hydroxide from the solution of its salt, followed by washing and dehydration of the gel precipitate [1–6]. The sol–gel process consists of the following main stages: formation of a metal hydroxide hydrosol, gelation of sol droplets, washing of sol spheres, and drying [9, 10]. In the sol–gel process, the stages of sol and gel formation are separated in time. As a result, gel spheres are formed from the initial particles after their formation and have high mechanical strength and elastic skeleton, which allows their shape to be retained in the subsequent stages of washing and drying. All this allows preparation of metal hydroxides in the form of mechanically strong spheres of prescribed size with reproducible properties.

Here we report on a sol–gel process for the preparation of globular zirconium(IV) hydroxide, which involves formation of sol by electrolysis of zirconium(IV) chloride solution, gelation of sol droplets in aqueous ammonia, and washing and drying of gel spheres.

Among many methods for preparing zirconium(IV) hydroxide hydrosols, direct electrochemical synthesis attracts the most attention [9, 11, 12]. The method is based on removal of hydrochloric acid, which is the product of the salt hydrolysis, from aqueous solutions of metal chlorides by decomposing it on the electrodes into chlorine and hydrogen on passing electric current. Owing to the hydrolysis, the dissolution of zirconium(IV) oxide dichloride, $ZrOCl_2$, in water yields hydrochloric acid. The concentration of free hydrochloric acid is approximately equal to the molar concentration of zirconium in the solution [6, 13]. The decrease in the hydrochloric acid concentration during electrolysis of zirconium chloride solution promotes further hydrolysis and polymerization of zirconium(IV) hydroxo complexes and results in the forma-

1070-4272/02/7509-1394$27.00 © 2002 MAIK "Nauka/Interperiodica"

tion of zirconium hydroxide as a sol. The electrolysis can be performed in a one-compartment cell using platinum, graphite, titanium, zirconium, and other electrodes resistant to hydrochloric acid.

The hydrolysis and polymerization of zirconium ions in aqueous solutions were studied in numerous works [4–6, 14]. It was shown by different physical methods that, in solid salts and aqueous solutions, zirconyl ions are absent, and the main structural unit in these compounds is a tetranuclear hydroxo complex $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$. The X-ray scattering, Raman spectroscopy, and other methods [14–18] showed that, upon dissolution of zirconium oxide dichloride in water, the complex $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ as the main structural unit is preserved. The hydrolysis and polymerization of this hydroxo complex determine further behavior of zirconium in solution. These processes are considered in more detail in [6]. The degree of polymerization of hydroxo complexes can be characterized by the fraction α of bridging zirconium ions. In the limiting case, when polymerization is 100% complete, there will be four bridging bonds per hydroxo complex consisting of four zirconium atoms. Therefore, the degree of polymerization of zirconium hydroxo complexes can be found from the relationship $\alpha = (n/4) \times 100$, where n is the number of bridging bonds per tetranuclear complex.

In [18] we used the methods of electrical conductivity, Raman spectroscopy, and determination of the solution viscosity in relation to shear stress for studying formation of zirconium hydroxide sol in the course of electrolysis of zirconium oxide dichloride solution in a one-compartment cell. The dependences of the electrical conductivity and the relative content of bridging zirconium ions on the Cl/Zr atomic ratio in the course of the electrolysis of 1 M $ZrOCl_2$ solution are shown in Fig. 1. It is seen that, with decreasing Cl/Zr ratio, the fraction of bridging zirconium ions increases, which shows that hydroxo complexes polymerize as hydrochloric acid is removed from the solution. The polymerization is also confirmed by the Raman spectra of the solutions taken in the course of the electrolysis. At Cl/Zr = 0.55, the fraction of bridging zirconium ions is 54%. Reinten [6] found that, in a $ZrOCl_2$ solution neutralized with alkali with formation of zircomium(IV) hydroxide, the fraction of bridging zirconium ions is the same (52–56%). This shows that, in the course of the electrolysis of zirconium chloride solution to a Cl/Zr atomic ratio less than 0.6, a colloidal solution (sol) of zirconium(IV) hydroxide is formed, with the degree of polymerization being maximal for colloidal particles of this size. Further decrease in the Cl/Zr ratio in a solution is not accompanied by the polymerization and involves neutralization of surface chloride ions and free hydrochloric acid and coagulation of colloidal particles. The electron diffraction [9] showed that the colloidal particles are amorphous.

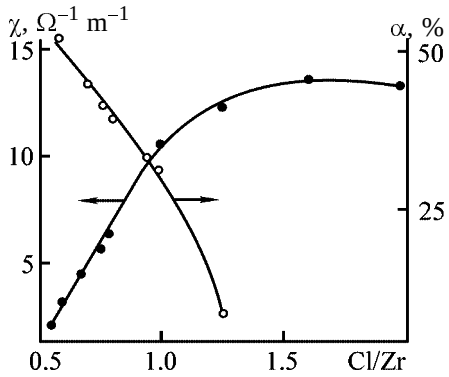

Fig. 1. Electrical conductivity χ and fraction α of bridging zirconium ions vs. Cl/Zr atomic ratio in the course of the electrolysis [18].

The chemical composition of the colloids can be conventionally described by the formula $\{Zr(OH)_4\} \cdot Zr(OH)_{4-x}^{x+} \cdots x Cl^-$, where $2 < x < 4$. The particle core is formed by zirconium(IV) hydroxide, and the surface layer, by zirconium hydroxochloride. The chloride ions are not bonded directly to zirconium, but instead are arranged in the outer coordination sphere and neutralize the positive charge of colloids. Experimental data on the electrical conductivity show that, e.g., at Cl/Zr = 0.55 the concentration of free hydrochloric acid is 0.055 M, which corresponds to only about 10% of the amount chloride ions present in the system. The remaining 90% of ions are bound in polymeric complexes as counterions. Therefore, the chemical composition of sol colloids, e.g., at Cl/Zr = 0.5 is $\{Zr(OH)_4\}Zr(OH)_3^+ \cdots Cl^-$.

The solution viscosity in the course of the zirconium chloride electrolysis to Cl/Zr = 1.0 does not noticeably vary. Decreasing the above ratio increases viscosity, with the increase being especially pronounced at a Cl/Zr ratio less than 0.6. In rheological properties, solutions with Cl/Zr > 0.6 are Newtonian liquids, and those with Cl/Zr < 0.6 are weakly structured colloidal systems.

In the course of the electrolysis of zirconium chloride solution, the following processes occur:

at the cathode,

$$2H^+ + 2e \rightarrow H_2\uparrow, \quad (1)$$

$$2H_2O + 2e \rightarrow H_2\uparrow + 2OH^-; \quad (2)$$

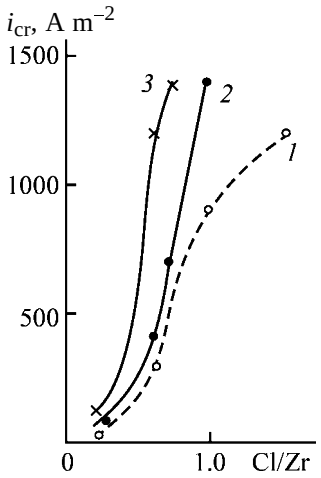

Fig. 2. Critical current density i_{cr} vs. Cl/Zr atomic ratio [20]. Temperature (°C): (*1*) 25, (*2*) 40, and (*3*) 60.

and at the anode,

$$2Cl^- - 2e \rightarrow Cl_2\uparrow, \quad (3)$$

$$2H_2O - 4e \rightarrow O_2\uparrow + 4H^+. \quad (4)$$

Evolution of chlorine and oxygen at the anode by reactions (3) and (4) in chloride melts was extensively studied previously [19]. In [20], we recorded the cathodic polarization curves on platinum as functions of the current density, Cl/Zr atomic ratio in solution, and temperature within 25–80°C with the aim to study the cathodic evolution of hydrogen in the course of electrolysis of 1 M $ZrOCl_2$ solution. The cathodic polarization in solutions with the Cl/Zr ratio varied from 2.0 to 1.6 is weak. With decreasing Cl/Zr ratio, i.e., concentration of hydrochloric acid in solution, the character of the polarization curves changes. At a certain current density, which can be referred to as critical density i_{cr}, the slope of the curves changes. A sharp increase in the cathode polarization is due to impeded diffusion of hydrogen ions toward the cathode and by the discharge of water molecules. The hydrogen evolution by reaction (2) results in the alkalization of the near-cathode space, formation of basic zirconium salts, and spontaneous termination of the process. At higher temperatures, the above diffusion hindrance appears at smaller Cl/Zr ratios, which is due to accelerated hydrolysis of the salt. At 80°C, the critical current density is not observed even for Cl/Zr = 0.86. The dependences of the critical current density on the Cl/Zr ratio are shown in Fig. 1. As the Cl/Zr ratio in solution is decreased, the critical current density decreases also; this trend is the most pronounced at the Cl/Zr ratios from 1.0 to 0.6.

The temperature dependence of the critical current density is also significant. Elevated temperatures accelerate hydrolysis and decrease the solution viscosity. As a result, the hydrogen discharge overvoltage decreases, and i_{cr} grows. Thus, for preparing a zirconium(IV) hydroxide sol with Cl/Zr < 0.6, the electrolysis of zirconium chloride solution should be performed at a cathodic current density not exceeding the critical value. From the start of the electrolysis to a moment of attaining the ratio Cl/Zr ≈ 1.4, the current efficiency by chlorine is more than 100%, which is due to removal of a part of hydrochloric acid from the solution with gaseous electrolysis products. As the Cl/Zr ratio is decreased, the current efficiency by chlorine decreases also. For the electrolytic method of sol preparation, the average current efficiency by chlorine is about 80%.

The second stage of the sol–gel process is dispersion of the zirconium hydroxide gel in aqueous ammonia. The diffusion of ammonia into sol droplets neutralizes free hydrochloric acid and chloride ions bound to colloids and causes gelation of sol droplets into spheres. The gelation conditions (the properties of sol and gelating medium) are chosen so as to prevent breakdown of gel spheres and preserve their shape after transformation of sol droplets, and also to ensure high mechanical strength of the gel spheres, sufficient to withstand the subsequent stages of washing off electrolytes and drying. The chemical processes occurring upon the sol–gel transformation of zirconium(IV) hydroxide can be presented by the following equation:

$$\{Zr(OH)_4\}Zr(OH)_{4-x}Cl_x + xNH_4OH$$
$$= 2Zr(OH)_4 + xNH_4Cl.$$

The gel spheres consist of a three-dimensional network of primary particles separated by water-filled pores. Conventionally, the moisture content of the gel spheres is within 60–80% depending on the sol concentration. Therefore, gel spheres are fairly diluted finely dispersed porous substances. Their chemical composition corresponds to zirconium(IV) hydroxide. According to an electron-microscopic study [6], the particle size is about 3 nm. Similar to the majority of hydroxides, zirconium(IV) hydroxide has a layered structure. The layer consists of tetrameric ions bound with each other by hydroxy groups arranged above and below the plane of the layer [4]. As a result, each zirconium atom is surrounded by eight hydroxy groups in the form of a distorted cube.

The gel spheres are washed to remove excess am-

monia and electrolytes and dried at a temperature from 20 to 150°C. Since zirconium(IV) hydroxide is a cation exchanger in alkaline media, the gel spheres after washing contain certain amount of ammonium ions. To exhaustively remove ammonium ions, gel spheres are washed with dilute hydrochloric acid. Drying gel spheres decreases several-fold their volume and results in the formation of the adsorbent pore structure. According to the most popular concept [21, 22], the gel skeleton is compressed upon drying under the action of capillary forces whose value depends on the capillary radius. The strength of the gel skeleton, increasing upon drying, resists the capillary compressive forces. The final pore structure of the adsorbent is fixed when the counteractive forces come in equilibrium. Therefore, the equilibrium pore structure of the sorbent formed upon drying the gel depends not only on the drying conditions (temperature, water vapor pressure, surface tension of water, and other factors), but also on the procedures of gel formation and treatment [21, 22]. Since in the final stages of drying the capillary radii of porous substances are fairly small, the capillary forces attain high values (several kilobars). The chemical reactions in solids are considerably activated by mechanical stress [23]. Therefore, the chemical transformation of hydroxide into oxide may occur even in the course of drying of gel spheres.

Drying of gel spheres at 100–150°C results in the formation of globular, mechanically strong amorphous products classed with microporous sorbents [24, 25] according to Dubinin's classification. The chemical composition of the xerogel strongly depends on the drying conditions, first of all, on temperature. There is still no common opinion in the literature on the chemical composition of the xerogel. However, the majority of researches [4, 6] consider it as oxohydroxide $ZrO_x(OH)_{4-2x}$, where x varies from 0 to 2. Upon calcination of xerogel, the hydroxide is converted into oxohydroxide and oxide, which can be conventionally represented by the following scheme:

$$Zr(OH)_4 \xrightarrow{\Delta} ZrO_x(OH)_{4-2x} + xH_2O \xrightarrow{\Delta} ZrO_2 + (2 - x)H_2O.$$

The chemical reactions are complete at temperatures below 350°C and are accompanied by dehydration, pore structure transformation, and changes in the phase composition and other physicochemical properties of the product [25].

CONCLUSIONS

(1) Electrolysis of zirconium(IV) chloride solution in a one-compartment cell is accompanied by hydrolysis and polymerization of four-membered zirconium hydroxo complexes, and at a Cl/Zr ratio less than 0.6 zirconium hydroxide is formed in the form of stable sol. The preparation of zirconium hydroxide sol by electrolysis is limited by cathodic evolution of hydrogen.

(2) When the sol is dispersed in aqueous ammonia, free hydrochloric acid and chloride ions bound to colloids are neutralized, and gelation of sol droplets with formation of gel spheres takes place.

Received November 9, 2001; in final form, June 2002

Abstract—The spectral sensitivity of Sn(II) complexes in acid and alkaline solutions of $SnCl_2$ in photostimulated oxidation with oxygen was studied. The reaction mechanism was revealed. A spectrophotometric method for prompt monitoring of the composition of $SnCl_2$ solutions was proposed.

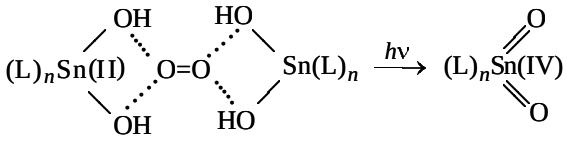
Tin(II) compounds have pronounced reductive properties and can be oxidized even with atmospheric oxygen, both in solutions and in the solid phase, as, e.g., in films of Sn(II) hydroxo compounds [1–4]. The oxidation can be considerably accelerated by UV irradiation [5–8]. This specific feature of chemistry of Sn(II) compounds has found application in photoforming, i.e., manufacture of selective thin-film structures using photochemical processes. These processes occur upon irradiation of films of Sn(II) hydroxo compounds adsorbed on the surface of dielectrics [1–3, 8–11]. After treating samples in $PdCl_2$ solutions, the Sn(II) hydroxo compounds that remained intact in the regions not subjected to irradiation reduce adsorbed Pd(II) with the formation of catalytically active centers. These centers may initiate deposition of metals from solutions in which spontaneous reduction of these metals from complex compounds is kinetically hindered. This results in selective deposition of conducting film components.

Despite a great deal of papers on the metal plating of dielectrics using Sn(II) and Sn(IV) compounds [1, 2], in most of them the transformation of tin and palladium has been considered only schematically. In [12–17], the photostimulated oxidation of Sn(II) compounds was studied without taking into account a number of important factors, such as a change in the solution composition upon storage owing to mutual influence of dark oxidation and hydrolysis of tin(II) compounds, and formation, coagulation, and sedimentation of colloidal particles. The influence of all the above factors on the efficiency of participation of Sn(II) compounds in photoforming processes was not considered. Unfortunately, specific methods of controlling properties of tin-containing films and coatings prepared from $SnCl_2$ solutions are found only empirically.

It is known that the light-sensitive tin species in photostimulated oxidation are tin oxo- and hydroxochlorides such as $Sn_4(OH)_6Cl_2$ and $Sn_2Cl_{16}(OH)_{14}O_6$ incorporated into island films [10, 11]. However, the rate and mechanism of oxidation of Sn(II) complexes and the sensitivity of Sn(II) compounds in both solution and condensed phase have not been analyzed in detail.

Based on experimental data on the order of photostimulated oxidation with oxygen of Sn(II) complexes in $SnCl_2$ aqueous solutions, a chain oxidation mechanism was proposed [12–14, 17] in which $Cl^{\bullet}$ and $HO_2^{\bullet}$ radicals and H_2O_2 and O_2 molecules are oxidants, Sn(III) is an intermediate, and Sn(IV) is the final product.

A molecular mechanism of photostimulated oxidation of Sn(II) with participation of polydentate organic compounds, described in [15, 16], is confirmed in experiments with isotopically substituted water:



$$+ H_2O \rightarrow (L)_nOSn(OH)_2.$$

The published works do not take into account how the composition of Sn(II) complexes in $SnCl_2$ solutions with various pH affects the pathways and rate of photostimulated reactions and the formation of colloidal particles in solutions. The spectral sensitivity of Sn(II) compounds was not analyzed; no data are available on the quantum yields of photochemical

1070-4272/02/7509-1399$27.00 © 2002 MAIK "Nauka/Interperiodica"

oxidation in relation to the radiation wavelength and composition of the irradiated solution, which, in turn, depends on the completeness of oxidation, hydrolysis, and formation of colloidal particles. The same is true about the spectral sensitivity of Sn(II) compounds differing in the composition.

In this work, we studied the total and spectral photosensitivity of Sn(II) compounds in photostimulated oxidation of Sn(II) with oxygen in $SnCl_2$ solutions and the effect exerted on the quantum yield by the concentration of H^+, OH^-, and Cl^- ions and by the presence of ligands. These data are important for development of the theory of photostimulated oxidation of Sn(II) compounds, and also for practical applications (photochemical activation of dielectrics, choice of materials for phototemplates, determination of exposure conditions in the course of production of conducting thin-film structures of a prescribed configuration). First of all, they are of interest for manufacturing printed-circuit boards and integrated circuits for electronic engineering.

EXPERIMENTAL

We studied $SnCl_2$ solutions in which tin(II) ions occur as chloride complexes (acid solutions containing excess chloride ions) or as hydroxo complexes coexisting with tartrate or EDTA complexes (alkaline solutions) (M): no. 1, $SnCl_2$ 0.11 and HCl 0.11; no. 2, $SnCl_2$ 0.11 and HCl 0.06; no. 3, $SnCl_2$ 0.11, HCl 0.11, and KCl 1.60; no. 4, $SnCl_2$ 0.11 and HCl 0.66; no. 5, $SnCl_2$ 0.11, HCl 0.66, and KCl 1.60 (acid solutions); no. 6, $SnCl_2$ 0.22, NaOH 1.40, and EDTA 0.1; no. 7, $SnCl_2$ 0.22, NaOH 1.50, and NH_3 0.4; no. 8, $SnCl_2$ 0.22 and NaOH 2.50; and no. 9, $SnCl_2$ 0.22, NaOH 1.00, and $KNaC_4H_4O_6$ 0.28 (alkaline solutions). The compositions of these solutions correspond to those used for activating the surface of dielectrics [1, 2, 5–9]. The binding of ions into complexes is used to prevent hydrolysis and stabilize $SnCl_2$ solutions. Special calculations showed that different complex ions always coexist in equilibrium in the solutions studied, with some of them prevailing. The major components are as follows: solution no. 1, hydroxochlorides; solution no. 2, aqua and hydroxo complexes; solution nos. 3–5, chloride complexes; and solution nos. 6–9, hydroxo complexes. The content of Sn(II) in the solutions was determined by iodometric titration to within ± 0.0025 M [18]. The solutions were analyzed before and after irradiation. Because the composition of $SnCl_2$ solutions is affected by the Sn(II) oxidation and hydrolysis in the course of storage [10, 12], both fresh solutions and those stored for 1–30 days at 18–20°C were studied.

The absorption spectra of the solutions were measured in the range 200–1600 nm on an SF-4A spectrophotometer in a 1-cm quartz cell against distilled water.

The photochemical oxidation of Sn(II) with dissolved oxygen was initiated with a DRT-1000 mercury–quartz lamp as a source of UV radiation with linear spectrum. We used for irradiation both the total spectrum and single spectral lines cut with glass filters from a DOST 9411–75 kit and with chemical light filters [12, 19]. The incident light intensity, determined with a $K_3[Fe(C_2O_4)_3]$ chemical actinometer, was 1.07×10^{-2} J einstein^{-1} [19].

The $SnCl_2$ test solutions were irradiated in a glass cell with darkened bottom and side walls. The cell was open from the top when irradiated within the total spectrum and covered by a light filter when irradiated at a specific wavelength. The contact area of solutions with glass was 10.2 cm^2, which is important for taking into account tin adsorption on the cell walls. The solution thickness (1.3 cm) ensured the minimal UV absorption upon irradiation. Photostimulated oxidation of Sn(II) with atmospheric oxygen was performed with free access of air (10^5 Pa) to the solution at 20 ± 2°C. The decrease in the Sn(II) concentration upon irradiation did not exceed 20 at. %, and the oxygen consumption for oxidation was compensated by its free diffusion into solution. Using the reference data [20] on the diffusion coefficient of oxygen in water at 20°C, the first Fick law, and laws of mass transfer in aqueous solution and through the air–solution interface, and taking into account the volume of the irradiated solution, we can estimate the time in which the solution in the cell is saturated with oxygen (2 min). In determination of the quantum yield, the irradiation time was no less than 3–6 min. This suggests that the concentration of oxygen in the $SnCl_2$ solutions was approximately constant. Because stirring strongly affects the adsorption and diffusion rates and is dufficult to control in small cells, the solutions were not stirred during irradiation, which allowed us to obtain more or less reproducible results.

The number of Sn(IV) atoms formed by the photostimulated reaction with oxygen was determined from the decrease in the Sn(II) concentration in solution and then corrected for the dark oxidation and adsorption of Sn(II) and Sn(IV) compounds on the cell walls, as well as for the formation of colloidal particles owing to hydrolysis. The above correction for the dark

oxidation was found from analysis of reference solutions placed in darkened cells in the vicinity of the irradiated samples.

The quantum yield Φ of the Sn(IV) formation was calculated from the ratio of the number of tin(IV) atoms, ΔnSn(IV), formed in the solution of a given volume and concentration in a certain time to the number of absorbed photons by the formula (19]

$$\Phi\text{Sn(IV)} = [\Delta n\text{Sn(IV)}] : [n_{\text{abs.phot}}],$$

where $\Delta n\text{Sn(IV)} = 6.02 \times 10^{23} V_{\text{exp}} \Delta\text{Sn(II)} : 1000$; $n_{\text{abs.phot}} = I_0 t S(1 - T_1^h)$; V_{exp} is the irradiated solution volume (ml); I_0, incident radiation intensity (phot s^{-1} cm^{-2}); t, exposure time (s); S, cell area (cm^2); $1 - T_1^h$, absorption of irradiated solution of thickness h; and T_1, transmission of 1-cm-thick solution (experimental).

To determine the photosensitivity of Sn(II) compounds, we synthesized $Sn_6O_4(OH)_4$ and $Na[Sn(OH)_3]$ according to [21–23]. To preparing $Sn_6O_4(OH)_4$, a saturated solution of Na_2CO_3 was gradually added to a solution of $SnCl_2$ in 10% hydrochloric acid containing phenolphthalein indicator to weak pinkish color [21, 22]. The precipitate was washed by decanting four times with 5% Na_2CO_3 solution and twice with distilled water. $Na[Sn(OH)_3]$ was synthesized in two stages [23]. First, $Sn(OH)_2$ was synthesized from colloidal milk-white aqueous solution of $SnCl_2$ by adding a 10% solution of $NH_3 \cdot H_2O$. The $Sn(OH)_2$ precipitate was filtered off on a Büchner funnel and repeatedly washed with distilled water. Then, the pasty $Sn(OH)_2$ precipitate was placed in a flask with a 50% NaOH solution at 50–60°C. Reduced pressure in the flask was provided by a water-jet pump. $Sn(OH)_2$ dissolved with formation of $Na[Sn(OH)_3]$ upon shaking. The Sn(II) concentration in the solution was determined by titration. A small amount of the SnO_2 precipitate was filtered off. The $Na[Sn(OH)_3]$ solution and the $Sn_6O_4(OH)_4$ suspension were irradiated similarly as $SnCl_2$ solutions. In the course of irradiation, the suspension was shaken mechanically.

The results of titrimetric determination of Sn(II) in $SnCl_2$ acid solutions (nos. 1–5) irradiated with the total UV spectrum for different times show that the irradiation causes a a rapid decrease in the Sn(II) concentration (Fig. 1a). The Sn(II) loss is the fastest during the first 5–10 min of irradiation (0.10–0.18 mol l^{-1} h^{-1}), and then it decelerates, probably as a result of decrease in the Sn(II) concentration due to oxidation, hydrolysis, and formation of colloidal particles. The mean rate of photostimulated oxidation of

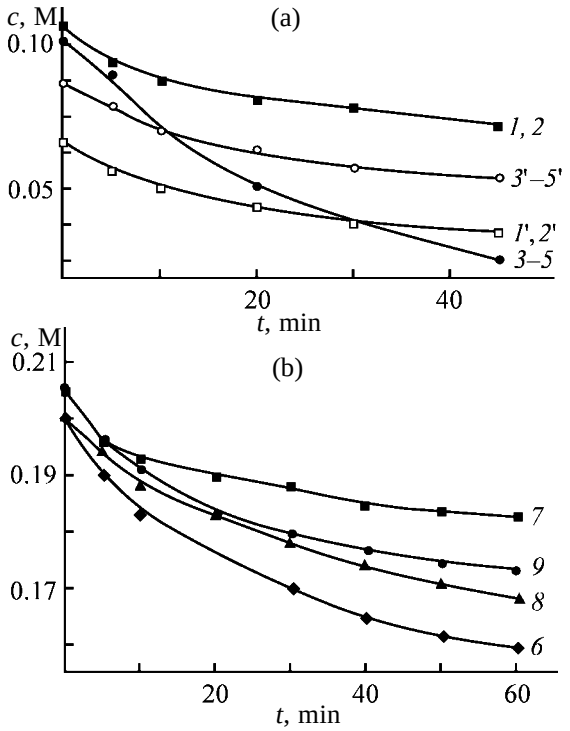


Fig. 1. Sn(II) concentration c in (a) acid and (b) alkaline solutions of $SnCl_2$ vs. irradiation time t with the total spectrum of a DRT-1000 UV lamp. Storage time, days: (*1*–*9*) 0 and (*1'*–*5'*) 12. Curve numbers are solution numbers; the same for Figs. 2c and 3.

Sn(II) in acid solutions in the range of linear variation of the concentration with time is about 0.030–0.075 mol l^{-1} h^{-1}. In the solutions stored in the dark, at the similar concentration of dissolved oxygen determined by the solution temperature, the mean oxidation rate was 0.6×10^{-4}–1.9×10^{-4} mol l^{-1} h^{-1} [6].

We studied how the composition of fresh $SnCl_2$ solutions affects the rate of the photostimulated oxidation of Sn(II). We found that, in solution no. 1 containing hydroxochloride complexes as major species and in solution no. 2 with prevailing aqua and hydroxo complexes, the Sn(II) concentration decreases considerably more slowly than in solution nos. 3–5 with chloride complexes as major species (Fig. 1). Comparison of the dependences of the Sn(II) concentration on the irradiation time for $SnCl_2$ solutions stored for 12 days and then irradiated with a total spectrum of a mercury–quartz lamp shows that, irrespective of solution composition, the Sn(II) oxidation rate in the first 10 min of irradiation approaches the minimal value of ~0.10 mol l^{-1} h^{-1} characteristic of solution no. 1.

The hydrolysis in $SnCl_2$ solutions upon storage decreases the content of chloride complexes [10,

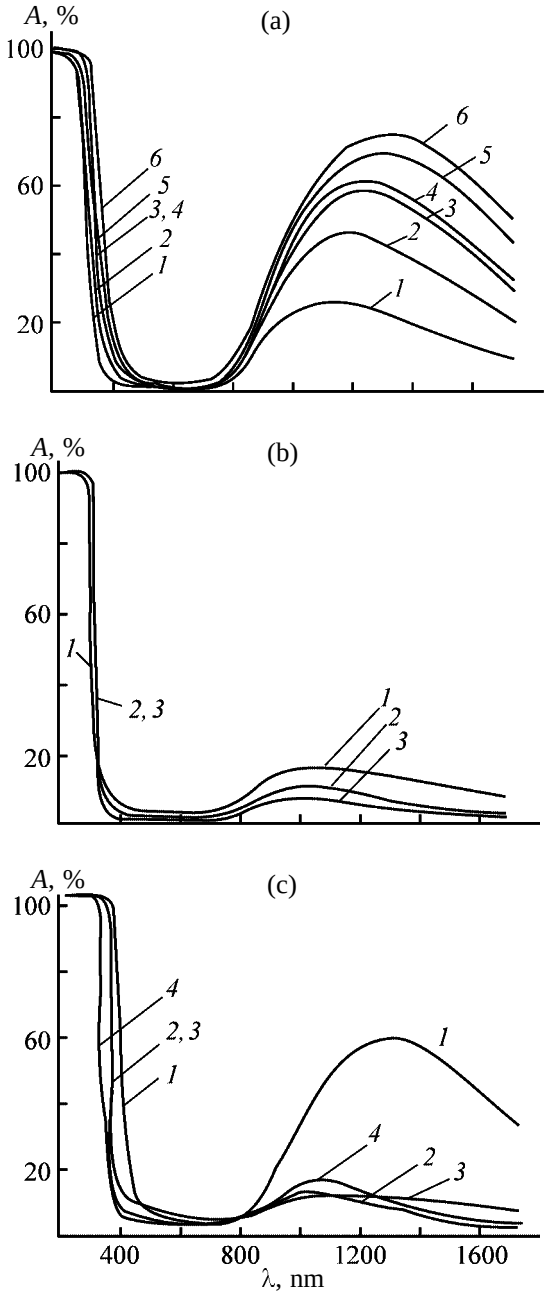

Fig. 2. Absorption spectra of $SnCl_2$ solutions: (a) no. 1, (b) no. 3, and (c) acid solutions. (*A*) Absorption and (λ) wavelength; the same for Fig. 3. Storage time (h): (a) (*1*) 1, (*2*) 24, (*3*) 48, (*4*) 96, (*5*) 190, and (*6*) 212; (b) (*1*) 1, (*2*) 48, and (*3*) 96; and (c) 48.

11]. The experimental data obtained show that the chloride-containing Sn(II) complexes are oxidized faster than hydroxo compounds.

The results of studying photostimulated oxidation of Sn(II) in the volume of $SnCl_2$ solutions showed that, under the similar conditions of irradiation with the total spectrum of a DRT-1000 lamp, the oxidation rate in alkaline solution (0.015–0.040 mol l^{-1} h^{-1}) is somewhat lower than in acid solution (Fig. 1b). This may be due to the lower photosensitivity of Sn(II) hydroxo complexes, which are major species in these solutions, as compared to chloride complexes in acid solutions.

To determine the UV photosensitivity of the individual Sn(II) compounds, a fresh solution of $Na[Sn(OH)_3]$ and an $Sn_6O_4(OH)_4$ suspension were irradiated with the total spectrum of a DRT-1000 lamp. It was found that the decrease in the Sn(II) concentration in these solutions does not go beyond the experimental error of titration and does not exceed the concentration change upon dark oxidation of Sn(II). Taking into account the experimental error, we can state that, in contrast to $Sn_4(OH)_6Cl_2$ and related compounds, Sn(II) hydroxo compounds containing no chloride ions are virtually insensitive to UV radiation. Therefore, in irradiation of $SnCl_2$ solutions, the contribution of Sn(II) hydroxo compounds to photostimulated oxidation can be neglected.

Data on the radiation absorption by $SnCl_2$ acid solutions in a wide spectral range, from 200 to 1600 nm, allow us to distinguish three ranges of the spectrum (Figs. 2a–2c). In the range λ = 200–300 nm, total absorption is observed (the absorption coefficient $A > 99.5\%$). In the range from 300 to 350–450 nm, the absorption sharply decreases to A = 3–5% for most solutions. In the visible range, the solutions are nearly totally transparent (A = 2–5%). In the range from 750 to 1800 nm, the absorption passes through a flat broad maximum; its value appreciably depends on the solution composition and storage time.

For the solutions stored for the similar time, the positions of the UV absorption edge differ only slightly (within 30–100 nm). This is apparently indicative of the fact that the first stage of photostimulated oxidation is similar for all the photosensitive Sn(II) compounds. As suggested in [13], the first stage of chemical activation of the Sn(II) complexes is scission of the Sn–Cl bond with the formation of the $Cl^{\bullet}$ radical and Sn(III) ion. Following this hypothesis, the position and smearing of the right edge of the UV absorption band for each specific Sn(II) complex would be determined by the energy of the Sn–Cl bond.

A drastic decrease in the absorption intensity within 300–400 nm is characteristic of solution nos. 3–5 with high concentrations of H^+ and Cl^- ions and of fresh solution no. 1 containing a small amount of aqua and hydroxo complexes and Sn(II) chloride complexes as major species (Figs. 2a–2c). At longer storage time, the absorption band edge becomes less steep and

shifts toward visible region, to 410 nm and even longer waves (Figs. 2a, 2b). This may be due to the accumulation and polymerization of hydroxo complexes on storage.

It is known that the near IR absorption is mainly due to the interaction of electromagnetic waves with groups of atoms and small particles. Not only the IR absorption but also the scattering take place, with the scattering increasing with growing particle size. Moreover, following the Mie theory, with increasing particle size the absorption coefficient also increases and the absorption maximum shifts toward longer wavelengths [24]. Therefore, it may be suggested that the character of the IR absorption of $SnCl_2$ solutions is governed by the presence of colloidal particles accumulated in storage (Figs. 2a–2c). The absorption spectra of $SnCl_2$ solutions stored for different times, in combination with electron-microscopic data on the size and concentration of colloidal particles formed in the solutions [25–27], show that the higher the particle concentration, the higher the IR absorption coefficient. The experimental data also show that the larger colloidal particles, the longer the IR absorption wavelength.

The absorption spectra of $SnCl_2$ alkaline solutions stored for different times show that, with storage time, the absorption band edge shifts from the UV to visible range; this trend is similar to that observed with acid solutions (Figs. 3a, 3b).

A previous electron-microscopic study of $SnCl_2$ solutions showed that colloidal particles in alkaline solutions are larger by an order of magnitude than those in acid solutions (100–150 nm against 5–10 nm) and that the number of particles in alkaline solutions is very small [21]. Correspondingly, the absorption maximum in the IR region, clearly pronounced in the spectra of acid solutions, is absent for alkaline solutions.

Thus, the UV absorption edge in the spectra of $SnCl_2$ solutions becomes more diffuse and shifts toward visible region in storage accompanied by Sn(II) hydrolysis and oxidation. With accumulation and growth of colloidal particles, the IR absorption maximum becomes stronger and shifts toward longer wavelengths. These facts allow the UV and IR absorption spectra of $SnCl_2$ solutions to be used for prompt monitoring of their composition and formation of colloidal particles.

The efficiency of photostimulated oxidation with oxygen of Sn(II) compounds in $SnCl_2$ solutions was quantitatively estimated from the quantum yield Φ of oxidation, taking into account, as noted above, a decrease in the $SnCl_2$ concentration due to dark processes. Note that, in determination of Φ, the irradiation time (3–6 min) did not exceed the value at which the Sn(II) concentration decreases linearly with exposure (Fig. 1). The experimentally determined quantum yields of the photostimulated Sn(II) oxidation in $SnCl_2$ solutions are given in the table. Despite a con-

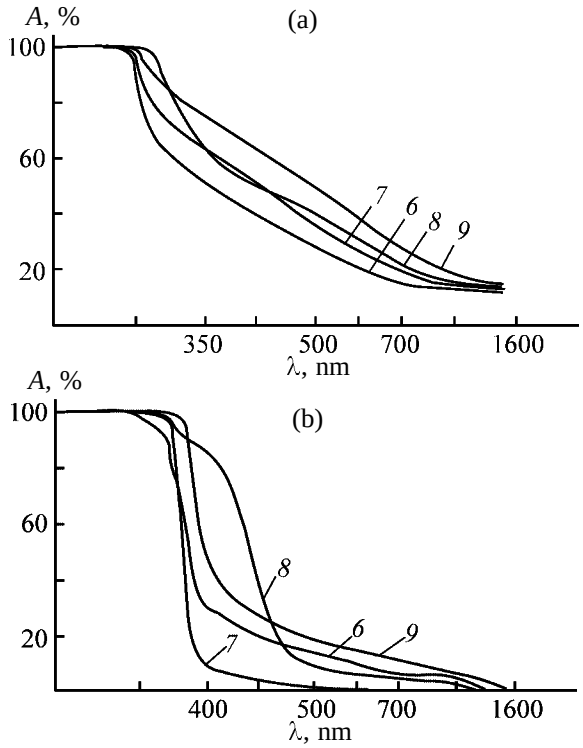

Fig. 3. Absorption spectra of $SnCl_2$ alkaline solutions stored for (a) 1 h and (b) 15 days.

Quantum yield Φ of photostimulated oxidation of Sn(II) in acid and alkaline $SnCl_2$ solutions irradiated at various UV wavelengths ($\Delta\Phi = 0.5$)

siderable experimental error ($\Delta\Phi = \pm 0.5$), comparison of the Φ values for the solutions with prevailing complex species of given chemical composition, irradiated at specific wavelengths in a wide spectral range (250–440 nm) and with the total spectrum of the UV source, allows quite reliable conclusions.

We found that the average quantum yields for the solutions irradiated within the total spectrum lie within 0.2–5.0; the highest quantum yield Φ is observed in acid solutions containing Sn(II) chloride complexes as major species (nos. 3, 5). The photosensitivity of Sn(II) compounds in all alkaline solutions is comparatively low. For example, owing to the low UV sensitivity of tin hydroxo compounds, the quantum yield of the photostimulated oxidation of Sn(II) in all alkaline solutions could be determined only upon irradiation within the total spectrum of a DTR–1000 lamp (see table). Among alkaline solutions, the quantum yield Φ is the highest for solution nos. 6 and 7 containing hydroxo complexes as major species and, probably, Sn(II) hydroxo chloride complexes as minor species. For solution nos. 8, 9 containing virtually no hydroxochloride complexes, in which Sn(II) is in the form of hydroxo, tartrate, and EDTA complexes, the Φ value is lower by an order of magnitude than in $SnCl_2$ acid solutions. As follows from the experiment, these complexes have virtually no photosensitivity, irrespective of the procedure for solution preparation (dissolution of $SnCl_2$ in NaOH solution or synthesis of individual compounds).

The dependence of Φ in photostimulated oxidation of Sn(II) on the incident radiation wavelength showed that the quantum yield is the highest in the region of far UV ($\lambda = 253.7$ nm), which is in agreement with the published data [8, 9]. We found that, with increasing incident radiation wavelength, Φ sharply decreases. Nonetheless, for solutions with high concentration of Sn(II) chloride complexes the quantum yield is 0.2–0.4 even at $\lambda = 435.8$ nm and decreases to zero only at longer λ (~450 nm). This fact confirms once again the published data [8, 9] on the spectral range of photosensitivity of Sn(II) compounds and also explains the possibility of exposing island films based on tin compounds using Dacron phototemplates, which almost totally absorb the UV radiation but are transparent in the visible range [2]. As indicated above, such processes are used in photochemical activation of substrates intended for selective metal deposition.

The fact that the quantum yield of the photostimulated oxidation of Sn(II) in $SnCl_2$ solutions is sometimes considerably larger than unity (see table) is confirmed quite reliably ($\Phi \gg \Delta\Phi$) and is indicative of occurrence of a chain process. The quantum yields of photostimulated oxidation of Sn(II) compounds in $SnCl_2$ solutions show that the chain reaction mechanism is characteristic of solutions containing Sn(II) chloride complexes as major component. This mechanism is not realized in solutions containing Sn(II) hydroxo or tartrate complexes as major species (nos. 7–9). Consequently, the Φ value and, correspondingly, the mechanism of photostimulated oxidation strongly depend on the composition of the irradiated solution. With increasing λ the quantum yield decreases, which is in accordance with the published data on the photosensitivity of Sn(II) compounds.

CONCLUSIONS

(1) A correlation was established between the absorption spectra of $SnCl_2$ solutions and the composition of major Sn(II) complex species in them. A method was proposed for prompt qualitative monitoring of the composition of $SnCl_2$ solutions, based on the absorption spectra.

(2) For $SnCl_2$ solutions irradiated with the total spectrum of a mercury–quartz lamp with an intensity of 1.07×10^{-2} J einshtein^{-1}, the rate of the photostimulated oxidation of Sn(II) with oxygen is higher by two orders of magnitude than the rate of the dark oxidation. The rate of photostimulated oxidation depends on the chemical composition of tin compounds and irradiation wavelength. The oxidation rate and the quantum yield are the highest for Sn(II) chloride complexes; the oxidation efficiency for the hydroxo compound is lower by several orders of magnitude. The photostimulated oxidation of the chloride complexes occurs by a chain mechanism ($\Phi > 1$).

(3) The radiation at a wavelength shorter than 350 nm ensures the highest efficiency of initiation of Sn(II) oxidation. At $\lambda = 400-435$ nm, the oxidation also occurs, but at a considerably lower rate.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Correlation Equations for Predicting the Temperature Depression in Boiling of Aqueous Solutions of Nonvolatile Substances

Received May 27, 2002

Abstract—Three-constant correlation equations describing the boiling point of aqueous solutions of nonvolatile substances and temperature depression in boiling of the solutions under normal and arbitrary pressures are considered. The three constants appearing in the correlation equations are tabulated for aqueous solutions of 19 nonvolatile substances, and formulas for determining these constants for other aqueous solutions of nonvolatile substances from experimental data are presented.

In calculating evaporation installations, especially those with multiple casings, a necessity arises for repeatedly determining the boiling point of water as a function of pressure, pressure as a function of the boiling point of water, and temperature depression as a function of solute concentration and pressure. In doing so, the temperature depression Δ at various pressures is defined in terms of the normal temperature depression Δ_n [1–3]. With the effect of the differential heat of dehydration disregarded because of its being weak or unknown for a given solution, the following equation is proposed [2]:

$$\Delta = r_n T^2 \Delta_n / (T_n^2 r), \quad (1)$$

where r, T, r_n, and T_n are the current values of r and temperature and their corresponding normal values.

When Eq. (1) is used, a necessity arises for using three experimental tables, namely, tabulated dependences of T and r on pressure and that of Δ_n on solute concentration. This creates severe difficulties, especially when account is taken of the fact that an interpolation procedure is to be carried out each time. Not without reason, it was proposed in [3] to tabulate $r_n T^2/(T_n^2 r)$ values in relation to pressure.

Furthermore, Eq. (1) is approximate and, at large deviations of pressure from the normal value, is in strong disagreement with the Babo rule, which is a particular case of the fundamental Kirchhoff law [1] at zero dehydration heat, assumed in Eq. (1). For example, at Δ_n = 30°C and pressure P = 10 atm, Δ = 46.76°C according to the Babo rule and Δ = 49.24°C in accordance with Eq. (1). The discrepancy is 2.57°C. Such an error in prediction of the temperature depression in calculating an evaporator apparatus intended to operate at a useful temperature difference ΔT_u = 10°C leads to an error exceeding 25% in prediction of the necessary heat-exchange surface area.

The lack of correlation equations describing the concentration dependences of the normal temperature depression makes it necessary to use, in working with the tables, linear interpolation leading in some cases to errors of about several degrees. For example, normal temperature depressions Δ_{n1} = 126.5 and Δ_{n2} = 190.3°C were reported in [4] for a KOH solution with x_1 = 70 and x_2 = 80 wt %. For a concentration x_3 = 75.76 wt %, linear interpolation gives Δ_{n3} = 163.25°C, which exceeds by 3.25°C the value Δ_{n3} = 160°C reported for x_3 = 75.76 wt % in [2]. Unhappy combination of this error with the above-mentioned inexactness of Eq. (1) may lead to considerable errors in prediction of the required heat-exchange surface area.

The aim of this study was to derive a correlation equation for predicting the temperature depression in boiling of aqueous solutions of nonvolatile substances in relation to pressure and solute concentration. Such an equation would make unnecessary repeated use of experimental tables and the related repeated interpolation.

For correlating the boiling point of water and pressure, compact interconvertible equations have been proposed previously [4]:

$$T = 100\frac{11.693 + 2.279\ln(P/P_n)}{11.693 - \ln(P/P_n)}, \quad (2)$$

1070-4272/02/7509-1406$27.00 © 2002 MAIK "Nauka/Interperiodica"

$$P = P_n \exp[11.693(T - 100)/(T + 227.9)], \quad (3)$$

where T is temperature, and P_n is the pressure under normal conditions.

In the pressure range P = (0.04–50) atm, deviations of values yielded by Eq. (1) from reference data are lower than 0.1°C, and those for Eq. (2) do not exceed 0.2%.

As regards both the applicability range and correlation accuracy, Eqs. (2) and (3) are quite satisfactory for practical calculations of evaporator apparatus.

The dependences of the normal temperature depression on the concentration x

$$\Delta_n = f(x) \quad (4)$$

for solutions of various nonvolatile substances are so strongly diverse that no correlation equation describing these dependences has been found until now, despite some effort in this direction [5].

Being aware of the complicatedness of correlating directly the dependences (4) with a single equation, even if with numerous coefficients dependent on the solute nature, we found that the following dependences have the same character for different solutions:

$$\ln(P_{equiv.n}/P_n) = f(z), \quad (5)$$

where $z = x/(1 - x)$ is the relative solute concentration, P_n is the normal pressure, and $P_{equiv.n}$ is the equivalent pressure at normal pressure in the apparatus.

The term equivalent is used here for the saturated vapor pressure of water (solvent) at the solution boiling point.

The dependences (5) are well correlated with the equation

$$\ln(P_{equiv.n}/P_n) = Az + Bz^2 + Cz^3. \quad (6)$$

Substitution of this equation into (2) gives an equation for predicting the solution boiling point under normal pressure

$$T_{b.s.n} = 100\frac{11.963 + 2.279(Az + Bz^2 + Cz^3)}{11.963 - (Az + Bz^2 + Cz^3)}. \quad (7)$$

Since $\Delta_n = T_{b.s.n} - 100$, the following equation is obtained for predicting the normal temperature depression:

$$\Delta_n = 100\left[\frac{11.963 + 2.279(Az + Bz^2 + Cz^3)}{11.963 - (Az + Bz^2 + Cz^3)} - 1\right]$$

or, after some transforms,

$$\Delta_n = 327.9[11.693/(Az + Bz^2 + Cz^3) - 1]^{-1}. \quad (8)$$

It can be shown by simple transforms that the best (least-squares) fitting of the experimental data by Eq. (8) is provided with the coefficients given by

$$C = \frac{\alpha_1/\beta_1 - \alpha_2/\beta_2}{\gamma_1/\beta_1 - \gamma_2/\beta_2}, \qquad B = \frac{\alpha_1 - C_1}{\beta_1},$$

$$A = (E_1 - BB_1 - CC_1)/A_1 \quad (9)$$

at

$$\alpha_1 = E_1/A_1 - E_2/A_2, \ \beta_1 = B_1/A_1 - B_2/A_2,$$

$$\gamma_1 = C_1/A_1 - C_2/A_2;$$

$$\alpha_2 = E_2/A_2 - E_3/A_3, \ \beta_2 = B_2/A_2 - B_3/A_3,$$

$$\gamma_2 = C_2/A_2 - C_3/A_3,$$

where

$$A_1 = \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^4 z_i^2, \qquad B_1 = A_2;$$

$$A_2 = \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^4 z_i^3, \qquad B_2 = A_3;$$

$$A_3 = \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^4 z_i^4, \qquad B_3 = \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^4 z_i^5;$$

$$C_1 = A_3, \qquad E_1 = 11.693 \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^3 \Delta_{n_i} z_i;$$

$$C_2 = B_3, \qquad E_2 = 11.693 \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^3 \Delta_{n_i} z_i^2;$$

$$C_3 = \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^4 z_i^6,$$

$$E_3 = 11.693 \sum_{i=1}^{n} (\Delta_{n_i} + 327.9)^3 \Delta_{n_i} z_i^3;$$

Table 1 presents the coefficients of Eqs. (6)–(8) for solutions of some salts and alkalis, found from the experimental data reported in [2, 6].

Table 2 compares the values calculated using Eq. (8) with the experimental normal temperature

depressions for solutions of some nonvolatile substances, reported in [2, 6]. The deviations of the calculated values from the experimental data very rarely exceed 0.2°C. This is to be considered quite satisfactory, if account is taken of the fact that, in some cases, even greater discrepancies are observed between two independent experimental values [2, 6].

According to the Kirchhoff law [1], at zero differential heat of dehydration

$$P_{equiv}/P = P_{equiv.n}/P_n = \text{const}, \quad (10)$$

i.e., the Babo rule is valid. Consequently, with the effect of the differential dehydration heat neglected, we can write for any arbitrary pressure

$$P_{equiv}/P = Az + Bz^2 + Cz^3. \quad (11)$$

According to (2), the boiling point of a solution is given by

$$T_{b.s} = 100\,\frac{11.693 + 2.279\ln(P_{equiv}/P_n)}{11.693 - \ln(P_{equiv}/P_n)}$$

$$= 100\,\frac{11.693 + 2.279[\ln(P/P_n) + \ln(P_{equiv}/P_n)]}{11.693 - \ln(P/P_n) - \ln(P_{equiv}/P_n)}$$

or, with account of (11),

$$T_{b.s} = 100\,\frac{11.693 + 2.279[\ln(P/P_n) + Az + Bz^2 + Cz^3]}{11.693 - [\ln(P/P_n) - Az + Bz^2 + Cz^3]}. \quad (12)$$

It can be readily seen that the last equation transforms into (7) at $P = P_n$.

Since the boiling point of water under pressure P is given by Eq. (2), the temperature depression under pressure P can be found from the equation

$$\Delta = 100\,\frac{11.693 + 2.279[\ln(P/P_n) + Az + Bz^2 + Cz^3]}{11.693 - [\ln(P/P_n) - Az + Bz^2 + Cz^3]} - 100\,\frac{11.693 + 2.279\ln(P/P_n)}{11.693 - \ln(P/P_n)}$$

or, after some rearrangements,

$$\Delta = 3834[11.693 - \ln(P/P_n)]^{-1}\left[\frac{11.693 - \ln(P/P_n)}{Az + Bz^2 + Cz^3} - 1\right]^{-1}. \quad (13)$$

Naturally, the last equation turns into (8) at $P = P_0$.

Table 3 compares the temperature depressions found from Eqs. (1) and (13) with the values determined using the Babo rule.

It can be seen that the approximate equation (1) is in strong disagreement with the Babo rule at pressures much exceeding the normal pressure, especially at high normal temperature depressions. The small but systematic deviation of Eq. (13) from the values found using the Babo rule can be accounted for by the experimental deviations of the normal temperature depressions used in calculations based on the Babo rule from the true concentration dependence of the normal

temperature depression. Therefore, the temperature depressions found using Eq. (13) are more reliable than those determined from the Babo rule.

CONCLUSIONS

(1) An equation is proposed for analytical prediction of the solution boiling point in relation to the solute concentration, and its constants are calculated.

(2) Equations for analytical prediction of the normal temperature depression in relation to the solute concentration, boiling point of solution in relation to pressure and concentration, and temperature depression in relation to pressure in apparatus and concentration are derived. When data on the equation constants are lacking, these constants can be found from experimental data using the equations proposed.

Abstract—The influence of surface oxidation of anthracite with humid air, followed by impregnation with alkali metal compounds and calcination in inert atmosphere before activation, on the efficiency of steam–gas activation and on the development of the pore structure of the resulting carbon adsorbents was studied.

Coals are a major raw material for preparing various carbon adsorbents [1, 2]. Among them, the most attractive is anthracite because of increased content of carbon and low ash residue; furthermore, activated carbon prepared from it has high mechanical strength.

At the same time, the activation of anthracite for preparing sorbents is impeded by its low reactivity in high-temperature contact with traditional gaseous activators, superheated steam and carbon dioxide. This is due to the high degree of metamorphism of anthracite (well-organized supramolecular structure with short-range and partly long-range order). Therefore, direct gas–steam activation of anthracite often fails to develop its pore structure and attain the high specific parameters of porosity.

It is also known that alkali metal (AM) compounds catalyze activation of carbon-containing materials. Using published basic data [3, 4] and the results of our studies, including quantum-chemical calculations [5–9], we suggested the possibility of formation of layered intermediate compounds by intercalation of a metal into the interlayer space of carbon planes (graphite-like clusters) of microcrystallites; this factor is responsible for the increased reactivity of the microcrystallites in oxidative gas activation.

Indeed, in the course of high-temperature (600–800°C) treatment of carbon materials impregnated with AM ions (thermochemical modification), these ions can be reduced to zero oxidation state. The metal being formed penetrates into slitlike pores of graphitic microcystallites, donating its valence *s* electrons to the π-conjugated systems of condensed aromatic rings. As a result, structural radical anions are formed, which are highly reactive in contact with electron-acceptor molecules.

The formation of the interphase of carbide-like compounds with essentially ionic M–C bonds and low hydrolytic resistance is also responsible for the increase in the reactivity of a carbon material under the above conditions and facilitates activation with superheated steam.

In any case, the activation efficiency should depend on the impregnation procedure, which should ensure the required content of alkali metal ions and their uniform distribution and deep penetration in the carbon matrix. It seemed promising to perform impregnation by ion exchange in contact of a solution of an AM compound with preliminarily oxidized anthracite samples.

In this work, we studied how the extent of oxidation of anthracite after impregnattion with alkali metal compounds and heat treatment affects the efficiency of the subsequent activation with steam and the transformation of the resulting pore structure.

The initial material was weakly activated A grade anthracite (Sverdlovantratsit Production Association, Donets coal fields). The initial raw material contained (wt %) 90 carbon, 3–4 ash, 6–7 volatiles, and less than 2 sulfur. Its particle size was 0.25–1.0 mm. The oxidative treatment of the anthracite samples was performed at 360–400°C in humid air. The total number of proton-donor (phenolic and carboxy) groups on the surface of anthracite was determined by titration with 0.1 N NaOH solution and by calculation of the static exchange capacity (SEC). In the course of the oxidation, we obtained samples differing in the extent of oxidation (with SEC 0.6, 1.0, 1.4, and 1.8 mg-equiv g^{-1}).

The impregnation of samples with AM salt (preac-

tivation heat treatment) was performed in the similar mode. Oxidized anthracite samples were impregnated with a 5 wt % solution of sodium nitrate at a liquid-to-solid volume ratio of 1 : 1 and kept for 5–6 h at 120°C to complete drying. Then, the impregnated samples were placed in a quartz reactor in a horizontal furnace and calcined at 900°C for 1 h in argon. After that, the samples were activated with steam at the same temperature. The flow rate of steam (0.1 l h^{-1}) ensured a 8–9-fold excess of water with respect to stoichiometry in gasification of condensed carbon.

To reveal the effect of oxidative treatment combined with the subsequent impregnation with sodium nitrate and heating, we also performed direct activation of anthracite (without treatment before activation) and activation of anthracite samples oxidized to the above values of SEC and heat-treated in Ar before activation.

In all stages of the study, variation of the pore structure of the samples was monitored by measuring the pore volume by benzene [10]. The radius distribution of macro- and mesopores was determined by the mercury porosimetry on a Pore-Sizer 9300 device (Cultronix, France). In the course of the activation, the sample yield with respect to mass and volume, R_m and R_v, the bulk density Δ, and the degree of burn-out ω were determined.

The kinetic curves of burn-out of anthracite samples prepared by different procedures in the course of the steam activation at 900°C are shown in Fig. 1. As seen, for the initial anthracite sample subjected to direct activation, the kinetic curve approaches the linear dependence. In this case, 50 and 75% burn-out was attained in 2.5 and 4.25 h, respectively. The preliminary oxidation to SEC from 0.6 to 1.8 mg-equiv g^{-1} and subsequent heating in argon at 900°C before activation do not noticeably affect the burn-out dynamics (Fig. 1a). The corresponding kinetic curves are close, within insignificant scatter of experimental data, to the dependence obtained for direct activation of anthracite at the initial burn-out rate of about 20% h^{-1}.

Thus, the oxidative treatment of anthracite does not affect the rate of activation with superheated steam.

At the same time, impregnation of the initial anthracite with sodium nitrate followed by heating in argon at 900°C before activation considerably enhances the reactivity of condensed carbon (Fig. 1b). The initial rate of the anthracite burn-out increases two-fold (~40% h^{-1}), and 50 and 75% burn-out is attained in a considerably shorter time (1.75 and 3 h, respectively).

The reactivity increased to a still greater extent when preliminarily oxidation was followed by impregnation with $NaNO_3$ and calcination in inert

atmosphere before activation. The initial rate of the activation exceeds 50% h^{-1}, reaching 70% h^{-1} at a high burn-out. In this case, 50% and 75% burn-out is attained within 0.5–1.25 and 1.25–2.5 h, respectively. It is interesting that oxidation of samples to SEC within 0.6–1.4 mg-equiv g^{-1} ensured approximately similar increase in the carbon reactivity. Only at fairly large extents of oxidation (SEC 1.8 mg-equiv g^{-1}), the carbon skeleton underwent rapid weight loss in the course of activation; the process resembled combustion rather than pore formation.

It is important to know how the activation index and the sorption volume by benzene vary with the degree of burn-out of the samples (Fig. 2). The variation of R_m/R_v ratio shows that the oxidized anthracite samples show stronger tendency to combustion than samples obtained by direct activation of the initial anthracite (Fig. 2a). This is due to the removal of CO and CO_2 from the surface oxides during activation. Upon activation of anthracite and its oxidized modifications impregnated with sodium nitrate, the pore formation always dominates over combustion (Fig. 2b, lines *A* and *C*, resectively). The only exception is the strongly oxidized sample with SEC 1.8 mg-equiv g^{-1}, for which the contribution of combustion also considerably increases. Apparently, this is due to the extremely high content of surface oxides present on anthracite and replacement of a part of protons in protono-donor groups by sodium ions. For all other modifications of anthracite activated with sodium nitrate, the curves virtually coincide to 65% burn-out and deviate toward combustion only at higher degrees of burn-out.

The sorption volume by benzene is virtually similar for samples obtained by direct activation and for those activated after oxidation (Fig. 2c). In this case, W_s by benzene is maximal, 0.5 cm^3 g^{-1}, at 50–75% combustion. The impregnation with sodium nitrate (Fig. 2d) results in somewhat lower values of W_s for nonoxidized anthracite samples and considerably increased values, for oxidized samples. In this case, W_s passes through a maximum with increasing amount of oxygen-containing groups. For samples with SEC 1.0 mg-equiv g^{-1}, W_s of 0.6 cm^3 g^{-1} and higher is attained at 60–75% burn-out. Anthracite samples oxidized to SEC 1.0–1.4 mg-equiv g^{-1} are the best from the viewpoint of development of the sorption pore volume. Apparentlty, at further oxidation the reactivity of the matrix sharply increases, which intensifies combustion and facilitates formation of macropores, in particular, by destruction of walls of micro- and mesopores.

Our results show that the SEC values within 1.0–1.4 mg-equiv g^{-1} are optimal for anthracite oxidation.

The results of studying the samples by mercury porosimetry (see table) confirm our assumptions concerning the character of development of the anthracite pore structure upon different activations. For example, the data of the table show that the volume V^{Hg} of the mercury being pressed is minimal for the sample obtained by direct activation, is markedly higher for that activated after oxidation, and is also higher (by a factor of 1.5) for the sample impregnated with sodium nitrate. Upon combined treatment (oxidation, impregnation, and heat treatment) before activation, V^{Hg} grows with increasing SEC. At SEC 1.4 mg-equiv g^{-1}, the volume of Hg-filled pores increases twofold as compared to direct activation.

At the same time, the growth of the macropore

Activation: (*1*) direct, (*2*) heat-treated sample oxidized to SEC 1.0 mg-equiv g^{-1}; (*3*) heat-treated initial sample impregnated with sodium nitrate; and (*4*) heat-treated sample oxidized to SEC 1.0 mg-equiv g^{-1} and impregnated with sodium nitrate.

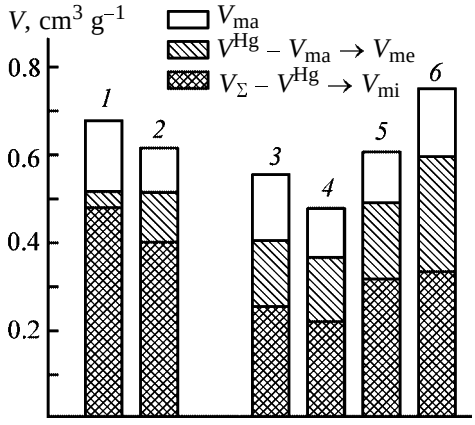

Fig. 4. Histogram of the ratio of micro-, meso-, and macropores in anthracite samples activated by different procedures. (V) Pore volume. Activation: (*1*) direct; (*2*) heat-treated sample oxidized to SEC 1.0 mg-equiv g^{-1}; (*3*) heat-treated initial sample impregnated with sodium nitrate; and (*4–6*) heat-treated oxidized samples (SEC 0.6, 1.0, and 1.4 mg-equiv g^{-1}, respectively) impregnated with sodium nitrate.

volume was not noticeably affected by activation. In this case, the difference $V^{Hg} - V^{Hg}_{ma}$, which is close to the absolute mesopore volume, V_{me}, increases, which shows that the combined treatment before activation results in efficient development of the mesopore structure.

At the same time, the anthracite sample obtained by direct activation has one of the lowest apparent densities by mercury ρ. As a rule, the activated anthracite samples subjected to preliminary oxidation, impregnation with sodium nitrate, or combined treatment have a higher apparent density. And only after fairly deep oxidation (to SEC 1.5 mg equiv g^{-1}) the apparent density attains the values similar to, or lower than those yielded by direct activation. Correspondingly, the comparable and even larger total pore volume V_Σ is attained under these conditions. Thus, preactivation treatment of samples shifts the ratio of the micro-to-mesopore volume toward formation of mesopores. This is clearly illustrated by the differential curves of pore distribution with respect to equivalent radius (Fig. 3) and also by the ratios of the pore volumes for all types of pores developed in the anthracite samples activated by different procedures (Fig. 4). Indeed, whereas the anthracite sample obtained by direct activation contains insufficient amount of transition (meso-) pores (micro- to mesopore ratio 5 : 1), the proposed combined treatment before activation allows the activation to be shifted toward formation of mesopores (micro- to mesopore ratio 3 : 2). In the process, the sorption volume $V_{mi} + V_{me}$ in the resulting samples at comparable burn-out can be increased by 20–25% compared to direct activation. The specific surface area of such sorbents with polymodal pore structure, as estimated from thermal desorption of argon, reaches 900–1000 $m^2 g^{-1}$.

CONCLUSIONS

(1) The preliminary oxidative treatment followed by impregnation with alkali metal compounds and treatment in an inert gas before activation allow the reactivity of anthracite to be increased 2–3-fold. The sorption pore volume of the resulting samples is larger than in the case of direct activation, and the mesopore structure is formed.

(2) In the course of the anthracite activation, the catalytic effect of alkali metal compounds increases when oxygen-containing groups (including proton-donor groups) are present on the surface of the carbon matrix. The optimal degree of the anthracite oxidation, ensuring the largest pore volume upon activation, corresponds to the static exchange capacity of 1.0–1.4 mg-equiv g^{-1}.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Exfoliation of Coatings from Silicon Crystals Electroless-Plated with Nickel and Electroplated with Gold

O. Girchene and E. Matulenis

Institute of Chemistry, Vilnius, Lithuania

Received February 19, 2002

Abstract—The microhardness and content of carbon in electroplated gold coatings were studied as influenced by the operation time of citrate and citrate–phosphate gold-plating electrolytes. Such physicomechanical properties as porosity, microhardness, internal stress, plasticity, and microstructure of electroless-plated and electroplated nickel coatings were studied and analyzed.

Electroplated gold coatings [1–3] are widely used in semiconductor industry owing to chemical stability, small and constant contact resistivity, high soldering ability, and formation of low-melting eutectic with silicon, which provides prolonged safe operation of electronics. In special cases gold is deposited to protect the nickel ohmic contacts in the course of further treatment of the silicon crystals with aggressive etching agents and to improve soldering of the electric contacts. Such electroplated coatings should exhibit high adhesion to nickel support and minimal porosity.

According to the preparation procedure of the ohmic contacts, electroplating with gold is preceded by electroless deposition of the second nickel layer on silicon plates electroless-plated with nickel. For uncertain reasons, in some cases, exfoliation of coatings is observed when cutting silicon plates. In the course of electrolysis, anodic oxidation of citrates in gold-plating electrolytes occurs, and its products can be incorporated in the gold coatings [4]. Electroless-plated nickel can also contain impurities, whose content depends on the solution pH, temperature, and some other factors [5]. Therefore, during coating of silicon plates with nickel and gold, even slight changes in the plating mode can affect the physicomechanical properties of the coatings and cause low adhesion at the Au–Ni and Ni–Ni interfaces.

The goals of this work were to reveal factors responsible for exfoliation of coatings from silicon crystals at their cutting and to develop the optimal preparation procedure providing high adhesion at the Au–Ni and Ni–Ni interfaces. The dependences of microhardness and content of carbon in electroplated gold coatings as influenced by the operation time of citrate and citrate–phosphate gold-plating electrolytes were studied, and various physicomechanical properties of electroless-plated and several electroplated nickel coatings were determined.

EXPERIMENTAL

All the solutions for gold plating and for electroless and electrolytic nickel plating were prepared by dissolution of appropriate chemically pure grade and analytically pure grade chemicals in distilled water. The compositions of the resulting solutions are listed in Tables 1 and 2.

The samples were coated with metals in 0.2-l electrolyzers equipped with a magnetic stirrer. A platinized titanium plate was used as an anode in gold electroplating.

The content of carbon in the electroplated gold coatings was determined on an AN-7529 express carbon analyzer. The microstructure of the nickel coatings was studied on a JXA-50A electron microscope-microanalyzer. The microhardness H_μ (kgf mm^{-2}) of the electroplated coatings with thickness $d \geq 10$ μm at 20-g load was registered on a PMT-3 microhardness meter according to the Vickers procedure [6]. The plasticity of the nickel coatings was tested by bending at right angles; the bending areas were examined with a microscope.

To determine the porosity of nickel coatings, they were deposited on a 1 cm^2 copper plate. On this plate (acting as anode), we put a photographic paper treated with a fixer and impregnated with a 1% NH_4NO_3 solution (the emulsion-coated side toward the coat-

ing), over which an aluminum cathode was placed. The resulting assembly was pressed (1 MPa) and treated with an electric current (5 mA cm^{-2}) for 0.5–1.0 min. Then, the photographic paper was developed in a 1% solution of dimethylglyoxime. The through pores in the nickel coating were observed as brown-green spots [7].

The internal stress IS in the nickel coatings was measured by a flexible cathode procedure [6]. The coating was deposited on a brass plate (0.46 mm thick); it was fixed in a special holder preserving its position on a test desk. The cathode bend was determined from the difference of measurements before and after coating. The IS values were calculated from

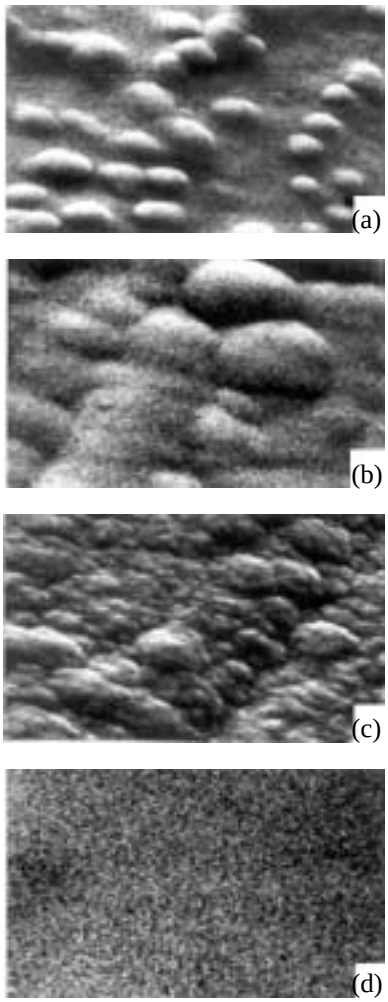

Fig. 1. Microstructure of nickel coatings deposited form electrolyte nos.: (a) 1, (b) 2, (c) 3, and (d) 4. Magnification $\times 3000$.

the following equation [6]:

$$IS = (Ed^2 z)/(3gl^2),$$

where E is the Young's modulus (kg cm^{-2}); d, the plate thickness (cm); z, the cathode deviation (cm); g, the coating thickness (cm); and l, the plate length (cm).

The measurement error was ±5%.

Coating of the nickel-plated silicon plates with gold was performed from citrate (99.9% Au) and citrate–phosphate (99.9% Au) electrolytes (Table 1, nos. 3, 3a, 1, 2, and 2a–2c, respectively). Since gold anodes are insoluble in such electrolytes, we used as anodes platinized titanium plates. In the course of electrolysis, oxidation of citrates at the anode is observed [4]. The oxidation products are accumulated in solution and can be incorporated into the gold coating, affecting its physicomechanical properties [4].

We determined the content of carbon in the gold coatings electroplated from freshly prepared solutions and from those used for a long period (Table 1, nos. 1–3 and 2a–2c, 3a, respectively). It was found that, in the case of citrate electrolyte (nos. 3, 3a), with increasing operation time from 0 to 100 A h l^{-1} the content of carbon increases from 0.72×10^{-2} to 1.07×10^{-2}% (Table 1). In the gold coatings prepared in citrate–phosphate electrolytes, with increasing operation time to 150 A h l^{-1}, the content of carbon remains approximately constant and varies from 0.95×10^{-2} to 1.08×10^{-2}% (Table 1, electrolyte nos. 1, 2, 2a–2c). With increasing operation time, the microhardness of the gold coatings obtained from all the electrolytes studied increases by only 6–10% (Table 1).

These data show that H_μ and content of carbon in the gold coatings do not change significantly with increasing operation time of gold electrolytes to 150 A h l^{-1}.

In the preparation of the ohmic contacts, the first fine layer of nickel is electroless-plated on the silicon plate, and the second layer of nickel is electroless-plated directly before gold electroplating. As seen from published data [1, 5, 8], when hypophosphite is used as a reducing agent, nickel electroless-plated from acidic and alkali solutions contains 6–15 and 3–7 wt % phosphorus, respectively. Phosphorus in the coating is distributed nonuniformly, causing layered structure of the nickel coatings. It is often considered that freshly prepared electroless-plated nickel coatings are the supersaturated solid solutions of phosphorus in nickel. As shown in [1], the Ni–P solid solution is susceptible to passivation and it should be soldered directly after deposition. The plasticity of electroless-plated nickel is low. The IS values of the electroless-plated nickel coatings depend on the conditions of their deposition [5], and variations in the deposition procedure can affect the physicomechanical properties of the resulting coatings. Taking into account the above facts, we studied and analyzed physicomechanical properties (porosity, microhardness, internal stress, plasticity, and microstructure) of the electroless-plated and several electroplated nickel coatings deposited from various nickel-plating electrolytes [9, 10]. The compositions of the nickel-plating electrolytes and physicomechanical properties of the resulting nickel coatings are listed in Table 2.

Analysis of the microstructure showed that the coatings deposited from electrolyte nos. 1 and 2 (Figs. 1a, 1b) are similar. In the electroless deposition of coatings from nickel-plating solutions, ellipsoidal spherical aggregates of up to 2 μm size are formed (Fig. 1a), whereas in deposition from Watts solution

no. 2 coarser aggregates of up to 5 μm size appear (Fig. 1b). When nickel coatings are deposited from sulfamic electrolyte no. 3, a fine-grained precipitate is formed, and separate crystallites and concretions are observed (Fig. 1c). From electrolyte no. 4, finely crystalline and lustrous nickel coating is deposited (Fig. 1d). Our tests showed that all the nickel coatings of 0.3 μm thickness are porous. With increasing thickness of nickel coatings to 1 μm, their porosity decreases, and at 3 μm they become poreless. As seen from the comparison of 1-μm coatings, the nickel coating prepared by electroplating from electrolyte nos. 2 and 3 are less porous and simultaneously the most plastic.

One of the most important characteristics of nickel coatings is their internal stress. Significant internal stresses cause fracture of the deposit and its exfoliation from the support. It is known that the internal stresses in the nickel coatings depend on the presence of anions of the nickel salts used in the synthesis. According to [10], the IS value grows in the following order: sulfamates < bromides < fluoroborates < sulfates < chlorides.

With increasing solution temperature, IS decreases [5]. The data on IS and H_μ listed in Table 2 show that the smallest internal stresses are typical for the coatings deposited from electrolyte solutions containing saccharin (lustrous no. 4). This fact agrees with published data [11], where small additives of saccharin or 1,4-butynediol in nickel-plating electrolytes are recommended to reduce IS. The H_μ values of the electroless-plated and lustrous electroplated nickel coatings are similar (Table 2, electrolyte nos. 1, 4).

Our experimental and published [1, 5, 8] data suggest that the electrolytic nickel coatings in some properties (plasticity, porosity, and internal stress) are even more appropriate for deposition of the second nickel layer. Moreover, electroless-plated nickel coatings contain phosphorus and other impurities, which may cause exfoliation of the coatings from silicon crystals when cutting the plates.

To study the possibility of replacement of the electroless-plated nickel coatings by electroplated samples, a series of silicon plates were electroplated with nickel (layer thickness of 3 μm) using electrolyte nos. 2–4 (Table 2) with subsequent deposition of the gold coatings. The entire series successfully passed the industrial tests, and no exfoliation of the coatings was observed. This confirms our assumption that exfoliation of the coatings from silicon crystals at their cutting is due to changes in the physicomechanical properties of the electroless-plated nickel coatings, which deteriorates adhesion at the Ni–Ni and Ni–Au interfaces. We recommend to substitute the second layer of electroless-plated nickel with an electroplated coating (nearly 3 μm thick) deposited from electrolyte of the following composition, g l^{-1}: 280 $NiSO_4 \cdot 7H_2O$, 35 $NiCl_2 \cdot 6H_2O$, and 30 H_3BO_3; pH 3.5–5.5 (Table 2, electrolyte no. 3). This electrolyte contains no organic additives which could be incorporated into the nickel coatings.

CONCLUSIONS

(1) With increasing operation time of the gold-plating electrolytes from 0 to 150 A h l^{-1}, the content of carbon in the gold coatings and H_μ change insignificantly.

(2) To exclude exfoliation of coatings from the crystals at cutting, the second layer of electroless-plated nickel should be substituted with electroplated coating (nearly 3 μm thick) deposited from electrolyte of the following composition, g l^{-1}: 280 $NiSO_4 \cdot 7H_2O$, 35 $NiCl_2 \cdot 6H_2O$, and 30 H_3BO_3; pH 3.5–5.5.

Abstract—The catalytic activity of manganese dioxide samples in oxidation of CO and decomposition of hydrogen peroxide was studied. The promise of manganese dioxide obtained from fluorine-containing electrolytes as a catalyst for carbon monoxide oxidation was considered.

Carbon(II) oxide is one of the most toxic components of industrial waste gases and exhaust gases of automobiles; also, it is formed in regeneration of hydrocarbon cracking catalysts [1–3]. Its maximum permissible concentration is 3 mg m^{-3}. Despite active research in this field, the problem of CO conversion into CO_2 remains topical.

Oxidation of carbon monoxide is accompanied by a considerable decrease in the Gibbs energy (ΔG^0_{298} = –242 kJ mol^{-1}). However, no CO_2 is formed without a catalyst at temperatures below 923 K. As catalysts for CO oxidation, both metals and oxides MnO_2, Co_3O_4, and CuO are used [1]. With some oxides, the process temperature can be decreased to 393–423 K.

It is known that such structural factors as phase composition, size and orientation of crystallites, dispersity of the material, presence of various kinds of defects, and the extent to which the composition of a compound deviates from the stoichiometry determine its chemical properties [4, 5]. It has also been shown that the catalytic activity of a material grows when its structure becomes disordered [4–6]. An interesting object in this regard is manganese dioxide. Only β-MnO_2 is a stoichiometric compound. The composition of other manganese oxides is commonly represented as MnO_x, where $1.7 < x < 2.0$ [7–9]. Account should also be taken of the fact that manganese dioxide is one of the most common and least expensive oxide materials. The structure of this compound depends very strongly on a method by which it is obtained. Electrochemical manganese dioxide is distinguished by more disordered structure, compared with the chemically synthesized compound.

The aim of this study was to analyze oxidation of carbon monoxide in the presence of various samples of manganese dioxide.

It was shown previously [10, 11] that the use of fluorine-containing electrolytes to obtain manganese dioxide allows control over its composition and properties. In this connection, we made a comparative study of the catalytic activity of various kinds of manganese dioxide, including those prepared electrochemically from fluorine-containing electrolytes (see table, sample nos. 1 and 2).

EXPERIMENTAL

The model reaction of hydrogen peroxide decomposition is frequently used in choosing catalysts for oxidation reactions. Being carried out in aqueous solutions at room temperature, it is very convenient. The reaction progress was monitored by the volume of evolved oxygen, and the activity of manganese dioxide was evaluated from the reaction rate constant:

$$W = kc^nS, \quad (1)$$

where W is the reaction rate; k, the rate constant of the reaction (s^{-1}); n, the reaction order; and S, the specific surface area ($m^2\ g^{-1}$).

The time reckoning was from the instant when the catalyst and a solution were brought in contact. The weighed portion of the catalyst was 10 mg. Experiments were performed with a 30% solution of analytically pure grade hydrogen peroxide whose concentration was checked by titration with 0.1 N $KMnO_4$ solution by the standard procedure [11]. The concentration and volume of the H_2O_2 solution in the reaction vessel

were 4.92 M and 25 ml. The measurements were done without stirring. The temperature of the hydrogen peroxide solution was maintained at $25 \pm 1°C$ with a U-10 thermostat.

The oxidation of carbon monoxide was studied in a flow-through reactor. The gas flow rate was 1.67×10^{-6} $m^3\ s^{-1}$, the weighed portion of the catalyst was 0.5 g, and the carrier gas was helium. The temperature of the catalyst bed was measured with a Chromel–Alumel thermocouple. The mixture of reactants (O_2, CO, CO_2) was analyzed with an LKhM-8MD chromatograph in which this mixture was separated at 355 K in a column packed with activated carbon impregnated with nickel sulfate. This analytical procedure detects O_2, CO, and CO_2 in amounts of 0.01 vol % with accuracy of 10%. The sample volume subjected to analysis was 1.3 ml. Composition of the reaction mixture (vol %): carbon monoxide 1, oxygen 20, and helium 79. The specific rate of the reaction, W_{sp} ($mol\ s^{-1}\ m^{-2}$), was calculated by the formula

$$W_{sp} = (cU)/(gS), \quad (2)$$

where c is the CO concentration at the reactor outlet ($mol\ m^{-3}$), g is the weighed portion of the catalyst (kg), and S is the specific surface area of the catalyst ($m^2\ kg^{-1}$).

The reaction order with respect to reagent concentrations was found from the slope of a plot constructed in the $\ln W_{sp}$–$\ln c$ coordinates.

The X-ray phase analysis of manganese dioxide was carried out on a DRON-3 instrument with MoK_α radiation.

The chemical analysis of manganese dioxide was made in accordance with GOST (State Standard) 25823–23. The content of manganese(II) was found using the procedure described in [12]. Data on the content of low-charged manganese ions were recalculated to Mn(II) and Mn(III). The x value was calculated for all of the samples studied from the content of differently charged manganese ions [13]:

$$x = (2 + 1.5R)/(1 + R), \quad (3)$$

where $R = [Mn(III)]_s/[Mn(IV)]_s$.

Thermogravimetric measurements were done on an OD-2 derivatograph (Hungary) with Al_2O_3 reference under heating (20–600°C) in air. The sample weight was 250 mg, and the heating rate, 5 and 10 deg min^{-1}. The content of OH groups was found from the mass loss (thermogravimetric curve) in the following temperature ranges: surface OH groups at 130–200°C and total OH groups (with the exception of physically adsorbed water) up to 400°C.

The specific surface area was determined by high-temperature adsorption of argon, using samples with the known surface area as reference [14]. The measurements were carried out on an LKhM-8MD chromatograph (model 1). The working mixture contained 12% argon and 88% helium. The reference adsorbent was Al_2O_3 with the specific surface area of 26 $m^2\ g^{-1}$. The use of the chromatographic technique gave an error of 10%.

The ESR spectra were measured at room temperature on a Radiopan SE/x-2547 microwave spectrom-

eter (3 cm) equipped with a computerized spectral analyzer.

The results obtained in determining the catalytic activity in hydrogen peroxide decomposition, acidity, and specific surface area of several manganese dioxide samples are presented in the table. It can be seen that the difference in composition between the samples is reflected in the rate constant of H_2O_2 decomposition.

With all of the samples studied, hydrogen peroxide decomposition is a first-order reaction. Therefore, the rate constant was found as the slope of the curve in the $\log c$–τ coordinates. The highest catalytic activity was observed for nonstoichiometric manganese dioxide (sample no. 1) obtained from fluorine-containing electrolytes, and the lowest, for stoichiometric manganese dioxide (sample no. 4).

Figure 1 presents the degree of catalytic conversion of carbon monoxide as a function of temperature. It can be seen that the temperature of full CO conversion increases in the following order of manganese dioxide samples studied: nos. 1, 2 < 3 < 5 < 4.

When the temperature is lowered, which corresponds to the reverse run of the dependence (Fig. 1), all the samples exhibit hysteresis; namely, the degree of conversion in heating of a sample exceeds that in cooling. This catalytic reaction is also first-order, which is indicated by the linear dependence of the rate of catalytic oxidation of carbon monoxide on its concentration.

The lowest temperature of full conversion of CO at its concentration of 1% is characteristic of sample no. 2 obtained from a fluorine-containing electrolyte. The working temperature of this catalyst is about 100°C. It should be noted that this catalyst can be used at even lower temperature, e.g., at 90°C, with the degree of conversion being still sufficiently high: about 80%.

The activation energy of the reaction at constant reactant concentrations was found in the range 40–100°C. The lowest activation energy was observed for sample no. 2 with the lowest temperature of full CO conversion into CO_2. The activation energy of hydrogen peroxide decomposition was determined using the isothermal method from the rate constants of the catalytic reaction at 25, 30, 35, and 40°C. The activation energies calculated for both catalytic processes are close, in the range from 15 to 30 kJ mol^{-1}. According to the results obtained, the catalytic decomposition of hydrogen peroxide can be used as model reaction in studying catalytic oxidation reactions.

In [15], data on catalysis of various reactions on manganese dioxide were summarized and correlated with structural parameters of the material. Here we made an attempt to consider in the same terms the problem of carbon monoxide conversion and hydrogen peroxide decomposition on manganese dioxide.

According to X-ray diffraction patterns, two-phase sample nos. 1 and 2 (γ-MnO_2 with impurity of the α-phase), sample no. 4 (with well-formed structure of β-MnO_2), and sample nos. 3 and 5 (structure of the γ-MnO_2 type) can be distinguished.

A relationship is observed between the activity of

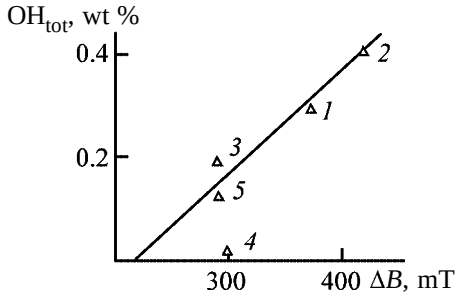

Fig. 3. Correlation between the ESR signal broadening ΔB and the total content of OH groups, OH_{tot}, in the samples studied.

the samples in both the catalytic reactions and their structural disorder.

One of the most important criteria of nonstoichiometry of manganese dioxide is the presence of OH groups. These groups ensure electroneutrality in the case of cationic vacancies of manganese in the lattice and provide charge stabilization of differently charged manganese ions Mn(III)/Mn(IV) in the structure of this oxide. Mention should be made of the dependence of the activity on the number of surface OH groups in catalysis of hydrogen peroxide decomposition (Fig. 2a). The relationship between the temperature of full conversion of carbon monoxide and the content of surface OH groups, revealed in the samples studied, demonstrates that catalytic oxidation of CO is governed by the defectiveness of the catalyst structure (Fig. 2b).

Important information about the defectiveness of the manganese dioxide structure is furnished by ESR spectroscopy. According to the data obtained, the observed broadening of the ESR signal indicates an intensive exchange interaction between differently charged manganese ions in the lattice. This quantity correlates satisfactorily with the content of differently charged manganese ions and OH groups in the structure [16] (Fig. 3). The stoichiometric sample falls out of this dependence, presumably because of differences in the structure (β-MnO_2) and in the mechanism of compensation of the charge of defects.

Thus, the defects, including OH groups and differently charged manganese ions, govern the catalytic activity of the manganese dioxide samples studied.

CONCLUSIONS

(1) The catalytic properties of manganese dioxide can be improved significantly by changing the method of its preparation. Manganese dioxide obtained from fluorine-containing electrolytes is a promising catalyst for CO oxidation.

(2) The activity of the samples is governed by the defectiveness of their structure, which can be judged from the concentration of OH groups.

Abstract—The catalytic activity of a series of metal oxides in oxidation of ethylene glycol was studied.

Transformations of alcohols into lower aliphatic carbonyl compounds are performed in industry on a large scale [1]. These reactions are catalyzed by *d*-metal oxides (V_2O_5, MoO_3, etc.) and complex systems based on them [2].

Partial oxidation of lower alcohols (methanol, ethanol) into carbonyl compounds on oxide catalysts has been extensively studied [3–5]. However, only scarce data are available on oxidation of dihydric alcohols on oxide catalysts. In particular, for oxidation of ethylene glycol (EG) on complex molybdenum-containing catalysts, only the composition of the reaction products was reported [6], without detailed discussion. In this work, we studied selective oxidation of EG on a series of individual oxide catalysts.

EXPERIMENTAL

We tested as catalysts V_2O_5, MoO_3, WO_3, CuO, and Cr_2O_3. This choice was governed by the following factors. According to published data on catalytic oxidation of monohydric alcohols to carbonyl compounds [7], these individual oxide catalysts exhibit acid properties, i.e., they readily adsorb alcohols. Furthermore, the oxygen binding energy in the crystal lattice of these oxides is high, which favors partial oxidation of organic compounds [2, 7]. It is also known that addition of Cr_2O_3 or WO_3 to vanadium catalytic systems appreciably enhances the catalytic activity of V_2O_3 in oxidation of methanol into formaldehyde [8, 9]. Supported copper oxide catalyst is fairly active in oxidation of EG to glyoxal [10, 11].

The catalysts were prepared as follows: WO_3, by decomposition of $(NH_4)_2WO_4$ at 600°C for 4 h; MoO_3, by decomposition of $(NH_4)_6Mo_7O_{24}$ at 350–400°C; V_2O_5, by decomposition of NH_4VO_3 at 450°C for 3 h; and Cr_2O_3 and CuO, by decomposition of the corresponding hydroxides, $Cr(OH)_3$ and $Cu(OH)_2$, precipitated with NH_4OH from metal nitrate solutions, followed by drying of the precipitates at 200°C and calcination at 450–500°C for 3 h. The specific surface area of the resulting oxide systems was 7.6, 5.0, 7.6, and 20.0 $m^2 g^{-1}$ for WO_3, MoO_3, V_2O_5, and Cr_2O_3, respectively.

Experiments were performed in a flow quartz reactor (d = 20 mm) with a fixed bed of a catalyst (bed height 1 cm). The contact time of the reaction mixture with the catalyst was 0.1 s, and the content of EG in air, 3.5 vol %. Liquid reaction products were analyzed with a Chrom-5 chromatograph (flame ionization detector, 1.6-m column, stationary phase 15% Reoplex-400 on Chromaton N, carrier gas nitrogen; flow rates, ml min^{-1}: nitrogen 25, hydrogen 40, and air 500; temperatures, °C: column 146, vaporizer 200, and detector 190). Analyses were performed by the procedure described in [12] for determination of glyoxal in scrubber waters in the form of quinoxaline.

Gaseous reaction products were analyzed on an LKhM-80 chromatograph (thermal conductivity detector; 2-m column packed with silica gel or 3-m column packed with CaA molecular sieves; carrier gas argon; temperature, °C: columns 80 and detector 150; detector current 120 mA) [13].

Figure 1 shows that the EG conversion increases with temperature on all the catalysts tested, reaching 100% at 350°C (except MoO_3, on which the conversion, though growing with temperature, does not reach 100% even at 400–450°C).

With respect to the product composition, the oxide systems can be subdivided into the following groups: (1) CuO and Cr_2O_3, on which EG is oxidized to CO_2; (2) V_2O_5 and WO_3, on which EG undergoes partial oxidation to formaldehyde, formic acid, methyl formate, and CO; and (3) MoO_3, on which EG undergoes polycondensation to give polyethylene glycols.

Deep oxidation of EG to CO_2 on the first group of

1070-4272/02/7509-1424$27.00 © 2002 MAIK "Nauka/Interperiodica"

oxide catalysts (Cr_2O_3, CuO) is due to the presence on their surface of molecular weakly bonded oxygen responsible for deep oxidation of organic compounds [14]. Figure 2a shows experimental data on the catalytic activity of Cr_2O_3. At low temperatures (~200°C), the EG conversion on Cr_2O_3 is low (~10%), with the main product being formaldehyde. As the temperature is increased to 250°C, the conversion of EG increases to 60%, with formation of CO_2 becoming prevalent. At 300–350°C, the EG conversion reaches 100%.

The low activity of Cr_2O_3 at 200°C may be due to rapid reduction of the catalyst surface to Cr(II) under the action of the reaction medium [15]. Under such conditions, transformation of EG is limited by reoxidation of the surface, and the process attenuates with time. Since the main product of EG conversion on Cr_2O_3 is formaldehyde, the active centers of partial oxidation of EG are, presumably, Cr^{2+} ions [16]. At 350–400°C, the catalyst surface is reoxidized faster, and deep oxidation of EG to CO_2 becomes prevalent (Fig. 2a). The yield of CO passes through a maximum (12%) at approximately 300°C. At higher temperatures, the CO yield decreases to 4%, which may be due to the fact that CO is formed from formaldehyde in a consecutive process; note that the yield of formaldehyde passes through a maximum at 250–300°C.

Figure 2b illustrates the activity of V_2O_5 in EG oxidation. With increasing temperature, the yields of formaldehyde and CO_2 pass through a maximum at 250–300°C. The yield of formic acid decreases with temperature, which is due to its further oxidation to CO_2. The consecutive-parallel reaction pattern includes the initial formation of formaldehyde (by scission of the C–C bond in EG), whose secondary adsorption on the catalyst surface is followed by oxidation to formic acid and CO_2. The yield of CO monotonically increases with temperature, which may be due to thermal decomposition of formaldehyde.

Among all the oxide systems studied, V_2O_5 is the most selective with respect to formation of formaldehyde and formic acid. The yield of HCOOH reaches 10% (Fig. 2b). The major product of EG oxidation at elevated temperatures is CO.

At low temperatures (~200–250°C), up to 5% of glyoxal is formed. The low yield of glyoxal may be due to structural features of EG, which mainly exists in the conformation with an intramolecular hydrogen bond and *cis* location of the hydroxy groups at the C–C bond [16]. In the excited state, the *cis* configuration of glyoxal is the most stable [17]. The distance between the vanadium cations in the V_2O_5 lattice varies from 4.369 (the longest distance, perpendicular

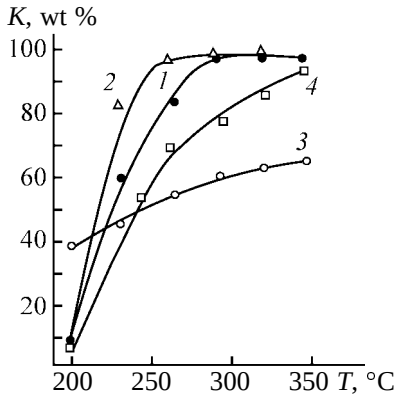

Fig. 1. Temperature dependence of EG conversion *K* in vapor-phase oxidation on oxides: (*1*) Cr_2O_3, (*2*) V_2O_5, (*3*) MoO_3, and (*4*) WO_3.

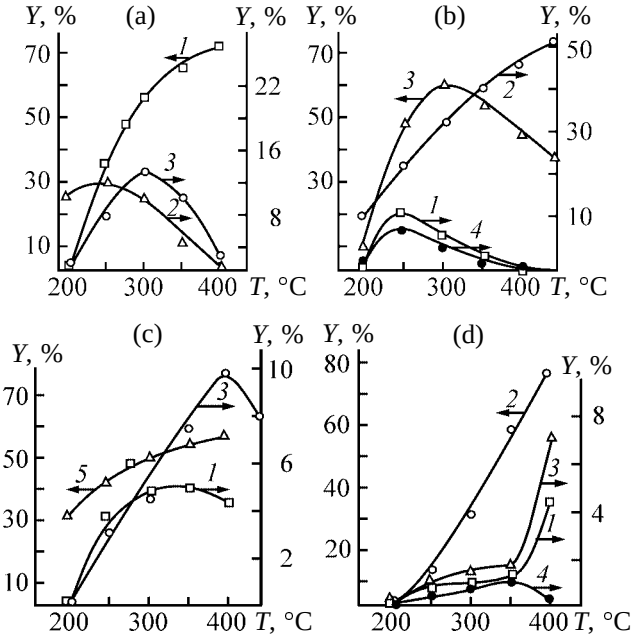

Fig. 2. Oxidation of EG on (a) Cr_2O_3, (b) V_2O_5, (c) MoO_3, and (d) WO_3. (*Y*) Yield and (*T*) temperature. (*1*) CO_2, (*2*) H_2CO, (*3*) CO, (*4*) HCOOH, and (*5*) EG ethers.

to the plane of the bipyramid network layer) to 3.42 Å (along cogged chains formed by distorted VO_4 tetrahedra) [18]. In view of preferableness of EG adsorption on paired centers [19], it can be presumed that, in the precatalysis stage, EG and its carbonyl derivatives are adsorbed via two hydroxy (or aldehyde) groups, extending the C–C bond whose length is 1.54 and 1.47 Å in EG and glyoxal, respectively. Stabilization of the system should involve scission of the C–C bond and formation of formaldehyde as the major product of vapor-phase oxidation of EG.

These assumptions are supported by the fact that the yield of glyoxal decreases with increasing temper-

ature. It is interesting that, at 350–400°C, glycolaldehyde is formed (i.e., only one functional group is oxidized). Dehydration in the course of EG oxidation can be ruled out, since no olefins were detected in the gas phase.

Experimental data on the temperature dependence of the catalytic activity of MoO_3 are shown in Fig. 2c. The major products of EG conversion are di- and triethylene glycols. MoO_3 is less active than the other oxides tested (Fig. 1). The EG conversion at 400°C is as low as 60%. The activity of MoO_3 in partial oxidation of monohydric alcohols (methanol, ethanol) is also low [5, 20], but the selectivity reaches 90%. It is known [21] that WO_3 and MoO_3 effect fast isomerization of 1-butene, which is the model process for determining the surface acidity function. However, the necessary condition for high activity of a catalyst is low strength of oxygen bonding with the catalyst surface, Q_s. In pure MoO_3, on the contrary, Q_s is fairly high. In WO_3, Q_s is somewhat lower but still not optimal for the process [7]. Since etherification involves proton transfer, the strong surface acidity of MoO_3 and WO_3 presumably results in predominant polycondensation of EG to form polyethers.

The activity of WO_3 is illustrated by Fig. 2d. The major products of EG oxidation are formaldehyde and CO. The yield of formic acid passes through a maximum at 300–350°C. Presumably, HCOOH is formed after readsorption of formaldehyde on the catalyst surface. With increasing temperature, the yield of partial oxidation products decreases, and the yield of EG condensation products grows.

CONCLUSIONS

(1) With respect to the activity in partial oxidation of ethylene glycol, oxide catalysts can be ranked in the following order: $V_2O_5 > WO_3 > MoO_3 > Cr_2O_3 > CuO$. The major products are formaldehyde and formic acid.

(2) The low (~5%) yield of glyoxal on V_2O_5 is presumably due to scission of the C–C bond upon adsorption of ethylene glycol on the catalyst surface.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Gas-Chromatographic Determination of Acrylic Acid in Aqueous Solutions

Abstract—A procedure was developed for determining acrylic acid in aqueous solutions at its concentration within 0.5–20 MPC.

Analysis of water from reservoirs and especially wastewater for the content of microimpurities of harmful substances is a complicated problem, because, first, the substances to be determined have low maximum permissible concentrations (MPC), and, second, the analysis results can be affected by numerous concomitant impurities present in wastewater from both a given enterprise and neighboring plants.

In the past years, the production and consumption of acrylic monomers, polymers, and composites based on them considerably increased; new applications arose, and new countries became involved in the production. Therefore, environmental control of plants producing these substances is an urgent problem.

At the majority of plant laboratories, wastewater is analyzed using unified procedures. However, as the requirements to potable water and to wastewater treatment became more stringent, it appeared necessary to develop advanced analytical procedures with low detection limits for determining impurities of highly toxic substances. Major attention is given to reducing the time required for analysis, since at many plants the composition of natural water and especially wastewater varies with time.

The most widely used procedure for determining trace amounts of organic substances in multicomponent mixtures is gas chromatography. To determine organic pollutants, such methods are recommended as capillary gas chromatography, high-performance liquid chromatography, supercritical fluid chromatography, IR spectroscopy, and exclusion chromatography [1, 2].

Aqueous solutions containing more than 10% organic acids can be, in principle, chromatographed without pretreatment. However, analysis of aqueous solutions of polar compounds such as free acids is complicated by sorption; this is a serious problem not only with traces but even with macroamounts of acids. Gas-chromatographic determination of organic acids is also complicated by their low volatility, requiring the use of high temperatures, close to the limiting working temperatures of the majority of available stationary phases; furthermore, acids tend to associate in the vapor phase. To overcome these difficulties, especially in analysis of trace amounts, acids are converted to more volatile and less polar derivatives, most often to esters [3]. This increases the analysis sensitivity and eliminates interferences caused by adsorption. However, lower acids, in contrast to their higher homologs, cannot be esterified quantitatively.

High-molecular-weight acids can be efficiently recovered and concentrated from sea and ground waters by extraction with organic solvents [4]. Extraction of acids with diethyl ether in the presence of a salting-out agent allows the acid detection limit to be decreased. However, this concentrating procedure is time- and labor-consuming.

All these problems pertain equally to chromatographic determination of traces of acrylic acid (AA) in wastewater.

Traditional methods for preliminary concentration of a sample (sorption on solid adsorbents, extraction followed by solvent evaporation, distillation, headspace analysis) show poor efficiency in concentrating AA from aqueous solutions and do not ensure the required sensitivity of analysis [5–7].

The goal of this work was to develop a simple, reliable, and highly sensitive procedure for determination of AA microimpurities in aqueous solutions.

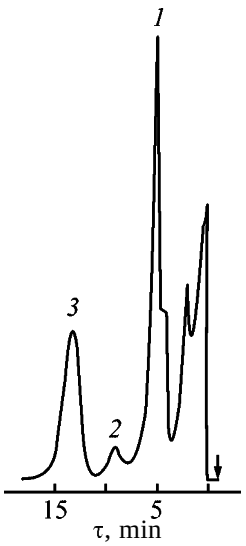
EXPERIMENTAL

Determinations were performed with an LKhM-80 gas chromatograph (flame ionization detector, 100 × 0.3-cm steel column, stationary phase 10 wt % polyethylene glycol on Polysorb-1, 0.025–0.05 cm).

The optimal chromatographing conditions are as follows: column temperature 165°C, vaporizer temperature 190°C, detector temperature 170°C, and carrier gas (nitrogen) flow rate 30 $cm^3\ min^{-1}$. The measured peak areas were recalculated to the electrometer scale of 50×10^{-12} A. To suppress sorption of acrylic acid by the surface of the sorbent and pipelines, the carrier gas was saturated with formic acid vapor [8].



Chromatogram of impurities in wastewater from acrylate production. Packed 1000 × 3-mm steel column; stationary phase polyethylene glycol, 10% on Polysorb-1 (0.25–0.5 mm). (τ) Time. Acid: (*1*) acrylic, (*2*) methacrylic, and (*3*) isovaleric (internal reference).

Acrylic acid was converted to a salt, the salt solution was evaporated to dryness, and the resulting concentrate was subjected to analysis.

Quantitative determination was performed by the graphical method of internal reference. A series of calibrating solutions containing AA in amount of 0.5–20 MPC were prepared from accurately weighed portions of chemically pure grade AA by successive dilution. As internal reference we chose isovaleric acid. With this method, it is not necessary to strictly reproduce the dosage; furthermore, the components of a mixture to be analyzed can be determined irrespective of the presence or absence of other peaks in the chromatogram.

The analytical procedure was as follows. A sample, after adding a known amount of the reference and converting acrylic and isovaleric acids into salts with an alkali (phenolphthalein indicator), was evaporated to dryness in a porcelain cup. The dry residue was dissolved in 1 ml of 0.5 M HCl. The solution was transferred in a volumetric vessel, and a 5-μl sample was injected into a chromatograph. The AA concentration in the sample was determined from the calibration function. Solutions were evaporated on a water bath or, for quicker analysis, on a glycerol bath at 120°C. Experiments were performed in the presence of butyl acrylate and butanol, which may be present in amounts of up to 20 MPC in the wastewater being analyzed. We found that, in the presence of alkali, butyl acrylate was hydrolyzed to 1-butanol and AA. 1-Butanol in amounts of up to 20 MPC does not interfere with the chromatographic analysis by our procedure, as it fully volatilizes in the course of evaporation. We also found that, under the analysis conditions, butyl acrylate, when present in wastewater in amounts of up to 100 MPC, does not interfere with the determination of AA because of the low (<10%) degree of its hydrolysis and partial volatilization during evaporation.

The results of analysis of artificial mixtures (introduced–found, see table) demonstrate the feasibility of determining AA in aqueous solutions in the range 0.5–20 MPC. The relative error of the chromatographic determination for the ranges 0.5–5, 5–10, and 10–20 MPC is 17, 10, and 7%, respectively. The analysis time, including the concentration stage, does not exceed 2 h.

The proposed procedure for AA determination in aqueous solutions was tested with real wastewater samples from acrylate production (see figure). In

chromatographic analysis of impurities in wastewater, major attention should be given to their identification, since identification of microamounts by the retention parameters is not always reliable, especially when a sample contains substances of different classes. In our procedure, identification was based on comparing, under the same conditions, the retention times of particular substances which were added to the solution both separately and as model mixtures. This is associated with the fact that the retention times of the acids appeared to be strongly dependent on the substance amount in the sample.

CONCLUSION

The procedure developed for analysis of natural water and wastewater is suitable for assessing the efficiency of wastewater treatment facilities at plants producing acrylic polymers, for revealing discharge sources, and for evaluating their impact on water reservoirs. The sample preparation procedure is simple, and the analysis is performed with equipment series-produced in Russia.

Abstract—Changing the design of small-size tubular turbulent apparatus of diffuser–confuser design and the hydrodynamic mode of moving dispersed flows allows effective control over the quality of emulsions obtained from two immiscible fluids.

There are a great number of heterophase processes occurring under phase-separation conditions in a fluid–fluid system. To these belong, in particular, sulfation of α-olefins with sulfuric acid in an organic solvent, emulsion (co)polymerization of divinyl with α-methylstyrene, decomposition and washing of electrophilic catalysts and Ziegler–Natta catalytic systems in synthesis of stereoregular isoprene and divinyl rubbers, sulfuric acid alkylation of isoparaffins with olefins, etc. [1]. A specific feature of heterophase processes is the necessity for substance (reagent) transfer from one phase into another, with the efficiency of the process as a whole and quality of the products obtained depending on the specific surface area of phase contact, F [2, 3]. The mass transfer is complicated in systems in which rather fast chemical reactions occur (characteristic time of chemical reaction $\tau_{ch} < 0.01–0.001$ s). In this case, one of the most effective ways to form heterophase disperse systems fluid–fluid with developed phase boundary is intensification of the degree of turbulence in the flow mixing zone, which, simultaneously, much intensifies the chemical process. For example, in the case of α-olefin sulfation with concentrated sulfuric acid in a solution of a saturated hydrocarbon, the reaction mixture stratifies because of the significant difference in density and viscosity between the flows of the starting reagents ($\rho_{H_2SO_4} : \rho_{\alpha\text{-olefin}} = 2.63$; $\eta_{H_2SO_4} : \eta_{\alpha\text{-olefin}} = 75.1$) in their introduction into an apparatus in classical volume stirred or plug-flow reactors. This leads to a dramatic decrease in the phase contact area and retards the chemical reaction, despite that this reaction can be classed with fast chemical processes [1]. In this case, an increase in the degree of turbulent mixing in the reaction zone makes the chemical reaction faster (Fig. 1) and, correspondingly, allows shorter residence time of the reactants in the reactor, τ_r. As a result, the yield of the target products, monoalkyl sulfates, increases and the contribution of side processes yielding undesirable dialkyl sulfates decreases.

Thus, of primary importance in performing fast heterophase chemical reactions is preparation of homogeneous finely dispersed emulsions with developed phase contact surface. According to [4], the best results are obtained with small-size tubular turbulent apparatus with local hydrodynamic resistances of the diffuser–confuser design because of the possibility of attaining in this case a strongly turbulent mode at moderate fluid flow rates.

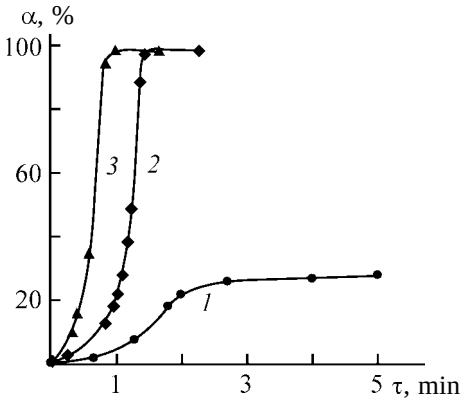

Fig. 1. Conversion curves for sulfation of α-olefins of the $C_8–C_{16}$ fraction (~97 wt %) with concentrated (~95 wt %) sulfuric acid in volume well-stirred apparatus. α-Olefins/H_2SO_4 = 3.9 (v : v), T = 298 K. (α) Conversion and (τ) time. Stirring rate (rpm): (*1*) 100, (*2*) 500, and (*3*) 1000.

1070-4272/02/7509-1430$27.00 © 2002 MAIK "Nauka/Interperiodica"

The aim of this study was to analyze experimentally the fundamental aspects of emulsion formation from two immiscible fluid flows in tubular turbulent apparatus of the diffuser–confuser design with varied channel geometry.

For this purpose, an experimental setup was assembled, shown schematically in Fig. 2. We used glass six-section (N_s = 6) tubular turbulent apparatus of the diffuser–confuser design [4] with varied geometry of the stirring mode (see table).

The frequency curves of the size distribution of drops of the dispersed phase were obtained by video recording in high-intensity transmitted light with a Hitachi VM2980E video camera (12/1 focus). Rapid video recording minimizes the influence exerted by drop image smearing because of the high drop motion velocity. To account for image distortions because of the curved shape of the apparatus casing, zinc-plated calibration threads of a known diameter (0.2, 0.5, and 1 mm) were introduced into the apparatus volume [5]. The calculations performed were based on the central part of the apparatus cross section with dimensions $0.74 \times d_d$, in which the discrepancy between the real dimensions of the calibration threads and their values calculated from the images obtained was less than 1%. This technique also ruled out image distortion associated with the influence exerted by the refractive index of the glass casing of the apparatus and took into account systematic errors. Since rather small volumes of the dispersed phase were used [flow rate of the dispersed phase was 1–1.5 ml s^{-1}, and that of the dispersion medium (V), 40–200 ml s^{-1}], images of all particles in the flow cross section were obtained.

A frame-by-frame inspection of a computer-synthesized image of moving dispersed systems (24 frames per second) with tenfold magnification, with linear dimensions of particles of the dispersed phase (all particles were spherical in the chosen range of flow rates) compared with the linear size of the calibration threads, allows calculation of the true drop size (or, more precisely, the projection area of a spherical drop). The drops were counted in the following ranges (mm): 0–0.4, 0.4–0.6, 0.6–0.8, 0.8–1.0, 1.0–1.5, 1.5–2.0, and more than 2. To estimate the experimental error, eight images of some part of the flow were chosen. The experimental data obtained were used to evaluate the distribution variance s^2:

$$s^2 = (N - 1)^{-1} \sum_{1}^{N} (d_i - d)^2, \quad (1)$$

where N is the number of measurements, d_i is the drop diameter in a chosen interval, and d is the average drop diameter.

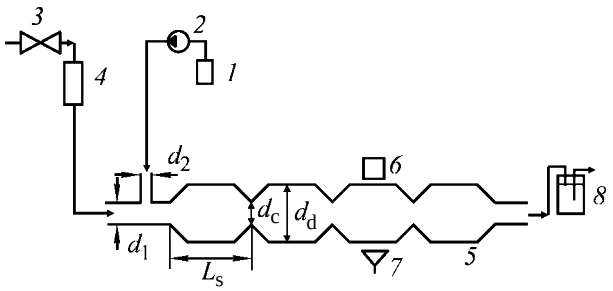

Fig. 2. Schematic of the experimental setup: (*1*) vessel for the dispersed phase (hexane, ρ = 0.66 g cm^{-3}, η = 0.3 mPa s), (*2*) peristaltic pump, (*3*) feed line for delivery of the dispersion medium (water), (*4*) rotameter, (*5*) tubular turbulent apparatus of the diffuser-confuser design (d_1 = 10 mm, d_2 = 5 mm), (*6*) video camera, (*7*) light source, and (*8*) receiver.

The standard error Δ at confidence probability α = 0.95 was calculated as $\Delta = \pm 2.4 s N^{-1/2}$. The average measurement error was ±7%.

The dispersion process in a fluid–fluid system in turbulent flows for the hydrodynamic operation mode of tubular apparatus of the diffuser–confuser design can be conveniently described using the volume–surface diameter of drops of the dispersed phase, d_{32} [6]:

$$d_{32} = \frac{\sum m_i d_i^3}{\sum m_i d_i^2}, \quad (2)$$

related to the specific surface area F of the spherical particles of the dispersed phase by

$$F = \frac{6}{d_{32}} = \frac{6 \sum m_i d_i^2}{\sum m_i d_i^3}, \quad (3)$$

where m_i is the number of drops of ith fraction, and d_i is the drop diameter in ith fraction.

Characteristics of diffuser–confuser apparatus* (d_d = 24 mm)

Apparatus no.	d_c, mm	d_d/d_c	L_s, mm	L_s/d_d
1	15	1.6	48	2
2	12	2	48	2
3	8	3	48	2
4	15	1.6	72	3

* d_d and d_c are the diameters of, respectively, the diffuser and confuser parts of the apparatus; L_s is the length of the diffuser–confuser section.

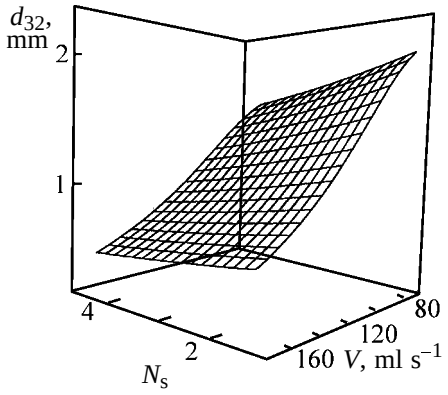

Fig. 3. d_{32} vs. flow rate V of a heterophase flow and number N_s of diffuser–confuser sections for apparatus no. 1 (see table).

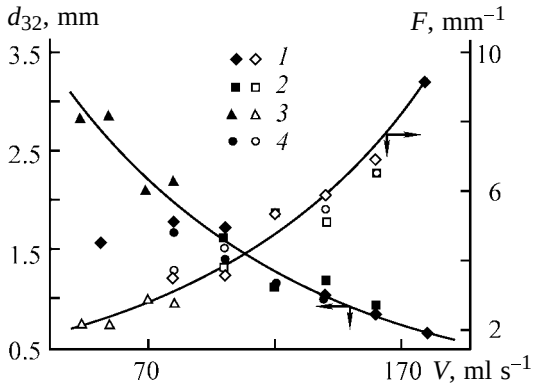

Fig. 4. Variation of the volume–surface diameter d_{32} of particles in the dispersed phase and the specific phase boundary surface area F with the design of a tubular turbulent apparatus and flow rate. (*1–4*) Apparatus nos. (see table). Points, experimental data; lines, calculation by Eqs. (3) for F and (5) for d_{32}.

As in the case of small-size tubular turbulent apparatus of the cylindrical design ($d_d/d_c = 1$, $L/d_d \approx 40$) [4], the size distribution of drops in the dispersed phase in the diffuser–confuser channels becomes narrower with increasing flow rate V of immiscible fluid flows, and the curves are shifted to the region in which homogeneous finely dispersed systems are formed [7, 8].

On the basis of experimental data, we obtained equations relating the efficiency of emulsification (percentage n of drops with diameter $d \le 0.8$ mm in the dispersed phase) in tubular channels of the diffuser–confuser design to the flow rate V of the flows (R is the correlation coefficient):

$$\begin{aligned} n &= 0.78V - 51.0 \quad \text{(apparatus no 1, } R = 0.96\text{)},\\ n &= 0.88V - 58.2 \quad \text{(apparatus no 2, } R = 0.98\text{)},\\ n &= 0.90V - 30.1 \quad \text{(apparatus no 3, } R = 0.99\text{)},\\ n &= 0.72V - 35.6 \quad \text{(apparatus no 4, } R = 0.97\text{)}. \end{aligned} \tag{4}$$

Raising the flow rate V of the flows and the number of diffuser–confuser sections N_s from 1 to 4 makes the volume–surface diameter of drops smaller and the specific interface area, correspondingly, larger (Fig. 3). This, in the case of fast chemical reactions, intensifies the chemical process as a whole. The inexpedience of using tubular turbulent apparatus with number N_s of diffuser–confuser sections exceeding 4 makes these devices compact (with length not exceeding 8–10 diameters: $L/d_d \le 8$–10) and simple in fabrication and operation.

Figure 4 presents the dependence of d_{32} on the flow rate of heterophase flows in diffuser–confuser channels of varied design. Statistical processing of the experimental data obtained for $d_d = 24$ mm yielded an equation approximating this dependence:

$$d_{32} = 4.74\,e^{-0.011V}. \tag{5}$$

Comparison of the experimentally obtained data with the calculated values shows (Fig. 4) that relation (5) describes with satisfactory accuracy the influence exerted by V on the particle size d_{32} in the dispersed phase (average deviation 6%). At the same time, there exists a certain range of rates of heterophase flows to which corresponds a diffuser–confuser channel with the optimal d_d/d_c ratio. This range is bounded by the zone of stratified flow [9] from below, and by energy loss associated with increasing pressure drop at apparatus ends in accordance with the relation $\Delta p \sim V^2$, from above. In particular, the interval $44 < V < 80$ ml s^{-1} corresponds to the ratio $d_d/d_c = 3$, and $80 < V < 180$ ml s^{-1}, to $d_d/d_c = 1.6$. Apparently, further increase in the flow rate of the dispersed system ($V > 180$ ml s^{-1}) makes necessary further decrease in the d_d/d_c ratio (Fig. 4), down to $d_d/d_c = 1$, in which case small-size tubular apparatus of cylindrical design are rather effective. The same restrictions govern the boundary conditions of applicability of the dependences (4). In accordance with Eq. (3), a characteristic change in the specific phase boundary surface area is observed (Fig. 4), which determines the intensity of the mass-exchange process.

Thus, in tubular turbulent apparatus of the diffuser–confuser design, as compared with apparatus with cylindrical channels, a flow in which particles of the dispersed phase are uniformly distributed over the apparatus volume is formed at lower flow rates of the dispersed system, and the decrease in the required V value is the greater, the larger the d_d/d_c ratio.

Another important quantity characterizing the quality of the emulsions obtained is the polydispersity

factor k [10]:

$$k = \frac{\sum m_i d_i^3 \sum m_i d_i}{\sum m_i d_i^4 \sum m_i}. \quad (6)$$

For monodisperse systems $k = 1$, and for polydisperse systems $k < 1$, with the parameter k being the smaller, the wider the scatter of the particle sizes. As also in the case when dispersions with volume–surface diameter d_{32} are obtained (Fig. 4), the L_s/d_d ratio has virtually no effect on the polydispersity of the emulsions obtained. With increasing d_d/d_c ratio, the scatter of particle size in the dispersed phase becomes more pronounced, with rather homogeneous emulsions formed in the diffuser–confuser channel of a tubular apparatus with $d_d/d_c = 1.6$. In particular, for L_s/d_d = 2–3, the k value is 0.72–0.75 at $d_d/d_c = 1.6$ and decreases to 0.63 and 0.41 at d_d/d_c ratios equal to, respectively, 2 and 3.

Thus, use of small-size tubular turbulent apparatus of the diffuser–confuser design allows effective dispersion in fluid–fluid systems and makes it really possible to increase the specific surface area of spherical particles belonging to the dispersed phase. Varying the flow rate V of fluid flows in tubular apparatus and the d_d/d_c ratio is virtually the only, but quite effective way to affect the nature of the dispersion process and the quality of the emulsions obtained. This enables easy control over rather fast heterophase chemical and mass-exchange physical processes occurring in emulsions. The relationships revealed make it possible to obtain, when necessary, fine homogeneous dispersions in the fluid–fluid systems without any technical difficulty and to use small-size tubular turbulent apparatus of simple diffuser–confuser design for intensifying the chemical and mass-exchange physical processes. This can be done, in the first place, because of the formation of finely dispersed emulsions under the optimal conditions at a minimum time of reactant residence in the mixing zone. Tubular turbulent apparatus of the diffuser–confuser design can be recommended for industrial use both as a basic reactor for performing fast heterogeneous chemical reactions and as a prereactor for formation of fine homogeneous emulsions and their subsequent delivery in volume stirred vessels. This technology will apparently be able to diminish the time necessary for heterophase processes to occur in fluid–fluid systems.

CONCLUSIONS

(1) Raising the flow rate of a dispersed system and the number of diffuser-confuser sections from 1 to 4 leads to an increase in the specific interface area in tubular turbulent apparatus, which allows use of mixers with length equal to 8–10 diameters.

(2) Raising the d_d/d_c ratio in tubular turbulent apparatus of the diffuser–confuser design makes lower the flow rate of the dispersed system, necessary for obtaining a flow with uniform distribution of the dispersed phase. In this case, the polydispersity of the forming emulsions is higher at comparable output capacities of the apparatus, all other conditions being the same.

(3) Emulsions with comparable specific interface areas F and polydispersities k are formed in tubular turbulent apparatus at L_s/d_d = 2–3.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Optimization of Synthesis of Mono-*O*-methylglycerol Isomers

S. V. Koshchii

Institute of Problems of Cryobiology and Cryomedicine, National Academy of Sciences of Ukraine, Kharkov, Ukraine

Received January 23, 2002

Abstract—Parameters were refined for synthesis of glycerol 1-monomethyl ether by methylation of glycerol with dimethyl sulfate in the presence of alkali; a gas–liquid chromatographic procedure was proposed for identification of structural isomers of mono-*O*-methylglycerol.

Procedures for preparing glycerol 1-monomethyl ether (1-MG) are diverse and are summarized in reviews [1–4]. These procedures give relatively low (compared to other glycerol monoalkyl ethers) yield of the target product, are multistage, and require large (up to tenfold) excess of methanol and sodium metal [5, 6]. Only Fairbaurne [7] reported on preparation of noticeable amounts of the second isomer, glycerol 2-monomethyl ether (2-MG), with the major product being 1-MG.

Glycerol monomethyl ether is a promising cryoprotector in low-temperature preservation of blood cells, bone marrow, and reinoculated cell cultures [8, 9]. In view of the necessity of producing pilot batches of 1-MG for large-scale biological tests and with the aim to reveal the effect of isomerism on the cryoprotective properties, we performed experiments to refine the conditions for preparing 1-MG and 2-MG. Our goal was to find the method and conditions ensuring the highest yield of the target products, with the procedure being as simple as possible. As the route to 1-MG and 2-MG, we chose methylation of glycerol with dimethyl sulfate (DMST) in the presence of alkali. Fairbaurne [7] reported on synthesis of sodium glycerate from excess glycerol and aqueous NaOH; its methylation with DMST, after removing water under reduced pressure, yielded a mixture of 1-MG and 2-MG. Cross and Jacobs [5] reported on another convenient procedure involving preparation of sodium glycerate from equimolar amounts of anhydrous glycerol and powdered NaOH, followed by alkylation with alkyl halides to obtain glycerol 1-monoalkyl ethers. It seemed appropriate to refine the effect of the synthesis parameters (molar ratio of components, concentration of aqueous alkali) on the yield and isomeric composition of the product. To this end, we tested several procedures based on Fairbaurne's method [7] (Table 1).

EXPERIMENTAL

Run no. 1. Synthesis of 1-MG and 2-MG involved the following stages [7]: (1) mixing of glycerol with 47% aqueous NaOH in the molar ratio glycerol : NaOH = 3 : 1; (2) distillation of water under reduced pressure (40 mm Hg) on an oil bath, with the bath temperature gradually increased to 150°C; (3) addition of DMST to the resulting sodium glycerate (GONa) at 120–125°C over a period of 1 h in the molar ratio GONa : DMST = 1 : 0.5; (4) removal of Na_2SO_4 from the reaction mixture; (5) distillation of a mixture of 1-MG and 2-MG from the bottoms at 140°C/2 mm Hg; and (6) separation of 1-MG and 2-MG by repeated vacuum distillation on a column with cutting 1°C fractions in the range 91–140°C/2 mm Hg. The total yield of the isomers was 45%, with the isomer ratio 1-MG : 2-MG = 6 : 1.

Run no. 2 was performed similarly to run no. 1, except that NaOH was taken as 69% solution (instead of 47% solution) to reduce the time for water distillation under reduced pressure. The total yield of the isomers was 41%, with the isomer ratio 1-MG : 2-MG = 8 : 1.

Run no. 3. Sodium glycerate was prepared as described in [5] by heating anhydrous glycerol and powdered NaOH with vigorous stirring, with the molar ratio glycerol : NaOH = 2 : 1. The temperature in the oil bath was raised to 120–145°C. After removal of water, the temperature was decreased to 110–115°C, with the stirring continued, and 0.5 mol of DMST was added dropwise. The resulting Na_2SO_4 was filtered off. After distillation of the bottoms in a vacuum

Table 1. Ratio of reactants and reaction products in methylation of glycerol with DMST in the presence of NaOH

Molar ratio of reactants				Total yield of isomers, %	1-MG : 2-MG ratio
glycerol	NaOH	DMST	H_2O		
3	1	0.5	2.5	45	6 : 1
3	1	0.5	1	41	8 : 1
2	1	0.5	–	33	10 : 1
3	1	0.5	–	63	15 : 1

(up to 140°C/5 mm Hg) and repeated fractionation, 1-MG and 2-MG were obtained in a 10 : 1 ratio; total yield 33%.

Run no. 4. The procedure ensuring the highest content of 1-MG was as follows. A three-necked flask equipped with a stirrer and a thermometer and purged with an inert gas was charged with equimolar amounts of purified anhydrous glycerol and powdered NaOH. The mixture was heated to 145°C with continuous vigorous stirring. At 120°C, release of water formed in the synthesis started, and the mixture warmed up to 145°C with foaming. After short stirring at this temperature, a uniform paste formed. The temperature was decreased to 90°C, and, with the stirring continued, anhydrous glycerol was added over a period of 30 min to dissolve the resulting sodium glycerate; the final molar ratio glycerol : NaOH was 3 : 1. Then, 0.5 mol (relative to NaOH) of DMST was added from a dropping funnel, with the temperature maintained within 90–100°C. In the course of reaction, white fumes liberated, the mixture slightly warmed up, and Na_2SO_4 precipitated. The precipitate was filtered off. 1-MG was isolated by vacuum distillation at 92–93.5°C/5 mm Hg; yield 59%. Along with 1-MG, a small (3–5%) amount of 2-MG was obtained.

Run no. 5. 1-MG was prepared by an independent procedure: reaction of glycerol 1-monochlorohydrin (1-MCHG) with sodium methylate in a tenfold excess of absolute methanol [6]. The synthesis involved the following stages: (1) preparation of sodium methylate; (2) reaction of 1-MCHG with sodium methylate; (3) filtration to remove the NaCl precipitate; (4) distillation of excess methanol under reduced pressure; and (5) isolation of 1-MG. Yield 42%. The necessity of performing this labor-consuming and fire-hazardous procedure was dictated by the need in obtaining a 1-MG sample free of its isomer, 2-MG. The sample was used for identification of structural isomers of glycerol monomethyl ether.

The structures of the products were confirmed by molecular refraction and IR spectroscopy. The spectra are discussed in detail in [10]. The refractive index n_D^{20} was determined with a URL-M1 refractometer. The IR spectra were recorded on a Specord 75-IR spectrophotometer (thin film between KBr plates).

The molecular weight of 1-MG and 2-MG was determined by gel permeation chromatography on a Waters GPC-200-1 Model 200 gel chromatograph under the following conditions: eluent tetrahydrofuran; three styrogel columns 200, 500, and 1000 Å; 25°C; flow rate 1.2 ml min^{-1}. Samples (2 ml) contained about 0.2 wt % of the substance. The product purity was checked by GLC (LKhM-80 chromatograph, 1000 × 3-mm column, stationary phase 20% Carbowax 20M on Chromaton N-Super, flame ionization detector, carrier gas He, flow rate 50 ml min^{-1}, programmed column heating from 60 to 280°C). A 0.1-g sample was dissolved in 0.2 ml of purified anhydrous pyridine, and 0.4 ml of hexamethyldisilazane and 0.1 ml of trimethylchlorosilane were added. The mixture was allowed to stand for 2–3 h and then injected into the chromatograph vaporizer. The main constants of the products are listed in Table 2 together with published data.

The IR spectra contain the following characteristic absorption bands (cm^{-1}): 3385, 3395 (OH); 2928, 1465 (CH_2); 2830 (OCH_3); 1360 (CH_3); 1190 (COC).

The isomers are difficult to separate and identify, as their have close physicochemical parameters (except n_D^{20}) and similar IR spectra. In the gel chromatogram, both compounds give a narrow symmetrical peak with the same retention volume V_R corresponding to M 106. Their separation by vacuum distillation requires repeated thorough fractionation with collection of close-cut (1–2°C) fractions; the isomer percentage in the fractions gradually changes with increasing temperature. Fairbaurne [7] suggested to identify isomers by refractive indices. However, examination using an LKhM-80 chromatograph and the procedure developed in [12] showed that, even at the same n_D^{20}, samples may contain 1-MG and 2-MG in

V	99–101	1.4450	57.9	45.1	–
VI	101–104	1.4454	22.4	77.6	–
VII	104–106	1.4464	20.8	79.2	–
VIII	106–108	1.4476	19.1	80.9	–
IX	108–109	1.4478	18.4	80.3	1.3
X	109–110	1.4480	–	99.0	1.0

different ratios. The chromatograms contain two major narrow symmetrical peaks. The isomer ratio was evaluated from the peak areas. The scheme of fractionation of structural isomers obtained in run no. 1 is given in Table 3.

Table 3 shows that the first three fractions have the same refractive index, n_D^{20} = 1.4444, but differ in the isomeric composition by up to 15%. The refractive index of fraction IV is very close, n_D^{20} = 1.4446, at the isomer ratio 1-MEG : 2-MEG = 57 : 43. Comparison of these data shows that the refractive index n_D^{20} is unsuitable for identifying 1-MG and 2-MG in synthesis of glycerol methyl ethers by methylation of glycerol with DMST in the presence of aqueous alkali (run nos. 1, 2). Run nos. 1–4 show that variation of the reactant ratio (Table 1) and the use of aqueous alkali as solvent result in formation of products containing different ratios of 1-MG and 2-MG. The highest content of 1-MG was obtained in run no. 4. Heating of glycerol with equimolar amount of powdered NaOH, followed by addition of excess glycerol (to the ratio glycerol : NaOH = 3 : 1) to dissolve the resulting sodium glycerate ensure increased yield of 1-MG (59%). Excess glycerol (run no. 3) complicates fast removal of water from sodium glycerate, which is hygroscopic and moisture-sensitive [5]. It is also known that prolonged heating of glycerol in the presence of alkali favors formation of polyglycerol [13]. Apparently, these facts are responsible for the low yield of 1-MG in run no. 3. The synthesis under conditions of run no. 4 is simpler, because no water is added (cf. run nos. 1, 2) and hence the stage of water removal under reduced pressure after the completion of sodium glycerate formation and before isolation of 1-MG is eliminated. Furthermore, under conditions of run no. 4 the by-product 2-MG is formed in a small amount and does not appreciably complicate isolation of 1-MG.

At the same time, if 2-MG is the target product, the conditions of run no. 1 are preferable. The use of water as solvent in the reaction of glycerol with aqueous alkali favors formation of appreciable amount of

2-MG along with 1-MG. As the water content in the NaOH solution is decreased from 63 (run no. 1) to 31% (run no. 2), the content of 2-MG decreases (Table 1), and with anhydrous glycerol and dry NaOH (run no. 4) it becomes as low as 3%. More dilute NaOH solutions were not tested because of more difficult isolation of the reaction product.

CONCLUSIONS

(1) The procedure for preparing glycerol 1-monomethyl ether by methylation of glycerol with dimethyl sulfate in the presence of NaOH was optimized by varying the reactant ratio; the yield of the target product was increased to 59%, and the isolation procedure was simplified.

(2) The highest yield of glycerol 2-monomethyl ether is attained when methylation of glycerol with dimethyl sulfate is performed using 47% NaOH.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Improvement of a Process for Synthesis of Thioglycolic Acid

V. R. Islamgulova, E. N. Shitova, S. G. Akhmerova, and A. P. Tomilov

Research and Technological Institute of Herbicides and Plant Growth Regulators with Pilot Plant, Ufa, Bashkortostan, Russia

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received November 26, 2001; in final form, June 2002

Abstract—An environmentally clean process was proposed for synthesis of thioglycolic acid by condensation of monochloroacetic acid with sodium disulfide, followed by electrochemical reduction of the resulting mixture.

Thioglycolic acid (TGA) and its derivatives are used in production of polymers, drugs, pesticides, dyes, flotation agents, and perfumes [1].

The known routes to TGA are based on reactions of monochloroacetic acid (MCAA) in the form of sodium salt with various sulfur derivatives. MCAA reacts with sodium hydrosulfide in one stage under H_2S pressure of 5–50 atm; yield of TGA 81.0–90.8% [2–5]. The reaction of MCAA with sodium thiosulfate yields sodium 5-carboxymethyl thiosulfate; its hydrolysis in the presence of oxidants affords TGA, yield 92–96% [6–8]. The reaction is sensitive to oxidants, whose presence results ion formation of dithiodiglycolic acid (DTDGA) as impurity [8]. DTDGA can be prepared in a reasonable yield by the reaction of sodium disulfide with sodium monochloroacetate [9] and can be subsequently reduced to TGA (yield 98–99%) on hydrogenation catalysts at 140°C and hydrogen pressure of 50 atm [10]. DTDGA can also be reduced electrochemically (yield 80%) [11].

Thus, the known procedures for preparing TGA either involve the use of high pressures or require thorough protection of the reaction mixtures from atmospheric oxygen. Taking into account published data and the availability of starting compounds for commercial synthesis, we chose the route based on the reaction of MCA with sodium disulfide, followed by electrochemical reduction of the resulting DTDGA.

MCA reacts with sodium disulfide as follows:

$$Na_2S_2 + 2ClCH_2COOH \rightarrow HOOCCH_2SSCH_2COOH + 2NaCl.$$

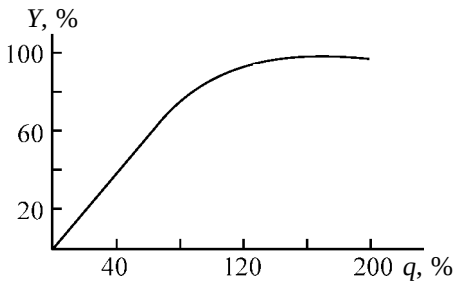
First, we determined the optimal conditions for this reaction: 70–80°C, 30 min. Below 70°C the reaction takes much longer time, and above 80°C by-products start to form. Under the optimal conditions, the yield of DTDGA is nearly quantitative.

Electrochemical reduction of DTDGA occurs with the consumption of $2F$ of electricity per mole:

$$HOOCCH_2SSCH_2COOH + 2e + 2H^+ \rightarrow 2HSCH_2COOH.$$

According to published data, the reaction occurs with a high yield in a sulfuric acid solution on a lead anode; however, the process was not optimized.

For the success of the electrochemical synthesis, TGA should be stable under the electrolysis conditions. We have studied the behavior of pure TGA in aqueous sulfuric acid at 25–30°C and current density of 200 A m^{-2}. The amount and purity of TGA remained unchanged after passing $2F$ of electricity per mole. Similar results were obtained when a double amount of electricity was passed in the course of electroreduction of DTDGA (see figure). The maximal amount of TGA formed remains unchanged after passing 200% amount of electricity relative to the stoichiometry, with the optimal amount being 140–150%.



TGA yield Y as a function of the amount of electricity passed q (relative to stoichiometry). 20–25°C; current density 200 A m^{-2}.

* Gradual decrease in the current density.

Table 2. Influence of temperature on the TGA yield and DTDGA conversion. Current density 200 A m^{-2}; 0.3 mol of DTDGA loaded; amount of electricity passed 140% relative to stoichiometry

Run no.	T, °C	Obtained, mol		TGA yield, %	Current efficiency, %	DTDGA conversion, %
		TGA	DTDGA			
1	20–23	0.289	0.008	96.3	68.8	97.71
2	40–43	0.290	0.007	96.7	69.0	97.3
3	60–62	0.288	0.007	96.0	68.6	97.7
4	70–75	0.285	0.005	95.1	67.9	98.3

To find the optimal parameters of the electrochemical synthesis of TGA, we studied the cathodic reduction of pure DTDGA in 2 N sulfuric acid. The influence of the current density on the yield of TGA is illustrated by Table 1.

As seen from Table 1, with increasing current density the DTDGA conversion and the current efficiency by TGA decrease, which is due to water decomposition with the release of hydrogen. Electrolysis at a low (100 A m^{-2}) or gradually decreased (from 500 to 100 A m^{-2}) current density affords higher yield and purity of TGA. At low current density, the electrolysis takes longer time; therefore, the gradual decrease of the current density is preferable.

We have studied how the reaction temperature affects the process parameters and the quality of TGA in the range 20–80°C (Table 2).

Table 2 shows that variation of temperature in the range 20–75°C has no appreciable effect on the TGA yield. Slightly decreased yield at elevated temperatures may be due to self-esterification of TGA. Thus, the optimal conditions for the electrochemical reduction of DTDGA are as follows: i_c = 100–400 A m^{-2}, T = 20–40°C, and amount of electricity 140–150% relative to stoichiometry.

We have studied under the same conditions the electrochemical reduction of mixtures from the reaction of MCA sodium salt with sodium disulfide. The yield of TGA in the process was 92–97% based on MCA, and the purity, 94–98%; the amount of wastewater was 2–2.5 times lower as compared to published procedures for TGA synthesis.

EXPERIMENTAL

The content of TGA in the reaction mixture and finished product was determined by iodometric titration, and the total content of TGA and DTDGA, by bromatometric titration in the presence of KBr in acid solution. The DTDGA content in reaction mixtures and isolated products was determined from the difference.

Electrochemical reduction was performed in a glass electrolyzer with a ceramic diaphragm, equipped with a stirrer and a heat-exchange jacket. A lead cathode was used; working surface area 120 cm^2. Solutions were prepared in double-distilled water.

A solution of 11 g (0.1 mol) of sodium disulfide in 60 ml of water was addded to an aqueous solution of 23.3 g (0.2 mol) of sodium monochloroacetate in 26 ml of water, heated to 70–80°C. The resulting

solution was stirred for 30 min, according to [9]. To the cooled reaction mixture, 19.6 g (0.2 mol) of concentrated sulfuric acid was added, and the solution was subjected to electrochemical reduction at 20–45°C and current density gradually decreased from 500 to 100 A m^{-2}; 8 A h of electricity was passed. After the electrolysis completion, the catholyte was extracted with ethyl acetate, and the solvent was evaporated; 17.8 g of 95.2% pure TGA was obtained. Yield 92.0%. The waste was a solution of 11.7 g (0.2 mol) of NaCl and 14.9 g (0.1 mol) of Na_2SO_4 in 80 ml of water.

CONCLUSION

The optimal parameters were determined and a process was developed for the synthesis of thioglycolic acid from sodium monochloroacetate and sodium disulfide without isolation of intermediates. The yield of the target product is as high as 92–97%, with the amount of wastewater being considerably reduced.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thermodynamic Analysis of High-Temperature Transformations of *p*-Diethylbenzene

B. Yu. Smirnov and I. P. Kalinina

Samara State Technical University, Samara, Russia

Received February 22, 2002

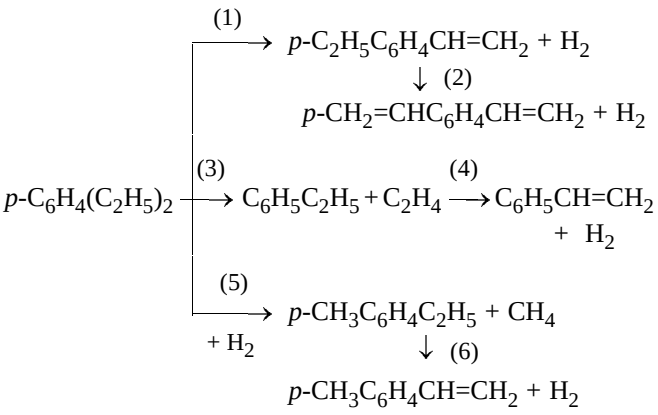
Abstract—Analysis of the maximum efficiency of complex chemical transformations of *p*-diethylbenzene was performed by computer simulation. Major pathways of *p*-diethylbenzene transformations were determined depending on the process conditions.

Isomeric divinylbenzenes are important precursors in the synthesis of a wide assortment of ion-exchange resins, synthetic rubbers, sorbents, membranes, and other polymeric materials [1–4]. Due to stability of their carbon skeleton to the action of acids, alkalis, radiation, and heating and high reactivity in copolymerization, they are widely used as cross-linking agents in various polymeric materials. It is known that *p*-divinylbenzene is the most efficient in this respect [5].

The modern process of preparation of isomeric divinylbenzenes is based on catalytic dehydrogenation of the corresponding diethylbenzenes at high temperatures and high dilution of the initial dialkylbenzene with steam and is accompanied by formation of a series of by-products. Dehydrogenation of commercial diethylbenzene, which is a mixture of *ortho*, *meta*, and *para* isomers, yields a difficultly separable mixture of divinylbenzene isomers [6–8].

The preferred synthesis of individual *p*-divinylbenzene became possible starting from *p*-diethylbenzene, which, in turn, is synthesized by alkylation of ethylbenzene with ethylene in the presence of zeolite catalysts [9, 10]. Increase in the completeness and selectivity of the raw material conversion in the process is urgent from both economical and environmental viewpoint. For this purpose, it is necessary to study equilibrium transformations of *p*-divinylbenzene, which was the goal of this work. Earlier, such a study was performed only with respect to the target reaction [11].

Based on published data [12, 13] and preliminary estimation of the Gibbs energies of reactions, we proposed the following scheme of successive-parallel transformations of *p*-diethylbenzene:



The system of equations for the equilibrium constants of the individual reactions, composed on the basis of the mass action law, was used as a mathematical model. The algorithm of solving this system is the direct thermodynamic problem, whose solution is the equilibrium composition of products and equilibrium degree of raw material conversion [14]. The calculated equilibrium constants were used in a computer experiment based on the program for realization of the above algorithm. It should be noted that the calculated equilibrium constants of reaction (1) are in good agreement with the experimental values found in [11].

Calculations were performed for the 700–1000 K range and degree of dilution of diethylbenzene with water vapor from 0 to 80 mol/mol. The above intervals cover the traditional industrial ranges of these parameters.

The results obtained show that higher temperatures and stronger dilutions increase the equilibrium con-

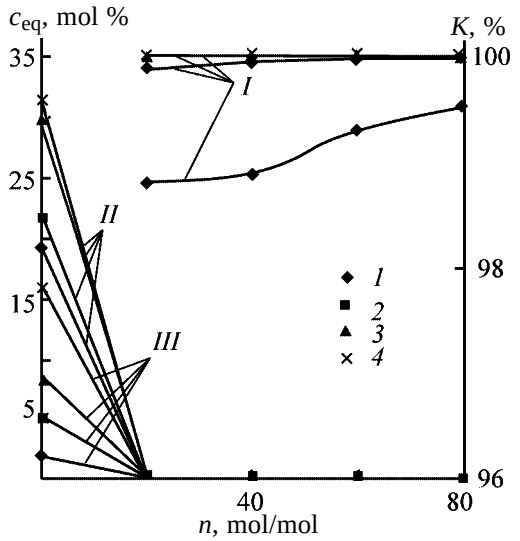

Fig. 1. Dependence of (*I*) *p*-diethylbenzene equilibrium conversion *K* and equilibrium concentrations c_{eq} of (*II*) *p*-ethyltoluene and (*III*) methylstyrene on the dilution degree *n* at various temperatures. Temperature (K): (*1*) 700, (*2*) 800, (*3*) 900, and (*4*) 1000; the same for Figs. 2 and 3.

version of *p*-diethylbenzene, and virtually complete conversion of the initial alkylbenzene can be attained (Fig. 1).

Without diluent, the equilibrium shifts to formation of *p*-ethyltoluene and *p*-methylstyrene [reactions (5) and (6)] (Fig. 1). Introduction of water vapor strongly affects the direction of the prevalent transformation of *p*-diethylbenzene: ethylbenzene (at 700 K) and styrene (at 1000 K) become the main products (Fig. 2). This is probably caused by the fact that the equilibrium of reaction (5) is independent of the inert component, while the equilibria of the other reactions shift to formation of the corresponding products with dilution.

With increasing temperature from 800 to 1000 K, in the presence of the diluent, the styrene concentration gradually decreases (Fig. 2), and the contribution of reactions (1) and (2) leading to substantial increase in the content of *p*-divinylbenzene becomes noticeable (Fig. 3). This increase is limited by 40–50-fold water vapor excess at 800–900 K and 20-fold excess at 1000 K. This dependence allows preliminary evaluation of the appropriate degree of diethylbenzene dilution with water vapor at various temperatures.

CONCLUSIONS

(1) The thermodynamic analysis of the assumed reactions of *p*-diethylbenzene allows determination of the major pathways of its transformation under various conditions. This analysis can be the basis for developing a scheme of catalytic transformations of *p*-diethylbenzene, predicting its behavior in the precatalytic zone of the reactor in the process of *p*-divinylbenzene production, and estimating the working parameters of the reaction apparatus.

(2) Because of the above-noted high styrene content in the equilibrium reaction mixture, it is thermodynamically feasible and attractive to perform joint dehydrogenation of *p*-diethylbenzene and ethylbenzene with the aim to produce *p*-divinylbenzene,

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Photochemical Reactions in Gaseous Mixtures of C_2F_4 and CF_3I[1]

V. P. Fokanov, A. B. Pavlov, V. N. Semenov, and A. V. Morozov

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

Received January 17, 2002

Abstract—Products of photochemical reactions occurring in gaseous mixtures of C_2F_4 and CF_3I under vacuum-UV irradiation were studied. The major photolysis products are linear perfluoroparaffins C_nF_{2n+2} and linear perfluoroalkyl iodides $C_nF_{2n+1}I$. The product ratio is consistent with the suggested kinetic scheme of chain reactions of telomers.

Radical or homolytic telomerization is a convenient route to homologous series of compounds of various classes and is of much promise for practice [1–4]. The products of these reactions are, in particular, iodofluoroalkane telomers, which are used in syntheses of many important products: fluorinated surfactants, rubbers, chemically resistant lubricants and heat carriers, drugs, etc.

Formation of telomers in the reaction medium is initiated by free radicals, which are generated by three main methods: heating (thermal initiation), addition of radical-generating compounds (chemical initiation), and irradiation (photo- or radiation initiation).

With thermal initiation, the heat released in the process results in the temperature and pressure rise, and telomers with a broad molecular-weight distribution are obtained. With chemical initiators, telomerization can be performed under controllable conditions, with the formation of telomers with relatively narrow molecular-weight distribution. However, contamination of the resulting telomers with initiator fragments is a serious drawback of this procedure. Photochemical initiation is free of the above drawbacks. The process parameters can be readily controlled and varied in the course of the reaction. Proper choice of the irradiation spectrum allows variation of the reaction pathways in the same mixture and, correspondingly, the control over the product composition. Vacuum-UV (VUV) irradiation can produce telomerization initiators that cannot be generated by other methods. In this connection, it is interesting to study telomerization in mixtures of fluoroolefins with iodofluoroalkanes.

EXPERIMENTAL

Irradiation of C_2F_4 and a mixture of C_2F_4 with CF_3I was performed in a closed reactor. The reactor was a quartz tube, with a low-pressure mercury lamp arranged along its axis. The distance from the lamp surface to tube walls was about 4 mm. The cell was evacuated to a pressure of 1.3 Pa. In the course of the experiment (3 min), the pressure increased to 26 Pa. The lamp output was 70 W, of which UV radiation at λ = 254 nm made up 30%. The VUV radiation at λ = 185 nm made up only 5% of the output at λ = 254 nm.

Tetrafluoroethylene used in the experiments contained less than 1% impurities. Photolysis was performed both with pure C_2F_4 and with 10 : 1 and 1.5 : 1 mixtures of C_2F_4 and CF_3I (total pressure 3.7–5.7 kPa). Photolysis products were studied by gas chromatography–mass spectrometry and analyzed on the basis of the developed kinetic model. The following reaction scheme was assumed:

$$C_2F_4 + h\nu\ (\lambda = 185\ \text{nm}) = C_2F_4(S), \quad (1)$$

$$C_2F_4(S) = C_2F_4, \quad (2)$$

$$C_2F_4(S) = :CF_2 + :CF_2, \quad (3)$$

$$C_2F_4(S) + C_2F_4 = \text{cyclo-}C_4F_8, \quad (4)$$

$$:CF_2 + :CF_2 = C_2F_4, \quad (5)$$

$$C_2F_4 + :CF_2 = C_3F_6, \quad (6)$$

$$CF_3I + h\nu\ (\lambda = 254\ \text{nm}) = {\cdot}CF_3 + I^*, \quad (7)$$

$$I^* + M(I_2, C_2F_4) = I + M(I_2, C_2F_4), \quad (8)$$

$$\cdot C_4F_9 + I_2 = C_4F_9I + I, \quad (38)$$

$$\cdot C_5F_{11} + I_2 = C_5F_{11}I + I, \quad (39)$$

$$C_2F_5I + C_2F_4(S) = C_3F_7I + :CF_2, \quad (40)$$

$$C_2F_5I + C_2F_4(S) = C_4F_9I, \quad (41)$$

$$C_3F_7I + C_2F_4(S) = C_4F_9I + :CF_2, \quad (42)$$

$$C_3F_7I + C_2F_4(S) = C_5F_{11}I, \quad (43)$$

$$C_4F_9I + C_2F_4(S) = C_5F_{11}I + :CF_2, \quad (44)$$

$$C_4F_9I + C_2F_4(S) = C_6F_{13}I, \quad (45)$$

$$\cdot C_nF_{2n+1} + C_2F_4 = \cdot C_{n+2}F_{2n+5}, \quad n = 5, 16, \quad (46)$$

$$\cdot C_nF_{2n+1} + \cdot C_mF_{2m+1} = C_{n+m}F_{2(n+m)+2},$$
$$n = 5, 16, \quad m = 1, 2, 3, \quad (47)$$

$$\cdot C_nF_{2n+1} + :CF_2 = \cdot C_{n+1}F_{2n+3}, \quad n = 5, 17. \quad (48)$$

Photodissociation of CF_3I results in the generation of $\cdot CF_3$ radicals [reaction (7), absorption cross section $\sim 5 \times 10^{-19}$ cm^2] and excited iodine $I^*(^2P_{1/2})$. $\cdot C_2F_5$, $\cdot C_3F_7$, $\cdot C_4F_9$, and related radicals are formed by secondary reactions with C_2F_4 and $:CF_2$ [reactions (12), (14), (17), (21), (26), (27), (46), (48)], and also by photodissociation of C_2F_5I, C_3F_7I, and C_4F_9I [reactions (16), (18), (23), (25)].

Irradiation of C_2F_4 at $\lambda = 185$ nm generates excited $C_2F_4(S)$ molecules (probably singlet), which either emit quanta or dissociate into $:CF_2$ radical [5]. The $:CF_2$ radicals participate in chain propagation reactions $\cdot C_nF_{2n+1} + :CF_2 = \cdot C_{n+1}F_{2n+3}$. The addition reactions $CF_3I + :CF_2 = C_{n+1}F_{2n+3}I$ and $C_nF_{2n+2} + :CF_2 = C_{n+1}F_{2n+4}$ were taken into account in the preliminary calculations, but their contribution to the overall process appeared to be insignificant. Reaction of excited $C_2F_4(S)$ with ground-state C_2F_4 yields cyclo-C_4F_8 [reaction (4)]. Chains are terminated by recombination of radicals [reactions (9), (10), (19), (20), (29)–(39), (47)]. We also included in the calculation scheme the reactions of excited $C_2F_4(S)$ with perfluoroalkyl iodides (CF_3I, C_2F_5I, C_3F_7I, C_4F_9I) yielding higher-molecular-weight perfluoroalkyl iodides and $:CF_2$ radicals [reactions (40)–(45)].

The system of ordinary differential equations constructed according to the above-given kinetic scheme was integrated by the Gear method [6, 7]. The rate constants of chemical reactions were taken from [8–10] or determined by extrapolation in the homologous

* For C_2F_4 (3990 Pa) and CF_3I (0 Pa), the experimental and calculated values are as follows, %: C_2F_4, 90 and 90.2; cyclo-C_4F_8, 8 and 9.3, respectively.

series, taking into account steric factors. The experimental and calculated data on the composition of the gaseous mixture after irradiation are given in the table.

In the photolysis products of a mixture of C_2F_4 with CF_3I, we detected small amounts of C_2F_3I and C_3F_5I, which may originate from background reactions of fluorine elimination. Fluorine may arise from photodissociation of perfluoroalkyl iodides under the influence of the irradiation with λ = 185 nm [11] (absorption cross section 3×10^{-20}–1.5×10^{-19} cm^2 depending on particular compound).

As the irradiation time is increased, the process shifts toward formation of higher-molecular-weight perfluoroalkyl iodides. The amounts of such components as determined from the gas composition may be underestimated because of condensation on the reactor walls, especially for compounds containing more than 15 carbon atoms.

As seen from the table, stepwise telomerization is the main process occurring upon UV and VUV irradiation of a gaseous mixture of C_2F_4 with CF_3I. Two interrelated radical chain processes occur simultaneously in the system: telomerization of tetrafluoroethylene with the telogen CF_3I and telomerization of C_2F_4 with the arising telomer T_1 (C_3F_7I). This is indicated by the increase in the content of T_1 and T_2 ($C_5F_{11}I$) in the reaction products as the reaction time is increased from 1 to 3 min. The following reaction is mainly responsible for initiation:

$$R_FI + h\nu\ (\lambda = 254\ \text{nm}) = R_F + I^*,$$

where R_F = $^{\cdot}CF_3$, $^{\cdot}C_2F_5$, $^{\cdot}C_3F_7$, etc.

Under conditions of VUV irradiation, this major process is accompanied by formation of $:CF_2$ and, apparently, IF, as judged from the composition of the reaction products. The following reactions probably occur in the system:

$$C_2F_4 + h\nu\ (\lambda = 185\ \text{nm}) = 2{:}CF_2,$$

$$CF_3I + h\nu\ (\lambda = 185\ \text{nm}) = {:}CF_2 + IF,$$

$$IF + C_2F_4 = C_2F_5I.$$

They give rise to a new telogen which subsequently participates in telomerization; however, this pathway was not taken into account in the kinetic scheme.

As seen from the table, for the C_2F_4–CF_3I mixture, the calculation results reasonably agree with the experiment only at $C_2F_4 : CF_3I = 1.5 : 1$. This may be due to considerable excess rotation, vibration, and forward motion energy, sufficient to induce additional reactions that were not taken into account in the calculations.

CONCLUSIONS

(1) Telomers $C_nF_{2n+1}I$ and C_nF_{2n+2} can be prepared from a mixture of tetrafluoroethylene and trifluoromethyl iodide under conditions of UV and VUV initiation. On longer irradiation, the process shifts toward formation of higher-molecular-weight perfluoroalkyl iodides. At decreased concentration of CF_3I, the yield of telomers C_nF_{2n+2} grows.

(2) When photolysis of a C_2F_4–CF_3I mixture is performed with VUV radiation, new reactions may be promoted, accelerating telomerization and involving a new telogen, C_2F_5I, in the process.

(3) At comparable concentrations of CF_3I and C_2F_4, the calculated yields of telomeric photolysis products reasonably agree with the experiment.

Mechanism of Cyclohexane Ozonolysis Considering Alternative Pathways

A. M. Syroezhko, V. A. Proskuryakov, and O. Yu. Begak

Received March 15, 2002

Abstract—Ozonolysis of cyclohexane was considered taking into account the alternative pathway of recombination of peroxy radicals to form cyclohexanol and cyclohexanone. The rate constants of the reactions involved were determined experimentally or by calculations (optimization of the process model).

The mechanism of cyclohexane ozonolysis [1] taking into account formation of unstable hydrotrioxide (ROOOH) and recombination of peroxy radicals to form alcohol and ketone, and also cyclohexene and cyclohexyl hydroperoxide was substantiated in [1].

However, an alternative mechanism of cyclohexane ozonolysis can be considered, with different pathways of recombination of peroxy radicals, formation of cyclohexyl hydroperoxide, and transformations of cyclohexanol.

According to [2], disproportionation of peroxy radicals yields only cyclohexanol and cyclohexanone, without formation of cyclohexene and cyclohexyl hydroperoxide.

In this case, the experimentally detected cyclohexyl hydroperoxide originates, most probably, from recombination of $HO_2^{\bullet}$ and $RO_2^{\bullet}$ radicals.

The mechanism of cyclohexane ozonolysis that we discuss does not include the reaction of the adduct $RH\cdots O_3$ with the hydrocarbons for the reason given above.

Transformation of cyclohexanol was supplemented by the pathway of formation of unstable hydrotrioxide, in conformity with the overall kinetic scheme of cyclohexanol ozonolysis established in [2].

The kinetic scheme under consideration includes only major (but not all) pathways of transformation of cyclohexanol into cyclohexanone.

The rate constants of elementary reactions of the mechanism of cyclohexane ozonolysis were refined on the basis of the mathematical model and results of optimizing the scheme of cyclohexanol and cyclohexanone ozonolysis [3].

Taking into account data in [1], the alternative mechanism of cyclohexane ozonolysis at high degrees of conversion includes 29 reactions:

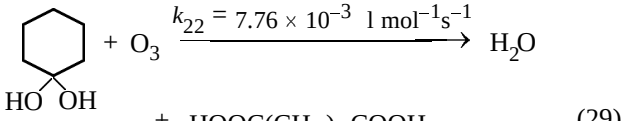
IV **V** (28)



+ $HOOC(CH_2)_4COOH$ (29)

The concentrations x_i of ith radical, cyclohexane hydrotrioxide, or cyclohexanol hydrotrioxide are determined from the condition of steady state, $dx_i/dt = 0$. Let us introduce the following ratios of constants:

$$k_0/k_{05} = Z_1,\ k_{08}/k_{09} = Z_2,\ k_{06}/k_{05} = Z_3,\ k_{07}/k_{05} = Z_4,$$

$$k_6/k_{14} = Z_5,\ k_{13}/k_{14} = Z_6,\ k_4/k_{14} = Z_7,\ \ k_8/k_9 = Z_8.$$

Let us take into account that

$$R_0'c = R_{05} + R_{06} + R_{07},$$

$$R_3 = 2R_4 + R_6 + R_{10} + R_{13} + R_{14} = R_0'b + R_1 + R_{12} + R_{16} + R_{20},$$

$$R_{12} = bR_0' + dR_2 + R_{08} + R_{09} + 2R_{11} + R_8 + R_{14} + R_{17},$$

$$R_{06} + R_{07} = R_{08} + R_{09},\qquad R_{05} + R_{07} + R_{19} = 2R_{010} + R_{10},$$

$$dR_2 = R_7 = R_8 + 2R_{09},\qquad R_{14} = R_5 = R_{16} = R_{17},$$

$$\xi R_2 = R_{19} = R_{20},$$

$$2R_4 + R_{10} - 2R_{14} = (\xi + d)R_2 + 2bR_0 + R_{05} + R_{06} + R_{08} + R_{09} + R_8 + 2R_{11}.$$

The system of differential equations for the rates of consumption of the hydrocarbon and ozone and accumulation of ozonolysis products is as follows:

$$\frac{d[RH]}{dt} = (1 + b)R_0 + \left[\frac{c + c[O_3](2Z_3 + Z_4)}{1 + [O_3](Z_3 + Z_4)}\right]R_0 + R_6[1 + ([R{=}O]Z_6)/([O_3]Z_5) + 3/Z_5)] + (\xi + d)R_2 + R_8 + 2R_{11},$$

$$\frac{d[ROH]}{dt} = a + \left[\frac{c(1 + [O_3]Z_3)}{1 + [O_3](Z_3 + Z_4)}\right]R_0 + R_6[1 + ([R{=}O]Z_6)/([O_3]Z_5)] - R_2 + R_4,$$

$$d[ROOH]/dt = R_{10} - R_{11},$$

$$d[H_2O]/dt = R_{010} = 0.5R_0\left[\frac{c(1 + [O_3]Z_4)}{1 + [O_3](Z_3 + Z_4)}\right] + 0.5(\xi R_2 - R_{10}),$$

$$\frac{d[H_2O]}{dt} = \left[b + \frac{c[O_3](Z_3 + Z_4)}{1 + [O_3](Z_3 + Z_4)}\right]R_0 + (1 - \xi)R_2 + R_8 + 2R_6/Z_5 + 2R_{11} + R_{15} + R_{21} + R_{22},$$

$$d[\mathbf{II}]/dt = R_9 - R_{15},$$

$$\frac{d[R{=}O]}{dt} = \frac{c[O_3]Z_4}{1 + [O_3](Z_3 + Z_4)}R_0 + (1 - d/2 - \xi)R_2 + R_4 + R_{8/2} + R_{11} + ([R{=}O]Z_6R_6)/([O_3]Z_5) + R_{21},$$

$$d[\mathbf{III}]/dt = ([R{=}O]Z_6R_6)/([O_3]Z_5) - R_{18},$$

$$d[HOOC(CH_2)_4COOH]/dt = R_6/Z_5 + R_{15} + R_{18} + R_{22},$$

$$d[\mathbf{II}]/dt = \xi R_2 - R_{21} - R_{22}.$$

Rate of ozone consumption:

$$W_{O_3} = \left[1 + \frac{c[O_3](Z_3 + Z_4)}{1 + [O_3](Z_3 + Z_4)}\right]R_0 + R_2 + R_6(1 + 2/Z_5) + R_8 + R_{11} + R_{15} + R_{22}.$$

Rate of oxygen accumulation:

$$W_{O_2} = \left[a + b + \frac{c[O_3]Z_3}{1 + [O_3](Z_3 + Z_4)}\right]R_0 + 2.5R_0\left[\frac{c[O_3]^2Z_2(Z_3 + Z_4)}{\{1 + [O_3](Z_3 + Z_4)\}([O_3]Z_2 + 1)}\right] + R_0\left[\frac{c[O_3](Z_3 + Z_4)}{\{1 + [O_3](Z_3 + Z_4)\}([O_3]Z_2 + 1)}\right] + R_{010} + (1 - \xi)R_2 - R_4 + R_6[1 - ([R{=}O]Z_6R_6)/([O_3]Z_5)] - R_2 + 2R_8 + R_9 + 2R_{11} + 0.5(R_{15} + R_{18}),$$

The above differential equations include the rates R_0, R_2, R_4, R_6, R_8–R_{11}, R_{15}, R_{18}, R_{21}, and R_{22}. To

calculate the rates R_4, R_6, R_8, R_9, R_{010}, and R_{10}, it is necessary to know the concentrations of the radicals $RO_2^{\bullet}$, $HO_2^{\bullet}$, and **I**.

The sought-for rates R_0–R_{22} are determined from the expressions

$$R_0 = [RH][O_3]k_0,\ R_2 = [ROH][O_3]k_2,\ R_4 = [RO_2^{\bullet}]^2k_4,$$

$$R_6 = [RO_2^{\bullet}],\ R_8 = [\mathbf{I}][O_3]k_8,\ R_9 = [\mathbf{I}]^2k_9,$$

$$R_{010} = [HO_2^{\bullet}]k_{010},\ R_{10} = [HO_2^{\bullet}][RO_2^{\bullet}]k_{10},$$

$$R_{11} = [ROOH][O_3]k_{11},\ R_{15} = [\mathbf{II}][O_3]k_{15},$$

$$R_{18} = [\mathbf{III}][O_3]k_{18},\ R_{21} = [\mathbf{IV}]k_{21},\ R_{22} = [\mathbf{IV}][O_3]k_{22},$$

$$R_{05} = \left[\frac{c}{1 + [O_3](Z_3 + Z_4)}\right]R_0,$$

$$R_{06} = \frac{c[O_3]Z_3}{1 + [O_3](Z_3 + Z_4)}R_0,$$

$$R_{07} = \frac{c[O_3]Z_4}{1 + [O_3](Z_3 + Z_4)}R_0,$$

$$R_{08} = \frac{c[O_3]^2Z_2(Z_3 + Z_4)}{\{1 + [O_3](Z_3 + Z_4)\}([O_3]Z_2 + 1)}R_0,$$

$$R_{09} = \frac{c[O_3](Z_3 + Z_4)}{\{1 + [O_3](Z_3 + Z_4)\}([O_3]Z_2 + 1)}R_0,$$

$$R_4 = [RO_2^{\bullet}]^2k_6Z_7/Z_5 = R_6^2Z_7/[O_3]^2k_6Z_5,$$

$$R_{13} = [\mathbf{V}]Z_6R_6/([O_3]Z_5),\ R_{14} = R_6/Z_5.$$

The concentrations of the radicals $RO_2^{\bullet}$, $HO_2^{\bullet}$, and **I** are

$$[HO_2^{\bullet}] = f[RO_2^{\bullet}] = \left[\frac{R_{05} + R_{07} + R_{19}}{2k_{010} + k_{10}/f}\right]^{1/2},$$

$$f = \frac{-[k_{10}(D - P)] + \{[k_{10}(D - P)]^2 + 16DPk_{010}k_4\}^{1/2}}{4Dk_{010}},$$

$$P = R_{05} + R_{07} + R_{19},$$

$$D = (\xi + d)R_2 + R_{05} + R_{06} + R_{08} + R_{09} + 2bR_0 + R_8 + 2R_{11},$$

$$[RO_2^{\bullet}] = (-[HO_2^{\bullet}]k_{10} - 2[O_3]k_{14})/4k_4 + \{([HO_2^{\bullet}]k_{10} - 2[O_3]k_{14})^2 + 8k_4D\}^{1/2}/4k_4,$$

$$[\mathbf{I}] = \frac{-k_9[O_3]Z_8 + \{(k_9[O_3]Z_8)^2 + 8k_9dR_2\}^{1/2}}{4k_9}.$$

The system of differential equation was integrated on a computer using the standard DERE program, PL/1 language. The system was solved by the method of rational extrapolation, based on discrete approximation when calculating the concentration of *i*th product. The parameters Z_1–Z_8 are as follows: $Z_1 = 0.027$, $Z_2 = 2.27 \times 10^7$, $Z_3 = 7.1$, $Z_4 = 137.8$, $Z_5 = 1.27 \times 10^5$, $Z_6 = 54.5$, $Z_7 = 1.45 \times 10^8$, and $Z_8 = 5 \times 10^{-9}$. The calculation results are given in the table and in the scheme of the mechanism of cyclohexane ozonolysis.

Comparative analysis of the table shows that the largest discrepancy between the calculations and experiment is observed for hydrogen peroxide, hydroxycyclohexyl hydroperoxide, and adipic acid, whereas for the other products the agreement is much better. Both calculated and experimental kinetic curves of the hydrocarbon consumption become straight lines in the semilog coordinates. The differential equation for the hydrocarbon consumption includes the rates R_0, R_2, R_6, R_{11}, and R_8. These rates (except R_8) are comparable and vary insignificantly in the steady-state mode of the process. The rates vary in the following ranges: R_0, $(1.42–1.32) \times 10^{-5}$; R_2, $(2.03–2.78) \times 10^{-5}$; R_6, $(0.422–0.468) \times 10^{-5}$; and R_{11}, $(0.427–0.562) \times 10^{-5}$ mol l^{-1} s^{-1} (τ = 1–5 h). The hydrocarbon is consumed in a bimolecular reaction with ozone and by a chain pathway (reaction of the peroxy radical with ozone). In the developed process, an appreciable contribution is made by bimolecular reactions of cyclohexanol and cyclohexyl hydroperoxide with ozone.

In the differential equation of the ozone consumption, the terms corresponding to each reaction contain the ozone concentration to the first power, except the term

$$R_0\{1 + c[O_3](Z_3 + Z_4)/[1 + [O_3](Z_3 + Z_4)]\}.$$

Substituting in the above expression the values $Z_3 = 7.1$ and $Z_4 = 137.8$ found by mathematical analysis of the model, we obtain

$$c[O_3](Z_3 + Z_4)/\{1 + [O_3](Z_3 + Z_4)\} \ll 1.$$

Actually, there are no noticeable deviations from the first order with respect to ozone. Ozone is con-

sumed in bimolecular reactions with cyclohexanol, cyclohexyl hydroperoxide, cyclohexanone, 1-hydroxycyclohexyl hydroperoxide, and peroxy radical. Calculations show that only 0.67 mol of oxygen is released per mole of consumed ozone (usually, only one of three oxygen atoms in the ozone molecule is involved in oxidation). Comparison of the total amounts of oxygen incorporated in the reaction products, ozone consumed, and oxygen released shows that the reaction involves not only oxygen generated in the event of reaction of ozone with the reaction medium, but also oxygen continuously fed to the reactor as a component of the ozone–oxygen mixture.

CONCLUSION

A mathematical model was developed for low-temperature selective ozonolysis of cyclohexane to cyclohexanone. The reaction selectivity is due to recombination of peroxy radicals with formation of cyclohexanol and cyclohexanone, fast oxidation of cyclohexanol and cyclohexyl hydroperoxide to cyclohexanone, and relatively slow oxidation of cyclohexanone to acids and ε-caprolactone.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of Poly(Ethylene Terephthalate) Track Membranes by Sorption of Poly(Ethylene Glycol)

A. Yu. Solov'ev, I. Yu. Ryadnova, and L. K. Shataeva

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 15, 2002

Abstract—Sorption of poly(ethylene glycol) on poly(ethylene terephthalate) track membranes was studied at different pH. The hydrophilic-hydrophobic properties of the intact membranes and those modified with poly(ethylene glycol) are compared. The membrane–aqueous human serum albumin and membrane–aqueous insulin adhesive tensions were determined for modified membranes. The competitive sorption of human serum albumin and poly(ethylene glycol) from aqueous solution on the track membranes is analyzed.

Poly(ethylene terephthalate) (PET) track membranes (TMs) are widely used for microfiltration to separate filterable viruses, fractionation of colloid solutions, and plasmophoresis to separate blood corpuscules of a donor blood from its plasma [1]. However, relatively high hydrophobicity of the surface of these membranes [2] results in nonselective sorption of proteins from aqueous solutions, resulting in plugging of membrane pores and microfiltration deceleration. There are diverse techniques for chemical modification of PET surface [3] to decrease the nonselective sorption. Poly(ethylene terephthalate) track membranes can be modified by immobilization of hydrophilic groups on the pore surface via covalent bonding. Such modification, as a rule, results in significant pore narrowing [4]. Track membranes can also be hydrophilized by immobilization of hydrophilic nonionic substances, e.g., nonionic surfactants, on the surface of membrane pores by the sorption mechanism. Track membranes can be modified with poly(ethylene glycol) (PEG), which is amphiphilic biocompatible polymer widely used in biochemistry, molecular biology, and medicine [5]. It is known that the chemical grafting of PEG decreases the nonselective sorption of blood plasma proteins on the surface of track membranes [6–8]. The immobilization of PEG on TM surface by the sorption mechanism also decreases the sorption of serum albumin from model aqueous solutions [6].

In this work we studied the sorption of PEG on the TM surface and the influence of PEG sorption on the hydrophilicity of the track membranes and their sorption power with respect to various biopolymers.

EXPERIMENTAL

In our experiments we used 10 μm thick microfiltration poly(ethylene terephthalate) track membranes with the nominal pore diameter d = 0.35 μm and the specific porosity $N = 1.2 \times 10^8$ pore cm^{-2}. A plasmophoretic setup manufactured by Plazmofil'tr Research and Production Association (St. Petersburg, Russia) was equipped with microfiltration track membrane modules with the filtering surface of area 480 cm^2. Track membranes with the nominal pore diameters of 0.05 and 0.03 μm were also used in our experiments. The porosity of these membranes was not precisely determined by the manufacturer (Joint Institute for Nuclear Research, Dubna, Russia).

The track membrane surface was modified by sorption of PEGs with the average molecular weights M of 3 and 40 kDa (Ferak). The influence of such modification on the nonspecific sorption of proteins was studied in the following solutions: 0.02 M human serum albumin HSA (Reanal, Czechia) in phosphate buffer, pH 5.7; 0.05 M crystalline insulin in phosphate buffer, pH 6.8; and 5% HSA for perfusion (Lipetsk, Russia) in distilled water.

Sorption of PEG from different aqueous solutions on track membranes was performed under static conditions for 24 h at 25°C. In these experiments, the following aqueous PEGs were used: $(1–125) \times 10^{-6}$ M PEG (M = 3 and 40 kDa) in distilled water at pH 6.2; $(25–400) \times 10^{-6}$ M PEG (M = 3 kDa) in distilled water at pH 6.2; $(1–20) \times 10^{-6}$ M PEG (M = 40 kDa) in the acetate buffer at pH 8.5; and PEGs of the same molecular weights and concentrations as for the

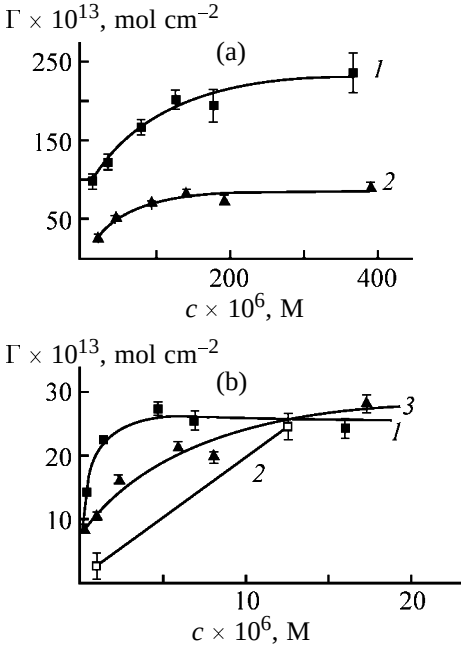

Fig. 1. Sorption of PEG on poly(ethylene terephthalate) track membranes with the pore diameter of 350 nm. (*c*) PEG concentration and (Γ) membrane sorption capacity. M_{PEG} (kDa): (a) 3 and (b) 40. pH: (*1*) 2.8, (*2*) 6.2, and (*3*) 8.5.

above-noted systems in 1% aqueous acetic acid at pH 2.8.

To obtain the PEG sorption isotherms, a weighed portion of a track membrane (1.5–2.0 g) preliminarily treated by the technique reported in [2] was immersed in aqueous PEG (15 ml). The PEG concentration in the equilibrium aqueous phase was determined by the optical absorption of a PEG molecular complex with iodine. Prior to determination, an I_2 + KI saturated solution was diluted with water by a factor of 100 to obtain the working solution. 1 ml of aqueous $BaCl_2$ (5%) and 1 ml of the working I_2 + KI solution were added to 2 ml of the solution to be analyzed. After the lapse of 2 min, the optical density of the solution was measured at 535 nm against water. The calibration curve was obtained with aqueous PEG solutions of the concentrations similar to those in the sorption experiments. The difference between the initial and final PEG amount in the liquid phase was accepted as the PEG amount sorbed on the track membrane. After completion of the sorption experiment, the track membranes were washed with distilled water and air-dried. The presence of sorbed PEG on the track membrane surface was confirmed with modified Dragendorff reagent [9]. To characterize the wettability of the modified membranes, the contact angles θ (the flowing angles) were determined with a VT-500 torsion balance by the Wilhelmi plate method [2]. The contact angle was calculated by the equation

$$\cos\theta = \frac{m - m_0 + V(\rho - \rho_0)g}{\Pi\gamma}, \quad (1)$$

where m_0 and m are the weights of the dry membrane and that partly immersed in the liquid phase, respectively; V, the volume of the membrane part immersed in a liquid: P, the perimeter of the membrane–liquid contact; γ and ρ, the surface tension and the density of the liquid, respectively; ρ_0, the membrane density; and g, the free fall acceleration. The mean error in measuring cos θ was about 10%, which corresponds to scattering of the contact angles within ±3° for the contact angles exceeding 80°.

Because of lack of the data on the HSA and insulin surface tension, the wetting power of these proteins with respect to the track membrane surface was characterized by the adhesive tension [10]:

$$A = \gamma\cos\theta = \frac{m - m_0 + V(\rho - \rho_0)g}{\Pi}. \quad (2)$$

The adhesive tension is defined as the difference between the surface tension at the solid surface–vapor phase contact and that at the solid surface–equilibrium liquid phase contact. Therefore, the adhesive tension reflects the energy of interactions between a solid surface and a solution at the constant vapor pressure of the solvent.

In our experiments, the track membranes were wetted with distilled water, and the water–membrane contact angle characterized the influence of PEG sorption on the hydrophobicity of the membrane surface.

A membrane microfiltration module was modified by recirculating aqueous PEG (M = 40 kDa) for 7 days, an then the module was washed with distilled water. 5% aqueous HSA (100 ml) was pumped through both the modified and control (intact) modules. The second control module was not contacted with aqueous HSA. After completion of microfiltration of aqueous HSA, the modules were disassembled, and the hydrophilicity of the track membranes (hereinafter denoted as MTM) was determined.

The isotherms of sorption on track membranes of PEG with different molecular weights from aqueous solutions of different pH are shown in Figs. 1a and 1b. These isotherms show that acidity of solutions significantly affects the sorption isotherms. For low-molecular-weight PEG (M = 3 kDa), passing from

acidic (pH 2.8) to neutral (pH 6.2) solutions decreases the membrane sorption capacity. A similar pattern is observed with PEG of higher molecular weight, M = 40 kDa.

One of the stages of preparation of poly(ethylene terephthalate) track membranes is their treatment with aqueous alkali solutions to etch the initial radiation tracks in a PET matrix. In so doing, carboxy and hydroxy groups arise on the sorbing surface of the membrane pores. Along with these new hydrophilic sites, hydrophobic sites also remain on the surface [11]. Therefore, amphiphilic surfactants can be sorbed on both hydrophilic and hydrophobic sites of the track membrane surface. The effect of pH on sorption of PEG on track membranes shows that PEG macromolecules are sorbed by the mechanism of hydrogen bonding with the hydrophilic sites. It is known that, in hydrogen bonding, PEG macromolecules are the electron acceptors only. Therefore, sorption of PEG from acidic solution occurs by the hydrogen bonding between oxygen atoms of its ether groups (proton acceptors) and the carboxy and hydroxy groups (proton donors) located on the pore surface. With increasing acidity of solution, the protonation of the hydrophilic groups on the surface of track pores increases, and, as a result, the hydrogen bonding is strengthened. The number of such hydrogen bonds increases with increasing PEG molecular weight.

The degree of saturation of the pore surface with PEG macromolecules was evaluated from the average pore surface area per PEG macromolecule (M = 3 and 40 kDa).

The specific pore surface area (specfic sorbing surface area) of track membranes was calculated by the equation

$$S_{sp} = \pi dN/r_0, \quad (3)$$

where d is the pore diameter, N is the pore number per unit filtering surface area, and ρ_0 is the TM density (1.21 g cm^{-3}).

In our experiments we used the membranes with the specific pore surface area of 1.09 m^2 g^{-1}.

Using the reference data on the intrinsic viscosity of aqueous PEG [12] (7.5 and 32.0 cm^3 g^{-1} for PEG with M = 3 and 40 kDa, respectively) and assuming that these values are the exclusion volumes of the hydrated PEG macromolecules, we can calculate the average area of the projection of the hydrated macromolecule onto the sorbing surface. These calculations show that PEG molecules with M = 3 and 40 kDa occupy the surface area of 11 and 165 nm^2, respectively. We found that, at the limiting sorption of these PEGs on the membranes, the total surface area occupied by the PEG macromolecules exceeds the specific sorption surface area of the membranes by a factor of 1.5–2.0. These results are indicative of the dense occupation of the sorbing surface by PEG macromolecules and their certain dehydration.

Table 1. Characteristics of PEG sorption on the track membranes with the pore diameter of 0.35 μm

M_{PEG}, kDa	K			W, kJ mol^{-1}		
	at indicated pH					
	2.8	6.2	8.5	2.8	6.2	8.5
3×10^3	17	7	–	7.0	4.8	–
4×10^4	133	20	33	12.1	7.4	8.7

The PEG sorbability to the pore surface can be qualitatively estimated from the distribution factor calculated from the slope of the initial portion of the sorption isotherm. In the systems under consideration, the PEG macromolecules are distributed between the bulk of the liquid phase and the membrane surface layer whose volume cannot be determined experimentally. For simplification, we can assume that PEG is distributed between the bulk of the aqueous solution, in which the PEG concentration can be determined, and the pore solution. The amount of pore solution in the membranes used in our experiments was 0.09 cm^3 g^{-1}. The distribution factor K was calculated by the equation

$$K = c/c_s, \quad (4)$$

where c is the PEG concentration in the porous solution and c_s is the PEG concentration in the equilibrium liquid phase.

The distribution factor K of a macromolecule allows estimation of the work of its sorption W by the equation [10]

$$W = RT\ln(c/c_s). \quad (5)$$

The experimental distribution factors of PEGs and the corresponding W values calculated by Eq. (5) are listed in Table 1. These results show that the work of sorption of PEG with M = 40 kDa exceeds that of PEG with M = 3 kDa. This difference reflects the fact that, with increasing PEG molecular weight, the number of the molecular contacts between PEG and the pore surface increases.

The hydrophilicity of the polymer surface is com-

monly estimated by the polymer–water contact angle. The smaller the contact angle, the more hydrophilic is the solid surface. As a rule, sorption of nonionic surfactant on a hydrophilic surface results in its hydrophobization, whereas sorption of a nonionic surfactant on a hydrophobic surface causes its hydrophilization [13]. To elucidate how sorption of PEG affects the hydrophilicity of the membrane surface, we measured the contact angles (θ) for both the intact membranes and those modified by sorption of PEG. Along with the TMs with the pore diameter of 0.35 μm, whose sorption power with respect to PEG was thoroughly studied, the contact angles were also determined for membranes with the pore size of 0.05 and 0.03 μm whose specific porosity was not characterized. Table 2 shows that, for all the membranes, regardless of their characteristics, the sorption of PEG decreases the contact angle. Thus, the sorption of PEG makes the membrane surface more hydrophilic. This effect is apparently caused by formation of a hydrate shell around the sorbed PEG macromolecules [14]. These results also show that hydrophilization of the track membranes increases as the pore diameter is increased from 0.03 and 0.05 to 0.35 μm.

It is known that an increase in the hydrophilicity of track membranes substantially decreases sorbability of biologically active macromolecules [7, 8]. We studied the effect of hydrophilization of the track membranes with PEG on their wettability with aqueous HSA and insulin solutions of widely varied concentrations.

The membranes were modified with PEG (M = 40 kDa) by recirculation of aqueous PEG (M = 40 kDa) through a membrane module for 7 days, after which the membrane module was washed with water.

We found that the rate of microfiltration of water through a membrane module modified by sorption of PEG decreased, on the average by 5–12% as compared to the intact module. Thus, the hydrodynamic resistance of the modified module exceeds that of the intact modules. This fact shows that PEG is sorbed on the pore surface and, therefore, narrows the effective pore diameter. The similar increase in the hydrodynamic resistance was observed in microfiltration of HSA through both the intact and modified membranes. In view of the fact that PEG and HSA can be sorbed not only on the membrane surface but also on the other parts of a module, our experiments show only a tendency in the effects of macromolecule sorption on microfiltration.

Upon completion of passing 5% aqueous HSA through both the intact and modified modules, these were disassembled and the membrane (MTM)–water contact angles (θ) and membrane–aqueous HSA (A_{HSA}) and membrane–aqueous insulin (A_{ins}) adhesive tensions were determined (Table 3). The membrane–water contact angles θ show that sorption of HSA makes the TM surface more hydrophilic than sorption of PEG. Therefore, the (MTM + PEG + HSA) membrane–water and the (MTM + HSA) control membrane–water contact angles are similar within the limits of the experimental error. The qualitative analysis of the (MTM + PEG + HSA) membrane for PEG with Dragendorff reagent has not revealed these macromolecules. Most likely that, on contact of (MTM + PEG) membrane with 5 wt % aqueous HSA, this protein displaces PEG from the sorption layers. It should be noted that the replacement of PEG is not observed at lower HSA concentrations (0.1, 0.2, and 0.5 wt %). These facts show that HSA replaces PEG not by the mechanism of competitive sorption of separate macromolecules, but by a colloidal mechanism involving replacement of PEG macromolecules by an HSA solution with the lower surface tension.

Figure 2 shows the plot of the membrane–liquid adhesive tension vs. the surface tension of different liquids [10, 15]. As seen from this plot, the mem-

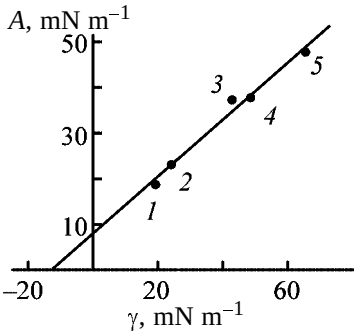

Fig. 2. Membrane–liquid adhesion tension A as a function of the surface tension of liquid γ for (*1*) hexane, (*2*) ethanol, (*3*) chloroform, (*4*) ethylene glycol, and (*5*) glycerol.

brane–liquid adhesive tension correlates with the membrane–liquid contact angle [2].

Therefore, the membrane–aqueous protein adhesive tension qualitatively characterizes their surface tension. For an example, with increasing HSA concentration, the adhesive tension decreases to a level corresponding to liquids with low surface tension. This effect shows that HSA is a strong surfactant. As opposed to HSA, aqueous insulin apparently exhibits higher surface tension and, therefore, cannot displace PEG from the sorption layer. By the same reason, PEG immobilized on the TM surface is not displaced by aqueous mineral salts but is desorbed only by liquids with a low surface tension, e.g., by chloroform.

CONCLUSIONS

(1) Sorption of poly(ethylene glycol) with the molecular weight of 3 and 40 kDa on track membranes was studied at different pH. The sorbability of poly(ethylene glycol) and selectivity of its sorption increase with decreasing pH.

(2) The water–membrane contact angles were measured for both intact track membranes and those modified with poly(ethylene glycol). Sorption of poly(ethylene glycol) on the track membranes decreases the membrane–water contact angle, indicating the increased hydrophilicity of the membrane surface.

(3) The membrane–aqueous human serum albumin and membrane–aqueous insulin adhesive tensions show that, as opposed to insulin, human serum albumin makes the track membranes more hydrophilic than poly(ethylene glycol) does.

(4) Owing to relatively low surface tension, 5 wt % aqueous human albumin completely displaces poly(ethylene glycol) from the surface of the modified track membranes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of Vinylformamide by Michael Addition to Methyl Acrylate and Methyl Vinyl Ketone, and Copolymers Derived from the Resulting Products

A. Yu. Ershov, I. I. Gavrilova, and E. F. Panarin

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

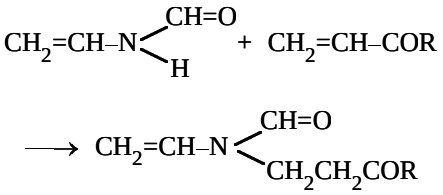
Received June 18, 2002

Abstract—Vinylformamide reacts with methyl acrylate and methyl vinyl ketone under conditions of base catalysis, following the Michael addition pattern, to give methyl 3-(vinylformylamino)propionate and previously unknown 4-(vinylformylamino)-2-butanone. Radical copolymerization of these compounds with vinylformamide and *N*-vinylpyrrolidone was studied.

Targeted transport of a physiologically active substance to a definite organ, cell, or tissue of a living body is an important problem in modern pharmacology. Efficient carriers for such transport can be water-soluble copolymers derived from *N*-vinylamides, which show enhanced affinity for proteins owing to the presence of similar amide groups and other functional moieties.

Polymers derived from *N*-vinylpyrrolidone and *N*-vinylacetamide and its *N*-alkyl analogs were studied previously [1–3]. Introduction of hydrophobic alkyl radicals into side chains of such polymers opens up possibilities for control of their conformational state and increases the probability of their binding with hydrophobic sections of cell membranes.

In this work, with the aim to develop new copolymers based on vinylformamide (VF) and containing functional fragments in pendant chains, we studied modification of VF by the reactions with methyl acrylate (MA) and methyl vinyl ketone (MVK) under conditions of base catalysis, following the Michael addition pattern:



Ia, Ib

where R = OCH_3 (**Ia**), CH_3 (**Ib**).

We found that the reaction occurs within 24 h at room temperature without a solvent in the presence of catalytic amounts of an alkali. The products are liquids readily distillable in a vacuum. The physicochemical characteristics of the compounds are listed in Table 1.

The ^1H NMR spectra of **Ia** and **Ib** fully confirm their structure. In particular, the spectra (Fig. 1a) contain a characteristic *ABX* pattern of vinyl protons (4.5 and 6.5 ppm) and two multiplets of methylene protons (2.5 and 4.0 ppm, CH_2CH_2N). Some signals are doubled because of braked rotation of the formyl group about the C–N bond (Table 2).

Thus, Michael addition of vinylformamide to com-

Table 1. Physicochemical characteristics of **Ia** and **Ib**

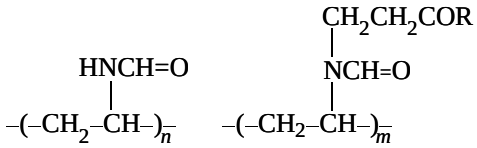
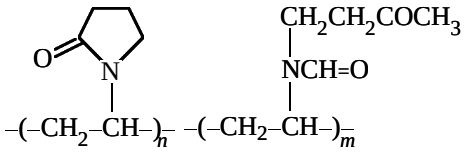
pounds containing an activated C=C bond (MA, MVK) is a convenient route to modified vinylformamide derivatives, which are of interest as monomeric precursors of water-soluble copolymers containing a functionally substituted vinylamide moiety:



IIa, IIb



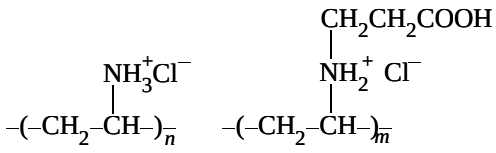
III

where R = OCH_3 (**IIa**), CH_3 (**IIb**).

Copolymerization of VF and VP with modified VF analogs, methyl 3-(vinylformylamino)propionate (VFMA) and 4-(vinylformylamino)-2-butanone (VFVMK) was performed by heating of the monomers dissolved in isopropanol at 60°C in glass ampules under nitrogen, with azobis(isobutyronitrile) initiator (1 wt % relative to comonomers). The conditions for preparing copolymers **IIa**, **IIb**, and **III** and their intrinsic viscosities [η] are listed in Table 3. The procedure allows preparation of random water-soluble copolymers in high yields.

The compositions of the copolymers were determined from the integral intensities of the characteristic ^{1}H NMR signals, namely, of those of H–C=O (8 ppm) and CH_2 (2.8 ppm) groups in the case of **IIa** and **IIb** (Fig. 1b, Table 4) and of H–C=O group (8 ppm) and H^5 atom in the pyrrolidone ring in the case of copolymer **III** derived from VP. The measurement error was ±3–5%.

Copolymers **IIa** were hydrolyzed to vinylamine–3-(vinylamino)propionic acid copolymers (in the form of hydrochlorides, **IV**) by heating in 10% HCl at 120°C for 24 h; the products were isolated by precipitation into acetone.



IV

	65	35	70	62	38	0.18
III	80	20	98	82	18	0.21
	70	30	75	75	25	0.13
IV	85	15	65	85	15	0.15
	50	50	75	60	40	0.12
	25	75	70	35	65	0.10

Table 4. ^{1}H NMR spectra of copolymers in D_2O

Compound	δ, ppm					
	$-CH_2-$	–CH–	H–C=O or H^3, H^4, H^5	CH_2CO	CH_2N	CH_3
IIa	1.97	4.02	8.12 (H–C=O)	2.76	3.56	3.78
IIb	1.98	4.12	8.20 (H–C=O)	3.08	3.61	2.46
III	2.03	3.97	2.24 (H^4), 2.48 (H^3), 3.53 (H^5)	3.13	3.44	2.41
IV	2.21	4.04	–	3.13	3.64	–

The degree of hydrolysis was evaluated from the Cl^- content, determined by conductometric titration with 0.01 M $AgNO_3$, and also from the ^{1}H NMR spectra (disappearance of the formyl proton signal at 8.0 ppm and of the methoxy group signal at 2.8 ppm; Fig. 1c). The conditions for synthesis of copolymers **IV** and their intrinsic viscosities are given in Table 3.

Thus, Michael addition of vinylformamide to compounds containing an activated double bond is a convenient route to modified derivatives of this monomer. The procedure allows introduction into pendant chains of ester and carbonyl groups for subsequent modification by functional binding of physiologically active substances.

EXPERIMENTAL

Elemental (C, H, N) analysis was performed with a Hewlett–Packard 185B analyzer. The ^{1}H NMR spectra were recorded on a Bruker AC 200 spectrometer. Titration was performed with a TV-6L-1 conductometer. The intrinsic viscosity was measured with an Ubbelohde viscometer in water at 25°C. Compound **Ia** was prepared as described in [4].

4-(Vinylformylamino)-2-butanone Ib. A 35-g (0.5-mol) portion of VF was added dropwise with cooling (the temperature was maintained within 20–25°C) to a mixture of 40 g (0.55 mol) of freshly distilled MVK, 0.56 g of KOH, and 0.01 g of hydroquinone in 10 ml of methanol. The mixture was left overnight at room temperature and, after addition of 0.5 g of sodium acetate, distilled in a vacuum.

CONCLUSIONS

(1) Michael addition of vinylformamide to methyl acrylate and methyl vinyl ketone, yielding new monomers, methyl 3-(vinylformylamino)propionate and 4-(vinylformylamino)-2-butanone, was studied.

(2) Copolymers of these monomers with vinylformamide and *N*-vinylpyrrolidone were prepared, and their acid hydrolysis was studied. The *N*-formyl and ester groups can be quantitatively removed with the

formation of vinylamine–3-(vinylamino)propionic acid copolymers in the form of hydrochlorides.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of 1-Vinyl-4,5,6,7-tetrahydroindole with Vinyl Chloride in the Presence of a Radical Initiator

N. S. Shaglaeva, O. V. Lebedeva, A. I. Mikhaleva, G. A. Pirogova, R. G. Sultangareev, N. N. Chipanina, and G. A. Gavrilova

Favorskii Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received March 21, 2002

Abstract—Copolymerization of 1-vinyl-4,5,6,7-tetrahydroindole with vinyl chloride in the presence of azobis(isobutyronitrile) occurs as a two-step process. The copolymer is initially formed by the radical mechanism. Then, the eliminated hydrogen chloride initiates cationic oligomerization of 1-vinyl-4,5,6,7-tetrahydroindole, enriching the copolymer with units of this monomer.

N-Vinylpyrroles, which became accessible after the discovery and comprehensive study of pyrrole synthesis from ketoximes and acetylene [1, 2], are a subject of active research as monomers for preparing new macromolecular compounds with a set of valuable properties. *N*-Vinylpyrroles are used for preparing special semiconductors, synthetic dyes [1], photosensitive materials, and biologically active compounds [4, 5].

Introduction of functional groups into *N*-vinylpyrrole polymers will extend applications of pyrrole-containing polymers. Owing to the potential modifying effect of *N*-vinylpyrroles on polymers prepared by radical polymerization, growing attention is given to radical copolymerization of these monomers with commercial monomers such as vinyl chloride, vinyl bromide, vinylidene chloride, methyl methacrylate, acrylamide, and acrylonitrile.

For example, heterocyclic nitrogen-containing compounds are used for enhancing the adhesive properties of vinyl chloride (VC) homo- and copolymers and for stabilizing them against light and heat [6].

In this work, we studied radical copolymerization of *N*-vinyl-4,5,6,7-tetrahydroindole (VTHI) with VC in the presence of azobis(isobutyronitrile) (AIBN). The results are listed in the table.

Copolymers are formed in the entire examined range of the monomer ratios and are enriched in VTHI units as compared to the initial monomer mixture. As the VTHI content in the monomer mixture is increased, the yield of the copolymer grows and its viscosity decreases. The compositions of the obtained copolymers were calculated from elemental analyses.

Determination of the content of VC units from the weight fractions of chlorine and nitrogen gives different results. This fact suggests occurrence of dehydrochlorination:

Copolymerization of VTHI with VC (1.5 wt % AIBN, 60°C, 6 h)

Mole fractions of monomers		Mole fractions of monomer units, calculated from N and Cl content				$[\eta]$, dl g^{-1}	Yield, %

The released HCl can initiate cationic oligomerization of VTHI and protonate the pyrrole ring in the macromolecular chain.

We found that passing HCl through VTHI monomer at 22°C results in instantaneous formation of the oligomer. Its IR spectrum (Fig. 1b) is similar to the spectrum of the cationic VTHI oligomer (Fig. 1a) prepared in the presence of $ClSiEt_3$ [7]. The spectrum of the VTHI–VC copolymer (Fig. 1c) is, on the whole, similar to the spectra of the oligomers (Figs. 1a, 1b). This fact suggests the presence of blocks formed by cationic oligomerization of VTHI under the action of the eliminated HCl. The rate of cationic oligomerization of VTHI is considerably higher than the rate of radical copolymerization of VTHI with VC.

In block copolymerization of VTHI with VC in the presence of AIBN at 60°C, the viscosity of the medium growth only slightly even after 10 h: initial mixture, η_{rel} = 0.08; after 10 h, η_{rel} = 0.10. At the same time, HCl converts monomeric VTHI into an insoluble solid within 5–10 min at 22°C. The higher activity of VTHI as compared to VC, in contrast to the published data that VTHI is characterized by low rate of radical polymerization [8, 9], may be due to fast cationic polymerization of VTHI in the presence of HCl, resulting in enrichment of the copolymer with VTHI units.

Cationic oligomerization of VTHI in the course of copolymerization does not yield a separate product, as indicated by the results of turbidimetric titration (Fig. 2) and TLC.

Thus, initially copolymerization of VTHI with VC occurs by the radical mechanism. Then, the released HCl initiates oligomerization of VTHI resulting in grafting of short blocks of the cationic oligomer to the backbone of the VTHI–VC copolymer:

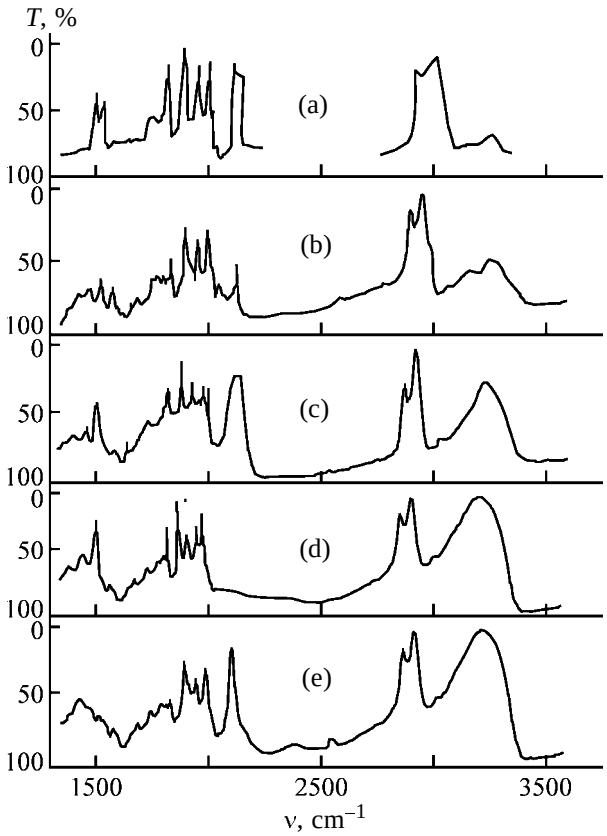

Fig. 1. IR spectra of (a) VTHI oligomer prepared in the presence of $ClSiEt_3$; (b) VTHI homopolymer prepared in the presence of dry HCl; (c) VTHI–VC copolymer; (d) VTHI homopolymer prepared by the radical mechanism; and (e) the same, after treatment with dry HCl. (*T*) transmission and (ν) wave number. (a) Thin film and (b–e) KBr pellets.

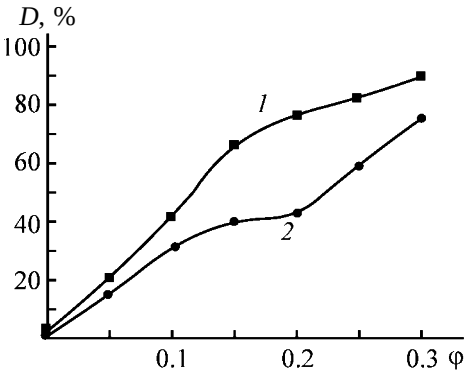

Fig. 2. Turbidimetric titration curves of (*1*) VTHI–VC copolymer and (*2*) a blend of VTHI and VC homopolymers. (*D*) Absorption and (φ) volume fraction of substance.

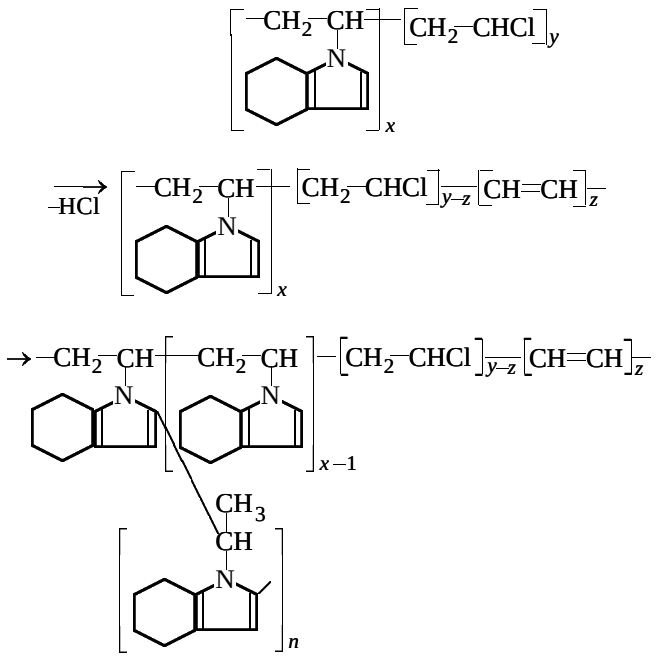
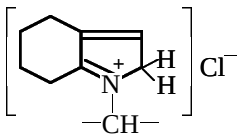


Also, the eliminated HCl partially protonates the tetrahydroindole moieties in the macromolecule. This conclusion follows from comparison of the IR spectra of the VTHI homopolymer obtained by AIBN-initiated radical polymerization (Fig. 1d) and of its protonated form (Fig. 1e). In the IR spectra of both the protonated form of the homopolymer and the VTHI–VC copolymer, an immonium absorption band appears at 1680 cm^{-1} [10]:



EXPERIMENTAL

N-Vinyl-4,5,6,7-tetrahydroindole was prepared as described in [2]. Copolymerization was performed in sealed ampules at 60°C in the presence of AIBN under argon.

The reaction mixture was dissolved in benzene, and the copolymer was precipitated with heptane. The copolymers were reprecipitated from benzene solution into heptane and vacuum-dried to constant weight.

The VTHI homopolymer was prepared by AIBN-initiated radical polymerization. Protonation was performed by passing dry HCl through VTHI or a solution of the homopolymer. The products were filtered off and washed.

The IR spectra were recorded on a Specord 751-IR spectrophotometer. Turbidimetric titration was performed with a KFK-2 photocolorimeter (solvent benzene, precipitant hexane). TLC was performed on Silufol UV-254 plates (eluent hexane–ether, 2 : 1; developer I_2).

CONCLUSION

Radical copolymerization of 1-vinyl-4,5,6,7-tetrahydroindole with vinyl chloride is accompanied by polymer-analogous transformations, namely, by dehydrochlorination and graft cationic oligomerization of 1-vinyl-4,5,6,7-tetrahydroindole.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Polymerization of Methyl Methacrylate in the Presence of Aromatic Nitroso Compounds

D. F. Grishin, M. V. Pavlovskaya, E. V. Kolyakina, and L. L. Semenycheva

Research Institute of Chemistry, Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received March 26, 2002

Abstract—Features of radical polymerization of methyl methacrylate in the presence of various aromatic nitroso compounds (nitrosobenzene, nitrosodurene, 2,4,6-tribromonitrosobenzene) as potential sources of stable nitroxyl radicals controlling the chain propagation were studied.

Polymerization under conditions of reversible inhibition attracts growing researchers' attention both in Russia and in other countries. Within a short period, these processes have occupied a prominent place among nontraditional methods of polymer synthesis, primarily are to the fact that controllable radical polymerization allows synthesis of polymers with preset properties. The most widely used chain-terminating agents are sterically hindered stable nitroxyl radicals, e.g., 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) and its substituted analogs, which show high performance in the temperature range 120–140°C and, as a rule, are used in polymerization of styrene and its deriva tives [1–8].

It was proposed previously to use spin traps, in particular, *C*-phenyl-*N*-*tert*-butylnitrone [9] and 2-methyl-2-nitrosopropane (MNP) [10], for controlling polymerization under conditions of radical initiation. It was found that these compounds as potential sources of stable radicals allow controllable synthesis of polymers at lower temperatures (50–70°C) and can be successfully used for preparing not only polystyrene, but also polymethacrylates.

With the aim to find new chain-terminating agents, it is interesting to study radical polymerization of methyl methacrylate (MMA) initiated with azobis(isobutyronitrile) (AIBN) in the presence of various aromatic nitroso compounds: nitrosodurene (ND), 2,4,6-tribromonitrosobenzene (TBNB), and nitrosobenzene (NB).

EXPERIMENTAL

Methyl methacrylate was purified as described in [11] by repeated washing with 5–10% alkali solution, followed by washing with distilled water to neutral reaction, drying over $CaCl_2$, and distillation under reduced pressure. ND and NB were prepared as described in [12–14], and TBNB, as described in [15]. The physicochemical constants of the compounds agree with published data. The polymerization kinetics was monitored gravimetrically, dilatometrically [16], and calorimetrically [17]. Samples were prepared as follows: The monomer was placed in glass ampules, degassed three times, and polymerized at residual pressure of 1.3 Pa. The molecular weight M of polymethyl methacrylate (PMMA) was determined viscometrically at 25°C in chloroform [18]. The molecular-weight distribution (MWD) of PMMA was analyzed by gel permeation chromatography (GPC) using a set of five styrogel columns with the pore diameter of 1×10^5, 3×10^4, 1×10^4, 1×10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector; the eluent was tetrahydrofuran. Close-cut polystyrene (PS) references were used for calibration [19]. Recalculation of M from polystyrene to PMMA was performed by the formula $\log M_{PMMA} = 1.019 \log (0.644 M_{PS})$. The ESR spectra were recorded with an AE-4700 radiospectrometer. In the magnetic field calibrations, Mn^{2+} ions in the MgO lattice were used as reference.

We found that aromatic nitroso compounds appreciably affect the MMA polymerization kinetics (Fig. 1). In particular, addition of NB, TBNB, or ND in the presence of AIBN initiator shifts the gel effect to higher conversion and decreases its intensity. These changes are the more pronounced, the higher the nitroso compound concentration. When taken in amounts of 0.01–0.03 mol %, the nitroso compounds fully suppress the effect of polymerization autoacceleration.

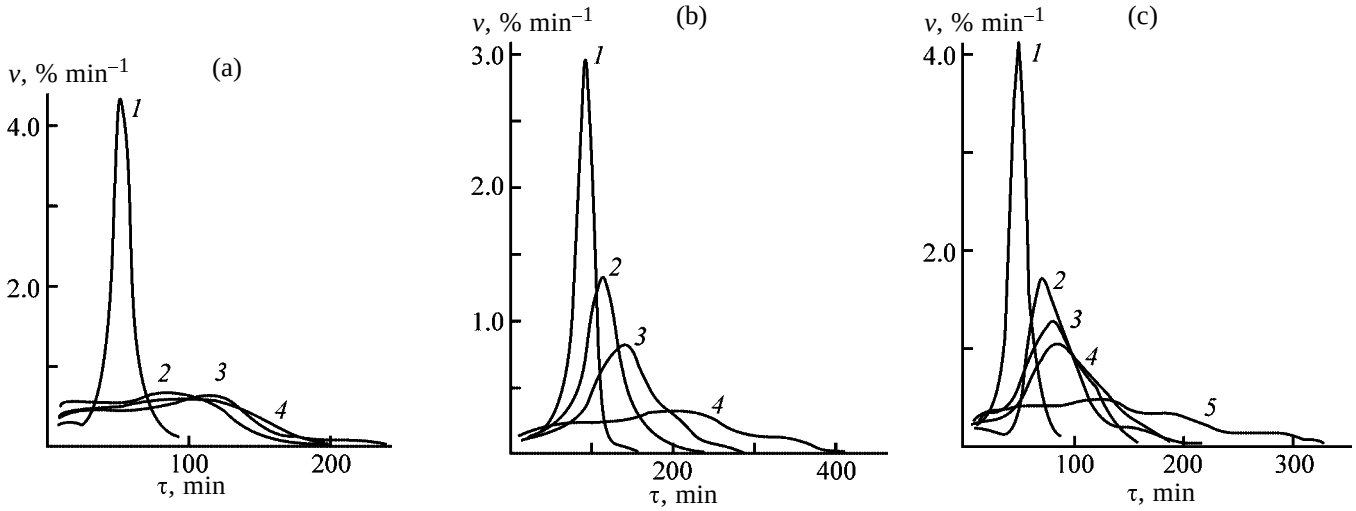

Fig. 1. Differential kinetic curves of MMA polymerization in the presence of aromatic nitroso compounds at (a, c) 70 and (b) 65°C. Initiator AIBN, 0.1 mol %. (*v*) Polymerization rate and (τ) time. Additive: (a) NB, (b) ND, and (c) TBNB; the same for Figs. 2 and 3. Concentration of the additive, mol %: (a) (*1*) 0, (*2*) 0.01, (*3*) 0.02, and (*4*) 0.03; (b) (*1*) 0, (*2*) 0.005, (*3*) 0.01, and (*4*) 0.025; (c) (*1*) 0, (*2*) 0.005, (*3*) 0.015, (*4*) 0.01, and (*5*) 0.03.

It should be noted that, in the presence of NB, ND, or TBNB, as in the case of TEMPO, an induction period is observed, with its duration depending on the structure and concentration of the additive and ranging from 20 min to several hours (Table 1). It should be noted that, with any of the aromatic nitroso compounds, the induction period is somewhat longer than with their aliphatic analogs, e.g., MNP [10], which may be due to differences both in the rate constants of scavenging of propagating radicals with aliphatic and aromatic nitroso compounds and in the stability of the resulting nitroxyl spin adducts:

$$\sim P_n^{\bullet} + R\text{–}N{=}O \rightarrow \sim P_n\text{–}N\underset{(T^{\bullet})}{(O^{\bullet})}\text{–}R, \qquad (1)$$

where $\sim P_n$ is the propagating radical; R = phenyl, 2,4,6-tribromophenyl, 2,3,5,6-tetramethylphenyl (duryl), or *tert*-butyl.

Formation of the above spin adducts in the course of MMA polymerization in the presence of nitroso compounds was detected by ESR. In particular, the ESR spectra contains triplets with the hyperfine coupling constants a_N of 13.5 and 15.4 Oe in the case of ND and TBNB, respectively, or a triplet (a_N = 12.4 Oe) additionally split due to coupling with protons (a_H = 1.9 and 0.9 Oe) in the case of NB.

The nitroxyl spin adducts subsequently participate in the chain propagation stage by reversibly reacting with the propagating radicals $P^{\bullet}$ to form a labile bond, following the reversible inhibition pattern:

$$\wedge\!\wedge\!\wedge P\text{–}T \underset{k_c}{\overset{k_d}{\rightleftarrows}} \wedge\!\wedge\!\wedge \overset{\frown}{P}^{\bullet} + {}^{\bullet}T. \qquad (2)$$

A similar propagation scheme in polymerization of styrene in the presence of phosphorus-containing nitroxyl spin adducts (analogs of TEMPO) was proposed in [20].

As expected from the constants of radical scavenging with ND and TBNB [21], with ND the induction

period in MMA polymerization is somewhat longer than with TBNB. Table 1 shows that, as the nitroso compound concentration is increased, the induction period becomes longer, and the MMA polymerization (as compared to the process performed with a common radical initiator without additives) decelerates. However, it is important for practice that the polymerization deceleration is less significant than with

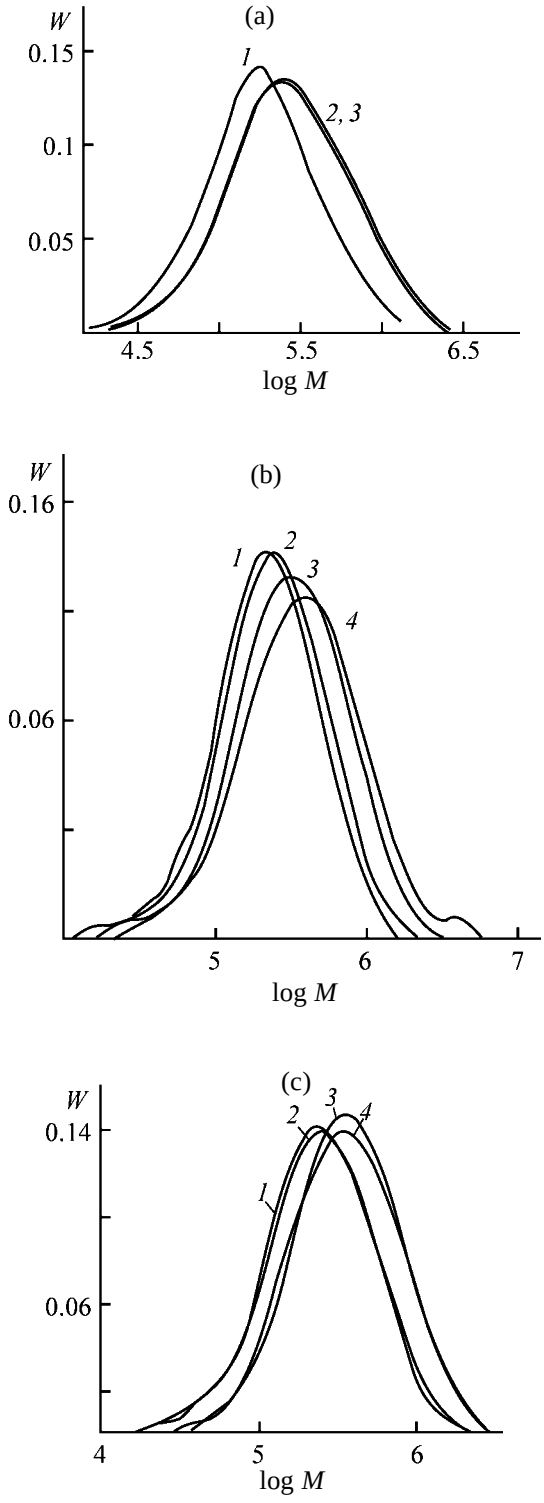

Fig. 3. MWD curves for PMMA samples with various MMA conversions: (*W*) wt fraction and (*M*) molecular weight. Concentration of the additive, mol %: (a, c) 0.03 and (b) 0.025. Conversion, %: (a) (*1*) 12, (*2*) 60, and (*3*) 93; (b) (*1*) 4.8, (*2*) 22.0, (*3*) 50.7, and (*4*) 74.0; (c) (*1*) 16.1, (*2*) 10.8, (*3*) 96.3, and (*4*) 67.7.

TEMPO and its analogs [1–8] with which the polymerization rate decreases by an order of magnitude and more.

Thus, the kinetic study shows that NB, ND, and TBNB efficintly control the kinetic parameters of MMA polymerization. It should be noted that the effect is only slightly dependent on substituents in the aromatic nitroso compound.

Examination of the molecular-weight characteristics of the polymers prepared confirms the conclusions based on the kinetic data. As seen from Figs. 2a–2c (curves *1*), in polymerization of MMA with no nitroso compounds added, a gel effect with an abrupt growth of the molecular weight is observed. Addition of NB, ND, or TBNB suppresses the polymerization autoacceleration, and both viscosity-average and number-average molecular weights linearly increase with conversion (Figs. 2a–2c, curves *2* and *3*, respectively).

Figure 3 shows the MWD curves for PMMA synthesized in the presence of additives at various MMA conversions. It is seen that, on adding NB (Fig. 3a), ND (Fig. 3b), and TBNB (Fig. 3c), the unimodal MWD curves uniformly shift toward higher M with increasing conversion. For PMMA prepared in the presence of aromatic nitroso compounds, the polydispersity coefficients are relatively low, within 1.8–2.0, and do not change noticeably in the course of polymerization. The MMA polymer prepared under comparable conditions (but without additive) has a considerably higher polydispersity coefficient, 2.4 (Table 2). It should be noted that the strongest changes in the molecular weight of the polymer are observed with TBNB (Table 2). This may be due to considerably smaller participation of this additive in chain transfer, as compared to NB and ND [21]. This data also show that the polymeric chain grows in the controllable mode.

Table 2. Molecular-weight characteristics of PMMA prepared at 70°C (0.1 mol % AIBN)

CONCLUSIONS

(1) Polymerization of methyl methacrylate at 65–70°C, initiated with azobis(isobutyronitrile) and performed in the presence of aromatic nitroso compounds as sources of stable nitroxyl radicals, exhibits the main features of controllable radical polymerization: the absence of gel effect, uniform increase in M of the polymer and shift of unimodal molecular-weight distribution curves toward higher molecular weights with increasing conversion, and relatively low polydispersity coefficients of the resulting polymer.

(2) On adding nitrosobenzene, 2,4,6-tribromonitrosobenzene, or nitrosodurene, the polymerization time increases by a factor of no more than 2 as compared to the process without additives; the weaker decelerating effect is an advantage of these additives over 2,2,6,6-tetramethylpiperidine-1-oxyl and its analogs traditionally used for performing polymerization in the "living" chain mode.

(3) The structure of substituents in aromatic nitroso compounds has no noticeable effect on their performance.

Abstract—Radical polymerization of *N*-vinylcaprolactam in isopropanol, initiated with azobis(isobutyronitrile), was studied with the aim to prepare polyvinylcaprolactam of controllable molecular weight. The rate and degree of polymerization are influenced by the reaction mixture composition.

A set of unique properties of polyvinylcaprolactam (PVCL) make it promising for microbiology, medicine, and agriculture. The properties of this polymer in solutions are largely governed by its molecular weight *M*. Therefore, development of simple and efficient procedures for preparing PVCL of required *M* is a key problem in the chemistry of this type of polymers [1]. It is known that, in polymerization of vinylpyrrolidone (VP), isopropyl alcohol (IPA) can be used as chain-transfer agent, and in some cases it is preferred as a means for controlling *M* [1]. In this connection, the goals of this work were to study radical polymerization of *N*-vinylcaprolactam (VCL) in IPA and reveal the advantages and shortcomings of this approach as compared to VCL polymerization in the presence of allyl compounds [2, 3].

EXPERIMENTAL

Polyvinylcaprolactam was prepared by radical polymerization in glass ampules in the presence of AIBN initiator. Air was removed by repeated freeze–pump–thaw cycles in a vacuum to a residual pressure of 0.13 Pa. The polymers were reprecipitated into diethyl ether. The intrinsic viscosity ($cm^3\ g^{-1}$) of the polymers was determined in dimethylformamide at 25°C. The molecular weights of PVCL samples were estimated from the Mark–Kuhn–Houwink equation, $[\eta] = 0.0743M^{0.53}$. This equation was derived from the dependence of the intrinsic viscosity on the number-average increment of *M*, evaluated previously from the MWD curves of PVCL [3]. The polymerization kinetics at 60°C were studied dilatometrically. The initiation rate was evaluated from the induction period of polymerization in the presence of a stable nitroxyl radical, tetramethylpiperidine-1-oxyl (TEMPO). The induction period was linearly dependent on the TEMPO concentration in the system.

The polymerization rate was studied in relation to the reaction mixture composition, VCL/IPA. It is known that, in classical radical polymerization, the reaction is first-order with respect to the monomer. In our case, when the monomer concentration was decreased by a factor of 15, at a constant AIBN concentration of 10^{-2} M, the polymerization rate decreased by a factor of only 7.9. As a result, the reduced polymerization rate $V_p[VCL]^{-1}$ grows with increasing content of IPA, until the IPA : VCL ratio of approximately 8 : 1 is reached. Such a dependence shows that the effect of IPA on the polymerization kinetics is significant. Similar dependences were observed previously for radical polymerization of VP in water and ethanol [4]. The solvent effect is also confirmed by experiments on radical polymerization of VCL in a mixture of IPA with dioxane. We found that, at a constant concentration of the monomer and initiator, the polymerization rate grows with increasing content of IPA in the reaction mixture (Fig. 1). Isopropyl alcohol is not an inert solvent in radical polymerization of VCL. It is known that, in protic solvents, vinyllactam molecules can form hydrogen bonds with the solvent. The hydrogen bonding increases the polarity of the vinyl C=C bond owing to its conjugation with the C=O group via nitrogen atom. This is characteristic of polymerization of both VP and VCL [1, 5]. Apparently, IPA can also form hydrogen bonds with VCL molecules. As a result, we actually deal with copolymerization of the free and solvated monomer species, differing in the polarization of the double bond.

We have examined the dependence of the initiation

rate v_{in} on the reaction mixture composition (Fig. 2). With increasing VCL content in solution, v_{in} grows. This may be due, among other things, to increased initiation efficiency at high monomer concentrations [6]. From the initiation and polymerization rates, we calculated the ratios of the propagation and termination constants, $K_p K_t^{-0.5}$. This parameter increases with dilution of the reaction mixture, which confirms the assumption that the free and solvated monomer species have different reactivity (Fig. 2). The viscosity-average molecular weights M_η of PVCL synthesized at various VCL : IPA ratios are listed in the table. This parameter decreases with dilution of the reaction mixture. The chain-transfer constant was $C_s \sim 6 \times 10^{-4}$. As noted previously [1], in radical polymerization of VP in IPA the main reaction limiting M is the chain transfer to IPA [1]. Analysis of the equation

$$P^{-1} = (K_t K_p^{-2})(v_p[M]^{-2}) + C_s[S][M]^{-1},$$

where [M] and [S] are the concentrations of, respectively, the monomer and chain-transfer agent (IPA), shows that, in our case, at high concentrations of the monomer the first and second summands are comparable, and the chain transfer to IPA becomes a decisive factor limiting M in polymerization of VCL in dilute IPA solutions.

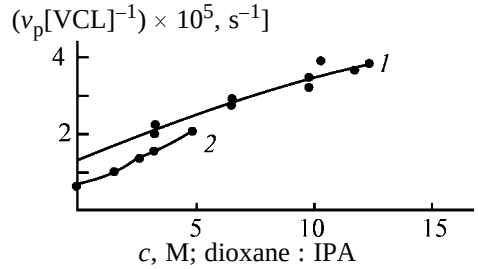

Fig. 1. Reduced rate of VCL polymerization, $v_p[VCL]^{-1}$, as a function (*1*) of IPA concentration c in IPA–VCL mixtures ratios and (*2*) of dioxane : IPA ratio at a constant VCL concentration of 3.71 M. AIBN concentration 10^{-2} M; the same for Fig. 2.

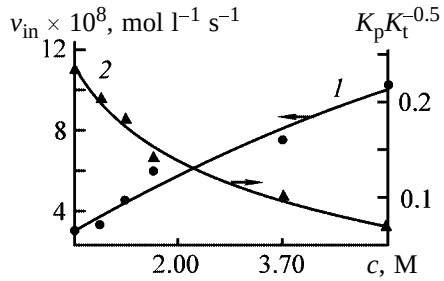

Fig. 2. (*1*) Initiation rate v_{in} and (*2*) parameter $K_p K_t^{-0.5}$ as functions of the VCL concentration in IPA c.

Comparison of theses results with previous data on polymerization of VCL in the presence of allyl compounds [2, 3] shows that both approaches allow preparation of low-molecular-weight PVCL, but the control mechanisms are different. With allylbenzene and allylcaprolactam, the main reaction limiting M of PVCL is degradation chain transfer; its specific feature is that the allyl radical formed by the chain transfer is stabilized by conjugation; therefore, it is low-active and virtually incapable of reacting with the double bond of the monomer. Such chain transfer is essentially equivalent to monomolecular termination. In polymerization of VCL in IPA, an ordinary chain transfer occurs, with bimolecular termination. With allylbenzene and allylcaprolactam, the chain-transfer constants are considerably higher [2, 3] than with IPA. From this viewpoint, IPA has no advantages over allyl compounds. Polyvinylcaprolactam with low M can be prepared only in dilute solutions of the monomer in IPA. At the same time, it should be noted that IPA can be readily removed from the reaction mixture after reaction completion, whereas removal of unchanged allyl chain-terminating agents is a serious problem. Furthermore, by performing polymerization of VCL in IPA, it is feasible to prepare oligomers with terminal hydroxy groups, which may be of particular interest.

Growing attention is given today to synthesis of biodegradable polymers. It is known that polyvinyl-

lactams undergo biodegradation difficultly. The problem can be solved by introducing groups capable of chemical or enzymatic hydrolysis into the backbone [7]. Apparently, one of possible routes to such polymers is the use of VCL oligomers with terminal hydroxy groups as macromonomers capable of reaction with bifunctional compounds to form polymers with heteroatoms in the backbone.

CONCLUSION

Isopropyl alcohol can be used for controlling *M* of polyvinylcaprolactam in radical polymerization. Because of relatively small constant of chain transfer to isopropyl alcohol, low-molecular-weight polymers can be prepared in dilute solutions of vinylcaprolactam in isopropyl alcohol. The observed deviations of the polymerization kinetics from the classical relationships (variation of the parameter $K_pK_t^{-0.5}$ with increasing content of isopropyl alcohol in the reaction mixture) are due to hydrogen bonding of the monomer with the solvent and the presence of free and solvated monomer species, differing in the polarization of the double bond.

Received April 12, 2002

Abstract—Preparation of films from a blend of limitedly compatible epoxy oligomers was considered. The composition and structure of the films were studied by IR spectroscopy and scanning power microscopy, and the film asymmetry was demonstrated. The influence exerted by the composition and curing conditions on the phase separation of the compounds and the structure of the films was revealed.

Polymer–polymer composite coatings structurally nonuniform across the thickness find growing application owing to the possibility of controlling the surface, interface, and bulk properties of the films [1].

These goals are commonly accomplished by multilayer coating with paint-and-varnish materials differing in the composition and purpose. However, preparation of such coatings is time- and labor-consuming; furthermore, additional problems often arise with a poor adhesion between the layers. Self-segregating films based on thermodynamically incompatible or limitedly compatible polymer–polymer, polymer–oligomer, or oligomer–oligomer compounds are free of all these drawbacks [2]. Problems related to preparation of asymmetric films from water-dispersible, soluble, and latex formulations are discussed in [3–5].

Of particular interest in this respect are active glycidyl diluents, which are widely used in commercial production of epoxy lacquers and paints [6]. To obtain asymmetric films, it is necessary to use diluents that are limitedly compatible with the epoxy oligomer and provide controllable distribution of components in the coatings (e.g., due to different densities).

In this work, we examined the possibility of preparing such asymmetric films from E-40 epoxy–4,4'-isopropylidenediphenol (Dian) oligomer and glycidyl esters of phosphorus acids. These esters, as shown in [7, 8], are high-performance active diluents of epoxy oligomers and allow preparation of polymers with a high level of service properties (adhesion, softening point, heat and fire resistance, etc.).

EXPERIMENTAL

Experiments were performed with E-40 epoxy–Dian oligomer and the following glycidyl esters of phosphorus acids (GEPs): triglycidyl phosphate **I**, diglycidyl methyl phosphate **II**, and diglycidyl methylphosphonate **III**; their characteristics are listed in Table 1. As curing agent we used monocyanoethyldiethylenetriamine UP-0633M (stoichiometric coefficient 0.92, viscosity 0.2 Pa s at 25°C, density 1.1 g cm^{-3}).

The compatibility of ED-40 with GEPs was evaluated microinterferometrically with an MI-2 device [9], and the phase diagrams were constructred. The surface tension was determined by the Du Nouy method from the force of detachment of a platinum ring. The size and size distribution of emulsion droplets were evaluated from the turbidity spectra [10, 11]. Optical measurements were performed with an SF-26 spectrophotometer. The viscosity of epoxy oligomer mixtures was measured with a Hoeppler viscometer.

thick, were prepared on various supports (glass, Teflon). The coating structure was examined by scanning power microscopy (SPM) with a Solver P47-SPM microscope in the semicontact mode. For this purpose, we made brittle chips of coatings on glass cooled in liquid nitrogen.

The IR ATIR spectra of the upper and lower surfaces of the coatings on Teflon were recorded with a Bruker IFS-66 V/S Fourier transform spectrometer using KRS-5 prisms (45°).

Figure 1 shows the phase diagram of the systems in hand. It is seen that all the GEPs are limitedly compatible with E-40; however, the incompatibility range contracts in going from **I** to **III**, and the upper critical solution temperature decreases.

In the insolubility range, all the compounds form fairly stable emulsions. This may be due to close surface tensions of the mutually saturated E-40 and GEP phases (Table 2).

The particle size distribution in emulsions is given in Table 3. Gradient coatings are formed by settling of the heavier phase (GEP saturated with E-40) and floating-up of the less dense phase (E-40 saturated with GEP). According to the Stokes equation, the settling or floating-up rate of emulsion particles is determined by their size and by the difference between the phase densities. Owing to broad particle-size distribution of emulsion particles and, correspondingly, broad distribution with respect to settling (or floating-up) rates, the composition changes gradually across the layer thickness.

The settling sharply decelerates as the viscosity of the compounds grows in the course of curing. The curing rate depends on the composition and temperature of the medium. The gel time was determined from the viscosity growth curves in the course of cross-linking of the oligomeric systems. The gel times for various compounds and temperatures are listed in Table 4. It is seen that increased content of GEP and elevated temperatures accelerate gelation and "freeze" settling. Curing of compounds of different compositions at different temperatures allows preparation of coatings with variable gradient of the component concentrations and hence with controllable structure and properties.

The structures of these samples were studied by SPM. Figure 2 shows as example the SPM images of a coating based on E-40–**I** (content of **I** 30 wt %, curing temperature 20°C), made at different heights. It is seen that, in going from the upper to the lower surface, the polymer structure gradually changes from

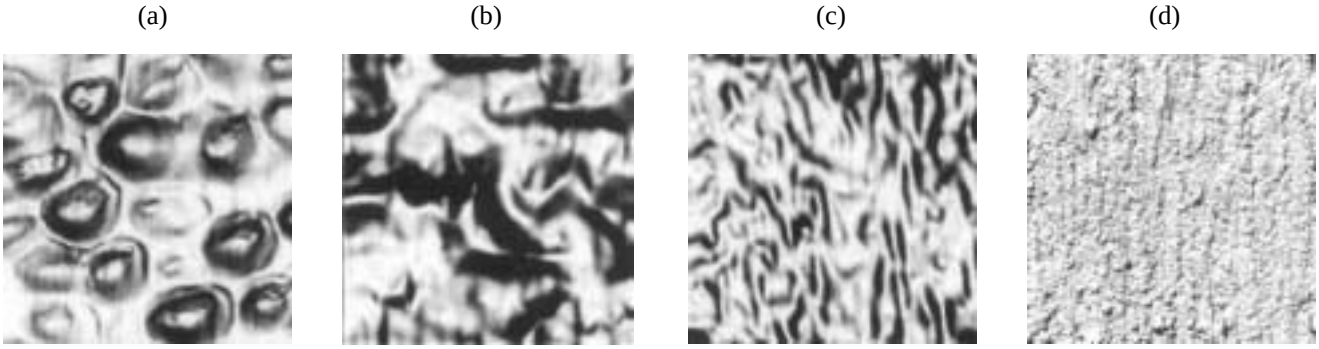

Fig. 2. SPM images of a chip of a coating based on E-40–**I** at various heights. Scanned area 500 × 500 nm; height, μm: (a) 1, (b) 20, (c) 40, and (d) 80.

globular, typical of cured E-40 resin, to nonglobular, typical of densely cross-linked polymer based on **I**. Similar images were taken for all the examined systems at various GEP concentrations and various curing temperatures. We found that, at higher curing temperatures, the coating structure varies more gradually. At lower curing temperatures, the gel time is longer, settling occurs to a greater extent, and the transition from the globular to nonglobular structue is sharper. With decreasing concentration of GEP, the polymer layer with the globular structure becomes thicker.

The concentration ratio of E-40 and GEP in the upper and lower layers of the coatings can be determined from the IR ATIR spectra of the upper and lower surfaces (Fig. 3). The concentration ratio was evaluated from the intensity ratio of the absorption bands of the benzene ring (1610 cm^{-1}, E-40) and phosphoryl or phosphate group (1250 and 1025 cm^{-1}, respectively; GEP). With a 45° KRS-5 prism, the effective penetration thickness was 2.0 ± 0.5 μm depending on the analytical band and the refractive index of the compound. The calculated ratios of E-40 and GEPs in the upper and lower layers of the coatings of different gross composition, cured at different temperatures, are listed in Table 5. It is seen that the GEP content in the upper layer corresponds to its maximal solubility in E-40 (Fig. 1), and the lower layer is the GEP-based phase containing dissolved E-40 in the saturation concentration.

CONCLUSIONS

(1) Asymmetric films with a compositional and structural gradient across the film thickness were prepared.

(2) The phase separation is affected by the nature and concentration of the oligomeric components and by the curing temperature.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Directed Regulation of Biological Activity of Multicomponent Polymeric Structures

G. U. Ostrovidova and A. V. Makeev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received November 29, 2001; in final form, April 2002

Abstract—Biological activity of multicomponent polymeric films based on polyvinyl alcohol, polyvinylpyrrolidone, and lactic acid, containing trypsin and kanamycin, is studied. The degrees of degradation and biodegradation of multicomponent film coatings can be controlled by introduction of polyvinylpyrrolidone or lactic acid and also by variation in their electroforming parameters.

Searching for and developing materials destined for operating in contact with tissues and biological liquors of a living body have attracted growing attention, with a special emphasis made on the structure and composition of the surface, biocompatibility, biodegradation, and antimicrobial action [1, 2].

The existing methods for modification of various materials with biologically active compounds (BACs) not always provide the whole combination of desired properties as well as the prolonged effect of immobilized BACs [3–6]. For example, polyvinyl alcohol (PVA) films with immobilized protease C and polyhexamethyleneguanidine hydrochloride, obtained on the basis of forming solutions of various compositions by the impregnation method, practically lose their enzymatic (in 2–3 h) and antimicrobial activities (in 24 h) [6].

Polymeric structures demonstrating a directional physiological action may be obtained by electroforming on the surface of various materials [7].

EXPERIMENTAL

As polymeric matrices for BACs we used hydrogels obtained on the basis of PVA, polyvinylpyrrolidone (PVP) (content of opened lactam rings ~1%) [7], lactic acid (LA), or their mixtures. To improve the biocompatibility and antimicrobial activity, we introduced a proteolytic enzyme (trypsin) and an antibiotic (kanamycin) in the coating formula. The polymeric matrices were formed on the surface of the composite support (CS) [graphite-extended polydimethylsiloxane rubber (SKTV-med)] or silicon wafers. Properties of the coatings are strongly affected by the working composition formula and forming procedure (in the electric field or by impregnation) [8]. The optimal conditions of forming of multicomponent hydrogel coatings are realized in performing the process in the electric field (field strength 25–30 V cm^{-1}, time 0.5–4 min). In this case, the basic structure-forming components of the polymeric matrix are PVA and boric acid. Electroforming was performed at pH 4.5–6 (in this pH range, PVP molecules are positively charged by virtue of the presence of opened lactam rings). The degree of cross-linking and degradation of the polymeric structures were characterized by the difference in the sample weight upon exposure to water. The adhesive strength of the coatings was determined by the lattice cut method according to GOST (State Standard) 15140–78. Heating of the samples at 50–60°C for 1 h increased the degree of cross-linking of a PVA gel and the adhesive strength and decreased its degradation. To improve the ductility of the coatings formed, glycerol (3 wt %) was added to the working composition.

The concentration and proteolytic activity of trypsin were determined spectrophotometrically (λ = 280 nm) with a casein solution as a substrate [9]. The hemocompatibility of the materials was characterized *in vitro* using the procedure described in [10]. The antimicrobial action of the antibiotic immobilized on the polymeric film was determined by the biological method (diffusion to agar) with *Staphylococcus citreus* culture as a probe [11].

High biocompatibility of the individual polymeric components (PVA, PVP) [7, 12] suggests that the polymeric structure obtained on their basis will be also sufficiently biocompatible with tissues and blood

cells of a living body. Hemocompatibility tests (monitoring of the coagulation rate of normal human plasma in contact with the surface of the tested materials) showed that materials with the hydrogel coating do not initiate processes resulting in thrombosis (Fig. 1). For example, SKTV-med produced only slight coagulation, and the presence of a hydrophilic surface structure reduces this effect, thus improving the hemocompatibility. This fact demonstrates a favoring effect of PVA-based electroformed polymeric systems on the interaction of the material with blood. The biocompatibility, particularly hemocompatibility of a material can be improved by introducing a proteolytic enzyme in the coating formula (Fig. 1).

The use of trypsin as a proteinic molecular probe for characterization of the biocompatibility of the electroformed coatings is based on the sensitivity of the most of enzymes to inactivating effects of the environment [13, 14]. For example, some of the fibrillation factors are associated with alterations in the tertiary structure of protein globules, which cause irreversible transformation of fibrinogen into insoluble fibrin grumes. The power and nature of the effect of the multicomponent polymeric matrix on the trypsin molecule were estimated from the difference in its activity. The experimental results showed that the composite hydrogels based on PVA and PVP have no considerable inactivating effect on immobilized trypsin (see table).

In the electric field of an infralow frequency (meander-line signal), all the components are simultaneously involved in formation of the polymeric system. A PVA–borate hydrogel network is formed at the negative electrode. Its structure may include PVP or LA molecules. In this case, the interaction between PVA and PVP is of the physical (nonspecific) nature. Since the trypsin (amphoteric polyelectrolyte) and kanamycin molecules are positively charged under the experimental conditions [13, 15], the amount of immobilized BACs on the negatively charged support surface can be varied (from 1 to 10 wt %) by changing the process time, which, in its turn, allows control of the enzymatic activity and antimicrobial action. It follows from the results obtained (table, Fig. 2) that increasing immobilization time in the electric field increases the amount of immobilized BACs, which is accompanied by slightly decreasing proteolytic activity of the enzyme. This can be attributed to strengthening of the intermolecular interaction. The electric field strength can affect the enzymatic activity also, as demonstrated in [8, 16]. Data on the amount and activity of immobilized bioactive compounds in the hydrogel coatings based on PVA, PVP, and lactic acid showed that electrical immobilization ensures an effective and controllable concentration of active compounds in the polymeric hydrogel layer (see table and Fig. 2). The amount of immobilized active compounds was found to be well comparable with that obtained in their chemical fixation on polymeric supports [17, 18]; however, the activity of electroimmobilized BACs appeared to be considerably higher. The observed high activity of the coatings obtained is due to the fact that in the electric field, when the enzyme molecules are exposed to simultaneous and specific effect of the adsorption, electrostatic, and dispersion forces, the rate of enzyme immobilization in the hydrogel matrix formed increases by an order of magnitude, as compared to impregnation (see table). With the experimental parameters of the electric field, denaturation of protein molecules is excluded. Formation of the complexes protein–polymeric matrix becomes more favorable in the presence of a hydro-

Bioactive properties of polymeric structures

philic environment, since in this case the free energy is not consumed to compensate the loss in the translational and rotational entropy of the enzyme globule in its adsorption on the hydrogel matrix. As a result, the degree of inactivation decreases. These factors make electroimmobilization of BACs on hydrogel structures highly efficient, preventing denaturation of the enzyme.

Biological tests performed by the method of diffusion to agar [10] showed that the hydrogel structures with the immobilized antibiotic, obtained in the electric field for 2–4 min, have an enhanced antimicrobial activity, as compared to the coatings prepared by impregnation. The zone of growth suppression of the test microorganisms was no less than 40 mm for all the composites studied (Fig. 2). The coatings based on PVA and PVC + PVP demonstrate the most pronounced and prolonged (at least 10 days) antimicrobial action (Fig. 3).

Lactic acid has a considerable effect on the degradation rate. It is known that lactic acid acts as a condensing agent in gelation in aqueous PVA solutions. It is also used to accelerate disintegration of PVA-based goods [12]. Thanks to its tendency to hydrolytic decomposition under the action of biological fluids (blood, saliva, etc.) [19], it is advisable to use lactic acid as a component of PVA-based matrices for controlled release of bioactive agents. Lactic acid is a weaker cross-linking agent for PVA than boric acid, since it forms weaker bonds with hydroxy groups of PVA. Data on degradation of hydrogel structures (Fig. 4) demonstrate that lactic acid totally leaves the polymeric coating in 2 days, favoring gradual degradation of the hydrogel network and release of the antibiotic (Fig. 3). Variation of the lactic acid content in the hydrogel coating allows control of the degradation rate and, therefore, the period of antimicrobial and enzymatic activity. At the same time, introduction of lactic acid in a high concentration (above 50%) results in considerable decrease in the proteolytic

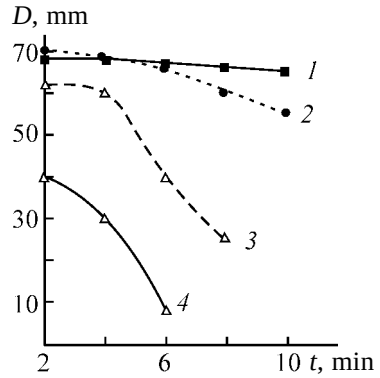

Fig. 3. Kinetic curves of biodegradation of polymeric film antimicrobial structures. Component ratio 1 : 1; kanamycin concentration in the initial composition 1 wt %. (*D*) Growth suppression zone and (*t*) time. (*1*) PVA, (*2*) PVA + PVP, (*3*) PVA + LA (electroforming for 4 min), and (*4*) PVA + lactic acid (impregnation for 30 min).

activity of the immobilized enzyme, trypsin. Therefore, the use of neutral and basic enzymes in coatings containing lactic acid is inadvisable.

CONCLUSIONS

(1) Electroforming of multicomponent film structures based on the hydrogels studied allows effective control of their enzymatic and antimicrobial activities.

(2) At the electric field strength of 20–30 V cm^{-1}, a film containing 1–4 mg cm^{-2} kanamycin and 0.18–0.49 cm^{-2} trypsin is formed in 1–4 min on the surface of material under modification, providing high antimicrobial and proteolytic activities in the course of at least 10 days.

(3) Introduction of such components as polyvinylpyrrolidone or lactic acid and also variation of the electroforming parameters allow directional control of the degradation rate of the resulting film coatings. The degree of degradation in 24 h of the hydrogel structures based on polyvinyl alcohol and composites of polyvinyl alcohol with polyvinylpyrrolidone or lactic acid is 20, 38, and 60%, respectively.

(4) Depending on the formulation of the composite consisting of polyvinyl alcohol, polyvinylpyrrolidone, and lactic acid, its antimicrobial activity is preserved for 4–10 days.

ACKNOWLEDGMENTS

The authors are grateful to M.M. Shamtsyan for help in study of the antimicrobial properties of multicomponent polymeric coatings. The work was financially supported by INTAS FOOD (project no. 00-876).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structural Features of Carbonization of Copolyimides

A. V. Gribanov, M. V. Mokeev, and Yu. N. Sazanov

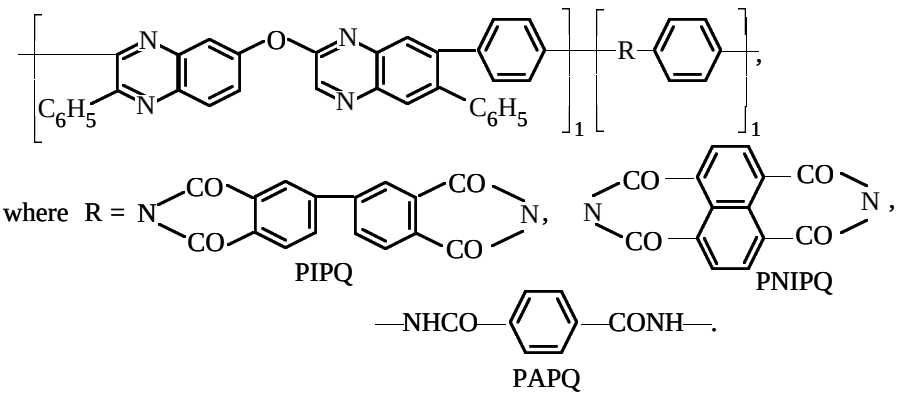
Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 20, 2002

Abstract—The influence of nitrogen-containing heterocycles on the main parameters of carbonization of aromatic copolyimides was considered for aromatic copolyimides containing phenylquinoxaline units as an example. The structural characteristics of intermediates and final products of carbonization were determined.

It is well known that polyimides occupy a very important place among polymeric materials operating under severe thermal conditions [1–3]. In some cases, these conditions result in a certain thermochemical transformation of the polyimide structure to the carbonized structure; the mechanism of this transformation was studied previously [4, 5]. It was found that the nitrogen atom of the benzimide ring of polyimides plays a decisive role in formation of carbonized products. In addition, other nitrogen atoms entering into the composition of polymer composites with polyimide participate in thermochemical cross-linking of the composites and copolymers, imparting qualitatively new characteristics to these materials. For example, copolyimides produced from standard polyimide PM and compounds containing pyrimidine rings have higher strength and heat resistance than polyimide PM and give a larger amount of the coke residue in carbonization [6].

Since the cyclic structure of pyrimidine contains two nitrogen atoms conjugated by the main chain with the benzimide structure, it was of some interest to examine their influence on the copolyimide characteristics as compared to the characteristics of another copolyimide containing two nitrogen atoms in the comonomer, namely, polyphenylquinoxaline (PQO). For this purpose, we used copolyimides of phenylquinoxaline and aromatic polyimide polyimidophenylquinoxaline (PIPQ), polynaphthylimidophenylquinoxaline (PNIPQ), and polyamidophenylquinoxaline (PAPQ) of the general formula



(1)

where R =

PIPQ

PNIPQ

PAPQ

In addition, PQO with the structure corresponding to the left part of formula (1) was carbonized under the similar conditions.

EXPERIMENTAL

The copolymers were produced by the procedure described in [7]. Thermal analysis was carried out on a derivatograph in the self-generated medium at a heating rate of 10 deg min^{-1} with weighed portions of 50 mg. Thermolysis of the samples was carried out on a device for thermal volumetric analysis [8]. High-resolution ^{13}C NMR spectra in solids were recorded at room temperature on a Bruker CXP-100 spectrometer using MAS and cross-polarization. The ^{13}C NMR

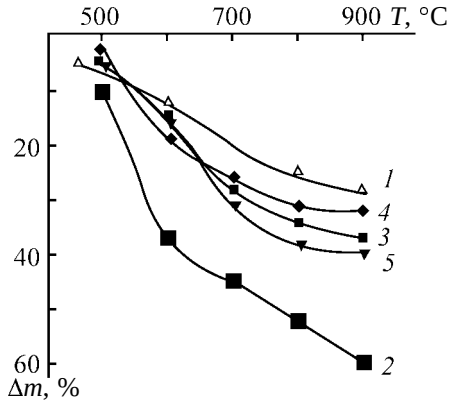

Fig. 1. TGA curve for the initial stage of carbonization of copolyimides. (Δ*m*) Weight loss and (*T*) temperature; the same for Fig. 3. (*1*) PI-PM, (*2*) PAPQ, (*3*) PIPQ, (*4*) PQO, and (*5*) PNIPQ.

spectra were run at 25.18 MHz, the rotation frequency of the samples was 3000–4000 rpm. Chemical shifts (ppm) were referred to TMS (tetramethylsilane).

As known, one of the main criteria of carbonization is the amount of coke residue (CR). The curves for weight loss under the conditions of vacuum thermolysis of the film samples in comparison with polyimide PM are shown in Fig. 1. It is evident that, in the initial stage of carbonization in the range 500–600°C, the weight loss noticeably differs depending on the polymer structure. Even at 600°C, the CR values for copolyimides containing naphthylimide units are lower by only 3–5% than those for polyimide PM. For the PQO sample, these values are lower by a factor of 2 than those for polyimide PM. As regards the PAPQ sample, at 600°C it loses almost 40% of the initial weight. The ratio between the CR values remains approximately the same at higher (up to 900°C) temperatures. With variation of the carbonization conditions (decrease in the heating rate and increase in the keeping time at stepwise heating), in the range 500–600°C, the CR values varied in some cases. To elucidate distinctions in the carbonization kinetics depending on the chemical structure of copolyimides and also to determine the structural features of the products of their carbonization, we studied high-resolution ^{13}C NMR spectra in solids using dipole decoupling.

The high-resolution ^{13}C NMR spectrum of PQO obtained by the standard MAS procedure and cross-polarization (Fig. 2, spectrum *1*) corresponds completely to the structure of its elementary unit. This spectrum consists of the signals at 160 (carbon atoms of aromatic rings at ether bond), 155 (external carbon atoms of pyrimidine rings), 140 (carbon atoms of pyrimidine ring and carbon atoms of other benzene rings directly bonded to them), and 129 ppm (all other carbon atoms of aromatic structures). With proton decoupling, the spectrum changes so that only the signals of carbon atoms not directly bonded to hydrogen atoms remain. The spectra of the intermediates of PQO carbonization at 500 and 600°C (Fig. 2, spectra *3* and *4*) do not differ significantly from the spectrum of the initial product. This suggests that, despite significant weight loss (approximately 20% at 600°C),

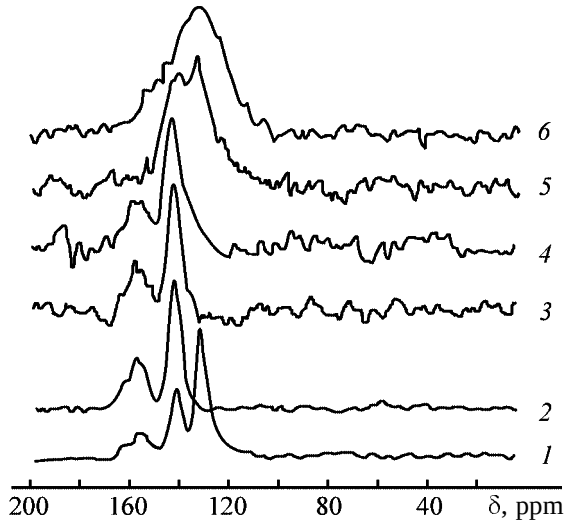

Fig. 2. High-resolution ^{13}C NMR spectra of PQO. (δ) Chemical shift. (*1*) Initial polymer; (*2*) decoupling technique; products of PQO carbonization at *T* (°C): (*3*) 500, (*4*) 600, (*5*) 700, and (*6*) 800°C; the same for Fig. 4.

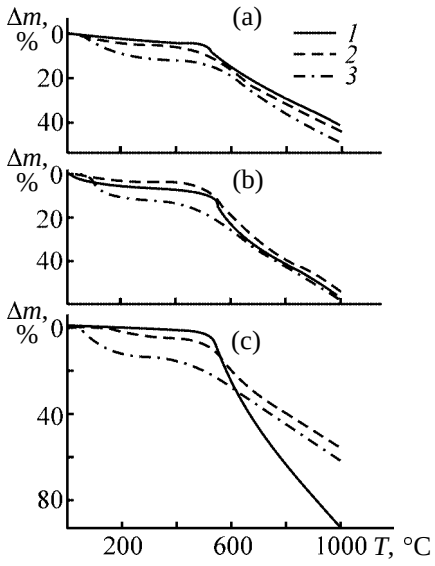

Fig. 3. TGA curves of preheated samples. Preheating temperature (°C): (*1*) 500, (*2*) 600, and (*3*) 900. Sample: (a) PQO, (b) PIPQ, and (c) PNIPQ.

the main structure of the polymer remains the same. As regards the weight loss at the above temperature, it can be assigned to phenyl groups that are side substituents at pyrimidine rings of PQO, and also to some low-molecular-weight fragments formed by rupture of the ether bond at the ends of PQO macromolecules. Such a direction of thermochemical transformations of this polymer is confirmed by the absence of weight loss up to 600°C for the PQO samples preheated to 500°C and 600°C (Fig. 3a). The spectrum of the sample heated in a vacuum to 700°C (Fig. 2, spectrum *5*) is indicative of significant transformation of the structure. There is only a signal at 140 ppm, suggesting high thermal stability of phenylquinoxaline ring; its decomposition starts only above 800°C with appearance of a signal at 128 ppm, showing the onset of formation of a polyheteroaromatic structure (Fig. 2, spectrum *6*). With further heating to 900°C, only the signal at 128 ppm remains. This rearrangement is also reflected in the shape of the TG curve of the sample preheated to 900°C (Fig. 3a). The weight loss at 100–300°C, caused by removal of low-molecular-weight products of thermal degradation, is well pronounced.

The ^{13}C NMR spectrum of PIPQ (Fig. 4a, spectrum *1*) is also in good agreement with the proposed structure of the unit (signals at 168, 155, and 140 ppm). The spectra of the pyrolysis products obtained with proton decoupling (Fig. 4a, spectrum *2*) vary insignificantly up to 600°C. The polymer structure does not vary appreciably, and the appearance of weak signals in the range 170–150 ppm can be explained by degradation of polymeric chains, in particular, by the above changes in the structure of the phenylquinoxaline fragment and also the onset of thermal degradation of the imide ring. As expected, with further heating in the temperature range 600–700°C, the decomposition of the imide ring mainly proceeds with the release of carbon oxides. By the end of this period, the signals of carbon atoms bonded to oxygen atoms disappear completely. Above 700°C, approximately 50% of pyrimidine rings remain in the resulting carbonized products, and the signals corresponding to the mixed heteroaromatic structures formed, similar to the products of thermal degradation of straight polyimide, grow in intensity. As in the case of PQO, for PIPQ preheating to 500–900°C affects the rate of weight loss (Fig. 3b).

The spectrum of the initial PNIPQ obtained by the standard CP MAS technique (Fig. 4b) is consistent with the structure of this polymer. However, this spectrum has poor information content.

In the spectrum obtained with proton decoupling

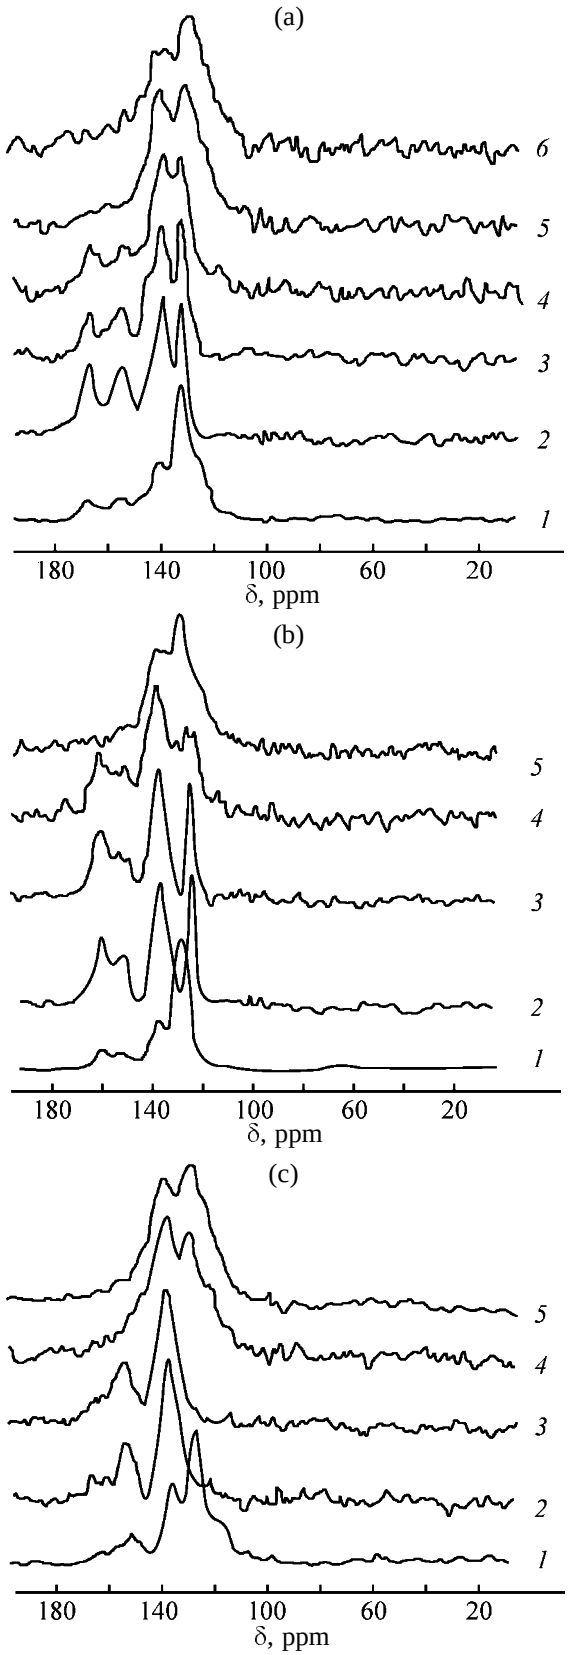

Fig. 4. Hihg-resolution ^{13}C NMR spectra of (a) PIPQ, (b) PNIPQ, and (c) PAPQ.

(Fig. 4b, spectrum *2*), there is a separate relatively narrow signal at 127 ppm assigned to the group of carbon atoms in symmetrical diimidonaphthalenetetracarboxylic dianhydride (hydrogen-free carbon atoms). In this case, the narrow signal is in good agreement with the concept that this group in the above polymer has a planar structure, which is a center of "oriented" carbonization. This structure remains fairly stable up to 600°C and is essentially the dominant of formation of heteroaromatic rings at further heating. The spectral feature of the carbonized product of this copolymer is the presence of a weak narrow signal corresponding to the diimidonaphthalene group at the background of extremely broad (more than 40 ppm) signal of aromatic carbons.

This suggests extremely high thermal stability of this fragment and, evidently, its incomplete incorporation into the resulting polyheteroaromatic structure of the carbonized product. The shape of TG curves (Fig. 3c) also suggests the presence of this structural heterogeneity. The difference in thermal degradation of ordered and disordered domains of PNIP carbonized at various temperatures is also evident from these curves. If carbonized PNIP sample is considered as some turbostratic structure in which the most ordered domain is formed by planar aggregates of diimidonaphthalenetetracarboxylic acid and quinoxaline structures, the disordered linking units are cleaved first in thermal treatment. Low-molecular-weight products of their thermolysis determine the difference in the weight loss in the entire temperature range (Fig. 3c).

The spectrum of PAPQ obtained with proton decoupling (Fig. 4b, spectrum *2*) has the highest information content. It is characterized by fairly early (at 500°C) decrease in the intensity and, later on, disappearance of the signal of amide carbonyl carbon. The other fragments show fairly high thermal stability. Formation of a polyaromatic structure starts at 600°C. The final product of carbonization is also characterized by the presence of a significant amount of heteroaromatic rings (signal at 140 ppm). However, as expected, the presence of labile amide bonds limits the stability of this polymer, which is evident from Fig. 1 (weight loss more than 40%).

CONCLUSIONS

(1) Carbonization of polyphenylquinoxalines and their copolymers with imides and amides proceeds by the mechanism of homolytic and heterolytic thermally induced cross-linking involving nitrogen atoms of the heterocycles.

(2) Contrary to polyimides, introduction of nitrogen atoms into the phenylquinoxaline fragments causes neither adequate enhancement of the thermal stability of the polymers nor significant increase in the amount of the coke residue after thermolysis.

(3) The decisive role of nitrogen-containing rings in formation of stable carbonized structures of turbostratic organization was established.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thoms Effect as Influenced by the Concentration and Molecular Parameters of the Cationic Copolymer of Acrylamide

V. A. Myagchenkov, S. V. Chichkanov, V. E. Proskurina, and A. V. Myagchenkov

Abstract—The Thoms effect observed with water-soluble cationic copolymer of acrylamide was studied in relation to the concentration, molecular weight, and molecular weight polydispersity of the polymeric additive, with its composition and composition polydispersity being constant.

The Thoms effect, i.e., a decrease in the apparent viscosity of turbulently flowing liquids (aqueous media change from laminar to turbulent flow at Reynolds numbers $Re \geq 2 \times 10^3$) due to minor additions of polymers with high molecular weight *M*, is widely used in diverse branches of economy. For example, the Thoms effect underlays measures aimed to increase the velocity of high-speed ships, submarines, and torpedos, accelerate well drilling, and decrease the power consumed by driving systems in various stages of oil extraction and transportation, as well as to increase the hitting range of water jets of fire pumps in putting out severe fires [1, 2]. The Thoms effect depends on a large number of system parameters, above all, on the molecular characteristics and concentration *c* of the polymeric component. It should be noted that many aspects of assessing the Thoms effect as dependent on the molecular characteristics of copolymers require in-depth understanding and more precise determination, as the effect generally depends on both the molecular weight *M* and the composition α of the copolymer. Most of the works devoted to the Thoms effect observed in the presence of copolymers did not take into account these major complications in interpreting the experimental data.

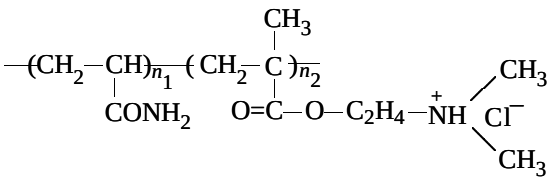
Among the most promising and fairly inexpensive turbulence "quenchers" are (co)polymers of acrylamide (AA) [3]. The major body of information on the Thoms effect as dependent on the molecular characteristics refers to nonionic and anionic derivatives of polyacrylamide [4–8]. For cationic copolymers of AA, the data on the Thoms effect are fragmentary, and the results are not discussed comprehensively [3, 4].

In this work, we correctly estimated the Thoms effect as influenced by the molecular characteristics (*M* and polydispersity in *M*) of water-soluble ionic (cationic) random copolymers of AA with dimethylaminoethyl methacrylate hydrochloride (for all the copolymers studied, the content of ionic units α was 16.3 wt %). Account should be taken of the fact that, for nonionic AA copolymers, most of physical and physicochemical characteristics (in particular, Thoms effect) of the copolymers and compositions thereof are much more strongly dependent on α and chemical heterogeneity (polydispersity in α) than for nonionic AA copolymers [9]. This is due mainly to the fact that the conformation of the macromolecules of ionic copolymers strongly depends on α and polydispersity in α.

To *a priori* ensure constant α and polydispersity in α for the copolymers studied, we chose a nonconventional method of their preparation, namely, random scission of backbone C–C bonds in the macromolecules.

EXPERIMENTAL

As the initial (basic) copolymer for degradation we used high-molecular-weight cationic copolymer of AA with dimethylaminoethyl methacrylate hydrochloride ($M = 2.3 \times 10^6$) of the structural formula



1070-4272/02/7509-1485$27.00 © 2002 MAIK "Nauka/Interperiodica"

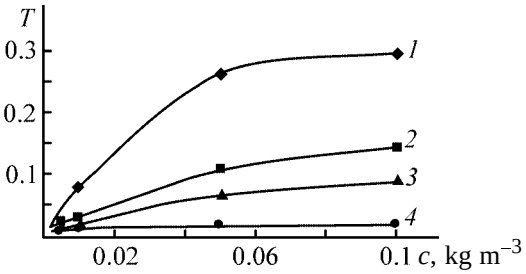


Fig. 1. Thoms effect as a function of the copolymer concentration c. $M \times 10^{-6}$: (*1*) 2.3, (*2*) 0.69, (*3*) 0.24, and (*4*) 0.025.

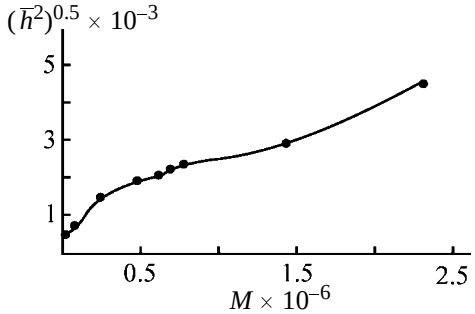

Fig. 2. Root-mean-square distance between the ends of the macromolecule $(\bar{h}^2)^{0.5}$ as a function of the molecular weight of the copolymer M.

Degradation in 0.1% aqueous solution, effected by a radical initiator ($K_2S_2O_8$, 1% of the copolymer mass), was carried out under mild conditions (45–60°C, 6 h). Current monitoring of the degradation kinetics was based on viscometry. We obtained nine samples of cationic copolymers with identical α and polydispersity in α and with strongly (by two orders of magnitude) differing molecular weights M (maximal $M = 2.3 \times 10^6$, minimal $M = 2.5 \times 10^4$). The constancy of α and polydispersity in α for the samples studied can be most easily proven by analyzing the simplified scheme of the copolymer degradation

$$-(A)_n-(B)_m + \dot{R} \rightarrow -(A)_{n-n'}-(B)_{m-m'} + -(A)_{n'}-(B)_{m'} + \dot{Z},$$

where A and B are fragments of AA and ionic monomer, respectively, and $\dot{Z}$ are inactive (toward scission of the backbone bonds of the macromolecules) radicals.

According to Enikolopyan's theory [10, 11], comparative analysis of the molecular characteristics of macromolecular "fragments" does not necessarily require knowing the detailed mechanism of the totality of radical multistage reactions of macromolecule degradation. It is sufficient to be certain that degradation occurs randomly without depolymerization. In our work, these requirements were satisfied, as evidenced by a number of special experiments, in particular, by gravimetric analysis.

For all the copolymer samples studied in this work (even those with the lowest molecular weight, $M = 2.5 \times 10^4$), the degrees of polymerization $(n' + m')$ and $(n + m - n' - m')$ were much greater than 100. Thus, the equality

$$\frac{n}{n + m} = \frac{n'}{n' + m'} = \frac{n - n'}{n + m - n' - m'} \quad (1)$$

holds, as suggested by the general theory of copolymerization [9, 12]. This proves the validity of the previously assumed identity of all the nine samples of the copolymers in both α and polydispersity in α.

The Thoms effect in a turbulent flow of aqueous media was studied by the following scheme. A special pump forced the polymer solutions at a constant pressure through a 0.5×38-mm capillary. Under these conditions, the Reynolds number for water was 5.2×10^3. The Thoms effect was quantitatively characterized by the dimensionless parameter T:

$$T = \frac{m - m_0}{m_0}, \quad (2)$$

where m and m_0 are, respectively, the masses of the copolymer solution and distilled water that passed through the capillary within the time $t = 30$ s.

We measured m_0 and m on an AND (Japan) automatic one-arm electronic balance. Figure 1 shows that the Thoms effect is strongly dependent on the concentration c and molecular weight M of the cationic copolymers of AA. The $T = f(M)$ and $T = f(c)$ plots run in parallel: The Thoms effect increases with M and c. It is convenient to analyze the $T = f(M)$ dependence by comparing the T values for fixed copolymer concentrations. The experimentally observed $T = f(M)$ dependence can be fairly simply explained as follows. Growing M tends to increase the apparent size of the macromolecular coils, which is responsible for their enhanced efficiency in turbulence wave quenching both in the immediate vicinity of the capillary walls and in the course of wave propagation deep inside the liquid [13].

Figure 2 shows how the size of the macromolecules varies with M. The root-mean-square distances between the ends of the macromolecule $(\bar{h}^2)^{0.5}$ with different molecular weights M were calculated under

the assumption that aqueous solutions of cationic copolymers adhere (to a first approximation) to the Flory equation [14]:

$$(\bar{h}^2)^{3/2}\Phi = M[\eta], \quad (3)$$

where $[\eta]$ is the intrinsic viscosity, $cm^3\,g^{-1}$, and $\Phi = 2.8 \times 10^{23}$ is the Flory constant.

The generally accepted views on the role played by the polymeric component in decreasing the effective viscosity of liquids flowing in the turbulent mode agree well, in principle, with the experimentally observed $T = f(c)$ dependences (for fixed M values): The more macromolecules participate in turbulence quenching, the greater T (Fig. 1).

To assess more rigorously the contribution from each new portion of the dosed polymer to the cumulative effect, it is convenient to change from T to reduced Thoms effect T/c. Figure 3 shows that, for fixed M values, the reduced Thoms effect decreases with increasing c, which suggests a decrease in the specific efficiency of quenching the flow turbulence for higher doses. This should be taken into account when choosing the optimal concentration of the (co)polymer c_{opt} for a liquid to be transported through a pipe in the turbulent mode. Clearly, the choice of c_{opt} should take into account, along with M, the costs of the additive and the target product, transportation costs, etc. [2]. The mentioned complex pattern of variation of the reduced Thoms effect with c and M stimulates experiments on assessing the Thoms effect for copolymer mixtures with different molecular weights M. Figure 4 presents the concentration dependence of T for 1 : 1 (by weight) copolymer mixtures including copolymer samples most strongly differing in M ($M_1 = 2.3 \times 10^6$ and $M_2 = 2.5 \times 10^4$). Dashed line is the theoretical dependence (with additive scheme assumed). For this curve we calculated individual points for fixed c values by the formula

$$T_{calc}(c) = \omega_1 T_1(c) + \omega_2 T_2(c), \quad (4)$$

where T_1, T_2 and ω_1, ω_2 are the Thoms effects and the weight fractions of the copolymers with molecular weights M_1 and M_2, respectively.

It should be specified that, in our case, $\omega_1 = \omega_2 = 0.5$. Figure 4 shows that the mixture components exert a synergistic effect, namely, mutually enhance their turbulence quenching powers.

Comparison of the calculated and experimental data for mixtures of cationic copolymers with different molecular weights M suggests that the Thoms effect depends not only on M but also on the polydispersity in M. To prove (or reject) this assumption, we used copolymer samples with different M (and identical α and polydispersity in α) for preparing mixtures with fixed average molecular weight $\bar{M} = 6.1 \times 10^5$ and with *a fortiori* different polydispersities in M. We will illustrate the formulation procedure taking a simple binary mixture of copolymers with $M_a > \bar{M}$ and $M_d < \bar{M}$ as an example. The weight fraction of the component with $M = M_a\omega_a$ was determined from the relation

$$\omega_a M_a + (1 - \omega_a)M_d = \bar{M}, \quad (5)$$

The polydispersity in M for the compositions of copolymer samples with different molecular weight M_i (i = 1–9) was quantitatively characterized by the Schulz parameter F [14]:

$$F = \bar{M}_w/\bar{M}_n - 1 = \sum_{i=1}^{k} \omega_i M_i \sum_{i=1}^{k} \omega_i/M_i - 1, \quad (6)$$

where $\bar{M}_w$ and $\bar{M}_n$ are the weight-average and number-average molecular weights of the mixtures,

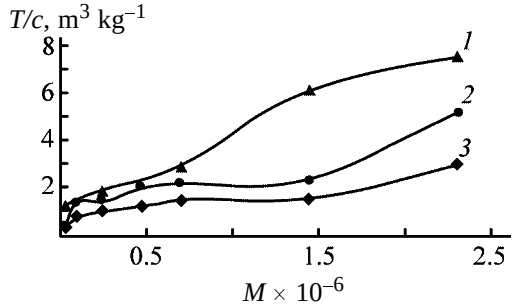

Fig. 3. Reduced Thoms effect T/c as a function of the molecular weight of the copolymer M. $c \times 10^2$, $kg\,m^{-3}$: (*1*) 1, (*2*) 5, and (*3*) 10.

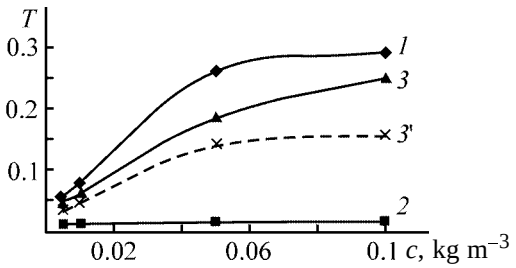

Fig. 4. Thoms effect T as a function of the concentration c of (*1*, *2*) copolymers with different molecular weights and (*3*, *3'*) 1 : 1 mixture of these copolymers. $M \times 10^{-6}$: (*1*) 2.3 and (*2*) 0.025. (*3*) Experiment and (*3'*) calculation by the additive scheme.

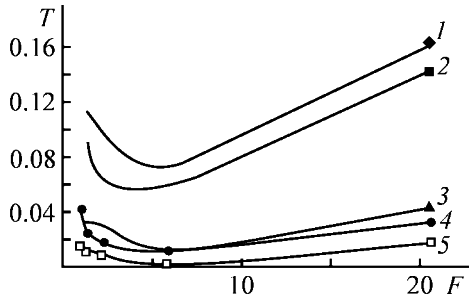

Fig. 5. Thoms effect T as a function of the Schulz parameter F for mixtures of copolymers with $\overline{M} = 6.1 \times 10^5$. $c \times 10^3$, kg m^{-3}: (*1*) 100, (*2*) 50, (*3*) 10, (*4*) 5, and (*5*) 1.

respectively, and ω_i and M_i are the content (weight fraction) and the molecular weight of *i*th polymeric component in the mixtures.

The larger the Schulz parameter F, the greater the polydispersity in M for a composition. The Enikolopyan's theory [11] states that, for each copolymer sample prepared by random scission without depolymerization, the Schulz parameter F is to be taken as unity. Figure 5 shows that the Thoms effect depends on the polydispersity in M for all the copolymer concentrations studied. The maximal Thoms effect corresponds to the largest Schulz parameters F. This, in principle, agrees with the synergistic effect exerted by the components of the mixture of copolymers with the molecular weights M_1 and M_2 (see Fig. 4), as specifically this system is characterized by the largest Schulz parameter (F = 23.5). The minimum in the $T = f(F)$ plot (Fig. 5) and the mentioned synergistic effect exhibited by the copolymer mixture components (Fig. 4) suggest that the contributions from individual fractions of cationic copolymers of AA with different molecular weights M to the cumulative Thoms effect are not additive. Without touching upon the complex and, in many respects, disputable theories concerning the Thoms effect in the case of mixed polymeric additions, we will assume the following. The relationships for the Thoms effect revealed in this work are due to the changes in the local concentrations and in the ratio of the mixture components in a thin layer of the liquid adjacent to the liquid–solid interface in the close proximity to the capillary walls [15].

CONCLUSIONS

(1) Cationic copolymers of acrylaminde exhibit a minimum in the plot of the Thoms effect vs. the polydispersity in the molecular weight, provided that the composition and polydispersity in the composition of the copolymer are constant.

(2) The components of a binary mixture of copolymers with strong polydispersity in the molecular weight exhibit a synergistic effect in flow turbulence quenching.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Degree of Binding of Double-Charged Cations in Solutions of 2-Acrylamido-2-Methylpropanesulfonate Copolymers

V. F. Kurenkov, I. Yu. Kolesnikova, and O. A. Antonovich

Kazan State Technological University, Kazan, Tatarstan, Russia

Received December 11, 2001; in final form, April 2002

Abstract—The degree of binding of Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} cations with polysulfonate anions in aqueous solutions of 2-acrylamido-2-methylpropanesulfonate polymers and their binary mixtures with acrylamide and *N*-vinylpyrrolidone with various molecular characteristics was studied by the Terayama–Wall viscometric procedure.

Water-soluble polymers of salts of 2-acrylamido-2-methylpropanesulfonic acid (H-AMS) and their binary copolymers with acrylamide (AA) and *N*-vinylpyrrolidone (VP) are effective structure-forming agents and regulators of rheological properties of solutions for drilling and petroleum production [1, 2], flocculants [3–5], adhesives, and antistatic agents [6]. The nature of cation strongly affects the preparation and properties of the (co)polymer solutions. For example, the effect of double-charged cations in H-AMS salts was found previously in the course of their polymerization [7] and copolymerization with AA [8] and VP [9, 10]. The qualitative dependences of the counterion association in polyelectrolyte solutions were determined previously in [11]. In this work, the degree of binding of Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} cations in solutions of salts of poly-H-AMS (H-PAMS) and binary copolymers of H-AMS salts with AA and VP was quantitatively evaluated by the Terayama–Wall viscometric procedure, which is important for monitoring the radical copolymerization of H-AMS salts in aqueous solutions and for controlling the properties of aqueous (co)polymer solutions.

EXPERIMENTAL

In our work, we used samples of Na-PAMS and copolymers of Na-AMS with AA and VP prepared by radical polymerization [7] and copolymerization [8, 9] in aqueous solutions. The polymers were recrystallized from aqueous solutions in acetone, washed with acetone, and dried in a vacuum desiccator at room temperature to constant weight. The properties of the polymers studied are listed in Table 1. The viscosity-average molecular weight M_η of Na-PAMS was calculated from the following equation [13]:

$$[\eta] = 1.95 \times 10^{-5} M_\eta^{0.83},$$

where the intrinsic viscosity $[\eta]$ ($cm^3\ g^{-1}$) was determined in 0.5 M NaCl solution at 25°C.

The intrinsic viscosity $[\eta]$ of copolymer solutions was measured with an Ubbelohde viscometer (d_c = 0.56 mm). The content of ionic groups in the copoly-

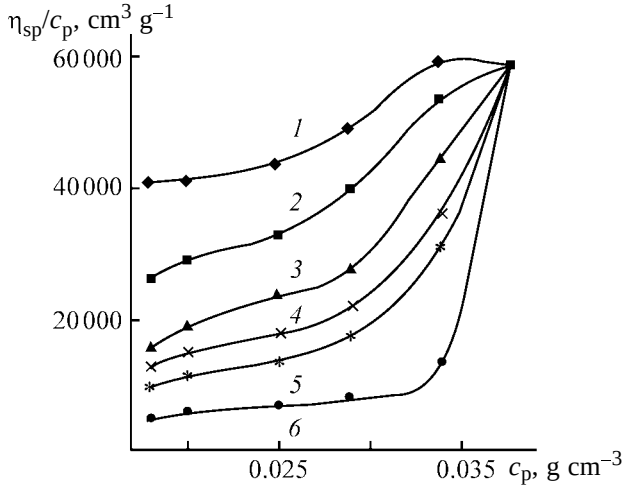

Fig. 1. Reduced viscosity η_{sp}/c_p of aqueous solutions of Na-AMS-AA copolymer (sample B) as a function of the copolymer concentration c_p at isoionic dilution with NaCl solution. c_e/c_p: (*1*) 0.46, (*2*) 1.38, (*3*) 2.31, (*4*) 4.61, (*5*) 23.1, and (*6*) 32.4.

mers was determined from the content of sulfur [14]. In our work we used chemically pure grade reagents. To study the counterion association, samples of Na-PAMS and binary copolymers of Na-AMS with AA and VP were converted into the hydrogen form by ion exchange on KU-2 × 8 sulfonic acid cation exchanger, which was pretreated according to the procedure given in GOST (State Standard) 10896–78. The salts of polyelectrolytes with double-charged cations were prepared by potentiometric titration, with cooling and stirring, of solutions of H-PAMS and binary copolymers of H-AMS with AA and VP to pH 7 using a solution of NaOH or suspensions of $Mg(OH)_2$, CaO, SrO, and $Ba(OH)_2$, with subsequent removal of the insoluble residue.

The intrinsic viscosity $[\eta]$ of copolymer solutions was measured at 30°C using a VPZh-3 viscometer (d_c = 0.56 mm). The kinetic energy correction was as low as 2% and thus was not taken into account in the evaluation of the reduced viscosity of the solutions η_{sp}/c_p, where c_p is the polymer concentration.

The potentiometric titration was performed using a pH-121 pH-millivoltmeter equipped with an ESL-63-07 working glass electrode and an EVL 1M-3 silver chloride reference electrode.

The degree of binding of counterions, which can be used as a criterion of interaction of cations with anions in polyelectrolyte solutions, is determined by the following expression:

$$\alpha_b = 1 - \alpha_f,$$

where α_f is the fraction of free counterions.

To determine α_b of metal cations with polysulfonate anions derived from H-AMS salts, we used the Terayama–Wall viscometric procedure [12]. This method is based on the analysis of the $\eta_{sp}/c_p = f(c_p)$ curves registered in the course of isoionic dilution of a polyelectrolyte solution with a solution of a low-molecular-weight electrolyte with a similar cation. The conformation of the polyanion in the polyelectrolyte solution is determined by its charge, and, according to the Terayama–Wall assumption, the isoionic dilution of the polyelectrolyte solution (in which the polymer conformation is retained) can be used to determine α_b. These conditions correspond to the linear dependence $\eta_{sp}/c_p = f(c_p)$; in this case, $\alpha_f = c_e/c_p$, where c_e is the concentration of low-molecular-weight electrolyte at which the $\eta_{sp}/c_p = f(c_p)$ is a linear function. Commonly, the $\eta_{sp}/c_p = f(c_p)$ dependence passes through a minimum at high c_e and a maximum at small c_e. Thus, the shape of the $\eta_{sp}/c_p = f(c_p)$ curve allows evaluation of the electrolyte concentration c_e at which the dependence studied will be linear. The values of α_b for K^+ cations in solutions of potassium salts of cellulose sulfate [12] agree with the data of electrochemical analysis. As found in [15], α_b for Cd^{2+} in solutions of poly-*p*-styrenesulfonic acid determined by the Terayama–Wall method and by polarography are in good agreement.

The $\eta_{sp}/c_p = f(c_p)$ curves registered at isoionic dilution of Na-AMS–AA copolymer (sample B) with an NaCl solution are shown in Fig. 1. No linear sections of the $\eta_{sp}/c_p = f(c_p)$ dependence were found in a wide range of NaCl concentrations, which makes evaluation of α_b impossible. Similar phenomenon was found for solutions of Na-PAMS and Na-AMS–VP copolymer. The fact that the Terayama–Wall procedure is inapplicable for quantitative evaluation of α_b for Tl^+ in poly-*p*-styrenesulfonic acid solutions was mentioned previously in [15].

To assess the possibility of the viscometric evaluation of α_b for double-charged cations in solutions of polyelectrolytes in question, we recorded the $\eta_{sp}/c_p = f(c_p)$ curves for the homopolymers (Mg-, Ca-, and Sr-PAMS) in the presence of respective salts ($MgCl_2$, $CaCl_2$, and $SrCl_2$). In all the above cases, we determined the optimal c_e at which the $\eta_{sp}/c_p = f(c_p)$ curves becomes linear. The $\eta_{sp}/c_p = f(c_p)$ dependence at isoionic dilution of Mg-PAMS solution (sample A) with $MgCl_2$, which becomes linear at c_e/c_p = 0.41, is shown in Fig. 2 as example. As seen from Table 2, in

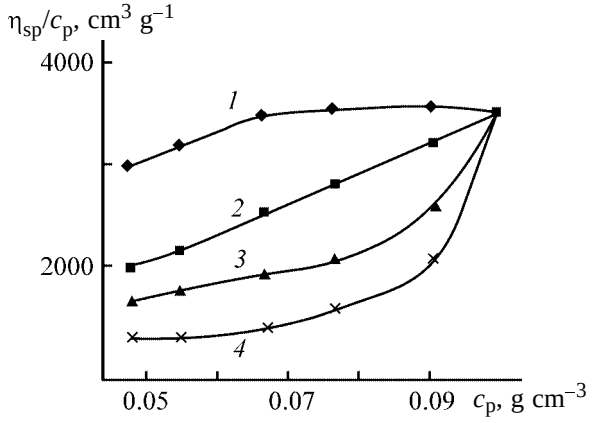

Fig. 2. Reduced viscosity η_{sp}/c_p of aqueous solutions of Mg-PAMS polymer (sample A) as a function of the polymer concentration c_p at isoionic dilution with $MgCl_2$ solution. c_e/c_p: (*1*) 0.30, (*2*) 0.41, (*3*) 0.61, and (*4*) 0.81.

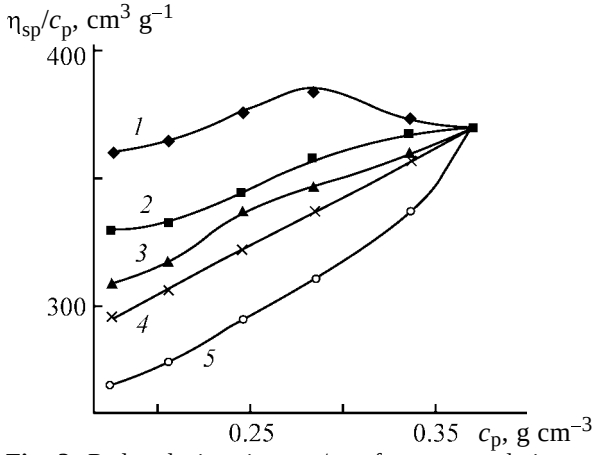

Fig. 3. Reduced viscosity η_{sp}/c_p of aqueous solutions of Ca-AMS copolymer with AA (sample C) as a function of the copolymer concentration c_p at isoionic dilution with $CaCl_2$ solution. c_e/c_p: (*1*) 0.06, (*2*) 0.11, (*3*) 0.14, (*4*) 0.22, and (*5*) 0.23.

the case of homopolymers (H-PAMS salts, sample A), α_b decreases in the order $Sr^{2+} > Ca^{2+} > Mg^{2+}$.

This dependence agrees with the effect of strontium, calcium, and magnesium cations on the η_{sp}/c_p values at c_p = const for solutions of H-PAMS in the presence of $MgCl_2$, $CaCl_2$, and $SrCl_2$ [11], and published data for the salts of poly-*p*-styrenesulfonic and polyvinylsulfonic acids, obtained by conductometry, osmometry, dilatometry, and IR spectroscopy [16, 17].

We analyzed binding of Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} cations with polysulfonate anions of H-AMS salt copolymers with AA (samples C, D). The copolymers differed in [η] and in the chemical composition (Table 1). The resulting linear dependences $\eta_{sp}/c_p = f(c_p)$ (see, e.g., Fig. 3, curve *4*) allowed evaluation of α_b and α_f, which are presented in Table 2. For copolymers with various molecular characteristics α_b decreases (at c_p = const) in the order $Mg^{2+} > Ca^{2+} > Ba^{2+}$ (Sr^{2+}).

The binding of cations with polysulfonate anions was also successfully evaluated for copolymers of Mg-, Ca-, Sr-, and Ba-AMS with VP (samples E, F). As seen from Fig. 4, the $\eta_{sp}/c_p = f(c_p)$ curve becomes linear at c_e/c_p = 0.74 (curve *3*); the resulting α_b values are listed in Table 2. These data show that, similar to the case of H-AMS salt copolymers with AA, for H-AMS salt copolymers with VP α_b decreases in the following order: $Mg^{2+} > Ca^{2+} > Sr^{2+}$ (Ba^{2+}).

The data given in Table 2 indicate that the binding efficiency of double-charged cations with polysulfonate anions in copolymers varies in the opposite direction as compared to homopolymers (H-PAMS salts). This is true for H-AMS salt copolymers with both AA and VP, irrespective of the variations in the molecular weight (determined from [η]) and chemical composition of the polymer macromolecules (Table 1). Similar inversion of the binding efficiency of double-charged cations with polyanions on passing from homopolymers to copolymers with the same polyanions was found previously in [11]. Such variation in α_b for copolymers as compared to homopolymers is probably due to the interaction of sulfonate and amide groups of binary copolymers of H-AMS salts with VP [18] and AA [19] in aqueous solutions.

Our study showed that the above dependences in

Table 2. Degree of cation binding with polyanions in solutions of polyelectrolytes based on H-AMS salts

Sample	c_p, %	Cation	$\alpha_b = 1 - \alpha_f$
A	0.100	Mg	0.59
		Ca	0.67
		Sr	0.96
C	0.371	Mg	0.81
		Ca	0.78
		Ba	0.22
D	0.008	Mg	0.23
		Ca	0.17
		Sr	0.09
E	0.623	Mg	0.84
		Ca	0.78
		Ba	0.26
F	0.210	Mg	0.64
		Ca	0.55
		Sr	0.13

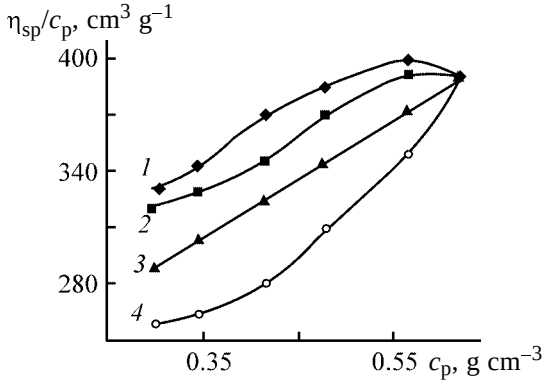

Fig. 4. Reduced viscosity η_{sp}/c_p of aqueous solutions of Ba-AMS copolymer with VP (sample E) as a function of the copolymer concentration c_p at isoionic dilution with $BaCl_2$ solution. c_e/c_p: (*1*) 0.41, (*2*) 0.57, (*3*) 0.74, and (*4*) 0.82.

binding of double-charged cations with polysulfonate anions are general, because they were determined for (co)polymers with equal molecular weight and at c_p = const (Table 1), and the reverse order in variation of α_b depending on the double-charged cation radius (Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+}) for copolymers (as compared to homopolymers) was found for the samples with different molecular properties (molecular weight, chemical composition, and nature of nonionic groups) and in a wide concentration range (0.006–0.6%). The dependences of the counterion association can be useful for interpretation of specific features of solutions of strong polyelectrolytes based on H-AMS and for their direct synthesis in aqueous solutions, because they explain the effect of the cation on the kinetics of homopolymerization of H-AMS salts [7] and their copolymerization with AA [8] and VP [9, 10]. This fact is probably due to the effect of the degree of cation binding with polyanions on the intensity of electrostatic interactions and on the conformation state of growing macroradicals, which affect the reactivity of the ionic monomers and their macroradicals in radical reactions [20, 21].

CONCLUSIONS

(1) The Terayama–Wall viscometric procedure can be used for quantitative evaluation of the degree of binding of cations in solutions of binary (co)polymers of magnesium, calcium, strontium, and barium 2-acrylamido-2-methylpropanesulfonates with acrylamide and *n*-vinylpyrrolidone, but it is inapplicable to the (co)polymers of sodium 2-acrylamido-2-methylpropanesulfonate.

(2) The degree of binding decreases in the order $Sr^{2+} > Ca^{2+} > Mg^{2+}$ for polymeric salts of 2-acrylamido-2-methylpropanesulfonic acid, and in the reverse order, $Mg^{2+} > Ca^{2+} > Sr^{2+}$ (Ba^{2+}), for binary copolymers of metal 2-acrylamido-2-methylpropanesulfonates with acrylamide and *N*-vinylpyrrolidone with various molecular properties.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Metal Complex Binding on the Properties of Polymethyl Methacrylate

R. S. Davletbaev, I. M. Davletbaeva, Yu. G. Galyametdinov, and K. E. Kalachev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received January 18, 2002; in final form, March 2002

Abstract—Coordination binding of polymethyl methacrylate with copper(II) ions was studied by IR spectroscopy and viscometry.

Metal complex modification of polymers is a promising way to affect macrochain conformation, their structure, formation of supramolecular structures, and, ultimately, the performance of the materials produced. Metal-complex binding, along with cross-linking action, imparts new specific properties to polymers (magnetic, electric, nonlinear-optical, catalytic, etc.). Coordination binding of macrochains may proceed in solutions and melts of polymers and in the course of their synthesis [1, 2].

Synthesis and properties of metal-coordinated polyurethanes (MCPU) are described in [3–5]. Preparation of MCPU involves preliminarily synthesis of metal complexes and their introduction into the urethane-forming reaction system. It was found that metal complex modification of polyurethanes changes their physicomechanical properties and sharply (by 4–5 orders of magnitude) decreases the volume and surface electrical resistivity. The physicomechanical properties of MCPU pass through several extrema. The first maximum lies in the region of very small metal ion concentrations. Studies performed showed that these phenomena are caused by formation of additional intermolecular interactions due to coordination binding of electron-donor groups.

Therefore, it was interesting to study the effect of metal complex binding on the properties of the other polymers whose macrochains contain electron-donor groups. In this work, we chose polymethyl methacrylate (PMMA). It contains ester groups capable of coordination binding, has a linear structure, and is well soluble in polar organic solvents. In addition, methyl methacrylate, similar to methyl acrylate, is the initial reagent for synthesis of paramagnetic mesomorphic comb-shaped metal-coordinated polymers [6]. The features of metal complex binding of PMMA can serve as a model for the further study of coordination binding of comb-shaped polymers. The product of the reaction between $CuCl_2$ and *N*,*N*'-diethylhydroxylamine (DEHA) was used as a metal complex modifier. In this reaction, the oxidation degree of a part of copper(II) ions decreases, DEHA is oxidized to nitrone, and polynuclear complexes in which both copper(I) and copper(II) ions are bound by chloride bridges [7] are formed. It was found that copper(I, II) binds heteroatoms of the macrochain with substitution of labile chloride bridges by electron-donor groups. To confirm this mechanism, copper(II) chloride was also used in metal complex modification of PMMA.

To prepare modified samples, $CuCl_2$–DEHA or $CuCl_2$ were introduced into a solution of PMMA in acetone. The resulting polymer was examined as acetone solution or as films. In the IR spectrum of the product of PMMA interaction with a $CuCl_2$–DEHA mixture, the band at 1730 cm^{-1} belonging to stretching vibrations of the PMMA carbonyl groups becomes narrower as compared to the initial PMMA, and a new strong band at 1630 cm^{-1} appears (Fig. 1). According

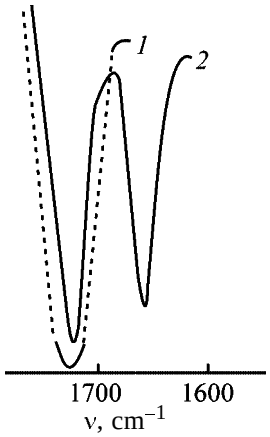

Fig. 1. IR Spectra of (*1*) PMMA and (*2*) product of PMMA reaction with $CuCl_2$–DEHA mixture. (ν) Wave number.

1070-4272/02/7509-1494$27.00 © 2002 MAIK "Nauka/Interperiodica"

to [5, 8], these changes result from coordination binding of PMMA carbonyl groups. They are not observed when straight Cu(II) chloride is added to PMMA. This confirms the main role of chloride bridges in coordination binding between the metal ion and electron-donor groups of macrochains.

The influence of metal complex binding on conformation of PMMA chains was studied by viscometry. As seen from Fig. 2, the dependence of the intrinsic viscosity on the $CuCl_2$ concentration has two maxima. The twofold increase in the intrinsic viscosity indicates that two adjacent PMMA molecules coordinate with Cu(II) via their carbonyl groups. As a result, the macromolecules get unrolled and increase in size.

The intrinsic viscosity of a PMMA solution in acetone and of this solution modified with a $CuCl_2$–DEHA mixture decreases similarly with temperature rise (Fig. 3). This shows that the coordination binding of macrochains is preserved on heating. At the same time, the intrinsic viscosity of solutions containing PMMA and $CuCl_2$ changes insignificantly as compared to that of the initial PMMA solution (Fig. 2). In this case, measurements were performed within a narrow range of $CuCl_2$ concentrations because of the low $CuCl_2$ solubility in acetone. Since the IR spectra of films prepared from a PMMA solution and a solution containing both PMMA and $CuCl_2$ are similar, we can suggest that PMMA macrochains are located in the outer coordination sphere of the Cu(II) ion. In parallel with increase in the intrinsic viscosity of PMMA modified with $CuCl_2$–DEHA, the hardness and luster of films obtained from solutions noticeably increase (Fig. 4). Such effect of metal complex binding on the mechanical properties of PMMA films can be caused by additional interactions between PMMA macrochains, which are preserved after solvent evaporation. On the contrary, the hardness of films obtained from PMMA–$CuCl_2$ solutions somewhat decreases.

The comparison of the concentration dependences of the mechanical properties of MCPU [5], hardness of modified PMMA samples, and intrinsic viscosity of their solutions shows that the properties of these polymers as functions of the $CuCl_2$ content in the $CuCl_2$–DEHA modifying system also pass through extrema. For example, the MCPU hardness in the region of small $CuCl_2$ contents has a maximum. For PMMA, the intrinsic viscosity of solutions and hardness of solid films pass through maxima.

The decrease in the volume resistivity by 4–5 orders of magnitude is the most substantial effect in

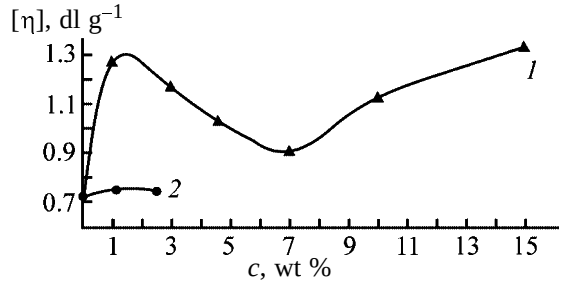

Fig. 2. Intrintic viscosity [η] as a function of $CuCl_2$ concentration c for PMMA solutions modified with (*1*) $CuCl_2$–DEHA mixture and (*2*) $CuCl_2$.

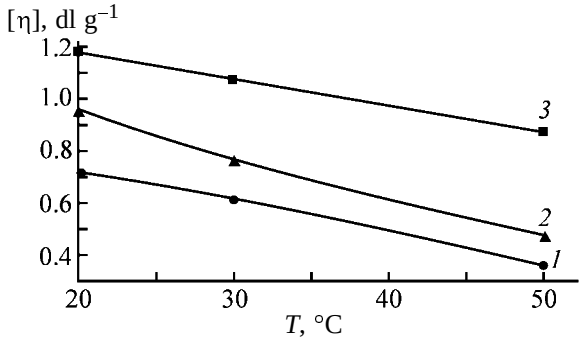

Fig. 3. Intrinsic viscosity [η] of PMMA solutions in acetone modified with $CuCl_2$–DEHA mixture as a function of temperature T. $CuCl_2$ concentration (wt %): (*1*) 0, (*2*) 3, and (*3*) 5.

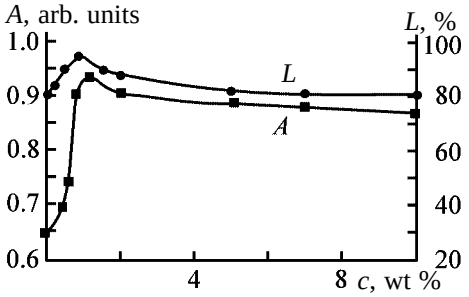

Fig. 4. Hardness A and luster L of films obtained from acetone solutions of PMMA modified with $CuCl_2$–DEHA mixture as functions of $CuCl_2$ concentration c.

metal complex binding of polyurethanes. It decreases jumpwise within the $CuCl_2$ concentration range 0.1–0.3% depending on the nature of the flexible polyurethane chains. As the content of metal complex modifier is increased further, the specific volume resistivity slightly increases. The main role in the mechanism of charge transfer in MCPU belongs to electron-donor groups of the polyurethane matrix and to the presence of copper ions in two oxidation states (I) and (II). In this connection, we studied electrophysical properties of PMMA modified with the $CuCl_2$–DEHA system.

It follows from Fig. 5 that the volume resistivity of films of modified PMMA sharply decreases in the

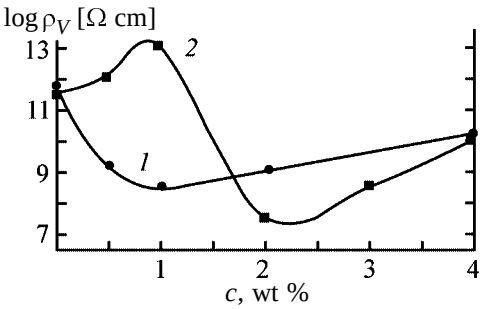

Fig. 5. Volume resistivity ρ_V of PMMA films modified with (*1*) $CuCl_2$–DEHA mixture and (*2*) $CuCl_2$ as a function of $CuCl_2$ concentration *c*.

region of small copper(II) chloride concentrations. At higher $CuCl_2$ concentrations, the volume resistivity somewhat increases. For PMMA modified with $CuCl_2$ only, a decrease in the resistivity after its initial increase occurs at higher $CuCl_2$ concentrations. This is probably due to appearance of Cu(II)–Cu(I) exchange pairs because of partial copper(II) reduction in acetone solutions [9]. As a whole, the experimental dependences obtained allow us to rule out the ionic mechanism of the electrical conductance and to follow the electronic model of charge transfer, previously proposed for MCPU [3].

EXPERIMENTAL

N,N'-Diethylhydroxylamine was distilled at 48°C and 13 hPa. Pure grade $CuCl_2 \cdot 2H_2O$ was dehydrated by heating for 5–6 h at 110°C. Copper(II) chloride was dissolved in DEHA at a molar ratio of 1 : 1.

The IR spectra were recorded on a Perkin-Elmer 16 C FT-IR Fourier spectrometer. The error in determination of the IR frequency was ±1 rel. %. Films prepared from acetone solutions were used as samples.

The intrinsic viscosity was measured with an Ubbelohde viscometer at 20°C. The film hardness was determined on an M-3 pendulum device. The luster was measured with an FB-2 photoelectric device. The volume resistivity of films was measured on an E6-13A teraohmmeter with a 2.5% error. Films were cast on a conducting glass, which was placed into a special measuring cell.

CONCLUSIONS

(1) In reaction of polymethyl methacrylate with $CuCl_2$–*N,N'*-diethylhydroxylamine mixture, the polymethyl methacrylate ester groups coordinate with copper ions, which results in cross-linking of adjacent macrochains. As a result, the intrinsic viscosity of polymethyl methacrylate increases (twofold), and its films become harder. Modification of PMMA with straight copper(II) chloride does not produce similar effects.

(2) Metal complex binding of PMMA decreases the volume resistivity by four orders of magnitude. The charge transfer has electronic but not ionic mechanism.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reaction of Copper(II) with Polyacrylic Acid and Its Copolymers in Dilute Solutions

V. N. Kislenko and L. P. Oliinyk

L'viv'ska Politekhnika National University, Lviv, Ukraine

Received April 19, 2002

Abstract—The effect of the concentration of copper(II) and polyacrylic acid (or its copolymers) and of pH on the amount of bound copper in precipitation of copper salts with poly acids was studied.

Carboxyl-containing polymers find growing application for precipitation [1] and separation [2] of heavy metals. This requires further study of interaction between metal ions and polymeric acids in aqueous solutions. Mandel and Leyte [3] showed that copper(II) nitrate reacts with polymethacrylic acid to form complexes with one and two carboxy groups of the polymer. In the latter case, the reaction proceeds in two stages. At high copper(II) concentrations, 1 : 1 complexes and, at low concentrations, 2 : 1 complexes are formed [4]. Viscosimetric study showed that each copper(II) ion can react with one, two, and four carboxy groups of polymethacrylic acid [5, 6]. In the presence of Cu(II), the molecular weight of polymethacrylic acid increases, which suggests formation of bridges between two macromolecules [6, 7]. It follows from the kinetic study that the activation energy of Cu(II) chelation with polymethacrylic acid is fairly low and amounts to 24–28 kJ mol^{-1}, the activity of isotactic polymethacrylic acid being 1.5 times higher than that of the syndiotactic acid [8]. At the same time, it should be noted that colloid-chemical features of formation of copper(II) precipitates with poly acids are studied insufficiently.

Polyacrylic acid reacts with copper(II) sulfate in dilute solutions to give insoluble copper polyacrylates. The concentration of bound copper(II) ions in the reaction mixture decreases with increasing polyacrylic acid concentration and reaches a minimum at the molar ratio of carboxy groups to bound copper ions equal to 2 (Fig. 1, curve *1*). This confirms published data [5, 6] that chelates are formed in which the copper ion binds two carboxy groups of the poly acid.

The concentration of bound copper increases with decreasing the initial concentration of the poly acid. This is probably due to increase in pH. The dependence between the amount of bound copper and pH is linear (Fig. 1, curve *2*). Probably, polyacrylic acid favors precipitation of copper(II) basic salts formed by hydrolysis of copper(II) sulfate in dilute aqueous solutions. Indeed, at the constant concentration of polyacrylic acid, the concentration of bound copper(II) ions linearly increases with increasing the initial concentration of copper sulfate (Fig. 2).

The curves of titration of freshly precipitated copper hydroxide suspension with polyacrylic acid have a plateau at pH ~ 5 (Fig. 3, curves *1, 2*) indicating salt formation. The molar ratio of copper to carboxy groups equal to 1 suggests formation of copper(II) basic salts with polyacrylic acid within the pH range 4.5–5.0. An increase in the initial concentration of polyacrylic acid decreases the plateau length, probably due to changes in the size of macromolecule globules in the solution. This is confirmed by the shape of the curve of titration of a copper(II) hydroxide suspension with a dispersion of acrylic acid–acrylonitrile copolymer (Fig. 3, curve *3*). In this case, the plateau is absent, since the reaction proceeds only between the

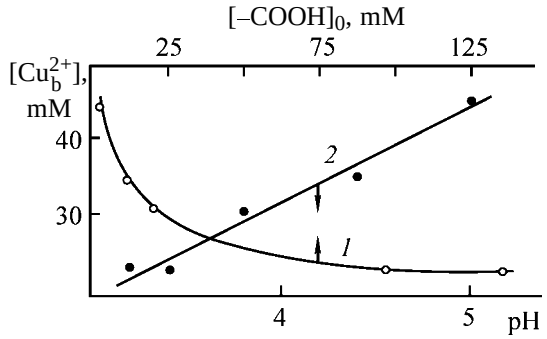

Fig. 1. Concentration of bound copper(II) ions, $[Cu_b^{2+}]$, as a function of the (*1*) initial concentration of polyacrylic acid carboxy groups $[–COOH]_0$ and (*2*) pH. Initial concentration of copper(II) sulfate 62 mM.

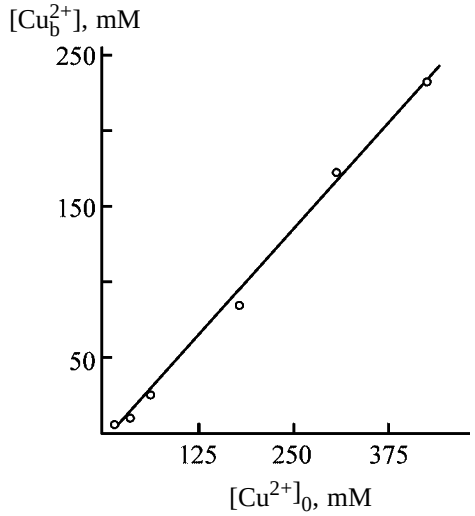

Fig. 2. Concentration of bound copper(II) ions, [Cu$_b^{2+}$], as a function of the initial concentration of copper(II) sulfate, [Cu^{2+}]. Initial concentration of polyacrylic acid 1.4 g l^{-1}.

surface carboxy groups of copolymer particles and copper(II) hydroxide groups located on the surface of dispersion particles. As a result, insoluble basic salts formed on the surface of the reacting particles stop the reaction.

Then we studied the reaction of copper ammine complexes with ammonium polyacrylates at decreasing pH. Titration of ammonium polyacrylate with hydrochloric acid showed that, at pH close to 6, there is an inflection in the titration curve, probably caused by conformational transitions in the polyacrylic acid macromolecule (Fig. 4, curve *1*). At pH 2.5–3.0 polyacrylic acid precipitates. The titration curve of the copper ammine complex has two plateaus (Fig. 4, curve *2*). The first plateau at pH ~8 probably corresponds to formation of chloride salts of the copper ammine complex, and the second plateau at pH 5.0–5.5, to complete decomposition of the complex and formation of a copper hydroxide precipitate. At pH decreased further, the precipitate dissolves with formation of copper(II) chloride. Titration with hydrochloric acid of a mixture of ammonium polyacrylate and copper ammine complex showed that initially, at pH ~8, salts of the copper ammine complex with polyacrylic acid are formed. At the further decrease in pH, copper ammine complex completely decomposes, and basic copper salts with polyacrylic acid are formed. Copper polyacrylates precipitate only at pH 3.0–3.5. Light green color of the solution over the precipitate at pH 3 shows that copper(II) chloride is partially formed. Similar titration curves are obtained when mixtures of the copper ammine complex and ammonium salts of acrylic acid–acrylonitrile copolymers are titrated with hydrochloric acid. A decrease in the concentration of carboxy groups in the copolymer increases pH of the copper salt precipitation.

As seen from Fig. 5, an increase in the ratio of the initial molar concentrations of the carboxy groups of poly acids and copper ions decreases the copper ion concentration in the solution after precipitate formation. Thus, a decrease in the acrylic acid content in the copolymer allows more complete binding of copper ions and hence decrease in their concentration in the solution over the precipitate. This is probably due to

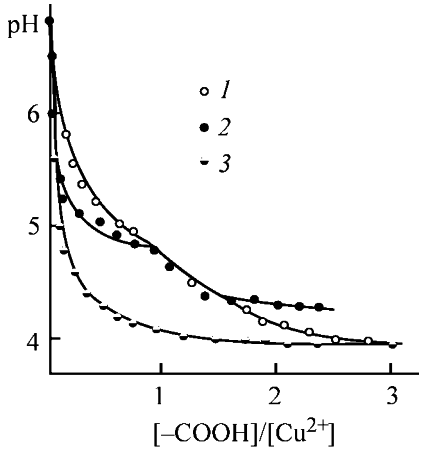

Fig. 3. Titration of copper(II) hydroxyde suspension with (*1, 2*) polyacrylic acid and (*3*) acrylic acid–acrylonitrile copolymer PAAN-1. Initial concentration of copper(II) hydroxide in the suspension 6.3 g l^{-1}. Concentrations (g l^{-1}): polyacrylic acid (*1*) 22 and (*2*) 11; PAAN-1 copolymer (*3*) 31.

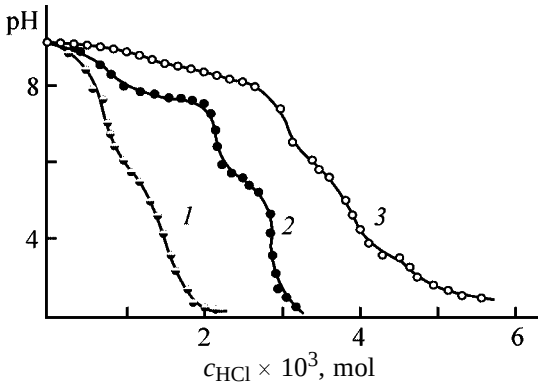

Fig. 4. Titration of (*1*) ammonium polyacrylate, (*2*) copper(II) ammine complex, and (*3*) their mixture with 0.1 M hydrochloric acid. Initial concentrations: polyacrylic acid carboxy groups 60 mM and copper(II) ions 12 mM. (c_{HCl}) HCl amount.

the fact that the copper salt with the acrylic acid–acrylonitrile copolymer is formed at higher pH (up to pH 5.0 for PAAN-3 copolymer). This favors formation of copper(II) hydroxide, which precipitates together with basic copper polyacrylates.

An attempt to calculate complex formation constants of copper with polyacrylic acid and its copolymers with acrylonitrile failed, probably because of colloid-chemical features of the process, which is accompanied by two parallel reactions: formation of insoluble copper salts with poly acids and formation of copper(II) hydroxide at pH close to 5. Copper polyacrylate forms a shell around copper hydroxide particles, which prevents $Cu(OH)_2$ dissolution during titration with hydrochloric acid. At the same time, the dependence of the concentration of bound copper ions on the initial concentration of the copper ammine complex and ammonium polyacrylate is well approximated by a straight line in the logarithmic coordinates [Fig. 6, Eq.(1)]:

$$\log([Cu_b^{2+}]) = \log A + K\log([COOH]_0/[Cu^{2+}]_0). \quad (1)$$

The correlation coefficients and constants of copper salt formation with poly acids, calculated by Eq. (1), are presented below:

Polymer	R	$\log A$	K
PAA	0.911	0.9 ± 0.5	0.84 ± 0.18
PAAN-1	0.982	-2.4 ± 0.2	0.70 ± 0.08
PAAN-2	0.926	-3.1 ± 0.4	0.52 ± 0.16

Equation (1) and the constants found allow calculation of the amounts of polyacrylic acid and its copolymers with acrylonitrile that should be added to the copper ammine complex to decrease the copper ion concentration in the solution to the required level (at pH ~ 3 for polyacrylic acid and 4 for acrylic acid–acrylonitrile copolymer).

EXPERIMENTAL

Chemically pure grade anhydrous copper(II) sulfate and freshly distilled acrylic acid and acrylonitrile were used. Polyacrylic acid and its copolymers were prepared by polymerization initiated with potassium persulfate. The monomer conversion, which was determined by the bromide–bromate method, in all cases exceeded 99.5%. Acrylic acid–acrylonitrile copolymers were obtained as dispersions stabilized with ammonia. The content of acrylic acid in copolymers was determined by potentiometric titration in dimethylformamide. The molar ratio of acrylic acid to acrylonitrile in the copolymers was 3.43 (PAAN-1), 1.22 (PAAN-2), and 0.78 (PAAN-3). The molecular weight of polyacrylic acid, measured viscometrically, was 1.6×10^5. The intrinsic viscosity of polyacrylic acid and its copolymers, determined in dimethylformamide at 26°C, was 1.303 (acid), 1.324 (PAAN-1), 1.436 (PAAN-2), and 1.275 (PAAN-3). Copper hydroxide dispersion was prepared by precipitation with sodium hydroxide and was washed with distilled water to negative reaction for sulfate ions.

The copper(II) concentration in the solution after separation of the copper salt precipitate was determined spectrophotometrically at 448 nm (absorption of the copper ammine complex). The concentration of

bound copper was determined as difference between the initial copper concentration and the copper ion concentration after the precipitate separation.

CONCLUSION

The influence of colloid-chemical factors on the amount of bound copper during precipitation of copper salts with poly acids was characterized.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Formation of Hydrogen Bonds in the System Polyamidine–Low-Molecular-Weight Dye

A. S. Bobashova, M. M. Dudkina, and M. N. Nikolaeva

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received May 13, 2002

Abstract—The interaction of poly-1,10-decamethyleneacetamidine with some low-molecular-weight additives was studied. It was shown by nuclear magnetic relaxation and IR spectroscopy that linear dyes of the bis-hydroxyalkanone type form hydrogen bonds with amidine groups of the polymer, and the strength of these bonds depends on the degree of dissociation of the dye.

Amidines are widely used in medicine and technology; also, they are the subjects of active research in organometallic chemistry. At present, low-molecular-weight amidines are well known, while polymers containing amidine groups, which are of interest for many applications, are not adequately studied [1]. The structure and characteristics of these polymers were studied by ^{1}H, ^{15}N, and ^{13}C NMR both in solids and in solutions, and also by thermal gravimetric analysis [1–3]. Polyamidines have the general formula –NH–CR=N–, where R is an aliphatic or aromatic group.

It is known [4] that polymeric networks of polyamidines, formed by hydrogen bonds with dyes, are capable of nonlinear optical (NLO) behavior. As regards production of complexes with NLO behavior, polyamidines show much promise, which is due to high basicity of amidine groups [5]. In this work, we studied the structure of complexes of ionogenic comb-shaped polymers, namely, poly-1,10-decamethyleneacetamidine, with the functional group in the main chain and low-molecular-weight polyconjugated NLO dyes of the bis-hydroxyalkanone type. It was shown previously [4] that poly-1,10-decamethyleneacetamidine can form fairly heat-resistant, stable for a long time (more than 1 year) film-forming polymeric complexes with dyes, capable of efficient generation of the third harmonic. However, the relationship between the chemical structures formed by polyamidine with NLO dyes and macroscopic characteristics of the resulting associates has not been adequately studied [6].

Here we paid attention to variation of the characteristics of the polymers as a result of formation of comb-shaped structures and their possible supramolecular ordering. It was important to study the mechanism of formation of supramolecular polymer structure upon addition of the dye and the mechanism of rupture of the existing hydrogen-bonded polymer network. In addition, it is believed that the relationship between the acidity of the low-molecular-weight compound and the basicity of the polyamidine should significantly affect the structure of the complexes. To confirm this assumption, the compounds having similar structure but different dissociation constants pK_a were selected as low-molecular-weight additives. The aim of this work was also to determine the temperature range of existence of hydrogen bonds in the system polyamidine–low-molecular-weight additive and to elucidate changes in the supramolecular structures with time.

Formation of hydrogen bonds in the above systems was studied by NMR relaxation and IR spectroscopy. IR spectroscopy is widely used for analysis of systems forming hydrogen bonds [7]. NMR relaxation allows monitoring of the mobility of polymer chains and determination of structural changes of molten systems in time.

In this work we studied the interaction of poly-1,10-decamethyleneacetamidine (hereinafter, polyamidine)

Apparently, the characteristics of the resulting polymer networks will depend on the number of deprotonated hydroxy groups. The choice of the first three low-molecular-weight additives is based on the fact that the negative logarithms of the dissociation constants pK_a of these compounds are different. Considering the possibility of deprotonation of hydroxy groups of dyes **III** and **IV**, we can assume that deprotonation takes place and these hydroxy groups form hydrogen bond with the amidine group of the polymer, since the pK_a values for these dyes are lower than for polyamidine (pK_a 10.8 [5]): for dye **III**, pK_a is 8.6 [8], and for dye **IV**, 9.2. In the case of dye **III**, both hydroxy groups can be deprotonated, but to a different degree, since their dissociation constants are different. Therefore, in spite of possible formation of hydrogen-bonded network, the ionicity of the resulting bonds at different pK_a should be different: the lower pK_a, the more ionic are the bonds and, hence, the higher is their strength. This is also apparently true for the molecules of the other dyes. With dye **IV**, whose acidity is close to the acidity of dye **III**, only comb-shaped structures can be formed. 4,4'-Dihydroxydiphenyl, having low acidity (pK_a ~ 13), is not, most likely, deprotonated in a mixture with polyamidine and, probably, forms weak hydrogen bonds with the functional groups of the polyamidine. Thus, the basicity of polyamidine must be sufficient for deprotonation of molecules of **III** and **IV**, while dye **II** should remain protonated. Possible effect of the steric structure of the dye on formation of the polymer network was studied with complexes of polyamidine with phenolphthalein having nonlinear structure.

EXPERIMENTAL

The spin–spin relaxation time T_2 for polyamidine and a mixture of polyamidine with low-molecular-weight chromophores was measured in the temperature range 70–180°C. The measurements were carried out in melts on an RRP-1 relaxometer.

The melting point of polyamidine is approximately 70°C, and that of dye **III**, approximately 245°C. As a result of heating of the polymer with dyes, melts are formed, and the color of the system changes. The spin–spin relaxation times T_2 increased with time for all mixtures of substances, reaching some stable level (Fig. 1).

The increase in T_2, shown in Fig. 1 for 90°C, is also characteristic of other temperatures at which the experiments were carried out.

The results obtained refer to the first type of sample heating (from 80°C gradually to 180°C). In the second case, to obtain the relaxation dependences for polyamidine and its mixture with chromophores, the samples were heated to 180°C, kept at this temperature for 15 min, cooled to 80°C, and then heated again to 180°C.

The concentration of the dyes was 15 mol %. The choice of this concentration is due to the fact that the maximum capacity of polymer with respect to the dye is 20 mol %.

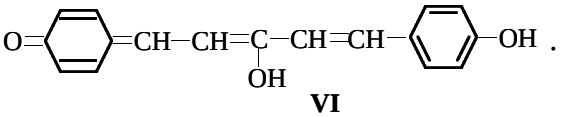
The IR spectra of the above mixtures, polyamidine, and dye **III** were recorded on a Bruker IFS 88 spectrophotometer in KBr pellets (in the case of individual dye) and in films (in the case of polyamidine and a mixture of polyamidine with dye).

It is known [1] that polyamidine molecules form stable interchain hydrogen bonds. Addition of a dye should result in competition of the functional groups of the dye and polymer for formation of hydrogen

bonds. As seen from comparison of the IR spectra (Fig. 2a), a hydrogen bond is formed between the polymer and dye **III**. Since the NMR relaxation method used in the experiments furnishes information on the proton mobility, variation of the relaxation rate in the samples also suggests variation of the bond strength between the components.

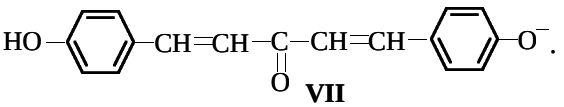
The data obtained from relaxation measurements allow a conclusion that the energy of the hydrogen bond between the polymer and low-molecular-weight additives in the melts of their mixtures and also in straight polyamidine varies in time. Since the time dependences of the spin–spin relaxation time were obtained at varied temperature, we can assume that the apparent increase in T_2 is caused by the presence of crystalline and amorphous phases of polyamidine. On heating, the fraction of the amorphous component of the polymer increases, and the polymer structure returns to the initial structure within several months. In addition to increase in T_2 with time, T_2 also varied depending on the particular additive (Figs. 1, 3). It is well known that, with increasing viscosity, the spin–spin relaxation time T_2 decreases [9] and, with increasing temperature, the trend is usually reverse [9]. Since the melt viscosity should not vary significantly with addition of substances with close molecular weights, we can conclude that the shorter relaxation time for a mixture of poyamidine with **III** as compared to its mixture with **II** suggests formation of stronger bonds for a mixture with dye **III**. One of the possible mechanisms of the interaction of the polyamidine with the additives is deprotonation of the OH group of the dye and formation of a hydrogen bond with the amidine group of the polymer with the degree of ionicity depending on the degree of deprotonation.

Deprotonation of hydroxy groups of low-molecular-weight dyes can result in formation of a structure of the quinoid type, which is confirmed by the appearance of absorption bands in the range 480–530 nm. For example, in a mixture of polyamidine with dye **III** this absorption band appears at 500 nm [6]. For dye **III** this quinoid structure has the form



VI

The deprotonated nonquinoid structure has the form



VII

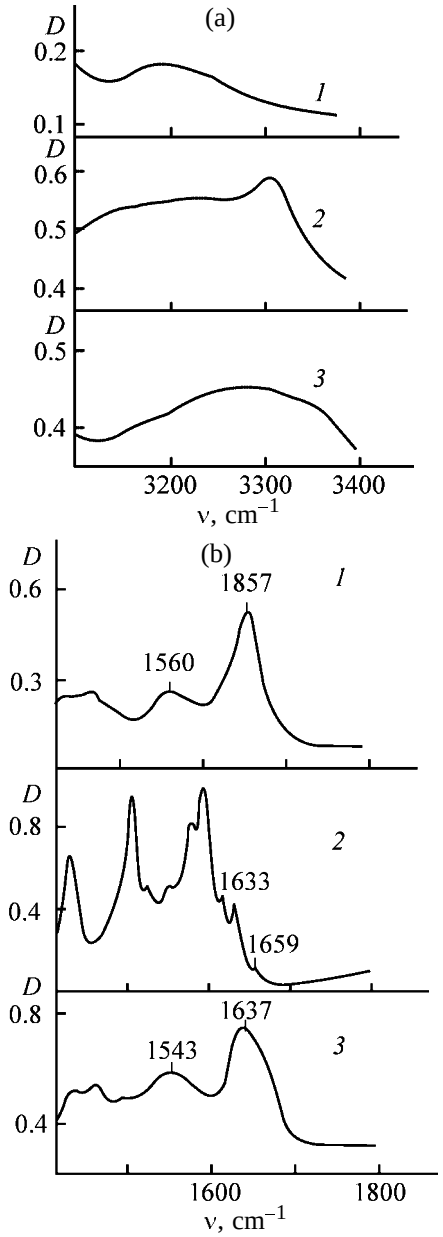


Fig. 2. IR spectra of (*1*) polyamidine, (*2*) bis(4-hydroxybenzylidene)acetone, and (*3*) a mixture of polyamidine with 15% of bis(4-hydroxybenzylidene)acetone in the range of (a) hydrogen and (b) double bonds. (*D*) Optical density and (ν) wave number.

As follows from NMR data, in a mixture of polyamidine with dye **III** in deuterated methanol the content of quinoid structures is approximately 10% [6]. Deprotonation of dye **III** in a mixture with the polyamidine is evident from the ^{13}C CPMAS spectra; in this case, the degree of deprotonation increases with increasing polymer concentration in the mixture.

The absorption band of the C=N stretching modes in the polyamidine is observed at approximately

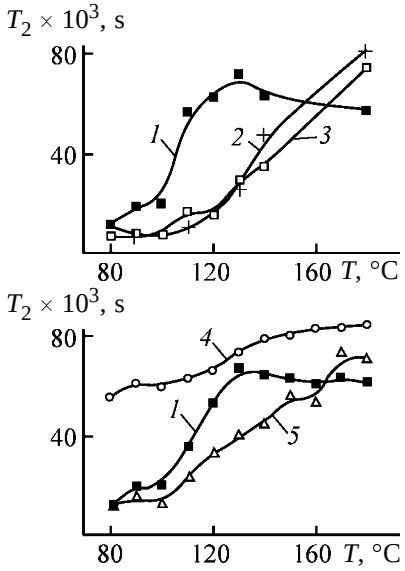

Fig. 3. Spin–spin relaxation time T_2 as a function of temperature T for (*1*) polyamidine and (*2*–*5*) polyamidine with various additives. Additive (15%): (*2*) bis(4-hydroxybenzylidene)acetone, (*3*) (4-hydroxy-4′-methoxybezylidene)acetone, (*4*) dihydroxydiphenyl, and (*5*) phenolphthalein.

1650 cm^{-1}, while the absorption band of the keto groups is usually observed at a higher frequency [10]. The absorption band of the keto group of dye **III** in the solids is significantly shifted toward low frequencies (Fig. 2b; 1633 and 1659 cm^{-1}), which suggests the formation of an intramolecular hydrogen bond. This assumption is confirmed by theoretical calculations [6] and X-ray diffraction data [2]. The absorption bands of the C=N bond are shifted, which suggests participation of this group in the bonding. Comparison of the two main peaks (Fig. 2b) in the spectra of the polyamidine and a mixture of polyamidine with dye **III** shows appearance of shoulders in the spectrum of the mixture. These shoulders are absent in the spectrum of straight polyamidine. This suggests the presence of two forms of the amidine group in the system: bonded to dye and free amidine group.

In addition, in a mixture of the polymer with dye **III**, the bands of the stretching modes of the benzene ring are shifted (absorption bands at approximately 1500, 1600, and 3030 cm^{-1}). The positions of these bands are governed by the substitution pattern; therefore, this shift can be explained by the interaction of hydroxy groups of dye **III** with the polyamidine. It is evident that, in the system polyamidine–dye **III**, several types of hydrogen bonds can coexist. This is confirmed by the fact that, in the spectrum of a mixture of polymer with dye **III**, the absorption bands assigned to hydrogen bonds differ from those in the spectrum of straight dye **III** (Fig. 2a). Hydrogen bonds are formed between polyamidine molecules [1, 11] and between polyamidine and dye **III** molecules both via the peripheral hydroxy group of the dye and via the lateral hydroxy group of the quinoid form of the dye or the keto group of its major form [8]. Formation of hydrogen bonds in the examined mixtures of the polyamidine with additives of various chemical structures via peripheral oxygen atoms of the dye and the resulting noticeable changes in the mobility of polymer chains can be assumed from the NMR relaxation data (Fig. 3).

The relaxation time T_2 of a mixture of polyamidine with 15% of both dyes **III** and **IV** is shorter than T_2 for the straight polyamidine (Fig. 3), which suggests decreased mobility of the polymer chains.

Addition of **II** to the polymer increases the relaxation time of the mixture (Fig. 3), since the mobility of the polymer chains increases. This suggests that, in this case, contrary to the complexes of dyes **III** and **IV** forming ionic bonds with the polymer, a strong bond between the components is not formed. It should be noted that the difference in the spin–spin relaxation time of polyamidine complexes with **III** and **IV** is insignificant, despite close pK_a values (the difference is approximately 0.6). This may be caused by the fact that molecules of these dyes form, to a large extent, the bonds with the polymer via keto groups, which, to a some extent, levels out the influence of formation of network structures. This assumption is consistent with the results of quantum-chemical calculations [6] suggesting distribution of the negative charge between the oxygen atom in dye **III** in the ratio enol : phenolate 3 : 7.

The theoretical calculations of thermodynamic compatibility were carried out for polyamidine with addition of **II** and **III** by the procedure described in [12]. These calculations, considering both van der Waals and specific interactions (among them, formation of a hydrogen bond), showed that dye **III** has a higher solubility parameter than **II**, i.e. it is better compatible with polymer.

It was found that addition of phenolphthalein decreases the mobility of the polymeric chains of the polyamidine, but to a lesser extent than addition of chromophores **III** and **IV**, evidently, owing to their nonlinear structure. This is manifested in a longer spin–spin relaxation time T_2 for the most of temperatures, as compared to the relaxation time obtained with the above additives (Fig. 3).

For all cases, T_2 increases with temperature, since

the mobility of protons in melts increases with temperature.

CONCLUSIONS

(1) The IR data show that linear dyes of the bis-hydroxyalkanone type form comb-shaped structures with poly-1,10-decamethyleneamidine owing to formation of hydrogen bonds between molecules of the low-molecular-weight dye and amidine groups of the polymer.

(2) The NMR relaxation data show that the mobility of polymeric chains varies on adding low-molecular-weight dyes: the strength of the bond between poly-1,10-decamethyleneacetamidine and dye depends on the degree of dissociation of the dye.

(3) The bond between the dye and poly-1,10-decamethyleneacetamidine can be formed at a temperature not exceeding 160°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of *n*-Alkanes on Hardening and Selected Properties of Gelatin Shells of Microcapsules

A. V. Baranov and K. N. Zheleznov

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received May 13, 2002

Abstract—The influence of aliphatic hydrocarbons encapsulated in gelatin shells on hardening and heat resistance of these shells was studied by linear dilatometry, gravimetry, and pH-metry.

Microencapsulation attracts now particular attention owing to the fact that microcapsules of functional substances, obtained by such technologiles, endow conventional and new articles, products, and materials with a set of valuable properties and new benefits. Of greatest importance in storage, processing, and utilization of microcapsules are heat resistance, mechanical strength, and permeability of the shells, i.e., characteristics governed by the shell structure [1].

The performance characteristics, in particular, thermophysical properties, of gelatin shells of microcapsules are largely determined by the course of their hardening. Therefore, the conditions of this process are of decisive importance. It should be noted that, despite a great number of papers devoted to microencapsulation technologies and the properties of the resulting microcapsules, the influence exerted by the core substance on hardening of the shells and their properties still remains to be understood.

In this work, we studied the influence of aliphatic hydrocarbons C_6–C_{10} on hardening and selected properties of gelatin shells of microcapsules.

EXPERIMENTAL

As core substances we used homologs of saturated hydrocarbons (*n*-alkanes) C_nH_{2n+2} (n = 6–10). The shell material for microcapsules was active, brand A, low-viscosity photographic gelatin [OST (Branch Standard) 6-17-421–84] with the isoelectric point p*I* 4.7. Microencapsulation was performed by simple coacervation of gelatin dissolved in water at 50–55°C using sodium sulfate (see [2]). The dispersion of the microcapsules with primary coacervation shells was cooled and subjected to chrome–syntane–tannide hardening [3]. This involved two-stage successive treatment with solutions of chromium–potash alums $CrK(SO_4)_2 \cdot 12H_2O$ and synthetic hardening agent no. 2 (syntane no. 2). The latter is the product of condensation of phenol and formaldehyde, sulfonated with sulfuric acid. The aqueous dispersions of the microcapsules were washed to remove the chemicals until the washing and initial waters had identical pH. The microcapsules were hardened, washed, and dried at room temperature. The encapsulation product was a friable powder containing microcapsules with the average diameter of 70 μm. The hydrocarbon content in the capsules was 82–87 wt %.

To study the properties of the shells, we withdrew microcapsules in various stages of the process, and dried and opened them mechanically, whereupon the contents (core) was left to evaporate.

Model samples were fluoroplastic-supported films prepared from the initial gelatin solutions. Selected samples were kept in *n*-alkanes and hardened by chrome–syntane–tannide procedure [3].

The behavior of the initial gelatin, its coacervate, and microcapsule shells on heating was studied by linear dilatometry, which is particularly sensitive to changes in the mobility of the molecules and structural elements in polymeric systems. We used a specially designed setup shown schematically in Fig. 1. The setup was equipped with a balance producing a minimal mechanical effect on the sample, which is very important for studying polymers transforming to devitrified state during heating. The samples studied were shaped as cylinders 5 mm in diameter and 20 mm in length made from the shell material. The sample heating rate was 5 deg min^{-1}.

Figure 2 presents the temperature dependences of the linear dimensions for the initial gelatin, gelatin

1070-4272/02/7509-1506$27.00 © 2002 MAIK "Nauka/Interperiodica"

coacervate, microcapsule shells subject to chrome hardening with hexane as the core, and microcapsule shells that passed the full hardening cycle, with alkane as the core. The resulting dilatometric curves show that the initial gelatin, coacervate, and shells that passed the chrome hardening only tend to grow in linear size and, therefore, to expand. The onset temperature for expansion of the sample of the initial gelatin is 125°C, which is the middle of the temperature range 80–180°C, corresponding to melting of less heat-resistant crystalline zones in the structure of this polymer [4]. More heat-resistant crystalline zones melt at 200°C. In the case of coacervate, the expansion onset temperature for the sample decreases to 90°C. This is due to the specific action of inorganic salt on an aqueous gelatin solution and, therefore, to the specific structure of the coacervate. As shown in [5, 6], adding a neutral salt into a homogeneous solution of the protein favors coagulation of the macromolecules, thus facilitating the coil–helix transition, which is specifically responsible for gelatin coacervation. As a result, dried coacervate differs from the initial gelatin by a much larger proportion of the macromolecules taking the helical form (α form of gelatin). The vitrified α form of gelatin has a significantly lower density and, therefore, a significantly lower cohesion energy than the collagen-like β form [7]. This difference in the cohesion energy is specifically responsible for the fact that the molecular mobility of the coacervate is manifested in the course of heating at a lower temperature compared to the initial gelatin.

Figure 2 (curve *3*) shows that hardening with chrome hardener enhances the heat resistance of the coacervate, but the onset temperature of the sample expansion remains unchanged. This suggests that certain domains in the microcapsule shell material contain no hardener.

Complete treatment cycle, i.e., two-stage hardening of microcapsules, imparts to them a strong tendency to thermal contraction (Fig. 2, curves *4*–*9*). Notably, the onset temperatures for thermal expansion and contraction are almost identical (curves *1*–*9*), which suggests identical character of molecular mobility in gelatin.

Figure 2 shows that, with increasing concentration of syntane no. 2 in the hardening solution and the hardening time (curves *8*, *9*), the contractibility of the shells tends to increase. These factors beneficially affect the sorption of the hardener, as confirmed by the pattern of variation of pH in solution during hardening (Fig. 3). The observed sharp decrease in pH of the hardening solution is due to deprotonation of the $-NH^{3+}$ groups of gelatin by hydrogen bonding with –OH groups of the hardener. Under favorable conditions, the functional groups of the hardener and gelatin approach each other and get covalently bound,

Gelatin film thickness as influenced by the pretreatment conditions and hardening mode

Sample no.	Pretreatment conditions and hardening mode	Film thickness change, %
1	Chrome hardening without pretreatment in *n*-alkane	–11
2	Chrome hardening after 5-min treatment in water and 15-min treatment in nonane	+3
3	Chrome–syntane–tannide hardening without pretreatment in *n*-alkane	+120
4	Chrome–syntane–tannide hardening after 24-h treatment in nonane	+158
5	Chrome–syntane–tannide hardening after 5-min treatment in water and 15-min treatment in nonane	+207
6	Chrome–syntane–tannide hardening after 20-min treatment at the water–nonane interface	+177

eliminating water molecules. It should be noted that, along with the hardener molecules chemically bound to gelatin, the microcapsule shells contain weakly bound hardener occurring as associates, which can be extracted during washing. The correlation established between sorption of syntane no. 2 and thermal contraction of gelatin shells of microcapsules proves indirectly that contraction is due to pores created by extraction of syntane no. 2 weakly bound by gelatin, during washing of the microcapsules.

A study of gelatin shell hardening as influenced by the core substance showed that the capability of the shells for thermal contraction strongly depends on the nature of the core. In view of the fact that *n*-alkanes are unable of specific interaction with gelatin and hardener, we can suggest that the difference in the thermal behavior of shells is due to different amounts of *n*-alkane contained in the shell material. We carried out isothermal drying of the samples of films pretreated in *n*-alkanes at room temperature for 20 h and examined the compatibility between the hydrocarbons and gelatin, which proved to widely vary (Fig. 4): The plot of the compatibility vs. the molecular weight of *n*-alkane has a maximum corresponding to octane. Such a plot is indicative of the clathrate mechanism of dissolution of *n*-alkanes in gelatin, when sorption occurs in voids inside the associates of the polymeric material.

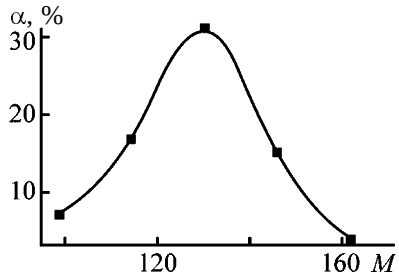

Fig. 4. Compatibility α of *n*-alkane with gelatin film as a function of the molecular weight *M* of *n*-alkane.

The *n*-alkane occurring in gelatin affects substantially the degree of swelling of the gelatin film and, hence, the accessibility of the polymer interior for syntane no. 2 molecules, as well as the gelatin hardening efficiency. The table shows how the alkane incorporated into gelatin film and the conditions of its incorporation into gelatin prior to hardening affect the film thickness as measured after hardening, washing with distilled water, and drying. It is seen that, unlike chrome hardening, which results in a minor thickening of the sample, hardening with syntane no. 2 significantly increases the film thickness. The film thickening is due to the selectivity of sorption of syntane no. 2 from aqueous solution. As noted above, syntane no. 2 is not entirely bound covalently by the active centers of gelatin and, thus, is partially extracted during washing. This affords a certain porosity of the gelatin shell. The alkane occurring in the microcapsule shells strongly hinders chrome hardening of the shell and, thus, affects its swelling and, correspondingly, the accessibility of the gelatin interior for the hardener molecules. Also, the alkane occurring in the shell affects the thermodynamic affinity of syntane no. 2 for the shell material and the ratio between the amounts of the syntane no. 2 bound to gelatin and sorbed. Evidently, the porosity of the shells is the largest in the case when a high sorption power of the shell with respect to syntane is combined with a low degree of fixing of the hardener on the active centers of the polymer. The strongest capability for thermal contraction, exhibited by the shells in the case of hexane (Fig. 2), suggests that, when in minor amounts in the shell material, hexane makes the interior of the shell material accessible for the hardener and does not substantially decrease the affinity for gelatin of syntane no. 2. By contrast, large amounts of heptane, octane, and nonane in the shell material shield the functional groups of gelatin, thus decreasing the selectivity of sorption of syntane no. 2 and, hence, the degree of hardening of the shells.

CONCLUSION

A study of hardening and selected properties of gelatin shells as influenced by aliphatic hydrocarbons C_6–C_{10} showed that chrome hardening enhances the heat resistance of the gelatin coacervate. Treatment (chrome–syntane–tannide hardening) endows the microcapsule shells with a prominent capability for thermal contraction. Increases of the concentration of the hardening solution of syntane no. 2 and of the hardening time tend to increase the thermal contraction of the shells, depending on the *n*-alkane homolog encapsulated. The plot of the gelatin–*n*-alkane compatibility vs. the molecular weight of *n*-alkane has a maximum.

Received May 14, 2002

Abstract—A method was proposed for differential determination of bound carboxylic acids in mixed cellulose esters containing residues of acetic and higher carboxylic (capric, lauric, myristic, palmitic) acids.

Mixed cellulose esters containing residues of acetic and higher carboxylic acids (e.g., capric, lauric, myristic, palmitic) show promise as compounds exceeding cellulose acetate in solubility, hydrophobicity, and resistance to acid and base hydrolysis [1].

Study of such mixed cellulose esters requires development of reliable analytical methods. The existing methods of analysis of cellulose esters [2–4] containing lower acyl groups are unsuitable for joint determination of acetyl and higher acyl groups in mixed cellulose esters. Here we propose a simple method for differential determination of these groups.

A mixed cellulose ester is saponified with a titrated KOH solution. Potentiometric titration of excess KOH with HCl allows determination of the alkali consumed for formation of potassium carboxylates in the course of saponification:

$$[(C_6H_7O_2)(OCOCH_3)_x(OCOC_{2n}H_{2n+1})_y(OH)_{3-x-y}]_m + mH_2O \xrightarrow{(x+y)KOH} [C_6H_7O_2(OH)_3]_m + xCH_3COOK + yC_nH_{2n+1}COOK,$$

where n = 9–15.

Determination of higher carboxylic acids is based on the well-known property of these acids and their soluble salts, distinguishing them from lower carboxylic acids, to form insoluble salts in reaction with $Ca(NO_3)_2$ [5]:

$$2C_nH_{2n+1}COOK + Ca(NO_3)_2 \rightarrow (C_nH_{2n+1}COO)_2Ca\downarrow + 2KNO_3.$$

The content of higher carboxylic acids was calculated from the results of titrating excess Ca^{2+} with Na_2EDTA (murexide indicator). The content of bound acetic acid was determined from the difference between the total acid content (saponification with KOH) and the content of higher acids (precipitation of Ca^{2+}).

EXPERIMENTAL

Highly substituted mixed cellulose esters were prepared by treatment of dispersed cellulose (α-cellulose content 95.5–96.0%) with acylating mixture consisting of acetic anhydride, higher carboxylic acid, and trifluoroacetic acid (TFAA) [6, 7]. Preparation of mixed esters can be described as follows:

$$[C_6H_7O_2(OH)_3]_m + mx\,(CH_3CO)_2O + my\,C_nH_{2n+1}COOH \xrightarrow{CF_3COOH} -mxCH_3COOH \downarrow [C_6H_7O_2(OCOCH_3)_x(OCOC_nH_{2n+1})_y(OH)_{3-x-y}]_m.$$

The synthesis procedure is given in [7].

The content of bound carboxylic acids in mixed cellulose esters was determined as follows. A 100-ml conical flask was charged with a 0.35 ± 0.01-g portion (weighed with an accuracy of 0.0002 g) of mixed cellulose ester. Then 10 ml of ethanol was added, and the flask was stoppered and placed for 15 min in a thermostat heated to 56–57°C for better swelling. After that, 10 ml of 0.5 M KOH was added, and the sample was saponified (55–60°C, 1 day). The resulting mixture was titrated potentiometrically with 0.5 M HCl (glass indicator electrode, silver chloride refer-

1070-4272/02/7509-1510$27.00 © 2002 MAIK "Nauka/Interperiodica"

ence electrode). After titration completion, 2 M KOH (to pH 12.5–13.0) and then 10 ml of 0.1 M $Ca(NO_3)_2$ were added. The precipitated calcium salts of higher carboxylic acids, together with the saponified product, were filtered off on a Büchner funnel in a water-jet-pump vacuum. The precipitate was washed with four 10-ml portions of water. Then the filtrate was quantitatively transferred into a 250-ml Erlenmeyer flask (the Bunsen flask was rinsed with 10-ml portions of water, which were combined with the filtrate). To the resulting solution, murexide was added, and excess $Ca(NO_3)_2$ was titrated with 0.1 M Na_2EDTA until the indicator changed color from pink to violet.

The content of bound higher carboxylic and acetic acids was determined by the formulas

$$P_1 = \frac{(k_1 - 0.1V_1)M_1 \times 100}{1000g},$$

$$P_2 = \frac{(5k_2 - 0.5V_2) \times 100}{1000g} - (P_1M_2)/M_1,$$

where P_1 is the content of bound higher carboxylic acid, %; P_2, content of bound acetic acid, %; k_1, correction for the titer of 0.1 M $Ca(NO_3)_2$ solution; k_2, correction for the titer of 0.5 M KOH solution; V_1, volume of 0.1 M Na_2EDTA solution consumed for back-titration of excess $Ca(NO_3)_2$, ml; V_2, volume of 0.5 M HCl solution consumed for back-titration of excess alkali, ml; M_1, molar weight of higher carboxylic acid, g mol^{-1}; M_2, molar weight of acetic acid (60.0), g mol^{-1}; and g, weight of the sample of mixed cellulose ester, g.

The analytical procedure was checked with artificial mixtures containing acetic and higher carboxylic acids (Table 1).

As seen from Table 1, the method ensures fairly high repeatability of the results.

In our procedure for analysis of mixed cellulose esters, particular attention should be given to the completeness of their saponification. The saponification completeness was judged from the IR spectra of the saponified hydrated cellulose (absence of the carbonyl stretching band at 1720–1740 cm^{-1}). Experiments showed that the esters under consideration are completely saponified under the following conditions: saponification time 20 h, KOH concentration 0.5 M, temperature ≥55°C.

The main metrological characteristics of the method, determined from the results of analysis of cellulose acetopalmitate as example (Table 2), are as follows (for bound acetic and palmitic acids, respectively): variance S^2 0.057, 1.29; standard deviation of the average S_r 0.119, 0.568; confidence range ε_p 0.379, 1.807; accuracy Δ 1.095, 4.563%. For analysis of cellulose acetomyristate, acetolaurate, and acetocaprate, the metrological characteristics are similar.

Table 1. Analysis of artificial mixtures of acetic (AA) and palmitic (PA) acids

Mixture composition, wt %		Found, wt %	
AA	PA	AA	PA
0	100.0	0	99.96
10.0	90.0	9.93	89.94
20.0	80.0	20.05	80.05
40.0	60.0	39.94	60.15
60.0	40.0	60.14	39.84
80.0	20.0	79.95	19.90
100.0	0	99.95	0

Table 2. Chemical analysis of cellulose acetopalmitate. Acylation conditions: 50°C; 20 g of TFAA per gram of cellulose; 0.5 ml of palmitic acid per mole of acetic anhydride

Run no.	Content of bound acid, wt %	
	AA	PA
1	34.42	38.41
2	34.43	38.86
3	34.93	40.15
4	34.58	40.87
Result	34.6 ± 0.4	39.6 ± 1.8

Table 2 demonstrates good reproducibility of the results; the procedure is suitable for analysis of mixed cellulose esters in a wide range of concentrations of bound acetic and higher carboxylic acids (Table 3).

The results of analysis for the content of bound carboxylic acids in various mixed cellulose esters prepared under comparable conditions are listed in Table 4.

CONCLUSION

A procedure was developed for determination of the content of bound carboxylic acids in mixed cellulose esters. The results of determination of bound acetic and higher carboxylic acids in mixed cellulose

Abstract—Flax fiber treated by conventional and ultrasonic procedures was studied. IR spectroscopic procedures were developed to estimate the degree of fiber decontamination from lignin and noncellulose fractions and to study supramolecular transformations of cellulose.

Flax fiber recovered from flax bast should be chemically treated before spinning [1, 2]. This treatment increases the degree of separation of crude fiber and hence enhances its spinning properties. The fiber rigidity is believed [3, 4] to be due to lignin present in the cell walls and middle plates. The agglutination of fibers is determined by the presence on the fiber surface of noncellulose polysaccharides and low-molecular-weight celluloses, which in total are termed as readily hydrolyzable polysaccharides (RHP) [5]. Hence, to prepare flax fiber with good spinning properties, crude fiber is boiled in alkali solution at elevated pressure for many hours and bleached by different procedures to partially destroy the middle plates and to remove lignin from the cell walls of the fibers. However, mechanical treatment can initiate mechanochemical reactions and result in degradation and amorphization of polymers [6]. Various mechanical treatments such as rolling, crushing, grinding, combing, etc. are used in industrial processing of polymers.

In this work we studied finishing of crude flax fiber by ultrasonic treatment. It is known [7] that regions with developed cavitation in the form of pulsation and oscillation of vapor gas bubbles are formed in the bulk of liquids at the intensity of an unltasonic field higher than 0.3 W cm^{-2}. This phenomenon is used for a long time to clean surfaces and to disperse films and coating in metallurgy and mining. In addition, the collapse of bubbles in the compression phase is accompanied by strong adiabatic heating of gas in the bubbles and its ionization, which can initiate chemical reactions. Probably, these processes can affect the structure of flax bast fiber by destroying the middle plates, removing fat films, and increasing the solubility of the concomitant compounds.

In this work we performed comparative IR spectroscopic study of structural transformations of bast fibers treated by ultrasonic and conventional chemical [1] procedures.

Ultrasonic treatment was performed in an aqueous solution of surfactant [laundry soap, GOST (State Standard) 7696–55, 5 g l^{-1}] at room temperature for 20, 60, 100 min in a bath of a standard UZU-0.25 ultrasonic unit operating at 18 kHz. The intensity of ultrasonic vibrations did not exceed 0.5 W cm^{-2}. After the treatment, the fiber was thoroughly washed with running water and dried in air in the free state. The IR spectra were recorded on an IR-75 spectrophotometer in KBr pellets. For the whole spectrum, the baseline corresponding to the window transparency was drawn.

To compare the efficiency of various procedures for removing lignin and RHP from flax, reliable methods should be developed for estimating the degree of decontamination of the initial flax and suitability of the flax for commercial purposes. In this work we propose an IR spectroscopic procedure for estimating the degree of flax decontamination from lignin and RHP. The IR spectra of the initial bast and the bast treated by the conventional and ultrasonic procedures for 20 min are shown in Figs. 1a and 1b, respectively. In the spectrum of the initial sample, two narrow bands at 2920 and 2855 cm^{-1} are observed against the background of a broad band of stretching vibrations of the CH_2 and CH groups of cellulose. Based on the results of [8], these bands are assigned to antisymmetrical and symmetrical stretching vibrations of the CH_2 groups of RHP (Fig. 1a). In the spectrum of the treated samples, the bands at 2920 and 2855 cm^{-1} are weaker, and the band at 2900 cm^{-1} of the stretching vibrations of the CH_2 groups of cellulose becomes well-defined. The changes in the other region of spec-

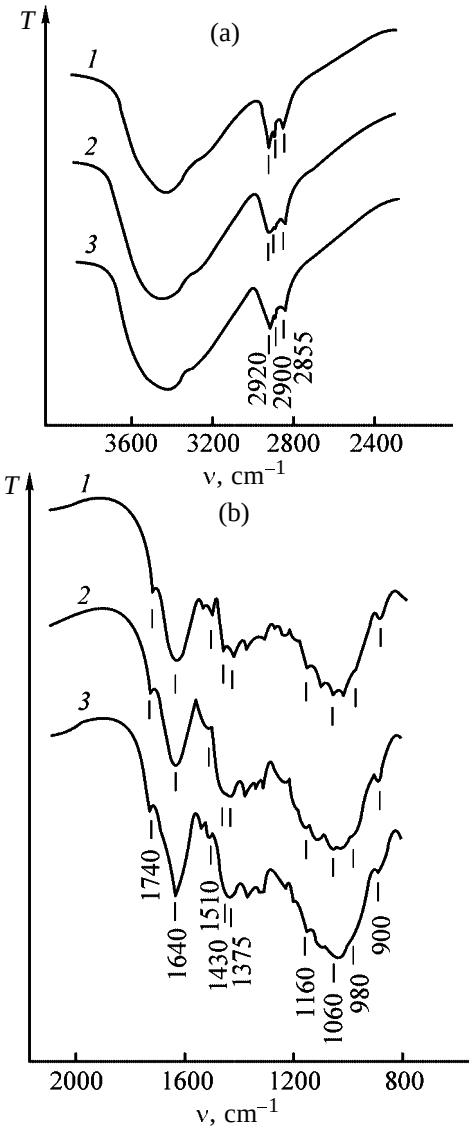

Fig. 1. IR spectra of flax fiber in the range (a) 2400–4000 and (b) 800–2000 cm^{-1}. Sample: (*1*) initial, (*2*) treated by the conventional procedure, and (*3*) ultrasonically treated for 20 min. (*T*) Transmission and (ν) wave number (cm^{-1}).

trum are less pronounced and require quantitative estimation (Fig. 1b).

To estimate quantitatively the spectral transformation, the internal reference, i.e., a band remaining unchanged after the treatment, should be chosen. Taking into account the results of [9], we used the band at 2900 cm^{-1} as the internal standard. Although in the spectrum of the initial sample this band appears only as a shoulder on the RHP band at 2920 cm^{-1}, the RHP bands, as noted above, are narrow enough to determine the optical density of this band with small error, even in the spectrum of the initial sample. The optical densities of some RHP and lignin bands normalized to the density of the band at 2900 cm^{-1} are presented in Table 1. The degree of lignin decontamination from RHP was estimated using the bands at 2920, 2855 (stretching vibrations of CH_2 groups), 1460 (bending vibrations of CH_2 groups), and 1740 cm^{-1} (vibrations of carboxy groups formed by hydrolysis of polysaccharides). The characteristic bands of lignin are the bands of skeletal vibrations of the aromatic ring at 1510 and 1600 cm^{-1}. However, the band at 1600 cm^{-1} is a constituent, along with the bands at 1660 and 1640 cm^{-1} of a complex band with a maximum at 1640 cm^{-1}. The band at 1660 cm^{-1} is assigned to the C=O groups of lignin. The strongest band at 1640 cm^{-1} is due to the bending vibrations of the OH groups of water present in all the samples. Thus, only a single band at 1510 cm^{-1} can be used to estimate the degree of flax decontamination from lignin.

As seen from Table 1, the intensities of the bands at 2920, 1740, and 510 cm^{-1} located in the transparence range of cellulose decrease after conventional and ultrasonic treatments to the similar extent: by 22 and 18%, respectively. This fact indicates that the internal reference was chosen correctly. This relationship does not hold for the bands at 2855 and 1460 cm^{-1} overlapping with strong cellulose bands. As seen from Fig. 1b, in the spectra of the treated samples the complex band at 1640 cm^{-1} is appreciably narrowed, which indicates a decrease in the content of lignin absorbing at the wings of this band.

Thus, the degree of flax decontamination from RHP and lignin can be estimated using the bands at 2920, 1740, and 1510 cm^{-1}. We propose as the estimation parameter the relative change of the optical density at the maxima of these bands. The degree of decontamination from lignin estimated by this method agrees with the data of Lebedeva and Shibaeva [10], confirming the correctness of the proposed criteria. In should be noted in conclusion that, since the degree of decontamination does not noticeably increase at longer ultrasonic treatment of the initial bast, we present in Table 1 only the data for the shortest treatment (20 min).

It was of interest to study the structural transformations of cellulose under different treatments of the initial fiber and manifestation of these transformations in the IR spectra. Several parameters were proposed for evaluation of supramolecular structural changes of polymeric chains and degree of cellulose mercerization in the course of purification of the crude fiber. To estimate the information content of these parameters, we present in Table 2 the optical densities of

Table 1. Normalized optical densities of the bands of lignin and RHP in the spectrum of bast treated by different procedures

ν, cm^{-1}	D_1/D_{2900}	D_2/D_{2900}	D_3/D_{2900}	$(D_1 - D_2)/D_1$	$(D_1 - D_3)/D_1$
2920	1.41	1.11	1.16	0.21	0.18

1375	1.49	1.65	1.49	0.11	0.00

the strongest cellulose bands normalized to the optical density of the band at 2900 cm^{-1}.

It is known that cellulose is mercerized by phase transition of cellulose 1 to cellulose 2 in the course of boiling of bast in an alkali solution. The structure of native cellulose 1 is formed by the system of intermolecular hydrogen bonds stabilizing a definite conformation of the polymeric chains. At elevated temperature, these bonds are ruptured, which allows partial rotation of the macromolecules around the glucoside bonds. As a result, a new network of mainly intramolecular hydrogen bonds stabilizing the new macromolecule conformation in the structure of cellulose 2 is formed. In the IR spectra, this phase transition should be manifested by a change in the optical densities of the bands of glucoside bridge and of OH groups involved in the hydrogen bonding.

There are two bands of glucoside bridge at 1060 [ν_a(COC)] and 900 cm^{-1} [ν_s(COC) + $\delta(C_1H)$] [12]. The bending vibrations of OH groups contribute to almost all bands located in the range lower than 1300 cm^{-1}. Among them, the strongest are 1160 [δ(OH) + $\delta(CH_2)$] and 980 cm^{-1} [δ(OH) + δ(CH)]. The relative optical densities of all the above bands are summarized in Table 2. The degree of cellulose mercerization is estimated from the change in the optical densities of the bands at 900 and 980 cm^{-1} [12]. As seen from Table 2, the changes in the optical densities of these bands are similar. The estimated degree of mercerization of samples treated by the conventional and ultrasonic procedures is 18 and 12%, respectively. It should be noted that the degree of mercerization can also be estimated using the band at 1160 cm^{-1}. The band at 1060 cm^{-1} strongly overlaps with adjacent bands and cannot be used for this purpose.

The degree of crystallinity of the initial fiber can change after boiling of the fiber in polar solvents. Since recrystallization is usually accompanied by phase transitions, the degree of crystallinity should be evaluated from the ratio of the optical densities of the bands that are insensitive to the crystal lattice type. As the crystallinity index, Nelson and O'Connor proposed the ratio of the optical densities of the bands at 1375 and 2900 cm^{-1} [9]. The degree of crystallinity estimated by this index slightly increases for the samples treated by the conventional procedure (Table 2) and remains the same for the samples treated by ultrasonic procedure. It is interesting to check whether this phenomenon will be observed for other samples, since a decrease in the fiber rigidity is very important for spinning process. The fiber rigidity does not appreciably decrease after boiling of the fiber with alkali and bleaching, although lignin is removed after this treatment. The causes of this phenomenon are unclear. Our data show that the rigidity of treated fiber may be due to crystallization of cellulose during treatment in a hot liquid. Ultrasonic treatment may leave the

degree of crystallinity unchanged, since in this case the polymer is subject to only local and short heating.

The time dependence of lignin removal from the fiber during ultrasonic treatment flattens out. This is due to the fact that the maximal dispersity of flax fiber complexes at the given power of ultrasonic radiation is reached within 20 min. In the process, lignin is removed only from destroyed middle plates but not from the cell walls of the fibers. To remove lignin from the cell walls, the fiber should be divided to microfibrils, which requires higher energies.

CONCLUSIONS

(1) An IR spectroscopic procedure was developed to determine the degree of flax decontamination from lignin and readily hydrolyzed polysaccharides after pretreatment of crude fiber and to estimate the degree of crystallinity and mercerization of cellulose.

(2) The degree of decontamination of the fiber ultrasonically treated for 20 min is comparable to that obtained by the conventional procedure.

(3) In the course of the both treatments cellulose is mercerized without an additional crystallization.

Abstract—Isolation of pectins form flax pedicels and fibers was studied. Isolated pectins and flax fibers treated by various chemical procedures were studied by IR spectroscopy. The morphology of fascicles of flax fibers was studied by electron microscopy as influenced by chemical treatment.

Linen clothes, among various cellulose materials produced from plant fibers, have good consumer's properties owing to peculiar fine structure and morphology of flax fibers and the presence of concomitant compounds. Linen clothes are characterized by good durability and physicomechanical properties; an increased comfort provided by linen wear is due to permeability of flax fibers to air, their low electifiableness, and strong sorption of moisture [1, 2]. The physicomechanical properties of fibers and the consumer's properties of linen clothes depend on impurities present in them. Fats, lignin, pectins, and hemicellulose weaken the surface tension of the fiber as compared to purified cotton fiber [3] and increase the hygroscopicity of the fibers [1, 4]. Pectin impurities decrease the resistance of the fiber to the action of microorganisms [5]. One of disadvantages of mechanical cottonizing of flax fiber is relatively high yield of fairly thick and rigid fibers. Compounds, including pectins, that accompany cellulose are removed in the course of mechanical cottonizing. The pectin content in flax straw exceeds 4–5 wt %, whereas in recovered fibers it is as low as 0.25–0.35%. Thus, hemicelluloses including pectins are removed in the course of recovery of flax fibers and their finishing. Combination of mechanical and chemical cottonizing of fibers allows production of fibers with improved spinning properties and recovery of valuable polysaccharides such as pectins.

Flax pectins, unlike pectins contained in fruits and vegetables, are poorly studied. To determine the potential fields of application of these pectins and practicable (efficient) procedures for recovering them, a comparative study of physicochemical and biological properties of pectins should be performed.

The aim of this work was to study recovery of flax pectins from flax straw and short fibers. Flax straw was used as experimental raw material for pectin recovery.

EXPERIMENTAL

Flax straw and short flax fibers produced at Nevel' flax processing plant (Russia) were used as the initial material. Isolated pectin was characterized by IR spectroscopy (Specord M80 spectrometer, KBr pellets).

The chemical composition of short fibers and flax straw was determined (Table 1). The cellulose content was determined by the Kürschner–Hoffer's procedure [6]; the lignin content, by the Komarov's procedure; the contents of fat, ash, and moisture, by the procedure in [6, 7]; and the pectin content, by the calcium pectate procedure [7].

Table 1. Chemical composition of flax pedicels and fibers

Component	Content, wt %	
	flax straw	short fibers
Fats and waxes	2.9	1.5
Lignin	39.4	5.2
Ash	1.5	1.4
Cellulose and hemicelluloses including:	48.8	87.5
cellulose	37.2	71.1
pectin	2.2	1.6
other hemicelluloses	9.4	14.8
Moisture content	7.4	4.4

Table 2. Isolation of pectin from straw and short flax fiber by different procedures

Run no.	Initial material	Treatment conditions of plant material	Conditions of pectin isolation from solutions	Pectin yield, %
1	Flax straw	Treatment with 0.03 N HCl, washing with hot water, treatment with 1% ammonium citrate solution, washing with water	Neutralization of solution and saponification of pectin in the solution with 4% NaOH, acidification with CH_3COOH to pH 6.0, precipitation of pectin with 44% $CaCl_2$ solution, washing of the precipitate with 0.5% $CaCl_2$ solution and water	2.15
2.1	″	Treatment with 0.03 N HCl, washing with hot water	″	1.3
2.2	Flax straw treated with HCl solution and washed with water	Treatment with 1% ammonium citrate solution, washing with water	Saponification of pectin in the solution with 4% NaOH, acidification with CH_3COOH to pH 6.0, precipitation of pectin with 44% $CaCl_2$ solution, washing of the precipitate with 0.5% $CaCl_2$ solution and water	0.85
3	Flax straw ″	Treatment with 0.03 N HCl, washing with hot water	Alkalization with aqueous ammonia to pH 6.0, evaporation of pectin solution on a rotary evaporator, precipitation of pectin with 50% aqueous ethanol, washing of the precipitate with ethanol and acetone	2.7
4	″	″	Alkalization with aqueous ammonia to pH 6.0, evaporation of pectin solution on a rotary evaporator, precipitation of pectin with acetone, washing of the precipitate with acetone	2.95
5	″	″	Addition of saturated CaO solution to pH 6.0; evaporation of pectin solution on a rotary evaporator, precipitation of pectin with acetone, washing of the precipitate with acetone	2.7
6	Short flax fiber	Treatment with 0.03 N HCl, washing with hot water, treatment with 1% ammonium citrate solution, washing with water	Saponification of pectin in the solution with 4% NaOH, acidification with CH_3COOH to pH 6.0, precipitation of pectin with 44% $CaCl_2$ solution, washing of the precipitate with 0.5% $CaCl_2$ solution and water	1.6
7	″	Treatment with 0.03 N HCl, washing with hot water	Alkalization with aqueous ammonia to pH 6.0, evaporation of pectin solution on a rotary evaporator, precipitation of pectin with 50% aqueous ethanol, washing of the precipitate with ethanol and acetone	1.43

As seen from Table 1, the pectin content in the fibers is 1.6%, which agrees well with the results of other works [2, 8].

There are several methods for recovering pectins from plant materials [7–10]. One of classical methods is the calcium pectate procedure. It is based on hydrolysis of pectic acid with dilute HCl, followed by treatment with ammonium citrate to form soluble complexes. Then dissolved pectin is hydrolyzed with an NaOH solution to form polygalacturonic acid; its calcium salt is precipitated with aqueous $CaCl_2$ [7].

To improve pectin extraction, the initial flax straw was preliminarily milled in an MN-250 knife mill. Isolation of pectins from straw and fibers was performed by various methods. Prior to isolation, all samples of straw and fibers were treated with an alcohol–benzene mixture to remove grease and waxes [6]. The isolation conditions and the pectin yields are presented in Table 2.

Isolation of pectin in the form of calcium pectate was performed in two steps: treatment with 0.03 N HCl with subsequent washing with hot water and an

ammonium citrate solution (Table 2, run no. 1). From an industrial standpoint, the number of treatments should be minimized. In addition, it is not appropriate to use food citric acid for recovering another food substance, polysaccharide. Analysis of the pectin yield (Table 2, run nos. 1, 2.1, 2.2) shows that the major portion (60% of the isolated pectins) of pectins passes into the solution in the course of treatment with an HCl solution. The remaining 40% of pectins is dissolved when flax straw is treated with a ammonium citrate solution. Hence, the latter step involving the food reagent is not necessary. Saponification of polygalacturonic acid in solution, followed by its precipitation with a $CaCl_2$ solution, is time-consuming. It is difficult to filter off and wash the precipitate of calcium pectate. To overcome this difficulties, we studied isolation of pectin from a solution by precipitation of polygalacturonic acid with an organic solvent from evaporated working solutions. To suppress hydrolysis of polygalacturonis acid in the course of evaporation on a rotary evaporator at 80°C, these solutions were neutralized with aqueous ammonia to pH 6.0.

As seen from Table 2, pectin and a fraction of hemicelluloses (run no. 3) are precipitated with ethanol from concentrated (evaporated) pectin solutions. The precipitate amount is higher than that in the conventional procedure (run no. 1). The highest amount of pectins and hemicelluloses (2.95%) is isolated by precipitation with acetone (run no. 4), which is due to coprecipitation of chlorides insoluble in acetone. The presence of chloride ions in the precipitate was confirmed by reactions with $AgNO_3$.

Removal of chloride ions from the precipitate by washing is a labor- and time-consuming procedure. To exclude the presence of chloride ions, we used a CaO solution for isolation of pectins (Table 2, run no. 5). We suggested that insoluble calcium polygalacturonate would be formed, as in the case of $CaCl_2$. However, calcium oxide is only sparingly soluble in water. The volume of the CaO solution was 3 times larger than that of the initial (not evaporated) pectin solution. The precipitate amount (2.7%) formed after evaporation of the solution and precipitation of pectin with acetone is higher than that in the calcium pectate procedure. Probably, calcium oxide is partially precipitated during evaporation of the pectin solution, which makes the pectin content overestimated. This is the case in isolation of pectins from fibers (Table 2, run nos. 6, 7).

It should be noted that the amount of the precipitate formed by treatment of flax fiber with 0.03 N HCl, followed by evaporation of the resulting pectin solution and precipitation of pectin with ethanol (run no. 7), is 89% of the yield of pectin prepared by the conventional procedure (run no. 6). We suggest that hemicelluloses that passed into the solution during treatment of the fibers with dilute HCl partially coprecipitate with pectins. Unlike wood, flax pedicels and fibers have high content of hemicelluloses which pass into the solution during boiling in 0.03 N HCl.

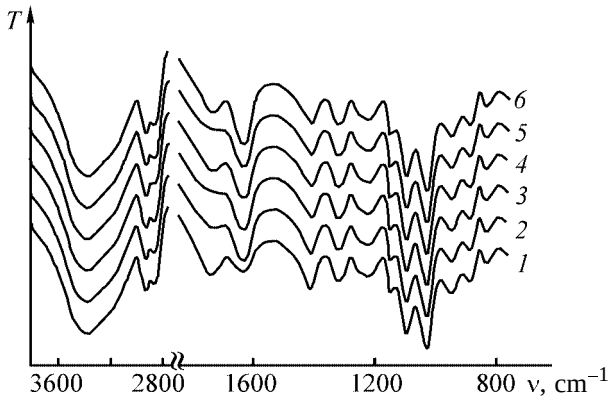

Fig. 1. IR spectra of (*1*) apple pectin and (*2*–*4*) pectins isolated by different procedures. (*T*) transmission and (ν) wave number; the same for Fig. 2. Run no. (Table 2): (*2*) 1, (*3*) 2.1, (*4*) 3, (*5*) 6, and (*6*) 7.

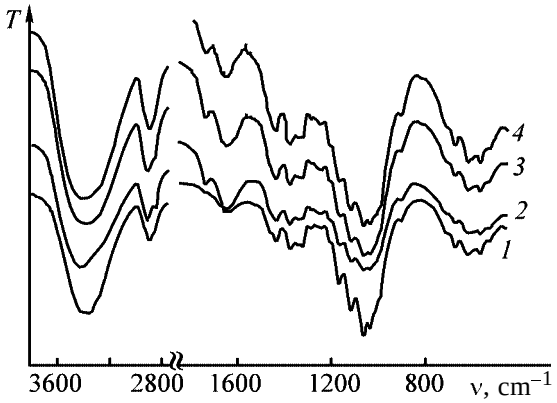

Fig. 2. IR spectra of (*1*) cotton cellulose, (*2*) initial flax fiber, and flax fiber treated to remove (*2*) fats and waxes and (*3*) fats, waxes and pectins.

The IR spectra of isolated pectins are shown in Fig. 1. Apple pectin was used as the reference.

The IR spectra of pectins contain characteristic absorption bands of free COOH groups of polygalacturonic acid at 1740 cm^{-1} and the bands of symmetric and asymmetric vibrations of COO^- groups at 1615 and 1410 cm^{-1}, respectively. In the range 2850–2950 cm^{-1}, a single broad band or two bands at 2875 and 2925 cm^{-1} assigned to stretching vibrations of CH_2 and CH groups can appear [9].

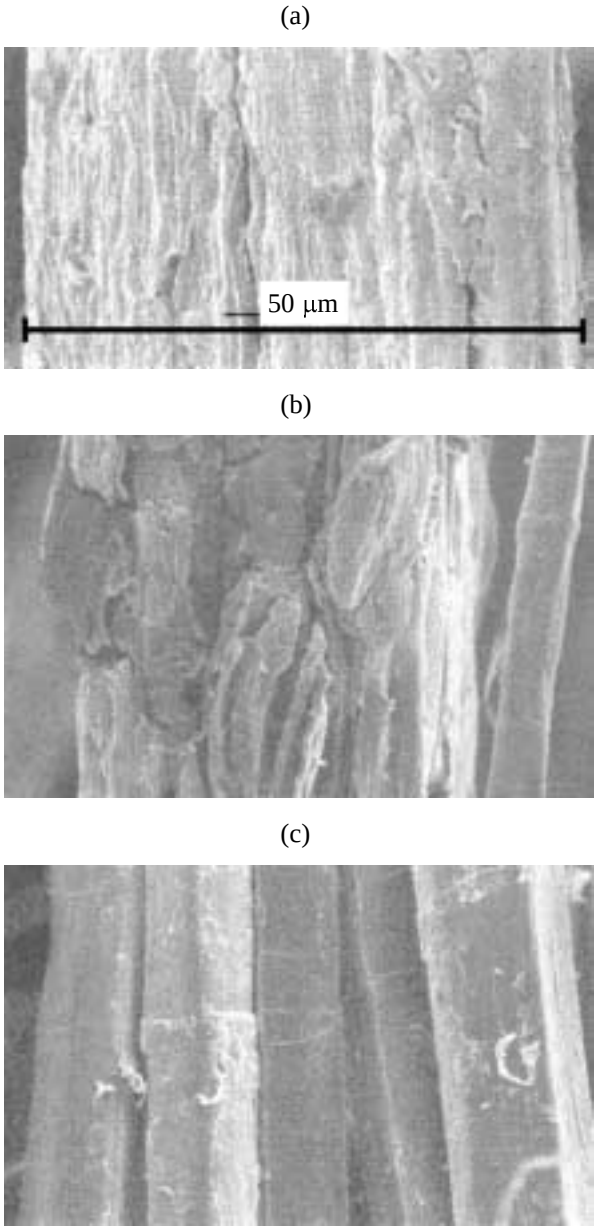

Fig. 3. Electron micrographs of flax fibers: (a) crude fibers and fibers treated to remove (b) fats and waxes and (c) fats, waxes, and pectins. Magnification ×1500.

The presence of strong bands at 1410 and 1615 cm^{-1} in the IR spectra of pectins isolated by the calcium pectate procedure from flax pedicels and fibers (Fig. 1, curves *2*, *3*, and *5*) indicates that the most of carboxy groups of the pectin are ionized. A weak band at 1740 cm^{-1} appears as a shoulder. An increased absorption at 1740 cm^{-1} in the spectrum of pectins prepared by evaporation of solutions (without saponification of pectin) followed by precipitation with ethanol and acetone is due to an increase in the fraction of free COOH groups (spectra *4*, *6*). The intensity of the bands at 1740 and 2900 cm^{-1} in the spectra of pectins isolated under the same conditions from straw and fibers by evaporation of solutions and precipitation with ethanol differ. We suggest that, in this case, the additional absorption, especially at 2875 cm^{-1}, is due to a contribution of hemicelluloses which pass with pectin into the solution and then precipitate.

Sobolev and Krasivskaya [8] noted that pectins are incompletely removed from flax fibers in the course of treatment with solutions of HCl and ammonium citrate. To determine the completeness of pectin removal, we recorded the IR spectra of flax fiber after removal from them of fats and waxes and then pectins (Fig. 2). The IR spectrum of bleached cotton linter was recorded as a reference.

The IR spectrum of purified cotton cellulose contains the following characteristic bands: a broad band in the range 3000–3700 cm^{-1} of free OH groups and OH groups involved in intra- and intermolecular hydrogen bonds; the band of CH_2 and CH groups at 2900 cm^{-1}, which is symmetrical in the spectrum of pure cellulose [12].

The IR spectrum of crude wood cellulose and cellulose isolated from flax pedicels contain characteristic lignin bands at 1600, 1500, and 850 cm^{-1} [11, 12]. Thus, the impurity content in cellulose samples can be qualitatively estimated by IR spectroscopy.

As seen from Fig. 2, in the spectrum of crude flax fibers the band at 1740 cm^{-1} and a broader band in the range 1650–1600 cm^{-1}, as well as the bands at 2925 and 1875 cm^{-1}, indicate the presence of pectins. It should be noted that the vibrations of CH_2 and CH groups of fatty acids (i.e., fats and waxes) can additionally contribute to the absorption in the region of 2900 cm^{-1}. The presence of lignin can be determined by comparing the IR spectra of crude flax fibers and bleached cotton cellulose (Fig. 2, curves *1* and *2*). Broadening of the band in the range 1650–1600 cm^{-1} in the spectrum of flax fiber can be due to the presence of lignin (1600 cm^{-1}) and pectin (1615 cm^{-1}). The IR spectra of all flax samples, unlike the cotton spectra, contain the lignin band at 850 cm^{-1}.

Fatty acids are removed by treatment with a benzene–ethanol mixture (Fig. 2, curve *3*), which is indicated by the decrease in the absorption at 2900 cm^{-1} and the sharper shape of the lignin bands. A shoulder at 1500 cm^{-1} and a sharp band at 850 cm^{-1} appear. The band at 2900 cm^{-1} becomes more symmetrical after removal of fats and pectins (Fig. 2, curve *4*),

although the pectin bands at 2925 and 2875 cm^{-1} appear as shoulders on this band. The characteristic lignin band at 850 cm^{-1} is also observed.

Pectins are contained not only in intercellular layers but also in primary walls of a single fiber. To remove pectins binding single flax fibers in fascicles, more rigid conditions are required. Under these conditions, cellulose can appreciably degrade.

The distinctions in the morphology of fiber fascicles are seen in the electron micrographs of flax fibers treated under different conditions (Fig. 3). Comparison of the micrographs shows how each chemical treatment affects, on the one hand, the contamination of the surface of flax fiber fascicles with concomitant compounds and, on the other hand, the degree of rupture of bonds between single fibers in fascicles, i.e., the degree of fiber cottonizing.

The surface of untreated flax fibers isolated from bast is contaminated with the following substances: parenchyma, pectins, and other components of external pedicel layer in which the fascicles of bast fibers were incorporated. After removal of fats and waxes (Fig. 3b), the relief of pectin residues on the fibers as well as defects on the surface of single fibers and fascicles become more pronounced. The content of residual substances on the fibers remains high. These substances are removed and the fibers in fascicles are separated (FIg. 3b) after treatment of the fibers with an ethanol–benzene mixture and removal of pectins with solutions of HCl and ammonium citrate. At the same time, relatively large amount of noncellulose components remain on the fiber surface, and complete separation of fibers (their cottonizing) is not observed.

Thus, pectins are incompletely removed from flax fibers by treatment with solutions of HCl and ammonium citrate. The most part of pectins (up to 90% of the total amount) is removed from the fibers with dilute HCl. Hemicelluloses of flax fiber entering into the composition of polycarbohydrate complex of flax fiber cellulose partially passes with pectins into the solution. Pectins isolated by evaporation of the solution with subsequent precipitation with organic solvent contain ionized and free carboxy groups. The degree of separation of fibers in fascicles increases after the treatment of flax fibers to remove fats, waxes, and pectins.

CONCLUSIONS

(1) Methods for isolating pectins from flax pedicels and fibers were studied.

(2) Pectins isolated from flax pedicels and fibers by chemical treatment were studied by IR spectroscopy. The ratio of free and ionized carboxy groups in isolated pectins depends on the isolation procdure. Hemicellulose entering into the composition of polycarbohydrate complex of flax fiber cellulose partially passes with pectins in the solution.

(3) Flax fibers chemically treated by different procedures were studied by IR spectroscopy and electron microscopy. The surface of fibers in fascicles is cleaned and the degree of separation of fibers increases after the treatment of flax fibers to remove fats, waxes, and pectins.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Kinetics of Dinitrile Dioxide Curing of Polyurethanes Containing Double Bonds in the Chain

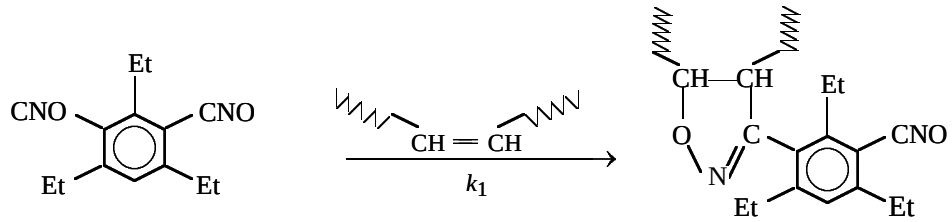
M. A. Okhotnikov and V. I. Valuev

Research Institute of Synthetic Rubber, Federal State Unitary Enterprise, St. Petersburg, Russia

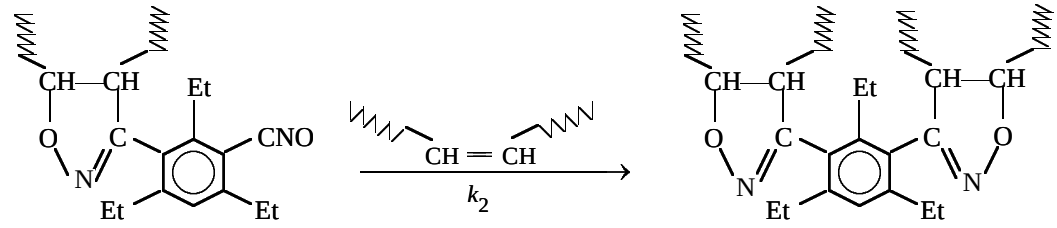
Received May 30, 2002

Abstract—The kinetics of cross-linking of highly plasticized polyurethanes conrtaining C=C bonds in the chain with a low-temperature dinitrile dioxide curing agent was studied by IR spectroscopy and gel permeation chromatography.

Dinitrile dioxide vulcanizing agents came recently into use for curing polyurethanes containing unsaturated bonds in the chain. Therefore, kinetic and mechanistic studies of this process are urgent. Nitrile oxide groups of a curing agent react with double bonds of a polyurethane in two stages, following the 1,3-dipolar cycloaddition pattern and giving five-membered isoxazoline rings [1]:



(P1)



(P2)

One of the major advantages of curing agents of this type, as compared to other curing agents, is their capability to cross-link polyurethanes at relatively low temperatures, 30–40°C, which is due to high reactivity of nitrile oxide groups in [3+2]-cycloadditions [2].

In this work, using IR spectroscopy and gel permeation chromatography (GPC), we studied the kinetics of the reaction of nitrile oxide groups of the curing agent with C=C bonds of polyurethane, including calculation of the rate constants of the main curing stages, and examined the effect exerted by temperature and polymer structure on the rate constants.

EXPERIMENTAL

Experiments were performed with linear polyurethane rubbers of ester structure, containing C=C bonds (M_w = 5000–60000), and with 2,4,6-triethyl-1,3-benzenedi(nitrile oxide) as curing agent.

The IR spectra were taken on a Specord IR-75 spectrophotometer. Samples for recording the spectra were prepared as a microlayer between CaF_2 plates. The kinetics of polyester urethane curing with nitrile oxides was monitored by IR spectroscopy, namely, by the intensity of the ν(C≡N) band of the nitrile oxide

1070-4272/02/7509-1522$27.00 © 2002 MAIK "Nauka/Interperiodica"

group at 2290 cm^{-1}. One of the plasticizer bands was used as internal reference.

The IR spectra furnished comprehensive information on the kinetics of the polymer reaction with the curing agent as influenced by temperature and the polymer structure. Nevertheless, IR spectroscopy has certain limitations. In particular, the process kinetics cannot be monitored in thin film at high (>40%) conversions of the functional groups of the curing agent, because the gel point is attained. Furthermore, it is impossible to determine the rate constant of the reaction of C=C bonds in the polymer with the CNO groups incorporated into the macromolecular fraction in the first stage of curing, i.e., the rate constant of cross-linking proper. The combined use of IR spectroscopy and GPC allows solution of problems that cannot be solved by these methods used separately. These methods are mutually supplementing: IR spectroscopy allows monitoring of the total concentration of nitrile oxide groups, and GPC, monitoring of the content of the free curing agent in the system, decreasing owing to incorporation into the macromolecular fraction.

Polymeric compounds were chromatographed on a Waters-244 module-type gel chromatograph. Three columns packed with styrogel (pore size 100, 500, and 1×10^3 Å) were used. The eluent was tetrahydrofuran (flow rate 1 ml min^{-1}), and the detector, UV spectrophotometer (working wavelength 255 nm).

Experimental data show that the calculated rate constants of the reaction of CNO groups with the polyurethane C=C bonds, as determined by IR spectroscopy and GPC, at ~15% conversion of the curing agent agree within the instrumental error (Table 1). This fact suggests that, at low conversions of the curing agent, the major process is the reaction of nitrile oxide groups of the free curing agent with C=C bonds of the polymer (rate constant k_1). With increasing conversion of dinitrile dioxide, the differences between the rate constants determined by IR spectroscopy and GPC become more pronounced, with suggests the occurrence of cross-linking by the reaction of the second CNO group with the C=C bond (rate constant k_2).

The activation energy of the reaction between the functional groups of the polymer and curing agent, determined from the Arrhenius plot (Fig. 1), is relatively low, 42 ± 4 kJ mol^{-1}, which confirms the concerted reaction mechanism.

The differences between the kinetic parameters determined by IR spectroscopy (combination of k_1 and k_2) and GPC (k_1 only) allow determination of the concentration of cross-links (P2) in the system before the gel point.

Table 1. Rate constants of the reaction of the curing agent with double bonds of the polymer (IR and GPC data)

T, °C	$k_1 \times 10^4$, l mol^{-1} s^{-1}	
	IR	GPC
18	0.041	0.038
40	0.210	0.223
60	1.425	1.408
70	2.382	2.286

Let us denote the total concentration of CNO groups, determined by IR spectroscopy, as c_{IR}, and the concentration of the free curing agent, determined by GPC, as c_{GPC}. Since in the first stage the free curing agent becomes incorporated in fragment P1, the decrease in the concentration of the free curing agent is presumably equivalent to the increase in the concentration of P1. The concentration of P1 units, assuming that they do not react with C=C bonds of the polyurethane to form cross-links P2, is found from the formula

$$c_{P1(GPC)} = c_{0GPC} - c_{\tau GPX},$$

where c_{0GPC} and $c_{\tau GPC}$ are the concentrations of free dinitrile dioxide at the initial instant and in time τ after the start of curing, respectively.

However, actually formation of P1 fragments is accompanied by their reaction with C=C bonds. Since the quantity c_{IR} includes the concentrations of CNO groups in the free curing agent (equal to $2c_{GPC}$) and CNO groups incorporated in P1, the concentration of P1 fragments can be determined by subtracting $2c_{GPC}$ from c_{IR}:

$$c_{P1} = c_{IR} - 2c_{GPC}.$$

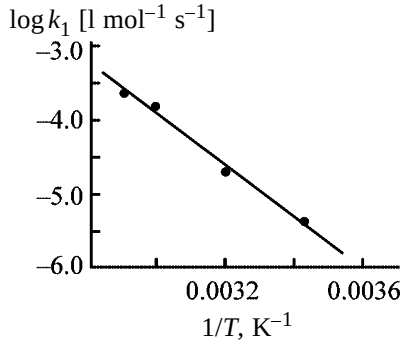


Fig. 1. Temperature dependence of the rate constant k_1.

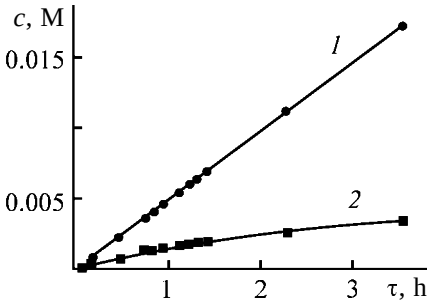

Fig. 2. Kinetic curves of accumulation of fragments (*1*) P1 and (*2*) P2 in the initial stage of curing (60°C): (*c*) concentration and (τ) time.

Finally, knowing the actual concentration of P1 fragments and their expected concentration in the absence of cross-linking, we can determine the concentration of cross-links:

$$c_{P2} = c_{P1(GPC)} - c_{P1}.$$

We found that, in the initial stage of curing, cross-linking is insignificant (Fig. 2), i.e., the curing occurs as essentially two-stage process, with predominant formation of P1 fragments in the first stage.

Table 2. Differences in the reactivity of internal (randomly located in the chain) and terminal double bonds

T, °C	$k_1 \times 10^4$, l mol^{-1} s^{-1}	
	internal double bonds	terminal double bonds
18	0.04	0.80
40	0.21	2.05
60	1.42	8.32
70	2.38	10.74

Table 3. Influence of M_w of polyurethane on the kinetics of its reaction with the curing agent

T, °C	$k_1 \times 10^4$, l mol^{-1} s^{-1}, at indicated M_w	
	5200	22 600
18	0.78	0.80
40	2.14	2.05
60	8.40	8.32
70	10.63	10.74

The rate constant k_2 was calculated from the kinetic curve of accumulation of P2 fragments. We found that the constant k_2 is by a factor of 2 lower than k_1 (k_2 = 0.73×10^{-4}, 60°C), which is apparently due to steric shielding of CNO groups in P1 by bulky polymeric chains.

Examination of the influence exerted by the structure of polyurethanes on the curing kinetics revealed significant differences in the reactivity of internal and terminal double bonds in the macromolecules with respect to the CNO groups (Table 2). This result may also be due to the steric factor, namely, to stronger shielding of internal double bonds as compared to the terminal bonds.

With the aim to reveal the influence of the polyurethane molecular weight on the kinetics of its curing, we performed curing of two polyurethane samples containing terminal double bonds, with M_w 5200 and 22 600. The results are listed in Table 3. They show that, within the examined range, the influence of the chain length on the reactivity of the double bonds is insignificant.

CONCLUSIONS

(1) The curing kinetics of polyester urethanes containing double bonds in the chain with 2,4,6-triethyl-1,3-benzenedi(nitrile oxide) was studied by IR spectroscopy and gel permeation chromatography. A procedure was proposed for determining the content of cross-links in the compound in the course of curing from the data furnished by these two methods.

(2) The rate constants of the reactions of the CNO groups of the curing agent with terminal double bonds are several times higher than those of the reactions with the internal double bonds in the polymeric chain.

(3) Within the examined range of molecular weights of polyurethane (M_w = 5000–23 000), the reactivity of terminal double bonds is independent of the length of the polymeric chain.

Received January 9, 2002

Abstract—BND 60/90 and BND 89/130 paving asphalts were modified by addition of DST-30 elastoplastic and petroleum plasticizers. Their performance at temperatures from –(32–35) to +(90–95)°C was examined in comparison with that of commercial unmodified asphalts, which are efficient at temperatures from –(23–27) to +(44–50)°C.

Petroleum asphalts are the main binding material in pavements. About 80% of the produced asphalt is used for paving; the remainder is used in production of roofing materials, house building, erection of various hydraulic structures, laying of pipings; it is also used in electrical engineering, chemical industry, and some other fields [1, 2].

The durability of an asphalt concrete pavement depends not only on the quality of the bed preparation and of mineral fillers used, but also on the asphalt quality.

In north-western Russia, the main supplier of asphalts is Kirishinefteorgsintez Production Association. Because of specific features of tars from commercial West-Siberian crude oil (increased content of paraffinic and naphthenic compounds), used for producing paving asphalts, the asphalts do not always have the required performance and quality characteristics (softening point, penetration before and after standard heat treatment, ductility, brittle point).

Since, in the forecastable future, oil refineries producing asphalt by oxidation of petroleum tar with air will have no ways of significantly improving their consumer's characteristics, one of the promising ways to obtain high-quality materials is compounding of asphalts with polymers [2].

In this work, we examined the possibility of improving the quality of oxidized paving asphalts by adding rubber. As noted in [2], asphalt–rubber compounds are considerably more durable than common asphalts [3].

In modification of a paving asphalt, it is desirable to increase its softening point, make penetration less temperature-dependent, make asphalt less susceptible to elastic reverse deformation, increase the ductility (especially at low temperatures), enhance the adhesion of the asphalt to mineral fillers of asphalt concrete, and extend the range of working temperatures.

To this end, it is first necessary to ensure good compatibility of rubbers with asphalts. However, elastoplastics are not all compatible with asphalts. Their compatibility depends on the chemical composition of both asphalts and elastoplastics. It is known that high-molecular-weight rubbers to be compounded with asphalt require, for swelling and subsequent dissolution, larger amount of oils than that contained in paving asphalts. Furthermore, these rubbers (elastoplastics) can induce coagulation of asphaltenes, which are the major structuring components of asphalts; this is inadmissible in production of high-performance paving asphalts.

Therefore, in this work, we examined how the properties of rubber-modified paving asphalts are affected by addition of not only elastoplastics but also available and relatively cheap plasticizers.

EXPERIMENTAL

Experiments were performed with commercial paving asphalts BND 60/90 and BND 90/130 (Kirishinefteorgsintez). As modifier we used DST-30 divinyl–styrene elastoplastic rubber [Voronezh Synthetic Rubber Plant, TU (Technical Specifications) 38-40365–76], as the most economically acceptable. This elastoplastic is well soluble in asphalt.

As plasticizers we used commercial products: second vacuum gas oil (SVG) from AVT-2 installation

1070-4272/02/7509-1525$27.00 © 2002 MAIK "Nauka/Interperiodica"

(Kirishinefteorgsintez), density 912 kg m^{-3}, boiling range 390–499°C (50% distillation at 455°C), flash point 254°C, and polyalkylbenzene (PAB) from LAB-LABS installation, boiling range 315–480°C. Alkyl substituents in PAB are linear aliphatic chains containing 12–14 carbon atoms.

Polymer–asphalt compounds were prepared as follows. To the asphalt heated to 180–200°C, we added DST-30 rubber, and the blend was stirred for 1.5 h at 1250 rpm. The rubber amount was varied in steps from 1 to 6 wt % relative to the asphalt. Then, maintaining the temperature at 180–200°C, we added a plasticizer (SVG or PAB) in amount of 3, 5, 10, 15, or 20 wt % with vigorous stirring; the resulting compound was stirred for 15 min.

The performance characteristics of the resulting modified compounds were measured as prescribed by the corresponding standards for paving asphalts: the ring-and-ball softening point, according to GOST (State Standard) 11506–73; penetration at 25°C, P_{25}, according to GOST 11505–75; Fraas brittle point, according to GOST 11507–78 on a VRAZ device (Petrotest); and ductility, D_{25} (mm), according to GOST 11505–75 on a laboratory ductilometer.

The component composition of the initial and modified asphalts was determined with an IATRO-ACAN-5 device (Japan).

The component composition (wt %) of asphalts was as follows: BND 60/90, paraffinic and naphthenic compounds (PNCs) 9.34, arenes 46.65, resins 24.85, and asphaltenes 19.16; BND 90/130 (softer and more plastic asphalt), PNCs 10.03, arenes 47.85, resins 25.23, and asphaltenes 16.88. It is seen that harder BND 60/90 asphalt contains more resins and asphaltenes, whereas more plastic BND 90/130 asphalt contains more saturated and aromatic hydrocarbons (oils).

It is known that properties of asphalt compounds are improved at good compatibility of an asphalt with a rubber.

BND 60/90 asphalt having higher softening point is worse compatible with DST-30 elastoplastic than BND 90/130 asphalt. Rubber molecules swell in malthenes, altering the dispersion medium of the compound, since, in the course of swelling, they adsorb polar aromatic hydrocarbons and also heteroatomic components from the oil fraction of the asphalt.

The main characteristics of compounds based on BND 60/90 and BND 90/130 asphalts, as influenced by the plasticizer content, are listed in Figs. 1a and 1b. Figure 1a shows that, on adding DST-30 in proportion with a plasticizer, the softening point of the compound increases. Apparently, swollen rubber forms in the bulk of asphalt an elastic network, and the plasticizer facilitating uniform distribution of the rubber decreases the softening point to the greater extent, the higher its content in the compound. For BND 60/90 asphalt, according to GOST 22245–90, the softening point should be no lower than 47°C.

The effect of SVG plasticizer on the penetration of the compounds based on BND 60/90 asphalt is also seen from Fig. 1a. The penetration is an approximately linear function of the plasticizer content, i.e., increased content of the plasticizer enhances the solubility not only of the elastoplastic, but also of the resins and asphaltenes. The alkylaromatic plasticizer (PAB) decreases the viscosity (and hence increases the penetration) to the greater extent, i.e., in this case the structure of the compound is more plastic and mobile than with SVG. According to GOST 22245–90 for BND 60/90 asphalt, the penetration P_{25} should be within 60–90 mm. The following formulations meet these requirements: (1) 1 wt % DST-30, (2) 1 wt % DST-30 and 3 wt % SVG or PAB, (3) 3 wt % DST-30 and 3–5 wt % PAB or 3–10% SVG, and (4) 6 wt % DST-30 and 10–15 wt % SVG.

Asphalts modified with DST-30 and SVG differ from the initial asphalt not only in the softening point, penetration, and ductility, but also in the brittle point. The lower brittle point (down to –32°C) and higher softening point (up to 95°C) extend the working temperature range of the asphalt, which is important for territories with, respectively, cold and hot climate.

The softening points sharply decrease on adding 0–3% plasticizer and more gradually, with further additions.

The ductility of rubber–asphalt compounds varies differently depending on the formulation. For example, for the compounds based on BND 60/90, the ductility in most cases increases on adding SVG, but in the case of the compound with 1 wt % DST-30, it starts to decrease when the amount of the added SVG exceeds 3%. That is, the cohesion of the three-dimensional network formed by the asphalt, elastoplastic, and plasticizer becomes lower than that of the initial asphalt. Addition of the tested plasticizers decreases the brittle point in all the cases. Generally, PAB is a better plasticizer than SVG.

Similar trends are observed with compounds based on BND 90/130 (Fig. 1b). The softening point of this asphalt, according to GOST, should be now lower than 43°C; this requirement is met by all the compounds except that containing 1 wt % DST-30 and

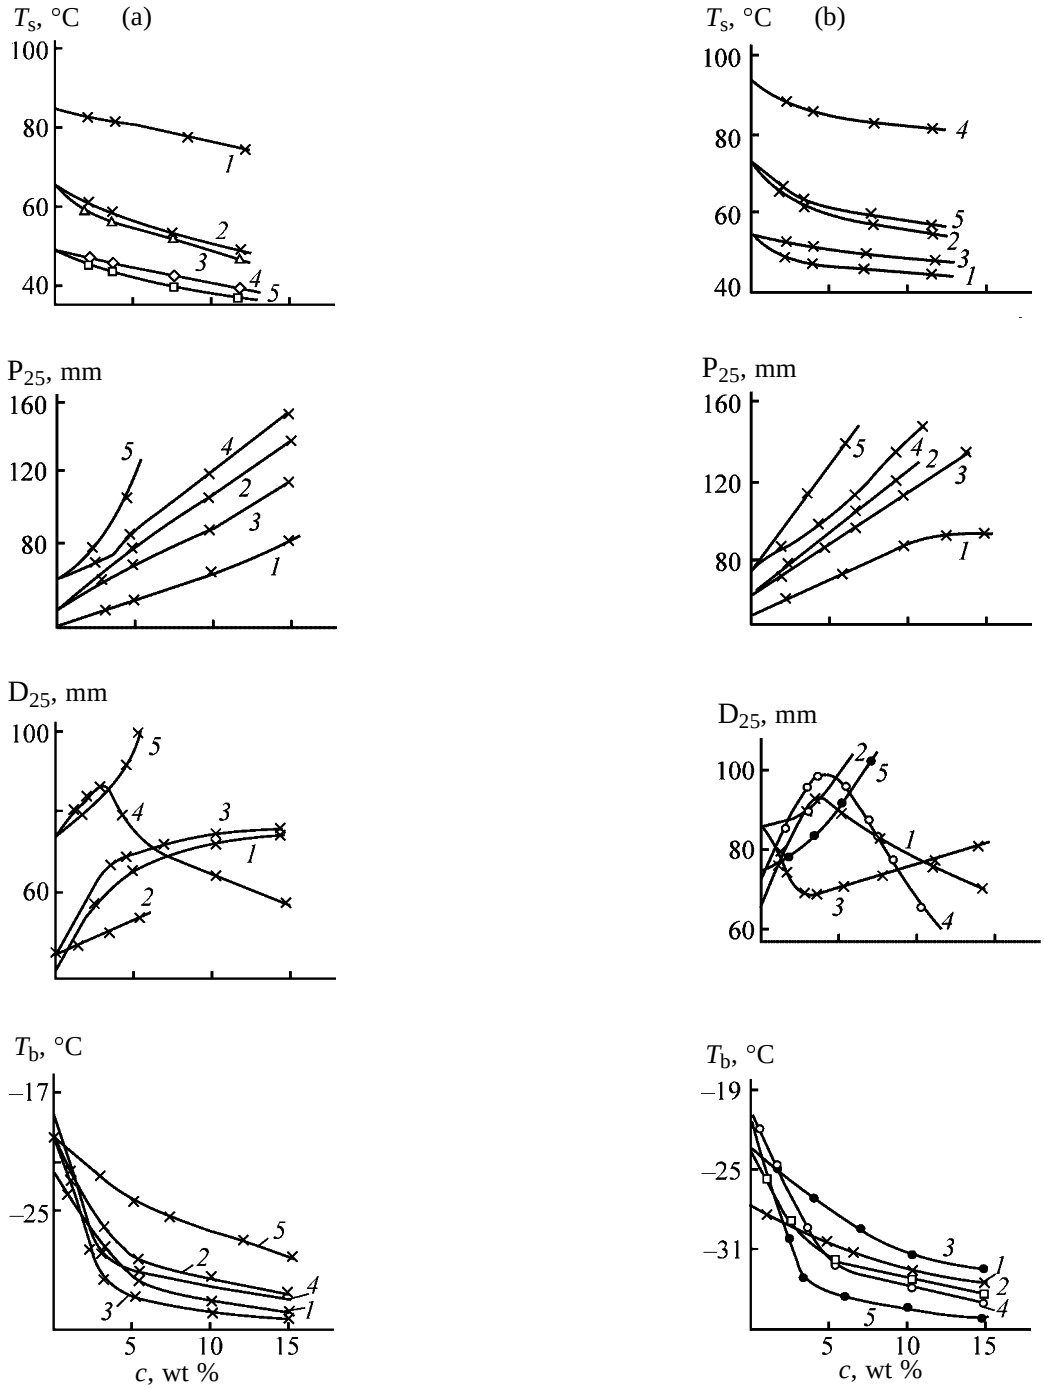

Fig. 1. Softening point T_s, penetration P_{25}, ductility D_{25}, and brittle point T_b of compounds based on (a) BND 60/90 and (b) BND 90/130 as functions of the plasticizer content c at various concentrations of DST-30 rubber. Plasticizer: (*1*, *3*, *4*) SVG and (*2*, *5*) PAB. DST-30 content, wt %: (*1*) 6, (*2*, *3*) 3, and (*4*, *5*) 1.

15 wt % SVG. As for penetration, the requirements of the standard are met by the following compounds: (1) 1 wt % DST-30 and 3 wt % PAB; (2) 3–5 wt % SVG and 1 wt % DST-30; (3) 3 wt % DST-30 and 10–15 wt % SVG or 3–5 wt % PAB; and (4) 6 wt % DST-30 and 10–15 wt % SVG.

The effect of the modifying additives on the ductility of BND 90/130 asphalt is also ambiguous. Addition of the elastoplastic sharply decreases the stretchability of the asphalt into a thread (by a factor of 1.5–2). However, on adding SVG, the ductility passes through an extremum at approximately 3 wt % content

of the plasticizer. Since the rubber does not react chemically with bitumen components (oils, resins, asphaltenes), it is, most likely, dispersed in the asphalt; on adding a plasticizer, the structure becomes more coarsely dispersed.

According to the standard, the stretchability of BND 90/130 asphalt should be no less than 65 cm. All the compounds meet this requirement, except the compounds containing 1 wt % DST-30 + 15 wt % SVG and 3 wt % DST-30 + 3 wt % SVG.

Figure 1b shows that addition of the elastoplastic increases the brittle point of the binary compound owing to formation of an elastic network structure. However, on adding a plasticizer, such structures become more stable, with PAB additions decreasing the brittle point to a greater extent. Thus, combined modification of oxidized petroleum paving asphalts BND 60/90 and BND 90/130 with DST-30 elastoplastic and SVG or PAB plasticizer appreciably extends the working temperature range of the asphalt (from the brittle point to the softening point), which will extend possible applications of the modified asphalts.

CONCLUSION

Modification of BND 60/90 and BND 90/130 paving asphalte with DST-30 elastomer (1–6 wt %) and petroleum plasticizers (polyalkylbenzene, 3–5 wt %; vacuum gas oil, 3–15 wt %, boiling range 390–499°C) extends the working range of the compounds [from –(32–35) to +(90–95)°C], as compared to unmodified asphalts [from –(25–27) to +(44–50)°C].

BRIEF COMMUNICATIONS

Synthesis of Highly Oriented α-PbO_2 Layers on the Surfaces of Single-Crystal Silicon and Quartz by Successive Ionic Layer Deposition

V. P. Tolstoi and E. V. Tolstobrov

St. Petersburg State University, St. Petersburg, Russia

Received January 2, 2002

Abstract—Conditions for the synthesis of α-PbO_2 layers on silica surfaces by successive ionic layer deposition were determined. These layers were studied by X-ray spectral microanalysis, X-ray diffraction, IR Fourier spectroscopy, UV-Vis spectroscopy, and ellipsometry.

Layers of Pb(IV) oxides are used in electrochemical current sources as precursors in the synthesis of Li-conducting solid electrolytes, high-temperature superconductors, etc.

The synthesis of such layers by successive ionic layer deposition technique (SILD) is the aim of this work. Earlier this technique was applied to the syntheses of layers of other oxides, hydroxides, and peroxides of metals, e.g., of $SnO_2 \cdot nH_2O$ [1], FeOOH [2], and $CeO_{2+x} \cdot nH_2O$ [3]. This method allows precise adjustment of the thickness of the synthesized layer (at the level of fractions of nanometer or several nanometers) and synthesis on the surface of a complex-shape support.

EXPERIMENTAL

Fused quartz of KU (quartz for ultraviolet region) brand and [100] silicon single crystal of KEF-7.5 brand polished to grade 14 were used as supports. Quartz supports were washed in acetone and were kept for 10 min in concentrated HNO_3 at 90–100°C and then rinsed with water, a KOH solution (pH 9), and again water. After etching in HF, single-crystal silicon supports were treated with concentrated HNO_3 at 90–100°C for 0.5 h, rinsed with distilled water, a KOH (pH 9) solution, and again water.

Nanolayers of α-PbO_2 were synthesized as follows. After a standard treatment, supports were fixed in holders of a computer-aided installation for syntheses and were immersed in various solutions in the sequence according to a scheme corresponding to an elementary ILD cycle, namely, in a $Pb(NO_3)_2$ solution (c = 0.01 M, pH ~5.8, in the presence of CH_3COONa), distilled water, $KMnO_4$ solution (c = 0.005 M, pH ~9.5 was adjusted by adding KOH), and in distilled water again. These reagents were chosen on the basis of considerable experimental work, which included tests of a number of other lead salts and solutions of oxidants, in particular, H_2O_2 and NaClO solutions. However, these experiments showed that the best conditions for SILD were attained with $Pb(NO_3)_2$ solutions containing CH_3COONa and alkalized $KMnO_4$ solutions. The duration of the treatment with each reagent was 0.5 min. As a result of the above-mentioned process sequence, one nanolayer of lead oxide was formed on the support surface. The subsequent nanolayers were synthesized by multiple repetition of SILD cycles.

As experimental methods we used UV-Vis and IR Fourier transmission spectroscopy, ellipsometry, X-ray diffraction, and X-ray spectral microanalysis. The transmission spectra of the synthesized layers were recorded in the UV and Vis ranges on a Perkin–Elmer Lambda-9 spectrophotometer (scanning rate 50 nm min^{-1}, slit program 2 nm), and the IR Fourier transmission spectra, on a Perkin–Elmer 1760X spectrophotometer at a resolution of 4 cm^{-1}. Ellipsometric measurements were carried out on an ellipsometer with an incidence angle of 45° and wavelength of 632.8 nm. The X-ray patterns were obtained on a DRON-3.0 diffractometer with CuK_α radiation. The X-ray spectral microanalysis was carried out on a CAMSCAN-4 scanning electron microscope (accelerating voltage 20 kV) integrated with an AN-10000 semiconductor spectrometer of characteristic

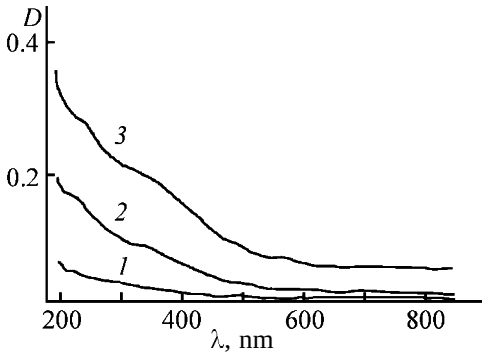

Fig. 1. Transmission spectra of α-PbO_2 layers synthesized on quartz surface by SILD: (*D*) optical density and (λ) wavelength. Number of SILD cycles: (*1*) 10, (*2*) 20, and (*3*) 30.

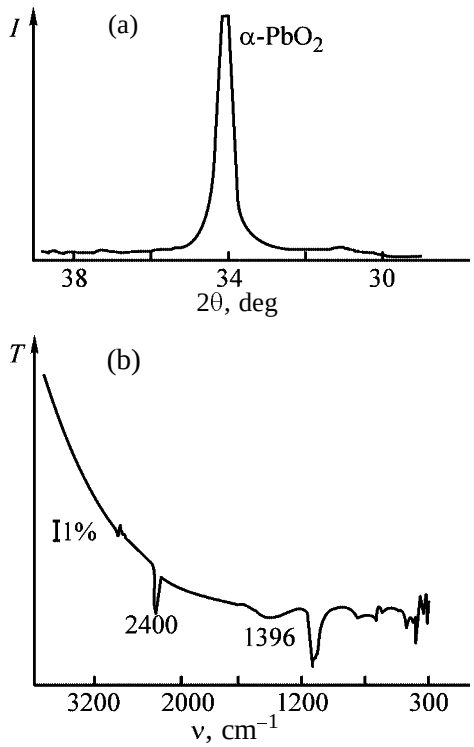

Fig. 2. (a) X-ray pattern and (b) FTIR transmission spectrum of an α-PbO_2 layer synthesized on the silicon surface by 40 SILD cycles and heated in air at 100°C for 0.5 h. (a) (*I*) Intensity and (2θ) Bragg angle; (b) (*T*) transmission and (ν) wave number.

X-ray radiation. Layers synthesized on single-crystal silicon served as samples for the X-ray spectral microanalysis, X-ray diffraction, ellipsometry, and FTIR spectroscopy, and layers on the quartz surface, for UV-Vis transmission spectroscopy. The support was chosen so as to ensure the highest efficiency of each method. The point is that the layers synthesized by SILD are very thin, and thus they can be studied only under conditions of the highest sensitivity of each method. Such conditions are attained when silicon and quartz supports are used in studies by FTIR and UV-Vis spectroscopy, respectively, because of their transparency in these spectral regions. The X-ray spectral method is the more efficient with a silicon support owing to its higher conductivity and smaller amount of surface charges. X-ray diffraction and ellipsometry are more efficient in studying layers on a silicon surface: the first method, owing to the higher intensity of the useful signal, and the second, owing to the wider range of the linear dependence of the ellipsometric parameters on the layer thickness.

When a quartz plate is subjected to 10, 20, and 30 SILD cycles, a broad absorption band appears in its UV-Vis transmission spectrum in the range 200–450 nm (Fig. 1); its integral intensity grows with increasing number of cycles. According to ellipsometric measurements, the thickness of a layer formed in one cycle is 0.45 nm. The X-ray spectral analysis showed that the layer consists of lead and oxygen atoms. No manganese and potassium ions pass into the layer from the solution. The X-ray pattern (Fig. 2a) suggests that the layer has the crystal structure of rhombic α-PbO_2 (a = 0.4038, b = 0.503, c = 0.5486 nm), with the c axis being normal to the support surface. The layer also contains OH groups, which can be identified by their bending band at 1356 cm^{-1} in the FTIR spectrum (Fig. 2b). It should be noted that the presence of OH groups is consistent with the structure model of the α-PbO_2 layer accepted, e.g., in [4].

The following model offers the most probable explanation of our results. The treatment of the support with a $Pb(NO_3)_2$ solution results in adsorption of Pb^{2+} or $PbOH^+$ ions [5]. Then excess $Pb(NO_3)_2$ is removed from the surface in the stage of washing with water. In the subsequent stage, the support containing a sorbed layer of Pb^{2+} ions is treated with an alkalized $KMnO_4$ solution, which results in the oxidation of Pb(II) to Pb(IV) and the reduction of Mn(VII), apparently to Mn(V) which subsequently reacts with excess $KMnO_4$ to form MnO_4^{2-}. We believe that such a process is the most probable, since specifically the MnO_4^{2-} ions can be removed most readily from the surface in the stage of washing off excess $KMnO_4$ from the support. The process is repeated in each subsequent SILD cycle. This scheme also allows us to explain the high crystal-chemical perfection of the synthesized layer, as in each SILD stage the reaction products are removed from the surface, which reduces steric hindrances to the layer growth.

CONCLUSION

The possibility of preparing α-PbO_2 layers by successive ionic layer deposition on silicon and quartz surfaces was shown. The thickness of the resulting layers is precisely specified by the number of ionic deposition cycles.

Abstract—Electrochemical halogenation of 4-oxo-2,2,6,6-tetramethylpiperidine (triacetonamine) in the electrolytes triacetonamine–KX–CH_3ONa (X = Cl, Br, I) was studied, and a procedure was developed for preparing 3-methoxycarbonyl-2,2,5,5-tetramethylpyrrolidine by this reaction.

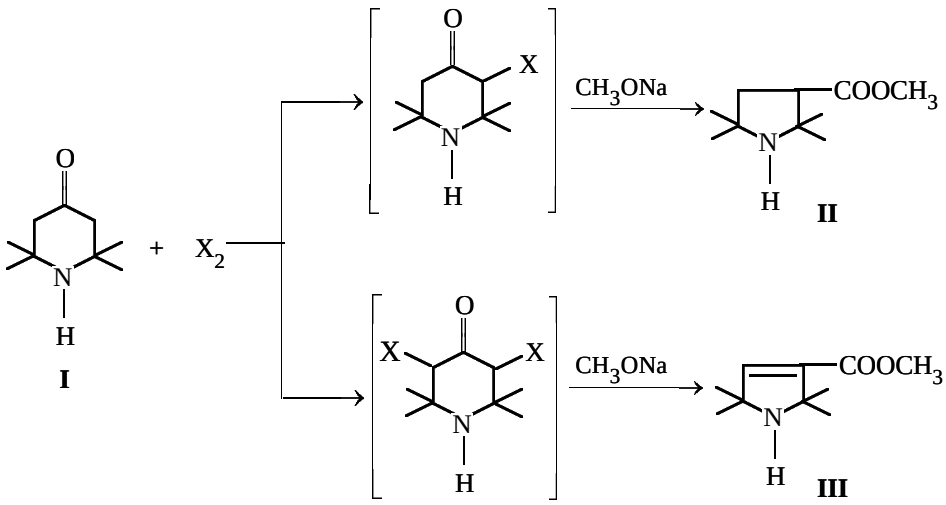
Compounds of the 2,2,5,5-tetramethylpyrroline and 2,2,5,5-tetramethylpyrrolidine series are used for preparing spin markers in studies of polymers, biopolymers, and drugs [1]; however, synthesis of these compounds is difficult. 3-Methoxycarbonyl-2,2,5,5-tetramethylpyrrolidine **II** is an important synthetic precursor of nitroxyl radicals of the pyrrolidine series [2]. It is prepared from 4-oxo-2,2,6,6-tetramethylpiperidine (triacetonamine, TAA, **I**) in several steps [3]. In this work we developed a procedure for preparing **II** by electrochemical halogenation of **I**.

Electrochemical halogenation of **I** in a sodium methylate solution is accompanied by the Favorskii rearrangement [4] and yields a mixture of **II** with 3-methoxycarbonyl-2,2,5,5-tetramethylpyrroline **III**. Apparently, the reaction occurs via mono- and dihalo derivatives of TAA. The process involves the following transformations:

at the anode: $2Br^- - 2e \rightarrow Br_2$,

at the cathode: $2CH_3OH + 2e \rightarrow 2\ CH_3O^- + H_2$,

in solution:



where X = Cl, Br, I.

As sources of halide ions, we used KCl, KBr, and KI. The ratio of **II** and **III**, determined by gas–liquid chromatography (GLC), depended mainly on the halide ion. The total yield of **II** and **III** was 80–87% irrespective of the halide ion. Pure 3-methoxycarbonyl-2,2,5,5-tetramethylpyrrolidine **II** was prepared by reduction of a mixture of **II** and **III** with sodium amalgam.

	4	62	84	12	50
	8	100	80	16	84
Br^-	2	24	87	6	18
	4	72	85	20	52
	8	100	85	38	62
I^-	2	18	84	8	10
	4	69	81	30	39
	8	100	82	46.8	53.2

EXPERIMENTAL

Chromatographically pure TAA was purchased from Sintez Joint-Stock Company (Tambov, Russia); organic solvents were of pure grade. Gas chromatography was performed with an LKhM-8MD chromatograph (thermal conductivity detector; sensitivity 1 : 3; carrier gas helium, flow rate 0.4 ml s^{-1}; stationary phase PEG-4000 on Chromaton N-AW; temperatures: vaporizer 270, detector 200, and column 150; 1500 × 3-mm column).

Electrochemical halogenation of **I** was performed in a sodium methylate solution. Electrolysis was performed in a 200-ml diaphragmless electrolyzer equipped with a magnetic stirrer, a reflux condenser, and an electrode stack (anode: platinum plate, surface area 7.5 cm^2; cathode: two stainless steel plates of the same surface area; distance between the anode and cathode 3 mm). The electrolyzer was charged with 6 g (0.038 mol) of TAA, 0.067 mol of a potassium halide, and 100 ml of methanol containing 2.3 g (0.1 mol) of dissolved sodium. Electrolysis was performed under vigorous stirring with a current of 1 A (current density 0.1 A cm^{-2}). The reaction completion was judged from disappearance of **I** (TLC, Al_2O_3, Brockmann grade II, eluent CH_2Cl_2, development with I_2 vapor). After electrolysis completion, the solvent was distilled off, 50 ml of water was added, and the products were extracted with CH_2Cl_2 (3 × 30 ml). The extract was evaporated in a rotary evaporator, and the oily residue was distilled in a vacuum; the fraction boiling within 80–85°C/3 mm Hg was collected. The composition of the mixture was determined by GLC from the peak areas, assuming equal sensitivity of the detector to **II** and **III**. The peak areas were measured with an accuracy of 5 rel. %.

Compound **III** was reduced to **II** with sodium amalgam. Synthesis was performed in a diaphragm electrolyzer made of a 200-ml battery housing. The cathode was mercury added in an amount sufficient to fully cover the bottom. The surface area of the mercury electrode was 38.5 cm^2. Current was fed with a copper wire insulated with Teflon, except the tip (0.3 cm) immersed in mercury [5]. The anode was a platinum spiral (surface area 10 cm^2).

The cathodic compartment was charged with 50 ml of 7% NaOH, and the anodic compartment, with 5% alkali. Electrolytic preparation of the amalgam was performed at a current of 5.2 A (current density 0.1 A cm^{-2}) at 30–40°C with stirring. The electrolysis was completed after passing 2.2 F mol^{-1} (0.9 A h) of electricity. After the electrolysis completion, the alkali solution was removed, and the electrolyzer was charged with a solution of a mixture containing 2 g (0.011 mol) of **II** + **III** and 30 ml of methanol. The reaction completion was judged from disappearance of **III** (TLC, Al_2O_3, Brockmann grade II, eluent CH_2Cl_2, development with I_2 vapor). After the reaction completion, the solvent was removed, and 1.8 g (90%) of **II** was obtained; oily substance, melting point of the picrate 124–126°C. Mixing the picrate sample obtained with an authentic sample gave no melting point depression [6].

CONCLUSION

Electrochemical halogenation of triacetonamine in a sodium methylate solution is accompanied by the Favorskii rearrangement, giving in a high yield a mixture of 3-methoxycarbonyl-2,2,5,5-tetramethylpyrroline and 3-methoxycarbonyl-2,2,5,5-tetramethylpyr-

rolidine; a procedure was developed for the reduction of 3-methoxycarbonyl-2,2,5,5-tetramethylpyrroline to 3-methoxycarbonyl-2,2,5,5-tetramethylpyrrolidine with sodium amalgam.

Abstract—A procedure was developed for preparing alginate fibers with controllable calcium content. The effect of ethonium and Katamin AB on desorption of calcium ions from the alginate fiber was studied.

Alginate fibers are used in medicine and in food and textile industries. Alginate fibers prepared by the existing process contain about 10–12% calcium ions (0.25–0.30 mol per 100 g of fiber).

Alginate fibers show promise as dressings and resolving materials in medicine; also, soluble alginate fibers give useful effect in textile industry. In these cases, the calcium content on the fiber should not exceed 2–6% (0.05–0.15 mol per 100 g of fiber), depending on particular application. To prepare alginate fibers containing 2–6% Ca^{2+}, the initial fiber was subjected to multistep time-consuming treatments [1, 2]. The fiber was treated for 20 min with a sodium hypochlorite solution, which was followed by successive washing with an aqueous solution of sodium thiosulfate, water, and calculated amount of hydrochloric or another acid for 30 min. After that, the fiber was again washed with water and neutralized with alcoholic NaOH. Finally, it was treated with 95% methanol.

Experiments on preparation of alginate fibers with antimicrobial activity showed that treatment of alginate fibers with some nitrogen-containing antimicrobial agents considerably reduces the calcium content on the fiber, even when performed under common conditions [3]. Data on the content of calcium ions on alginate fiber after treatment under static conditions with 1% aqueous solutions of agents (1 h, 20°C) and, for comparison, with distilled water are listed in the table.

The best results were obtained with agents containing a quaternary nitrogen atom. Ethonium contains two quaternary nitrogen atoms per formula unit, and Katamin AB, only one; correspondingly, ethonium is more effective. These two agents were chosen for further experiments aimed at controlling the Ca^{2+} content on the alginate fiber.

Detailed study of calcium removal as influenced by the concentrations of the nitrogen-containing agents (Fig. 1) showed that the optimal concentration of ethonium is 5% (85 mM), and that of Katamin AB, 3% (70 mM). Treatment with such solutions reduces the Ca^{2+} content to 0.102 (4.0%) and 0.140 mol per 100 g of fiber (5.6%), respectively. In the course of treatment, the solution pH increases from 3.8–4.0 to 5.0–5.3. The ratio of the optimal concentrations of the agents correlates to some extent with the ratio of their critical micelle concentration: ethonium, 3.2; Katamin AB, 2.5 mM [4], although our experiments were performed at considerably higher concentrations of these agents.

Apparently, the extremum in the curves, when further additions of the nitrogen-containing agent decrease its performance, is due to active micelle formation. Data on the content of free carboxy groups on

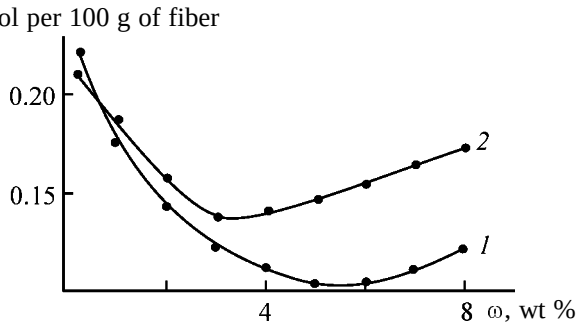

Fig. 1. Content of calcium ions *c* on alginate fiber as a function of concentration ω of (*1*) ethonium and (*2*) Katamin AB in solution. 20°C; the same for Fig. 2.

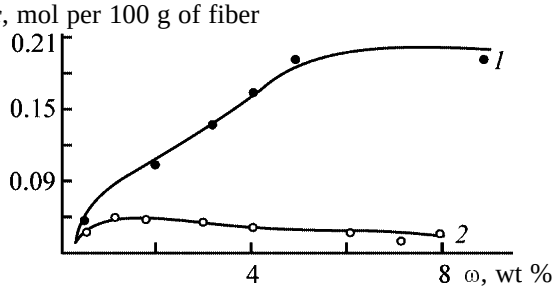

Fig. 2. Content of free carboxy groups *c* on alginate fiber as a function of concentration ω of (*1*) ethonium and (*2*) Katamin AB in solution.

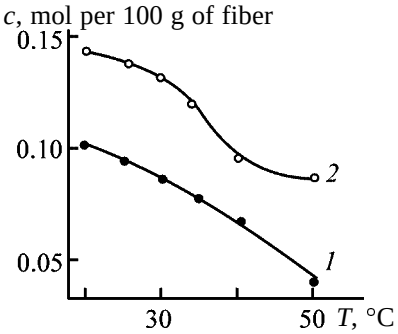

Fig. 3. Content of calcium ions *c* on alginate fiber as a function of temperature *T* of treatment with (*1*) 5% ethonium solution and (*2*) 3% solution of Katamin AB. Treatment time 1 h.

the fiber can be interpreted from the same standpoint (Fig. 2). With ethonium, the curve first linearly ascends and then flattens out, whereas with Katamin AB a short linearly ascending portion is followed by a slow descent. These curves are resultant of two processes: release of carboxy groups due to removal of Ca^{2+} ions and their reaction with quaternary ammonium compounds. Bulky ethonium ion reacts with carboxy groups very slowly, whereas Katamin AB reacts actively. This is indirectly confirmed by data on their antimicrobial activity. The diameter of the growth suppresion zone for *Staphylococcus aureus 209* is 25 mm with ethonium-treated alginate fiber and 42 mm with the Katamin AB treated fiber.

The Ca^{2+} content on the fiber can be controlled still more efficiently by varying the treatment temperature (Fig. 3). In this case, the Ca^{2+} content on the fiber can be reduced to 0.05 mol per 100 g of fiber (2%), which is very important for medicine. The treatment temperature should not exceed 50°C, since at higher temperatures the fiber undergoes irreversible deformations.

The developed procedure allows preparation of alginate fiber with preset and well-reproducible calcium content. The fluctuations of the calcium content do not exceed 3%, whereas in treatment with sodium hypochlorite, because of the multistep procedure, they reach 10%.

EXPERIMENTAL

An accurately weighed 1-g portion of calcium-containing alginate fiber was placed in an aqueous solution containing a prescribed amount of a nitrogen-containing agent; liquid-to-solid ratio 30. After the treatment, the fiber was washed with distilled water (liquid-to-solid ratio 1000), squeezed with filter paper, and air-dried.

To determine the calcium content on alginate fiber, an accurately weighed 0.3-g portion of the fiber was placed in a porcelain cup, 5 ml of 2.0 M HCl was added, and the cup was placed on a boiling water bath. The solution was evaporated by half with stirring, and an additional 5 ml of HCl was added. The hydrochloric acid extract was quantitatively transferred onto a filter, with collection of the filtrate and wash waters. To the solution, 12.5 ml of 2.0 M NaOH was added dropwise with stirring, and the solution was titrated with Na_2EDTA.

The content of free carboxy groups in the alginate fiber was determined as follows. To an accurately weighed fiber sample (0.3 g), we added 30 ml of 0.1 M NaOH, kept for 1 h until the sample completely dissolved, and titrated with 0.05 M sulfuric acid (phenolphthalein indicator).

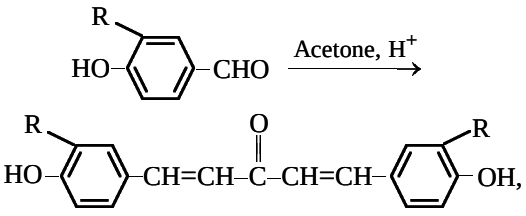
Abstract—Coordination bonding of 1,5-diphenylpentadienone was studied with the aim to prepare compounds exhibiting third-order nonlinear optical properties. The volume resistivity of these compounds was studied as influenced by the third-order nonlinear susceptibility tensor.

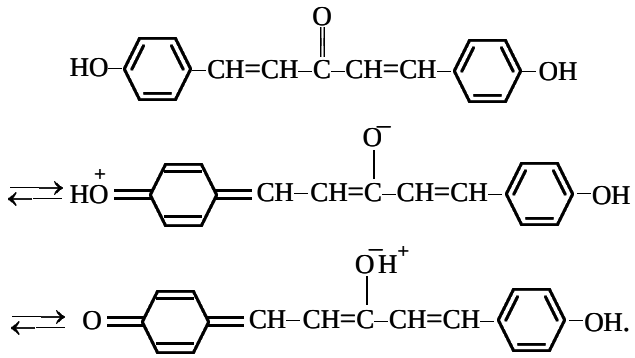
Preparation of materials exhibiting nonlinear optical (NO) effects, in particular, third-order nonlinear susceptibility, is today one of the most promising lines of research. These effects find application in fiber-optics communication systems. The structural features of compounds exhibiting NO effects are the presence of a system of conjugated bonds and the polarizability and capability for uniaxial orientation of their molecules.

The known approach to preparing nonlinear isotropic media involves synthesis of highly oriented metal complex oligomeric systems. In particular, Bubeck [1] synthesized oligomers in which complexes of ruthenium with phthalocyanines were bound into "stacks" by *p*-phenylene diisocyanate bridges. It was assumed that the optical properties of such oligomers are primarily determined by the two-dimensional π-conjugation system of the phthalocyanine moieties. These oligomers have one of the largest known third-order nonlinear susceptibility tensor $\chi^{(3)}$ (3.7×10^{-12} CGSE units).

We showed in [2] that 1,5-bis(4-hydroxyphenyl)-1,4-pentadien-3-one (HPPD) and 1,5-bis(4-hydroxy)-3-methoxyphenyl)-1,4-pentadien-3-one (HMPPD) can exhibit third-order NO effects:



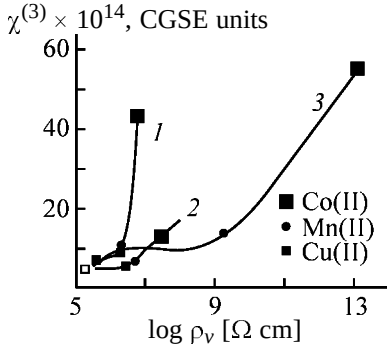
where R = H (HPPD) (**I**) and CH_3O (HMPPD) (**II**). With this specific chemical structure, these compounds can have the following resonance structures:



The structures of HPPD and HMPPD suggest that the NO response of their derivatives can be increased by enhancing the degree of polarization of the conjugation system and orientation of the HPPD and HMPPD macromolecules by coordination bonding. The choice of coordination compounds based on chlorides of 3*d* metals ($CoCl_2$, $CuCl_2$, $MnCl_2$) and monoethanolamine (MEA) or *N*,*N*'-diethylhydroxylamine (DEHA) as complexing agents was based on the previously revealed [3, 4] capability for self-organization of oligomers containing electron-donating (in particular, carbonyl) groups with the formation of liquid-crystalline compounds.

For the reaction products of HPPD and HMPPD with metal complexes, we measured the third-order nonlinear susceptibility tensors $\chi^{(3)}$ and the volume resistivity ρ_v (see figure).

1070-4272/02/7509-1537$27.00 © 2002 MAIK "Nauka/Interperiodica"



Variation of the third-order nonlinear susceptibility tensor $\chi^{(3)}$, CGSE units, with the volume resistivity ρ_v, Ω cm, for the products of the reactions between HPPD and metal complexes.

A combined study of the electrical and optical properties of the synthesized metal complexes revealed a correlation between their volume resistivity and nonlinear optical susceptibility: $\chi^{(3)}$ increases in parallel with ρ_v, and both these parameters are strongly influenced by the nature of the coordination center.

Our results can be explained by coordination bonding of the metal ion with the carbonyl group, which disturbs the conjugation system in HPPD and HMPPD, thus increasing ρ_v.

The ρ_v increment depends on the nature of the 3*d* ion. For example, with Cu(II), Mn(II), and Co(II) as coordination centers, ρ_v increases by one, four, and eight orders of magnitude, respectively.

These profound changes in ρ_v suggest that the strength of coordination bonding affects the electron density redistribution in the resonance structures of HPPD and HMPPD. For example, the greatest coordination power and, hence, the strongest disturbance of the π-electron system delocalization in compounds **I** and **II** is characteristic of the Co(II) ion, and the smallest, of the Cu(II) ion.

The coordination power of metal complexes with respect to HPPD and HMPPD is also suggested by IR spectra. For example, the absorption bands near 1650 cm^{-1}, corresponding to vibrations of the carbonyl group in HPPD, get significantly broadened, and the intensity and width of the absorption bands at 1600 cm^{-1}, corresponding to stretching vibrations of C=C double bonds, remain unchanged.

Our studies showed that increase in $\chi^{(3)}$ is due, above all, to enhanced polarizability of the HPPD and HMPPD molecules owing to changes in the electronic structure of the carbonyl group resulting from its coordination.

CONCLUSIONS

(1) Metal ions coordinated to the carbonyl group in 1,5-bis(4-hydroxyphenyl)-1,4-pentadien-3-one draw off the lone electron pair from the oxygen atom, thus disturbing the conjugation system of this compound. This increases the volume resistivity of the films from 10^5 to 10^{14} Ω cm. Increase in ρ_v tends to increase the third-order nonlinear susceptibility tensor $\chi^{(3)}$ from 5×10^{-14} to 6×10^{-13} CGSE units.

(2) The ρ_v increment is strongly influenced by the nature of the 3*d* ion. With Cu(II), Mn(II), and Co(II) as the coordination centers, ρ_v increases by one, four, and eight orders of magnitude, respectively.

Abstract—The activity and selectivity of coarse-porous H-mordenite in synthesis of cyclic and linear dimers of α-methylstyrene were studied.

Numerous homogeneous and heterogeneous acid catalysts are used to synthesize dimers and trimers of α-methylstyrene; these include sulfuric, phosphoric, chloroacetic, and *p*-toluenesulfonic acids, cation-exchange resins [1, 2], metal oxides [3], and zeolite-like aluminophosphates [4]. However, data on the effect of zeolites in this reaction are scarce. Synthesis of linear dimers of α-methylstyrene in CH_2Cl_2 solution in the presence of zeolites Y with various Brønsted acidities was studied in [5]. Utilization of a solvent in this case requires additional stage of distillation, which complicates the process and deteriorates its feasibility characteristics.

In this work we studied oligomerization of α-methylstyrene in the presence of mordenite type zeolite.

EXPERIMENTAL

Oligomerization of α-methylstyrene was performed in a batch reactor at atmospheric pressure in the 20–140°C range. The reaction products were analyzed by gas–liquid chromatography (GLC).

The mordenite type zeolites were prepared from aqueous solutions of sodium aluminate, sodium hydroxide, and white black (samples I, II) or the waste from production of crystalline silicon (sample III) [6, 7]. The SiO_2/Al_2O_3 molar ratio in the resulting samples was 12.2 (I), 9.8 (II), and 10.0 (III). Sample I was a fine-porous (static capacity for benzene vapor 0.02 $cm^3\ g^{-1}$), and samples II and III, coarse-porous (static capacity for benzene vapor 0.11 and 0.12 $cm^3\ g^{-1}$, respectively) modifications of mordenite.

To prepare catalysts in the H form, the samples were treated with NH_4NO_3 solutions to the residual content of Na_2O ≤0.1 wt % and then calcined in air for 4 h at 540°C.

As in the case of the other acid catalysts [1–5], oligomerization of α-methylstyrene on mordenite yields the cyclic dimer c-D (1,1,3-trimethyl-3-phenylindane), linear dimers α-D and β-D (4-methyl-2,4-diphenyl-1-pentene and 4-methyl-2,4-diphenyl-2-pentene), trimers, and tetramers. The composition of the reaction products is determined by the catalyst properties and reaction conditions.

As seen from Table 1, Na-mordenite is inactive in this reaction, whereas the H-form exhibits a catalytic activity strongly depending on the pore size in the mordenite crystal lattice. No conversion of α-methylstyrene occurs at 120–140°C in 6 h with fine-porous mordenite I (10–20 wt % relative to the feed), and significant conversion *K* is observed only in the presence of 50–60 wt % of this catalyst, which suggests that the reaction proceeds predominantly at the outer zeolite surface.

In the presence of coarse-porous catalysts II and III, a mixture of α-methylstyrene oligomers is formed, and in the case of catalyst III the content of trimers and tetramers reaches 30 wt %.

Mordenite II is the most active and selective catalyst providing conversion of α-methylstyrene into the linear dimers α-D and β-D. The data on oligomerization of α-methylstyrene in the presence of this catalyst at various temperatures are listed in Table 2. The reaction starts even at a low content of catalyst II (1–2 wt %) at 60°C, with the selectivity *S* of formation of dimers α-D and β-D being 61.4%; however, the

20	140	1	93.3	–	–	6.7	100.0	–

monomer conversion is relatively low. With increasing content of the catalyst to 10–15 wt %, at 80–110°C, the conversion of α-methylstyrene reaches 97%, with 80–90% selectivity. Under the more rigid conditions, the yield of the cyclic dimer increases, and at 140°C and 20 wt % content of mordenite II the yield of c-D is 93.3 wt %.

It should be noted that mordenites II and III, having similar characteristics, differ in the catalytic properties: The conversion of α-methylstyrene and selectivity in the presence of catalyst II are significantly higher as compared to catalyst III. This is probably due to the different composition of the initial silicon-containing materials used in the mordenite preparation.

CONCLUSION

The coarse-porous H-mordenite prepared from the aqueous solutions of sodium aluminate, sodium hydroxide, and white black with the subsequent removal of cations and annealing at 540°C exhibits high activity and selectivity in oligomerization of α-methylstyrene.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Vladimir Fedorovich Alekseev (on 150th Anniversary of His Birthday)

Vladimir Fedorovich Alekseev, a prominent Russian physical chemist of the end of the XIX century, carried out a number of classical experimental investigations in the theory of solutions and heterogeneous equilibria involving liquid phases.

V.F. Alekseev was born on October 12, 1852, in St. Petersburg. He received secondary education at the Second St. Petersburg Military College. In 1867, he entered the Mining Institute and graduated from the institute as a mining engineer in 1873. Alekseev started his studies in chemistry already when being a student, under supervision of Prof. K.I. Lisenko (1836–1903), a known scientist working in the field of technical chemistry. In 1873–1877, Alekseev worked as laboratory assistant at the chemical laboratory of the Mining Institute and conducted research in preparative organic chemistry and mutual solubility of liquids. In 1877–1879, he held the position of assistant assayer at the Mint, without terminating his studies of solutions. In 1879, Vladimir Fedorovich defended his dissertation *On Mutual Solubility of Liquids* at the Mining Institute and became an adjunct at the chair of chemistry of the same institute. This was the beginning of the twenty years of Alekseev's pedagogical activities at the Mining Institute.

During his work on the dissertation, the young scientist established for the first time the existence of a temperature at which two liquid layers mix with each other in any proportion to form a homogeneous mixture. The author proposed a rather simple and original optical method for determining the mutual solubility of liquids.

The first Russian chemist to become interested in the mutual solubility of liquids was D.N. Abashev (1829–1880), a graduate from St. Petersburg University (1851) and, later, a professor of Kiev and Novorossiya (Odessa) Universities. In 1858, he defended his master's dissertation *Studies of Mutual Solubility of Liquids.* Abashev's experiments became the starting point for extensive investigations carried out in this field by Alekseev. Using the method developed by him, he obtained systematic data on the mutual solubility of a wide variety of liquids, with many of these data still found in reference books. As noted by

N.S. Kurnakov (1860–1941), "V.F. Alekseev was the first to present the facts for constructing full solubility diagrams for binary systems characterized by formation of two liquid layers" [1]. Alekseev was also the first to present experimental data on the mutual solubility in the form of graphical phase diagrams, published first geometric images of phase diagrams for liquid systems, and indicated the homogeneity and phase separation regions.

One more thing is associated with Alekseev's name, the "rectilinear diameter rule," according to which the arithmetic mean of the composition (presented in wt %) of equilibrium liquid phases varies linearly with temperature, and the point of intersection of the straight line expressing this dependence with the boundary of the phase separation region (binodal curve) corresponds to the critical solution temperature, which is a critical point [2, 3]. A detailed analysis of the history of this discovery and the evidence of Alekseev's priority have been presented [4] by S.A. Pogo-

1070-4272/02/7509-1541$27.00 © 2002 MAIK "Nauka/Interperiodica"

din, a known physical chemist and historian of chemistry.

Alekseev's active investigations into various properties of solutions and heterogeneous equilibria involving such solutions were carried out since 1875 until 1886. During this period of time, he published 17 papers and made 31 reports at meetings of the Russian Physicochemical Society. To elucidate the nature of solutions, the scientist studied a wide variety of their properties: specific heat, heats of mixing, saturated vapor pressure, and surface tension. In contrast to the standpoint of D.I. Mendeleev (1834–1907), Alekseev believed that chemical interaction is not a necessary condition for dissolution. Later, I.F. Shreder (1858–1918), also a professor of the St. Petersburg Mining Institute, considered solutions with the minimum extent of chemical interaction between their components as a special group of solutions. Alekseev believed that the fundamental aspects of behavior are the same for widely diverse classes of solutions, including metal alloys. However, alloys were the subject of only a single Alekseev's paper concerned with the mutual solubility of bismuth and mercury. A detailed analysis of Alekseev's works in the field of mutual solubility of liquids and solution properties can be found in a paper by Ya.I. Gerasimov [5] and monograph by A.Ya. Kipnis [6].

Together with studying various solutions, Alekseev paid much attention to general problems of the chemical thermodynamics of that time. In 1884, he published an interesting "Treatise of the Present State of Chemical Mechanics" [*Gornyi Zhurnal* (Journal of Mining), 1884] devoted to the theory of chemical equilibrium. The treatise, in particular, read: "Chemical mechanics plays an exceedingly important role in applied chemistry, and clear understanding of at least such fundamental processes as, e.g., the evergreen Bessemer process and blast-furnace melting is impossible without it" [7]. Here, the works of H. Saint-Clair Deville (1818–1881), a French chemist, in the field of thermal dissociation and theory of chemical equilibrium are meant in the first place. The same treatise presented, for the first time in the Russian chemical literature, the notion of entropy and also gave an account of J. Gibbs' (1839–1903) equilibrium principle.

In 1886, Alekseev ceased studies of solutions and devoted himself entirely to problems of applied chemistry. In Kurnakov's opinion [1], "... the reason why this occurred is V.F.'s passionate and not always balanced temper, a financial position that became complicated, and changes in his social standpoint under the influence of Leo Tolstoy's concepts." Alekseev started to study coals and peat and developed methods for testing these. In 1895, he published his fundamental work "Fossil Coals of the Russian Empire and Their Composition" (St. Petersburg, 1895). To achieve an efficient use of peat deposits in northern regions of Russia, Alekseev founded a special laboratory in St. Petersburg and a peat plant in Tver Province.

After 25 years of service at State institutions, Alekseev ceased teaching at the Mining Institute and retired. Beginning in 1901, he lived at his Sosno manor in the Vyshni Volochek District of Tver Province, where he did farming, studied problems of peatery, and was engaged in social activities. He died on September 12, 1919. The obituary written by Academician Kurnakov read: "The general chemistry and its new field, physicochemical analysis, lost in V.F. Alekseev's person an outstanding researcher, whose works will undoubtedly grow in importance for the understanding of the fundamental properties of equilibrium systems with the development of science" [1]. Later (in 1928), he noted: "Three chemists, V.F. Alekseev, D.P. Konovalov, and I.F. Shreder, originating from the chemical laboratory of the Mining Institute, had great impact on the development of such a field of general chemistry as physicochemical analysis" [8].

BOOK REVIEWS

Volkov, V.L., Zakharova, G.S., and Bondarenka, V.M., *Kserogeli prostykh i slozhnykh polivanadatov* (Xerogels of Simple and Complex Polyvanadates)

Yekaterinburg: Inst. Khimii Tverdogo Tela, Ural. Otd., Ross. Akad. Nauk, 2001, 194 pp.

The appearance of this book has been stimulated not only by achievements in the understanding of the nature of hydrated vanadium(V) oxide, but, to no lesser extent, by success in use of its unique properties for creating practically important materials. The present level in this field has been attained mainly owing to fruitful investigations of several research groups, one of which is constituted by the authors of the monograph in question, well familiar with the object of study.

The monograph generalizes the results of investigations of synthesis procedures, chemistry, and physicochemical properties of simple and complex polyvanadates with vanadium(V) oxide structure and possible ways of their use. The book comprises 5 chapters, 67 figures, 35 tables, and a list of 411 references.

The first chapter presents results of X-ray diffraction and structural studies of hydrated and anhydrous vanadium(V) and (VI) oxides, and also data on synthesis and structure of a xerogel of vanadium(V) oxide, which is a solid polyvanadic acid $H_2V_{12}O_{31-\delta}\cdot nH_2O$. The structure of vanadium(V) oxide xerogel forms a basis for polyvanadate xerogels, compounds in which part of vanadium atoms in vanadium–oxygen layers are replaced by elements of Groups IV–VI or interlayer protons are displaced by other cations.

The second chapter considers xerogels of polyvanadates of mono-, di-, and trivalent metals. These compounds are represented as hydrated interstitial alloys of variable composition, isostructural to polyvanadic acid. The state of vanadium and oxygen–hydrogen groups in xerogels have been studied using ESR, ^{1}H NMR, and XPE spectroscopy.

The third chapter generalizes the results obtained in studying xerogels of complex polyvanadates obtained through substitution of vanadium ions in $V_2O_5\cdot nH_2O$ xerogels by tetra-, penta-, and hexavalent ions. The best studied were xerogels of polyvanadomolybdic acid and polyvanadomolybdates of alkali metals, for which thermal dehydration patterns, structural characteristics, and evidence concerning the valence state of vanadium and molybdenum ions have been obtained. Data on xerogels obtained by substitution of vanadium by tungsten, selenium, rhenium, titanium, silicon, germanium, and antimony are presented. Also considered are closely related layered compounds isostructural to vanadium phosphates, obtained through introduction of metal cations and of organic and organometallic compounds into the interlayer space of phosphovanadates.

The fourth chapter considers physicochemical properties of polyvanadate xerogels, which are governed by the properties of both the basic polymeric vanadium–oxygen lattice and cations and molecules introduced into the interlayer space. Readily obtainable as films, xerogels have layered structure with weak interaction between layers, into which both metal cations and organic or organometallic molecules can be intercalated. Intercalation of organic compounds may be accompanied by redox reactions, which are of interest as means of obtaining oligomers and polymers of such compounds as pyrrole, aniline, and ethylene oxide, with unique electrical properties. The chapter presents thermodynamic data characterizing the state in xerogels of water molecules with different types of chemical bonding with the matrix, and also that of hydrogen and lithium ions.

The chapter also describes investigations of the electrical conductivity of polyvanadate xerogels, including those in the form of films, whose electrical properties exhibit clearly pronounced anisotropy. The conductivity of compounds studied is constituted by electronic and protonic components, and is determined both by their chemical composition and by the content of water, which, in turn, depends on the moisture content of the medium. The possibility of widely varying the physicochemical properties of xerogels by changing the chemical composition of both the main lattice and the interlayer components enables control over the semiconducting, optical, magnetic, and inter-

1070-4272/02/7509-1543$27.00 © 2002 MAIK "Nauka/Interperiodica"

calation properties of xerogels, which creates prerequisites for their practical use.

The fifth chapter considers directions of practical application of polyvanadate xerogels. The high mobility of lithium ions in the interlayer space of polyvanadates stimulated their studies as cathode materials for chemical power cells with lithium anode. The specific energy of lithium incorporation into electrode materials was 1137 W h kg^{-1} for V_2O_5 xerogel. Polyvanadate xerogels are of interest as solid electrolytes with ionic conduction and as electrochromic and sensor materials.

Vanadium oxide gels show promise as precursors of supported vanadium catalysts obtainable by the sol–gel method, which makes it possible to achieve deposition uniformity, highest homogeneity, and good adhesion to substrate of nanoparticles of the active component.

Polyvanadate xerogels can also serve as starting compounds for "mild" synthesis (at temperatures below 500°C) of vanadium oxide compounds, including structures that cannot be obtained at higher temperatures. Recent studies in this field have been concerned with application of the given process to synthesis of vanadium oxide nanotubes.

In conclusion, the authors emphasize that the achieved level of fundamental knowledge in the field of vanadate xerogels and the development of simple methods for their synthesis in the form of finely dispersed powders and films provide a basis for their wide practical application. The book will undoubtedly be of interest both to specialists in inorganic and solid-state chemistry and to researchers using vanadium compounds in various fields of science and technology.

BOOK REVIEWS

Kedrinskii, I.A. and Yakovlev, V.G., *Li-ionnye akkumulyatory* (Li-Ion Batteries)

Krasnoyarsk: Platina, 2002, 268 pp.

In the last 3 decades, R&D work in the field of lithium power cells has led to appreciable positive results. This is largely associated with the unique technical characteristics of lithium power cells, higher energy density as compared to the conventional chemical power cells, wide range of working temperatures, and use of relatively inexpensive and readily available materials. However, the development of secondary lithium power cells encountered difficulties in ensuring reversible operation of the lithium electrode, which are associated with the high chemical activity of lithium toward the electrolyte solutions employed. For primary lithium power cells, the formation of a passivating film on the lithium surface has a positive effect: it protects the metal from corrosion in the solvent. At the same time, passivation is a serious obstacle in development of lithium batteries on the basis of aprotic organic solvents.

In the 1990s, secondary lithium power cells using no metallic lithium in their design have been widely recognized. These cells employ as electrode materials various compounds of transition metals (oxides, chalcogenides), graphite, and other materials that can intercalate and deintercalate lithium ions. When a battery of this kind is being charged, lithium ions are deintercalated from the cathode and reversibly intercalated into the anode material. Discharge involves deintercalation of lithium from the anode and its intercalation into the cathode. Chemical power cells of this kind have been named lithium-ion batteries. Much has been done for promotion of these batteries at the world market by Japanese companies. The book by A.I. Kedrinskii and V.G. Yakovlev is the first domestic monograph concerned with lithium-ion batteries.

The book comprises 17 relatively small chapters, each with its own reference list. The brief introduction (pp. 5–9) explains the principle of operation of Li-ion batteries and presents a list of abbreviations and designations. The following types of Li-ion batteries are distinguished: batteries with liquid electrolyte (LiIB) and those with solid or thickened electrolyte with a polymeric basis, organic or inorganic (PLi-IB). The book is mainly concerned with batteries of the first type (Li-IB).

Chapter 1 (pp. 10–18) gives general characterization of Li-ion batteries. Their main rivals, Ni–Cd and Ni–MH batteries, have a voltage of 1.25 V and energy densities of 40–60 and 60–80 W h kg^{-1}, respectively. For Li-IA, these highly important characteristics are 3.6 V and 100–150 W h kg^{-1}.

Chapters 2 (pp. 19–22), 3 (pp. 23–30), and 4 (pp. 31–41) describe, respectively, the mechanism of Li-IB operation, the intercalation process, and the crystal structure of the electrode materials. Chapter 5 is primarily concerned with analysis of components of the equilibrium electrode potential of the intercalate. The authors put emphasis on the specificity of its nature. Chapters 6 (pp. 59–81) and 7 (pp. 82–102) discuss the charging of Li-IB and kinetic characteristics of the intercalation and deintercalation processes. Chapters 8 (pp. 103–115) and 9 (pp. 136–158) analyze the requirements imposed on the materials for the positive and negative electrodes of a battery. Chapter 10 (pp. 159–174) considers the electrolyte properties. Chapter 11 (pp. 175–193) briefly describes basic physical (X-ray phase analysis, various spectroscopies) and electrochemical (chronopotentiometry, cyclic voltammetry, impedance measurements) techniques for studying processes and materials related to Li-IB. Chapter 12 presents methods for studying and testing both separate electrodes and batteries as a whole under laboratory and industrial conditions. A small chapter 13 (pp. 213–215) outlines the history of development of Li-IB. Chapter 14 (pp. 216–232) describes the assortment and characteristics of commercial articles manufactured by leading foreign companies. The undeniable priority in manufacture of Li-IB for domestic appliances belongs to Japan. The leading position in development and manufacture of industrial batteries belongs to France. Chapters 15 (pp. 233–251), 16 (pp. 252–264), and 17 (p. 265) are devoted to analysis of the world market of Li-IB,

1070-4272/02/7509-1545$27.00 © 2002 MAIK "Nauka/Interperiodica"

promising theoretical and applied research aimed to improve Li-ion batteries, and investigations carried out in this field in Russia and CIS countries.

The book has a peculiar structure: each chapter is, in fact, an independent review of the present state of affairs concerning one or another problem. The chapters come in a certain logically substantiated order, but there is no close relationship between them. This makes the monograph more a reference book, as regards the manner of presentation. The authors of the book made a major contribution to investigations of lithium power cells in our country, they could combine the rather high scientific level of presentation with simplicity for a wide audience of readers.

REVIEWS

On Transformations of Iron, Nickel, and Cobalt Arsenides and Sulfoarsenides under Thermal Treatment in Various Media

L. N. Ertseva and L. B. Tsymbulov

Institut Gipronikel' Joint-Stock Company, St. Petersburg, Russia

Abstract—Published data on phase transformations of iron, nickel and cobalt arsenides and sulfoarsenides under thermal treatment are reviewed.

Arsenide and sulfoarsenide minerals constitute a major part of ores in a number of technologically important cobalt deposits in Morocco (Bou-Azzer), Canada (Werner Lake), US (Sunshine), and Russia (Tuva) [1–3]. Possible products of their high temperature treatment are highly toxic arsenic compounds. In this context, evidence concerning transformations of main arsenic-containing minerals of nickel, cobalt, and iron under thermal treatment is necessary in studying the behavior of arsenide and sulfoarsenide minerals in ore raw materials [4].

The present review systematizes and analyzes the relevant published data.

1. EQUILIBRIUM DIAGRAMS

Transformations occurring when a complex compound is heated are largely determined by phase equilibria in the corresponding systems at a particular temperature. There is a vast body of published data on double (M–As) and more complex (M(M')–As–S) equilibrium diagrams. The most complete review of binary and ternary phase diagrams, with reference to original sources, was made in [5], with the studies reviewed aimed in the first place at analysis and prognostication of mineral-formation in ore deposits and, therefore, emphasis placed upon the agreement or disagreement of the real mineral associations with the phase associations of the equilibrium system.

According to results of various studies [6–20], the following compounds exist in the systems Co–As, Fe–As, Ni–As: Co_2As, Co_3As_2, CoAs, $CoAs_2$ (natural analogue safflorite), $CoAs_{3-x}$ (natural analogue skutterudite), Fe_2As, FeAs, Fe_3As_2, $FeAs_2$ (natural analogue loellingite, $NiAs_2$ (natural analogues rammelsbergite and pararammelsbergite), $Ni_{5-x}As$, $Ni_{11}As_8$ (natural analogue maucherite), $Ni_{1\pm x}As$ (natural analogue nickeline), and Ni_2As with parameters close to those of orsellite mineral.

In the systems Co–Fe–As, Co–Ni–As, and Fe–Ni–As, an extended region of a ternary solid solution formed by $CoAs_{3-x}$ and $FeAs_3$ (up to 24 wt %) has been established. The compound $CoAs_2$ corresponds to the end member of the safflorite $(Co,Fe)As_2$ mineral series. The solid solution of $CoAs_2$ and $FeAs_2$ is complete when a temperature of 800°C is reached. A large region of ternary solid solutions of $CoAs_{3-x}$ and $NiAs_3$ (up to 65 wt %) at 800°C and complete solubility between $NiAs_2$ and $CoAs_2$ in solid state has been found. A ternary phase, $(Fe,Ni)As_{3-x}$, corresponding to skutterudite stable at 800°C in the range 49.5–76 wt % $NiAs_3$, has been demonstrated. The mutual solubility of $NiAs_2$ and $FeAs_2$ is incomplete: it covers compositions from $FeAs_2$ to ~70 wt % $NiAs_2$ and from $NiAs_2$ to ~6 wt % $FeAs_2$. A second ternary phase, $(Fe,Ni_2)As$, corresponding to oregonite mineral has been synthesized. The Fe–As–S system has an only ternary compound, arsenopyrite FeAsS. The only ternary phase in the Ni–As–S system, corresponding to the gersdorffite mineral with commonly accepted formula NiAsS, shows widely varying As/S ratio. It is homogeneous from $NiAs_{1.77}S_{0.23}$ to $NiAs_{0.77}S_{1.23}$ at 700°C. With increasing M/(As + S) ratio, there exist a continuous series of solid solutions of $Ni_{1\pm x}As$ and $Ni_{1-x}S$ (700°C) with general formula Ni(As,S). The decomposition temperature of this solid solution into $Ni_{1\pm x}As$ and $Ni_{1-x}S$ at varied As/S ratio has been established. In contrast to Fe–As–S and Ni–As–S, the system Co–As–S has been studied insufficiently. The section CoS_2–$CoAs_2$ has been analyzed in part in studying the stability of cobaltine and alloclasite in the systems Co–As–S and Co–Ni–As–S. The composition of cobaltine on the $CoAs_2$ side corresponds to the formula CoAsS, whereas the boundary on the CoS_2 side has not been determined. It has been

1070-4272/02/7510-1547 $27.00 © 2002 MAIK "Nauka/Interperiodica"

established that sulfur cannot be substituted by arsenic in the cobaltine lattice at any temperature without structural transformations. Replacement of cobalt by nickel must stabilize the cobaltine structure at arsenic content higher than that in CoAsS. It has been established that any metal replacements to form solid solutions are possible between FeS_2, CoS_2, NiS_2, CoAsS, and NiAsS. The extension of these solutions in the system FeAsS–CoAsS–NiAsS has been determined.

2. PHASE TRANSFORMATIONS UNDER THERMAL TREATMENT

2.1. Nickel Arsenides and Sulfoarsenides. First publications concerning the thermal stability of arsenide minerals of nickel appeared in the early 1960s. In [21], DTA curves obtained in air for nickeline (two deposits) and gersdorffite were reported. The heating rate was 500 deg h^{-1}, and the grain size of the material, 300 μm. It was established that, in nickeline oxidation, exothermic effects occur in the temperature range 450–700°C and are represented by triple overlapping peaks (with the second peak weakly pronounced), and in the case of gersdorffite, at 350–650°C, also with a triple exothermic peak (with the second, poorly pronounced peak). The authors attributed the appearance of several peaks to the existence of successive transformation stages (as yet unknown). It was shown that the heat of oxidation of the minerals studied, calculated in curve processing, can be found to a first approximation on the basis of their chemical composition. The presence of NiO and Fe_2O_3 in products obtained at temperatures higher than the oxidation temperature was obseved. In [9], DTA curves obtained in air for three compounds: orsellite, maucherite, and nickeline, were presented in describing a new mineral—orsellite. The richer a mineral in the metal, the higher the onset temperature of the effects: 400°C for nickeline (a total of three effects), 575°C for maucherite (two effects), and 600°C for orsellite (a single effect). Comparison of the obtained DTA curves with mass loss (TG) curves suggests that the oxidation occurs in two stages. The first stage, characterized by loss of mass as a result of partial removal of arsenic(IV), is accompanied by enrichment with the metal:

$$\mathrm{NiAs} \rightarrow \mathrm{Ni_{1.2}As} \rightarrow \mathrm{Ni_{1.5}As\,(maucherite)} \rightarrow \mathrm{Ni_2As\,(orsellite)}. \quad (1)$$

The second stage is characterized by mass gain caused by the formation of a mixture of Ni(II) oxide and diarsenate:

$$\mathrm{Ni_2As + O_2 \rightarrow NiO + Ni_2As_2O_7}. \quad (2)$$

A detailed study of the behavior of arsenides, sulfides, and sulfoarsenides in thermal analysis in air was reported in [22]; DTA was applied to classify oxidation reactions of 19 minerals, including nickeline, gersdorffite, cobaltine, and skutterudite (heating rate in air 12 deg min^{-1}, grain size of material −400 + 200 μm). All the exothermic effects revealed in the DTA curves have been attributed to oxidation [22]. After each thermal effect, the reaction products formed were identified by X-ray phase (XPA) and chemical analyses. It was established that the reactions of nickeline and gersdorffite oxidation are of different types. In nickeline oxidation, there occurs partial oxidative removal of the nonmetal, with a single or several metal-enriched arsenides remaining in the residue. At 500°C, nickeline is converted into maucherite, which is further transformed into orsellite at 680°C; then, the metal is oxidized. The scheme of nickeline oxidation is as follows.

$$\mathrm{NiAs + O_2 \rightarrow Ni_{11}As_8 + As_2O_3(g) \rightarrow Ni_2As + Ni_3As_2O_8 + NiO + As_2O_3(g)}^{1} \rightarrow \mathrm{Ni_3As_2O_8 + NiO + As_2O_3(g)}. \quad (3)$$

For gersdorffite, there occurs complete oxidation and removal of arsenic, with sulfur remaining in the residue—sulfide (400–450°C).

$$\mathrm{NiAsS + O_2 \rightarrow NiS + As_2O_3(g) \rightarrow NiO + SO_2(g)}. \quad (4)$$

Domestic investigations [23–25] have been aimed to reveal specific features of DTA of minerals, including gersdorffite, arsenopyrite, and cobaltine. The final objective of these studies was to use DTA for identification of these minerals and to find conditions for their selective oxidation. The authors analyzed the behavior of the minerals heated in an inert medium with protection from oxidation. The heating rate was 10–15 deg min^{-1}, and the grain size of the materials, about 0.05 mm. The products were identified by XPA and chemical analysis.

---

[1] One of the main characteristics of any equilibrium between a condensed phase and vapor is the change in the composition of equilibrium phases in the course of evaporation. Analysis of reactions in which As_4S_4, As_4O_6, and As_2O_3 are formed not always makes clear their aggregative state. Commonly, the formula As_2O_3 characterizes the solid state, and the formula As_4O_6, the gaseous state. We ventured to give the schemes and reaction equations as it was done by the authors of [22].

In the case of heating in an inert medium, the authors noticed an endothermic effect at 800–860°C and presented the following scheme of gersdorffite transformations:

$$(Ni,Fe)AsS \rightarrow NiAs + (Ni,Fe)_9S_8 + Fe_{1-x}S + As_4S_4 + As_4. \quad (5)$$

Chunaeva and co-authors have studied the thermal stability of synthetic gersdorffite and cobaltine in an inert medium [26–28]. A tentative scheme of gersdorffite decomposition at 830°C was suggested [26]

$$20NiAsS \rightarrow Ni_9S_8 + Ni_{11}As_8 + 3As_4S_4(g) \quad (6)$$

and an opinion was voiced that more complete removal of arsenic requires higher temperature, vacuumization, or addition of a sulfidizing agent.

In [27], stages of gersdorffite decomposition were considered:

$$8NiAsS \xrightarrow{750-770^\circ C} 4NiAs + 4NiS + As_4S_4(g) \quad (7)$$

and, further,

$$36NiAs + 36NiS \rightarrow 4Ni_{11}As_8 + 4Ni_7S_6 + As_4S_4(g) + 4S_2 \quad (8)$$

with $Ni_{11}As_8$ considered molten.

The overall reaction is as follows

$$72NiAsS \xrightarrow{800^\circ C} 4Ni_{11}As_8 + 4Ni_7S_6 + 6As_4S_4(g) + 8As_2S_3.^2 \quad (9)$$

The authors made a conclusion that the process occurs in two stages: (1) decomposition proper and (2) interaction of decomposition products whose phase composition was determined by XPA.

In our opinion, the presence of NiAs and NiS in the products formed at 750–770°C is in the first place due to decomposition of the solid solution M(As, S) [14], formation of $Ni_{11}As_8$ is accounted for by decomposition of nickeline [9, 22], and conversion $NiS \rightarrow Ni_7S_6$ is associated with partial removal of sulfur. Thus, the interaction of the products formed in decomposition of gersdorffite by reaction (9) seems to be unlikely, and the final composition is determined by successive transformations of the products formed in the first stage of decomposition.

Wilson and Mikhail's work [30], one of later and more detailed studies, is devoted to dissociation and oxidation of nickeline. The authors compare the results obtained in [9, 21, 22], attributing some data discrepancy to the uncertainty of composition of compounds in the system Ni–As. The dissociation of nickeline (synthetic and natural) in an inert medium and the effect of particle size and partial pressure of oxygen on the oxidation process was studied by DTA, TG, XPA, spectral, and chemical analyses. Heating rate, 6–7 deg min^{-1}; grain size of synthetic and natural nickeline, –90 + 74 μm and –38, –53 + 45, –105 + 74 μm, respectively; partial pressure of oxygen, 0.05, 0.21, 0.50, and 1.0 atm.

Wilson and Mikhail identified successively NiAs, $Ni_{11}As_8$, and Ni_5As_2 in products of dissociation of synthetic nickeline (according to the DTA curve showing an endothermic effect at around 850°C) and suggested the following scheme of thermal decomposition

$$11NiAs \rightarrow Ni_{11}As_8 + \frac{3}{4}As_4, \quad (10)$$

$$5Ni_{11}As_8 \rightarrow 11Ni_5As_2 + \frac{9}{2}As_4. \quad (11)$$

The loss of mass begins for natural nickeline at a temperature approximately 40°C higher than that in the case of the synthetic compound; further, the rate at which mass is lost by natural NiAs is lower than that of the synthetic material. Dissociation is independent of grain size within the limits 45–105 μm.

The liquid phase may appear in the system at $T > 800^\circ C$ [8]; the authors of [30] name three possible causes of melting: $[Ni_{5-x}As_2 + Ni_{11}As_8]$, eutectic reaction at 818 ± 5°C; incongruent melting of $Ni_{11}As_8$ (830 ± 5°C); overall melting at $T > 818^\circ C$.

The most probable of these is the first one.

In oxidizing heating of natural nickeline in pure oxygen, steplike oxidation was revealed (four exothermic peaks and three steps of mass change):

$$11NiAs + \frac{9}{4}O_2 \rightarrow Ni_{11}As_8 + \frac{3}{4}As_4O_6, \quad (12)$$

$$5Ni_{11}As_8 + \frac{27}{2}O_2 \rightarrow 11Ni_5As_2 + \frac{9}{2}As_4O_6, \quad (13)$$

$$Ni_5As_2 + 4O_2 \rightarrow 5NiO + \frac{1}{2}As_4O_6, \quad (14)$$

$$3Ni_5As_2 + 17O_2 + As_4O_6 \rightarrow 5Ni_3As_2O_8. \quad (15)$$

[2] It should be noted that representation of As_2S_3 in the gas phase by this formula is conventional, the true composition of the vapor of this compound being complex [29].

Reactions (12) and (13) may occur in two stages, including thermal dissociation of arsenide to give As_4 and oxidation of As_4 to As_4O_6(g).

The authors of [30] have presented dependences of the intensity and position of endothermic peaks (oxidation stages) on particle size and partial oxygen pressure. The particle size determines the intergranular spaces filled with oxidation products; the partial pressure governs the extent of formation of impermeable oxide layers hindering the oxidation reaction and the extent of nickel arsenate formation. The results obtained indicate that complete removal of arsenic from ores in their calcination in inert and oxidizing atmospheres is unattainable.

In monograph [29], it was noted that higher nickel arsenides dissociate in inert and reducing atmospheres, whereas in oxidizing atmosphere, they are oxidized to give arsenic(III) oxide and thermally stable arsenates $NiO \cdot As_2O_5$; however, the book contains no reference to concrete investigations concerned with this issue.

When carrying out [31, 32], we were not aware of a part of investigations mentioned above; however, the use of direct techniques for determining the composition of the transformation products, electron microscopy and microprobe analysis, allowed us to suggest a scheme of nickeline oxidation

$$NiAs + O_2 \rightarrow Ni_{11}As_8 \rightarrow Ni_5As_2 \rightarrow NiO \rightarrow Ni_3(AsO_4)_2 \quad (16)$$

totally coinciding with those presented in most of the reports cited.

It has also been established that thermal dissociation of gersdorffite occurs to give a solid solution M(As, S) with As/S ratio of about unity

$$MAsS \rightarrow M(As,S) + \frac{1}{4}As_4S_4(g), \quad (17)$$

with further solid-phase decomposition into MAs and MS.

According to the data obtained in [32], formation of some or other products of gersdorffite oxidation is determined both by the temperature and time of calcination and by conditions under which the material interacts with the gas phase and its oxidizing capacity. Under the conditions used in experiments, a number of products are formed successively, of which the primary is the solid solution M(AsS) with A/S ≈ 0.1–0.3:

$$MAsS + O_2 \begin{cases} \rightarrow M_2(AsO_4)_3 \\ \rightarrow M(AsS) \rightarrow MS \rightarrow MSO_4 \rightarrow MO. \end{cases} \quad (18)$$

The results obtained confirm the fact that arsenic is mainly removed from gersdorffite in oxidizing calcination, established in [22].

2.2. Cobalt Arsenides and Sulfoarsenides. Thermal dissociation of higher cobalt arsenides has been studied in sufficient detail; however, there has been no common opinion regarding the temperatures, stages, and products of transformations.

Isabaev and co-authors [33] have analyzed the available data on thermal stability of $CoAs_2$ and presented experimental results obtained in studying the decomposition of synthetic safflorite (heating rate 8–10 deg min^{-1}):

$$8CoAs_2 \xrightarrow{870°C} 4Co_2As_3 + As_4, \quad (19)$$

$$4Co_2As_3 \xrightarrow{940°C} 8CoAs + As_4. \quad (20)$$

The product composition was confirmed by XPA.

In [34], the thermal behavior of synthetic higher arsenides $CoAs_2$ and $CoAs_3$ was studied with the gas (N_2) flow rate varied between 35 and 65 ml min^{-1} and heating rate of 5–4 deg min^{-1}. Analysis of TG curves revealed a two-stage decomposition of $CoAs_3$ (gas flow rate 50 ml min^{-1}):

$$CoAs_3 \xrightarrow{500–850°C} CoAs_2 + \frac{1}{4}As_4, \quad (21)$$

$$CoAs_2 \xrightarrow{750–950°C} CoAs + \frac{1}{4}As_4 \quad (22)$$

and single stage decomposition of $CoAs_2$

$$CoAs_2 \xrightarrow{550–950°C} CoAs + \frac{1}{4}As_4. \quad (23)$$

The onset of decomposition is independent of the heating rate, and the temperature of process completion grows with increasing heating rate.

DTA was performed at a heating rate of 20 deg min^{-1}. The DTA curve for $CoAs_3$ shows two endothermic peaks at 830 and 980°C, and that for $CoAs_2$, a single peak at 980°C, which correspond to decomposition to, respectively, $CoAs_2$ and CoAs. The starting material at 450°C and products sampled at 590, 700, 730, 810, and 878°C were analyzed. Only a single intermediate, $CoAs_2$, was found between $CoAs_3$ and CoAs. At 878°C, trace amounts of Co_2As, the presumed product of CoAs decomposition at temperatures below 940°C (the lower stability limit of Co_3As_2), were found.

The following results have been obtained in studying the oxidizing heating of cobalt arsenides. Asensio and Sabatier [21] presented DTA curves measured in

air for skutterudite from two deposits. The curves show a single exothermic peak at about 600–650°C. Cobalt oxides were identified in the products, and the oxidation heat of the material was calculated.

In [22], a single endothermic peak was also found at around 600°C in the DTA curve measure in air for natural skutterudite of composition $(Co_{0.6}Ni_{0.3}Fe_{0.1})As_3$. The reaction products contain a complex arsenate or a mixture of arsenates of general formula $5(CoO \cdot NiO \cdot FeO) \cdot 2As_2O_5$. The authors noted the lack of data that can be used to completely identify the X-ray diffraction pattern. Thus, arsenic is partly removed only in the form of As_2O_3. No other data on oxidation of cobalt arsenides could be found in the literature.

Oxidation-free heating of natural cobaltine has been studied by Shlyapkina [24], and a decomposition scheme of iron-containing cobaltine was suggested

$$(Co,Fe)AsS \xrightarrow{885-905^\circ C} CoS_2 + Fe_{1-x}S + As_4S_4 + As_4 + S_2. \quad (24)$$

Noteworthy is the fact that the decomposition products contain no cobalt arsenides.

Dissociation of synthetic CoAsS was studied in [26, 33, 35], and the following decomposition schemes were presented in [26]:

$$2CoAsS \xrightarrow{870^\circ C} CoS_2 + CoAs_2, \quad (25)$$

$$4CoS_2 + 4CoAs_2 \xrightarrow{950^\circ C} 4CoS + 4CoAs + As_4S_4(g) \quad (26)$$

and further refined in [33, 35]:

$$8CoAsS \xrightarrow{850^\circ C} 4CoS + 4CoAs + As_4S_4(g). \quad (27)$$

In the authors' opinion, the forming Co_2As_3 reacts, in the initial stage of cobaltine dissociation, with sulfur:

$$16CoAsS \rightarrow 8CoS + 4Co_2As_3 + As_4S_4 + 2S_2, \quad (28)$$

$$4Co_2As_3 + 2S_2 \rightarrow 8CoAs + As_4S_4. \quad (29)$$

Further,

$$48CoS + 42CoAs \xrightarrow{890^\circ C} 12Co_4S_3 + Co_3As_2 + 3As_4S_4 + \frac{1}{2}As_4. \quad (30)$$

The overall reaction is as follows:

$$96CoAsS \rightarrow 12Co_4S_3 + 6CoS + 14Co_3As_2 + 15As_4S_4(g) + \frac{1}{4}As_4. \quad (31)$$

Since the authors used in study the same investigation techniques—DTA, XPA, and chemical analysis, the results obtained are questionable, since CoS_2 and $CoAs_2$ or CoAs and CoS are named as dissociation products at the same temperatures (850–870°C).

Pashinkina and co-authors [36] have calculated the chemical equilibria in the systems Co–As–S at 973 K and Co–As–S–O at 1200 K and constructed partial pressure diagrams. The results obtained account for the specific features of thermal dissociation and oxidation of CoAsS. The authors believe that the equilibrium MAsS → MS + 1/4 As_4 is not monovariant in the system Co–As–S, and, therefore, it is difficult to judge the thermal stability of cobaltine on the basis of the data of [25]. The run of equilibrium curves in the partial pressure diagram of the system Co–As–S (923 K) in the coordinates $\log P_{S_2}$–$\log P_{As_4}$ points to a higher thermal stability of CoAsS with respect to liberation of arsenic, compared with that of arsenopyrite, but CoAsS is less stable with respect to reactions associated with liberation of sulfur. At equilibrium between cobaltine and higher cobalt arsenides, the content of As_4S_4 in the gas phase is higher than that in the equilibrium FeAsS–$FeAs_2$. Thus, the scheme (24) of CoAsS decomposition could be only operative (with account of the higher temperatures) in the case of selective removal of arsenic (with increasing $P_{As_4S_4}$, P_{S_2} and decreasing P_{As_4}), and scheme (31), in the case of a simultaneous decrease in P_{S_2}, P_{As_4}, and $P_{As_4S_4}$, i.e., with simultaneous removal of sulfur and arsenic. As for CoAsS oxidation, it follows from the diagram obtained for a part of the system Co–As–S–O (P_{SO_2} = 0.5 atm) that cobalt arsenates can only be formed via the stage of CoO formation:

$$CoAsS + O_2 \rightarrow CoO \rightarrow 3CoO \cdot As_2O_5 \rightarrow 2CoO \cdot As_2O_5. \quad (32)$$

Asensio and Sabatier [21] have established, when performing DTA of natural cobaltite in air, the presence of a double thermal effect at 750–850°C, but did not identify the products formed.

Maurel [22] has also established the stage nature of oxidation of natural cobaltite (with even a third weak peak present) at 750–850°C and reported the oxidation products

$$CoAsS + O_2 \rightarrow Co_3As_2O_8 + CoO + As_2O_3(g) + SO_2. \quad (33)$$

In the author's opinion, the nature of a metal plays an important part in the appearance of various oxidation reactions (cf. selective oxidation of arsenic in gersdorffite).

In [37], an assumption was made, with the results of [36] invoked, that arsenate formation can be precluded if As_4O_6 is removed from the system. The authors studied the effect of pressure (100–26.6 kPa), air flow rate ($1.2-4.8^{-8}$ $m^3\,h^{-1}$), and temperature (650–800°C) on the rate of oxidation of synthetic cobaltine. It was established that, when pressure is lowered at an oxygen consumption factor $\alpha = 0.5$, the formation of CoO and arsenates decreases and the deceleration of sulfur oxidation to SO_2 makes higher the rate of dissociation processes; $CoAs_2$, CoAs, and the starting product were found among the products. By contrast, at $\alpha = 1–1.5$ products contain arsenates and CoO, with sulfur removed completely:

$$4CoAsS + 9O_2 \rightarrow 4CoO + 4SO_2(g) + As_4O_6(g), \quad (34)$$

$$6CoO + 0.5As_4O_6 + O_2 \rightarrow Co_6As_2O_{11}, \quad (35)$$

$$Co_6As_2O_{11} + 0.5As_4O_6 + O_2 \rightarrow 2Co_3As_2O_8. \quad (36)$$

Thus, the calcination of cobaltine is characterized by simultaneous oxidation of sulfur and arsenic, with sulfur removed completely, and arsenic, partly, into the gas phase and thermally stable arsenates formed in the final products.

2.3. Iron Arsenides and Sulfoarsenides. Studies of the thermal dissociation and oxidation of iron arsenides and sulfoarsenides are due to the necessity for, first, improving the technology of gold-bearing arsenious concentrates for ecologically safe removal of arsenic, and, second, obtaining high-purity arsenic in a vacuum.

Thermal dissociation of synthetic iron arsenides FeAs and $FeAs_2$ was studied in [38] at heating rate of 10 deg min^{-1} under pressure of 0.08 mm Hg, with grain size of the material of 0.074–0.14 mm. It was found that, upon grinding, the extent and rate of decomposition of the material increases approximately twofold. The authors present the following decomposition scheme of arsenides:

$$FeAs_2 \xrightarrow{>700^\circ C} FeAs \xrightarrow{>900^\circ C} Fe_2As. \quad (37)$$

The maximum extent of decomposition is observed at 790 and 960°C, respectively.

To determine the optimal conditions of arsenic recovery from FeAsS, FeAs, and Fe_2As, Mil'ke and Spivak [39] sulfidized the arsenides with sulfur, with the mixtures heated under inert conditions. It was found that Fe_2As reacts with sulfur at 300–400°C to form FeAs and then

$$2FeAs + S \rightarrow FeAs_2 + FeS \quad (38)$$

the products are sulfidized. $FeAs_2$ starts to react with sulfur at 400°C to give $Fe_{1-x}S$, FeAsS, and FeS_2. A mixture of arsenic sulfides was found in the sublimates formed.

The behavior of iron arsenides is of interest to researchers, since it is with their decomposition that the completeness of arsenic removal from raw materials is associated. However, published data on the dissociation kinetics of arsenides are extremely scarce. One of goal-seeking works is a study of how synthetic $FeAs_2$ dissociates in a vacuum by Khrapunov a co-authors [40] at a heating rate of 10 deg min^{-1}, grain size of 0.1 mm, and pressure of 3.5×10^2 Pa. The following process scheme was established:

$$FeAs_2 \xrightarrow{>510-690^\circ C} FeAs_{1.62} \xrightarrow{690-805^\circ C} FeAs \xrightarrow{>805^\circ C} FeAs_{0.57} \xrightarrow{>1200^\circ C} Fe_2As + Fe. \quad (39)$$

The first mention of results of oxidizing heating of loellingite can be found in [21]. The DTA curve measured in air for two natural $FeAs_2$ samples show only a single exothermic peak at 550–700°C. This was explained by Maurel [22], who confirmed the peak position and identified the following oxidation products:

$$FeAs_2 + O_2 \rightarrow Fe_2O_3 + As_2O_3(g). \quad (40)$$

One of the first domestic reports on studies of neutral heating of arsenopyrite was that by Zhuchkov and co-authors [41], in which the following scheme of FeAsS (grain size $-0.15 + 0.10$ mm) decomposition was presented:

$$4FeAsS \rightarrow 4FeS + As_4 \quad (41)$$

with the iron sulfide formed as troilite, which is confirmed by XPA. The arsenic vapor pressure becomes equal to 1 atm at 730°C, the decomposition starts at about 600°C to reach a maximum at 750°C.

Isakova and co-authors [42] have pointed to the presence of As_4, As_4S_4, S_2, and As_2S_3 in products

of arsenopyrite decomposition. The same authors [43] have studied the phase composition of FeAsS decomposition in a vacuum and revealed the formation of pyrrotine ($Fe_{1-x}S$) and $FeAs_2$.

Slyapkina [23–25] has presented a decomposition scheme of natural arsenopyrite in an inert medium, differing from that suggested in [41], despite that the investigations were carried out under identical conditions.

$$FeAsS \xrightarrow{670-740^\circ C} FeAs_2 + Fe_{1-x}S + As_4S_4(g) + As_4. \quad (42)$$

The reasons for the difference between the reaction products require separate discussion.

Mil'ke and co-authors [44] believe that natural arsenopyrite decomposes in a neutral medium by the reactions

$$68FeAsS \xrightarrow{700-720^\circ C} 4Fe_{16}S_{17} + 4FeAs_2 + 15As_4, \quad (43)$$

$$2Fe_{16}S_{17} + 2FeAs_2 \xrightarrow{870-900^\circ C} 34FeS + As_4. \quad (44)$$

Thus, removal of arsenic from arsenopyrite occurs in two stages, with FeS and As_4 as final products.

In all probability, some authors describe the products formed in the first stage of arsenopyrite decomposition, and others, the final products. We are not aware of any explanation why the second stage (if at all present) is not observed.

Of indubitable interest in studying the arsenopyrite decomposition are the results obtained by Pashinkin and co-authors [36, 45–48], who calculated the chemical equilibria in the systems Fe–S–As and Fe–As–O and constructed the phase diagram of Fe–As–S in the coordinates $\log P_{As_4}$–$\log P_{S_2}$ at 923 K [45]. They determined the dissociation pressure of an arsenopyrite of composition $FeAs_{0.96}S_{1.04}$ (595–696°C) and proposed a scheme of its decomposition

$$FeAs_{0.96}S_{1.04} \rightarrow FeS + 0.23As_4(g) + 0.01As_4S_4(g). \quad (45)$$

In [47], they ascertain, with account of the data on phase equilibria from [13], that the dissociation of arsenopyrite is determined by the equilibrium FeAsS + $Fe_{1-x}S$ + L + V, i.e., confirm the scheme they suggested.

A similar diagram for a temperature of 800 K has been constructed by Spivak and co-authors [49], who used it for developing a technology for synthesis of arsenopyrite.

In [46, 48], a diagram of partial pressures of Fe–As–O at 923 and 1200 K is given

$$FeAs_2 + O_2 \rightarrow Fe_3O_4 + O_2 \rightarrow Fe_2O_3 + As_4O_6(g) \rightarrow Fe_2O_3 \cdot FeAsO_4 \rightarrow FeAsO_4, \quad (46)$$

$$FeAs + O_2 \rightarrow FeO \rightarrow Fe_3O_4 \rightarrow Fe_2O_3. \quad (47)$$

Thus, formation of iron arsenides is possible at the given temperature via the stage of formation of iron oxides. The authors believe that, with intensive removal of As_4O_6, the scheme presented may end in Fe_2O_3 formation. Presumably, the author of [22] did not test products for iron arsenate.

It was noted in a study concerned with the thermal behavior of arsenopyrite [50] that only iron sulfides were found in final dissociation products in some investigations, and iron sulfides and arsenides, in others. The dissociation pressures of natural arsenopyrite, found by different methods, do not coincide, which is due to the wide homogeneity region of arsenopyrite, presence of pyrite admixtures, and difficulties in identification of the vapor composition. The authors studied heating of natural and synthetic arsenopyrite in a vacuum and inert (He) medium in the temperature range 300–1200°C by Mossbauer spectroscopy and mass spectrometry. The natural arsenopyrite was found to contain 1.5 wt % FeS_2. The heating rate was 10 deg min^{-1}. The products formed upon heating in a vacuum and inert medium are identical, with only the rate of processes being higher in the vacuum; no differences in behavior between the synthetic and natural materials were observed. The authors identified $Fe_{1-x}S$, FeS, and $FeAs_2$ in the products and represented the process as occurring in two stages: decomposition of arsenopyrite to troilite (550–800°C) and dissociation of troilite (>1100°C). The reactions occur successively:

(a) $$2FeAsS \xrightarrow{>300^\circ C} FeAs_2 + FeS_2,$$

(b) $$FeAs_2 \xrightarrow{520-680^\circ C} FeAs_{1.5} + \frac{1}{8}As_4,$$

(c) $$FeAs_{1.5} \xrightarrow{680-850^\circ C} FeAs + \frac{1}{8}As_4,$$

(d) $$2FeAs \xrightarrow{850-950^\circ C} Fe_2As_{1+x} + \frac{1-x}{2}As_2,$$

(e) $$Fe_2As_{1+x} \xrightarrow{1100-1200^\circ C} Fe_2As_{1-y} + \frac{x+y}{2}As_2,$$

(f) $$FeS_2 \xrightarrow{620-800^\circ C} FeS + \frac{1}{2}S_2,$$

(g) $$FeS \xrightarrow{>1100^\circ C} FeS_{1-x} + \frac{x}{2}S_2$$

and concurrently

(a) $2FeAs_2 + S_2 \rightleftarrows 2FeS + As_4$,

(b) $4FeAs + 2S_2 \rightleftarrows 4FeS + As_4$,

(c) $4Fe_2As + 4S \rightleftarrows 8FeS + As_4$,

(d) $\frac{n}{4}As_4 + \frac{m}{2}S_2 \rightleftarrows As_nS_m$.

Thus, the solid products of decomposition are the following

$$FeAsS \rightarrow FeS_2 + FeAs_2 \rightarrow FeS_{1-x} + Fe_2As. \quad (48)$$

To confirm the possibility that iron oxides can react with sulfur, the authors heated natural FeAs with and without sulfur vapor [50] (750°C, 1.33 kPa). In the experiments without sulfur, the residue contained (as found by X-ray fluorescence microanalysis) pyrrotine of composition $FeS_{1.03–1.04}$ and arsenide of composition $FeAs_{0.91–0.94}$; in experiments with sulfur, no arsenides were found and a pyrrotine of composition $FeS_{1.14–1.18}$ was identified.

As for the oxidizing heating of arsenopyrite, it was first mentioned in [21], where a single endothermic peak was observed (500–650°C) in DTA of natural arsenopyrite (mispickel), but the composition of the products was not indicated. The temperature range of the conversion was confirmed in [22], and an oxidation scheme was presented:

$$FeAsS + O_2 \rightarrow Fe_2O_3 + SO_2 + As_2O_3(g). \quad (49)$$

An opinion has been put forward [22] that loellingite and arsenopyrite oxidize by a widely occurring type, with complete removal of nonmetals and formation of metal oxides. The absence of iron arsenates in the products may be due to removal of $As_4O_6(g)$ from the system.

Oxidation of natural arsenopyrite (grain size –0.15 + 0.10 μm) was studied in the temperature range 20–1000°C and a scheme of transformation was presented (XPA, IR spectroscopy, high-temperature X-ray diffraction analysis) in [51]:

$$FeAsS \begin{cases} \xrightarrow{480–540^\circ C} FeS \xrightarrow{500–600^\circ C} Fe_3O_4 \xrightarrow{600–700^\circ C} \gamma\text{-}Fe_2O_3 \rightarrow \alpha\text{-}Fe_2O_3, \\ \xrightarrow{500–800^\circ C} \Phi_1 \xrightarrow{750–900^\circ C} Fe_4As_2O_{11} \xrightarrow{850–950^\circ C} \Phi_2 \xrightarrow{>940^\circ C} Fe_2O_3 + As_2O_3(g), \end{cases} \quad (50)$$

where Φ_1 and Φ_2 are arsenates of unidentified formula.

In [51], formation of dense melted structures of the eutectic type as a result of the possible interaction of oxidation products was noted.

In studying the behavior of arsenic-containing concentrates in the course of calcination [52], partial pressure diagrams have been calculated and constructed for the system Fe–As–S–O at 798 and 973 K. These modifications of diagrams were used to calculate the results of heating of natural and synthetic arsenopyrite in inert, reducing, and oxidizing atmospheres created by mixing CO, CO_2, He, and O_2 in various proportions. The experimental results demonstrated that the reducing and oxidizing atmospheres are more effective in arsenic removal than the inert one. The largest amounts of arsenic are removed in the oxidizing atmosphere to give As_4O_6, which readily volatilizes from $As_2O_5(s)$, or $FeAsO_4$ if the pressure P_{As_4} is high. When heating is done in an inert atmosphere, sulfur is also released, and arsenic sulfides constitute the main form of arsenic removal.

Oxidation of arsenopyrite under normal and lowered pressure has been studied by Potselueva and coauthors [53]. The effect of temperature (400–700°C), pressure (6.6 kPa, 1 atm), and air flow rate [$(3.6–28.8) \times 10^{-4}$ m^3 h^{-1}] on the extent and rate of oxidation of natural arsenopyrite (grain size –0.174 + 0.074 mm) was analyzed. It was found that raising the temperature from 400 to 700°C makes the oxidation 2 times faster, as also does lowering the pressure to 6.6 kPa. Raising the airflow rate accelerates the process 6-fold at 700°C (6.6 kPa). No mention was made of the reaction products.

CONCLUSIONS

Summarizing published data, we can make the following conclusions. The sequence of nickeline and gersdorffite transformations in inert and oxidizing calcination has been studied in sufficient detail, but there is no evidence concerning transformations in the reducing medium. Data on transformation of higher nickel arsenide—$NiAs_2$—rammelsbergite (pararammelsbergite) are lacking in the literature. Dissociation of higher cobalt arsenides has been studied extensively, but there is no common opinion about the products formed in dissociation of natural compounds. Oxidation and reduction of synthesized and natural cobalt

arsenide have virtually not been studied at all. There are no reliable published data on products formed in dissociation and reduction of natural cobaltine, its oxidation has been studied insufficiently, and there is no common opinion concerning the composition of products formed in the process. Evidence concerning the kinetics and products of neutral and oxidizing heating of arsenopyrite are exceedingly contradictory, and the body of data on reducing heating is insufficient.

Thermodynamic data and dissociation pressures of nickel, cobalt, and iron arsenides and sulfoarsenides, in particular, obtained by different authors are frequently contradictory and require special consideration.

Abstract—Coprecipitation of tin(II, IV) and antimony(III) from chloride solutions was studied by X-ray phase analysis, thermogravimetry, IR spectroscopy, and elemental analysis.

Tin-antimony oxide materials of the $Sn_{1-x}Sb_xO_2$ solid solution type find wide application as catalysts in organic synthesis, semiconducting elements in chemical sensors, and components of thick-film resistors [1–3]. These solid solutions, which contain up to 20–30 at.% antimony, are obtained both by coprecipitation of tin(II, IV) and antimony(III) from chloride or nitrate solutions, with subsequent calcination of their hydrolyzed forms, and by heat treatment of mixtures of the corresponding metal oxides [2, 4].

Synthesis of tin and antimony oxide materials is based, as a rule, on coprecipitation of tin and antimony ions from hydrochloric acid solutions of Sn(IV) and Sb(III) or Sb(V) chlorides in their neutralization with aqueous ammonia solution to pH > 5, followed by precipitate drying at 120°C and calcination at 500–1000°C [1]. Variants have been proposed for synthesizing the materials by separate treatment of metallic tin and antimony with nitric acid solutions, mixing the resulting precipitates, their washing with water, drying, and calcination [1, 5–7]. The possibility of synthesizing tin and antimony materials by adding water to a mixture of SnO and Sb_2O_5 oxides, stirring the paste obtained for 16 h, and subsequent drying and calcination at 540°C has been demonstrated [8].

Synthesis conditions have a profound impact on the properties of the tin and antimony materials. The catalysts prepared by coprecipitation of tin(II, IV) and antimony(III) from chloride solutions are characterized by high activity and selectivity in organic syntheses. We emphasize that, in the synthesis of tin and antimony oxide materials from metals by the nitrate scheme, the stage of their treatment with nitric acid is accompanied by release of toxic nitrogen oxides into the atmosphere [1]. When tin(II, IV) and antimony(III) are coprecipitated by adding an alkali reagent to their chloride solutions, the precipitate contains antimony(III) as oxo chloride, and its calcination results in partial sublimation of antimony as a chloride, which disrupts the stoichiometry of the material and also leads to pollution during calcination.

This communication presents the results obtained in studying the influence exerted by the pH of the medium on the extent of Sn(II), Sn(IV), and Sb(III) precipitation from hydrochloric acid solutions and on the composition of the resulting precipitates, and also the effect of calcination temperature on the phase composition of tin and antimony oxide compounds.

EXPERIMENTAL

The starting solutions of antimony(III) chloride were prepared by dissolving analytical-grade antimony(III) oxide in 9 M hydrochloric acid solution (special-purity grade 20-4); those of tin (IV) chloride, by dissolving $SnCl_4 \cdot 5H_2O$ (pure grade) in the 1 M hydrochloric acid solution; and those of tin(II) chloride, by dissolving $SnCl_2 \cdot 2H_2O$ (pure grade) in 1 M hydrochloric acid solution. Also, solutions obtained by dissolving pure-grade metallic tin in 9 M hydrochloric acid solution were used.

Sn(II, IV) and Sb(III) were precipitated by adding an aqueous solution of an alkali reagent (3–6 M NH_4OH, or 1–3 M NaOH, or 1–2 M Na_2CO_3) to tin- and antimony-containing solutions, with the following com-

positions (g l^{-1}): Sn(IV) 150, Sn(II) 100, Sb(III) 100, and free hydrochloric acid 70, 35, and 210, respectively. The experiments were carried out in fluoroplastic containers with stirrers. The sludge was stirred for 1 h. After settling for 2 h, the precipitate was filtered off, washed with distilled water on a filter, and dried in air. The X-ray phase analysis (XPA) was carried out on a DRON-3 diffractometer with Cu_{K_α} radiation at counter rotation rate of 0.5 deg min^{-1}. The curves of differential thermal (DTA) and thermogravimetric (TGA) analyses of the samples under study were recorded on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1}. The IR absorption spectra were recorded on a Specord IR-71 spectrophotometer in the frequency range 400–4000 cm^{-1}. The samples were prepared as pellets with calcined KBr. The ammonia concentration and the solution pH were measured on an OP-264/1 pH-meter (Hungary) with a renewable electrode [9]. Macroscopic amounts of bound antimony and tin in the liquid and solid phases were determined by iodometric titration, and their microscopic amounts, by the atomic-absorption method on a Saturn-2M spectrophotometer.

A study of antimony(III) precipitation from chloride solutions with aqueous solutions of ammonia or sodium hydroxide showed (Fig. 1, curve *3*) that the degree *R* of antimony(III) extraction into the precipitate strongly depends on the nature of an alkaline reagent. With increasing pH, the degree of antimony(III) extraction into the precipitate grows to become 99.75% at 1 M acidity of the medium, and the residual concentration of Sb(III) is 10–15 mg l^{-1}. In the pH range 0.5–13, antimony(III) precipitates almost completely (*R* ~99.98%), with the residual concentration of Sb(III) in the solution being approximately 1–3 mg ml^{-1}. The pH value increases to 13.3–13.5 on adding a sodium hydroxide solution (the residual concentration of NaOH in the solution is about 0.15 M), which leads to a decrease in *R* owing to the formation of sodium antimonite Na[$(Sb(OH)_4]$ [Sb(III) concentration in solution becomes as high as 1.2–1.4 g l^{-1}]. According to XPA (Fig. 2, curve *1*) and IR spectral data (Fig. 3, curve *1*), the product of hydrolysis of an antimony(III) chloride solution at pH 1.6–1.8 is an oxo chloride of composition $Sb_4O_5Cl_2$. The X-ray diffraction patterns of the samples obtained at pH 2–7 show lower fraction of $Sb_4O_5Cl_2$ reflections. In this case, diffraction peaks appear, with *d*/*n* of 4.57, 3.494, 3.142, 2.65, 2.456, 2.058, 1.929, 1.805, 1.675, 1.572, and 1.523 Å, which correspond to antimony oxide Sb_2O_3 [10]. The IR spectra of the sam-

ples reveal vibrations at 420, 495, 605, 725, and 840 cm^{-1}, related to only the antimony–oxygen bond [11]. The product of hydrolysis at pH 7 is antimony(III) oxide, with the residual content of chloride ions not exceeding 1%.

When tin(IV) is precipitated from chloride solutions, the degree of its extraction into the precipitate first grows with increasing pH, to become 99.9% at pH 1.0–10.6 [residual concentration of Sn(IV) in solution is 5–20 mg l^{-1}]. Further increase in pH results in a decrease in *R*, and, at pH 14, the concentration of Sn(IV) in the solution is approximately 9.8 g l^{-1}. This is due to the fact that Sn(IV) precipitates from chloride solutions as an X-ray-amorphous hydrated tin dioxide or α-stannic acid, which easily dissolves in an alkaline medium to give salts containing $[Sn(OH)_6]^{2-}$ complex ions. The composition of hydrated tin dioxide is represented as $\{SnO_2\}Sn(OH)_4$ [6, 12].

The precipitation of Sn(II) from chloride solutions occurs in the pH range 1.2–5.5, being complete (*R* ~99.98%) at pH ~6 [the residual concentration of Sn(II) in solution is 0.5–1.0 mg l^{-1}]. With the pH value increasing to 12–13, a minor decrease in *R* is observed [residual concentration of Sn(II) in solution is about 17–20 mg l^{-1}]. The X-ray diffraction pattern of the Sn(II) precipitate contains peaks with *d*/*n* of 3.55, 3.31, 3.00, 2.82, 2.52, 1.92, and 1.77 Å (Fig. 2, curve *2*), typical of hydrated tin dioxide with composition $Sn_3O_2(OH)_2$ [10].

Thus, depending on the pH of solution, coprecipitation of Sn(IV) and Sb(III) is possible in the pH range 1–10, and that of Sn(II) and Sb(III), only at pH 5.5–11. In this case, the tin/antimony molar ratio in the precipitates may vary widely.

According to the XPA data, an X-ray-amorphous product containing 5 to 20 at.% antimony(III) is formed in coprecipitation of tin(IV) and antimony(III) from chloride solutions upon addition of an alkaline reagent to make pH 7. Thermal treatment of these samples initiates structural phase transformations. Calcination of the precipitates at 250–600°C results in loss of mass and is accompanied by an endothermic effect (Fig. 4, curve *1*) associated with dehydration of hydrated tin dioxide. The X-ray diffraction patterns contain peaks with *d*/*n* of 3.35, 2.644, 1.765, 1.675, 1.595, and 1.498 Å (Fig. 2, curve *3*), related to tin dioxide with rutile structure [10]. No formation of antimony compounds is observed. Raising the calcination temperature further, to 1000°C, leads to higher degree of crystallinity and results in the formation of

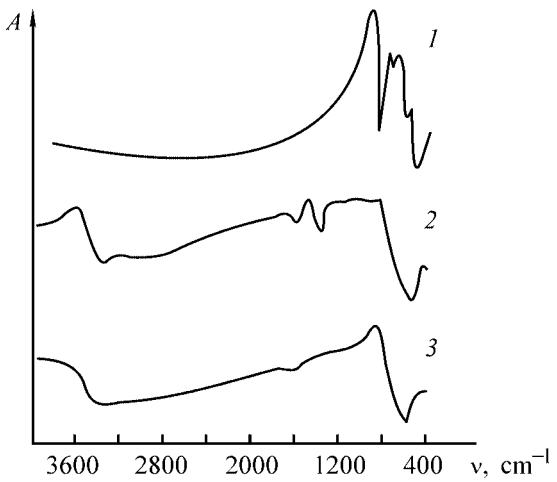

Fig. 3. IR spectra of (*1*) $Sb_4O_5Cl_2$ synthesized by hydrolysis of antimony(III) chloride at pH 1.6 and of products of coprecipitation of (*2*) Sn(IV) and Sb(III) and (*3*) Sn(II) and Sb(III) from chloride solutions at pH 7. (*A*) Absorption and (ν) wave number.

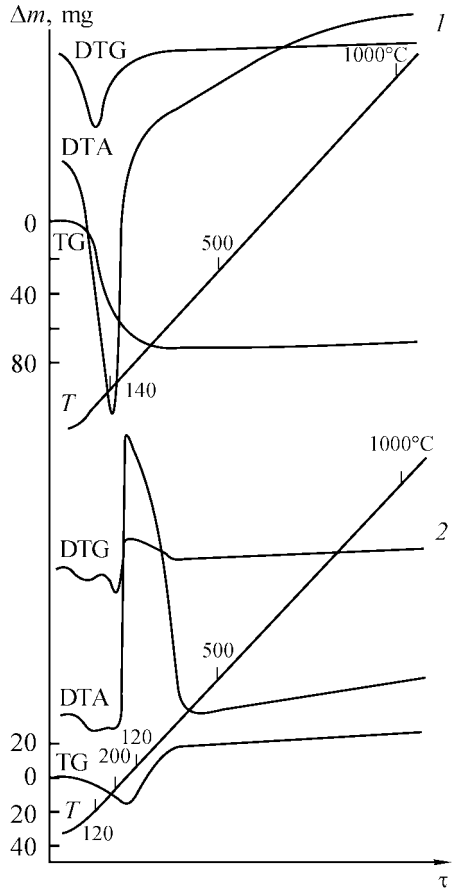

Fig. 4. Thermograms of products formed in coprecipitation of (*1*) Sn(IV) and Sb(III) and (*2*) Sn(II) and Sb(III) at pH 7. Initial Sb(III) content 20 at.%, sample weight 500 mg. (Δ*m*) Mass change, (τ) time, and (*T*) temperature.

Lattice parameters *a* and *c* of tin(IV) oxide with various initial concentrations of Sb_2O_x (calcination temperature 1000°C)

Sb_2O_x, mol %	*a*	*c*
	Å	
0	4.738	3.188
5	4.741	3.191
10	4.745	3.192
15	4.750	3.193

isotype solid solutions of antimony in tin dioxide. In this case, chemical analysis shows the presence of Sb(III) and Sb(V) ions in the samples. The ionic radii of Sn^{4+} (0.067 nm), Sb^{3+} (0.090 nm), and Sb^{5+} (0.062 nm) allow them to be incorporated in the same lattice. The formation of solid solutions of antimony in tin dioxide is confirmed by X-ray studies of SnO_2 unit cell parameters. The experimental data presented in the table show that the parameters *a* and *c* grow with the content of Sb_2O_x increasing to 15 at.%, with the period *c* changing only slightly. The increase in the volume of SnO_2 unit cells can be attributed to introduction of antimony(III) ions, having a somewhat greater ionic radius than Sn(IV).

The IR spectra of dried samples, containing up to 20 at.% Sb(III) show only bands of dried hydrated tin dioxide: bands at 3400, 1620, and 1405 cm^{-1}, related to stretching and bending vibrations of water molecules, and a broad absorption band below 600 cm^{-1} with a shoulder at 620 cm^{-1} and a slightly diffuse maximum at 570 cm^{-1}, related to Sn–O stretching vibrations (Fig. 3, curve *2*).

The IR spectra of the samples containing up to 20 mol % Sb_2O_x and calcined at 1000°C show absorption bands at 560 and 600 cm^{-1} (shoulder corresponding to SnO_2). The absorption band at 645 cm^{-1}, related to the Sn–O stretching vibrations, is shifted to lower frequencies:

Sb_2O_x, mol %	0	5	10	20
ν, cm^{-1}	645	640	625	615

This shift, determined by the content of antimony, is attributed to the formation of a solid solution based on SnO_2, since the character of the IR spectrum of tin(IV) oxide is preserved.

The X-ray diffraction patterns of samples obtained by coprecipitation of Sn(II) and Sb(III) from a hydrochloric acid solution with Sb(III) content of up to 20 at.% upon addition of an alkali reagent, to make pH 7 contain peaks with *d*/*n* 5.68, 3.55, 3.31, 3.00, 2.82, 2.52, 1.92, 1.77, and 1.56 Å corresponding to a hydrated tin(II) oxide of composition $Sn_3O_2(OH)_2$. The IR spectra of samples dried in air and containing up to 20 at.% Sb(III) show only bands of hydrated tin(II) oxide (Fig. 3, curve *3*). With increasing content of Sb(III) in the mixture, the absorption band at 540 cm^{-1}, associated with Sn–O stretching vibrations, is shifted to higher frequencies:

Sb(III), at.%	0	5	10	15	20
ν, cm^{-1}	540	550	570	580	590

In thermal treatment of the products of Sn(II) and Sb(III) coprecipitation, the following processes occur successively: dehydration (endothermic effects at 100 and 220°C) associated with loss of water molecules and Sn(II) oxidation to Sn(IV) (exothermic effect at 270–320°C) (Fig. 4, curve *2*). The X-ray diffraction patterns of samples calcined at temperatures above 400°C contain peaks related to tin dioxide with rutile structure, whereas diffraction peaks associated with $Sb_2O_{4\pm1}$ phases are absent. Therefore, a conclusion can be made that thermal treatment at temperatures higher than 400°C results in the formation of structures based on tin dioxide alloyed with antimony, of the type of $Sn_{1-x}Sb_xO_2$ solid solutions.

CONCLUSIONS

(1) It is established that coprecipitation of tin(IV) and antimony(III) from chloride solutions at pH 1–10, and of tin (II) and antimony(III) at pH 5.5–11, makes it possible to obtain precipitates containing these elements in various proportions.

(2) Whatever the nature of the initial reagents, solid solutions of antimony oxide in tin dioxide are formed upon calcination of precipitates containing up to 20 at.% Sb. Use of Sn(II) as a starting reagent makes it possible to lower the temperature of solid solution formation from 800–1000°C [with Sn(IV) used in the starting mixture] to 500–600°C.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetics of Lead Sulfide Precipitation from Citrate Solutions of Thiourea

N. S. Belova, A. A. Uritskaya, and G. A. Kitaev

Ural State Technical University, Yekaterinburg, Russia

Received May 7, 2001; in final form, March 2002

Abstract—The kinetics of lead sulfide precipitation with thiourea from alkaline solutions at 30, 40, and 50°C under conditions of spontaneous nucleation of the solid phase in the solution bulk was studied.

Lead sulfide is a material widely used to fabricate semiconductor devices operating in the IR spectral range [1]. At present, a chemical method of lead sulfide precipitation in the form of deposits and thin films on a solid surface is widely employed. The properties of the precipitated material strongly depend on the technology of its preparation.

This study is concerned with the kinetics of lead sulfide precipitation from alkaline solutions containing citrate lead(II) complexes and thiourea.

Upon introduction of sodium citrate into an aqueous solution of a lead(II) salt in an alkaline medium, the following complex ions are formed [2]:

$$Pb^{2+} + Cit^{3-} \rightleftarrows PbCit^{-},\ \beta_1 = 3.07 \times 10^6;$$

$$Pb^{2+} + 2Cit^{3-} \rightleftarrows Pb(Cit)_2^{4-},\ \beta_{1,2} = 3.03 \times 10^8;$$

$$Pb^{2+} + Cit^{3-} + OH^- \rightleftarrows Pb(OH)Cit^{2-},\ \beta'_1 = 5.25 \times 10^{13};$$

$$Pb^{2+} + OH^- \rightleftarrows Pb(OH)^+,\ \beta''_1 = 7.95 \times 10^6;$$

$$Pb^{2+} + 2OH^- \rightleftarrows Pb(OH)_2,\ \beta''_{1,2} = 6.28 \times 10^{10};$$

$$Pb^{2+} + 3OH^- \rightleftarrows Pb(OH)_3^-,\ \beta''_{1,2,3} = 1.99 \times 10^{13},$$

where β_i are the formation constants of the complex ions.

The analytical concentration of lead(II) in solution is given by

$$c_{Pb} = [Pb^{2+}] + [PbCit^{3-}] + [Pb(Cit)_2^{4-}] + [Pb(OH)Cit^{2-}] + [Pb(OH)^+] + [Pb(OH)_2] + [Pb(OH)_3^-]. \quad (1)$$

The partial mole fraction of each complex ion can be calculated with account of the above formation constants [3, 4], e.g., as follows:

$$\alpha_{Pb^{2+}} = [Pb^{2+}]/c_{Pb} = \{1 + \beta_1[Cit^{3-}] + \beta_{1,2}[(Cit)^{3-}]^2 + \beta'_1[OH^-][Cit^{3-}] + \beta''_1[OH^-] + \beta''_{1,2}[OH^-]^2 + \beta''_{1,2,3}[OH^-]^3\}^{-1}. \quad (2)$$

The calculated partial mole fractions of lead ions and complex ions in solution are presented in Table 1 in relation to the pH of the medium and concentration of free sodium citrate.

It can be seen that mainly the $Pb(OH)Cit^{2-}$ complex exists in alkaline solutions at pH 10.5–12.5, and the $Pb(OH)_3^-$ complex, at pH > 13.

In aqueous solution, thiourea undergoes hydrolysis to form weak dibasic acids, hydrosulfuric acid H_2S and cyanamide H_2NCN [5]:

$$(NH_2)_2CS \rightleftarrows H_2S + H_2NCN. \quad (3)$$

Table 1. Partial concentrations of lead(II) in a sodium citrate solution ($[Cit^{3-}] = 25 \times 10^{-3}$ M)

The equilibrium constant of reaction (3) was determined experimentally in [5].

Upon introduction of thiourea into an alkaline solution of a complex salt of lead(II), the clear solution turns turbid because of the formation of a solid phase, PbS, by the reaction

$$Pb(OH)Cit^{2-} + N_2H_4CS + OH^- = PbS + Cit^{3-} + H_2NCN + 2H_2O. \quad (4)$$

The rate of this heterogeneous reaction is determined by reactant concentrations, pH value, temperature, and the surface area of the PbS solid phase nucleating in the initially homogeneous system and changing in the course of the process because of the growth of particles in the solution bulk and as a result of their coagulation and sedimentation. To prevent sedimentation, we carried out the process with stirring, which maintained the particles in the suspended state.

We studied the process kinetics by sampling the solution. The concentration of lead(II) in a sample was determined by direct complexometric titration at pH 5 with visual indication of the end point with Xylene Orange indicator [6, 7].

The experiments were carried out at 303, 313, and 323 K. We prepared the working solutions in volumetric flasks by pouring together appropriate volumes of the starting solutions in the following order: 1 M solution of sodium citrate, 1.0 M solution of lead acetate, 3.9 M solution of alkali, 0.5 M solution of thiourea, and distilled water. The experimental data obtained are presented in Table 2 and Fig. 1.

As it can be seen from Fig. 1, the typical kinetic curve is S-shaped, which is characteristic of heterogeneous autocatalytic processes, in which the surface of the forming solid phase acts as a catalyst. In this case, the rate of lead sulfide formation in the system must be proportional to the surface area of the solid phase nucleating in the reaction mixture bulk and to the concentrations of the main reactants, complex salt of lead and thiourea. Therefore, we described the reaction rate with the equation, which, in our opinion, can be named model:

$$\omega = \frac{d(c_{0,A} - c_A)}{d\tau} = k_{exp}(c_{0,A} - c_A)^{2/3} c_A c_B, \quad (5)$$

where $c_{0,A}$ and c_A are the concentrations of the complex salt of lead (M) at, respectively, $\tau = 0$ and $\tau > 0$; $c_{0,B}$ and c_B are the concentrations of thiourea (M) at $\tau = 0$ and $\tau > 0$; $(c_{0,A} - c_A) = (c_{0,B} - c_B) = x$ is the amount of lead sulfide (M) formed during a time τ from the beginning of the reaction; $(c_{0,A} - c_A)^{2/3} = x^{2/3}$ is a quantity proportional to the surface area of PbS particles nucleated in a homogeneous solution.

We assume that the particles of the nucleating solid phase have the shape of sphere of radius r, their number N remains constant, and the mass and surface area of each particle increase in the course of the process [8].

Let us express the surface area S of the solid phase in terms of the number of particles, N, and the surface area of a single particle, $s_0 = 4\pi r^2$, which can be found from the volume of a particle, $v_0 = 4/3\pi r^3$:

$$S = N_{s_0} = (36\pi N)^{1/3}(v_0 N)^{2/3}.$$

Let us define the volume $v_0 N$ of the solid phase by the time elapsed τ from the beginning of the reac-

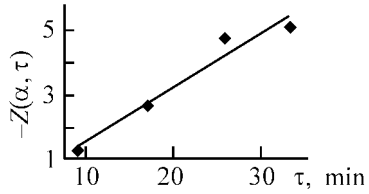

Fig. 2. Graphic representation of Eq. (6).

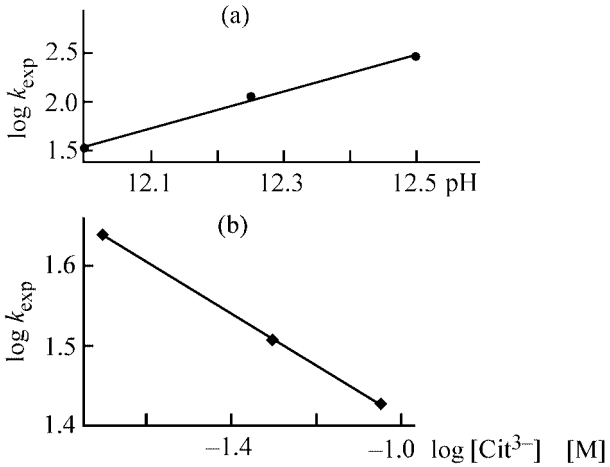

Fig. 3. Graphic determination of the reaction order with respect to concentration of (a) OH^- ions and (b) citrate ions. (k_{exp}) Reaction rate constant. (a) T = 323 K; [Cit^{3-}] = 0.025, [Pb^{2+}] = 0.005 M. (b) T = 313 K; pH 12.77, [Pb^{2+}] = 0.005 M.

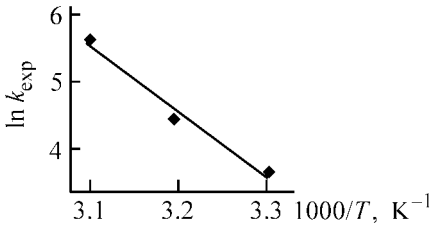

Fig. 4. Determination of the activation energy from the Arrhenius equation. [Pb^{2+}] = 0.005, [Cit^{3-}] = 0.025, [N_2H_4CS] = 0.025 M. (k_{exp}) Reaction rate constant and (T) temperature.

tion in terms of the molar mass M_{PbS}, density ρ_{PbS}, and number of moles, n_{PbS}:

$$v_0 N = (n_{PbS} M_{PbS})/\rho_{PbS},$$

by expressing n_{PbS} in terms of the initial, $c_{0,A}$, and running, c_A, concentrations of the lead salt in a reaction mixture of volume V. Then

$$S = B(c_{0,A} - c_A)^{2/3},$$

where B is a constant incorporated in the rate constant k_{exp} in Eq. (5) and equal to

$$B = \sqrt{36\pi N M_{PbS}^2 V^2/\rho_{PBS}^2}.$$

Let us integrate Eq. (5) by reducing it to a tabulated integral [9]. Upon introduction of the dimensionless quantities $\alpha = c_A/c_{0,A}$ and $\beta = c_{0,B}/c_{0,A}$, the equation takes the form

$$Z(\alpha,\tau) = \frac{1}{2}\ln\frac{[1-(1-\alpha)^{1/3}]^3}{\alpha} - \frac{1}{2\beta^{2/3}}\ln\frac{[\beta^{1/3}-(1-\alpha)^{1/3}]^3}{\beta-(1-\alpha)}$$

$$- \sqrt{3}\,\mathrm{arctg}\frac{2(1-\alpha)^{1/3}+1}{\sqrt{3}} + \frac{\sqrt{3}}{\beta^{2/3}}\,\mathrm{arctg}\frac{2(1-\alpha)^{1/3}+\beta^{1/3}}{\beta^{2/3}\sqrt{3}}$$

$$- \frac{\sqrt{3}\,(1-\beta^{2/3})}{\beta^{2/3}}\,\mathrm{arctg}\frac{1}{\sqrt{3}} = c_{0.A}^{5/3}(1-\beta)k_{exp}\tau. \quad (6)$$

A graphic representation of Eq. (6) in the coordinates $Z(\alpha, \tau)$–τ is a straight line (Fig. 2) whose slope K_{exp} is used to calculate from $K_{exp} = c_{0,A}^{5/3}(1-\beta)k_{exp}$ the experimental rate constant k_{exp} of the process. This constant depends on temperature and yields information about the influence exerted on it by all substances involved in the process and about the number N of nucleated particles.

The experimental data obtained were processed using MathCAD 2000 Professional software package. The results obtained make it possible to determine the reaction orders with respect to each of reactants from the experimental reaction rate constants at different initial ligand and thiourea concentrations and pH value. The kinetic orders of the reaction with respect to the components were calculated using the equation

$$\ln k_{exp} = \ln k_i + n_i \ln c_i, \quad (7)$$

whose graphic solution is presented in Figs. 3a and 3b. The reaction orders n_i with respect to the components are given below:

Reactant	$Pb(OAc)_2$	N_2H_4CS	OH^-	Cit^{3-}
n_i	1.0	1.0	1.85	–0.33

Using the experimental reaction rate constants obtained by processing the kinetic curves in terms of Eq. (6) at 303, 313, and 323 K, the activation energy of the process was found using the Arrhenius equation (Fig. 4) to be 83000 J mol^{-1}. The pre-exponential of the Arrhenius equation was calculated from the rate constant k_0 of reaction (4), related to unit concentration of the reaction mixture components (with account of the reaction order with respect to the components):

$$k_0 = \frac{k_{exp}}{c_{OH^-}^{1.85} c_{Cit^{3-}}^{-0.33}} = 1.37 \times 10^{17}. \quad (8)$$

Our study of lead sulfide precipitation with thiourea in alkaline citrate solutions yielded a kinetic equation that can be used to set process conditions necessary for obtaining a required process rate, on which depends the morphology of the deposit and of the lead sulfide film:

$$\frac{dx}{d\tau} = 1.37 \times 10^{17} \exp\left(-\frac{83000}{8.314T}\right) x^{2/3} c_{Cit^{3-}}^{-0.33} c_{OH^-}^{1.85} \times (c_{0,A} - x)(c_{0,B} - x). \quad (9)$$

CONCLUSIONS

(1) A model equation was proposed for describing the kinetics of lead sulfide preparation in aqueous alkaline solutions of thiourea.

(2) Reaction orders with respect to thiourea, alkali, and ligand (citrate ion) were determined. The activation energy and the pre-exponential of the Arrhenius equation were calculated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetics of Fe(III) → Fe(0) Reduction on Aluminum in Aqueous Solutions

A. F. Dresvyannikov and M. E. Kolpakov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received February 19, 2002

Abstract—The reduction of iron(III) ions by dispersed aluminum in chloride-containing aqueous solutions and the influence exerted by the initial iron(III) ion concentration and the degree of aluminum dispersion on the kinetics of the process were studied.

Spent industrial solutions (solutions for etching, electrolytes for iron plating, etc.) contain a great amount of iron, which is mainly in the oxidation state (III). Therefore, these solutions can be considered potential sources of metallic iron.

Recovery of metallic iron from aqueous solutions with the use of such conventional reducing agents as hydrogen, calcium hydride, and potassium or sodium borohydride, and also by means of electrolysis of solutions, is not always sufficiently effective. This is due to specific features of the reduction process Fe(III) → Fe(0) and also to the great number of equilibrium forms of iron, which hampers its isolation in certain cases. It is necessary to note that, in contrast to other metals, which can be reduced from aqueous solutions of their salts, the polarization observed in electrochemical reduction of iron is high. Iron electroreduction is characterized, along with high overvoltage, by low densities of the exchange current (10^{-8}–10^{-9} A cm^{-2} [1–3]) and a noticeable shift of the stationary potential from the equilibrium value, which is caused by the irreversibility of the process $M^{2+}_{aq} + 2e \rightleftarrows M$.

When iron is electrodeposited, iron ions are discharged together with proton donors [4], which changes the solution pH near the electrode. The joint discharge of iron ions and proton donors leads to the formation of difficultly soluble basic compounds, which not only promote formation of finely crystalline structure of iron precipitates through their adsorption onto the cathode, but also enter into the deposit composition themselves.

The possibility of using metallic aluminum for reducing iron ions in aqueous solutions was mentioned in [5, 6]; however, no detailed studies were carried out. In this connection, the question concerning the kinetics of reduction of iron(III) ions with aluminum remains open. Meanwhile, essential differences between the properties of compact and dispersed aluminum, including its reactivity, have been reported [7, 8].

The aim of this study was to analyze the influence exerted by the size of aluminum particles on the kinetics of iron(III) reduction in aqueous solutions and to consider the possibility of reducing iron(III) ions to iron(0) with aluminum. The processes occurring in interaction of an iron(III) salt solution with aluminum samples of varied dispersity are to be investigated.

EXPERIMENTAL

We used in the experiments narrow-fractionated samples of dispersed aluminum (with purity of no less than 99.0%) and A-999 aluminum foil 100 μm thick. As the main reagent served $FeCl_3 \cdot 6H_2O$ (analytically pure grade) without additional purification. We maintained the reaction mixture pH at 0.5 by adding appropriate amounts of hydrochloric acid to the initial solution in the process of its dilution. In doing so, we used a glass temperature-controlled vessel equipped with an electric stirrer. Preliminarily purified argon was bubbled through the solution to remove dissolved oxygen. Preliminary experiments carried out with inert gas bubbling and with natural aeration demonstrated that the presence of atmospheric oxygen has little effect on the rate of the iron(III) reduction by aluminum. For this reason, the experiments were carried out in part under natural aeration. The process kinetics was studied by taking samples at fixed intervals of time and their subsequent potentiometric titration to determine iron(II) by dichromatometry and iron(III) by

1070-4272/02/7510-1566 $27.00 © 2002 MAIK "Nauka/Interperiodica"

by complexometry [9]. The equivalence points were indicated with a specially designed differentiating device [10]. The total iron in solution was additionally monitored by X-ray fluorescent analysis on a Carl Zeiss VRA-20L instrument.

The initial aluminum samples and the products formed were studied by X-ray phase analysis on a DRON-3M installation with Co_{K_α} radiation and by electron microscopy on a REMMA-202M installation. The X-ray diffraction patterns obtained were identified using a JCPDS data file. In addition, the X-ray diffraction patterns were processed with MAUD software.

Prior to analysis, part of deposits were kept in an alkali to remove the excess amount of aluminum, washed with twice-distilled water to neutral reaction and then with ethanol, and dried in a vacuum at 60°C.

As shown by the experiments performed, solutions of iron(III) chloride react with aluminum differently, depending on the size of aluminum particles, initial concentration of iron(III) solutions, and other factors (temperature and pH). When a solution of iron(III) chloride reacts with compact aluminum, iron(II) ions are mainly accumulated, whereas with dispersed aluminum, the process yields free iron. In the latter case, a brown solution turns colorless with blue tint upon iron(III) reduction, and ferromagnetic particles are formed. A more detailed study has shown that the reaction occurs in two successive stages: 1) reduction of iron(III) ions to iron(II) and 2) reduction of iron(II) to iron(0).

Replacement of the iron(III) chloride solution with a solution of iron(III) sulfate leads to complete termination of Fe(0) formation. In all probability, this is due to the ability of chloride ions to migrate across an oxide film to the metal (via defective sites, in the first place) [11]. Filling of the film with anions raises the cationic conductivity, and the passivating film gains the capacity to pass a high current density. Furthermore, chloride ions can be adsorbed on the oxide layer with the formation and subsequent dissolution of chloride "islands" catalyzing the dissolution of the film [11]. Sulfate ions are much larger than chloride ions, and, therefore, their migration across the oxide layer on the aluminum surface is hindered [5]. The microstructure of the oxide surface layer on aluminum particles is characterized by the presence of a number of cracks and defects, which may appear due to high stresses in oxide film, resulting from the considerable difference in molar volumes between the metal and oxide, and also by the different densities of amorphous and crystalline oxides [12, 13]. This facilitates migration of chloride ions across the oxide layer to the metal surface, and, correspondingly, the intensity of aluminum ionization increases. These features of dispersed aluminum are responsible for the nature of its reaction with solutions containing iron(III) ions. The temperature and pH of a medium strongly affect the reactions considered above. It was found that, with a compact metal (as pellets or plates), mainly the process Fe(III) → Fe(II) occurs, whereas use of dispersed aluminum allows the second stage, Fe(II) → Fe(0), to be clearly detected. Since this process can be classified with consecutive reactions, it can be described in terms of a model based on the classical formal kinetics.

Using the graphical and Ostwald–Neues methods, we found that the decrease in the concentration of iron(III) ions in solution in presence of an excess amount of aluminum is described by a first-order (or pseudo-first-order) kinetic equation. In this connection, we assume all stages of the process to fit such equations. The experimental data suggest that the redox process involves the following stages

$$\mathrm{Fe(III)} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{Fe(II)} \underset{k_4}{\overset{k_3}{\rightleftarrows}} \mathrm{Fe(0)}.$$

Formally, they can be represented as

$$\mathrm{Fe(H_2O)_6^{3+}} + \mathrm{e} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{Fe(H_2O)_6^{2+}}, \quad (1)$$

$$\mathrm{Fe(H_2O)_6^{2+}} + 2\mathrm{e} \underset{k_4}{\overset{k_3}{\rightleftarrows}} \mathrm{Fe^0} + 6\mathrm{H_2O}. \quad (2)$$

Here k_1–k_4 are the respective rate constants.

The stage of the process, which is characterized by the constant k_4 of reaction (2), may result from several side reactions, e.g.,

$$2\mathrm{Fe(H_2O)_6^{3+}} + 6\mathrm{H_2O} + \mathrm{Fe^0} \rightarrow 3\mathrm{Fe(H_2O)_6^{2+}}, \quad (3)$$

$$\mathrm{Fe^0} + \mathrm{H_3O^+} + 5\mathrm{H_2O} \rightarrow \mathrm{Fe(H_2O)_6^{2+}} + 1/2\mathrm{H_2}. \quad (4)$$

Our calculation demonstrated that the rate constant k_2 of reaction (1) is very small as compared with the other constants ($\sim 10^{-5}$ s^{-1}), and, therefore, it can be neglected. In this context, we further consider the following scheme of the process:

$$\mathrm{Fe(III)} \xrightarrow{k_1} \mathrm{Fe(II)} \underset{k_4}{\overset{k_3}{\rightleftarrows}} \mathrm{Fe(0)},$$

which can be described in terms of formal kinetics by the following set of equations

$$\frac{dc[\mathrm{Fe(III)}]}{d\tau} = -k_1 c[\mathrm{Fe(III)}], \quad (5)$$

$$\frac{dc[\mathrm{Fe(II)}]}{d\tau} = -k_1 c[\mathrm{Fe(III)}] - k_3 c[\mathrm{Fe(II)}] + k_4 c[\mathrm{Fe(0)}], \quad (6)$$

$$\frac{dc[\mathrm{Fe(0)}]}{d\tau} = -k_3 c[\mathrm{Fe(II)}], - k_4 c[\mathrm{Fe(0)}]. \quad (7)$$

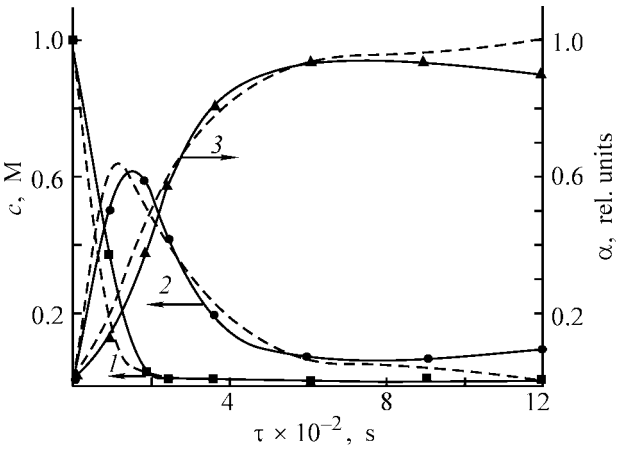

Fig. 1. Kinetic curves of iron(III) reduction by dispersed aluminum. (*c*) Concentration, (α) degree of α-iron transformation, and (τ) time. Size of aluminum particles 71–100 μm, initial $FeCl_3$ concentration 1 M, temperature 298 K; the same for Fig. 3. Compound: (*1*) Fe(III), (*2*) Fe(II), and (*3*) Fe(0). (*1–3*) experiment; *dashed lines*, calculation by Eqs. (8), (13), and (15).

The solution of system (5)–(7) results in the following expressions:

$$c[\mathrm{Fe(III)}] = c_0[\mathrm{Fe(III)}]\exp(-k_1\tau), \quad (8)$$

$$c[\mathrm{Fe(II)}] = \frac{c_0[\mathrm{Fe(III)}]}{K_{eq} + 1}[1 - \exp(-k_1\tau)], \quad (9)$$

$$c[\mathrm{Fe(0)}] = \frac{c_0[\mathrm{Fe(III)}]K_{eq}}{K_{eq} + 1}[1 - \exp(-k_1\tau)]. \quad (10)$$

Here $K_{eq} = k_3/k_4$.

Since Fe(0) is in the nonionic state, we replace c[Fe(0)] with m[Fe(0)]:

$$m[\mathrm{Fe(0)}] = \frac{m_0[\mathrm{Fe(III)}]K_{eq}}{K_{eq} + 1}[1 - \exp(-k_1\tau)]. \quad (11)$$

Hence, introducing a degree of transformation, α, we obtain

$$\alpha = \frac{m[\mathrm{Fe(0)}]}{m_0[\mathrm{Fe(III)}]} = \frac{K_{eq}}{K_{eq} + 1}[1 - \exp(-k_1\tau)]. \quad (12)$$

However, a comparison of the calculated characteristics with the experimental data demonstrated that Eqs. (9) and (12) disagree somewhat with the experimental data. A detailed analysis revealed that $k_4 << k_3$, and, therefore, k_4 can be neglected. As a result, we obtain

$$\mathrm{Fe(III)} \xrightarrow{k_1} \mathrm{Fe(II)} \xrightarrow{k_3} \mathrm{Fe(0)}.$$

Analysis of this scheme gives

$$c[\mathrm{Fe(II)}] = \frac{c_0[\mathrm{Fe(III)}]k_1}{k_3 - k_1}[\exp(-k_1\tau) - \exp(-k_3\tau)], \quad (13)$$

$$m[\mathrm{Fe(0)}] = m_0[\mathrm{Fe(III)}] \times \left[1 - \frac{k_3}{k_3 - k_1}\exp(-k_1\tau) + \frac{k_1}{k_3 - k_1}\exp(-k_3\tau)\right], \quad (14)$$

$$\alpha = \frac{k_3}{k_3 - k_1}\exp(-k_1\tau) + \frac{k_1}{k_3 - k_1}\exp(-k_3\tau). \quad (15)$$

Changes in the concentration c[Fe(III)] are calculated using Eq. (8). The experimental and calculated kinetic curves are shown in Fig. 1. Their satisfactory agreement indicates that the kinetics of Fe(III) reduction by dispersed aluminum can be described by Eqs. (8), (13), and (15).

Deviations of c[Fe(II)] and α, calculated using Eqs. (13) and (15), from the experimental values corresponding to the initial and final periods of the reaction are attributable to imperfection of the model proposed. In particular, it disregards the diffusion and adsorption processes, and also other specific features of the reactions occurring at the interface. The calculated and experimental data quite satisfactorily coincide in the time interval 0–600 s after the beginning of the process. Further, deviations appear, caused, in all probability, by the above-mentioned factors and also by the intensification of dissolution of deposited iron(0). This intensification occurs virtually from the very beginning of Fe(III) ion reduction when compact aluminum is used, and also in the case of dispersed aluminum (particles greater than 200 μm) under the following conditions: elevated temperature, low concentrations of the initial solution, and long duration of the process (>600 s after its beginning).

The rate of the process, and also the yield of α-iron grow with increasing concentration of iron(III) solutions (Fig. 2a), with the yield reaching a value of 99% at $c \geq 2.0$ M. It is necessary to note that the process under consideration is not isothermal, and its exothermic effect becomes more pronounced with increasing concentration of iron(III) chloride. Elevating the temperature also accelerates iron deposition, with, however the yield of iron decreasing in this case. Most likely, a rise in temperature essentially accelerates side reactions (3) and (4).

The size of aluminum particles strongly affects relative the rates of the redox stages under consideration (Fig. 2b). An increase in the particle size leads, on passing a certain conditional boundary of ~200 μm, to a sharp decrease in k_1 and k_3 and, correspondingly, in the iron(0) yield. This is attributable to a difference in structure and physicochemical properties of surface oxide layers between compact and dispersed alumi-

num. The film on the surface of particles of finely dispersed aluminum is not ideally smooth and shows a shallow profile in the form of folds, pits, and bulges. We assume that the profile on oxide layers originates from volume shrinkage of the metal in transition from a melt to the solid state, and also from the difference in thermal expansion coefficients between the metal and the oxide (by approximately a factor of 4) [14]. Stresses arising in the surface oxide layers of aluminum particles are rather substantial, which may be due to the significant difference in modulus of elasticity between the metal and the oxide phase [14, 15].

The crystalline oxide formed in dry air or upon high-temperature heating of powders stretches the metal lattice at room temperature and compresses it at elevated temperatures [16]. The appearance of shearing stresses, which are more or less uniformly distributed throughout the particle volume, results from differences in structure and thermal expansion between aluminum and its oxide. Trace amounts of crystalline aluminum oxide mono- and trihydrates were detected in the oxide layers of aluminum powders, except in those obtained at high temperatures [12, 17]. The formation of hydroxides on the particle surface is due to hydration of the amorphous oxide and finely dispersed γ-Al_2O_3 in storage with access of air containing water vapor. Ultramicroscopic quantities of a foreign phase (e.g., Si, Fe, Zn, K, Mg, etc.) are also present in the surface layers.

Thus, the surface microstructure of the oxide layer on aluminum particles is characterized by the presence of a large number of microcracks [16–19]. Furthermore, the oxide films on particles have a great number of structural defects [12, 14]. These features of dispersed aluminum predetermine the nature of its reaction with solutions containing iron(III) ions.

The aforesaid suggests the following course of the process: when iron(III) chloride is dissolved, it undergoes hydrolysis, which leads to liberation of a certain amount of hydrochloric acid; however, in strongly acid or concentrated solutions the hydrolysis of iron ions does not result in the formation of difficultly soluble basic compounds. The liberated Cl^- anions are depassivators, being adsorbed to displace or partially replace the passivating oxygen on the metal surface to give a surface complex [11] that can further pass into solution. Chloride ions play a double role [20]: they depassivate the electrode and are involved in the kinetic stage of aluminum ionization.

The oxidation of aluminum in the course of corrosion is accompanied by reduction of proton donors

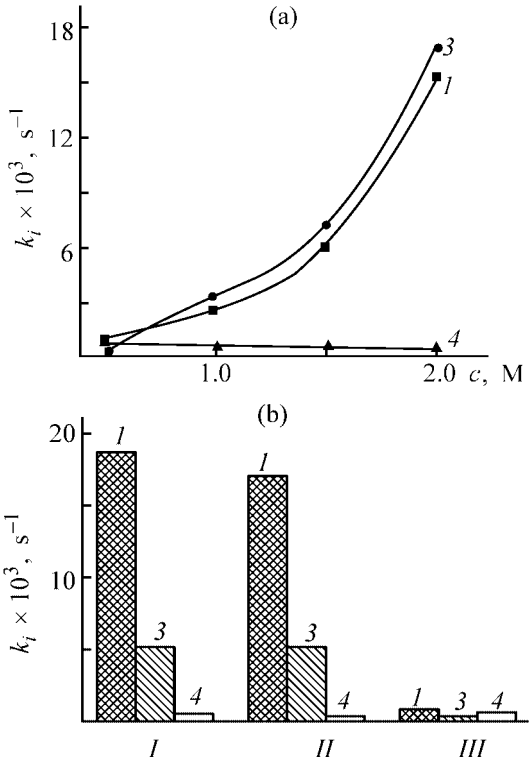

Fig. 2. Effects of (a) initial $FeCl_3$ concentration c and (b) size of aluminum particles on the rate constants k_i of various stages of iron(III) reduction. Temperature 298 K, (b) initial $FeCl_3$ concentration 1 M. *Digits 1, 3,* and *4* correspond to k_1, k_3, and k_4, respectively. Size of aluminum particles (μm): (*I*) 71–100, (*II*) 140–250, and (*III*) 250–400.

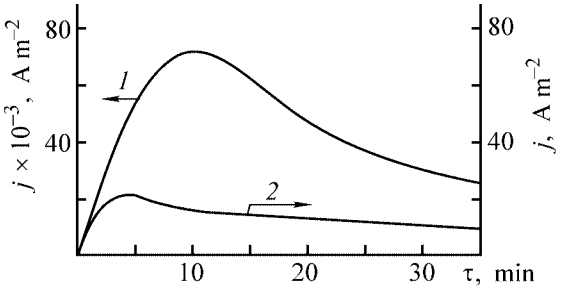

Fig. 3. Rates j of (*1*) iron deposition and (*2*) hydrogen evolution on aluminum microparticles vs. time τ.

(hydrogen depolarization) and iron ions (oxidizing agent). As shown above, the latter process includes two stages and culminates in precipitation of α-iron.

The conjugate deposition of iron and hydrogen evolution on aluminum is illustrated in Fig. 3. It is necessary to note that the rate of hydrogen liberation is, in this case, lower than that of iron precipitation by more than 3 orders of magnitude. Such a disagreement

with the data presented above is attributable to the following: difference in the nature of the supporting metal; hydrogen liberation only on the metal being deposited, owing to an essential difference between the overvoltages of hydrogen liberation on aluminum and iron [21]; and high rate of metal deposition, resulting from a developed aluminum surface and nonisothermal character of the process (exothermic effect). In this case, the solution pH grows essentially, by approximately two pH units.

Since basic compounds of iron are formed in its deposition, it makes sense to determine qualitatively and quantitatively the composition of deposits formed on aluminum. According to X-ray phase analysis and local microanalysis, samples obtained with the use of dispersed aluminum (71–100-μm fraction) are formed by a mechanical mixture of crystals of α-iron and aluminum. We found that a deposit kept in a concentrated NaOH solution (3.0 M) consists of a single phase of α-iron. It is necessary to note that the size of mosaic iron blocks obtained by reduction of $FeCl_3$ solutions with dispersed aluminum is 24.569 nm. Correspondingly, the lattice constant a is 0.28662 ± 0.00001 nm, in agreement with reference data [22, 23] (a = 0.28665 nm). Some parameters of crystallites of the α-iron obtained are given below:

h	*k*	*l*	Crystallite size, nm	Microstrain
1	1	1	24.569	0.00402
2	0	0	13.791	0.00419
2	1	1	24.569	0.00402
2	2	0	24.569	0.00402

When a deposit is not kept in an alkali, an amorphous phase, most likely pseudoboehmite, appears in the deposit. In the course of time, bayerite crystals formed from metastable products of aluminum dissolution also appear.

The resulting iron particles are spherical or nearly so and have different sizes. Large particles (40–50 μm) bear on their surface spherical subparticles 0.5–5 μm in size and an open-work network of thread-like nuclei in microcracks and pores.

CONCLUSIONS

(1) It is established for the first time that reduction of iron(III) ions by dispersed aluminum in chloride-containing aqueous solutions may occur in two successive stages Fe(III) → Fe(II) → α-Fe, with α-Fe yield as high as 99%. In this case, the rate of iron deposition exceeds that of conjugate hydrogen liberation by approximately 3 orders of magnitude.

(2) The decisive influence on the kinetics of this process is exerted by the initial concentration of iron(III) ions and the degree of aluminum dispersity.

(3) It is established by X-ray fluorescent and X-ray phase analyses and electron microscopy that the deposits formed in this process are formed of α-iron (crystallographic Miller indexes 110, 200, 211, and 220) with a minor amount of admixtures.

Received May 13, 2002

Abstract—Reasons for a decrease in recovery of lanthanides by sulfuric acid leaching from separate lots of phosphosemihydrate produced by Voskresenskie Mineral'nye Udobreniya joint-stock company were studied.

Khibiny apatites are one of the most promising Russian raw sources of lanthanides [1, 2]. The sum of lanthanides in the apatite concentrate (AC) obtained from ores mined at the Khibiny field is about 1 wt % [3], with the relative contents of elements being close to the optimal in the pattern of consumption [4].

In 1996, more than 80% of the 4.82 million tons of AC supplied to Russian plants were processed by the sulfuric acid technology. This technology was implemented in the form of semihydrate and dihydrate processes, which produce as a recrement, together with H_3PO_4, either "phosphosemihydrate" $2CaSO_4 \cdot H_2O$ (PSH) or "phosphodihydrate" $CaSO_4 \cdot 2H_2O$ (PDH), respectively.

The semihydrate process is used at two largest Russian fertilizer plants: Ammofos joint-stock company (Cherepovets) and Voskresenskie Mineral'nye Udobreniya joint-stock company (Voskresensk, Moscow oblast). This method is more economical and will gradually replace the dihydrate process at other Russian plants. With the semihydrate process, up to 95% of lanthanides is extracted to PSH from the apatite concentrate [5, 6].

An efficient technology for recovery of lanthanides from PSH has been developed at the Ammofos joint-stock company [7–15]. According to this scheme, the same H_2SO_4 solution is used for leaching of several PSH portions. In each leaching stage, concentrated sulfuric acid (93.5 wt %) is added to the solution to maintain its concentration. Lanthanides are extracted from the sulfate solution by ionic flotation.

In the case of acid leaching, only lanthanides forming independent phases in PSH can pass into solution. Part of lanthanides in PSH do not crystallize isomorphically with hydrated calcium sulfate, but form independent phases precipitating on celestine ($SrSO_4$) grains. The most probable compounds of lanthanides in these phases are phosphates and binary sulfates of rare-earth and alkali metals [16].

Some authors [17] believe that the limiting concentration of lanthanides in solutions (1.1–1.2 g l^{-1}) is determined by the salting-out action of H_2SO_4, which lowers the solubility of lanthanide sulfates. However, the solubility of lanthanide sulfates is an order of magnitude higher in H_2SO_4 solutions with the concentrations under study, compared with that reached in leaching solutions.

Phosphoric acid is accumulated in leaching solutions [7, 9, 17] because of the dissolution of lanthanide and calcium phosphates in H_2SO_4 and also because of its inflow from unwashed PSH.

The solubility of lanthanide orthophosphates in acid sulfate-phosphate solutions grows with increasing concentration of sulfuric acid and falls with increasing concentration of orthophosphoric acid [13]. The use of more concentrated acidic sulfate solutions allowed the sum of lanthanides in the leaching solution to be raised to 3 g l^{-1} and more [13]. As a result, the volume of solutions decreased to a level permitting their utilization in manufacture of fertilizers without disturbing the water balance and carrying out their concentration by evaporation.

When working with PSH, the Voskresenskie Mineral'nye Udobreniya joint-stock company found that previously obtained data on leaching of lanthanides with H_2SO_4 solutions could not be reproduced for separate lots of the product.

The aim of this study was to analyze the reasons for the decrease in recovery of lanthanides by leaching from PSH with H_2SO_4.

EXPERIMENTAL

The following methods and instruments were used in analyzing the products: oxalic gravimetry (lanthanides, calcium, and strontium); atomic–emission spectrometry with inductively coupled plasma, Perkin Elmer Plasma 400 instrument (lanthanides, calcium, strontium, and titanium); X-ray fluorescence analysis (lanthanides and phosphorus); atomic–absorption spectrometry in an acetylene-air flame, Carl Zeiss AAS-30 (Jena) instrument (sodium and potassium); and spectrophotometry (phosphorus, fluorine, and silicic acid) [18, 19].

The results obtained in analyzing solutions suggest that increased content of sodium and potassium hexafluorosilicates in PSH can hinder accumulation of lanthanides in solution. Sodium and potassium ions, which pass into an acidic sulfate solution, must bind lanthanides into poorly soluble binary sulfates $MLn(SO_4)_2$ by the reaction

$$M_2SO_4 + Ln_2(SO_4)_3 = 2MLn(SO_4)_2 \ (M = Na, K).$$

Calculations with the use of the data of [20] on the solubility of binary sulfates of lanthanides in water demonstrated the following.

(1) With increasing concentration of sulfuric acid, the solubility of binary sulfates of rare-earth and alkali metals decreases substantially, especially for potassium. With increasing content of water-soluble compounds of sodium and potassium in PSH, binary sulfates may form and precipitate.

(2) The solubility of binary sulfates of lanthanum, cerium, and alkali metals, whose total content in the "apatite sum" exceeds 70%, is particularly small [21]. This accounts for the observed [7] increase in the content of yttrium-group lanthanides in the sum of lanthanides leached out by sulfuric acid from PSH, compared with their content in the initial PSH.

It is not improbable that fluoride ion passing into solution together with Na_2SiF_6 and K_2SiF_6 and also upon decomposition of apatite remainder, can hinder lanthanides from passing into solution. The rather low solubilities of Na_2SiF_6 and K_2SiF_6 [22] predetermine the difficulty of their removal in washing PSH with water on revolving filters. Although lanthanide fluorosilicates are readily soluble in inorganic acids [23], fluoride ions are formed in solution through SiF_6^{2-} hydrolysis. They can bind lanthanides into poorly soluble fluorides LnF_3 [24].

It is known [24] that the solubility of lanthanide fluorides grows with increasing acidity, and at pH ~1 it falls in the range 0.17–0.4 g l^{-1} (in terms of Ln_2O_3) for various lanthanides. Further increase in the solution acidity seems to raise the solubility of lanthanide fluorides.

The probability of formation of lanthanide fluorides in sulfuric acid leaching solutions is estimated below. When SiF_4 is absorbed by sulfuric acid with concentration of 62.5 wt % and lower, silicic acid is formed by the reaction [25]

$$SiF_6^{2-} + 2H_2O = SiO_2 + 4H^+ + 6F^-. \qquad (1)$$

The equilibrium constant of reaction (1) has been found by different researchers to fall in the range $n \times 10^{-27}$–$n \times 10^{-28}$ [25]. For our calculations we adopted the maximal value of 2.3×10^{-27}, since in this case, the equilibrium content of fluoride ions in solution will be the highest.

We assumed in our calculations that the Na_2SiF_6 solubility in sulfuric acid, as also that in water, is 0.7 wt % and the ion activities are equal to their concentrations. The estimated concentrations of F^- ions in acidic sulfate solutions are given below:

$c_{H_2SO_4}$, wt %	2	4	6	8	10	20
c_{F^-}, mg l^{-1}	1.10	0.69	0.54	0.44	0.38	0.24

These data show that the concentration of F^- ions in acidic sulfate solutions is several orders of magnitude lower than it follows from the data [24] on the solubility of lanthanide fluorides in acidic solutions, i.e., lanthanide fluorides must not precipitate.

As mentioned above, solutions containing 3 g l^{-1} and more of lanthanides were obtained by processing four portions of PSH (from Ammofos joint-stock company) with average extraction of 32.6–38.7%, using the same H_2SO_4 solution, to which new portions of the acid were successively added to maintain its concentration. In this case, one leaching cycle with 2–6% solution of sulfuric acid within 1 h resulted in that 150–160 mg l^{-1} of Na_2O and 94 mg l^{-1} of K_2O passed into solution.

Table 1. Leaching of lanthanides from PSH (0.45wt % Ln_2O_3 in PSH) with 6% H_2SO_4 solution (V_l : V_s = 3 : 1) (duration of leaching 0.5 h, 3% H_2SO_4 added in each of cycles 2–4)

3	4 + 1 + 1	6.28	1.82	0.28	27.2
4	4 + 1 + 1 + 1	6.77	2.14	0.38	18.1

We found that the efficiency of lanthanide leaching sharply decreased when working with certain PSH samples manufactured by Voskresenskie Mineral'nye Udobreniya joint-stock company (Table 1). The concentration of lanthanides in solution increased somewhat starting from the second stage (probably, yttrium and medium lanthanides, whose solubility as binary sulfates is high and the content in the sum of lanthanides in PSH is low, continued to dissolve). The concentrations of sodium and potassium ions remained virtually unchanged.

In some cases, washing of such a PSH with water resulted in a sharp increase in recovery of lanthanides into leaching solutions (Table 2).

The experiments demonstrated that, with washing for 0.5 h at V_l : V_s = 2 : 1, the main part of sodium and potassium ions is washed out of PSH by water. However, when the washing water is reused for processing the subsequent PSH portions, the efficiency of washing in solution much decreases, although the concentration of sodium and potassium ions in solution is much less than that corresponding to the equilibrium solubility of Na_2SiF_6 and K_2SiF_6.

However, in the case of certain PSH lots manufactured at the Voskresenskie Mineral'nye Udobreniya joint-stock company, even washing with water increased the efficiency of sulfuric acid leaching only slightly. As a rule, the content of lanthanides in these lots was too low for PSH, namely, no more than 0.43 wt %, instead of the usual 0.57 wt %. When such PSH lots were treated with HNO_3 solutions with various concentrations (Table 3), effective leaching of lanthanides was achieved in the first stage, a significant amount of PSH being dissolved in this case. The greatest increase in the REE extraction was obtained with 4–6% HNO_3 solution, with 4.64–6.11% of PSH passing into solution.

When HNO_3 solution is used for successive leaching of several portions of such a PSH, the efficiency of rare-earth leaching decreases sharply even upon addition of nitric acid to maintain its concentration (Table 4).

We were able to transfer in solution 96.28 % of rare-earth elements by twofold leaching of a single portion of such a PSH with fresh portions of nitric acid (Table 5). This fact confirms the data of [16],

Table 5. Processing of a single PSH portion with two successive portions of fresh HNO_3 ($V_s : V_l = 1 : 3$) (duration of leaching 1 h, Ln_2O_3 content in the concentrate 0.43 wt %)

1	4	5.04	1.03	3.91	71.86
2	4	5.04	0.35	3.91	24.42

according to which the main part of lanthanides in the PSH studied is not isomorphically crystallized with $2CaSO_4 \cdot H_2O$ (bassanite) and 10.1 % Ca(Sr)O contained in PSH.

The data of Tables 4 and 5 suggest that the PSH lots most difficultly leached with sulfuric acid were obtained with violations of the semihydrate technology (by a "mixed" process) and are, in fact, PSH grains with a PDH crust. The solubility of calcium sulfate in fresh nitrate solutions is rather high, and crusts hindering the access of the acid to rare-earth-containing grains are dissolved. In this case, lanthanides are leached by nitric acid. After the acidic nitrate solution is saturated with calcium sulfate, it becomes difficult for lanthanides to pass into solution.

CONCLUSIONS

(1) Increased content of soluble compounds of sodium and potassium (Na_2SiF_6 and K_2SiF_6) in the phosphosemihydrate and(or) production of phosphosemihydrate in a mixed semihydrate-dihydrate process lead to a sharp decrease in the extent of recovery of lanthanides in their sulfuric acid leaching from phosphosemihydrate.

(2) Loss of lanthanides in sulfuric acid leaching of phosphosemihydrate is less probable owing to the formation of poorly soluble fluorides.

(3) It has been established experimentally that the main part of lanthanides do not crystallize isomorphically with phosphosemihydrate.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Hydrated Sodium Silicates on Cement Paste Hardening

A. S. Brykov, V. V. Danilov, V. I. Korneev, and A. V. Larichkov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 29, 2002

Abstract—The hydration of cement clinker minerals occurs at a high rate in the presence of sodium silicates owing to a decrease in the initial pH of pore solutions of cement pastes and to intensive formation of calcium hydrosilicates.

We have attempted earlier [1] to find an explanation for the accelerated setting and hardening of portland-cement pastes with addition of hydrated sodium silicates (hydrosilicate powders, or HSP). According to the mechanism suggested in [1] for the case of simultaneous dissolution of a part of clinker phases and HSP, OH^- ions formed in clinker dissolution interact in the liquid phase with polymeric silicate anions originating from HSP. The consequence of this process is a high rate of hydration, whereas in the case of HSP-free portland cement pastes, a prolonged induction period begins almost immediately.

In the present study, we measured the pH of pore solutions of cement pastes with HSP additives. These data supplement the concepts put forward in [1].

EXPERIMENTAL

Hydrated sodium silicates under study are characterized in Table 1. Pastes were prepared from a PTs500 DO cement (Oskoltsement) with the following phase composition (wt %): $3CaO \cdot SiO_2$ 52–55, $2CaO \cdot SiO_2$ 20–22, $3CaO \cdot Al_2O_3$ 20–22, and gypsum 5. The pH values of pore solutions were measured on a pH-673.M pH-meter.

The pastes were prepared as follows. Hydrosilicate powders 2.0 and 2.8 were mixed with the cement in amounts of 1, 3, and 5% relative to the cement weight for each powder. The resulting composition was mixed with water. The water-dried cement ratio (water-to-cement ratio) was 0.35. The HSP hydration water was disregarded.

The $Na_2SiO_3 \cdot 5H_2O$ compound was mixed with cement in amounts of 1 and 5% relative to the cement weight (in terms of $Na_2O \cdot SiO_2$). The metasilicate hydration water was taken into account in such a way that this water and water added to the cement (tempering water) ensured a water-to-cement ratio of 0.35.

The intrinsic pH values of solutions of sodium silicates in cement tempering water are presented in Table 2.

Table 1. Physicochemical properties of powders of hydrated sodium silicates

Characteristic	Sodium silicate		
	$Na_2SiO_3 \cdot 5H_2O$	HSP 2.0	HSP 2.8

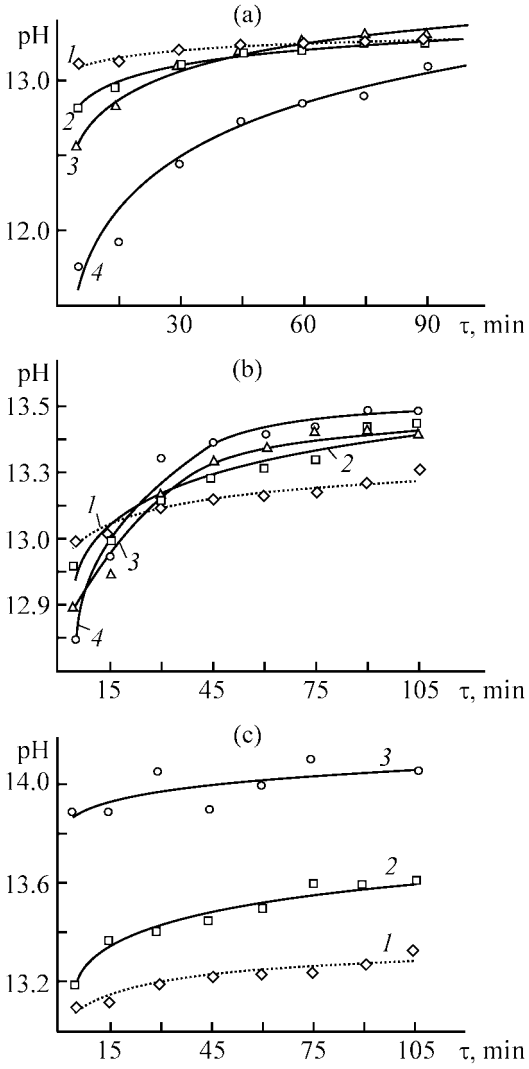

Fig. 1. pH of pore solutions of cement pastes with sodium hydrosilicates having silica modulus of (a) 2.8 and (b) 2.0, and (c) with sodium metasilicate vs. time τ. Addition of sodium hydrosilicate (% relative to cement weight): (*1*) 0 (pure paste), (*2*) 1, (*3*) 3, and (*4*) 5.

Within 5 min after mixing the cement formulation with water, the first paste sample was taken, filtered, and the pH of the obtained pore solution (filtrate) was measured. Further paste samples were taken every 10–15 min during 1.5 h. The data obtained are shown in Figs. 1a–1c.

During the period under study, the hydration of alite, $3CaO \cdot SiO_2$, is the main process in the cement solution free of alkaline silicates. Within about 10 min after mixing cement with water, OH^- and Ca^{2+} ions and a minor amount of SiO_2 are present in the pore solution in the following concentrations (M): SiO_2 $(4–5) \times 10^{-5}$; OH^- 2.0×10^{-2}, and CaO 3×10^{-2}. At the resulting solution alkalinity (as seen from Figs. 1a–1c, pH is about 13 for the pure, HSP-free paste) soluble silica species are predominantly in the form of dimeric anions with a certain average degree of ionization [2].

The initial hydration results in the formation of a thin layer of calcium silicates on the surface of clinker grains, and after that a 2-h induction period starts. Then the hydration rate increases to reach a maximum within approximately 10 h. Throughout the experiment, the pore solution concentrations change only slightly as compared with the initial values, which gives no way of distinguishing the induction and active periods of hydration on the basis of pH measurements.

In the case of simultaneous hydration of clinker and dissolution of HSP (whose solution has, in the concentration range under study, a pH of 11.3–11.4, which is lower than the pH of the pure, HSP-free paste) OH^- ions liberated as a result of hydration react with silicate ions of HSP by the reactions:

$$\equiv Si{-}OH + OH^- \rightarrow H_2O + \equiv SiO^-, \quad (1)$$

$$\equiv Si{-}O{-}Si\equiv + OH^- \rightarrow \equiv SiOH + \equiv SiO^-, \quad (2)$$

It follows from these data that cement pastes with high-modulus (silica modulus higher than 1.5–2.0), i.e., low-alkaline, silicates must have lower pH than the pure cement paste. The decrease in pH must occur at least in the initial period, after mixing cement and water. Since cement is in excess with respect to HSP, reactions (1) and (2) can proceed until a pH value close to the pH of the cement paste is attained in solution. Throughout this time, clinker minerals are hydrated at a high rate. A certain polymeric composition of the solution with respect to silica must correspond to the attained pH value. As noted above, dimeric SiO_2 species ionized in accordance with this pH value are the most probable forms.

A different type of behavior in the pore solution must be observed for low-modulus sodium silicate (metasilicate), since the pH values of its own solutions (13.1–13.5) are higher than, or comparable with the pH of the pure cement paste. If sodium metasilicate is added to the paste, the pore solution must turn highly alkaline almost instantly.

Calcium ions, which appear in the solution at the instant when the cement starts to react with water, and silicate ions passing into solution from HSP or sodium silicate form difficulty soluble calcium sil-

Table 3. Calculated and experimental pH values of pore solutions

Sodium silicate	pH values at indicated content of HSP additive, wt %					
	1		3		5	
	calculated	experimental	calculated	experimental	calculated	experimental
Na_2SiO_3	13.51	13.6	–	–	14.23	14.1
HSP 2.0	13.27	13.46	13.72	13.44	13.95	13.5
HSP 2.8	13.16	13.3	13.60	13.33	13.83	13.25

icate. For example, for the simplest monomeric silicate anions, the salt can be formed by the scheme:

$$Ca(OH)_2 + 2NaH_3SiO_4 \rightarrow Ca(H_3SiO_4)_2 + 2NaOH. \quad (3)$$

In this case, an equivalent amount of NaOH appears in the solution. Consequently, final pH values higher than those in the case of pure cement pastes would be expected.

It is evident from Figs. 1a and 1b that, during the initial period after mixing the formulations with water, the pH values of the cement pastes with HSP (2.0 and 2.8) are lower than those of the pure paste. In the case under consideration, the pH of the pure paste is 13.1, i.e., is higher than the value reported in the monograph [2]. Possibly, this is due to the high content of alkalis in the cement clinker. Raising the amount of HSP added to the paste results in a more pronounced decrease in pH. The time required for the pH to restore to about 13 is 15, 30, and 100 min for HSP 2.8 added in amounts of 1, 3, and 5%, respectively (Fig. 1a). With increasing silicate modulus, the initial pH values become lower (Figs. 1a and 1b).

According to Figs. 1a and 1b, pastes with HSP 2.0 and sodium metasilicate become more alkaline than the pure cement paste. In the case of HSP 2.0, this occurs not immediately, but only after an initial decrease in pH to 12.8–13.0, whereas in the case of sodium metasilicate, a highly alkaline medium is created, as expected, very fast.

Thus Figs. 1a–1b reflect the concepts presented above and in the preceding publication [1].

Table 3 lists the pH values calculated for pore solutions of cement pastes with HSP for the case of complete precipitation of silicate anions with calcium ions, when an equivalent amount of free alkali is formed in the solution by reaction (3). The experimental pH values (Figs. 1a–1c) are shown in Table 3 for comparison.

The data of Table 3 suggest that silicate-ions are precipitated in almost all of the cases studied, though at different rates depending on the type and amount of an HSP additive. It is clear that the higher alkalinity of the medium, the easier reaction (3) occurs. For example, addition of any sodium silicate in amount of 1% results in the maximal pH value corresponding to complete precipitation of calcium silicate during the time of experiment. If 5% HSP is added, the maximal pH value can be attained only with sodium metasilicate. For the pastes with HSP 2.8, the final pH value exceeds that of the pure paste only slightly.

Thus, HSP silicate ions are actively bound in the paste by calcium cations passing into the pore solution. It can be shown that the amount of SiO_2 introduced into a paste with HSP additive may be as high as 20% relative to the SiO_2 content in $3CaO \cdot SiO_2$. If we assume that silica from HSP is entirely consumed for the formation of calcium hydrosilicates by reaction (3), this amount may be quite sufficient for the cementation to start. In any case, the induction period does not begin while calcium hydrosilicates are formed intensively.

When sodium silicates with SiO_2/Na_2O ratio of about 2 and higher are added to the paste before, or simultaneously with, the precipitation of calcium hydrosilicates, there occurs depolymerization of low-polymeric silica acids, involving hydroxide ions present in the pore solution. This depolymerization significantly accelerates the hydration process. Thus, after mixing cement with water in the presence of HSP the hydration occurs at a high rate until high pH values, typical of the pure cement paste, are attained. This is indicated by the dependence of the paste setting time on the silicate modulus of HSP added [1].

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Interaction between Components in the System Potassium–Sulfur

A. G. Morachevskii and E. A. Maiorova

St. Petersburg State Polytechnical University, St. Petersburg, Russia

Received May 13, 2002

Abstract—Thermodynamic properties of the system potassium–sulfur in molten and solid state are compared and discussed.

The phase diagram of the system potassium–sulfur has been repeatedly studied [1]. According to refined data [2], potassium and sulfur form six congruently melting compounds: K_2S (mp 948 ± 20°C), K_2S_2 (487°C), K_2S_3 (302°C), K_2S_4 (154°C), K_2S_5 (206°C), and K_2S_6 (189°C) (Fig. 1). Thermal analysis of the potassium–sulfur system is difficult because of the tendency of the alloys toward supercooling. Potassium monosulfide, having the highest melting point among polysulfides, is characterized by considerable fraction of ionic bonding. The available data on the melting point of K_2S are rather controversial. For example, T_{mp} is 835°C according to [3]. A review [2] presented Dworkin and Bredig's experimental data [4]. For other potassium polysulfides, the error in determining the melting point does not probably exceed ±5%. Apart from thermal analysis, differential scanning calorimetry (DSC) [5, 6] and the electromotive force (EMF) method [7–9] have been used to obtain data on the position of the liquidus line and boundaries of the stratification region in the sulfur-rich part of the system. The upper critical temperature in the K–K_2S system is 900°C, and the monotectic horizontal lies at 883°C [10].

Potassium and sulfur start to interact with considerable heat effects even upon weak heating. Data on the enthalpy of formation of the compounds and on the standard entropies and enthalpies of melting are summarized in Table 1. In [3], separate data available to the authors were used to calculate the enthalpy of K_2S formation. In [11], the enthalpies of formation of potassium polysulfides were estimated from the heat effects of their interaction with a 0.1 N solution of H_2SO_4 at 25°C. In reference book [13], these values were only recalculated with account of more recent data on thermodynamic properties of substances involved in the process. In [12], the enthalpy of K_2S formation was obtained using the method of fluorine calorimetry.

The standard entropies were estimated in reference book [13] for compounds K_2S, K_2S_2, K_2S_3, and K_2S_4 by Latimer's method [17]. For K_2S, a method proposed by Voronin [14] was also used. A closely similar S^0_{298} value (117 J mol^{-1} K^{-1}) was calculated for this compound by Kelly's method [18]. For the com-

	–473.6 ± 5.0 [13]		14.6** [15]				27.6 [5]

* Calorimetric data. ** DTA data. *** Data obtained in the present study by extrapolation.

pound K_2S_5, S^0_{298} was calculated from the experimental heat capacities C_p in the temperature range 10–298 K [16]. The S^0_{298} value calculated by Latimer's method is equal to 248.5 J mol^{-1} K^{-1}. Figure 2 shows the standard entropy for potassium polysulfides as a function of the number of sulfur atoms in a polysulfide molecule. The S^0_{298} value for K_2S_6 in Table 1 was obtained by graphical extrapolation.

In [15], the calorimetric ("throwing-in") method was used to determine the H^0_T–H^0_{298} values for a number of potassium polysulfides in the temperature range 298–804 K and to estimate the enthalpies of their melting. In the same study, the enthalpies of mixing were obtained by DTA. The results of both methods are in rather satisfactory agreement for K_2S_3 and K_2S_6 and differ strongly for K_2S_4 and K_2S_5 (Table 1). The DTA values are higher by 70–250% than those obtained in a calorimetric experiment. Probably, this is due to common difficulties encountered in studying phase transformations in substances subject to supercooling and vitrification. The enthalpies of melting of potassium polysulfides were also determined in [5, 6] by the DSC method (Table 1). In Janz and Rogers' opinion [5, 6], the vitrification in the potassium–sulfur system is the most pronounced in the composition range K_2S_4–K_2S_5. The chemical properties and preparation of potassium polysulfides are considered in detail in a monograph [1].

The thermodynamic properties of melts in the system potassium–sulfur were studied in [7–9] by the EMF method with solid glassy or ceramic electrolytes. The EMF of the following cells ($0.023 \le x_K \le 0.293$, 12 compositions, 354–450°C, x_K is the molar fraction of potassium in the alloy) was measured in [7].

$$(-)\ \mathrm{K}\ |\ \text{Glass}\ |\ \text{Salt melt}\ |\ \text{Glass}\ |\ \mathrm{K, S}\ (+) \qquad (1)$$

The experiments were carried out with a commercial C-48-1 glass containing 3.8 wt % K_2O. As intermediate electrolyte served the eutectic mixture KCl–$ZnCl_2$ (mp 228°C). As shown previously [19], such cells are suitable for studying thermodynamic properties of potassium-based liquid alloys. At 450°C, the following results were obtained:

0.293	2.128	–205.4	1.44×10^{-15}

where ΔG_K is the partial molar Gibbs energy, and a_K is the potassium activity in an alloy.

The EMF of the cell is constant (2.345 ± 0.003 V) within the stratification region. The average values of ΔG_K and a_K in this range are -226.3 ± 0.3 kJ mol^{-1} and 4.47×10^{-17}, respectively. Estimating the partial molar entropy of a component in the heterogeneity region is always difficult [20]. However, the temperature coefficient (dE/dT) of EMF is negative, i.e., the EMF of the potassium–sulfur cell increases with decreasing temperature.

More recently, Grosbie [8] studied, using EMF method with β"-alumina solid electrolyte exhibiting ionic conduction by potassium ions, the thermodynamic properties of liquid alloys of the system K–S

Table 2. EMF of K | Solid electrolyte | K, S cells according to [8]

($x_K \le 0.412$, 225–325°C). In the stratification region at 250°C (phase region S–K_2S_6), EMF is 2.414 V [8]. For potassium-richer alloys the EMF values were estimated at various temperatures in this study on the basis of data on ΔG_K from [8] (Table 2).

In a more recent study [9], both glass and potassium-containing β-alumina were used as solid electrolytes with ionic conductivity in analyzing the thermodynamic properties of liquid alloys of potassium and sulfur ($0.065 \le x_K \le 0.412$, 230–330°C). Since the commercial brands of glasses are characterized by relatively low content of potassium and high electrical resistivity, it is difficult to use them as solid electrolyte below 400°C. For this reason, a glass with high content of potassium oxide, having the following composition (wt %): K_2O 31–34, SiO_2 56–58, and B_2O_3 9–11 [21], was synthesized in a special experiment. A ceramic solid electrolyte based on potassium polyaluminate was obtained by replacing sodium ions in the crystal lattice of sodium polyaluminate with potassium ions. A test tube made of sodium-containing β-alumina was alternately treated with sodium chloride vapor and molten potassium nitrate [22]. The content of potassium in the polysulfide melts was determined by flame photometry. The EMF of the following cells was measured.

$$(-)\ \mathrm{K}\ |\ \text{Solid electrolyte}\ |\ \mathrm{K, S}\ (+) \qquad (2)$$

In both cell (1) and cell (2), the EMF values measured were the same when temperature was raised and then lowered within a temperature range. As noted previously [9], a small systematic discrepancy between EMF values measured in cells with glass and ceramic electrolytes is observed at 325°C. The discrepancy is the strongest in the stratification region, but, even in this case, it does not exceed 2.5% of measured value. Analysis and comparison of the data obtained in [7, 9] makes it possible to recommend the averaged values of such basic thermodynamic functions (Table 3) as potassium activity a_K, partial molar Gibbs energies and enthalpies of mixing for potassium, and also integral molar Gibbs energies and enthalpies of mixing (ΔG_K, ΔH_K, ΔG, and ΔH) for characterization of the potassim–sulfur system at 325°C.

Since a value of –377 kJ mol^{-1} was reported for the enthalpy of K_2S formation under standard conditions, ΔH^0_{298}, in the most recent review [2] citing reference books published in 1985 and 1989, it is this value that was used to calculate the standard Gibbs energy of formation of K_2S from elements at 598 K (ΔG^0_{598}).

The ΔG^0_T value at 598 K, calculated for the reaction

$$2\mathrm{K(l)} + \mathrm{S(l)} = \mathrm{K_2S(s)} \qquad (3)$$

with account of the H_{598}–H_{298} and S_{598}–S_{298} values for all the reagents, is –341 kJ. Correspondingly, for a mole of $K_{0.667}S_{0.333}$, this value is –113.7 kJ mol^{-1}. Calculation of ΔG^0_T for reaction (3) by the equation

$$\Delta G^0_T = \Delta H^0_{298} - T\Delta S^0_{298} \qquad (4)$$

with heat capacities of the components disregarded, yields the following: ΔG^0_{598} = –346 kJ mol^{-1}, which is rather close to the above value (–341 kJ mol^{-1}).

The standard Gibbs energy of formation of solid K_2S_2 from pure liquid components by reaction

$$2\mathrm{K(l)} + 2\mathrm{S(l)} = \mathrm{K_2S_2(s)} \qquad (5)$$

was estimated using Eq. (4). The ΔG_{598} value is –406.1 kJ mol^{-1}; for a mole of $K_{0.5}S_{0.5}$, ΔG_{598} = –101.5 kJ mol^{-1}.

Based on the experimental data ($x_S \le 0.60$) and calculations performed, the dependences of the integral molar Gibbs energy (Fig. 3) and partial molar Gibbs energy of potassium (Fig. 4) at 325°C on composition were plotted. ΔG_K values at 325°C were reported in [8] for a number of composition, which allows their comparison with the recommended values of ΔG_K (Table 3). According to the data of [8]:

Potassium polysulfide	Molar fraction of sulfur, x_S	ΔG_K, kJ mol^{-1}
$K_2S_{5.3}$	0.726	–228.4
K_2S_4	0.666	–215.1
K_2S_3	0.600	–190.8
$K_2S_{2.86}$	0.588	–186.2

As seen from Fig. 4, the ΔG_K values are in good agreement with the recommended dependence.

In [8], experimental data on the integral molar Gibbs energy at 250°C were presented for some potassium polysulfides. In particular, ΔG_{523} is –460.7 kJ mol^{-1} for potassium polysulfide K_2S_4, which melts at 154°C [8]. Calculation using Eq. (4) and the data of Table 1 for the reaction

$$2K(l) + 4S(l) = K_2S_4(s) \quad (6)$$

yields for ΔG at 250°C a value of –460.8 kJ mol^{-1}. In this case, the enthalpy of formation, ΔH_{298}, is taken from [13], and the enthalpy of K_2S_4 melting, from [5]. As in preceding calculations, account is taken of the enthalpies and entropies of melting of potassium and sulfur.

The aforesaid suggests that rather satisfactory and correlated data on the thermodynamic properties of liquid and solid phases in a relatively broad temperature range are presently available for the composition range K_2S–S in the potassium–sulfur system.

There is good reason to believe that the electrochemical behavior of potassium polysulfides in the molten state is similar to that of other potassium-containing ionic melts. This assumption was confirmed by studies of the cathodic polarization of antimony in a number of nitrate–nitrite molten systems (KNO_2–KNO_3–$CsNO_3$, KNO_2–KOH, and KNO_2–KNO_3–KOH) [23] and in molten polysulfide K_2S_4 [24]. A number of two-phase regions, which are formed successively, in accordance with the phase diagram of the system, on the antimony electrode at 240°C, which is reflected on the potential–current curve. First, a layer with Sb + KSb_2 intermetallic compound with the lowest content of metal being deposited is formed on the anode. Further, two-phase

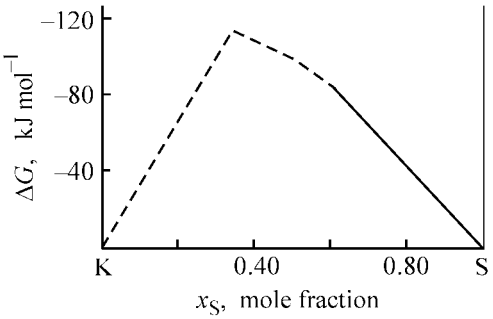

Fig. 3. Integral molar Gibbs energy ΔG vs. composition of the potassium–sulfur system at 325°C. (x_S) Sulfur content; the same for Fig. 4.

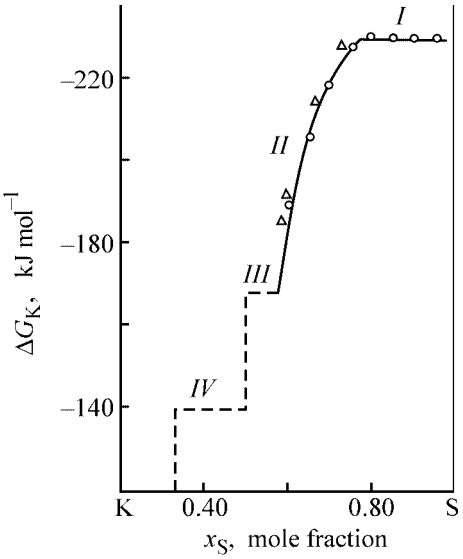

Fig. 4. Partial molar Gibbs energy of potassium ΔG_K in the potassium–sulfur system at 325°C in different phase regions. Region: (*I*) two liquid phases, (*II*) liquid phase, (*III*) K_2S_2(s) + liquid phase, and (*IV*) K_2S_2(s) + K_2S(s).

regions with other intermetallic compounds of potassium and sulfur, such as KSb, K_5Sb_4, and K_3Sb, are formed stratification. The discharge of potassium ions and the alloy formation constitute a single electrochemical event. As shown in [23, 24], the potentials of phase boundaries in the formation of the alloys in nitrate–nitrite melts and in molten potassium polysulfide coincide rather nicely. The same has been observed for the cathodic polarization of bismuth in salt mixtures and polysulfide melts [25].

CONCLUSION

The values of the basic thermodynamic functions for solid and liquid phases of the system potassium–sulfur in the K_2S–S composition range are recommended on the basis of an analysis and comparison of the available experimental and reference data.

Abstract—Two methods for obtaining aqueous dispersions of silver nanoparticles, stable during several months, from their reverse micellar solutions in an organic solvent: (i) centrifugation of a two-phase system formed by micellar solution and water and (ii) mixing of micellar solution with water, followed by settling.

One of the main directions in the development of modern nanotechnology is chemical synthesis of metal nanoparticles, with ultradispersed metal particles obtained by reducing the corresponding ions in solution [1–9]. A most important task in this field is to make longer the lifetime of such metal sols, since real ways of their practical use is only possible at their sufficiently high stability in ultradispersed state.

The most widely used variants are those based on chemical synthesis in aqueous solutions with the use of known reducing agents (hydrazine, sodium borohydride, etc.) [1, 6–9] or solvated electrons (radiochemical synthesis) [2–5] and nanoparticle stabilization with special additives (commonly polymer solutions). However, the lifetime of such particles does not exceed several days. Recently, successful synthesis of nanoparticles in a two-phase system formed by water and organic solvent has been reported [10]. This method can be used to obtain longer-lived metal sols in an organic solvent without special stabilizing agents, with particle stabilization achieved by using metal salts with long-chain organic anions. More efficient from the standpoint of nanoparticle stability is chemical synthesis in reverse micelles—in a ternary system formed by $M(H_2O)$, surfactant, and nonpolar solvent [11, 12]. In this case, the part of a stabilizing agent is played by surfactant molecules constituting a micelle shell in which nanoparticles are formed. Here, the same chemical reducing agents are used as in the other variants of synthesis, mentioned above.

In the present communication, two new methods for synthesis in reverse micelles are proposed. As reducing agents in these methods serve solvated electrons [4] or biologically active substances belonging to flavonoids (biochemical synthesis) [13, 14]. These methods yield a reverse-micelle solution of silver nanoparticles in an organic solvent (further, micellar solution), in which they are stable from several months to a year and more. Owing to such a high stability, it became possible to study the adsorption of nanoparticles from solution onto solid materials [15]. Introduction of micellar solutions of silver nanoparticles into some liquid-phase systems allows production of paintwork materials with stable antimicrobial activity with respect to a number of pathogens and viruses [16]. Studies of the catalytic activity of copper nanoparticles obtained by biochemical synthesis in a micellar solution and on solid supports demonstrated their high efficiency as catalysts for isomerization of dichlorobutenes [15].

In developing various nanoparticle applications, it is important to obtain their stable dispersions not only in organic solvents (hydrocarbons, in particular), but also in a polar medium, water in the first place. For example, use of silver nanoparticles in the form of an aqueous dispersion is preferable for obtaining aqueous dispersion paints or new makeup preparations with bactericidal properties. Aqueous dispersions are also more convenient for developing technologies aimed to create solid materials with deposited silver nanoparticles, which can be used in water purification to re-

1070-4272/02/7510-1585 $27.00 © 2002 MAIK "Nauka/Interperiodica"

move bacterial contaminants, e.g., in various tanks or filter units [17]. There is good reason to believe that stable metal nanoparticles in aqueous dispersions can find use in biotechnology and medicine [1].

The present communication reports the possibility of obtaining stable aqueous dispersions of silver nanoparticles from their micellar solutions. Two procedures for preparing such dispersions are described: (i) centrifugation of a two-phase system constituted by a micellar solution and water and (ii) mixing a micellar solution with water and its subsequent settling. The optical properties of nanoparticles in solutions were monitored by optical absorption spectra; the particle size distribution in the micellar solution and aqueous dispersions was determined by photonic correlation spectroscopy.

EXPERIMENTAL

Silver nanoparticles in reverse micelles were obtained by a previously described biochemical technique [14]. First, a reverse micellar solution of quercetin (Qr) flavonoid, a system composed of Qr, AOT, and saturated hydrocarbon, where AOT is a surfactant forming the shell of a micelle (with polar heads directed inwards, and nonpolar tails, outwards) is prepared; as saturated hydrocarbon serve heptane, octane, or isooctane. Then, an aqueous solution of $AgNO_3$ is introduced into the reverse micellar solution to make the concentration of the silver salt in the latter, $c(AgNO_3)$ = 3 mM. Nanoparticles are formed as a result of reduction with quercetin of Ag^+ ions to atoms and subsequent aggregation of silver atoms and ions in the water core of a reverse micelle formed upon introduction of an aqueous solution of the silver salt. The nanoparticle size is mainly determined by the diameter of the water core, which depends on the degree of hydration $w = [H_2O]/[AOT]$. In the present study, nanoparticles were obtained at w = 3.7. Aqueous dispersions were prepared from micellar solutions of silver nanoparticles, which attained a steady state (with constant optical density in the absorption band peak) and demonstrated a sufficiently high intensity of light scattering, which made it possible to measure particle sizes. The system came to a steady state 10–14 days after being synthesized.

Aqueous dispersions of silver nanoparticles were obtained by centrifuging a two-phase system composed of a micellar solution of nanoparticles (organic phase) and water (aqueous phase). In both cases, deionized water with conductivity of $(5–10) \times 10^{-8}$ S, obtained using a Khimpribor Vodolei instrument, was used, and equal amounts (commonly 3 + 3 or 4 + 4 ml) of the organic and aqueous phases were taken. The centrifuging was done on a T52.I.MLW laboratory centrifuge (Germany) in test tubes 14 mm in diameter. First, water was poured into the test tubes and then a micellar solution was slowly introduced from above, until a system with sufficiently distinct phase boundary was formed. The parameters of a centrifuging stage are as follows: rotation speed, 5300 rpm; time, 15 min.

The formation of nanoparticles and changes in their concentration in the liquid phase were monitored spectrophotometrically, with optical absorption spectra measured in the spectral range 230–900 nm on a Specord M40 spectrophotometer in quartz cells with optical path l = 1 mm. The particle size in solution was determined by photonic correlation spectroscopy on a Coulter Electronic Coulter N4 MD laser spectrometer (US). This method makes it possible to determine the size of reverse micelles [18, 19] or other particles present in solution. For small micelles (several nanometers in diameter), measurements give the size of their water core, d_w, as the difference $d_m - 2r$, where d_m is the micelle diameter, and r is the length of the surfactant molecule forming the micelle shell [18]. The diameter of the water core can be regarded as the upper limit to nanoparticle diameter. In the case in question, the water core diameter coincides with the silver nanoparticle diameter in reverse micellar systems, found by electron microscopy.

Optical absorption spectra of the starting micellar solution and aqueous dispersions of silver nanoparticles obtained upon centrifuging of the two-phase system composed of the micellar solution and water are shown in Fig. 1. The micellar solution of nanoparticles has intense red-brown color, with the absorption band peaked at 420–430 nm, in agreement with published data for silver nanoparticles in reverse micelles [3, 18]. The optical density at the absorption band peak, D_{max}, can be used to determine the degree of conversion of Ag^+ ions in nanoparticle formation.

With the use of the published value of the extinction coefficient of silver nanoparticles in a reverse micellar system, $\varepsilon = 7.2 \times 10^3$ M^{-1} cm^{-1} [20], it is found for the micellar solution in Fig. 1 that the concentration of silver ions present in the form of nanoparticles (and the concentration of the silver salt, numerically equal to the ionic concentration), $c(AgNO_3) = D_{max}/(\varepsilon l) = 2.16$ mM. At a total concentration of the silver salt in the micellar solution, $c(AgNO_3)$ = 3 mM, the degree of conversion of silver ions is 2.16/3 = 0.72 (i.e., the yield of nanoparticles is 72%). In addition to the characteristic absorption band associated

with nanoparticles, λ_{max} = 420 nm, the spectrum of the micellar solution contains a less intense band with λ_{max} = 295 nm, presumably related to the presence in solution of either minor clusters of silver or large complexes of Qr molecules with silver clusters [21, 22].

After centrifuging, the lower (aqueous) phase turns yellowish brown because nanoparticles pass into it from the micellar solution. An 3–5-mm-thick AOT layer is formed at the phase boundary, and the adjacent water layer turns slightly turbid because of the formation of colloid particles (aggregates) from AOT. A dark brown precipitate, readily soluble in water, is formed at the test tube bottom. To measure absorption spectra and particle size and to perform subsequent tests for stability, the middle (transparent) layer of the aqueous phase was sampled. After a single centrifuging, only a minor part of nanoparticles present in the micellar solution pass into water. To make higher the concentration of nanoparticles, the obtained aqueous solution of nanoparticles can again be subjected to centrifuging, with fresh portions of the micellar solution used as the organic phase.

Figure 1 shows optical spectra of aqueous dispersions, measured 1–2 h after one-, two-, and three-stage centrifuging. On the assumption that the extinction coefficients of nanoparticles are the same in micellar and aqueous solutions, the extent to which nanoparticles pass into the aqueous phase can be evaluated from the ratio of optical densities at absorption band peaks; this parameter equals 15–30 (one stage), 30–40 (two stages), and 50–60% (three stages) relative to their concentrations in the micellar solution. The absorption band of nanoparticles is shifted in the aqueous dispersion relative to that in the micellar solutions. A similar shift of bands was observed in [20] in extraction of silver nanoparticles from a micellar solution by a similar centrifuging procedure, with the reasons for such a shift not discussed. Probably, this may be due to a change in the polarity of the medium near the surface of a particle passing into the aqueous phase (penetration of water molecules into the micelle core).

The resulting aqueous dispersions of nanoparticles proved to be stable for a long time (no less than 1 month) when stored in air at room temperature. As an example, Fig. 2 shows how optical absorption spectra of aqueous dispersions prepared by two-stage centrifuging vary with time. It can be seen that the position of the band associated with nanoparticles remains unchanged during a month. The optical density at the band peak increases by 20–30% (not shown)

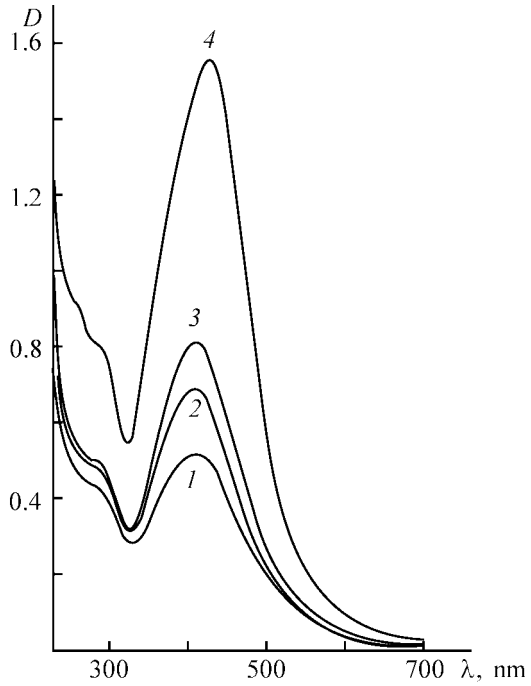

Fig. 1. Optical absorption spectra of aqueous dispersions of silver nanoparticles, measured 1.5–2 h after centrifuging in (*1*) one, (*2*) two, and (*3*) stages, and (*4*) spectrum of the micellar solution. (*D*) Optical density and (λ) wavelength; the same for Figs. 2 and 5.

during the first weak, with the band half-width simultaneously decreasing somewhat. Then the system reaches its steady state, and D_{max} changes by no more than 10% during the following three or four weeks. An increase in D_{max} in storage was observed for all

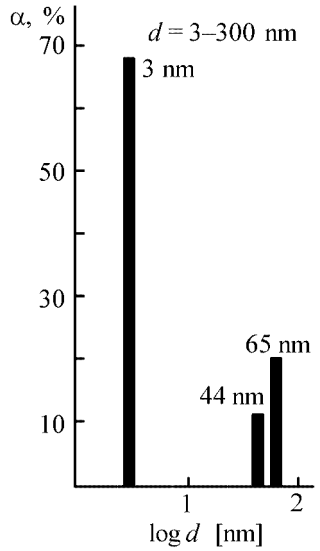

Fig. 3. Histogram of silver nanoparticle size distribution in micellar solution. (α) Fraction of particles and (*d*) particle diameter; the same for Figs. 4 and 6.

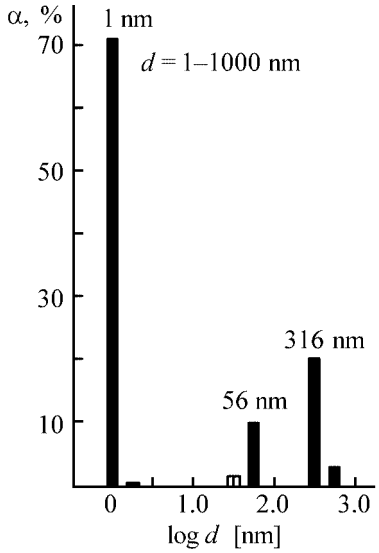

Fig. 4. Histogram of particle size distribution for aqueous dispersion of silver nanoparticles 5 days after single-stage centrifuging.

of the samples studied after centrifuging in one, two, or three stages. Such a change in D_{max} in the steady state may be due to a minor increase in nanoparticle concentration as a result of water evaporation.

Typical particle size distributions in micellar solution and aqueous dispersion are shown in Figs. 3 and 4.[1]

[1] The size of 1–3 nm, obtained in light scattering measurements by analyzing the correlation function by means of the CONTIN software, should be understood in the given case not literally, but only as an indication of the presence in solution of fine particles about several nanometers in size.

Correlation between the optical absorption spectra and particle size distributions in micellar solutions suggests that it is fine micelles that contain silver nanoparticles. Moreover, the solutions also contain particles 30–70 nm in size. It may be assumed that these particles are either formed through aggregation of fine micelles or reflect the initial stage of nanoparticle oxidation, which eventually leads to appearance of silver oxide crystals of micrometer dimensions [8].

The histogram for an aqueous dispersion of nanoparticles shows, during the first several hours after centrifuging, large particles 300–600 nm in size. With account of the fact that, at the chosen AOT concentration in the micellar solution, its concentration in water may be high enough for a lamellar phase to be formed [22], it may be assumed that large particles are fragments of AOT lamellas, formed when AOT passes into water from the micellar solution. These particles are unstable and disintegrate in 1 or 2 days, and after that fine particles predominate in the solution during the entire time of storage. Possibly, disintegration of AOT aggregates is responsible for the change in the absorption spectra during the first days after centrifuging. The particle size distribution in the aqueous dispersion in the stationary stage is shown in Fig. 4. It can be seen that the ratio of concentrations of fine micelles and larger particles is similar to that in the starting micellar solution; a minor "admixture" of particles about 300 nm in size is, probably, the remainder of AOT aggregates. It is noteworthy that, in the given case, fine micelles must have a shell composed of two, rather than one monolayer of the surfactant, since its molecules must have polar heads facing both water and nanoparticles. In other words, the nanoparticles have, in the given case, shells composed of a bilayer, rather than a monolayer, of AOT molecules.

A stable aqueous dispersion of silver nanoparticles can also be obtained by simply mixing a micellar solution of nanoparticles with water and subsequent settling until separation into the organic and aqueous phases. In this case, the concentration of nanoparticles in water is much higher than in the case when nanoparticles pass into water under centrifugation. As seen from Fig. 5, the aqueous dispersion of nanoparticles obtained by mixing equal volumes of water and micellar solution has optical density at the peak of the band associated with nanoparticles close to that of the micellar solution. The halfwidth of the band in the aqueous dispersion is much narrower in the given case, compared with that in the micellar solution: $\Delta\lambda_{1/2}$ (mic.sol.) = 117.4 nm, and $\Delta\lambda_{1/2}$ (aq.disp.) = 86.1 nm. In storage in air, the intensity of the band

in the aqueous dispersion remains virtually unchanged for no less than 1–1.5 months. As also in the case of extraction by centrifuging, the position of the nanoparticle-related band in the aqueous dispersion is shifted toward the UV region by 10–15 nm, compared with that in the micellar solution.

The evolution of particle dimensions in a dispersion of this kind is similar to that observed after centrifuging: large particles, initially present in great number, gradually disintegrate, so that that the fraction of small micelles several nanometers in size increases, and then the system reaches its steady state and the size distribution stabilizes. However, large particles are now bigger (300–3000 nm) and, in contrast to the preceding case, the contribution from these particles remains in the steady state more significant that that from small micelles (Fig. 6). This may result from the fact that the AOT concentration in the aqueous phase after mixing exceeds that after centrifuging. As a result, larger part of nanoparticles are "enclosed" in AOT lamellas and cannot be recorded in light-scattering measurements as fine micelles. At the same time, these nanoparticles strongly absorb light, with no band broadening or increased long-wavelength absorption, both of these characteristic of nanoparticle aggregation to form fractal clusters [23], observed in the spectrum (Fig. 5). Hence follows that the average distance between the nanoparticles in lamellas is rather large, so that they absorb light as isolated particles.

Thus, both methods yield aqueous solutions of silver nanoparticles, which are stable for a long time. It is planned that, after appropriate tests for antimicrobial activity, solutions of this kind will be proposed as bactericidal additives to various materials. Deposition of silver nanoparticles from aqueous solutions onto solid supports can give modified solid materials applicable as filtering elements for purification of water or other liquids to remove bacterial contaminants.

CONCLUSIONS

(1) Two methods for obtaining aqueous dispersions of silver nanoparticles from their micellar solutions: (i) centrifuging of a two-phase system composed of a micellar solution and water and (ii) mixing of a micellar solution with water with subsequent settling are proposed.

(2) It is shown that nanoparticles remain stable in aqueous dispersions for a long time, which enables their use as bactericidal additives or coatings.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Fire Retardant from Dilute Aqueous Solutions onto Viscose Fiber

Abstract—The adsorption isotherms of the product of transesterification of dimethyl methylphosphonate (ZG-2), used as fire retardant, from dilute solutions on viscose fiber were determined experimentally at various temperatures. The parameters of pore structure of the fibrous sorbent were estimated using the general equation of the theory of volume filling of micropores.

Impregnation of finished fiber with a solution of fire retardant (FR) is the most promising method of fire protection of viscous fibers [1]. The mechanism by which fibers react with FR is affected not only by the chemical structure of the fiber, but also by their pore structure, which governs sorption characteristics of fibrous sorbents. To explain sorption phenomena, thermodynamic methods can be used [2].

Studies of sorption processes are always focused on determining the pore structure parameters (micropore volume and prevalent pore diameter). The conventional methods for studying the pore structure require complicated equipment and have a number of limitations [3, 4].

The present study is concerned with adsorption of FR from dilute aqueous solutions onto viscose fiber (VF) with the aim to estimate the pore structure parameters.

Chemical fibers can be subdivided into two groups according to the classification of adsorbents proposed by Dubinin [5]: macroporous fibers [which are, in some cases, adequately approximated by the equation of micropore filling theory (MFT) at $n = 1$], and mesoporous and microporous fibers, on which the sorption is described by the MFT equation with $n = 2$ or $n = 3$.

Analysis of published data [6–8] shows that VFs can be regarded as microporous sorbents, whose pore structure parameters can be estimated using the general equation of MFT

$$n_i^1 = n_{i0}^1 \exp[(A/E)^n - \alpha(T - T_0)],$$

where n_i^1 is the amount of sorption (mmol g^{-1}) at a temperature T; n_{i0}^1, the limiting sorption (mmol g^{-1}) at temperature T_0; $A = RT\ln(c_s/c)$, the differential molar work (J mol^{-1}); E, the characteristic sorption energy (J mol^{-1}); n, the order of the MFT equation; $\alpha = -(\mathrm{d}\ln n_i^1/\mathrm{d}T)_{\Delta G}$, the thermal coefficient of sorption; c, the equilibrium concentration (mM); and c_s, the saturation concentration (mM).

The product of transesterification of dimethyl methylphosphonate (ZG-2) containing 25 wt % phosphorus was used as an FR.

For studying sorption isotherms, we used interferometry. A weighed portion of the sorbent was placed in a tightly stoppered flask, and 10 ml of aqueous FR solution of a definite concentration was added. From the direct relationship between the scale readings of the interferometer compensator and the concentration, determined by calibration with the initial solution, we evaluated the composition of the equilibrium solution and the transesterification adsorption, n_i^1 (mmol g^{-1}):

$$n_i^1 = (c_{in} - c_{eq})V/m,$$

were c_{in} and c_{eq} are the initial and equilibrium concentrations of the solution (mM); V, the solution volume (ml); and m, the weighed portion of the sorbent (g).

The experimental and calculated isotherms of FR adsorption on VF at various temperatures are shown in Fig. 1. This shape of isotherms is characteristic of the adsorption onto microporous sorbents [8].

To estimate the pore structure parameters for the sorbents, we used the MFT equation in the linear form

$$\log n_i^1 = \log n_{i0}^1 - (0.434/E^n)A^n.$$

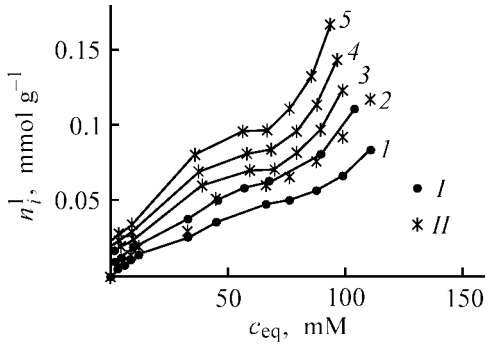

Fig. 1. Isotherms of FR adsorption from dilute solutions onto VFs. (n_i^1) Amount of adsorption and (c_{eq}) equilibrium concentration of FR. Temperature, °C: (*1*) 20, (*2*) 40, (*3*) 50, (*4*) 60, and (*5*) 70. Data: (*I*) experimental and (*II*) calculated.

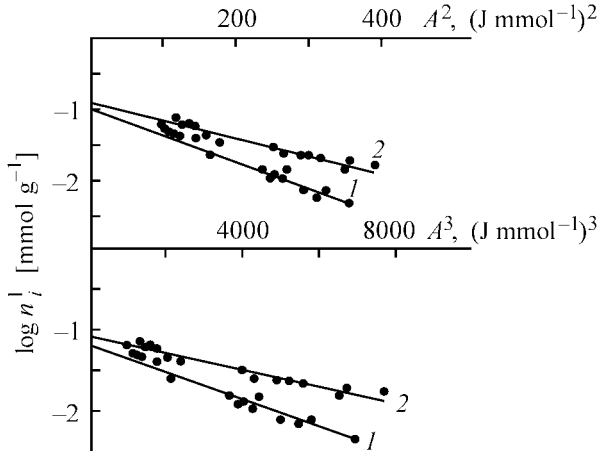

Fig. 2. Linear isotherms of FR adsorption from dilute solutions onto VFs. (n_i^1) Amount of adsorption and (A) differential molar work. Temperature, °C: (*1*) 20 and (*2*) 40.

The MFT equation was tested at parameter n equal to 2 and 3.

The isotherms of FR adsorption onto viscous fiber, ploted in the coordinates in which the MFT equation is linear, are shown in Fig. 2. It is seen that the MFT equation describes the experimental data adequately at $n = 3$.

The limiting adsorbed volume W_0 was evaluated from the molecular weight of FR, its density, and the limiting adsorption. To estimate the limiting adsorbed volume, we assumed that the FR density in the adsorbed state is the same as in the solution.

The pore half-width X was evaluated with the use of the Stackley equation [9]

$$2X = 10.8/(E - 11.4),$$

were E is the characteristic energy of sorption (J mol^{-1}). The correlation of the calculated data is 3–5%.

The calculated limiting values of adsorption n_{i0}^1, limiting adsorbed volumes W_0, characteristic energy E, and pore half-width X (our and published data) are listed in the table.

From the experimental data on the adsorption of FR from aqueous solutions onto VFs, we evaluated the thermal adsorption coefficient $\alpha = -\mathrm{d}\ln n_{i0}^1/\mathrm{d}T$, used then for calculating the adsorption of FR from solutions at other temperatures (Fig. 1) by the equation

$$n_i^1 = n_{i0}^1 \exp[-\alpha(T - T_0)].$$

As seen from Fig. 1, the experimental and calculated data are in good agreement.

A small rise in the FR adsorption with increasing temperature and, hence, also the temperature coefficient of adsorption are governed by the structures of the solvent, FR, and adsorbent. All these factors result in small positive values of FR adsorption from dilute solutions. It seems likely that, in this adsorption system, interaction of solvent molecules with the adsorbent becomes weaker with increasing temperature, and the competing effect of the solvent molecules becomes less pronounced.

The adsorption isotherms carry no information on the true pattern of adsorption on the surface of a fibrous sorbent. Therefore, thermodynamic analysis of the adsorption equilibrium is of interest. For thermodynamic consideration of adsorption systems, we used the Gibbs method of excess quantities [11]. This method allows evaluation of the main thermodynamic characteristics of sorption systems as a whole on the basis of the excess values of adsorption determined in the experiments.

According to [11], the change in the chemical potential of the sorbent was calculated using the equation

Parameters of pore structure of VFs evaluated from the MFT equation (system FR–H_2O–VF)

VF at T, °C	n_{i0}^1, mmol g^{-1}	$E \times 10^{-3}$, J mol^{-1}	W_0, cm^3 g^{-1}	X, nm
25	0.063	27.4	0.011	0.34
40	0.070	27.6	0.014	0.34
[5, 8, 10]	0.066	15–30	0.016–0.039	0.37

$$\Delta\Phi = RT\int_0^{x_1}\frac{n_i^1}{x_1x_2}dx_1,$$

where $\Delta\Phi$ is the change in the chemical potential of the sorbent upon wetting with a binary solution ($J\,g^{-1}$), x_1 and x_2 are the mole fractions of FR and the solvent, and n_i^1 is the adsorption value ($mmol\,g^{-1}$).

Calculation of $\Delta\Phi$ was carried out using graphical integration, by evaluating the area under the curve:

$$n_i^1/(x_1x_2) = f(x_1).$$

The change in the Gibbs energy of the sorption system as a result of wetting of the sorbent with the solution of concentration x was calculated by the equation

$$-\Delta G = -\Delta\Phi - \Sigma n_i(\mu_{i0} - \mu_i),$$

where $(\mu_{i0} - \mu_i)$ is the change in the chemical potential of a component.

Analysis of the concentration dependences of $\Delta\Phi$ and ΔG (Fig. 3) shows that the largest changes in the chemical potential of the sorbent and Gibbs energy of the system as a result of sorbent wetting with FR solution take place at low x_1. This may be due to the specific features of interaction between the components, caused by the fact that FR molecules can penetrate into amorphous and defective regions of the fiber, enhancing the sorption by the fibrous surface.

The adsorption equilibria in the FR–H_2O–fiber systems studied here allow evaluation of the structural characteristics of the fiber and, on their basis, prediction of the features of interaction between the components.

CONCLUSION

Use of the theory of micropore volume filling for describing adsorption equilibria in the systems fire retardant–H_2O–fiber allows description of adsorption onto viscous fiber at various temperatures and evaluation of the pore structure parameters of fibers, using the general equation of this theory.

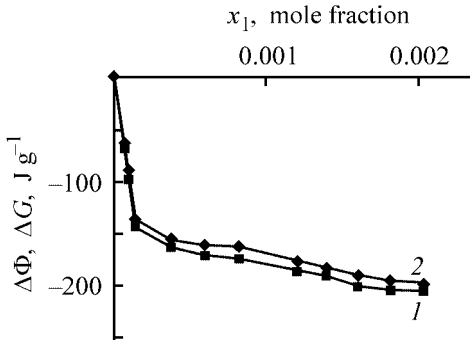

Fig. 3. Change in (*1*) the chemical potential $\Delta\Phi$ of the sorbent and (*2*) Gibbs energy ΔG of the system FR–H_2O–fiber vs. the FR mole fraction in solution, x_1.

SORPTION AND ION-EXCHANGE PROCESSES

Recovery with Calcium Oxide Sorbent of Conversion Products of Rhodium Catalyst for Ammonia Oxidation

N. I. Zakharchenko

Zhukovsky National Aerospace University, Kharkov, Ukraine

Received June 4, 2002

Abstract—The chemical aspects of recovery with a calcium oxide sorbent of rhodium lost in high-temperature oxidation of ammonia were studied. The physicochemical properties of this compound and conditions of its formation were considered.

Catalytic oxidation of ammonia to nitrogen(II) oxide underlies the industrial method for manufacture of nitric acid [1]. Industrial catalysts (Pt, Rh, and Pd alloys) undergo physicochemical transformations in technological processes, with the surface structure and the chemical composition of the catalysts changed [1–6]. A set of such transformations of platinoid catalysts leads to loss of deficient and expensive metals of the platinum group. An effective way to diminish the loss of platinum metals is their partial recovery by sorption masses mainly based on calcium oxide [1, 7–17].

The mechanism of platinum recovery with calcium-containing sorbents and the chemical aspect of the process are rather extensively covered in the scientific literature [1, 7–20]. At the same time, there is no evidence concerning the mechanism of recovery of rhodium, entering into the composition of industrial catalysts for ammonia oxidation (alloy nos. 1 and 5), with a calcium oxide sorbent; there are no data, either, on what kind of chemical compounds are formed in interaction between the products of conversion of rhodium catalysts and sorbents [1].

The present communication reports the results obtained in studying the recovery with a calcium oxide sorbent of rhodium lost in high-temperature oxidation of ammonia.

As a starting compound for preparing the sorbent was used calcium oxide of chemically pure grade. The reagent was ground and treated with a 70% aqueous solution of ethynol (2–3% relative to the sorbent mass) and compacted into pellets under pressure of 150 MPa. After thermal treatment of the mass in air at 473, 673, 873, and 1253 K (2 h at each temperature), the sorbent was crashed into grains and a fraction with grain size of 2×3 mm was selected.

Since recovery of lost metals and their compounds is mainly effected by the surface layer of sorbents [1, 7–16, 18–20], the sorbent grains were ground after every 40 h of operation and subjected to repeated forming and thermal treatment in an inert medium (Ar) in accordance with the scheme considered above.

The catalytic process of ammonia oxidation was carried out in a flow-through installation with quartz reactor 50 cm in diameter. As a catalyst served rhodium in the form of a package of five grids with thread diameter of 0.06 mm. The 17-cm-high bed of sorbent grains was placed at a distance of 0.8 cm from the catalyst grids.

The temperature of ammonia oxidation was 1253 K; the pressure in the system, 0.101 MPa; the content of ammonia in the ammonia–air mixture, 11.5 vol %; and the linear flow velocity of the mixture, 0.40 m s^{-1}. The time of catalyst operation and absorption mass testing was 600 h. An X-ray phase analysis of the compounds was made on a Siemens D-500 diffractometer with $Cu_{K\alpha}$ radiation. A differential-thermal analysis was done on an MOM Q-derivatograph (Hungary). The heating rate was 5 deg min^{-1} in the temperature range 293–1773 K.

During reactor shutdowns, the system was purged with dried argon and isolated from air with moisture absorbers. After being discharged from the reactor, the sorbent was stored in hermetically sealed vessels filled with dried argon.

The X-ray phase analysis of the sorbent demonstrated that it contains CaO and a rhodium compound

1070-4272/02/7510-1594 $27.00 © 2002 MAIK "Nauka/Interperiodica"

of unknown composition (Fig. 1). To eliminate the effect of unreacted sorbent on the X-ray diffraction patterns obtained, the sorbent was dissolved in 25% HNO_3 of chemically pure grade at 308 K. In doing so, account was taken of the fact that rhodium compounds do not dissolve in HNO_3 of this concentration at moderate temperatures [21]. The liquid phase was separated from the solid phase and removed. The solid phase was thoroughly and repeatedly washed with hot twice-distilled water (antil no Ca^{2+} and NO_3^- ions were contained in washing water) and subjected to thermal treatment in an inert medium (Ar) at 473–523 K to constant weight.

The X-ray diffraction patterns of the solid residue contained only lines characteristic of the compound $CaRh_2O_4$ (Fig. 1). The parameters of the X-ray patterns of this compound are presented in the table.

The set of lines in the diffraction patterns (interplanar spacings d and intensities I) is in good agreement with data from the ASTM file [22], which indicates that the chemical compound $CaRh_2O_4$, having rhombic lattice (a = 0.9169, b = 1.0747, c = 0.3087 nm) of the $CaFe_2O_4$ structural type with Pnam space group, is formed in the sorbent.

The composition of the $CaRh_2O_4$ compound was confirmed by X-ray phase and chemical analyses [23].

A thermogram of the compound $CaRh_2O_4$ is presented in Fig. 2.

When the substance is heated in an inert medium (argon) to prevent high-temperature oxidation of Rh and its sublimation in the form of rhodium(III) oxide [21, 23] in the temperature range 1713–1763 K, loss of mass (15.49%) is observed, associated with endothermic decomposition of the compound by the equation

$$2CaRh_2O_4 = 2CaO + 4Rh + 3O_2. \quad (1)$$

The products of dissociation are calcium oxide, rhodium metal, and oxygen, which is characteristic of double oxides including a noble metal [23]. The X-ray diffraction patterns of products of $CaRh_2O_4$ decomposition, cooled in an inert medium (Ar), contain, in addition to reflections related to calcium oxide (0.276, 0.239, 0.169, 0.1447, 0.1383, 0.1203, 0.1072, 0.0980 nm), also reflections from metallic rhodium (0.2196, 0.1902, 0.1345, 0.1147, 0.1098, 0.0951, 0.0872, 0.0850 nm). An endothermic peak appears in the DTA curve at 1743 ± 10 K.

For the $CaRh_2O_4$ compound, the loss of mass in decomposition virtually did not exceed the expected

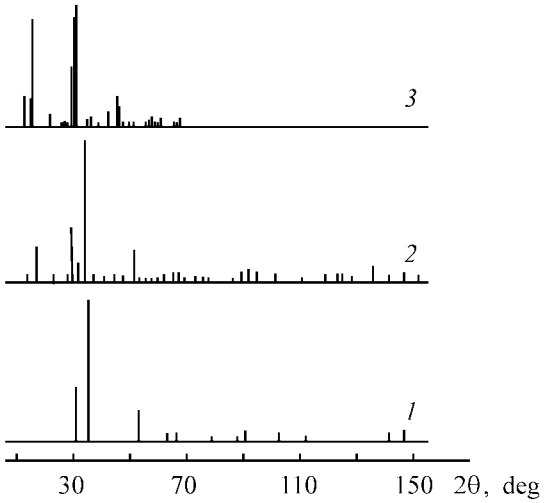

Fig. 1. X-ray diffraction patterns of the sorbents and products of rhodium recovery. (2θ) Bragg angle. (*1*) Initial sorbent, (*2*) sorbent after 600 h of catalyst operation, and (*3*) product of interaction between the sorbent and rhodium compounds ($CaRh_2O_4$).

value calculated using Eq. (1), which indicates that the inert medium rules out any influence of rhodium sublimation in the form of rhodium(III) oxide [21, 23].

The formation of $CaRh_2O_4$ in the sorbent can be accounted for on the basis of a comparative analysis of the conditions under which the products of rhodium catalyst conversion are recovered and the conditions of synthesis of the given compound.

The authors of [24] synthesized $CaRh_2O_4$ by prolonged (for no less than 150°C) heating in air

0.2265	11	0.1340	9
0.2114	4	0.1277	7
0.2001	9		

(T = 1173–1373 K, P = 0.101 MPa) of a mixture of rhodium(III) oxide (or rhodium metal) with calcium oxide (carbonate). Under these conditions, metallic rhodium is converted into rhodium(III) oxide [21, 23, 24].

In high-temperature oxidation of ammonium, the rhodium catalyst undergoes a number of physicochemical transformations [1, 25] in accordance with the reaction equations

$$4Rh_{(c)} + 3O_{2(g)} = 2Rh_2O_{3(c)}, \quad (2)$$

$$Rh_{(c)} = Rh_{(g)}, \quad (3)$$

$$4Rh_{(c)} + 3O_{2(g)} = 2Rh_2O_{3(g)}, \quad (4)$$

$$4Rh_{(g)} + 3O_{2(g)} = 2Rh_2O_{3(g)}. \quad (5)$$

At a process temperature of 1253 K rhodium sublimates predominantly in the form of rhodium(III) oxide [21, 26]. However, in the gas phase too, rhodium is readily oxidized by the oxygen present in the reaction medium to rhodium(III) oxide. Rhodium(III) oxide dissociates at 1333 K [21], being, therefore, stable at the reaction temperature.

The forming products of reactions (2)–(5), Rh and Rh_2O_3, carried away by the flow of the reaction mixture, are starting compounds in processes yielding the $CaRh_2O_4$ compound on the sorbent surface in accordance with the reaction equations

$$Rh_2O_3 + CaO = CaRh_2O_4, \quad (6)$$

$$4Rh + 3O_2 + 2CaO = 2CaRh_2O_4. \quad (7)$$

Thus, the products of conversion of the rhodium catalyst in high-temperature oxidation of ammonia are bound by the calcium oxide sorbent into the compound $CaRh_2O_4$. This fact is to be taken into account when using industrial catalysts for ammonia oxidation (with sorbents based on calcium oxide) containing rhodium. In rhodium recovery from calcium-containing sorbents, account should be taken of the high thermal and chemical stability of the $CaRh_2O_4$ compound [24], and the appropriate temperature and reagents should be used.

CONCLUSIONS

(1) The products of conversion of rhodium lost in high-temperature oxidation of ammonia are bound by the calcium oxide sorbent into the $CaRh_2O_4$ compound.

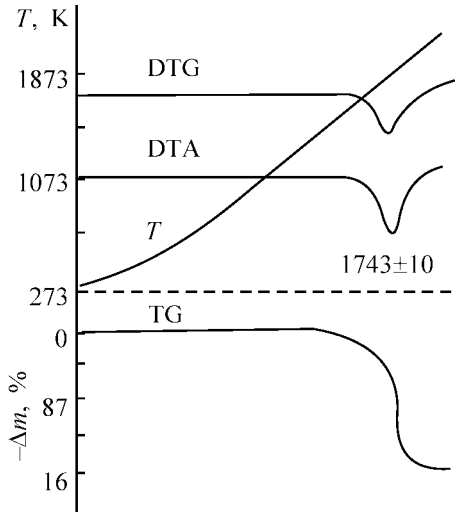

Fig. 2. Thermogram of $CaRh_2O_4$. Substance mass 100 mg, heating rate 5 deg min^{-1}. (T) Temperature and (Δm) mass change.

(2) Data on chemical aspects of recovery with the calcium oxide sorbent of rhodium lost in high-temperature oxidation of ammonia can be used in developing theoretical foundations for creation of effective sorption masses.

Abstract—The influence of potential and time of anodic treatment of dispersed graphite in an HNO_3 solution on the intercalation rate and possible concurrent reactions was studied.

Graphite intercalation compounds (GIC) and products of their hydrolysis, whose volume may increase manyfold upon fast heating (thermal expansion) are widely used for manufacture of graphite foil, pressed carbon articles, fireproof materials and coatings, and various-purpose composites [1, 2]. Industrial production of thermally expandable graphite (TEG) is mainly based on chemical synthesis of such GIC as graphite hydrosulfate and nitrate [3]. The chemical synthesis involves interaction of graphite with concentrated acids containing an additional oxidant. The action of the oxidant on graphite gives rise to a distributed positive charge on polyarene networks, after which spaces between carbon planes are successively, in accordance with the step-by-step model [4], filled with anions and molecules of the acid to give a GIC of general formula [5]:

$$C^{+}_{24n}A^{-} \cdot (2\text{–}2.5)HA,$$

where A is HSO^{-}_{4} (graphite hydrosulfate) or NO^{-}_{3} (graphite nitrate), and n = 1, 2, 3, is intercalation step.

In HNO_3 solutions with concentration higher than 15 M, intercalation occurs spontaneously without any additional oxidant. HNO_3 molecules act simultaneously as an oxidant, intercalating component (intercalate), and a source of solvate ligands [6]. In a 17–18 M HNO_3 solution, graphite nitrate of the second step is formed, with the decrease in concentration leading to lower content of the intercalate in the interlayer spaces (the step number increases). In a 15 M HNO_3 solution, no intercalation reactions are observed. The composition of graphite nitrate synthesized by liquid-phase chemical method [7] is determined by the redox-potential of an oxidizing solution, whose being lowered to 0.995 V (silver chloride electrode) stops the intercalation.

GIC can also be prepared with acids by anodic oxidation of graphite [8–11]. A considerable body of data on electrochemical synthesis has been obtained with pyrolytic graphite plate electrodes in galvanostatic polarization mode, using concentrated acids [12–14]. The system graphite–H_2SO_4 has been studied to a greater extent. Publications devoted to anodic oxidation of graphite nitrate appear irregularly [15–17]. Unlike liquid-phase spontaneous intercalation, the electrochemical synthesis ensures the first step of intercalation [18, 19] and allows the HNO_3 concentration to be lowered to 15 M, i.e., to a value at which GIC of composition $C^{+}_{48}NO^{-}_{3} \cdot 2HNO_3$ can be formed. The chemical and electrochemical syntheses of GIC with acids proceed by the same mechanisms [7]. This conclusion is based on the dependences of the CIG formation kinetics and step of intercalation on the type and concentration of the oxidant in a reagent mixture in the chemical method (redox-potential) [7] and on the potential and quantity of electricity supplied in anodic treatment of graphite in the electrochemical method [18]. Undoubtedly, the electrochemical method allows the potential of carbon material to be varied more widely, with the maximal potential limited by involvement of water in the electrode processes. When graphite is polarized anodically in HNO_3 solutions with sufficient content of water, a set of reactions occurs [20, 21]. For example, the intercalation is preceded by charging of the electrical double layer and oxidation of surface functional groups (SFG), which involves water and is accompanied by an increase in

1070-4272/02/7510-1598 $27.00 © 2002 MAIK "Nauka/Interperiodica"

the content of oxygen in SFG. Depending on the acid concentration and polarization potential, the electrochemical intercalation

$$24C + 3HNO_3 = C_{24}^{+}NO_3^{-} \cdot 2HNO_3 + H^+ + e \quad (1)$$

may be accompanied by SFG peroxidation [20]

$$C_{24}^{+}NO_3^{-} \cdot 2HNO_3 + 3HNO_3 \rightarrow 2C_{12}^{+}NO_3^{-} \cdot 2HNO_3 + H^+ + e, \quad (2)$$

formation of graphite oxide [20]

$$8C + 4H_2O \rightarrow C_8O_2(OH)_2 + 6H^+ + 6e, \quad (3)$$

or by complete or incomplete hydrolysis of graphite nitrate [20]

$$C_{24}^{+}NO_3^{-} \cdot 2HNO_3 + H_2O \rightarrow C_{24}^{+}OH^{-} \cdot 2H_2O + 3HNO_3. \quad (4)$$

In the final stage of synthesis, or simultaneously with bulk reactions (1)–(3), oxygen may be evolved if a necessary potential is attained, in the form of CO, CO_2, and O_2 [21]:

$$=\overset{|}{C}-\underset{|}{\overset{|}{C}}=O + H_2O \rightarrow =\overset{|}{C}-H + CO_2 + 2H^+ + 2e, \quad (5)$$
$$\quad\quad\quad

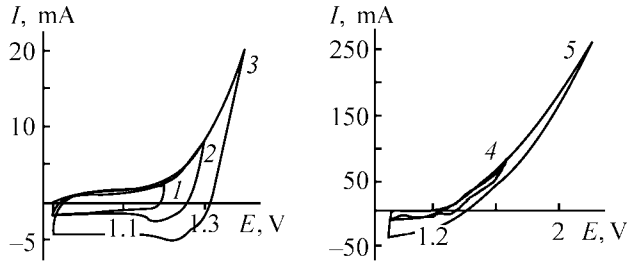

Fig. 1. Cyclic potentiodynamic curves (10th cycle) for GSM-1 graphite in a 13.5 M HNO_3 solution at various reverse potentials E_{rev}. V = 20 mV s^{-1}, T = 20°C. (*I*) Current and (*E*) potential. E_{rev} (V): (*1*) 1.20, (*2*) 1.30, (*3*) 1.40, (*4*) 1.65, and (*5*) 2.2.

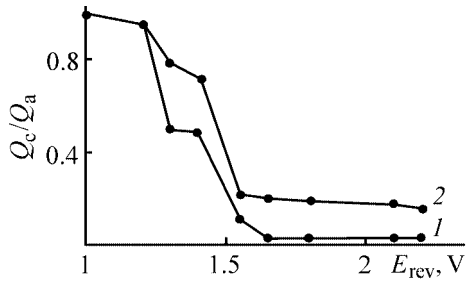

Fig. 2. Q_c/Q_a ratio vs. reverse potential E_{rev} of cyclic potentiodynamic curves measured on a GSM-1 graphite electrode in a 13.5M HNO_3 solution. Cycle: (*1*) 1st and (*2*) 10th.

cyclic potentiodynamic curve, Q_a, grows steadily with increasing E_a, but decreases in cycling (Fig. 1, Table 1). Since the graphite electrode area is virtually constant, the higher anodic currents in the first cycles are due to the possibility of intercalation of all interlayer spaces; it is not improbable that terminal carbon atoms and defects of the graphite matrix may be oxidized by reaction (6) at higher E_a. The quantity of electricity consumed in the reverse cycles in the cathodic region will be determined by the reduction currents of SFG, GIC, and, in part, graphite oxide and adsorbed oxygen. With extending range of potential sweep, as well as in the course of cycling, Q_c increases. The Q_c increase in cycling at a simultaneous decrease in Q_a can be accounted for solely by the increased contribution to the total current of the intercalation–deintercalation bulk reactions, which is apparently due to the ordering of the carbon material structure. The degree of reversibility of the occurring processes can be estimated from the Q_c/Q_a ratio. Regarding the degree of reversibility of the anodic reactions, the potential range studied can be conventionally divided into three regions (Fig. 2). In the range from E_{st} to 1.2 V, where no GIC is formed, the anodic processes are virtually completely reversible (Q_c/Q_a = 0.99–0.96), which also indicates that no reactions occur with gas evolution.

Table 1. Anodic Q_a and cathodic Q_c quantities of electricity in cyclic potentiodynamic curves for graphite in a 13.5 M HNO_3 solution in relation to E_{rev} and cycle number (V = 20 mV s^{-1}, T = 20°C)

	7–10	0.133	0.029
1.65	1	1.833	0.055
	7–10	0.453	0.091
2.20	1	4.047	0.162
	7–10	2.022	0.324

In the transition region E_a = 1.2–1.6 V, the Q_c/Q_a ratio decreases steeply (Fig. 2), which may be due to the irreversibility of intercalation reactions or to acceleration of surface reactions (5)–(7). It should be noted that, in this range of potentials, the rate of GIC formation grows, since the currents in the cathodic region, which are mainly due to deintercalation, also increase. At higher potentials (E_a > 1.6 V) the Q_c/Q_a ratio ceases to vary, the revealed tendencies in the influence of cycling are retained, and the deintercalation currents increase further.

To confirm the assumptions concerning the nature of the processes occurring at various anodic polarization potentials, potentiostatic syntheses of GIC were performed, and the properties of the resulting carbon compounds were assessed by means of XPA and heat treatment, with bulk density of TEG determined.

The X-ray diffraction patterns of the samples synthesized samples contain broad diffuse reflections corresponding to defective graphite (d_{002} = 3.4–3.5 Å), i.e., reveal no graphite nitrate. At the same time, the compounds obtained can be thermally expanded. To confirm the occurrence of bulk intercalation reactions under the potentiostatic treatment of graphite, the variation of current with time was measured simultaneously with the thickness of a carbon material layer (Fig. 3). In the course of formation of graphite intercalation compounds, graphite undergoes structural transformations caused by an increase in the interplanar spaces *a* [1]. For example, *a* increases from 3.35 to 8.2 Å in graphite nitrate [7] and may increase

* I_i, I_{av}, and I_f are, respectively, the initial, average, and final currents in the potentiodynamic curve; I_{av} is calculated from Q and synthesis time.

to 6.6 Å in graphite oxide [28]. As a result, the thickness of a graphite layer must increase in the course of the GIC formation.

The potentiostatic curves I–τ are of classical shape (Fig. 3). A sharp rise in the current is observed at the beginning of the process, whose magnitude tends grow with increasing potential of the anodic polarization (Fig. 3, Table 2). The decrease in current is caused by charging of the electrical double layer and by SFG oxidation. Further run of the curve is characterized by a number of inflections corresponding to successive formation of GIC belonging to different steps (Daumas–Herold model [4]). Then, the current virtually ceases to change with time.

Similar intervals of time can also be distinguished in the curves of piston displacement (Fig. 3, Δl–τ). A zero or, in some cases, negative change in the graphite layer thickness corresponds to a fast decrease in the current, which indicates that only surface reactions proceed during this interval of time. Thus, it was demonstrated experimentally that the intercalation is preceded by the induction period during which the composition of SFG on the graphite surface changes. Previously, the induction period has been mentioned as an assumption in [12, 28]. According to Fig. 3, the time of graphite matrix preparation for intercalation decreases steadily with increasing E_a, since the initial currents I_i (Table. 2) in the potentiostatic curves grows, and the necessary quantity of electricity supplied to graphite during the induction period must be the same.

It should be noted that the system used to measure the change in the graphite layer thickness shows time lag because of the piston-loading pressure and friction

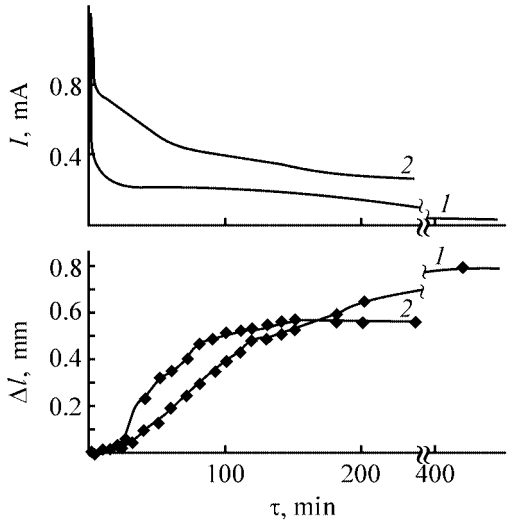

Fig 3. Current I and thickness Δl of the graphite electrode vs. time τ of anodic treatment with the same quantity Q = 450 mA h g^{-1} of passed electricity. (*1*) E_a = 1.75 V, d_{TEG} = 2.2 g dm^{-3}; (*2*) E_a = 2.1 V, d_{TEG} = 1.8 g dm^{-3}.

Table 3. Variation of thickness Δl of a graphite layer with time in anodic potentiostatic treatment in a 13.5 M HNO_3 solution

1.75	11	29	40	52	61

forces. For this reason, bends in the Δl–τ curves may be shifted along the time axis relative to those in the potentiostatic curves, especially at the beginning of synthesis.

As predicted previously, the bulk reactions of electrochemical intercalation do entail an increase in the graphite layer thickness (Fig. 3), with the entire time during which the piston goes up divided into two portions with different piston displacement velocities. The Δl curves (Fig. 3) show that the layer thickness grows faster at the beginning of the process and the piston motion slows down. Similar changes are characteristic of the I–τ curves. Such a run of the curves is due to deceleration of the electrochemical intercalation processes, caused by diffusion hindrance increasing upon intercalate penetration into the graphite clusters.

After the intercalation is complete, and the volume of the graphite anode stops to increase, the potentiostatic curves continue to show currents, which may be due to peroxidation of the already formed GIC or to surface reactions, with the piston at rest.

With increasing anode potential, the current grows in all the three stages of TEGC synthesis, distinguished here (Fig. 3, Table 2). At higher positive E_a, the piston velocity grows with graphite converted into GIC. At the same time, the highest values of Δl are, conversely, attained at lower anodic polarization (Fig. 3, Δl–τ). This can be understood with account

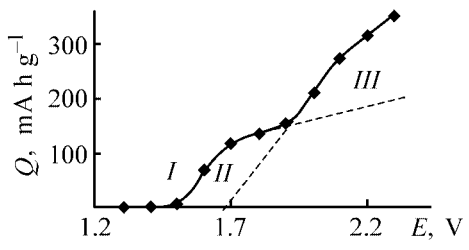

Fig. 4. Amount of electricity Q passed through graphite anode for 2 h vs. potential E of anodic potentiostatic treatment in a 13.5 M HNO_3 solution.

of the fact that the possibility of graphite oxide formation becomes higher with increasing anode potential. The theoretically possible (judging from a values) increase in the graphite volume in formation of graphite nitrate must be 30% higher than that in graphite conversion into graphite oxide. The experimentally observed discrepancy of Δl is also about 30% (Fig. 3, Table 3). Consequently, it may be assumed that the main product of synthesis at E_a = 1.75 V is graphite nitrate undergoing hydrolysis, whereas at E_a = 2.1 V compounds similar to graphite oxide are formed.

The assumptions made are also indirectly confirmed by the data on the TEG density. Despite that the quantity of passed electricity is the same and the volume expansion is smaller, the TEG compounds formed by anodic treatment at E_a = 2.1 V have smaller bulk density (1.8 g dm^{-3}) than samples synthesized at E_a = 1.75 V (d_{TEG} = 2.2 g dm^{-3}). This is in agreement with published data [12], whence follows that graphite oxide has larger coefficient of thermal expansion.

The data of Table 2 show that the thermal expandability of the compounds synthesized depends on the E_a value and is determined by the quantity of electricity passed through the carbon material. With increasing Q, d_{TEG} decreases steadily, whereas K_{te} increases. If the Q–E_a dependence is regarded as a stationary polarization curve of the overall electrode process, three main potential ranges can be distinguished (Fig. 4). In range I (up to 1.5 V), no electrochemical intercalation occurs, with reversible GIC oxidation reactions being predominant. This assumption is confirmed experimentally. Prolonged (20 h) anodic treatment of graphite at E_a = 1.3 V does not lead to any increase in the graphite layer thickness in electrolysis or TEGC formation. Treatment at E_a = 1.5 for the same time yields samples with K_{te} of up to 20–30. Consequently, the threshold potential of GIC formation in a 13.5 M HNO_3 solution is within 1.4–1.5 V. In range II (Fig. 4) the electrochemical intercalation reactions are predominant. However, the XPA and the high degree of irreversibility of the electrode reactions (Fig. 2) show that graphite nitrate formed by reaction (1) undergoes fast hydrolysis or reoxidation. Both the products of reactions (2) and (4) are less electrochemically reversible, compared with graphite nitrate, because of the formation of covalent bonds between the intercalate and the carbon layers. In range III, the run of the polarization curve reveals a new electrode process, which onsets at E_a = 1.6–1.7 V, as shown by extrapolation to the potential axis (Fig. 4). A rise in current is observed in the potentiodynamic curves in this potential range, confirmed by the data of Table 1. At the same time, the Q_c/Q_a remains vir-

tually unchanged (Fig. 2). Consequently, the contribution of surface reactions (5)–(7), which are already possible thermodynamically [20, 23], is insignificant. It is therefore appropriate to conclude that the nature of the electrochemical intercalation of graphite changes. Presumably, the intercalation process occurs in range III to give mainly GIC of the type of graphite oxide. These assumptions are consistent with published data [28], which show that graphite oxide is formed at potentials more positive by 200–700 mV, compared with those in the case of GIC, and a decrease in the width of this interval with increasing water content in the electrolyte would be expected. The absence of intensive oxidation of carbon to CO and CO_2 is also confirmed by the rather high current efficiencies by carbon (Table 2).

To ensure a considerable thermal expandability of GIC synthesized under the experimental conditions, the quantity of electricity to be passed through the graphite anode should be 150 mA h and more per 1 g of graphite. It is reasonable, in this case, to perform synthesis at potentials of 2.0–2.1 V, which not only considerably accelerates intercalation, but also results in the formation of TEGC with the highest K_{te} (Table 2), as mentioned above. Further increase in E_a and also passing more than 250 mA h g^{-1} of electricity through a graphite sample do not decrease the TEGC density, with the thermal expansion coefficient even decreasing somewhat. Under the given conditions, the partial contribution of reactions (5) and (6) to the total current of the electrode process increases, which results in the aggravation of defects of the graphite matrix and makes removal of intercalate from the interlayer spaces in heat treatment inefficient. The experiments performed revealed the fundamental aspects of the potentiostatic synthesis of TEGC in a 13.5 M HNO_3 electrolyte with the use of a dispersed carbon material. The possibility of obtaining compounds with prescribed coefficient of thermal expansion by controlling the potential and time of anodic treatment of graphite was demonstrated.

CONCLUSIONS

(1) Electrochemical studies and measurements of the change in the thickness of a dispersed graphite layer in anodic polarization in a 13.5 M HNO_3 electrolyte showed that the threshold potential of intercalation is 1.3–1.4 V relative to a silver chloride reference electrode. At lower potentials, reversible electrode reactions involving surface functional groups occur. At potentials higher than 1.7 V, intercalation compounds like graphite oxide can be formed. The intercalation is preceded by an induction period involving oxidation of surface groups of the graphite matrix.

(2) XPA data and cyclic potentiodynamic curves showed that the graphite intercalation compounds formed are hydrolyzed or reoxidized owing to the high content of water in the electrolyte. The compounds obtained may undergo effective thermal expansion upon heating.

(3) The influence exerted by the potential of potentiostatic anodic treatment and by the quantity of electricity passed through graphite electrode on the thermal expansion coefficient of the compounds synthesized was determined. For example, to ensure a less than 3 g dm^{-3} density of thermally expanded graphite, the synthesis should be performed at 2.1 V for 1.5–2 h with 200–280 mA h g^{-1} of electricity passed.

Abstract—Anodic layers containing M(II) phosphates, e.g., $Mg_3(PO_4)_2$, $Mn_2P_2O_7$, $Mn(PO_3)_2$, and $NaZnPO_4$, were obtained.

Anodic coatings containing electrolyte components have been formed on aluminum, its alloys, and titanium in electrolytes with M(II) and M(III) polyphosphate complexes (MPC) at sparking voltages [1–6]. The elemental composition of the coatings depends on the MPC concentration and the [polyphosphate]/metal cation] molar ratio in an electrolyte. A possible mechanism of incorporation of the electrolyte components into coatings is thermolysis in near-breakdown regions of hydrated metal polyphosphates being deposited onto anode [1]. However, the phase composition of coatings has not been determined.

This study is concerned with the phase composition of anodic-spark coatings on aluminum alloys with phosphorus(V) and magnesium(II), manganese(II) or zinc(II).

EXPERIMENTAL

The electrolytes were prepared using commercial reagents $Na_6P_6O_{18}$ (pure grade) and $Mg(CH_3COO)_2 \cdot 4H_2O$, $Mn(CH_3COO)_2 \cdot 4H_2O$, $Zn(CH_3COO)_2 \cdot 2H_2O$ (all chemically pure grade). The electrolyte preparation, electrochemical cell, and power source were similar to those described in [2–4].

The coatings were formed on samples made of AD1 alloy at a constant current density $j = 0.05$ A cm^{-2} in the course of 10 min. The first sparking discharges appeared on the anode surface during the first minute of the process. After anodization, the samples were washed with distilled water and dried in air at 70–80°C.

The samples were in the form of a 30-cm^2 foil bent as an "accordion," with the coating partially peeling off when the accordion is stretched.

The phase composition of the coatings separated from a support was determined from X-ray diffraction patterns obtained on a DRON–2.0 diffractometer with Cu_{K_α} radiation. The coating material was annealed in air for 30 min.

Figure 1 shows the content of aluminum(III), phosphorus(V), and zinc(II) in coatings on an AMtsM aluminum alloy in relation to the $n = [P_6O_{18}^{6-}]/[Zn^{2+}]$ molar ratio in the electrolyte bulk. Similar dependences have been obtained for coatings formed in the electrolytes containing $Na_6P_6O_{18}$ or $Na_5P_3O_{10}$ and other M(II), M(III) salts [1–4]. Analysis of these data shows that the electrolyte elements are incorporated

into coatings in noticeable amounts when n is less than a certain value n_0. For zinc coatings $n_0 \approx 3$. Coatings formed in electrolytes with $n < n_c$, where n_c characterizes the transition of an electrolyte into a colloid state, consist virtually solely of the electrolyte components and oxygen. For the system considered in Fig. 1, $n_c \approx 1$. It has also been shown [4] that the content of the electrolyte components in the coating is only slightly affected by presence of alloying additives in the aluminum alloy. Therefore, it is appropriate to compare the elemental composition of coatings on AMtsM alloy (Fig. 1) with the phase composition (described below) of coatings on the AD1 alloy.

The initial coatings formed in the electrolyte with $Na_6P_6O_{18}$ and $Mn(CH_3COO)_2 \cdot 4H_2O$ at n = 1 contain $AlPO_4$, Al_2O_3, and $Mn(PO_3)_2$ phases, and those formed at n = 0.5, $AlPO_4$. After annealing, the crystallinity of the coatings increases (Fig. 2), and, in the coating formed in the electrolyte with n = 0.5, the $Mn(PO_3)_2$ phase crystallizes (Fig. 2). It should be noted that, in the initial coatings formed in the given electrolyte in the decreasing power mode at U_0 = 440 V, a $Mn_2P_2O_7$ phase is present (Fig. 2, curve *e*). This is probably due to large current densities passing through the sample at the beginning of coating formation in the given mode, and, consequently, to different thermal conditions on the anode surface in near-breakdown regions.

The coatings formed in the electrolytes with $Na_6P_6O_{18}$ and $Mg(CH_3COO)_2 \cdot 4H_2O$ at a 0.5 molar ratio of the components, also contain the $AlPO_4$ crystalline phase. Annealing of this coating results in the crystallization of the $Mg_2P_2O_7$ and $Mg_3(PO_4)_2$ phases (Fig. 3). Coatings formed in a similar electrolyte at n = 2, which corresponds to lower concentrations of phosphorus and M(II) in them (Fig. 1), contain η- and γ-Al_2O_3 (Fig. 3, curve *d*).

Coatings formed in a polyphosphate electrolyte with $Zn(CH_3COO)_2 \cdot 2H_2O$ at n = 0.5 contain, along with $AlPO_4$, also double orthophosphate $NaZnPO_4$ (Fig. 4). Annealing of this coating at 750°C makes higher the intensity of reflections related to these phases and leads to crystallization of $ZnAl_2O_4$ spinel and orthophosphate $Zn_3(PO_4)_2$.

To confirm the assumption that the electrolyte components are incorporated into a coating in the sparking mode as a result of the thermolysis of a deposit from the electrolyte in near-breakdown regions, the following experiment was performed: sediments were isolated from solutions containing $Na_6P_6O_{18}$ and the Mg(II) and Mn(II) acetates at $[P_6O_{18}^{6-}]/[M^{2+}]$ = 0.33, which corresponds to hexametaphosphates of composition $M^{II}_3P_6O_{18}$, after 1 day of settling at room temperature, filtered off, and dried in air at about 60°C for 1 h. Then, the sediments were suc-

	initial	450	650	800	950
Mg(II)	X_{ra}^*	$Na_2Mg(PO_3)_4$	$Mg(PO_3)_2$, $(NaPO_3)_x$	$Na_2(PO_3)_4$, $Mg_2P_2O_7$	$Na_2Mg(PO_3)_4$, $Mg(PO_3)_2$, $Mg_2P_2O_7$
Mn(II)	X_{ra}	$Mn_2P_2O_7$, $Mn(PO_3)_2$, $NaMn(PO_3)_2$	$Mn_2P_2O_7$, $Mn(PO_3)_2$, $NaMn(PO_3)_2$	$Mn_2P_2O_7$, $Mn(PO_3)_2$, $NaMn(PO_3)_2$	$Mn_2P_2O_7$

* (X_{ra}) X-ray-amorphous sample.

cesively annealed for 30 min at temperatures ranging from 450 to 950°C. The results obtained are presented in the table.

The deposits separated were always X-ray-amorphous. In the course of the annealing, various polyphosphates, including double polyphosphate, crystallize. The final products of thermolysis are M(II) meta- and diphosphates.

Comparison of the calcination products of the sediments obtained from solutions with the compounds incorporated into coatings shows that the components of the electrolyte containing M(II) polyphosphate complexes are incorporated into the coatings through thermolysis of hydrated M(II) polyphosphates

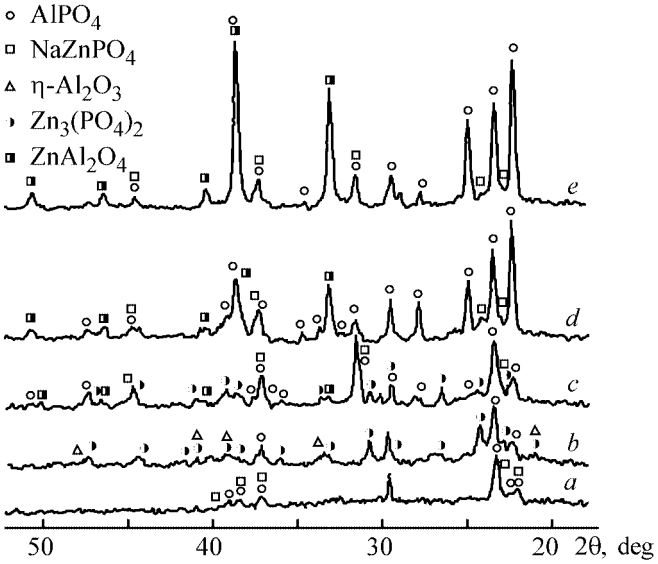

Fig. 4. X-ray diffraction patterns of coatings formed on AD–1 aluminum alloy in an electrolyte containing 0.05 M $Na_6P_6O_{18}$ and $Zn(CH_3COO)_2 \cdot 2H_2O$ with $n = 0.5$, subjected to annealing at different temperatures and detached from the support. (*a*) Initial sample; Calcination conditions: (*b*) 500°C, 30 min; (*c*) 750°C, 30 min; (*d*) 900°C, 30 min; and (*e*) 1000°C, 1.5 h.

in the near-breakdown regions on the anode. Owing to the conditions existing in the near-breakdown regions (electric field, sharp drops of temperature and pressure, presence of aluminum substrate, Al_2O_3, etc.), the thermolysis of a deposit in the course of coating formation occurs in a somewhat different way than that in calcination of a sediment in a crucible.

Thus, the coatings formed on aluminum alloy under the action of electric discharges in electrolytes with MPC contain high-temperature M(II) phosphates. Depending on the type of M cation, the phosphates can be used in the following, widely diverse fields: as phosphate grounds and protecting-decorative layers [7], in catalysis [8], as solid lubricants [9], as bioinert coatings [10, 11], and in luminescent and cathodoluminescent devices [12]. It is noteworthy that the coatings formed in electrolytes with MPC and containing P(V) and Zn(II), Pb(II) or Cd(II) show a marked biocide effect.

CONCLUSIONS

(1) Anodic layers formed at electric breakdown voltages on aluminum alloy in aqueous electrolytes with M(II) polyphosphate complexes [M(II) is Mn, Mg, and Zn] contain M(II) phosphates, e.g., $Mn(PO_3)_2$, $Mg_2P_2O_7$, $NaZnPO_4$, and $AlPO_4$.

(2) The phase composition of the coatings depends on the n = [polyphosphate]/[M cation] molar ratio in an electrolyte.

(3) Phosphorus(V) and metal ions are incorporated into coatings from an electrolyte owing to thermolysis of hydrated metal polyphosphates on the anode in near-breakdown regions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodialysis of Hydrosols of Ultradispersed Diamonds

A. G. Ovcharenko and A. V. Frolov

Biisk Technological Institute, Polzunov Altai State Technical University, Biisk, Altai Krai, Russia

Received November 2, 2001; in final form, April 2002

Abstract—The electrical conductivity of hydrosols of ultradispersed diamonds was studied. The electromembrane method for cleaning and concentrating of ultradispersed diamonds in hydrosols was considered. The influence exerted by the concentration of the dispersed phase on the electrical characteristics of the cleaning process was analyzed. A mathematical relation making it possible to evaluate the output characteristics of the process and to determine the geometrical characteristics of the apparatus was proposed.

Ultradispersed diamonds (UDD) formed in detonation synthesis are used in composite electrochemical metal-diamond coatings, finishing and superfinishing polishing formulations, grinding materials, resins, antiwear additives to lubricants, and components for fabrication of magnetic recording media [1]. After being prepared, UDD contain a large amount of undesirable impurities classed into several types [2]: water-soluble ionized (free electrolytes), water-insoluble (salts and oxides of various metals), adsorbed and chemically bound (functional surface groups), and those incorporated in the crystal lattice and encapsulated. For UDD to be usable in the above technologies, a dry diamond powder or a diamond hydrosol must be characterized by high degree of purity, determining its physicochemical properties.

The electromembrane method is proposed as the most efficient technique for cleaning of UDD hydrosols, which not only removes undesirable impurities, but also yields a diamond concentrate.

The aim of this study was to analyze the behavior of the given ultradispersed system under the action of an electric field and to determine its electrical properties.

EXPERIMENTAL

The study was carried out on an electrodialysis cell in a periodic mode with ion exchange membranes (Fig. 1). The cell case *1* comprises two fluoroplastic plates attached to each other with stainless steel studs. Each plate of the case has two connecting pipes for inlet of distilled water and outlet of brine. Graphite electrodes *2*, to which dc voltage is applied, are mounted in the cell. Between the case and the central frame *3*, anion- *4* and cation-exchange *5* membranes are fixed on rubber gaskets *6*. The working interelectrode chamber *7* is filled with water suspension of diamond with varied concentration of the solid phase. The distilled water in the brine chambers is circulated by a peristaltic pump. The volume of each chamber is 100 ml, the intermembrane spacing is 5 mm, and the active surface area of the membranes is 130 cm^2. The dialysis chamber is separated from the brine chambers by ion-exchange membranes MA-40 and MK-40.

The main stage of the process of UDD cleaning after synthesis is acid treatment [2]. As a result of oxidation, the surface of UDD particles possesses a large number of oxygen-containing groups (carboxy, carbonyl, hydroxy), which impart to this surface in an aqueous solution a charge whose sign and magnitude are determined by the concentration of these groups, solution pH, and concentration of the supporting electrolyte. The adsorption of H^+ and OH^- ions, resulting from dissociation of the surface groups and adsorption of potential-determining ions in the case of an indifferent electrolyte, was determined by potentiometric titration enabling direct measurement of the surface charge. The adsorption Γ, g-equiv g^{-1} (total number of oxygen-containing groups), was found using the formula

$$\Gamma = \frac{c\Delta V}{m}, \quad (1)$$

where c is the concentration of alkali added (g-equiv cm^{-3}); $\Delta V = V_2 - V_1$ is the difference of, respectively, alkali volume added to achieve a given pH value in titration of a supporting electrolyte and

that added in the presence of a sample (cm^3); and *m* is the sample weight (g).

The specific surface charge σ_0 ($C\ m^{-2}$) was found using the formula

$$\sigma_0 = \frac{\Gamma F}{S}, \qquad (2)$$

where *F* is the Faraday number, and *S* is the specific surface area of a particle ($m^2\ g^{-1}$).

The mechanism by which the surface charge is formed is reflected by the dependence of the electrophoretic mobility or electrokinetic potential (ζ-potential) on the pH value. The ζ-potential, which depends on the number of counter ions in the diffusion layer of a particle, in fact determines its charge.

The required pH value was attained using a KOH solution in distilled water. To maintain constant the ionic strength, a KCl solution of appropriate concentration was introduced into the hydrosol. The experimental results are presented in Fig. 2. The particles acquire a negative charge at pH 3–11. When the pH values are shifted to the alkaline region, the dependences of Γ and σ_0 on pH become stronger, which can be accounted for by an increasing degree of dissociation of surface functional groups. It is believed that mainly carbonyl groups dissociate at pH < 8, carboxy groups, at pH 8–10, and hydroxy groups, at pH > 10. The increase in the magnitude of the negative ζ-potential and, consequently, in the electrophoretic mobility of particles with increasing pH is apparently due to ionization of functional groups. It can be seen from Fig. 2 that the ionic strength of the electrolyte affects only the magnitude of the ζ-potential and has virtually no effect on the type of the ζ-pH dependence. Further decrease in the ζ-potential is presumably due to specific adsorption of the K^+ counter ion and to compression of the electrical double layer of a particle with increasing concentration of OH ions. The presence of a negative charge forces the particles toward the anode and, when a solution passes across the membrane, UDD is concentrated and accumulated. When ionexchange membranes are used, there occurs an additional process of electrodialysis of soluble impurities and those adsorbed on the surface of diamond particles.

The main elements contained in insoluble impurities in a UDD hydrosol are the following (wt %): Ca 0.17, Fe 0.26, Si 0.25, S 0.15, Ti 0.08, K 0.08, and trace amounts (sum total less than 0.1 wt %) Al, P, Na, Cu, and Zn.

The electromembrane method gives no way of carrying out complete cleaning of the ultradispersed system to remove all of these elements and compounds of these. Therefore, a combined technology was proposed, consisting in the following stages: acid cleaning of UDD to remove metals; dilution of the system to neutral system; and electrochemical cleaning to remove P, S, Na, K, and acid residues.

The amount of incombustible (sol) impurities after acid treatment is 0.7–0.9 wt %. The subsequent electrochemical treatment can decrease this value to 0.12–0.15 wt %. The time of electrochemical treatment can be made shorter because of the use of simultaneous concentrating and cleaning of UDD in a single apparatus [3]; in addition, the stages used in the basic technology (alkaline treatment, concentrating on an ultrafiltration installation) are excluded. As a result of electrochemical treatment, the UDD hydrosols acquire enhanced aggregative and sedimentation stability in a wide range of UDD concentrations, since the concentration of ions in the ultradispersed system do not exceed 3×10^{-5} $g\ l^{-1}$.

The dependences of the current density on the time of cleaning, *j*–τ, and of the current density on the concentration of electrolyte in the ultradispersed system,

j–*c*, were obtained in the study. The dependences *j*–τ for a UDD hydrosol with concentration of 0.1 wt % at varied concentration of the supporting electrolyte and *j*–τ for an electrolyte containing no dispersed phase are presented in Fig. 3.

The key contribution to the total electrical resistance of the electrodialyzer comes from the dialysis chamber. The run of the dependences of current density on time is determined by changes in the resistance of the whole cell in the course of electrodialysis. Comparison of the dependences (*1*–*3*) and (*1*'–*3*') shows that the initial current densities are lower in the second case. This can be accounted for by the difference between the electrical conductivities of the ultradispersed system and the supporting electrolyte and by accumulation of a UDD sediment on the anion-exchange membrane, which makes the rate of ion permeation across the membrane lower and the total time of cleaning longer.

Since no data on the electrical conductivity of aqueous UDD suspensions are available in the literature, experiments were performed for determining the conductivity in relation to the concentrations of the solid phase and the supporting electrolyte. The measurements were done in a glass cell with platinum electrodes, connected to a slide-wire bridge. As seen from Fig. 4, the electrical conductivity of the system $æ_s$ exceeds that of the electrolyte, æ, at low concentrations *c*. At an electrolyte concentration of 0.2 g l^{-1}, the $æ_s$ and æ values are close, and, with the concentration increasing further, $æ > æ_s$. Since the solid particles are nearly spherical and electrically nonconducting, the electrical conductivity of a dispersed system with volume fraction of the dispersed phase, $p = 3 \times 10^{-4} << 1$, is described by the well-known Maxwell formula [4]

$$\Delta æ_s = 3/2 p æ, \quad (3)$$

$$æ_s = æ - \Delta æ_s. \quad (4)$$

The dependence of æ on *c* can be understood as follows. According to the data of [4],

$$æ_s/æ = \alpha/F, \quad (5)$$

where α is the efficiency factor, $1 \le \alpha \le F$; and *F* is the coefficient of structural resistance.

At high electrolyte concentrations, when the influence of the surface conductivity is insignificant, the right-hand side of the equation is equal to 1/*F*. The decrease in the electrical conductivity of UDD suspensions is due to the nature of diamond particles,

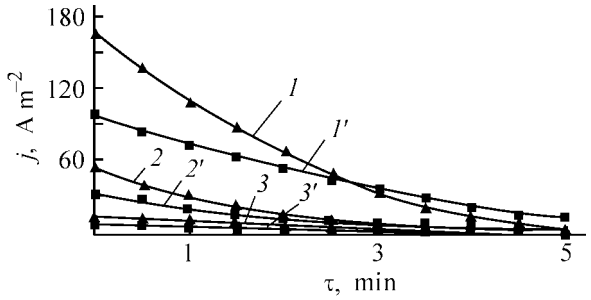

Fig. 3. Current density *j* vs. time τ of electrochemical treatment of (*1*–*3*) KNO_3 electrolyte and (*1*'–*3*') ultradispersed system 0.1 wt % UDD + KNO_3. Electric field strength $E = 16$ kV m^{-1}. KNO_3 concentration (g l^{-1}): (*1*, *1*') 0.4, (*2*, *2*') 0.1, and (*3*, *3*') 0.02.

which have large specific surface area and a developed electrical double layer. When salt ions are added to the hydrosol, these ions are partly captured by the outer layer of the particles. The resulting decrease in the number of unbound ions in the suspension makes the electrical conductivity lower.

When an electric field is applied to the system, the lines of current round the surface of nonconducting particles, which is equivalent to a decrease in the electrical conductivity of the system.

With decreasing electrolyte concentration, the conductivity deficiency in the system is compensated for by the increasing influence of the surface conductivity of UDD particles. At a certain electrolyte concentration the electrical conductivity of the ultradispersed system is equal to the conductivity of the equilibrium electrolyte. Measurements demonstrated that the electrical conductivity of the system is independent of the volume fraction of the dispersed phase at the isoconductivity point. At concentrations lower than that corresponding to the isoconductivity point the ultradispersed system has, despite the decrease in the effective cross-section for a current to flow through, higher electrical conductivity than the equilibrium electrolyte because of the surface conductivity of UDD particles.

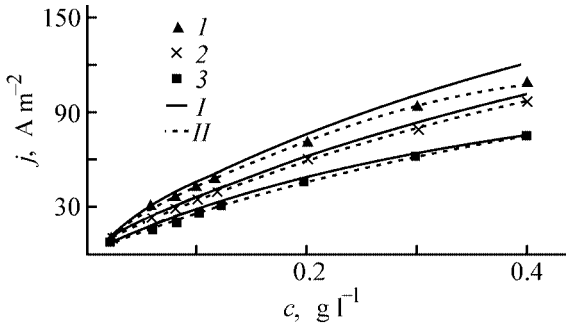

Fig. 5. Current density j vs. concentration c of the supporting electrolyte KNO_3 in a dispersed system with 0.1 wt % UDD. Electric field strength E (kV m^{-1}): (*1*) 20, (*2*) 16, and (*3*) 12. (*I*) Calculated curves and (*II*) experimental data.

The results obtained in an experimental study of the initial electrical properties of the ultradispersed system made it possible to propose a mathematical description of the process occurring in a cell to which an electric field is applied. Two processes, electrodialysis of dissolved salts and electrophoresis of UDD particles, occur in the cell simultaneously. The task to be accomplished consisted in obtaining a relation that could be used in design calculations of installations for electrochemical cleaning of ultradispersed systems with account of the influence exerted by the solid UDD phase on the characteristics of the electrodialysis process.

The solution consisted in describing the process of electrodialysis for a model system characterizing the dispersion medium and correcting the expressions obtained with account of the dispersed phase introduced into the system.

The system under study was considered for the following conditions: maximum concentration of the supporting electrolyte not exceeding 0.4 g l^{-1}; electrochemical treatment at current density higher than the limiting value, which much improves the output capacity and the degree of cleaning; batch mode of the process; permanent washing of side chambers with distilled water, which allows the initial salt concentration in the chambers to be considered constant.

In deriving the equation describing the dependence of the current density on the electrolyte concentration, account was taken of the Nernst–Planck film theory, and an equation for the total voltage drop across an electrochemical cell was used. The following assumptions were made: a constant voltage is applied to the system, the thickness of the diffusion layer on the eluate side is constant, and the electrolyte concentration along the chambers is invariable. The following semiempirical relation was obtained:

$$j = \frac{U_e - \frac{RT}{F}\left(\ln\frac{c_b}{c_d} - \varphi_{el}\right)}{R_a + R_c + \frac{\rho_d\delta_d\left[K_1\left(\frac{\nu}{D}\right)^{1/3} + 2K_2\frac{\delta_b}{\delta_d} + 1\right]}{1 + 0.02(T + 18)}}, \quad (6)$$

where R_a and R_c are the membrane resistivities (Ω m^2); ρ_d is the electrical resistivity of the diluate chamber (Ω m); δ_d and δ_b are the chamber widths (m); ν is the kinetic viscosity of the medium (m^2 s^{-1}); D is the diffusion coefficient (m^2 s^{-1}); c_b and c_d are the salt concentrations in the chambers (g l^{-1}); U_e is the cell voltage (V); φ_{el} is the electrode potential (V); T is temperature (K); $K_1 = 25$; $K_2 = 30$.

The coefficients K_1 and K_2, obtained by carrying out a set of experiments to make corrections to the equation, determine the effect of diffusion on the concentration of ions in side chambers and in the boundary layer.

After introduction of the UDD solid phase into the model system, the obtained relation was corrected. The following assumptions were made: the concentration of the solid phase is less than 1 wt % since larger amount leads to an increase in the specific hydraulic resistance of the sediment and, as a result, to lower desalting rate. It was also assumed that the layer of diamond particles on the membrane surface prevents formation of a boundary layer since it controls, by virtue of its adsorbing capacity, the transport of ions across the membrane, which prevents depletion of the near-membrane layer. Subject to the condition that the sedimentation of particles onto the membrane is complete, a coefficient K_3 is introduced, which accounts for changes in the electrical resistivity of the sediment, depending on the electrical resistivity of the electrolyte in the dialysis chamber. With account of the aforesaid, the following expression was obtained for UDD hydrosols

$$j = \frac{U_e - \frac{RT}{F}\left(\ln\frac{c_b}{c_d} - \varphi_{el}\right)}{R_a + R_c + \frac{\rho_d\left[K_1\frac{\delta_d}{2}\left(\frac{\nu}{D}\right)^{1/3} + 2K_2\delta_b + K_3\delta_s + \delta_d\right]}{1 + 0.02(T + 18)}}, \quad (7)$$

where δ_s is the sediment layer thickness (m), and $K_3 = 17000$.

Equations (6) and (7) make it possible to determine, from the current densities measured, the ion concentration in the dialysis chamber and to take into

account the electrical and geometric parameters of the apparatus, and enable determination of the desalting time.

To verify calculations by the equations obtained, experiments with a three-chamber electromembrane cell were carried out. The experimental results obtained confirm the calculated data (Fig. 5). The difference between the calculated and experimental values does not exceed 15% at field strengths lower than 16 kV m^{-1}. Previous studies of how the electric field strength depends on the cleaning time have shown that, with the field strength increasing to more than 16 kV m^{-1}, the energy expenditure grows, but the time of treatment decreases only slightly. At the same time, on lowering the field strength to 8 kV m^{-1} the cleaning time increases severalfold. This allowed the electric field strength of 16 kV m^{-1} to be recommended as the value optimal for operation of the electrochemical cleaning apparatus.

The results obtained found use in developing an engineering procedure for calculating a pilot-industrial installation for cleaning and thickening of a UDD hydrosol [3].

CONCLUSIONS

(1) It was established that the electrical conductivity of hydrosols of ultradispersed diamonds depends on the volume fraction of the solid phase. The isoconductivity point of the dispersed system was determined.

(2) It was found that addition of the solid phase to the dispersed system makes lower the initial current densities, all other conditions being the same. The weakening of the dependence of the current density on the treatment time is determined by changes in the electrical conductivity of the ultradispersed system.

(3) A design equation was obtained, which makes it possible to evaluate the output characteristics of the electrochemical cleaning process and determine the geometrical parameters of a cleaning apparatus. The equation was used in developing a procedure for engineering calculations of electrochemical cleaning apparatus.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Cobalt Porphyrin–based Solid-Contact Electrode Sensitive to Pyridine Concentration

A. B. Valiotti and R. A. Abakumova

St. Petersburg State University, St. Petersburg, Russia

Received October 26, 2001; in final form, March 2002

Abstract—A solid-contact electrode based on cobalt tetraphenyl porphin, sensitive to pyridine concentration, was studied. The properties of this electrode were analyzed.

Extracoordination of various compounds, including nitrogen-containing heterocycles, with metal porphyrins has been extensively studied recently [1–3]. The present communication demonstrates the possibility of fabricating a potentiometric sensor for determining the concentration of pyridine, which is based on a redox system composed of cobalt(III) tetraphenyl porphin [$Co(III)TPP^+$] and cobalt(II) tetraphenyl porphin [Co(II)TPP].

It is known [4] that this redox system can enter into various electrochemical reactions, with the result that (1) reversible change in the formal oxidation level of the central metal ion

$$Co(III)TPP^+ + e \rightarrow Co(II)TPP$$

and (2) reversible or irreversible partial disruptions of conjugation in the porphyrin ring may occur.

The present consideration takes into account the redox reaction involving only the central metal (cobalt) atom. Cobalt porphyrins can be involved in extracoordination reactions with various ligands. As ligands may act species able to form σ-donor and π-acceptor bonds. The capacity of cobalt porphyrins for extracoordination of pyridine was used to create a molecular-selective potentiometric sensor for determining the pyridine concentration. For this purpose, a solid-contact electrode was designed. Electrodes of this kind were fabricated from a graphite rod and graphite powder (dispersity ~70 mesh), which ensured the electronic conduction. As potential-determining system served the redox system Co(II)TPP–$Co(III)TPPClO_4$ in 1 : 1 molar ratio. The graphite rods were used to fabricate electrodes in the form of pellets with shallow depressions drilled out on their edges. Then copper conductors were glued into these depressions to serve as current leads. After that the pellets were fixed in standard PVC tubes with an epoxy adhesive.

Membranes for the solid-contact electrodes were prepared as follows. Weighed portions of cobalt porphyrins and graphite powder were dissolved in the minimum possible amount of chloroform, and then the solvent was removed by evaporation to obtain uniform distribution of cobalt porphyrins over the surface of graphite grains. Then weighed portions of PVC and a plasticizer (dibutyl phthalate, DBP) were dissolved under heating in tetrahydrofuran (THF) and the graphite powder with porphyrin was added to the solution. The mixture obtained was deposited onto a cleaned graphite surface of the electrode. After THF was evaporated, the process was repeated, in all, 5 or 6 times. The cobalt porphyrin : PVC : plasticizer : graphite mass ratios were varied between 1 : 1 : 0 : 0 and 1 : 2 : 8 : 8.

The potential of the solid-contact electrode was found by measuring the emf of the electrochemical cell

Cu | Ag | AgCl, KCl (sat.) | Working solution | Membrane | Graphite | Cu

The pH of a solution under study was determined using a glass electrode preliminarily calibrated with standard buffer solutions. The emf of the galvanic cells was measured with a pH-121 pH-meter-millivoltmeter whose output signal was delivered to an in-series connected KSP-4 printing unit. The solid-contact electrode under study operates on the reaction of electron transfer between the oxidized and reduced

1070-4272/02/7510-1614 $27.00 © 2002 MAIK "Nauka/Interperiodica"

forms of CoTPP under the conditions of complexation with pyridine.

The heterogeneous redox reaction occurring in the system under study at the interface between the electrode and the external solution in the absence of a ligand can be represented as

$$Co(III)TPP^{+}_{(s)} + A^{-}_{(s)} + e = Co(II)TPPL_{(s)} + A^{-}, \quad (1)$$

with the index *s* referring henceforth to the solid phase, and A^- being a counter ion, ClO_4^- in the given case.

Writing the redox reaction in this way assumes that the electrode-active substance Co(III)TPPA is in the totally dissociated state. Then the expression for the potential of the given solid-contact electrode, which is of the redox type, has the form

$$E = E^0 + 2.3\frac{RT}{F}\log\frac{c^{s}_{Co(III)TPP^{+}}c^{s}_{A^-}}{c^{s}_{Co(II)TPP}c_{A^-}}. \quad (2)$$

In the presence of pyridine in the working solution, complexation is possible by the scheme

$$Co(II)TPP_{(s)} + L = Co(II)TPPL_{(s)}, \quad (3)$$

where L is an extra ligand, pyridine in the given case.

The complexation constant K^R is defined by

$$K^R = \frac{c^{s}_{Co(II)TPPL}}{c^{s}_{Co(II)TPP}c_L}. \quad (4)$$

For the oxidized form

$$Co(III)TPP^{+}_{(s)} + L = Co(III)TPPL^{+}_{(s)}, \quad (5)$$

$$K^0_1 = \frac{c^{s}_{Co(III)TPPL^{+}}}{c^{s}_{Co(III)TPPL^{+}}c_L}, \quad (6)$$

$$Co(III)TPPL^{+}_{(s)} + L = Co(III)TPPL^{+}_{2(s)}, \quad (7)$$

$$K^0_2 = \frac{c^{s}_{Co(III)TPPL^{+}_2}}{c^{s}_{Co(III)TPPL^{+}}c_L}. \quad (8)$$

With account of (3)–(8), Eq. (2) is transformed into

$$E = E^0 + 2.3\frac{RT}{F}\log\frac{c^{OX}}{c^{RED}} + 2.3\frac{RT}{F}\log(1 + K^Rc_L) - 2.3\frac{RT}{F}\log(1 + K^0_1c_L + K^0_1K^0_2c^2_L) + 2.3\frac{RT}{F}\log\frac{c^{s}_{A^-}}{c_{A^-}}, \quad (9)$$

where

$$c^{OX} = c^{s}_{Co(III)TPP^{+}} + c^{s}_{Co(III)TPPL^{+}} + c^{s}_{Co(III)TPPL^{+}_2},$$

$$c^{RED} = c^{s}_{Co(II)TPP} + c^{s}_{Co(II)TPPL}.$$

With the coefficient $2.3RT/F$ denoted by ϑ, Eq. (9) takes, at $c^{OX} = c^{RED}$ and $c^{s}_{A^-}/c_{A^-} = \text{const}$, the form

$$E = E^{0'} + \vartheta\log(1 + K^Rc_L) - \vartheta\log(1 + K^0_1c_L + K^0_1K^0_2c^2_L), \quad (10)$$

where

$$E^{0'} = E^0 + 2.3\frac{RT}{F}\log\frac{c^{s}_{A^-}}{c_{A^-}}.$$
