Abstract—A comparative analysis of the phase relationships in the ternary mutual systems CaO,SrO‖SiO_2, GeO_2; CaO,BaO‖SiO_2,GeO_2; and SrO,BaO‖SiO_2,GeO_2 was performed and the crystal-chemical properties of the phases crystallizing in them were determined.

Study of the phase equilibria in silicate-based and related systems is one of the central problems in chemical materials science. This work completes our series of studies of the phase relationships in the systems of metagermanosilicates of alkaline-earth metals (Ca, Sr, Ba). The chemical composition of the simplest pyroxenoids is expressed by the general formula $M_n[SiO_3]_n$, where M is a group of double-charged cations with the large ionic radii presented in various integral and fractional ratios [1–4]. Systematic study of the ternary mutual germanosilicate systems CaO, SrO‖SiO_2,GeO_2; CaO,BaO‖SiO_2,GeO_2; and SrO, BaO‖SiO_2,GeO_2 is of undoubted theoretical and practical importance. Extending the chemical composition of pyroxenoids, studying the phase relationships among them, and establishing the concentration regions of homogeneity in these systems is one of the necessary stages in the development of new materials (enamels, electroceramics, etc.). Extended isomorphism of the end members of the systems considered is a prerequisite for the preparation of technical materials based on them.

Figure 1a–1c shows the phase diagrams of the edge sections of the three concentration quadrangles, $CaSiO_3$–$CaGeO_3$–$SrGeO_3$–$SrSiO_3$, $CaSiO_3$–$GaGeO_3$–$BaGeO_3$–$BaSiO_3$, and $SrSiO_3$–$SrGeO_3$–$BaGeO_3$–$BaSiO_3$. The limiting boundaries of solubility in the solid solution systems at 1200°C are shown schematically in their central parts. The concentration limits of stability are plotted on the basis of studying the phase relationships on the edges and in the diagonal sections of the quadrangles considered [5–18]. In these works the characteristic of the end members of all the sections is given in detail, along with the experimental technique. Let us briefly consider the structural properties of the phases crystallizing in the system. All end members of the systems studied can be ranked as one of two structural types of anionic sublattices: chain-like pyroxenoid (β-$CaSiO_3$, $CaGeO_3$, β-$BaSiO_3$, β-$BaGeO_3$) and ring-like pseudowollastonite (α-$CaSiO_3$, α-$SrSiO_3$, α-$SrGeO_3$, α-$BaSiO_3$, α-$BaGeO_3$).

In all the three concentration quadrangles the homogeneity fields were revealed for the phase of variable composition isostructural with walstromite $Ca_2BaSi_3O_9$ (W). This compound has a distorted ring-like pseudowollastonite structure [19, 20].

The phase diagrams show the temperature and concentration limits of feasible variations of the chemical composition of each phase in the series of the systems considered (Figs. 1a–1c). The experiment has shown that more complex chemical composition due to isomorphous transitions and the considerable dissimilarity in sizes of replaced cationic pairs $Ca^{2+}Si^{4+} \rightleftarrows Sr^{2+}Si^{4+}$, $Ca^{2+}Si^{4+} \rightleftarrows Sr^{2+}Ge^{4+}$, $Sr^{2+}Si^{4+} \rightleftarrows Ba^{2+}Si^{4+}$ result in the formation of a wide homogeneity region based on the berthollide phases crystallizing in the walstromite structure. Passing from one structural type to another in each system is realized either via gradual isomorphous transitions or via discrete-stoichiometric variations of the chemical composition.

Let us consider the specific features of phase relationships in the systems studied. For the ternary mutual system CaO,SrO‖SiO_2,GeO_2 the α-$CaSiO_3$ lattice (pseudowollastonite structure) allows extended isomorphism in both the cationic ($CaSiO_3$‖$SrSiO_3$) and anionic ($SrSiO_3$‖$SrGeO_3$) sublattices (Fig. 1a). Replacement of silicon(IV) by germanium(IV) in the

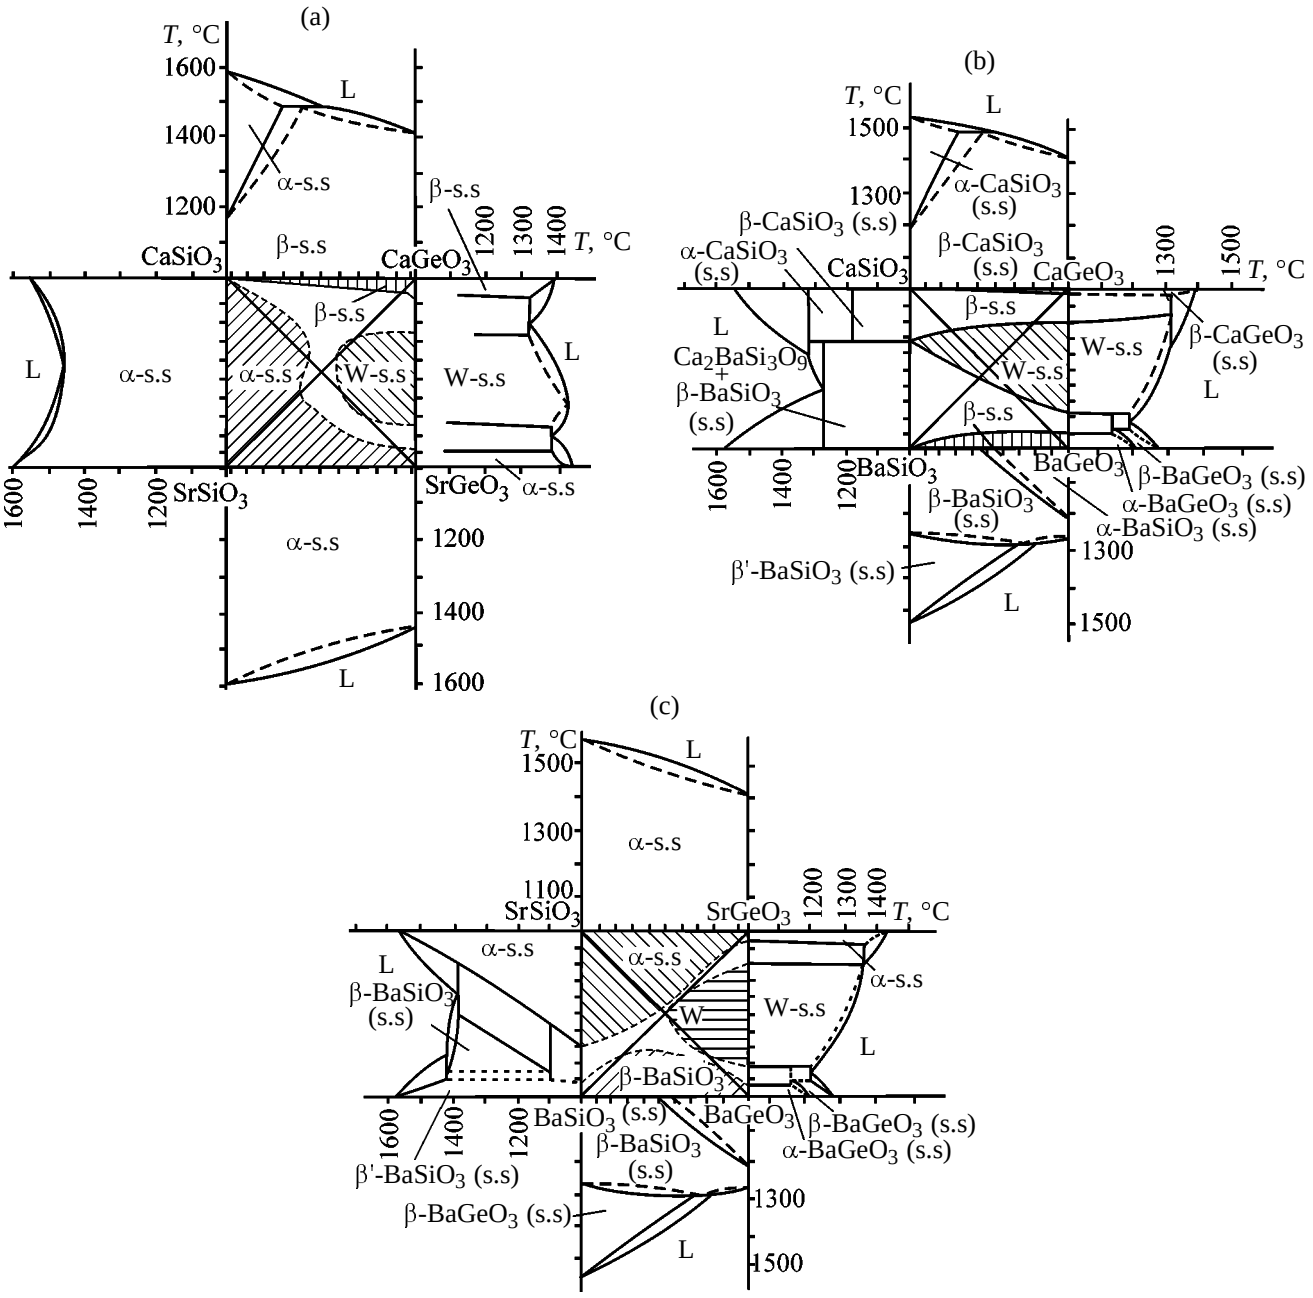

Fig. 1. Phase relationships in the ternary mutual systems. (*T*) Temperature. System: (a) CaO,SrO‖SiO_2,GeO_2; (b) CaO, BaO‖SiO_2,GeO_2; and (c) SrO,BaO‖SiO_2,GeO_2.

$CaSiO_3$ lattice results in the stabilization of the β-wollastonite structure. However, introduction of the strontium(II) ion into the cationic sublattice of β-$CaGeO_3$ drastically limits the concentration boundaries of stability of this structural form (up to 10 mol % $SrGeO_3$) and results in the morphotropic transition β-$CaGeO_3$ → walstromite → α-$SrGeO_3$. The walstromite-like solid solution mainly exists in the region of germanium(IV)-rich compositions.

The phase relationships in the ternary mutual system CaO,SrO‖SiO_2,GeO_2, where calcium is replaced by the larger (compared to strontium) barium ion, drastically differs from the systems considered above. Actually, the concentrational field of the walstromite solid solution is the largest as compared to the other solid solutions (Fig. 1b). In the section $CaSiO_3$‖$BaSiO_3$ this phase is realized solely as incongruently melting compound $Ca_2BaSi_3O_9$. In the

case of conjugate isomorphism $Ca^{2+}Si^{4+} \rightleftarrows Ba^{2+}Ge^{4+}$, $Ca^{2+}Ge^{4+} \rightleftarrows Ba^{2+}Si^{4+}$, the walstromite solid solutions with a reasonably wide homogeneity region exist in the diagonal sections of the concentration quadrangle. In the germanate section $CaGeO_3$–$BaGeO_3$ the solid solution concentration range is even wider. The isothermal section has no field of the α-solid solution and the limited homogeneity regions of the β-$CaSiO_3$ and β-$BaSiO_3$ solid solutions (Fig. 1b).

The isothermal section of the ternary mutual system SrO, $BaO\|SiO_2$, GeO_2 has three homogeneity regions: α-$SrSiO_3$ solid solutions, walstromite-like solid solution, and solid solution based on pyroxenoid $BaSiO_3$. Similar to the $CaO,SrO\|SiO_2,GeO_2$ system, the main phase is the hexagonal α-solid solution. The two other solid solutions have the narrower homogeneity fields.

The performed comparison of the phase relationships in the three mutual systems studied revealed the criteria determining the stability of a given phase and regular trends of physicochemical properties in the similar systems. The obtained data show that the temperature affects to a considerably lesser extent the mutual solubility of the components than the physicochemical nature of the cations occupying the octahedral and tetrahedral positions. It was found that the α-$CaSiO_3$ lattice in which the three-unit ring $[Si_3O_9]^{6-}$ is the main structural element allows the most extended isomorphism. For example, in the pure silicate systems considered, $CaSiO_3\|SrSiO_3$ and $SrSiO_3\|BaSiO_3$, the cationic radii differ considerably (r_{Ca} = 1.00 Å , r_{Sr} = 1.18 Å, and r_{Ba} = 1.35 Å). At the same time, the miscibility of the edge members is higher than in the analogous germanate systems.

Replacement of the silicon ion by the larger germanium ion (r_{Si} = 0.26, r_{Ge} = 0.39 Å) in the anionic sublattices of $CaSiO_3$, $SrSiO_3$, and $BaSiO_3$ results in the stabilization of the corresponding solid solutions. Probably, the condition that the same cation occupies the cationic sublattice plays the decisive role in these cases. Passing to more complex chemical composition in the germanate systems ($CaGeO_3\|SrGeO_3$, $CaGeO_3\|BaGeO_3$, $SrGeO_3\|BaGeO_3$) and in the diagonal sections (conjugate isomorphism) results in the appearance of the discrete intermediate berthollide phases crystallizing in the walstromite structure. Probably, the isomorphous transitions in these systems give rise to size mismatch in the structure of the solid solutions based on the edge members. As a result, the miscibility is broken, and the walstromite-like phases with the distorted pseudowollastonite structure are formed. Apparently, the latter structure allows more considerable variation of the sizes of the large cations occupying the corresponding sublattice. This process is also facilitated by the arrangement of the germanium ions in the anionic sublattice of these phases. Compared to the Si–O bond, the chemical bond Ge–O is less rigid, ensuring greater tolerance of the ring geramanate–silicate systems to the isomorphous replacements in the cationic sublattice. Probably, this fact can explain formation of the walstromite phases in the given systems. The relative size mismatch occurring upon replacements in the cationic and anionic sublattices of this structure is compensated by the partial distortion of the anionic skeleton owing to the possible deformation of the Ge–O bonds in the tetrahedra.

To conclude, the extended isomorphism of the crystalline phases in the germanate–silicate systems studied is largely determined by the stoichiometric and energy compatibility of the structural elements and by the similarity in the sizes of atoms and groups involved in the replacement. The extended isomorphism, generally found in the multicomponent systems studied, makes a quite encouraging experimental basis for development of novel materials.

CONCLUSIONS

(1) The phase relationships in the ternary mutual germanosilicate systems $CaO,SrO\|SiO_2,GeO_2$; $CaO,BaO\|SiO_2,GeO_2$; and $SrO,BaO\|SiO_2,GeO_2$ were compared.

(2) In the systems studied, the temperature and concentration fields of homogeneity based on the different crystalline structures were revealed. The correlation between the chemical composition of the crystallizing phases and the limits of their isomorphous capacity were established.

(3) The conditions of formation of the berthollide phases crystallizing in the walstromite structure were determined.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Composition of the Lead–Tin Oxide System

I. A. Kurzina, S. I. Galanov, and L. N. Kurina

Tomsk State University, Tomsk, Russia

Received May 15, 2001

Abstract—The influence of the component ratio, support type, and preparation procedure on the phase composition of the lead–tin oxide catalysts was studied.

Oxide systems containing SnO_2 are catalytically active in oxidative dehydrodimerization of hydrocarbons [1–3]. The lead–tin oxide systems are active in oxidative dehydrodimerization of propylene [4] and methane [5]. The supported catalysts exhibit enhanced thermal stability. To reveal the correlation between the activity and physicochemical properties of catalytic systems, it is necessary to know their phase composition.

In this work, we studied the influence of the composition, preparation procedure, and support type on the phase composition of the Pb–Sn–O catalysts.

EXPERIMENTAL

The lead–tin oxide catalysts (neat and supported) were used. The monolithic lead–tin samples were prepared by calcination at 800°C for 10 h in air of a mixture of tin(II) and lead(II) hydroxides. Supported samples were prepared by alternate impregnation of the support with solutions of $Pb(NO_3)_2$ and $SnSO_4$, and also by applying a wet paste of a mixture of tin(II) or tin(IV) and lead(II) hydroxides with subsequent drying at 200°C for 2 h and calcination at 800°C for 10 h. Supports were corundum α-Al_2O_3, aluminosilicate (40 wt % SiO_2), and commercial pumice sample. The support surface was preliminarily treated with a $Ca(OH)_2$ saturated solution at 200°C for 20 min, and then the samples were calcined at 800°C for 6 h. The amount of the lead–tin oxide composition applied to the support was 20 wt %.

The thermogravimetric curves of the hydroxide mixtures dried at 150°C and heated in air at a rate of 10 deg min^{-1} were taken on an MOM derivatograph (Hungary). The phase composition of the lead–tin samples was studied by X-ray phase analysis (DRON-0.5 diffractometer, CuK_α radiation). The specific surface area S_{sp} of the samples was determined chromatographically by thermal desorption of argon (S_{sp} = 2.1–2.5 $m^2\ g^{-1}$).

The X-ray phase analysis of the initial Pb–Sn–O compositions differing in the component ratios revealed tetragonal SnO_2 and rhombic PbO (Fig. 1a). The lead ortho- and metastannates are formed in the system at higher PbO content. The samples with 40–80 wt % PbO contain small amounts of lead metastannate $PbSnO_3$. The reflections assigned to lead orthostannate Pb_2SnO_4 are observed in the diffraction patterns of all the mixed Pb–Sn–O systems. Increasing lead oxide content in the samples increases the Pb_2SnO_4 content.

The thermogravimetric curves of the Pb–Sn–O samples of different compositions are shown in Fig. 1b. The DTA curves show several maxima corresponding to the different stages of phase formation in the system. The endothermic effects at 195 and 860°C, which correspond to dehydration of $Pb(OH)_2$ to PbO and to the melting of PbO, respectively [6], were observed with lead hydroxide. The diffuse exothermic effect at 360°C is assigned to the formation of nonstoichiometric lead oxides, Pb_3O_4 and Pb_2O_3. Further decomposition of these oxides to PbO and the phase transitions $PbO_{tetr} \rightleftarrows PbO_{rh}$ are accompanied by the endothermic effects at 450 and 510°C [6, 7]. On heating $Sn(OH)_2$ in air, two processes occur simultaneously: dehydration of tin hydroxide to SnO and its oxidation to SnO_2, which is revealed as two typical effects at 240 and 330°C. The TG curve shows weight loss (up to 240°C) followed by weight gain (up to 380°C) due to the SnO oxidation to SnO_2.

The DTA curves of the lead–tin systems containing 20, 40, and 60 wt % lead oxide (Fig. 1b) show, apart from the above thermal effects, also the exothermic peaks at 415–480°C attributable to the formation of

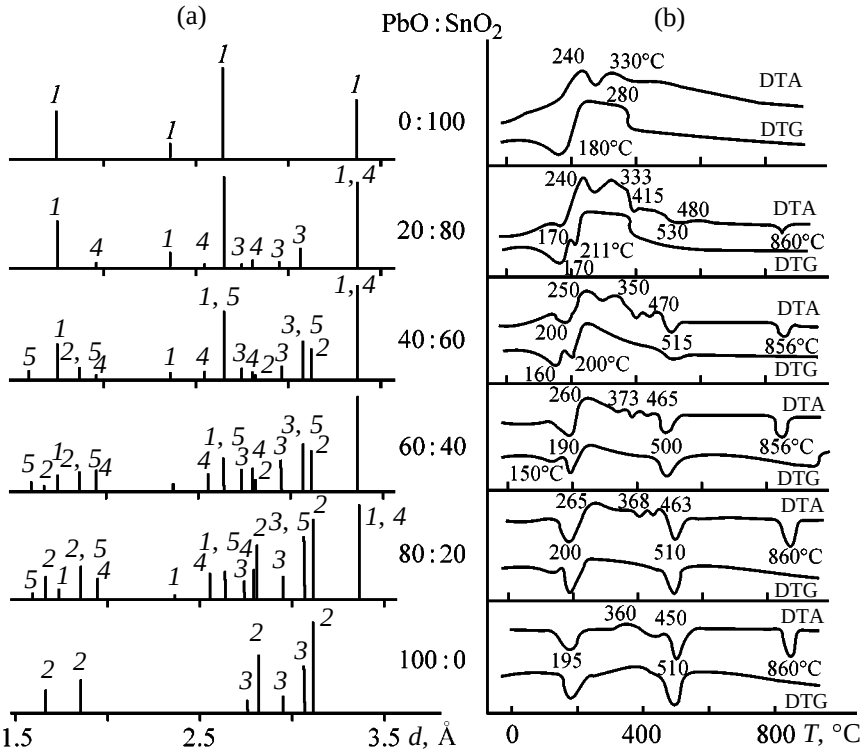

Fig. 1. (a) X-ray diffraction patterns and (b) thermograms of the Pb–Sn–O oxide systems. (*d*) Interplanar spacing and (*T*) temperature. Phase: (*1*) SnO_2, (*2*) PbO_{rh}, (*3*) PbO_{tetr}, (*4*) Pb_2SnO_4, and (*5*) $PbSnO_3$.

lead meta- and orthostannates [4, 6]. As seen, the lead orthostannate phase is formed even at 20 wt % PbO. Increasing lead oxide content increases the amount of this phase.

Thus, over the entire range of the component ratios, tin and lead oxides interact with the formation of multiphase systems, which alters the bulk and surface properties of the samples. Study of the catalytic properties of SnO_2 and of mixed Pb–Sn–O samples of different compositions in oxidative dehydrodimerization of methane (ODM) has shown that the increase in the PbO content in the samples increases the yield of ethane and ethylene. The sample of the composition (wt %) $PbO : SnO_2 = 80 : 20$ has the highest activity in ODM [5]. The results of [5] show that the yield of ethane and ethylene correlates with the total concentration of lead oxide and chemical compounds Pb_2SnO_4 and $PbSnO_3$. The multiphase composition of the systems enhances the catalytic properties of the samples [8].

To increase the thermal stability of the lead–tin samples in ODM, the most selective system of composition (wt %) $PbO : SnO_2 = 80 : 20$ was applied to a number of supports. In view of the fact that the most used supports for ODM catalysts are silicon and aluminum oxides [9, 10], the supports chosen in this study contained oxides SiO_2 and Al_2O_3 in different concentrations and had the close specific surface areas. To enhance the selectivity of ODM catalysts, it is proposed to decrease the acidity of the supports by treating them with NaOH, $Ca(OH)_2$, $Mg(OH)_2$, and other hydroxides. In this work, pumice, aluminosilicate (40% SiO_2), and corundum, pretreated with the saturated solution of $Ca(OH)_2$ and calcined at 800°C for 6 h, were used as supports. The supports show low activity in methane oxidation. The reaction products contain insignificant amounts of carbon monoxide.

It was found that the phase formation of the supported lead–tin samples significantly depends on the support type and application procedure. The phase composition of the Pb–Sn–O system prepared by applying a wet paste of a mixture of $Pb(OH)_2$ and $Sn(OH)_2$, with subsequent drying at 200°C for 2 h and calcination at 800°C for 10 h, is presented in Table 1 and Fig. 2. Use of the SiO_2-containing supports results in the formation of lead aluminosilicates, $Pb_3Al_2Si_4O_{14}$ and $Pb_4Al_2Si_2O_{11}$.

The X-ray analysis showed that in the case of the Pb–Sn–O/α-Al_2O_3 system the active component does

not interact with the support. Evidently, it is a result not only of the α-Al_2O_3 stability, but of its compact structure as well [11]. The latter impedes diffusion of metal ions and facilitates the uniform distribution throughout the surface of active phase.

The X-ray phase analysis revealed lead orthostannate and tin and lead oxides in the Pb–Sn–O/α-Al_2O_3 system. However, the phase ratio and the sequence of phase formation depend on the preparation procedure (Fig. 3, Table 2).

The samples based on the tin(II) compounds (samples *I*–*III*) contain lead orthostannate, in addition to tin and lead oxides. The comparison of the reflection intensities with d = 2.75 Å revealed the highest content of Pb_2SnO_4 in sample *I* (Fig. 3). Sample *V* prepared by applying to α-Al_2O_3 a mixture of $Pb(OH)_2$ and H_4SnO_4 contains trace amounts of lead metastannate.

The study of the influence of the support type and preparation procedure showed that the optimal support for the Pb–Sn–O composition is α-Al_2O_3, because it does not react chemically with the active phase. The lead–tin catalysts of the composition (wt %) Pb : Sn =

80 : 20, prepared by application to α-Al_2O_3 of a mixture of $Sn(OH)_2$ and $Pb(OH)_2$, exhibit thermal stability and stable activity in oxidative dehydrodimerization of methane [5].

CONCLUSION

The X-ray phase and thermal analyses showed formation of $PbSnO_3$ and $PbSnO_4$. The lead orthostannate phase, Pb_2SnO_4, affects the activity of the Pb–Sn–O systems. Use of SiO_2-containing supports results in the formation of the compounds $Pb_4Al_2 \cdot Si_2O_{11}$ and $Pb_3Al_2Si_4O_{14}$.

Abstract—The influence of titanium alloying with iron on the temperature dependence of the rate constants and activation energy of oxidation in air at 973–1473 K was studied.

In the previous communication [1], I reported on the kinetics of oxidation of titanium–iron alloys in air of controlled humidity at 1023–1473 K. It was found, in particular, that the rate of this process (up to 30 h) for Ti–Fe alloys (C_{Fe} = 1.5, 5.0, 10.0 wt %) is for the most part described by the Evans equation

$$K_l q^2 + K_p q = K_l K_p \tau + C',$$

where q is the mass of the gases taken up, τ is time, C' is a constant, and K_l and K_p are the rate constants of oxidation by the linear and parabolic laws, respectively.

As known [2], the fulfillment of this equation indicates that the oxidation process is nonstationary and, consequently, its rate is controlled to comparable extents by diffusion and interphase reaction. As for the question of how the iron concentration affects the temperature dependence of the rate constants of alloy oxidation and its activation energy, which are the most important characteristics of the process, it remains open. An attempt to find an answer to it is the subject of the present study performed in air at 973–1473 K.

The procedure used in the experiments with alloys of the above composition and refined titanium was described in [1].

According to the results obtained in [1], two, and occasionally more forms of the Evans equation are observed in isothermal oxidation of alloys (3 h) at above 1023 K. These forms, successively replacing one another, have different rate constants K_l and K_p. The time during which the initial form of this equation is operative may vary in the range from 15 to 30 min and more. Figure 1 shows as an example the temperature dependence of K_l and K_p for the initial and subsequent periods of oxidation of the Ti–5.0 wt % Fe alloy. Being similar in shape, these dependences are, naturally, not identical. This is mainly due to the difference in the constants K_l and K_p themselves for the mentioned stages of testing. In addition, the boundaries of some temperature zones (Fig. 1a) and also the slopes of the respective plots may be different for K_l and K_p, which points to different oxidation mechanisms in the initial and subsequent periods. In the case of pure titanium, such differences in the temperature dependences of K_l and K_p for these stages of oxidation are less significant. This fact makes difficult unambiguous interpretation of the effect of titanium alloying with iron on the temperature dependence of K_l and K_p and on the activation energy of oxidation. In principle, this effect can be assessed using data for both periods of the process, or even on the basis of averaged values of K_l and K_p. However, by virtue of the above circumstances, and also because of the discrepancy between the times of transition of the oxidation process to the second stage for different alloys and for parallel runs, it seems appropriate to use the results obtained during the initial stage of the test.

The data obtained (Fig. 2) indicate that the temperature dependence of K_l and K_p is complex and is affected by the content of iron in the alloys. This is manifested in an abrupt change in the slope of these dependences at certain temperatures. For pure titanium, this change in slope is observed for $\log K_l = f(1/T)$ at around 1173 K, and for Ti–Fe alloys this occurs twice: near 1173 (C_{Fe} = 1.5 wt %) and 1123 K (C_{Fe} = 5.0, 10.0 wt %) for the first time, and at around 1223 (C_{Fe} = 1.5, 5.0 wt %) and 1173 K (C_{Fe} = 10.0 wt %) for the second. As seen, the temperature of the first change in the slope of this dependence tends

1070-4272/02/7501-0009$27.00 © 2002 MAIK "Nauka/Interperiodica"

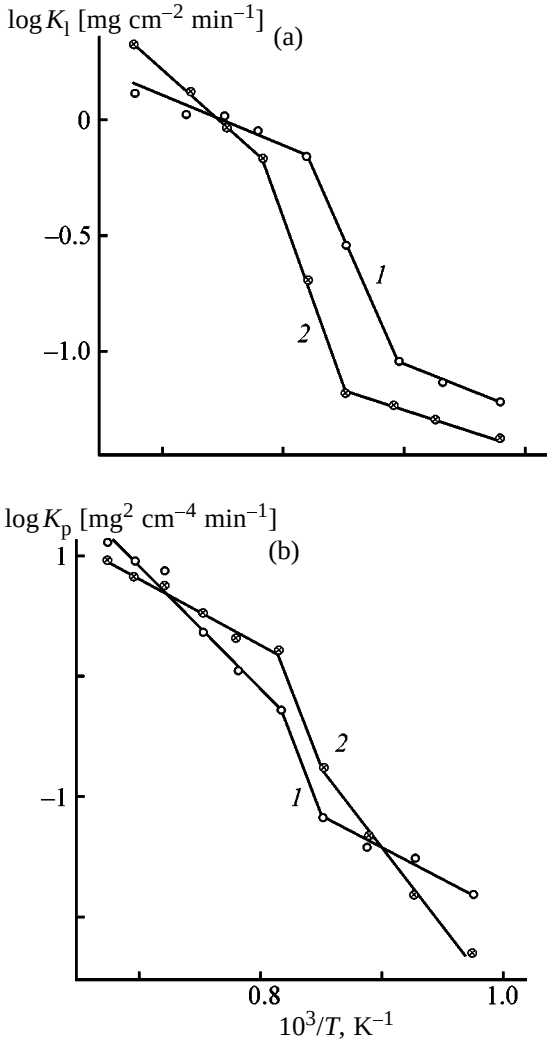

Fig. 1. Temperature dependences of (a) K_l and (b) K_p for the (*1*) initial and (*2*) supsequent oxidation periods of the Ti– 5.0 wt % Fe alloy.

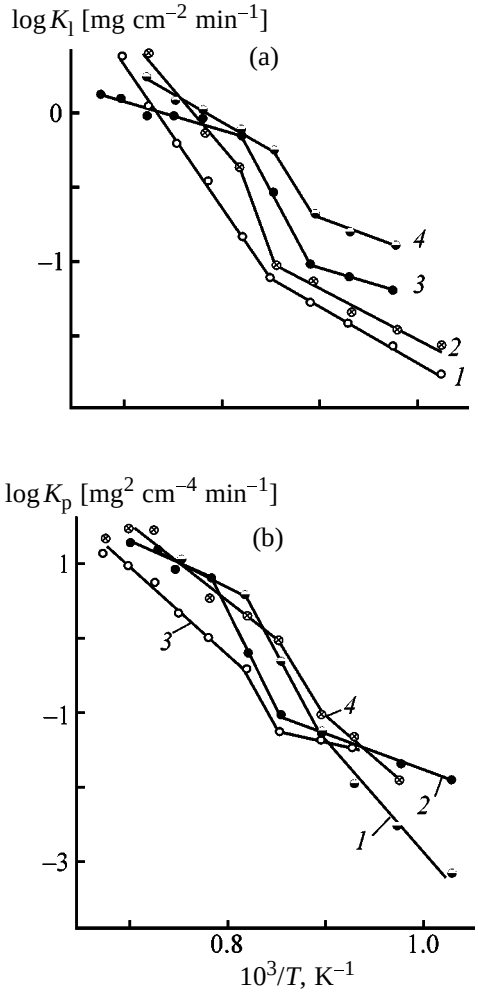

Fig. 2. Temperature dependences of (a) K_l and (b) K_p for the initial stage of oxidation of (*1*) titanium and (*2*–*4*) Ti–Fe alloys. Content of iron in alloy (wt %): (*2*) 1.5, (*3*) 5.0, and (*4*) 10.0.

to decrease with increasing C_{Fe} in the alloys. Thus, in contrast to pure titanium, alloys are characterized by the existence of a transition temperature zone 1123(1173)–1223 K, in which the temperature coefficient K_l markedly decreases with increasing C_{Fe}. In the adjacent temperature zone, the dependence of K_l on C_{Fe} is more complex.

In the interval 973–1473 K, the temperature dependence of K_p (Fig. 2b), similarly to $\log K_l = f(1/T)$, exhibits two changes in slope: at 1123 and 1223 K for titanium; and at around 1173 and 1273, 1173 and 1223, and 1123 and 1173 K for alloys with 1.5, 5.0, and 10.0 wt % Fe, respectively. In going from titanium to alloys and with increasing C_{Fe} in the alloys, the transition temperature zone shows a tendency toward narrowing. With increasing C_{Fe}, the temperature of the first change in the slope of the dependence $\log K_p = f(1/T)$ decreases, and for the second change in the slope this decrease is more pronounced. In all cases, the temperature coefficients of K_l and K_p increase at 1123 (1173) K and decrease markedly above 1223 K (Fig. 2).

Table 1 presents the apparent activation energies E (kJ mol^{-1}) of oxidation of titanium and Ti–Fe alloys by the linear (E_l) and parabolic (E_p) laws for the initial ($E_l^{(1)}$, $E_p^{(1)}$) and subsequent ($E_l^{(2)}$, $E_p^{(2)}$) periods of testing, calculated from the linear portions of the temperature dependences of K_l and K_p. The temperature intervals for each E value are given in parentheses. The errors in determining E for titanium and Ti–Fe alloys are, respectively, ±(3–5) and ±(3–7)%, respectively. Approximate values are given for the temperature zone 1123 (1173)–1223 K because of its narrow

Table 1. Effect of various factors on the apparent activation energy E of oxidation in air of titanium and its alloys with iron

width (50–100 K). The data of Tables 1 and 2 make it possible to assess the effect of temperature, titanium alloying with iron, and C_{Fe} in the alloys on E_l and E_p, and also to determine their change in going from the initial to the subsequent stage of oxidation.

The changes in the slopes of the temperature dependences of K_l and K_p (Fig. 2) and in the E_l and E_p values (Table 1) are due to changes in the mechanism of oxidation, remaining, however, nonstationary. It follows from Table 1 and Fig. 2 and from the equilibrium phase diagrams of the corresponding systems [3, 4] that the interval 1123 (1173)–1223 K with high E_l and E_p includes, or is close to, the temperature of allotropic ($\alpha \rightleftarrows \beta$) transition in the metal phase, equal to 1155 K for pure titanium. It is the ($\alpha \rightleftarrows \beta$) transition, accompanied by weakening of the interatomic bonding in the metal lattice, excitation of atoms, and acceleration of diffusion processes,

that is, presumably, the main reason for a dramatic increase in E_l and E_p at 1123 (1173) K. In the case of alloys with iron, which stabilizes the β phase, a decrease in the temperature at which the ($\alpha \rightleftarrows \beta$) transition starts to affect the oxidation process would be expected, which does not contradict the data obtained (Table 1, Fig. 2). However, the actual course of the process is complicated by the following two factors. On the one hand, absorption of oxygen, which stabilizes the α phase, by the metal exerts the opposite influence on the temperature of the ($\alpha \rightleftarrows \beta$) transition. On the other hand, the process is affected by specific features of redistribution in the metal of iron, which changes conditions and rate of the growth of the oxygen diffusion layer.

As seen from Table 2, the K_l/K_p ratio decreases with increasing temperature, at least to a certain extent, for all formulations. This indicates the increasing part played by interphase reactions in the control over the rate of nonstationary oxidation and does not contradict the existing general theories. Comparison of the data of Tables 1 and 2 and Fig. 2 shows that the zones of abrupt changes in K_l/K_p values, on the one hand, and temperature coefficients of K_l and K_p (E_l and E_p), on the other, virtually coincide. This means that the contribution of interphase reactions to the control over the oxidation rate increases to the greatest extent in the temperature interval 1123–1223 K. The reason is that the rate of diffusion processes grows in this range most abruptly, which is due, in particular, to the above-mentioned influence of the ($\alpha \rightleftarrows \beta$) transition formation in the metal phase.

In the temperature range above 1223 K, in which the second change in the temperature coefficients K_l and K_p (E_l and E_p) is observed, with the single-phase β structure being the same for all the compositions, the part played by the allotropic ($\alpha \rightleftarrows \beta$) transition in the oxidation process is, presumably, markedly diminished.

According to Table 1, the E_l and E_p values for both oxidation stages markedly increase in the interval 1123–1223 K upon alloying of titanium with 1.5 wt % iron, and steadily decrease with increasing C_{Fe} in the alloys. Outside this temperature zone, the E_l values for titanium for the initial and subsequent stages of tests ($E_l^{(1)}$, $E_l^{(2)}$) are higher than those for the alloys. The E_l value, as a rule, decreases (or remains unchanged) with C_{Fe} increasing from 1.5 to 5.0 wt %, and increases noticeably on passing to C_{Fe} = 10.0 wt %. A decrease in $E_p^{(1)}$ upon alloying of titanium with iron is only observed in the interval 973–1173 K, whereas at 1223–1373 (1473) K the trend is opposite. At the same time, the dependence of $E_p^{(1)}$ and $E_p^{(2)}$ on C_{Fe} in allows shows no regular behavior, in contrast to E_l. In the interval 973–1173 K, alloys with 1.5 and 5.0 wt % iron have virtually coinciding values of $E_p^{(1)}$ and $E_p^{(2)}$.

Thus, according to Table 1, E_l and E_p are the highest in the intermediate temperature zone 1123 (1173)–1223 K. At higher temperatures, the E_l value much exceeds that in the interval 973 (1023)–1123 (1173) K for all the formulations. In the case of alloys, the temperature dependence of $E_p^{(1)}$ is similar, in contrast to $E_p^{(1)}$ for titanium, which is much lower above 123 K than that in the interval 973–1173 K. At the same time, the $E_p^{(2)}$ value markedly decreases in going from 973 (1023)–1173 K to temperatures higher than 1223 K.

The change in the activation energy of oxidation in going from titanium to Ti–Fe alloys and with increasing C_{Fe} in the corresponding temperature zones is presumably accounted for, among other factors, by a decrease in the chemical bonding strength in the titanium lattice upon its alloying with iron [5], which stabilizes the β phase, and by an increase in the role of cation diffusion in scale formation as a result of incorporation into the rutile lattice of iron ions having lower charge than titanium ions. With increasing C_{Fe}, the composition and structure of the oxide film and the gas-saturated zone of the metal change as a result of metal redistribution in oxidation under the action of absorbed oxygen stabilizing the α phase with exceedingly low solubility of iron. This leads to an increase in the iron concentration in the β phase and enrichment with iron of the metal–scale interface [1, 6, 7], which markedly changes the conditions of titanium and oxygen transport across the interface.

The established dependence of $E_l^{(1)}$ on temperature and material composition may be due, in particular, to a change in the degree of delocalization of the chemical reaction front, e.g., by an increase in the part played by processes occurring by a different mechanism at the oxide–gas interface as a result of increasing concentration of cationic defects in the scale under the action of temperature rise and iron dissolution in the rutile lattice. The results obtained for the initial stage of alloy oxidation (Table 1) do not contradict the concept that the part played in scale formation by bulk diffusion characterized by high energy consumption, compared with intercrystallite diffusion, becomes more important with increasing temperature. The disagreement with this concept of the data for titanium and, during the second stage of oxidation, for all

formulations indicates the existence of other factors of opposite action. To these can be assigned, e.g., increasing total, or fraction of open, porosity of the oxide film with growing temperature, resulting in more important role of surface and, possibly, even gas diffusion.

According to Table 1, transition from the initial to the subsequent stage of oxidation for all formulations in the interval 973 (1023)–1373 (1473) K is accompanied in most cases by a decrease in E_l, even though differences in its values are frequently within the experimental error, i.e., $E_l^{(1)} \geq E_l^{(2)}$. In the case of a parabolic law of titanium oxidation, the E_p value markedly decreases in going from the initial to the second stage at 973–1073 K, and remains virtually unchanged above 1123 K. It was found in tests with Ti–Fe alloys in the temperature range 973–1373 (1473) K that, with few exceptions, $E_p^{(1)} < E_p^{(2)}$.

Since the decrease in K_l/K_p in going from the initial to subsequent stage of oxidation occurs through decrease in K_l and increase in K_p [1], it may be assumed that one of the reasons for this transition is the increase in the diffusion permeability of the oxide film as a result of, e.g., local disruptions of its continuity. This presumably causes the corresponding change in the mechanisms of the interphase reaction and diffusion processes and, consequently, in their activation energy.

Because of the lack of the necessary data, it is hardly appropriate to attempt to make any deeper interpretation of the obtained results concerning the dependence of E_l and E_p on various factors. Solving this problem requires additional special-purpose investigations.

CONCLUSIONS

(1) The temperature dependence of the linear and parabolic rate constants of nonstationary oxidation in air of Ti–Fe (1.5, 5.0, 10.0 wt %) alloys in the temperature interval 973–1473 K changes its slope twice: at around 1123 (1173) and at 1223 K, with the temperature of the first change becoming lower with increasing C_{Fe}. In titanium oxidation, a similar behavior is observed for $\log K_p = f(1/T)$, with a single change in the temperature coefficient K_l at around 1173 K.

(2) In titanium alloying with iron up to 5.0 wt %, the activation energy of oxidation in the interval 1123 (1173)–1223 K increases, and at C_{Fe} = 10.0 wt % decreases somewhat or remains virtually unchanged. Outside this temperature zone, E_l and E_p for the initial stage of oxidation decrease upon introduction into titanium of 1.5–10.0 wt % iron, with the exception of $E_p^{(1)}$ at 1223–1373 K.

(3) With C_{Fe} increasing from 1.5 to 10.0 wt %, the E_l and E_p values for both stages of oxidation decrease steadily in the interval 1123 (1173)–1223 K. Outside this region, E_l decreases or remains constant in going from 1.5 to 5.0 wt % iron, and, with C_{Fe} increasing to 10.0 wt %, grows. The dependence of E_p on C_{Fe} is more complex.

(4) The E_l and E_p values are the highest for all the formulations in the temperature interval 1123 (1173)–1223 K. At T > 1223 K, the E_l value for the initial stage of oxidation for titanium and the alloys, and E_p only for the alloys, are much higher than those in the region below 1123 (1173) K, whereas in the case of titanium, an inverse dependence is observed for E_p.

(5) In the interval 973 (1023)–1373 (1473) K, in a transition from the initial to the subsequent stage of oxidation, $E_l^{(1)} \geq E_l^{(2)}$ for most of formulations, and $E_p^{(1)} < E_p^{(2)}$ for alloys and $E_p^{(1)} \geq E_p^{(2)}$ for titanium.

Abstract—Barium sulfate, which is recycled according to a new flowsheet of sodium sulfide production, was reduced by various carbon-containing materials (oil and furnace coke and Zh-grade coal). The reduction process was studied in comparison with the reduction of natural barite concentrate.

Sodium sulfide used in concentration of nonferrous metal ores, dyeing of fabrics, dressing of leather, and also in production of dyes, soda products, cellulose, and glass is presently produced in Russia by the reduction of packaged sodium sulfate by furnace coke in shaft furnaces [1]. This process is now out of date; it does not meet modern requirements to the environmental protection and to the product quality and is characterized by low utilization of the raw material.

A new low-waste technology is based on obtaining sodium sulfide by the reaction [2, 3]

$$BaS + Na_2SO_4 = BaSO_4 + Na_2S. \quad (1)$$

Barium sulfide is regenerated by reductive roasting of the forming barium sulfate, and, therefore, a barium raw material theoretically is not consumed, and only its loss should be replenished. The reductive roasting of natural barite raw material is widely used in industrial production of barium salts.

The regeneration of barium sulfide is a key stage of the new process; therefore, we have carried out laboratory studies with the aim to reveal features of the reduction of barium sulfate formed by reaction (1) with various reducing agents (oil and furnace coke and Zh-grade coal).

The reduction of barium sulfate with carbon has been described in sufficient detail [4–8]. According to modern views, this process involves stages of solid carbon gasification (2) and barium sulfate reduction (3)

$$C + CO_2 = 2CO, \quad (2)$$

$$BaSO_4 + 4CO = BaS + 4CO_2. \quad (3)$$

The overall process is expressed by the total reaction

$$BaSO_4 + 2C = BaS + 2CO_2. \quad (4)$$

The following reactions yielding acid-soluble barium compounds occur concurrently:

$$BaSO_4 + SiO_2 + C = BaSiO_3 + SO_2 + CO, \quad (5)$$

$$BaS + CO_2 + H_2O = BaCO_3 + H_2S. \quad (6)$$

It is noted [9] that the reduction of barium sulfate is intensified as soon as the first particles of barium sulfide are formed, as they catalyze the process similarly to calcium and sodium sulfides in the case of the reduction of sulfates of these metals.

EXPERIMENTAL

To obtain a comparative pattern, we have carried out experiments with charges containing either barite concentrate (BC) or recycled barium sulfate, with reducing agent dosages being 125 and 155% of the stoichiometric amount according to Eq. (4).

The chemical compositions of the raw materials are given in Table 1. The dispersity of all the components was 0.25 mm.

Reductive roasting of charges was carried out under static conditions in a muffle at 1000°C for 30 min in alundum crucibles closed by lids. These conditions suppress the secondary reactions of barium sulfide carbonation and oxidation, and also prevent burning-out of carbon-containing materials. The resulting melt was cooled in a desiccator and analyzed. We determined the content of BaS and BaS_2O_3 by iodometric titration, of water-soluble (ws) and acid-

soluble (as) barium and calcium compounds (in terms of BaS_{ws}, CaS_{ws} and BaS_{cr}, CaS_{cr}, respectively) by complexometric titration, and of the water-insoluble residue (carbon), gravimetrically.

From the chemical analysis data we calculated the degree of $BaSO_4$ reduction η_1 and the degree of $BaSO_4$ conversion to BaS η_2 by the formulas

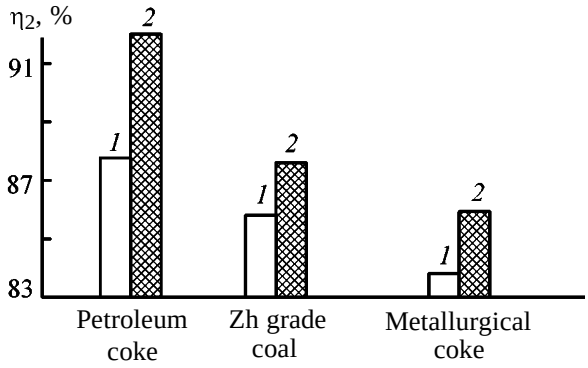
$$\eta_1 = \frac{(m_{ch}BaSO_{4ch} - m_f BaSO_{4f}) \times 100}{m_{ch}BaSO_{4ch}},$$

$$\eta_2 = \frac{1.3778 m_{ch}BaS_{ch} \times 100}{m_{ch}BaSO_{4ch}},$$

where m_{ch} is the charge weight (g); m_f is the weight of the fused barium sulfide product (g); $BaSO_{4ch}$, $BaSO_{4f}$, and BaS_f are contents of barium sulfate in the charge and in the fused product and of barium sulfide in the fused product, respectively (wt %); 1.3778 is the scaling ratio for the conversion from BaS to $BaSO_4$.

The experimental data are given in Table 2, each result being an average of two parallel experiments.

A criterion for estimating the optimal dosage of the reducing agent was the quality of the resulting fused barium sulfide product. We found that a better quality of the fused product was reached with barite concen-



Degree of $BaSO_4$ conversion to BaS η_2 at 125% dosage of the reducing agent in the charge. (*1*) Barium concentrate and (*2*) recycled $BaSO_4$.

trate (run nos. 1, 3, 5) and with recycled barium sulfate (run nos. 7, 9, 11) at a 125% dosage (against the stoichiometry) of any of the tested reducing agents. Therefore, this dosage is preferential for the stationary roasting conditions.

Comparing the activity of the reducing agents at their optimal dosage in the chage, we see that all the tested carbon-containing materials are highly reactive, as the degree of the $BaSO_4$ reduction is 95.09–100.00% (Table 2). A low degree of the $BaSO_4$ reduction (85.19 and 85.86%) at an elevated dosage of furnace coke and Zh-grade coal (155%) is attributable to the fact that, as carbon is gasified, the surface of barium sulfate grains is screened to a greater degree by the ash residue of the reducing agent, which hampers the contact of $BaSO_4$ with carbon(II) oxide. However, of practical interest for the new procedure of sodium sulfide production is the degree η_2 of the $BaSO_4$ conversion to BaS, as barium sulfide is the supplier of S^{2-} ions into the final product Na_2S; therefore, it makes sense to estimate the activity of the reducing agent by η_2. As seen from the figure, petroleum coke is the best reducing agent for both the barite concentrate and recycled barium sulfate, probably owing to sulfiding action of sulfur contained in petroleum coke, for example, by the reaction

$$2BaCO_3 + 2S + C = 2BaS + 3CO_2. \quad (7)$$

Furthermore, petroleum coke belongs to low-ash reducing agents, so that the contents of water-insoluble impurities in the fused barium sulfide product is less than 0.7%, i.e., four times less than in the fused product obtained by the reduction with furnace coke and Zh-grade coal and almost ten times less than in the fused product obtained from the barite concentrate reduced with petroleum coke. Such a product does not require additional labor-consuming operations for removing water-insoluble impurities, which considerably simplifies the flowsheet of sodium sulfide production.

Examination of the data obtained shows that recycled barium sulfate is more effectively reduced than the barite concentrate, which may be due to the fact that freshly precipitated barium sulfate, owing to its high dispersity, is more active than natural barium sulfate. Thus, we have found experimentally that with petroleum coke used for the reduction of barium sulfate it is possible to obtain high-quality fusedf barium sulfide product at rather high utilization of the raw material and a high degree of conversion of barium sulfate to sulfide.

The data of laboratory experiments on the reductive roasting of a charge with petroleum coke as a reducing agent were confirmed by semicommercial tests. A charge (16.4 t) was reduced in a rotary kiln with a volume of 14 m^3 at a specific charge load of 35 kg m^{-3} h^{-1}. The content of BaS_{ws} in the fused product reached 63.4–64.6% at 96.20% conversion of $BaSO_4$ to BaS_{ws}, which is at a level of parameters of industrial production of barium salts.

It should be noted that unchanged reducing agent is recycled together with barium sulfate, which provides its full utilization.

The use of petroleum coke as a reducing agent simultaneously solves the problem of the utilization of coal breakage, which is formed as a waste of the production of lump electrode petroleum coke, and owing to its low ash residue the sodium sulfide production becomes virtually wasteless.

CONCLUSIONS

(1) All the tested carbon-containing reducing agents (petroleum coke, Zh-grade coal, and furnace coke) have a high reducing power with respect to barium sulfate. The reducing agent is taken in an amount of 125% relative to the stoichiometry of Eq. (4). The best reducing agent for barium sulfate is petroleum coke, as proved by semicommercial tests.

(2) The reductive roasting of recycled barium sulfate has no principal differences from the industrial roasting of barite concentrate with petroleum coke as reducing agent. Therefore, its flowsheet and equipment can be utilized without changes in the new procedure for producing sodium sulfide, which ensures its high reliability.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Additions of Silica Gel and Certain Salts of Inorganic Acids on Corrosion Resistance of Cement Stone

V. E. Akhrimenko

Kuban State Agricultural University, Krasnodar, Russia

Received April 28, 2001

Abstract—Effect of additions of silica gel and certain salts on the rheological parameters of cement mortar and corrosion resistance of cement stone was considered.

Building of ports, docks, and breakwaters and also of oil and gas wells requires cement mortars forming corrosion-resistant cement stone on hardening.

The aim of this work was to study the effect of additions of silica gel and salts of inorganic acids on the corrosion resistance of cement stones. We used oil-well portland cement for cold wells produced by Oktyabr' Plant (Novorossiisk) and silica gel produced by Azot Production Association (Nevinnomyssk) [1].

As the chemical treatment of grouting mortars is the main means of the control over their process parameters (flowing, setting time, and sedimentation stability), we determined the properties of cement mortars along with the corrosion resistance of cement stones.

EXPERIMENTAL

We studied cement stone corrosion by keeping stone samples in the chosen aggressive solutions under conditions the most closely simulating the actual operation conditions of a cement stone in a well.

As aggressive media we used 50 g l^{-1} solutions of sodium and magnesium chlorides and sulfates, which corresponds to highly mineralized stratal waters. In tempering liquids for cementing agents under study the salt content was the same.

Cement mortars were prepared by thorough mixing of cement with silica gel and by tempering this mixture with drinking water or salt solutions. The resulting cement mortars were tested according to the procedure in [2] and GOST (State Standard) 26798.2–85.

We molded cement beams from cement mortars. For this purpose we filled with cement mortar metallic molds ($20 \times 20 \times 100$ mm), placed them in a desiccator with drinking water, and left to harden at $20 \pm 2°C$.

After hardening for two days, cement beams were taken from the molds, marked, and placed in a bath with drinking water or salt solutions for 7, 14, 28, and 90 days. On completion of hardening terms, the cement samples were taken from the baths, and their compression strength was determined. The results (average of three experiments) are given in Table 1.

These experiments have shown (Table 1) that a cement with silica gel added is more sedimentation-stable; the water separation of such a solution is four times less than that of a mortar solution without silica gel.

As fluid-conducting channels, which are responsible for interstratal crossflows, arise in the cement stone structure in the course of hardening of a sedimentation-unstable cement mortar, it was necessary first of all to obtain a sedimentation-stable cement mortar.

It follows from Table 1 that the addition of silica gel to a cement mortar considerably accelerates structure formation, which reduces the setting time of the cement mortar. The cement mortar with sodium sulfate as a tempering liquid starts to set in 8 h 50 min, whereas the same cement mortar containing silica gel starts to set in 3 h 20 min.

The capacity of silica gel to accelerate the hydration is probably due to taking up a considerable part of a free tempering liquid, so that the fluid phase becomes oversaturated with respect to calcium hydrosilicates, which accelerates their separation from the solution. The precipitated calcium hydrosilicates act

* Hardening in drinking water at 20±2°C.

as crystallization nuclei for new hydrate formations, intensifying structure formation in cementing systems.

To make more descriptive the effect of salts on the corrosion resistance of the cement stone, we determined the factor of cement corrosion resistance (CR), which represents the ratio of the average ultimate compression strength of the cement stone C_1 after keeping samples in an aggressive medium for 3 month to the average ultimate compression strength C_2 of cement beams made of the same cement after hardening for 3 months in drinking water.

Our experiments have shown that in all cases the additions of salts to a cement increase the strength of the cement stone both at the beginning of hardening and after three-month aging. It follows from Table 1 that the additions enhance the corrosion resistance of the cement stones obtained from both pure portland cement and from portland cement with silica gel added.

Table 1 shows that from the beginning of hardening up to 28 days the strength of the cement stone obtained from oil-well portland cement increases most intensively. The strength of the cement stone of portland cement with silica gel added increases slowly at the beginning of hardening and more actively after 14-day hardening.

Our data indicate that the strength of the cement stone of portland cement and of portland cement with silica gel added increases in the medium of sodium chloride and sodium sulfate, respectively. The experiments show that within the 90-day observation period the strength of the cement stone is not affected by leaching corrosion, and the addition of sodium chloride further enhances the cement stone resistance against this kind of corrosion. The strength of cement stone samples hardened in water and tempered with water was 50.0 MPa after 3 months. The cement stone strength reached 51.27 MPa for cement stone samples tempered and hardened in a sodium chloride solution.

As for sodium sulfate, hardening of a cement stone without additions in its solution is accompanied by a decrease in the corrosion resistance factor (CR = 0.87) as compared to control samples hardened in drinking water (CR = 0.96).

The main reason for the degradation of cement stone in a solution of sodium sulfate is the reaction of Na_2SO_4 with unchanged calcium aluminate $3CaO \cdot Al_2O_3$ and calcium hydroxide $Ca(OH)_2$ with the formation of ettringite $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O$, which increases in volume by a factor of 2.5 on crystallization and destroys the cement stone.

When sodium sulfate is added to tempering water, a reverse pattern (CR = 0.94) is observed. This may be due to the fact that the main amount of gypsum contained in the cement was bonded in ettringite in the beginning of hardening before a rigid inductile structure of the cement grout is formed, which is of importance for the subsequent formation of stable cement stone in sulfate solutions.

Table 2. Effect of salt additions on the corrosion resistance of cement stone after hardening for 3 months

Cementing agent	Series no.	Tempering solution	Hardening medium	Ultimate compressing strength, MPa		CR
				in aggressive medium	in drinking water

	2.5	H_2O	$MgCl_2$	40.15	46.88	0.856
	2.6	$MgCl_2$	$MgCl_2$	41.73	47.03	0.887
	2.7	H_2O	$MgSO_4$	45.83	46.88	0.977
	2.8	$MgSO_4$	$MgSO_4$	46.27	46.54	0.953

The greater fraction of the initially present aluminates will be chemically bound in the initial hardening stage, the more resistant will be the cement stone later on. Furthermore, the addition of sodium sulfate increases the solubility and hydrolysis of cement silicate components by binding the hydrolysis product [$Ca(OH)_2$] in a sparingly soluble compound and thus accelerates the formation of low-basic silicates, which are mainly responsible for the cement stone strength. The introduction of sodium sulfate in tempering water for a portland cement with a silica gel addition increases the corrosion resistance of the cement stone: in the first case CR = 0.96 and in second, 1.04 (Table 2).

Our experiments have shown that the portland cement with an addition of silica gel forms a cement stone more resistant against sulfates than the portland cement stone without silica gel, which agrees with the data of [3]. The added silica gel reacts with portland cement lime and converts it to difficultly soluble calcium silicates.

The effect of added magnesium salts on the hardening rate of cement stones prepared from cements with and without silica gel can be seen in Table 1, which shows that the addition of magnesium salts to a cement mortar considerably reduces its setting time. Pure portland cement and the cement with silica gel added, both tempered with water, start to set in 9 h and in 5 h 40 min, whereas the same cements tempered with an $MgSO_4$ solution start to set in 6 h 30 min and 3 h 35 min, respectively.

The reduction in the setting time of cement mortars also affects the early strength of the cement stone, which somewhat increases in the case of the cement stone containing magnesium salts. Later on the strength parameters of the cement stone decrease owing to magnesia corrosion.

Magnesium hydroxide formed in the reaction of $MgCl_2$ with cement $Ca(OH)_2$ precipitates in the initial stage of the hardening, fills vug holes in the pore space of a cement stone, and thus compacts its structure, which enhances its corrosion resistance.

In time the amount of soluble lime becomes insufficient to neutralize $MgCl_2$, which arrives from a storage medium to the cement stone surface and diffuses into the depth of its structure. Then $MgCl_2$ destroys the cement stone structure by reacting with calcium silicate and other hydrates that form this structure.

In solutions of magnesium chloride and sulfate the cement stone of pure portland cement is destroyed faster (CR = 0.753) than the cement stone of oil-well cement with silica gel added (CR = 0.856), which is probably due to the mudding action of finely dispersed silica gel on the pore space and thus to general compaction of the cement stone structure.

The introduction of magnesium salts in a tempering solution increases the corrosion resistance of the

cement stone for both portland cement (CR = 0.785) and portland cement with silica gel added (CR = 0.887), apparently at the expense of the equalization of salt concentrations in the pore space of the cement stone and in stratal water. This results in suppression of osmotic processes and consequently in decreased permeability of the cement stone, which suppresses the destructive processes.

Thus, we showed that salts contained in stratal waters or silica gel should be added to a cement mortar to increase the corrosion resistance of the cement stone when wells drilled in saline horizons are cemented.

CONCLUSIONS

(1) The effect of silica gel and certain salts of mineral acids on the corrosion resistance of cement stone was studied.

(2) Silica gel affects the sedimentation stability of cement mortar and the kinetics of its hardening.

(3) Addition of silica gel to a cement mortar increases the corrosion resistance of the cement stone.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Equilibrium Composition of Formaldehyde Oligomers in Aqueous Solutions from IR Data

R. S. Ryabova, G. I. Voloshenko, V. D. Maiorov, and G. F. Osipova

Semenov Institute of Chemical Physics, Russian Academy of Sciences, Moscow, Russia

Received April 16, 2001

Abstract—The complex band of formaldehyde at 950–1150 cm^{-1} in the IR spectrum of its aqueous solutions was resolved into individual bands by computer analysis. The calculated band intensities were compared with known concentrations of monomeric, dimeric, and trimeric formaldehyde species. The IR data are consistent with the published NMR data.

To establish the mechanism of the reaction of formaldehyde (FA) with various reagents in aqueous solutions, it is necessary to know the equilibrium composition of its oligomers. When dissolved in water, gaseous FA forms methylene glycol (MG), $HOCH_2OH$ [1]. The ^{13}C NMR study of FA aqueous solutions at various FA concentrations [2, 3] showed that MG easily oligomerizes to form hydrated FA polymers $HO(CH_2O)_nH$. Botlan *et al*. [2] determined the per cent content of oligomers in formaldehyde units within a fairly wide interval of FA concentrations (0.5–50 wt %) at 30°C. Data of [2, 3] on the equilibrium composition of oligomers show that the concentration of the monomer $HOCH_2OH$ decreases and the concentrations of oligomers $HO(CH_2O)_nH$ with n = 2–6 increase, as the FA content in the solution is increased.

The goal of this work is to analyze the IR spectra of the FA aqueous solutions and to assign the bands to the individual FA oligomers.

EXPERIMENTAL

Aqueous solutions of FA were prepared by the method in [3]. The data of [2, 3] were used to calculate the molar composition of oligomers (Table 1).

The IR spectra were recorded in the 900–1200 cm^{-1} range on a UR-20 spectrophotometer equipped with a multiple attenuated total internal reflection (MATIR) device [4]. The Ge prism with a 30° incidence angle and 8 reflections was used. The solution was placed into Teflon cavities adjoining to prism facets. The effective thickness of the absorption layer at 2000 cm^{-1} was 3.72 μm. The spectra of 6–25 wt % FA solutions were obtained at 30°C.

The IR spectra were treated by a universal program for treatment of spectra (UPTS) [5] based on the method of differential moments. To determine the number of bands, plots of the second derivatives for the complete series of the spectra were analyzed. The peak was assumed to be existing when the corresponding minimum occurred in all the plots. Then the number of bands was fixed and their position, width, and shape characteristics were varied [5]. When any parameter was the same for all the series of the spectra, its average value was used. When the band width and location varied noticeably (> 5% for width) and monotonically, it was assumed that the band consists of two peaks with parameters differently depending of the solution composition, and, correspondingly, one more band was considered. To describe the contours of spectra of eight solutions, the minimum possible number of bands was 5. It is impossible to describe the spectra of the series considered using the smaller number of bands under the condition of the constancy of the band parameters [spectral location, width, and contour (Gaussian, Lorentzian, or mixed)].

The final treatment of the series of spectra included only variation of the band optical density D. The solution becomes stable when independent calculations for each of eight solutions at the constant number of bands give the set of the constant parameters. Therewith, the calculated optical densities form smooth curves, and the calculation results are independent of the initial values of the optical densities assigned. The accuracy of the results was checked both by the root-mean-square deviations for the experimental and

* M, D, T_3, and T_4 are monomer, dimer, trimer, and tetramer of FA, respectively.
** The concentrations of oligomers determined in this work are given in parentheses.

simulated spectra and directly by the difference between these spectra, which was plotted. As a rule, deviations were no more than 5%.

The result of the computer analysis of one of the spectra studied is shown in Fig. 1. The following set of bands was obtained: 992, 1026, 1050, 1072, and 1100 cm^{-1}. The band intensities are listed in Table 2.

According to [2, 3], FA exists in aqueous solutions as a mixture of monomer (n = 1) and polymers (n > 2).

The bands observed in the examined 900–1200 cm^{-1} range correspond to the stretching vibrations of the C–O bonds in the C–O–H groups of the monomer and polymers and in C–O–C bridges of polymers [6]. The experimental spectrum is the contour consisting of several overlapped bands. This contour changes as the FA content in the solution is varied. This reveals the bands belonging to different oligomers.

The intensity of the strongest band at 1026 cm^{-1} is proportional to the FA concentration up to 7.8 M (Fig. 2), i.e., this band is the sum of bands of FA oligomers. The band at 1050 cm^{-1} can be assigned to the FA monomer. Its intensity is proportional to the monomer concentration determined in [2] up to 7.8 M FA (Fig. 3). At an FA concentration of 9.1 M, the intensity of this band increases in spite of decrease in the monomer concentration [2] (Table 1). Deviation from the linearity of the plot of I_{1050} vs. monomer concentration can be caused by inaccurate determination of the latter in [2]. It follows from Fig. 3 that the monomer concentration in the most concentrated solution of FA is underestimated by about 0.5 M. At c^0_{FA} = 25 wt %, it should be 3.4 ± 0.3 M.

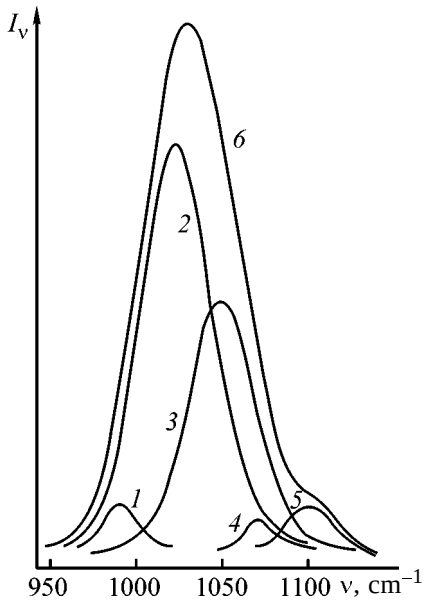

Fig. 1. IR spectrum of FA aqueous solution (c_{FA} = 14.47 wt %) resolved into individual bands: (*1*) intensity and (ν) frequency. ν (cm^{-1}): (*1*) 992, (*2*) 1026, (*3*) 1050, (*4*) 1072, and (*5*) 1100; (*6*) initial experimental spectrum.

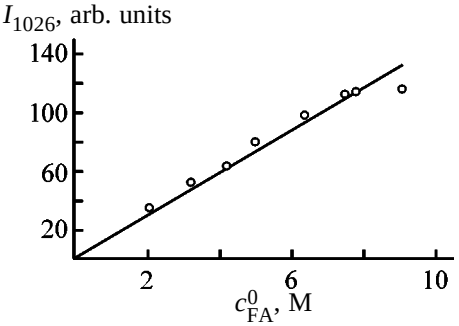

Fig. 2. Intensity of the band at 1026 cm^{-1}, I_{1026} as a function of the initial FA concentration, c^0_{FA}.

Table 2. Intensities I_ν of constituent bands in the IR spectra, calculated by computer analysis

c^0_{FA}, M	I_ν, arb. units, for indicated ν, cm^{-1}				
	992	1026	1050	1072	1100
2.07	1.6	35.0	12.0	2.0	3.7
3.2	2.0	52.0	37.0	2.0	4.4
4.2	3.5	64.0	41.0	6.7	6.0
5.0	9.4	80.0	50.0	7.0	7.9
6.4	11.6	98.0	53.0	12.0	8.7
7.5	18.2	112.0	60.0	12.0	11.4
7.8	25.2	114.0	62.0	17.9	14.0
9.1	26.3	115.9	66.0	17.3	16.0

The band at 1072 cm^{-1} was assigned to the dimer (Fig. 4). The intensity of this band well correlates with the dimer concentration determined in [2]. However, the intensity of this band increases faster than the dimer concentration. The refined values of the dimer concentration are listed in Table 1.

The intensity of the band at 1100 cm^{-1} well correlates with the concentration of the trimer (T_3)

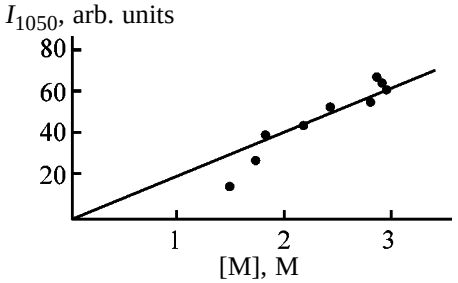

Fig. 3. Intensity of the band at 1050 cm^{-1}, I_{1050} as a function of the FA monomer concentration, [M].

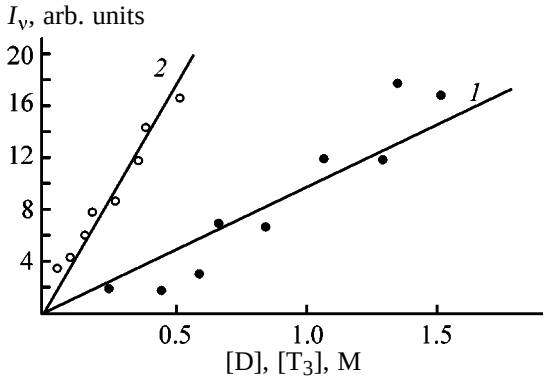

Fig. 4. Intensities of the absorption bands I_ν as functions of concentrations of (*1*) dimer, [D] and (*2*) trimer, [T_3]. ν (cm^{-1}): (*1*) 1072 and (*2*) 1100.

(Fig. 4). It follows from Table 1 that the trimer content in the 9.1 M FA solution is overestimated by about 0.05 M (Table 1). The band belonging to the tetramer was not found, probably because of its low concentration within the FA concentration range studied.

The intensity of the band at 992 cm^{-1} rapidly increases in concentrated FA solutions. This shows that it belongs to FA polymers. However, the variation of the band intensity shows no correlation with the concentration of any of the above oligomers. Probably this band reflects the existence of dimers, trimers, and other polymers with different absorption coefficients.

CONCLUSIONS

(1) The IR spectra of aqueous solutions of formaldehyde (6–25 wt %, 30°C) within the 900–1200 cm^{-1} range were resolved into the individual components.

(2) The component bands were assigned to separate formaldehyde oligomers.

(3) The oligomer concentrations measured using ^{13}C NMR agree with the intensities of the bands assigned to separate oligomers. The concentrations of formaldehyde oligomers were refined on the basis of the IR spectroscopic data obtained.

ACKNOWLEDGMENTS

The authors are indebted to A.P. Kucherov for submitting the UPTS program for treatment of the complex spectra.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermal Behavior of Aluminum Trialkyls

A. K. Baev and M. A. Shishko

Belarussian State Technological University, Minsk, Belarus

Received September 19, 2000; in final form, October 2001

Abstract—Thermal behavior of tributylaluminum at 273–475 K under static conditions was studied. The composition of the gaseous thermolysis products was determined.

Aluminum trialkyls are used in organic synthesis as catalysts or alkylating agents. To optimize conditions of their industrial production, thermodynamic parameters of these compounds should be determined. Among all aluminum trialkyls used in practice, reliable thermodynamic parameters were obtained only for $AlMe_3$ and $AlEt_3$ [1, 2]. The thermodynamic data for other aluminum trialkyls [3–7] are contradictory. The vaporization parameters of $AlBu_3$ are confined to the ethalpy of vaporization (66.6 kJ mol^{-1}) referred to the boiling point under normal conditions [8]. The determination method is not reported. Spontaneous reversible dissociation of aluminum trialkyls [9] and exchange of their alkyl groups are frequently ignored when these compounds are used for synthetic purposes. However, the following reaction is possible [9]:

$$AlAlk_3 \rightleftarrows AlHAlk_2 + C_nH_{2n}.$$

This reaction of $AlEt_3$ was studied for the first time in our previous work [10]. The thermodynamic parameters of the components and of the process as a whole were determined. The equilibrium also involves condensation processes such as

$$(AlAlk_3)_2(l) \rightleftarrows Alk_2AlHAlAlk_3(l) + C_nH_{2n}.$$

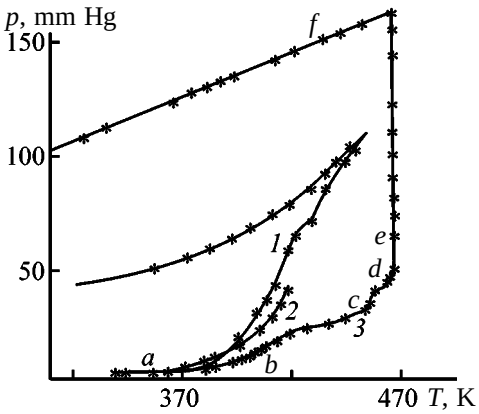
At 453 K, 85.6% of $AlBu_3$ is decomposed [11]. The sample contains the following compounds (mol %): $AlBu_2H$ (38.4), $AlBu_3$ (13.4), $AlBu_2$(*i*-Oct) (13.7), hydrocarbons (34.5) including *n*-C_4H_8 (25.5), *i*-C_8H_{16} (4.9), *n*-C_8H_{18} (2.0), and also H_2 (2.5).

The discrepancy in the thermodynamic parameters of aluminum trialkyls, obtained by different authors, is due to the above processes. In this work we studied equilibrium vaporization, dissociation, and thermolysis of $AlBu_3$, $AlPr_3$, and $AlEt_3$.

EXPERIMENTAL

Thermal behavior of tributylaluminum under static conditions was studied with a membrane zero gage [10]. The $p = f(T)$ dependence for three $AlBu_3$ samples with different volume concentrations is shown in the figure. The slope of the *p*–*T* curve and the total pressure depend on the initial amount of the sample.

The dependence of the slope on the $AlBu_3$ concentration in the chamber confirms dissociation of the compound. Since the reverse process is hindered, the heating and cooling curves differ (curves *1*, *2*). However, after cooling of the system with liquid nitrogen and prolonged keeping at a definite temperature the vapor pressure is reproduced, which indicates that the $AlBu_3$ dissociation is reversible. A large difference in the vapor pressures of a freshly prepared sample and a sample distilled into the gage chamber at a high



p–*T* diagram of tributylaluminum at 320–471 K with formation of unsaturated vapor. (*1*–*3*) samples differ in the volume concentration: $m_1v_1 > m_2v_2 > m_3v_3$: (*a*) Equilibrium vaporization; (*b*) vaporization with decomposition; (*c*) reversible thermolysis; (*d*, *e*) irreversible thermolysis of $AlHBu_2$; and (*f*) gas expansion.

volume concentration indicates partial dissociation of $AlBu_3$ during distillation to form more volatile products. On the contrary, the equilibrium vapor pressures of the samples kept for a prolonged period at a definite temperature in the range 340–390 K (curves *1–3*) are similar. However, at higher temperatures the reproducibility of the *p–T* curve on heating and on cooling, on the one hand, and the dependence of the slope of these curves on the concentration of the sample in the chamber, on the other hand, confirm equilibrium dissociation of $AlBu_3$. The temperature dependence of the vapor pressure of $AlBu_3$ up to the onset of its thermal dissociation (383 K, section *a*) [8] is reversible and reproducible within the limits of the experimental error. The vapor pressure in the chamber does not exceed 5 mm Hg. The processes occurring at 383–458 K (section *b*) are also reversible. At temperatures higher than 471 K $AlBu_3$ decomposes irreversibly (sections *d, e*) to form a gray deposit (probably metallic aluminum) on the chamber walls. Chromatographic analysis showed that the main gaseous thermolysis products are (mol %) unsaturated hydrocarbons 1-butene (32.8), *trans*-2-butene (23.4), *cis*-2-butene (11.2), and hydrogen (30.9). Methane (0.9 mol %), ethane and ethylene (0.4 mol %), and propane and propylene (0.2 mol %) were also detected.

Based on these results and the concept of equilibrium decomposition of $AlAlk_3$ [9], $AlBu_3$ dissociation can be described by a series of consecutive or consecutive-parallel steps. Up to the onset of the decomposition (320 K, section *a*) dimeric and monomeric $AlBu_3$ molecules vaporize. At 320–433 K (section *b*) vaporization is accompanied by $AlBu_3$ dissociation. The reproducibility of the *p–T* curves obtained on heating and on cooling indicates that these processes are reversible. Occurrence of all these processes is indicated by the dependence of the slope of the *p–T* curves on the $AlBu_3$ concentration in the chamber. A change in the initial concentration affects mainly the dissociation

$$AlBu_3 \rightleftarrows AlHBu_2 + C_4H_8.$$

On heating above 433 K (curve *3*), all liquid components of the system completely vaporize. Section *c* corresponds to formation of unsaturated vapor. At these temperatures $AlBu_3$ and $AlHBu_2$ dimers dissociate, which is indicated by the reproducibility of the *p–T* dependence and the fact that the vapor pressure in the system is higher than that determined by the Gay–Lussac law.

The average molecular weights of the system calculated from the experimental results (433–440 K) and from the above equilibrium are similar and equal to 264. This value does not contradict the existence of this equilibrium in the gas phase. At 440–458 K the processes occurring in the system remain reversible, but the course of the *p–T* dependence differs from the gas expansion line. This indicates that process increasing the number of moles of gases in the system occurs to a significant extent. Proportional increase in the vapor pressure and the fact that experimental and calculated molecular weights are close (198 and 203, respectively) are consistent with the assumed dissociation of the dimeric species and intense dissociation of $AlBu_3$.

The pressure jump at 459 K and the discrepancy between the *p–T* curves (section *d*) measured on heating and cooling indicate that thermolysis of $AlBu_3$ and $AlHBu_2$ becomes irreversible.

The average molecular weight of the gaseous products, determined by chromatography, is 38.4. The vapor pressure in the system, calculated from this molecular weight, is 142 mm Hg, which agrees, within the limits of the determination error, with the experimental value (150 mm Hg). On cooling (curve *f*) down to hydrogen condensation temperature, the *p–T* dependence obeys the Gay–Lussac law. Thus, gas-phase thermal dissociation of $AlBu_3$ occurs in two steps by the olefin–hydride mechanism. The first step is reversible dissociation to form $AlHBu_2$, the olefin, and the mixed dimer $Bu_2AlBuAlHBu_2$. The second step is irreversible thermolysis of $AlHBu_2$ to form hydrogen, 1(2)-butene, and probably aluminum. Calculation of the mass balance by the procedure in [12] showed slightly overestimated content of carbon and hydrogen.

The fact that the vaporization parameters are irreproducible can be explained in terms of the proposed scheme by the reversible dissociation. The enthalpy of vaporization (66.6 kJ mol^{-1}) reported in [11] cannot be taken into account since the $AlBu_3$ pressure should be measured below 380 K. However, this procedure cannot be used because of the low vapor pressure (5 mm Hg) and noticeable determination error. It should also be noted that the enthalpy (65.8 kJ mol^{-1}) and entropy (131 J $mol^{-1}K^{-1}$) of vaporization calculated form the total vapor pressure (Fig. 1, curves *1*, *2*) agree well with the data presented in [11], which indicates that these parameters are doubtful. Since thermal transformation of $AlBu_3$ to $AlHBu_2$ is almost quantitative, small amount of methane, ethane, ethylene, and propane, determined by chromatography, can originate from thermolysis of the possible oligomer

$Al(C_4H_8)_n$:

$$Al(C_4H_8)_n \rightarrow aCH_4 + bC_2H_4 + cC_2H_6 + dC_3H_8 + Al(C_2H_4)_n.$$

Taking into account the nature of the gaseous products, generation and termination of radicals involve a sequence of free-radical reactions but are not the chain processes. Thermolysis of $AlHBu_2$ occurs by radical and olefin–hydride mechanism. By the analogy with hydrocarbon thermolysis [13], autoinhibition of $AlBu_3$ thermal degradation is probably due to recombination of butyl radical and its reaction with atomic hydrogen:

$$\dot{C}_4H_9 + \dot{C}_4H_9 \rightarrow C_4H_8 + C_4H_{10},$$

$$\dot{C}_4H_9 + \dot{H} \rightarrow C_4H_{10}.$$

The study of the gas-phase thermolysis of $AlHEt_2$ showed that its rate is almost independent of the initial $AlHEt_2$ concentration and hence is described by the first-order kinetic equation. At definite initial $AlEt_3$ concentrations the kinetic curves of $AlEt_3$ thermolysis do not pass through the origin of the coordinates because of partial decomposition of the sample during heating to the experimental temperature. These curves were approximated by equations of different orders. The degree of thermolysis of a sample by a definite time was calculated as $\Delta p/p_{tot}$, where Δp is the pressure increment and p_{tot} is the total pressure of $AlEt_3$. The experimental results are described well by the first-order kinetic equation. The rate constants at 469.3 and 503.3 K, calculated by the least-squares treatment of the kinetic data by the first-order equation, are 1.04×10^{-5} and 10.96×10^{-5} s^{-1}, respectively.

The chromatographic analysis of the gaseous products of $AlEt_3$ thermolysis showed the presence of the following components (mol %): hydrogen (28.6), CH_4 (28), C_2H_6 (21.0), C_2H_4 (12.0), C_3H_8 (20.2), C_4H_{10} (0.9), *n*-C_4H_8 (0.07), C_4H_6 (0.03), the total of C_5 (1.8), and the total of C_6 (12.6). The walls of the reaction chamber were coated with a gray nontransparent nonuniform film. The main gaseous products were hydrogen, ethane, ethylene, propane, and C_6 hydrocarbons. As in the case of $AlBu_3$ thermolysis, the high content of hydrogen and ethylene suggests the olefin–hydride mechanism of the thermolysis. However, high content of saturated hydrocarbons suggests occurrence of radical reactions, and high propane yield is due to the following transformations of the C_2H_5 radical:

$$AlHC_2H_4 + C_2H_5 \rightarrow 1/2H_2 + C_4H_9 + Al,$$

$$\dot{A}lC_2H_4 + \dot{C}_2H_5 \rightarrow \dot{A}lCH + \dot{C}_3H_6.$$

The products of these reactions form nonuniform film on the membrane surface. Propane formation suggests formation of the AlC_2H_4 radical. It probably decomposes to form CH_3 radical which reacts with C_4H_9 and C_2H_5 radicals to form small amounts of methane and C_5 hydrocarbons. The high yield of C_6 hydrocarbons indicates appreciable contribution of the following reactions:

$$\dot{A}lHC_2H_4 + \dot{C}_2H_5 \rightarrow \dot{A}lHC_4H_9,$$

$$\dot{A}lHC_4H_9 \rightarrow AlH + \dot{C}_4H_9.$$

Butyl radical C_4H_9 reacts with ethyl radical

$$\dot{C}_4H_9 + \dot{C}_2H_5 \rightarrow C_6H_{14},$$

$$\dot{C}_4H_9 + \dot{C}_2H_5 \rightarrow C_4H_8 + C_2H_6$$

to form small amounts of 1(2)-butenes. Autoinhibition of the thermolysis is probably due to these reactions and recombination of ethyl radicals:

$$\dot{C}_2H_5 + \dot{C}_2H_5 \rightarrow C_4H_{10}.$$

Reactions of radical formation and chain termination in the course of $AlEt_3$ thermolysis involve a sequence of nonchain free-radical processes. Thus, $AlEt_3$ thermolysis occurs by the radical and olefin–hydride mechanism. Based on the results of this work and the data on thermal behavior of $AlOct_3$ [10], the reactivity of aluminum tri-*n*-alkyls with respect to olefin-hydride thermolysis increases with an increase in the length of the carbon chain in the following order: $AlMe_3 < AlEt_3 < AlPr_3 < AlBu_3 < AlOct_3$. This agrees with data of [11].

These results show that $AlPr_3$ vaporization should be studied at low temperatures. The vapor pressures determined in separate experiments agree well with each other. The molecular weight of this compound in the gas phase, calculated from the unsaturated vapor pressure produced by a definite weighed portion of the sample in the volume of the membrane chamber, is 165.0. The formular weight is 156.0.

The overestimation of the molecular weight by 11.0 is due to the presence of gaseous dimers whose contribution to the vapor pressure does not exceed

3%. The low polymerization degree of gaseous $AlPr_3$ is consistent with the decrease in the tendency to polymerization in the series Al_2Me_6 > Al_2Et_6 > Al_2Pr_6. The onset temperature of thermal degradation of $AlPr_3$ (465 K) was determined by heating with a 1 K increment and subsequent thermostatic control. However, when the system was thermostatically controlled for several days, the onset temperature was determined to be 413 K. Up to this temperature no additional increase in the unsaturated vapor pressure was observed. The treatment of the temperature dependence of the saturated vapor pressure by various equations gave the following equation:

$$\log p = 7.28 - 2246/T.$$

The enthalpy and entropy of vaporization of tripropylaluminum are 43 ± 2.0 kJ mol^{-1} and 88 ± 6 J mol^{-1} k^{-1}, respectively. These low values are due to weaker association of $AlPr_3$ as compared to $AlEt_3$.

CONCLUSION

Conditions of equilibrium dissociation of tributylaluminum, irreversible thermolysis of dibutylaluminum hydride, and vaporization of tripropylaluminum were determined. These data can be used for optimizing the preparation of these compounds and their application as catalysts and alkylating agents.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Decomposition Kinetics of Alkali Metal Gallams in Hydroxide Aqueous Solutions

I. A. Tikhomirov, P. I. Lavrenyuk, A. A. Orlov, and D. G. Vidyaev

Tomsk Polytechnic University, Tomsk, Russia

Received May 18, 2001

Abstract—The decomposition kinetics of alkali metal gallams in LiGa–LiOH, NaGa–NaOH, KGa–KOH, LiGa–NaOH, LiGa–KOH, and KGa–NaOH systems in the 40–80°C range was studied. The rate constant and current density of decomposition were determined. The rate equation of gallam decomposition under the given experimental conditions was obtained.

Thanks to the high environmental safety and valuable properties of gallium and its compounds, the areas of their practical use are steadily expanding. In particular, in the exchange separation and purification of alkali metals to prepare alkali metal hydroxides [1] the substitution of highly toxic amalgams by gallium compounds (gallams) [2, 3] is of particular importance. The efficiency of the exchange reaction depends on the decomposition kinetics of the intermetallic compound (gallam) at contact with aqueous solution of alkali metal hydroxide, because at its decomposition alkali metal partially passes into solution. If the rate of gallam decomposition is higher than or equal to the rate of element exchange in the system studied, the separation of alkali metals is impossible. Thus, analysis of the kinetics and mechanism of the above processes is urgent. In this work we studied the kinetic parameters of decomposition of gallams upon their contact with aqueous alkali solutions in the LiGa–LiOH, NaGa–NaOH, KGa–KOH, LiGa–NaOH, LiGa–KOH, and KGa–NaOH systems.

EXPERIMENTAL

Lithium, sodium, and potassium gallams were prepared by direct dissolution of the corresponding alkali metal in gallium. In our work we used LE-1 brand lithium, chemically pure grade (99.9%) gallium, and pure grade sodium and potassium. The aqueous solutions of lithium, sodium, and potassium hydroxides were prepared by dissolving the corresponding chemically pure grade hydroxide in distilled water. The experiments were performed at 40–80°C, because gallam solidified at the concentration more than 1.5 M and temperature lower than 40°C [4], whereas at temperatures higher than 80°C the aqueous solution of alkali metal hydroxide strongly evaporates, which is unacceptable for the separation processes.

The scheme of the experimental unit is shown in Fig. 1. The experiments were carried out in a cylindrical cell *1* (30 mm in diameter) equipped with a water jacket, which was heated to a required temperature with a thermostat *2*. In the course of experiments the cell was first charged with hydroxide solution *3*,

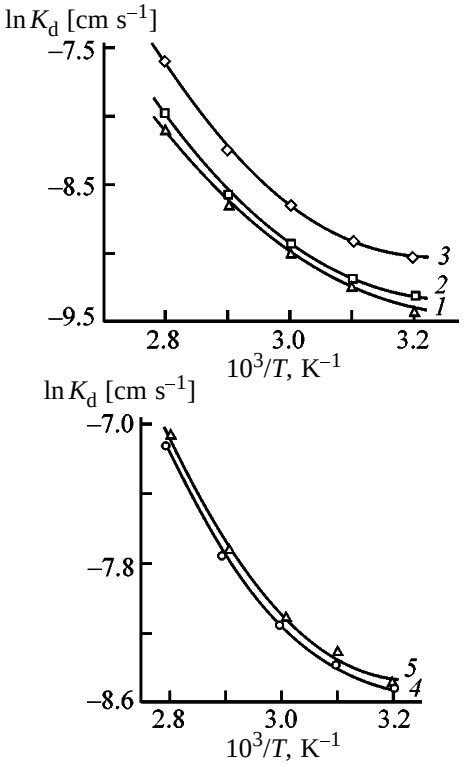

Fig. 3. Rate constant of gallam decomposition K_d as a function of temperature *T*. System: (*1*) KGa–KOH, (*2*) NaGa–NaOH, (*3*) LiGa–LiOH, (*4*) LiGa–NaOH, and (*5*) LiGa–KOH.

and then, when the required temperature was attained, a gallam *4* was charged directly to the cell bottom using a funnel with a long tip. The phases were mixed with a propeller stirrer *5* using an electrical motor *6* (750–800 rpm). No dispersion of gallam on stirring was observed. The area of the phase contact was calculated as the area of the cone formed at the gallam–solution boundary upon stirring. After experiments the hydroxide solution was removed from the top of the exchange cell, whereas the gallam was removed through a valve *7*. When the decomposition kinetics of alkali metal gallams in the LiGa–LiOH, NaGa–NaOH, and KGa–KOH systems were studied, aliquots of hydroxide solutions were sampled from the cell at certain intervals and the gallam concentration was determined by their titration. In the case of LiGa–NaOH, LiGa–KOH, and KGa–NaOH systems aliquots of the hydroxide solution and gallam were taken. The gallam samples were decomposed with freshly distilled hydrochloric acid. Then the resulting salt solutions and the hydroxide solutions sampled directly from the exchange cell were analyzed by flame photometry [5]. The measurement errors were calculated by the standard procedure [6]. The kinetic parameters of decomposition of lithium, sodium, and potassium gallams in the systems of the Me_1Ga–Me_1OH and Me_1Ga–Me_2–OH types were evaluated by the procedures given elsewhere [7, 8].

The decomposition kinetics of lithium, sodium, and potassium gallams in aqueous solutions of the respective alkali metal hydroxides was studied in the 40–80°C range using the following concentrations of the reacting phases, M: lithium (sodium) gallam 0.95, potassium gallam 0.92, and sodium and potassium hydroxides 4.00. In all the cases the experimental kinetic dependences of the gallam concentration plotted in the semilog coordinates are straight lines (Fig. 2). Thus, the reaction order of lithium (sodium, potassium) oxidation is 1. From the slopes of these straight lines we determined the apparent rate constants of decomposition depending on the temperature and hydroxide concentration. The resulting kinetic parameters of gallam decomposition in the LiGa–LiOH, NaGa–NaOH, and KGa–KOH systems are given in the table. The experimental error in K_d measurements was ±15%.

To study the influence of temperature on the decomposition rate constant in the systems in question, we plotted the dependences in the $\log K_d$–$10^3/T$ coordinates (*T* is the absolute temperature) (Fig. 3, curves *1–3*). As seen, with increasing temperature the rate of decomposition significantly increases, whereas with increasing hydroxide concentration it decreases (Fig. 4). Moreover, the shape of these curves suggests that the oxidation of alkali metals (lithium, sodium, and potassium) and reduction of hydrogen proceed simultaneously. The gallams of lithium, sodium, and potassium were used in experiments without purification. This suggests that, similarly to the case of decomposition of lithium (sodium, potassium) amalgam

under the industrial conditions, in this case two mechanisms operate simultaneously: electrochemical decomposition of gallam with separation of the anodic (on gallium) and cathodic (on the impurities) processes and its chemical decomposition. At low temperature (40–50°C), the diffusion processes control the decomposition rate of gallams, and with increasing temperature their effect decreases.

To determine the reaction order with respect to hydroxide, we plotted the dependences in the $\log K_d$–$\log C_{OH^-}$ coordinates (C_{OH^-} is the hydroxide ion concentration). These dependences are straight lines with different slopes; the typical dependence determined in the LiGa–LiOH system [9] is shown in Fig. 4. The slopes are different; hence, the reaction order depends on the hydroxide ion concentration, and the temperature dependence of the decomposition rate cannot be described by the Arrhenius equation. The decomposition rate of lithium, sodium, and potassium gallams can be described as follows:

$$W = -dC_{gl}/d\tau = -KC_{gl} = KC'_{gl}e^{-K\tau}, \quad (1)$$

where

$$K = (K_1 + K_2)/C_{OH^-}, \quad (2)$$

W is the rate of the gallam decomposition, K is the decomposition rate constant (s^{-1}), C_{gl} and C'_{gl} are, respectively, the current and initial gallam concentrations (M), τ is the time (s), and K_1 and K_2 are two components of the decomposition rate constant.

In this case we assumed that the rate of the reverse reaction can be neglected. The K_1 and K_2 values were determined as the limits in the $\log K_d$–$10^3/T$ dependence with an inflection point; at low temperatures $K_1 > K_2$, whereas at high temperatures $K_1 < K_2$. The expressions for K_1 and K_2 in the final form are given below:

$$K_1 = K_{01}e^{-96\,500/(RT)}, \quad (3)$$

$$K_2 = K_{02}e^{-10\,000/(RT)}, \quad (4)$$

where T is the absolute temperature (K) and R is the universal gas constant (J mol^{-1} K^{-1}).

For K_{01} and K_{02} we obtained the following expressions:

$$K_{01} = ae^b, \quad (5)$$

$$K_{02} = cC_{OH^-}/(1 + C_{OH^-})e^d. \quad (6)$$

The a, b, c, and d parameters for the systems in question are listed below:

* (I_d) Decomposition current density and (K_d) decomposition rate constant.

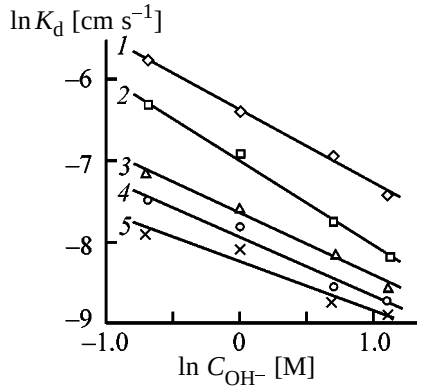

Fig. 4. Rate constant of lithium gallam decomposition K_d as a function of concentration of lithium hydroxide C_{OH^-}.

For comparison of our data with the published values, the decomposition rate constants (s^{-1}) were converted to the cm s^{-1} dimension. The resulting rate constants are given in the table. As seen, the agreement between the experimental and calculated K_d is quite satisfactory. The maximal deviation in the LiGa–LiOH, NaGa–NaOH, and KGa–KOH systems does not exceed 15, 13, and 9%, respectively.

Our study showed that with increasing temperature the decomposition rate of alkali metal (lithium, sodium, and potassium) gallams in the systems in question increases, and thus it is advisable to perform exchange at 40°C. Data on the decomposition kinetics suggest that the rate of gallam decomposition increases in the following order: sodium < potassium < lithium. The kinetic parameters of decomposition of lithium, sodium, and potassium gallams in the aqueous solutions of the respective alkali metal hydroxides were evaluated. Comparison of the kinetic parameters in the gallam systems studied with the data characterizing decomposition in the analogous amalgam systems [10] shows that the rate of gallam decomposition at 40°C is two times higher than the decomposition rate of the corresponding amalgams at 20°C. This is probably due to the lower hydrogen overvoltage at gallium. The hydrogen evolution is the slowest stage and thus it determines the overall rate of gallam decomposition.

Under the real exchange conditions the mixed alkali metal gallams decompose in aqueous solutions containing a mixture of hydroxides of these metals. It was of interest to study decomposition of the mixed gallams. Gallam decomposition was performed in the LiGa–NaOH and LiGa–KOH systems at 40–80°C using the following concentrations of the reacting phases, M: lithium gallam 0.95 and sodium and potassium hydroxides 4.00. Because of high fire risk of the potassium gallam–aqueous potassium hydroxide system, due to the high reactivity of potassium toward water and its vapor, the tests were performed under the following experimental conditions: 40°C, concentrations of gallam and hydroxide 0.92 and 4.00 M, respectively.

In the LiGa–NaOH and LiGa–KOH systems the experimental kinetic dependences of the gallam concentration are also linear, and thus the reaction order of lithium (potassium) oxidation is 1. The experimental kinetic characteristics of the gallam decomposition in the Li–Na and Li–K systems are listed in the table along with the theoretical decomposition rate constants calculated from Eqs. (2)–(6) using the following parameters *a*, *b*, *c*, and *d*:

System	*a*	*b*	*c*	*d*
LiGa–NaOH	0.655	32.3	0.278	3.1
LiGa–KOH	0.708	32.3	0.291	3.1

The measurement error of K_d was 15%.

As seen from the table, the agreement between the experimental and calculated K_d is quite satisfactory. The maximal divergence in the LiGa–NaOH and LiGa–KOH systems does not exceed 11 and 13%, respectively. For potassium gallam–sodium hydroxide aqueous solution we obtained the following kinetic characteristics: I_d = 0.16 kA m^{-2} and K_d = 1.81×10^{-4} cm s^{-1}. The experimental dependences of the decomposition rate constants on reciprocal temperature are shown in Fig. 3 (curves *4, 5*). As seen, in the LiGa–NaOH and LiGa–KOH systems the rate of gallam decomposition increases with temperature. On the average, the decomposition rate of mixed gallams at 40°C is two times greater than that of the corresponding amalgams at 20°C [10].

CONCLUSIONS

(1) At gallam decomposition, oxidation of lithium, sodium, and potassium proceeds simultaneously with reduction of hydrogen. With increasing temperature the rate of gallam decomposition increases, whereas with increasing hydroxide concentration it decreases.

(2) Similarly to decomposition of alkali metal amalgams, two processes probably occur simultaneously in the course of decomposition of the alkali metal gallams: chemical decomposition and electrochemical decomposition with separation of the anodic (on gallam) and cathodic (on the impurities) processes.

(3) The decomposition rate of the alkali metal gallams at 40°C is, on the average, two times higher than the decomposition rate of the corresponding amalgams at 20°C.

SORPTION AND ION-EXCHANGE PROCESSES

Influence of Exchangeable Cation on Dehydration and Thermal Stability of FIBAN K-1 Fibrous Sulfonic Cation Exchanger

Abstract—The influence of exchangeable cation on dehydration, desulfonation, and thermal oxidative degradation of FIBAN K-1 fibrous sulfonic cation exchanger in the hydrogen, alkali metal, and alkaline-earth metal forms was studied.

FIBAN K-1 gel-like fibrous sulfonic cation exchanger in the H form is the efficient catalyst of methyl *tert*-butyl ether synthesis [1] and alcohol dehydration [2]. It was reported also [3, 4] that palladium applied to this ion exchanger in the Ba form actively catalyzes hydrogen oxidation [3, 4].

In catalysis at elevated temperatures, ion-exchange resins are dehydrated to some extent, which results in deterioration of their physicochemical characteristics, in particular, of the thermal stability. This fact is important for industrial catalytic processes with catalysts based on ion-exchange resins.

Published data show that at present there is no generally accepted approach to evaluation of the ion exchanger thermal stability. The thermal stability of resins is characterized by several factors: weight loss, change of the exchange capacity (EC) and moisture capacity, and also the amount and composition of volatile thermal degradation products. It is evident that all these factors specifically reflect the degradation of functional groups. Therefore, to characterize the thermal stability of an ion exchanger, the temperature of the onset of functional group degradation should be determined. For catalysts based on sulfonic cation exchangers, this temperature should be established for sulfonic groups.

The state of water in KU-2 granular sulfonic cation exchanger in various cationic forms and its influence on desulfonation of these resins was studied in [5–7]. It was found that desulfonation of this cation exchanger in the presence of excess water involves not only associated but also dissociated sulfonic groups. The water molecules bound in the first hydration shell are not involved in the limiting stage of desulfonation.

The influence of exchangeable cation nature on the heat resistance of granular sulfonic cation exchangers in air was studied in [8–10]. It was found that cation exchangers in the metal cationic form exhibit higher thermal stability than those in the H form. It is difficult to exhaustively explain this effect, because along with thermal degradation, various reactions of resin oxidation with atmospheric oxygen occur, among them the thermal oxidative degradation of the polymeric matrix.

In this work we studied the effect of exchangeable cation on dehydration of FIBAN K-1 fibrous sulfonic cation exchanger and also on its thermal and thermal oxidative degradation. To prevent the reactions of the resin with atmospheric oxygen and ensure high precision of the results, the temperature of the onset of the functional group degradation was determined by mass spectrometry.

Mass spectrometry is widely used in studying macromolecular compounds, in particular, for determination of their composition [11, 12]. However, we found no available data on mass-spectrometric characterization of the thermal stability of sulfonic cation exchangers.

EXPERIMENTAL

FIBAN K-1 fibrous sulfonic cation exchanger was prepared by radiation grafting of copolymer of styrene (98%) and divinyl benzene (2%) to a polypropylene staple fiber, followed by sulfonation of poly(styrene–divinylbenzene) matrix with concentrated sulfuric acid [13]. In experiments we used samples of the cation exchanger in the H form with EC 0.6, 1.3, 2.2, 2.6, and 3.2 mg-equiv g^{-1}. The samples of completely sub-

1070-4272/02/7501-0034$27.00 © 2002 MAIK "Nauka/Interperiodica"

stituted ion exchangers in the Li, Na, Cs, Mg, Ca, and Ba forms were prepared by passing an excess of I N solution of the corresponding metal chloride through a column packed with the ion exchanger in the H form (EC 3.2 mg-equiv g^{-1}) to the neutral reaction of the filtrate. Thereafter the resin was washed with distilled water to complete removal of chloride anions and dried in air at room temperature.

Mass-spectrometric analysis of the volatile products of the ion exchanger degradation was carried out on an MKh-1320 mass spectrometer. In these experiments a portion of ion exchanger placed into a standard test tube was inserted into the inlet unit of the mass spectrometer. This sample was electrically heated with platinum coil, simultaneously functioning as a temperature-sensitive element. The mass spectra of the products of thermal desorption and thermal degradation of the ion exchanger were recorded at the ionizing voltage of 50 V and accelerating voltage of 2.5 kV.

Thermogravimetric study of sulfonic cation exchangers was carried out on an MOM (Hungary) derivatograph. In the first experimental series the weight loss was measured for ion exchanger samples in the H form with the different exchange capacities on heating from 20 to 200°C at a heating rate of 5 deg min^{-1}. In the second experimental series the resin resistance to thermal oxidative degradation was studied for samples with similar exchange capacity but containing different exchangeable cations. The samples were heated from 20 to 250°C at a heating rate of 5 deg min^{-1} and then kept at the maximal temperature for 5 min. The extent of thermal oxidative degradation of the poly(styrene–divinylbenzene) matrix was evaluated by measuring the concentration of paramagnetic centers (PCs).

The ESR spectra of heat-treated sulfonic cation exchangers were registered on a small-scale ESR spectrometer with sensitivity of 10^{10} spin g^{-1}, equipped with a software ensuring the multiple scan mode and fast data processing. MgO doped with Mn^{2+} ions was used as external reference.

Figure 1 illustrates the temperature dependence of the weight loss for resins with different exchange capacities. The water loss starts at a temperature lower than 50°C. On heating from 100 to 200°C (especially in the temperature range 100–150°C) the plot of the weight loss vs. *T* is steeper for ion exchangers with higher EC.

According to [14], ion exchangers contain two types of water molecules: those bound in the first

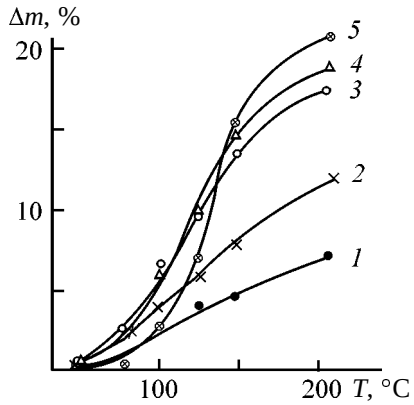

Fig. 1. Weight loss Δm of cation exchangers in the H form as a function of temperature *T*. Exchange capacity (mg-equiv g^{-1}): (*1*) 0.6, (*2*) 1.3, (*3*) 2.2, (*4*) 2.6, and (*5*) 3.2.

hydration shell and "free" (unbound) water molecules. The water state in cation exchangers was analyzed in more detail by Selemenev *et al*. [15]. They believe that water molecules in KU-2 granular sulfonic cation exchanger occur in three energetically different forms. The first form, so-called freely bound water, is mainly localized in the external (third) hydration shell and is bound by intermolecular dipole–dipole interactions. This water is removed from the cation exchanger in the first dehydration stage in the temperature range 50–80°C. In the second dehydration stage (80–115°C), water of the second hydration shell is removed. These water molecules form associates localized near hydrophilic sites of the ion exchanger. In the third dehydration stage, at temperatures higher than 115°C, water molecules of the first hydration shell bound to the metal ions by ion–dipole interaction are removed. In the DTA curves the endothermic peaks of different intensity appear in the temperature ranges 90–120 and 150–180 °C. The low-temperature peak can be assigned to intensive dehydration of the cation exchanger. The high-temperature peak is probably due to structural transformations of the functional groups.

It is known [16, 17] that in deep dehydration of sulfonic cation exchangers in the H form the functional groups are transformed from the dissociated to the nondissociated state. The oxygen atoms of the nondissociated sulfonic groups are stronger electron acceptors than those of the dissociated groups. Therefore, the protons of the SO_3H groups are bound to oxygen atoms of the adjacent sulfonic groups to form associates containing two and more sulfonic groups bound with hydrogen bonds. We believe that the high-temperature endothermic effect (150–180 °C) is due to breakdown of these associates.

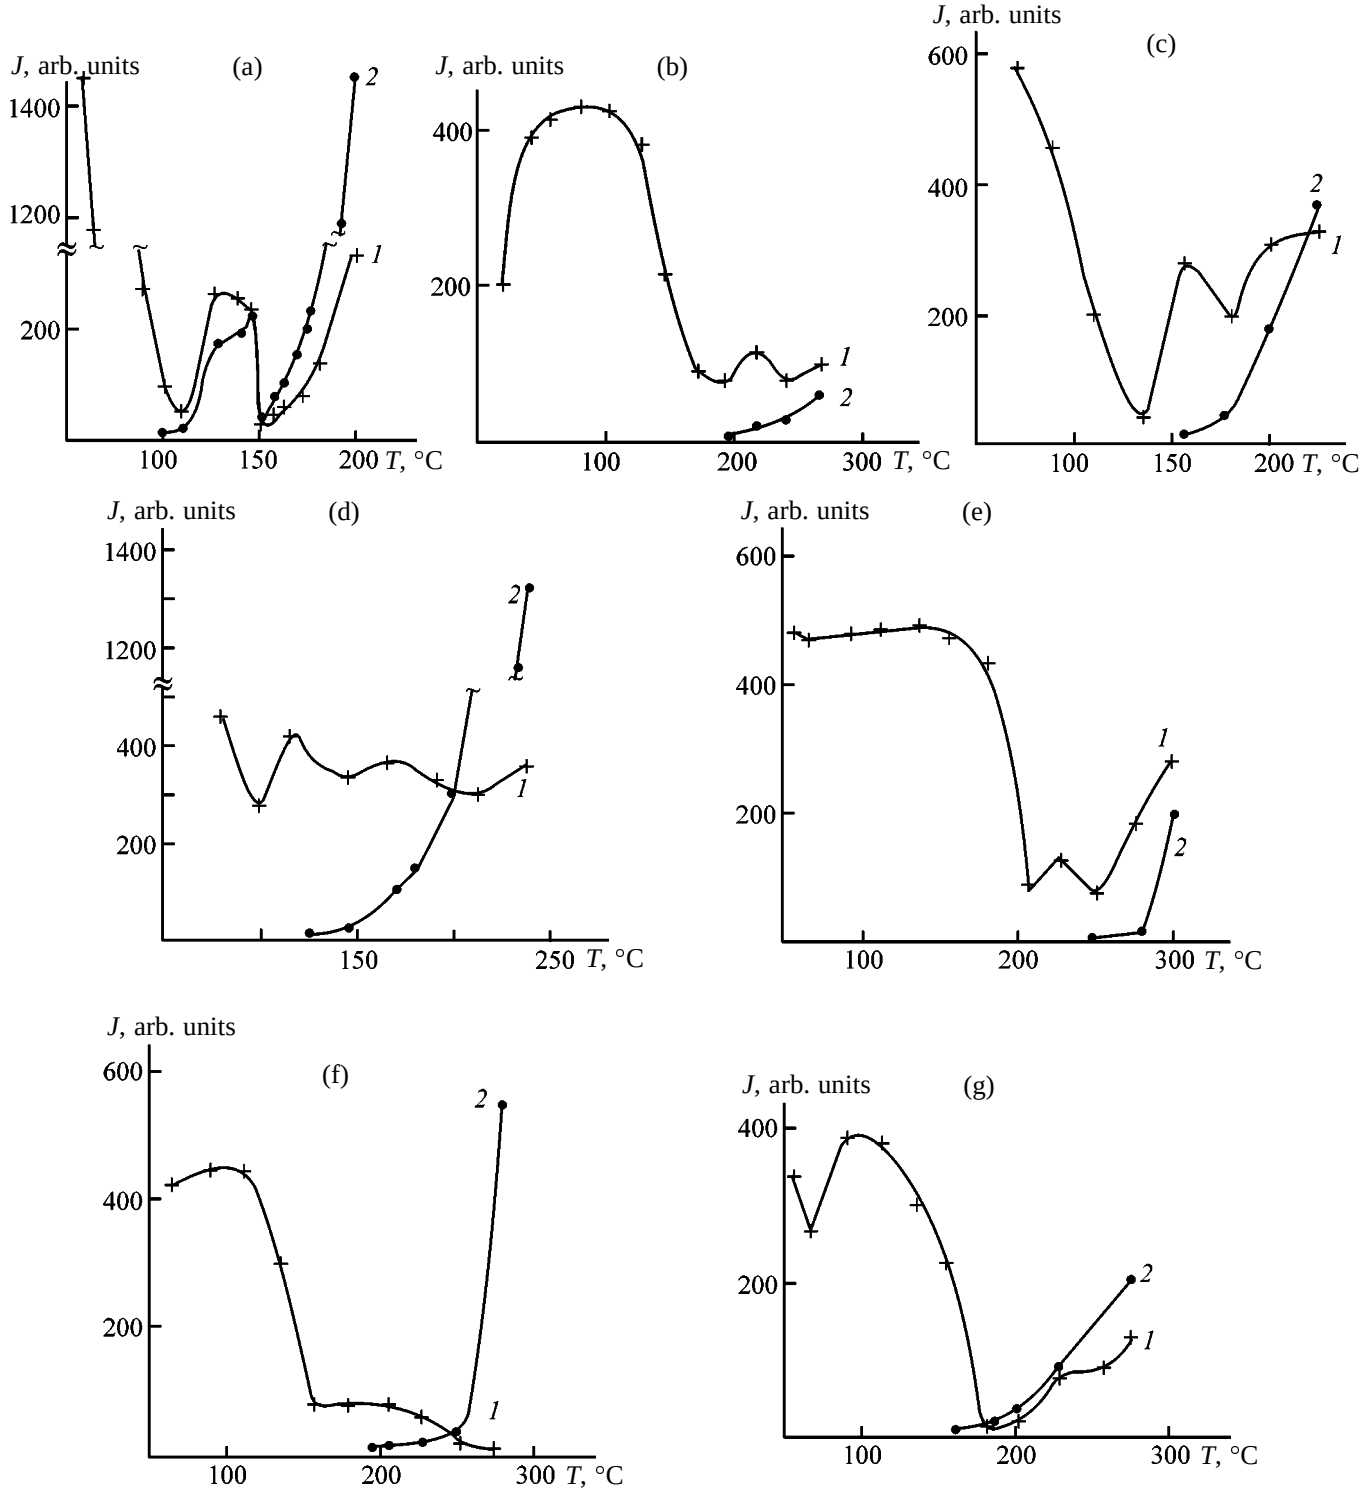

Fig. 2. Temperature dependence of the relative content J of (*1*) H_2O^+ and (*2*) SO_2^+ ions in the mass spectra. Cation exchanger form: (a) H, (b) Li, (c) Na, (d) Cs, (e) Mg, (f) Ca, and (g) Ba.

Figure 1 shows that the weight loss for the samples with EC 0.6, 1.3, 2.2, 2.6, and 3.2 mg-equiv g^{-1} in the temperature range 115–200°C is 3.9, 7.0, 9.5, 11.1, and 16.0%, respectively. This weight loss is due not only to dehydration of ion exchangers but also to breakdown of the functional groups. Figure 2 illustrates the temperature dependence of the relative content in the mass spectra of H_2O^+ and SO_2^+ ions

with *m*/*z* 18 and 64, respectively. Curve *I* shows that the temperature dependence of water evolution has three portions at 20–110, 110–150, and 150–200°C separated by sharp minima at 110 and 150°C. We believe that in the temperature range 20–110°C the free and weakly bound hydration water is removed from the cation exchanger. In the range 110–150°C relatively small amount of water and sulfur dioxide is evolved into gas phase, apparently originating from dehydration and degradation of dissociated sulfonic groups. Increase in the content of H_2O^+ and SO_2^+ in the mass spectra at temperatures higher than 150°C is apparently due to breakdown of both nondissociated and associated sulfonic groups.

The thermogravimetric and chemical analyses showed [8, 18–20] that heating of sulfonic cation exchangers in air in the temperature range 150–220°C results in their desulfonation by hydrolytic cleavage of the C–S bonds to form sulfuric acid. Further heating is accompanied by the matrix resulfonation and reaction between sulfuric acid and reducible matrix groups. The latter reaction yields sulfurous acid which decomposes into water and sulfur dioxide. In the first stage of desulfonation of anhydrous sulfopolystyrene in a vacuum (residual pressure ≤0.1 torr), the sulfonic groups react with the polymeric matrix at 200–230°C to form sulfones and water [21]. At higher temperature the reaction involves two sulfonic groups and yields sulfuric acid.

We found that the course of sulfonic cation exchanger desulfonation in the mass-spectrometric experiments somewhat differs from that determined by thermogravimetric analysis. Namely, in the mass-spectrometric experiment sulfur dioxide is evolved from the cation exchanger at lower temperatures starting from 90°C. This effect is apparently due to both higher sensitivity of the mass-spectrometric technique and considerable influence of a high vacuum (10^{-7} torr) on the mechanism and rate of desulfonation. Under high vacuum the reactions in question can occur at lower temperature, and, along with hydrolytic cleavage of the C–S bonds, their heterolytic cleavage is possible.

Figures 2b–2d show that temperature dependences of water and sulfur dioxide evolution from the cation exchanger in the Li, Na, and Cs forms differ substantially from those for the cation exchanger in the H form.

The water molecules tightly bound to the counterions are removed at 240, 180, and 150°C for cation exchanger in the Li, Na, and Cs forms, respectively. These results correlate with decrease in the ionic potential z/r^2 in the series Li^+, Na^+, and Cs^+ (1.47, 1.02, and 0.61, respectively).

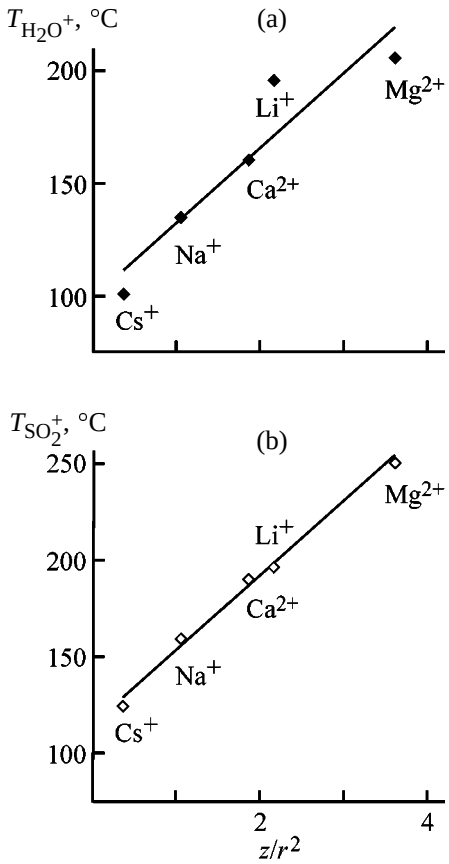

Fig. 3. Temperature (°C) of the onset of (a) water evolution from the first hydration shell $T_{H_2O^+}$ and (b) desulfonation $T_{SO_2^+}$ as a function of the ionic potential z/r^2.

The functional groups of sulfonic cation exchangers in the Li and Na forms decompose to form SO_2^+ ions at temperatures close to those of evolution of the water molecules bound to the counterions. As seen from Figs. 2b–2d (curves *2*), by contrast to the cation exchanger in the H form, for the cation exchanger in the metal cation form there is no correlation between SO_2^+ and H_2O^+ peak intensities because the SO_2^+ content continuously increases with temperature. This is apparently due to the fact that the sulfonic groups of the cation exchanger in the metal cation forms are incapable of association. The temperature of the onset of desulfonation of the cation exchanger in the Li, Na, and Cs forms is 190, 160, and 125°C, respectively.

Comparison of Figs. 2e–2g shows that decomposition of the sulfonic cation exchanger in the alkali and alkaline-earth metal forms occurs similary. The temperature of the onset of SO_2^+ evolution from the sulfonic cation exchanger in the Mg, Ca, and Ba forms is 250, 190, and 150°C, respectively.

As seen from Figs. 3a and 3b, the temperature of the onset of water evolution from the first hydration shell and formation of SO_2^+ ions varies in direct proportion with the ionic potential z/r^2 of the exchangeable cations. These results suggest that desulfonation of the fibrous sulfonic cation exchanger involves breakdown of the cation hydration shell.

Along with H_2O^+ and SO_2^+, heavier ions were detected, originating from thermal degradation of the polymeric matrix. We found that on heating of the sulfonic cation exchanger in the H form, organic fragments appear in the gas phase even at 90–120°C. The polymeric matrix of the cation exchanger in the alkali and alkaline-earth metal forms is more heat-resistant, and therefore the gaseous organic fragments are generated at 130–220°C. The most heat-resistant are the cation exchangers in the Mg and Ca forms.

We studied also thermal oxidative degradation of fibrous cation exchanger in various cationic forms in air by thermogravimetric analysis. The following concentrations of paramagnetic centers were determined (spin g^{-1}) for the respective forms: H 1995, Li 11, Na 21, Cs 8, Mg 10, Ca 14, and Ba 15.

These results show that the concentration of PCs generated by thermal oxidative degradation of the ion exchanger in the H form is higher by two order of magnitude than that for the cation exchanger in the alkali and alkaline-earth metal forms. It is possible that intermediate compounds of alkali and alkaline-earth metals formed in oxidative degradation of the ion exchanger inhibit the resin oxidation with atmospheric oxygen.

CONCLUSIONS

(1) The thermal stability of FIBAN K-1 fibrous sulfonic cation exchanger is sensitive to the nature of the exchangeable cation. Substitution of protons by alkali, and to a still greater extent, by alkaline-earth metal cations significantly increases the resistance of the cation exchanger to thermal and thermal oxidative degradation.

(2) Decomposition of sulfonic groups is associated with breakdown of the hydration shells of the cations. With increasing ionic potential of the exchangeable cation, the resistance of sulfonic group to thermal degradation increases.

Received April 5, 2001

Abstract—Theoretical concepts of multiple gas extraction are checked experimentally. The possibility is studied of preparing stable gas–vapor mixtures with fixed concentrations of styrene, acrolein, and other volatile organic compounds.

The measurement assurance demand [1] and rapidly growing topicality of determining traces of toxic compounds in the environment, medico-biological objects, food, agricultural, and industrial products necessitate unification and metrological control of trace analyses. Among the most important measures directed at increasing quality of gas analysis is perfection of the existing methods and development of new advanced methods for preparation of reference vapor mixtures with precisely fixed microconcentrations of components. The methods now employed in analytical practice do not solve to full measure the problem of preparing reference vapor mixtures containing concentrations of volatile components at a level of milligram per liter and lower [2]. The major cause is that such mixtures appear to be unstable as a result of loss through sorption and chemical interactions. Furthermore, reliable methods of preparing reference vapor mixtures containing unstable and reactive compounds are practically lacking at all.

Dynamic and static methods differ in the vapor mixture preparation technique. Dynamic methods produce gas streams used immediately. Although these methods are time-consuming and require sophisticated instrumentation, they are more frequently used as compared to static methods, which, even being simpler, appear to be hardly suitable for preparing stable gaseous mixtures with low component concentrations, based on homogeneous systems.

The levels of theoretical and technical development of these methods differ considerably [2], the less known and frequently employed being those based on phase equilibria [3–6]. However, it is such methods utilizing the headspace analysis (HSA) principles [7–9] that appear to be the most effective in many cases. In principle, is appropriate to use the equilibrium between the gas and condensed phases in all variations of HSA techniques, including static and dynamic modes with constant or regularly varying component concentration in a gas flow.

The idea of using the partition law in the liquid–vapor systems for preparing gas mixtures with fixed concentrations of volatiles dates as far back as the beginning of the 1960s. In the first publication on this problem a static method for calibration of an Ar ionization detector with aqueous acetone and ethanol was reported [10]. Nearly at the same time dynamic variations of HSA, continuous gas extraction of volatile hydrocarbons from squalane solutions with a nitrogen gas flow, was recommended for calibration of gas chromatographic detectors over a wide concentration range [11–13].

However, the lack of precise data on the partition coefficients in the system liquid–gas limited the use of this promising method. Later publications on the dynamic headspace method of preparing standard gas mixtures dealt with the problem of obtaining mixtures of constant compositions only [14–18]. The gas–liquid equilibrium under static conditions also was employed on a very limited scale. The available information refers to calibration of flame ionization detectors with mercaptans [19] and of flame photometric detectors with sulfurous compounds [20].

Wider application of the static method has been limited by the lack of sufficiently simple and precise techniques of measuring the partition coefficients needed for estimating the equilibrium vapor composi-

tion. The optimum conditions for the use of heterogeneous systems as concentration standards likewise remained obscure.

The above-indicated and other problems of application of HSA principles to gas analysis are considered in [3–5]. There was introduced the concept of buffer effect of heterogeneous systems as well as parameters for its quantitative characterization. In these works were eliminated the divergences found in the literature on the theory of gas extraction. Finally, in these works methods for preparing gas mixtures with constant or regularly changing in time microcomponent concentrations were proposed, not requiring *a priori* knowledge of the partition coefficients.

The distinguished features of this approach are as follows. Gas mixtures can be prepared over wide ranges of micro- and ultramicroconcentrations of volatile compounds not only by dynamic, but also by static methods; both static and dynamic methods can produce gas mixtures not only with constant concentration, but also with concentration regularly changing with time, which allows detector calibration with one sample over a range covering several orders of magnitude; in principle, new solutions can be obtained on the basis of discrete and multiple gas extraction and also with systems in which the phase equilibrium liquid–vapor is combined with chemical (acid–base or complexation) equilibria in the solution. Even having certain advantages, allowing elimination of a series of certain limitations characteristic of the existing, among them official methods, such methods are not practically employed in analytical work. The major cause is that no simple technique is developed that would demonstrate indisputable advantages over the existing methods not only in the accuracy, but also in the analysis time, labor-intensiveness, and cost.

Therefore, the main goal of the work was to experimentally confirm the possibility of using HSA principles for preparation of gas mixtures with constant microconcentrations of volatile components by the dynamic method. An integral part of the work was also development of simple engineering solutions best suited for practical realization in research and plant laboratories. Of particular interest was preparation of mixtures containing vapors of unstable compounds.

THEORY

Buffer Effect of Heterogeneous Systems

By analogy with the well-known concept of the buffer capacity of solutions [21], we introduced the concept of the buffer effect of heterogeneous systems manifested in the resistance of one (gas) phase to changing component concentration due to its equilibrium with the other (condensed) phase. If, as a result of sorption or interaction with parts of the equipment or with compounds sorbed on its walls, an amount of a microcomponent q is absorbed, then, according to the material balance equation, the decrease in its concentration in the isolated gas phase $\Delta c'_G$ is written as

$$\Delta c'_G = q/V_G. \quad (1)$$

where V_G is the gas volume.

If the gas (V_G) and liquid volumes (V_L) are in equilibrium, the same loss in the amount of the component in the gas phase will result in a smaller change in its concentration in this phase, which is given by Eq. (2).

$$\Delta c_G = \frac{q}{KV_L + V'_G}, \quad (2)$$

where K is the partition coefficient expressed as a ratio of the equilibrium concentrations of the volatile component in liquid (c_L) and gas phases (c_G):

$$K = c_L/c_G. \quad (3)$$

As a measure of the buffer effect of the heterogeneous system can serve the relative concentration difference which may be expressed via K and the phase volume ratio $r = V_G/V_L$ by Eq. (4)

$$\frac{\Delta c'_G - \Delta c_G}{\Delta c'_G} = \frac{K}{K + r} = B, \quad (4)$$

where B is the buffering factor numerically equal to the fraction of the component in the condensed phase.

By definition, B can change from zero to unity. At $B \to 0$ the buffer effect in the system is practically lacking because of a nearly zero partition coefficient or liquid phase volume. At another limit ($B \to 1$) the buffer effect is the maximal, i.e., the preset component concentration is stable ($\Delta c_G \sim 0$) even at large loss of the component in the gas phase. Therefore, the composition of the gas mixture in equilibrium with a sufficiently large volume of the solution containing the given volatile component characterized by high K, in principle, may be stabilized arbitrarily exactly.

Backgrounds of Dynamic Headspace Analysis

Single-stage continuous gas extraction. This dynamic procedure of standard mixture preparation is

based on continuous gas extraction (CGE) realized by bubbling of pure gas through a fixed volume V_L of a liquid contained in a vessel with a gas volume V_G above it. Regularly changing concentration of a volatile component in the gas flow at the outlet was treated by several authors [7–9], and considerably different final expressions were obtained. When analyzing the CGE theory, we demonstrated [22] that it is preferable to avoid considerable "dead" gas volumes above the solution and to perform extraction in vessels with negligibly small V_G. In this case a rather simple approximation holds true at a sufficient accuracy:

$$c_G = (c_L^0/K)\exp(-V_g/KV_L) = (c_L^0/K)\exp(-X), \quad (5)$$

where c_L^0 is the fixed initial concentration of the volatile component in the liquid phase, V_g is the volume of the gaseous extractant passed through, and X is the extraction coefficient expressed as

$$X = \frac{V_g V_L^{-1}}{K}. \quad (6)$$

The applicability of Eq. (5), i.e., the maximal dead volume of the gas in a vessel for CGE which can be neglected in calculations, is controlled by the maximal permissible error of setting the volatile component concentration in the gas flow δ (fraction), partition coefficient, and the solution volume:

$$V_G \le \delta K V_L. \quad (7)$$

Multiple continuous gas extraction involves extraction of volatile compounds with an extractant gas flow successively from several vessels with the initial liquid mixture. This procedure allows an abrupt increase in the CGE efficiency, particularly in the systems with insufficient buffer effect, when B is much below unity.

The theory of multiple CGE was considered in [23, 24]. It was demonstrated that if the solution volume V_L with the initial concentration of the volatile component c_L^0 is divided into N equal portions, each portion is placed in a separate vessel, and a gas flow of a volume V_g is passed successively through i vessels with assurance of the equilibrium condition of CGE or the constancy of K, then the volatile component concentration in the gas phase at the outlet from the Nth vessel c_G^N can be written as

$$c_G^N = \frac{c_L}{K}\sum_{i=1}^{N}\frac{X^{i-1}}{(i-1)!}\exp(-X). \quad (8)$$

Finally, the relationships derived for single-stage and multiple CGE techniques allow estimation of the stabilization effect of the condensed phase on the volatile component concentration in the gas flow, depending on the characteristics of the heterogeneous system and its buffering action.

EXPERIMENTAL

Measurements were carried out on a Tsvet-500 chromatograph with a flame ionization detector interfaced with a Multikhrom v. 1.39 data processing system. A mixture of aromatic hydrocarbons (benzene, *p*-xylene, and styrene) and acrolein was analyzed with a 200 × 0.3 cm steel column packed with Chromaton N-AW-DMWS (grain size 0.250–0.315 mm) containing 5% Carbowax 20 M. Gas mixtures containing organic compounds at concentrations below 10 mg m^{-3} were analyzed on a 50 m × 0.32 mm quartz capillary column coated with OV-101 liquid phase (film thickness 1 μm).

Chromatographic conditions were as follows. The packed column: column temperature 90°C, carrier gas (He) flow rate 30 ml min^{-1}; gas–vapor mixtures were injected into the column using a six-way on–off gas valve (Valco Model W) thermostated at 150°C. The capillary column: column temperature 120°C, carrier gas (nitrogen) flow rate 5.5 ml min^{-1}; gas–vapor mixtures with an aromatic hydrocarbon concentration below 1 mg m^{-3} were injected with preliminary cryofocusing of the components to be determined in the initial section of the column at the liquid nitrogen temperature.

In the work we used benzene and *p*-xylene (chemically pure grade) and styrene and acrolein (chemically pure grade) stabilized with hydroquinone. As practically nonvolatile solvents for aromatic hydrocarbons we used transformer oil [GOST (State Standard) 10121–76], VM-1 vacuum oil (GOST 5.671–70) and for acrolein, dibutyl phthalate (extra grade). The solvents were purified prior to use to remove volatile impurities by bubbling an inert gas (continuous gas extraction) at 70°C for 24 h (gas flow rate 50 ml min^{-1}). The quality of the solvents was controlled by GC. For all the solvents used the noise level was below 50 μV (charge amplifier scale 2×10^{-12} A).

The procedure for preparing gas–vapor mixture by dynamic single-stage gas extraction was as follows. An inert gas (nitrogen or helium) flow was passed through a thermostated saturator (220-ml Drechsel bottle equipped with a glass filter to obtain a finely dispersed jet) containing 200 ml of the liquid phase

Table 1. Partition coefficients in systems low-volatile solvent–helium at 25°C

at 25 ± 0.1°C. The gas flow rate (50–150 ml min^{-1}) was set and maintained constant to within 1% with a BPG-167 standard gas flow controller of the chromatograph and measured with an IRG-100 digital gas flow meter. The gas volume passed through was estimated from its flow rate and the extraction time (in the case of constant flow rate) or measured by an electromechanical counter (at variable gas flow rate). The multiple gas extraction was realized using series-connected 30-ml glass vials and a bubbler with a tip drawn into a capillary.

Let us consider the potentialities of the method and the techniques developed for static and dynamic headspace analysis with examples of preparation of gas–vapor flows with constant concentrations of quite reactive and unstable components. In the single-stage extraction procedure, as such components we selected aromatic hydrocarbons (benzene, *p*-xylene, and styrene); and in the multiple extraction, acrolein. Selection of these compounds, first of all styrene and acrolein, which are very reactive, was dictated also by the topicality of the problem of developing sufficiently simple techniques for preparing stable gas–vapor flows with constant microconcentrations of labile compounds. Such systems are needed for calibration and check resting of gas analyzers and also for quality assurance testing of techniques for determination of trace amounts of volatile compounds in gaseous media.

The best suited low-volatile solvent for continuous gas extraction of the indicated aromatic hydrocarbons (with respect to physicochemical properties, possibility of being purified to remove interfering impurities, availability, and cost) appeared to be transformer and vacuum oils, and for acrolein, dibutyl phthalate.

Single-stage procedure of continuous gas extraction. To prepare a gas–vapor flow with a fixed concentrations of volatile compounds by the dynamic HSA technique, it is necessary to preset the corresponding concentration of the compound in the liquid phase, which, in turn, requires knowledge on the partition coefficient K.

The partition coefficients of the above-indicated aromatic hydrocarbons in the system transformer oil–helium were determined by comparison of the results of GC determination of the volatile component concentrations c_G^* and c_G in the gas flows obtained with a Mikrogaz standard system and by continuous gas extraction from a solution with a precisely set concentration of the hydrocarbon to be determined c_L, respectively. The partition coefficients were estimated by Eq. (9) with allowance for the chromatographic peak areas of the aromatic hydrocarbons in the gas flow from the Mikrogaz system (A_G^*) and in that obtained by CGE from the solution (A_G):

$$K = \frac{c_L}{c_G}\frac{A_G^*}{c_G}. \quad (9)$$

The partition coefficients at 25°C of the investigated hydrocarbons are given in Table 1. The error of determination was estimated as a sum of the relative errors of presetting c_G^* and c_G and of measuring A_G^* and A_G to be no more than 5–7%.

The features of continuous gas extraction along with experimental data obtained on the partition coefficients allows optimization of the preparation procedure of gas–vapor mixtures with constant concentrations of volatile components, as well as estimation of the major parameters of the systems used. The concentration in the gas flow c_G at a given temperature is estimated from the base relationship of the partition law (3) with known K and fixed c_L. The maximal volume of the gas–vapor mixture V_g^{lim} which can be obtained with constant volatile component concentration is controlled primarily by the buffer capacity of the system and limited by the admissible deviation of the actual concentration c_G from the preset value. This deviation, in its turn, is controlled by the difference from zero of the extraction factor X. The vapor flow volume in which the volatile component concentration differs from the preset value by no more than the admissible value δ can be estimated by Eq. (10):

$$V_g^{lim} = KV_L \ln(1 + \delta). \quad (10)$$

Therefore, setting the tolerable decrease in the component concentration in the gas flow δ (fraction) and knowing V_L and K, one may always estimate the volume of the gas that can be passed through at practically constant concentration. For example, if 1 l of a solution of a volatile compound with $K = 5 \times 10^3$

and c_L = 50 mg l^{-1} (~0.005%) in a practically nonvolatile solvent is used for preparation of a gas–vapor mixture, with presetting c_G to within δ = 2% one may obtain 99 l of a gas–vapor mixture with a concentration of 10 mg m^{-3}. With increasing δ to 10%, all other parameters being unchanged, the volume will increase to 476 l. The estimated maximal volume of gas flow with practically constant benzene concentration is given in Table 2. The values estimated by Eq. (10) for various δ are well consistent with those obtained experimentally.

The measured current concentrations of benzene, *p*-xylene, and styrene in the gas flow in the course of their continuous gas extraction from 200 ml of the solution in transformer oil at the initial concentration c_L^0 of 96.7, 889.7, and 1864 mg l^{-1}, respectively, are in a good agreement with the theoretical results (Fig. 1). The differences between the c_G values estimated by Eq. (5) and those obtained experimentally were within 10%. Evidently, the major contribution to this difference is due to the errors of GC determination of such low concentrations of the organic compounds in the gas–vapor mixtures.

The stability of the volatile component concentration at the outlet from the vessel with the stabilizing solution depends on the quality of the solvent, degree of linearity of the partition isotherm, and *K* of volatile components. The maximal concentrations of volatile compounds in the gas flow are limited primarily by their saturated vapor pressures, being 20, 50, and 320 g m^{-3} for styrene, *p*-xylene, and benzene, respectively. However, the maximal concentrations corresponding to the ends of the linear section of the partition isotherms, i.e., of the region of infinitely dilute solutions characterized by constant *K*, are lower by approximately an order of magnitude. When dealing with such concentrations one should take into account that *K* may change on passing to the nonlinear section of the partition isotherm of volatile compounds between the stabilizing solution and the gas phase.

The lower limit of the preset component concentration is controlled by the desired signal/noise ratio, i.e., by the impurity level in the low-volatile solvent. At a signal/noise ratio of 10 : 1 the solvents used in this work allowed preparation of gas–vapor mixtures with the minimal concentration of about 5 and 1 mg m^{-3} for transformer and vacuum oils, respectively (the quality of vacuum oil was higher). Further decrease in the volatile compound concentration can be realized by either increasing quality of the low-volatile solvent or diluting the gas flow at the outlet from the vessel with the stabilizing solution.

Table 2. Maximal volume of gas flow with constant target component concentration as a function of δ*

δ, %	V_g^{lim}, l		
	benzene	*p*-xylene	styrene
1	1.5	15	19
3	4	47	58
5	7	72	97
10	15	160	200

* Estimated by Eq. (10) at V_L = 200 ml with *K* taken from Table 1.

The temperature of CGS and its stability in the vessel with the stabilizing solution throughout the process strongly affect the concentration of interested volatile components in the gas flow. For the most of organic compounds changing temperature by 1°C results in change in *K* and therefore c_G within 3–8% [7]. Therefore, the lesser the accepted error in setting c_G, the more stable should be the temperature throughout continuous gas extraction. The experimental temperature dependence of *K*, obtained for the infinite dilution region of the partition isotherms of *p*-xylene and styrene ($c_L \le 0.03\%$) in the system transformer oil–nitrogen at 15–30°C, demonstrates practically ideal linearity when plotted as $\ln K$ vs. T^{-1} (Fig. 2), allowing estimation of the required degree of temperature stabilization.

For example, in the cases of *p*-xylene and styrene, when $\delta \le 0.02$ is fixed, the temperature should be stable to within 0.4°C. To attain a reproducibility of the analytical signal within 1%, the temperature stability should be within 0.2°C, and with changing temperature of the stabilizing solution by 1°C the analytical signal variation should be within 5%. The estab-

lishment of equilibrium, which is the necessary condition of successful use of the CGE method, was controlled by measuring the volatile component concentrations (chromatographic peak areas) at various gas flow rates. It was demonstrated that with the quite viscous solvents used, solution column of no less than 10 cm, and finely dispersed jet of the gas extractant (0.3-mm orifices) this condition is realized at the flow rate from 10 to 400 ml min^{-1}.

The stability in time of solutions of the volatile compounds in the low-volatile solvents, which were used for preparing gas–vapor flows with preset *p*-xylene and styrene concentrations of about 30–35 mg m^{-3}, was monitored for a year by measuring c_G of each component with allowance for possible change in the sensitivity of the detectors. The correction factor was determined as the peak area ratio of the interested component and an external reference (propane). The results showed that the differences from the preset styrene and *p*-xylene concentrations in the gas flow at the outlet from the vessel were within 3%.

Multistep procedure of continuous gas extraction. The expedience of using this somewhat more complicated procedure of gas extraction is caused primarily by the possibility of considerable increase in the volume of the gas flow with practically constant concentration of volatile components, all other conditions being equal. The schematic flowsheet of multiple continuous gas extraction is presented in Fig. 3.

The major trends of multiple CGE were experimentally checked by studying the distribution of acrolein between dibutyl phthalate and nitrogen. The partition coefficient of acrolein in this system was measured previously by the CGE method [7] to be 320 (Table 1). It is easy to demonstrate that in the single-stage procedure, 600 ml of the solution is needed to obtain 10 l of the gas flow with a stable concentration of acrolein (δ = ±5%, 25°C). In the five-step procedure this may be realized with only 80 ml of the solution.

The dependence of the acrolein vapor concentration in the gas flow on the gas extractant volume passed through 50 ml of an acrolein solution in dibutyl phthalate (c_L = 190 mg l^{-1}) is presented in Fig. 4, demonstrating a satisfactory agreement of the theoretical and experimental data and an abrupt increase (by a factor of about 7) in the volume of the gas flow with practically constant acrolein concentration V_g^{lim} on passing from a single-step to a five-step extractor. The process was theoretically treated using Eq. (8) at K = 320.

Such a considerable increase in V_g^{lim} in multiple CGE is provided by progressive saturation of the gas-extractant in the first extraction steps. In this case the volatile component concentration in the solution in the last steps remains practically unchanged. As the solution in the initial steps is exhausted, the next steps start to take the stabilizing function, which is clearly demonstrated by the dynamics of variation of the acrolein concentration in the gas flow at the outlet of each cell, estimated by Eq. (8) and given in Fig. 5.

Similar effect providing considerable increase in V_g^{lim} in multistep extractors as compared to single-step devices was experimentally demonstrated also for the case of benzene distribution between vacuum oil and nitrogen. Passing from a single-step extractor to a three-step one at a fixed volume of the liquid phase V_L increases V_g^{lim} by a factor of about 5, and in the case of a ten-step extractor, by a factor of almost 10. Further increase in N appeared to be inexpedient, as

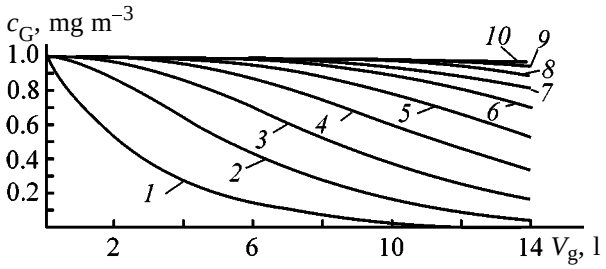

Fig. 5. Acrolein concentration in the gas flow at the outlet from each of ten cells c_G as a function of the volume of the gas-extractant V_g. The figures at the curves correspond to the cell number.

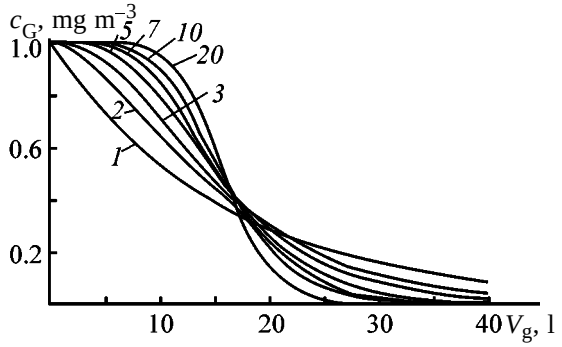

Fig. 6. Benzene concentration in the gas flow at the outlet from the last cell c_G as a function of the volume of the gas-extractant V_g at the same total volume of the liquid phase (0.05 l) and various cell numbers (from 1 to 20). The figures at the curves correspond to the total number of the cells.

only slightly increasing V_g^{lim}. Figure 6 shows the theoretical data on benzene distribution between vacuum oil and nitrogen (V_L = 50 ml, K = 490) for N 1–20. The optimal number of steps with the same solution volume can be determined from the dependence of V_g^{lim} on N.

To conclude, the potentialities of the method for preparing gas–vapor flows with a preset microconcentration of volatile components are not restricted to only the compounds studied in this work (aromatic hydrocarbons and acrolein). Basing on the headspace analysis principles and using heterogeneous systems having sufficient buffer capacity ($B \le 0.5$), it is possible to prepare stable gas–vapor mixtures with volatile component concentration varying over the range covering up to seven orders of magnitude (from several μg m^{-3} to tens g m^{-3}). The spectrum of compounds suitable in this method is limited by their saturated vapor pressure, which should fall in the range 10^{-2}–10^2 mm Hg at normal conditions.

CONCLUSIONS

(1) Stable gas–vapor mixtures with a fixed volatile compound concentration ranging from several μg m^{-3} to tens g m^{-3} can be prepared by dynamic headspace analysis technique.

(2) Appropriate liquid–gas systems are proposed for preparing stable gas–vapor mixtures of such reactive compounds as styrene and acrolein.

(3) The theoretically derived features of multiple continuous gas extraction are checked experimentally. Use of the multistep procedure allows considerable improvement of the performance of continuous gas extraction, particularly, increase in the volume of the gas flow with practically constant concentration of a target compound.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Coulometric Generation of Molecular Iodine

A. V. Kaverin, A. M. Pisarevskii, and S. B. Sapogova

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received September 17, 2001

Abstract—Coulometric generation of molecular iodine at the Pt anode in acid 0.2 M KI solutions was investigated in a cell without diaphragm. The current efficiency by iodine was studied in a wide range of anode current densities (3–100 mA cm^{-2}).

Iodometric titration has gained such a strong position in quantitative chemical analysis that it is perceived as standard technique in comparison and certification of various analytical methods [1, 2]. In this connection, the iodometric equipment is being constantly improved and electrochemical methods (ammetric [3], potentiometric [4], and coulometric [5, 6] titration) have become customary, together with the classical titration.

It has been shown, on the basis of electrochemical studies of redox system iodine–iodide on a platinum electrode, that the components of this redox system are chemisorbed to modify the electrode surface [4, 7]. As a result, the exchange current in the system iodine–iodide decreases only 2–3-fold, whereas the exchange currents in a great number of redox systems decrease by 3 to 4 orders of magnitude [4]. Such a dramatic decrease in the rate of electrode processes in "competing" redox systems, including O_2/H_2O and H^+/H_2, leads to important practical results.

(1) It is possible to perform equilibrium redox measurements in solutions of the system iodine–iodide down to as low concentrations of molecular iodine as about 10^{-6} [8] or even 3×10^{-7} M [9], although measurements at these concentrations are markedly affected by the solution agitation mode and concentration of dissolved oxygen.

(2) Electrochemical oxidation of iodide ions to molecular iodine at the Pt anode occurs with 100% current efficiency.

(3) It is convenient to use a Pt electrode with point surface, at which only molecular hydrogen is evolved during electrolysis [10], and low rate of homogeneous reaction between H_2 and I_2 allows coulometric generation of iodine without separation of the cathode and anode spaces. The competing process of anodic oxidation of H_2 can be disregarded in the given case because of the low exchange current in the system H^+/H_2 at a modified platinum electrode [4].

An important issue in iodometric techniques relying upon coulometric generation of molecular iodine is the choice of the generation current. If relatively large amounts of iodine are to be obtained, it is advantageous to make the generation time shorter by raising the anode current density, with 100% current efficiency by iodine preserved. As a rule, the choice of the generation current is limited from theoretical considerations to the region of small deviations of the anode potential from the equilibrium value. Below are presented data on the generation currents used in a number of experimental studies:

KI, M	i, mA cm^{-2}	References
0.005	0.6	[11]
0.2	3–20	[8, 10]
0.1–1.0	16.7	[12]

It is seen that in [10, 12] anodic oxidation with 100% current efficiency was performed at relatively large overvoltages; however, in these cases too, as judged from the descriptions of the experiments, the limiting diffusion current was not reached. It is known that, in 1 M salt solutions that were not stirred intentionally, the limiting diffusion current is about 25 mA cm^{-2} [13]. Use of a magnetic stirrer does not specify the agitation mode strictly; however, the limiting diffusion current increases by an order of magnitude even under weak stirring [14]. Unfortunately, no data concerning the upper limit of 100% current efficiency ω in electrochemical production of iodine from KI solutions were reported in the papers cited.

The aim of this study was to analyze the region in which 100% current efficiency is preserved in a cell

without diaphragm in a wide range of anode current densities.

EXPERIMENTAL

As anode served smooth Pt electrode with electrode surface in the form of a plate ($S \approx 1$ cm^2), as cathode was used Pt electrode of the EPV-1 type ($S < 1$ mm^2). Between measurements the electrodes were kept in an acid solution of the system iodine–iodide. The current was set in electrolysis with a B5-50 dc power source and monitored with a V7-21 milliammeter with resolution down to 0.01 mA. During electrolysis, the KI solution was stirred with an MM-5 magnetic rabble (speed of rotation of about 500 rpm). The generated amount of iodine was titrated with 0.01 M sodium thiosulfate solution with a microburette with scale-division value of 0.02 ml. As indicator of the process completion was used starch solution.

The current efficiency ω by iodine was studied in acid 0.2 M solutions of potassium iodide, containing 0.0016 M of H_2SO_4. The results of titrimetric determination of iodine generated at a current density under study are presented in the table.

In discussing the presented results, mention should be made of the fact that a current efficiency by iodine, equal to 100% within the natural error of titrimetry (1%), is obtained at $i \le 30$ mA cm^{-2}, in full agreement with published data [8, 10–12]. At the same time, in experiments performed at generation currents exceeding 50 mA m^{-2}, it was found that the current efficiency by iodine approaches 100% with decreasing time of electrolysis. In the case of electrolysis durations of 20–30 s, the 100% current efficiency is preserved over nearly entire range of current densities studied; however, obviously understated values were observed with the time of electrolysis increasing to 100 s and longer, and even more so at 100 mA cm^{-2}. These observations could be explained after analysis of the state of the anode surface during electrolysis. The entire range of anode current densities studied can be divided into three parts.

(1) Range $i \le 30$ mA cm^{-2} (Fig. 1a). In this range, the whole amount of iodine generated on the electrode is instantaneously washed away into the solution. As expected, stable 100% current efficiencies were obtained in this set of experiments.

(2) Range $30 < i < 50$ mA cm^{-2} (Fig. 1b). In this range of currents the current efficiency by iodine is more strongly affected by hydrodynamic conditions. In this case, the generated iodine already has no time to diffuse entirely into the solution bulk, and the appearance of a thin layer of concentrated iodine solution was observed in the near-electrode space. Even minor changes in the solution flow rate lead either to electrode "baring" or to formation of a crust of crystalline iodine on the electrode surface. Actually, this range is intermediate between the first and third, and the current efficiency by iodine is unstable in this range and is accompanied by abrupt changes in anode potential during electrolysis.

(3) Range $i > 50$ mA cm^{-2}. At these currents the 100% efficiency can only be observed in the initial stage of electrolysis (20–30 s). Later on, the formation of a crust of deposited iodine is visually observed. Also, it is noticed that a parallel process of molecular oxygen evolution sets in on that part of the surface which is still free of undissolved iodine, and the potential shifts to anodic values.

CONCLUSION

The choice of the anode current for reliable generation of iodine with 100% current efficiency is governed by a number of factors: electrode geometry, position of the electrode surface with respect to the solution flow, stirring intensity, and KI concentration.

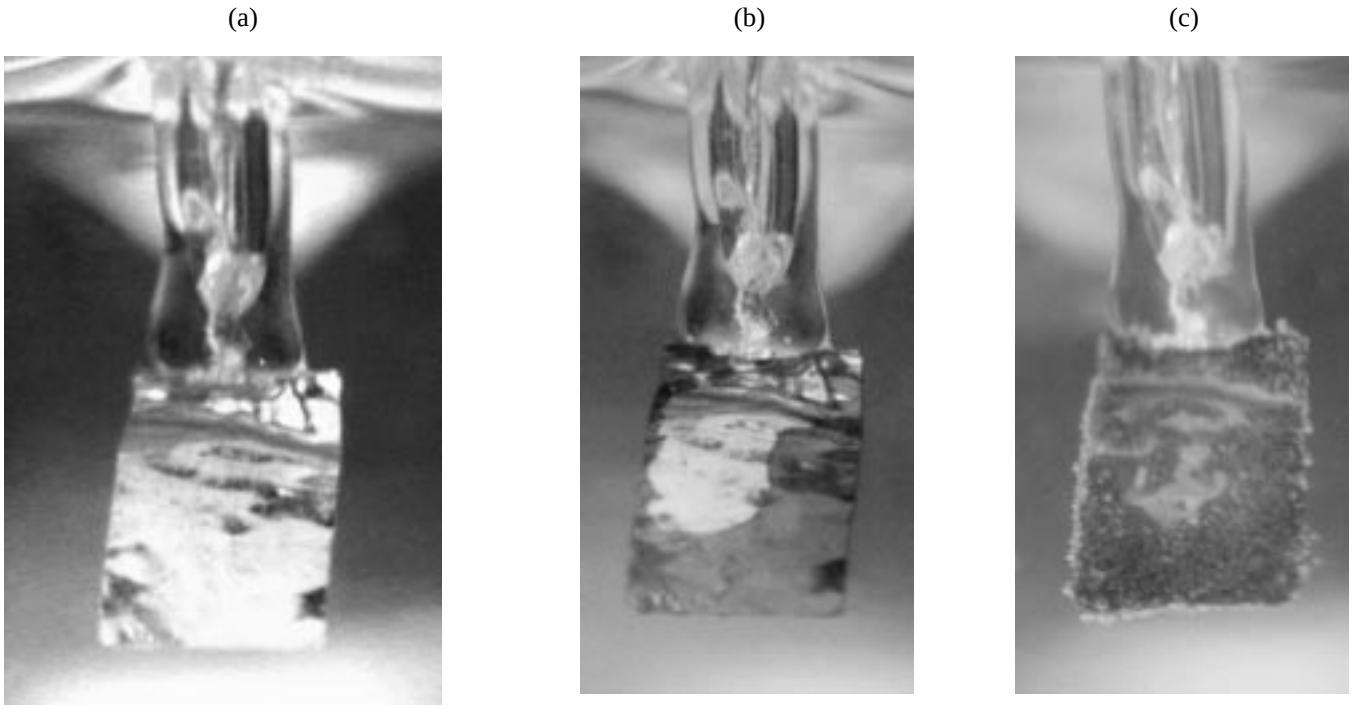

Fig. 1. State of the anode surface at (a) $i < 30$, (b) $30 < i < 50$, and (c) $i > 50$ mA cm^{-2}.

It was shown experimentally that a 100% current efficiency by iodine is preserved in 0.2 M KI solutions stirred with a magnetic rabble at current densities equal to, or less than 30 mA cm^{-2}.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Synthesis of Zinc and Nickel Carbonates by Anodic Dissolution of Metals in Electrolyte Solutions under Elevated Carbon Dioxide Pressure

Z. M. Aliev, M. V. Vladimirova, T. A. Kharlamova, and L. S. Malofeeva

Moscow State University of Food Industry, Moscow, Russia

Received April 25, 2001

Abstract— The process of single-stage electrochemical preparation of pure zinc and nickel carbonates in solutions saturated with carbon dioxide under elevated pressure was studied.

Special-purity zinc and nickel carbonates find use in medicine, semiconductor technology, and manufacture of various sorbents and catalysts. Purification of carbonates to remove impurities is a labor-consuming process, and, therefore, it is advisable to obtain pure products directly, by anodic dissolution of the corresponding metals.

Electrochemical methods for carbonate preparation have been described in the literature. For example, an electrochemical method for production of basic zinc carbonate is known [1], according to which zinc is anodically dissolved in an electrolyte containing 15–20 g l^{-1} of sodium hydroxide and 90–100 g l^{-1} of sodium nitrate. The process is carried out at a current density of 0.09–0.10 A cm^{-2}.

In order to obtain carbonates of various metals, the authors of [2] subjected a metal (Pb, Ni, Zn, etc.) to anodic dissolution in an ammonium carbonate solution at high current density with simultaneous continuous bubbling-through of ammonia and carbon dioxide. The method yields target products with high current efficiency.

An electrochemical method has been described for obtaining metal carbonates by anodic dissolution of the corresponding metal in an aqueous ammonium carbonate solution with bubbling of carbon dioxide through the aqueous solution at a current density of 0.10–0.15 A cm^{-2} and constant carbon dioxide pressure in the autoclave of 0.5–1.0 MPa [3].

The study [4] was also concerned with preparation of basic lead and copper carbonates in anodic dissolution of the corresponding metal in a diaphragm electrolyzer with the use of multicomponent electrolytes.

The common disadvantage of all the proposed methods consists in use of concentrated solutions of various electrolytes, from which it is difficult to isolate pure carbonates. In order to lower to the maximum possible extent the electrolyte concentration and obtain sufficiently pure zinc and nickel carbonates in a single stage, we studied the process of their electrochemical preparation in solutions saturated with carbon dioxide under elevated pressure.

EXPERIMENTAL

Measurements under elevated pressure were done in a specially designed autoclave made of a corrosion-resistant titanium alloy [5]. Valves for gas supply, pressure gage, and current leads for the electrodes were built in the autoclave cover.

The electrical conductivity of carbon dioxide saturated water and aqueous electrolyte solutions was determined using a versatile bridge with thermostating at a prescribed temperature. Potentiostatic measurements were carried out with a P-5827 M potentiostat. Zinc and nickel plates were used as working electrodes; platinum foil, as auxiliary electrode; and saturated silver chloride electrode, as reference.

The effect of carbon dioxide pressure on electrochemical synthesis of zinc and nickel carbonates was studied in distilled water and dilute aqueous solutions of potassium carbonate (0.01 M) and sodium chloride (0.05 M) in the same autoclave, with zinc and nickel of, respectively, TsV and N1 U brands of 99% purity used as anode materials. The current efficiencies (CE) by carbonates were determined gravimetrically after drying a deposit to constant weight.

One of the main parameters of the economic feasibility of the proposed way to obtain pure carbonates is the electrical conductivity of solutions subjected to electrolysis. Calculations of the volume of carbon dioxide dissolved in water and its solubility in relation to temperature T and pressure P by means of Rolf–Stinhof and Sechenov formulas [6] show that the solubility of CO_2 in water and dilute NaCl and K_2CO_3 solutions increases approximately 10-fold in the pressure range 0.2–2.0 MPa.

Also, we studied the effect of CO_2 pressure on the electrical conductivity χ of water in the temperature interval 20–90°C (Fig. 1). At low pressures, its electrical conductivity grows somewhat with increasing CO_2 pressure, irrespective of water temperature. At CO_2 pressure exceeding 2.0 MPa, the situation changes significantly: the electrical conductivity grows more steeply, and the more so, the higher the water temperature. The conductivity grows particularly strongly with increasing pressure at a temperature close to the boiling point.

Analysis of the experimental dependence of the electrical conductivity on the CO_2 pressure at various temperatures yields the following relations:

$$1/\chi = -2.07\log P + 4.4,\ 40°C,$$

$$1/\chi = -2.30\log P + 4.7,\ 60°C,$$

$$1/\chi = -2.10\log P + 4.5,\ 70°C,$$

$$1/\chi = -2.34\log P + 4.8,\ 80°C,$$

$$1/\chi = -2.75\log P + 2.7,\ 90°C,$$

where χ is the electrical conductivity (Ω^{-1} cm^{-1}), and P is pressure (MPa).

The measurements demonstrated that it is advisable to carry out investigations in aqueous SO_2 solutions at elevated pressures and temperatures.

Polarization curves of anodic dissolution of zinc in an atmosphere of pure CO_2 were measured at pressures of 0.05 to 0.9 MPa (Fig. 2). At gas pressures of up to 0.2 MPa two regions are observed in which the anodic process is inhibited (Fig. 2, curve *1*). The onset potential of the first passivation region is approximately –0.64 V, and that of the second, –0.35 V. At gas pressure exceeding 0.4 MPa the polarization curves have no bends (Fig. 2, curve *2*) corresponding to a transition into the passive state, which may be due to a pronounced decrease in the solution pH, promoting intensive dissolution of zinc [7].

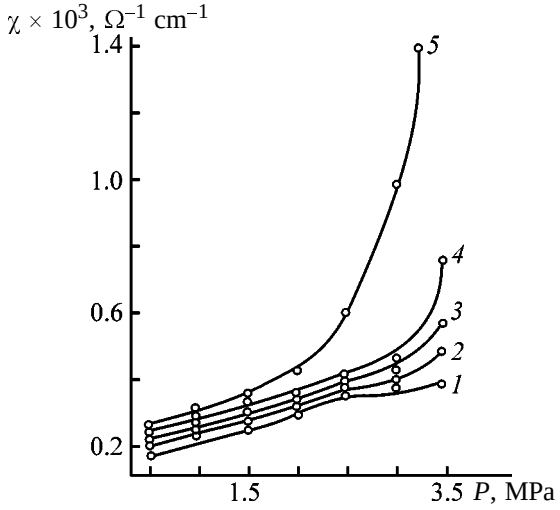

Fig. 1. Electrical conductivity χ of water vs. carbon dioxide pressure P at different temperatures. Temperature (°C): (*1*) 20, (*2*) 40, (*3*) 60, (*4*) 80, and (*5*) 90.

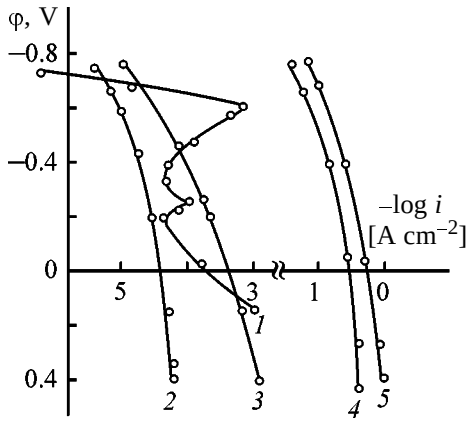

Fig. 2. Polarization curves for Zn electrode in water. (φ) Potential and (*i*) current density; the same for Figs. 3 and 4. CO_2 pressure (MPa): (*1*) 0.2, (*2, 4*) 0.4, and (*3, 5*) 0.9. (*4, 5*) NaCl concentration 0.05 M.

The time dependence of the anode current was studied for zinc electrode passivation regions at negative potentials of –0.4, –0.2, and –0.1 V at CO_2 pressure of 0.05 MPa. At a potential of –0.4 V the corrosion current density is virtually time-independent. At potentials of –0.1 and –0.2 V the corrosion current density decreases with time in accordance with the relation

$$i = K/\tau,$$

where i is the corrosion current density (A cm^{-2}), τ is time (min), and K is a coefficient equal to 0.20 and 0.24 A min cm^{-2} at potentials of –0.1 and –0.2 V, respectively. This behavior is preserved for 2 h.

It is inexpedient to perform electrolysis in pure

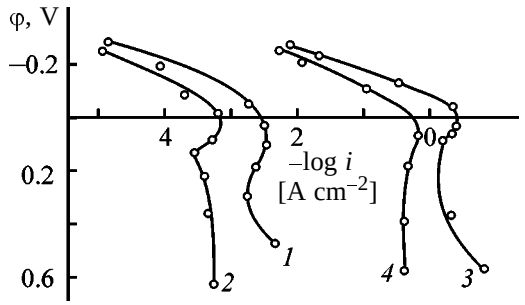

Fig. 3. Polarization curves for Ni electrode in water. CO_2 pressure (MPa): (*1, 3*) 0.1 and (*2, 4*) 0.9. (*3, 4*) K_2CO_3 concentration 0.01 M.

water because of its low electrical conductivity. In this connection, the anodic dissolution of zinc was studied in electrolyte solutions of K_2CO_3 and NaCl under elevated pressure of CO_2.

Addition of 0.01 M of K_2CO_3 to a solution being analyzed raises the zinc dissolution rate at pressures of 0.1, 0.4, and 0.9 MPa by nearly three orders of magnitude. However, a peak appears in the polarization curves, which is not observed in water in an atmosphere of pure CO_2 at the same pressures. The region of intensive metal dissolution is observed at potentials ranging from –0.6 to +0.2 V. With the potential increasing further, the rise in the current density slows down (prepassivation region) and, at a potential of –0.05 V, the metal becomes passive.

The behavior of zinc does not change significantly upon addition of NaCl. The polarization curves measured in a 0.05 M NaCl solution at CO_2 pressure of 0.1 to 0.9 MPa show no portions of passive film formation at potential in the range from –0.9 to +0.6 V (Fig. 2, curves *4* and *5*). Noteworthy is the pronounced increase in the anode current, compared with that in water and K_2CO_3 solution. The value of $\log i$ also grows with increasing CO_2 pressure. For example, $\log i$ equals –0.88 (0.1 MPa), –0.64 (0.4 MPa), and –0.52 (0.9 MPa) at a potential of –0.3 V.

The polarization curves for nickel in water at a CO_2 pressure of 0.1–0.9 MPa have a single peak (Fig. 3, curve *1*). At potentials of –0.3 to –0.1 V, the metal dissolves intensively. Then the current density passes through a maximum at potentials close to +0.05 V and then falls. A passive region is observed at potentials in the range from +0.05 to +0.25 V, ending in current rise. Raising the CO_2 pressure exerts the same influence on the region of intensive dissolution of the metal: the rate of nickel dissolution decreases with increasing CO_2 pressure. For example, the maximum values of $\log i$ are –2.40, –2.63, and –3.05 at CO_2 pressures of, respectively, 0.1, 0.4, and 0.9 MPa. The passivation region begins at a pressure of 0.9 MPa approximately 0.04 V earlier, compared with that at 0.1 MPa.

The polarization curves measured upon addition of K_2CO_3 to the solution differ only slightly from those obtained in an aqueous solution of CO_2; however, the rate of metal dissolution increases noticeably. The pattern in which the current density decreases with increasing CO_2 pressure in the region of intensive metal dissolution is preserved (Fig. 3, curves *3* and *4*). The maximum $\log i$ values are +0.4, +0.25, and –0.20 at CO_2 pressures of, respectively, 0.1, 0.4, and 0.9 MPa.

The presence of chloride ions in solution strongly affects the run of the polarization curves and the rate of dissolution of the nickel anode (Fig. 4). At NaCl concentration of 0.05 M and CO_2 pressure of 0.1 and 0.4 MPa the peak potential (Fig. 4, curves *1* and *2*) shifts to the positive region, and the passive state of nickel is disrupted already at potentials close to +0.25 V, which is manifested in abrupt change from decrease in the current to an increase in the metal dissolution rate. No inhibition of the electrode process is observed at potentials in the range from –0.3 to +0.6 V at a CO_2 pressure of 0.9 MPa (Fig. 4, curve *3*), which indicates the absence of passivation of the nickel anode.

The polarization measurements performed demonstrated that the anodes are passivated in anodic dissolution of zinc and nickel aqueous solutions of both CO_2 and potassium carbonate, which is presumably due to formation on the electrode surface of a film of metal carbonates and oxides. The passivation phenomenon is completely eliminated in a sodium chloride solution. Here it is important to note that this occurs even at sodium chloride concentration of 0.05 M. Electrolysis in chloride solutions was carried out with account of these data.

To choose the optimal conditions, carbonates were synthesized with pressure and temperature varied within 0.2–1.0 MPa and 20–100°C. An analysis of the data obtained demonstrated that raising both pressure and temperature results in a certain increase in CE by carbonates, with pressure exerting stronger influence than temperature. For example, the increase in CE was about 20% on raising the CO_2 pressure from 0.2 to 1.0 MPa, and only about 6% on elevating temperature from 20 to 100°C.

Syntheses of carbonates with the use of various cathode materials demonstrated that, under the same conditions, the CE depends on the nature of the cathode material (0.05 M NaCl solution):

Cathode	Anode	CE, %
Copper	Nickel	90.8
Platinum	Nickel	98.2
Copper	Zinc	94.1
Platinum	Zinc	96.8

The effect of the cathode material on the CE can be accounted for by reduction of metal ions at the cathode, which makes lower the CE of the target product. The maximum CE values in NaCl solution are observed with platinum as the cathode.

The rate of anodic dissolution of zinc in water and aqueous solutions of K_2CO_3 and NaCl grows with increasing pressure at any preset potential (from –0.6 to +0.4 V). However, nickel dissolves anodically only up to potential of 0.0 V. Further, its potential remains constant to high current densities, which can be attributed to shielding of the electrode surface by firmly adsorbed insoluble compounds of zinc with ions formed in the system in CO_2 dissolution.

The table presents the results obtained in studying the effect of CO_2 pressure on the current density at two fixed potentials of –0.2 and 0.0 V in anodic dissolution of Zn and Ni in water and aqueous solutions of K_2CO_3 and NaCl.

It can be seen that the rate of anodic dissolution of Zn and Ni in an NaCl solution is higher as a result of the depolarizing action of chloride ions. Under the chosen optimal conditions, nickel and zinc carbonates are obtained at current densities of up to 0.35 A cm^{-2} in nearly quantitative yields.

Effect of CO_2 pressure on the current density at constant potential in anodic dissolution of zinc and nickel

φ, V	*P*, MPa	–log *i* in indicated solution, M

	0.9	3.4	3.1	0.7	0.2	0.35	0.38

CONCLUSION

The preparation of pure Zn and Ni carbonates can be intensified by performing electrolysis in solutions saturated with CO_2 under elevated pressure.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of External Polarization on Hydrogen Diffusion across Steel Membrane in Dilute HCl Solutions Containing a Number of Aromatic Amines

V. I. Vigdorovich, S. E. Sinyutina, and L. V. Chivilev

Derzhavin State University, Tambov, Russia

Received September 4, 2001

Abstract—The effect of a number of aromatic amines on the hydrogen diffusion flux across a steel (St.3 brand) membrane under conditions of anodic and cathodic polarization in weakly acidic solutions, including media containing hydrogen sulfide, was studied. The experimentally observed dependences are interpreted in terms of the Horiuti approach.

Hydrogenation of metalware under industrial conditions in acid media [1] and highly mineralized nearly neutral media containing hydrogen sulfide [2] and carbon dioxide [3] is one of the most dangerous kinds of corrosive destruction. The hydrogen embrittlement of metallic structural materials, impairing their strength characteristics, causes huge direct and indirect losses. Despite numerous studies [4–7], the mechanism of the process remains nearly totally unclear, which markedly hinders a theoretically substantiated search for inhibitors of hydrogenation in various media. In acids, the build-up of cathodic polarization within certain limits raises the rate of hydrogen diffusion across a steel membrane, i_H; then a region with $i_H \neq F(i_c)$ is observed, where i_c is the cathode current density; and then a transition occurs from the first stage

$$H_3O^+ + e \xrightarrow{i_1} H_{ads} + H_2O \qquad (1)$$

to water discharge

$$H_2O + e \rightarrow H_{ads} + OH^-$$

and to an increase in pH in the near-electrode layer [8]. Various additives may change substantially the type of the $i_H = F(i_c)$ dependence [6].

In the case of cathodic polarization, the function $i_H = F(\Delta E_c)$, where $\Delta E_c = E_{cor} - E_c$, and E_c and E_{cor} are the potentials of the working side of the membrane under the conditions of a flowing external cathode current and under self-dissolution conditions, has a maximum in a wide range of pH values [9].

A similar maximum is observed at small shifts of the potentials to the anodic region. The type of the $i_H = F(\Delta E_a)$ dependence [10] is accounted for by the negative difference effect as a result of emergence into solution of low-charge species inducing chemical decomposition of water and giving rise to H_{ads}. Hydrogenation in a weakly alkaline borate buffer solution also occurs at potentials that are more positive than that of the equilibrium hydrogen electrode, E_r [11]. The authors attribute the observed experimental facts to H_3O^+ accumulation as a result of anodic ionization of iron in accordance with the scheme [12]

$$Fe + 2H_2O \rightleftarrows Fe(OH)_{ads} + H_3O^+ + e, \qquad (2)$$

$$Fe(OH)_{ads} \rightarrow Fe(OH)_{solv} + e,$$

$$Fe(OH)_{solv} \rightleftarrows Fe^{2+} + OH^-.$$

The forming hydroxonium ions can be reduced by reaction (1), and it is this factor that is responsible for metal hydrogenation.

Marshakov *et al.* [4] developed this approach [11] using a modified Bokris scheme for the mechanism of iron ionization in weakly acidic sulfate solutions, having replaced in this scheme the reactive OH^- ions (because of their low concentration) with H_2O. However, the questions remain as to whether reaction (1) at $E > E_r$ and H_3O^+ accumulation are possible if proton donor is formed in the quasi-equilibrium reaction (2) and consumed in the reaction

$$Fe(OH)^+ + H_3O^+ \rightleftarrows Fe^{2+} + 2H_2O \qquad (3)$$

1070-4272/02/7501-0054$27.00 © 2002 MAIK "Nauka/Interperiodica"

in stoichiometric amounts. According to [13], the effect occurs if reaction (3) proceeds by the Kolotyrkin–Florianovich mechanism

$$Fe(OH)_{ads} + HSO_4^- \rightleftarrows FeSO_4 + H_2O + e,$$

in which the hydrosulfate ion acts as a source of H_3O^+. However, in chloride media, in which iron ionization proceeds by the scheme [14]

$$Fe + 2H_2O + Cl^- \rightleftarrows (FeClOH^-) + H_3O^+ + e,$$

$$(FeClOH^-) \rightarrow FeClOH + e,$$

$$FeClOH + H_3O^+ \rightleftarrows Fe^{2+} + Cl^- + H_2O,$$

H_3O^+ ions are not accumulated and i_H must not grow in anodic polarization, in contradiction with experimental data.

The rise in i_H is possible through an increase in the concentration of adsorption centers for hydrogen atom as a result of anodic activation of passivated parts of the metal surface, existing at $E \le E_{cor}$ [5]. However, a situation of this kind is also observed in ethylene glycol solutions of HCl [15], in which, according to photoelectric polarization data, there are no passive regions on the iron surface. Thus, many fundamental aspects of steel hydrogenation have no satisfactory theoretical interpretation.

In the presence of inhibiting additives, the situation becomes even more complicated [16]. Therefore, in continuation of [16], the present study employs an approach [17, 18] according to which two H_{ads} species exist on the iron surface. One of these determines, all other conditions being the same, the flux of the solid-phase diffusion of hydrogen [15]. With account of these results, the present study analyzes and gives an interpretation of the influence exerted by a number of aliphatic amines on i_H under conditions of anodic and cathodic polarization.

EXPERIMENTAL

The studies were carried out in a two-chamber Pyrex glass cell of the Devanathan type, with a partition in the form of vertical steel membrane (St.3 steel) 0.3 mm thick with area of 3.63 cm^2, using the procedure described in [19]. The working solution was introduced into the polarization part of the cell, and a precisely measured amount of titrated 0.01 N potassium permanganate solution, into the diffusion part. According to the theory of the method, hydrogen diffusing across the membrane reacts on its diffusion side with $KMnO_4$, converting it into manganese dioxide on the electrode surface:

$$3H_{ads} + MnO_4^- = MnO_2 + H_2O + OH^-.$$

The amount of hydrogen that passed across the membrane was determined from the change in the concentration of the $KMnO_4$ solution by its titration with an oxalic acid solution in accordance with the equation

$$5H_2C_2O_4 + 2KMnO_4 + 3H_2SO_4 \rightarrow 2MnSO_4 + K_2SO_4 + 8H_2O + 10CO_2.$$

The amount of potassium permanganate consumed for passivation of the membrane surface was determined in a blank run without filling the polarization compartment of the cell. The amount of hydrogen diffused across the membrane, expressed in current density units, was calculated as follows. The amount of reacted potassium permanganate is given by

$$n(KMnO_4) = \Delta C(KMnO_4)V_{cell}/(5 \times 1000),$$

where C is the equivalent concentration of $KMnO_4$.

The amount of atomic hydrogen that reacted with potassium permanganate was calculated using the relation

$$n(H) = 3n(KMnO_4).$$

Since $M(H) = 1$ g mol^{-1}, then $n(H)$ and $m(H)$ are numerically equal. In this case, the current density of hydrogen diffusion across the membrane, i_H (A m^{-2}), can be calculated by the formula

$$i_H = mF/E_H S\tau = 0.016\Delta CV_{cell}/S\tau,$$

where E_H is the molar mass of the chemical equivalent of hydrogen, τ is the experiment duration (h), and S is the membrane area (m^2).

The polarization was done with a P5827m potentiostat, silver chloride electrode served as reference, and Pt was used as auxiliary electrode. The working solution was prepared by saturation of distilled water with dry hydrogen chloride and subsequent adjustment to the prescribed concentration.

Hydrogen sulfide was introduced by saturation of hydrochloric acid solutions with gaseous H_2S and subsequent dilution with the working solution. All experiments were carried out at room temperature in the course of 2 h. The aromatic amines listed in the table were used.

Physicochemical constants of compounds

Compound	Empirical formula	Hammett constant σ_H [20]	pK_b [20]	Dipole moment $\mu \times 10^{30}$, C m [20]
p-Anisidine (**I**)	$CH_3O–C_6H_4–NH_2$	–0.268	5.29	6.11
p-Toluidine (**II**)	$CH_3–C_6H_4–NH_2$	–0.170	5.12	4.49
Aniline (**III**)	$H–C_6H_4–NH_2$	0.000	4.58	5.28
p-Bromoaniline (**IV**)	$Br–C_6H_4–NH_2$	0.232	3.91	9.87

In uninhibited 5 M HCl solutions, the diffusion flux grows with ΔE_c increasing within the limits $0 < \Delta E_c < 0.1$ V. Further, i_H is virtually independent of ΔE_c (Fig. 1Ia, curve *1*). Introduction of 1 mM of *p*-anisidine (**I**), *p*-toluidine (**II**), and aniline (**III**) leads to an $i_H = F(\Delta E_c)$ dependence with a maximum at ΔE_c equal to 0.05 (**I**, **III**) or 0.1 V (**II**). Introduction of *p*-bromoaniline (**IV**) diminishes i_H to virtually zero, with no extremum observed in the corresponding dependence (Fig. 1Ia, curve *5*).

In the presence of hydrogen sulfide (6 mM) in a buffer solution without addition of aromatic amines, a maximum appears in the $i_H = F(\Delta E_c)$ dependence (Fig. 1Ib, curve *1*) and the absolute value of i_H (ΔE_c = const) markedly increases. The nature of the relationship between i_H and ΔE_c upon introduction of aniline and its derivatives depends on a substituent. In the presence of aniline, an increase in ΔE_c to 0.05 V makes i_H lower; further, the diffusion flux remains virtually unchanged (Fig. 1Ib, curve *4*). The compound $C_6H_5NH_2$ strongly diminishes the absolute value of i_H under conditions of cathodic polarization. A similar situation is observed in the presence of **I**. Introduction of *p*-toluidine (**II**) leads to a dependence of i_H on ΔE_c with a clearly pronounced maximum. Finally, 1 mM of *p*-bromoaniline (**IV**) in a weakly

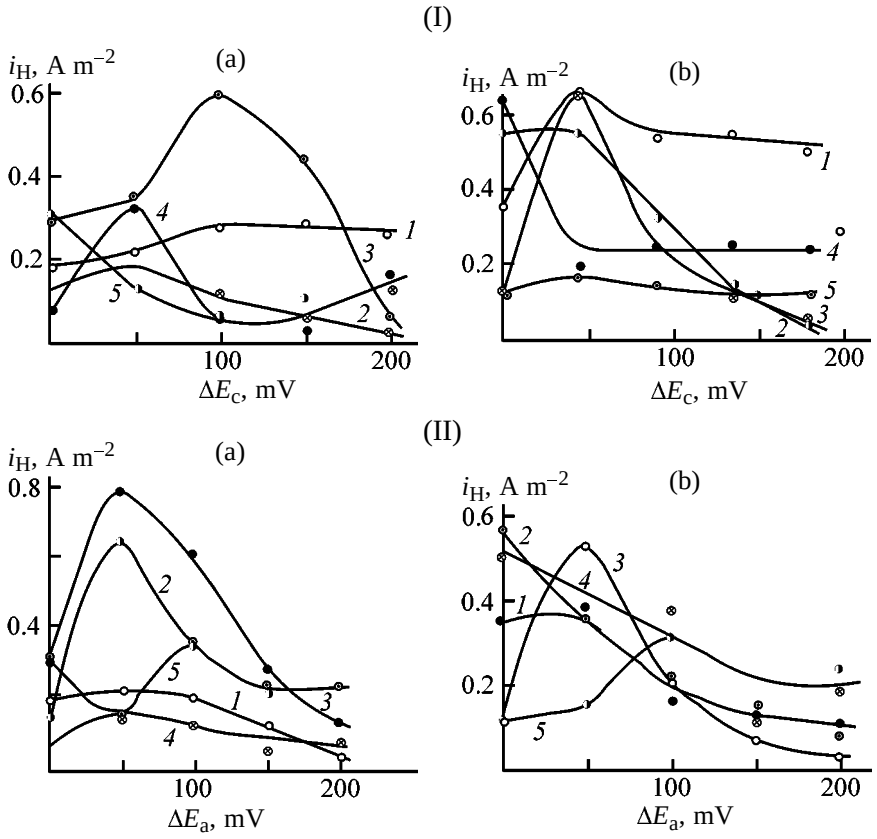

Fig. 1. Current of hydrogen penetration vs. (I) cathodic and (II) anodic polarization ΔE of a steel membrane in 5 mM HCl solutions containing 1 mM of aromatic amines. Temperature 20°C, test duration 2 h. (*1*) No additive; amine added: (*2*) **I**, (*3*) **II**, (*4*) **III**, and (*5*) **IV**. H_2S concentration (mM): (a) 0 and (b) 6.

acidic H_2S-containing medium markedly lowers i_H (ΔE_c = const). At the same time, i_H is virtually independent of ΔE_c.

In the case of anodic polarization ($\Delta E_a = E_a - E_{cor}$, where E_a is the potential of the working side of the membrane on applying an external anodic current) in uninhibited buffer solution, the dependence $i_H = F(\Delta E_a)$ has a maximum (Fig. 1IIa, ΔE_a = 0.05 V). Upon introduction of 1 mM of **I**–**III**, this maximum is reproduced, and in the presence of **I** and **II** the maximum is more clearly pronounced, with the last two additives acting as hydrogenation stimulants.

The presence of 6 mM of hydrogen sulfide in an uninhibited buffer solution leads to narrowing of the peak in the $i_H = F(\Delta E_a)$ curve, without changing its coordinate along the ΔE_a axis (Fig. 1IIb). i_H grows in absolute value (ΔE_a = const), especially so at small ΔE_a.

In solutions of **I** and **III** there is no maximum, whereas upon introduction of **II** or **IV** it is rather clearly pronounced at E_a of, respectively, 0.05 and 0.10 V.

Thus, the presence of an extremum in the $i_H = F(\Delta E_a)$ dependence occurs rather frequently.

Other conditions being the same, the diffusion flux is governed by at least two factors: first, by decreasing surface coverage by atomic hydrogen whose adsorption in buffer solution is determined by stage (1); in the presence of hydrogen sulfide, a concurrent reaction appears

$$H_2S + e \xrightarrow{i_4} H_{ads} + HS^-. \quad (4)$$

On introduction of aromatic amines, the following processes become possible:

$$R\text{–}NH_3^+ + e \xrightarrow{i_5} H_{ads} + R\text{–}NH_2. \quad (5)$$

Second, it may be determined by pathways of H_{ads} removal, which may occur via the concurrent stages

$$H_{ads} + H_{ads} \xrightarrow{i_6} H_2, \quad (6)$$

$$H_{ads} + H_3O^+ + e \xrightarrow{i_7} H_2 + H_2O, \quad (7)$$

$$H_{ads} + H_2S + e \xrightarrow{i_8} H_2 + HS^-, \quad (8)$$

$$H_{ads} + R\text{–}NH_3^+ + e \xrightarrow{i_9} H_2 + R\text{–}NH_2, \quad (9)$$

$$H_{ads} \xrightarrow{i_{10}} H_{ads}, \quad (10)$$

where i_j are the rates of the respective reactions.

The predominant rise in i_{10} in the case of valid inequality

$$\Delta i_{10} > \Delta(i_6 + i_7 + i_8 + i_9) \quad (11)$$

stimulates hydrogenation, whereas reversal of (11) reduces the diffusion of hydrogen into the metal. The occurrence of a maximum in the $i_H = F(\Delta E_a, \Delta E_c)$ curves is determined by the existence of at least two oppositely acting factors. Actually, the number of these factors is probably larger.

It is noteworthy that two adsorbed atomic hydrogen species are present on the metal surface [17, 18]: oversurface H^r and subsurface H^s, whose two-dimensional concentrations are determined by the equilibrium

$$H^r \rightleftarrows H^s. \quad (12)$$

The corresponding coverage factors are denoted by θ^r and θ^s. The H^r species are bound to individual atoms of the metal crystal lattice and, owing to difference between the electronegativities of hydrogen and iron [21], have a dipole moment μ of 0.53×10^{-30} C m.

The $\mu(H^4)$ value is nearly 3 times lower (0.2×10^{-30} C m). It is believed that H^r atoms are responsible for stages (6)–(9), and H^s atoms, for stage (10) [15].

In addition, the dependence $i_H = F(\Delta E_a, \Delta E_c)$ is determined by the nature of successive discharge–molization stages and that of inequality (11). If the mechanism of proton donor discharge is determined by the successive occurrence of reactions (1) and (7), then, according to [22],

$$\theta = K_1/(K_1 + K_2).$$

The index of a rate constant characterizes the number of the corresponding reaction. At $K_7 \gg K_1$ stage (1) is rate-determining and, therefore, θ_H and i_H are small. Moreover, K_1 and K_7 are independent of the proton donor concentration, but are functions of the potential

$$K_i = K_i^{\dagger} \exp(-\alpha EF/RT)$$

(E is potential, α is the Brønsted coefficient, other designations are conventional). Therefore, to a first approximation, i_H depends on the electrode potential only slightly in a wide range of E.

At $K_1 \gg K_7$ the state of the surface is close to saturation [22], and, consequently, the i_H value changes only slightly, or not at all, with increasing ΔE_c ($\theta_H \to 1$).

In the case of a mechanism with successive stages (1) and (6), of which the first is rate-determining, $K_1 \gg K_{-1}$ and $K_1(1 - \theta_H) \gg K_{-1}\theta_H$ [17]. At $i_6 \gg i$ and $i_6 \gg i_{-6}$, θ_H is equal to the equilibrium value θ_H^0. Then [22]

$$\theta_H^0 = \frac{K_1^0/K_{-1}^0}{K_1^0/K_{-1}^0 + 1} = \frac{(K_{-6}^0/K_6^0)^{1/2}}{(K_{-6}^0/K_6^0)^{1/2} - 1}.$$

Using the approach of [23] and setting the ratio K_1^0/K_{-1}^0, one can readily demonstrate how fast θ_H^0 grows under the specified conditions.

K_1^0/K_{-1}^0	1	2	5	10	20	100
K_{-6}/K_6	1	1.42	2.21	3.62	4.36	7.00
θ_H^0	0.50	0.67	0.83	0.91	0.95	~1.00

In terms of the classical recombination theory, when stage (4) is rate-determining, θ_H is related to K_i by

$$K_1/K_6 = 1/(1 - \theta_H).$$

The relationship between the ratio K_1/K_6 and θ_H in the case of Tafel reaction limiting the discharge of proton donors is characterized below:

K_1/K_6	2	3	6	11	20	100
θ_H	0.50	0.67	0.83	0.91	0.95	0.98

Since K_1 is a function of the electrode potential, and K_6, being the chemical reaction constant, is independent of this potential, it can be readily seen at what values of the K_1/K_6 ratio the rise in cathodic polarization ceases to affect i_H at invariable process mechanism. For example, if already under free-corrosion conditions ($E = E_{cor}$) $K_1/K_6 \to 100$, then $\theta_H \to 1$ and $i \neq F(\Delta E_c)$. Simultaneously, the cathodic process may occur at the limiting current of the lateral diffusion. Contrariwise, at $K_1/K_6 \ll 100$, an increase in ΔE_c makes the ratio of these K_i higher and θ_H grows. Independent investigations with the use of Armco ion demonstrated that, according to the criterial quantities $dE/d\log i_c$, $(d\log i_c/d\log C_{H^+})E$, $dE/d\log C_{H^+}$, $d\eta/d\log i_c$ $(d\log i_c/d\log C_{H^+})_\eta$, $d\eta/d\log C_{H^+}$, the hindered stage on Armco iron in acid chloride solutions with 0.99–0.01 M H_3O^+ (constant ionic strength equal to unity) is the discharge reaction (1). The weak dependence of i_H on ΔE_c (Fig. 1Ia, curve 1) satisfactorily correlates with this conclusion.

The presence of hydrogen sulfide makes i_H higher in the region of small cathodic polarizations (Fig. 1, Ib, rising portion of curve *1*). Probably, partly hindered discharge gives way to hindered recombination (6) or electrochemical desorption (7) or (8), which leads to rise in i_H. The possibility of parallel discharge of proton donors with different hindered stages was indicated in [24]. With the subsequent increase in ΔE_c, the effective adsorption energy of H_{ads}^r decreases because of the shift of the surface charge to negative values. Simultaneously, in accordance with the dependence [25]

$$\Delta H_{ads}/E_m \geq 5$$

the activation energy of migration, E_m, also decreases, which makes higher the rate of stage (6) and lowers the contribution of (11) to H_{ads} drain and diffusion flux into the metal. The subsequent independence of i_H from ΔE_c is presumably due to the constancy of θ_H as a result of a simultaneous increase in adsorption of H_{ads} atoms and their removal via molization and evolution into the gas phase.

In the presence of aromatic amines **I**–**III** (Fig. 1I, buffer solution), the experimental dependence $i_H = F(\Delta E_c)$ can be accounted for by the same factors. Introduction of **IV** presumably shifts the equilibrium (12) virtually entirely to the left, and $i_{10} \to 0$ with increasing ΔE_c. The presence of H_2S together with $R–NH_2$ leads to possible parallel adsorption of H_{ads} by schemes (1)–(5) and removal in accordance with stages (6)–(10), which determines the existence of additional secondary factors. In particular, cathodic polarization affects differently the adsorption energies of H_2S molecules and $R–NH_3^+$ cations. Blocking certain active centers under conditions of energy nonuniformity of the steel surface, they change markedly ΔH_{ads} and the conditions of surface diffusion of H^r atoms, and also the contribution of stage (10) to the removal of atomic hydrogen and the i_H value.

In the case of anodic polarization of the working side of the membrane in a buffer sulfuric acid solution, one more factor should be taken into account. With increasing ΔE_a, proton donor reduction slows down, which, in principle, must only make i_H lower. However, the build-up of positive charge on the surface changes in different ways the energies of binding to the surface for H^r and H^s atoms carrying different amounts of negative charge. If the binding energy of H^r to the surface grows faster, then the contribution from reaction (10) and i_H value increase. The descending portion of curve *1* in Fig. 1IIb is determined by the effect of decreasing rate of proton donor reduction under conditions of anodic polarization, irrespective of the nature of the rate-determining stage. In a similar way can be interpreted the dependence $i_H = F(\Delta E_a)$ in a hydrochloric acid solution containing H_2S (Fig. 1IIb, curve *1*) and also the extrema in the curves measured in the presence of aromatic amines. The absence of an extremum and the descending run of the dependence

of i_H in the interval $0 < \Delta E_a \le 0.2$ V are related to the key influence exerted by θ_H decreasing with anodic shift of the potential of the working side of the membrane. At the same time, the performance of aromatic amines as potential inhibitors in the multifactor phenomenon of steel hydrogenation from weakly acidic solutions, including those containing process stimulants (H_2S), cannot be unambiguously related to the physicochemical parameters of their molecules (σ_H, pK_b, and μ). Presumably, the complexity of the observed kinetics of the process is determined not only by the nature of the occurring reactions, but also by the concomitant, and rather important, factors: competitive adsorption of atomic hydrogen, H_2S, amines, and solvent molecules and the energy nonuniformity of the steel surface. The last factor results in that the adsorbabilities of the competing species in different θ regions are strongly dissimilar. As a result, the functional dependences $\theta_i = F(\Delta H^i_{ads})$ of the competing *i*th species may intersect. Then, the contributions from the reactions of molization, (8) and (9), with H_2 evolution into the gas phase, on the one hand, and adsorption by metal, (10), on the other, must change substantially.

CONCLUSIONS

(1) As a rule, the dependence $i_H = F(\Delta E_a, \Delta E_c)$ in weakly acid chloride solutions in the presence of hydrogen sulfide and aromatic amines has a maximum whose position is determined by the nature of R_i–NH_2.

(2) The quantitative characteristics of the dependence of i_H on the anodic and cathodic polarization are in the first place determined by the nature of successive discharge–molization stages and by the relative contributions of the corresponding reactions to the total removal of adsorbed hydrogen.

(3) The effect of aromatic amines on the hydrogenation cannot be unambiguously related to physicochemical parameters of their molecules.

Stability of Fibrous Carbon Materials in Cathodic Polarization in Nitric Acid Solutions

V. K. Varentsov, V. I. Varentsova, and E. V. Renard

Institute of Solid-State Chemistry and Mineral Raw Material Processing, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received November 23, 2000; in final form, October 2001

Abstract—Stability and electrical conductivity of graphitized and carbonized fibrous carbon materials are studied in cathodic polarization in nitric acid solutions.

Fibrous carbon materials (FCMs) are widely used as electrode materials for intensification of redox reactions in aqueous solutions in hydrometallurgy, electroplating, and other branches of industry [1–4] and also in fuel elements. In all these cases the problems necessarily arise associated with the stability of FCMs in aqueous solutions and also with variation of their properties in the course of electrolysis, since it is well known that under polarization the surface of carbon materials can change as a result of formation of various kinds of surface compounds [5, 6].

Nitric acid solutions are widely used in electrosynthesis of a number of compounds, for example, for preparation of graphite intercalates [7, 8], as active components in chemical power sources [8], for dissolution of spent fuel of nuclear power plants [9], etc. Previously it was demonstrated that FCMs are corrosion-resistant in sulfuric acid solutions. Even at high current density cathodic treatment resulted in longitudinal fracturing of fibers and their partial degradation due to hydrogen gas liberation [10]. Altered surface condition of a carbon fiber is reflected in FCM weight loss and shift of the electrode potential in the negative direction. However, changes in the stationary potential are reversible, and the initial value is restored in 24–48 h.

The goal of this work was to study the stability of fibrous graphitized carbon materials upon cathodic polarization in nitric acid solutions. For comparison are reported the results obtained in sulfuric acid solutions.

EXPERIMENTAL

The effect of cathodic polarization on FCM characteristics was monitored by the weight loss and electrical conductivity, i.e., by the properties determining the performance of FCM in electrochemical processes [1].

For the study we selected carbonized (NT-1) and graphitized carbon materials (VINN-250) with a graphite content of 85 and 99.8 wt %, respectively. A laboratory setup for studying the effect of polarization was described elsewhere [10]. Cathodic polarization was carried out in 0.25 M sulfuric acid and 1.5 or 3.5 M nitric acid solutions for 1–3 h using a TES-41 dc source. Circulation of the solution throughout the bulk of the electrode was provided by a PP-2-15 peristaltic pump. The acids used were of chemically pure grade. Cathodic treatment experiments were conducted without or with separation of the electrode spaces with an MK-40 ion-exchange membrane. The area of the fibrous carbon cathode was 2 cm^2. The cell includes a Pt anode and a perforated current lead. The electrode after treatment was thoroughly washed with distilled water to constant pH and dried at 80°C. The electrical conductivity of the test materials was measured with a VM-509 ac bridge [11]. The redox potential E was measured with a V7-22A high-resistance voltmeter using a Pt electrode relative to a silver chloride electrode. The Pt electrode was immersed in an intermediate vessel through which the working solution circulated.

Data on the FCM weight loss after cathodic polarization in nitric and sulfuric acid solutions under various process conditions are given in the table.

The results show that the nature and concentration of an acid used as well as the process conditions (current density and treating time) affect the stability of FCMs. In sulfuric acid solutions cathodic treatment does not appreciably change the weight of the graph-

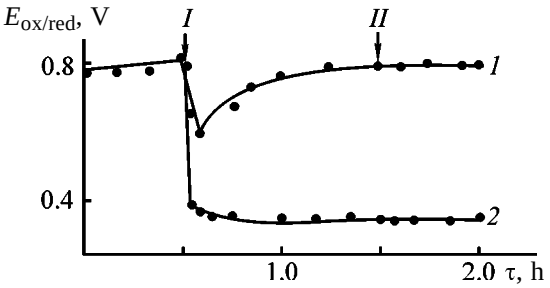
itized FCM (loss is within 1.3%). The carbonized material is less stable, and the weight of NT-1 decreased by 5–6% regardless of the process conditions.

Different trends are observed in nitric acid solutions. In this case the treatment conditions considerably influence the stability of FCMs. Upon polarization in 3.5 M HNO_3 (no separation of the cathode and anode spaces), the weight loss in the carbonized FCM is nearly the same as in polarization in the sulfuric acid solution; in the case of the graphitized material the weight loss is somewhat larger (up to 2–3%), which is probably due to degradation of the FCM fibers by liberated hydrogen gas in more concentrated HNO_3 solutions.

Cathodic treatment of graphitized FCMs in the cell with separated electrode spaces has no effect on the material weight loss. For the carbonized FCM the weight loss in 1.5 M HNO_3 is 0.3–1.9%, depending on the treatment conditions. In 3.5 M HNO_3 the material weight even increases under certain treatment conditions or without treatment (see table). The results obtained can be interpreted as follows. It is known that in nitric acid solutions oxidized layers of a complex composition are formed on the surface of carbonaceous materials [5]. This is primarily due to complex redox behavior of nitric acid solutions. Among possible nitric acid reduction products are NO, NO_2, N_2O_4, HNO_2, N_2O_3 [13], hydroxylamine, and ammonia [8, 14]. Upon cathodic polarization various redox reactions can proceed in parallel, as having close standard potentials. The resulting nitrous acid can also be reduced to various nitrogen oxides and other compounds [8]. Finally, under the experimental cathodic treatment conditions hydrogen ions can be reduced.

In the absence of a membrane separator in the cell, nitric acid reduction products can be partially oxidized on the anode in parallel with oxidation of water. In the presence of the separator these products can be accumulated in the solution, shifting the equilibrium and changing the redox potential E [12]. Without polarization the redox potentials realized on Pt in 1.5 and 3.5 M HNO_3 are +0.70 and +0.81 V, respectively. Variation of E in time in 3.5 M HNO_3 under cathodic treatment of FCMs with and without a membrane separator in the cell is illustrated in the figure.

In cathodic treatment in the cell without a separator, E initially abruptly decreases (curve *1*) and then turns back to the initial value. Similar result was obtained in sulfuric acid solutions. In the cell with a separator, accumulation of nitric acid reduction products shifts E in the negative direction (curve *2*). In this case the condition of the carbon fiber surface can change as a result of interaction with the solution components. In the table are given the changes in the electrical conductivity of FCMs, resulting from their cathodic treatment in sulfuric and nitric acid solutions. For the both types of FCMs the conductivity increases



Redox potential E of VINN-250 in 3.5 M HNO_3 as a function of cathodic treatment time τ at a current density of 1000 A m^{-2}: (*1*) no separation of electrode spaces and (*2*) separated electrode spaces. (*I*) Switch on and (*II*) switch off.

after cathodic treatment, which is consistent with data of [10] and can be attributed to desorption of chemisorbed oxygen from the fiber surface.

Upon cathodic treatment in nitric acid solutions, the conductivity trend depends on the experimental conditions. In the cell without a separator the conductivity of the graphitized FCM does not change, and that of the carbonized FCM decreases by a factor of 1.25–1.27. In the cell with a separator the conductivity of VINN-250 decreases by 12–30%, and that of NT-1, by a factor of 2–4, depending on the nitric acid concentration and polarization parameters. The observed decrease in the conductivity of the tested FCMs is due to formation of low-conducting layers on the fiber surface [5, 6, 15].

Finally, the graphitized FCM demonstrates a high stability upon cathodic treatment in nitric and sulfuric acid solutions under various polarization conditions. The stability of the carbonized FCM depends on the acid nature and cathodic polarization conditions, which should be taken into account in evaluating its suitability for the use as a cathode material in aqueous solutions, for example, in electroplating and hydrometallurgy, particularly, in recovery of small amounts of fission platinoids from nitric acid solutions.

CONCLUSIONS

(1) Stability of the tested fibrous carbon materials upon cathodic treatment in nitric acid solutions considerably depends on the polarization conditions. Separation of the cathode and anode spaces by an ion-exchange membrane reduces the weight of the graphitized FCM by 5–6%. Also this reduces the electrical conductivity of the graphitized and carbonized fibrous carbon materials by 12–40% and by a factor of 2–4, respectively.

(2) The differences in the stability of the tested fibrous carbon materials upon cathodic treatment in nitric acid solutions, observed in the cell with a membrane separator, are associated with changing redox potentials of the systems due to accumulation of nitric acid reduction products.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Properties and Composition of the Wastes of Monoethanolamine Treatment of Hydrogen to Remove Carbon Dioxide

S. V. Khitrin, S. L. Fuks, and S. V. Devyaterikova

Vyatka State University, Kirov, Russia

Received June 14, 2001

Abstract—The properties and composition of the wastes of monoethanolamine treatment of pyrolysis hydrogen to remove carbon dioxide and their effect on corrosion of ferrous and non-ferrous metals in various media were studied.

At present, pyrolysis hydrogen is treated to remove carbon dioxide with monoethanolamine (MEA) solution; this solution in the course of prolonged operation accumulates impurities, which form a gummy fraction consisting of various organic compounds and products of apparatus corrosion [1]. The bottoms of the absorption procedure are often burned out, but their components can be valuable raw materials. The data on the bottoms composition determined by various authors [1–5] are ambiguous. For example, in [1, 4] it was suggested that the reaction of MEA with carbon dioxide yields oxazolidone-2, which then converts successively into imidazolidone-2 and *N*-(2-hydroxyethyl)ethylenediamine, whereas in [5] it was found that the main reaction product was *N*,*N*-diethylolurea. As seen from the published data [1–3], the bottoms can contain various amine-containing components. In this work we studied the composition of bottoms and the feasibility of using them or their components to inhibit corrosion of ferrous and non-ferrous metals in various media.

EXPERIMENTAL

The bottoms composition was studied by gas chromatography–mass spectrometry at programmed heating in the 50–250°C range using a Hewlett–Packard MD-800 Fisous Instruments GS 8000 unit equipped with a mass-selective detector and a PC for identification of the experimental mass spectra (Masslab software). The mixtures were separated on a standard glass column (30 m long, 0.32 mm in diameter) coated with the DB-Sms stationary phase (0.25-μm layer); the flow rate of the carrier gas (He) was 4 ml min^{-1}.

Our analytical results showed that the bottoms contained more than 50 organic compounds. The main components, along with residual MEA, are nitrogen- and oxygen-containing linear and cyclic compounds given in Table 1. The presence of carbonyl compounds suggests occurrence of oxidation and hydrogenation with subsequent nucleophilic addition and condensation, which can explain formation of some main and trace component of the bottoms.

Our calculations showed that the composition of the bottoms was as follows, %: *N*-ethylolethylenediamine 37.9, MEA 20, piperazine and its derivatives 20, 2-aminoheptane 5, DEA 4, saturated hydrocarbons 1, and esters of fatty acids 1.

To determine the properties of the bottoms components and the possibility of their utilization, we performed the vacuum distillation of the bottoms at 4 mm Hg. The content of primary, secondary, and tertiary amines in the fractions after distillation is given in Table 2.

It is known [6] that amines are used as inhibitors of the metal corrosion. Therefore, we studied the effect of bottoms in question on the corrosion processes. In our tests we used 65G, 60S2A, and 65S2VA spring steels after their thermal treatment. The content of the inhibitor was selected using published data [7–10] and was varied within 10–75 ml l^{-1}. The corrosion tests were performed in the solutions of hydrochloric acid (210 g l^{-1}), off-gas hydrochloric acid (150 g l^{-1}), sodium chloride (3%), and sodium sulfate (3%). The corrosion rate was evaluated using the weight corrosion parameter $K_w = \Delta m/(S\tau)$ (g cm^{-2} h^{-1}, Δm is the weight loss in the course of corrosion, S is the sample area, and τ is the corrosion time), the depth corrosion parameter $K_d = K_w \times 8.76/\rho_M$ (mm per year, ρ_M is

the metal density), and the protection degree $Z = 1 - (K_w/K_w^0) \times 100$ (%, K_w^0 is the weight corrosion parameter in the individual solution) [6].

The corrosion parameters for the steel treated for 164 h in hydrochloric acid solution containing bottoms are listed in Table 3.

As seen from Table 3, the bottoms in question inhibit corrosion in the acidic media, but the protection degree is rather low, 44–60%, i.e., 9 points according to the scale of protection efficiency, and this inhibitor belongs to class V [6]. Thus, this bottoms can be used as corrosion inhibitors only at short contacts of metals with acid solutions.

We also studied the inhibiting effect of the bottoms on the steel corrosion in off-gas hydrochloric acid (150 ml l^{-1}). The results of our tests (330 h) are listed in Table 4.

As seen from Table 4, the bottoms at the 75 ml l^{-1} content strongly decelerate the corrosion rate of the steel in off-gas hydrochloric acid solution and decrease the depth corrosion parameter; the deceleration coefficient reaches 78.7% at 330-h contact.

The effect of bottoms in sodium chloride solution

is almost independent of the test time, and certain decrease in the corrosion rate is observed (Fig. 1). At 75 ml l^{-1} content of the bottoms the protection degree is satisfactory (7 points [6]).

Our visual tests showed that the corrosion pitting on the sample surface appeared in acid solutions after 164-h contact, whereas in neutral solutions the evidences of corrosion were observed only after 900 h.

During vacuum distillation of the bottoms some volatile fractions were separated. In this connection we studied the effect of bottoms on the rate of atmospheric corrosion. Steel samples were stored in a sealed vessel at room temperature over the sodium chloride solution containing bottoms (10–75 ml l^{-1}).

As seen from Fig. 2, the corrosion rate is the highest at the bottoms content of 10 ml l^{-1}. At the bottoms content increased to 75 ml l^{-1} the rate of atmospheric corrosion is several times lower. Visual examination showed that pitting appeared on the sample surface at bottoms content of 10 ml l^{-1} after 900 h.

We also studied the effect of bottoms on the corrosion of non-ferrous metals and alloys, in particular, M06 copper, L85 brass, and AD31 aluminum in 3% sodium chloride and sodium sulfate solutions. As seen, at bottoms content of 35 ml l^{-1} the rate of metal dissolution increases. The dependence of the catalytic effect $G = K_w/K_w^0$ of the additive on the time of copper and brass treatment in sodium chloride solution (Fig. 3a) shows that the catalytic effect of bottoms increases with time, and the most pronounced catalytic effect is observed in the case of brass corrosion (Fig. 3a, curve *2*).

Our visual observation showed that both in the absence and in the presence of bottoms the sample surface is coated with a dense smooth film, whose main component is CuOHCl, which is consistent with the data given in [9]. In solution containing bottoms this film appears after a longer period, the surface becomes glossy and retains the decorative properties for a long time.

The brass is coated with the oxide film after a longer time as compared to copper, and its decorative properties are higher.

As seen from the kinetic dependences of the catalytic effect of bottoms on copper and brass dissolution in sodium sulfate solutions (Fig. 3b), the catalytic effect on the copper corrosion is higher (curve *1*) as compared to brass (curve *2*). It should be noted that in the solution containing bottoms the sample surface after prolonged treatment remained clean and lustrous without any visual evidence of corrosion. Thus, the bottoms in question can be recommended as a polish-

Copper	NaCl	35	0.060/0.050	0.050/0.040	0.050/0.110
Brass	Na_2SO_4	35	0.060/0.240	0.040/0.100	0.080/0.380

* The content of amines before and after the tests is given in the numerator and denominator, respectively.

ing agent for copper and its alloys with prolonged preservation of the decorative properties.

The bottoms in the chloride-containing solution catalyze the corrosion of aluminum, and the corrosion rate of aluminum is more than two orders of magnitude higher than in the bottoms-free solution. The aluminum sample in the bottoms-containing solution was coated with the corrosion products in several hours, and the corrosion rate was high throughout the period of visual observations.

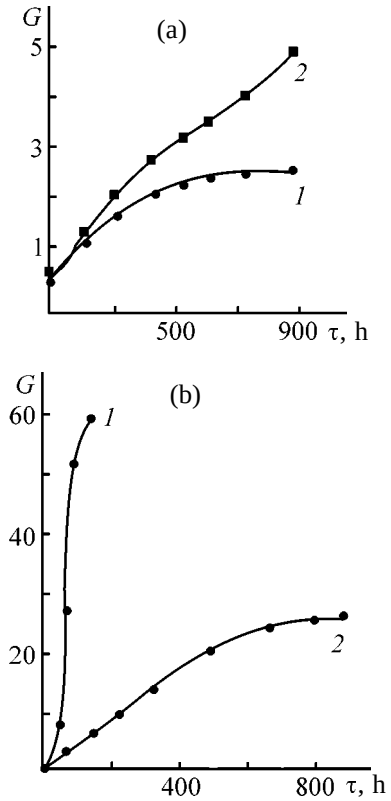

Fig. 3. Catalytic effect of bottoms *G* as a function of time τ in solutions of (a) sodium chloride and (b) sodium sulfate; (*1*) copper and (*2*) brass.

We also studied changes in the composition of corrosion-active media after corrosion of various alloys. In this case, the content of amines before and after the tests was determined by potentiometric titration; the results are listed in Table 5.

The increase in the amine content observed in most cases is probably due to the decomposition of amine compounds. The decrease in the content of primary and secondary amines in the tests with copper is probably caused by their conversion under the influence of corrosion products.

CONCLUSIONS

(1) The composition of the large-scale wastes from monoethanolamine treatment of pyrolysis hydrogen to remove carbon dioxide was studied.

(2) The bottoms after monoethanolamine treatment inhibit corrosion of steel with relatively poor and satisfactory protective power in acidic and neutral solutions, respectively, whereas in the case of nonferrous metals they catalyze corrosion and can be used as polishing agent for copper and brass.

(3) The bottoms inhibit the atmospheric corrosion of steel at their content in solution of 75 ml l^{-1}.

(4) In the course of corrosion tests the content of primary and secondary amines increases (or slightly decreases) in the case of copper.

CATALYSIS

Carbonylation of Methanol with Carbon Monoxide in the Presence of Sulfur-containing Catalysts

Yu. A. Aleksandrov, V. M. Shekunova, A. O. Kolmakov, and E. H. Tarasov

Research Institute of Chemistry, Lobachevskii Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received June 25, 2001

Abstract—Physicochemical features of methanol carbonylation with carbon monoxide catalyzed with sodium sulfides Na_2S_x (x = 1, 2, 4) were studied. The effect of admixtures of sulfur dioxide in the gas phase on the yield of the target product (methyl formate) was revealed.

Methanol is a versatile intermediate, which can be used in syntheses of various chemical substances by the reaction with carbon monoxide or synthesis gas [1]. Some of such syntheses are performed on the commercial scale, e.g., production of acetic acid by catalytic carbonylation of methanol using complex rhodium homogeneous catalyst. It is well known [2] that base catalysts effect formation of methyl formate by reaction of carbon monoxide with methanol at elevated pressure:

$$CH_3OH + CO \xrightarrow{\text{Cat.}} HCO_2CH_3. \quad (1)$$

Methyl formate is formed in a high yield with sodium methylate as catalyst. However, metallic sodium is required for the synthesis of this catalyst, which restricts its use.

It was shown previously [3, 4] that sulfur-containing catalysts can be used for the synthesis of urethanes by carbonylation of aromatic nitro compounds with carbon monoxide in methanol.

The goal of this work was to study carbonylation of methanol with carbon monoxide in the presence of sulfur-containing catalysts.

Sodium sulfides Na_2S_x with x = 1, 2, 4, which are relatively available and cheap commercial products, were used as catalysts.

As seen from Table 1, anhydrous sodium monosulfide is the most active catalyst. With increasing its concentration within the 0.3–1.2 M range, the yield of the target product (methyl formate) increases to 95%. As opposed to nitrobenzene carbonylation [5], V(V) compounds, pyridine, or polyethylene glycol added as activators of sulfur-containing catalysts did not increase the methyl formate yield.

The catalytic activity of sodium sulfide in carbonylation of methanol with carbon monoxide depends on the solvent (Table 2). This reaction proceeds most easily in neat methanol or in aromatic hydrocarbons (benzene, toluene). The yield of methyl formate at the constant Na_2S : methanol ratio increases with increasing methanol concentration in benzene from 1.3 to 5.0 M. The further growth of the methanol concentration up to pure methanol does not increase the methyl formate yield. The above results can be explained by variation of the solvent polarity and CO solubility in the solvent.

Water added to methanol even in small amounts (0.2–0.4 M) noticeably inhibits the reaction and practically stops it at concentrations higher than 0.9 M (Table 3). This effect is probably caused by deactivation of the catalyst due to its shielding by the hydrate shell.

Table 1. Activity of sulfur-containing catalysts in carbonylation of methanol with carbon monoxide* (1 h, temperature 80°C, CO pressure 15 MPa)

Catalyst	C_c, M	Y_{mf}, %	P_c, g l^{-1} h^{-1}

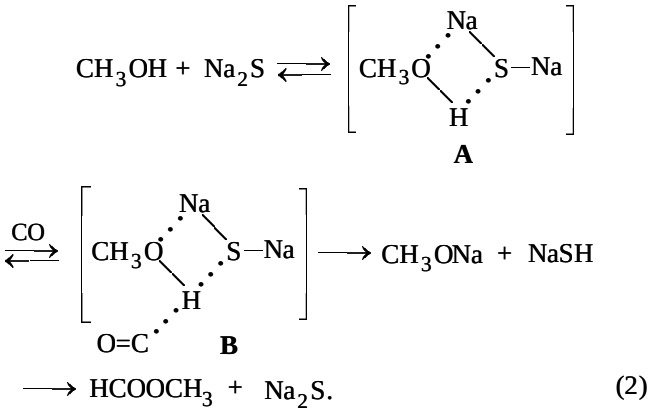
* Molar ratio Na_2S : methanol = 0.024; the same for Tables 4 and 5.
** K_{CH_3OH} is the methanol conversion; S is the selectivity with respect to methyl formate.

The effect of the CO pressure on the methanol carbonylation in benzene in the presence of sodium sulfide was also studied (Table 4). As the CO pressure is increased from 3 to 7 Mpa, the methyl formate yield grows substantially, but it does not appreciable grow further at the pressure of about 15 MPa.

The carbonylation rate noticeably increases with the CO pressure. For instance, at the CO pressure of 10 MPa the methyl formate yield in 10 min is the same as in 60 min at 7 MPa; in 10 min at 7 MPa the yield is lower by half.

The temperature also affects the methanol carbonylation with CO (Table 5). The maximal yield is observed at 80°C. At lower temperatures, the reaction is too slow. At higher temperatures, the methyl formate yield also decreases probably because of low thermal stability of the intermediate participating in the catalytic step; both methanol conversion and reaction selectivity with respect to methanol decrease.

The above results suggest the following scheme of the catalytic carbonylation of methanol with CO:



(2)

Methanol forms hydrogen-bonded intermediate **A** with sodium sulfide and then **A** reacts with CO to form intermediate **B**. The latter rearranges through sodium methylate and hydrosulfide and converts into methyl formate with regeneration of sodium sulfide. In addition, **A** can decompose with formation of sodium methylate and sodium hydrosulfide.

Saturation observed with increasing the methanol concentration in the solvent (Table 2) and the effect of the temperature on the target product yield (Table 5) confirm formation of intermediate **B**. Inhibition of the reaction by water is explained by blocking of the active centers of the catalyst by the hydrate shell. It is well known [6] that small admixtures of sulfur compounds in exhaust gases deactivate many catalytic systems. Therefore, we studied the effect of acidic gaseous admixtures, in particular, sulfur dioxide, which are present together with CO in exhaust gases of metallurgic, heat and power, and other plants and can affect carbonylation of methanol with carbon monoxide.

The initial SO_2 concentration in the gas mixture was varied within the 0–5.61 vol % range (Table 6). As seen, at an SO_2 content from 0.72 to 1.30 vol % carbonylation of methanol is inhibited, and at 5.61 vol % it completely stops.

EXPERIMENTAL

Anhydrous Na_2S was prepared by dehydration of $Na_2S \cdot 9H_2O$ [7]. Na_2S_2 and Na_2S_4 were synthesized by fusion of anhydrous Na_2S with stoichiometric amounts of chemically pure grade sulfur [8].

CO and SO_2 were used without additional purification. Methanol, benzene, toluene, dioxane, tetrahydrofuran, chlorobenzene, ethyl acetate, and carbon tetrachloride were purified by common procedures [9].

Carbonylation of methanol was performed in a stainless steel (KhM-18) 50 cm^3 autoclave charged with the calculated amounts of methanol and catalysts. The autoclave was purged with carbon monoxide at continuous agitation of the reaction mixture. After that CO was pumped to a pressure of 6–10 MPa. Then the temperature of the experiment, which was monitored with a thermometer inserted into the body of the autoclave, and the required pressure were set. This instant was taken as the reaction start. The reaction process was monitored by the pressure decrease. After the reaction completion, the autoclave was cooled, and the pressure was relieved. Liquid reaction products were analyzed by GLC on a Tsvet-101 chromatograph with a thermal conductivity detector. Helium was used as a carrier gas (flow rate 30 $cm^3\ min^{-1}$); 3000×3 mm glass column was used; stationary phase PEG 1500, temperature 60°C.

CONCLUSION

Anhydrous sodium sulfide is the effective catalyst of carbonylation of methanol with carbon monoxide. Sulfur dioxide as an admixture in CO deactivates the reaction.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Sorption of Cr(VI) on the Anion-Exchange Fibrous Material Based on Nitron

Abstract—The kinetics and thermodynamics of Cr(VI) sorption under the static and dynamic conditions on the fibrous sorbent SMA-1 prepared by chemical modification of polyacrylonitrile were studied.

One of the main environmental problems is treatment of industrial wastewaters and sources of drinking water to remove ions of toxic metals (e.g., Zn, Cr, Cu, etc.) [1]. Among them the removal of chromium is the most urgent, because its compounds, being strong oxidants, negatively affect the human vital organs such as kidneys, liver, and brain. The removal of Cr(VI) from aqueous (especially acidic) solutions by sorption is rather difficult, because it oxidizes functional groups of the sorbent and causes its degradation. In the literature, major attention has been concentrated on the treatment of industrial wastewaters using granular anionic AV-17 × 8 [2] and EDE-10P [3] and some amphoteric ion exchangers [4]. The highest sorption of Cr(VI) on the AV-17 × 8 anion exchangers is observed at pH 1–4, and with increasing pH it gradually decreases. The EDE-10P anion exchanger is readily oxidized by dichromate ions, and thus is unsuitable for removing chromium from industrial wastewaters.

The advantage of fibrous anion exchangers as compared to granular sorbents is their strongly developed active surface providing high rates of sorption and desorption.

The sorption properties of the VION-AN-1 modified polyacrylonitrile ion-exchange fiber in removal of Cr(VI) from electroplating production wastewaters were studied in [5]. This fiber contains basic vinylpyridine groups with the static exchange capacity (SEC) of 1.1–1.2 mg-equiv g^{-1}, but the capacity of such sorbents for chromium is as low as 15 mg g^{-1} sorbent. Moreover, in the course of regeneration, due to the opening of pyridine rings with alkali, the above sorbents undergo strong degradation.

The anion-exchange fibrous sorbents were prepared by chemical modification of the Nitron fiber using nitrogen-containing bases such as hydroxylamine, hydrazine, ethylenediamine, and hexamethylenediamine (HMD) [6]. It was found that, among the ion exchangers prepared, the SMA-1 sorbent prepared by modification of Nitron fiber with HMD is the best suited for sorption removal of Cr(VI) from aqueous solutions.

The sorption of Cr(VI) was studied at pH 1–10 under the static conditions. A sorbent sample (1 g) in the chloride form was placed into an aqueous solution (200 ml) of potassium dichromate whose concentration was varied a wide range. The content of $Cr_2O_7^{2-}$ ions before and after sorption was analyzed by photocolorimetry using the calibration plot of the optical density of solutions on the concentration of dichromate ions at λ = 364 nm. The specific sorption $\Delta X/m$ was calculated from the following equation:

$$\Delta X/m = (C_0 - C_\tau)V/Mm,$$

where ΔX is the amount of sorbed anions (M), m is the sorbent weight (g), C_0 and C_τ are the concentrations of dichromate ions in solution before and after sorption (g l^{-1}), V is the solution volume (l), and M is the molecular weight of the ions (g mol^{-1}).

The sorption of dichromate anions by SMA-1 sorbent was studied as influenced by the time, temperature, and concentration of $Cr_2O_7^{2-}$ ions in the initial solution. As seen from Figs. 1 and 2, in all the cases the sorption equilibrium between the fiber and solution is attained in 3–5 min. With increasing temperature the specific sorption slightly decreases.

The sorption isotherms of $Cr_2O_7^{2-}$ ions on the SMA-1 sorbent at various temperatures are shown in Fig. 3. As seen, with increasing concentration of dichromate ions in the initial solution their sorption in-

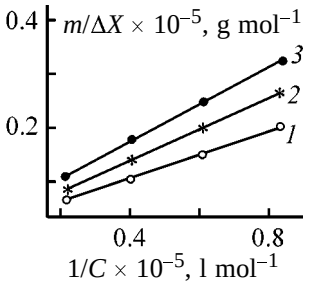

Fig. 4. Plot of $1/\Gamma$ vs. $1/C$.

creases, whereas with increasing temperature it decreases.

It is known that, in terms of the law of mass action, heterogeneous processes of addition and substitution involving the constant number of functional groups can be described by the Langmuir equations [7], and thus the sorption isotherms are presented as follows:

$$\Gamma = \Gamma_\infty KC/(1 + KC),$$

where K is the adsorption equilibrium constant, C is the current solution concentration (M), and Γ_∞ is the maximal sorption for the given temperature.

To determine K and Γ_∞, the Langmuir equation is often brought to the form

$$1/\Gamma = 1/\Gamma_\infty + (B/\Gamma_\infty)(1/C),$$

where $B = 1/K$.

Then, the $1/\Gamma$–$1/C$ dependences are plotted; the slope and the section cut off on the ordinate axis give the B/Γ_∞ and $1/\Gamma_\infty$ values, respectively. Such typical dependences for sorption of $Cr_2O_7^{2-}$ ions with SMA-1 sorbent at various temperatures are shown in Fig. 4.

The thermodynamic functions were calculated from the temperature dependence of the equilibrium constant. For this purpose the $R\ln K$–$1/T$ dependence was plotted, and then ΔH was calculated from the slope of this dependence. The ΔS value was calculated from the equation

$$\Delta S = (\Delta H - \Delta G)/T.$$

As seen from Table 1, the equilibrium sorption constants are significantly greater that 1, which suggests the selectivity of dichromate ion sorption on the SMA-1 sorbent; sorption proceeds with decrease in the free energy, enthalpy, and entropy of the system. The decrease in the two latter parameters indicates very strong binding of Cr(VI) with the sorbent.

0.5	300	165	58	4.1	5.8
0.5	375	160	56	4.1	5.8

To evaluate the performance of SMA-1 sorbent in treatment of industrial wastewaters to remove chromium(VI) compounds, the dynamic sorption mode was developed using model solutions. The sorbent prepared by modification of polyacrylonitrile with HMD (SMA-1) was packed into a column (0.2 g cm^{-3} bulk density) and activated with 0.1 M hydrochloric acid solution, after which a potassium dichromate solution (1 g l^{-1}) was passed. The dynamic exchange capacity (DEC) of the sorbent for chromium(VI) reached 390 mg g^{-1} at pH 4.2 (Table 2). As seen from these data, the sorption of Cr(VI) compounds depends on pH influencing the speciation of chromium ions.

It is known that at pH < 7 the solution contains $HCrO_4^-$ and $Cr_2O_7^{2-}$ ions, whereas at pH > 7 $HCrO_4^-$ and CrO_4^{2-} prevail [8]. Owing to the presence of highly basic groups in the sorbent, the sorption of Cr(VI) at pH 8–10 is sufficiently strong.

The sorbent was regenerated with 5% aqueous solution of potassium hydroxide. We found that the sorbent exhibits high chemical stability and can be reused. As seen from Table 3, after ten sorption–desorption cycles DEC remains rather constant. The data on DEC as influenced by the $K_2Cr_2O_7$ concentration in solution and flow rate of the solutions through the sorbent bed are listed in Table 4. In the pH range

studied our sorbents efficiently recover chromium(VI) compounds from solution even at concentrations of the order of 1 mg l^{-1} (Table 2).

At a 3–4-fold increase in the flow rate of the model solution through the sorbent bed, the sorption capacity of the SMA-1 sorbent remains high and can meet the requirements of the water treatment process.

CONCLUSION

(1) The sorption properties of the SMA-1 sorbent prepared by chemical modification of Nitron fiber with hexamethylenediamine exceed the properties of all the known ion exchangers based on acrylonitrile.

(2) Sorption proceeds without diffusion hindrance, and the sorption capacity of the sorbent for chromium reaches 137 mg g^{-1}. The sorbent developed can be used in the treatment of electroplating production wastewaters to remove chromium(VI) compounds and in concentration of process solutions.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Specific Features of Reversed-Phase High-Performance Liquid Chromatography as Applied to Determining the Distribution Coefficients of Pesticides in the Hexane–Acetonitrile System

O. K. Ostroukhova, I. G. Zenkevich, O. S. Yuzikhin, and V. I. Dolzhenko

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia
Russian Institute of Plant Protection, St. Petersburg, Russia

Received May 10, 2001

Abstract—The suitability of reversed-phase high-performance liquid chromatography for determining the distribution coefficients of organic compounds in the hexane–acetonitrile system was considered. A version of the necessary additional step in the sample preparation procedure was proposed, namely, changing from nonpolar hexane to a solvent unlimitedly miscible with the eluent. The distribution coefficients were determined for 20 pesticides by the proposed method and compared with those determined by gas chromatography.

Extensive use of chemical agents for plant protection (pesticides) requires efficient methods of their identification and determination of the residual amounts of them in agricultural products and environmental objects [1]. This problem can be solved by taking new approaches to development of the procedures for determining the residual amounts of pesticides. Many of these approaches are based on such characteristic of pesticides as their distribution coefficient K_d in heterophase systems of organic solvents.

The distribution coefficients K_d can be regarded as a characteristic of organic compounds like boiling point, refractive index, gas-chromatographic retention index, etc. Reference books usually cite, e.g., for pesticides, along with other physicochemical constants, the logarithms of their distribution coefficients in the octanol–water system ($\log P$) characterizing the lipophilic properties of these compounds [2] and their sorption and bioaccumulation abilities [3–5]. Thus, $\log P$ is an important parameter indirectly characterizing the behavior of toxicants in the environmental objects [3, 4]. But this characteristic is of little use for analytical purposes because of unsatisfactory rheological (high viscosity) and chromatographic (aqueous solution dosing is undesirable) properties of the system components. It is more convenient to use systems of low-boiling organic solvents, e.g., hexane–acetonitrile, as these solvents are most widely used as extracting agents for determining the residual amounts of pesticides in various objects [6]. Also, this system was suggested for identification of pesticides based on the K_d parameters [6].

Up to now, K_d has been mostly determined by three methods: titrimetric, photometric, and gas-chromatographic. The two first-named methods are typically used for aqueous–organic systems, in particular, for measuring $\log P$. The third, gas-chromatographic method, which received the independent name of partition chromatography [7, 8], is preferable for heterophase systems comprised of organic solvents exhibiting limited miscibility with respect to each other. However, this method is unsuitable for thermally unstable and low-volatile substances. Liquid chromatography virtually was not used for determining K_d of this kind of substances (in particular, pesticides), though such possibility was mentioned in the monograph [8].

The aim of this work was to study the specific features of reversed-phase high-performance liquid chromatography (HPLC) as applied to determining K_d of pesticides extensively used now in the Russian Federation.

EXPERIMENTAL

For determining K_d we selected 20 pesticides belonging, for the most part, to three chemical groups (organophosphorus compounds, heterocyclic compounds, namely, derivatives of pyridine, triazole, and tetrazole, and pyretroids, that is, derivatives of cyclopropanecarboxylic acid). They were dissolved (1 mg ml^{-1}) in acetonitrile (ultrapure grade) saturated with hexane (as recommended in [9], in K_d determina-

1070-4272/02/7501-0075$27.00 © 2002 MAIK "Nauka/Interperiodica"

tion the sum of the concentrations of the substances being characterized should not exceed 3 wt % as calculated for the total volume of the two phases).

To determine K_d of the pesticides by gas chromatography (reference method) we placed 3 ml of the solution of pesticide in acetonitrile into standard 10-ml test tubes. Next, an equal volume of hexane (chemically pure grade) saturated with acetonitrile was added. After shaking for 1 min, the test tubes were kept for 5–10 min at room temperature (21 ± 2°C). Each layer was analyzed chromatographically on a Mega (Carlo Erba, Italy) gas chromatograph with a flame-ionization detector and a 10 m × 0.53 mm capillary column (HP-1 stationary phase as 2.65-μm-thick film; temperature programming within 120–280°C, 10 deg min^{-1}). The flow division ratio was 1 : 5. The vaporizer temperature was 280°C. Equal volumes of each layer of the heterophase system (1 μl) were dosed with a Hamilton microsyringe. To prevent contamination of the lower-layer sample (acetonitrile) during passing of the syringe needle through the upper layer (hexane), the sample volume taken was increased to 5 μl and brought to the desired volume (1 μl) immediately before introduction into the chromatograph. The peak area was determined using Multichrom software. The parameter K_d for the pesticides was calculated by the formula

$$K_d = S_1/S_2. \quad (1)$$

Here, S_1 and S_2 are the peak areas of the analyzed substance in the hexane and acetonitrile phases, respectively.

In reversed-phase HPLC experiments we placed into standard 15-ml test tubes 5 ml of the solution of pesticide in acetonitrile, to which equal volume of hexane saturated with acetonitrile was added. After shaking for 1 min the test tubes were kept for 5–10 min at 16°C. Next, the heterophase system was transferred to a separatory funnel, and the lower acetonitrile layer was separated from the hexane layer. The hexane solution was placed into a weighing bottle, and the solvent was evaporated in a vent hood at room temperature. Acetonitrile (1 ml) was added to the dry residue, and the weighing bottle was placed into an ultrasonic bath for 5 min (for exhaustive dissolution of dry residue). Each layer was analyzed on a Waters liquid chromatograph with a Nova-Pak C18 (3.9 × 150 mm) column and UV detector. The detection wavelengths were 220 and 254 nm.

As mobile phase for compound nos. 1–16 (Table 1) in isocratic mode we used 50% aqueous acetonitrile and for compound nos. 17–20, 80% aqueous acetonitrile. The eluent flow rate was 1 ml min^{-1}.

The samples were dosed (5 μl) and injected automatically. The peak areas were determined using the Millenium software. The K_d parameters for the pesticides were calculated by the equation

$$K_d = S_1/(S_2 k). \quad (2)$$

Here, $k = V_1/V_2$ is the degree of concentration, i.e., the ratio of the hexane phase volume V_1 to that of the resulting solution in acetonitrile V_2 after changing to another solvent (k = 5 or 8).

The reproducibility of the K_d values was judged from attaining relative standard deviations under 0.15 for 3–5 measurements [9].

The distribution coefficient is essentially the ratio of the equilibrium concentrations of a substance in the coexisting layers of the heterophase system of solvents [8, 10]. Also, the distribution coefficient can be calculated using the parameter $\bar{P}$, as suggested by Beroza and Bowman [7]. This parameter is defined as the ratio of the concentrations of the analyzed substance in the nonpolar phase before and after adding the polar phase. The parameters K_d and $\bar{P}$ are interrelated as

$$K_d = \frac{\bar{P}}{\alpha(1 - \bar{P})}, \quad (3)$$

Here, α is the volume ratio of two immiscible phases (typically α = 1).

By contrast to direct methods of determining K_d, that is, from the ratio of the intensities of the analytical signals for the coexisting phases with arbitrary volume [formula (1)], the inaccuracies in calculating K_d by formula (3) depend not only on those of determining the chromatographic peak areas but also on those of measuring the phase volume ratio α.

Direct determination of K_d (titrimetrically and photometrically), as well as determination of the parameters $\bar{P}$, typically involves analysis of only one of the two phases of the heterophase system before and after mixing. Based on the difference, one determines the concentration of the substance in the other phase, which makes it possible to calculate K_d. The main sources of inaccuracy in determining K_d are unequal phase volumes analyzed before and after mixing, the inaccuracy of determining the equivalent point (in the case of titrimetric analysis), and falling of the optical density of the samples beyond the range

of validity of the Bouguer–Lambert–Beer law (photometric analysis) [11].

When applied to the system of limitedly miscible low-boiling organic solvents, gas chromatography allows direct analysis of each phase of the heterophase system. Therefore, the main sources of inaccuracy in measuring K_d are those in measuring the peak areas and the possible variability of the concentration ratio of the substances being characterized at variations of their concentrations (deviations from Henry's law).

Analysis of each phase of the heterophase hexane–acetonitrile system by reversed-phase HPLC (by contrast to GLC) requires additional sample preparation procedure so as to exclude dosing into chromatograph of solutions of the samples in nonpolar solvents (especially with organic solvent–water mixtures as eluents). For such samples, hydrophobic solvents should be replaced by hydrophilic solvents. The procedure proposed in this work consists in the following. Hexane solutions are evaporated, whereupon the pesticides to be characterized are redissolved in acetonitrile or other suitable solvent. At the same time, this procedure increases the concentrations of compounds relative to those in the initial nonpolar phase, which decreases the inaccuracy in determining small K_d values, especially for $K_d < 0.01$. The amount of the substances under study can also be increased by varying the volumes of the samples dosed into chromatograph (5–100 μl), which is equivalent to additional 20-fold concentration. Further sources of inaccuracy in determining K_d for the sample preparation procedure considered are relatively high volatility at room temperature and irreversible sorption of the pesticides on the glass surface [12] during evaporation.

Table 1 presents the K_d parameters for the pesticides studied in this work (these are arranged in accordance with increasing molecular weight). These parameters were determined by GLC and HPLC (at UV detection wavelengths of 220 and 254 nm and the degree of concentration after changing to another solvent $k = 5$). Also, by taking GLC conventionally as

* Recalculated using the p values by formula (3).

the standard method, it is possible to estimate the relative deviations from the standard of the K_d values determined by different methods. Table 1 shows that for 12 of the 20 pesticides studied the K_d values determined by the two chromatographic methods exhibit a good convergence (accurately to within the absolute measurement errors). The relative deviations of K_d (except for those of Tetraconazole and Prochloraz) vary from –46 to +53%. Nevertheless, our data suggest random scatter of the K_d values of the pesticides, as the average value of the relative deviations calculated with the sign taken into account is only –0.3%, the standard deviation being 28%. This proves the lack of any systematic errors in determining K_d by the two methods considered.

The K_d(HPLC) values listed in Table 1 for different wavelengths, namely, 220 and 254 nm, show that K_d is virtually unaffected by variation of the detection wavelength. Therefore, K_d(HPLC) of substances can be determined at any wavelength.

For the six pesticides whose relative divergences between the K_d(GLC) and K_d(HPLC) values are over 30% (Table 1), we repeatedly determined K_d(HPLC), now at the degree of concentration increased to $k = 8$ (Table 2). The results proved once again the random character of the divergences between the K_d(GLC) and K_d(HPLC) values for all the compounds except for Prochloraz. The relative divergences varying from –52 to +40% at $K_d < 0.1$ do not exceed the scatter in K_d revealed by such comparison for other methods. The average relative deviation for repeatedly determined K_d(HPLC) is –4%, which, similar to the previous run, is smaller than its standard deviation (±41%).

In the case of Prochloraz, a large difference in the K_d(GLC) and K_d(HPLC) values can be due to both unaccounted sorption effects and to instability of the compound itself during chromatographic analysis. It should be noted that for Tetraconazole [K_d(GLC) = 0.01] we succeeded in decreasing the relative differences in these values from +220 to +20% by increasing the degree of concentration (from 5 to 8), which suggests a typical outlier in the former case.

To test independently the method for determining K_d proposed in this work, it is reasonable to compare the K_d(HPLC) values for the pesticides obtained by us with the published data [13] (Table 3). Interestingly, $K_d < 1 \times 10^{-2}$ for dimethoate reported in [13] suggests that, by contrast to the method proposed by us, it is in principle impossible to precisely determine indirectly small K_d values (<0.01) using the P value. Comparison of the data obtained by us with those reported by other authors shows that their agreement does not contradict the modern views on interlaboratory reproducibility of the distribution coefficients in the octanol–water [14] and hexane–acetonitrile systems (in the form of the P value) [15].

Thus, we demonstrated the suitability of reversed-phase HPLC as an alternative chromatographic procedure for determining the distribution coefficients of a series of pesticides as an example. The inaccuracies in measuring K_d of the pesticides by different chromatographic methods are random. Moreover, it can be supposed that more reliable K_d values can be obtained by combining these methods.

CONCLUSION

A new method was proposed for determining the distribution coefficients of thermally unstable and low-volatile compounds, containing chromophore groups, in the heterophase hexane–acetonitrile system by reversed-phase high-performance liquid chroma-

tography. This method involves changing from a hydrocarbon to another solvent and additionally concentrating the samples. This method affords more reliable determination of small distribution coefficients typical for the majority of currently used pesticides.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

NMR Study of Decomposition of Monoethanolamine under Conditions of Industrial Gas Treatment

V. P. Talzi and S. V. Ignashin

Omsk Branch, Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Omsk, Russia

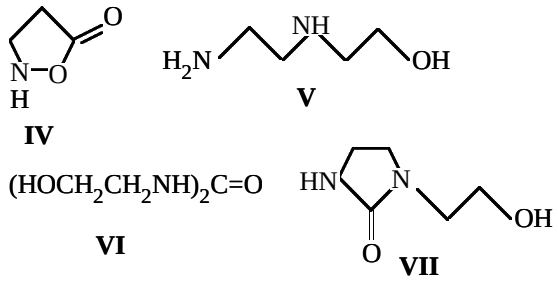
Received July 18, 2000; in final form, January 2001

Abstract—The main impurities in aqueous solution of monoethanolamine used in various stages of gas treatment at the Omsk Oil Refinery Joint-Stock Company were identified by ^{1}H and ^{13}C NMR spectroscopy. A mechanism of their formation was proposed. A probable dependence of service characteristics of the absorbent on its composition was considered.

Process gases are commonly treated in industry to remove acidic impurities (CO_2, H_2S, CS_2, and COS) using aqueous solutions of amino alcohols, among which monoethanolamine (MEA) is the most frequently used. For decades of industrial exploitation of gas treatment equipment, the optimum process parameters were selected, the main process problems were revealed, and measures intended to solve these problems were developed. Nevertheless, data on variation of the absorbent composition during its operation and the effect of the arising impurities on the efficiency of gas treatment are difficultly accessible, though it is well known that it is these impurities, unremovable in regeneration, that are often responsible for significant increase in the corrosion rate of the equipment, unwanted foaming, and the loss of absorption ability of the absorbent [1–5].

Under the conditions of industrial gas treatment the compounds formed in the reaction of MEA with CO_2, COS, and CS_2, are mainly carbamate $[HOCH_2CH_2 \cdot NHCO_2^-][H_3N^+CH_2CH_2OH]$ (**I**), thiocarbamate $[HOCH_2CH_2NHCOS^-][H_3N^+CH_2CH_2OH]$ (**II**), and dithiocarbamate $[HOCH_2CH_2NHCSS^-][H_3N^+CH_2 \cdot CH_2OH]$ (**III**) [1, 2].

The reversible formation and decomposition of **I**–**III** and also of monoethanolamine sulfide are the main reactions governing the process of amine gas treatment. Thio analogs of carbamate **I** are considerably more stable with respect to decomposition to COS or CS_2 and MEA [6]. Theoretical considerations suggest that specifically thiocarbamate (**II**) as a result of further transformations can give most likely the impurities unremovable by regeneration of the absorbent [2]. Isoxazolidone-5 (**IV**), 5-amino-3-aza-1-pentanol (**V**), *N*,*N*'-di(2-hydroxyethyl)urea (**VI**), and 1-(2-hydroxyethyl)imidazolidone-2 (**VII**) were described as these impurities [2]:



By NMR analysis of the absorbent samples (the samples were withdrawn from various installation units and stages of gas treatment at the Omsk Oil Refinery), we refined their composition and the mechanism of formation of impurities.

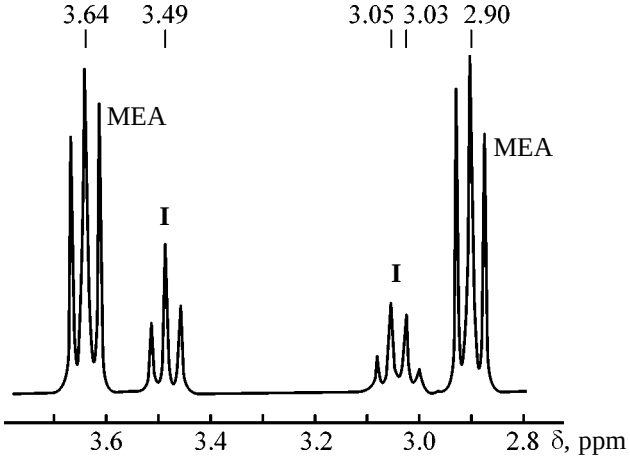


Fig. 1. Fragment of the ^{1}H NMR spectrum of aqueous solution of MEA before regeneration (ISP). (δ) Chemical shift.

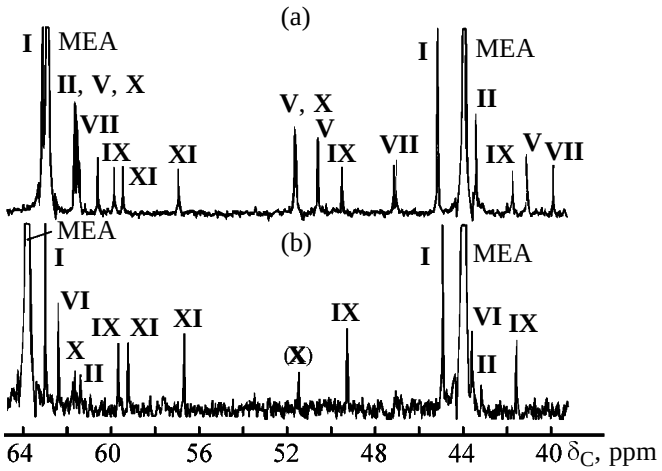

Fig. 2. Fragment of the ^{13}C NMR spectrum of (a) regenerated absorber (gas-fractionation setup, GFI) and (b) aqueous solution of MEA after regeneration (ISP). (δ_C) Chemical shift, ppm; the same for Fig. 3.

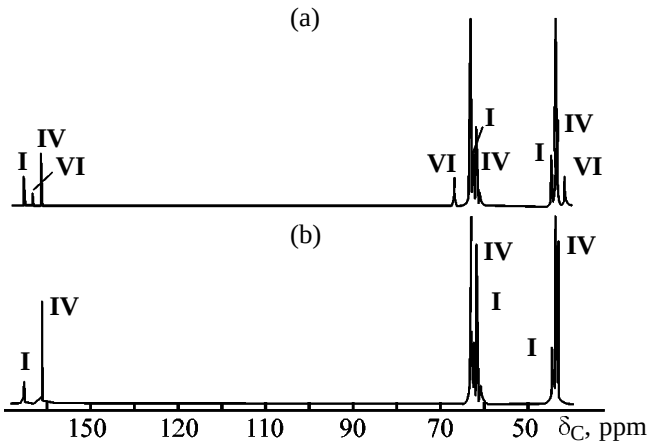

Fig. 3. ^{13}C NMR spectrum of COS solutions in aqueous MEA (20%) after boiling for (a) 10 and (b) 30 min.

The ^{1}H NMR spectrum of one of MEA solutions, saturated with acidic gases, before its regeneration (installation for sulfur production, ISP) is shown in Fig. 1. This solution contains approximately 4% of carbamate **I**. The spectrum of **I** contains a triplet at δ 3.49 ppm and two overlapped triplets at δ 3.03 and 3.05 ppm, corresponding to methylene protons in the α-position to oxygen atoms and nitrogen atoms of the anionic part of its molecule. The corresponding cation gives the signal overlapping with the MEA signal [6]. The identification of **I** was proved by independent synthesis (passing of carbon dioxide through aqueous solution of MEA).

After regeneration, the main impurity in the absorbent is usually carbamate **I** (approximately 0.5%). Along with carbamate **I**, we attempted to find thiocarbamates **I** and **III** considering the ^{13}C NMR spectra of the individual compounds formed by dissolving COS and CS_2 in aqueous MEA (see table). However, in the ^{13}C NMR spectra of samples withdrawn from the ISP the corresponding signals are lacking (Fig. 2b).

At the same time, ^{13}C NMR analysis of solutions obtained by bubbling of COS through 15–20% aqueous solutions of MEA under laboratory conditions showed that compounds **IV** and **VI**, giving the characteristic ^{1}H and ^{13}C NMR spectra (see table; Fig. 3a), are formed only on heating (70–100°C) or prolonged storage of the solutions obtained by this procedure and containing a mixture of carbamate **I** and thiocarbamate **II**.

Formation of **IV** and **VI** in saturated solutions of CO_2 in MEA was not observed. On heating of these solutions (≤120°C) only signals of MEA and carbamate **I** are present in their NMR spectra.

In the ^{13}C NMR spectra of the samples withdrawn from the ISP the signals at δ_C 62.4 and 43.8 ppm are the most intense (see table; Figs. 2b, 3a). These signals correspond to urea **VI**, suggested previously as an intermediate [5]. The signal of carbonyl carbon δ_C 162 ppm corresponding to **VI** has low intensity and is not always observed in the ^{13}C NMR spectra of the industrial absorbents.

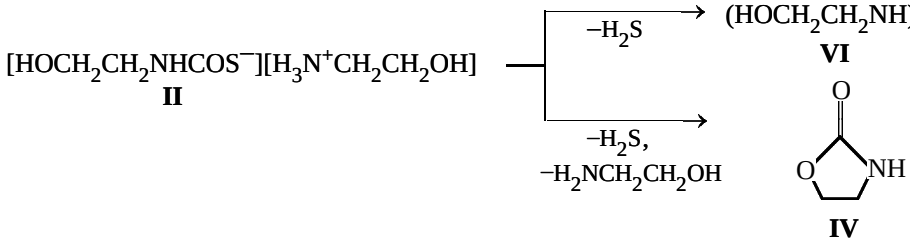
Assignment of the signals in the ^{13}C NMR spectra of model compounds and samples of industrial absorbents (aqueous solutions of MEA)

Compound	Assignment of the ^{13}C NMR signals, δ_C, ppm		
	NCH_2	CH_2OH	C=O
MEA	43.89	63.57	
I	44.93	63.00	166.1
II	43.00	60.41	182.3
III	51.34	60.21	213.2
IV	40.52	66.71	163.3
V	50.75, 51.23, 39.05	60.30	
VI	43.59	62.41	161.8
VII	38.34, 46.82, 47.03	60.02	165.9
VIII		64.13	159.2
IX	49.20, 39.52	58.93*	**
X	51.24	60.32	
XI	56.48**	59.13	

* The signal is overlapped with the MEA signal.
** Signals were not registered owing to low intensity.

The signals of **IV** are lacking in the spectra of the industrial samples, while, as mentioned above, the signals of this compound along with the signals of urea **VI** are the most intense in the spectra of the laboratory samples obtained by absorption of COS with aqueous MEA (Fig. 3a). It turned out that the intensity of signals of **IV** initially increased and then decreased and became equal to zero in boiling of the saturated solutions for 0.5 h (Fig. 3b).

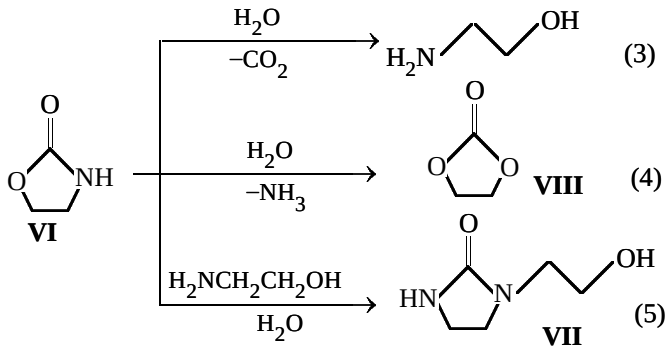
As known, **IV** and **VI** are formed by the well-known transformations of thiocarbamate **II** [reactions (1) and (2)] [2]:

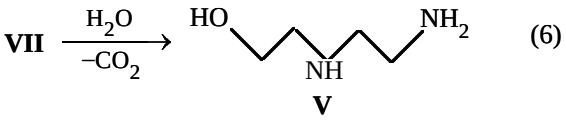


(1)

(2)

The formation of impurities **V** and **VII**, identified previously in the absorbent, can be due to the reactions of **IV**. In our opinion, there are at least three pathways [Eqs. (3)–(5)] for conversion of **IV**, which are well-known amidation and hydrolysis reactions [7]:





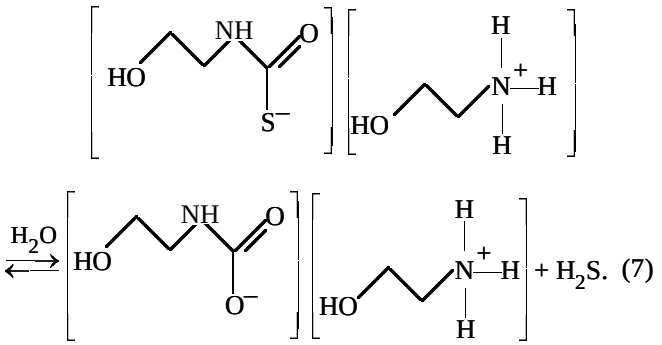
Reaction (3) results in the above-noted disappearance of the signals of **IV** from the ^{1}H and ^{13}C NMR spectra of laboratory samples of the absorbent during boiling (Fig. 3b) and causes the absence of **IV** in process solutions. In some cases the laboratory solution of COS in aqueous MEA after boiling or prolonged storage gives a mixture with the ^{13}C NMR spectrum in which, according to calculated and reference data, the strongest signals are the characteristic signals of methylene and carbonyl carbon atoms of compound **VII** described previously (see table) [8]. More frequently, in such experiments in ^{13}C NMR spectrum we observed, instead of the signals of **VII**, the signals of diamine **V**, which are also sufficiently characteristic to allow identification based on the reference data (see table). The above reaction (6) was proposed to explain formation of diamine **V** in the course of gas treatment [5].

Formation of **VII** by dehydration of urea **VI** [5] is unlikely, since **VI** remains the main impurity in the absorbent after its prolonged boiling (Fig. 3b).

Reaction (4) was not described previously in the publications devoted to absorption treatment of process gases; however, in the ^{13}C NMR spectra of laboratory and many of the industrial samples there is a weak characteristic signal at δ_C 64 ppm corresponding precisely to **VIII** [8]. The signal of the carbonyl carbon atom of carbonate **VIII** appears at δ_C of approximately 159 ppm (see table).

As was shown by laboratory experiments simulating treatment of gases to remove CO_2 and COS, specifically thiocarbamate **II** gives many of impurities accumulated in the industrial sorbents under operating conditions. There are no published data on the pathway of formation of thiocarbamate **II** under conditions of gas treatment, namely, whether it is formed exclusively owing to the presence of COS in the gases to be treated or also by the reaction of H_2S with carbamate **I**, reverse to hydrolysis of thiocarbamates [9] (see below).

To elucidate this problem, 20% aqueous solutions of MEA were saturated with CO_2 and H_2S under laboratory conditions, but neither signals of thiocarbamate **II** nor signals of urea **VI** formed from **II** in the stage of solution regeneration were registered in the

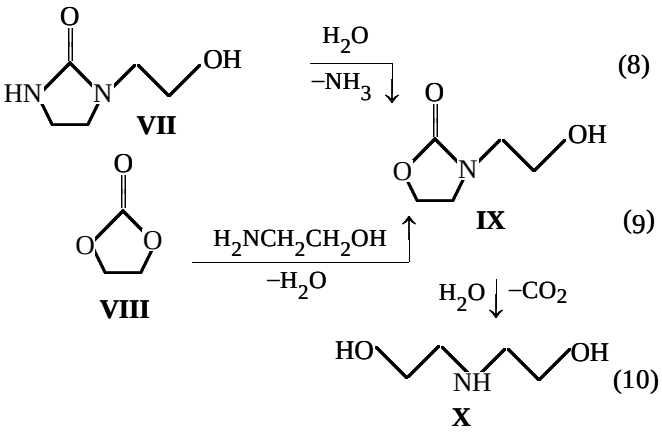


(7)

^{13}C NMR spectra. Thus, thiocarbamate **II** is formed exclusively by uptake of carbonyl sulfide (COS), apparently formed by the well-known reaction of CO with sulfur vapor (350°C) in the particular installation.

It was established that, along with the presence of oxidizing agent (dissolved oxygen), the ability of one of the components of the liquid medium to form complexes with metal ions is the most important factor of corrosion activity [10]. This causes the corrosion activity of MEA and diethanolamine. Previously [2] it was proposed that the corrosion activity of aqueous solution of MEA increases with increasing content of impurity of diamine **V** giving stable complexes with iron. Thus, evidently, the corrosion activity of absorbents increases with increasing probabilty of formation of thiocarbamate **II**, which is active complexing agent itself and gives diamine **V** by reactions (2), (5), and (6). It is well known [1–5] that decreased concentration of MEA solutions results in decreased probability of side reactions giving the impurities in hand, which is caused, in our opinion, by increased probability of hydrolysis of thiocarbamate **II** by reaction (7).

Turning back to the absorbent composition in the ISP, it should be noted that along with the signals of MEA, **I**, and **VI**, the ^{13}C NMR spectra (Fig. 2b) contain five more or less strong signals at δ_C 39, 49, 56, 58, and 59 ppm, which occur simultaneously in the majority of several tens of the studied samples withdrawn from various installations and have the same ratio of intensities as in Figs. 2a and 2b. It is significant that these signals were registered in the spectra of some aqueous MEA solutions saturated and regenerated under laboratory conditions only after absorption of COS but not CO_2. Considering characteristic reference and calculated data [8], three of five signals belong to compound **IX**, which has not been described as a component of the absorbents in hand and is the analog of **VII** formed by its hydrolysis [reaction (8)]. Compound **VII** is absent in the ISP absorbents. The fourth signal of **IX** is not observed owing to overlap with the signals of other components (see table). One further pathway of formation of **IX** is probably amidation of carbonate **VIII** [reaction (9)]:



(8)

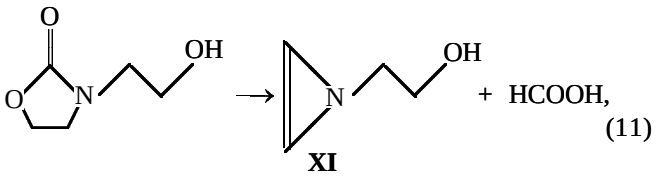
(9)

(10)

In accordance with reaction (5), diethanolamine **X** is formed by hydrolysis of **IX** [reaction (10)]. The characteristic signal of amine **X** is observed in the spectra of various samples of absorbents (Figs. 2a, 2b). This fact was established using an authentic sample of **X**. Amine **X** gives the NMR signal in the range close to that of dithiocarbamate **III**, so that special experiments using appropriate model systems were required for correct identification.

The other pathway of synthesis of amine **X** by the reaction of MEA with ethylene oxide formed by decomposition of MEA to give components used for its industrial production (NH_3 + CH_2CH_2O) can be ruled out because of the total absence of signals of ethylene glycol in all the samples studied. Thus, the presence of amine **X** in the absorbents additionally proves the indentification of **IX**.

The remaining two of the five considered signals in the ^{13}C NMR spectra at δ_C approximately 56 and 59 ppm are close to the characteristic signal of triethanolamine. Addition of triethanolamine to the absorbents gives the other pair of signals in the ^{13}C NMR spectrum, noticeably shifted downfield relative to the first two signals. These signals were tentatively assigned to azirine **XI** taking into account that it always accompanies **IX**, forming by its cleavage:



(11)

Attempts to register the signals of methine carbon atoms of **XI** failed. However, we have no other as-

sumptions concerning the structure of this component of commercial absorbents.

Formic acid presumably formed in synthesis of **XI** [reaction (11)] was registered in the industrial absorbents and is usually believed to originate from oxidative thermal degradation of MEA. Formic acid gives a peak in the ^{13}C NMR spectra at δ_C 172 ppm, observed in the spectra of industrial absorbents in the range corresponding to signals of carbonyl carbon atoms. In the same range, the signal of oxalic acid formed by oxidation of MEA is observed (δ_C 174 ppm) [2].

Along with the signals of MEA, **VI**, **IX**, and **XI**, in the spectra of samples withdrawn from the ISP there are some weaker signals. Two of these signals were assigned to amine **X**, and two other signals, to thiocarbamate **II** (see table).

Compound **II** detected in the absorbents withdrawn from the ISP was identified on the basis of the ^{13}C NMR spectra of the samples withdrawn from the GFI. In the GFI the content of thiocarbamate **II** is higher than that in the ISP. In some samples of regenerated absorbent withdrawn from the GFI only MEA has a higher concentration (Fig. 3a). Thus, we were able to find that two signals of methylene carbon atoms assigned to **II** correspond to the characteristic signal of the carbonyl carbon atom at δ_C of approximately 182 ppm, assigned to the NCOS fragment (see table).

The absorbent withdrawn from the GFI (approximately 20% MEA) has a more complicated composition than that withdrawn from the ISP. The strongest signals (excluding signals of MEA) in the ^{13}C NMR spectrum of the absorbent after regeneration are the signals of thiocarbamate **II**; in this case, the signals of carbamate **I** and urea **VI** are extremely weak.

The spectrum, whose fragment is shown in Fig. 2a, contains additional relatively strong signals of **V** and **VII**, which are absent in the spectra of the absorbents withdrawn from the ISP.

In addition, the spectrum of the absorbents withdrawn from the GFI contains the signals of two methyl carbon atoms (δ_C 23 and 24 ppm) of unidentified compound or compounds, to which correspond two singlets in the ^1H NMR spectrum in the region of δ 1.8 ppm.

According to process data, this absorbent has low absorption power with respect to CO_2 and H_2S, which is apparently caused by the fact that acidic salt **II**, whose content is higher in the GFI than in ISP, induces decomposition of carbamate **I** and MEA sulfide by the mechanism of general acid catalysis observed for carbamates of low-basic amines such as MEA [11]. Impurities of formic and oxalic acids exert the similar effect.

EXPERIMENTAL

The ^{13}C and ^1H NMR spectra of the absorbent samples were recorded on a Bruker ACP-200P spectrometer using standard procedures.

Under laboratory conditions the gas treatment process was simulated on a setup consisting of a flask for production of gases and absorption flasks. CO_2 and COS were produced in this setup by the reaction of sulfuric acid with sodium bicarbonate and potassium (ammonium) thiocyanate, respectively. H_2S, CS_2, diethanolamine, and triethanolamine were commercial chemicals of chemically pure grade.

Regeneration of absorbents was simulated by either heating on a water bath or boiling.

CONCLUSIONS

(1) Salts of ethanolamine with (2-hydroxyethyl)carbamic and (2-hydroxyethyl)thiocarbamic acids, 5-amino-3-aza-1-pentanol, *N*,*N*'-di(2-hydroxyethyl)urea, 1-(2-hydroxyethyl)imidazolidone-2, 1,3-dioxolanone-2, 3-(2-hydroxyethyl)-1,3-oxazolidone-2, and 3-aza-1,5-pentanediol were identified by ^{13}C NMR in the industrial absorbent based on aqueous solution of monoethanolamine. Among these compounds, isoxazolidone-2 is absent.

(2) The increase in the corrosion activity of the absorbent is apparently caused by the presence of active complexing impurities, such as monoethanolammonium (2-hydroxyethyl)thiocarbamate and 5-amino-3-aza-1-pentanol.

(3) The decrease in the absorption power of the absorbent with respect to CO_2 and H_2S is due to the presence of thiocarbamate and also oxalic and formic acids, inducing decomposition of (2-hydroxyethyl)carbamate and monoethanolamine by the mechanism of the general acid catalysis.

(4) Large amount of impurities unremovable by regeneration of the absorbent originate from transformations of thiocarbamate formed in absorption of COS.

ACKNOWLEDGMENTS

We are grateful to A.A. Ferber and M.A. Plekhanov (Omsk Oil Refinery) for submitting the samples of the industrial absorbent and process data.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Kinetics of Phenol Oxidation under Flash Corona Electric Discharge

N. A. Aristova and I. M. Piskarev

Abstract—A study was made of the kinetics of phenol oxidation in a 3.5-l (liquid) tank at the initial chemical oxygen demand of the solution of 200–6000 mg O l^{-1}. The total current of flash corona electric discharge from 50 electrodes was 3 mA.

The technical and economic requirements to the quality and cost of wastewater treatment are now so stringent that neither of the known treatment methods fully satisfies them. Solving this problem requires the use of different methods. The place and role of each method are assessed in the development stage by mathematical simulation.

Phenol-containing wastewaters are widespread; therefore, it is of interest to develop new processes for their oxidation. In [1], we considered specific reactions induced by electric discharge, namely, by flash corona electric discharge generating a small volume concentration of active particles, extremely high electric field intensity in the discharge space, and pulse electric current. Also, we formulated the main features of the electric discharge utilized for initiating the reactions [1], described the reaction kinetics [2], and showed that under certain conditions this reaction has advantages over ozonation [3]. In this work, we analyzed the kinetics of phenol oxidation in a tank of a sufficiently large volume and compared the results with the characteristics of the known processes.

EXPERIMENTAL

The liquid was treated in a 35×60 cm^2 tank with a polyethylene bottom and 25-cm-high glass walls. The tank volume was 50 l. Along the bottom perimeter and in the central area longitudinally, a contact electrode made of aluminum wire, 3 mm in diameter, was mounted. The tank was filled with 3.5 l of liquid. Fifty discharge electrodes were placed at a distance of 5 mm from the liquid surface. Each discharge electrode was 12 cm long. The electrodes were mounted on a Teflon sheet arranged under the tank cover. The electrodes were separated from one another by 5 cm. The 10-kV negative-polarity voltage was applied to each electrode via the untying resistance of 10 MΩ. The total discharge current from all the electrodes was 3 mA. In the case of measurements in an oxygen medium, before the voltage was switched on, the tank was purged with oxygen at a rate of 3 l h^{-1} for 24 h. During the experiments, oxygen was supplied at the same rate. Oxygen was fed through the holes in the tank bottom (through the liquid), and gases were removed through the holes in the tank cover. During experiments in air, the ventilation holes were additionally opened at the tank cover, and oxygen purge was stopped. During treatment the liquid was mixed by ion movement and by "electric wind", which is a specific feature of the electric discharge mode chosen [1]. As working liquids served phenol and KI solutions of different concentrations in distilled water. The reagents were of chemically pure grade. The phenol concentration was 84 (COD 200 mg O l^{-1}, 840 (COD 2000 mg O l^{-1}), and 2520 mg l^{-1} (COD 6000 mg O l^{-1}). The phenol concentration in the initial and treated solutions was determined by extraction followed by spectrophotometry.

The active species yield Y was estimated by us previously for the treated liquid volumes of 20–100 ml at the discharge current of 0.1 mA [2, 4]. These yields were as follows: $Y(OH^{\bullet})$ = 14.4, $Y(H)$ = 18.0, and $Y(O)$ = 2.5 mol mol^{-1} electrons (or molecules per electron passed in the circuit). In [2] we showed that in the presence of ozone the H atoms are transformed into $OH^{\bullet}$ radicals, and their total yield $Y(OH^{\bullet})$ is about 32 mol mol^{-1} electrons, or 32 $OH^{\bullet}$

1070-4272/02/7501-0086$27.00 © 2002 MAIK "Nauka/Interperiodica"

radicals per electron passed in the circuit. The voltage on the electrode relative to the liquid surface is 10 kV, which means that the energy spent for transfer of this electron is equal to 10 keV. Then the average energy cost of formation of one $OH^{\bullet}$ radical will be 312 eV, or 0.32 $(100\ eV)^{-1}$. Additionally, the yield of ozone under the actual experimental conditions was determined. To this end, the tank was filled with 3.5 l of 0.1 M KI solution, and the iodine oxidation yield was measured. The oxidation of I^- and the accumulation in solution of $1/2I_2$ were calculated in terms of the process model considered previously [2]. In the calculation we used the above-cited yields of active species, the liquid volume V_l = 3.5 l, the gas phase volume V_g = 46.5 l, the liquid surface area $S_l = 2.1 \times 10^3$ cm^2, and the discharge current I = 3 mA. The ozone yield was treated as a free parameter. The calculated and experimental data proved to be consistent at the ozone yield of 135 mol mol^{-1} electrons. This value is somewhat lower than that obtained in [2], namely, 180 mol mol^{-1} electrons for one electrode. A decrease in the ozone yield on changing from one to a system of 50 electrodes is probably due to inaccurate arrangement of the electrodes and to the scatter in the distance between the electrodes and the surface. Namely, for a significant number of electrodes the distance from the liquid surface is not optimal.

We studied the decrease in the chemical oxygen demand (COD) for the phenol solution contained in the tank under the following conditions: experiment no. 1, under oxygen; during the discharge treatment, alkali (NaOH) was added to maintain pH within 6–7; experiment no. 2, under oxygen in the absence of alkali; and experiment no. 3, in air without alkali. For all the solutions the initial COD was 2000 mg O l^{-1}. The results are shown in Fig. 1. The concentration of phenol itself was monitored in experiment no. 1. The amount of the alkali utilized for maintaining pH in experiment no. 1 was 14 mol of NaOH per mole of electrons.

Figure 1 shows that within about 60 h the COD decreases by on order of magnitude, whereas the content of phenol itself decreases 1000-fold within about 5 h. Rapid consumption of phenol proper in the reaction under study is confirmed by our previous experiments [4]. Among intermediate reaction products, the most easily identifiable is benzoquinone. Its presence is confirmed by the fact that the initially colorless solution turns reddish-yellow within several hours of treatment, and this color is retained virtually until the experiment is complete. Within 45 h of treatment the solution turns colorless again.

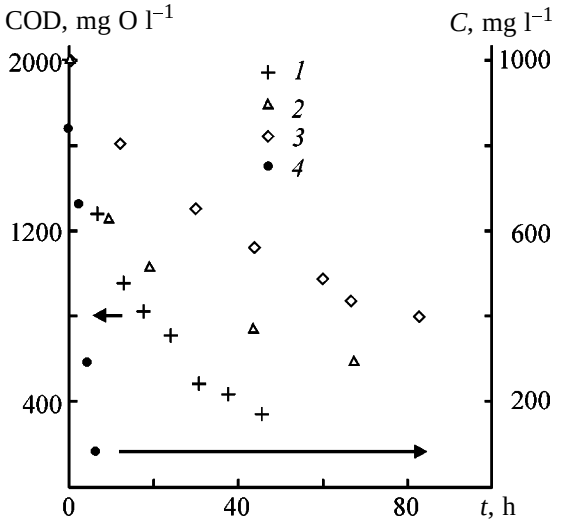

Fig. 1. Variation of the COD of the 840 mg l^{-1} phenol solution (COD_0 = 2000 mg O l^{-1}) with time t of treatment in the tank at the discharge current of 3 mA. Experiment no.: (*1*) 1, (*2*) 2, and (*3*) 3; (*4*) variation of the phenol concentration C, mg l^{-1}, in experiment no. 1.

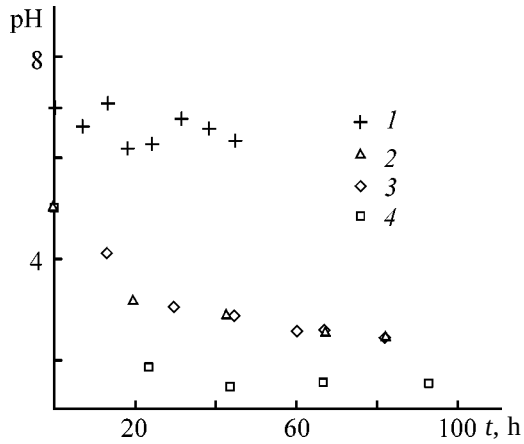

Fig. 2. Variation with treatment time t of the pH of the phenol solutions with the initial COD of (*1–3*) 2000 and (*4*) 6000 mg O l^{-1}. Medium: (*1, 3*) oxygen and (*2, 4*) air.

In the case of oxidation under oxygen without adding alkali (Fig. 1, experiment no. 2), within the first 10–12 h the oxidation rate is identical to that in the case of adding alkali (experiment no. 1), but then the oxidation rate tends to decrease with decreasing pH. Figure 2 shows how pH varies with the treatment time in experiment nos. 1–3. It is seen that within 15–20 h in experiment nos. 2 and 3 pH decreases from 5 to 3–4. The patterns of variation of pH with the time of treatment under oxygen and in air (experiment nos. 2 and 3) are virtually identical. This suggests a little significance of nitric acid formation under discharge in air. Accumulation of nitric acid under the same

type of discharge over the distilled water surface is about 5 mol mol^{-1} of electrons [5], and the rate constants of oxidation of atomic nitrogen and phenol are of the same order of magnitude [6]. However, the concentration of the oxidizable impurities in water at COD > 2000 mg O l^{-1} is much greater than that of atomic nitrogen forming under electric discharge. Therefore, at a high concentration of the impurities the active species are consumed, above all, for oxidation of these impurities, and nitric acid virtually does not form under discharge in air. Nitric acid can be accumulated in noticeable amounts in later stages, when slowly oxidizable products remain in solution and their concentration is low.

Experiment no. 4 for the phenol solution with the initial COD 6000 demonstrates how the pH is influenced by the phenol oxidation products (Fig. 2). It is seen that in this case the decrease in pH of solution is more pronounced than in the case of COD 2000. This is due to accumulation in solution of a large amount of organic acids. Table 1 presents the experimental rates of oxygen uptake (COD decrease) in the different stages of phenol oxidation. At the beginning of oxidation under discharge in oxygen COD decreases at a rate of 190–210 mol O mol^{-1} electrons, irrespective of adding the alkali.

In the case of discharge in air (experiment no. 3) the oxidation rate is lower owing to a decrease in the ozone yield with decreasing oxygen concentration. At the end of all the experiments the oxidation rate decreases by an order of magnitude. The reason is twofold: accumulation in the solution of products oxidized at a lower rate by both ozone and $OH^{\bullet}$ radicals and decrease in the concentration of the oxidizable substances. At the end of the experiment, the yields for discharges under oxygen and in air in the absence of alkali (experiment nos. 2 and 3) are approximately the same, namely, 12–13 mol O mol^{-1} electrons. This suggests that in this stage the major role belongs to $OH^{\bullet}$ radicals whose yield is determined by the partial pressure of the water vapor [4].

Let us compare the oxidation rates for organic impurities obtained in different works (Table 2). The

yield of oxygen uptake (decrease in COD at COD_0 2000 mg O l^{-1}) obtained in this work, i.e., approximately 2 $(100\ eV)^{-1}$, corresponds to the uptake of 11.9 g of oxygen per 1 kW h. The COD for phenol is 2.38 g O g^{-1} phenol. Therefore, when recalculated for phenol, the yield of oxidation of organic substances will be equal to 5 g $kW^{-1}\ h^{-1}$, or 0.14 $(100\ eV)^{-1}$. In many works, the CODs of phenol solutions during treatment are not given; presented is the content of phenol proper and of selected compounds, namely, its oxidation products. As phenol proper is oxidized in the reaction under study at an approximately 10-fold higher rate than its degradation products, the yield of oxidation of phenol proper at COD_0 2000 mg O l^{-1} will be equal to 50 g $kW^{-1}\ h^{-1}$, or 1.5 $(100\ eV)^{-1}$. At lower phenol concentrations, COD_0 200 mg O l^{-1}, the initial yield of oxidation determined in an additional experiment was about 27 g phenol $(kW\ h)^{-1}$, or 0.8 $(100\ eV)^{-1}$. It should be emphasized that the initial yield of oxidation is connected with consumption of phenol proper.

The phenol oxidation products were identified in [7–11]. For oxidation of phenol to hydroquinone, benzoquinone, and muconic acid the COD recalculated for one molecule decreases by 7.5, 17, and 28%, respectively. Further oxidation of these compounds is a slower process, and the total oxidation rate decreases. The data presented in other works for the phenol concentration of 1 mM (COD_0 ~230 mg O l^{-1}) are listed in Table 2. It is seen that among the works cited, the highest yield of phenol oxidation was achieved by catalytic ozonation [7]: 5 mol of ozone per mol of phenol. It should be noted, however, that the use of catalysts (e.g., Fe in that work) poses additional problems connected with contamination of the water with the catalyst itself. The yield achieved in electrode-free reaction is of the same order of magnitude as in catalytic ozonation, though the yield of ozone in the process under study per unit energy consumed is approximately 3 times lower than in conventional ozonizers [2].

CONCLUSION

The yield of phenol oxidation under flash corona electric discharge at the maximal electric field intensity in the discharge space and small density of generated active species is of the same order of magnitude as in the case of catalytic ozonation and exceeds that achieved by conventional ozonation.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Simulation of Steam Distillation of Multicomponent Mixtures of Higher Aliphatic Acids

V. A. Plesovskikh, A. A. Bezdenezhnykh, and A. N. Polosin

Received March 19, 2001

Abstract—A mathematical model of steam distillation of multicomponent mixtures of higher aliphatic acids is proposed, based on solving the equation of equilibrium states for closed systems with account of the nonideal behavior of a solution.

Higher aliphatic acids obtained from oils and fats of vegetable and animal origin are open-chain monobasic aliphatic (fatty) carboxylic acids, which are saturated and unsaturated compounds with the number of carbon atoms from C_{10} to C_{22} and boiling point in the range 300–370°C. In the industry, the acids are purified to remove various substances determining the color, odor, and other quality characteristics of target products (soaps, perfumes, cosmetics, detergents, etc.), with wide use of steam distillation.

In designing practice, distillation of multicomponent mixtures of fatty acids with and without steam is commonly calculated using the scheme for binary systems. In doing so, the properties of a multicomponent mixture are assessed with regard to its most difficultly volatile (highest-boiling) component. For most mixtures of higher aliphatic acids this is stearic acid. It is adopted *a priori* that the vapor phase obeys ideal gas laws, and the liquid phase, the laws of ideal solutions. However, this way to calculate the distillation of mixtures of aliphatic acids allows only approximate evaluation of the mode parameters (pressure, temperature, consumption rates, etc.) since the physicochemical properties of a multicomponent system and its equilibrium states markedly differ from the properties and states of stearic and other acids.

Here we propose to use equations of equilibrium states for closed systems, with account of the nonideality of the liquid phase, for calculating distillation of fatty acids in both batch and continuous modes.

The mathematical model of equilibrium states is based on the condition for thermodynamic equilibrium vapor–liquid, governed by the equality of volatilities or fugacities for, respectively, the vapor and liquid phases $f_{vi} = f_{li}$, with

$$f_{vi} = \nu_i y_i P_{mix}, \quad (1)$$

$$f_{li} = \gamma_i x_i P_i, \quad (2)$$

where y_i and x_i are the mole fractions of the ith component in the vapor and liquid phases; P_{mix} and P_i are the total saturated vapor pressure over solution and saturated vapor pressure of a pure component (mm Hg); ν_i and γ_i are the fugacity and activity coefficients of the ith component.

For the vapor phase, the fugacity coefficient ν_i characterizes the extent to which the gas (vapor) departs from the ideal state. At $P_{mix} \to 0$, $\nu_i \to 1$ for all the i components [1]. For higher fatty acids distilled under reduced pressure (5–30 mm Hg), it may be considered, to a first approximation, that $\nu_i = 1$, and the following assumption can be made: the multicomponent mixture of vapors of higher fatty acids is a mixture of ideal gases and is described by the equation of state for ideal gases with fugacity

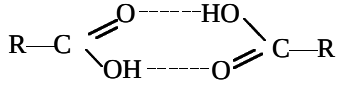
$$f_{vi} = y_i P_{mix}. \quad (3)$$

For the liquid phase, the activity coefficient γ_i is a measure of solution nonideality and depends on solution composition, pressure, and temperature. Experimental studies of the equilibrium compositions of the liquid and vapor of binary mixtures of higher fatty acids [2] (selected results are presented in Table 1) demonstrated that the activity coefficient $\gamma_i = 0.9$–1.0 for the concentration x_i of ith component varying between 0 and 1. This means that, with the ideal solution model adopted for the liquid phase, the relative

1070-4272/02/7501-0090$27.00 © 2002 MAIK "Nauka/Interperiodica"

error in calculations of the component concentration in the vapor phase may be as high as +10 mol %.

In the general case, the solution nonideality, as a rule, originates from differences between characteristics of equitype and mixed interactions in the solution [3]. In the opinion of the majority of researchers, the nonideality of solutions of higher fatty acids is due to association between molecules of the acids



caused by rather strong polarity of the carboxy group COOH, resulting from the presence of dipole moments of the polar bonds C=O and O–H.

Thus, on the assumption that the vapor phase is ideal and the liquid phase shows nonideal behavior, the equation of the vapor–liquid equilibrium in a multicomponent mixture of higher aliphatic acids can be written as

$$y_i P_{\text{mix}} = \gamma_i x_i P_i, \quad (4)$$

$$y_i = \gamma_i x_i P_i / P_{\text{mix}}. \quad (5)$$

Equation (5) provides a basis for constructing a mathematical model of equilibrium states and completely determines its adequacy to the real process. In the presence of steam in the vapor phase, the total pressure P in the closed system at the equilibrium temperature is given by

$$P_0 = P_{\text{mix}} + P_{\text{v}} = \sum_{i=1}^{N} P_{ci} + P_{\text{s}}, \quad (6)$$

where P_{ci} and P_{s} are the partial pressures of the vapor of ith component and steam (mm Hg).

The mixture will start boiling when the pressure of its saturated vapor reaches the value $P_{\text{mix}} = P - P_{\text{s}}$. As a result, the boiling point of a mixture of acids decreases upon introduction of steam, compared with the boiling point without steam.

In the course of distillation, the initial molar flow rate of the initial mixture of acids is divided into the liquid and vapor phases (bottoms and distillate). The overall and partial material balance equations of the process will be, correspondingly, written as

$$G_0 = G_x + G_y, \quad (7)$$

$$G_{0i} = G_0 x_{0i} = G_{xi} + G_{yi} = G_x x_i + G_y y_i, \quad (8)$$

where G_0 is the molar flow rate of the starting mixture in the system (kmol h^{-1}); G_x, G_y are the molar flow rates of the liquid and vapor phases (kmol h^{-1}); and G_{0i}, G_{xi}, G_{yi} are the molar flow rates of ith component in, respectively, the starting mixture and liquid and vapor phases (kmol h^{-1}).

Expressing x_i and y_i in terms of the molar flow rates, $x_i = G_{xi}/G_x$ and $y = G_{yi}/G_y$ and substituting the result in Eq. (5), we obtain

$$G_{yi}/G_y = \gamma_i P_i (G_{xi}/G_x)/P_{\text{mix}} = \gamma_i P_{ci}/P_{\text{mix}}.$$

Whence

$$P_{ci} = P_i (G_{xi}/G_x). \quad (9)$$

Substituting the expression for P_{ci} from (9) into (6), we have

$$\sum_{i=1}^{N} [P_i (G_{xi}/G_x)] + P_{\text{v}} = P. \quad (10)$$

Solving Eqs. (7) and (8) for G_{yi} and G_{xi} with account of the vapor–liquid equilibrium equation (5), we find

$$G_{yi} = \gamma_i (P_i/P_{\text{mix}})(G_{xi}/G_x)(G_0 - G_x), \quad (11)$$

$$G_{yi} = \frac{G_{0i}}{1 + \gamma_i (P_i/P_{\text{mix}})[(G_0/G_x) - 1]}. \quad (12)$$

Substituting the expressions for the flow rate G_{xi} from

(12) in (10), we obtain an equation of equilibrium states for the flow rate and composition of the liquid and vapor phases of a multicomponent mixture of higher fatty acids in steam distillation

$$\sum_{i=1}^{N} \frac{G_{0i}(P_i/P)}{G_0\gamma_i(P_i/P_{\text{mix}}) - G_x[\gamma_i(P_i/P_{\text{mix}}) - 1]} + P_s/P = 1. \quad (13)$$

In the general case, the partial pressure P_s of steam in Eq. (13) may correspond to the pressure of both saturated and superheated steam. This is due to the fact that, in practice, steam distillation of fatty acids is done both with saturated and with superheated steam.

In saturated-steam distillation, the vapor–liquid system is characterized by the following parameters: number of phases $\Phi = 3$ (steam, water, and multicomponent mutually soluble mixture of acids, fixed in a single phase); number of independent components $N + 1$; number of external factors affecting the equilibrium in the system, $n = 2$ (temperature, pressure); number of constraints on the concentration variables specifying the composition of the mixture of acids, $m = N - 1$. According to the Gibbs phase law, the number of degrees of freedom of the system, $C = (N + 1) - 3 + 2 - (N - 1) = 1$; in superheated-steam distillation, the water phase is absent and the number of degrees of freedom of the system $C = (N + 1) - 2 + 2 - (N - 1) = 2$. This means that, in superheated-steam distillation, the P_v value is determined by the distillation temperature and cannot be chosen or set arbitrarily, without taking into account the equilibrium conditions (13). In superheated-steam distillation, $C = 2$ and, consequently, at a given total pressure in the system, the partial pressure P_s of steam is not stringently related to the distillation temperature and can be varied irrespective of the equilibrium state. Since distillation of fatty acids is commonly done with superheated steam, such an independent choice of the pressure P_s makes markedly simpler the use of Eq. (13) and, in particular, enables the close system to attain equilibrium via change in the distillation temperature at a given pressure in the system.

According to the Clapeyron equation for a mixture of steam and a mixture of acid vapors, it can be written

$$P_sV = G_sRT = (G_s''/M_s)RT,$$

$$P_{\text{mix}}V = G_yRT = (G_y''/M_y)RT,$$

where G_s is the molar flow rate of steam (kmol h^{-1}); G_s'', G_y'' are the gravimetric flow rates of steam and mixture of acid vapors (kg h^{-1}); M_s, M_y are the molecular weights of steam and mixture of acid vapors (kg $kmol^{-1}$); V is the volume of the system (m^3); R is the universal gas constant (J mol^{-1} K^{-1}); and T is temperature (K).

Dividing the equalities one by another, we obtain

$$G_s = G_y''\frac{M_s}{M_y}\frac{P_s}{P_{\text{mix}}}. \quad (14)$$

In Eq. (14), P_{mix} corresponds to the saturated vapor pressure of a mixture of fatty acids. The saturation is reached at well-developed interface between the bubbling steam and liquid being evaporated and their prolonged contact. However, it is impossible in most cases to create such conditions in the still, and the pressure P_{mix} is lower than the saturated vapor pressure corresponding to the boiling point of the mixture. To correct P_{mix}, the coefficient of steam saturation with the vapor of a substance being distilled, $\varphi = 0.3$–0.8, is introduced and Eq. (14) is written as

$$G_s'' = G_y''\frac{M_s}{M_y}\frac{P_s}{\varphi P_{\text{mix}}} = G_y''\frac{M_s}{M_y}\frac{P_s}{\varphi(P - P_s)}. \quad (15)$$

For superheated-steam distillation of fatty acids, the saturation coefficient is taken to be $\varphi = 0.7$ in design calculations [5].

Equation (15) makes it possible to determine the gravimetric flow rate of steam from the flow rate of the vapor phase (evaporated mixture of acids) at given P and P_{mix} (or P_s) values or vice versa.

As practice shows [5], depression of the boiling point of fatty acids and their agitation with bubbling steam, close to ideal mixing, are achieved in continuous steam distillation of fatty acids at steam feed equal to 7–10 wt % relative to the amount of the liquid mixture of acids being evaporated, i.e., $G_s'' = (0.07–0.1)G_y''$. Hence, the specific consumption of steam per 1 kg of acids being distilled is given by

$$d = \frac{G_s''}{G_y''} = \frac{M_s}{M_y}\frac{P_s}{\varphi P_{\text{mix}}} = \frac{M_s}{M_y}\frac{P_s}{\varphi(P - P_s)} = 0.07–0.1. \quad (16)$$

The use of the equation of equilibrium states (13) is predetermined by the availability of data on the saturated vapor pressure P_i of a pure component and its activity coefficient γ_i.

The vapor pressure P_i was found using equations

derived in terms of Prigogine's molecular-statistic theory [6]:

$$\ln(P_i/P_i^*) = A_i - B_i/T - C_i/T^2, \quad (17)$$

where T is the boiling point of the mixture of acids (K); P_i^* is the characteristic pressure (in Prigogine's terms, mm Hg); A_i, C_i, B_i are constants functionally dependent on the number of carbon atoms in acid molecule.

The P_i, A_i, C_i, and B_i values for higher fatty acids are presented in Table 2.

The activity coefficient γ_i was determined using the equations of the ASOG model, method of group constituents.

On the whole, Eqs. (11)–(13), (16), and (17) and the equations of the ASOG model allow calculation of the equilibrium states of the composition of the liquid and vapor phases in a multicomponent mixture of fatty acids in steam distillation and quantitative determination of their material flows. One of the possible procedures for design calculations is as follows.

(1) Input data are taken: G_0'', G_x'', G_y'', x_{0i}'' (i = 1, 2, ..., N), M_i (molecular weights of individual acids), M_s, P, d, φ.

(2) Using formulas for recalculation of weight concentrations into molar concentrations, x_{0i} (i = 1, 2, ..., N) and M_0 (average molecular weigth of fatty acids) are found and the flow rates G_0, G_x, G_y, and G_{0i} (i = 1, 2, ..., N) are determined on the assumption that $M_x = M_y = M_0$.

(3) The partial pressure P_s of steam is calculated using formula (16).

(4) For a given temperature T the vapor pressures P_i (i = 1, 2, ..., N) of fatty acids are found using Eq. (17), and the activity coefficients γ_i, by the equations of the ASOG model.

(5) It is found whether or not the left-hand side of the equation of equilibrium states (13) is identically equal to unity (with prescribed precision). If the identity is not valid, the temperature is raised (left-hand

side less than unity) or lowered (left-hand side exceeding unity) and the calculations according to items 4 and 5 are repeated. The iterative search is continued until the identity (13) is satisfied.

(6) The molar flow rates of individual fatty acids in the liquid and vapor phases, G_{xi} and G_{yi}, and also the compositions of the liquid residue (bottoms) x_i and distillate y_i are calculated using formulas (11) and (12) for $i = 1, 2, .., N$.

(7) The average molecular weights of the liquid and vapor phases, M_x and M_y, are determined.

(8) The calculation according to items 3–7 is repeated.

The efficiency of the proposed algorithm for determining the equilibrium compositions and material flows was verified for the example of calculation of a sectioned industrial fatty acid distiller. The results obtained in calculating the first section of the distiller are presented in Table 3.

It can be seen that the relative discrepancy between the calculated and experimental values is 0.003% for distillate and 3.06% for still bottoms, which may serve as a proof of the adequacy of the developed model to the real process.

CONCLUSIONS

(1) A model of equilibrium states of multicomponent mixtures of higher aliphatic acids in steam distillation is proposed.

(2) An algorithm for calculation of single- and multiple-section distillers for both batch and continuous distillation was developed.

(3) The calculation algorithm can serve as a basis for creating systems for automated design of higher fatty acid distillation processes.

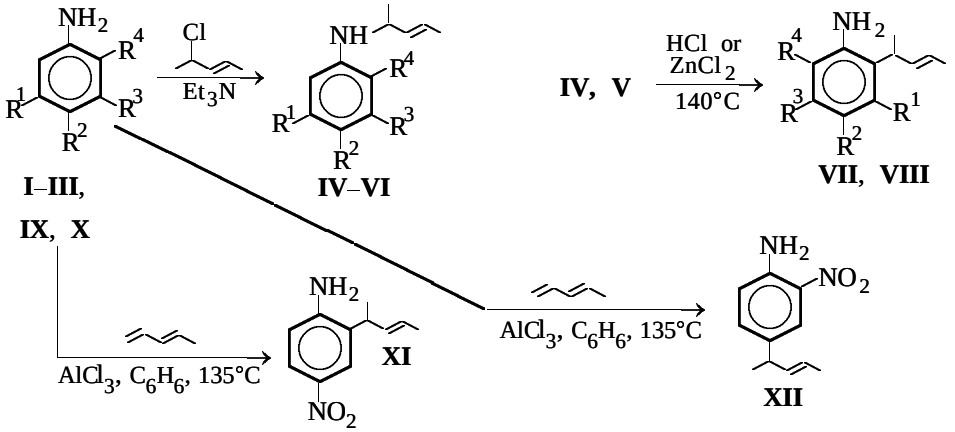
Abstract—*N*-Alkenyl derivatives of di- and trifluoroanilines were prepared by their reaction with 2-chloro-3-pentene. Their transformations under conditions of the Claisen rearrangement were studied. *C*-Alkenylnitroanilines were prepared by reaction of piperylene with *o*- and *p*-nitroanilines in the presence of $AlCl_3$.

Commercially available piperylene and 2-chloro-3-pentene, which can be readily prepared from piperylene, are widely used in syntheses of alkylarylamines [1–3]. At present, the best studied and most convenient route to these derivatives is rearrangement of *N*-(2-methyl-1-butenyl) derivatives into the *o*- and *p*-substituted products, occurring on heating in the presence of acids. The ratio of the *ortho* and *para* isomers is largely influenced by substituents in the aromatic ring. The aromatic amino-Claisen rearrangement has been well studied for *N*-alkylanilines and alkylnaphthalenes, but examples of this rearrangement with *N*-alkylanilines containing electron-withdrawing substituents in the aromatic ring are few [4, 5] and concern *N*-alkyl-3,4-difluoroanilines.

In this work we prepared *N*-substituted derivatives of di- and trifluoroanilines and studied their rearrangement at 140°C under the action of HCl or $ZnCl_2$. 2-Chloro-3-pentene readily reacts with fluorinated anilines **I**–**III** in triethanolamine to give *N*-alkenyl derivatives **IV**–**VI**. Heating of hydrochloride of **IV** in *o*-xylene at 140°C yields compound **VII** as major product. Hydrochlorides of **V** and **VI** remain unchanged under these conditions. The yield of **VII** and **VIII** under conditions of vacuum distillation could be higher, but the available amounts of **I**–**III** were insufficient to prepare compounds **IV**–**VI** in amounts required for these experiments. Heating of **V** with $ZnCl_2$ in *o*-xylene yields aniline **VIII**, whereas amine **VI** undergoes virtually no rearrangement under these conditions. This is probably due to the presence of the fluorine atom at C^2, whose strong –*I* effect deactivates the 6-position of the aromatic ring. Experiments on alkenylation of nitroanilines **IX** and **X** confirm this assumption:



where $R^1 = R^3 = F$, $R^2 = R^4 = H$ (**I**, **IV**, **VII**); $R^1 = R^2 = R^3 = F$, $R^4 = H$ (**II**, **V**, **VIII**); $R^1 = R^2 = R^4 = F$, $R^3 = H$ (**III**, **VI**); $R^1 = R^3 = R^4 = H$, $R^2 = NO_2$ (**IX**); $R^1 = R^2 = R^3 = H$, $R^4 = NO_2$ (**X**).

1070-4272/02/7501-0095$27.00 © 2002 MAIK "Nauka/Interperiodica"

Reactions of nitroanilines **IX** and **X** with piperylene in autoclave in the presence of $AlCl_3$ yield a mixture of products from which we isolated and identified compounds **XI** and **XII**.

Thus, increase in the number of electron-withdrawing substituents in the aromatic ring prevents aromatic amino-Claisen rearrangement of fluorinated *N*-alkenylanilines.

The composition and structure of the synthesized compounds were determined by elemental analysis and spectroscopy. The ^1H NMR spectra allow reliable identification of all the anilines. The ^1H NMR spectrum of **VII** in the region of aromatic protons contains two one-proton signals of H^4 (d.t) and H^6 (d.d). The ^1H NMR spectrum of **VIII** in this range contains only the one-proton signal of H^6 (d.d.d). The location of H^4 between the fluorine atoms is confirmed by the fact that its signal is a triplet with large coupling constants *J*. Alkenylation of nitroanilines at the *o*- and *p*-positions was confirmed by the ^1H and ^{13}C NMR spectra. In both cases, in the region of aromatic protons there are two doublets and one singlet, which is possible only for the presumed structures. The H^3 signals in the spectra of both compounds are characterized by low remote coupling constant *J* with H^5 (1.9–2.2 Hz).

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were recorded on a Bruker AM-200 spectrometer (300 and 75 MHz, respectively, $CDCl_3$, internal reference TMS). The IR spectra were recorded on a UR-20 spectrometer (mulls in mineral oil). The reaction progress was monitored by GLC (Chrom-5 chromatograph, carrier gas helium, linear heating rate 12 deg min^{-1}) and TLC (Silufol UV-254 plates, benzene).

N-Alkenylation of fluoroanilines **I**–**III** was performed as follows: 2.2 mmol of 2-chloro-3-pentene was added to a solution of 2 mmol of **I**–**III** in 5 ml of triethylamine, and the mixture was refluxed for 3 h. After cooling to room temperature, 30 ml of CH_2Cl_2 was added, and the mixture was treated with 10 ml of 20% aqueous NaOH. The organic phase was separated, dried over KOH, and filtered; the solvent was evaporated in a water-jet-pump vacuum. The resulting amines **IV**–**VI** were purified by column chromatography (silica gel 100/40 μm, hexane).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

"Relay" Stabilization of Polyimides

Yu. N. Sazanov

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received May 8, 2001

Abstract—With triphenyl phosphate as example, thermal stabilization of polyimides was studied in a wide temperature range, and the step mechanism of the process, termed "relay" stabilization, was suggested.

By now, a large experience has been gained in synthesis of heterocyclic heat-resistant polymers. Some of these compounds (polyimides, polybenzimidazoles, polybenzoxazoles, and other compounds based on nitrogen-containing heterocycles) are produced on the commercial scale and are widely used in modern engineering. Initially these polymers in the form of various articles, preserving their service characteristics at considerably higher temperatures as compared to the previous generation of heat-resistant polymers, met the specialists' requirements. However, the requirements to articles operating under extreme conditions grew, and it became necessary to further enhance the heat resistance. Attempts to prepare new organic polynuclear heterocyclic structures have not led to appreciable success. In this connection, the necessity again arose in stabilization of polymers, but now this concerned cyclochain aromatic and heterocyclic polymers. Furthermore, the requirements to stabilizers sharply increased also, as these stabilizers should be effective at considerably higher temperatures (300–500°C and higher) than in the previously used systems. Only a narrow range of potential stabilizing agents, especially organic, meet this requirement.

In the course of the search for new thermal stabilizers for heat-resistant polymers, the main requirements to these agents were formulated. We believe that the main feature of such agents is their polyfunctional performance. Namely, a stabilizer should suppress the degradation of polymers at high temperatures and facilitate processes improving the service characteristics of a polymeric article under such conditions. At approximately 500°C, cardinal changes are observed in the kinetics and pathways of thermochemical processes in polymers. Apparently, stabilizers of the new type should be versatile, and their polyfunctional performance should cover the whole working range of the polymer.

This reasoning leads to the concept of "relay" stabilization of heat-resistant polymers, when a stabilizer in a ready polymer or prepolymer in the course of heating or service undergoes successive transformations in which it or its transformation products suppress undesirable processes. For polyimides, in the stage of synthesis of the prepolymer (polyamido acid, PAA) such a stabilizer should behave as catalyst. In the course of transformation of PAA into the polyimide, the stabilizer should protect intermediates and oligomers from reverse reactions (hydrolysis, acidolysis, etc.) and control the molecular weight of the polymer. At higher temperatures, it should suppress oxidative and secondary oxidative thermal hydrolytic reactions characteristic of intramolecular cyclization of heterochain polymers. Transforming into intermediate products of thermal oxidation and thermal hydrolysis, such a stabilizer protects the polymer from the attack of oxygen and hydroxide ions. Suppression of these degradation processes provides favorable conditions for high-temperature carbonization of the polymer, with a high yield of the carbon polymer. Thus, the "relay" stabilization of a polyimide, involving appropriate transformations of the stabilizer and its thermolysis products with increasing temperature, enhances the heat resistance of polymers at elevated temperatures.

It is well known that organic derivatives of P, Sb, B, and V were used as stabilizers of various heat-resistant polymers [1]. One of the first heterocyclic compounds with which such stabilizers (organophosphorus compounds, in particular, triphenyl phosphate, TPP) were tested was PM polyimide [1–6].

Triphenyl phosphate is used for a long time as plasticizer in production of many polymeric articles. A question arises: To what extent does TPP exert the plasticizing effect in synthesis of polyimides and how does it affect the heat resistance of the final product? Usually TPP is added to a PAA solution. Cyclodehydration of a film cast from such a solution occurs in the presence of TPP. Without TPP, degradation of PAA and incomplete cyclodehydration result in ac-

1070-4272/01/7501-0098$27.00 © 2002 MAIK "Nauka/Interperiodica"

cumulation in the polyimide macromolecules of "defective" structures: terminal groups and amido acid residues considerably reducing the heat resistance of the final product [5].

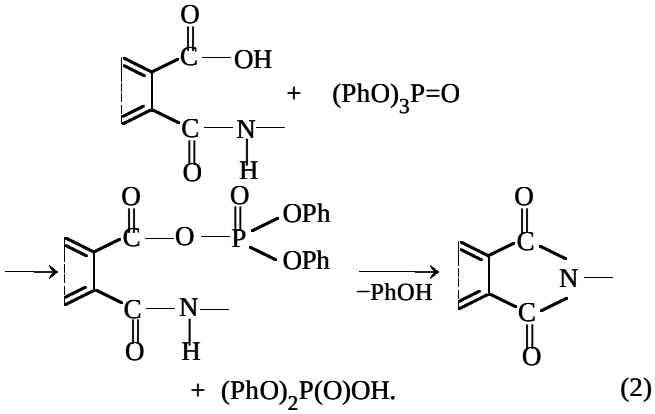
Using MTA, TG, and DTA, we examined the effect of TPP on transformation of PAA into the polyimide. Figure 1 shows the MTA curves for PAA derived from pyromellitic acid and diaminodiphenyl ether (PM PAA) without and with addition of TPP. It is seen that TPP remains in the film until the cyclodehydration is virtually complete, after which its loss starts. The temperature range in which PAA undergoes cyclodehydration in the presence of TPP is by 50°C narrower than in the absence of TPP. The activation energy of this process, calculated from the water release curve, decreases on approaching the curve maximum from 113 to 76 kJ mol^{-1} in the presence of TPP and from 80 to 58 kJ mol^{-1} without TPP.

Acceleration of cyclodehydration as a result of the plasticizing effect of TPP results in that the degree of intramolecular decomposition of PAA decreases, and the imidization becomes more complete as compared to the sample without TPP; as a result, the heat resistance of the polyimide is enhanced, and its deformation and strength properties are improved [7].

It should be noted that the effect of TPP on cyclodehydration cannot be reduced merely to its plasticizing effect. When PAA contans TPP, water released in the course of imidization can induce partial hydrolysis of TPP to form the acidic ester, which exerts approximately the same catalytic effect as phosphoric acid, the known catalyst of many polycondensations:

$$(PhO)_3P{=}O + H_2O \rightarrow PhOH + (PhO)_2P(O)OH. \quad (1)$$

Another probable mechanism of reaction of TPP with PAA, accelerating imidization, can be ring closure with intermediate formation of the mixed anhydride:



+ $(PhO)_2P(O)OH$. (2)

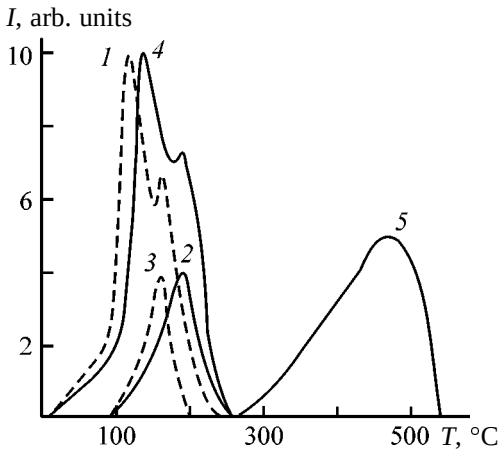


Fig. 1. Mass thermograms of cyclodehydration of a PM PAA film: (*I*) intensity and (*T*) temperature. (*1*) DMF and (*2*) H_2O from straight PAA; (*3*) DMF and (*4*) H_2O from the mixture PAA + 10% TPP; (5) TPP.

As a rule, thermal dehydration of PAA is accompanied by intramolecular decomposition. Water present in the system can hydrolyze the terminal anhydride groups arising in the course of decomposition, giving carboxylic acids which are inactive in acylation. Triphenyl phosphate, reacting with acids by the mechanism similar to that shown in scheme (2), facilitates the back synthesis of PAA, which increases the molecular weight of the polyimide and makes the structure less defective.

The question as to whether phosphorus-containing compounds remain in the polyimide becomes of principal importance. To answer this question, we analyzed by mass spectrometry the gaseous products released from the polyimide on heating. Figure 1, curve *5* shows that, along with degradation products, TPP is released from the film on heating to 500°C, and its content can be estimated gravimetrically. Apparently, even in a high vacuum the polyimide film retains a certain amount (1–3%) of TPP at temperatures of up to 500°C and higher, when degradation becomes appreciable. Naturally, under actual service conditions (atmospheric pressure, presence of moisture, oxygen, etc.) the degradation can start at lower temperature, and the amount of TPP remaining in the film can be higher than in our experiment; hence, the effect of TPP on degradation is beyond question. To elucidate the mechanisms by which TPP affects degradation of polyimides, we used data obtained for polyimides and model compounds using comparative thermal analysis [8] consisting essentially in quantitative determination of carbon oxides released during isothermal heating of samples in sealed ampules.

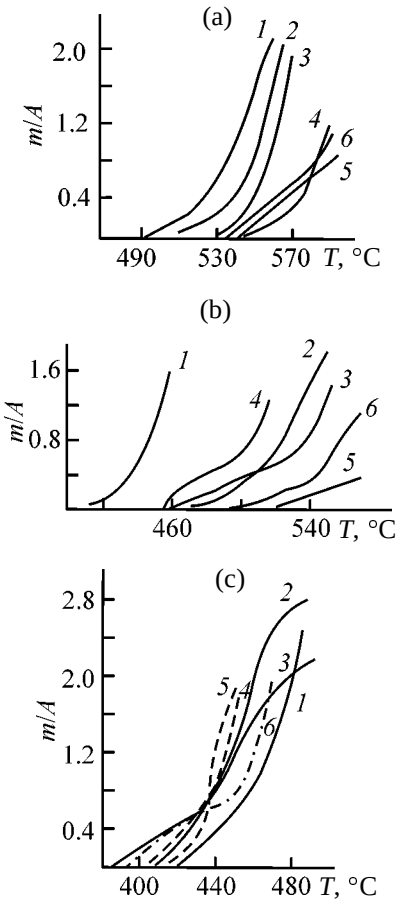

Fig. 2. Comparison of high-temperature degradation curves, as monitored by release of carbon oxides. (*m*/*A*) Number of moles of released CO and CO_2 per structural unit of the polymer and model; (*T*) temperature. (*1*–*3*) PM polyimide film and (*4*–*6*) PPI film. Stabilizer (5 wt %): (*1*, *4*) none, (*2*, *5*) B_2O_3, and (*3*, *6*) TPP. (a) Thermal degradation in a vacuum, (b) thermal hydrolysis, and (c) thermal oxidative degradation.

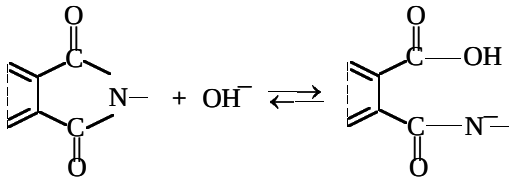
Figure 2 shows the total curves of gas release from polyimide and *N*-phenylphthalimide (PPI) films in the course of thermal degradation in a vacuum with and without addition of TPP and boric anhydride (5 wt %) [9]. For PPI the effect is insignificant, whereas polyimide is stabilized with the above compounds. It is noteworthy that, despite different chemical nature, both additives act similarly. Apparently, defective structures present in polyimide degrade at lower temperatures than regular fragments; the substances (in particular, water) released in the course of their degradation can promote degradation of the main structure.

Water can react with TPP and B_2O_3 to form in both cases a relatively strong acid. In this connection, several possible mechanisms of stabilization of the imide structure can be considered. It was repeatedly noted that TPP and B_2O_3 exert a stabilizing effect in thermal hydrolysis of polyimides and model imides [10, 11]. The examples are curves of gas release in the course of thermal hydrolysis of polyimides and PPI (Fig. 2). The stabilizing effect is appriximately equal for TPP and B_2O_3.

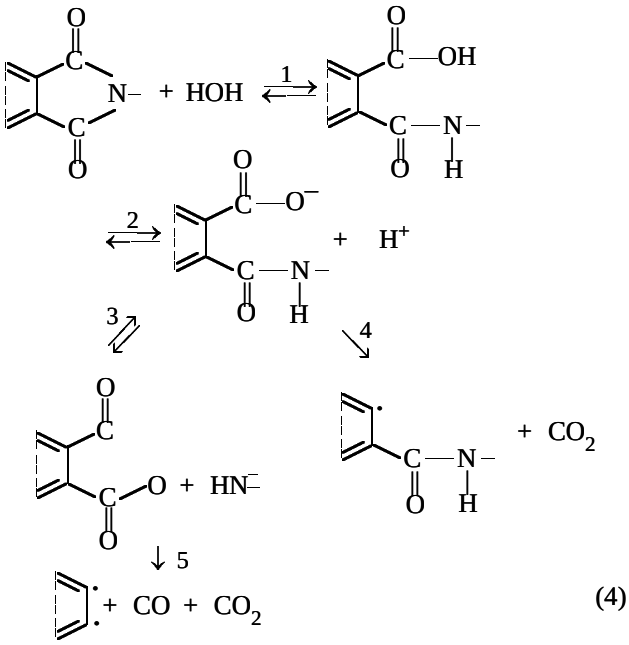
It is commonly believed that hydrolysis of imides starts with the nucleophilic attack of the carbonyl carbon atom by the H_2O molecule or by the stronger nucleophile, hydroxide ion:



(3)

The concentration of hydroxide ions and hence the rate of polyimide hydrolysis increase with temperature. Appearance of strong acids in the system results in considerably increased concentration of protons and decreased concentration of hydroxide ions, which is one of the factors responsible for suppressed hydrolysis of imides.

However, the stabilizing effect of TPP is not limited to this factor. Because at high temperatures the imide ring should be noticeably hydrolyzed with water, amido acid fragments will arise in the system. Their further transformations can occur by several pathways:



(4)

It is known that *o*-amido acid tends to form the imide ring, whereas dissociation of the acid group

facilitates the intramolecular cleavage of the amido acid group to form the anhydride and amine [reaction (3)]. In the temperature range under consideration (>400°C), the anhydride groups actively decompose with release of gaseous products [reaction (5)]. Furthermore, the acid undergoes decarboxylation [reaction (4)].

Thus, the stabilizing effect of TPP derivatives (and also of other acid additives) is due to suppression of dissociation of carboxyl in the amido acid group. Considering scheme (4), we can note the following positive aspects of such effect: stabilization of the imide ring due to the shift of equilibrium (1) toward cyclodehydration, stabilization of amido acid fragments due to decreased contribution of depolycondensation by reaction (3), and suppression of the dissociation of carboxy groups by itself.

The first two effects were discussed above, and the third effect is confirmed by observations of a strong thermostabilizing effect of TPP and B_2O_3 [10, 11]. This fact confirms once again that the mechanism of the stabilizing effect of these additives is similar. It can be shown that thermal oxidation and hydrolysis of polyimides and model imides promote each other (Fig. 2c). Because thermal oxidation is accompanied by release (accumulation in a closed system) of water, in a certain stage thermal oxidation and hydrolysis are superimposed. Naturally, beginning specifically from this moment, the protective effect of TPP on thermal hydrolysis of the imide structure should become operative. Comparison of Figs. 2b and 2c shows that, indeed, in the initial period of thermal oxidation TPP exerts no stabilizing effect, and only above 450°C the stabilizing effect becomes noticeable.

Comparison of the resistance to thermal oxidative degradation of polyimide films modified with various phosphorus compounds (Fig. 3) shows that the strongest effect is exerted by TPP and hexamethylphosphoramide. Organic derivatives of trivalent phosphorus do not inhibit thermal oxidation of polyimides. There are certain grounds to believe that some Sb and V compounds participate in "relay" stabilization of polyimides and polybenzimidazoles. However, in preliminary experiments with these compounds we observed only separate cases of stabilization, requiring more detailed study.

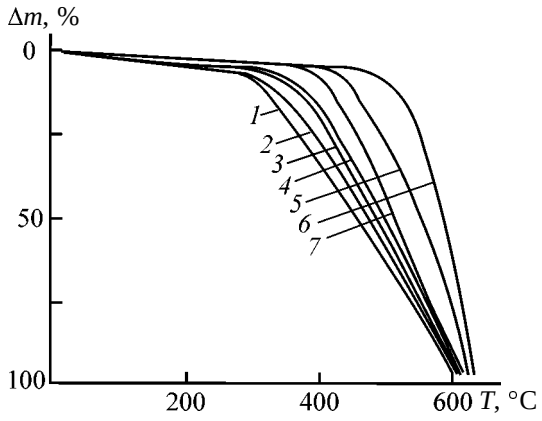


Fig. 3. TGA curves of a PM polyimide film in the presence of (*1–4*) P(III) acid esters, (*5*) hexamethylphosphoramide, and (*6*) TPP; (*7*) no additives. (Δ*m*) Weight loss and (*T*) temperature.

CONCLUSIONS

Stabilization of polyimides in the temperature range 20–500°C with triphenyl phosphate involves several stages. Participation of triphenyl phosphate and its derivatives in reactions with polyimide and its intermediate decomposition products is associated with the "relay" transfer of the stabilizing effect from one reaction to another, which results in suppression of the destructive effects of the environment and improvement of the quality of the polymeric materials.

Received October 10, 2001

Abstract—The features of polycondensation of allyl bromide, diglycidyl resorcinol ether, and polyethylenepolyamine were studied by ^{13}C NMR.

Curing of polymer–polymer systems formed on the basis of epoxy and allyl oligomers was studied by NMR spectroscopy [1]. The structures of copolymers of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride with *N*-vinylpyrrolidone [2], polymers based on glycidyl methacrylate, and its copolymers with methyl methacrylate [3] were studied.

The aim of this work is to study the features of polycondensation of allyl bromide (AB), diglycidyl resorcinol ether (DRE), and polyethylenepolyamine (PEPA) in the precondensation stage by ^{13}C NMR.

EXPERIMENTAL

Anion exchangers were synthesized in dimethylformamide (DMF) at 24°C with subsequent curing of the resulting gel at 80°C [4].

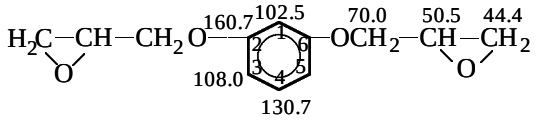
The ^{13}C NMR spectra of the initial compounds and reaction products were recorded at room temperature on a Bruker WP-80 spectrometer operating at 20.13 MHz.

Because aliphatic di- and polyamines are polyfunctional, three-dimensional polycondensation can be performed in two stages. At first precondensation was carried out in the presence of a solvent and then the precondensate was cured to form the maximum cross-linked polymer.

Cross-linked anion exchangers were synthesized by polycondensation of AB, DRE, and PEPA in DMF, since the initial products are readily soluble in DMF and the final products and intermediates readily swell in DMF. Polycondensation was carried out in a solution since in the absence of a solvent, owing to a high reactivity of the initial compounds and accessibility of the reaction centers of the reacting molecules, the process occurs at a high rate with formation of a heterogeneous gel. The use of a solvent allowed control of the process rate and excluded local over-heating resulting from the exothermic effect.

The signals in the ^{13}C NMR spectrum were assigned considering data obtained from the spectra of the initial compounds.

It is seen from the ^{13}C NMR spectrum of DRE that the carbon atom of the methylene group of the epoxy ring gives the signal at higher field (44.4 ppm) as compared to the exocyclic methylene group (70.0 ppm). Abnormally large difference in the chemical shifts can be attributed to the shielding effect of the three-membered ring. For the same reason, the signal of the methine group is shifted upfield and is observed at 50.5 ppm. The signals observed in the range 100–165 ppm belong to the carbon atoms of the aromatic ring. They were assigned using the shielding constants of substituents and the additive equation used for evaluating chemical shifts [5]. The calculated chemical shifts of carbon atoms C_1, $C_{2,6}$, $C_{3,5}$, and C_4 are 100.2, 161.4, 106.9, and 131.1 ppm, respectively, and are consistent with the experimental values of 102.5, 160.7, 108.0, and 130.7 ppm:



In the ^{13}C NMR spectrum of AB, there are three signals, two of which (119.4 and 135.1 ppm) correspond to the terminal methylene and methine groups of the olefin fragment, and the third signal (33.3 ppm) corresponds to the methylene group adjacent to

^{13}C chemical shifts of PEPA and its composition

bromine atom:

$$\overset{119.4}{CH_2}=\overset{135.1}{CH}-\overset{33.3}{CH_2}Br$$

In the ^{13}C NMR spectrum of PEPA, there are seven strong and a series of weak signals. The signals were assigned on the basis of the ^{13}C NMR data obtained previously in studying the structure of commercial PEPA of the A grade [6] and macromolecular polyethylenimines [7]. It is well known that PEPA is a mixture of polyfunctional ethylenamines of various structures and various molecular weights. The dependence of the PEPA reactivity as cross-linking agent on its composition and content of amino groups of various basicities was clearly shown in [8]. Therefore, it was appropriate to determine the composition and structure of PEPA in hand as a component for production of the ion-exchange polymer.

According to chemical shifts evaluated by the additive scheme and found in the experiments for a series of model compounds [6, 7], the two strongest signals at 42.0 and 52.7 ppm were assigned to the methylene groups of $NH_2CH_2CH_2NH$– fragment. Four other signals at 39.0, 46.2, 55.0, and 62.1 ppm belong to *N*-2-aminoethylpiperazine. The signal at 49.6 ppm corresponds to the symmetrical fragment –$NHCH_2$–CH_2NH–. It should be noted that the observed values of chemical shifts do not noticeably differ from published data. The fraction of methylene groups in the structure fragments was evaluated from the ratio of the integral intensities, and then the relative content of these fragments was determined.

The assignment of the signals in the ^{13}C NMR spectrum of PEPA and its composition are presented in the table. The results obtained suggest predominance of three fragments, two of which are terminal (92%) and the third is middle (6%). The fraction of the other fragments is as low as 3%. Thus, PEPA in hand mainly consists of low-molecular-weight ethylenamines of linear and cyclic structure: diethylenetriamine, triethylenetetramine, and *N*-2-aminoethylpiperazine. Small amounts of ethylenamines of branched structure and also ethylenamines with the piperazine ring incorporated in the middle of the polymer chain were detected. It was found [8] that both low- and high-molecular-weight fractions containing components of the linear structure are highly reactive. In the first case, this is caused by a great number of primary amino groups, and in the second case, by increased functionality. It was noted that the presence of tertiary amino groups and piperazine ring decreases the reactivity of PEPA.

The ^{13}C NMR data obtained show that the quantitative and qualitative composition of PEPA differs dramatically from the composition of the commercial PEPA of the A grade [6]. The studied PEPA sample consists of considerably fewer components but contains a large amount of linear terminal fragments with the primary nitrogen atom, and hence it should be very reactive.

In the spectrum of the sample withdrawn 1 h after mixing of AB, DRE, and PEPA taken in the 2 : 1 : 1 ratio, the signal of the methylene group adjacent to the bromine atom disappears, and the signals characteristic of epoxy ring are lacking. In this case, the intensity of the signal of the methylene groups of $NH_2CH_2CH_2NH$– fragment abruptly decreases, and that of the signal of the methylene groups in the middle fragment of the linear structure increases. The signals of carbon atoms of the aromatic ring do not vary, whereas the signal of the OCH_2 groups adjacent to the aromatic ring is broadened and insignificantly

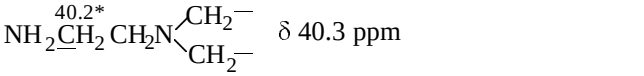
shifted downfield. The signals of olefin carbon atoms are also broadened and somewhat shifted downfield. Simultaneously, new signals appear, assigned to the methine carbon atom at the hydroxy group (69.0 ppm) and methylene group located between the olefin substituent and secondary (53.0 ppm) or tertiary (58.1 ppm) nitrogen atom. The intensities of the signals corresponding to the linear-branched structures $-NHCH_2CH_2N<$ (47.2 and 54.5 ppm) and $>NCH_2CH_2N<$ (53.7 ppm) increase.

The signals of piperazine fragments remain in the spectrum. Disappearance of the signals of the initial compounds and appearance of new signals primarily suggest occurrence of condensation of AB with PEPA, proceeding by nucleophilic attack of the unsaturated carbon atom of the allyl monomer by the nitrogen atom [9]. In this case, the electron density of the double bond is shifted and halide ion is eliminated. The second cause of spectrum changes is nucleophilic attack of the carbon atom of the terminal methylene group of the DRE epoxy ring by the nitrogen atom of PEPA, which results in ring opening and addition of PEPA with formation of zwitterionic structures [10] transforming then into the neutral adduct. As a result of these processes, as would be expected, the content of linear-branched fragments with secondary and tertiary amino groups increases.

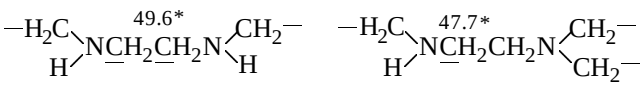
Thus, in the initial stage molecules of AB and bifunctional DRE are completely consumed for formation of dimers and small branched oligomers. Owing to the presence of active centers of various basicities, these oligomers react with each other to form macromolecules with a high molecular weight.

Actually, the spectrum of the precondensate withdrawn in 24 h differs from the spectrum of the reaction products in the early stage. All signals are broadened, excluding the signals of the carbon atoms of the aromatic ring and methylene group (40.3 ppm) directly adjacent to the primary amino group in the terminal branched fragment $NH_2CH_2CH_2N<$ whose concentration is low in comparison with the other fragments. This is caused by growth of the polymer chains owing to increase in the size of the initially formed oligomer molecules. The signals observed can be divided into three groups. The first group includes three signals at 48.7, 53.6, and 58.2 ppm, assigned to methylene groups adjacent to the nitrogen atoms in the intermediate fragments. The second group is presented by two signals at 68.7 and 71.5 ppm, corresponding to methine groups adjacent to the hydroxy group and ether oxygen. The third group includes two broadened signals of the olefin carbon atoms at 117.8 and 133.6 ppm. These signals suggest that the reaction in the precondensation stage does not involve complete cleavage of double bonds.

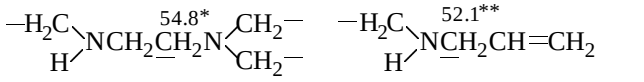
The signals in the ^{13}C NMR spectrum of the anion exchanger based on AB, DRE, and PEPA (before additional curing) in DMF were assigned with the aid of the spectra of the unitial compounds using the additive scheme and model compounds for evaluation of chemical shifts:

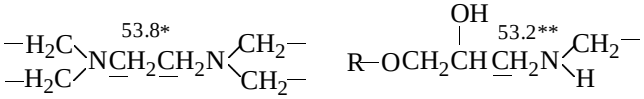


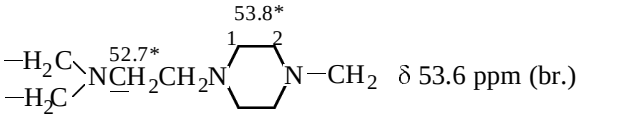
δ 40.3 ppm



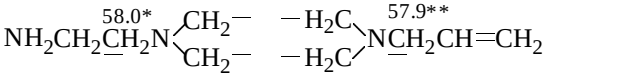
δ 48.7 ppm (br.)

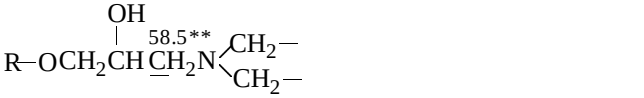




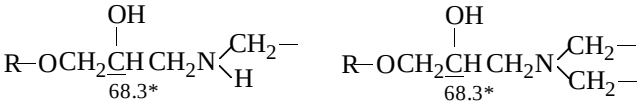


δ 53.6 ppm (br.)

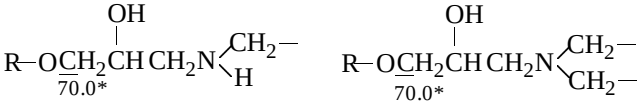




δ 58.2 ppm (br.)



δ 68.7 ppm (br.)



δ 71.5 ppm (br.)

where R = 
* Experimental, ** calculated.

Thus, the ^{13}C NMR study of polycondensation of AB, DRE, and PEPA before additional curing showed that short oligomers with linear and branched structures are formed in the early stage by nucleophilic attack of the unsaturated carbon atom of the allyl compound and terminal carbon atoms of the epoxy rings of DRE by the nitrogen atom of PEPA. In turn, the intermediate oligomers further react through unchanged functional groups to form macromolecules with a high degree of branching.

Abstract—The pore structure of filled films of ultra-high-molecular-weight polyethylene prepared by the gel process was studied by IR spectroscopy and optical microscopy. The moisture and water absorption and the maximal sorption capacity of the material were determined gravimetrically and examined in relation to the degree of filling of films with peat and to the molecular weight of the polymer.

Considerable researchers' efforts in the polymer technology are aimed at development and promotion of new materials with valuable properties, in particular, of porous materials. The most widely used procedure for preparing porous materials involves condensation cross-linking based on spontaneous physicochemical processes in polymer solutions [1, 2]. Polymers can also be processed into porous materials by extrusion of a polymer melt at a high flow velocity, followed by annealing of samples crystallized at room temperature, uniaxial drawing of the annealed samples, and thermal fixation [3].

One of promising processes in polymer technology is the sol–gel process. Interest in this process arose in mid-1970s and was due to the possibility of preparing ultra-high-strength fibers from solutions and gels of flexible-chain polymers [4, 5]. Researchers' efforts [6–8] were aimed at production of highly porous polymeric materials by the sol–gel process and at their structural study. In this connection, structural study of polymeric xerogels (dry gel without solvent), which are highly porous materials, becomes topical. It is also interesting to examine the effect of fillers on the gelation process and structure of the resulting filled porous materials, which can be used as sorbents for petroleum and other products.

The goal of this study was to reveal the effect of a disperse filler (peat) on the properties and structure of filled film materials prepared from ultra-high-molecular-weight polyethylene (UHMWPE) by the gel process.

EXPERIMENTAL

UHMWPE (M_w 1.5×10^6 and 4.0×10^6) was purchased from Hoechst. Films were prepared from a 2 wt % solution of UHMWPE in solid paraffin C_{24}–C_{40} [8]. As compared to traditionally used UHMWPE solvents such as xylene or decalin, paraffin is less active. In such a solvent, conditions for interaction of the polymer molecules and hence for formation of the three-dimensional polymer network are more favorable. Less active solvents are also preferable in production of filled materials [9].

As a UHMWPE filler we used peat. Peat was finely divided without preliminary drying and sieved through a standard set of sieves; the fraction with the grain size of 0.15–0.25 mm was collected. Among natural environmentally clean and cheap sorption-active materials, peat occupies a particular place. In the air-dry state it has low density, high porosity, high hygroscopicity, and high moisture- and gas-absorption power. In practice, peat sorbents are used as compacted briquettes, granules, and finely divided peat. However, studies showed that the impact of high temperatures in the course of briquetting appreciably impairs the sorption power of peat. Furthermore, in water peat briquettes swell and break down. The direct use of finely divided peat as a sorbent requires additional water treatment because of washing out of humic acids in the course of service [10, 11].

Filled film materials were prepared as follows. UHMWPE was dissolved in two stages. The first stage (swelling) was performed at vigorous stirring

1070-4272/01/7501-0106$27.00 © 2002 MAIK "Nauka/Interperiodica"

of a mixture of UHMWPE powder with the solvent at heating to 120°C at a rate of 2.7 deg min^{-1}. In the second stage, stirring was stopped, and the temperature was increased to 160–170°C. Within the subsequent 50–60 min, the solution became homogeneous. After complete dissolution of the polymer, the temperature was decreased to 140°C to avoid oxidative degradation of the polymer. The filler, preliminarily finely divided and fractionated, was charged in portions to the homogeneous UHMWPE solution at 140°C. The mixture was stiired for 10 min and poured onto a metallic table heated to 160°C, after which it was covered with a metallic lid, also heated to 160°C.

The table was cooled to room temperature at a rate of 1.6 deg min^{-1}. To remove the solvent, the films were extracted with heptane in the fixed state in a Soxhlet apparatus at 70–75°C. After extraction, the films were dried at room temperature to constant weight.

The moisture and water absorption and the maximal sorption capacity were determined gravimetrically. To determine the moisture absorption, a weighed portion of the sample was placed in a weighing bottle and dried to constant weight at 50°C in a thermostat. The dried sample was allowed to stand in air at room temperature for 1 h. The moisture absorption B was determined by the formula

$$B = \frac{b - a}{a} \times 100\%, \quad (1)$$

where a is the weight of the absolutely dry sample (immediately after weighing) and b is the weight of the sample after standing for 1 h under ambient conditions.

To determine the water absorption, samples were placed in a vessel under a layer of distilled water for no less than 24 h. The water absorption W was determined by the formula

$$W = \frac{p_2 - p_1}{p_1} \times 100\%, \quad (1)$$

where p_1 is the sample weight under ambient conditions, and p_2 is the weight of the wet sample.

To determine the sorption capacity for petroleum products, samples were placed in a vessel with machine oil for 1 h. The sorption capacity was calculated from the weight gain of the sample after sorption, related to 1 kg of the sorbent.

The apparent density of the sample was determined as the ratio of the sample weight to its volume.

The porosity of UHMWPE films filled with peat was studied by IR spectroscopy, and the sizes of scattering areas (peat particles and pores) were determined. The IR spectra of the films were taken on a Specord IR-75 spectrophotometer equipped with an attachment for taking attenuated total internal reflection (ATIR) spectra. The porosity on the surface and in the bulk of samples was determined according to [7]. In the IR spectrum of the polymer, we chose the most intense absorption band, as weakly sensitive to structural changes as possible. In UHMWPE, this was the band at 720 cm^{-1} originating from the rocking vibrations of the CH_2 groups in the crystalline phase of the polymer. The sample porosity (in relative units) was calculated by the formula

$$\varepsilon = D/d, \quad (3)$$

where ε is the extinction coefficient, which is the measure of the total porosity; D is the optical density in the maximum of the IR absorption band; and d is the film thickness.

The maximal pore diameter was determined from the limiting frequency (wave number) ν_m at which the scattering areas cease to affect the IR spectrum. The wave number and the corresponding wavelength determining the pore size were found at the IR transmission $T = 50\%$ [7, 12].

The surface of filled porous films was also examined by optical microscopy on an MIM-8 horizontal metallographic microscope equipped with a transmitting light attachment and a Sharp-135 video camera. The image was transmitted through the optical channel to the video camera and then, through a video amplifier, to the computer interface.

The influence of the degree of filling on the properties of UHMWPE-based film materials is illustrated by Table 1. It is seen that introduction of a disperse filler into the porous UHMWPE matrix significantly affects the apparent density ρ of the film materials, which is an indirect characteristic of the porosity. Introduction of 1 wt % disperse filler sharply increases the apparent density as compared to the unfilled sample. At the filler content increased further, the apparent density of the film decreases, reaching a minimum at 50% filling. This may be due to the fact that interaction of the polymeric chains of the crystallizing polymer with the filler particle affects the molecular mobility of the chains, which, in turn, affects the UHMWPE crystallization kinetics. The polymer crys-

tallization in the presence of a filler is influenced by two factors: (i) interaction of a polymer with a filler, resulting in appearance on the polymer–filler interface of adsorbed chain sections promoting crystallization; (ii) increase in the viscosity owing to the presence of a filler, which should prevent crystallization. These factors are determined by the nature of the filler surface and by the filler concentration [13]. Apparently, at a low filler content (1–10%) the crystallization rate increases, with the filler particles acting as crystallization nuclei. This results in formation of a denser structure and hence in decreased porosity of film materials. As the filler concentration is increased from 10 to 50%, crystallization is inhibited, and a more porous structure is formed, with the porosity reaching a minimum at 50% filling. At the degree of filling exceeding 50%, the filler particles form areas separated by very thin UHMWPE layers. The film porosity therewith decreases, and the apparent density correspondingly increases (Table 1).

Figures 1 and 2 confirm the assumption that the porosity decreases at a low degree of filling and increases at a higher filler content. Figure 1 demonstrates the influence of the porous structure on the IR spectrum of filled films of UHMWPE of two molecular weights.

The scattering in the samples can be caused by areas of both increased (crystallites) and decreased (pores, cracks, disperse phase particles) density. The higher the total porosity of a sample, the more significant is its influence on the IR transmission due to the scattering effect. Figure 1 shows that, as the filler content increases, the transmission at 730 cm^{-1} decreases. This is due to scattering of the incident IR radiation on the filler particles themselves. The increased transmission of filled films with a low filler content (up to 10%), as compared to unfilled polyethylene films, is probably due to the fact that intro-

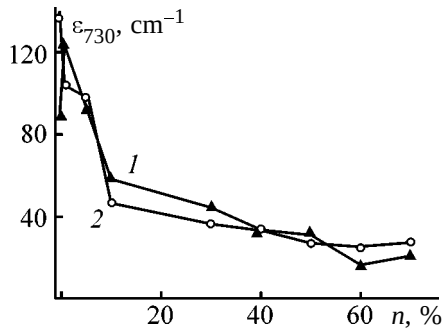

Fig. 2. Extinction coefficient at 730 cm^{-1} ε_{730} of UHMWPE films as a function of the degree of their filling *n*. $M_w \times 10^{-6}$: (*1*) 1.5 and (*2*) 4.0; the same for Fig. 3.

duction of low concentrations of filler particles favors more uniform distribution of the polymer in the bulk of the sample and hence formation of thinner films.

Figure 2 illustrates the influence of the filler concentration on the extinction coefficient of the film at 730 cm^{-1}. It is seen that, as the filler concentration is increased, the absorption decreases, indicating considerable increase in the total porosity. The observed slight increase in the total porosity with increasing M_w of the polymer is probably associated with the looser structure of the sample and with increased viscosity of the three-component system at increased filler concentration. This may be due to the lower mobility (larger length) of the macrochains in the high polymer, which affects the structure of the resulting films. As the filler content in the solution is increased, the film thickness increases, and simultaneously grows the pore size. These two factors (thickness and high porosity) significantly complicate recording of the IR spectra of such samples in the transmission mode at the degree of filling exceeding 50%.

The maximal pore diameter in samples with different M_w virtually coincides (Table 2), despite different total porosity, and slightly increases with increasing filler content. The larger d_p in unfilled samples is due to their loose structure.

However, some of the pores are open. The open porosity significantly affects the sorption and diffusion. The ATIR spectroscopy furnishes information on the structure of the sample surface layers. Figure 3 shows the extinction coefficient at 730 cm^{-1}, calculated from the ATIR spectra, of the film surface contacting the metallic table as a function of the filler concentration. The dependence is similar to those in Fig. 2; it shows that the porosity decreases with increasing filler concentration. The porosities of the polymer samples of different molecular weights virtually coincide, suggesting identical structure of the surface layers. The surface porosity of the films from the side of the metallic table was lower than the bulk porosity, whereas the surface porosity of the films from the opposite side (contacting air) was higher. Visual examination also confirmed that the film surface contacting the metallic table was smoother and less porous.

Figure 4 shows the photomicrographs of films of UHMWPE xerogels filled to 0, 50, and 85%. It is seen that the unfilled xerogel has a network skeleton structure reflecting the structure of the gel. The pore structure parameters of xerogels significantly differ depending on the filler concentration. The estimates

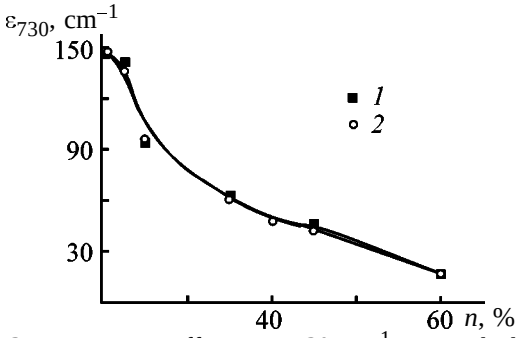

Fig. 3. Extinction coefficient at 730 cm^{-1} ε_{730}, calculated from the ATIR spectrum, of the surface of the UHMWPE film contacting the metallic table, as a function of the degree of filling *n*.

of the xerogel pore size, made by IR spectroscopy, are consistent with the results of optical microscopic examination. Figure 4 shows that the film surface is rough, but there are no coarse pores. Comparison of the pore size (Table 2) shows that the filled xerogels prepared in this work mainly preserve the morphology of the initial gels. The porosity of the unfilled sample is higher than that of the samples filled to 50 and 85%. This is due to its looser structure and to the fact that at an 85% filling the filler forms a layer on which a very thin polymer film is distributed; as a result, the total porosity decreases. Thus, by taking a filler for gel preparation in different concentrations, it is possible to vary in a wide range the morphology and hence the mechanical and sorption properties of xerogel films.

The moisture absorption increases with increasing content of the hydrophilic filler, except the films with the lowest filling, which is due to their increased apparent density, i.e., to the character of the porous structure formed at a 1% filling. The water absorption also increases with increasing degree of filling with the hydrophilic filler, but it remains considerably lower than that of peat (950–1780%).

Study of the sorption capacity of filled film materials for petroleum products based on Mobil Suns S oil

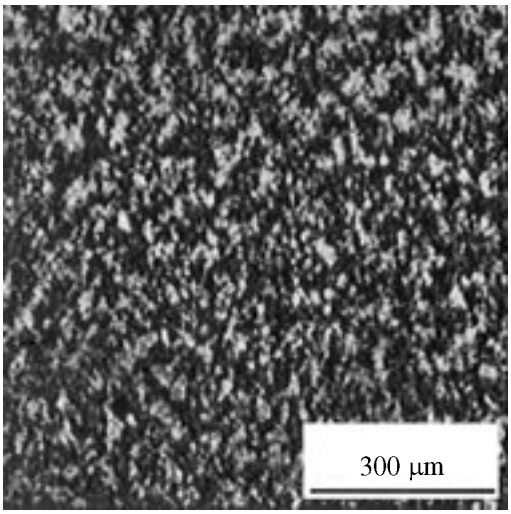
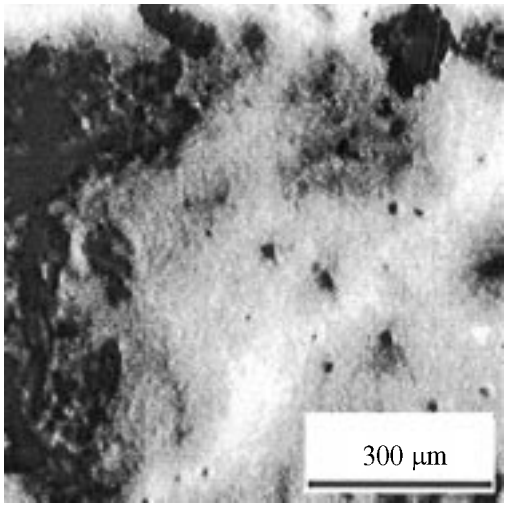
(a)



(b)



(c)

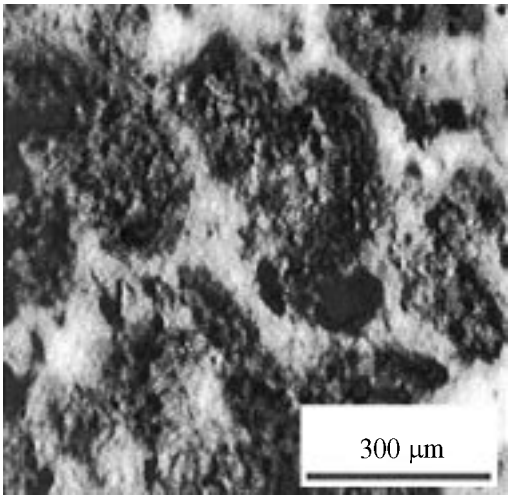


Fig. 4. Photomicrographs of UHMWPE films (M_w 1.5 × 10^6) filled with peat to (a) 0, (b) 50, and (c) 85%.

showed (Table 1) that the lowest sorption capacity is exhibited by the samples filled to 1–10%, and the highest sorption capacity, by the samples filled to 50%, which is consistent with variation of the apparent density. As the degree of filling is increased from 50 to 85%, the sorption capacity of the filled film materials decreases, because the porosity of the polymeric matrix decreases and the matrix itself ceases to participate in sorption.

Thus, our studies showed that the use of the sol–gel process for producing porous materials eliminates the main drawback of peat (high water absorption) with preservation of the high sorption power, which is realized at appropriate ratio of the filler and polymer in the polymeric xerogel.

CONCLUSIONS

(1) Ultra-high-molecular-weight polyethylene films with the degree of filling with peat of up to 85% were prepared by the gel process.

(2) The influence of filler (peat) and molecular weight of the polymer on the character of pore formation both in the bulk and on the surface of the film was studied. At a low filler content (1.0–10%), the film porosity is low. As the filler content is increased from 10 to 50%, the film porosity increases, but at a still higher filler content the porosity decreases.

(3) The optimal peat content in an ultra-high-molecular-weight film, required for efficient sorption of water and petroleum products, was determined.

Abstract—The static bending strength and dynamic elastic, relaxation, and dissipative properties of two types of unidirectional carbon-fiber-reinforced plastic materials based on blend and binary prepregs were studied by the bending resonance vibration method in various directions in the course of curing (pressing).

Separate application of binder components (SCA) is one of the most efficient techniques for increasing the pot life of prepregs [1, 2]. In this method mixing of components goes directly in course of curing. The mixing proceeds through two physical processes. The first, rapid process, dominant in the initial curing steps, is initiated by the action of the mechanical field and involves mechanical mixing of binder components in the vertical and horizontal directions against the prepreg layers. The second process dominating in later curing steps involves mutual diffusion of binder components at the background of chemical cross-linking [3]. Evidently, the intensity of the indicated processes will depend on the nature and structure of binder components and also on the curing mode which should be optimized taking into account all specific structural and kinetic features of the binary technique. Transformations in the polymer matrix (PM) structure occurring with this technique and the corresponding evolution of the mechanical and relaxation properties of the resulting fiber glass plastic materials are considered in [1, 2, 4, 5]. In contrast to fiber glass plastic materials, carbon fibers (CF) are characterized by a considerable porosity and, as a result, a higher sorption capacity [6], affecting the curing kinetics and, correspondingly, the structure [7] and relaxation properties of unidirectional carbon-fiber-reinforced plastics (CFRPs) based on conventional blend carbon fiber woven prepregs.

In this work we studied the features of formation of the structure and mechanical, elastic, relaxation, and dissipative properties of carbon-fiber-reinforced plastic materials based on a binary prepreg (CFRP-II) in comparison with those of the composites based on a blend prepreg (CFRP-I).

EXPERIMENTAL

In the work we used an epoxy system containing 0.9 g-equiv of EN-6 polyglycidyl ether of novolac phenol–formaldehyde resin, 0.1 g-equiv of EKhD tetraglycidyl derivative of 3,3'-dichloro-4,4'-diaminodiphenylmethane, and 1 g-equiv of SF-0113 novolac phenol–formaldehyde resin.

As a reinforcement we used LU-P-0.1 carbon fiber band. Prepregs were prepared by impregnation of the carbon fiber band with alcohol–acetone solutions of the starting epoxy system and separate components using a laboratory-scale impregnator. Samples of CFRPs were prepared by pressing of the prepregs at 180°C under a pressure load of 5.5–6 MPa, followed by cooling under an asbestos cloth and weight (0.1 MPa; native samples). The binder content in CFRP-I varied from 23 to 25 wt % and the density, from 1410 to 1430 kg m^{-3}; those for CFRP-II were 20–22 wt % and 1390–1540 kg m^{-3}, respectively. Note that higher binder content in CFRP-I is realized by virtue of its lower fluidity upon pressing as a result of more rapid hardening and binder viscosity growth with blend prepregs.

The bending strength σ_b was determined following ISOR61/S11 regulations.

1070-4272/01/7501-0112$27.00 © 2002 MAIK "Nauka/Interperiodica"

Dynamic mechanical properties, the real part of the dynamic modulus of elasticity E' and mechanical loss tangent $\tan\delta$, were determined by the resonance bending vibration method with dead-ended samples over the frequency range 10–100 Hz on a setup described elsewhere [9].

The structural and kinetic studies in the course of curing of CFRPs obtained on the basis of various prepreg techniques revealed specific features of formation of their properties in the case of carbon fiber binary prepregs, particularly in the dynamics of evolution of the mechanical characteristics including the elastic, relaxation, and dissipative properties.

Mechanical properties of CFRPs. Figure 1 shows the bending strength as a function of the pressing time, i.e., the degree of conversion of functional groups of unidirectional CFRP-I and CFRP-II. The strength was determined in the longitudinal direction (along reinforcing fibers). The results show that starting from a curing time of 0.5 h (degree of conversion of the binder by this time is 55% [8]) σ_b of CFRP-I considerably decreases, whereas that of CFRP-II remains practically unchanged. To gain a better insight into the observed behavior of the static mechanical properties of the tested CFRPs in the course of curing, we studied their dynamic elastic, relaxation, and dissipative properties as determined in the longitudinal and transverse directions (relative to the reinforcement) by the resonance bending vibration technique. Previously it was demonstrated that this method is highly sensitive to structural transformations in polymeric [10] and composite materials [11–13].

Elastic properties of CFRPs. The real part of the dynamic modulus of elasticity at room temperature E'_{25} of unidirectional CFRP-I and CFRP-II is plotted in Fig. 2 against the time of pressing in the longitudinal and transverse directions (relative to the reinforcement).

In the transverse direction the properties of CFRPs are governed essentially by the contribution of the binder [8]: E'_{25} of CFRP-I after 0.5 h of pressing considerably decreases, whereas that of CFRP-II remains practically unchanged throughout pressing. For CFRP-I, E'_{25}, initially being considerably higher, to the end of curing becomes markedly lower than that of CFRP-II. Note that in the course of curing the trends of the transverse elastic properties of CFRPs are similar to the evolution of their structural behavior under bending stress. In the longitudinal direction the properties of CFRPs are controlled by the contribution of the reinforcement. Therefore, E'_{25} of the both materials in the longitudinal direction is markedly

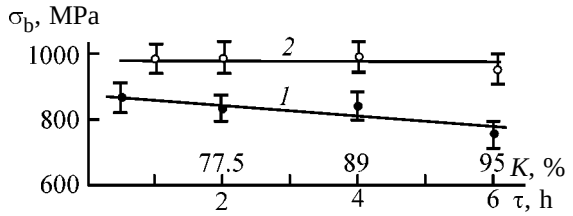

Fig. 1. Bending strength σ_b as a function of the pressing time τ: (*1*) CFRP-I and (*2*) CFRP-II. (*K*) Conversion.

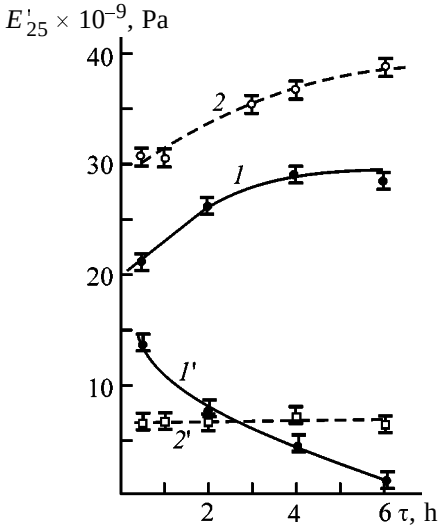

Fig. 2. Real part of the dynamic modulus of elasticity at room temperature E'_{25} as a function of the pressing time τ: (*1*, *1'*) CFRP-I and (*2*, *2'*) CFRP-II. Pressing direction: (*1*, *2*) longitudinal and (*1'*, *2'*) transverse.

higher as compared to that in the transverse direction. The higher modulus of elasticity of CFRP-II is probably due to higher degree of reinforcement as a result of higher fluidity of the binder in pressing of the binary prepreg. Note also that the trends of the elastic characteristics of CFRPs in the longitudinal direction do not correlate with evolution of their mechanical properties.

Relaxation properties. It was demonstrated previously [9, 13–17] that the relaxation properties of unidirectional CFRPs and organoplastics are strongly different, depending on the direction of testing. The nature of differences in properties of CFRP-I in the transverse and longitudinal directions in the course of curing was analyzed in [8]. It was demonstrated that the relaxation spectrum of CFRPs in the transverse direction is characterized by a single α-peak, which is practically identical to that of the starting binder. In the longitudinal direction the spectrum consists of two peaks (α_1 and α_2) of considerably lower intensity, which are strongly shifted to the high-temperature range.

This phenomenon was attributed to the effect of

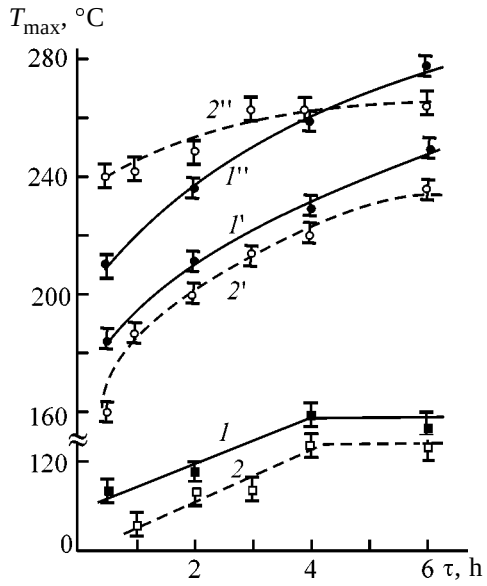

Fig. 3. Peak temperatures of α processes T_{max} as functions of the pressing time τ: (*1*, *1*', *1*") CFRP-I and (*2*, *2*', *2*") CFRP-II. Pressing direction: (*1*, *2*) transverse and (*1*', *1*", *2*', *2*") longitudinal.

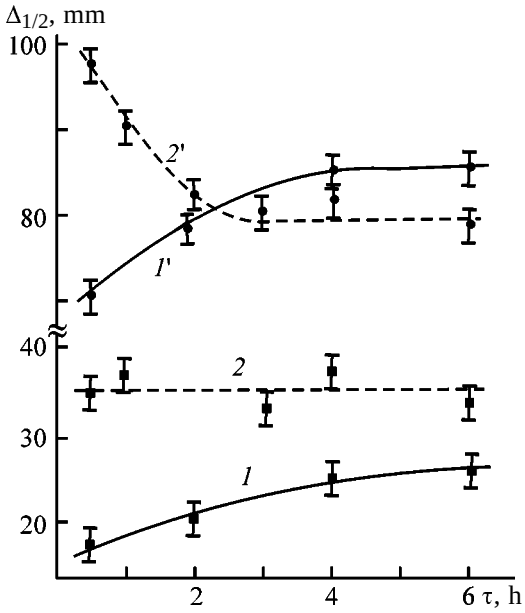

Fig. 4. Half-width of α peak $\Delta_{1/2}$ as a function of the pressing time τ: (*1*, *1*') CFRP-I and (*2*, *2*') CFRP-II. Pressing direction: (*1*, *2*) transverse and (*1*', *2*') longitudinal.

strong residual internal strain (RIS) of the thermal nature, localized at the PM–CF boundary. Splitting of the α peak is interpreted in terms of manifestation of different effect of bending stress on different (by the cross-linking density) microvolumes in structurally nonuniform polymer matrix.

From this standpoint we analyzed the differences in relaxation characteristics of the two CFRPs in the course of curing. As the basic parameters in analysis of the relaxation spectra we selected T_{max} (position of α peak) and $\Delta_{1/2}$ (half-width of α peak).

Evolution in time of T_{max} of the corresponding relaxation peaks is shown in Fig. 3 for CFRP-I and CFRP-II in the transverse and longitudinal directions. As seen, in the both directions the mechanical vitrification temperatures increase until completion of hardening of the polymer matrix. In the transverse direction T_{max} of CFRP-I (curve *1*) increases over the range 0.5–6 h from 115 to 130°C, which is practically identical to T_{max} of the starting binder [8]. For CFRP-II T_{max} (curve *2*) is noticeably lower, though the trend of variation is similar to that of curve *1*. In the longitudinal direction the initial values of T_{max} as well as their increase in the course of curing are higher for the both CFRPs as compared to the corresponding transverse values. For CFRP-II T_{max} of α_1 peak (curve *2*') is slightly lower, and T_{max} of α_2 peak, somewhat higher (curve *2*") than for CFRP-I.

The time dependences of $\Delta_{1/2}$, characterizing the relaxation homogeneity of PM in CFRPs, are presented in Fig. 4. The transverse $\Delta_{1/2}$ of CFRP-I increases in the course of curing, whereas that of the starting binder decreases [8]. For CFRP-II the initial $\Delta_{1/2}$ is considerably higher, remaining, however, practically unchanged in the course of curing. The initial longitudinal $\Delta_{1/2}$ of CFRP-I is much higher than that in the transverse direction, and its increase in the course of curing is higher also. CFRP-II demonstrates higher initial $\Delta_{1/2}$ values, which considerably decrease then, becoming lower than the corresponding values of CFRP-I to the end of curing.

Dissipative properties. The dissipative properties of CFRPs were analyzed on the basis of the relaxation spectra using two parameters. The first parameter, the internal friction background (IFB), was determined as the mechanical loss tangent at room temperature $\tan\delta_{25}$, i.e., at the CFRP testing temperature. Note that IFB can serve as a parameter characterizing the structural organization and intermolecular interaction in the polymer matrix itself [17] and also the internal friction (adhesion interaction) at the PM–CF boundary [18]. The second parameter, the energy dissipation in the α process, was determined as the α peak area or, approximately, the product of the α peak height ($\tan\delta_{max}$) by the α peak half-width $\Delta_{1/2}$. It should be pointed out that the energy dissipation in the α process can affect the binder strength at room temperature [19].

Figure 5a demonstrates the effect of the time of pressing in the transverse and longitudinal directions on $\tan\delta_{25}$ of CFRP-I and CFRP-II. For CFRP-I the transverse $\tan\delta_{25}$ slightly decreases in the course of curing (curve *1*), and for CFRP-II it is somewhat higher, remaining practically unchanged. The trend of evolution of the transverse IFB is similar to that of the structural behavior. The longitudinal IFB is considerably higher than the transverse IFB. For CFRP-I $\tan\delta_{25}$ slightly increases in the course of curing (curve *1*'). For CFRPII $\tan\delta_{25}$ passes through a maximum at τ of about 3 h (curve *2*'), generally being higher as compared to CFRP-I. Note that we found no correlation between IFB and the longitudinal structural behavior.

The dependences of $\tan\delta_{max}$ on the pressing time are shown in Fig. 5b. In the transverse direction, where the contribution of the polymer matrix dominates, $\tan\delta_{max}$ of CFRP-I (curve *1*), initially high, decreases considerably to the end of curing. For CFRP-II (curve *2*) $\tan\delta_{max}$ decreases for about 2 h and then remains unchanged until the end of curing. The longitudinal $\tan\delta_{max}$ regularly decreases for CFRP-I and remains unchanged for CFRP-II; in the end of curing $\tan\delta_{max}$ of the latter being higher. It should be pointed out that in the longitudinal direction this parameter, characterizing the dissipative properties of the α process, correlates with the structural behavior for the both tested CFRPs.

In Fig. 6 are presented the time dependences of the generalized dissipation factor of the α process in CFRPs, i.e., of the $\delta_{max}\Delta_{1/2}$ product. In all cases this factor decreases in the course of curing, reflecting, evidently, the general trend of the molecular segmental mobility in polymer matrices to decrease (increase in the averaged relaxation time). The most pronounced decrease in $\tan\delta_{max}\Delta_{1/2}$ was observed for CFRP-I in the longitudinal direction (curve *1*) and for CFRP-II in the transverse direction (curve *2*'). In the first case the decline is linear until the end point of curing. In the second case the dissipation factor abruptly decreases for about 2 h and then remains practically unchanged. Similar trends of $\tan\delta_{max}\Delta_{1/2}$ are observed for CFRP-II in the longitudinal direction (curve *1*') and for CFRP-I in the transverse direction (curve *2*).

To interpret the observed anisotropy of properties of the CFRPs under study in the course of curing, the following findings and considerations should be taken into account.

(1) The observed evolution in the properties of CFRPs in the course of curing is a resultant of the

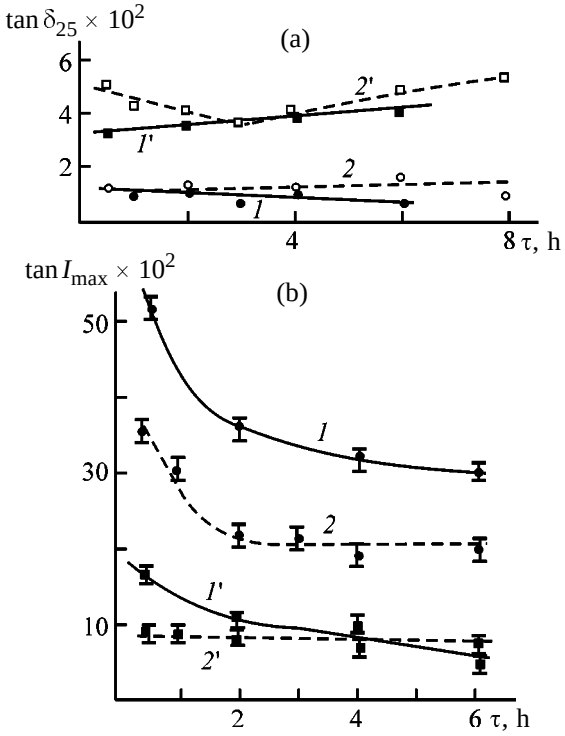

Fig. 5. (a) Internal friction background and (b) α peak intensity I_{max} as functions of the pressing time τ: (*1*, *1*') CFRP-I and (*2*, *2*') CFRP-II. Pressing direction: (*1*, *2*) transverse and (*1*', *2*') longitudinal.

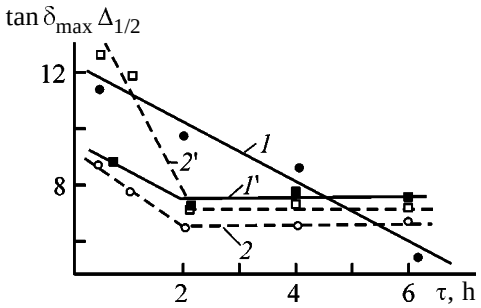

Fig. 6. Dissipation factor $\tan\delta_{max}\Delta_{1/2}$ as a function of the pressing time τ: (*1*, *1*') CFRP-I and (*2*, *2*') CFRP-II. Pressing direction: (*1*, *2*) transverse and (*1*', *2*') longitudinal.

effect of the structural and deformation factors [8, 20]. The structural factor is considered to mean the topological effects in the structure of the polymer matrix, which are associated with growing number of cross-links and functionality. By the deformation factor is meant the effect of residual internal strains, which are different in their value and action. Note that in unidirectional CFRPs the polymer matrix is subject to shrinkage stress in the transverse direction and to more strongly pronounced stretching effects due to thermal RIS in the longitudinal direction [8]. In the initial stages of curing (τ 2–3 h) the structural factor dominates. According to NMR data [7], in the initial

period the volume fraction of faulted microvolumes in the polymer matrix of CFRP-I approaches the minimum. In the subsequent stages of curing the deformation factor dominates.

(2) When analyzing the evolution of properties of CFRPs in the course of curing, it is necessary to take into account the specific features of dynamic mechanical spectrometry methods: under transverse load the entire bulk of PM contributes to the mechanical response, while under longitudinal load, only its small fraction, specifically, the layers directly contacting the CF surface [8, 20, 21]. It may be suggested that these layers concentrate the most faulted microvolumes of PM. In the case of CFRP-I they contain components which are specifically sorbed (immobilized) in CF pores [7, 8], and in the case of CFRP-II, not mechanically mixed binder components [20]. Evidently, for CFRP-II the initial structural inhomogeneity and, correspondingly, the molecular mobility in PM should be more pronounced, more so in the boundary layers.

(3) The initial inhomogeneity is responsible for the subsequent transformations in the PM structure. Thus, in the case of CFRP-II, the total number of chemical cross-links in the bulk of PM increases irregularly in the course of curing: the dominating process is local aftercure in topologically faulted low-cross-linked microvolumes of PM by virtue of diffusion-controlled reactions of functional groups [8]. Subsequently this should result in leveling of the structural parameters and, therefore, of various characteristics throughout the PM volume.

(4) The trends in variation of the relaxation characteristics of PM in CFRPs can be influenced by chemical relaxation (chemical debonding in locally overstrained PM microvolumes [22], for example, at the PM–CF boundary [2]).

Generally, the above considerations are sufficient to interpret the observed trends of the structural, elastic, relaxation, and dissipative properties of the tested CFRPs in the course of curing of different prepregs. However, a series of experimental results needs more detailed analysis. For example, we observed unexpected decrease in the transverse E'_{25} for CFRP-I and its constancy for CFRP-II , i.e., in the case when the contribution of the binder should dominate. It seems more likely that with further curing after a 55% conversion of functional groups (τ 0.5 h) the modulus of elasticity should necessarily increase. The observed behavior can be interpreted in terms of the Perepechko's effect [23], whose essence is that the growth in the number of chemical cross-links in the binder results in decreasing number of intermolecular contacts (bonds) providing the major contribution to the dynamic modulus of elasticity of the binder in the glassy state. The constancy in E'_{25} for CFRP-II can be attributed to the specific features of formation of the PM structure with binary prepregs [4, 5, 20]. In this case the total number of chemical cross-links in the bulk of PM increases irregularly in the course of curing: the dominating process is local aftercure in topologically faulted low-cross-linked microvolumes of PM by virtue of diffusion-controlled reactions of functional groups [8], which should result in leveling of the elastic characteristics throughout the PM volume. For the both CFRPs the growth in the longitudinal E'_{25} in the course of curing is caused by simultaneous effect of the structural and deformation factors. Taking into account the above-mentioned specific features of CF prepregs in PM boundary layers contributing to the mechanical response in the longitudinal direction, low-cross-linked, faulted microvolumes can be formed, where the Perepechko's effect is not pronounced yet. Therefore, the dynamic modulus of elasticity in this direction keeps on to increase. Furthermore, the increase in E'_{25} in this direction may be caused by strong stretching action due to residual internal strains of the thermal origin. As we suggested in [8], it is the effect of these strains that is responsible for considerable increase in the temperature of mechanical vitrification in the longitudinal direction. Decrease in the segmental mobility in PM in the longitudinal direction under the action of the stretching force due to residual internal strains should be reflected also in the elastic characteristics of CFRPs. This suggestion is supported by data given in [24–26] that the surface of the reinforcing agent in CFRPs and organoplastics favors formation of some ordered (consolidated) cluster structures in polymer matrices. These structures are oriented along the fibers, having a high degree of the cooperativity (hindrance) of segmental motion [24]. Evidently, they are realized under the effect of strong stretching thermal RIS directed along the fiber in the surface layer of PM. Note that in organic and carbon fibers the thermal expansivity coefficient in the longitudinal direction is negative, being $(-1 \div 6) \times 10^{-6}$, and that for epoxy binders, $(40 - 60) \times 10^{-6}$ K^{-1} [27].

Let us also discuss significant differences in the relaxation properties of the investigated CFRPs with an example of the α-peak half-width $\Delta_{1/2}$ characterizing the relaxation homogeneity of the spectrum. According to data reported in [8, 20], this parameter allows adequate evaluation of the effects of the structural and deformation factors on the polymer matrix in the course of curing. Increase in the transverse

$\Delta_{1/2}$ of CFRP-I with this parameter being decreased in the initial binder means that the observed broadening of α peak is caused essentially by the effect of the deformation factor, i.e., by increasing shrinking RIS. Higher $\Delta_{1/2}$ in this direction in CFRP-II, which remains unchanged in the course of curing, signifies that the structural heterogeneity in PM is higher in this case, but occurrence of low-cross-linked (having shorter relaxation time) microvolumes of microheterogeneous PM favors more efficient relaxation of residual internal strains in CFRP-II in the course of curing. The higher initial half-width of α peak in the longitudinal direction for the both CFRPs as compared to that in the transverse direction is caused by the effect of the structural factor, i.e., by more pronounced topological microheterogeneity of PM in the surface layers. At the same time, stronger increase in $\Delta_{1/2}$ for CFRP-I in the course of curing is due to a stronger effect of the deformation factor, i.e., the stretching effect of heavy thermal RIS. High initial $\Delta_{1/2}$ in CFRP-II and its subsequent decrease, in principle, would be attributed to the effect of the structural factor. More intense reaction in the deepest stages of curing in less cross-linked, topologically faulted microvolumes [5] should increase the homogeneity of the PM structure and decrease the half-width of α peak. However, if this were the case, similar effect should be observed in the transverse direction also. Therefore, taking into account stronger RIS in the longitudinal direction, the observed decrease in $\Delta_{1/2}$ as well as initial decrease in $\tan\delta_{25}$ and increase in IFB, evidently, are due to chemical relaxation (debonding) of overstrained bonds [2, 22].

Finally, study of the curing kinetics allows comparative analysis of the behavior of the bending strength for the both CFRPs and evolution in the elastic and dissipative properties and also the intensity of stress of PM in the longitudinal and transverse directions. The constancy of σ_b in CFRP-II and its decrease in the course of curing are well consistent with the trends of the dynamic modulus of elasticity, $\Delta_{1/2}$, and $\tan\delta_{25}$ in the transverse direction, and also of the $\tan\delta_{max}$ and, in part, $\tan\delta_{max}\Delta_{1/2}$ in the longitudinal direction. These results suggest that the bending strength of unidirectional carbon-fiber-reinforced plastics in the longitudinal direction is governed by three major factors: (1) relaxation characteristics of the polymer matrix, especially in the surface layers responsible for relaxation of the most harmful stretching residual internal stresses acting along the fiber–polymer matrix boundary; (2) elastic properties of the polymer matrix in the transverse direction, which provide efficient propagation of strains between carbon fibers and, therefore, a higher degree of cooperativity of their degradation; and (3) adhesion preventing peeling of the polymer matrix from carbon fibers due to tensile stress caused by residual internal strains originating from shrinkage.

CONCLUSION

Carbon-fiber-reinforced plastic materials prepared by the binary prepreg technique may surpass plastics based on the conventional blend prepregs by all the three mechanical parameters (elasticity, dissipation, and stress–strain behavior) in certain directions, which is caused primarily by the mosaic, partly gradient structure of the polymer matrix realized with the binary prepregs. This structure is characterized by an increased content of topologically faulted microvolumes, especially in its surface layers. The faulted microvolumes originating from incomplete mixing of the binder components favor efficient relaxation of various internal residual stresses, especially along the fibers.

Abstract—The feasibility was studied for producing polymeric materials by high-temperature copolymerization of maleic acid with styrene distilation bottoms from joint production of styrene and propylene oxide. Regression equations were derived to predict the conditions for preparing the copolymer with the required properties. The structure, properties, and fields of possible application of the copolymer were studied.

A major problem of petrochemical industry is utilization of bottoms from production of vinylaromatic monomers. These bottoms are large-tonnage wastes. There are two main procedures for commercial production of styrene: dehydrogenation of ethylbenzene and dehydration of methylphenylcarbinol (MPC) formed in joint production of styrene and propylene oxide. Whereas synthesis of polymeric materials from styrene distillation bottoms (SDB) from the former process has been studied comprehensively, and the application fields of the resulting polymers are well examined, SDB from the latter process are studied poorly [1]. At the same time, maximal utilization of the whole amount of SDB with production of nontoxic polymeric products containing no styrene or other hazardous compounds is an urgent problem [2].

Reaction of styrene with maleic acid in the presence of MPC and acetophenone, which are the main components of SDB from joint production of styrene and propylene oxide, yields a polymeric product which can show the film-forming properties. The process is multistage and depends on many factors. Study of separate stages will give insight into the process mechanism and reveal the major factors affecting the yield and quality of the copolymer.

In this work we studied how the copolymer yield depends on the temperature, weight ratio of acetophenone-containing SDB and maleic acid, content of styrene in acetophenone-containing SDB, and process time. However, experimental assessment of the joint effect of these factors on production of the target product is time-consuming, which makes it particularly important to use simulation procedures. Study and construction of mathematical models requires thorough design of the experiment.

The experimental design was based on the fourth-order Greek–Latin square. With this design, the volume of experiments necessary to reveal separate significant factors, evaluate their effect, and obtain regression equation is considerably reduced. It becomes possible to evaulate simultaneously the effect of all the factors and to determine the factor values (within their variation range) providing the best result with respect to one or another criterion characterizing either the product quality or the process efficiency. This is particularly important when interaction between the factors is absent or can be neglected. The structure of the square [3] follows from the theory of experimental design.

Experimental study of the copolymer preparation involved (1) choice of the process temperature and time, reactant ratio, and content of styrene in the initial acetophenone-containing SDB as the main parameters affecting copolymerization; (2) estimation of the main copolymerization parameters, within the preset limits of their variation, ensuring the highest yield of the copolymer of the required quality; and (3) elucidation of the dependence of parameters characterizing the copolymer on the preparation conditions.

Under laboratory conditions, the copolymer was prepared in a glass reactor equipped with a reflux condenser, a Dean–Stark trap, and a stirrer; the reactor was placed in a thermostat to maintain the prescribed temperature. The major components of acetophenone-containing SDB were acetophenone (~35 wt %) and

* The synthesis temperature and time are given; the total synthesis time is given in parentheses.

MPC (~14 wt %); the styrene content, according to the experimental plan, was varied from 15 to 45 wt %. The remainder was tar containing polystyrene and other high-boiling compounds. Acetophenone-containing SDB and maleic acid in a prescribed ratio were simultaneously charged to the reactor and gradually heated with continuous stirring to the prescribed temperature, maintained to within ±2.5°C. The reaction progress was monitored chromatographically and viscometrically. After synthesis completion, acetophenone and nonpolymerized substances were distilled off in a vacuum (5–8 mm Hg, 165–170°C).

As factors affecting the process we chose the process temperature and time, the styrene content in the initial bottoms, and the amount of maleic acid added *d*. The plan of the experiment is given in Table 1. According to the plan, copolymerization is a three-stage process, with the stages differing in the temperature and time. As response functions we chose the copolymer yield and such its characteristics as molecular weight, acid number, and ester number, determining the main properties of the copolmer and its application fields.

To estimate the target functions and predict their values, the experimental results were processed to obtain the regression equations

$$Y = SF_1(t)F_2(\tau)F_4(d), \quad (1)$$

where Y is the target function; S is the coefficient; $T = T_2T_3/T_1 - (T_2T_3/T_1)_{min}$, T_1, T_2, T_3 are the temperatures of the first, second, and third reaction stages (°C); $\tau = \tau_2\tau_3/\tau_1 - (\tau_2\tau_3/\tau_1)_{min}$, τ_1, τ_2, and τ_3 are the times of the first, second, and third reaction stages (h); the subscript min means that the smallest of the possible values of T_2T_3/T_1 and $\tau_2\tau_3/\tau_1$ is taken; c is the concentration of styrene in acetophenone-containing SDB (wt %); d is the amount of maleic acid added (wt %); F_n is the function of single variable: $F_1 = F_1(T)$, $F_2 = F_2(\tau)$, $F_3 = F_3(c)$, $F_4 = F_4(d)$ characterize the influence of the process temperature and time, styrene concentration, and maleic acid content, respectively, on the value of the target function.

Temperature parameter T	0, 4.54, 9.11, 13.80
Time parameter τ	0, 4.50, 1.83, 5.83
Styrene concentration c, wt %	15–45
Maleic acid content d, wt %	1–10

In formula (1), the functions $F_1(T)$ and $F_2(\tau)$ are discrete and defined only for the T and τ values listed in Table 2. The T and τ values were chosen so as make convenient calculation of $F_1(T)$ and $F_2(\tau)$, approximated by third-degree polynomials. Because the levels of the temperature and time factors A and B are presented by sets of three numbers, it is insufficient to characterize their effect by a single number. The functions $F_1(T)$ and $F_2(\tau)$ in this model are discrete and only reproduce the experimental results.

The functions $F_3(c)$ and $F_4(d)$ are continuous, the possible experimental errors are smoothed assuming that the dependence has the form of a quadratic polynomial. Regression equations (1) for calculating the copolymer yield Y_y, molecular weight $Y_{\bar{M}_v}$, acid number Y_{an}, and ester number Y_{en}, after processing of the experimental data, have the form

$$Y_y = 2.14 \times 10^{-6}(75.3 + 0.3355T - 7.69 \times 10^{-2}T^2 + 6.24 \times 10^{-3}T^3)(76.8 + 7.47\tau - 3.40\tau^2 + 0.375\tau^3) \times (42.0 + 2.05c - 0.0251c^2)(69.1 + 2.91d - 0.187d^2),$$

$$Y_{\bar{M}_v} = 8.15 \times 10^{-5}(17.4 + 4.53T - 0.542T^2 + 1.63 \times 10^{-2}T^3)$$
$$\times (22.5 - 0.108\tau - 0.775\tau^2 + 0.162\tau^3)(29.3 - 0.449c$$
$$+ 6.80 \times 10^{-3}c^2)(19.4 + 1.174d - 6.44 \times 10^{-2}d^2),$$

$$Y_{an} = 6.84 \times 10^{-4}(12.6 - 0.571T + 8.06 \times 10^{-2}T^2$$
$$- 3.72 \times 10^{-3}T^3)(10.5 + 1.77\tau - 0.239\tau^2 - 1.39 \times 10^{-2}\tau^3)$$
$$\times (5.92 + 0.287c - 3.03 \times 10^{-3}c^{-2})(5.73 + 0.148d + 0.151d^2),$$

$$Y_{en} = 4.16 \times 10^{-5}(37.9 - 5.22T + 0.691T^2 - 2.72 \times 10^{-2}T^3)$$
$$\times (2.2 + 13.2\tau - 3.83\tau^2 + 0.299\tau^3)(18.6 + 0.517c$$
$$- 4.95 \times 10^{-3}c^2)(11.8 + 2.78d + 0.122d^2).$$

The ranges of variation of the response functions obtained with this experimental plan are given below:

Copolymer yield, wt %	69–90
Molecular weight of copolymer $\bar{M}_v$	12 120–42 660
Acid number, mg KOH g^{-1}	5–25
Ester number, mg KOH g^{-1}	11–81

The mean deviation of the calculated data from the experiment (by the absolute value, %) is as follows: for copolymer yield, 5.0; for average molecular weight, 16.4; for acid number, 3.6; and for ester number, 8.6.

The regression equation obtained allows presentation of the experimental results in the general form and calculation of the response functions for the conditions that differ from the tested conditions (Table 1) but fall within the variation range of the corresponding factors. The equations fairly reliably predict the possble results under conditions differing from those realized according to the fourth-order Greek–Latin square plan, allowing adjustment of process parameters and copolymer composition depending on the conditions of using the copolymer in composite materials.

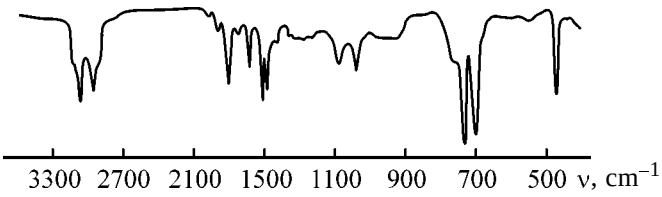

Fig. 1. IR spectrum of copolymer based on acetophenone-containing SDBs. (ν) Wave number.

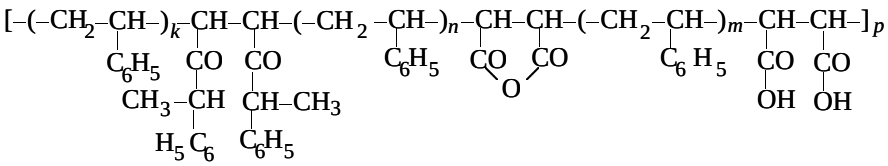
The experimental results allow us to suggest the composition of the copolymer chain containing carboxy, anhydride, and ester groups. In all cases the ester number, determining the content of ester groups, is higher than the acid number. This fact suggests that the ester group is formed both by reaction of maleic acid with MPC and, possibly, by reaction of MPC with the carboxy groups of the copolymer chain. The presence of all the three kinds of groups in the copolymer chain is confirmed by IR spectroscopy.

Figure 1 shows a typical IR spectrum of the copolymer, taken on an IKS-29 spectrometer in the range 600–3200 cm^{-1}. The polystyrene base is confirmed by bands at 1640, 1030, 906, 750, and 700 cm^{-1}. Strong absorption at about 1820 and 1770 cm^{-1} is characteristic of anhydride groups (styrene–anhydride combination in the polystyrene chain and maleic anhydride). A band at 1710 cm^{-1} characterizes free maleic acid (dimer), with a shoulder at 1710–1660 cm^{-1} confirming the presence of the C=C bond with the *cis* geometry. The band at 1800–1850 cm^{-1} belongs to the anhydride group, and at 1740 cm^{-1}, to the ester group [4].

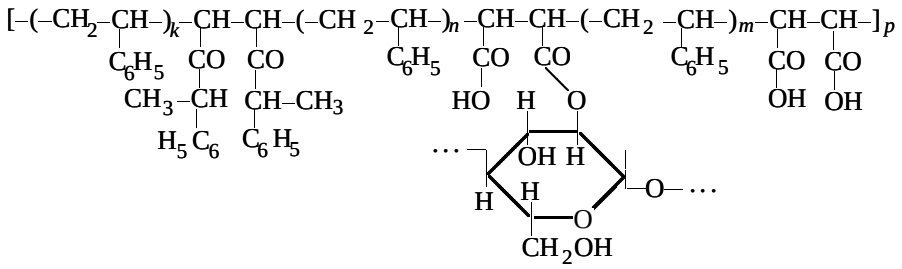
The structure of the synthesized copolymer can be represented as follows:



Thus, the experimental results allow us to propose conditions for joint processing of acetophenone-containing SDB and maleic acid to obtain the copolymer of required quality with the maximal yield.

At present, major attention is given to treatment of wood materials with the aim of enhancement of their water and moisture resistance, protection from biological degradation, prolongation of the service life, etc.

[5–9]. The structure and properties of the SDB copolymer obtained suggest that one of the promising fields of its application can be treatment of wood-fiber boards (WFBs) to enhance their water and moisture resistance and strength. The high content of functional groups suggests that this copolymer will interact with polymeric components of wood and bind with them chemically. The product, with cellulose as example, can be represented as follows:



It should be assumed that grafting of low-molecular-weight SDB copolymer to cellulose macromolecules will eliminate such drawback of impregnating agents as their washout from articles in the course of their service.

The impregnating solution based on SDB copolymer was prepared by its dissolution in a mixed solvent widely used in production of paint-and-varnish materials: a 4 : 1 mixture of xylene with acetone. Experiments were performed according to the plan of a 4 × 4 Greek–Latin square. As the main factors exerting the strongest effect on the water resistance and strength of WFBs we chose the impregnation time (30, 60, 90, and 120 s, factor *A*), heat treatment temperature (120, 140, 160, and 180°C, factor *B*), heat treatment time (1.5, 3.0, 4.5, and 6.0 h, factor *C*), and copolymer concentration in solution (29, 42, 55, and 68 wt %, factor *D*). The polymer content in WFBs was determined gravimetrically from the weight gain. The modified boards were cooled in air to room temperature. After conditioning, the boards were tested according to GOST (State Standard) 19592–80. The content of the SDB copolymer in modified WFBs varied from 3.5 to 16.2 wt % depending on process conditions.

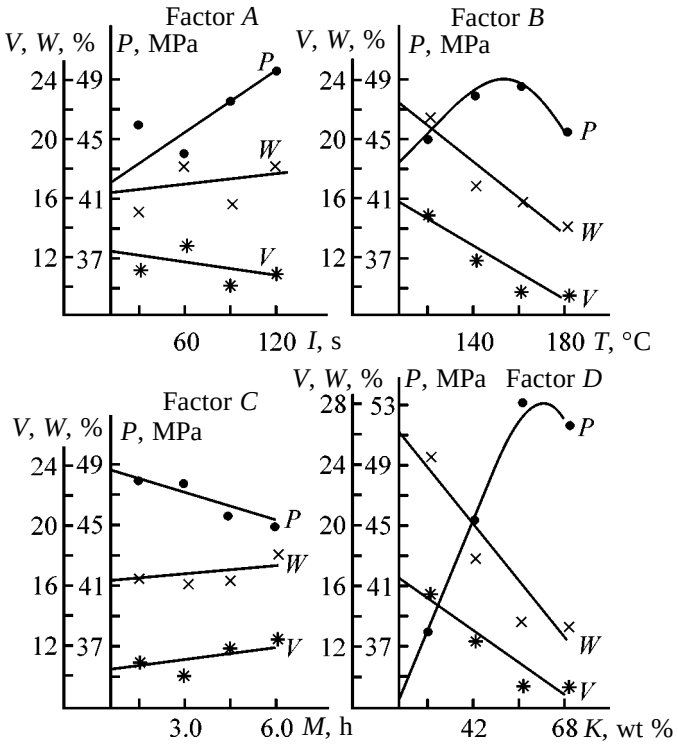


Fig. 2. Swelling with respect to thickness *V*, water absorption *W*, and bending strength *P* as functions of the impregnation time *I* (factor *A*), heat treatment temperature *T* (factor *B*), heat treatment time *M* (factor *C*), and impregnating solution concentration *K* (factor *D*).

Data on the strength and water resistance of WFBs are given in Table 2. Analysis of the dependences shows that the most significant effect on the properties of modified WFBs is exerted by the heat treatment temperature and concentration of the impregnating solution and, to a lesser extent, by the time of impregnation and heat treatment.

By processing the experimental results, we obtained the regression equations describing the effect of the chosen process parameters on the strength and water resistance of WFBs. The regression equations for the response functions are as follows: for the ultimate bending strength (MPa),

$$Y_{str} = 9.8 \times 10^{-6}(43.2 + 0.048a)(-41.9 + 1.2b - 3.98 \times 10^{-3}b^2)(49.6 - 0.76c)(1.04 + 1.64d - 1.3 \times 10^{-2}d^2),$$

Table 3. Experimental and calculated data on the strength and water resistance of WFBs

Parameter	Calculation	Experiment	Control
Ultimate bending strength, MPa	59.0	58.5–60.3	48.1–50.7
Swelling with respect to thickness in 24 h, %	7.9	6.6–7.1	10.2–11.8
Water absorption in 24 h, %	13.4	10.9–12.4	14.4–15.2

* Control boards were impregnated with tall oil used in production of enhanced-strength hard boards [10].

for swelling with respect to thickness (%),

$$Y_{sw} = 6.92 \times 10^{-4}(12.3 - 1.24 \times 10^{-2}a)(24.9 - 8.94 \times 10^{-2}b) \times (9.66 + 0.447c)(19.9 - 0.171d),$$

and for water absorption (%),

$$Y_{w} = 2.13 \times 10^{-4}(15.06 - 2.33 \times 10^{-2}a)(34.3 - 0.11b) \times (15.6 + 0.304c)(31.4 - 0.291d).$$

The optimal conditions for WFB modification with SDB copolymer are as follows: impregnation time 120 s, heat treatment temperature 160°C, heat treatment time 1.5 h, and concentration of SDB copolymer in solution about 60 wt %. The strength and water resistance of modified WFBs, calculated for these process parameters, and given in Table 3 in comparison with the experimental data. The calculation results reasonably agree with the experiment.

CONCLUSIONS

(1) Optimal conditions for production of polymeric materials based on styrene distillation bottoms from joint production of styrene and propylene oxide were determined by mathematical experimental design.

(2) The structure and properties of the copolymers were determined.

(3) One of the promising application fields of the resulting copolymers is modification of wood-fiber boards, enhancing their water and moisture resistance and strength.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Photoinitiated Polymerization of Acryloyl Chloride

G. G. Egorova, I. I. Migunova, I. V. Mukhina, N. V. Girbasova, and A. Yu. Bilibin

St. Petersburg State University, St. Petersburg, Russia

Received December 27, 2000; in final form, April 2001

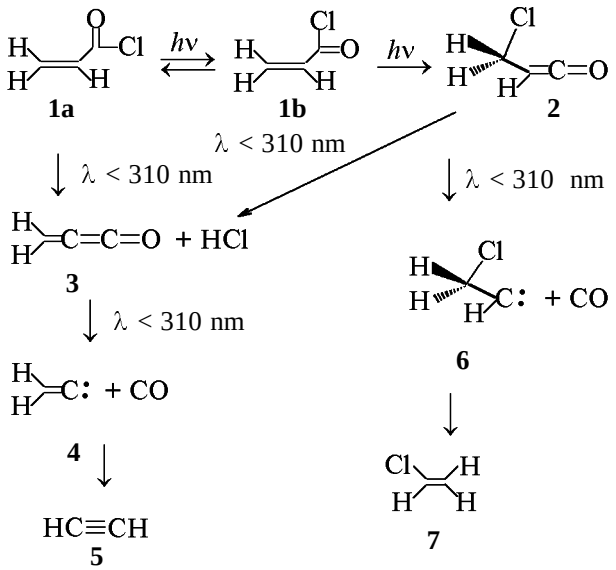
Abstract—Polymerization of acryloyl chloride in the bulk and in solution, induced by 300-nm UV radiation, was performed. The conditions were determined under which the polymer does not precipitate from the solution and is formed in a nearly quantitative yield, which allows its use in polymer-analogous transformations without isolation.

Thanks to high reactivity, poly(acryloyl chloride) (PAC) is used for preparing new polymers by polymer-analogous transformations in cases when polymerization of the corresponding monomers is difficult. In particular, such a procedure is used for incorporating complex structural fragments into the polymeric chain, including biologically active substances and drugs [1, 2].

A procedure was described for preparing PAC by radical polymerization of acryloyl chloride (AC) at 50°C in dioxane in the presence of azobis(isobutyronitrile) (AIBN) for 48 h. The degree of polymerization of the resulting product is 140–400 [3]. The reactants used in the experiment should be thoroughly purified and dried. Experiments on synthesis of PAC by the procedure described in [3] showed that the polymerization results are poorly reproducible; in some experiments the polymer did not form at all. It is known that homopolymerization of AC is difficult [4]. Therefore, in some studies, including recent papers, polymerization of AC was examined in detail [5, 6]. The best results were obtained when the reaction was performed in benzene or cyclohexane. However, the forming PAC precipitates from solution as a separate phase, which is unfavorable for its subsequent use in polymer-analogous transformations. Introduction of the isolation, drying, and redissolution stages increases the probability of PAC hydrolysis, which results in partial loss of the acyl chloride functional groups.

Thus, development of a simple and reproducible route to PAC allowing preparation of the polymer of a sufficiently high molecular weight in a high yield in solution remains urgent. Solution of this problem was the goal of our study.

To effect polymerization of AC, we chose photochemical initiation, allowing the process to be performed under mild conditions with a high efficiency. Because published data on photoinitiated polymerization of AC are scarce [7], it was appropriate to study this process both in the bulk and in solution. As solvent we used thoroughly dried dioxane, and as UV source, a PRK-2 continuous-spectrum lamp. The photoinitiator was AIBN (λ_{max} 340 nm). Initially the reaction was performed in quartz test tubes to use the whole spectrum of the UV radiation of the lamp. We found that under these conditions the polymer undergoes cross-linking, which may be due to photolysis of AC [8]:



According to the above scheme, under broad-spectrum UV irradiation AC **1** undergoes isomerization and transformation into chloromethylketene **2**. This is followed by a series of transformations of **1** and **2**, yielding biradicals **4** and **6** causing cross-linking of

1070-4272/01/7501-0124$27.00 © 2002 MAIK "Nauka/Interperiodica"

PAC in the course of polymerization. According to the scheme, these species are mainly generated by the light with $\lambda < 310$ nm. Hence, by cutting off short-wave UV radiation, it is possible to prevent formation of **4** and **6** and thus to exclude cross-linking.

In subsequent experiments the AC polymerization was performed in glass test tubes transmitting radiation with $\lambda \geq 300$ nm. The process was performed in the bulk and in solution; the reaction time and the content of the initiator were varied. To determine the yield of the polymer and its molecular weight, PAC was converted to poly(methyl methacrylate) (PMA) by adding excess methanol. From the amount of the PMA formed, we calculated the yield of PAC in polymerization, and from the viscosity-average molecular weight of PMA calculated by the Mark–Kuhn–Houwink equation (30°C, chloroform [9])

$$[\eta] = 3.221 \times 10^{-4} M^{0.678}$$

we estimated its molecular weight.

Table 1 shows that the yield of the polymer increases with time and with increasing initiator concentration. This is accompanied by the growth of the viscosity, up to a full loss of the fluidity (run no. 5). The product dissolves in dioxane very slowly, and removal of the unchanged monomer is necessary. As a result, the probability of hydrolysis of acyl chloride groups sharply increases, which makes the polymer unsuitable for polymer-analogous transformations.

Our results show that, to preserve reactive acyl chloride groups in PAC, it is appropriate to perform polymerization of AC in solution using the solvent in which the polymer is soluble. For this purpose, we studied polymerization of AC in dioxane. The results are listed in Table 2.

Table 2 shows that the molecular weight of the polymer only slightly depends on the initiator concentration. The polymer yield reaches a maximum at 1.8 mol % AIBN. In all cases, the polymers fully soluble in dioxane were obtained.

The assumption that the use of PAC solution without preliminary isolation of the polymer allows the loss of acyl chloride groups to be fully avoided was confirmed by the reaction with methanol followed by examination of the resultng PMA. The solution of PAC in dioxane was obtained under conditions of run no. 4 (Table 2).

It should be noted that the PMA sample in hand contained no residual chlorine, which shows that the conversion of the acyl chloride groups was complete. The analytical data, within determination error, are consistent with the calculations made for the PMA unit. The structure was also confirmed by ^{1}H NMR.

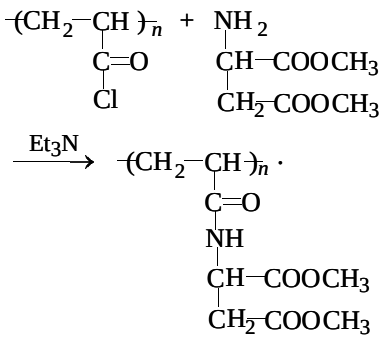
Table 1. Photoinitiated polymerization of AC in the bulk (30°C, distance from the source 25 cm)

Run no.	[I], mol %	τ, h	Yield, wt %	$\overline{M}_\eta$ of PMA
1	0.3	0.5	Traces	–
2	0.3	1	9	75 000
3	0.3	1.5	27	62 000
4	0.6	1.5	48	42 000
5	1.8	1	60	42 000

Table 2. Photoinitiated polymerization of AC in dioxane (AC concentration 50 vol %, 40°C, 2 h, distance from the source 15 cm)

Run no.	[I], mol %	Yield, wt %	$\overline{M}_\eta$ of PMA
1	0.3	63	15 000
2	0.6	58	10 000
3	1.2	83	16 000
4	1.8	99	16 000
5	2.4	90	13 000

It is known that PAC readily reacts with primary amines, including amino acids [10], to form the corresponding substituted polyacrylamides. For example, the reaction with leucine at room temperature occurs with a 94–100% yield in 48 h [10]. We performed the reaction between PAC prepared under conditions of run no. 4 (Table 2) with dimethyl aspartate:



According to the ^{1}H NMR spectra and results of analysis for nitrogen, the conversion in 24 h at room temperature was as high as 96 mol %.

EXPERIMENTAL

The ^{1}H NMR spectra were taken on a Bruker DPX-300 spectrometer.

Acryloyl chloride was prepared as described in [11]. Polymerization was performed in a glass test tube, which was charged with 1 ml of AC, 1 ml of dry dioxane, and the calculated amount of AIBN. The mixture was irradiated for the prescribed period. In experiments on bulk polymerization, 4 ml of dioxane was added after reaction completion to dissolve the polymer.

To prepare PMA, a solution of PAC in dioxane was transferred into a 50-ml flask, 2.5 ml of absolute methanol was added, and the mixture was allowed to stand for 24 h. Then the solvent was removed in a vacuum, and the polymer was reprecipitated from chloroform into absolute diethyl ether. Yield 98%.

Found, %: C 55.76, H 7.27.
$C_4H_6O_2$. Calculated, %: C 55.81, H 6.98.

Molecular weight $\overline{M}_\eta$ 17000. ^{1}H NMR spectrum ($CDCl_3$, δ, ppm): 1.40–2.00 (2H, CH_2), 2.35 (1H, CH), 3.60–3.80 (3H, OCH_3).

Dimethyl aspartate was prepared as described in [12].

The reaction of PAC solution with dimethyl aspartate was performed as follows. Dimethyl aspartate hydrochloride (2.56 g, 0.013 mol) was placed in a flat-bottomed flask equipped with a dropping funnel and a $CaCl_2$ tube. Chloroform (30 ml) and triethylamine (3.13 ml, 0.022 mol) were added. The mixture was stirred with a magnetic stirrer. Then, a solution of PAC (0.84 g, 0.0093 mol) in dioxane was added dropwise with cooling (–10°C). The mixture was stirred for 1 h and then allowed to stand for a day at room temperature. The mixture was washed twice with water, the chloroform layer was dried over sodium sulfate and filtered, and the solvent was vacuum-evaporated. The polymer was reprecipitated from chloroform into diethyl ether. Yield 82% (1.4 g).

Found, %: C 49.67, H 6.07, N 6.43.
$C_9H_{13}NO_3$. Calculated, %: C 50.23, H 6.04, N 6.51.

^{1}H NMR spectrum ($CDCl_3$, δ, ppm): 1.30–2.70 (3H, CH_2CH), 2.70–3.30 (2H, CH_2), 3.40–4.30 (6H, OCH_3), 4.35–5.20 (1H, CH), 7.55–8.5 (1H, NH).

CONCLUSIONS

(1) Acryloyl chloride readily polymerizes in dioxane under UV irradiation ($\lambda \geq 300$ nm) to give soluble poly(acryloyl chloride) in up to 99% yield.

(2) Reactions of polyacryloyl chloride solutions with methanol and dimethyl aspartate yield products structurally similar to the corresponding homopolymers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Oligodimethylsilane Initiators for Photochemical Vulcanization of Siloxane Rubber

V. V. Semenov, E. Yu. Ladilina, N. F. Cherepennikova, and T. A. Chesnokova

Razuvaev Institute of Organometallic Chemistry, Russian Academy of Sciences, Nizhni Novgorod, Russia

Receibed May 3, 2001

Abstract—Photolytic vulcanization of siloxane rubber films in the presence of trimethylsiloxy-substituted di- and trisilanes, oligodimethylsilanosiloxanes $(Me_2SiO)_m(SiMe_2)_n$, $Me(Me_2SiO)_m(SiMe_2)_nMe$, oligodimethylsilanes $Me(Me_2Si)_nMe$, and volatile pyrolysis products of polydimethylsilane was studied.

Oligoorganosilanes are suggested as vulcanizing agents for photolytic curing of silicone rubber [1]. Methyl and phenyl derivatives of linear and cyclic structure, containing chains of 3–6 silicon atoms, were tested. Trisilanes containing, along with methyl groups, also one or two phenyl groups exhibit a good or satisfactory initiating activity [2, 3]. Octamethyltrisilane is considerably less effective than phenyl-containing trisilanes [2]. In this work we studied vulcanization of rubber in the presence of trisilanes with Me_3SiO substituents and of oligomers containing both Me_2Si and Me_2SiO units. Such compounds, in contrast to phenyl-substituted oligosilanes, are readily soluble in polydimethylsiloxanes. Also tested were curing agents prepared by the Wurtz reaction from dimethyldichlorosilane and by thermal decomposition of polydimethylsilane. The synthesis of the oligomeric initiators, their electronic absorption spectra, and photolysis pathways are reported. Transparent silicones cured by UV radiation exhibit high thermal and radiation resistance and biological inertness; they are used as protective sheaths for quartz fiber light guides [4], in microelectronics [5], and in production of antiadhesion paper [6] and of artificial crystalline lenses and irises of human eyes [7, 8].

To evaluate the curing activity of compounds, we used as substrate liquid siloxane rubber (polymethylvinylsiloxane PMVS-2) containing 2% randomly distributed vinyl groups and terminal hydroxy groups [9]. In the table we present the absorption maxima and extinction coefficients in the UV spectra, and also the curing times for two series of permethylated oligosilanes [10–15]. Compounds **I**–**XI** were prepared by us previously [11, 15]. Syntheses of **XII**–**XV** were performed after analyzing the dependence of the curing time on the structure of **I**–**XI**. It is seen from the table that only compounds containing a chain of no less than three Si atoms are effective as vulcanizing agents. Disilanosiloxanes **IV**–**VII** and hexamethyldisilane **I** are inactive. Replacement of one to four methyl groups in Me_6Si_2 by trimethylsiloxy groups (compounds **IV**–**VII**) does not enhance the activity. At the same time, introduction of the same substituent into octamethyltrisilane **II** (position 1, compound **VIII**, or 2, compound **IX**) considerably shortens the vulcanization time. 1-Methylsiloxyheptamethyltrisilane **VIII** is by a factor of 2 more active than its isomer **IX**. Replacement of one more methyl radical in position 2 by the Me_3SiO group (compound **X**) decreases the initiating power. Compound **XI** containing two trisilanyl fragments is even less active than the related trisilanosiloxanes **IX** and **X**. Analysis of the UV spectra of **I**–**XI** shows that introduction of the Me_3SiO group into both hexamethyldisilane and octamethyltrisilane molecules shifts the absorption maximum toward longer waves by 2 (**I**, **IV**) and 5 nm (**II**, **VIII**), respectively, with the decrease in the extinction coefficients by factors of 1.3 and 3.9, respectively. Introduction of the trimethylsiloxy group into position 2 (compound **IX**) causes more complex changes, as compared to position 1 (compound **VIII**). Two maxima at 224 and 238 nm are shifted toward longer waves, but both have higher extinction coefficients compared to **VIII**. Compounds **X** and **XI** exhibit a single maximum, and it exhibits a still larger bathochromic shift than in **IX**.

Thus, introduction of one or two oxygen-containing substituents into octamethyltrisilane causes a bathochromic shift, but the vulcanizing activity of the compound increases only if the oxygen atom is lo-

* For **I**–**III**, λ and ε were taken from [10].
** In methylene chloride.
*** The UV spectrum was not measured, because the hexane solution became turbid.

cated at the end of the Si–Si–Si triad. Hence, for fast curing it is appropriate to use linear oligomers with $–(SiMe_2)_n–$ chains ($n \geq 3$) containing siloxy substituents at the ends of the blocks but not in their middle. Such derivatives, oligosilanosiloxanes [10, 16–19], can be prepared by the Wurtz reaction from α,ω-dichlorooligodimethylsiloxanes, dimethyldichlorosilane, and lithium [18] or sodium [19]. In our study we used a siloxane tetramer containing minor amounts of the trimer (7%) and pentamer (4%). The reactions were performed in nonane in the presence of trimethylchlorosilane as endcapping agent, or without it. It is known [19] that in such processes the siloxane fragments are redistributed; therefore, the final product should contain not only tetrameric siloxane blocks but also shorter and longer sequences:

$$ClMe_2Si(OSiMe_2)_2OSiMe_2Cl + Me_2SiCl_2$$

$$\xrightarrow[-NaCl]{Na} (Me_2SiO)_m(SiMe_2)_n,$$

XII

$$ClMe_2Si(OSiMe_2)_2OSiMe_2Cl + Me_2SiCl_2 + Me_3SiCl$$

$$\xrightarrow[-NaCl]{Na} Me(Me_2SiO)_m(SiMe_2)_nMe.$$

XIII

The resulting products are colorless viscous liquids readily soluble in polydimethylsiloxanes. The yields of **XII** and **XIII** are, respectively, 0.23 and 0.37 g per gram of the mixture of the chlorides. When heated in a vacuum, compounds **XII** and **XIII** release, respectively, 29 and 17 wt % of volatile oligomers. Both volatile (**XIIa**, **XIIIa**) and nondistillable (**XIIb**, **XIIIb**) fractions exhibit a high initiating activity. In the presence of **XIIIb** vulcanization occurs somewhat faster. The nondistillable oligomers, according to GPC, have the following molecular-weight characteristics: **XIIb**, M_w 1860, M_n 990, M_w/M_n 1.88; **XIIIb**, M_w 2150, M_n 1180, M_w/M_n 1.82. It is seen that in the presence of the endcapping agent compounds with somewhat higher M are obtained. This is probably due to the fact that the system α,ω-dichlorooligosiloxane–dimethyl-

dichlorosilane shows a greater tendency to form rings, and Me_3SiCl to a certain extent suppresses the ring formation. The gel chromatograms of **XIIb** and **XIIIb** (Fig. 1) show a low-molecular-weight maximum at about M 400.

The number of $SiMe_2$ units in the $–(SiMe_2)_n–$ chains was calculated from the results of bromine cleavage of the oligomers according to Stolberg's procedure [20]. It was found that compounds **XIIb** and **XIIIb** contain 42.73 and 37.45% Me_2Si groups, respectively. Knowing the molecular weights of the oligomers, it is possible to find the mean values of m and n: $(Me_2SiO)_{15}(SiMe_2)_{15}$ (**XIIb**), $(Me_2SiO)_{19}\cdot(SiMe_2)_{15}$ (**XIIIb**). It is seen from these formulas that somewhat higher M of **XIIIb** is due to the larger number of siloxane groups, whereas the number of dimethylsilanediyl fragments in the oligomer molecules is, on the average, the same. It should be noted that the $–(SiMe_2)–$ units do not form a single block with n = 15 but form several shorter blocks separated by siloxane groups. The sets of Si_n blocks in **XIIb** and **XIIIb** can be estimated from the UV spectra. These spectra reflect the complex structure of the copolymers and show that they consist of blocks of different lengths. For example, the spectrum of **XIIIb**, along with two major bands at 215 and 265 nm, shows weaker absorption at about 237 and 278 nm (Fig. 2). The UV spectrum of **XIIb** contains two bands at 216 and 255 nm. Oligodimethylsilanes $Me(Me_2Si)_nMe$ absorb in the following regions (nm): octamethyltrisilane (n = 3) and oligomer with n = 8, at 215; oligomers with n = 5 and 6, at 250–260; and oligomers with n = 7 and 8, at 270 [21]. In view of the fact that the oxygen atoms in the $SiOSi_n$ and $SiOSi_nOSi$ groups shift the absorption toward longer waves by approximately 5 nm, the spectra suggest that compound **XIIb** contains $Si_3–Si_6$ blocks, and compound **XIIIb**, $Si_3–Si_8$ blocks.

Figure 2 shows the UV spectra of the photoinitiators, and Fig. 3 illustrates the decay of UV absorption under irradiation for compound **XIIIb** dissolved in the rubber and in the free state. The main changes in the spectrum occur within 2 min of exposure. In the course of irradiation, the intensity of the long-wave absorption bands decreases rapidly, and that of the short-wave bands, more slowly. A pronounced hypsochromic shift is observed, suggesting degradation of longer Si_n chains (n = 6–8) and their transformation into shorter chains (n = 3–4). After a 3-min exposure, only the band at 218 nm remains, belonging to di- and trisilanyl groups SiOSiSiOSi and SiOSiSiSiOSi, which are the most stable to UV radiation. Irradiation

of **XIIIb** in the rubber causes vulcanization of the rubber, whereas a thin film of the neat oligomer remains visually unchanged (liquid) upon exposure.

Photochemical decomposition of **XIIIb** in the rubber follows the linear law $-c_\tau/c_0 = k\tau$ to 80% conversion (Fig. 4). The initial decomposition rate of the neat photoinitiator (2.2×10^{-2} s^{-1}) is higher than that of the photoinitiator diluted with the rubber ($9.1 \times$

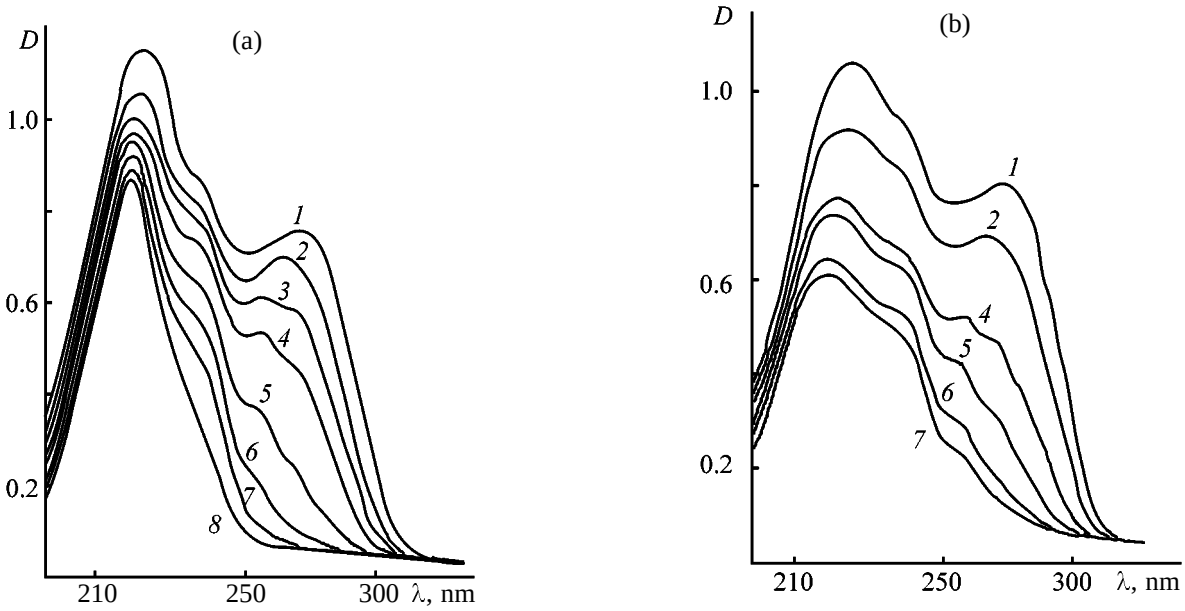

Fig. 3. Decay of UV absorption of **XIIIb** under irradiation: (a) film of solution in a rubber and (b) neat substance film. Exposure time, s: (*1*) 0, (*2*) 10, (*3*) 20, (*4*) 30, (*5*) 60, (*6*) 90, (*7*) 120, and (*8*) 180.

10^{-3} s^{-1}), but then the decomposition rate decreases. The conversion of **XIIIb** in 2 min is 92% in the rubber and 75% in the neat form. The reaction deceleration is probably due to accumulation in the neat oligomer film of the decomposition products absorbing at 254 nm. The observed transformation of the spectrum under UV irradiation is typical of oligoorganosilanes.

Such processes make shorter the Si_n lengths; they are accompanied by elimination of silylenes and formation of silyl radicals [22]. Such species cause crosslinking of the polysiloxane molecules.

Oligodimethylsilanes $Me(Me_2Si)_nMe$ (n = 4–6) showed high initiating activity [2, 3]. It was interesting to examine the vulcanizing power of methyl oligomers with n > 6. It is known [23] that, as n is increased, the absorption maximum of the polysilane is shifted toward longer waves, and the extinction coefficient per disilanediyl fragment increases. Therefore, for long-chain silanes we can expect enhanced initiating activity. Oligo- and polydimethylsilanes were prepared by the Wurtz reaction from dimethyldichlorosilane and sodium, with trimethylchlorosilane as endcapping agent. From 194 g of Me_2SiCl_2, 54 g of Me_3SiCl, and 90 g of Na we obtained 51.5 g of solid polydimethylsilane **XIVa** insoluble in silicones, 5 g of waxy polymer **XIVb**, 7.2 g of oligomers **XIVc** in the form of a light yellow transparent viscous mass, and 11.9 g of oligomers **XIVd** in the form of a transparent liquid distillable in a vacuum (the UV spectrum is shown in Fig. 2). The two latter types of oligosilanes are compatible with liquid rubber and initiate its curing. Fraction **XIVc** containing oligomers with n > 8 shows a higher initiating activity as compared to decamethyltetrasilane **III** (n = 4) and fraction **XIVd** (n = 4–8). However, its mixture with PMVS-2 is turbid, which suggests incomplete dissolution of oli-

godimethylsilanes. Fractions **XIVa** and **XIVb** are insoluble in the rubber and cannot be used as vulcanizing agents.

Our results show that, despite a fairly high content of the endcapping agent, trimethylchlorosilane, the yield of the soluble oligodimethylsilanes is low. The major product is solid insoluble polydimethylsilane. It is isolated from the reaction mixture when unreacted sodium is decomposed with alcohol and water; this product is a colorless coarse powder. After washing with water and drying, its solubility in organic solvents becomes incomplete. In chloroform and toluene, the polymer swells with insignificant dissolution. The product resembles the known polydimethylsilane [24, 25] used as the initial substance in production of silicon carbide ceramics [26]. It is known from the published data [27] that thermal decomposition of this polymer yields linear and cyclic silanes $Me(Me_2Si)_6 \cdot Me$, $Me(Me_2Si)_nH$ (n = 2, 3, 5, 6), $H(Me_2Si)_nH$ (n = 2–4), and $(Me_2Si)_n$ (n = 5–8). Tests of their initiating activity showed that volatile products formed by heating **XIVa** to 320–340°C are very effective in photochemical vulcanization. The curing time is 1.5 min. The primary distillate (compound **XVa**) is a viscous turbid liquid. Addition of this initiator (2 wt %) to transparent liquid rubber causes its turbidization, which, however, does not prevent vulcanization of up to 70 μm thick films. Transparent colorless photoinitiators **XVb** and **XVc** are obtained after repeated distillation of the initial distillate **XVa** or its successive treatment with CCl_4, aqueous NaOH, and Me_3SiCl in the presence of triethylamine (the UV spectrum of transparent photoinitiator **XVb** prepared by distillation of **XVa** is shown in Fig. 2). Such a sequence of treatments results in transformation of SiH groups into $SiOSiMe_3$ groups. It is known [28] that polymethylhydrosilanes quantitatively transform into polymethylchlorosilanes on dissolution in CCl_4. No catalyst is required. Fraction **XVa** was dissolved in CCl_4, heated, and hydrolyzed with aqueous NaOH, after which it was treated with trimethylchlorosilane in the presence of triethylamine. A mixture of colorless transparent trimethylsiloxy-substituted oligosilanes **XVc**, readily soluble in the siloxane rubber, was obtained. After such treatment, the bands at 2080 [ν(Si–H)] and 880 cm^{-1} [δ(Si–H)] virtually disappeared, and the intensity of the band at 1030 cm^{-1} [ν(Si–O)] increased considerably.

EXPERIMENTAL

The UV spectra were recorded on a Specord M-40 spectrophotometer (solutions on hexane or methylene chloride and films on quartz glass), and the IR spectra, on a Perkin–Elmer-577 spectrophotometer. The molecular-weight distribution of the oligomers was determined by gel-permeation chromatography on an installation consisting of three Styrogel columns (porosity 25, 25, and 8 nm), with THF as eluent and an RIDK-101 differential refractometer as detector. The calibration was performed with reference poly(propylene glycol) samples. Gas-chromatographic analysis of organosilicon compounds was performed with a Tsvet-530 chromatograph (0.3 × 200-cm stainless steel column, 5% SE-30 on Chromaton N-AW-DMCS, thermal conductivity detector, carrier gas helium).

PMVS-2 rubber was prepared by the procedure described in [9]. The photoinitiator was added in an amount of 2 wt %. Films, 30–70 μm thick, were formed on quartz glass supports from solutions in hexane. Irradiation was performed with a total spectrum of a PRK-4 medium-pressure mercury lamp (220 W), placed at a distance of 14 cm. The vulcanization time was determined and the kinetic curves of oligosilane decomposition were calculated by the procedure described in [3]. The relative optical density of the layer α, proportional to the relative photoinitiator concentration $c_\tau c_0^{-1}$, was expressed as $\alpha = (D_\tau - D_\infty)/(D_0 - D_\infty)$, where D_0, D_τ, and D_∞ are, respectively, the optical densities of the layer at λ = 265 nm before exposure, after exposure for time τ, and after prolonged exposure (until the absorption decreased to a constant limit). Compounds **I**–**III** [10], **IV** [11], **V** and **VIII** [12], **VI** and **VII** [13], **IX** [14], and **X** and **XI** [15] were prepared by known procedures.

Oligodimethylsilanosiloxane XII. A solution of 15.9 g of dichlorooctamethyltetrasiloxane and 5.85 g of dimethyldichlorosilane in 20 ml of nonane was added with vigorous stirring and heating (120°C) to a suspension of 4.7 g of Na in 200 ml of nonane. The reaction mixture was heated for 25 h at 130–140°C; after cooling, a mixture of 10 ml of methanol and 10 ml of glacial acetic acid and then 100 ml of distilled water were added. The organic layer was separated, washed with water, and dried over $CaCl_2$; the solvent was distilled off. From the residue, 1.51 g of a colorless transparent liquid was isolated, bp 100–105°C (0.1 mm Hg), fraction **XIIa**, n_D^{20} 1.4240. The nondistillable residue **XIIb** (3.54 g) was a viscous liquid. UV spectrum (hexane), λ_{max}, nm (ε, l mol^{-1} cm^{-1}): 216 (3500), 255 (2400).

Found, %: Me_2Si 42.73.
$(Me_2SiO)_{15}(SiMe_2)_{15}$. Calculated, %: Me_2Si 43.95.

Oligodimethylsilanosiloxane XIII was prepared similarly from 6.2 g of Na, 18.1 g of 1,7-dichlorooctamethyltetrasiloxane, 6.7 g of dimethyldichlorosilane, and 3.76 g of trimethylchlorosilane. Compound **XIIIa**: yield 1.8 g, bp 100–140°C (0.1 mm Hg), n_D^{20} 1.4310; **XIIIb**: 8.74 g. UV spectrum (hexane), λ_{max} (ε, l mol^{-1} cm^{-1}): 215 (2100), 265 (12 800). IR spectrum, ν, cm^{-1}: 2940, 2880, 2840, 1400, 1255, 1245, 1085, 1030, 850, 800, 760, 680; n_D^{20} 1.4475.

	Found, %:	Me_2Si 37.45.
$(Me_2SiO)_{19}(SiMe_2)_{15}$.	Calculated, %:	Me_2Si 38.24.

Oligo- and polydimethylsilanes XIV. To a suspension of 90 g of Na in 700 ml of toluene, prepared at 110°C and cooled to 90°C, we added dropwise with vigorous stirring 194 g of dimethyldichlorosilane and 54 g of trimethylchlorosilane. The mixture spontaneously warmed up to reflux. The stirring was continued for 25 h at 110°C until the mixture of chlorides was completely consumed (monitored by acid–base titration). The mixture was cooled with ice-cold water, and 150 ml of isopropyl alcohol and then 150 ml of distilled water were added. After addition of water, an abundant white precipitate formed. The solid polymer was filtered off, washed with water to neutral reaction, and dried, first in air at 20–25°C and then in a vacuum at 90–110°C. Polydimethylsilane **XIVa** (51.5 g) was obtained as white coarse powder. IR spectrum, ν, cm^{-1}: 1240, 830, 740, 725, 685, 625. The organic layer was washed with distilled water to neutral reaction and dried over $CaCl_2$, and the solvent was distilled off under argon. Vacuum distillation of the residue gave 11.9 g of liquid oligodimethylsilanes **XIVd**, bp 125–130°C (10 mm Hg), n_D^{20} 1.4880. UV spectrum (hexane), λ_{max}, nm (ε, l mol^{-1} cm^{-1}): 225 (6600), 255 (6100), 262 (4400). IR spectrum, ν, cm^{-1}: 2940, 2880, 1390, 1240, 1040, 830, 795, 765, 725, 685, 645. The residue was dissolved in 150 ml of hexane and filtered. To the filtrate 5 g of AG-3 activated carbon was added, and the mixture was stirred for 5 h at 25°C. After filtration and removal of hexane, 7.2 g of oligodimethylsilanes **XIVc** was obtained as a pale yellow viscous mass. IR spectrum, ν, cm^{-1}: 2940, 2920, 2880, 2840, 1395, 1240, 1045, 830, 800, 760, 730, 685, 625. When stored in air, the product turns dark. The hexane-insoluble fraction **XIVb** (5.3 g) is a waxy mass insoluble in polysiloxanes.

Pyrolysis of polydimethylsilane **XIVa** with simultaneous distillation of volatile oligodimethylsilanes was performed in an evacuated round-bottomed flask connected to a received for liquid products through an air-cooled condenser. The flask containing 100 g of the polymer was heated on an electric hot plate to 320°C. At this temperature slow distillation of liquid products started. For 12 h, the temperature was kept within 320–340°C, and the residual pressure, within 0.05–0.10 mm Hg. In the course of pyrolysis, 40.3 g of a viscous turbid liquid (fraction **XVa**) was collected in the receiver. This liquid was subjected to repeated vacuum distillation. The fraction boiling in the range 55–120°C (2 mm Hg) was collected. A mixture of oligodimethylsilanes (fraction **XVb**, 10.3 g) was obtained as a colorless transparent liquid; yield 10.3 g, n_D^{20} 1.4810. IR spectrum, ν, cm^{-1}: 2940, 2980, 1394, 1255, 1240, 800 ($SiCH_3$), 2080, 880 (SiH), 1075, 1020 (SiO). A 20-g portion of fraction **XVa** was dissolved in 100 ml of CCl_4 and refluxed for 5 h; after cooling, 100 ml of 1 N aqueous NaOH was added. The mixture was stirred at 25°C for 5 h; the organic layer was separated, washed with distilled water, and dried over $CaCl_2$. To the resulting solution, 20 g of trimethylchlorosilane and 20 g of triethylamine were added. The mixture was heated with stirring for 7 h and filtered; the filtrate was washed with distilled water, dried over $CaCl_2$, and vacuum-evaporated. A colorless transparent viscous liquid was obtained (**XVc**, 12.6 g); n_D^{20} 1.4840. IR spectrum, ν, cm^{-1}: 2940, 2910, 2880, 2840, 1390, 1250, 1245, 830, 795, 755 ($SiCH_3$), 1030 (SiO).

ACKNOWLEDGMENTS

The study was supported by INTAS (grant 97-1785) and Russian Foundation for Basic Research (project nos. 99-03-3211, 00-02-81 206 Bel 2000).

The analyses were performed in the Analytical Center, Razuvaev Institute of Organometallic Chemistry, Russian Academy of Sciences with the financial support of the Russian Foundation for Basic Research (project no. 96-03-40-042).

CONCLUSIONS

(1) Tests of the initiating activity of a series of trimethylsiloxy-substituted di- and trisilanes in photolytic curing of liquid polydimethylsiloxane rubber containing 2 wt % of randomly distributed vinyl groups showed that the most active are trisilanes containing Me_3SiO terminal groups.

(2) Effective photoinitiators, oligodimethylsilanosiloxanes, readily soluble in rubber, were prepared by

the Wurtz reaction from dimethyldichlorosilane, 1,7-dichlorooctamethyltrisiloxane, and sodium in the presence of trimethylchlorosilane as endcapping agent or without it.

(3) A series of liquid and solid oligo- and polydimethylsilanes were prepared similarly from dimethyldichlorosilane, trimethylchlorosilane, and sodium. The liquid oligomers are effective vulcanizing agents compatible with the rubber. Thermal decomposition of solid polydimethylsilane yields liquid soluible photoinitiators.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Use of Fullerite (C_{60}/C_{70}) as Modifier of Epoxy–4,4'-Isopropylidenediphenol Oligomers

N. Yu. Loginova, L. G. Panova, and I. F. Gun'kin

Technological Institute, Saratov State Technical University, Engels, Saratov oblast, Russia

Received May 11, 2001

Abstract—The use of fullerite as modifier of ED-20 epoxy–4,4'-isopropylidenediphenol oligomer cured with polyethylenepolyamine was considered. Interaction of fullerite with the polymer was evaluated. The effect of fullerite on combustion and heat resistance of the epoxy compound and on formation of the three-dimensional network structure was determined.

Fullerenes as a new form of elemental carbon attract a particular researchers' interest. Fullerenes are highly symmetrical carbon clusters in which the carbon atoms are arranged in the vertices of regular penta- and hexagons on the sphere surface.

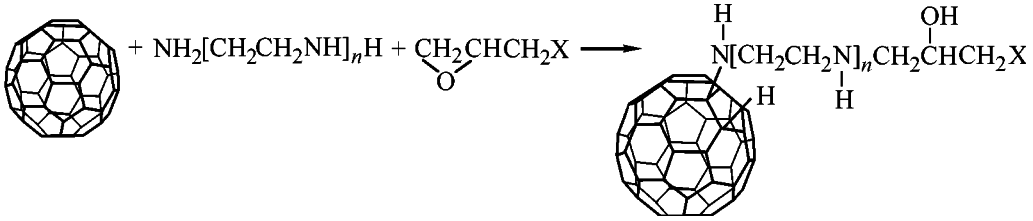
Fullerite was prepared as described in [1]. Fullerenes C_{60} and C_{70} were recovered from carbon black by extraction with toluene. Usually this procedure yields a dark brown solution; after distillation of toluene under argon, a mixture containing 85% C_{60}, 14% C_{70}, and 1% higher fullerenes (fullerite) is obtained. To separate low-molecular-weight and cumulene structures, fullerite was washed with CCl_4 and ether. After repeated washing with these solvents, the solid extract contained 99% C_{60} + C_{70} in the ratio $C_{60} : C_{70}$ = 84 : 15. This was confirmed by chromatography–mass spectrometry.

Despite major attention given to fullerenes and fullerene-containing materials, interaction of fullerenes with polymers was studied considerably less extensively.

To evaluate interaction of fullerite with polymers, it was added to ED-20 epoxy–4,4'-isopropylidenediphenol oligomer curable with polyethylenepolyamine (PEPA).

It is known that fullerene is an acceptor and reacts with nucleophilic agents [2]. The PEPA molecule contains an NH_2 group via which it bind with the C_{60} molecule. Such binding was confirmed by IR spectroscopy.

The IR spectra were recorded on a Specord M80 spectrophotometer in the range 400 – 4000 cm^{-1}. The IR spectra of the fullerite-containing epoxy compounds exhibit absorption assignable to C_{60} and to ED-20 + PEPA compound. The C_{60} molecule has four IR absorption bands: 528, 576, 1180, and 1428 cm^{-1}. In the spectra of the compound, the band at 1428 cm^{-1} disappears, and the bands at 528, 576, and 1180 cm^{-1} decrease in intensity. Furthermore, absorption bands appear in the range 1380–1248 cm^{-1}. These bands can be assigned to vibrations of the C–N bond formed between the C_{60} molecule and the NH_2 group of PEPA. The reaction apparently follows the scheme



where X = [—O—C$_6$H$_4$—C(CH$_3$)$_2$—C$_6$H$_4$—O—CH$_2$—CH(OH)—CH$_2$—]$_n$—O—C$_6$H$_4$—C(CH$_3$)$_2$—C$_6$H$_4$—O—CH$_2$—CH(O)—CH$_2$·

* (F) Fullerite; (T_o, T_e, T_{max}) temperatures of the onset, end, and maximal rate of weight loss; (CR_o, CR_e, CR_{max}) yields of the carbonized residue at T_o, T_e, and T_{max}.

The thermal behavior of the compound was studied by TGA on an MOM Q-1500D derivatograph (Hungary). Samples (0.2 g) were heated in air from 20 to 1000°C at a constant rate of 10 deg min^{-1}. The sensitivity was 1/3 for DTA and 1/10 for DTG. The measurement accuracy was 0.1%. Addition of fullerite to the epoxy compound, according to TGA, decreases the thermolysis onset temperature by 20°C, increases the yield of the carbonized residue after completion of the main degradation stage, and shifts the weight loss maximu toward higher temperatures (see table; Fig. 1a, curve *6*).

One of the major problems of polymer science is enhancement of the fire and heat resistance of polymeric materials. In [3, 4] it is suggested to use for this purpose fullerenes and related compounds. However, their effect is significant only at a high degree of filling. Introduction of more than 10 wt % fullerite is impossible because of the high viscosity of the formulation and nonuniform filler distribution. Therefore, fullerite was added to the epoxy–4,4'-isopropylidenediphenol oligomer together with compounds decreasing simultaneously the viscosity and combustibility: β-trichloroethyl phosphate $(ClCH_2CH_2O)_3PO$ (TCEP) or the product of reaction of methylphosphonic dichloride with glycidyl methacrylate $[CH_2=C(CH_3)\cdot C(O)OCH_2–CH(CH_2Cl)O]_2P(O)CH_3$ (FOM-2). These compounds were added at simple mechanical stirring

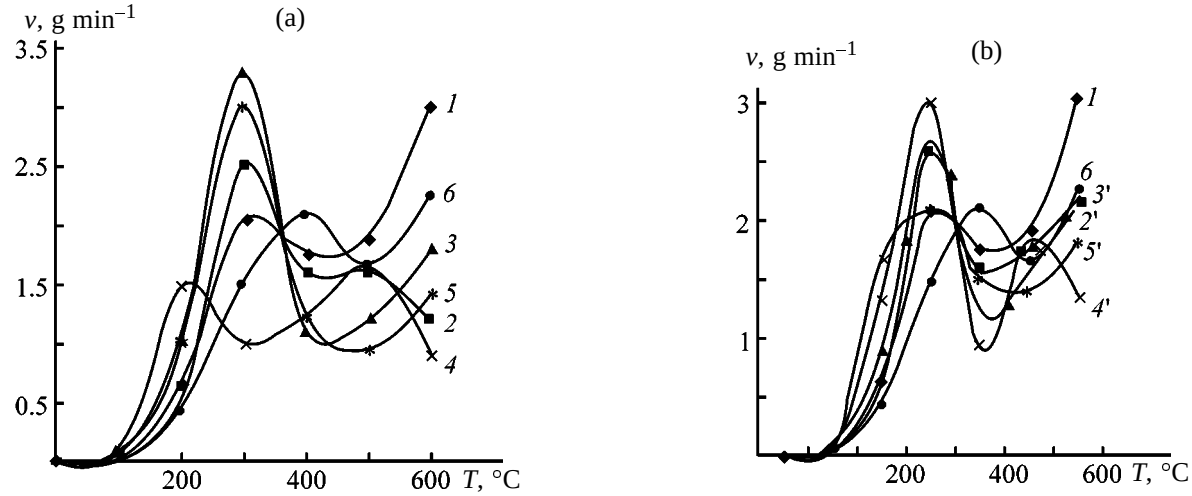

Fig. 1. Rate of weight loss v of compounds based on ED-20 + 10% PEPA with various additives. (a) Additives taken separately and (b) additives in combination with fullerite. (*T*) Temperature. Additive, %: (*1*) none, (*2*) 30 FOM-2, (*3*) 30 TCEP, (*4*) 40 TCEP, (*5*) 50 TCEP, and (*6*) 10 F; (*2'*–*5'*) the same as (*2*–*5*) but with addition of 10 F.

in amounts of 10, 15, 30, 40, and 50 wt %. Addition of only FOM-2 or TCEP decreases the onset temperature of thermal oxidative degradation, increases the rate of the weight loss (Fig. 1a, curves *2*–*5*), and decreases the yield of the carbonized residue after completion of the main stage. However, the oxygen index [GOST (State Standard) 12.1.044–89] characterizing the inflammability of the material increases from 19.8 to 24–25 vol %. This means that the combustion inhibitors present in TCEP and FOM-2 (P and Cl) affect mainly the gas-phase physicochemical transformations of the polymer.

According to TGA data for formulations containing TCEP and fullerite, the additives increase the degradation onset temperature and the yield of the carbonized residue (see table) and decrease the weight loss rate (Fig. 1b) after completion of the main degradation stage, as compared to the formulations containing TCEP only (Fig. 1a).

To evaluate the effect of components on formation of the three-dimensional network structure in the course of curing of the epoxy oligomer, we analyzed the kinetics of heat release. Curing of the epoxy oligomer with PEPA is exothermic (Fig. 2, curve *1*), the gelation time is 35–40 min, and the maximal temperature is 122°C. Modifiers decrease the maximal self-heating temperature from 120 to 27°C, and, with fullerite added, even to 21°C, which also confirms the chemical reaction of the additives with the epoxy oligomer and curing agent. The degree of conversion increases from 86 to 88%. The materials containing fullerite have a lower density (1181 kg m^{-3}) as compared to the initial materials (1562 kg m^{-3}).

CONCLUSIONS

The NH_2 groups of the curing agent react chemically with the C_{60} molecules. Fullerite alters the degradation mechanism of the polymeric matrix, enhancing its heat resistance, increasing the yield of the carbonized residue, and decreasing the combustibility. Fullerite affects formation of the three-dimensional network structure in the course of curing, decreasing the maximal temperature of the process from 120 to 21°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Silicon Oxide Fillers on Photochemical Curing of Compounds Based on Acrylic Monomers and Oligomers

D. L. Starokadomskii and T. N. Solov'eva

Institute of Surface Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received February 22, 2001

Abstract—The course of curing of photocurable compounds was studied as influenced by filling with disperse silicon oxide substances. The effect of the filler concentration on the conversion and rate of photopolymerization was examined.

The effect of inorganic fillers on polymerization attracts steady interest of researchers working in the field of development of new polymers. At the same time, photoinitiated polymerization of compounds filled with silicon oxide fillers is studied insufficiently, despite wide use of these materials in stomatology [1, 2]. By now, the number of publications concerning cationic, thermal, or radiation polymerization [3–9] considerably exceeds the number of papers on the effect of inorganic fillers on photoinitiated polymerization [10, 11–13]. Therefore, obtaining new data on the effect of fillers on photopolymerization (PP) is an urgent problem.

Addition of silicon oxide fillers transforms a compound into a colloidal disperse system with specific light scattering, reflection, refraction, and absorption properties. For example, the size of primary silica particles (10–50 nm) is smaller than the light wavelength, whereas the sizes of their aggregates (up to 300 nm [14]) and agglomerates (more than 1 μm [14]), and also the particle sizes of macrofillers (dispersed quartz, glass) are comparable to, or exceed the UV wavelength.

When studying photocurable polymers filled with the systems Aerosil–quartz, Aerosil–glass, Aerosil–Aerosil, and glass–quartz (to be used in production of stomatological materials), we found that the curing of compounds filled with silicon-containing fillers conforms to the generally accepted views on layer-by-layer PP of liquid unfilled compounds, described and theoretically substantiated in [15].

EXPERIMENTAL

The formulations contained the following components (chemically pure grade) in various ratios: bisphenol A glycidyl methacrylate (bis-GMA), oligomer of α,ω-bis(methacryloyloxyethyleneoxycarbonyloxy)-ethyleneoxyethylene (OCM-2), triethylene glycol dimethacrylate (TGM-3), methacrylic acid, and photoinitiator, benzil dimethyl ketal (BDK, λ_{max} = 340 nm, 0.3 wt %). The content of the monomer–oligomer base (matrix) was 30–85%, and that of the filler (Aerosil, Aerosil + dispersed glass + quartz), 15–70 wt %.

Aerosils A-175, A-300, and DK-100 [GOST (State Standard) 14922–77, TU (Technical Specifications) 6-18–78, Kalush Plant, Ukraine] were used; their specific surface area was 175, 300, and 100 $m^2 g^{-1}$, respectively (±30). Modification of Aerosils with methylvinyldichlorosilane was performed in the gas phase at 200–300°C for 2 h (1 h evacuation and 1 h reaction), with subsequent evacuation at 100–200°C for 1 h.

The degree of conversion α (measured as the percent ratio of the number of converted double bonds to their initial number) of compounds filled to less than 20 wt % was determined by IR spectroscopy. The decrease in the intensity of the band at 1635 cm^{-1} belonging to the vinyl groups of the oligomers was monitored. The degree of conversion of highly filled (>20 wt %) composites was measured by IR MATIR at 1635 cm^{-1} using a UR-20 device with a KRS-5 prism. The photopolymerization rate was determined from the slope of the curve of conversion α vs. irradiation time τ. The curing of highly filled composites was considered to be limiting if on further irradiation the intensity of the monitored absorption band and the strength of the cured photopolymer remained constant within measurement error. The enthalpy of polymerization was determined with a UIK-2101 microcalorimeter in a vacuum at 20°C. Sensitometric measure-

1070-4272/01/7501-0138$27.00 © 2002 MAIK "Nauka/Interperiodica"

ments were performed in UV-transparent (glass) or black (rubber, polyethylene) tubes of various heights (5–20 mm) and diameters (5–10 mm); curing of filled (thick) compounds in some experiments was performed in the open form. Curing was effected by UV irradiation from a Sakura photopolymerizing device (λ 340–500 nm).

Experiments show some differences in the photocuring of liquid unfilled monomeric formulations and their highly filled analogs.

Qualitative study of the effect of filling on photocuring of compounds revealed the following fact: On the whole, the curing of filled compounds occurs in the layer-by-layer fashion, which is consistent with the concept presented in [15], i.e., in a certain time after the start of irradiation a PP front (a boundary between the cured and liquid uncured mass) is formed, gradually moving into the depth of the compound.

In photopolymerization in transparent tubes and in the open form, the curing front moves in the perpendicular direction from the surface to the bulk of the material, until the whole volume is polymerized. However, a certain area in the bulk of the material can remain nonpolymerized (NPA), if the irradiation time is insufficient or the height and diameter of the sample are too large. As a result, when the sample is irradiated from all the sides, a cakelike structure is formed, with the outer well-cured "crust" and inner NPA. With a mirror support, curing occurs from the rear side also, whereas with a black support NPA outcrops to the rear surface of the sample.

When curing is performed in black tubes, i.e., when the light penetrates only through the upper surface of the sample, the upper polymerized layer is formed. However, in unfilled and filled samples the polymerized areas significantly differ in shape: In filled samples the cured area is a trunkated cone immersed in the nonpolymerized mass and narrowing in the direction from the surface to the bulk; in unfilled samples the conicity is manifested very weakly (e.g., in OCM-2 + 0.6 wt % BDK) or is not manifested at all (e.g., in bis-GMA + 0.6 wt % BDK), and the cured area only weakly differs from a cylinder.

The conical shape of the filled samples cured in black tubes may be due to absorption by black tube walls of the light escaping from the sample (primarily scattered light, and also reflected and refracted light). As a result, in the near-wall areas there is a deficiency of light, and no polymerization occurs. Furthermore, the polymerized area narrowing in the direction to the bulk will act as a lens promoting further narrowing of the cone. In unfilled compounds there is virtually no light scattering, and the conicity is not manifested to a significant extent.

Each photopolymer is characterized by a certain limiting curing thickness h_{lim} attained at a certain limiting irradiation time τ_{lim}; at $\tau > \tau_{lim}$, the thickness of the cured area does not increase further.

For example, in curing in transparent tubes, unfilled compounds OCM-2 + BDK and bis-GMA + DBK are cured to a depth of 15 mm within 30 s. We could not determine for the unfilled compounds the limiting thickness and limiting time; they exceed 20 mm and 45 min, respectively. Addition of 15 wt % Aerosil A-300 to these compounds makes h_{lim} measurable: 5 mm for OCM-2 + BDK and 3 mm for bis-GMA + BDK (τ_{lim} 20 min). Upon further irradiation, this thickness did not change. This example shows that addition of a filler causes a sharp decrease in h_{lim} and a noticeable increase in the time required to cure a layer of a given thickness. In curing filled samples (height >3 mm, diameter >5 mm) in transparent tubes or in the open form, a nonpolymerized area remains, which cannot be eliminated upon longer irradiation ($\tau > \tau_{lim}$).

A sharp decrease in h_{lim} (or increase in the time required for curing of a layer of a given thickness) after filling is due to the fact that in high concentrations (>15 wt %) the filler significantly shields the active radiation and acts as a light filter (absorption, reflection, and refraction effects).

The parameters h_{lim}, τ_{lim}, and the conicity angle are convenient characteristic parameters of individual filled photopolymeric composites.

Note that, when a sample is colored with dark pigments (umber, black iron oxide pigment, 0.01–0.1 wt %), the internal NPA increases as the content of the dark filler is increased, until an uncured vein cropping out at the rear surface is formed; correspondingly decreases the thickness of the completely cured layer.

The optical properties of a filled composite as a colloidal disperse system significantly affect the photocuring intensity [11]. At a 10–12 wt % content of Aerosil A-175, the parameter α considerably decreases as compared to the unfilled formulation (Fig. 1). This effect, as regards PP rate, has already been described [4] for radical (probably thermoinitiated) polymerization. However, as the filler concentration is increased further, α decreases. The same is true for Aerosil modified with methylvinyldichlorosilane, except that at any concentration with modified A-175

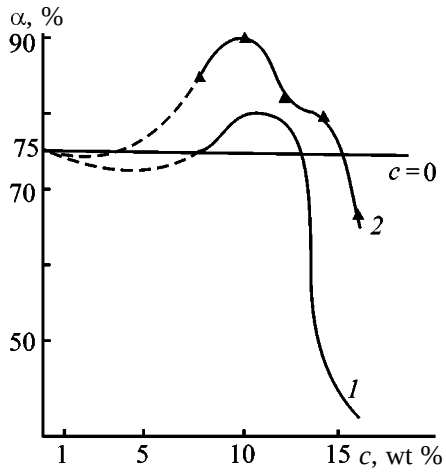

Fig. 1. Degree of photopolymerization (conversion) α as a function of concentration *c* of Aerosil A-175: (*1*) nonmodified and (*2*) modified with methylvinyldichlorosilane.

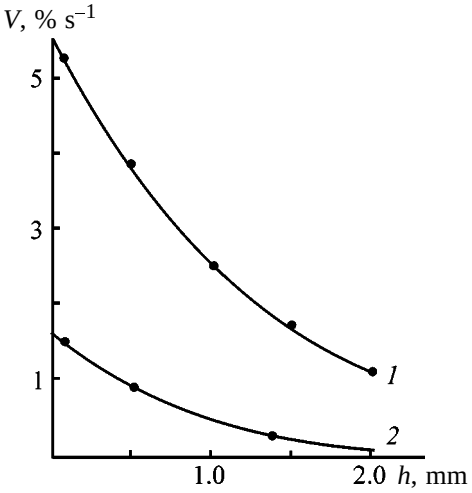

Fig. 2. Photopolymerization rate *V* as a function of the layer thickness *h* for (*1*) filled and (*2*) unfilled compounds.

α is higher than with the nonmodified Aerosil (Fig. 1, curve *2* lies above curve *1*).

Figure 2 shows that, as the filler concentration is increased, the deactivating effect of the layer thickness grows. As seen from Fig. 2, for an unfilled compound (composition, wt %: 55.4 OCM-2, 34 OUA2000T, 10 methacrylic acid, and 0.6 BDK) the photopolymerization rate V_0 (curve *1*) considerably exceeds *V* for the filled compound (25 wt % Aerosil DK-100 modified with methylvinyldichlorosilane; curve *2*). The V_0/V ratio increases with increasing *h*, i.e., from the surface to the depth of the compound. For example, at $h = 0.2$ mm $V_0/V = 3.5$, at $h = 2$ mm $V_0/V = 9$, and at larger *h* this ratio steadily grows. Thus, for the filled compound, as compared to the unfilled formulation, the photopolymerization rate in going from the surface to the depth of the compound decreases to a considerably greater extent.

The enthalpy of polymerization *H* of the compound 99.4 wt % OCM-2 + 0.6 wt % BDK at various concentrations of the filler (Aerosil A-175) is given below [data for the nonmodified and modified (with methylvinyldichlorosilane) Aerosil are given in the numerator and denominator, respectively]:

c, wt %	0	10	12	14	16
H, J g^{-1}	246.6 / 246.6	260.0 / 320.1	269.7 / 343.5	245.0 / 302.0	181.3 / 292.8

It is seen that filling to 10–12 wt % increases the enthalpy of photopolymerization. After modification, it increases by 20–30% at moderate fillings (up to 14 wt %) and to a still greater extent, at higher fillings. This fact suggests that grafted modifier molecules actively participate in photopolymerization, promoting the process.

The effect of Aerosil on the curing quality can be explained as follows. More complete curing after adding certain amounts of Aerosil (10–12 wt % in our case) is due to the fact that the light scattering, reflection, and refraction on particles of the disperse phase (Aerosil and its aggregates, quartz, etc.) become more active, enhancing the light intensity in the bulk of the compound; to cross-linking of the polymeric base [4] and increase in the viscosity; to immobilization by the silica surface of oligomer molecules and growing polymer chains, which increases their lifetime [6, 15, 16]; and to increase in the content of conformations favorable for polymerization [15].

Promotion of polymerization processes after modification with vinylsilane is due to replacement of the surface hydroxy groups of silica by organophilic groups, which activates immobilization processes and favors participation of grafted modifier molecules in photopolymerization [17]. Another significant factor is decrease in the amount of water physically adsorbed on the silica surface and negatively affecting the polymerization activity of the system [18]. Apparently, in the course of photopolymerization water adsorbed on the surface of silica particles acts as impurity ("process") water. Obviously, surface water also prevents compatibility of the phases. Therefore, hydrophobization of silica by chemical modification favors PP.

As the silica concentration is gradually increased (in our case, above 12 wt %), it starts to hinder photopolymerization, which is due to significant enhancement of the filtering (shielding) effect of the cured

layer, to the cage effect (sticking of active species in a cage of polymer chains and increase in the steric hindrance), to deactivation of primary radicals at the filler surface, and to the loss of the molecular mobility as a result of stronger physical interactions with the solid surface and between the macromolecules [4].

CONCLUSIONS

(1) Curing of oligoether compounds after filling with disperse silicon oxide substances, similar to that of unfilled compounds, occurs in the layer-by-layer fashion, with increased deactivating effect of the compound layer on the polymerization activity in the bulk.

(2) Curing of filled compounds in black tubes (illumination from the top) yields a polymer layer in the form of a cone narrowing to the depth; unfilled compounds of similar composition show practically no conicity of the polymer phase.

(3) When filled compounds are cured with illumination from the sides, a nonpolymerized area can remain, which can crop out at the rear surface; the nonpolymerized area is larger in pigmented samples.

(4) The limiting curing thickness h_{lim}, limiting curing time τ_{lim}, and conicity angle are convenient characteristic parameters of individual filled photopolymeric composites.

ACKNOWLEDGMENTS

The study was financially supported by Oksomat AN Research and Production Association. Calorimetric analysis and measurement of a part of IR spectra were performed by staffmembers of the Institute of Macromolecular Chemistry, National Academy of Sciences of Ukraine, under the guidance of G.M. Semenovich.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Distribution of Perfluoro(propyl Vinyl Ether) between the Latex Based on Tetrafluoroethylene Copolymer and the Gas Phase

Yu. P. Sokolov and A. P. Voznyakovskii

Lebedev Research Institute of Synthetic Rubber, St. Petersburg, Russia

Received June 20, 2000; in final form, September 2001

Abstract—The distribution factors of perfluoro(propyl vinyl ether) between the tetrafluoroethylene–perfluoro(propyl vinyl ether) copolymer and the gas phase in the temperature range 20–60°C were determined by gas chromatography. From the temperature dependence of the distribution factors, the integral heats of melting and vaporization and the partial molar excess enthalpy of solution of perfluoro(propyl vinyl ether) were calculated.

Despite numerous studies, determination of the solubility of monomers and polymers and the closely related problem of determination of residual monomers in latexes remain urgent. Data on the influence of temperature, pressure, and other factors on the solubility of monomers in polymers are important for mathematical description of polymerization and calculation of its kinetics. The content of residual monomers dissolved in latexes largely determines the industrial and environmental safety of polymer production by emulsion polymerization.

The procedures used to determine the solubility of monomers in polymers, as a rule, require either time-consuming sample preparation or the use of sophisticated and difficultly available equipment, which prevents their wide use in industry. As example we can mention a gas-chromatographic procedure [1] in which a polymer being tested is used as a stationary phase. This method allows calculation of the distribution factors of the monomers between the liquid and gas phases and of a number of thermodynamic parameters, but application of the polymer to a chromatographic support takes several days. A headspace analysis procedure was also described [2], allowing calculation of the content of volatile substances in the liquid and gas phases and of the distribution factor from the composition of the equilibrium gas phase, using a special attachment to a chromatograph.

Development of a procedure for determination of residual monomers in latexes that would not require sophisticated and difficultly available equipment, on the one hand, and would allow sampling directly from the polymerization reactor, on the other hand, will be very useful for both researchers and technologists.

Calculation of the distribution factors of volatile monomers between the liquid and gas phases in relation to temperature allows determination of the content of residual monomers in the latex and calculation of the monomer conversion from the concentration of the monomer vapor in the equilibrium gas phase over the latex.

The goal of this work was to determine the distribution factors of perfluoro(propyl vinyl ether) (PPVE) between the latex based on perfluorinated tetrafluoroethylene and PPVE (trade name Ftorelast A-2400) and the gas phase at various temperatures.

EXPERIMENTAL

Ftorelast A-2400, a copolymer exhibiting high resistance to high temperatures, corrosive media, and frost, was prepared by emulsion copolymerization of tetrafluoroethylene and PPVE. According to ^{19}F NMR, the copolymer contained 59 mol % tetrafluoroethylene units and 41 mol % PPVE units.

The copolymer content in the latex was 250 g l^{-1}. To determine the copolymer content, a 5–10-g latex sample was taken and vacuum-dried at 60°C to constant weight. The copolymer content in the latex was calculated taking into account the weight of the emulsifier in the sample.

To remove traces of PPVE from the latex, it was purged with argon at 60°C for 1 h, with addition of distilled water to compensate for its evaporation. The completeness of PPVE removal from the latex was checked by GLC. A 10-μl latex sample was taken with a Hamilton microsyringe and introduced into the

1070-4272/01/7501-0142$27.00 © 2002 MAIK "Nauka/Interperiodica"

chromatograph vaporizer heated to 300°C.[1] The chromatographing conditions are given below.

The distribution of PPVE between the Ftorelast A-2400 latex and the gas phase was studied with a setup described in Fig. 1. A preliminarily evacuated 250-ml autoclave *1* equipped with a stirrer, a manometer, and a temperature-control jacket was charged with 150 ml of Ftorelast A-2400 latex and evacuated for 5 min at ambient temperature to remove air. Then a definite amount of PPVE was introduced through the upper valve, the required temperature was adjusted, and the autoclave was stirred with intermittent determination of the PPVE vapor content in the gas phase by the following procedure.

To the upper valve of the autoclave, we connected a 20-ml glass vessel *2*, preliminarily evacuated and kept at the same temperature. The upper valve was opened for 3–5 s, and a sample of the gas phase was taken. Then the valve was closed, vessel *2* was connected to an evacuated vessel *3*, and vessel *3* was filled with the carrier gas (helium) to excess pressure of 100 mm Hg, after which the gas mixture was introduced into a chromatograph through a gas dosing cock.

The PPVE vapor content in the gas phase in the course of stirring started to gradually decrease and reached a constant value within 30–40 min. Probably, within this time the introduced PPVE fully dissolved in the latex, and the PPVE concentration in latex particles became equal throughout their volume.

For calibration, vessel *2* was filled with air under normal conditions (273 K, 101.3 Pa), and the air peak area was determined by a similar procedure.

Chromatographing conditions: LKhM-80 gas chromatograph; carrier gas helium; flow rate 20 ml min^{-1}; catharometer; bridge current 100 mA; 1000 × 4-mm column; sorbent Polysorb-1 (a styrene–divinylbenzene copolymer, analog of Porapak Q), grain size 0.25–0.315 mm; column temperature 100°C; detector temperature 150°C. The peak area was determined with an I-02 electronic integrator.

The PPVE vapor concentration in the gas phase was calculated by the formula

$$C_{PPVE} = (S_{PPVE}/S_{air})K_{cor}C_{air}, \quad (1)$$

where S_{PPVE} is the PPVE peak area, S_{air} is the air peak area under normal conditions, K_{cor} is the molar correction coefficient (0.35 for PPVE [3]; taken as 1.00 for air), and C_{air} is the amount of air (moles) in 1000 cm^3 under normal conditions.

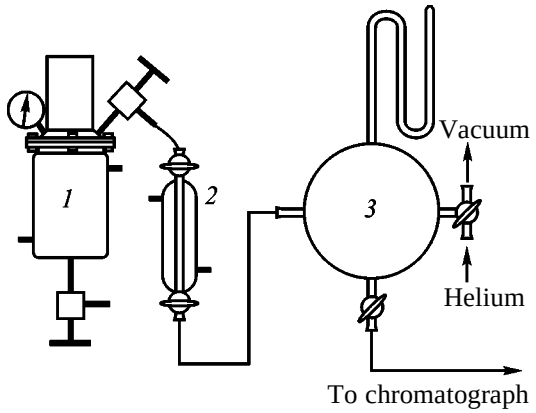

Fig. 1. Setup for analysis of gas–liquid samples under pressure: (*1*) stainless steel autoclave equipped with a stirrer with a packless gear, a manometer, and a temperature-control jacket; (*2*) calibrated glass vessel with a temperature-control jacket; and (*3*) glass vessel equipped with a mercury manometer and a three-way stopcock.

The PPVE distribution coefficients were calculated by the formula

$$K_d = C_2/C_1, \quad (2)$$

The concentration of PPVE dissolved in the polymer was calculated by the formula

$$C_2 = N_{PPVE}\,d_{pol}/(C_{pol}\,V), \quad (3)$$

where N_{PPVE} is the amount of PPVE (moles) added to the latex; C_{pol} is the polymer concentration in the latex; V is the latex volume; d_{pol} is the polymer density (the density of Ftorelast A-2400, measured by known procedures, was 1.95 g cm^{-3}).

The results of measuring the concentration of PPVE vapor in the gas phase at various temperatures and PPVE concentrations in the latex are listed in the table. In view of low solubility of PPVE in water (less than 0.001 wt %, according to [4]), it can be assumed that the whole amount of PPVE in the liquid phase is dissolved in the copolymer. Therefore, the PPVE concentration in the liquid phase is calculated for the volume of the copolymer in the latex and not for the whole latex volume.

In the case of incomplete PPVE dissolution, its undissolved part will form a separate phase (drops and/or micelles). Then the PPVE concentration in the

[1] It should be noted that this method can be recommended only for semiquantitative analysis, since for determination of traces of residual monomers large samples should be introduced, lying beyond the linear range of the catharometer response.

Concentration of PPVE vapor in the gas phase at various temperatures and PPVE concentrations in the polymer phase C_2

T, K	PPVE vapor concentration, M, in the PPVE–latex system at indicated C_2, M				
	0.08	0.28	0.48	0.84	PPVE–water
293	0.0019	0.0084	0.0119	0.0204	0.0274
303	0.0024	0.0106	0.0144	0.0267	0.0328
313	0.0035	0.0136	0.0209	0.0353	0.0454
323	0.0058	0.0199	0.0332	0.0461	0.0614
333	0.0085	0.0229	0.0501	0.0671	–

gas phase will be primarily determined by the saturated vapor pressure of PPVE occurring in the system as a separate liquid phase. To check whether dissolution of PPVE in the copolymer contained in the latex is complete, we performed similar measurements of the PPVE vapor concentration in the gas phase over the PPVE–water system in which PPVE is present as a separate phase.

Data on the PPVE concentration in the gas phase over the system PPVE–water are listed in the table. According to Raoult's law, with increasing concentration of PPVE dissolved in the polymer the PPVE vapor pressure at the same temperature should asymptotically approach the vapor pressure over neat PPVE. As seen from the table, the concentrations of PPVE vapor in the gas phases over the systems PPVE–latex and PPVE–water under similar conditions differ considerably (at least by 30–40%), which suggests the absence of PPVE undissolved in the latex.

According to the classical Yurzhenko–Harkins theory of emulsion polymerization [5], the polymer is formed in polymer–monomer particles. The main part

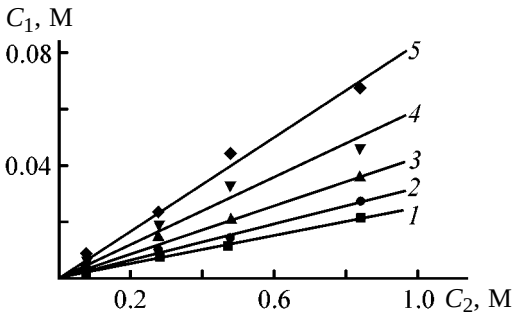

Fig. 2. PPVE concentration C_1 in the gas phase over the latex as a function of PPVE concentration C_2 in the polymer phase at various temperatures. Temperature, °C: (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, and (*5*) 60.

of the monomer in the polymerizing system occurs as a separate phase (drops), from which it passes to polymer–monomer particles owing to diffusion. Hence, with intermittent analysis of the gas phase in the course of polymerization, it is possible to detect the beginning of the final stage of emulsion polymerization (disappearance of liquid monomer drops) as the moment at which the partial pressure of PPVE vapor starts to decrease.

With increasing temperature, the PPVE vapor concentration noticeably increases. Figure 2 shows the dependence of the PPVE vapor concentration in the gas phase on the concentration of PPVE solution in the copolymer at various temperatures. Statistical treatment of the data obtained showed that in the examined temperature and concentration range the dependence is described by Henry's law and is practically linear (the correlation coefficient in all cases is 0.965–0.995, relative deviation does not exceed 8%).

The distribution factors of PPVE between the polymer and gas phases are given below:

T, K	K_d
293	40.0 ± 1.5
303	31.3 ± 1.5
313	23.3 ± 1.5
323	16.9 ± 3.8
333	12.0 ± 3.6

To calculate the thermodynamic characteristics of distribution, let us pass from the distribution coefficient to the Henry constant, replacing the concentration ratio in Eq. (2) by the activity ratio

$$K = a_2/a_1 = C_2\gamma_2/(C_1\gamma_1), \quad (4)$$

where a_2 and a_1 are the activities, and γ_2 and γ_1 are the activity coefficients of PPVE in the corresponding phases. Let us take as the standard state for the gas phase the ideal gas at a pressure of 1.013×10^5 Pa and temperature of the system, and for the liquid phase, pure liquid PPVE (thus, the mole fraction $n_2 = 1$ and $\gamma_2 = 1$). Note that attainment of the equilibrium between the liquid and gas phases implies equal partial molar energies: $G_2 = G_1$. Taking into account that $G_1 = G_1^0 + RT\ln n_1$ and $G_2 = G_2^0 + RT\ln n_2$, where G_1^0 and G_2^0 are the energies in the gas and polymer zones, we obtain

$$\Delta G^0 = G_1^0 - C_2^0 = -RT\ln K. \quad (5)$$

The correlation between ΔG^0 and the enthalpy of

solution ΔH_s is given by

$$\Delta H_s/R = \mathrm{d}(\Delta G^0/T)/\mathrm{d}(1/T). \quad (6)$$

Combination of Eqs. (5) and (6) gives the final expression for calculating ΔH_s:

$$\Delta H_s/RT^2 = \mathrm{d}\ln K/\mathrm{d}T. \quad (7)$$

From the data in the table, using the dependences $\ln K = f(1/T)$ in the examined temperature and concentration range, we calculated the enthalpy of PPVE solution in Ftorelast A-2400 copolymer (ΔH_s = -24.6 ± 1.3 kJ mol^{-1}). From the dependence of the logarithm of the PPVE vapor concentration on $1/T$ for the system PPVE–water, we calculated the enthalpy of vaporization of PPVE (ΔH_v = -21.1 ± 1.2 kJ mol^{-1}), i.e., the dissolution of PPVE in the copolymer is exothermic.

It was interesting to determine the excess partial molar enthalpy of mixing. The quantity $\Delta H^{E\infty}$ was calculated by the equation $\Delta H^{E\infty} = \Delta H_s - \Delta H_v$ as -3.5 kJ mol^{-1}. The negative value of $\Delta H^{E\infty}$ shows that PPVE is a thermodynamically good solvent for Ftorelast A-2400.

CONCLUSIONS

(1) The distribution coefficients of perfluoro(propyl vinyl ether) between the latex of the tetrafluoroethylene–perfluoro(propyl vinyl ether) copolymer (Ftorelast A-2400) and the gas phase in the range 20–60°C were determined.

(2) From the temperature dependence of the distribution coefficients, the enthalpy of solution, enthalpy of vaporization, and excess partial molar enthalpy of solution of perfluoro(propyl vinyl ether) were calculated.

(3) Perfluoro(propyl vinyl ether) dissolves in Ftorelast A-2400 latex with heat release. Perfluoro(propyl vinyl ether) is a thermodynamically good solvent for Ftorelast A-2400.

(4) The suggested analytical procedure allows determination of residual monomers in the latex directly in the polymerization reactor, from the composition of the gas phase.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Aprotic Solvents on Intermolecular Interaction of Cellulose Macromolecule with *N*-Methylmorpholine *N*-Oxide Monohydrate

N. P. Novoselov, E. S. Sashina, and E. V. Don'shina

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received April 10, 2001

Abstract—The influence of aprotic cosolvents dimethyl sulfoxide, dimethylformamide, and dimethylacetamide on interaction of *N*-methylmorpholine *N*-oxide with cellulose was studied.

Binary systems *N*-methylmorpholine *N*-oxide (NMMO)–cosolvent were suggested as cellulose solvents [1]. As cosolvents can be used organic liquids with the dipole moment no less than 3.5 D that, when taken separately, do not dissolve cellulose and do not react chemically with NMMO [2]. Cosolvents are added to decrease the solution viscosity and the consumption of expensive NMMO monohydrate. It is assumed [3] that the cosolvent behaves in the system as an inert component; however, our preliminary data [4] show that this is not the case.

EXPERIMENTAL

In this work we studied the effect of aprotic cosolvents dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and dimethylacetamide (DMAA) (dipole moments 4.30, 3.86, and 3.80 D, respectively) on dissolution and phase separation of cellulose solutions in binary systems. In our studies we used NMMO monohydrate (mp 343–345 K) and chemically pure grade cosolvents.

Using a Calvet calorimeter equipped with a 100-ml calorimetric vessel, we measured the enthalpies of solution of cellulose in the binary systems at various ratios of the solvent components, and also the enthalpies of cellulose transfer from NMMO monohydrate into the mixed solvent (Table 1). It is seen that addition of 10–50% DMSO to NMMO monohydrate makes the cellulose dissolution more exothermic as compared to pure NMMO. In the presence of the two other tested cosolvents (DMF, DMAA), there is no noticeable increase in the exothermicity of the interaction with cellulose. The exothermicity passes through a maximum at the NMMO : DMSO ratio of 2 : 1. Presumably, at this component ratio the solvating power of the binary solvent increases [5].

Complexation in cellulose solutions in NMMO·H_2O–DMSO mixtures can be monitored by variation of the crystallization temperature of 7% cellulose solutions depending on the component ratio; this temperature was determined from the change in turbidity (light transmission coefficient at λ 540 nm), using a KFK-2MP photoelectric colorimeter and a 20-mm

cell. As the crystallization onset temperature we took the temperature at which the light transmission of the sample gradually cooled from the initial temperature of 363 K abruptly decreases. As the DMSO content in the binary mixture is increased from 0 to 50 wt %, the crystallization onset temperature decreases from 333 to 310 K, but with further increase in the DMSO content the crystallization temperature starts to grow again, reaching 322 K. This value is attained at a DMSO content in the binary mixture of 67 wt %, which correlates with our data on the decrease in the system solvency [4]. In contrast to the system NMMO–DMSO–cellulose, in solutions of cellulose in $NMMO \cdot H_2O$–DMF and $NMMO \cdot H_2O$–DMA formation of crystallization centers is hindered. This is due to the tendency of these solutions to supercooling (the solutions do not crystallize for several hours at room temperature).

The effect of cosolvents on intermolecular interaction in cellulose solutions in NMMO can also be revealed by monitoring the phase separation of cellulose solutions in binary solvents. We studied the resistance of solutions to phase separation on adding water as a liquid that does not dissolve cellulose. The relative resistance to phase separation is proportional to the precipitation number PN and inversely proportional to the solvation number SN calculated as the molar ratio of the solvent and precipitant. To determine PN, we added the precipitant to the temperature-controlled cellulose solution, visually monitoring the solution transparency. After turbidization, corresponding to the onset of phase separation, we determined the precipitant consumption. The results are listed in Table 2.

Table 2. Precipitation (PN) and solvation (SN) numbers for 2% cellulose solutions in binary systems at precipitation with water

50	358	0.05	3.31
50	343	0.04	4.14
50	328	0.03	5.52

Table 2 shows that on adding DMSO to NMMO monohydrate the resistance to phase separation, proportional to the precipitation number, increases and starts to decrease only at a DMSO content in the solvent exceeding 50 wt %. This result correlates with the above-given data on the enthalpies of solution of cellulose in the binary mixtures. With decreasing temperature, the resistance of the system to phase separation decreases.

Knowing the features of phase transitions in cellulose solutions in $NMMO \cdot H_2O$ and binary mixtures is important for production of hydrated cellulose fibers by precipitation into an aqueous or aqueous-organic bath. The conditions of phase separation can be varied (to obtain cellulose particles of desired size) by adding into the precipitation bath a solvent or cosolvent. The nature and amount of the solvent in the precipitation bath determine the kinetics of cellulose coagulation, the resistance of the solution to the effect of the precipitant, and the "rigidity" of the precipitation conditions. Therefore, we studied the resistance of 2% solutions of cellulose in mixtures $NMMO \cdot H_2O$–aprotic solvent to the coagulating effect of a mixed precipitant, H_2O–NMMO. The results are shown in Figs. 1a–1c. The resistance of solutions to the coagulating effect of the precipitant was characterized by PN, determined as described above. Apparently, PN is the lower, and the precipitation conditions are the more rigorous, the less the precipitant consumption. Under rigorous precipitation conditions, cellulose readily coagulates from solution in the form of a flaky precipitate. Under milder conditions (PN $\geq$0.8), the precipitate becomes more finely dispersed, and precipitation is preceded by formation of a gelatinuous mass. At an $NMMO \cdot H_2O$ content in the precipitation bath above 60–65 wt %, a transition occurs from the rigorous to mild precipitation conditions, and the resistance of cellulose solutions to phase separation abruptly increases.

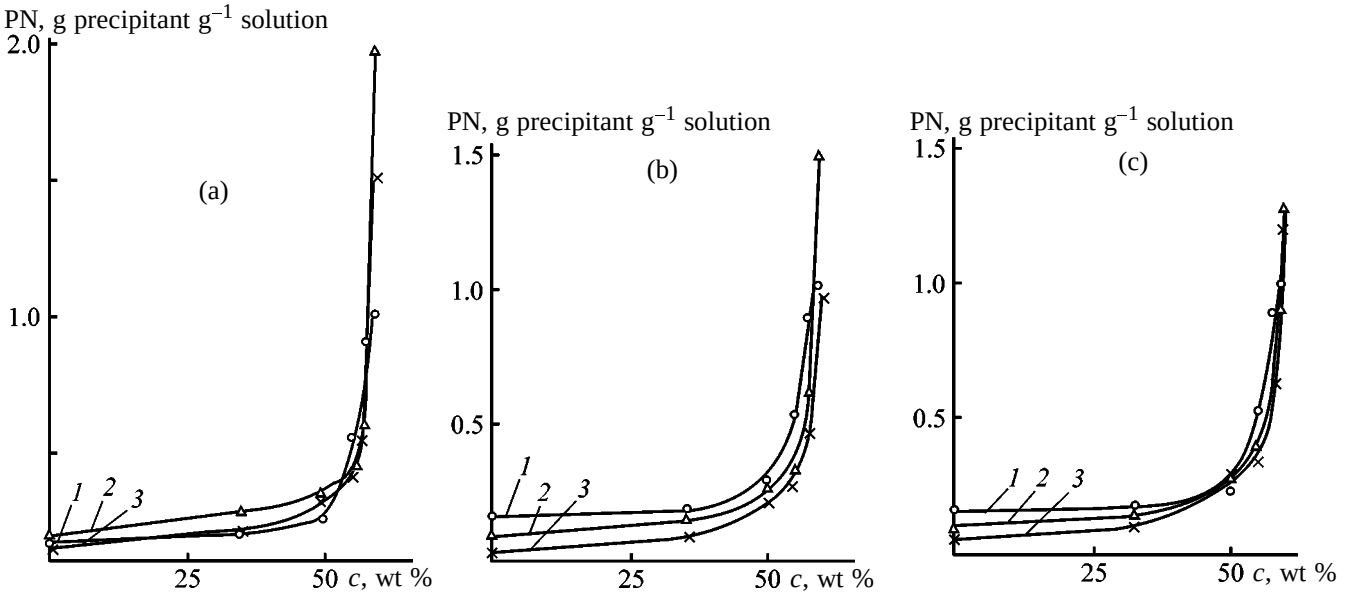

Fig. 1. Stability of 2% cellulose solutions in (*1*) NMMO monohydrate and in binary systems NMMO–cosolvent, (*2*) 2 : 1 and (*3*) 1 : 1, as a function of the NMMO content in the aqueous precipitation bath *c*. (PN) Precipitation number. Cosolvent: (a) DMSO, (b) DMF, and (c) DMA.

CONCLUSIONS

The tested aprotic cosolvents exert different effect on the intermolecular interaction in the binary system *N*-methylmorpholine *N*-oxide–cellulose. Addition of dimethyl sulfoxide makes the cellulose dissolution more exothermic, whereas with dimethylformamide and dimethylacetamide this trend is not observed. The presence of dimethylformamide and dimethylacetamide cosolvents in cellulose solutions decreases, and the presence of dimethyl sulfoxide increases the resistance of solutions to phase separation. Addition of *N*-methylmorpholine *N*-oxide to the aqueous precipitation bath enhances the resistance of cellulose solutions to phase separation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Dynamic Light Scattering Study of the Temperature Dependence of the Size-Distribution Pattern and Aggregation Stability of Sulfate Lignin and Wood Resin in Aqueous Alkali Solution

E. Yu. Dem'yantseva, N. P. Lysogorskaya, V. V. Klyubin, and S. V. Zaitseva

Received May 8, 2001

Abstract—A dynamic light scattering study in the temperature range 293–333 K was made for solutions of sulfate lignin and resinous wood components, which are limitedly soluble in water, as well as for their mixture in an alkaline medium (pH 12.7) of sulfate cooking lye. This study proved the heterogeneous nature of these systems.

Up to now, there have been no systematic colloid-chemical studies of the cooking process which is one of the most important processes in pulp and paper production. No systematic studies have also been made on the nature of solutions of organic wood components in sulfate cooking lyes. The exception are works on studying the dispersion of resinous components in neutral, acid, or weakly basic medium (up to pH 8), but these do not cover a higher pH range [1–3]. Recently, the aggregation and sedimentation stability was studied for aqueous solutions of sulfate lignin over a wide pH range, up to pH 12–13 [4, 5]. However, these works casted doubt on the possibility of aggregation of lignin macromolecules and formation of heterogeneous systems in alkaline media, while these phenomena were revealed in media with pH < 8 [5]. In this connection, it was of interest to study the nature of solutions of organic wood components (resinous substances, sulfate lignin, carbohydrate fraction, and their mixture) in sulfate cooking lyes (pH 12.7) and to elucidate whether they are homogeneous or heterogeneous, especially after cooking is complete and the cooking solution is cooled. Our previous studies [4] by indirect analytical methods (sedimentation and other) suggested the heterogeneous nature of the systems mentioned. This assumption needed confirmation by a direct independent method of dynamic light scattering. For this study, we chose pH of the medium of 12.7 and the temperature range 333–293 K, which correspond to the stage of sulfate cooking completion and discharge of cellulose from the boiler, as specifically this cooking stage is the most seriously responsible for the appearance of resinous hindrances [3]. At the same time, the knowledge of the particle-size distribution pattern of organic wood substances in the sulfate cooking lye will make it possible to develop scientific principles of improving the production processes for secondary products of cellulose cooking. This concerns preparation of purer tallic products, increase of the coefficient of extraction of sulfate soap and lignin from cooking lyes, and simultaneous reduction of the energy consumed and the time required for conducting processes involved in lye concentration by evaporation and settling.

The samples of sulfate lignin and resinous components were prepared by extraction from the birch chips with dioxane and diethyl ether, respectively. After drying to a constant weight, dioxane lignin and resin were subjected to a procedure identical to the conventional sulfate cooking of cellulose [4]. After the cooking was complete, sulfate lignin was isolated from the solution with sulfuric acid, and the resin was extracted with dichloroethane. The preparations were again dried to constant weight in a vacuum at 323 K and dissolved in aqueous solutions of sodium hydroxide (pH 12.7) at 363 K. The birch resin and sulfate lignin concentrations were 0.27 and 2.5%, respectively.

The particle-size distribution pattern of the solution was studied by dynamic light scattering which allows recording particles with sizes within 0.001–10 μm.

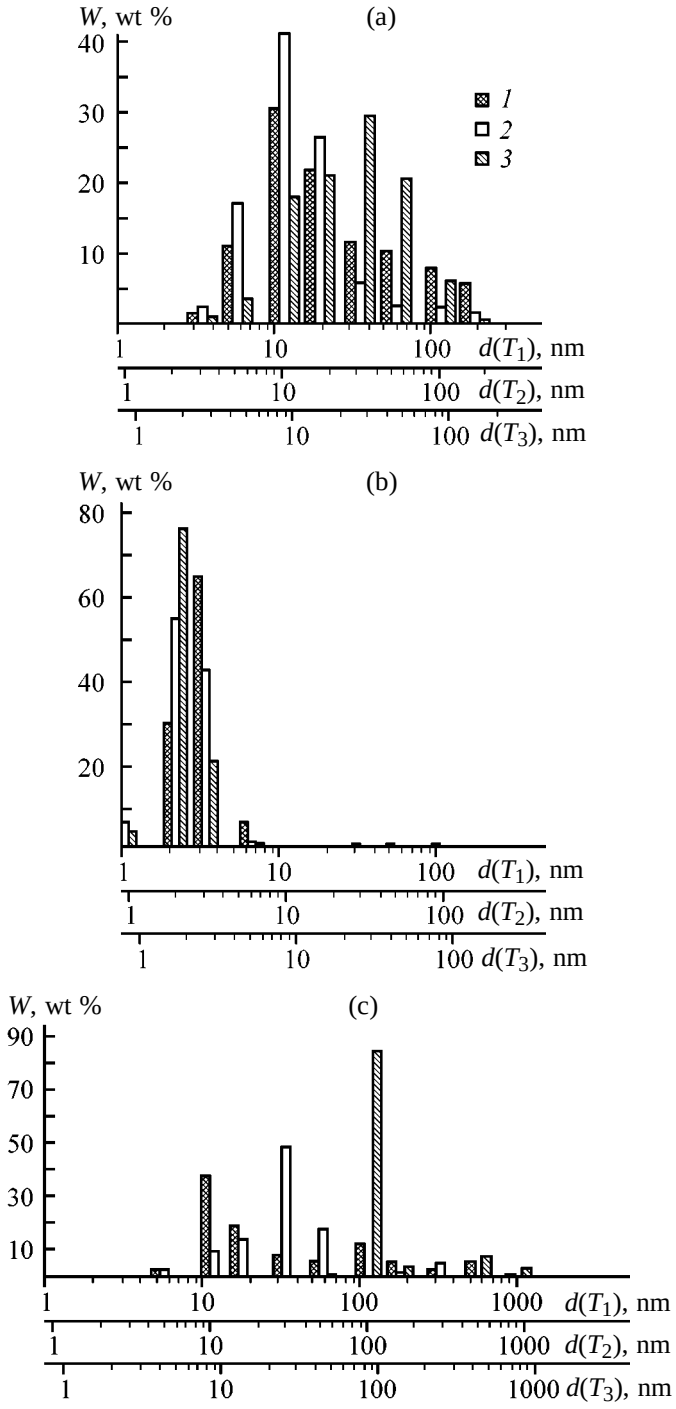

Fig. 1. Particle-size distribution pattern *W* for (a) sulfate lignin, (b) resin, and (c) sulfate lignin–resin mixture in an aqueous alkali solution (pH 12.7) at different temperatures. (*d*) Particle size; the same for Fig. 2. Temperature *T*, K: (*1*) 293, (*2*) 313, and (*3*) 333; the same for Fig. 2.

The measurements were carried out with a Coulter N 4 (Coultronics, France) dynamic light scattering correlator. The data obtained were processed by the previously developed routines [6]. The particle-size distribution patterns of the solutions are presented as histograms.

Figure 1a shows the particle-size distribution pattern for sulfate lignin at different temperatures. It is seen that the modal size of the particles of sulfate lignin dispersed at 293 and 313 K is 10 nm; at 333 K it increases to 30 nm. Clearly, rising temperature increases the aggregation instability of the sulfate lignin solution, as evidenced by increase in the particle size. Thus, we revealed thermal coagulation of sulfate lignin in the temperature range 313–333 K. This is evidently due to a decrease in the degree of hydration of sulfate lignin with rising temperature. Figure 1b shows that the birch resin particles dispersed at 333 K are much smaller than those of sulfate lignin (most of them are 2 nm in size). The aggregation stability of the resin solutions slightly decreases with cooling, by contrast to the sulfate lignin solutions (at 293 K the modal size of the particles is 3 nm); also, a minor amount of relatively large resin particles (316 and 562 nm) appears. Thus, the major part of the sulfate lignin and resin particles in the solutions under study are colloidal. From our data, we estimated the degree of aggregation of the molecules in the particles using the molecular weights of the substances determined by light scattering in organic solvents [7]. The degree of aggregation for the major part of the sulfate lignin and resin particles at 293 K was 55 and 27%, respectively. Thus, direct optical studies confirmed the heterogeneous nature of the systems, which was presumed earlier [3, 4].

We studied the particle-size distribution pattern for a 9 : 1 sulfate lignin–resin mixture corresponding to the real lye (Fig. 1c). It was found that the size of the revealed mixed particles also allows them to be classed with colloidal particles. The modal size of these particles tends to increase in the 293–333 K range from 10 to 100 nm, and at 333 K the fraction of small particles is completely absent. This may be due to the predominance in the mixture of sulfate lignin which exhibits aggregation instability at elevated temperatures. At 333 K, the modal size of the mixed particles is three times that of sulfate lignin and 50 times that of resin, as demonstrated by experiments on separate dispersion of the mixture components. Thus, dissolution of the sulfate lignin–resin mixture involves intensive heterocoagulation.

In view of the practical importance of this study we examined the particle-size distribution pattern for the real sulfate cooking lye comprising, along with the above-listed components, derivatives of wood carbohydrate fraction (primarily, sodium salts of α- and β-glucoisosaccharinic acid). These latter made with

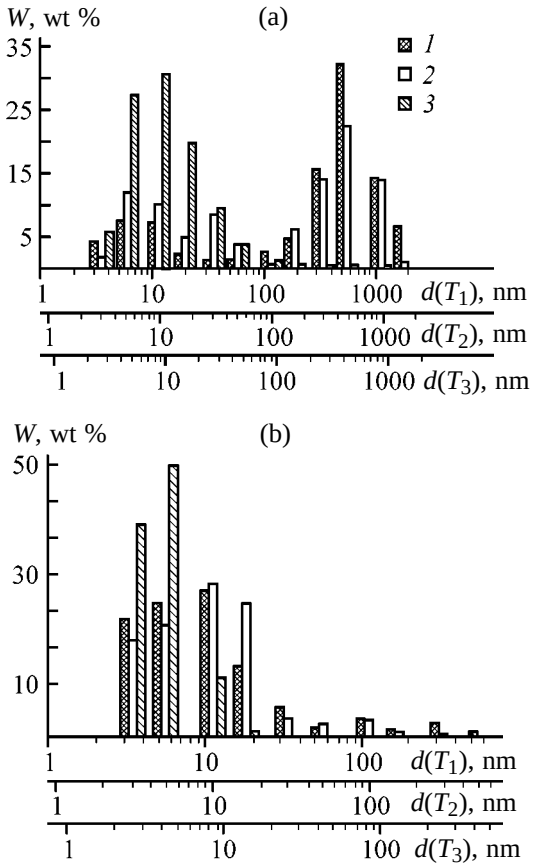

Fig. 2. Particle-size distribution pattern *W* at different temperatures for a mixture of organic substances (a) in sulfate solution, pH 12.7, and (b) in the presence of surfactant.

resin and sulfate lignin a 10 : 1 : 10 mixture. Figure 2a presents the results obtained. Studies of this mixture revealed particles from ultramicroheterogeneous (3–17 nm at 333 K) to finely and coarsely dispersed (300–1690 nm at 293 K). Pronounced heterocoagulation in the solution is observed upon cooling. In this dispersion, mixed particles are coarser than in the above-considered solutions. This is probably due to the presence in the mixture of a significant proportion of the wood carbohydrate fraction. Thus, during cooling the large particles revealed can precipitate onto the cellulose fiber, thus deteriorating the cellulose quality and causing resinous hindrances in fiber processing.

As known, these undesirable phenomena can be prevented by using a surfactant, Neonol AF 9–12, which is most suitable for alkaline medium [3, 8]. Figure 2b shows that Neonol additive decreases the size of the dispersed particles and increases their aggregation stability with lowering the solution temperature. The majority of the mixed particles are 10 nm in size at 293 K, which is comparable with the Neonol micelle size at pH 12.7 as determined previously [3]. Thus, adding Neonol to the cooking acid during cellulose cooking prevents enlargement and precipitation of the particles onto cellulose fiber, thus increasing the stability of these solutions and facilitating passing of the substances mentioned into solution. These factors govern the cellulose quality and the efficiency of using the secondary cooking products (sulfate lignin, sulfate soap, tall oil).

CONCLUSIONS

(1) Direct optical study by dynamic light scattering proved that aqueous solutions of sulfate lignin and resinous wood substances at pH 12.7 are dispersed systems, with nanoparticles dominating.

(2) The temperature dependence of the aggregation stability of dispersions of these substances is studied for the 293–333 K range.

(3) Joint dissolution of sulfate lignin, resinous substances, and wood carbohydrate fraction derivatives yields larger, compared to separate dispersion of the components, mixed particles forming by heterocoagulation.

(4) Adding Neonol decreases the size of the mixed particles and increases their aggregation stability.

Abstract—A formulation was developed of a fireproofing compound for coating metallic structures, based on urea–formaldehyde resins and mineral fillers. The component ratio in the compound was optimized.

Progress of mining in Siberia and development of new regions with rich resources involves wide use of metallic structures. In this connection, an important problem is their fire protection [1], because metallic structures exhibit a poor resistance to high temperatures and, when rapidly heated, lose their strength.

A possible way to solve this problem is the use of inflating fire-proofing coatings. Such coatings exhibit a high heat-insulating power under conditions of a fire. When subjected to impact of high temperatures, they decompose and considerably increase in volume, forming a porous protective layer.

The goal of this study was to develop the formulation of a fireproofing compound for coating of metallic structures, based on urea–formaldehyde resin and mineral fillers.

EXPERIMENTAL

Urea–formaldehyde resin {KF-Zh, GOST (State Standard) 14231–78 [2]} was used as binder. The combustibility of the resin was reduced by adding fireproofing agents: ammonium hydrophosphate $(NH_4)_2HPO_4$ and sodium tetraborate $Na_2B_4O_7$. The same additives were expected to act as inflating agents. As fillers we used vermiculite, phlogopite, clay, chopped fiber glass, and loose asbestos fiber. Initially we examined the effect of fillers with the formulation varied in a wide range (Table 1). To find the optimal composition, the best formulation was optimized by varying the component ratio in narrower limits (Table 2).

The performance of a fireproofing conating was evaluated according to GOST 30.247.0–94 [3] as the time required for heating the inner surface of the coating to 500°C; no less than three samples were tested, and the arithmetic mean was calculated. This time was considered as the refractoriness limit, and, after reaching 500°C, the tests were terminated.

The tests of coatings presented in Table 1 for the fireproofing performance showed that for the formulations containing inflated vermiculite (nos. 1, 2) the refractoriness limit does not exceed 0.5 h. A similar result was obtained for the formulation containing phlogopite (no. 3).

Introduction of clay in addition to vermiculite or phlogopite decreases the refractoriness limit to 0.4 and 0.5 h, respectively. The decreased performance is due to increased density of the carbon residue.

The presence of an additional fireproofing agent

Table 1. Properties of fireproofing coatings*

Compound no.	Component content, wt %		
	KF-Zh resin	ammonium hydrophosphate	inflated vermiculite
1	65	13	22

Table 2. Component content in samples

Component	Content, wt %, in indicated compound					
	no. 9	no. 10	no. 11	no. 12	no. 13	no. 14
KF-Zh resin	64	61	60	59	58	57
Ammonium hydrophosphate	19	18	18	18	17	17
Inflated vermiculite (0.25 mm)	8	10	11	12	12	13
Chopped fiber glass	8	10	11	12	12	13

(sodium tetraborate) decreases the refratrotiness limit from 0.4 to 0.2 h. The best results were obtained with formulation nos. 7 and 8 containing, along with inflated vermiculite, also aspestos or chopped fiber glass: The refractoriness limit was 0.6 and 0.7 h, respectively. For the latter coating, the inflation factor ranges from 1.5 to 2.0. The carbon residue is porous and shows a high adhesion to metal.

Figure 1 shows how the sample temperature varies with time. Three stages can be distinguished in the course of reaching the critical temperature of 500°C. In the initial stage (up to 5 min) the sample temperature reaches 30–80°C, and this is not accompanied by any changes in the state of the coating. In the second stage the coating decomposes with inflation and formation of a heat-insulating surface layer.

The loss of thermal energy for endothermic processes of water evaporation, binder decomposition, and evaporation of degradation products and the increased heat-insulating power of the inflated coating prevent the temperature growth under the protective layer.

In the final stage, the porous system is broken down, and the temperature rapidly grows to 500°C.

Our results (Fig. 1) show that formation of a porous protective layer on the surface of metallic structures is determined by the binder content, resin-to-filler weight ratio, and nature of the filler.

The results obtained with formulation nos. 4 and 5 show that the 46% resin content is insufficient to form a porous protective layer. In such coatings the second stage is virtually lacking. In the other samples (binder content >51%), the second stage is clearly pronounced. The time before the onset of the third stage ranges from 22 to 30 min. The major role in preservation of the protective layer is played by addition of a small amount of the reinforcing filler (asbestos and chopped fiber glass, formulation nos. 7 and 8). Without these additives the breakdown of the inflated layer starts within 22–23 min (formulation nos. 1–3, 6).

The rate of the temperature rise in the third stage largely depends on the resin content in the initial formulation and on the thermal conductivity of the filler. The samples protected with compound nos. 1 and 7 containing more than 65% binder show the most rapid temperature rise in the final stage. Replacement of inflated vermiculite by more heat-conducting phlogopite and clay also favors rapid temperature growth in the third stage.

The best result was obtained with formulation no. 8, which well competes with many commercially used [4] compounds in the fireproofing performance. For example, the fireproofing coating based on OPV-1 vermiculite ensures the refractoriness limit of 0.7 h at a protective layer thickness on a metallic structure of 22 mm [5]. At the same time, formulation no. 8 ensures the same refractoriness limit at a considerably smaller layer thickness (10 mm).

To attain the highest performance of the fireproofing coating and determine the optimal component content in formulation no. 8, we performed additional experiments with the content of the binder, fireproofing agent $(NH_4)_2HPO_4$, and filler being varied. The filler content (inflated vermiculite and fiber glass in equal amounts) was varied in the range ensuring the optimal fluidity. The compositions are listed in Table 2.

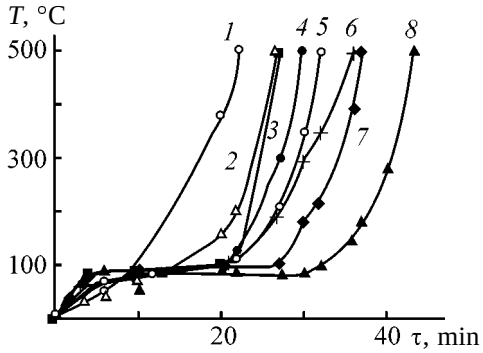

Fig. 1. Heating curves of fireproofing coatings of various compositions. Formulation no.: (*1*) 5, (*2*) 4, (*3*) 1, (*4*) 6, (*5*) 3, (*6*) 2, (*7*) 7, and (*8*) 8. (*T*) Temperature and (τ) time.

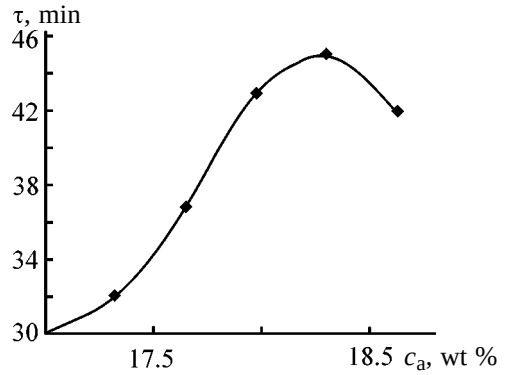

Fig. 2. Influence of the content of ammonium hydrophosphate (fireproofing agent) c_a on the coating refractoriness. (τ) Time; the same for Fig. 3.

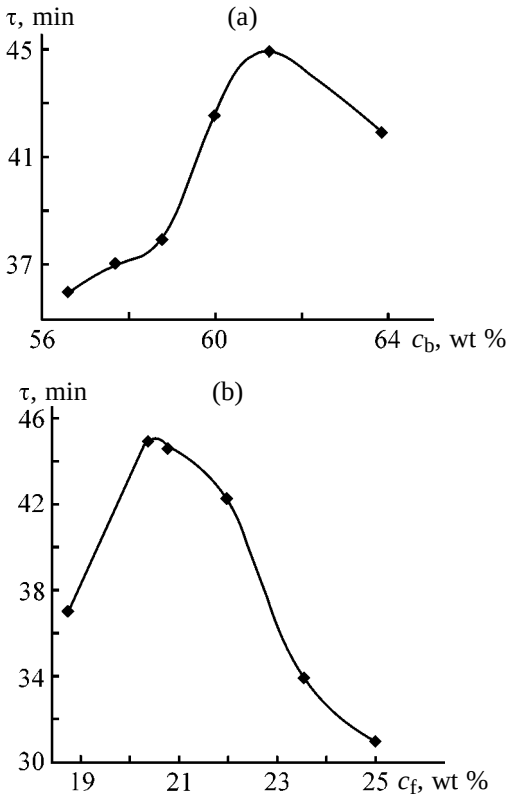

Fig. 3. Coating performance as a function of the content of (a) binder (KF-Zh resin) c_b and (b) filler (fiber glass, vermiculite) c_f.

Figure 2 shows how the refractoriness limit of the coating depends on the fireproofing agent content (at a constant weight ratio of fireproofing agent and resin, equal to 0.3). Formulation no. 10 shows the highest performance (refractoriness limit 0.8 h). It contains 61% KF-Zh urea–formaldehyde resin and 18% ammonium hydrophosphate.

The dependence of the coating refractoriness on the binder content is shown in Fig. 3a. It is seen that variation of the KF-Zh resin content affects the refractoriness limit to a lesser extent than variation of the $(NH_4)_2HPO_4$ content. The highest refractoriness limit (0.8 h) is exhibited by formulation no. 10 containing 61% resin. Apparently, at a lower resin content the heat-insulating performance of the inflated layer is lower, whereas at a higher resin content this layer is broken down faster, and the rate of temperature rise in the final stage increases.

Figure 3b shows how the performance of the fireproofing compounds depends on the filler content (fiber glass, vermiculite). It is seen that the vermiculite and fiber glass content lower than 19% does not ensure formation of a strong inflated layer with a low thermal conductivity. However, at a too high filler content (>23%) the fireproofing performance of the coating decreases, probably because of the increased thermal conductivity.

Thus, the highest performance (refractoriness limit 0.8 h) is shown by formulation no. 10 containing 61% resin, 18% fireproofing agent, 10% inflated vermiculite, and 10% chopped fiber glass. It should be noted that coatings of this compound surpass in the fireproofing performance those of OPV-1 and can have a considerably smaller thickness; thus, the load on the metallic structures being protected can be decreased.

Our results show thart the performance of a fireproofing coating is determined both by the nature of the binder and by the component ratio.

It is known that the decreased combustibility of the urea–formaldehyde resin is due to vigorous evolution of incombustible volatile products into the gas phase in the course of degradation and to accelerated coking. Decomposition of the urea–formaldehyde resin occurs with heat absorption and, owing to release of a large amount of gases, with formation of a protective layer with a porous, very pitted structure of the surface [6, 7]. However, the resin taken separately does not ensure the required fireproofing performance because of the low strength of this porous layer and strong tendency toward further degradation.

The walls of internal channels and pores of the protective layer formed by heating of a filled coating consist of partially degraded and sintered filler fibers, ensuring the required strength of the protective layer. Solid particles of coke, the final product of thermal degradation of the organic binder, are arranged between these fibers.

As the fireproofing coating is a composite material,

the major role is played by the nature of the filler, rather than by high-temperature cross-linking of the resin. Usually introduction of a mineral filler into polymers increases their thermal conductivity [8], which negatively affects the fireproofing performance. However, this effect is eliminated to certain extent by introducing inflated vermiculite. Fiber glass acts as a reinforcing filler, enhancing the strength of the inflated protective layer and thus increasing the refractoriness limit.

CONCLUSIONS

(1) The performance of compounds based on urea–formaldehyde resin as fireproofing agents for metallic structures was studied in relation to the nature and content of mineral fillers.

(2) The main stages of degradation of the fireproofing coating at high temperatures were revealed, and the effect of the coating components on this process was examined.

(3) Formulations were suggested for fireproofing coating, ensuring higher fireproofing power as compared to the commercially used compounds at a smaller thickness of the protective layer.

Thermal Behavior of Titanium Tetrabutylate and Niobium Pentapropylate

A. K. Baev and M. A. Shishko

Belarussian State Technological University, Minsk, Belarus

Received May 10, 2001

Abstract—Thermal behavior of titanium tetrabutylate and niobium pentapropylate in a wide temperature range under static conditions was studied with a membrane zero-gage. The vapor pressure under conditions when vaporization is not complicated by other processes was determined. The enthalpy and entropy of vaporization were calculated. The mechanism of thermolysis of $Ti(OBu)_4$ and $Nb(OPr)_5$ was studied.

Metal alcoholates show promise for preparing submicron metal oxide epitaxial films by metal-organic chemical vapor deposition. To optimize this process, the stability and conditions of preparation and thermolysis of these compounds should be determined. Thermal behavior of $Ti(OBu)_4$ was studied by DTA, mass spectrometry, and gas–liquid chromatography [1, 2]. Two forms of this compound, monomeric and polymeric, were detected [2–4]. The monomer is unstable and irreversibly degrades in the range $373 < T < 473$ K, whereas the polymer is stable up to 473 K. The main thermolysis products are 1(2)-butene, propene, butane, and propane. The thermodynamic data on vaporization and parameters of vaporization of $Nb(OPr)_5$ as well as the dissociation energy $D_{M–OR}$ are reported in our previous works [5, 6].

The $p = f(T)$ dependence for saturated and unsaturated vapor was measured on heating and on cooling (Fig. 1). At 323–418 K the pressure is reproduced with the limits of the determination error and the shape of the $p = f(T)$ curve is independent of the time of thermostatic control. The vapor pressure in this temperature range is described by the equation

$$\log p = (7.5 \pm 0.1) - (248 \pm 39)/T.$$

The calculated enthalpy and entropy of $Ti(OBu)_4$ vaporization are 47.6 ± 0.7 kJ mol^{-1} and $88.5 + 1.9$ J mol^{-1} K^{-1}, respectively. Unsaturated vapor pressure obeys the Gay–Lussac law; the molecular weight determined in two independent experiments (332 and 345) is close to the calculated value (339.9). Above 423 K $Ti(OBu)_4$ appreciably decomposes. In the range 443–449 K the pressure is higher by a factor of 5/4 than the unsaturated vapor pressure measured below 423 K, i.e., every fourth molecule of $Ti(OBu)_4$ decomposes:

$$4Ti(OBu)_4 \rightarrow 3Ti(OBu)_4 + Ti(OH)(BuO)_3 + C_4H_8. \quad (1)$$

In accordance with Eq. (1) the average molecular weight of the gaseous species should be 272. The experimental molecular weight ranges from 279 to 267 and agrees well with the calculated value. The molecular weight determined at 443–449 K is 151–147 owing to strong increase in the vapor pressure. The molecular weight calculated from the equation

$$4Ti(OBu)_4 \rightarrow 3Ti(OH)(BuO_3)_3 + Ti(OH)_2(BuO)_2 + 5C_4H_8 \quad (2)$$

is 150.

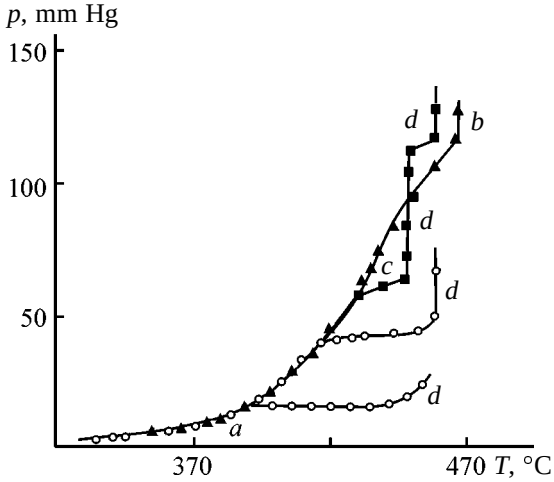

Fig. 1. p–T dependence for $Ti(OBu)_4$: (*a*) saturated vapor, (*b*) unsaturated vapor, (*c*) onset of thermolysis, and (*d*) intense thermolysis.

1070-4272/02/7501-0156$27.00 © 2002 MAIK "Nauka/Interperiodica"

Subsequent olefin elimination at these temperatures leads to formation of hydrated titanium oxide $TiO_2 \cdot nH_2O$.

Generally, $Ti(OBu)_4$ thermolysis occurs by the molecular mechanism and is described by the following scheme:

$$4Ti(OBu)_4 \xrightarrow[-C_4H_8]{} Ti(OH)(OBu)_3 \xrightarrow[-C_4H_8]{} Ti(OH)_2(OBu)_2 \xrightarrow[-2C_4H_8]{} TiO_2 \cdot H_2O \xrightarrow[-H_2O]{} TiO_2. \quad (3)$$

The formation of other unsaturated (propene) and saturated (prepane, butane) hydrocarbons in the $Ti(OBu)_4$ thermolysis is due to secondary radical reactions.

The $p = f(T)$ dependence for $Nb(OBu)_5$ was measured on heating and cooling (Fig. 2). Curve *1* contains the sections of $Nb(OBu)_5$ vaporization (up to 343 K) and its irreversible thermal dissociation (343–513 K). At 503 K $Nb(OBu)_5$ intensively decomposes. Since the vapor pressure of $Nb(OBu)_5$ below the temperature of its appreciable decomposition (358 K) is low (3 mm Hg), we cannot determine the thermodynamic parameters of vaporization of this compound. Our results suggest that the $\log p = f(T)$ dependence and parameters of $Nb(OBu)_5$ vaporization determined in the 383–434 K temperature range in our previous work [6] are doubtful. Above 503 K (Fig. 2, section *d*) the thermolysis is completed and the pressures increases owing to the gas expansion. On cooling (Fig. 2, curve *2*) the pressure decreases by the Gay–Lussac low (Fig. 2, section *e*), which is followed by stepwise condensation of thethermolysis products. The saturated vapor pressure of water (Fig. 2, section *f*), propanol (Fig. 2, section *g*), and propene (Fig. 2, section *h*) was determined from the total vapor pressure at different temperatures. The presence of propane and propene was confirmed by chromatography. Traces (~1%) of butane, 1(2)-butene, and methane were also detected. Based on these data and results of [2, 7], the mechanism of $Nb(OBu)_5$ thermolysis can be proposed.

The final thermolysis product of $Nb(OBu)_5$ was Nb_2O_5 [2, 7]. In the crystal structure of $[(RO)_5Nb]_2$ both terminal and bridging alkoxy groups are present, with the bridging M–OR bonds being considerably longer than the terminal bonds (2.3 and 1.9 Å, respectively). This difference and large bond angles at oxygen atoms of the terminal groups (135–160°) indicate strong $p_\pi d_\pi$ interaction in the $M–OR_t$ fragment. As a result, the multiplicity of these bonds increases and they become stronger. The p_π-donor power of the

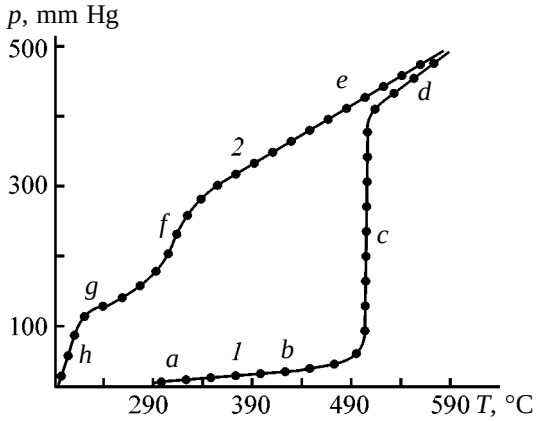

Fig. 2. p–T dependence for $Nb(OBu)_5$ (*1*) on heating and (*2*) on cooling: (a) $Nb(OBu)_5$ vaporization, (b) vaporization with partial decomposition of $Nb(OBu)_5$, (c) thermolysis, (d) thermolysis of the residue, (e) range of Gay–Lussac dependence; condensation of (f) water and isorpropanol, (g) propanol, and (h) propane and propylene.

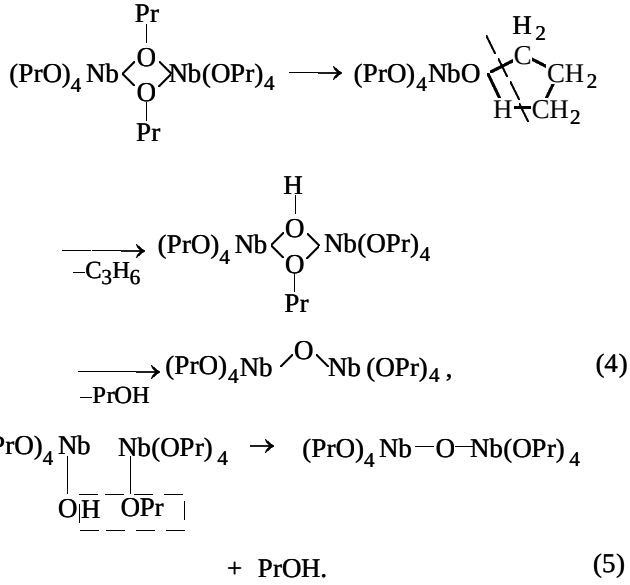
bridging oxygen atoms is lower than that of the oxygen atoms of the terminal groups. Hence, dissociation of the bridging bonds is more energetically favorable. The presence of propanol and propene among the thermolysis products indicates elimination of these compounds at temperatures higher than 358 K by the following reactions:



The volatility of $Nb(OPr)_5$ is low, and total pressure in the system is determined by the partial pressures of the alcohol and olefin. Niobium oxide Nb_2O_5 is formed with elimination of oxygen-containing compounds (the alcohol, ether, or H_2O). The ether content can be neglected since its yield in thermolysis of metal alkoxides decreases with an increase in the

length of the hydrocarbon chain of the alkoxy group and the ether yield in thermolysis of niobium ethylate is 0.1 mol. Propanol is formed only in the first step of thermal dissociation of $Nb(OPr)_5$.

Since all the other Nb–OR bonds are equivalent, we suggest that the mechanism of their cleavage is similar. Chromatographic analysis of the thermolysis products showed that the gas phase consists mainly of propene and propane in the 6 : 1 ratio. Thus, the next step of $Nb(OPr)_5$ dissociation is the olefin elimination to form hydrated niobium(V) oxide which at temperatures higher than 623 K is dehydrated to Nb_2O_5 [scheme (6)], i.e., five $[Nb(OPr)_5]_2$ molecules release five oxygen atoms in the form of single propanol molecule and four water molecules:

$$(PrO)_4Nb{-}O{-}Nb(OPr)_4$$

$$\xrightarrow[-C_2H_6]{} (PrO)_{4-x}(OH)_xNb{-}O{-}Nb(OH)_x(OPr)_{4-x}$$

$$\xrightarrow[-C_3H_6]{} Nb_2O_5\cdot 4H_2O \xrightarrow[-4H_2O]{} Nb_2O_5. \qquad (6)$$

The presence of ethylene and traces of methane, ethane, butane, and 1(2)-butene is due to the secondary free-radical processes occurring in the system. Thus, $Nb(OPr)_5$ thermally decomposes by the molecular mechanism. In accordance with the thermolysis scheme (3)–(5), 0.5 mol of isopropanol, 2 mol of water, and 4.5 mol of hydrocarbons are formed per mole of the initial substance.

EXPERIMENTAL

Thermal behavior of titanium tetrabutylate and niobium isopropylate under static conditions was studied with a membrane zero-gage. The temperature was measured with an accuracy of ± 0.1 K. The pressure was measured with an MChR-3 gage accurate to 0.1 mm Hg. The *p*–*T* dependence was measured on heating and on cooling. The initial compounds were purified by repeated vacuum distillation. As determined by elemental analysis, the purity of the initial samples was no less that 99.9%. The metal alcoholates were distilled into the gage chamber via an all-soldered glass system. Moisture traces were preliminarily removed from the system with the aid of a zeolite pump. The volatile thermolysis products were analyzed on an LKhM-72 chromatograph equipped with a 7-m column. The column was packed with 18% dinonyl phthalate on Chromaton-N (5 m) and a 20% ethylene glycol solution of $AgNO_3$ on Chromaton-N-AB (2 m).

Thermolysis of Dimethyltellurium and Its Mixture with Dimethylcadmium

A. K. Baev

Belarussian State Technological University, Minsk, Belarus

Received September 19, 2000; in final form, October 2001

Abstract—Thermolysis of dimethyltellurium and its mixture with dimethylcadmium (1:1) was studied. The composition of the thermolysis products was determined. The thermolysis mechanism was proposed.

The kinetic data on thermolysis of organometallic compounds are used to optimize the conditions of production of semiconductors and their low-temperature doping. However, the thermolysis mechanisms of practically important organometallic compounds and especially of binary mixtures [1] are studied insufficiently.

In this work we studied thermolysis of dimethyltellurium and its mixture with dimethylcadmium.

Thermal degradation of $Te(CH_3)_2$ to metallic tellurium at 623–773 K under static conditions was examined in [2]. The content of the main gaseous product, CH_4, decreases with increasing temperature. The process involves intramolecular disproportionation of CH_3 groups with intermediate formation of organotellurium polymer which degrades further to metallic tellurium:

$$n\mathrm{Te(CH_3)} \rightarrow n\mathrm{CH_4} + (\mathrm{TeCH_2})_n, \quad (1)$$

$$(\mathrm{TeCH_2})_n \rightarrow n\mathrm{Te} + n/2\mathrm{CH_4} + n/2\mathrm{C}. \quad (2)$$

In the condensed product CH_2 and CH groups were detected. The carbon content in metallic tellurium was 2.5%. Yablokov *et al*. studied thermolysis of $Te(CH_3)_2$ under static conditions [3]. The following temperature dependence of the rate constant was derived:

$$\ln k = (28.0 \pm 2.5) - (43\,200 \pm 3100)/RT.$$

In preliminary experiments the process was performed to a constant pressure in the system (~20 h). It was found that the degree of thermolysis at temperatures higher than 610 K is almost independent of temperature. The ratio of the attained constant pressure p_{const} and the initial pressure p_{in} at 603, 606, 617, 622, 633, and 641 K is 1.49, 1.50, 1.31, 1.33, 1.30, and 1.35, respectively.

Needle crystals and a translucent dark brown film were formed on the walls of the gage chamber. This agrees with data of Galliulina *et al*. [2] and indicates gas-phase thermolysis of the sample with subsequent condensation of the products on the walls of the gage chamber. At $\tau = 0$ the α–τ kinetic curves (Fig. 1) obtained at the initial $Te(CH_3)_2$ concentration of 3.8×10^{-4} M intercept different lengths on the ordinate, which is due to certain decomposition of the initial sample in the course of attaining the required temperature. Therefore, when treating the kinetic curves, we took as the start of the process the moment at which the constant temperature was attained. The kinetic data were approximated by equations of different orders. Up to the degree of decomposition of 0.8–0.9 the best fit was obtained with the first-order equation.

The experimental results are described well by the linear anamorphosis of the kinetic equation. The rate constants $k \times 10^5$ at 559.6, 577.2, 595.2, 603, 613,

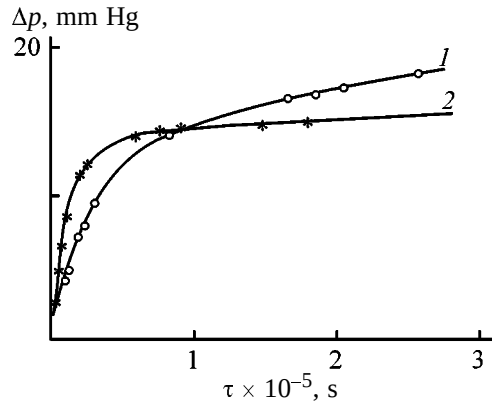

Fig. 2. Thermolysis of dimethyltellurium–dimethylcadmium mixture (molar ratio 1 : 1) at (*1*) 519.7 and (*2*) 536.2 K. (Δp) pressure change and (τ) time.

623, 633, 641, and 651 K, calculated by the least-squares treatment of the first-order equation, are 0.55, 1.48, 4.87, 10.6, 33.2, 68.4, 85.6, 177.6, 338.6, and 448 s^{-1}, respectively.

The first four values of k were calculated from our data and the other were taken from [3]. All these constants fall on the $\log k = (1/T)$ line. Least-squares treatment of the temperature dependence of the rate constant gave the Arrhenius equation

$$\log k = (13.45 \pm 0.56) - (10\,266 \pm 430)/T.$$

The calculated activation energy and pre-exponential factor are $196.7 + 6.1$ kJ mol^{-1} and $10^{13.45 \pm 0.7}$ s^{-1}, respectively.

Cooling of the zero gage to the liquid nitrogen temperature showed that the pressure in the system is produced by the saturated vapor of CH_4, and H_2 is absent in the thermolysis products. The composition of gaseous thermolysis products of $Te(CH_3)_2$ is independent of temperature. The main product (95.3–97.9%) formed at 548.6–565.2 K is methane. The content of unsaturated hydrocarbons is negligible. The mass-balance calculations performed by the procedure in [4] showed that 28–29% C and 6–8% H are present in the condensed phase.

Since the kinetics of $Te(CH_3)_2$ thermolysis obeys a simple law, the chain initiation is an elementary step of the process [5]. The high methane yield is due to reaction of CH_3 radicals with $Te(CH_3)_2$. The rate constants of recombination of CH_3CH_2 radicals and of CH_3 and CH_3CH_2 radicals are higher than those of the other reactions. However, the radical concentration is low and the recombination rate is usually comparable with those of other reactions. Low yield of C_2–C_4 hydrocarbons indicates negligible contribution of these reactions to the overall process. Analysis of thermolysis products showed that the hydrocarbon yield monotonically decreases with an increase in the length of the hydrocarbon chain. Based on these results, the thermolysis scheme was proposed. It should be noted that the composition of the tellurium film, estimated from the mass balance of the process, differs from $TeCH_2$ since these species reacts with CH_3 radicals [scheme (3)]. The products of this reaction are condensed on the wall of the gage chamber to form polymers degrading further with increasing temperature [scheme (4)]:

$$\dot{C}H_2Te + \dot{C}H_3 \rightarrow (CHTe)_n + CH_4, \quad (3)$$

$$(HCTe)_n \rightarrow nTe + n/4CH_4. \quad (4)$$

The occurrence of these reactions is confirmed by the presence of CH_2 and CH groups in the condensed product [3] and C : H = 0.65–0.90.

Methane formation is the major pathway of $Te(CH_3)_2$ thermolysis. The rate constant of the overall thermolysis process is about 1–3 orders of magnitude higher than that of generation of CH_3 radicals [6]. This fact and autoinhibition of the thermolysis [7] suggest its radical mechanism which agrees with the results of [4].

Dimethylcadmium appreciably decomposes at 423 K [8]. Based on the results of preliminary experiments, the temperature range for the study of thermolysis of the $Te(CH_3)_2$–$Cd(CH_3)_2$ mixture (1 : 1) was chosen to be 484–564 K. The experiments were performed at the total initial concentration of these compounds of 1×10^{-3} M. The kinetic curves are shown in Fig. 2. Analysis of these curves showed that at low temperatures the process is described by the first-order equation, but at higher temperatures the process kinetics is inconsistent with the orders of thermolysis of $Te(CH_3)_2$ and $Cd(CH_3)_2$ [8] (1 and 0.5, respectively). After cooling of the system with liquid nitrogen, no H_2 was detected in the gas phase. The gaseous thermolysis products were analyzed by chromatography. The main products formed at 484.0–564.2 K are CH_4 (53.8–86.2%) and C_2H_6 (8.3–35.7%). The yield of other alkanes is lower than 5%. The yield of methane decreases, the yield of C_2H_6, C_3H_8, and C_4H_{10} increases, and the yield of *iso*-C_4H_{12} and other thermolysis products remains virtually the same with increasing temperature.

Mass balance calculation of the composition of the condensation products showed that the H content in

this phase is maximal and the C : H ratio remains constant at 500–565 K. We suggest that, as compared to $Te(CH_3)_2$ thermolsysis, the decrease in the carbon and hydrogen content in the condensed phase and considerable increase in the C_2H_6 yield with increasing temperature are due to different thermolysis mechanism of these compounds. Since the activation energy of $Te(CH_3)_2$ thermolysis (196.2 kJ mol^{-1}) is higher than that of $Cd(CH_3)_2$ (129.2 kJ mol^{-1}), the rate constant of $Cd(CH_3)_2$ thermolysis is higher. Hence, in a $Te(CH_3)_2$–$Cd(CH_3)_2$ mixture $Cd(CH_3)_2$ starts to decompose at lower temperatures. The mechanism of $Cd(CH_3)_2$ thermolysis proposed in our previous work is confirmed by the experimental yield of C_2H_6 (18.95–20.9 %) at 521–536 K.

The C_2H_6 content in the products of thermolysis of a $Cd(CH_3)_2$–$Te(CH_3)_2$ mixture at 484 K is 8.3%, whereas in the case of $Te(CH_3)_2$ thermolysis it is 2.1–2.3%. This indicates that CH_3 radicals formed in the course of the thermal degradation react with $Te(CH_3)_2$. The reaction of CH_3 radical with $Cd(CH_3)_2$ and $Te(CH_3)_2$ increases the CH_4 yield in thermolysis of $Cd(CH_3)_2$–$Te(CH_3)_2$ mixture as compared to that in thermolysis of pure $Cd(CH_3)_2$. The corresponding decrease in the yield of the other products indicates greater contribution of reaction (5) owing to reaction of CH_2 radical with CH_4 [reaction (6)]:

$$Te(CH_3)_2 + \dot{C}H_3 \rightarrow \dot{C}H_2TeCH_3 + CH_4, \quad (5)$$

$$CH_4 + \ddot{C}H_2 \rightarrow C_2H_6. \quad (6)$$

These processes decrease the carbon content in a semiconductor. In this connection the temperature effect is of special importance, since the rate constant of radical initiation, especially of the reaction

$$\dot{C}H_2CdCH_3 \rightarrow \ddot{C}H_2 + \dot{C}H_3 + Cd, \quad (7)$$

increases [8] with temperature. It is the sharp increase in the C_2H_6 yield that indicates growing contribution of reaction (7). As the concentration of CH_2 radicals increases, the contribution of reaction (6) increases and hence the C_2H_6 yield increases and the CH_4 yield decreases. As a result, the total content of CH_4 and C_2H_6 remains virtually constant in the examined temperature range (94.92, 90.99, 92.28, 98.22, 88.84, 89.55%). The yield of other saturated hydrocarbons is almost equal to that in $Cd(CH_3)_2$ thermolysis. The increase in the content of unsaturated hydrocarbons C_5H_{10} and C_3H_6 by 2 and 1–1.5%, respectively, is due to reaction of $\ddot{C}H_2$ radical with C_nH_{2n+2}.

The most probable reactions of chain propagation and termination in thermolysis of a $Cd(CH_3)_2$–$Te(CH_3)_2$ mixture are similar to those occurring in thermolysis of the components. The CH_2 radical is involved not only in the above reactions but also in reaction (8)

$$Te(CH_3)_2 + \ddot{C}H_2 \rightarrow C_2H_5TeCH_3, \quad (8)$$

which decreases the C and H content in the condensed phase. With increasing temperature reactions of CH_2 radical decrease the CH_4 yield and the C : H ratio in the solid product. Thus, formation of $\ddot{C}H_2$ radical in thermolysis of $Cd(CH_3)_2$, which, in its turn, participates in thermolysis of $Te(CH_3)_2$, decreases the carbon content in the final product. Hence, the purity of the solid thermolysis product can be increased by increasing thermolysis temperature.

CONCLUSION

The data on thermolysis of dimethyltellurium, dimethylcadmium, and their mixture can be used to optimize the conditions of preparation of CdTe semiconductor and doping of other semiconductors with cadmium and tellurium by metal–organic chemical vapor deposition.

Resistance of Electrolyte in Pores of Lead Battery Electrodes

I. F. Khalizov, V. V. Bayunov, and G. A. Kolikova

Istochnik Battery Research Institute, Open Joint-Stock Company, St. Petersburg, Russia

Received June 13, 2001

Abstract—Relations for calculating the active resistance of electrolyte in pores of lead battery electrodes are proposed, and necessity for taking it into account in determining the active resistance of batteries is demonstrated.

Of particular interest in designing high-capacity lead batteries is determination of their electrical characteristics: dependence of the voltage U on the discharged capacity Q or time τ in various discharge modes at constant current I or power P:

$$U = f(Q),\ U = f(\tau) \text{ at } I = \text{const},\ P = \text{const}. \quad (1)$$

These calculations require that the internal resistance of a battery should be known. It is known that the internal resistance R of a battery is constituted by the active resistance R_a and polarization resistance R_p:

$$R = R_a + R_p. \quad (2)$$

The polarization resistance of a high-capacity battery can be found from service characteristics of a small battery using simulation. The components of the active resistance [resistances of positive and negative electrodes (R_+ and R_-), electrolyte with separator (R_e), and terminals (R_t)] are found by calculation:

$$R_a = R_+ + R_- + R_e + R_t. \quad (3)$$

The electrode resistance includes the resistances of current leads, active paste (as a conductor), contact resistance between the active paste and current lead, and resistance of active paste within cells.

From dependence (3) follows that the active resistance of the electrolyte in electrode pores is disregarded, and, therefore, it is included in calculations in the polarization resistance, which is not described by the Ohm law and depends on current. That is why an error is made in calculating the polarization resistance of small and large batteries. Let us evaluate this error.

In [1, 2], data on the porosity of the active paste, pore tortuosity, and relative resistance of electrolyte in pores of lead battery electrodes were reported. It is proposed to use these data to calculate the resistance of electrolyte in pores of positive and negative electrodes, R_{ep}, using the relations

$$R_{ep} = \frac{0.335\,\beta\, b/2}{SnP}\rho, \quad (4)$$

$$R_{ep} = \frac{0.335\,\rho_{rel}\, b/2}{Sn}\rho, \quad (4)$$

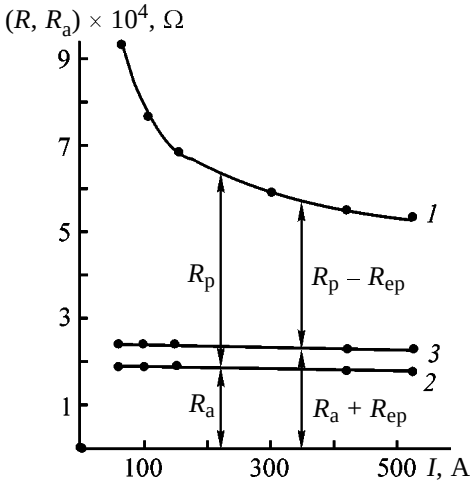
where b is the electrode thickness, S is the geometric surface area of the electrode, n is the number of positive or negative electrodes in a unit, β is the coefficient of pore tortuosity in the active paste, P is the porosity of the active paste, ρ_{rel} is the relative resistance of electrolyte in the electrode pores, ρ is the resistivity of electrolyte in the pores, and 0.335 is the coefficient of equivalence of the resistance of electrolyte in the electrode pores for the case of a uniform distribution of current density in the pores.

The resistances of electrolyte in pores of the positive and negative electrodes of a unit, calculated using relations (4) and (5), add up.

The resistances of electrolyte in the electrode pores, found using relations (4) and (5) for a stationary lead battery with capacity of 600 A h, differed by 23%. It is preferable to perform calculations with relation (5), since the error is diminished in this case because the relative resistance of the electrolyte in pores accounts for the pore tortuosity coefficient and the porosity of the active paste.

A calculation demonstrated that the active resistance R_a of the battery is, respectively, 1.69×10^{-4} and 1.768×10^{-4} Ω after 3–10 and 0.25–1 h of discharge,

1070-4272/02/7501-0162$27.00 © 2002 MAIK "Nauka/Interperiodica"



(*1*) Total (R) and (*2*, *3*) active (R_a) resistances of battery vs. discharge current I (*2*) without and (*3*) with account of the electrolyte resistance in pores.

and, with account of R_{ep}, 2.402×10^{-4} and 2.301×10^{-4} Ω for the same discharge modes. Thus, the active resistance R_a increased, with account of R_{ep}, by 28.5 and 30% after discharge for, respectively, 3–10 and 0.25–1 h.

The changes in the total battery resistance R, active resistance R_a, and polarization resistance R_p after 0.25–10 h of discharge, found with and without account of the electrolyte resistance in electrode pores, are presented in the figure. In calculations, the electrolyte densities in electrode pores and box of a charged battery were taken to be equal. The polarization resistance R_p decreased after 0.25 and 10 h of discharge by, respectively, 15 and 7%. These data point to the necessity for taking into account the resistance of electrolyte in the electrode pores, R_{ep} [relation (5)], in determining the active resistance of large and small batteries with the use of relation (3).

Efficient Synthesis of 3-Acyl-5-arylmethylene-4-oxothiazolidine-2-thiones

E. B. Aronova and A. I. Ginak

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 27, 2001

Abstract—An efficient procedure was suggested for preparing 3-acyl-5-arylmethylene-4-oxothiazolidine-2-thiones.

3-Acyl-5-arylmethylene-4-oxothiazolidine-2-thiones are intermediates in synthesis of practically important substances: pesticides, drugs, dyes, vulcanizing agents, antioxidants, etc. [1]. These compounds are prepared in solutions by reactions of appropriate acyl chlorides with 5-arylmethylene-4-oxothiazolidine-2-thiones in the presence of bases [2, 3]. The reactions are accompanied by hydrolysis with ring cleavage, which decreases the yield of the target products by 25–40% and complicates their isolation from reaction mixtures. Synthesis of 3-acyl-5-arylmethylene-4-oxothiazolidine-2-thiones by cyclization from appropriate amides and carbon disulfide [4] is multistage and gives poor yields. Therefore, we suggest in this paper a procedure for preparing 3-acyl-5-arylmethylene-4-oxothiazolidine-2-thiones by direct acylation of solid alkali metal salts of 5-arylmethylene-4-oxothiazolidine-2-thiones with vapors of appropriate acyl chlorides (see table). It is known [5] that nucleophilic substitution reactions of solid ambident substrates with gaseous electrophiles are selective and are not complicated by degradation.

The reaction was performed in a tubular reactor (1 cm in diameter, 10 cm high) equipped with controllable (70–250°C) electric heating. Acyl chloride vapor mixed with an inert gas (nitrogen, argon) was passed through a substrate bed. The reaction progress was monitored by TLC. After reaction completion, excess acyl chloride was removed in a vacuum.

The acylation pathway was judged from the hydrolysis products. Addition of the acyl group to the nitrogen atom in the heterocycle follows from formation of the initial 5-arylmethylene-4-oxothiazolidine-2-thione in hydrolysis, according to the scheme

Abstract—The structure of cellulose-containing materials (powdered cellulose and rice husk) subjected to mechanochemical treatment was studied.

Mechanical treatment is known to affect the reactivity of a solid and cause distortions in its structure [1, 2]. Because IR spectroscopy is widely used for monitoring various structural transformations of cellulose [3, 4], we chose this method for studying structural changes in mechanically treated cellulose samples. Experiments were performed with rice husk as a vegetable material containing about 40% cellulose; powdered cellulose was used as reference.

EXPERIMENTAL

The IR spectra were recorded on a Specord spectrophotometer in the range 400–4000 cm^{-1}. Samples were prepared as KBr pellets (1 mg of substance per 300 mg of KBr). The band at 900 cm^{-1} was resolved graphically. The IR spectral coefficients of the analytical absorption bands were calculated from the corresponding optical densities.

The mechanical activation of cellulose and rice husk samples was performed with an MA-1 laboratory planetary activator. The microstructure of the mechanically treated samples was studied with a Neophot-2 optical microscope equipped with a scanning attachment for transferring the image to a computer. The ESR spectra of mechanically treated samples were recorded with a Radiopan SE/X 2544 spectrometer operating at 9.1 GHz.

Cellulose and rice husk samples were mechanically activated for various times. Samples placed in an activator are subject to loads causing dispersion and plastic deformations; these processes affect the bond lengths in the molecules of sample components. The shearing component of the mechanical force field alters the bond angles. As a result, the band of the CH_2 rocking vibrations at 900 cm^{-1} grows in intensity. This effect is directly related to changes in the conformation of pyranose units, associated with the loss of the sample crystallinity in the course of crushing. The increased intensity of the band at 900 cm^{-1} in the spectra of samples with the lost crystallinity was noted in numerous papers [5, 6]. The IR examination of mechanically treated samples of rice husk and powdered cellulose also revealed broadening of the band at 1066 cm^{-1}. This effect depended on the time of mechanical treatment and for rice husk was noticeable from the first minutes of the treatment (the half-width increased by 20 cm^{-1}). For cellulose, this effect was more pronounced in samples activated for 10–30 min; the half-width increased by 10 cm^{-1}. The vegetable raw materials contain pectin substances, hemicelluloses, lignin, and low-molecular-weight components capable of generating radicals in the course of mechanical treatment. Tasking into account the ESR data, we can suggest that the radicals generated from the low-molecular-weight components of mechanically treated rice husk samples owing to self-heating in the activator recombine to form new C–C bonds (including rings) and C–O bonds whose vibrations overlap with the similar vibrations of the cellulose moiety, causing the band broadening. As a result, the intensity of the band at 900 cm^{-1} increases at the expense of increased absorption at the wing of the broad strong band at 1066 cm^{-1}. Variation of the spectral coefficients calculated for the graphically resolved band at 900 cm^{-1} (Fig. 1a) reflects the fact that the crystallinity of powdered cellulose and rice husk in the course of mechanical treatment passes through several extrema.

Variation of the spectral coefficients calculated for the band at 1430 cm^{-1}, originating from the in-plane bending vibrations of the C–H bonds in the CH_2OH group and characterizing the level of the supramolec-

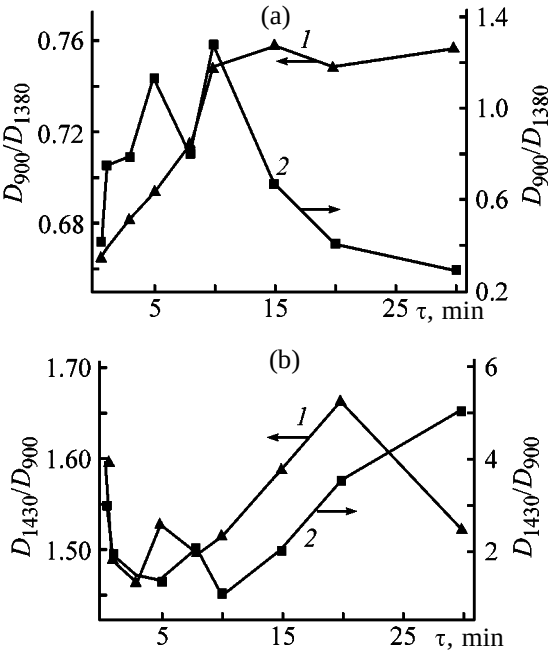

Fig. 1. Variation with the mechanical treatment time τ of the IR spectral coefficients (a) D_{900}/D_{1380} and (b) D_{1430}/D_{900} characterizing the crystallinity and supramolecular structure of the samples, respectively. (*1*) Powdered cellulose and (*2*) rice husk.

ular ordering of the polymer [5, 6], shows that at mechanical treatment of both rice husk and powdered cellulose samples the loss of the crystallinity is accompanied by formation of supramolecular structures (Fig. 1b). Hence, increase in the crystallinity of the samples involves the recrystallization stage, which is characteristic of crystalline polymers subjected to mechanical loads. Apparently, in mechanically treated rice husk samples containing radicals, the condensation products appearing after 10-min activation become centers of new enlarged formations, and the degree of supramolecular ordering increases (Fig. 1b, curve *2*). Simultaneously increases the degree of crystallinity (Fig. 1a, curve *2*). These data show that free radicals also participate in processes related to the loss of the total crystallinity of the samples.

In the samples of mechanically treated cellulose, in which the content of radicals is insignificant, the crystallinity and supramolecular structure vary to a lesser extent. After 20-min treatment, the crystallinity of the cellulose samples increases (Fig. 1a, curve *1*) owing to recrystallization, but the new formations with the more ordered supramolecular structure are not retained by exchange interaction forces because of the low content of radicals and are broken down under the action of mechanical forces, so that both the supramolecular ordering and the crystallinity decrease after treatment for 30 min (Figs. 1a, 1b, curves *1*). The observed rearrangement of the supramolecular structure of the samples is well consistent with variation in the course of mechanical treatment of the shape of some narrow bands in the range 1300–1500 cm^{-1}, sensitive to chemical and structural changes [7].

Photomicrographic analysis allows monitoring of changes occurring on the supramolecular level in cellulose and in cellulose components of rice husk in the course of mechanical treatment, namely, of the initial ordered structure of cellulose and of its breakdown under the action of mechanical forces. Changes in the relative intensity of the band at 1430 cm^{-1} also correspond to changes in the structure of rice husk and cellulose. The repeating processes of breakdown and formation of various crystalline modifications in the samples subjected to mechanical treatment give rise to several extrema in the curves of the relative optical densities, characterizing the changes in the crystallinity and supramolecular ordering, vs. activation time.

Our results can be used for studying the reactivity of cellulose-containing products subjected to mechanical and mechanochemical activation and developing procedures, based on mechanochemical treatment, for preparing new cellulose-containing polymeric compounds.

CONCLUSIONS

IR spectroscopic and optical microscopic study of the structure of powdered cellulose and rice husk subjected to mechanochemical activation revealed a complex (with several extrema) pattern of variation of their crystallinity and supramolecular ordering.

INFORMATION

222nd ACS National Meeting. International Symposium on PVC and Related Polymers (Chemistry and Applications)

The 222nd American Chemical Society National Meeting was held from August 26 to 30, 2001, in Chicago, IL (the United States). Generally, such meetings are held twice a year (Fall and Spring meetings), and the next meeting will be held in April 2002 in Orlando, FL. More than 15000 scientists primarily from the United States and also from practically all the industrial countries participated in this Fall Meeting. The Meeting included various sessions, theoretical and practical symposia, seminars, and exhibitions.

Let us focus on the symposium *"PVC and Related Polymers: Chemistry and Applications,"* which was held in the framework of the ACS Meeting from August 28 to 30, 2001. The symposium organizers were W.H. Starnes, Jr. (Williamsburg, the United States) and D.E. Witenhafer (Dublin, the United States). Note that it was the first symposium on PVC in recent two decades. The symposium covered the topical theoretical and applied aspects of PVC chemistry and technology. The symposium participants were about 150 scientists from Canada, China, Czech Republic, Egypt, France, Germany, Hungary, India, Italy, Japan, Poland, Russia, Singapore, Spain, Sweden, Switzerland, the United Kingdom, and the United States, representing more than 50 research centers all over the world.

More than 30 plenary lectures were presented, and a great body of information was given in the poster session that preceded the main program of the symposium. In the opening ceremony, Prof. W.H. Starnes outlined the topicality of the problems to be discussed and their importance from the theoretical and practical standpoints. The major attention was paid to such topics concerning PVC as polymerization, physical properties, structure, chemical modification, additives, PVC modifiers including stabilizers and plasticizers, PVC degradation and stabilization, and PVC flammability and fire retardance.

Four sessions were held. The topic of the first session was *Polymerization and Structural Modification.* The first lecture entitled *PVC: Origin, Growth, and Future* was given by D. Braun (Darmstadt, Germany). Particularly, he said that in 2001 the humanity commemorated the 70th anniversary of PVC industrial use, and presently PVC is a large-tonnage polymer, whose production steadily grows and application area expands. The next three lectures were devoted to efforts aimed at PVC manufacture by nonradical pathways. K. Endo, N. Kaneda, H. Waku, M. Saitoh, and N. Emori (Osaka, Japan) gave a lecture on controlled polymerization of vinyl chloride with butyllithium and metallocene catalysts. R.F. Jordan (Chicago, the United States) reported on the attempts to apply single site olefin polymerization catalysts to vinyl chloride. The third lecture of this series [H.W. Boone, M.J. Mullins, P.S. Athey, and R.V. Snelgrove (Freeport, the United States)] was devoted to the possibility of using transition-metal catalysts for polymerization of vinyl chloride and also to new approaches to effective employment of these catalytic systems. The next series of contributions concerned chemical modification of PVC and development of new materials on its basis. The first lecture of this series entitled *New Polymers by Living Radical Graft Copolymerization Initiated from the Structural Defects of Poly(vinyl chloride) and by Living Radical Polymerization of Vinyl Chloride* was given by V. Percec, A.D. Asandei, F. Asgarzadeh, E. Ramirez, and A. Capotto (Philadelphia, the United States). Z. Pi and J.P. Kennedy (Akron, the United States) reported on new PVC derivatives obtained by carbocationic techniques. M.N. Guarrotxena (Madrid, Spain) focused in his lecture on stereochemical microstructure dependence of physical properties of PVC. Finally, the last lecture of the first session given by T. Szakacs, B. Ivan, and F. Pollreisz (Budapest, Hungary) was devoted to degradative transformations of poly(vinyl chloride) to new potentially useful products. The topic of the second session was *Physical Properties and Blends*. The questions concerning cross-linking and orientation of PVC were considered in the lecture given by M. Gilbert and D.J. Hitt (Loughborough, the United Kingdom). Considerable interest was expressed by the participants in the results reported by D. Wang, D. Parlow, and C.A. Wilkie (Milwaukee, the United States) in their lecture entitled *PVC–Clay Nanocomposites: Preparation, Thermal, and Mechanical Properties.* The questions of retrostructural analysis of PVC particles were considered by R.E. Lukas (Prague, Czech Republic). G.R. Mitchell, T. Gkourmpis, Y.-S. Chiou,

1070-4272/02/7501-0168$27.00 © 2002 MAIK "Nauka/Interperiodica"

W.H. Starnes, and V.G. Zaikov (Williamsburg, the United States; Reading, the United Kingdom) reported on X-ray and neutron scattering study of the local structure of PVC. The lecture given by E.M. Pearce (New York, the United States) and K. Pielichowski (Krakow, Poland) was devoted to preparation and properties of PVC blends with conducting polymers. Compatibilization of blends containing poly(vinyl chloride) and a polyolefin elastomer by block chlorinated polyethylenes was reported by E.A. Eastwood, M.D. Dadmun, N. Pourahmady, and C. Lepilleur (Knoxville, the United States). The next lecture given by D. Garcia, F. Borden, and E. Bouveresse (Pennsylvania, the United States) concerned the problems of identification, quantitation, and qualification of PVC multifunctional additive systems with near-IR spectroscopy and chemometrics.

The topic of the third session was *PVC Degradation and Weathering.* The first lecture given by G.E. Zaikov (Moscow, Russia) and K.S. Minsker (Ufa, Bashkortostan, Russia) reviewed the works conducted in Russia on studying PVC degradation and searching for methods for its stabilization. Results on prediction of pinking of PVC profiles in mild climatic conditions were reported in the lecture given by J.E. Lemaire (Aubiere, France). C. Decker (Mulhous, France) spoke about photostabilization of PVC by protective coatings. The lecture given by J.W. Summers and E.B. Rabinovitch (Cleveland, the United States) was devoted to weatherability of PVC plastics, changing of their mechanical characteristics, and possible stabilization methods. The problems of environmental pollution with PVC wastes and possible protection measures were considered in the lecture entitled *Fate of PVC Polymer and Plasticizers in Landfills* given by I. Mersiowsky, M. Weller (Stuttgart, Germany), and J. Ejlertsson (Stockholm, Sweden).

The last two lectures of this session were devoted to chemiluminescence study of medical PVC degradation and comparison with other techniques [L. Woo, S.Y. Ding, and C.L. Sandford (Stanford, the United States)] and radiation-induced degradation of vinyl chloride/vinylidene chloride copolymers [B.A. Howell, S.I. Ahmed, and D.E. Beyer (Michigan, the United States)]. Finally, the topic of the fourth session was *Thermal Degradation and Stabilization*. I.W. Parsons and R.S. Lehrle (Birmingham, the United Kingdom) reported on HCl quantification in pyrolysis-gas chromatography studies of hydrochlorocarbon polymers. B. Ivan (Hungary) gave in his lecture a critical overview of PVC stabilization mechanisms in the light of recent experimental results. Considerable interest among the participants was generated by a lecture given by M. Edge, H. Chaudhry, and N.S. Allen (Manchester, the United Kingdom), which was entitled *Mechanistic Action of Costabilizers for PVC* and devoted to the mechanism of action of costabilizers including the synergistic and antagonistic effects. In the next lecture, S. Kodali, W. Hood, T. Jennings, and M. Fender (Dower, the United States) reported on highly basic calcium stearate compositions for rigid PVC.

The last three lectures in this session were devoted to the use of phosphite ester compositions for PVC stabilization [D.R. Stevenson, M.E. Harr, and M.R. Jakupca (Dower, the United States)], stabilization of vinyl chloride/vinylidene chloride copolymers using *N*-substituted maleimides [B.A. Howell and J. Zhang (Michigan, the United States)], and, finally, development of a remarkable new class of nonmetallic additives for PVC , "plasticizer thiols," which are simultaneously stabilizers and plasticizers [W.H. Starnes, B. Du, and V.G. Zaikov (Williamsburg, the United States)].

Finally, it follows from the contributions presented at the symposium that, regardless of anything, for example, of well-known environmental problems, the interest in PVC is steadily high, owing to its low cost and unique physicochemical characteristics (note that the annual world output of PVC is about 22 mln tons). Symposium contributions will be published in 2002 in *J. Vinyl Additive Technol*. (the United States).

The titles of all reports presented at the 222nd ACS National Meeting and presenters' names are available from the library of the Institute of Chemical Physics, Russian Academy of Sciences (Moscow, Russia).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Mechanochemical Synthesis of Nanosize Metastable Zirconium Oxide

P. N. Kuznetsov, A. M. Zhizhaev, and L. I. Kuznetsova

Institute of Chemistry and Chemical Engineering, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received June 26, 2001

Abstract—The formation of oxide phases in the course of mechanical activation of amorphous zirconium hydroxide was studied.

Zirconium(IV) oxide–based catalysts for low-temperature isomerization of alkanes are prepared in several prolonged stages including deposition of a precursor and its crystallization, sulfonation, and thermal activation. The catalyst activity is governed by the superacidic properties of the sulfonated surface [1, 2]. An important part is played by the phase composition of zirconium(IV) oxide, which can exist in several crystalline modifications: monoclinic, stable at temperatures of up to 1172°C; tetragonal, stable in the range 1172–2347°C; and cubic, stable above 2347°C. The monoclinic ZrO_2 has low catalytic activity in isomerization and alkylation and has no practical importance as catalyst for these processes, irrespective of the activation temperature [1]. The highest efficiency is exhibited by catalysts based on tetragonal ZrO_2 [1–3].

The tetragonal modification of zirconium(IV) oxide can coexist as a metastable phase with the monoclinic form at low temperatures, if it consists of fine crystallites ($D \le$ ~30 nm [1] or $D \le$ ~10–15 nm [2]). Small particles are stabilized by addition of ~2–3 mol % oxides in the lowest oxidation state (Y_2O_3, Fe_2O_3, Mn_2O_3, and CaO), which form a solid solution on the surface [1, 3–5]. Fine particles can also be stabilized by sulfonation of amorphous zirconium(IV) hydroxide [1–5]. This results in the formation and stabilization of the tetragonal phase upon crystallization in the presence of doping additives. At higher concentrations of dopants (~5 mol %) [5, 6], the cubic modification of zirconium dioxide is stabilized.

Crystallization of the tetragonal zirconium(IV) oxide is a necessary, but insufficient condition for the existence of its catalytic activity. The catalytic activity is exhibited by acidic centers on the catalyst surface. This factor is the most pronounced when Lewis and Brønsted acids are present on the surface simultaneously [5, 7]. The acidity creates a covalent sulfate localized at crystallographic defects of the ZrO_2 tetragonal phase. It has been established in a number of studies that it is the amorphous zirconium(IV) hydroxide that should be sulfonated [1, 3–5]. Samples prepared by direct sulfonation of any crystalline phase of ZrO_2 are virtually inactive [1, 3]. The presence of sulfate ions in crystallization initiates formation of a great number of defects, but no new defects appear in sulfonation in the already formed rigid structures. At the same time, a catalyst can be obtained on the basis of calcined crystalline samples, if they retain a sufficient number of OH groups [4, 7]. High-temperature methods are known to yield a material with very low content of OH^- groups, and, therefore, the activity of such catalysts is poor. Lowering the temperature of sol–gel synthesis allows preparation of a crystalline phase with high concentration of hydroxide ions, the most appropriate for sulfonation and formation of the catalytic activity [4, 6, 7].

It is known that preliminary high-energy mechanical treatment makes it possible to lower the temperature of subsequent chemical processes [8], including solid-phase synthesis of high-temperature oxide catalysts from a reagent mixture [9]. This method enables generation of new kinds of defects and formation of a strongly distorted crystal lattice, which is important for structure-sensitive catalytic reactions [9, 10]. Mechanical activation of hydroxides results in a redistribution of bulk hydroxide groups in favor of single surface groups and closely spaced terminal

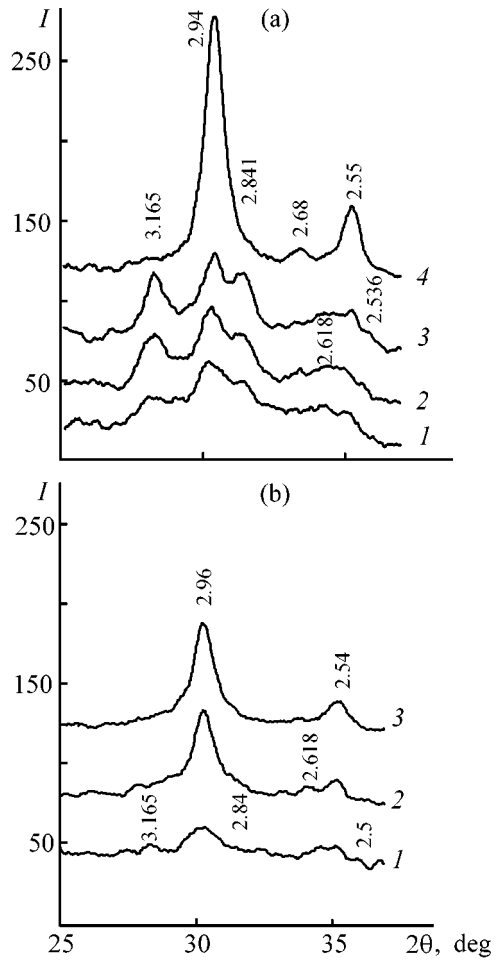

Fig. 1. Diffraction patterns of the fractions of the amorphous zirconium hydroxide mechanically activated in (a) dry and (b) wet regime. (*I*) Intensity and (2θ) Bragg angle; the same for Fig. 3. Treatment time τ (min): (*1*) 0.5, (*2*) 2, (*3*) 5, and (*4*) 15.

groups [10, 11]. A hydroxide "fringe" is formed around particles of oxide minerals, which facilitates sulfonation and formation of superacidic Lewis centers [4, 11] and acid Brønsted protons [5, 10]. Even when the required product is not formed in the course of activation of precursors (oxides or carbonates), the generated defects accelerate the diffusion and interaction of the reagents in the subsequent calcination [9, 12–14]. This makes it possible to lower the synthesis temperature and obtain mechanically activated crystalline products competitive with those produced with precursors prepared by sol–gel technology [11, 14–16].

Thus, there arises practical interest in use of mechanical activation of precursors of zirconium catalysts for lowering the synthesis temperature and enhancing the catalytic activity.

In this study, mechanochemical synthesis of a tetragonal modification of ZrO_2 was performed and the specific features of this process were analyzed.

EXPERIMENTAL

Highly dispersed amorphous zirconium hydroxide was obtained by precipitation from a 15% aqueous solution of $ZrOCl_2$ with 12% aqueous ammonia at room temperature and vigorous agitation. The gels prepared were kept for 3 h and then washed by decantation and on a filter with distilled water to negative reaction for Cl^- ions. The precipitate was dried in air at room temperature and then in a desiccator at 11°C for 15 h. Also, commercial reactive zirconium oxide of pure grade was used.

The mechanochemical activation was performed in an AGO-2 centrifugal-planetary mill for 0.5–22 min. The volume of the steel drums was 150 ml; weighed portion of a material, 3 g; mass of steel milling bodies 3 mm in diameter, 106 g; and load, 60 g. In the "wet" mode of activation, distilled water (3 ml) was poured into each drum. The drums were cooled with water in the course of the operation. Simultaneous grinding in dry mode was performed on an KM-1 lab vibration mill for 0.5–10 h (agate mortar, agate ball 3 cm in diameter, and 3-g weighed portion).

X-ray diffraction patterns were recorded on a DRON-3 diffractometer (Cu_{K_α} radiation, scan rate 1 deg min^{-1}).

An electron-microscopic study was done on a REMMA-202M scanning microscope. The statistical-average size of particles of the material studied was calculated from the specific surface area, as determined by thermal desorption of argon (BET).

The starting zirconium hydroxide prepared by precipitation is virtually completely X-ray-amorphous. Very weak reflections attributable to a monoclinic modification of zirconium dioxide are present in diffraction patterns in some cases. Zirconium hydroxide, having no regular crystal structure, is a mixture of compounds of variable composition $ZrO_n(OH)_{4-2n} \cdot xH_2O$, where $n = 0–2$. The presence of nuclei of the monoclinic phase, which starts crystallizing on heating the given sample even to 250–300°C, is rather probable. Dehydration in subsequent heating in the range 300–500°C leads to the formation of a monoclinic modification of the oxide phase (mainly) and its tetragonal modification (in minor amounts). At higher temperatures, the metastable tetragonal form transforms into a monoclinic oxide form. Calcination at 600–700°C yields virtually pure monoclinic zirconium dioxide.

The mechanical activation initiates fast crystallization of zirconium dioxide at room temperature. Weak diffuse reflections associated with this phase were recorded in diffraction patterns even after 30 s of treatment in a planetary mill (Fig. 1a, curve *1*). Further activation leads to recrystallization of the amorphous sample. Two crystalline modifications of ZrO_2 are formed, with the amount of the monoclinic phase growing faster (Fig. 1a, curves *1*–*3*). A sample treated for 5 min is a mixture of the monoclinic (d = 3.165, 2.841 Å, ICDPS, 24-1165) and tetragonal (d = 2.94 Å, ICDPS, 17-923) forms in 70 : 30 percentage ratio (Fig. 1a, curve *3*). The nearly equal intensities of the main reflections are a consequence of the higher symmetry of the tetragonal phase.

Figure 2 shows, according to the electron-microscopy data, the fractional composition of the samples studied. The differential characteristic of the starting amorphous zirconium hydroxide peaks around 3–5 μm. Its calcination in the range 600°C yields coarse particles of monoclinic ZrO_2 (with the peak in the differential characteristic shifted to 8–10 μm). The mechanical activation shifts the distribution maximum to the nanosize region, with mainly tetragonal zirconium dioxide formed.

Diffuse, but strong reflections, attributable solely to the tetragonal modification, are present in the diffraction pattern of the fraction treated for 15 min (Fig. 1a, curve *4*, main peak with d = 2.96 Å). The monoclinic phase is virtually absent. This means that further crystallization of the amorphous phase and recrystallization of the already formed monoclinic zirconium dioxide into the tetragonal form take place. The crystallite size of the tetragonal phase in this sample, calculated from the reflection broadening by the Debye–Scherrer formula, does not exceed 16 nm (see the table). It is interesting to note that the specific surface area of the samples decreases with increasing activation time, i.e., in this case the growth rate of the crystals is higher than their grinding rate.

The obtained result can be accounted for by the removal of "hydroxyl" water via local heating caused by collisions of milling bodies. However, the estimate using indirect data and the results of a calorimetric study shows that the local temperatures occurring in planetary mill treatment are low (not higher than 400–650°C [14]). For a monoclinic–tetragonal zirconium dioxide phase transition to occur, a temperature higher than 1172°C is necessary. The occurrence of that high local temperatures would cause a considerable warming-up of the material and grinding bodies. However, the temperature of the sample increases in the course of treatment only slightly.

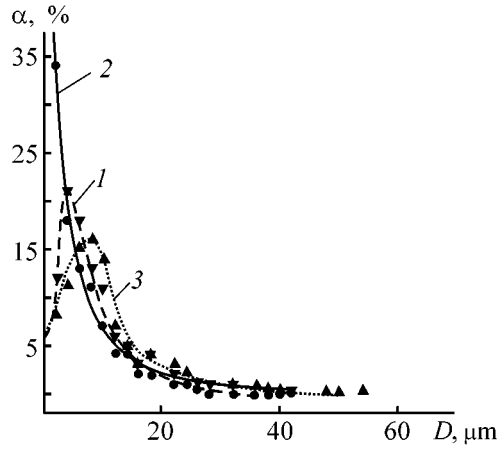

Fig. 2. The fractional composition of the samples studied (according to electron-microscopic data). (α) Particle fraction and (*D*) particle size. Hydroxide: (*1*) starting; (*2*) mechanically treated for 5 min, and (*3*) calcined at 600°C.

Figure 1b shows diffraction patterns of zirconium hydroxide samples mechanochemically activated in wet mode. A more condensed medium favors better removal of heat from the local points of impact interaction, which must lead to weaker crystallization and recrystallization of zirconium dioxide, if these processes are caused by local heating of the material. Nonetheless, the peaks associated with monoclinic (d = 3.165 Å) and tetragonal (d = 2.96 Å) zirconium dioxide are clearly seen in the diffraction patterns even after 2 min of treatment (Fig. 1b, curve *1*). Evidently, the tetragonal phase dominates, although its reflections are considerably broadened. Only trace amounts of monoclinic modification are recorded after 5 min of mechanical activation. At the same time, the reflec-

Dispersity of products obtained upon mechanical activation of amorphous zirconium dioxide*

15	〃	–	–	14

* S_{sp} is the specific surface area, D the statistical-average crystallite size, and D_{tet} the crystallite size of the tetragonal phase of ZrO_2.

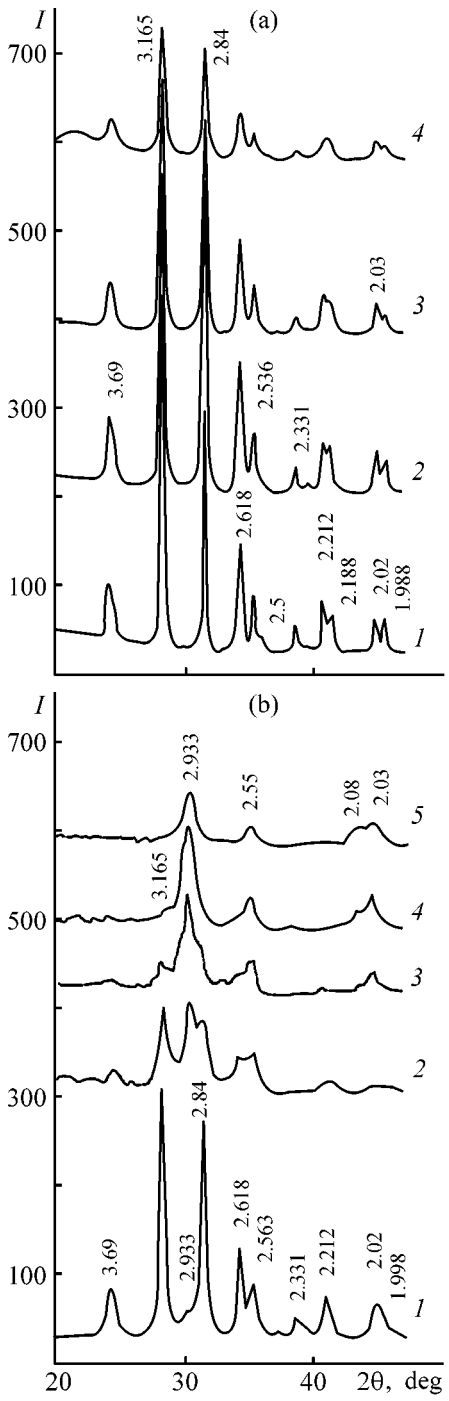

Fig. 3. Diffraction patterns of the fractions of the reactive zirconium dioxide treated in dry regime in (a) vibrational and (b) centrifugal-planetary mill. Treatment time (τ): (a) (*1*) 0.2, (*2*) 2, (*3*) 4, and (*4*) 9 h; (b) (*1*) 0.5, (*2*) 2, (*3*) 5, (*4*) 15, and (*5*) 22 min.

tions of the tetragonal modification are markedly intensified (d = 2.96 Å; Fig. 1b, curve *2*). After 15 min of treatment, the fraction consists of virtually pure zirconium dioxide of the tetragonal modification (Fig. 1b, curve *3*).

Taking into account the physical broadening of diffraction peaks shows that in the course of wet grinding of amorphous hydroxide the crystallite size of the tetragonal oxide phase increases from 7–9 to 14–15 nm (see table).

Thus, mechanical activation in wet mode, compared with the dry method, does not inhibit formation of crystalline phases essentially. Only the yield of the monoclinic zirconium dioxide is diminished (Fig. 1a, curve *3*; Fig. 1b, curve *2*). It may be concluded that it is this modification that is formed owing to the local rise in temperature upon collisions. By contrast, the tetragonal modification is formed under the action of impact pulses, as energy-favorable more closely packed lattice, and is stabilized as a result of the decreasing crystallite size. In the wet mode, grinding is facilitated, since the disjoining effect of a polar solvent impairs the crystallite strength. Brittle fracture dominates over plastic deformations, thus allowing preparation of more dispersed materials. The statistical-average size of the particles, as calculated from the specific surface area, virtually coincides with the value obtained from X-ray diffractometry (see table).

Of interest is the fact that the monoclinic modification of zirconium dioxide, formed in earlier stages, recrystallizes upon mechanical activation to give a tetragonal form. To confirm the occurrence of this process under the given conditions, reactive zirconium dioxide preliminarily calcined at 1000°C was taken as a starting material. The initial phase is represented solely by the monoclinic modification of ZrO_2 (Fig. 3a, curve *1*). All the reference peaks (down to 2% intensity) are excellently recorded. Already after 30 s of mechanical treatment, the intensity of the reflections of the starting oxide of this phase decreases and their broadening increases sharply. After only 2 min of mechanical activation, the diffraction pattern changes dramatically (Fig. 3b, curve *2*). The reflection intensities of the monoclinic phase diminish by more than an order of magnitude. The reflections are substantially broadened, which is indicative of more finely crystalline and(or) more defective structure, and a weak reflection associated with the new phase is observed in the range 2θ = 30–31° (Fig. 3b, curve *1*). A strong reflection with d = 2.933 Å, belonging to the cubic modification of zirconium dioxide, is revealed. The peak asymmetry points to the presence of the tetragonal phase, even if in minor amounts as compared with the cubic phase. The new phase exists in an amount of up to 40% relative to the main phase. After more prolonged activation, the presence of the monoclinic modification decreases to trace amounts

(Fig. 3b, curves *3* and *4*). After 15 min of treatment, the phase transition of the stable monoclinic oxide to the metastable cubic ZrO_2 is virtually complete. The cubic crystal system is even more closely packed lattice than the tetragonal and, especially, monoclinic lattices. Its formation under intensive energy supply to the system is reasonable. Further mechanical treatment (for 22 min) results in decreasing intensity and broadening of the reflections, which is a common result of mechanical activation of solids [8] (Fig. 3b, curve *5*).

Grinding of zirconium dioxide in a KM-1 mill for several hours leads to a significant decrease in the intensity of reflections in the diffraction patterns of the corresponding fractions (Fig. 3a, curves *2*–*4*). After 9 h of treatment the size of the coherent domains decreases from 1 μm to 25–30 nm. Further treatment yields even finer crystallites; however, no new phase is recorded in the process. Apparently, the rate of energy supply is insufficient for recrystallization of the monoclinic oxide.

In [10], the previously noted formation of a metastable cubic structure in the course of mechanical activation of hematite and lanthanum manganite was interpreted from the standpoint of a cooperative distortion of the sublattice of oxygen octahedra as a result of a change in the oxidation state of cations. In our case, the high abrasiveness of the starting material leads to the presence of a noticeable admixture of metallic iron ($d = 2.03$ Å, ICDPS, 6-696) and austenite (d = 2.08 Å, ICDPS, 31-619), originating from the walls of drums and stainless-steel milling bodies (Fig. 3b, curve *5*). This may lead both to partial reduction of cations Zr and to incorporation of iron into the crystal lattice of zirconium dioxide. However, an explanation in terms of the scaling factor seems to be preferable.

The known methods for stabilization of tetragonal zirconium dioxide at temperatures below the enantiotropic transition point involve introduction of doubly and triply charged metal cations or anions (SO_4^{2-} and WO_4^{2-}) into a precursor before crystallization [1–7]. In calcination, these additives hinder crystal growth owing to the formation of a solid solution on the particle surface or to blocking of the surface active centers. Under these conditions, the tetragonal phase exists as a metastable phase, if the size of its crystallites does not exceed 30 nm [1–3, 5, 6]. Consequently, a polymorphism of zirconium oxide, caused by the scaling factor, can be suggested. Sufficient energy supply (heating) results in the formation of nuclei of a new phase and isometric growth of crystallites. The particles are small in size and possess high surface energy. Under these conditions, the more energy-favorable crystals of higher symmetry (cubic) are preferentially formed.

With increasing crystallite size, the free surface energy decreases and the crystal growth directions become differentiated. Accelerated crystal growth occurs along the principal planes. The tetragonal modification becomes more energy favorable, and the cubic structure is replaced by the tetragonal structure.

Further increase in the crystallite size and decrease in the free surface energy in the course of crystallization allow formation of tabular crystals of the monoclinic crystal system, which are stable up to 1172°C. The process is monotropic at low temperatures.

The mechanical activation allows initiation of zirconium oxide crystallization from amorphous hydroxide at low temperatures and, at the same time, impedes growth of crystals exceeding a certain size. Two processes occur in the opposite directions. Their competition is responsible for the phase composition of the forming oxide phase. In the same way, the enantiotropic transition of monoclinic into tetragonal modification can be achieved without introduction of any doping additives at low temperature. The ΔH values of the polymorphous transition cubic $\rightarrow$ tetragonal $\rightarrow$ monoclinic zirconium dioxide are –13 and –8.4 kJ mol^{-1}, respectively. The energy supply of 10–60 W g^{-1}, provided in mechanical activation, gives the necessary energy for a reversible phase transition [14]. After the treatment is complete, the crystal growth at low temperature is impossible, and the given state is frozen in the form of a metastable phase.

CONCLUSION

Nanosize tetragonal zirconium hydroxide (metastable below 1172°C) was obtained by mechanical activation of amorphous zirconium hydroxide in a centrifugal-planetary mill at room temperature. The tetragonal ZrO_2, metastable at low temperatures, undergoes fast crystallization with the formation of an intermediate monoclinic modification. The possibility of recrystallization of the monoclinic phase into the cubic and tetragonal phases in the course of mechanical treatment is demonstrated. The phase stabilization is due to competition of crystallization and grinding. The size of the forming crystallites does not exceed 16 nm.

Abstract—The modifying action of various nonpolar reagents and their mixtures with surfactants on physical and mechanical properties (humidity resistance, degree of hydrophobization, and dynamic strength) of granulated potash fertilizers was studied.

In order to extend the assortment of new effective modifying agents for granulated potassium chloride, having high adhesion and well protecting potash fertilizers to increase their humidity resistance and strength and make longer the preservation of their granulometric composition, the modifying action of nonpolar water-repellent reagents of various types and their formulations with surfactants on granulated potash fertilizers was studied.[1]

As nonpolar reagents were used intermediate and by-products and wastes of chemical industry, containing various hydrocarbons: paraffin-naphthenes—low-molecular polyethylene, paraffin slack wax, slop wax fraction, petrolatum, and oily fractions I–III; terpenes—neutral rosin oil; and aromatic hydrocarbons—extract of phenolic oil purification. As surfactants were used higher aliphatic amines and carboxylic acids [1, 2].

We determined physicochemical characteristics of granulated potash fertilizers as it was done previously [1]: degree of hydrophobization, from moisture sorption; dynamic strength, from abradability; induction period of dissolution, from electrical conductivity; and hygroscopicity, after Pestov [3].

Nonpolar reagents are organic compounds that contain no functional groups, cannot dissociate, and are rather difficultly soluble in water [4]. According to their chemical composition, they are mainly paraffins, naphthenes, terpenes, and aromatic hydrocarbons with weak intermolecular interaction and low free surface energy. For example, the surface tension at the interface with air is 18–23, 24–29, and 30–36 mJ m^{-2} for paraffin, naphthene, and aromatic hydrocarbons, respectively. Such substances with low cohesion energy can spread over surfaces with higher energy (e.g., granulated potash fertilizers), thus imparting hydrophobic properties to a product under treatment.

As evident from Table 1, the use of nonpolar reagents makes it possible to reach almost the same parameters (50% degree of hydrophobization and less than 10% abradability of KCl) as in the case when a granulated fertilizer is conditioned with such a typical water-repellent agent as amine [1]; however, the expenditure of the reagent is high (3000 – 4000 g ton^{-1}). Further increase in the expenditure does not improve the physical and mechanical characteristics of a granulated fertilizer any more.

Paraffin-naphthene hydrocarbons are most effective with respect to modifying action, followed by terpenes and aromatic hydrocarbons. In view of the absence of solidophilic groups in molecules of nonpolar compounds, they cannot be strongly attached to the potassium chloride surface. Their adsorption is due to weak Van der Waals forces and has only physical nature. Therefore, hydrocarbons create on a KCl surface a sorption coating, which is, as the practice demonstrates, not strong under dynamic conditions, and has a number of defects and cracks of the hydrocarbon layer, mainly formed in transportation and transshipping of fertilizers.

We demonstrated that the strength of hydrocarbon attachment considerably increases in the presence of such surfactants as amines or carboxylic acids. The method of IR spectroscopy was applied to determine

the strength of hydrocarbon attachment to the surface of KCl granules. The spectra of hydrocarbons (with paraffin slack wax as an example) contain absorption bands at 3000–2800 cm^{-1}, associated with stretching vibrations of the CH bond, and also at 1400–1300 and 700 cm^{-1}, related to bending vibrations of CH bonds, which additionally confirms the composition of paraffin slack wax as a mixture of hydrocarbons [5]. To determine hydrocarbons quantitatively, we used the area of a composite absorption band in the range 3000–2800 cm^{-1}. This range includes peaks of stretching vibrations of methyl groups at 2962 and 2872 cm^{-1} and peaks of stretching vibrations of methylene groups at 2926 and 2853 cm^{-1}. We dem-

onstrated that approximately 30% of the total amount of hydrocarbon is removed from KCl granules treated with paraffin slack wax even after the first washing with hexane, whereas in the presence of amine, hydrocarbons almost completely remain on the surface of potassium chloride. Thus, the presence of a surfactant results in higher strength and elasticity of a hydrophobic coating. In this case, a feedback also exists: not only surfactants affect the creation of a strong hydrophobic amine-hydrocarbon film, but also nonpolar compounds promote amine adsorption onto the surface of potassium chloride [4]. For example, the adsorption of amine on KCl grains of size –1.6 + 1 mm increases by a factor of 1.1–1.8 in the presence of hydrocarbon, and the amount of firmly fixed amine, by more than a factor of 2.

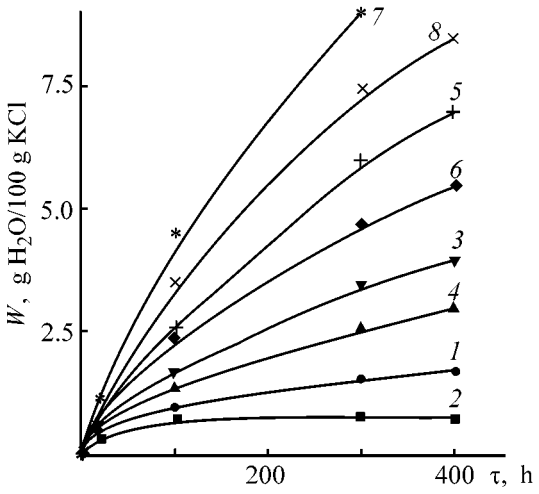
The role of a surfactant consists in the creation of a preliminary hydrophobic base layer, with its hydrocarbon part facing outwards, on the mineral surface by means of electrostatic or chemical forces. Hydrocarbons further interact with this layer to cover granules with an additional hydrophobic film of a nonpolar modifying agent. Naturally, this enhances the water-repellent effect owing to the concentration of the nonpolar reagent in the zone where the adsorbed layer of a modifying surfactant is situated (Tables 2 and 3).

The above data show that it is sufficient to add a minor quantity of a surfactant to a formulation in order to achieve a reliable protection of the surface of granulated potash fertilizers from sorption of moisture. When amine is used as a surfactant, the optimal amine : hydrocarbon and acid : hydrocarbon ratios are 1 : (10–20) and 1 : (5–10), respectively. Ternary mixtures containing a hydrocarbon, amine, and an acid in (15–40) : 1 : 1 ratio have the greatest water-repellent capacity (Table 2). Thus, at a total expenditure of such a formulation of 1500 g ton^{-1} and the 30 : 1 : 1 ratio of the components, or, in other words, at an expenditure of 1400 g of hydrocarbon per 1 ton of a granulate potash fertilizer (oily fraction II, in particular), and 50 g of amine and acid each, it is possible to achieve an approximately 70% degree of hydrophobization of the surface of floatation KCl and a decrease in its abradability to 3–4% against 22% for untreated samples. Further increase in the surfactant expenditure is unprofitable, as this does not improve noticeably the physical and mechanical properties of the granulated fertilizer. To provide a noticeable hydrophobization of a halurgic granulated fertilizer, a higher expenditure of modifying formulations is required (Table 3).

We found that carboxylic acids partially replace amine and thus reduce its expenditure. Furthermore, addition of the acids raises the solubility of amines owing to the formation of ionized complexes [2], and, consequently, makes more dilute amine–hydrocarbon formulations and extends their flowability ranges, which ensures a more even distribution of surfactants in the bulk of solutions and their stronger attachment to the fertilizer surface. The hygroscopicity of a granulated potash fertilizer is largely determined by the presence of readily soluble magnesium and calcium chlorides, and carboxylic acids transform these ions into insoluble forms. All this intensifies the hydrophobization of granulated potash fertilizers in the presence of carboxylic acids.

The efficiency of a protective hydrophobic film based on hydrocarbons and surfactants is reflected upon not only the moisture sorption, but also the solubility of granules in water. For example, the induction period of dissolution of modified granules is 20–30 s, in contrast to untreated samples, which are dissolved instantaneously.

The physical and mechanical parameters of potash granules strongly depend on the hygroscopicity of a product. Potash fertilizers are known to be hygroscopic substances [3]. Strong condensation of moisture on fertilizer grains starts above the hygroscopic point, and a layer of saturated solution (external diffusion) is formed on the surface of crystals. Initially, only layers directly bordering moist air participate



Moisture absorption W of KCl samples vs. time τ. KCl sample: (*1*), (*3*), (*5*), and (*7*) initial; (*2*), (*4*), (*6*), and (*8*) modified with a mixture fraction II : AM = 20 : 1. Air humidity (%): (*1*) and (*2*) 76; (*3*) and (*4*) 84.5; (*5*) and (*6*) 88.5; (*7*) and (*8*) 100.

in the moisture sorption. In this case, the absorbed moisture is not localized, but spreads over the bulk of the fertilizer under the action of capillary-diffusion forces, penetrating in pores of potassium chloride granules (internal diffusion) and acting as a propping agent inside them, which impairs the mechanical strength of granules and leads to their crushing into minute fragments. A change in the temperature mode of storage promotes crystallization processes with the formation of an external crystalline skeleton with high salt adhesion between fragments. It is the crystallization processes with the formation of salt bridges between fragments that give rise to strong phase contacts, which cement mineral fragments and lead to caking of the product and its transformation into a monolith. Therefore, moisture and temperature should be considered key factors, which strongly affect the properties of granulated fertilizers.

Table 4. Effect of various modifying agents on hygroscopicity parameters of granulated potash fertilizers (initial humidity of samples 0.5%)

System	Expenditure of modifying agent, g g^{-1}	h_0, %	Q, mg g^{-1} h^{-1}	K
KCl	–	70.5	0.66	2.24
KCl + addition:				
AM	500	72.0	0.60	2.06
OA	1000	71.0	0.63	2.16
AM + OA	1000	71.0	0.63	2.00
fraction II	2000	73.0	0.58	1.90
fraction II + AM	1500	74.0	0.51	1.36
fraction II + AM + OA	1500	74.0	0.51	1.36

The time dependence of the moisture absorption for modified samples at varied relative air humidity is shown in the figure in comparison with that of the initial samples. It is evident that, with increasing air humidity, the moisture absorption markedly grows for all KCl samples, which is especially pronounced at long exposures of the samples. For example, a change in humidity from 76 to 100% results in a threefold increase in the moisture absorption within a day (from 0.3 to 0.9 g H_2O per 100 g KCl), and an increase by a factor of 8 within 12 days (from 0.8 up to 6.5 g H_2O). However, a hydrophobic coating based on a surfactant and hydrocarbons is stable at any air humidity, 100% included, i.e., samples conditioned by the formulations absorb much lesser amount of moisture than untreated samples, and this difference becomes even greater with time.

The same refers to the effect of the ambient temperature on the moisture absorption by granulated potash fertilizers (Tables 2 and 3). For example, a 10°C increase in temperature (from 25 to 35°C) results in a decrease in the waterproofing effect by a factor of 3–10 for both floatation and halurgic granulated fertilizers. However, the negative temperature effect is greater for the halurgic granulated fertilizer, which requires a higher expenditure of modifying formulation to achieve a waterproofing effect at elevated temperatures. At 25°C, 1500 g ton^{-1} of a formulation based on oily fraction II and a surfactant ensures a 10% degree of hydrophobization, whereas at 35°C this effect is achieved at higher (3000 g ton^{-1}) expenditure of the formulation (Table 3).

Let us consider how the hygroscopicity of granulated potash fertilizers changes under the action of various modifying agents. The sample hygroscopicity is usually characterized by the hygroscopic point h_0 (relative air humidity at which a substance neither loses nor absorbs moisture); coefficient of moisture absorption rate, K (amount of moisture absorbed by unit surface area within unit time at 1% difference between the relative humidity of air and the hygroscopic point of a substance); and moisture absorption rate at 100% relative air humidity, Q. These parameters of granulated potash fertilizers, as determined by the "desiccator" technique after Pestov [3], are shown in Table 4. The expenditure of modifying formulations was selected so as to ensure, whenever possible, equal degrees of hydrophobization of granulated potash fertilizers. As seen, the modifying formulations

under consideration to a greater or lesser extent promote an increase in the hygroscopic point of KCl and slow down the moisture absorption. However, waterproofing formulations based on hydrocarbons and surfactants provide the greatest change in the indicated parameters. For example, a mixture of oily fraction II with amine and acid ensures a 4% increase in the hygroscopic point of a granulated potash fertilizer and a decrease in the coefficient of moisture absorption rate to 1.36 against 2.24 for untreated samples. In this case, the moisture absorption at 100% humidity decreases to 0.51 mg g^{-1} h^{-1} against 0.66 mg g^{-1} h^{-1} for untreated samples.

CONCLUSION

Treatment of both potash floatation and halurgic granulated fertilizers with anhydrous modifying formulations based on surfactants (higher aliphatic amines and carboxylic acids) and nonpolar reagents of predominantly paraffin-naphthene series results in a decrease in KCl hygroscopicity, which makes it possible to prolong the useful life of granulated potash fertilizers under conditions of temperature changes and high relative air humidity.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Manufacture and Processing of Titanium Tetrafluoride

E. G. Rakov and A. V. Grunskii

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received February, 15, 2001

Abstract—Combustion temperatures in fluorination of titanium dioxide and pyrohydrolysis of titanium tetrafluoride and tetrachloride in H_2–air, H_2–O_2, oxygen–hydrocarbon, and NH_3–HF–O_2 flames were calculated using the "Chemical workbench" software. Dependences of the temperatures on reagent ratios were determined.

Sulfuric acid and chloride methods for ilmenite ore processing are widely used on a global scale [1]. In order to produce titanium and its compounds, a method for fluorination of titanium-containing ores (with ammonium hydrofluoride, in particular) has been proposed recently [2–4].

The processes occurring in a self-sustaining flame combustion mode are known to be widely used in the technology of uranium fluorides [5–9]. Vacant facilities released in the conversion of the uranium industry can be used for production of rare metals by the fluorination method [10, 11]. Therefore, titanium-containing ores could be treated in a flame. Thus, a thermodynamic analysis of flame processes involving rare metals is topical. Comparison of such quantities as combustion temperatures of, e.g., uranium tetrafluoride and titanium oxide, suggests that industrial flame reactors can be used for manufacture of titanium tetrafluoride. A comparison of temperatures developed in reduction or pyrohydrolysis of uranium hexafluoride with the corresponding temperatures for titanium hexafluoride will allow us to evaluate the possibility of utilization of apparatus and processes created for uranium compounds in manufacture of titanium dioxide.

As found previously, flame reactors similar to those used in the uranium technology can be applied to fluorination of substances with combustion temperatures not lower than 1200–1300K [12].

The aim of this study was to calculate the adiabatic combustion temperatures for the reactions of production and processing of titanium compounds. The "Chemical workbench" software[1] was used in these calculations.

The calculated adiabatic temperatures of TiO_2 combustion for the initial temperature of 300K and various starting $F_2 : TiO_2$ N molar ratios in F_2 atmosphere are given below:

N	T_c, K	N	T_c, K	N	T_c, K
2.0	2305	2.8	2306	3.6	2218
2.2	2306	3.0	2306	3.8	2025
2.4	2306	3.2	2306	4.0	1837
2.6	2306	3.4	2306		

It is seen that high combustion temperatures are developed, with 100% titanium dioxide conversion being attainable even at 300 K.

The reaction of TiO_2 and HF is unusable for production of TiF_4, since the product yield is very low even in an excess of HF (3.6% at $HF : TiO_2 = 6.0$). Furthermore, this reaction is reversible and a decrease in the temperature of the reaction gases results in hydrolysis of the forming TiF_4.

Fluorination with NH_4HF_2 is more efficient since it can be carried out in such a way that H_2O vapors will be removed in the stage of NH_4TiF_5 or $(NH_4)_2TiF_6$ formation. However, it is difficult to calculate the equilibrium of the process since the required data are unavailable. Tentative calculations show that flame processes are unusable in this process.

Natural titanium raw materials are $FeTiO_3$ and $CaTiO_3$. The combustion temperatures of these compounds cannot be calculated owing to the lack of the required data. However, evaluations indicate a high conversion in the F_2 atmosphere, with the adiabatic combustion temperatures falling within the same range as those for TiO_2 fluorination. Calcium and iron fluorides are nonvolatile and, consequently, they would not contaminate TiF_4 to any appreciable degree.

Fluorination is only the initial stage of processing of titanium raw materials. A major part of TiF_4 or ammonium fluorotitanates must be converted to TiO_2, which can be done using pyrohydrolysis reactions. For comparison, we considered similar processes of titanium dioxide production from titanium tetrachloride, which is widely used in industry [13–16].

The temperatures developed in pyrohydrolysis of $TiCl_4$ (curve *1*) and TiF_4 (curve *2*) to TiO_2 in the flame of a burning stoichiometric H_2–O_2 mixture can be judged from Fig. 1a. It is evident that, at TiX_4 concentrations below 24%, the combustion temperature is 2304 K (melting point of TiO_2). Only further increase in the TiX_4 concentration results in a decrease in the combustion temperature. The linear part seems to correspond to the formation of a mixture of solid and melted TiO_2. The combustion in a hydrogen–air mixture (curves *3* and *4*) involves appreciably lower combustion temperatures.

According to our calculations (Fig. 2), complete conversion of TiF_4 in TiO_2 is achieved at the combustion temperatures if the $H_2 : O_2$ ratio is 2 : 1 and TiF_4 content in gaseous mixture is not greater than 10%. However, for greater $H_2 : O_2$ ratios, curves of TiO_2 yield against TiF_4 concentration have maximums attributable to the formation of additional products, TiF_3 in particular.

As follows from the calculations, the yield of TiO_2 decreases when $TiCl_4$–H_2–O_2 is diluted with hydrogen, because of the increasing $TiCl_3$ fraction.

With the TiF_4–N_2–O_2–H_2 mixture diluted with hydrogen, maximums appear in dependence of the TiO_2 yield on TiF_4 concentration, and, therefore, the composition of products changes: TiF_3 yield grows with increasing H_2 content.

Since the processes of TiF_4 and $TiCl_4$ pyrohydrolysis are rather similar, we might expect that the known features of the latter process can be extended to the pyrohydrolysis of TiF_4.

The pyrohydrolysis of the products of fluorination of titanium-containing raw materials with NH_4HF_2 is complicated by the presence of NH_3 and HF in the starting mixture. Nevertheless, high temperatures are developed in the nO_2 : (HF + NH_3) flame (HF : NH_3 = 1 : 1). The maximum combustion temperature of 2594 K is reached at n = 0.78. Introduction of TiX_4

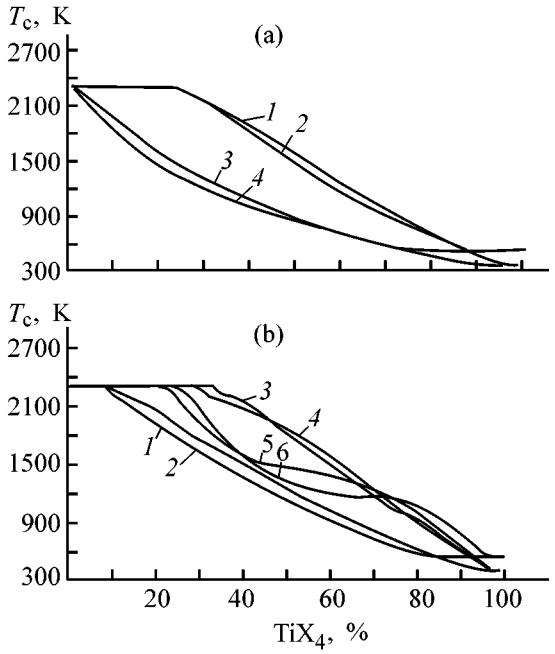

Fig. 1. Pyrohydrolysis combustion temperature T_c vs. [TiX_4] concentration in starting gas mixture. Mixture composition: (a) (*1*) $TiCl_4 + H_2 + O_2$ ($H_2 : O_2$ = 2.05), (*2*) $TiF_4 + H_2 + O_2$ ($H_2 : O_2$ = 2.05), (*3*) $TiCl_4 + N_2 + O_2 + H_2$ ($N_2 : O_2 : H_2$ = 4 : 1 : 2.12), (*4*) $TiF_4 + N_2 + O_2 + H_2$ ($N_2 : O_2 : H_2$ = 4 : 1 : 2.12); (b) (*1*) $TiF_4 + NH_3 + HF + O_2$ ($NH_3 : HF : O_2$ = 1 : 1 : 0.78), (*2*) $TiCl_4 + NH_3 + HF + O_2$ ($NH_3 : HF : O_2$ = 1 : 1 : 0.78), (*3*) $TiF_4 + CH_4 + O_2$ ($CH_4 : O_2$ = 0.55), (*4*) $TiCl_4 + CH_4 + O_2$ ($CH_4 : O_2$ = 0.55), (*5*) $TiCl_4 + C_2H_2 + O_2$ ($C_2H_2 : O_2$ = 0.7), (*6*) $TiF_4 + C_2H_2 + O_2$ ($C_2H_2 : O_2$ = 0.7).

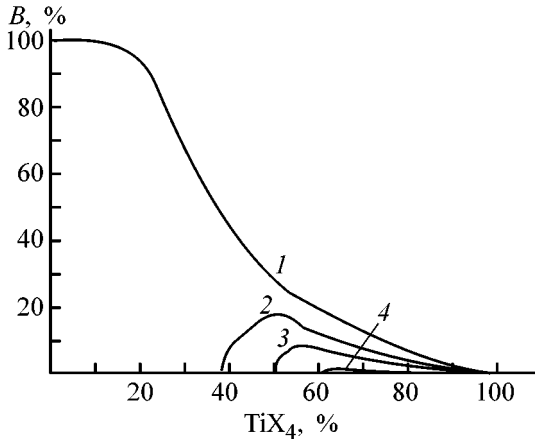

Fig. 2. TiO_2 yield B vs. TiF_4 concentration in starting H_2–O_2 gas mixture at the combustion temperature. $H_2 : O_2$ ratio: (*1*) 2 : 1, (*2*) 10 : 3, (*3*) 5 : 1, and (*4*) 10 : 1.

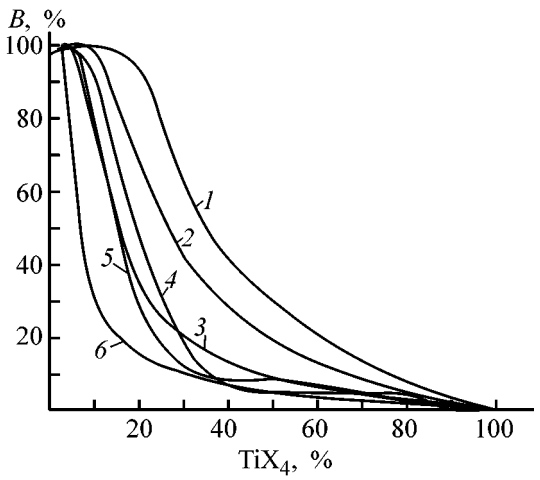

Fig. 3. TiO_2 yield B vs. TlF_4 concentration in starting gas mixtures at combustion temperature. Mixture composition: (*1*) $TiF_4 + CH_4 + 2O_2$, (*2*) $TiF_4 + CH_4 + 4O_2$, (*3*) $TiF_4 + CH_4 + 10O_2$, (*4*) $TiF_4 + C_2H_2 + 2O_2$, (*5*) $TiF_4 + C_2H_2 + 4O_2$, and (*6*) $TiF_4 + C_2H_2 + 10O_2$.

lowers the combustion temperature (Fig. 1b, curves *1* and *2*). In this case, a sharp decrease in temperature to 2304K occurs in the TiX_4 concentration range 0.001–0.005%. Further, the temperature remains unchanged up to addition of 8 vol % TiX_4 to the gaseous combustion mixture.

According to our calculations, the oxygen content in an NH_3–HF–O_2 mixture appreciably affects the TiO_2 yield B at a 20% TiF_4 concentration in this mixture:

n	1	2	4	10
T_c, K	1851	1531	1167	767
B, %	84.2	67.8	46.9	24.1

It is seen that TiO_2 yield decreases with increasing O_2 content in the NH_3–HF–O_2 mixture, because the reaction is not completed and a noticeable amount of titanium remains in the form of a tetrafluoride.

It is of interest to find out whether H_2 can be replaced with cheaper hydrocarbons. The results obtained in a study of TiX_4 in CH_4–O_2 and C_2H_2–O_2 mixtures are shown in Fig. 1b (curves *3*, *4*, and *5*, *6*, respectively). In these systems, as in the preceding cases, an increase in the TiX_4 concentration in hydrocarbon–O_2–TiX_4 mixtures results in a decrease in the combustion temperature.

The dependence of TiO_2 yield on TlF_4 concentration in hydrocarbon–O_2 mixtures is shown in Fig. 3 for various O_2 contents. It is seen that the TiO_2 yield decreases with increasing O_2 content because of the TiF_3 formation. The yield of TiO_2 reaches 100% if no more than 17 vol % TiF_4 is added to a CH_4–nO_2 (n = 2) mixture.

For comparison, we again consider the system containing $TiCl_4$. The calculated TiO_2 yields in hydrocarbon–O_2–50% $TiCl_4$ mixtures are shown below:

$C_2O_2 : O_2$	1 : 2	1 : 4	1 : 10
T_c, K	2044	1926	1681
B, %	16.1	40.1	71.4
$CH_4 : O_2$	1 : 2	1 : 4	1 : 10
T_c, K	1711	1898	1576
B, %	36.3	59.6	80.7

It is evident that TiO_2 yield grows with increasing O_2 content in the mixtures. In this case, $TiCl_4$ is converted incompletely to TiO_2 owing to the lack of oxygen, and a substantial amount of titanium remains in the tetrachloride.

Therefore, the calculations show that flame processes can be used, in principle, in fluorination of titanium raw materials with F_2 and also in pyrohydrolysis of TiF_4 or ammonium fluorotitanates to TiO_2. In these processes, apparatus similar to those employed in the uranium technology can be used. This conclusion was confirmed by an experimental study [17].

CONCLUSIONS

(1) Adiabatic temperatures of TiO_2 combustion in the F_2 atmosphere were determined for various ratios of these components.

(2) The combustion temperatures and yield of TiO_2 in TiF_4 pyrohydrolysis in a H_2–O_2 flame were calculated. It is shown that titanium dioxide is not virtually formed in a great excess of H_2, and the process yields TiF_3.

(3) The combustion temperatures and TiO_2 yield were calculated for TiF_4 pyrohydrolysis in the H_2–air flame. It is shown that the yield of TiF_3 grows with increasing hydrogen concentration in the TiF_4–N_2–O_2–H_2 system, and TiO_2 is scarcely formed under a great excess of hydrogen.

(4) The combustion temperatures and TiO_2 yield for the case of TiF_4 combustion in NH_3–HF–O_2 and also in hydrocarbon–O_2 flames were calculated. It was concluded that the greater the oxygen content in TiF_4–NH_3–HF–O_2 system, the larger the residual amount of titanium in the tetrafluoride. Introduction of a moderate amount of TiF_4 into the hydrocarbon–O_2

flame results in complete conversion of titanium tetrafluoride to TiO_2.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Modeling of Thermodynamic Properties and Fusion Diagrams of Ternary Oxosulfide Systems

AO Institut Gipronikel', St. Petersburg, Russia

Received August 23, 2001

Abstract—Three different approximations are used to determine the thermodynamic properties of components and fusion diagrams of ternary oxosulfide systems FeS–FeO–Cu_2S and FeS–FeO–Ni_3S_2. The coordinates of eutectic points and eutectic temperatures are obtained, and equations for calculating the thermodynamic activities of the components are derived for the system FeS–FeO–Cu_2S.

Oxosulfide systems are widely used to manufacture copper and nickel. Data on ternary systems can be, in principle, obtained on the basis of those on binary systems. Examples of successful solution of this problem were given in [1, 2]. Results of calculations of fusion diagrams were reported in [3, 4], where a good agreement between the calculated and experimental melting points and compositions was obtained for eutectic systems. Following the same procedure, but using more complex model concepts, we obtain data on thermodynamic properties and fusion diagrams of ternary systems. The principal difficulty of analysis consists in that the available experimental data for binary systems are frequently unreliable and contradictory, and lacking at all for many systems [5, 6].

System FeS–FeO–Cu_2S. Let us consider, as a first approximation, calculations for ideal systems. We denote the components of the system FeS–FeO–Cu_2S by numbers 1, 2, and 3, respectively. For a binary ideal system

$$RT\ln x_i = T\Delta S_i^{\mathrm{m}} - \Delta H_i^{\mathrm{m}}, \quad (1)$$

where ΔH_i^{m} and ΔS_i^{m} are the enthalpy and entropy of melting of i-th component, x_i its solubility at temperature T (K), and R the universal gas constant.

For a binary system, the eutectic temperature can be calculated by equating the expressions for the two liquidus lines in the eutectic system:

$$T^{\mathrm{eut}} = \frac{\Delta H_1^{\mathrm{m}}}{\Delta S_1^{\mathrm{m}} - 19.14\log x_1} = \frac{\Delta H_2^{\mathrm{m}}}{\Delta S_2^{\mathrm{m}} - 19.14\log x_2}, \quad (2)$$

where $x_1 + x_2 = 1$ (x_i is the molar fraction of a component).

The results of calculations performed for binary systems entering into the composition of the ternary systems FeS–FeO–Cu_2S and FeS–FeO–Ni_3S_2 with the use of the Schroeder's equation and reference values of enthalpies of melting and melting points [7] are presented below:

System	FeS–FeO	FeS–FeO	FeO–Cu_2S
T^{eut}, K	1210	1105	1310
x_2^{eut}, mole fraction	0.428	0.325	0.455
System	FeS–Cu_2S	FeO–Ni_3S_2	FeS–Ni_3S_2
T^{eut}, K	1015	985	965
x_2^{eut}, mole fraction	0.310	0.793	0.748

The second eutectic temperature and eutectic concentration in the system FeS–FeO were obtained in studies of iron sulfide "FeS" + 3.5% Fe, which melts at 1247 K. Comparison with experimental data [8–10] characterizing the system FeS–FeO as a eutectic system shows that the eutectic temperatures are 1181 [8], 1181 [9], and 1213 K [10], and the respective eutectic concentrations $x_{\mathrm{FeO}}^{\mathrm{eut}}$, 0.315 [8], 0.360 [9], and 0.42 [10].

For the ternary eutectic we use the same property of the system—intersection of the equilibrium lines of binary eutectics at the same point for all the three constituent binary systems. Then we have for the triple eutectic point

$$T^{\mathrm{eut}} = \frac{\Delta H_1^{\mathrm{m}}}{\Delta S_1^{\mathrm{m}} - R\ln x_1} = \frac{\Delta H_2^{\mathrm{m}}}{\Delta S_2^{\mathrm{m}} - R\ln x_2} = \frac{\Delta H_3^{\mathrm{m}}}{\Delta S_3^{\mathrm{m}} - R\ln x_3}, \quad (3)$$

where $x_1 + x_2 + x_3 = 1$.

1070-4272/02/7502-0186 $27.00 © 2002 MAIK "Nauka/Interperiodica"

For the system FeS–FeO–Cu_2S, Eq. (3) is written in the form

$$T^{eut} = \frac{32\,340}{22.09 - 19.14\log x_{FeS}} = \frac{32\,170}{19.54 - 19.14\log x_{FeO}} = \frac{11\,300}{8.08 - 19.14\log x_{Cu_2S}}, \quad (4)$$

where the enthalpies and entropies of melting are taken to be equal to their reference values [7].

Equation (4) was solved by the method of successive approximation, with the dependence of T on x plotted for each of the three systems on the assumption that $x_{Cu_2S} = 1 - x_{FeS} - x_{FeO}$. The calculation gave the following results: eutectic temperature 930 K (657°C, eutectic composition $x_{FeS} = 0.218$, $x_{FeO} = 0.171$, and $x_{Cu_2S} = 0.611$.

In view of the fact that the boundary systems FeS–Cu_2S and FeO–Cu_2S are nonideal, account should be taken of deviations from ideality. For regular binary solutions

$$T^{eut} = \frac{\Delta H_1^m + Q(1 - x_1)^2}{\Delta S_1^m - R\ln x_1} = \frac{\Delta H_2^m + Q(1 - x_2)^2}{\Delta S_2^m - R\ln x_2}. \quad (5)$$

The system FeS–Cu_2S cannot be described by regular solution equations on the basis of studies of the fusion diagram [11]. Therefore, we take into account the asymmetry of the thermodynamic properties in this system with the use of equations derived in [12]. The expression takes the form

$$T^{eut} = \frac{\Delta H_1^m + (Q_1 - Q_2)(1 - x_1)^2 + 2Q_2(1 - x_1)^3}{\Delta S_1^m - R\ln x_1} = \frac{\Delta H_2^m + (Q_1 + 2Q_2)(1 - x_2)^2 - 2Q_2(1 - x_2)^3}{\Delta S_2^m - R\ln x_2}. \quad (6)$$

For a ternary system with nonadditive energies of the components, we obtain for the excess Gibbs energy

$$\Delta G^{ex} = x_1x_2Q'_{12} + x_1x_2^2Q''_{12} + x_1x_3Q'_{13} + x_1x_3^2Q''_{13} + x_2x_3Q'_{23} + x_2x_3^2Q''_{23}. \quad (7)$$

We have in Eq. (7) the excess Gibbs energy related to one mole of solution. Therefore, to obtain the total energy of a ternary solution containing n_1, n_2, and n_3 moles of components 1, 2, and 3, it is necessary to multiply the molar value by the total number of moles:

$$\Delta G_\Sigma^{ex} = \Delta G^{ex}(n_1 + n_2 + n_3).$$

The chemical potentials of the components can be defined by the expressions

$$\mu_1^{ex} = \frac{\partial\Delta G^{ex}(n_1 + n_2 + n_3)}{\partial n_1},$$

$$\mu_2^{ex} = \frac{\partial\Delta G^{ex}(n_1 + n_2 + n_3)}{\partial n_2},$$

$$\mu_3^{ex} = \frac{\partial\Delta G^{ex}(n_1 + n_2 + n_3)}{\partial n_3},$$

Since $\mu_{1_k}^{ex} = RT\ln f_i$, then we obtain, with account of $x_i = n_i/\sum_{i=1} n_i$, equations for the component activity coefficients for the system FeS–FeO–Cu_2S, for which $Q'_{12} = Q''_{12} = Q''_{23} = 0$:

$$RT\ln f_1 = (x_3^2 + x_2x_3)Q'_{13} + (x_3^3 + x_3^2x_2 - x_1x_3^2)Q''_{13} - x_2x_3Q'_{23}, \quad (8)$$

$$RT\ln f_2 = -x_1x_3Q'_{13} - 2x_1x_3^2Q''_{13} + (x_1x_3 - x_3^2)Q'_{23}, \quad (9)$$

$$RT\ln f_3 = (x_1^2 + x_1x_2)Q'_{13} + 2(x_1x_2x_3 - x_1^2x_3)Q''_{13} + (x_1x_2 - x_2^2)Q'_{23}. \quad (10)$$

From the position of the eutectic point of the system FeS–Cu_2S ($T^{eut} = 1193$ K, $x_{FeS} = 0.71$, $x_{Cu_2S} = 0.29$) we find $Q'_{12} = -9200$, $Q''_{12} = 52\,500$ J mol^{-1}.

Using the same method and approximate data of [13]: $T^{eut} \cong 13\,500$ K, $x_{FeO} = 0.05$, $x_{Cu_2S} = 0.95$, we obtain for the system FeO–Cu_2S $Q'_{12} = 25\,100$ J mol^{-1} and $Q''_{12} = 0$.

With account of equations for ternary asymmetric systems, we obtain for FeS–FeO–Cu_2S ($Q'_{12} = Q''_{12} = 0$, $Q'_{13} = -9200$, $Q''_{13} = 52\,500$, $Q'_{23} = 25\,000$ J mol^{-1}):

$$\Delta T^{eut} = \frac{32\,340 - 9200(x_{FeO}x_{Cu_2S} + x_{Cu_2S}^2) + 52\,500(x_{FeO}x_{Cu_2S}^2 + x_{Cu_2S}^3 - x_{FeS}x_{Cu_2S}^2) + 25\,100x_{FeO}x_{Cu_2S}}{22.09 - 19.14\log x_{FeS}}$$

$$= \frac{32\,170 - 9200\,x_{FeS}x_{Cu_2S} - 105\,000\,x_{FeS}x_{Cu_2S}^2 + 25\,100(x_{FeS}x_{Cu_2S} + x_{Cu_2S}^2)}{19.54 - 19.14\log x_{FeO}}$$

$$= \frac{11\,300 - 9200(x_{FeS}^2 + x_{FeS}x_{FeO}) + 105\,000(x_{FeS}^2x_{Cu_2S} + x_{FeS}x_{FeO}x_{Cu_2S}) + 25\,100(x_{FeS}x_{FeO} + x_{FeO}^2)}{8.08 - 19.14\log x_{Cu_2S}}. \quad (11)$$

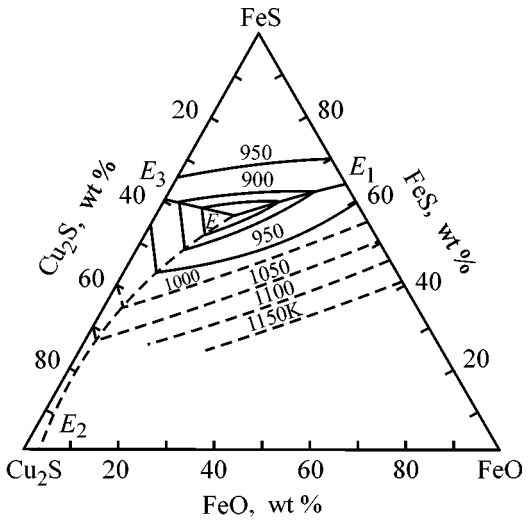

Fig. 1. Fusion diagram of the FeS–FeO–Cu_2S system [13].

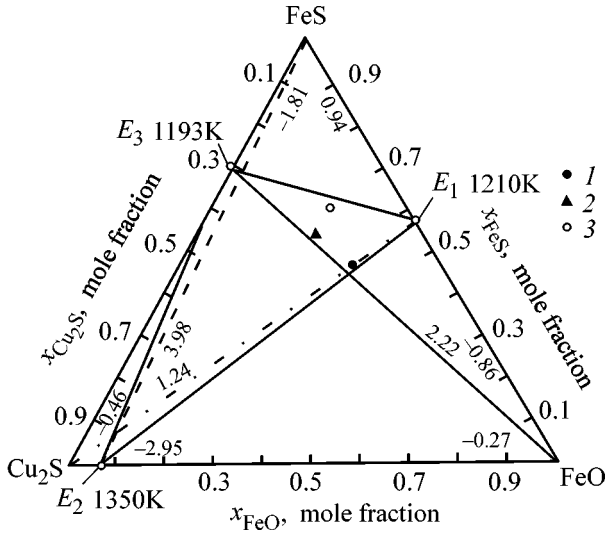

Fig. 2. Concentration triangle for the system FeS–FeO–Cu_2S. Ternary eutectic: (*1*) [13], (*2*) calculation by the method of successive approximations, and (*3*) calculation by the method proposed in [14].

The results of calculations give T^{eut} = 1085 K, x_{FeS} = 0.55, x_{FeO} = 0.22, x_{Cu_2S} = 0.23.

These values are in rather good agreement with the experimental data reported in [13], which can be seen in Fig. 1 presenting the concentration triangle for the system FeS–FeO–Cu_2S, with triple eutectic points found by different methods plotted in the figure.

Comparison of experimental and calculated values for an ideal system shows a significant shift of the triple eutectic to the iron sulfide–rich vertex of the diagram.

The composition and melting point of the ternary eutectic were calculated using the procedure proposed in [14] on the basis of data on binary systems. Data on the melting points of pure components and binary eutectics and on their compositions made it possible to calculate the relative changes in "reciprocal partial temperatures" of components A_i upon their transformation into eutectics:

$$A_i = \frac{2.303}{x_3^{i-3}} \log \frac{T_i^0 x_i^{i-3}}{T_{eut}^{i-3}}, \qquad (12)$$

where T_i^0 and T_{eut}^{i-3} are the melting points of pure *i*-th component and binary eutectic formed by this and the third components; x_3^{i-3} and x_i^{i-3} are the contents of 3rd and *i*-th component (i = 1 or 2) in the $i-3$ binary eutectic (mole fraction).

In Fig. 2, the A_i values are given at sides of the concentration triangle (e.g., $A_{Cu_2S}^{Cu_2S–FeS} = -0.48$, $A_{FeO}^{FeO–FeS} = -0.884$, $A_{FeO}^{FeO–Cu_2S} = -0.929$). With account of the results we obtained and the fact that the ternary eutectic lies in a field delimited by straight lines connecting the points corresponding to the compositions of the binary eutectics, we found the probable concentration region in which the ternary eutectic lies (delimited in Fig. 2 by the line E_1E_3 and the cut line originating from the binary eutectic E_3 and running toward the FeO vertex).

The quantities A_i were also used for evaluating the stability of the temperature surface folds. It was shown in [15] that, in ternary systems of eutectic type, ternary eutectics lie near intersection points of two the most stable folds. In the given case, these are the folds originating in binary systems Cu_2S–FeS and FeS–FeO. The corresponding cut lines in Fig. 2 are represented by solid lines.

The composition of the ternary eutectic of the system was found as the intersection point of these cut lines by solving the system of equations

$$x_{FeO}^{FeS–FeO–Cu_2S} : x_{FeS}^{FeS–FeO–Cu_2S} = x_{FeO}^{FeS–FeO} : x_{FeS}^{FeS–FeO},$$
$$x_{Cu_2S}^{FeS–FeO–Cu_2S} : x_{FeS}^{FeS–FeO–Cu_2S} = x_{Cu_2S}^{Cu_2S–FeS} : x_{FeS}^{Cu_2S–FeS},$$
$$x_{FeS}^{FeS–FeO–Cu_2S} + x_{FeO}^{FeS–FeO–Cu_2S} + x_{Cu_2S}^{FeS–FeO–Cu_2S} = 1. \qquad (13)$$

The obtained values are as follows: x_{FeS} = 0.46, x_{FeO} = 0.35, x_{Cu_2S} = 0.19.

The composition of the ternary eutectic was used to calculate its melting point by the formula

$$T_i^0 = \frac{1 - x_i^{1-2-3}}{1 - x_i^{j-k}} (T_i^0 - T_{eut}^{j-k}), \qquad (14)$$

where $j - k$ is the most readily fusible binary eutectic formed by i-th component.

The thus calculated melting point of the ternary eutectic was 1164 K.

The results obtained [Eqs. (8)–(10)] allow calculation of the component activity in this ternary system. The equations used have the form

$$RT\ln a_{FeS} = RT\ln x_{FeS} - 9200(x_{FeO}\,x_{Cu_2S} + x^2_{Cu_2S}) + 52\,500(x_{FeO}\,x^2_{Cu_2S} + x^3_{Cu_2S} - x_{FeS}\,x^2_{Cu_2S}) - 25\,100x_{FeO}\,x_{Cu_2S}, \quad (15)$$

$$RT\ln a_{FeO} = RT\ln x_{FeO} + 9200\,x_{FeS}\,x_{Cu_2S} - 105\,000\,x_{FeS}\,x_{Cu_2S} + 25\,100(x_{FeS}\,x_{Cu_2S} + x^2_{Cu_2S}), \quad (16)$$

$$RT\ln a_{Cu_2S} = RT\ln x_{Cu_2S} - 9200(x^2_{FeS} + x_{FeS}\,x_{FeO}) + 105\,000(x^2_{FeS}\,x_{Cu_2S} + x_{FeS}\,x_{FeO}\,x_{Cu_2S}) + 25\,100(x_{FeS}\,x_{FeO} + x^2_{FeO}). \quad (17)$$

Finally, the excess molar Gibbs energy of the ternary system can be calculated using the equations reported in [16].

FeS–FeO–Ni_3S_2 system. Data on boundary binary systems are lacking (FeO–Ni_3S_2 system) or contradictory (FeS–Ni_3S_2 system): deviations from ideality are positive and negative according to, respectively, viscosity or density measurements. In this connection, it is difficult as yet to construct the phase diagram of the ternary system FeS–FeO–Ni_3S_2 with account of deviations from ideality.

For the ideal system, the ternary eutectic is found from the equation

$$T^{eut} = \frac{32\,340}{22.09 - 19.14\log x_{FeS}} = \frac{32\,170}{19.54 - 19.14\log x_{FeO}} = \frac{24\,270}{21.01 - 19.14\log x_{Ni_3S_2}}. \quad (18)$$

Calculation by the method of successive approximations gives the value T^{eut} = 912 K (639°C) and eutectic composition x_{FeS} = 0.20, x_{FeO} = 0.15, $x_{Ni_3S_2}$ = 0.65. The concentration triangle for the ternary system FeS–FeO–Ni_3S_2 is presented schematically in Fig. 3. A calculation by the method proposed in [14] gives the eutectic composition x_{FeS} = 0.21, x_{FeO} = 0.16, $x_{Ni_3S_2}$ = 0.63, and eutectic temperature T^{eut} = 925 K. The results obtained using these calculation techniques are in good agreement.

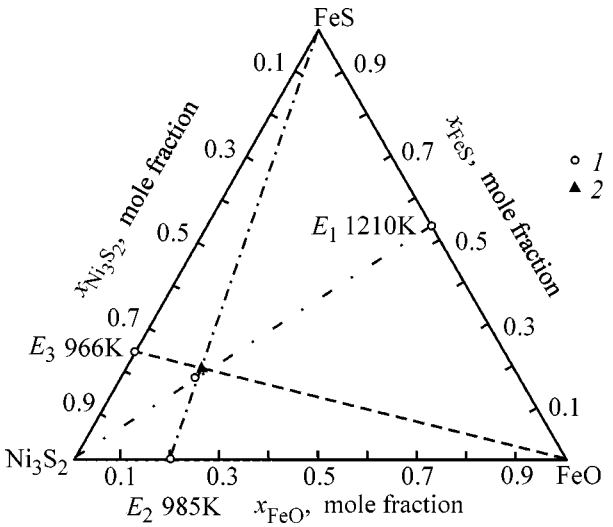

Fig. 3. Concentration triangle for the system FeS–FeO–Ni_3S_2. Ternary eutectic: (*1*) calculation by the method of successive approximations and (*2*) calculation by the method proposed in [14].

CONCLUSIONS

(1) Three calculation procedures were used for ternary oxosulfide systems FeS–FeO–Cu_2S and FeS–FeO–Ni_3S_2: (I) that relying upon the ideality approximation, (II) that based on reciprocal partial temperatures, and (III) that taking into account the interaction of the components. The following results were obtained for the ternary eutectic in the system FeS–FeO–Cu_2S: ideality approximation: T^{eut} = 930 K, x_{FeS} = 0.218, x_{FeO} = 0.171, x_{Cu_2S} = 0.611; procedure based on reciprocal partial temperatures: T^{eut} = 1164 K, x_{FeS} = 0.46, x_{FeO} = 0.35, x_{Cu_2S} = 0.19; equations taking into account the nonadditivity of the components: T^{eut} = 1085 K, x_{FeS} = 0.55, x_{FeO} = 0.22, x_{Cu_2S} = 0.23. The last set of values is in the best agreement with the available experimental data.

(2) Equations describing the component activity in the ternary system FeS–FeO–Cu_2S at various temperatures and melt compositions were derived for the first time.

(3) For the system FeS–FeO–Ni_3S_2, a calculation by the method of successive approximations gives T^{eut} = 912 K, x_{FeS} = 0.20, x_{FeO} = 0.15, $x_{Ni_3S_2}$ = 0.65; and that by the method of reciprocal partial temperatures, T^{eut} = 925 K, x_{FeS} = 0.21, x_{FeO} = 0.16, $x_{Ni_3S_2}$ = 0.63. The good agreement of the results obtained using these two methods gives reason to consider these results reliable.

Thermodynamic Analysis of Cerium(III) Extraction from Sulfate Solutions with Salts of Quaternary Ammonium Bases

I. A. Dibrov, D. E. Chirkst, and T. E. Litvinova

Plekhanov State Mining Institute, St. Petersburg, Russia

Received August 31, 2000; in final form, April 2001

Abstract—Cerium(III) distribution between an aqueous sulfate solution and a solution of trialkylbenzylammonium sulfate in xylene was studied. The Ce(III) distribution coefficient grows with increasing pH. The extraction is provided by the formation of cerium mono- and disulfate complexes in the aqueous phase. Schemes of extraction equilibria are proposed and Gibbs energies and equilibrium constants are found.

Russia has no domestic resources of purely rare-earth ores, such as bastnäsite, monazite, and xenotime, widely used in the rare-earth industry abroad. The rare-earth metals (REMs) are produced as coproducts with other less-common metals (niobium, uranium, etc.) in smaller amounts than it is necessary for the industry. Therefore, a search for new raw materials containing REMs, development and improvement of flow-sheets for their recovery and separation are topical tasks. Extraction recovery of REM from sulfate media is expedient when poor ores, e.g., eudialyte ores of the Alluive bed [1] or by-products of the chemical and metallurgical productions are processed. Published data on extraction recovery of REM sulfates are scarce. In particular, it is known that REM sulfates are poorly extracted with neutral organophosphorus compounds, e.g., tributyl phosphate (TBP) [2]. Other widely used extractants are salts of quaternary ammonium bases [3, 4].

The main features of the cerium extraction were studied in sulfuric acid (0.37–4.37 mol kg^{-1}) solutions of cerium sulfate at pH 0–4 and constant concentration of sulfate ion, 2.55 mol kg^{-1}, provided by adding a required amount of chemically pure grade magnesium sulfate. This concentration of sulfate ion corresponds to that used in the experiments on sulfuric acid leaching of eudialyte concentrate [5]. A 0.5 M solution of trialkylbenzylammonium sulfate with C_4–C_{10} alkyl radicals (TABAS) in xylene was used. The volume ratio of the organic and aqueous phases was 1 : 2. The Ce(III) molality in the organic phase C_{org} was found as the difference of metal molalities in the initial C_0 and equilibrium aqueous C_{aq} phases with regard to mass ratio of aqueous m_{H_2O} and organic m_{org} phases (m_{H_2O}/m_{org} = 2.4 under conditions of the experiment):

$$C_{org} = (C_0 - C_{aq})\frac{m_{H_2O}}{m_{org}}. \quad (1)$$

The Ce(III) content in the aqueous phase was monitored spectrophotometrically with arsenazo III [6].

The experimental distribution coefficient D was found by the formula

$$D_{Ce} = C_{org}/C_{aq}. \quad (2)$$

Phases were mixed with a magnetic stirrer and separated in a separatory funnel; the phase separation time was 15–20 min. Experiments were performed at room temperature without thermostatic control, since small variations of temperature (±5°C) do not affect substantially the distribution coefficient [7].

It is accepted that the photometric measurements are performed with 5% relative error at 95% confidence probability. Therefore, the distribution coefficients D were determined with ±7% relative error. The theoretical error of the calculated equilibrium constants and Gibbs energies of extraction was not determined because of the difficulty of its calculation. The arithmetic mean values of these parameters were found, and the root-mean-square deviation from the average with regard to Student's coefficient was taken as an error.

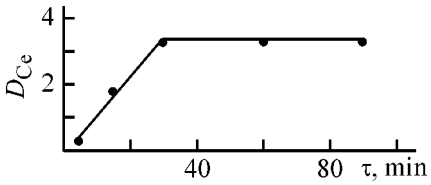

Fig. 1. Cerium(III) distribution coefficient D_{Ce} in the TABAS–$Ce_2(SO_4)_{3\,(aq)}$–$MgSO_4$–H_2SO_4 system vs. phase contact time, τ at pH 1.

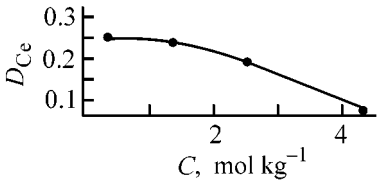

Fig. 2. Cerium(III) distribution coefficient D_{Ce} vs. H_2SO_4 concentration C.

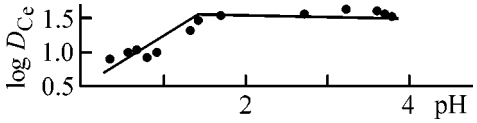

Fig. 3. Cerium(III) distribution coefficient D_{Ce} vs. pH.

To determine the time in which the thermodynamic equilibrium of extraction, we took at equal time intervals samples of phases and analyzed them for the Ce(III) content. The results are shown in Fig. 1. As seen, the equilibrium is attained within 30 min.

The dependence of D_{Ce} on sulfuric acid concentration was determined within the 0.05–4.37 mol kg^{-1} H_2SO_4 range at constant concentration of sulfate ion, 4.37 mol kg^{-1} (Fig. 2). As seen, the Ce(III) recovery from the concentrated acid solutions is very low, and the error in determination of D is high, since C_{org} is found as the difference of two close values.

The Ce(III) recovery becomes noticeable only at sulfuric acid concentrations of 0.1 mol kg^{-1} and lower. The dependence of the Ce(III) extraction on the equilibrium pH is presented in Table 1. The log D_{Ce}–pH plot is presented in Fig. 3. As seen, log D_{Ce} linearly increases in the range pH 0.4–1.65 and then becomes constant at higher pH in accordance with the following empirical equations:

$$\log D = 0.64 + 0.5\ \text{pH}\ (0.4 < \text{pH} < 1.65), \quad (3)$$

$$D = 35 \pm 4\ (1.65 < \text{pH} < 4.0). \quad (4)$$

To explain these dependences, we performed a thermodynamic calculation of the ionic composition of equilibrium aqueous phases, using the GIBBS program [8] based on minimization of the Gibbs energy of a multicomponent system. The equilibrium gross composition of the system and standard Gibbs energies of formation of the ions in aqueous solutions were used as input data for calculations [9, 10]:

Ion	HSO_4^-	SO_4^{2-}	H_2O	Ce^{3+}	$CeSO_4^+$	$Ce(SO_4)_2^-$
$-\Delta_f G^0_{298}$, kJ mol^{-1}	756.97	745.65	237.18	657.38	1440.97	2197.02

The GIBBS program allows calculation of the activity coefficients of ions in a second approximation of the Debye–Hückel theory. The following parameters were used: A = 0.509, B = 0.3284, a = 3 at the ion charge z = ±1, a = 4 at z = ±2, and a = 4.5 at z = ±3. The activity coefficients 0.43 for single-charged ions and 0.066 for double-charged ions at ionic strength of 10 were obtained. The results of the calculations are listed in Table 2.

Table 1. Distribution coefficient D_{Ce} at various equilibrium pH

3.81	0.02	1.98	0.018	0.06	0.38

As seen, the Ce species and the ratio of sulfate to hydrosulfate ions in the aqueous phase change with increasing pH. Before the break point of the $\log D_{Ce} = f(pH)$ dependence (Fig. 3), HSO_4^- ions, and after it, SO_4^{2-} ions prevail in the solution.

Before the break point (pH < 1.3–1.6), three cerium species coexist in the solution in comparable amounts: Ce^{3+}, $CeSO_4^+$, and $Ce(SO_4)_2^-$; at higher pH the Ce^{3+} and $CeSO_4^+$ contents decrease relative to the disulfate species.

After the break point, the disulfate species content is independent of pH and, on the average, amounts to 3.83×10^{-4} mol kg^{-1} at a total cerium(III) content of 4.5×10^{-4} mol kg^{-1}, which exceeds by a factor of 10 the content of the sum of Ce^{3+} and monosulfate complex (Table 2).

Thus, the change of the mechanism of Ce(III) extraction at pH 1.3–1.65 is caused by conversion of hydrosulfate into sulfate and by changes in the Ce(III) speciation in the aqueous phase.

To calculate the extraction constants and Gibbs energies of the Ce(III) extraction, we wrote extraction equations based on the following assumptions.

(1) Only prevailing ionic species of the equilibrium aqueous phase were taken into consideration; species, whose content is a factor 10 smaller were disregarded.

(2) TABAS cations interact only with anionic cerium species.

(3) The composition of extraction complexes was chosen based on the electroneutrality principle and data of [11, 12] on probable number of extractant molecules in the extraction complex.

The extraction constants were calculated with regard to activity coefficients. Taking into consideration that at pH <1.3–1.65 cerium occurs mainly as $CeSO_4^+$ and $Ce(SO_4)_2^-$, we can suggest occurrence of the following equilibria in the extraction systems:

$$Ce(SO_4)_{2(aq)}^- + R_4NHSO_{4(org)} \rightarrow R_4N[Ce(SO_4)_2]_{(org)} + HSO_{4(aq)}^-, \quad (5)$$

$$CeSO_{4(aq)}^+ + R_4NHSO_{4(org)} \rightarrow R_4N[Ce(SO_4)_2]_{(org)} + H_{(aq)}^+. \quad (6)$$

Each of them contributes to the Ce(III) extraction into the organic phase. The generalized equation of extraction involving both the extractable Ce species is as follows

$$[Ce(SO_4)_x]_{(aq)}^{3-2x} + R_4NHSO_{4(org)} \rightarrow R_4N[Ce(SO_4)_2]_{(org)} + (x-1)HSO_{4(aq)}^- + (2-x)H_{(aq)}^+, \quad (7)$$

where x is the number of the sulfate groups in the cerium aqueous complex, $1 \le x \le 2$.

Table 3. Calculated equilibrium constants and Gibbs energies of extraction of cerium(III) sulfate complexes

pH	$K_{(5)}$	$-\Delta_{solv}G^0_{298(5)}$, kJ mol^{-1}	$K_{(6)}$	$-\Delta_{solv}G^0_{298(6)}$, kJ mol^{-1}
	reaction (5)		reaction (6)	
0.38	66.8	10.4	53.1	9.6
0.61	58.7	10.1	49.4	9.7
0.71	49.4	9.7	46.9	9.5
0.80	35.1	8.8	33.6	8.7
0.94	29.7	8.4	33.5	8.7
1.33	38.1	9.0	40.3	9.2
1.43	40.9	9.2	45.5	9.6

For equilibria (5) and (6), the equilibrium constants are as follows:

$$K_{(5)} = \frac{a_{HSO_4^-} C_{org}}{a_{Ce(SO_4)_2^-} C_{TABAS}}, \quad (8)$$

$$K_{(6)} = \frac{a_{H^+} C_{org}}{a_{CeSO_4^+} C_{TABAS}}. \quad (9)$$

These constants and Gibbs energies of extraction calculated at various pH are listed in Table 3. a_H^+, C_{org}, and C_{TABAS} are experimental, while the activities of cerium sulfate complexes were calculated from data of Table 2 and from the activity coefficients calculated by the GIBBS program.

Calculations showed that the transfer of both cerium complexes into the organic phase is characterized by close equilibrium constants and Gibbs energies ($K_{(5)} = 46 \pm 12$, $\Delta_{solv}G^0_{298(5)} = -9 \pm 1$ kJ mol^{-1}; $K_{(6)} = 43 \pm 7$, $\Delta_{solv}G^0_{298(6)} = -9.3 \pm 0.4$ kJ mol^{-1}). The root-mean-square errors were calculated for the expected probability 0.95 at a number of experiments equal to 7.

Extraction reactions (5) and (6) are characterized by different coefficients at H^+, but none of them corresponds to the experimental slope of the $\log D_{Ce} = f(pH)$ dependence [Eqs. (3), (4) and (8), (9)].

Probably both complexes participate in Ce(III) extraction. Taking into consideration the experimental slope of 0.5 in Eq. (3) and close values of $K_{(5)}$ and $K_{(6)}$, we can propose the following equation of the overall extraction equilibrium:

$$0.5Ce(SO_4)_{(aq)}^+ + 0.5Ce(SO_4)_{2(aq)}^- + (R_4N)HSO_{4(org)} \rightarrow (R_4N)[Ce(SO_4)_2]_{(org)} + 0.5H_{(aq)}^+ + 0.5HSO_{4(aq)}^-, \quad (10)$$

for which the equilibrium constant can be calculated as geometric mean of $K_{(5)}$ and $K_{(6)}$:

$$K_{(10)} = \sqrt{K_{(5)}K_{(6)}}. \quad (11)$$

Table 4. Calculated equilibrium constants and Gibbs energies of extraction of cerium(III) from sulfate solutions

pH	K	$-\Delta_{solv}G^0_{298}$, kJ mol^{-1}
0.38	59.3	10.1
0.61	53.9	9.9
0.71	48.1	9.6
0.80	34.4	8.8
0.94	31.5	8.5
1.33	39.2	9.1
1.43	44.1	9.4
$\overline{K} = 44 \pm 9$		$-\Delta_{solv}\overline{G}^0_{298} = 9.3 \pm 0.5$
1.75	42.2	9.3
2.74	35.9	8.9
3.24	39.9	9.1
3.65	40.6	9.2
3.76	35.3	8.8
3.81	32.8	8.6
$\overline{K} = 38 \pm 3$		$\overline{G}^0_{298} = 8.9 \pm 0.3$

The results of the calculation are listed in Table 4. At pH > 1.65, the Ce(III) disulfate complex prevails in the equilibrium aqueous phase, and its extraction can be approximated by the scheme

$$Ce(SO_4)_{2\,(aq)}^- + 0.5(R_4N)_2SO_{4\,(org)} \rightarrow (R_4N)[Ce(SO_4)_2]_{(org)} + 0.5SO^{2-}_{4\,(aq)}. \quad (12)$$

This extraction mechanism is confirmed by the independence of the Ce(III) distribution coefficient from pH [Table 1, Eq. (4)]. The equilibrium constant of reaction (12) is

$$K_{(12)} = \frac{C_{org}a^{0.5}_{SO_4^{2-}}}{a_{Ce(SO_4)_2^-}\,0.5C^{0.5}_{TABAS}}. \quad (13)$$

The calculated equilibrium constants and the corresponding Gibbs energies are listed in Table 4.

The close values the equilibrium constants and Gibbs energies at various pH within any branch of the log $D = f$(pH) dependence indicate the validity of the proposed mechanisms of extraction equilibria.

CONCLUSIONS

(1) The distribution of Ce(III) between the sulfuric acid solution and trialkylbenzylammonium sulfate in dodecane was studied. The cerium distribution coefficient grows with increasing pH and at pH 1.65 reaches the maximal value D = 35. Extraction is provided by transition into the organic phase of cerium mono- and disulfate complexes. The content of the latter grows with increasing pH.

(2) Two schemes of extraction equilibria at pH < 1.65 and pH > 1.65 were proposed, based on coordination of two sulfate ions with the metal ion in the sulfate complexes and on thermodynamic calculations of the compositions of aqueous solutions at known pH and total cerium content.

(3) The invariability of the equilibrium constants and standard Gibbs energies in both pH ranges (0–1.65 and > 1.65) confirms the adequacy of the proposed schemes of the extraction equilibria.

SORPTION AND ION-EXCHANGE PROCESSES

Experimental Study of Zirconium(IV) Extraction from Fluoride-Containing Acid Solutions

I. A. Dibrov, D. E. Chirkst, and T. E. Litvinova

Plekhanov State Mining Institute, St. Petersburg, Russia

Received August 31, 2000; in final form, April 2001

Abstract—Zirconium(IV) extraction from acid solutions was studied, and the optimal parameters of the process were found. Extractants for zirconium(IV) recovery from nitric and sulfuric acid solutions in the presence of fluoride ions were selected. The distribution coefficients of zirconium(IV) and fluoride ion were determined.

Eudialyte is a promising source of rare-earth metals and zirconium. It is readily decomposed with acids, which allows its comparatively simple processing. A number of works devoted to processing of eudialyte ores and concentrates have been published [1, 2]. The main problem in this field is the formation during acid leaching of difficultly filterable silica gel precipitates, with incomplete transfer of target components and in particular, zirconium into the solution. Earlier, it has been shown that introduction into the pulp of small amounts of fluoride ions at the instant of ore breakdown eliminates the above disadvantage [3]. The use of sulfuric acid instead of nitric acid makes eudialyte processing more efficient.

Nitric acid solutions obtained from ore breakdown are traditionally treated by extraction. Extraction of zirconium from sulfuric acid solutions, especially in the presence of fluoride ions, has not been studied.

In this work, we studied the zirconium(IV) distribution between the organic and aqueous phases, using the model solutions with the zirconium content of 5–15 g l^{-1}. This concentration range allowed determination of the effect of the zirconium(IV) content in the aqueous phase on its distribution coefficient, taking into consideration fluctuations in the zirconium concentration during eudialyte breakdown. The F : Zr molar ratio was varied from 0 to 6. The required fluoride content was provided by addition of chemically pure sodium fluoride. Zirconium was extracted from 10–40% sulfuric or nitric acid solutions with the following extractants: (1) 0.5 M solutions of trialkylbenzylammonium sulfate or nitrate in xylene (TABAS, TABAN, respectively; alkyl = C_4–C_{10}) and (2) 20 vol % solution of tributyl phosphate (TBP) in dodecane. The volume ratio of the organic to aqueous phase was 1 : 2.

The extractants were chosen taking into account their opposite mechanisms of extraction. Extraction with TBP proceeds by the donor–acceptor mechanism, while extraction with amines and, in particular, salts of quaternary ammonium bases is due to the ion exchange.

The Zr(IV) concentration was monitored spectrophotometrically with arsenazo III in 2 M HCl [4], and the fluoride ion concentration, potentiometrically with a fluoride-selective electrode [5].

The content of zirconium and fluoride ion in the organic phase C_{org} was found as the difference between their concentrations in the initial C_0 and equilibrium C_{aq} aqueous phases with regard to the weight ratio of water and the organic phase m_{H_2O}/m_{org}:

$$C_{org} = (C_0 - C_{aq})\frac{m_{H_2O}}{m_{org}}, \quad (1)$$

which was 2.43 in our experiment.

The Zr(IV) distribution coefficient D was determined as

$$D = C_{org}/C_{aq}. \quad (2)$$

Usually, the quantitative analysis performed by physicochemical methods is characterized by relative error of 5% at confidence probability of 95%. Therefore, the relative error of determination of dis-

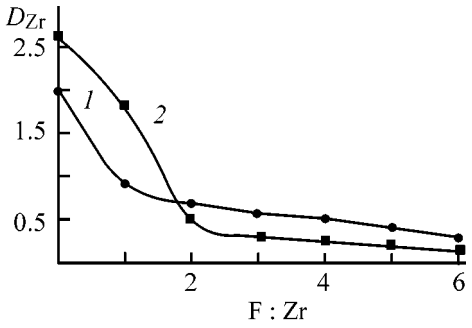

Fig. 1. Zirconium(IV) distribution coefficient vs. the F : Zr molar ratio in extraction with TBP (20% solution in dodecane). Acid (wt %): (*1*) H_2SO_4, 30; (*2*) HNO_3, 40 [7].

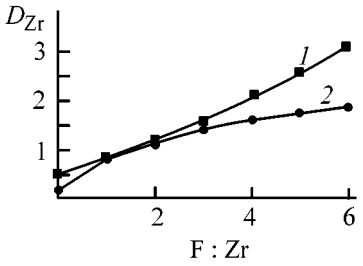

Fig. 2. Zirconium(IV) distribution coefficient vs. the F : Zr molar ratio in extraction with quaternary ammonium bases: (*1*) Extraction with TABAS (0.5 M solution in xylene) from 30% H_2SO_4 and (*2*) extraction with TABAN (0.5 M solution in xylene) from 40% HNO_3.

tribution coefficients D was estimated in this work to be ±7%.

The Zr(IV) extraction from fluoride-containing aqueous phases, and solution preparation were performed in Teflon vessels with mixing by means of a magnetic stirrer. The time of equilibrium attainment was determined experimentally and to be 30 min. Phases were separated in a separatory funnel at room temperature without thermostatic control, since small variations of temperature (±5°C) does not affect substantially the distribution coefficient [6]. The time of phase separation was 15–20 min.

In extraction with TBP, D decreases with increasing F to Zr molar ratio for systems containing sulfuric or nitric acid; at F : Zr > 2 the extraction from the sulfuric acid solution becomes more efficient than that from nitric acid solutions (Fig. 1).

In extraction with trialkylbenzylammonium salts, D grows with increasing F : Zr ratio, and extraction from sulfuric acid solutions is more efficient than that from nitric acid solutions at any F : Zr ratio (Fig. 2). The concentration of sulfuric and nitric acids in the aqueous phase was 30 and 20 wt %, respectively, which corresponds to the same equivalent concentration of 7.3 g-equiv l^{-1}.

The Zr(IV) distribution coefficients are presented in Table 1 in relation to the acid concentration in the aqueous phase within the 10–40 wt % range at F : Zr = 0 for TBP and 6 for TABAS and TABAN. As seen, the sulfuric acid concentration weakly affects the Zr(IV) extraction, while raising the nitric acid concentration leads to substantial increase in D.

To explain the above dependences, we performed thermodynamic analysis of the ionic composition of the equilibrium aqueous phases, using the GIBBS program [8]. This program is based on minimization of the Gibbs free energy of a multicomponent system. The equilibrium gross composition of the system and standard free energies of formation of ions studied in aqueous solutions [9] (Table 2) served as input parameters of the calculation. The results of the calculation are presented in Table 3.

ZrF_5^{-}	–	–	–	0.49	0.91	3.28	4.63
ZrF_6^{2-}	–	–	–	–	–	0.71	1.86

As seen, the dominating Zr(IV) species is $Zr(NO_3)_2^{2+}$ and $Zr(SO_4)_2^{0}$ in the fluoride-free nitric acid and sulfuric acid solutions, respectively.

Extraction of zirconium with TBP, TABAS, and TABAN from fluoride-free sulfuric and nitric acid solutions can be represented as extraction reactions written on the basis of a thermodynamic calculation (Table 3) and reference data indicating that the zirconium(IV) coordination number is 6 and the probable number of extractant molecules in the extraction complex is 2 [10, 11].

$$Zr(NO_3)_{2(aq)}^{2+} + 2NO_{3(aq)}^{-} + 2TBP_{(org)} \rightarrow Zr(NO_3)_4 \cdot 2TBP_{(org)}, \quad (3)$$

$$Zr(SO_4)_{2(aq)}^{0} + 2TBP_{(org)} \rightarrow Zr(SO_4)_2 \cdot 2TBP_{(org)}, \quad (4)$$

$$Zr(NO_3)_{2(aq)}^{2+} + 2NO_{3(aq)}^{-} + 2R_4N(NO_3)_{(org)} \rightarrow (R_4N)_2[Zr(NO_3)_6]_{(org)}, \quad (5)$$

$$Zr(SO_4)_{2(aq)}^{0} + 2R_4N(SO_4)_{(org)} \rightarrow (RN_4)_2[Zr(SO_4)_3]_{(org)} + H_{(aq)}^{+} + HSO_{4(aq)}^{-}. \quad (6)$$

Extraction from nitric acid solution involves nitrate ions. This accounts for the salting-out effect of nitric acid (D_{Zr} growing with increasing acid concentration). Sulfuric acid shows no salting-out effect because it is not involved in the corresponding extraction reaction.

The dependence of D_{Zr} on the initial zirconium content in 30% H_2SO_4 at F : Zr ratio of 0 for TBP and 6 for TABAS is presented in Table 4. As seen, the degree of Zr recovery with both extractants is independent of the initial metal concentration within the concentration range indicated above.

In the process developed for eudialyte concentrate breakdown [3], fluoride ions with molar ratio F : Zr > 3 always occur in solution after the ore breakdown. For such solutions, TBP is in efficient as extractant for both sulfuric and nitric acid solu-

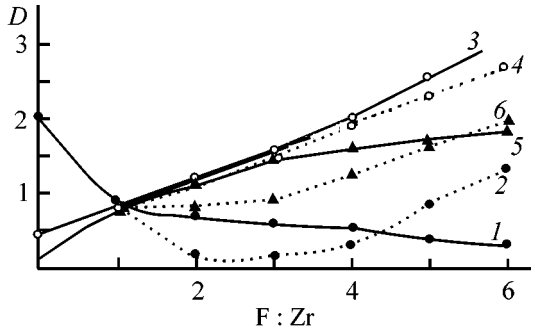

Fig. 3. (*1, 3, 5*) Zr(IV) and (*2, 4, 6*) F^- distribution coefficients D vs. the F : Zr molar ratio. Extraction: (*1, 2*) with TBP, data of [7]; (*3, 4*) with TABAS from 30% H_2SO_4; and (*5, 6*) with TABAN from 40% HNO_3.

tions (Figs. 1, 2). In addition, in extraction from sulfuric acid solution, the Zr(IV) distribution coefficient is independent of the acid concentration, which makes the extraction process more stable.

Further, we studied the distribution of the fluoride ion between the organic and aqueous phases in extraction with TABAS and TABAN. In these experiments, the initial zirconium concentration was 0.055 M. The results are listed in Table 5 and Fig. 3.

A comparison of the distribution coefficients of zirconium and fluoride ion showed that in extraction with TBP, when zirconium is absent, the distribution coefficient of fluoride ion is independent of its concentration within the concentration range studied and is equal to 1.2. In the presence of zirconium, the dependence of D_F on the F : Zr molar ratio has a minimum at F : Zr = 2–3 [7] (Fig. 3). It follows from Table 5 and Fig. 3 that the content of fluoride ion in the organic phase changes with its increasing content in the system, which indicates the change in the composition of the extractable complex. This change is nonmonotonic for the system with TBP (Fig. 5, curve *2*): the number of fluoride ions bonded with zirconium decreases to F : Zr = 2–3 and then increases again. The change in fluoride ion content and F : Zr ratio in the organic phase correlates with changes in the fluoride ion distribution coefficient. An analysis of the fluoride ion extraction with trialkylbenzylammonium salt showed that the given F : Zr molar ratio is virtually the same in both aqueous and organic phases within the entire range studied. In the organic phase, the F : Zr molar ratio is slightly lower than the initial one, which can be attributed to simultaneous extraction, along with $[ZrF_6]^{2-}$, of the other zirconium(IV) com-

Table 5. Distribution of Zr(IV) and F^- between the organic and aqueous phases in extraction with TABAS and TABAN from sulfuric and nitric acid solutions, respectively, with the same equivalent concentration

5	2.57	6.46	2.54	13.49	31.03	2.30	4.80
6	2.17	6.66	3.07	14.04	37.91	2.70	5.70
			40% HNO_3				
0	5.11	0.77	0.15	–	–	–	–
1	3.97	3.03	0.77	3.40	2.60	0.76	0.86
2	3.54	3.93	1.11	7.75	6.51	0.84	1.66
3	3.24	4.54	1.42	11.20	10.42	0.93	2.30
4	3.06	4.90	1.60	13.41	17.17	1.28	3.50
5	2.97	5.05	1.69	15.11	24.78	1.64	4.91
6	2.86	5.26	1.84	14.73	29.46	2.00	5.60

plexes $[ZrF_n]^{4-n}$ with n = 1–5. In general, we can suggest the following reaction:

$$[ZrF_x]^{4-x}_{(aq)} + 2(R_4N)An_{(org)} \rightarrow (R_4N)_2[ZrF_xAn_{6-x}]_{(org)} + (x - 4)An^-_{(aq)}, \quad (7)$$

where An is NO_3^- or HSO_4^- ($1/2SO_4^{2-}$), and x = 1–6.

For the most part x = 6. This well conforms to data of Shmidt [11] who proposed the following scheme of extraction of Zr(IV) chloride complexes with trioctylamine from sulfuric acid solutions:

$$[ZrCl_6]^{2-} + 2(R_3NH)HSO_4 \rightarrow (R_3NH)_2[ZrCl_6] + 2HSO_4^-. \quad (8)$$

Thus, we found the optimal conditions of Zr(IV) extraction from fluoride-containing sulfuric acid solutions: 0.5 M TABAS in xylene, molar ratio F : Zr = 6 at sulfuric acid concentration from 10 to 30 wt % and Zr(IV) initial concentration in the aqueous solution from 5 to 15 g l^{-1}; volume ratio of the organic to aqueous phase 1 : 2.

Further, we studied the Zr(IV) backwashing from the organic phase containing the $[ZrF_6]^{2-}$ complex. The following backwashing agents were tested: water, 1 M HCl, 1 M H_2SO_4, and HCl + KCl mixture at pH 1 and chloride ion concentration of 1 M. The ratio of aqueous to organic phase in backwashing was 1 : 2. The backwashing efficiency was estimated as the Zr(IV) concentration in the equilibrium aqueous phase. The initial Zr(IV) concentration in the organic phase was known beforehand from extraction experiments. The best backwashing agent for Zr(IV) is 1 M HCl: up to 98% of zirconium passes into the aqueous phase. Water strips about 40% of zirconium, and sulfuric acid (1 M), about 10%.

Then the extraction power of TABAS after treatment with HCl was evaluated to assess the possibility of repeated use of the extractant. The Zr(IV) recovery was compared in extraction with the fresh solution of TABAS in xylene and with TABAS solution treated with HCl after Zr(IV) backwashing. The virtually the same values of the Zr(IV) distribution coefficient in both experiments show that treatment with HCl weakly affects the TABAS extraction power.

We also found that, in the extraction-backwashing cycle, all fluoride ions pass, together with zirconium, into the aqueous phase on contact with HCl. This follows from the constancy of the F : Zr molar ratio in the initial aqueous solution, extract, and backwash, which allows repeated use of the extractant without its additional purification.

CONCLUSIONS

(1) Extractants for Zr(IV) extraction from nitric and sulfuric acid solutions were selected. TBP is inefficient when fluoride ions are present in the system, and in this case trialkylbenzylammonium sulfate can be recommended.

(2) The distribution coefficients of Zr(IV) and F^- were determined. Fluoride ions are coextracted with Zr(IV); the F : Zr molar ratio remains constant in both organic and aqueous solutions. D_{Zr} is about 3 at F : Zr = 6.

(3) The most complete Zr(IV) backwashing is ensured by 1 M HCl at a 1 : 2 volume ratio of the organic to aqueous phase.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Kinetics of Ba^2+, Cu^2+, and Y^3+ on KRF-10p Complexing Cation Exchanger

I. N. Poleshchuk and L. A. Pimneva

Tyumen State Architectural and Building Academy, Tyumen, Russia

Received 14 December, 2000; in final form, June 2001

Abstract—The ion-exchange sorption kinetics of barium, copper, and yttrium on KRF-10p cation exchanger from $BaCl_2$, $CuCl_2$, and $Y(NO_3)_3$ aqueous solutions was studied. The ionic diffusion coefficients were determined as a function of temperature and concentration.

The ion exchange rate is one of the important factors influencing the sorption efficiency of ion exchangers. A study of ion-exchange sorption kinetics gives better insight into the mechanism of the sorption process as a whole. Kinetic curves allow determination of such principal parameters influencing the sorption as the rate of sorption equilibrium attainment and the maximal operating sorption capacity of an ion exchanger at a given solution composition and temperature. These kinetic data are useful in analysis of cation–resin interactions and can be used to determine the diffusion coefficients controlling the internal and external mass transfer of the cations and the limiting stage of sorption.

The aim of this work was to study the sorption kinetics of Ba^{2+}, Cu^{2+}, and Y^{3+} on KRF-10p cation exchanger in the H^+ form from chloride and nitrate solutions containing various amounts of hydrochloric and nitric acids.

EXPERIMENTAL

Prior to experiment, the cation exchanger was treated by the procedures described in [1]. The ion exchange in the H^+–Ba^{2+}, H^+–Cu^{2+}, and H^+–Y^{3+} systems was studied by the technique reported in [2].

The initial salt solution (500 ml) was poured in a vessel and placed in a thermostat. After the required temperature was reached (25, 45, and 60°C), a weighed portion of swollen KRF-10p cation exchanger in the H^+ form (1 g dry weight) was placed in vigorously stirred solution, and simultaneously the process timing was started. The solution was sampled at regular intervals with 5-ml portions taken, and the metal content was determined. The total solution volume sampled in the course of the experiment was no more than 2% of the initial solution volume. The cation concentration was determined complexometrically [3, 4].

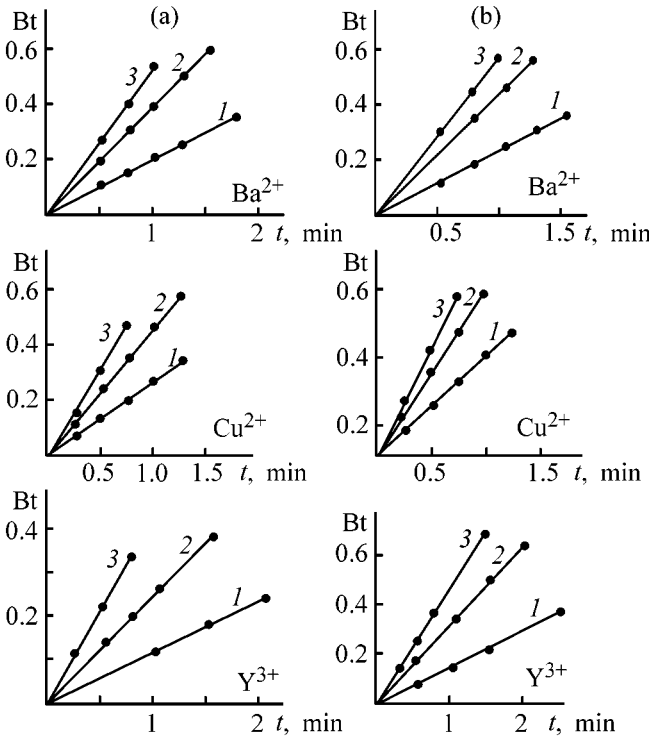

Fig. 1. The Bt parameter vs. time *t* for cation sorption from (a) starting 0.1 M $BaCl_2$, $CuCl_2$, and $Y(NO_3)_3$ solutions and (b) 0.1 M $BaCl_2$, $CuCl_2$, and $Y(NO_3)_3$ solutions containing 0.1M HCl (HNO_3) on KRF-10p cation exchanger in the H^+ form. Temperature (°C): (*1*) 25, (*2*) 45, and (*3*) 60.

The kinetics of cation-exchange sorption on KRF-10p is shown in Figs. 1–3 and table. The original experimental kinetic curves were processed using the Boyd–Adamson equation for pore diffusion [5, 6]

$$F = Q_t/Q_\infty = 1 - 6/\pi^2 \sum_{n=1}^{\infty} 1/n^2 \exp(-\mathrm{Bt}\, n^2), \qquad (1)$$

where F is the degree of ion exchange; Q_t and Q_∞ are the amounts of ions sorbed by the time of sampling t (s) and by the time of equilibrium attainment, respectively; $\mathrm{Bt} = (\bar{D}\pi^2 t)/r^2$ is the dimensionless parameter (Fourier homochronism criterium), and r is the ion-exchanger grain radius (mm).

The Bt parameters for different F were reported in [7].

The adequacy of Eq. (1) was confirmed in a set of sorption experiments with intermittent separation of the cation exchanger and aqueous phases [8]. It was found that the sorption rate increases after repeated contact of the cation exchanger and solution. This shows that the cation pore diffusion is the limiting stage of sorption. As seen from Fig. 3, this mechanism determines the sorption kinetics of Cu^{2+} on KRF-10p cation exchanger. Sorption of the other cations under consideration is characterized by similar kinetic curves. Our experimental results are satisfactorily fitted by Eq. (1), which is confirmed by the linear run of the plot of Bt vs. t for the systems under consideration at F ranging from 0 to 0.5–0.7 (Figs. 1a, 1b). These linear dependences also suggest that the pore diffusion within the resin grains is the limiting stage of mass transfer in cation sorption.

The diffusion coefficients were calculated by the equation

$$D = \frac{\mathrm{Bt}\, r^2}{\pi^2 t}.$$

Data in the table show that the cation diffusion coefficient grows with increasing acid concentration in the initial solution. Apparently, this trend is mainly caused by an increase in the concentration of the protonated ion-exchange groups on the surface and within ion exchanger grains, a decrease in the degree of cation hydration, an increase in the ionic strength of solution, and, as a result, an increase in the degree of ionization of the cation exchanger. The rate of cation exchange between the solution and cation exchanger is determined by the charge and radius of the cation and the strength of the bond between the cation and the sorbing site. The radii of cations under consideration increase in the following order: $Y^{3+} < Cu^{2+} < Ba^{2+}$.

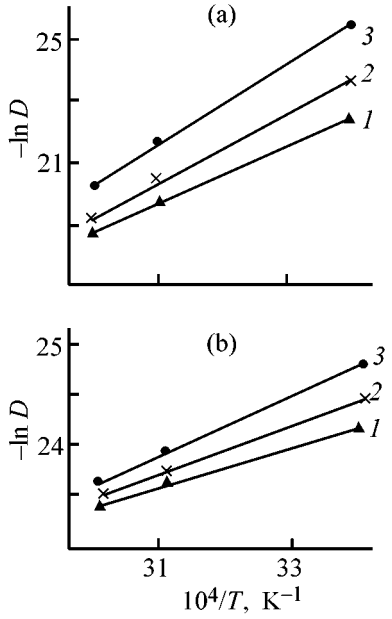

Fig. 2. Influence of temperature T on the diffusion coefficients D of (*1*) Cu^{2+}, (*2*) Ba^{2+}, and (*3*) Y^{3+} in their sorption from (a) starting $CuCl_2$, $BaCl_2$, and $Y(NO_3)_3$ solutions and (b) those containing 0.1 M HCl (HNO_3) on KRF-10p cation exchanger in the H^+ form.

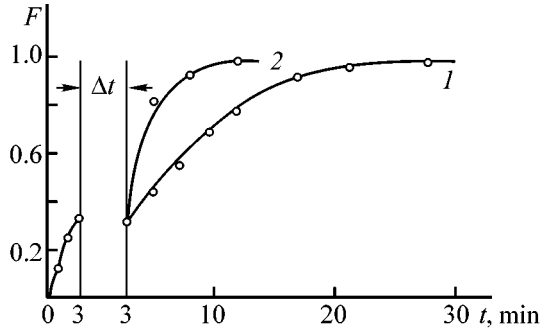

Fig. 3. Kinetic curves of copper sorption from 0.1 N $CuCl_2$ solution on KRF-10p cation exchanger. (F) Degree of exchange and (t) time; (*1*) at continuous contact between the liquid and cation exchanger phases and (*2*) with intermittent separation of the liquid and cation exchanger phases.

The ionic radii of these cations, reported in [8], are 0.93, 0.96, and 1.35 Å, respectively.

The diffusion coefficients increase in the following order: $Y^{3+} < Ba^{2+} < Cu^{2+}$.

The abnormally low yttrium diffusion coefficient in this series is due to its larger electrical charge. It is known [5] that the diffusion coefficients sharply decrease in passing to multicharged cations.

Kinetic parameters of Ba^{2+}, Cu^{2+}, and Y^{3+} diffusion transfer from 1 M $BaCl_2$, $CuCl_2$, and $Y(NO_3)_3$ solutions into grains of KRF-10p cation exchanger in the H^+ form

Cation	T, °C	$D \times 10^{12}$, $cm^2\ s^{-1}$		ΔE, kJ mol^{-1}	
		at indicated acid concentration, M			
		0	0.1	0	0.1
Ba^{2+}	25	20.08	23.12	22.53	20.52
	45	40.16	47.06		
	60	58.83	62.88		
Cu^{2+}	25	27.79	30.43	17.16	15.92
	45	48.89	52.33		
	60	63.29	65.93		
Y^{3+}	25	12.58	16.23	26.53	25.67
	45	30.43	39.15		
	60	46.25	54.77		

The activation energy of diffusion was calculated by the least-squares method by graphically solving the equation

$$\overline{D} = D_0 \exp(-E/RT). \quad (3)$$

The dependence $\ln \overline{D} = f(1/T)$ is plotted in Fig. 2.

The low activation energy of diffusion, obtained in our experiments, is typical of pore diffusion. These results show that cation exchange makes the major contribution to sorption. Therefore, we can assume that metals under consideration are mainly transferred within cation-exchanger grains in the cationic form. Our results on sorption kinetics can be used in designing sorption installations, solving problems of the ion-exchange dynamics, and optimizing the cation concentration and separation with KRF-10p phosphonic cation exchanger.

CONCLUSIONS

(1) The limiting stage of Ba^{2+}, Cu^{2+}, and Y^{3+} sorption is the pore diffusion of these cations within cation exchanger grains. The diffusion coefficients of these cations and the apparent activation energy were calculated by the pore-diffusion equation.

(2) The cation sorption is accelerated with increasing acid concentration in solution.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Thermal Treatment on Sorption Activity of Calcium and Magnesium Phosphates

N. V. Kitikova, I. L. Shashkova, and A. G. D'yachenko

Received April 11, 2000; in final form, March 2001

Abstract—The effect of thermal treatment in the range 20–800°C on the activity of hydrated calcium and magnesium phosphates in recovery of heavy metal ions from aqueous solutions was studied. The composition and sorption properties of materials obtained in all stages of thermal treatment of hydrophosphates and phosphates are considered. The manner in which the sorption activity of phosphates changes upon thermal treatment is interpreted.

Hydrated calcium and magnesium phosphates, precipitated from solutions of chlorides or nitrates of these metals with a solution of ammonium phosphate, are known as materials demonstrating high efficiency in recovery of ions of heavy and nonferrous metals M^{n+} (n = 2, 3) from aqueous solutions. In the case of a basic salt (calcium hydroxo apatite), the recovery of multicharged metal ions is due to the occurrence of ion-exchange processes [1–4], with capacity 1–3 mg-equiv g^{-1}. In the case of calcium and magnesium phosphates and hydrophosphates, the absorption of double- and triple-charged metal ions is a result of the occurrence of a chemical reaction between solid phosphates and M^{n+} ions [5–9], with the absorption of metal ions in these processes being as high as 25 mg-equiv g^{-1}. Compounds with such a capacity for absorption of ions of heavy and nonferrous metals are of indubitable practical interest.

Practical use of sorption-active materials assumes that data on their thermal stability must be available. Thermal treatment is a necessary operation in obtaining a granulated form of a sorbent and a widely adopted way of sorbent modification to unify or improve their properties.

Published data on the effect of temperature on the chemical activity of calcium and magnesium phosphates are lacking [10].

The present communication reports the results obtained in studying the effect of thermal treatment in the range 20–800°C on the sorption properties of calcium and magnesium phosphates and hydrophosphates precipitated from aqueous solutions.

EXPERIMENTAL

Phosphates $Mg_3(PO_4)_2 \cdot 22H_2O$ and $Ca_3(PO_4)_2 \cdot 3.45H_2O$; hydrophosphates $CaHPO_4 \cdot 2H_2O$, $MgHPO_4 \cdot 3H_2O$, and also a 1 : 1 mixture of $CaHPO_4 \cdot 2H_2O$ + $MgHPO_4 \cdot 3H_2O$ were studied. The salts $Mg_3(PO_4)_2 \cdot 22H_2O$, $CaHPO_4 \cdot 2H_2O$, and $MgHPO_4 \cdot 3H_2O$ were crystalline, and $Ca_3(PO_4)_2 \cdot 3.45H_2O$ was an amorphous substance.

The compounds studied were synthesized as follows. Crystal hydrates of the hydrophosphates and phosphates were precipitated from aqueous solutions of calcium or magnesium nitrates and ammonium phosphate at pH 5 and 10, respectively [10]. A sorption-active mixture of calcium and magnesium hydrophosphates was synthesized as described in [11], with natural dolomite used as raw material. A weighed portion of dolomite was placed in a 10% phosphoric acid solution (M_s : M_l = 1 : 6) and kept for a week with periodic stirring. Then the solution was decanted and the obtained precipitate of calcium and magnesium hydrophosphates was washed with water and dried in air.

The specific surface area of the synthesized compounds was determined from the low-temperature adsorption of nitrogen.

The thermal treatment of the phosphates was done stepwise in the temperature range 20–800°C in a muffle furnace. After 4 h of treatment at 200°C a specimen was cooled and sampled for determining its sorption activity, ground, and again placed in the furnace at higher temperature of 300°C, etc.

* M = Ca or Mg.

** Numerator, calculated; denominator, found.

*** Also contains acid-insoluble admixture of SiO_2 (1.6%).

The structure of the initial phosphates and products of their thermal treatment was determined by X-ray phase analysis (XPA) (DRON-2 diffractometer, Cu_{K_α} radiation) and IR spectroscopy (UR-20 spectrometer, frequency range 4000–400 cm^{-1}, in pellets with KBr, 2-mg weighed portions).

The sorption activity of the obtained materials was evaluated on the basis of absorption by these substances of Pb^{2+} ions from 0.2 N solutions of $Pb(NO_3)_2$ [4]. For this purpose, a weighed portion of a ground sorbent (0.09–0.25 mm fraction, 0.2 g) was placed in 25 ml of 0.2 N lead nitrate solution at room temperature and kept for 24 h with periodic stirring. The solution was separated from the solid phase and the residual content of lead ions in the filtrate was determined by complexometric titration. The error in determining the concentration of lead ions in solution was ±5%.

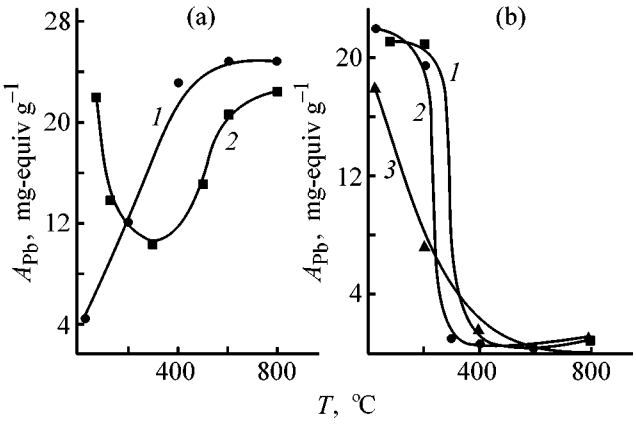

Fig. 1 Changes in sorption capacity of calcium and magnesium phosphates toward lead ions, A_{Pb}, upon thermal treatment. (*T*) Temperature. (a) (*1*) $Mg_3(PO_4)_2 \cdot 22H_2O$ and (*2*) $Ca_3(PO_4)_2 \cdot xH_2O$; (b) (*1*) $CaHPO_4 \cdot 2H_2O$, (*2*) $MgHPO_4 \cdot 3H_2O$, and (*3*) $CaHPO_4 \cdot 2H_2O$–$MgHPO_4 \cdot 3H_2O$.

The results of chemical analysis of the synthesized calcium and magnesium phosphates (Table 1) indicate that their composition corresponds to stoichiometry of hydrophosphates (M/P = 1) and phosphates (M/P = 1.5). Their X-ray and spectral characteristics are in agreement with those reported in the literature [10].

The manner in which the sorption capacity of the phosphates toward lead ions changes upon thermal treatment is shown in Figs 1a and 1b in the form of a plot of the amount A_{Pb} of lead absorbed from a 0.2 N $Pb(NO_3)_2$ solution against the sample heating temperature.

As seen from Fig. 1, the sorption activity of the phosphates changes upon thermal treatment in different ways. For calcium phosphate $Ca_3(PO_4)_2 \cdot 3.45H_2O$, the A_{Pb}–T dependence shows a minimum at 300°C (Fig. 1a). Upon thermal treatment at 20–300°C, the capacity for lead(II) decreases from 20.6 mg-equiv g^{-1} for the initial sample to 10.6 mg-equiv g^{-1} for a sample calcined at 300°C. With temperature raised further, to 800°C, the A_{Pb} value increases to 22.6 mg-equiv g^{-1}.

The sorption capacity of calcium and magnesium hydrophosphates, and a mixture of these, falls upon

thermal treatment irreversibly. The A_{Pb} value for the initial samples is 21.3, 22.1, and 18.1 mg-equiv g^{-1}, respectively. After thermal treatment at 600–800°C, the corresponding values lie in the range from 0.2 to 1.2 mg-equiv g^{-1}.

The sorption capacity of magnesium phosphate $Mg_3(PO_4)_2 \cdot 22H_2O$ grows upon thermal treatment at 20 – 400°C (Fig. 1a) as a result of a considerable loss of mass through dehydration, reaching the maximum value at 400°C, and remains virtually unchanged with temperature elevated further. The sorption capacity of magnesium phosphate in terms of anhydrous salt is virtually unchanged upon thermal treatment.

To explain the observed behavior of the sorption activity of the phosphates, the nature of physicochemical processes occurring in their thermal treatment was studied (Table 2).

The processes of dehydration of calcium and magnesium hydrophosphates and the phase and chemical composition of products formed in all stages of dehydration were described in detail in [10, 12, 13]. According to the available data, calcium and magnesium hydrophosphates polymerize in dehydration to give diphosphates, with calcium diphosphate formed directly from calcium hydrophosphate at 290°C by the scheme

$$CaHPO_4 \cdot 2H_2O \xrightarrow{120^\circ C} CaHPO_4 \xrightarrow{290-400^\circ C} Ca_2P_2O_7. \quad (1)$$

Dehydration of the magnesium salt is a more complex process. In the range 20–600°C, dehydration of magnesium hydrophosphate is accompanied by formation of a multicomponent mixture of amorphous phosphate polymers with 1 to 5 phosphorus atoms in the chain and magnesium oxide. At temperatures higher than 650°C the composition of the system becomes simpler because of the interaction of these components to give a diphosphate. The process can be represented as

$$MgHPO_4 \cdot 3H_2O \xrightarrow{T \le 600^\circ C} \left[\begin{array}{l}\text{Mixture of amorphous } P_1\text{–}P_5 \\ \text{phosphates of Mg and MgO}\end{array}\right] \xrightarrow{T > 600^\circ C} Mg_2P_2O_7 \quad (2)$$

The composition of the products formed in thermal treatment of a mixture of hydrophosphates $CaHPO_4 \cdot 2H_2O + MgHPO_4 \cdot 3H_2O$ in the temperature range 20–800°C has not been described in the literature.

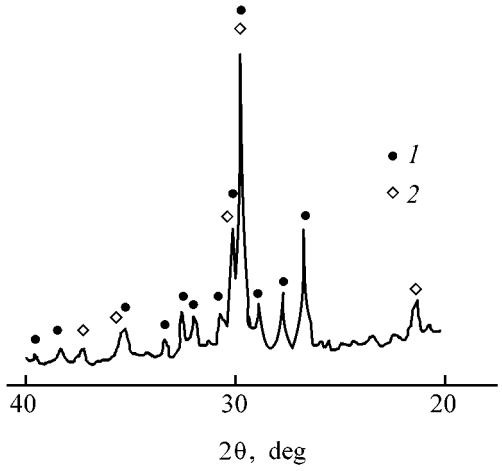

Fig. 2. X-ray diffraction pattern of the product of thermal treatment at 800°C of a mixture of calcium and magnesium hydrophosphates $CaHPO_4 \cdot 2H_2O$ + $MgHPO_4 \cdot 3H_2O$. (2θ) Bragg angle. (*1*) β-$Ca_2P_2O_7$ and (*2*) α-$Mg_2P_2O_7$.

Figure 2 shows an X-ray diffraction pattern of the compound obtained upon calcination of the mixture of hydrophosphates at 800°C. As seen, it contains reflections of calcium and magnesium diphosphates. Double calcium–magnesium diphosphate isolated in [14] from the system $CaO–MgO–P_2O_5$ at a higher temperature of 1050°C was not found in the present study.

Processes of mass loss have been studied in sufficient detail for orthophosphates; however, the information concerning the anionic composition of the forming compounds is rather scarce and contradictory. The final product of dehydration at 800°C is composed of anhydrous orthophosphates, but the issue of whether or not polymerization processes occur in intermediate stages of thermal treatment remains open. It has been noted that amorphous products of $Mg_3(PO_4)_2 \cdot xH_2O$ dehydration contain, in addition to orthophosphate, diphosphate (for a hydrate with x = 22) or di- and tripolyphosphate (for a hydrate with x = 8) [10, 15–17], but no quantitative assessment of these processes has been done. The corresponding information for calcium phosphate is available for a compound of composition $Ca_3(PO_4)_2 \cdot 0.5H_2O$. Up to 1.5–3.0% diphosphate is formed in a certain stage of dehydration of this compound [10].

If the hydrogen bond energy between water of crystallization and the phosphate anion does not exceed 40 kJ mol^{-1}, dehydration proceeds by the molecular mechanism leaving intact the structure of the phosphate anion [10]. Phosphates in which the hydrogen bond energy exceeds the above value are dehydrated by the dissociative mechanism characterized by polymerization of the orthophosphate anion in a certain temperature interval.

To determine the possibility of occurrence of polymerization processes in dehydration of the synthesized hydrated calcium and magnesium phosphates, the energy of their strongest hydrogen bond was evaluated on the basis of IR spectra (Table 3).

The hydrogen bond energy in the synthesized phosphates was calculated using the approximate formula [13]:

$$E = \frac{\Delta\nu}{\nu_0 \times 0.016} \times 4.184,$$

where $\Delta\nu$ is the long-wavelength shift of the frequency of stretching vibrations of the hydroxy group (cm^{-1}), and ν_0 is the frequency of stretching vibrations of the hydroxy group in an isolated water molecule.

In accordance with [16], the ν_0 value is taken to be 3700 cm^{-1}.

The calculated values were 20.0 and 19.8 kJ mol^{-1} for, respectively, $Ca_3(PO_4)_2 \cdot 3.45H_2O$ and $Mg_3(PO_4)_2 \cdot 22H_2O$. According to the existing concepts, dehydration of the calcium and magnesium orthophosphates synthesized must not be accompanied by polymerization. XPA and IR spectral data for the initial phosphates and products of their thermal treatment, presented in Tables 2 and 3, confirm this assumption.

As conclusive evidence in favor of polymerization of the orthophosphate anion in dehydration of calcium and magnesium phosphates would serve appearance of absorption bands associated with vibrations of bridge P–O–P groups in IR spectra of these compounds upon thermal treatment.

As seen from Table 3, products of thermal treatment of calcium and magnesium phosphates show no absorption bands characteristic of vibrations of bridge P–O–P groups and, in particular, symmetric stretching vibrations ν_s(P–O–P) at 650–800 cm^{-1} at any temperature [18–20]. The spectra of calcium and magnesium phosphates contain, in all stages of thermal treatment, only strong absorption bands at 1060–965 and 620–570 cm^{-1}, associated with stretching $\nu(PO_4)$ and deformation $\delta(PO_4)$ vibrations of the orthophosphate anion PO_4 [19]. Thus, calcium and magnesium orthophosphates are dehydrated by the molecular mechanism. The process can be represented schematically as

$$M_3(PO_4)_2 \cdot xH_2O \xrightarrow{20-800^\circ C} M_3(PO_4)_2, \qquad (3)$$

where x = 2.22, and M = Ca or Mg.

Comparison of the presented information on phase and chemical transformations of various phosphates in thermal treatment (Table 2) with changes in their sorption activity (Fig. 1) makes evident that the decrease in the sorption capacity of hydrophosphates and their mixture with the heating temperature increasing in the range 20–600°C is due to the occurrence of polymerization. Polymeric calcium and magnesium phosphates are characterized by lower solubility, compared with monomers, and do not enter into chemical interaction with lead ions; the obtained capacity value (0.2–1.2 mg-equiv g^{-1}) may be due to ion-exchange substitution of lead ions for calcium ions in the structure of these phosphates.

The sorption activity of those phosphates which are not polymerized in thermal treatment is high in all stages of dehydration. Anhydrous calcium and magnesium orthophosphates retain the ability of their hydrated analogues to enter into chemical interaction with lead ions. According to the data obtained, the minimum at 300°C in the A_{Pb}–T curve for $Ca_3(PO_4)_2$ has kinetic origin. In the range 20–300°C, the process of calcium orthophosphate dehydration is the most intensive, which leads to sintering of its particles and to a change in the kinetic parameters of the interaction between the phosphate and lead nitrate solution. With the time of contact between $Ca_3(PO_4)_2 \cdot 3.45H_2O$ calcined at 300°C and lead nitrate solution raised to

4 days and additional grinding performed, a sample sorbed 21.2 mg-equiv g^{-1} of lead(II).

CONCLUSION

Thermal treatment affects differently the properties of hydrated phosphates of alkaline-earth metals. Calcium and magnesium hydrophosphates polymerize upon thermal treatment, and the reaction products—anhydrous diphosphates, do not interact with ions of lead. Hydrated calcium and magnesium orthophosphates are dehydrated by the molecular mechanism and the forming anhydrous orthophosphates retain ability to enter into chemical interaction with lead ions in all stages of thermal treatment.

Received June 23, 2000; in final form, June 2001

Abstract—The constants and rate of filtration, optimal filtering layer thickness ensuring the maximum rate of filtration, and specific resistance of the filtering layer were determined for calcium hydrometasilicate powders of the C–S–H (I) type, obtained by processing natural diatomites and by reacting alkali-siliceous solution with $Ca(OH)_2$. The effects of heat treatment and carbonization of C–S–H (I) on its filtration and adsorption properties were studied. The filtration and adsorption properties of calcium hydrometasilicates and conventional commercial filtering powders are compared.

Recently, such cheap raw materials as natural diatomites have been increasingly studied and used to synthesize filtering powders and adsorbents [1–8]. It has been established [3, 9] that, under certain conditions, lime treatment of diatomites leads to destruction of their primary structure and formation of calcium hydrosilicates $xCaO \cdot ySiO_2 \cdot zH_2O$ of the C–S–H (I) type (by Taylor's classification [10]) with molar ratio $CaO : SiO_2 < 1.5$.

This study is a continuation of recent investigations [3, 5, 9, 11] devoted to synthesis of calcium hydrometasilicates of the C–S–H (I) type by reaction between $Ca(OH)_2$ solution (lime milk), diatomite, and alkaline-siliceous solution. The aim of the study was to analyze filtration and bleaching properties of the above-mentioned hydrometasilicates in purification of spent organic solvents.

EXPERIMENTAL

The experiments were carried out on a laboratory vacuum filtration installation, in which vacuum was maintained constant during an experiment. This installation was used to measure at ΔP = const across a filter the duration of passage of each 100 ml of a pure organic solvent and a spent solution containing soluble and insoluble admixtures through a layer of the hydrometasilicates under study. For comparison, we carried out experiments under similar conditions with the conventional commercial Special-2 and ZP-200 filtering powders [12] and carbonated calcium metasilicate obtained from alkali-siliceous solution (CCM) [11].

On the basis of the obtained data (Tables 1 and 2; Figs. 1 and 2), we calculated the filtration constants K

Table 1. Selected physicochemical characteristics of filtering powders

Powder	S_{sp}, $m^2\ g^{-1}$	ρ, $kg\ m^{-3}$	G, $kg\ m^{-3}$	pH of water extract
C–S–H (I) obtained from diatomite [3]	200	2200	160	9.5
SCM	92	2300	466	9.0
Special-2	22	2020	350	8.2
ZP-200	100	2170	532	6.95

Table 2. Filtration constants and specific resistance of the filtering layer of powders in filtration of pure white spirit

Powder	m	tan β	$K \times 10^4$, $m^2\ s^{-1}$	$C \times 10^3$, $m^3\ m^{-2}$	$r \times 10^{-10}$, $m\ kg^{-1}$

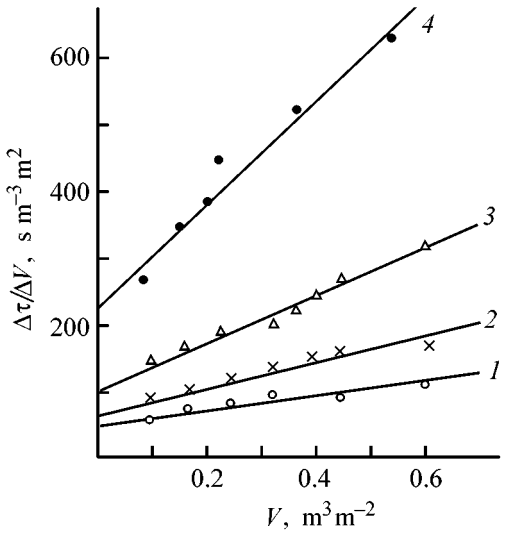

Fig. 1. $\Delta\tau/\Delta V$ vs. filtrate volume V for pure white spirit. (*1*) CCM, (*2*) calcium hydrometasilicate obtained from diatomite, (*3*) Special-2, and (*4*) ZP-200; the same for Fig. 2.

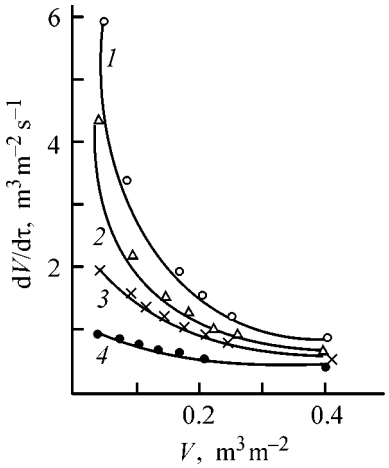

Fig. 2. Filtration rate of spent white spirit $dV/d\tau$ vs. filtrate volume V.

and C related to 1 m^2 of the filtering surface area, the rate of filtration $dV/d\tau$ (m^3 m^{-2} s^{-1}) through a layer of a filtering powder, and the specific resistance r (m kg^{-1}) of the filtering layer (per 1 kg of dry solid substance contained in it) [13]:

$$\frac{dV}{d\tau} = \frac{K}{2(V + C)}, \quad r = \frac{2\Delta P}{\mu G K}.$$

Here V is the volume (m^3) of filtrate passed through 1 m^2 of the filtering surface during a time τ (s); K the filtration constant taking into account the filtration regime and the physicomechanical properties of the precipitate and the solution (m^2 s^{-1}); C the filtration constant characterizing the hydraulic resistance of the filtering cloth (m^3 m^{-2}); ΔP the pressure drop across the filter (kg m^{-2}); μ the viscosity of the filtrate (kg s m^{-2}); and G the mass of dry solid substance precipitated on the filter upon passing 1 m^3 of a filtrate (kg m^{-3}).

Differential thermal analysis curves (DTA) were recorded on an MOM derivatograph (Hungary) with temperature raised at a rate of 5 deg min^{-1}. We determined the specific surface area of samples by the method of low-temperature adsorption of nitrogen by BET [14]; and the density, bulk density, and pH of water extract, by the standard procedures [15].

Table 1 shows that calcium hydrometasilicate obtained from diatomite has a substantially greater adsorption capability than commercial filtering powders, since its specific surface area exceeds by factors of 2 and 9 the specific surface of, respectively, ZP-200 and Special-2 powders. The specific resistance of the filtering layer of calcium hydrometasilicate to pure white spirit is less by factors of 1.8 and 4.3 than that of Special-2 and ZP-200 powders (Tables 2 and 3; Figs. 1 and 2.)

We studied the effect of the heat treatment temperature on the filtering and adsorption properties of calcium hydrometasilicates. It is shown that the specific surface area of C–S–H (I) is almost unchanged as the temperature raised to 550–560°C, irrespective of the $CaO : SiO_2$ molar ratio, and, with the temperature elevated further, to 750°C and more, it decreases abruptly owing to the transformation of porous calcium hydrometasilicate into wollastonite $Ca_3(Si_3O_9)$, which has a substantially more developed crystal structure. The adsorption (decolorizing) properties of calcium

Table 3. Changes in the rate of filtration of pure and spent white spirit through a layer of powders under study at various volumes of the forming filtrate

		C–S–H (I) [3]		CCM		Special-2		ZP-200	
Pure	0.08–0.4	6.7–67.8	11.8–6.5	4.2–34.2	16.9–11.7	10.2–79.1	7.7–4.13	4.2–217.7	3.51–1.83
Spent	0.04–0.4	9.0–615	4.35–0.65	7.0–540	5.94–0.81	20–746	2.0–0.57	41.8–980	0.96–0.44

hydrometasilicates are improved when the temperature of their heat treatment is raised to 350°C, and, with the temperature elevated further, to 650–800°C, they first slowly and then abruptly deteriorate. The volume of micro- and mesopores in C–S–H (I) samples heated to 350°C seems to change in such a manner that it does not affect the specific surface area of the samples, but improves their adsorption properties with respect to admixtures with appropriate molecule sizes, dissolved in organic solvents. The rate of filtering of organic solvents through a calcium hydrometasilicate layer grows steadily with the temperature of its heat treatment increasing to 750°C.

The data obtained in chemical and thermogravimetric studies suggest that calcium hydrometasilicates are readily carbonized. In this case, their CO_2 content increases 7–12-fold reaching a value of 15% CO 2, and the pH of the water extract decreases from 10 to 8.8. In the DTA curves of carbonated C–S–H (I) samples there appears and steadily grows an endothermic peak at 750–800°C (Fig. 3), associated with decomposition of calcium carbonate [16, 17]. The adsorption and filtering properties of calcium hydrometasilicates are improved 1.2–1.5-fold upon their carbonization.

A distinctive feature of high-quality filtering powders is the incompressibility of the filtering layer, which allows through pores to be preserved in it. These pores can let through the liquid but retain solid particles. It has been shown in our previous studies [5] that particles of calcium hydrometasilicate of the C–S–H (I) type have a shape preventing their packing with formation of a dense filtering layer.

A granulometric study of calcium hydrometasilicate of the C–S–H (I) type by the technique described in [18] showed that particles 20–100 μm in size prevail in the samples. Such a granulometric composition of samples ensures high degree of purification of organic solvents at a sufficiently high filtration rate.

With the aim of making conclusive recommendations concerning a filtering powder for purification of spent organic solvents, calcium hydrometasilicate obtained from diatomites was compared with other powders[1] on various machines with various filter designs. As criteria of complete purification served the intensity of filtration, degree of solvent transparency, and pressure on a filter, which was not to exceed 0.202 MPa.

The experiments showed that the intensity of filtration of spent solvents depends to a considerable extent on the thickness of the filtering powder layer. As seen from the data of Table 4, the optimal amount of calcium hydrometasilicate per 1 m^2 of the filter surface is 320–350 g.

Table 4. Rate of filtration of spent white spirit through a layer of C–S–H (I) [3] of varied thickness (content of insoluble admixtures in the starting solution 0.335 g l^{-1})

m, g	m, g per 1 m^2	l, mm	τ, s	$(dV/d\tau) \times 10^3$, $m^3\ m^{-2}\ s^{-1}$
0.0	0.0	0.15	188.1	2.12
0.2	80	0.25	76.0	5.26
0.4	160	0.40	63.0	6.35
0.6	320	0.75	51.0	7.84
1.0	400	0.95	53.0	7.55
1.5	600	1.25	60.0	6.67
2.0	800	1.60	63.0	6.35
3.0	1200	2.25	66.0	6.1

Note: m is the weight of C–S–H (I) powder, and l is the thickness of the precipitate layer after filtration.

Industrial experiments with batches of clothes showed that spent white spirit becomes transparent on being passed through a layer of calcium hydrometasilicate, and the light transmission of the solvent does not change till the 5th batch of clothes, and becomes 88.5 and 57% after 6 and 14th batches, respectively. The pressure on the filter changed from 0.030 to 0.101 MPa at the beginning of filtration of spent white spirit through a layer of calcium hydrometa-

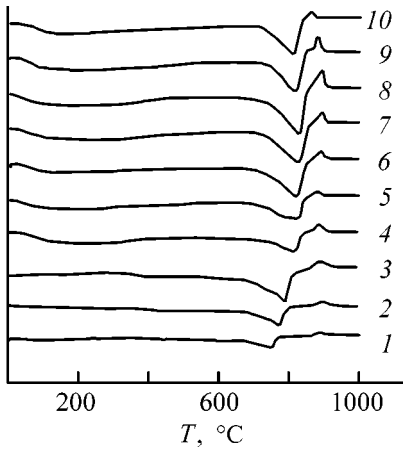

Fig. 3. DTA curves of diatomites treated with $Ca(OH)_2$ solution and carbonated for 15 min. Treatment temperature 95°C, duration 6 h. (T) Temperature. $CaO : SiO_2$ molar ratio in a starting reaction mixture: (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, (*4*) 0.4, (*5*) 0.5, (*6*) 0.6, (*7*) 0.7, (*8*) 0.8, (*9*) 0.9, and (*10*) 1.15.

[1] The tests were carried out at Arabkir dry-cleaning factory in Erevan.

silicate, and from 0.051 to 0.136 MPa at the end of filtration, in treating 1 to 14 batches of clothes, respectively. The color of white spirit passed through a layer of calcium hydrometasilicate appeared to be essentially lighter than that obtained with commercial Special-2 and ZP-200 powders. Moreover, use of calcium hydrometasilicate allowed treatment of 14 batches of clothes, whereas use of Special-2 powder, only 6. The use of calcium hydrometasilicate instead of Special-2 powder made it possible to cut down the solvent losses by 35–45%, shorten the total duration of drycleaning, raise more than twice the average productivity of degreasing machines, and reduce the frequency of filter cleaning 2–3-fold. Similar results were obtained with perchloroethylene used as a solvent.

CONCLUSIONS

(1) The specific resistance of a filtering layer and the main constants and rate of filtration of calcium hydrometasilicate powders obtained upon treatment of natural diatomite and alkali-siliceous solutions were calculated. Compared with the case of conventional commercial filtering powders, the specific resistance of the filtering layer of calcium hydrometasilicate is much lower, and the filtering and adsorption capacity, much better.

(2) The thermal treatment of calcium hydrometasilicate powders at temperatures of up to 350°C and carbonation (to CO_2 content of 15%) improve their filtering and adsorption properties.

(3) Industrial use of calcium hydrometasilicate in purification of spent organic solvents, instead of the conventional commercial filtering powders, improves the quality-related and economic characteristics of the processes and makes higher the productivity of the equipment.

ACKNOWLEDGMENTS

The authors are grateful to staff members of Arbakir factory for the possibility to test the obtained filtering powder (calcium hydrometasilicate).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Synthesis of Binary Oxide Systems Based on Manganese(II) Oxide

V. M. Nagirnyi, R. D. Apostolova, A. S. Baskevich, P. M. Litvin, and E. M. Shembel'

Received January 15, 2001

Abstract—Joint anodic deposition of manganese, cobalt, nickel, and chromium oxides, which form binary oxide systems, from two-component sulfate solutions of the constituent metals was studied under different electrolysis conditions.

Multicomponent oxide systems of the type $LiCo_x \cdot Mn_{2-x}O_4$, $LiCo_yMn_{2-y}O_4$, and MnV_2O_5, prepared by "doping" of traditional electrochemically active oxides of manganese, vanadium, etc., are of interest for developing efficient cathode materials for lithium batteries [1–4]. Such materials are mainly prepared by chemical-thermal synthesis of stoichiometric mechanical mixtures of thermally unstable salts of the corresponding metals (with simultaneous modification of the forming oxide compounds in the presence of lithium carbonate or hydroxide, if necessary). The essential drawback of this method is the difficultly controllable synthesis and the contamination of the final product with impurities formed in side reactions. This makes preferable the electrochemical synthesis of complex oxide systems by anodic deposition from aqueous solutions containing salts of co-deposited metals [5, 6]. The electrolytic synthesis is advantageous because of the possibility of preparing homogeneous materials, whose components, unlike the case of mechanical mixtures, have related structures and can interact at the molecular level. Along with this, the electrochemical method allows fabrication ballast-free cathodes by direct deposition of complex oxide systems onto a smooth or gauze stainless-steel substrate. Vanadium(V) oxide, synthesized simultaneously with manganese oxide, shows better electrochemical performance than the individually synthesized material [7].

Therefore, it was appropriate to study the possibility of preparing complex binary systems by joint electrolytic deposition of oxide compounds of manganese, cobalt, nickel, and chromium from mixed aqueous solutions of salts of metals co-deposited under varied electrolysis conditions. Data of this kind are unavailable in the literature.

The electrolysis was performed in a 0.2-dm^3 temperature-controlled glass cell. Smooth plates of technical grade VT-1 titanium served as a cathode. The oxides under study were deposited as compact coatings on two sides of gauze and plate-like 12X18H9T steel anodes of size $10 \times 10 \times 0.15$ and $10 \times 10 \times 0.3$ mm, respectively, at $S_a : S_c = 1 : 5$. An X-ray diffraction analysis was used to study on disperse deposits of weight 0.1–0.15 g, obtained on a smooth VT-1 titanium plate. The solutions were prepared from pure and analytically pure reagents and distilled water. Two-component solutions based on manganese, cobalt, nickel, and chromium sulfates were used in the study. The total concentration of the solutions studied was within the range 0.3–0.4 M at a ratio of the main to doping components from 5 : 1 to 1 : 5. All runs were performed at 85 ± 3°C and pH 2.0–2.5. The electrolysis parameters were chosen on the basis of preliminary experimental tests. The deposition rate V_{dep} (mg cm^{-2} h^{-1}) was determined from the weight gain upon electrolysis per unit surface per unit time. Polarization curves were taken in a special three-chamber cell on a plate-like 12X18H9T steel anode (S_a = 1 cm^2) with surface roughness corresponding to ∇ 7–8 at $S_a : C_c = 1 : 4$ and current densities in the range 0.5–50 mA cm^{-2}. The potentials were measured relative to a silver chloride reference electrode (E = +0.225 V) with a ShCh-4315 digital voltmeter. The X-ray diffraction analysis was done on a DRON-2 diffractometer. The microstructure of the surface of deposits (1–3.5 μm thick films) was studied with a nanoscope. The quantitative composition

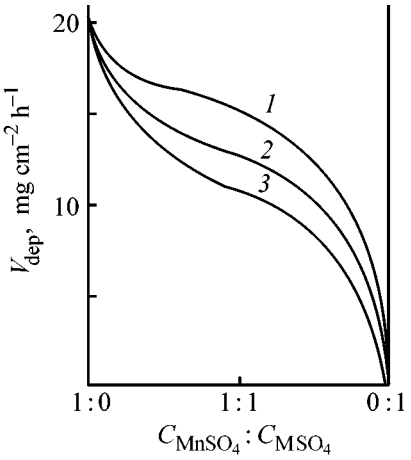

Fig. 1. Deposition rate V_{dep} of binary oxides vs. the concentration ratio of sulfates of co-deposited metals C (M). Total concentration 0.3–0.4 M, T = 85°C, pH 2.0–2.2, i_a = 15 mA cm^{-2}; the same for Fig. 4. System: (*1*) Mn–Co, (*2*) Mn–Ni, and (*3*) Mn–Cr.

of the deposits was estimated approximately by the oxalate technique chemical analysis [8].

Figure 1 shows how the deposition rate of the systems studied varies with the ratio of the main components in mixed solutions under the indicated conditions of electrolysis. With increasing "dopant" concentration in a solution, the deposition rate gradually decreases in all cases. Comparison of the deposition rates of individual manganese and cobalt oxides from their solutions under comparable conditions of electrolysis (20–25 and 2.5–3.0 mg cm^{-2} h^{-1}, respectively) shows that the efficiency of the anodic process decreases steadily with increasing dominating role of delayed formation of the "doping phase" in the anodic deposit (Fig. 1, curve *1*). Similar dependences were obtained for the systems Mn–Ni and Mn–Cr. However, the deposition rate for these systems decreases more sharply with increasing dopant concentration (Fig. 1, curves *2*, *3*). This is accounted for by the fact that, under the given conditions, nickel and chromium oxides cannot be deposited directly from their solutions, and are co-deposited with manganese oxide onto the anode. Apparently, the forming manganese oxide acts as a catalyst, energetically facilitating the transition of the conjugate metal ions into the oxide phase and the formation of stable oxide compounds in the joint anodic process.

The feasible anodic reactions corresponding to the systems studied can be represented by equations (1)–(6) [9, 10] and concurrent redox reactions (7), (8):

$$2Mn^{2+} + 3H_2O \rightarrow Mn_2O_3 + 6H^+ + 2e, \quad E^0 = 1.0\ V, \qquad (1)$$

$$Mn^{2+} + 2H_2O \rightarrow MnO_2 + 4H^+ + 2e, \quad E^0 = 1.23\ V, \qquad (2)$$

$$2Co^{2+} + 3H_2O \rightarrow Co_2O_3 + 6H^+ + 2e, \quad E^0 = 1.8\ V, \qquad (3)$$

$$2Ni^{2+} + 3H_2O \rightarrow Ni_2O_3 + 6H^+ + 2e, \quad E^0 = 1.75\ V, \qquad (4)$$

$$Ni^{2+} + 2H_2O \rightarrow NiO_2 + 4H^+ + 2e, \quad E^0 = 1.68\ V, \qquad (5)$$

$$2Cr^{3+} + 3H_2O \rightarrow 2CrO_3 + 6H^+ + 6e, \quad E^0 = 1.36\ V, \qquad (6)$$

$$Ni_2O_3 + Mn_2O_3 \rightarrow 2NiO + 2MnO_2, \qquad (7)$$

$$2CrO_3 + 3Mn_2O_3 \rightarrow Cr_2O_3 + 6MnO_2. \qquad (8)$$

Reactions (1)–(6) are related to standard redox systems. The standard electrode potentials for these reactions are given according to the data of [9, 10]. However, only reactions (1)–(3) can actually occur under the conditions considered. In the given case, reactions (4)–(6) are concurrent and can proceed to give oxide compounds only simultaneously with manganese oxidation. Reactions (7) and (8) are quite permissible, with account taken of the probable ionic and interphase interaction of conjugate components in anodic deposition under certain conditions. This is confirmed by X-ray diffraction analysis of the corresponding binary systems, in which the presence of all of the oxide phases described by equations (1)–(4) and (6)–(8) was revealed [reaction (5) is intermediate].

Probably, processes of joint deposition of the oxide systems studied may occur stage by stage or following other, more complex schemes. This is indirectly confirmed by comparative analysis of the i_a–E dependences characterizing the process of joint deposition (Fig. 2). A characteristic feature of these dependences is the presence of an intermediate plateau at potentials preceding the ascending branch. The relative position and the character of the corresponding curves depend on the manganese to metal salt concentration ratio Mn : M (where M is Co, Ni, and Cr) in solution. It can be seen in Fig. 2 that raising the "dopant" concentration makes the anodic polarization stronger and the current density lower. In this case, the relative shift of the upper portions of polarization curvers for the same binary system at the concentration ratio in solution varied from 3 : 1 to 1 : 3 is 0.23–0.25 V,

and that of the lower portions at the level of the inflection points, no more than 0.1 V. At current densities lower than 5 mA cm^{-2} the curves virtually merge together, irrespective of the above ratio.

The influence exerted by the nature of a doping component is manifested as enhancement of the anodic polarization in order Co < Ni < Cr, in agreement with the dependences of the deposition rate on the Mn : M ratio in solution (Fig. 1). Comparison of the lower portions of the i_a–E curves for binary systems with a similar dependence of the anodic deposition of manganese oxide from its solutions shows that oxidation of manganese to give oxide is the potential-determining process, irrespective of the Mn : M ratio. This process is accompanied by simultaneous reactions of binary oxide formation and hydrogen evolution, which are more intensive in the range of the upper ascending branches of the curves.

Probably, the less positive anode potentials in the lower portions of the curves result from the occurrence of reactions of the first stage of magnesium oxidation $Mn^{2+} \rightarrow Mn^{3+}$ and oxygen discharge on the initial weakly oxidized stainless-steel surface, proceeding with lower energy expenditure. After a solid oxide film is formed on the anode and the limiting diffusion current of the co-deposited metal ions is reached, the process passes into a new stage (upper portions of the curves), with the corresponding change in the relative rates of the concurrent anodic reactions: O_2 > oxide(Mn–M). The energy balance of the anodic process as a whole is determined by the polarization of electrode reactions invilving oxygen evolution on the anode surface shielded by a solid oxide film and of co-deposition of oxide compounds of the conjugate oxide system. In this case, raising the concentration of the "doping" phase causes a corresponding increase in the anodic polarization. This follows from a comparison of the upper portions of the curves for the systems with Mn : M ratio higher and lower than unity (Fig. 2, curves *3*, *3*'; *4*, *4*'; *5*, *5*'). As seen, the upper portions of curves *3*'–*5*' lie at more positive potentials than the corresponding portion for deposition of cobalt oxide from its solution.

The current density on the surface preliminarily coated with a solid film of the corresponding binary oxide steadily grows with increasing potential and reaches the limiting values for the given binary system without intermediate plateaus (Fig. 2, curve *5*, dashed line). This confirms the considered kinetic origin of the electrode processes studied at different current densities. The last assumption is in accord with the dependences of the deposition rate on the current density, observed for the binary systems studied at various Mn : M ratios (for the example of the Mn–Cr system; Fig. 3). The dependences are similar for all Mn : M ratios: the deposition rate sharply increases in a narrow range of current densities and reaches certain limiting values at i_a = 15–20 mA cm^{-2}. In this case, the limiting values of V_{dep} totally coincide with the corresponding values in the dependence of the deposition rate on the Mn : M ratio at constant current density (Fig. 1, curve *3*) and decrease at higher "dopant" concentrations.

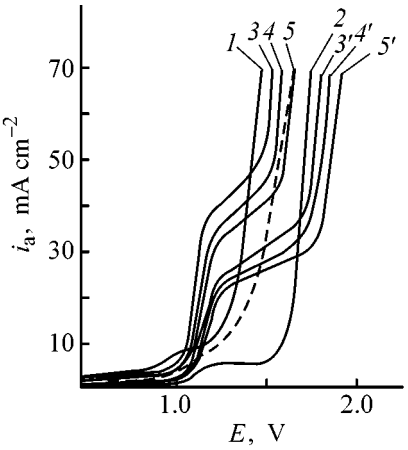

Fig. 2. Current–voltage characteristics of anodic formation of (*1*) manganese and (*2*) cobalt oxides from their solutions and binary oxides from mixed sulfate solutions of co-deposited metals at concentration ratios (*3*–*5*) 3 : 1 and (*3*'–*5*') 1 : 3. Fig. 3. Deposition rate V_{dep} of the double oxide Mn–Cr vs. anodic current density i_a at various C_{MnSO_4} : $C_{Cr_2(SO_4)_3}$ ratios. Total concentration 0.3–0.4 M, T = 85°C, pH 2.0–2.5. C_{MnSO_4} : $C_{Cr_2(SO_4)_3}$: (*1*) 5 : 1, (*2*) 3 : 1, (*3*) 1 : 1, (*4*) 1 : 3, and (*5*) 1 : 5.

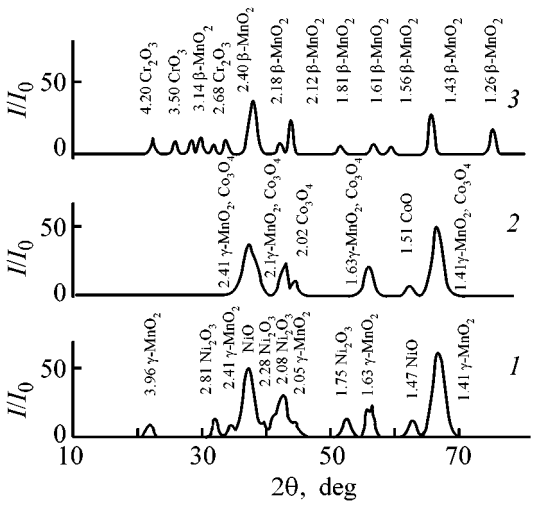

Fig. 4. Diffraction patterns of binary oxides (*1*) Mn–Ni, (*2*) Mn–Co, and (*3*) Mn–Cr, deposited from solutions with concentration ratios $C_{MnSO_4} : C_{MSO_4} = 1 : 3$ and heated in air to 420°C for 7 h. (I/I_0) Relative intensity and (2θ) Bragg angle.

After the limiting values are reached, the deposition rate gradually decreases with increasing current density, which is due to the growing contribution to the energy balance of the anodic process from the hindered reaction of doping phase formation and to the increasing fraction of joint oxygen evolution. This circumstance is in agreement with the current–voltage characteristics of the anodic formation of the corresponding binary systems (Fig. 2). Apparently, the fraction of the doping phase in the binary deposit must grow in the given case.

Such an increase also takes place when the Mn : M ratio in solution is changed toward increased concentrations of the concurrent component. For example, approximate quantitative estimate of the composition of the binary Mn–Co oxide shows that, with the Mn : Co ratio in solution changed from 1 : 2 to 1 : 3, the content of cobalt oxide in the deposit may increase from 12–15 to 20 wt %. For the Mn–Ni and Mn–Cr systems, these values are lower: 10–12 and 5–8 wt %, respectively. Similar relationships are retained for all of the systems studied When the total concentrations of the corresponding components in solution are raised, with other electrolysis conditions being the same. However, at Mn : M < 1 (1 : 2, 1 : 3, etc.) and total concentration above 100 g l^{-1}, the deposition rate decreases considerably owing to the increased contribution of the hindered formation of the doping phase.

According to the results of X-ray diffraction analysis, the materials studied are two-phase systems consisting of oxide compounds formed by joint deposition on the anode. These compound correspond to the most thermodynamically stable forms: MnO_2, CoO, Co_3O_4, NiO, Ni_2O_3, and Cr_2O_3 (Fig. 4). These systems are the most reliably identified by diffractometry at Mn : M = 3 : 1 and after high-temperature treatment at 400, 650, and 720–750°C. Simultaneous modification of the obtained complex oxides in the presence of lithium hydroxide or carbonate is a prerequisite to synthesis of electrochemically active oxide systems in the form of double spinels of the type $LiCo_xMnO_{2-x}O_4$, $LiCr_yMnO_{2-y}O_4$, etc.

Presently, the origin of the structural and molecular correlation in the bulk between the systems studied is unclear. A certain information can be obtained from a comparative analysis of the microstructure and microrelief of the surface of thin-film coatings of the corresponding oxides, deposited onto a smooth stainlesssteel substrate at Mn : M = 1 : 2 (Fig. 5).

Analysis of the presented data shows that the structures of individual oxides and mixed oxides differ significantly. For example, photomicrographs of the surface of the deposits, taken under the same magnification, show that the structure of manganese oxide is coarsely grained crystalline with typical layer-by-layer growth of separate grains (Fig. 5a). At the same time, the cobalt oxide structure is more finely grained, with random orientation of crystals (Fig. 5b).

The structure of co-deposited manganese and cobalt oxides in a mixed anodic deposit essentially differs from the structure of the individual oxides in that a peculiar pattern of finely grained randomly distributed "combs" is formed, which makes the specific surface area of the deposits considerably larger (Fig. 5c).

Deposits with a similar structure are also obtained in joint deposition of manganese and nickel oxides. This is possibly due to the similar mechanisms of formation of the double systems under consideration (Fig. 5d), governed by the interaction of conjugate phases in the stage of their formation and crystallization into grains.

Unlike these systems, Mn–Cr oxide is obtained on the anode in the form of finely grained columnar deposit with rather developed surface (Fig. 5e). These deposits are characterized by ordered structure with virtually symmetric alternation of nearly identical valleys and ridges. Apparently, the mechanism of nucleation and interaction of molecules of the conjugate phases is more intensive in this system, compared with deposition of the binary oxides considered in the present study. This impedes growth of manganese

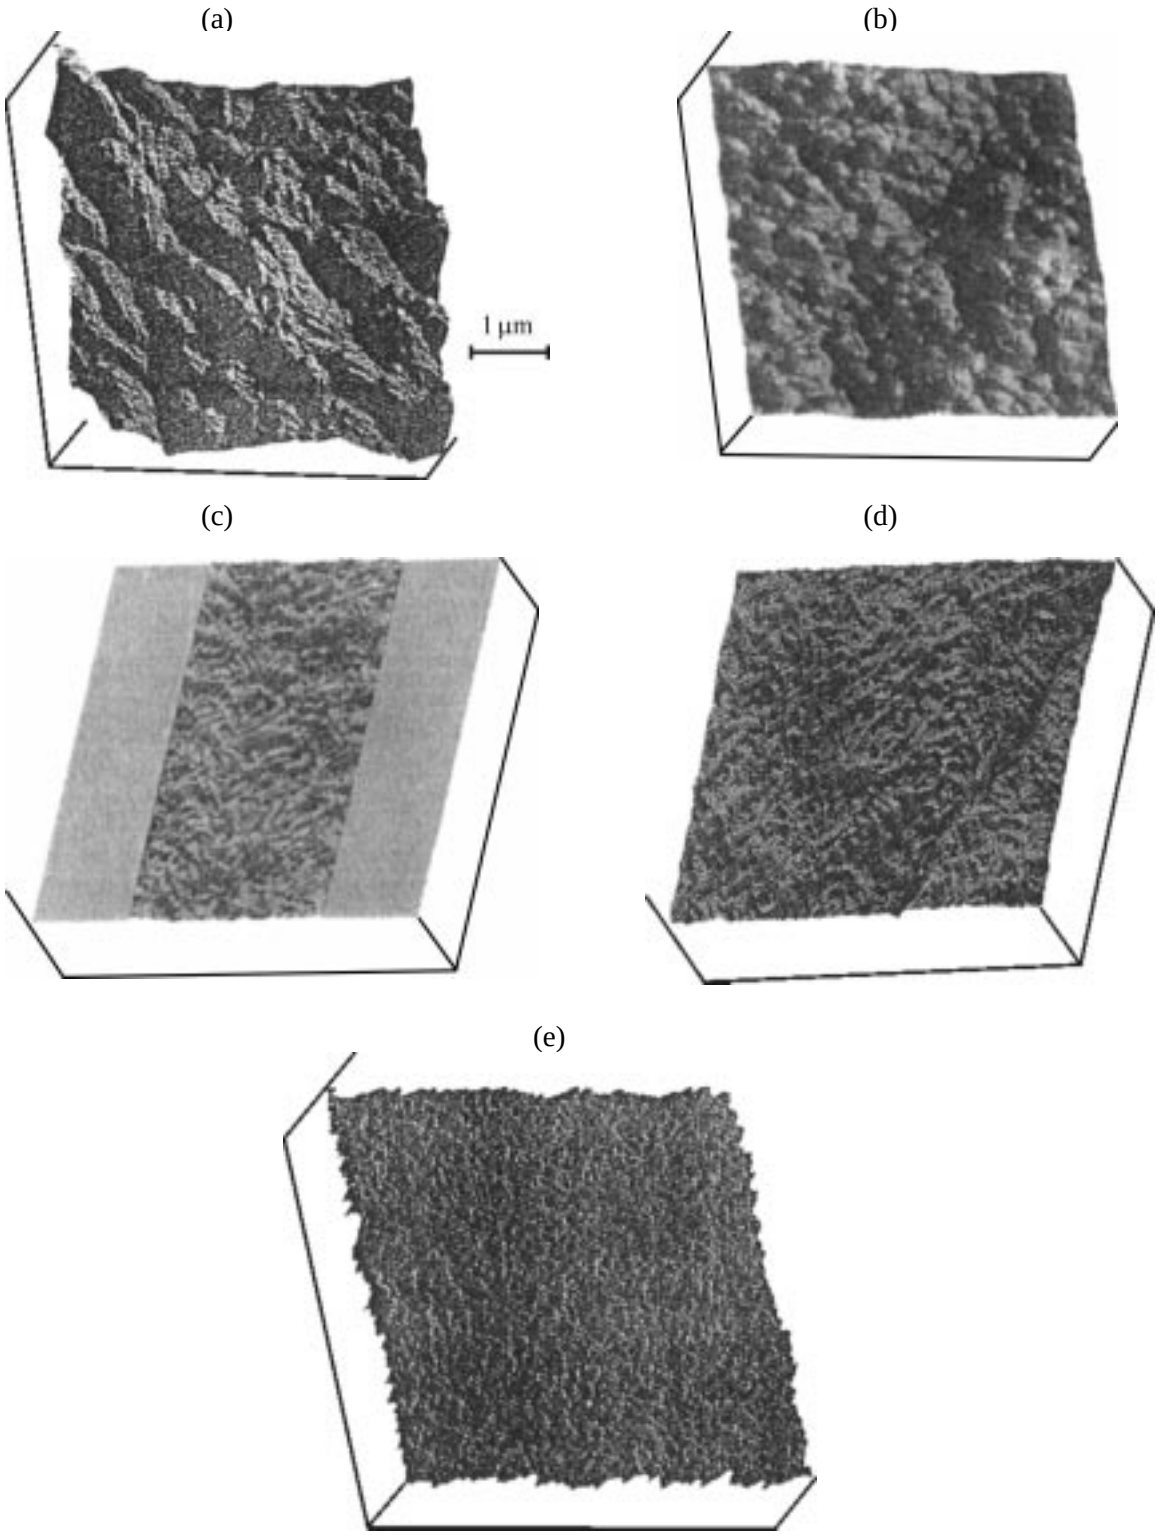

Fig. 5. Photomicrographs of the surface of the electrolytic deposits of (a) MnO_2, (b) Co_2O_3, and binary oxides (c) Mn–Co, (d) Mn–Ni, and (e) Mn–Cr obtained from solutions with 1 : 2 concentration ratio of sulfates of co-deposited metals.

oxide crystals and facilitates their degeneration in the early stage of development.

These data suggest that, from the standpoint of energetics, the binary oxides studied are a certain in-

termediate system between a homogeneous mechanical mixture and the single-phase chemical compound.

CONCLUSIONS

(1) It was demonstrated that complex oxide systems, showing promise as active supports for efficient cathodes of lithium batteries, can be obtained in various combinations (Mn–Co, Mn–Ni, Mn–Cr, etc.) by electrolysis of two-component solutions of Mn(II), Co(II), Ni(II), and Cr(III) sulfates at certain ratios of their concentrations and certain electrolysis parameters.

(2) The necessary condition for electrolytic synthesis of such materials is the presence of a base oxide material, which can be deposited individually on the anode in reasonably high yield, e.g., manganese and cobalt oxides.

(3) Of particular interest are binary oxides of the series studied, synthesized from solutions at 2 : 1–1 : 3 concentration ratios of the main to "doping" metal salts at average total concentration of 0.3–0.4 M. The electrolysis parameters are as follows: temperature 80–85°C, pH 2.0–2.5, and anodic current density 7.5–25 mA cm^{-2}.

Abstract—The process of electrodeposition of tin from a sulfate electrolyte containing $SnSO_4$, H_2SO_4, synthanol, formalin, and propargyl alcohol was studied.

Previously, electrodeposition of tin from a sulfate electrolyte in the presence of organic additives has been studied [1, 2]. It was shown that electrodeposition in an electrolyte containing synthanol and formalin, together with 1,4-butanediol and 2-butene- and 2-butyne-1,4-diols, yields lustrous coatings. The present communication reports the results obtained in studying electrodeposition of tin from a sulfate acid electrolyte in the presence of synthanol, formalin, and propargyl alcohol.

The investigation was carried out in an electrolyte containing (g l^{-1}): $SnSO_4$ 10–50, and H_2SO_4 90–100. The organic substances were introduced into the electrolyte in the following amounts: synthanol (DS-10) 1–4 g l^{-1}, formalin (37% solution) 1–10 ml l^{-1}, and propargyl alcohol 1–15 ml l^{-1}.

Tin was deposited onto copper substrates to a thickness of 6–15 μm. Polarization curves were measured with a P-5828 potentiostat. The luster was measured with an FB-2 photoelectric luster meter. The degree θ of surface coverage with organic additives was evaluated by the results of polarization measurements, using the formula [3]

$$\theta = 1 - \exp(\Delta E/b),$$

where ΔE is polarization, and b is the constant appearing in the Tafel equation, determined from polarization curves plotted in the ΔE–log i_c coordinates.

The leveling power P of the electrolytes was determined directly by profilometric measurements of the surface of samples with sinusoidal microprofile. The P value was calculated using the formula [4]:

$$P = 2.3a/2\pi h_{av}\log(H_0/H_i),$$

where a is the wave amplitude of the sinusoidal microprofile; h_{av} the average coating thickness (10 μm); and H_0 and H_i the initial and final amplitudes of the sinusoidal microprofile, respectively.

The capacitance of the electric double layer was measured in the course of electrolysis with a P-5021 ac bridge at a frequency of 30 kHz, using the series equivalent scheme.

The electrodeposition was done at 18–25°C with and without electrolyte agitation by means of a magnetic rabble.

The effect of organic additives on the outward appearance of coatings was studied in an electrolyte containing 50 g l^{-1} $SnSO_4$ and 100 g l^{-1} H_2SO_4. It was found that, with synthanol (1–4 g l^{-1}) added to the electrolyte, dull coatings are obtained. With formalin (1–10 ml l^{-1}), or propargyl alcohol (1–15 g l^{-1}), or a mixture of these, poor-quality coatings are deposited. The outward appearance of coatings is much improved if propargyl alcohol is added to an electrolyte containing synthanol (2–3 g l^{-1}) and formalin (6–8 ml l^{-1}). Data on the influence exerted by propargyl alcohol on the outward appearance of the coatings are presented in the table.

It can be seen that lustrous coatings are obtained in the presence of propargyl alcohol. The widest range of current densities at which lustrous coatings are obtained (i_c = 7–12 A dm^{-2}) is observed at propargyl alcohol concentrations of 7–10 ml l^{-1}.

With the formalin concentration outside the above limits, silvery coatings are obtained. At synthanol

concentrations of less than 2 g l^{-1} (1 g l^{-1}), the working interval of current densities for obtaining lustrous coatings becomes much narrower. At synthanol concentrations exceeding 3 g l^{-1} (4 g l^{-1}), the range of current densities yielding lustrous coatings remains unchanged, but electrolyte frothing is much enhanced, which hinders electrodeposition in an agitated electrolyte.

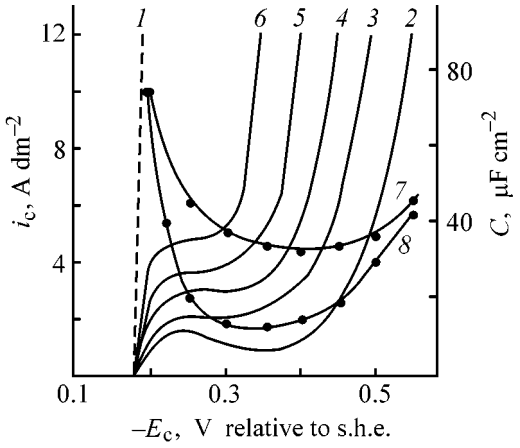

Fig. 1. (*1–6*) Cathodic polarization curves of tin, measured on a rotating disk electrode, and (*7*, *8*) capacitance C of electric double layer vs. electrode potential E_c in tin-plating electrolytes. (i_c) Current density. Electrolyte composition (g l^{-1}): $SnSO_4$ 50, H_2SO_4 100. (*1*, *7*) electrolyte; (*2*, *8*) 1 + 2 g l^{-1} synthanol, 6 ml l^{-1} formalin, and 7 ml l^{-1} propargyl alcohol; (*3*, *4*, *5*, *6*) 2 at disk electrode rotation rates of, respectively, 200, 500, 1000, and 2000 rpm.

In addition to the influence of organic substances, the study was concerned with effect of the $SnSO_4$ concentration on the working range of current densities for obtaining lustrous coatings. The investigation was carried out in an electrolyte containing 2 g l^{-1} synthanol, 6 ml l^{-1} formalin, and 7 ml l^{-1} propargyl alcohol. It was found that lowering the $SnSO_4$ concentration makes narrower the i_c range in which lustrous coatings are obtained. For example, lustrous coatings are obtained in the ranges i_c = 2–5 and 6–10 A dm^{-2} at $SnSO_4$ concentrations of, respectively, 10–20 and 30 g l^{-1}. The H_2SO_4 concentration in the electrolyte should be within 90–100 g l^{-1}. At concentrations lower than 90 g l^{-1} the electrolyte is unstable in operation and the i_c range in which lustrous coatings are obtained becomes narrower. At H_2SO_4 content exceeding 100 g l^{-1} the range of current densities at which lustrous coatings are obtained remains unchanged.

It should be noted that high-quality lustrous coatings are only obtained in an agitated electrolyte, with dull deposits formed otherwise.

The current efficiency (CE) by tin in electrolytes yielding lustrous coatings decreases with increasing i_c and grows as the $SnSO_4$ concentration becomes higher. CE = 95–75% at $SnSO_4$ content of 10–20 g l^{-1} and i_c = 2–5 A dm^{-2}, and CE = 95–90% at $SnSO_4$ content of 30–50 g l^{-1} and i_c = 6–12 A dm^{-2}.

To reveal the influence of organic substances on electrodeposition of tin, cathodic polarization curves were measured on a rotating disk electrode. As seen in Fig. 1, the cathodic polarization is enhanced in the presence of organic substances, with a plateau of limiting current observed in the cathodic polarization curve (curves *1* and *2*). With the disk electrode rotated, the i_{lim} value grows and the cathodic polarization decreases (curves *2–6*). The limiting current in the polarization curves is associated with adsorption of organic substances and formation of an adsorption layer on the cathode surface. This assumption is confirmed by measurements of the capacitance of the electric double layer. As seen in Fig. 1 (curves *7* and *8*), introduction of organic substances into the electrolyte makes the capacitance of the electric double layer lower. At potentials E_c = –0.3…–0.4 V, it decreases from 32 to 10 μF cm^{-2}. At higher cathode potentials, organic substances are desorbed from the electrode surface and the continuity of the adsorption layer is broken, which leads to an increase in the electric double layer capacitance.

Figure 2 presents the degree of coating luster and surface coverage θ as functions of the current density. It can be seen that the degree of coating luster passes through a maximum, and the coverage decreases steadily, with increasing current density (curves *1* and *2*). The θ value at i_c yielding lustrous coatings (i_c = 7–12 A dm^{-2}) varies between 35.0 and 27.7%. It should be noted that lustrous coatings can be obtained in an electrolyte with organic additives only in a certain range of i_c and θ. Presumably, the optimal values of these parameters correspond to the conditions in which the growing deposit has the minimum roughness.

The leveling power *P* was measured in a tin plating electrolyte as a function of the cathode current density (Fig. 2, curve *3*). It can be seen that the tin plating electrolyte with organic additives produces leveling effect. With increasing i_c, the *P* value grows and, at i_c = 10–11 A dm^{-2}, passes through a maximum (*P* = 0.98). At present, the mechanism of surface leveling is commonly explained in terms of the adsorption-diffusion theory [4] whose main concepts are as follows. All leveling additives inhibit electrodeposition of metals, with the degree of inhibition controlled by diffusion as a result of the diffusion-controlled expenditure of the additives in the course of electrolysis. According to [4], polarization curves measured at different rates of disk rotation on a rotating disk electrode model qualitatively the cathodic process of microprojections (fast rotation) or microdepressions (slow rotation). The uneven accessibility of the microprofile is the reason for nonuniform distribution of the supply rate of organic substances to different parts of the microprofile. Since the inhibiting influence exerted by leveling additives on the process of metal electrodeposition grows with increasing rate of additive's diffusion toward the cathode (fast rotation), this effect is manifested to a greater extent on microprojections, and to a lesser extent in microdepressions, which leads to a nonuniform distribution of the electrodeposition rate.

It was proposed on the basis of this circumstance to assess the action of various additives by measuring the cathode potential in an electrolyte with additive(s) in two agitation modes [4]. If the polarization grows with increasing speed of electrode rotation, then it would be expected that additive(s) will exert leveling influence under the given conditions.

Analysis of the cathodic polarization curves in a tin plating electrolyte, measured on a rotating disk electrode (Fig. 1, curves *3*–*6*), shows that they do not model the distribution of the electrodeposition rate

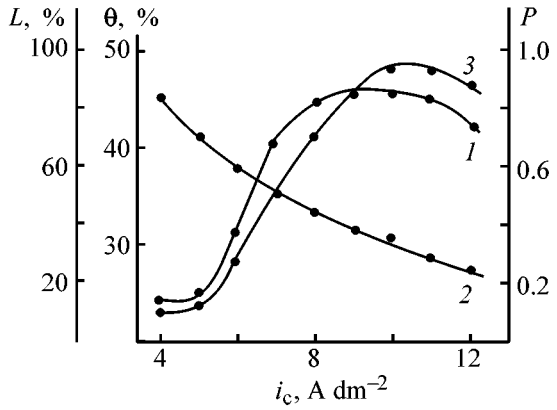

Fig. 2. (*1*) Degree of coating luster, *L*, (*2*) surface coverage θ, and (*3*) degree of leveling, *P*, vs. cathode current density i_c. Electrolyte composition (g l^{-1}): $SnSO_4$ 50, H_2SO_4 100, synthanol 2; formalin 6 ml l^{-1}; propargyl alcohol 7 ml l^{-1}. Mechanical agitation.

over the microprofile. The probable reason is that an adsorption layer of organic substances is formed on the electrode surface. Intensification of the hydrodynamic mode affects the process of formation and disintegration of such a layer. In this case, the rate of tin deposition grows on all parts of the microprofile, i.e., changes in such a way that this appears outwardly just like a manifestation of the antileveling effect.

It should be noted that the same phenomenon is observed in electrodeposition of a Sn–Sb alloy from a sulfate electrolyte in the presence of synthanol, formalin, and 2-butyne-1,4-diol, or synthanol, formalin, and coumarin [5].

The leveling in an electrolyte, in which an adsorption layer of organic substances is present on the electrode surface, can be accounted for on the assumption that this layer disintegrates with increasing speed of disk electrode rotation. This "strips" microprojections to a greater extent as compared with microdepressions. At the same time, a higher rate of supply of organic substances to microprojections is observed with increasing rate of electrode rotation, and the microprojections are more strongly inhibited than microdepressions, which leads to nonuniform distribution of the metal electrodeposition rate over the microprofile surface. The phenomenon of leveling is related to the luster of electroplated coatings, since luster formation is also a process of surface leveling. The leveling eliminates large microirregularities 0.2 to 100 μm and more in size; in luster formation, very fine submicroirregularities (of size about 0.15 μm and less) are smoothed out [6].

Thus, submicro- and microirregularities of the cathode surface are smoothed out in a tin plating elec-

trolyte containing synthanol, formalin, and propargyl alcohol.

Finally, it should be noted that the investigation performed made it possible to develop a sulfate acid tin-plating electrolyte of simple composition, which yields lustrous leveled coatings. The electrolyte composition is as follows (g l^{-1}): $SnSO_4$ 10–50, H_2SO_4 90–100, synthanol (DS-10) 2–3; formalin (37% solution) 6–8 ml l^{-1}; propargyl alcohol 7–10 ml l^{-1}. The process is performed with mechanical agitation of the electrolyte, i_c = 2–12 A dm^{-2}. The current efficiency is 75–95%.

Agitation with air impairs the stability of the electrolyte operation because of the fast oxidation of the electrolyte. The electrolyte temperature is 18–25°C. Above 25°C, the working i_c range in which lustrous coatings are obtained becomes narrower, electrolyte rapidly turns turbid, and a precipitate is formed on the bath bottom, which impairs the quality of the coatings obtained. The anodes should be made of pure tin. To prevent electrolyte contamination with sludge, the anodes are to be placed in sheaths of khlorin or propylene fabric.

The electrolyte is adjusted with respect to $SnSO_4$, H_2SO_4, and formalin, according to chemical analysis data [7]. The electrolyte adjustment with respect to synthanol should be done after 100 A h l^{-1} is passed through the bath by adding 1 g l^{-1} of synthanol. The expenditure of propargyl alcohol is 0.01 ml A^{-1} h^{-1}.

CONCLUSIONS

(1) A study of tin electrodeposition from sulfate acid electrolyte with organic additives demonstrated that, in the case of simultaneous presence of synthanol, formalin, and propargyl alcohol, lustrous coatings are formed at i_c = 2–12 A dm^{-2}, depending on the $SnSO_4$ concentration in the electrolyte.

(2) Cathodic polarization curves were measured on a rotating disk electrode. It was found that organic substances inhibit electrodeposition of tin. In this case, a plateau of limiting current is formed in the polarization curve. With increasing speed of disk electrode rotation, the limiting current grows and the cathodic polarization decreases.

(3) The degree of coating luster and the electrode surface coverage were measured in relation to the current density. It is shown that, with increasing i_c, the degree of luster grows and passes through a maximum, and the surface coverage decreases. The coverage varies between 35.0 and 27.7% in the range of current densities yielding lustrous coatings.

(4) The leveling power of a sulfate acid electrolyte with organic additives was studied. It is established that, in simultaneous presence of synthanol, formalin, and propargyl alcohol, the tin plating electrolyte shows positive leveling whose amount depends on i_c.

(5) The polarization curves obtained at different rates of disk electrode rotation cannot model the distribution of the rate of tin electrodeposition over the microprofile because of the sensitivity of the adsorption layer inhibiting the electrodeposition process to the hydrodynamic mode.

Received September 25, 2001

Abstract—The structure of electrochromic amorphous tungsten trioxide films electrodeposited from an aqueous tungsten-containing electrolyte and specific features of the optical and electrochemical characteristics of these films in different stages of their reversible coloration in a 1 N H_2SO_4 solution were studied.

Electrochromic characteristics of films of amorphous tungsten trioxide α-WO_3, obtained by electrochemical deposition onto cathode from aqueous solutions of tungsten-containing compounds, are comparable with characteristics of similar films obtained by vacuum evaporation and reactive sputtering [1], and, as regards response time and optical contrast in a proton containing electrolyte, are as good as anodic films on tungsten [2, 3]. Electrochromic films have response time of ~0.1 s at a contrast of about 80% in transmission and 95% in reflection [4], whereas electrodes based on anodic films operate only in reflection and need preliminary development of their characteristics by multiple cycling. The electrochromic effect in WO_3 is based on injection into the oxide bulk of electrons from the ohmic contact and the same number of protons from the electrolyte to a concentration of 10^{21}–10^{22} cm^{-3} [1]. The injected electrons are captured to free *d* levels of tungsten, wherefrom they can transit, on absorbing a quantum of light, to neighboring W centers by the charge transfer mechanism [5]. At the same time, films deposited onto cathode from aqueous electrolytes exhibit certain, inherent only in these films, features of structure and of the electrochemical process.

This communication presents the results obtained in a study of reversible changes in the optical absorption spectrum of such films, aimed to reveal the possibility of interpreting such changes with account of the structural features of a deposited layer.

EXPERIMENTAL

α-WO_3 films were obtained by cathodic electrodeposition from an aqueous electrolyte based on sodium tungstate [6], with a transparent conducting SnO_2 layer deposited onto glass used as a cathode. Oxide layers deposited at a cathode current density of about 1 mA cm^{-2} had smooth lustrous surface and exhibited good adhesion to the substrate and clearly pronounced electrochromic properties. The thickness *d* and refractive index *n* of an α-WO_3 layer at a wavelength of 0.6328 μm were determined directly in the course of deposition by means of double-beam laser interferometry [7]. The *d* and *n* values of dried films were measured with a Biolar-PI interference-polarization microscope. The structure of freshly prepared films was studied with optical and scanning electron microscopes, by thermogravimetry, and by IR spectroscopy. The electrochemical and optical characteristics of the fabricated α-WO_3 electrodes were measured in subsequent coloration–decoloration cycles in a 1 N H_2SO_4 solution on a setup described in [4]. For these measurements, the electrodes were placed in a transparent electrochemical cell with a platinum counter-electrode and silver chloride reference electrode, relative to which all electrode potentials *E* of the α-WO_3 layer are given.

The structure of the obtained α-WO_3 films demonstrates that they are X-ray-amorphous and contain a large number of fine pores, which are filled with

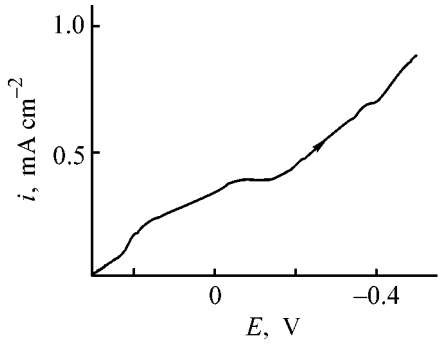

Fig. 1. Current i of coloration of an α-WO_3 film with d = 1 μm vs. cathodic polarization E at sweep rate of 10 mV s^{-1}.

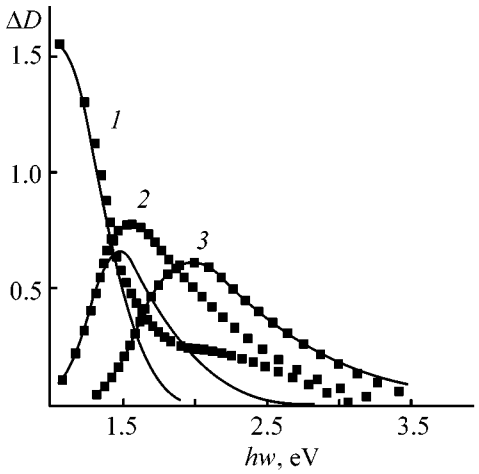

Fig. 2. Spectral distribution of the change ΔD in the optical density of an α-WO_3 layer with d = 1 μm at cathodic polarization E in three successive ranges on the potential scale. (hw) Quantum energy. E (V): (*1*) 0.3–0, (*2*) 0…–0.2, and (*3*) –0.2…–0.4 (*points*). *Solid lines*: three α-WO_3 absorption bands resolved in these spectra.

water molecules in the course of deposition. Most part of free water can be removed from the pores by drying the films in air at room temperature. A certain decrease in the oxide layer thickness, occurring in the process, indicates its densification, which is confirmed by an increase in the refractive index of decolorized α-WO_3 at wavelengths in the range 0.5–0.9 μm, from 1.6–1.7 to 1.9–2.0. In addition to free water in pores, cathodically deposited α-WO_3 layers contain water in capillary-bound and chemically bound (hydrate H_2O) states. The presence of such H_2O molecules is observed in all WO_3 films, irrespective of the preparation technique [1], but the content of the molecules in cathodic deposits (15% according to thermogravimetric analysis) is comparable with the amount of structural water in tungstic acid [8], which is confirmed by IR spectral data. In the region of W–O vibrations, IR spectra of such deposits are similar to the spectrum of yellow tungstic acid, with a broad asymmetric band at 450–1100 cm^{-1}. This band characterizes stretching vibrations of polymer chains of the type …–O–W–O–W–O–… [9] with terminal W=O bonds, whose presence is indicated by the narrow band peaked at 950 cm^{-1} [10, 11]. This gives reason to regard cathodically deposited films as high-polymer oxide compounds of tungsten with varied coordination of oxygen atoms, and the deposit can be represented by the formula $WO_{3-y} \cdot xH_2O$, where $x \approx 2$.

Figure 1 presents the dependence of the cathode current on potential, obtained in coloration of an α-WO_3 layer in a 1 N H_2SO_4 solution. Together with two portions ("waves") of rise in current, between E 0.3 and 0.15 and between –0.15 and –0.35 V, clearly manifested in such electrodes with a cathodically deposited oxide layer [12, 13] and, after cycling, also in anodic α-WO_3 films [3], one more wave is well discernible, having a maximum at $E \approx -0.05$ V. In coloration and decoloration of the electrochromic layer, the electrode current is proportional to the potential sweep rate, but, on passing to a fixed potential, it falls to zero in a time of about 0.1 s. At $E > -0.4$ V, the quasi-equilibrium potential established at the electrode after its disconnection from the power source is virtually equal to the potential which is set at the instant of disconnection (with the difference between these two not exceeding several millivolts). This makes it possible to regard the electrochromic material as a kind of electrolytic capacitor in which the charge of excess electrons captured to free d orbitals of W^{6+} centers, reducing them to W^{5+} [1], is neutralized by the charge of mobile protons in the form of OH_3^+ in channels and pores of the oxide layer. The concentration of injected electrons, N_e, at E = –0.4 V, found by integrating the dependence presented in Fig. 1, is $1.43 \times 10^{21} cm^{-3}$, which corresponds to an oxide in which 30–35% of tungsten atoms are reduced to W^{5+}. It should be noted that, with some α-WO_3 electrodes, a doublet structure of the wave is observed in the range E = –0.15…–0.35 V in the form of two bends in the current–potential dependence, spaced by about 0.15 V.

The optical characteristics of an electrode with a cathodically deposited α-WO_3 layer are presented in Fig. 2. The points represent experimental dependences of the change in optical density on the quantum energy, ΔD–hw. Measurements were done in the course of α-WO_3 layer coloration in three successive ranges of potential, corresponding to the position on the scale of potentials of three waves of the i–E dependence for this electrode in Fig. 1: 0.3–0, 0…–0.2, and –0.2…–0.4 V. In the initial stage of coloration, at a cathodic polarization E of 0.3 to 0 V, a broad

Parameters of three absorption bands in differential optical spectra in Fig. 2 and three types of W centers in the structure of cathodically deposited α-WO_3, corresponding to these bands

Spectrum	hw, eV	$\alpha \times 10^{-4}$, cm^{-1}	$W_{1/2}$, eV	$N_e \times 10^{-20}$, cm^{-3}	f	m_e^*
1	~1	3.57	~0.65	1.0	~1	~1.5

3	2.0	1.43	1.12	6.54	0.12	2.0

absorption band peaked at around hw = 1 eV appears in a preliminarily decolorized film (Fig. 2, spectrum *1*). However, its short-wavelength wing is distorted by superposition of one more absorption band with hw_{max} = 2.0 eV, which is identical to that in the range E –0.2…–0.4 V (Fig. 2, spectrum *3*), except that its intensity is 2.7 times lower. The undistorted short-wavelength wing of the band with $hw_{max} \approx 1$ eV, shown in Fig. 2 by a solid line, was obtained by subtraction from the overall spectrum *1* of the contribution from absorption in the band with hw_{max} = 2.0 eV. An analysis of the additional absorption appearing in the film in the next range of E variation, 0…–0.2 V, (Fig. 2, spectrum *2*) demonstrated that in this case, too, there occurs superposition of two bands; one, more intensive, peaked at 1.5 eV, and a band with hw_{max} = 2.0 eV, but having D_{max} 2 times smaller than that in spectrum *3*. The undistorted run of the dependence ΔD–hw, shown by solid line in Fig. 2, was also obtained by subtraction of absorption in the shorter-wavelength band of these two.

The values of hw_{max}, absorption coefficient α_{max}, and half-width $W_{1/2}$, found for the three bands in the presented optical absorption spectra of cathodically deposited α-WO_3, are listed in the table. The table also gives the concentration N_e of excess electrons, on W^{5+} centers, whose optical excitation corresponds to the appearance of each of these bands. The N_e value for the band with hw_{max} = 2.0 eV is found by integration of the i–E dependence (Fig. 1) over the E range –0.2…–0.4 V. The N_e values for this band in two other ranges of E were found by assuming proportionality between N_e and α_{max}. This made it possible to find out that in the initial stage of coloration, before E = 0 V, W centers giving rise to the band with hw_{max} = 2 eV account for 70% of electrons injected into the film, and only 30% is captured by centers responsible for the absorption in the band with $hw_{max} \approx 1$ eV. In the next interval, E 0…–0.2 eV, the fraction of electrons on such W centers is even higher, 75%. It follows from the presented data that, in coloration of αWO_3, more than 90% of the injected electrons is consumed for formation of W centers giving rise to absorption in the band with hw_{max} = 2.0 eV in all the three ranges of potential, although α_{max} for this band is lower than the values for the two other bands.

With hw increasing in the range of fundamental absorption of α-WO_3, the ΔD value in differential spectra *1*–*3* gradually decreases and then becomes negative, which corresponds to the effect of oxide "bleaching" because of the shift of the fundamental absorption edge to higher hw with film coloration in the visible spectral range. To eliminate the contribution from the wing of the absorption band with hw_{max} = 2.0 eV and obtain undistorted ΔD–hw dependences, the extrapolation of the wing of this band to higher hw was taken as zero ΔD.

The spectra of α-WO_3 layer bleaching, obtained for each of the successive ranges on the E scale (as in Fig. 2), are presented in Fig. 3. Each differential spectrum of this kind is in fact the contribution to the fundamental absorption from optical transitions involving only those electrons which were injected into the film in a given range of E. Spectrum *1*, corresponding to the initial interval E 0.3–0 V has an inflection at $hw \approx 3$ eV and an additional shoulder at lower hw, which are absent in spectra *2* and *3*.

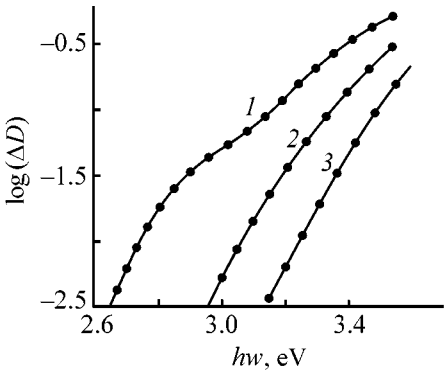

Fig. 3. ΔD–hw dependence in the fundamental absorption range of α-WO_3 layer with d = 1 μm. Polarization potential E (V): (*1*) 0.3–0, (*2*) 0…–0.2, and (*3*) –0.2…–0.4.

In the course of coloration, the quasi-equilibrium potential of the α-WO_3 electrode changes by ΔE = 0.7 V, which much exceeds that expected in accordance with the Nernst equation on the basis of the change in the proton activity ($\Delta E \approx 400$ mV for N_e changing by an order of magnitude). This change in the quasi-equilibrium potential is mainly due to a change in the electrochemical potential of electrons, i.e., is determined by the current position of the Fermi level E_F in the continuous energy spectrum of electronic states of the oxide [14, 15]. A shift of E_F to higher values on the energy scale upon coloration is also indicated by the shift of the fundamental absorption edge of α-WO_3 to higher hw, manifested in the differential spectra in Fig. 3. At a constant rate of E sweep, the coloration current in Fig. 1 can be regarded as a quantity proportional to the density of electronic states. Hence follows that the presented current–potential dependence reflects the distribution of the electronic states over the energy scale in a wide (~0.7 eV) range covered by the interval of E_F variation. The occurrence of three successive waves of rising injection current suggests that the energy spectrum of α-WO_3 includes three broad overlapping bands formed by d orbitals of three types of W centers differently bonded in the film to oxygen atoms and water molecules. Depending on the nature of such bonds, the ionization energies of the corresponding discrete electronic levels forming these bands are different (as also are the positions of these bands on the energy scale): at a difference ΔE between the peaks of separate waves in the current–potential dependence—by approximately $-e\Delta E$ on the average.

Three absorption bands with different positions of hw_{max} appear successively in the optical spectrum of α-WO_3 in the same E ranges which correspond to three waves of the cathodic current in Fig. 1. This confirms the presence appear successively in the structure of a colored cathodically deposited layer of W^{5+} centers of three types with different ionization energies, differing in the quantum energy necessary for initiating a transition of an excess electron to a neighboring W^{6+} center. They are also characterized by unequal probabilities of optical excitation of transitions between charge states of W centers, which is indicated by the oscillator strengths f of the absorption bands, evaluated using the relation [1]

$$f = 0.87 \times 10^{17} \frac{n}{(n^2 + 2)^2} W_{1/2} \frac{\alpha_{max}}{N_e}$$

with $n = 2$ for decolorized α-WO_3. According to these estimates, the higher the hw_{max} of an absorption band, the lower the f value, and the f value calculated for the band with hw_{max} = 2.0 eV for the first two ranges of E (Fig. 2, spectra *1* and *2*) is also equal to 0.12. The table lists effective masses m_e^* of excess electrons on levels of different W^{5+} centers, calculated using the equation [16]

$$m_e^* = 1 + 1.25\, hw_{max}/(6\pi hw_0),$$

where hw_0 is the phonon energy (~0.13 eV [16]).

The obtained m_e^* values are not the same for different W^{5+} centers, being close to the estimates of this parameter for tungsten bronzes Li_xWO_3 and Na_xWO_3 (m_e^* = 1.5 [17] and m_e^* = 2 [18]).

A shift of the absorption band peak to higher hw with decreasing f is observed in colored WO_3 films prepared by reactive sputtering, vacuum evaporation, and ion deposition in the case of broken long-range order and a transition to a more disordered, X-ray-amorphous structure, with double terminal bonds W=O formed instead of the ruptured bridge bonds W–O–W [19, 20]. Lowering the substrate temperature from 200 to 23°C in the course of reactive sputtering leads to an increase in the W=O/W–O–W ratio in the deposited layer from 0.08 to 0.36 and shifts hw_{max} of absorption in coloration from 1.05 to approximately 1.5 eV [19]. Similar changes in the position of hw_{max} of an absorption band, occurring directly in the course of coloration (in an electrolyte with Li^+ cations), were observed for samples of anodized tungsten in analyzing their reflection spectra [2]. The coloration of anodic films is accompanied by an increase in the intensity of the peak at 950 cm^{-1} in Raman spectra, associated with terminal W=O groups [21]. Therefore, the different positions of the absorption peaks hw_{max} in the initial and final stages of coloration are due [2] to the additional disordering of such films upon incorporation of Li^+ cations and to the appearance of W centers with different numbers of terminal W=O groups in the oxide. In a cathodically deposited α-WO_3, the degree of disordering and the number of terminal W=O group are even higher than those in anodic films, and the layer structure includes polymer chains of the type …–O–W–O–W–O–…, with W centers having two groups of this kind each. Therefore, it may be assumed that the main electronic band and the corresponding absorption band with hw_{max} = 2.0 eV are associated with optical excitation of electrons in W centers whose ligand environment includes two terminal oxygen atoms. The doublet structure and the extension of this band to lower energies can be related to different spatial arrangements of two terminal groups in the environment of the tungsten atom and to wide variety of hydrogen bonds of terminal oxygen atoms with water molecules.

The absorption band peaked at around 1 eV is also characteristic of single-crystal WO_3 and films deposited in a vacuum, after their crystallization by annealing at 500°C [1]. For this reason, the corresponding electronic band in a cathodically deposited α-WO_3 can be related to W centers in a regular octahedral ligand environment formed by oxygen atoms. The extension of the wave function of an electron captured by such a W center to neighboring W centers (according to ESR data for a single crystal, the residence time of an electron on neighboring W centers is nearly 2 times longer [22]) leads to an increase in its ionization energy, in agreement with the lower position of E_F on the energy scale upon filling of free levels of this band. As regards centers responsible for the absorption in the band with hw_{max} = 1.5 eV, it may be assumed that they are bonded to a single terminal atom of oxygen.

The probability of an optically induced transition of an excess electron between charge states of the W center and the energy necessary for its activation by absorbed quantum are determined by the overlapping of the electron wave functions in the initial and final states, i.e., depend on the extent of its localization on a W^{5+} center and distance to the nearest unoccupied W^{6+} center. In this connection, the absorption in the band with the lowest energy $hw_{max} \approx 1$ eV and the highest $f \approx 1$ in cathodically deposited α-WO_3 corresponds to excitation of excess electrons with the lowest degree of localization on a W^{5+} center, where the wave function of an electron partially extends, as in the case of a single crystal, to neighboring tungsten atoms. Such W centers are surrounded by bridge atoms of oxygen and their lowest unoccupied *d* orbitals form the lowest-energy electron band and are filled with injected electrons already in the initial stage of film coloration. The absorption in the other two bands, having higher hw_{max}, corresponds to optical excitation of electrons with higher degree of localization, which, according to the table, is confirmed by lower *f* values for these bands and heavier m_e^* of such electrons on discrete *d* levels in the other two, higher-energy electron bands formed by W centers with distorted ligand environment.

The optical gap E_g of α-WO_3 is found from the position of the fundamental absorption edge, for which is taken the point of intersection of extrapolated linear portion of the $D(hw)$ spectrum plotted in the $(Dhw)^{1/2}$–hw coordinates with the abscissa axis [11, 23]. The weak absorption at $hw < E_g$ is attributed to optical transitions involving the "tail" of the density of discrete electronic states with lower energy in disordered amorphous oxide. However, if it is assumed, on the basis of the data obtained, that disordering of WO_3 with disintegration of W–O–W bridge bonds and formation of a large amount of W=O terminal bonds is accompanied by formation of higher-energy electron bands, then it is necessary to regard as the fundamental absorption edge its beginning, lying in spectra *1–3* (Fig. 3) at $hw \approx 2.65$, 2.95, and 3.15 eV. The intervals between these values, equal to approximately 0.3 and 0.2 eV, correspond to $\Delta E_g \approx \Delta E_F \approx -e\Delta E$ between the initial *E* values of 0.3, 0, and –0.2 V, whereas the conventional technique for determining the edge position gives ΔE_g lower than 0.2 eV. With this approach to interpretation of the fundamental absorption spectra of α-WO_3, the region of spectra in Fig. 3, characterized by the highest $\log(\Delta D)$ values, can be attributed to transitions of valence electrons to free levels in the main electron band with the highest density of unoccupied electron states. When discrete levels in the other two bands are filled with injected electrons, they cannot be involved in optical transitions of electrons from the valence band, and, therefore, the additional shoulder associated with such transitions, present at low *hw* in the differential spectrum *1* in Fig. 3, is not observed in spectra *2* and *3*.

CONCLUSIONS

(1) The structure of amorphous oxide layer deposited onto the cathode, which is close to $WO_{3-y} \cdot 2H_2O$, is characterized by the presence of a great number of fine pores filled with water molecules. This leads to low refractive index (decolorized film in contact with electrolyte has n = 1.6–1.7) and makes shorter the time of coloration and decoloration of a layer of electrochromic material because of the high mobility of protons in the form OH_3^+.

(2) The reversible change in optical and electrochemical properties of such films in the course of coloration is associated with successive filling with injected electrons of three overlapping electron bands formed by discrete *d* levels of W centers having in their ligand environment different numbers of terminal oxygen atoms (W=O double bonds). In this case, the electronic Fermi level is shifted upwards on the energy scale, and the fundamental absorption edge of the oxide, to higher *hw* by a value determined by a change in the quasi-equilibrium potential ($\Delta hw \approx \Delta E_F \approx -e\Delta E$).

(3) The differences in hw_{max} position and oscillator strength between the three absorption bands, successively appearing in the optical spectrum in the course of coloration, are determined by the different degrees of localization of excess electrons on

the *d* levels of tungsten in the electron bands formed by these levels.

Abstract—Results of spectrophotometric measurements in concentrated polysulfide solutions used as electrolytes in regenerative photoelectrochemical transducers are presented. The equilibrium constants are determined and the distribution of ions species in the solutions is calculated. The effect of electrolyte solution on the output characteristics of a photoelectrochemical cell based on cadmium selenide and cobalt sulfide was studied.

Concentrated sulfide-polysulfide solutions are commonly used as electrolytes that can stabilize the operation of photoelectrochemical transducers (PECT) based on cadmium chalcogenides. It is believed that sulfide ions are oxidized by holes from the valence band

$$(x + 1)S_x^{2-} + 2h^+ \rightarrow xS_{x+1}^{2-} \quad (1)$$

at the semiconductor photoelectrode [1, 2], and polysulfide ions are reduced

$$xS_{x+1}^{2-} + 2e \rightarrow (x + 1)S_x^{2-}. \quad (2)$$

at the counter electrode. For simplicity, the electrically active species are designated as S_x^{2-}, although their true nature is unknown, since the electrolyte contains simultaneously a number of ions that can enter into electrode reactions (S^{2-}, HS^-, OH^-, S_x^{2-}, where x = 2–5). A comprehensive study of sulfide-polysulfide systems requires reliable methods for analysis of all the species present in these systems, and polysulfide species, in particular.

The distribution of polysulfide forms in an electrolyte is determined by the equilibrium

$$(x - 1)S_{x+1}^{2-} + HS^- + OH^- = xS_x^{2-} + H_2O, \quad (3)$$

where x = 2–4.

The equilibrium constants of the processes described by Eq. (3) were found in [3] from spectral data and refined in [4]. However, these data cannot be used and generalized to concentrated systems since (1) the superposition of absorption bands of HS^- and S^{2-} ions on the absorption bands of polysulfide ions in the UV range at high concentration of these ions in solution was disregarded, and (2) there is no dependence of the equilibrium constants on the ionic strength of the solution. The latter casts doubt on the appropriateness of using the values of the $K_{1/2}$ and $K_{2/3}$ constants, found for solutions with high ionic strength, in the case of solutions with low ionic strength, for which the constant $K_{3/4}$ was determined ($K_{1/2}$, $K_{2/3}$, $K_{3/4}$ are the equilibrium constants for the equilibrium between the polysulfide ions S_2^{2-} and S_3^{2-}, S_3^{2-} and S_4^{2-}, S_4^{2-} and S_5^{2-}, respectively).

In [4], some shortcomings of the calculations made in [3] were taken into account. For example, in determining the optical constants from absorption spectra, a correction was made for the strong absorption by HS^- and S^{2-} ions in the UV range, which leads to a significant change in the results obtained. However, no attempts were undertaken to make corrections to the equilibrium constants for different ionic strengths. Moreover, the second constant of dissociation of H_2S solutions, $K_{a_2} = 10^{-17}$ [5], was used in calculations, whereas rather widely varying pK_{a_2} values (12–17) can be found in the literature [6, 7]. Previously, the K_{a_2} values have been determined for H_2S in solutions with ionic strength I = 4–5 with the use

of a sulfide-selective electrode [8]. Figure 1 presents the pK_{a_2} values obtained in different studies in solutions containing an alkali. It can be seen that pK_{a_2} grows steadily with increasing concentration of OH^- ions. Also presented are the data obtained in [5] from spectra of sulfide solutions, according to which pK_{a_2} decreases with increasing alkali concentration.

Since the scatter of pK_{a_2} values in dilute solutions is known to be strong and data on the distribution of ion species in concentrated polysulfide solutions are virtually lacking, the aim of this study was to analyze the distribution of ion species in such solutions and reveal the reasons for the scatter of pK_{a_2} values, and also to determine the optimal electrolyte composition for PECT.

EXPERIMENTAL

Absorption spectra of concentrated alkaline sulfide and polysulfide solutions of potassium and sodium were studied. The solutions were prepared by dissolving the starting components MOH, M_2S, and S (M = Na, K) in deaerated twice-distilled water. The absorption spectra were measured with a Specord M40 spectrophotometer in cells of thickness $d = (5–35) \times 10^{-4}$ cm in the wave-number range 20 000–50 000 cm^{-1}. The redox potential E_{redox} was measured on a platinum electrode relative to silver chloride reference electrode.

In sodium and potassium sulfide solutions with high alkali content (>5 M) a new absorption band is observed at $\nu = 40 \times 10^3$ cm^{-1} (Fig. 2), which can be attributed to formation of an ion pair of K^+ (Na^+) with S^{2-} ions, rather than with a sulfide ion, as believed in [5] where the formation of an ion pair was ruled out because of the high dielectric constant of water ($\varepsilon = 80$). However, the activity of water falls dramatically at high concentrations of alkali [9] and the dielectric constant of the medium decreases [10], with the result that the probability of ion pair formation increases. In addition, the band at $\nu = 40 \times 10^3$ cm^{-1} depends on the solvent nature. Figure 3 shows absorption spectra of 0.5 M K_2S–15 M KOH solutions in water ($\varepsilon = 80$), formamide ($\varepsilon = 110$), and ethanol ($\varepsilon = 25$). It can be seen that the intensity of the band at $\nu = 40 \times 10^3$ cm^{-1} decreases with increasing dielectric constant of the medium.

One more argument in favor of the formation of ion pairs in concentrated polysulfide solutions is furnished by spectra of the crystal hydrates $Na_2S \cdot 5H_2O$ and $Na_2S \cdot 9H_2O$ [3]. The spectrum of $Na_2S \cdot 9H_2O$

Shows only a single strong band at $\nu = 44 \times 10^3$ cm^{-1}. The spectrum of $Na_2S \cdot 5H_2O$ contains a broad band in the range $\nu = 40 \times 10^3$–45×10^3 cm^{-1}. The structures of the crystal hydrates $Na_2S \cdot 9H_2O$ and $Na_2S \cdot 5H_2O$ are known. In $Na_2S \cdot 9H_2O$, a sulfur atom is surrounded by 12 oxygen atoms so that Na^+ and S^{2-} ions are spatially separated by water molecules. In $Na_2S \cdot 5H_2O$, a sulfur atom is surrounded by five oxygen atoms and one sodium atom, which is in direct contact with the sulfur atom, which virtually corresponds to formation of a contact ion pair. Consequently, the spectral data of [5] can be interpreted as follows: alkali sulfide solutions with alkali content of up to 5 M contain the same ion associates, including Na^+, S^{2-} ions and H_2O, as the crystal hydrate $Na_2S \cdot 9H_2O$.

With increasing alkali concentration, the spectra of aqueous sulfide solutions become similar to the absorption spectra of $Na_2S \cdot 5H_2O$ crystal hydrate, which can be related to the formation of a contact ion pair. In [5], such an explanation was considered, too, but was discarded because the absorption band at $\nu = 40 \times 10^3$ cm^{-1} could not be observed in absorption spectra of alkali metal halide solutions to the point of saturation. However, this fact cannot be regarded as ruling out the formation of ion pairs in alkali solutions, since the solubility of halides is much lower than that of hydroxide, and it is impossible to obtain in halide solutions the same cation concentrations as in alkaline solutions; the behavior of halide solutions markedly differs from that of hydroxide, sulfide, and polysulfide solutions. The average activity of a solution decreases in the series of alkali metal halides from Li to Cs, whereas the average activity of solutions of alkali metal hydroxides, sulfides, and polysulfides grows [11]. Such a difference in behavior can be accounted for in terms of the "local hydrolysis" model. According to this model, an anion interacts with a proton in the hydration shell of a cation

$$M^+...H_2O + A^- = M^+...OH^-...H^+...A^-.$$

As a result, an ion associate is formed, which can be regarded as a noncontact ion pair. The degree of such an association is directly related to the strength of an anion as proton acceptor and the polarizability of protons in the hydration shell. Chlorides, which are weak proton acceptors, will undergo pairing, as a result of local hydrolysis, to a lesser extent than sulfides and hydroxides, which are strong proton acceptors, and also polysulfides, which are bases intermediate in strength. Cations with large and strongly polarized hydration shells, e.g., Li^+, will undergo strong pairing because of the local hydrolysis with anions acting as strong proton acceptors, in contrast to cations having a small primary hydration shell or none at all, as, e.g., Cs^+. Consequently, the absence of the band corresponding to an ion pair in the spectra of chlorides cannot establish that ion pairs cannot be formed in alkaline sulfide (polysulfide) solutions.

The experimentally observed dependence pK_{a_2} on the alkali concentration may be due to a change in the ion distribution in favor of ion pair formation. For example, in strongly concentrated solutions, where ion pairing is manifested, the $[S^{2-}]$ value is low and the constant of sulfide ion hydrolysis, K_h, grows. Consequently, $K_{a_2} = K_w/K_h$, (K_w is the ion product of water) decreases, and $pK_{a_2} = -\log K_{a_2}$ grows, which is observed experimentally (Fig. 1, curve *1*).

The experimental data suggest that the S^{2-} ion forms in aqueous alkaline solutions a noncontact ion pair with water molecules and sodium (potassium) ions:

$$S^{2-} + H_2O + Na^+ = [S^{2-}–H_2O–Na^+].$$

The spectral band associated with such a pair may coincide with the band at 44×10^3 cm^{-1}, known in the literature as the band associated with HS^-. Experimentally, the band at $\nu = 44 \times 10^3$ cm^{-1} furnishes information about the sum of species in the form HS^-, S^{2-}, and $[S^{2-}–H_2O–Na^+]$. The band at $\nu = 40 \times 10^3$ cm^{-1} corresponds to the contact ion pair Na_2S, which is indicated, as already mentioned, by the spectra of the crystal hydrates $Na_2S \cdot 9H_2O$ and $Na_2S \cdot 5H_2O$.

It follows from the aforesaid that, in concentrated sulfide and polysulfide solutions, it is necessary to take into account, in addition to equilibria (3), also the following processes: hydrolysis of the sulfide ion

$$S^{2-} + H_2O = HS^- + OH^- \quad (4)$$

and formation of contact and noncontact ion pairs

$$Kt^+ + A^{z-} = [KtA]^{(z-1)-}, \quad (5)$$

$$Kt(H_2O)_n^+ + A^{z-} = [Kt(H_2O)_mA]^{(z-1)-}, \quad (6)$$

$$Kt(H_2O)_n^+ + A(H_2O)_l^{z-} = [Kt(H_2O)_mA]^{(z-1)-} + (l + n - m)H_2O. \quad (7)$$

In view of the complexity of the system, we perform calculations in terms of a simplified model taking into account Eqs. (4) and (5). The hydrolysis constant of the sulfide ion and the formation constant

of the ion pair, K_1, are related to the activities of the corresponding species by

$$K_h = a_{HS^-} a_{OH^-}/a_{S^{2-}} a_w, \quad (8)$$

$$K_l = a_{NaS^-}/a_{Na^+} a_{S^{2-}}, \quad (9)$$

where a_{NaS^-}, a_w, a_{Na^+}, a_{HS^-}, a_{OH^-}, and $a_{S^{2-}}$ are the activities of the ion pair, water, sodium ions, and hydrosulfide, hydroxide, and sulfide ions, respectively.

If the total concentration of sodium sulfide introduced into solution is denoted by C_{Na_2S}, then

$$C_{Na_2S} = [HS^-] + [S^{2-}] + [NaS^-], \quad (10)$$

where $[HS^-]$, $[S^{2-}]$, and $[NaS^-]$ are the equilibrium concentrations of hydrosulfide ions, sulfide ions, and the contact ion pair, respectively.

Assuming that the band at $\nu = 40 \times 10^3$ cm^{-1} corresponds to the contact ion pair NaS^-, rather than to the sulfide ion, and the band at $\nu = 44 \times 10^3$ cm^{-1}, to a sum of the HS^- and S^{2-} species, rather than to solely HS^-, we can write the expression for the equilibrium constant of the process (4), with account of ion pair formation, as

$$K_l^i = \frac{[S^{2-}]a_w}{[HS^-][OH^-]} = \frac{[NaS^-]a_w}{(C_{Na_2S} - [NaS^-])[OH^-]}, \quad (11)$$

whence follows

$$\frac{K_l^i[OH^-]}{a_w} = \frac{[NaS^-]}{C_{Na_2S} - [NaS^-]}. \quad (12)$$

Introducing the designation $[NaS^-]/(C_{Na_2S} - [NaS^-]) = x$, we obtain $[NaS^-] = xC_{Na_2S}/(1 + x)$.

It follows from spectral data that

$$[NaS^-] = D_l/\varepsilon_l d,$$

where D_l and ε_l are, respectively, the optical density and molar absorption coefficient for the band at $\nu = 40 \times 10^3$ cm^{-1}, and d is the layer thickness.

Solving simultaneously Eqs. (8)–(11), we obtain

$$x^{-1}a_{OH^-} = K_h\gamma_{NaS^-} a_w/K_l\gamma_{HS^-} a_{Na^+} + \gamma_{NaS^-}/K_l\gamma_{S^{2-}}, \quad (13)$$

where γ_{NaS^-}, γ_{HS^-}, and $\gamma_{S^{2-}}$ are the activity coefficients of the respective species.

Plotting $x^{-1}a_{OH^-}$ as a function of a_w/a_{Na^+}, we obtain a straight line whose equation is as follows:

$$x^{-1}a_{OH^-} = 162 + 4933a_w/a_{OH^-}.$$

The corresponding expressions for the constant of sulfide hydrolysis (in a sodium solution) and the constant of ion pair formation have the form

$$K_h = 30.5(\gamma_{HS^-}/\gamma_{S^{2-}}),$$

$$K_l = 6 \times 10^{-3}(\gamma_{NaS^-}/\gamma_{S^{2-}}).$$

Consequently, $pK_{a_2} = 15.48$. Using the presented constants, we recalculated the pK_{a_2} data of [5] (Fig. 1, points *6*). As follows from Fig. 1, the results of [5] recalculated with account of the ion pair formation are in agreement with the data obtained elsewhere [6–8].

A knowledge of the constants K_h and K_l makes it possible to calculate the distribution of ion species in polysulfide electrolytes with known introduced concentrations of alkali metal sulfide, alkali, and sulfur.

Let us write the material balance equations for the introduced sulfide, sulfur, and the hydroxide ion

$$C_{K_2S} = [S^{2-}] + [HS^-] + S_n, \quad (14)$$

$$C_{S^0} = \sum_{n=1}^{4} n[S_{n+1}^{2-}], \quad (15)$$

$$[OH^-] = C_{OH^-} + [HS^-], \quad (16)$$

where C_{K_2S} is the concentration of potassium sulfide introduced into solution, S_n a sum of equilibrium concentrations of polysulfide ions $S_n = \sum_{n=2}^{4}[S_n^{2-}]$, and C_{OH^-} the concentration of potassium hydroxide introduced into solution.

Solving the system of equations (8), (14)–(16), we obtain

$$[OH^-] = \frac{1}{2}\left\{C_{OH^-} - K_h + \sqrt{(K_h + C_{OH^-})^2 + 4K_h(C_{K_2S} - S_n)}\right\}, \quad (17)$$

$$[S^{2-}] = (C_{K_2S} - S_n) \times \left\{\frac{2K_h}{C_{OH^-} - K_h + \sqrt{(K_h + C_{OH^-}) + 4K_h(C_{K_2S} - S_n)}} + 1\right\}. \quad (18)$$

We find he concentrations of separate polysulfide ions and S_n from absorption spectra of polysulfide solutions. Despite the complexity of such spectra, arising from the superposition of individual absorption bands of polysulfide ions, modern software makes it possible to resolve in these spectra separate absorption

bands and to determine their parameters, namely, the position ν_c of a band, its width w, and peak height h. The concentrations of separate polysulfide ions can be determined from the equation

$$D(\nu) = d\sum_{i=2}^{5}[S_i^{2-}]h_i \exp\left\{\left(-\frac{\nu_i - \nu_c}{w_i}\right)^2\right\}, \qquad (19)$$

where $D(\nu)$ is the optical density at i-th point after subtraction of the absorption due to HS^- and S^{2-} ions; ν_c the position of the absorption band; w_i, h_i its width and height, respectively; and d the cuvette thickness.

The results of calculation for a 1 M KOH–1 M K_2S–1 M S solution are presented in the table. The absorption bands were identified in [3, 4]. Our data largely coincide with the results of [4].

Formation of ion pairs in an electrolyte leads to a decrease in the amount of electrically active species involved in the electrode processes occurring at the photo- and counter electrode, which affects adversely the operation of PECT. Consequently, an improvement of the PECT efficiency would be expected on passing to electrolytes less subject to ion pair formation.

With account of the aforesaid, the effect exerted by the electrolyte composition on the output characteristics of a photoelectrochemical cell (PECC) was studied. By the electrolyte composition are understood the concentrations of introduced alkali, and sulfide, and also the sulfur to sulfide ratio X_S. The alkali metal cation markedly affects, not being directly involved in the electrode processes, the PECC operation, improving it in the order Li < Na < K < Cs [11].

Figure 4 presents the characteristics of PECC in polysulfide electrolytes with varied X_S. It can be seen that the short-circuit current I_{sc} grows with X_S increasing up to $X_S = 2$, and starts to fall only in solutions strongly saturated with sulfur ($X_S > 2$). Such a behavior of I_{sc} can be accounted for by the interaction of several factors.

(1) Photooxidized products dissolve more rapidly in solutions with lower sulfur concentration. As believed by the authors of [12], the dissolution of products oxidized at the photoelectrode is the rate-determining stage of the anodic reaction.

(2) Processes of ion pair formation become faster with increasing ionic strength of solution and, consequently, with growing X_S. As already mentioned, ion pairing makes lower the concentration of electrically active species in solution, which impairs charge transfer and diminishes the current.

Species distribution in 1 M KOH–1 M K_2S–1 M S solution

Species	Concentration, M	Mole fraction, U_i^*
HS^-	0.3236	0.324
S^{2-}	0.03745	0.037
S_2^{2-}	0.03522	0.352
S_3^{2-}	0.1713	0.171
S_4^{2-}	0.1156	0.116

* $U_i = [S_i]/\Sigma S_i$.

The dependence of the open-circuit voltage U_{oc} on X_S is different from that of I_{sc} on X_S. It is known that U_{oc} is determined by the difference between the redox potential of a solution, E_{redox} and the flat-band potential of a semiconductor, E_{fb}:

$$U_{oc} = f(E_{redox} - E_{fb}).$$

E_{fb} is independent of the concentration of sulfur introduced into solution up to concentrations of 1 M [13]. As shown by our investigations, E_{redox} shifts to positive values with increasing X_S, changing from –660 mV at $X_S = 0.5$ to –630 mV at $X_S = 2$.

Hence follows that U_{oc} must grow with X_S increasing up to $X_S = 1$, which is the case in the experiment. A slight decrease in U_{oc} in solutions with high concentration of sulfur can be attributed to the influence of other factors (e.g., a shift of E_{fb} of *C*dSe to more positive values with increasing X_S). In this case, the dependence of cell efficiency on X_S (Fig. 4) has an extremum at $X_S = 1.5$.

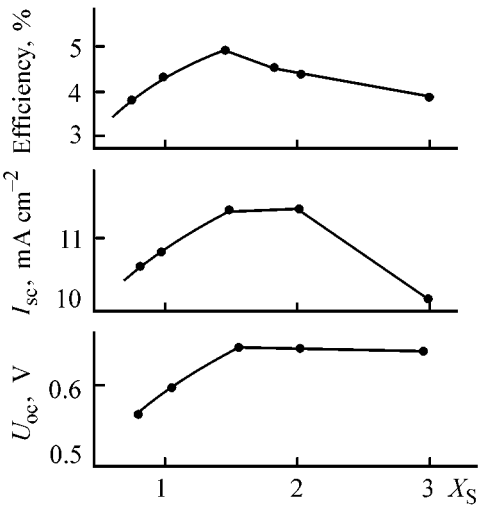

Fig. 4. Efficiency, short-circuit current I_{sc}, and open-circuit voltage U_{oc} vs. sulfur to sulfide ratio X_S. Illumination intensity 75 mW cm^{-2}.

Alkali is introduced into an electrolyte in order to shift the equilibrium of reaction (4) toward formation of the sulfide ion, which, in turn, affects the equilibrium of reaction (1) and, correspondingly, the output parameters of PECC. For example, U_{oc} is 0.6 V for a PECC with electrolyte containing 1 M NaOH, and only 0.54 V for an electrolyte containing no alkali, which is apparently due to a shift of the flat-band potential of the semiconductor to the negative side in view of the increasing concentration of sulfide ions.

With account of the presented calculations and experimental data, the optimal electrolyte is that containing alkali metal hydroxide and sulfide in amounts of 1–2 M each and characterized by $X_S = 1.5$.

CONCLUSIONS

(1) An analysis of published data on the second constant of dissociation of an H_2S solution demonstrated that the scatter of pK_{a_2} values obtained in different studies ($pK_{a_2} = 12–17$) depends on the alkali concentration in the solutions used for measurements.

(2) The observed rise in pK_{a_2} values with increasing alkali concentration can be accounted for by the formation of ion pairs. With account of this circumstance, the equilibrium constants were determined and the distribution of ion species in concentrated solutions of polysulfides used in regenerative photoelectrochemical transducers was calculated.

(3) It is shown that the electrolyte composition strongly affects the output characteristics of photoelectrochemical transducers. An optimization of the composition of the polysulfide electrolyte, carried out with account of the aforesaid, made it possible to raise by 20–25% the conversion efficiency of a photoelectrochemical cell with cadmium selenide photoelectrode and cobalt sulfide counter electrode and to achieve efficiencies of 10–12%.

Experimental Study of Gas-Fluid Jet Formed by Single-Flare Atomizer

O. I. Protod'yakonova, S. V. Aniskin, and I. E. Sleptsov

St. Petersburg State Technical University, St. Petersburg, Russia

Received November 15, 2001

Abstract—A gas-fluid jet outflowing from a single-flare atomizer and the possibility of a pronounced change in the nature of the spraying density distribution in a free polydisperse gas-fluid jet with increasing distance from the atomizer nozzle were studied experimentally.

Apparatus with gas-fluid jets formed with single-flare atomizers are widely used in wet cleaning of industrial gas discharges.

In [1, 2], a model of motion of such a jet was developed, possessing certain advantages over the previously proposed models [3]. For example, the gas velocity distribution had been assumed [3] to be uniform across the jet in constructing a model of a gas-fluid jet outflowing from a single-flare atomizer.

The model constructed in [1, 2] was based on the assumption of a nonuniform distribution of gas velocity across the jet, with a maximum on the jet axis. This kind of distribution of the parameter is characteristic of gas jets in general and those developing in a flow of fluid drops, in particular [4].

The hydrodynamic model proposed in [3] takes into account the type of spraying density distribution across the flare. However, this model replaces the real polydisperse flow of drops in a gas-fluid jet with a monodisperse flow with drops whose diameter is equal to the average volume-surface drop size of the polydisperse flow. The model of a gas-fluid jet, developed in [1, 2], takes into account not only the type of the spraying density distribution function, but also the type of the drop size distribution function, i.e., the dispersion composition of the gas-fluid jet. These functions should be set in the boundary conditions for the model equations.

The aim of this study was to confirm experimentally the validity of the model of the flow of a gas-fluid jet, developed in [1, 2]. The calculations performed in terms of this model demonstrated that finely dispersed fractions of drop starting their motion on the flare periphery are shifted toward its axis much faster than fractions with larger drops do [2]. An experimental verification of this result would give reason to consider the model discussed here adequate to the object of study.

To assess the adequacy of the given model, it is necessary to obtain experimentally the spraying density distribution function at different distances from the atomizer nozzle and compare it with a similar function found by solving the model equations.

However, to obtain this solution, it is necessary to specify the boundary conditions of these equations. To accomplish this task, it is necessary to have, first, the analytical form of the spraying density distribution function in the region close to the atomizer nozzle and, second, the drop size distribution function, i.e., a description of the dispersion composition of the drop flow. Obtaining such an information is also a part of the experimental verification of the model of a polydisperse jet, considered here.

Thus, the general task of the given study can be accomplished by solving successively the following two concrete problems.

One of these involves an experimental determination of the analytical form of the spraying density and drop size distribution functions. These functions appear in the boundary conditions of the equations constituting the gas-fluid jet model [2].

The other consists in solving the equations of the model of a gas-fluid jet with the specified boundary conditions and in verifying the adequacy of the gas-fluid jet model by comparing the obtained solution

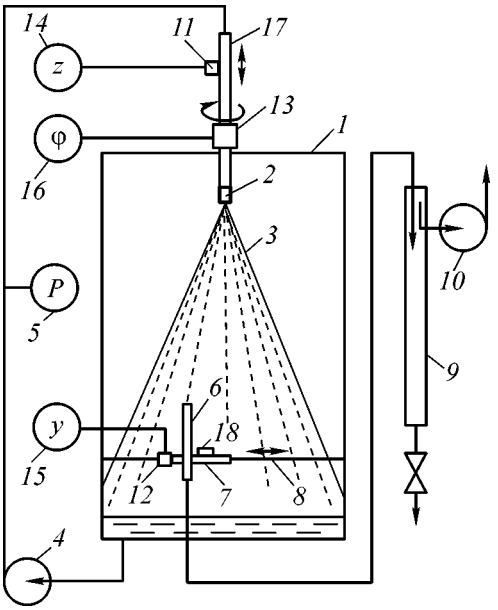

Fig. 1. Schematic of experimental setup: (*1*) chamber; (*2*) atomizer; (*3*) flare; (*4*) pump; (*5*) pressure gage; (*6*) drop trap; (*7*) slide; (*8*) rail; (*9*) separator; (*10*) suction pump; (*11*) vertical coordinate transducer; (*12*) horizontal coordinate transducer; (*13*) flare rotation angle transducer; (*14–16*) voltmeters showing, respectively, the vertical and horizontal coordinates and the angle of flare rotation with respect to a given point; (*17*) tube; and (*18*) cuvette.

to the model equations with experimental data on the spraying density at different distances from the atomizer nozzle.

The experimental setup for studying the hydrodynamics of gas-fluid jets includes chamber *1* with transparent Plexiglas walls, 1.7 m high and 1.2×1.2 m in cross-section. (Fig. 1). A centrifugal-jet atomizer *2* with nozzle diameter of 3 mm and cross-shaped insert serving to create a rather broad flare *3* filled with water drops is mounted in the upper part of the chamber.

As is known, the centrifugal-jet atomizer is a characteristic type of single-flare atomizers. Water flows down to the chamber bottom and then is again fed into the atomizer *2* by a pump *4*. The water pressure before the atomizer is measured with a pressure gage *5*. This pressure was 6 atm in the experiments. The study was performed with an atomizer with nozzle diameter of 3 mm.

The system for measuring the spraying density includes the following elements: drop trap *6*, slide *7*, rail *8*, separator *9* in the upper part, and suction pump *10*. The experimental setup makes it possible to determine the coordinates of a point at which the spraying density is measured, namely, the radial coordinate y and the rotation angle φ of a flare of atomized fluid relative to the given point. The systems for measuring the values of z, y, and φ include resistance transducers *11–13* and digital voltmeters *14–16*, respectively.

The specific feature of the experimental setup consists in that the flare position relative to the trap can be varied by moving the tube *17* in vertical direction and rotating it together with the rigidly fixed atomizer. This allows the trap to be placed at a certain radial angle φ with respect to the flare at a prescribed distance z from the atomizer nozzle. The radial displacement y of the trap is effected by slider *7* moved along rail *8* by an actuating motor with remote control.

The spraying density is measured at any prescribed point of the flare as follows. Drops arriving at the trap pass through its frontal opening having a sharp edge. The sharp edge of the entrance opening of the trap ensures better correspondence between the cross-sectional area of the fluid flow coming into the trap from the flare and the area of the entrance opening of the trap.

A minor amount of air finds its way into the trap together with the fluid. The gas-fluid mixture formed in the trap is transported into separator *9* by suction pump *10*.

As separator serves a burette with a glass tube in contact with the burette wall in its upper part. The fluid passes through the glass tube and flows down along the burette walls. Air is evacuated from the upper part of the separator by the suction pump *10*.

The time τ (s) in which the fluid volume in the burette increases by a prescribed amount V (m^3) is measured. The spraying density J ($m\ s^{-1}$) at a prescribed point of the flare is found using the formula

$$J = V/(F\tau), \qquad (1)$$

where F is the area of the frontal opening of the drop trap (m^2).

Strictly speaking, the flow rate of air evacuated by the suction pump from the separator is to be such that the isokineticity condition, according to which the velocity of the air flow approaching the trap must be equal to the velocity of air in its the entrance cross-section, should be satisfied in fluid uptake by the trap from the polydisperse flow. Satisfying this conditions makes it possible to assert that the gas flow velocity in the drop trapping zone and, consequently, the trajectories of entrapped drops (especially fine

drops) remain invariable in the course of spraying density measurements. Correspondingly, also invariable is the fluid flow in the trap and, consequently, no error occurs in determining the spraying density, all other measurement conditions being the same.

It was established in the experiments performed that varying within certain limits the flow rate of air evacuated by the suction pump from the separator does not lead to any noticeable changes in the results of spraying density measurements, all other experimental conditions being the same. This means that, in the given range of variation of the rate of the air flow passing through the suction pump, minor violations of the isokineticity condition have no essential effect on the accuracy with which the spraying density is determined. In this connection, the spraying densities measured at rates of air flow through the suction pump, falling within the mentioned interval, were used in further calculations.

The experimentally determined spraying densities, obtained at a distance of 0.2 m from the atomizer nozzle, are given in Fig. 2. Each of these values is a result of averaging of eight measurements done with the flare rotation angle successively changed by 45°. It is assumed that the type of spraying density distributions in flare cross-sections lying higher than the 0.2-m level are similar to the given one. On the basis of this assumption, the type of function, illustrated by Fig. 2, was used to formulate boundary conditions for the equations of the model at $z = 0$. To make, if necessary, convenient recalculation of spraying densities for different vertical coordinates z, the spraying densities and flare radius R are presented in Fig. 2 as, respectively, dimensionless quantities I and x. In this case,

$$I = J/\bar{J}, \tag{2}$$

where the average spraying density J is determined in a section circumscribed by a circle of radius R.

Within this section is contained 95% of the flow of atomized fluid.

The radius R was determined experimentally using the formula

$$0.95G_0 = 2\pi\rho_f\int_0^R Jy\,dy, \tag{3}$$

where G_0 is the rate of fluid flow through the atomizer (kg s^{-1}).

The flow coefficient of the fluid passing through the nozzle was determined by the formula

$$\mu = \frac{4G_0}{\pi d_n\sqrt{2P\rho_f}}, \tag{4}$$

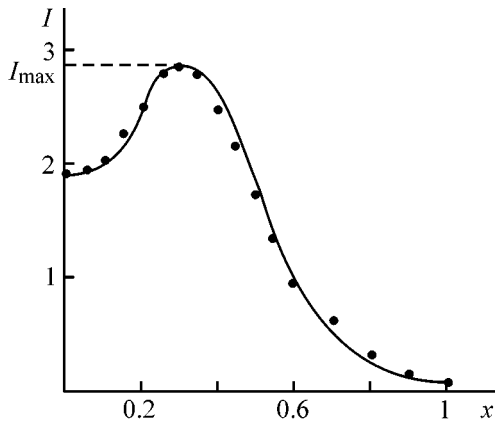

Fig. 2. Plot of the function approximating the experimentally obtained values of the spraying density distribution function. Distance from atomizer nozzle 0.2 m. (I) Relative spraying density and (x) relative radial coordinate.

where P is the fluid pressure before the nozzle (Pa), d_n the nozzle diameter (m), and ρ_f the fluid density (kg m^{-3}).

The aperture angle of the flare of the gas-fluid jet was calculated by the formula

$$\alpha = 2\arctan(R/z). \tag{5}$$

The dimentionless radial coordinate x was calculated by the formula

$$x = y/R. \tag{6}$$

The formula used to approximate the experimental dependence $I = f(x)$ was derived in this study:

$$I = \frac{a}{1 + bx^n} - \frac{c}{1 + dx^n}, \tag{7}$$

where a, b, c, and d are distribution constants.

The curve in Fig. 2 was obtained at the following values of the constants appearing in formula (7)

$$a = 3.0,\ b = 49.0,\ c = 1.06,\ d = 32\,544,\ n = 6.4. \tag{8}$$

The mean error of approximation was 3%.

The dispersion composition of drops of the atomized fluid was determined using the known procedure [5] which consists in drop catching with cuvette *18* containing an immersion medium and subsequent photographing and analysis of the obtained images. As immersion medium served transformer oil.

Drop sampling into the cuvette was done by cutting off a part of the drop flow with a shutter. The proce-

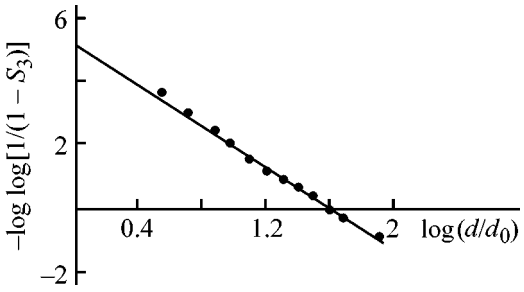

Fig. 3. Experimental distribution function S_3 of the total volume of fluid drops with respect to their size d. Fluid pressure before atomizer, P = 6 atm; atomizer nozzle diameter $d_n = 3 \times 10^{-3}$ m; constant $d_0 = 10^{-5}$ m.

dure ensured capture of a sufficiently large number of drops, which, however, was not large enough to lead to drop merging and overlapping of drop images on a photograph. Drops were photographed in the immersion medium on the background of a coordinate scale, using a Zenit camera with attachment rings. The obtained negatives were projected onto a screen and the size distribution of caught drops was determined.

As is known, the actual drop size distribution in fluid atomization with an atomizer is best described by the integral Rosin–Rammler distribution [5]

$$S = 1 - \exp[-(d/a)^l], \quad (9)$$

where d is drop diameter, and a and l are the distribution constants.

To determine the constants a and l from experimental data, it is necessary to reduce Eq. (2) to linear form

$$-\log\log[1/(1-S)] = 0.3622 + l[\log(a/d_0)] - l[\log(d/d_0)], \quad (10)$$

where d_0 is the constant preset to define the argument scale.

The integral drop size distribution function S for the total volume of drops captured by the cuvette was determined from its values S_j calculated by the formula

$$S_j = \frac{\sum_{i=1}^{j} K_i d_i^3}{\sum_{i=1}^{m} K_i d_i^3}, \quad (11)$$

where d is the average drop size of i-th fraction; K_i the number of drops in i-th fraction; and j the running number of i-th fraction, i = 1, 2, ..., j, ..., m, where m is the total number of fractions used in the measurements.

To calculate S_j by means of formula (4), the number of drops, K_i, was calculated in each of the 14 fractions, into which was divided the whole ensemble of the drops being analyzed, and their average diameter d_i was determined.

For an atomizer with nozzle diameter of 3 mm and water pressure of 6 atm, the diameter of drops constituting the main part of the sample varied within 20–500 μm. The results of measurements processed using formulas (3) and (4) are presented in Fig. 3 which makes it possible to find graphically the constants a and n of the Rosin–Rammler distribution. Constant n is numerically equal to the slope of the straight line in Fig. 3, and constant a, to the intercept on the abscissa axis.

Experimental data processing gave the following values of constants a and n

$$a = 0.34 \times 10^{-3}\,\text{m}, \quad n = 3.1. \quad (12)$$

In this case, the mean error of approximation, i.e., the mean deviation of the S value calculated by formula (9) with account of the obtained constants from the values S_j found experimentally with the use of formula (11) was 6%.

The obtained distribution functions (7) and (9) were used in calculating the spraying density at different distances from the atomizer by means of equations of the hydrodynamic model of free flare [1, 2]. These functions made it possible to specify the boundary conditions for the first and second zones of the jet. The first zone, characterized by fluid jet breakup into drops, is defined in the range from z = 0 to $z = L$ [1], where z is the axis of a cylindrical system of coordinates, coinciding with the atomizer axis and L is the distance from the atomizer nozzle exit section, which is the boundary of that region of gas-fluid jet flow at which the process of fluid flow breakup into drops is considered complete.

In [1], the L value is found from the condition that the volume content β of fluid at any point of the second zone of the jet should be less than 0.02. In calculating the flow of a gas-fluid jet, its cross-section was divided by concentric circles into 16 parts, each belonging to some i-th jet. The partitioning of the gas-fluid jet in question into separate jets, used in the calculation, is presented in Table 1.

It was found that dividing the jet cross-section into more than 16 parts does change significantly the results of calculation of the gas-fluid jet parameters.

As the maximum value of the dimensionless flare radius x_{16} was chosen the value 1.23, which accounted for 99% of the fluid outflow from the atomizer. The x_{16} value was determined from the equality

$$1.9\int_0^{x_{16}} I x \mathrm{d}x = 0.99. \quad (13)$$

The quantity y_i, necessary for specifying the conditions at the boundary of the first flow zone of the gas-fluid jet, was determined using formula (6)

$$y_i = R_\mathrm{n} x_i. \quad (14)$$

The distribution of the fluid flow rate among jets in the first flow zone of the gas-fluid jet, presented in Table 1, was found using the relation

$$G_i = 1.9 G_0 \int_{x_{i-1}}^{x_i} I x \mathrm{d}x. \quad (15)$$

In determining the type of boundary conditions for the second flow zone, characteristic geometric parameters—boundaries between the first and second zones, R and L, were calculated using the formulas

$$R = R_\mathrm{n}\sqrt{I_\mathrm{max}/\beta},\ \beta = 0.02; \quad (16)$$

$$L = \frac{R - R_\mathrm{n}}{\tan(d/2)}. \quad (17)$$

From formulas (16) and (17) follows that R and L depend on I_max, which is determined by the spraying density distribution function. It follows from Fig. 2 that I_max = 2.86, with R = 18 mm and L = 75 mm. In writing down the boundary conditions for the second flow zone of the gas-fluid jet, the polydispersity of the drop flow was accounted for by a distribution function defined by expressions (9) and (12). The drop flow passing through section $z = L$ was divided into six fractions. This decomposition is presented in Table 2.

The quantity h is defined by

$$h = d/a. \quad (18)$$

Its introduction is to some extent convenient in view of the use of the Rosin–Rammler distribution function (9).

The quantity d_j in Table 2 is average volume-surface Sauter diameter for each of the distinguished fractions of the drop flow

$$d_j = a(S_j - S_{j-1}) \Big/ \left(\int_{h_{j-1}}^{h_j} \frac{1}{h}\frac{\partial S}{\partial h}\mathrm{d}h \right). \quad (19)$$

Table 1. Partitioning of the gas-fluid flow into separate jets

i	x_i	$G_i \times 10^3$, kg s^{-1}	i	x_i	$G_i \times 10^3$, kg s^{-1}
1	0.1	4.57	9	0.55	20.6
2	0.2	15.3	10	0.6	16.7
3	0.25	14.1	11	0.65	12.9
4	0.3	18.4	12	0.7	9.62
5	0.35	21.7	13	0.8	12.2
6	0.4	24.0	14	0.9	6.65
7	0.45	24.7	15	1.0	3.74
8	0.5	23.5	16	1.23	3.86

Table 2. Decomposition of the drop flow passing through section $z = L$ into fractions*

j	h_j	d_j, μm	$S_j - S_{j-1}$
1	0.5	117	0.110
2	0.7	202	0.172
3	0.9	268	0.232
4	1.1	333	0.225
5	1.3	398	0.156
6	∞	453	0.105

* j is the fraction index, and h_j is the relative drop diameter setting the upper limit of a fraction.

The difference of the distribution function values S_j and S_{j-1} for j-th fraction has a meaning of the volume fraction of the fluid flow which is accounted for by j-th fraction. From expression (9) follows that this fraction is given by

$$S_j - S_{j-1} = \exp(-h_{j-1}^l) - \exp(-h_j^l). \quad (20)$$

The flow rates G_{kj} of fluid in jets with certain fraction composition, necessary for setting the boundary conditions [2], was calculated with account of the volume fractions of the fluid in the drop flow in each fraction by the formula

$$G_{kj} = G_i(S_j - S_{j-1}) \text{ at } k = i. \quad (21)$$

Thus, the boundary conditions obtained for the first flow zone of the gas-fluid jet at $z = 0$ are defined by relations (14) and (15) and parameter values in Table 1. The boundary conditions for the second flow zone at $z = L$ are defined by relations (17) and (19)–(21) and parameter values in Table 2. The obtained kind of boundary conditions reflects all specific

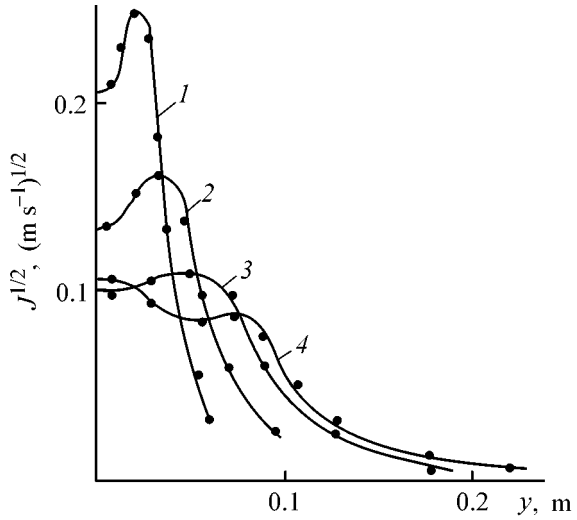

Fig. 4. Distribution of spraying density J along the radius of the flare of the gas-fluid jet. Fluid pressure before atomizer 6 atm, atomizer nozzle diameter $d_n = 3 \times 10^{-3}$ m, flare aperture 25°. Distance from the atomizer nozzle (m): (*1*) 0.3, (*2*) 0.7, (*3*) 0.9, and (*4*) 1.1.

features of the jet flow in the experimental setup under consideration. Therefore, the spraying density distribution at different distances from the atomizer nozzle, found theoretically by solving the equations of the model of the gas-fluid jet just with these boundary conditions, makes it possible to confirm the adequacy of the model correctly, by comparing this distribution with the results of its study on the experimental setup under consideration.

This comparison is illustrated by Fig. 4. The average discrepancy of the theoretical and experimental results does not exceed 7%. The results obtained in the performed experimental study of the flow of a free polydisperse gas-fluid jet confirm the possibility that the type of the spraying density distribution may change with distance from the atomizer nozzle. For example, if this distance is 0.30 m, the spraying density distribution virtually coincides with the initial distribution of this quantity, which has a minimum on the Z axis (Fig. 4), in full agreement with the theoretical results obtained in [2].

It is important to note that calculation of the jet under consideration without taking into account its polydispersity gives no way of revealing theoretically changes in the nature of the spraying density distribution with distance from the atomizer nozzle. The results of an experimental study concerned with this issue confirmed that the spraying density increases in the near-axis region of jet flow through displacement of finely dispersed drop fractions from the periphery of the gas-fluid jet toward its central part. This displacement occurs because of the radial gas motion inside the jet.

The general form of the spraying density distribution with a minimum and maximum at the Z axis, obtained in this study experimentally at different distances from the atomizer nozzle, is, as is known [3], rather characteristic of centrifugal-jet atomizers. It has been believed until now that the type of these distributions is only determined by design features of the atomizer itself and its operation mode and does not change in the development of a gas-fluid jet. However, a study of the hydrodynamics of a polydisperse gas-fluid jet, carried out in the present work, established experimentally that the spraying density distribution also changes in the process of development of this jet, and the dispersion composition of the drop flow affects the nature of this change. Hence follows that hydrodynamic calculation of a free polydisperse gasfluid jet is to be carried out with account of the dispersion composition of the drop flow.

CONCLUSIONS

(1) An experimental study of a gas-fluid jet outflowing from a single-flare atomizer confirms the adequacy of the hydrodynamic model developed in previous investigations of the authors.

(2) The possibility of a significant change in the nature of spraying density distribution in a free polydisperse gas-fluid jet with distance from the atomizer nozzle was confirmed experimentally.

(3) A strong influence exerted by the polydispersity of a drop flow on how the spraying density distribution function changes with distance from the atomizer nozzle was revealed.

Abstract—Thorough cleaning of argon and germanium tetrahydride to remove admixture of water with gas-separating membranes of the Lestosil type was studied. Schemes of the installation and the membrane unit necessary for performing thorough cleaning are presented. The selectivity of radial counterflow membrane units was studied and a mathematical model is presented making it possible to calculate their separating power and evaluate the effect of longitudinal agitation on the cleaning process.

The method of membrane gas separation is beginning to be used for gas cleaning to remove admixture of water. For example, raw natural gas can be cleaned to remove water to a level of $(1.4–1.5) \times 10^{-2}$ vol %, using cellulose acetate membranes [1]. Cleaning of nitrogen to remove water was studied in [2], and that of argon and helium, in [3, 4]. Of interest is to study the process of thorough cleaning of gases to remove admixture of water with highly permeable commercial membranes based on polydimethylsiloxane (of the Lestosil type).

The aim of this work was to study theoretically and experimentally the process of thorough cleaning of gases to remove admixture of water with a membrane of the Lestosil type for the example of germanium tetrahydride and argon.

The cleaning installation is shown schematically in Fig. 1. It comprises a unit for preparing a model mixture and sections for cleaning and analysis. The model mixture is prepared by bubbling a gas under study, contained in cylinder *1*, through water in vessel *2*. The gas pressure in vessel *2*, determining the concentration of water impurity at the temperature of experiment (293 K) is set with reducer *3* and monitored with pressure gage *4*. Reducer *5* is used to set the gas pressure in the high-pressure zone of the membrane unit *6*, monitored with pressure gage *7*. A membrane having higher permeability to water, than to gas being cleaned is employed. In the unit, part of a gas mixture with increased content of water impurity passes through the membrane into the low-pressure zone and may condense in cylinder *8* or be evacuated through cock *9*. Vacuum gages *10* and *11* serve for determining the pressure in the low-pressure zone. The flow rate of a cleaned gas mixture at the exit from the high-pressure zone is monitored with rotameter *12* and controlled with fine adjustment valve *13*. The rotameter *12* shows the total flow rate of the gas mixture at the unit inlet. At closed valve *13*, it shows the rate of the gas flow through the membrane into the low-pressure zone of unit *6*.

As membrane unit was used a counterflow radial element in which the gas mixture moves radially, from periphery to center, in the high-pressure zone and from center to periphery in the low-pressure zone. A schematic of the membrane unit is given in Fig. 2.

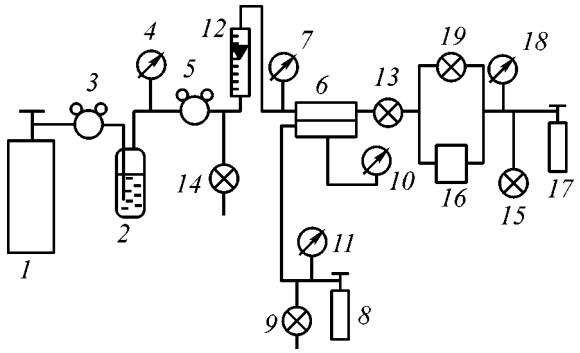

Fig. 1. Membrane installation: (*1, 8, 17*) cylinders, (*2*) bubbler, (*3, 5*) reducers, (*4, 7, 18*) pressure gages, (*6*) membrane unit, (*9, 13–15, 19*) valves, (*10, 11*) vacuum gages, (*12*) rotameter, and (*16*) dew point sensor.

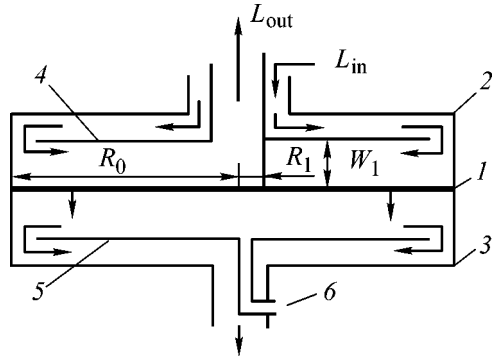

Fig. 2. Schematic of radial countercurrent membrane element: (*1*) membrane; (*2, 3*) high- and low-pressure zones, respectively; (*4, 5*) distributor disks; and (*6*) pipe for connecting a vacuum gage.

The arrows show the motion direction of the gas mixture. On the low-pressure side the membrane is supported by a plate of porous stainless steel or stainless steel mesh lying on a flange with a system of channels for gas mixture removal. The pressure difference between the central and peripheral regions in the chambers of the membrane element was not higher than 5 and 30% in the high- and low-pressure zones, respectively. The clearance in the high-pressure zone of the membrane element, W_1 = 0.1 cm, and the radius of the outlet channel from the high-pressure cavity, R_1 = 0.1 cm.

To perform a thorough cleaning of gases to remove admixture of water, it is necessary to eliminate the effect of the apparatus material, associated with diffusion of water vapor from air through polymeric lining and its desorption from apparatus walls. Therefore, the shut-off valves and fine adjustment stopcocks used in the line for discharge of cleaned gas from the membrane element have no polymeric sealing materials. To eliminate the possibility of water desorption from the apparatus walls, the installation was purged (through valves 9, 14, and 15) with dried gas to make the concentration of water level lower than the minimum experimentally observed value in cleaned gas. Further, a unit for model mixture preparation was connected to the installation, and experiments with a minimum rate of product removal and maximum cleaning efficiency were performed. Then the rate of removal of a cleaned gas mixture was raised using the fine adjustment cock, and, after the installation attained the steady-state mode, the impurity concentration under given process conditions was determined.

In membrane units, the membrane between flanges is sealed with polymeric linings. In the element employed, the sealing lining is situated on the periphery, and, therefore, a gas with water content close to the initial value, rather than cleaned gas, is in contact with polymer linings in both chambers of the unit. This is due to the fact that the gas mixture being cleaned moves from periphery to center in the high-pressure zone of the element, and as a counterflow, from center to periphery, in the low-pressure zone.

In the experiments, a membrane of the Lestosil type with working part diameter of 25.8 cm was used. Membranes of this type show rather high selectivity in separation of water vapor and a number of volatile inorganic hydrides and inert gases. For example, the ratio of permeabilities (separation factor) is 30 for water vapor and argon and 9.5 for water vapor and germanium tetrahydride. The membrane permeabilities to argon and GeH_4 are, respectively, 0.37×10^{-7} and 1.2×10^{-7} mol s^{-1} m^{-2} Pa^{-1}. It was also found that membranes of the given type retain their properties (selectivity and permeability) in inert gases and high-purity GeH_4 for more than three years.

The gases were analyzed for water content with a dew point sensor *16* preliminarily calibrated with a Baikal 3M coulometric hygrometer for low H_2O concentrations. As dew point was taken arithmetic mean temperature of appearance and disappearance of dew. The analysis error determined by the difference of temperatures of dew appearance and disappearance did not exceed 5 and 25% for the experimentally determined maximum and minimum concentration of water, respectively. The rate of gas flow through the sensor was maintained constant, the excess amount of the gas mixture was discharged through an additional line. The pressure in the line of analysis was determined with pressure gage *18*.

In experiments, the separating power of a membrane element (separation factor F) was found as a ratio of concentrations of water in the initial and cleaned mixture, discharged from the high-pressure zone of the element. The initial concentration of water was determined on the installation in the absence of pressure drop across the membrane, i.e., without evacuation of the gas mixture from the low-pressure zone of the element. The initial concentration coincides with the equilibrium content of water, corresponding to water temperature and gas pressure in the vessel for model mixture preparation.

Figure 3 presents experimental values of the separation factor of the membrane element in relation to the reciprocal of the degree of product discharge, $l_{out}^{-1} = L_{in}/L_{out}$. It can be seen that the efficiency of cleaning grows with decreasing rate of product discharge. At equal rates of product discharge, a greater

separation factor is observed for a mixture of argon with water impurity, for which the separation coefficient is higher.

A theoretical study of thorough cleaning of argon and germanium tetrahydride was carried out using equations taking into account the longitudinal mixing of the impurity in the element zones [4]:

$$\frac{1}{\mathrm{Pe}_1}\frac{\mathrm{d}^2c_1}{\mathrm{d}r^2} + \frac{1}{r}\left[\frac{1}{\mathrm{Pe}_1} + 1 - \frac{h}{2}(1 - P)(1 - r^2)\right]\frac{\mathrm{d}c_1}{\mathrm{d}r} + h(1 - \alpha - P)c_1 + Phc_2\alpha = 0, \quad (1)$$

$$\frac{1}{\mathrm{Pe}_2}\frac{\mathrm{d}^2c_2}{\mathrm{d}r^2} + \frac{1}{r}\left[\frac{1}{\mathrm{Pe}_2} - \frac{h}{2}(1 - P)(r^2 - r_1^2)\right]\frac{\mathrm{d}c_2}{\mathrm{d}r} + h[1 + (\alpha - 1)P]c_2 + hc_1\alpha = 0 \quad (2)$$

with boundary conditions

$$\frac{1}{\mathrm{Pe}_1}\frac{\mathrm{d}c_1}{\mathrm{d}r} + c_1 = 1, \ \frac{\mathrm{d}c_2}{\mathrm{d}r} = 0 \text{ at } r = 1, \quad (3)$$

$$\frac{\mathrm{d}c_1}{\mathrm{d}r} = 0, \ \frac{\mathrm{d}c_2}{\mathrm{d}r} = 0 \text{ at } r = r_1, \quad (4)$$

where $c_1 = C_1/C_{1\,\mathrm{in}}$, $c_2 = C_2/C_{1\,\mathrm{in}}$, $r = R/R_0$, $r_1 = R_1/R_0$, $\alpha = Q_\mathrm{A}/Q_\mathrm{B}$, $P = P_2/P_1$, $\mathrm{Pe}_1 = V_\mathrm{in}R_0/D_1$, $\mathrm{Pe}_2 = V_\mathrm{in}W_1R_0/(W_2D_2)$, $h = 2\pi R_0^2Q_\mathrm{B}P_1/L_\mathrm{in}$, $L_\mathrm{in} = 2\pi R_0W_1V_\mathrm{in}\rho$; C is the impurity concentration (mole fraction); D the coefficient of longitudinal mixing ($\mathrm{m^2\ s^{-1}}$); L the flow rate of the gas mixture ($\mathrm{mol\ s^{-1}}$); P the pressure of the gas mixture; Q the membrane permeability ($\mathrm{mol\ m^{-2}\ s^{-1}\ Pa^{-1}}$), R_0 the radius of the working part of the membrane (m); R_1 the radius of a channel for gas mixture discharge from the high-pressure zone (m); R the coordinate along the membrane radius (m); V the gas flow velocity ($\mathrm{m\ s^{-1}}$); W the clearance in a zone (m); ρ the gas density ($\mathrm{mol\ m^{-3}}$); indices: (*1*) high-pressure zone, (*2*) low-pressure zone, (A) impurity component, (B) main component, and (in) inlet of the high-pressure zone.

Equations (1)–(4) describe separation in a membrane element in the case of low impurity concentration in the initial mixture as compared with the concentration of the main component. These equations account for the influence exerted by longitudinal mixing of the impurity in the element cavities on the separation process.

From Eqs. (1)–(4) can be derived two limiting expressions for the separation factor

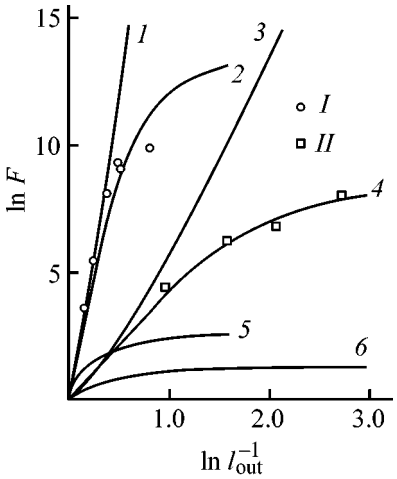

Fig. 3. Separation factor F vs. degree of product discharge l_out. Gas mixture composition: (*1, 2, 5*) argon–water impurity and (*3, 4, 6*) germanium tetrahydride–water impurity. Calculation by equation: (*1, 3*) (5), (*2, 4*) (1)–(4), and (*5, 6*) (6). Experimental data for mixture of water impurity with (*I*) argon and (*II*) germanium terahydride.

$$F = l_\mathrm{out}[1 + h_1(1 - l_\mathrm{out})^{-h_2}\psi(1), \quad (5)$$

$$F = \alpha^* - (\alpha^* - 1)l_\mathrm{out}, \quad (6)$$

where $h_1 = \alpha/(1 - P)$, $h_2 = P\alpha/(1 - P)$, $l_\mathrm{out} = L_\mathrm{out}/L_\mathrm{in}$, $\psi(1) = \int_{l_\mathrm{out}}^{1} l^{-(1+h_1)}(l - l_\mathrm{out})^{h_2}\mathrm{d}l$, $l = L(R)/l_\mathrm{in}$ the running relative flow rate of the gas mixture in the high-pressure zone, $L(R) = 2\pi R_0W_1V(R)\rho$, $\alpha^* = \alpha/[1 + (\alpha - 1)P]$ the effective separation coefficient, $V(R)$ the gas flow velocity in the high-pressure zone at a point with coordinate R ($\mathrm{m\ s^{-1}}$), the index "out" refers to the outlet of the high-pressure zone.

Expressions (5) and (6) correspond, respectively, to the ideal displacement mode in both zones ($\mathrm{Pe}_1 >> 1$, $\mathrm{Pe}_2 >> 1$) and complete mixing mode in the element cavities ($\mathrm{Pe}_1 << 1$, $\mathrm{Pe}_2 << 1$). At $P = 0$, relation (5) gives a simple expression

$$F = l_\mathrm{out}^{(1-\alpha)}. \quad (7)$$

Equation (7) characterizes the maximum possible separating power of the membrane unit. Under real conditions, the limiting values of F, according to Eqs. (5) and (7), are not reached because of the influence of longitudinal mixing, always occurring to some extent in the element zones.

Figure 3 presents theoretical and experimental dependences of the separation factor on the reciprocal of the degree of product discharge, l_out^{-1}, and also theoretical formulas for the limiting formulas (5) and (6)

for the systems argon–water impurity (curves *1* and *5*) and germanium tetrahydride–water impurity (curves *3* and *6*). Experimental points lie between the limiting curves corresponding to formulas (5) and (6). This means that in the membrane element zones there exists longitudinal mixing affecting the separation process and depending on the diffusion coefficients, concentration gradients, and gas flow nonuniformity.

The dependences of the separation factor on the product discharge rate, calculated numerically using the initial equations (1)–(4), were compared with experimental data. It was assumed in theoretical calculations that molecular diffusion occurs in the high-pressure zone, for which the diffusion coefficient can be calculated in terms of the kinetic theory of gases, using the Chapman–Enskog equation [5]. The parameters of the intermolecular potential of GeH_4 were taken from [6].

From the condition of minimum rms discrepancy of the theoretical and experimental dependences were found the values $W_2D_2 = 0.055$ cm^3 s^{-1} (argon–water impurity) and $W_2D_2 = 0.164$ cm^3 s^{-1} (germanium tetrahydride–water impurity) characterizing the longitudinal mixing in the low-pressure zone of the employed membrane units. The extent to which longitudinal mixing affects the cleaning efficiency can also be evaluated on the basis of Fig. 3 by the discrepancy between the experimental points and the limiting curves *5* and *6*. It can be seen that the separation conditions are closer to the ideal displacement conditions for argon, compared with GeH_4. This may be associated with the difference in W_2 values, associated with the low-pressure zone design.

CONCLUSION

The results of the investigation performed indicate that the method of membrane gas separation can be successfully used to clean argon and germanium tetrahydride to remove admixture of water. The employed mathematical model makes it possible to calculate the separating power of a membrane unit, evaluate the longitudinal mixing and choose the optimal technological parameters of the process.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparation of Fine Alumina Powders by Hydrolysis of Aluminum Isopropylate

E. E. Grinberg, V. V. Saradzhev, Yu. I. Levin, and E. A. Ryabenko

Federal State Unitary Enterprise, State Research Institute of Chemicals and Ultra Pure Compounds, Moscow, Russia

Received June 3, 2001

Abstract—Preparation of fine alumina powder by hydrolysis of aluminum isopropylate was studied.

Because of the stringent requirements to purity of materials used in modern industry, a necessity arises for using new raw materials, such as organic compounds of many classes. Prominent among them are metal alcoholates [1]. Hydrolysis, thermolysis, oxidation, and plasma degradation of these compounds are widely used to prepare high-purity metal oxides or hydroxides (sols and gels) [2, 3]. The higher stability of these colloids as compared with those prepared, e.g., by hydrolysis of metal halides is due to the complete absence of ions promoting sol coagulation [4]. Colloid solutions of metal hydroxides obtained from the corresponding alcoholates are widely used as film-forming agents for preparing coatings (e.g. Al_2O_3) by the "solution technology" [5–9].

Topical tasks in development of a procedure for preparing metal oxides by hydrolysis of the corresponding alcoholates are study of the mechanism and determination of the best conditions of formation of metal hydroxide gels. This stage involves determination of particle size, conditions for metal hydroxide dehydration (i.e., temperature of formation of metal oxides), surface area of the powders, their tendency to cake, etc. [4]. The demand for fine powders of high-purity aluminum oxides and hydroxides steadily grows. A promising procedure for preparing 5–30-μm alumina powders is hydrolysis of aluminum isopropylate [10].

As regards to physicochemical properties, aluminum isopropylate is the best suited for industrial production among aluminum alcoholates. The aluminum content in aluminum isopropylate is relatively high and the liquid phase of this compound exists in a wide temperature range which allows its purification by distillation. However, the requirements of high dispersity and purity of the product become mutually conflicting under conditions of liquid-phase hydrolysis. Preparation of fine alumina powder by liquid-phase hydrolysis is complicated by aggregation of the product and incorporation of isorpopanol and water in it. Introduction of various compounds maintaining the dispersity of the system decreases the purity of the product. Hydrolysis under conventional conditions yields highly hydrated aluminum oxides or their mixtures with variable composition. In addition, great volumes of dilute isopropanol solutions formed in this process are difficult to utilize.

A study of hydrolysis of aluminum isopropylate under various conditions showed [11] that the best procedure for preparing fine alumina powder is hydrolysis of aluminum isopropylate by steam, which can be performed as a single-step process:

$$2Al(OPr\text{-}i)_{3(l)} + 4H_2O = Al_2O_3 \cdot H_2O_{(s)} + 6i\text{-}PrOH_{(s)}.$$

In addition, easy control of the water-to-alcoholate ratio makes lower the water consumption and the yield of waste hydrolyzate.

EXPERIMENTAL

Aluminum isopropylate was hydrolyzed in a flow reactor. An aluminum isopropylate melt was sprayed into a reactor with a carrier gas through an injection nozzle. The reactor was heated to 120–160°C and purged simultaneously with steam fed from a steam generator, until the required temperature was reached at the outlet and water drops on the lid and walls of the reactor completely disappeared. Then a melt of aluminum isopropylate was charged into a preheated

Table 1. Conversion K of aluminum isopropylate into boehmite and the particle size d of alumina powder formed by spraying of $Al(OPr\text{-}i)_3$ melt with various carrier gases (temperature inside the reactor 130°C)

Carrier gas	P_n, mm Hg	Feed rate, g min^{-1}		Q_s, mol mol^{-1}	K, wt %	d, μm
		$Al(OPr\text{-}i)_3$	steam			
Technical-grade nitrogen	62	57	20	16.2	81	2–20
Argon	68	34	20	10.0	83	2–20
Air	61	47	20	13.2	82	2–20

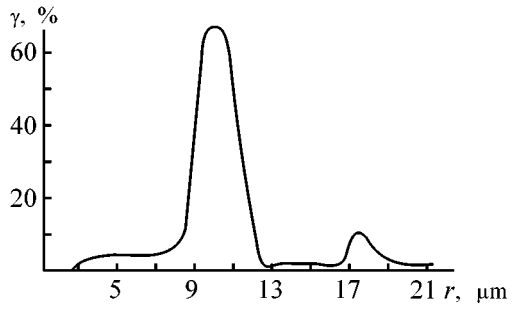
Notes: P_n is the residual pressure in the nozzle; Q_s is the overstoichiometric excess of steam.

Table 2. Conversion K of aluminum isopropylate into boehmite and particle size d of alumina at different temperatures of steam–gas mixture inside the reactor

T, °C	P_n, mm Hg	Feed rate, g min^{-1}		K, wt %	d, μm
		$Al(OPr\text{-}i)_3$	steam		
120	63	34	20	85	2–20
140	65	35	20	83	2–20
160	62	34	20	84	2–20

melter and sprayed through the nozzle with a carrier gas fed from a cylinder. Solid hydrolysis products were deposited on the lid and walls of the reactor, and the steam–gas mixture was passed through a condenser where steam and isopropanol vapor were condensed and drained to an attached vessel. The carrier gas and uncondensed vapors were discharged into the atmosphere. After emptying the melter, the steam feed was stopped and the hydrolysis was terminated. The steam generator was detached and reactor was purged with the carrier gas for 5–10 min to remove residual water vapor. Then the reactor was cooled, and the solid hydrolysis products were unloaded. The samples of the powder and condensate were weighed and analyzed.

To optimize the process parameters, we studied the hydrolysis as influenced by the nature of the carrier gas. For example, air can oxidize aluminum isorpopylate and affect the particle size distribution of the hydrolysis products.



Particle size distribution of alumina: (γ) fraction of particles of size r.

The results of experiments with argon, nitrogen, and air as carrier gases are presented in Table 1. The quality of hydrolysis products and the hydrolysis rate are independent of the nature of the carrier gas. Feeding steam in a tenfold excess over the stoichiometry has no effect on the hydrolysis.

As seen from Table 2, varying the temperature of the steam-gas mixture inside the reactor in the range 120–160°C has no effect on the particle size distribution and degree of hydrolysis of aluminum isopropylate.

The hydrolysis products were studied by DTA and powder X-ray diffraction. The particle size distribution was also determined. All the samples studied were found to be boehmite AlOOH, rather than $Al(OH)_3$ as would be expected from the moderate temperatures in the reaction zone.

The samples were calcined at 550–700°C. After this treatment γ-alumina powders were formed without agglomeration and caking. The particle size ranged from 2 to 20 μm (see figure). The BET surface area of γ-alumina was in the range 235–295 m^2 g^{-1}. This allows considerable simplification of the process flowsheet.

Table 3. Content of impurities in initial aluminum isopropylate and γ-alumina

Compound	Content, wt %									
	Fe	Mn	Ni	V	Cu	Ga	Mg	Na	Si	Cr
$Al(OPr\text{-}i)_3$	10^{-5}	$<10^{-6}$	$<10^{-6}$	$<10^{-6}$	2×10^{-5}	3×10^{-3}	10^{-5}	$<10^{-5}$	3×10^{-4}	$<10^{-6}$
Al_2O_3	2×10^{-4}	3×10^{-6}	3×10^{-6}	$<10^{-6}$	8×10^{-5}	10^{-2}	2×10^{-4}	3×10^{-5}	8×10^{-4}	5×10^{-6}

The slight increase in the impurity content in γ-alumina as compared with the initial aluminum isopropylate (Table 3) is due to a decrease in the weight of the target product. Thus, no additional impurities are introduced in the stages of hydrolysis and calcination, which confirms our initial assumptions.

CONCLUSIONS

(1) Aluminum isopropylate is hydrolyzed with a steam flow by spraying of its melt.

(2) The product of hydrolysis at 120–160°C is a boehmite powder. The chemicals and materials used in this process require no additional purification.

(3) Alumina powders prepared by this procedure do not agglutinate and agglomerate. The deviation of the particle size from the average value is negligible.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Pathways of Liquid-Phase Oxidation of Cyclohexanol

S. V. Puchkov, E. I. Buneeva, and A. L. Perkel'

Kuznetsk Coal Basin State Technical University, Kemerovo, Russia

Received September 11, 2001

Abstract—The kinetics of product accumulation in uncatalyzed oxidation of cyclohexanol at 403 K was studied. Along with the compounds originating from oxidation of cyclohexanol at position 1 (cyclohexanone, hydrogen peroxide, 1-hydroxycyclohexyl hydroperoxide), products formed by oxidation of C–H bonds at positions 2–4 were detected: 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides (*cis* and *trans* isomers), 1,2-, 1,3-, and 1,4-dihydroxycyclohexanes (*cis* and *trans* isomers), 2- and 4-hydroxycyclohexanones, and 2-cyclohexenone.

Liquid-phase oxidation of aliphatic and alicyclic hydrocarbons and their oxygen-containing derivatives to carboxylic acids is low-selective because of the multistage oxidation mechanism and possible occurrence of several transformation pathways of the substrate and intermediates [1–3].

In such processes, secondary alcohols are formed along with ketones in the stage of decomposition of secondary hydroperoxides [1–3]. It is commonly believed that their subsequent transformations mainly involve radical-chain oxidation of the activated (by a factor of 16–50 [4–6]) C–H bond at the α-position relative to the functional group, yielding 1-hydroxy hydroperoxide or ketone and hydrogen peroxide [2, 3, 7]. The possibility of oxidation of secondary alcohols at more remote C–H bonds is usually disregarded, and the reactivity of these bonds is assumed to be equal to that of the similar C–H bonds in hydrocarbons. At the same time, the contribution of alternative oxidation pathways must become more significant with increasing chain length and/or ring size in the substrates. Also, the hydroxy group exhibits electron-withdrawing properties and can deactivate the β- and γ-C–H bonds, as observed previously for the acetoxy group in reaction of cyclohexyl acetate with *tert*-butylperoxy radical [8].

The goal of this study was to evaluate, with cyclohexanol as example, the selectivity of liquid-phase oxidation of secondary alcohols. The choice of cyclohexanol was governed by the fact that, with this substrate, the reaction pattern is not disturbed by intramolecular isomerization of the peroxy radical, characteristic of long-chain aliphatic alcohols [9]. We also wished to gain insight into the mechanism of formation of degradation products in liquid-phase oxidation of cyclohexanol and cyclohexane.

EXPERIMENTAL

Cyclohexanol (analytically pure grade) was purified to remove ethers and cyclohexanone by azeotropic distillation of impurities with water, followed by treatment with a saturated solution of sodium hydrosulfite and fractional distillation in an argon flow under reduced pressure. The composition of the resulting sample was as follows (%): main substance (determined by GLC) 99.5 ± 0.1, cyclohexanol ethers (GLC) ≤ 0.01, and cyclohexanone (determined spectrophotometrically as 2,4-dinitrophenylhydrazone [10]) <0.005.

Oxidation of cyclohexanol with molecular oxygen was performed at 403 K in a glass bubbling reactor.

Separate determination of hydrogen peroxide and organic peroxides (1-hydroxycyclohexyl hydroperoxide) was performed by iodometric titration using the catalase enzyme [11]. The total content of cyclohexanone and 1-hydroxycyclohexyl hydroperoxide was determined by GLC (10% Carbowax-6000 on Chromaton N-AW-DHCS, 393 K, internal reference chlorobenzene) after reduction of the samples with triphenylphosphine, and the content of 2- and 4-hydroxycyclohexanones (in the form of acetates), on the same column at 448 K (internal reference decyl acetate). 2-Cyclohexenone was determined on a column

1070-4272/02/7502-0248 $27.00 © 2002 MAIK "Nauka/Interperiodica"

packed with Chromaton N-AW-super + XE-60 silicone at 358 K (internal reference chlorobenzene).

To determine isomeric 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides (*cis*- and *trans*-) and 1,2-, 1,3-, and 1,4-dihydroxycyclohexanes (*cis*- and *trans*-), samples of oxidized alcohol were concentrated under reduced pressure, the peroxides were reduced with a 50% solution of KI in 0.1 M HCl, and the products were extracted with 1,2-dichloroethane. The extract was dried over $MgSO_4$, the solvent was distilled off, and the diols were converted to diacetates by treatment with a 1 : 1 acetic anhydride–pyridine mixture for 2 h at 373 K [12]. A procedure for identification and quantitative determination of isomeric cyclohexanediol diacetates by GLC (20% diethylene glycol succinate on Chromaton N-AW-HMDS and 5% 1,2,3,4,5,6-hexakis-β-cyanoethoxyhexane on Chromaton N-AW-HMDS) is described elsewhere [8].

To accomplish our goals, we studied the kinetics of accumulation of products characteristic of various pathways of cyclohexanol oxidation with molecular oxygen at 403 K: hydrogen peroxide, 1-hydroxycyclohexyl hydroperoxide, cyclohexanone, 2- and 4-hydroxycyclohexanones, 2-cyclohexenone, 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides (*cis*- and *trans*-), and 1,2-, 1,3-, and 1,4-dihydroxycyclohexanes (*cis*- and *trans*-) (Fig. 1). The accumulation curves of hydrogen peroxide, organic hydroperoxides (of which the major product is 1-hydroxycyclohexyl hydroperoxide), and cyclohexanone shows that H_2O_2 and cyclohexanone are accumulated earlier than 1-hydroxycyclohexyl hydroperoxide, with the relative content of the latter increasing with conversion. This fact cannot be attributed to higher rate of hydrogen peroxide decomposition, because it is known [2] that adducts of H_2O_2 or organic hydroperoxides with cyclohexanone decompose faster than free hydroperoxides.

To refine the sequence of formation of products originating from cyclohexanol oxidation at the α-CH bond, we compared [1] the accumulation rates of the reaction products, determined by graphic differentiation of the kinetic curves (Fig. 1). Indeed, the ratios of the accumulation rates of organic hydroperoxides and H_2O_2, and also of organic hydroperoxides and cyclohexanone (Fig. 2) confirm the assumption that, under the experimental conditions, 1-hydroxycyclohexyl hydroperoxide is mainly formed by reversible nucleophilic addition of hydrogen peroxide to cyclohexanone [reaction (1a)], rather than from 1-hydroxycyclohexylperoxy radical [reaction (1b)]:

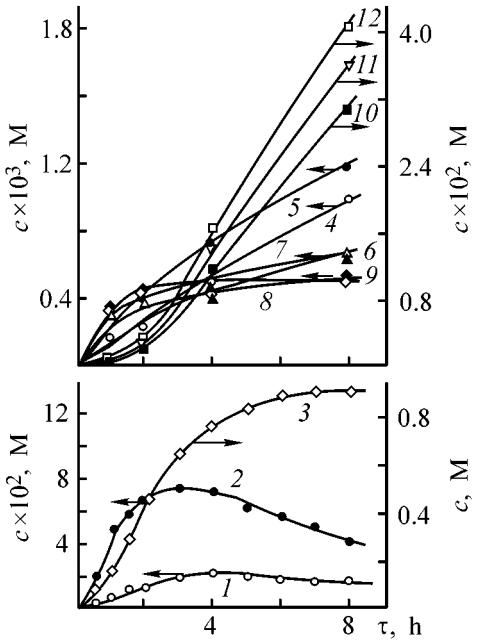

Fig. 1. Kinetic curves of product accumulation in oxidation of cyclohexanol at 403 K: (*c*) product concentration and (τ) time; the same for Fig. 4. (*1*) 1-Hydroxycyclohexyl hydroperoxide, (*2*) hydrogen peroxide, (*3*) cyclohexanone, (*4*) *cis*-2-hydroxycyclohexyl hydroperoxide and *cis*-1,2-dihydroxycyclohexane, (*5*) *trans*-2-hydroxycyclohexyl hydroperoxide and *trans*-1,2-dihydroxycyclohexane, (*6*) *cis*-3-hydroxycyclohexyl hydroperoxide and *cis*-1,3-dihydroxycyclohexane, (*7*) *trans*-3-hydroxycyclohexyl hydroperoxide and *trans*-1,3-dihydroxycyclohexane, (*8*) *cis*-4-hydroxycyclohexyl hydroperoxide and *cis*-1,4-dihydroxycyclohexane, (*9*) *trans*-4-hydroxycyclohexyl hydroperoxide and *trans*-1,4-dihydroxycyclohexane, (*10*) 2-hydroxycyclohexanone, (*11*) 2-cyclohexenone, and (*12*) 4-hydroxycyclohexanone.

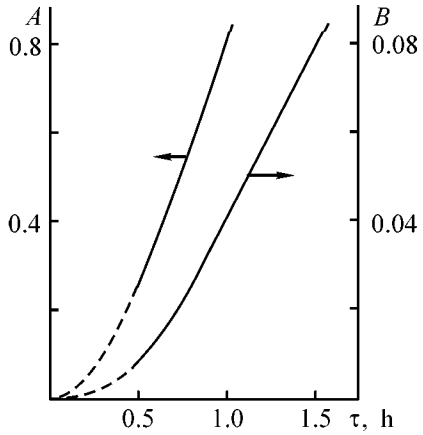

Fig. 2. Ratio of the rates of product accumulation in oxidation of cyclohexanol at 403 K: (*A*) cyclohexanone : 1-hydroxycyclohexyl hydroperoxide and (*B*) hydrogen peroxide : 1-hydroxycyclohexyl hydroperoxide. (τ) Time.

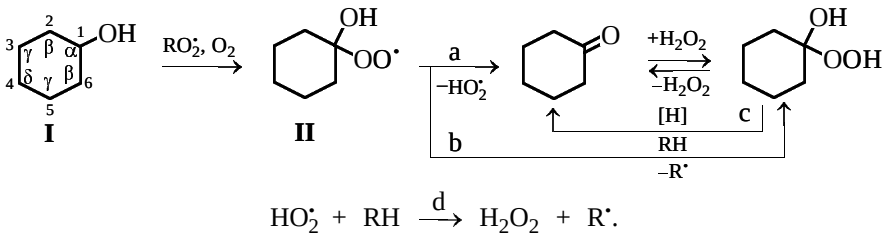


(1)

$$HO_2^{\bullet} + RH \xrightarrow{d} H_2O_2 + R^{\bullet}.$$

These results also show that the oxidation chain in oxidation of cyclohexanol at 403 K is led by the $HO_2^{\bullet}$ radical [reaction (1d)].

In parallel with the products of cyclohexanol oxidation at position 1, *cis* and *trans* isomers of 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides are also accumulated. These compounds, apparently, decompose to give the corresponding dihydroxycyclohexanes and also 2-cyclohexenone and 2- and 4-hydroxycyclohexanones.

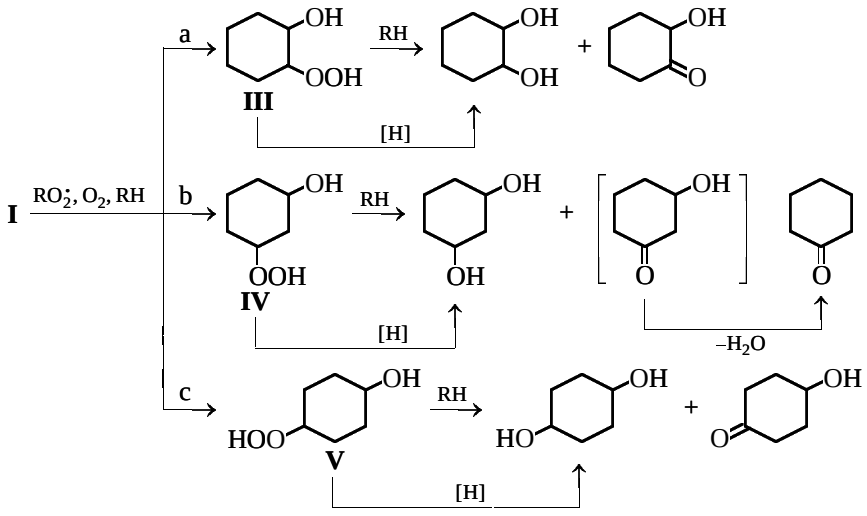
Table 1. Variation of the *trans*-to-*cis* isomer ratio C_{trans}/C_{cis} of 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides with time τ of cyclohexanol oxidation at 403 K

Positional isomer	C_{trans}/C_{cis} at indicated τ, h			
	1	2	4	8
2-	1.87	1.90	1.46	1.20
3-	2.0	1.60	1.20	1.00
4-	1.60	1.45	1.30	1.00

Formation of 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides and of 1,2- 1,3-, and 1,4-dihydroxycyclohexanes in the form of *cis* and *trans* isomers is quite natural, because the carbon-centered radical formed in the stage of chain propagation has a planar structure. Figure 1 and Table 1 show that the *trans* isomers somewhat prevail. For 2- and 4-hydroxycyclohexyl hydroperoxides, this may be due to the higher stability of the *trans* isomers. Indeed, the heats of formation of *trans*-1,2- and *trans*-1,4-dimethylcyclohexanes are lower by approximately 8 kJ mol^{-1} than those of the corresponding *cis* isomers [13]. At the same time, the reason for predominant formation of *trans*-3-hydroxycyclohexyl hydroperoxide are unclear, as the *cis* isomer of 1,3-dimethylcyclohexane is more stable than the *trans* isomer [13].

Furthermore, the higher relative content of *trans*-3-hydroxycyclohexyl hydroperoxide can hardly be attributed to the specific features of cyclohexanol oxidation with the $HO_2^{\bullet}$ radical, as the increased yield of this *trans*-1,3 isomer is also observed in reaction of cyclohexyl acetate with *tert*-butylperoxy radical [8].

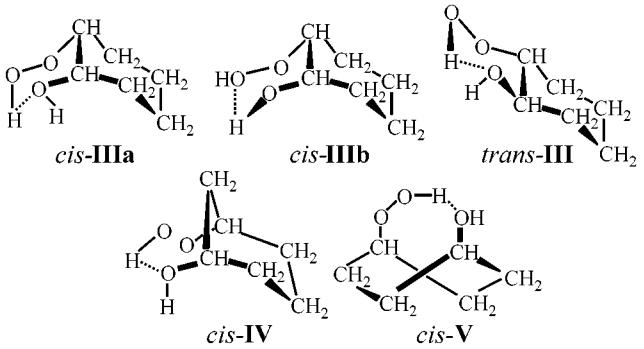
Possible pathways of cyclohexanol oxidation at positions 2 and 6 (2a), 3 and 5 (2b), and 4 (2c) are shown below:



(2)

Assuming that hydroxycyclohexyl hydroperoxides make a major contribution to the total content of hydroperoxides and diols (Fig. 1, curves *4*–*9*), we can evaluate the variation with the oxidation time of the relative mole fraction of each hydroxycyclohexyl hydroperoxide isomer (Fig. 3).

Figure 3 shows that, with conversion, the fractions of *cis*- and *trans*-2- and of *cis*-3-hydroxycyclohexyl hydroperoxides increase, and those of *cis*- and *trans*-4- and of *trans*-3-hydroxycyclohexyl hydroperoxides decrease. Because the decrease in the content of the last two products is accompanied by accumulation of their decomposition products (Fig. 1), the above trend is attributable to different stabilities of the isomers, so that the *trans*-to-*cis* isomer ratio decreases (Table 1). Indeed (Fig. 3), hydroxycyclohexyl hydroperoxides can be ranked in the following order with respect to their stability: *cis*-**III** ≥ *trans*-**III** > *cis*-**IV** > *trans*-**IV** ≥ *cis*-**V** > *trans*-**V**. Such a sequence well correlates with the capacities of hydroxycyclohexyl hydroperoxides for intramolecular hydrogen bonding:



It is known that 1-hydroxycyclohexyl hydroperoxide forms a strong intramolecular hydrogen bond [14]. Since formation of intramolecular hydrogen bonds with six- and seven-membered rings is preferable energetically [15], we should expect formation of a strong hydrogen bond in *cis*-**IIIa**, *cis*-**IIIb**, *trans*-**III**, and *cis*-**IV**.

In principle, hydroxy hydroperoxides can form two types of intramolecular hydrogen bonds via hydrogen atoms of hydroperoxy and hydroxy groups [2, 14]. Because the hydrogen atom of the OO–H bond is more acidic than that of the O–H bond, structure **IIIa** is preferable to **IIIb**. At the same time, although structure *trans*-**III** must be more stable than *cis*-**IIIa** (cf. *cis*- and *trans*-decalins [13]) owing to the steric factor, the difference in their stability can be decreased by the mutual effect of the polar groups of hydroxycyclohexyl hydroperoxides and by solvation effects.

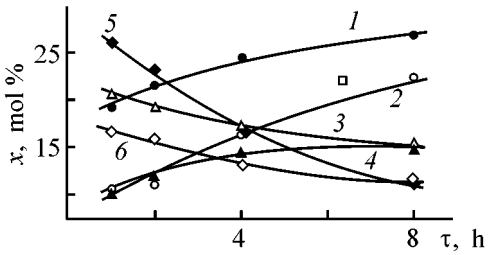


Fig. 3. Variaiton of the relative content of hydroxycyclohexyl hydroperoxide isomers with time of cyclohexanol oxidation at 403 K: (*x*) relative content and (τ) time. (*1*) *cis*-2-Hydroxycyclohexyl hydroperoxide, (*2*) *trans*-2-hydroxycyclohexyl hydroperoxide, (*3*) *trans*-3-hydroxycyclohexyl hydroperoxide, (*4*) *cis*-3-hydroxycyclohexyl hydroperoxide, (*5*) *trans*-4-hydroxycyclohexyl hydroperoxide, and (6) *cis*-4-hydroxycyclohexyl hydroperoxide.

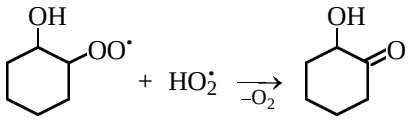
Formation of an intramolecular hydrogen bond in *cis*-4-hydroxycyclohexyl hydroperoxide (*cis*-**V**) is less probable than in 2- and 3-hydroxycyclohexyl hydroperoxides, as such a bond can be only occur in a more strained conformation [16]. In *trans*-3- and *trans*-4-hydroxycyclohexyl hydroperoxides, formation of an intramolecular hydrogen bond with a six-membered ring is impossible, and such bonds with larger rings would hardly be stable.

A strong intramolecular hydrogen bond in hydroxy hydroperoxides must prevent formation of linear intermolecular associates of the hydroperoxides with the substrate

$$\mathrm{ROOH + R'OH \rightleftarrows \underset{\displaystyle H}{\overset{|}{ROO}}\cdots H\text{–}OR' \rightarrow RO^{\bullet} + H_2O + R'O^{\bullet}}, \quad (3)$$

which are known [2] to decompose at higher rates than free hydroperoxides.

2-, 3-, and 4-Hydroxycyclohexanones can form not only by decomposition of the corresponding hydroxycyclohexyl hydroperoxides by reactions (2a), (2b), and (2c), but also by recombination of peroxy radicals:



(4)

Since the length of the kinetic chain of cyclohexanol oxidation is more than 100 under the experimental conditions {as calculated from the overall oxidation rate and the parameter $k_p(2k_t)^{-0.5}$ (403 K) = 1.03×10^{-2} $l^{1/2}$ $mol^{-1/2}$ $s^{-1/2}$ [2]}, the contribution of reaction (4) to the product formation is insignificant.

2-Cyclohexenone is probably formed from 3-hydroxycyclohexanone, because is it well known that

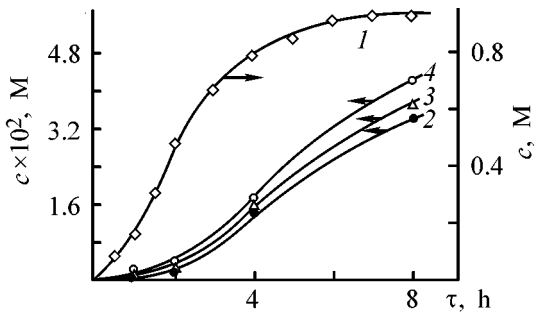


Fig. 4. Kinetic curves of product accumulation in oxidation of cyclohexanol at 403 K. Position of C–H bond: (*1*) 1, (*2*) 2 and 6, (*3*) 3 and 5, and (*4*) 4.

β-keto alcohols are unstable against dehydration [17]. Formation of 2-cyclohexenone from 2-hydroxycyclohexanone is considerably less probable. It is known that α-keto alcohols are dehydrated only under severe conditions [17]. We found that heating of a 0.1 M solution of 2-hydroxycyclohexanone in chlorobenzene at 403 K for 10 h under argon yielded no 2-cyclohexenone.

The kinetic curves of accumulation of cyclohexanone, 2- and 4-hydroxycyclohexanones, and 2-cyclohexenone (Fig. 1) show that hydroxycyclohexanones and 2-cyclohexenone can form in later oxidation stages by oxidative transformations of cyclohexanone.

The accumulation curves of the products characteristic of specific pathways of cyclohexanol oxidation [involving four different types of C–H bonds, schemes (1) and (2)] are shown in Fig. 4, and the initial rates of the product accumulation are listed in Table 2. Assuming that the reactivity of the C–H bond at position 4 is equal to that of the C–H bonds in cyclohexane, we can evaluate the relative reactivities of the C–H bonds in the cyclohexanol molecule (Table 2).

Table 2 shows that the hydroxy group enhances by a factor of more than 200 the reactivity of the C–H bond at position 1 and appreciably decreases the reactivity of the C–H bonds at positions 2 and 3. Similar trends were observed in the reaction of cyclohexyl acetate with *tert*-butylperoxy radical [8].

Table 2. Initial accumulation rates $v_{0,i}$ of products characteristic of specific pathways of cyclohexanol oxidation at 403 K and relative reactivities of the C–H bonds in cyclohexanol

Position of C–H bonds	Number of C–H bonds	$v_{0,i} \times 10^7$, mol l^{-1} s^{-1}	Relative reactivity
1	1	440	215
2, 6	4	1.85	0.22
3, 5	4	2.50	0.30
4	2	4.10	1.00

Oxidation of cyclohexanol, similar to that of cyclohexyl acetate, is a typical example of homolytic substitution in a hydrocarbon chain linked to an electron-withdrawing substituent. The polar (inductive + field) effect of such a substituent decreases the electron density on the hydrogen atom of the C–H bond subject to attack and thus hinders its interaction with electrophilic peroxy radicals [8, 18]. Furthermore, the electron-withdrawing substituent destabilizes the transition state and carbon-centered radicals formed by attack of the C–H bonds at positions 1–3 of cyclohexanol.

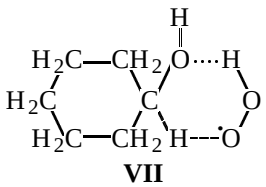
However, when a peroxy radical reacts with the C–H bond at position 1, the resulting hydroxyalkyl radical **VIa**, destabilized by the mechanism of the polar effect, is stabilized by conjugation of the unpaired electron with the lone electron pairs of the hydroxy group (structure **VIb**):

$$\underset{\textbf{VIa}}{H{-}\ddot{O}{\leftarrow}\dot{C}H{\leftarrow}R} \leftrightarrow \underset{\textbf{VIb}}{H{-}\dot{O}{=}CH{\leftarrow}R}. \qquad (5)$$

This effect must enhance the reactivity of the α-C–H bond in alcohols as compared with C–H bonds in hydrocarbons.

At the same time, so large (by more than a factor of 200) difference in the reactivities of the C–H bonds at positions 1 and 4 was unexpected. According to [5], at 353 K the reactivity of the α-C–H bond in cyclohexanol toward *tert*-butylperoxy radical exceeds that of the C–H bond in cyclohexane by a factor of 50. With increasing temperature and in going from the less active *tert*-butylperoxy radical to the more active $HO_2^{\bullet}$ radical [6], the difference between the reactivities of the C–H bonds must decrease, rather than increase.

The abnormally high reactivity of the C–H bond at position 1 in cyclohexanol toward the $HO_2^{\bullet}$ radical can be accounted for by assuming formation of a six-membered hydrogen-bonded transition state **VII**:

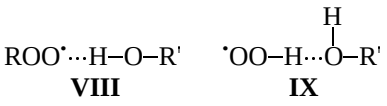


VII

The reaction via state **VII** is more favorable energetically and hence it must occur at a higher rate

than usual hydrogen abstraction from a substrate by a peroxy radical.

It is known [2] that alcohols form with peroxy radicals hydrogen-bonded associates **VIII**. In contrast to peroxy radicals, $HO_2^{\bullet}$ radicals can form associates **IX** of different kind:



VIII **IX**

Because the hydrogen atom in the $HO_2^{\bullet}$ radical is more acidic and shows stronger electron-withdrawing power than the hydrogen atom of the hydroxy group, and the hydroxyl oxygen, in turn, is a stronger electron donor than the electrophilic oxygen of the peroxy radical, associate **IX** is preferable to **VIII**.

Table 2 shows that oxidation of cyclohexanol by the α pathway initially occurs with fairly high selectivity (~98%), which is due to activation of the C–H bond at position 1 and its deactivation at positions 2 and 3.

The second most reactive C–H bonds in cyclohexanol are the C–H bonds at position 4. As already noted, oxidation of cyclohexanol at these bonds yields 4-hydroxycyclohexyl hydroperoxide, 1,4-dihydroxycyclohexane, and 4-hydroxycyclohexanone. Their further oxidative transformations may result in "burn-out" of two carbon atoms and formation of succinic acid, which, indeed, was detected in products of deep oxidation of cyclohexanol [19].

CONCLUSIONS

(1) In autooxidation of cyclohexanol at 403 K, the reaction chain is led by the $HO_2^{\bullet}$ radical. Along with oxidation products formed by cleavage of the 1-CH bond (cyclohexanone, hydrogen peroxide, 1-hydroxycyclohexyl hydroperoxide), products originating from the attack at the C–H bonds at positions 2–4 are formed: 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides (*cis*- and *trans*-), 1,2-, 1,3-, and 1,4-dihydroxycyclohexanes (*cis*- and *trans*-), 2-cyclohexanone, and 2- and 4-hydroxycyclohexanones.

(2) The different siabilities of isomeric 2-, 3-, and 4-hydroxycyclohexyl hydroperoxides (*cis*- and *trans*-) in the course of cyclohexanol oxidation are due to different extents of their stabilization by an intramolecular hydrogen bond: *cis*- and *trans*-2- and *cis*-3-hydroxycyclohexyl hydroperoxides are the most stable, and *trans*- and *cis*-4- and *trans*-3-hydroxycyclohexyl hydroperoxides, the least stable.

(3) In autooxidation of cyclohexanol effected by $HO_2^{\bullet}$ radical, the C–H bond at position 1 is strongly activated, and the C–H bonds at positions 2 and 3 are appreciably deactivated.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Photodegradation of Azo Dyes with Heterocyclic and Benzene Groups in Polymeric Matrix

N. B. Sokolova, L. P. Kovzhina, N. M. Dmitrieva, and N. V. Blinova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received May 24, 2001

Abstract—Lightfastness of individual azo dyes with benzene, thiophene, and furan groups and their binary mixtures in cellulose acetobutyrate was studied on an installation for accelerated photochemical aging. The dye pairs in which the components enhance the lightfastness of each other were determined.

Most of fat-soluble orange, red, and claret-colored dyes are azo dyes containing benzene groups with no sulfo groups. These dyes are widely used for coloring polymeric light filter films based on cellulose esters, which are mainly filters of the cutting type (see figure) [1]. However, the majority of azo dyes with benzene groups are characterized by parasitic transmission in the blue region. This drawback can be eliminated by adding yellow dyes having maximal absorption in this spectral range. The main component of the filter dyes are 1-phenyl-3-methyl-5-pyrazolone derivatives and recently developed derivatives of 2-phenyl-5-furanone and 2-phenyl-5-thienone [2, 3].

One of the main requirements to filtering dyes is high lightfastness in a polymeric matrix. Azo dyes have medium lightfastness. It can be increased by adding various photostabilizers, but the better choice is the use of dyes enhancing the lightfastness of one another [4].

In this work we studied the lightfastness of binary mixtures of two types of filter azo dyes: (1) benzene derivatives (red-violet component) and (2) derivatives of five-membered heterocycles, thiophene and furan (yellow component).

We prepared eight film light filters colored with pure dyes **I**–**VIII** (Table 1) and 16 light filters colored with binary mixtures of these dyes.

Dye photodegradation in the films was studied on a Standard Xenon Long-Life Fade Meter XFL-1 providing accelerated photochemical aging. The films were irradiated for 10 h simultaneously with a colorless film of cellulose acetobutyrate polymer. To determine the degree of photodegradation, the absorption at λ_{max} (analytical wavelength) of the dye was recorded 15, 30, 60, 120, 180 min, etc. after the start of the irradiation. To exclude contribution of photodegradation of the polymeric matrix, an irradiated colorless film was used as reference.

The optical density of yellow dyes at the analytical wave length was calculated as the difference between the measured density and the optical density of the red dye. The degree of photodegradation Φ_D for a certain irradiation time was calculated by the equation

$$\Phi_D = \frac{D_0 - D_i}{D_0} \times 100\%,$$

where D_0 and D_i are the optical densities at the analytical wavelength before and after irradiation.

I	8.40	+3.31				**V**	7.45	–2.19			
II + **VI**	60.40	+5.72				**VI** + **II**	3.76	+0.06			
III	6.26	+3.76				**VII**	6.25	–2.65			
IV	46.15	–3.94				**VIII**	2.44	+0.85			

The difference between the degrees of photodegradation of each dye in the film in the absence and in the presence of the second dye was calculated as

$$\Delta\Phi_D = \Phi_{D\,pur} - \Phi_{D\,mixt}.$$

The results are presented in Table 2. We compared the degrees of photodegradation after 1-h irradiation, since by this time the accumulation of the photodegradation products affecting the process is negligible. However, the data obtained after 10-h irradiation are also analyzed to give insight into the final steps of dye fade.

As seen from the results presented in Table 2 for the films colored with a single dye, the lightfastness of the azo dyes with benzene groups is higher than

that of the heterocyclic dyes; the azo dyes with thiophene groups are more stable under irradiation than the dyes with furan groups; derivatives of anthranilic acid are more stable to irradiation than derivatives of *m*-xylidine.

The data on the lightfastness of the films containing binary dye mixtures show that the azo dyes with benzene groups containing electron-acceptor substituents, NO_2 and Cl (**V**, **VI**, and **VIII**) decrease the photodegradation of all the heterocyclic dyes, excluding the azo dyes with thiophene groups **IV**. The Azo dye with the electron-donor group at the benzene ring (**VII**) increases photodegradation of heterocyclic azo dyes, and various substituents at the nitrogen atom of the amino group of the benzene ring have no effect on the lightfastness of the dyes. The lightfastness of the azo dyes with benzene groups increases in the presence of heterocyclic azo dyes, irrespective of the heterocycle nature (**I**–**III**). Derivatives of *m*-xylidine decrease the lightfastness of azo dyes with benzene groups, with this effect being the most pronounced for the dye with thiophene groups (**IV**).

These results agree well with the mechanism of photodegradation of heterocyclic azo dyes [5] and with the data on the fade of azo dyes with benzene groups [6]. Photodegradation of azo dyes with benzene groups containing acceptor and donor substituents occurs by the reduction and oxidation mechanism, respectively. Photodegradation of monoazo dyes proceeds by the reduction mechanism. Thus, the synergistic increase in photodegradation of binary dye formulations is observed when these dyes, e.g, **II** and **VIII**, degrade by different mechanisms. In the formulations containing the dyes degrading by the same mechanism, e.g, by the reduction mechanisms for dyes **I**–**IV** and **V**, each component partially "shields" the other component from irradiation, thus increasing its lightfastness. These formulations are preferable for preparing polymeric film light filters.

EXPERIMENTAL

Photodegradation of the films was performed on an installation providing accelerated photochemical aging. The sun irradiation was simulated with a 1.5-kW xenon lamp. Film samples of size 10×40 mm were automatically irradiated according to a certain program at 30°C and 65% humidity in the chamber. A colorless cellulose acetobutyrate film was irradiated simultaneously. Irradiated samples were kept in the dark for 24 h. The absorption spectra were recorded on an SF-16 spectrophotometer using a colorless film irradiated under the same conditions as the reference.

Polymeric film light filters were prepared by casting 10% solution of cellulose acetobutyrate containing a certain amount of the dye onto a polished glass plate restricted by a frame. A chloroform-ethanol mixture (85 : 15 weight ratio) was used as the solvent, and dibutylphthalate, as plasticizer. The system was allowed to stand at 25–28°C for 72 h. 10×10-cm films 0.15 ± 0.02 mm thick were prepared.

CONCLUSION

A mixture of hydrophobic heterocyclic azo dyes prepared from thiophene or furan and anthranilic acid and azo dyes with benzene groups containing electron-acceptor substituents shows promise for preparing polymeric light filtering films.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Phosphorus-Containing Salts of Polyhexamethyleneguanidinium for Protection of Metals from Corrosion, Biological Overgrowing, and Salt Deposition

L. M. Antonik, V. A. Lopyrev, N. A. Korchevin, and V. P. Tomin

Favorskii Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received April 26, 2001

Abstract—The procedure for preparing polyhexamethyleneguanidinium phosphate and polyhexamethyleneguanidinium hydroxyethylidenediphosphonate, protecting metals from corrosion and biological overgrowing, was optimized.

Polyhexamethyleneguanidinium (PHMG) salts exhibiting strong bactericidal activity can be used in medicine for disinfection of toolkits, operating and injection fields, in agriculture in storage of vegetables, in lumber industry as fungicides and preservatives, in wastewater treatment, etc [1–3]. Hence, synthesis of new PHMG salts and study of their properties is of special interest.

We prepared polyhexamethyleneguanidinium phosphate (PHMGP) and previously unknown polyhexamethyleneguanidinium hydroxyethylidenediphosphate (HPPG). Since these salts are potential inhibitors of metal corrosion, they were tested for multipurpose metal protection. Heat-exchange equipment of large-scale productions and pipe lines of circulating systems made from carbon and low-alloy steels can corrode and undergo salt deposition and biological overgrowing from the side of cooling water. However, the inhibitors produced in Russia are low effective, and those produced in other countries are rather expensive and cannot be used for multipurpose metal protection. For example, the well-known preparation of Kurita company, containing mainly polyphosphates, inhibits corrosion and salt deposition. To suppress microorganism growth, Polikrin is added to this preparation.

EXPERIMENTAL

We studied oligomeric PHMGP and HPPG [molecular weight M = 1100–1600 (n = 4–5)] prepared by neutralization of PHMG with phosphoric and 1-hydroxyethylidenediphosphonic (Xydiphone) acids, respectively, in an alcoholic solution [1–4]. The initial base (PHMG) was prepared from metacide hydrochloride [M = 800 (n = 4–5)] [5]. PHMGP and HPPG with M = 7000–8000 were synthesized by polycondensation of guanidinium carbonate and hexamethylenediamine (HMDA) [6]. The results of elemental analysis of the polymers are presented in Tables 1, 2. The IR spectra of the polymers, recorded on a Specord spectrophotometer, contain the following bands (ν_{max}, cm^{-1}): $-CH_2-$ (2920, 2860, and 1470), –NH– (3220–3240), and =NH (1650).

The structure of phosphorus-containing PHMG salts can be described by the general formula

where R = OH,  ; n = 4–30.

The inhibition of corrosion, salt deposition and biological overgrowing by solutions of PHMG salts with concentration from 0.01 to 0.1 g l^{-1} was studied under conditions simulating the operation conditions of water circulating systems [7]. The pH of aqueous solutions containing 0.02 g l^{-1} of the polymer and 1 g l^{-1} of NaCl was measured with an ION-1 conductometer (Table 1). The inhibition of metal corrosion was evaluated by electrochemical procedure [8] with the use of a PI-50-1M potentiostat, PR-8 programmer, YaKD-004 automatic recorder, and YaES-1 cell. A silver chloride electrode and a pol-

ished and degreased 1-cm^2 steel (St. 20) electrode (test sample) were used as the reference and working electrodes, respectively. An aqueous solution with total salt content of 0.15 g l^{-1} and content of Ca^{2+} cations of 0.03 g l^{-1} was used as the corrosion medium. The measurements were performed at potential sweep rate of 0.2 mV s^{-1} and polarization of +300 mV. In each experiment, the polarization resistance was measured within 24 h. The corrosion current was calculated from the polarization resistance by the Stern–Geary procedure. The corrosion current density (A m^{-2}) is proportional to the corrosion rate. In the absence of inhibitor, the corrosion current density in the being solution tested was 0.48 A m^{-2}. For each salt, three measurements were performed at a certain concentration of the salt in the corrosion solution. The corrosion current and protecting effect of PHMGP-3, PHMGP-5', HPPG-2, and HPPG-6, averaged over three experiments, are presented in Table 3. The results of corrosion experiments with PHMGP-1 and HPPG-1 were poorly reproducible. In Table 3, we present the best data for these salts for a more reliable comparison with other polymeric salts prepared by neutralization of PHMG with equivalent amount of the acid.

Salt deposition in the course of 4-h electrolysis of hard water (2 mg-equiv g^{-1} of Ca^{2+}) at a current density of 1 A m^{-2} and cathodic polarization was estimated gravimetrically. The inhibition of salt deposition was estimated by a fast test [9].

The biocidal properties were estimated from the number of bacteria in 1 ml of water, which, in turn, was determined by the TTC test proposed by Kurita company. The antibacterial action of PHMGP and HPPG on various bacterial stains and the toxicity of these polymers were studied in detail in [1–3].

The preparation conditions and the results of elemental analysis of PHMGP oligomers and HPPG prepared by addition of various amounts of phosphoric and 1-hydroxyethylidenediphosphonic (Xydiphone) acids to an alcoholic solution of metacide with *M* = 800 and *n* = 4–5 are presented in Table 1. It can be seen that the oligomer yield depends on the amount of the acid added. At PHMG : acid molar ratios of 1 : 1.3 and 1 : 2.5, the yield of the reaction products

does not exceed 47–70% and the results of elemental analysis of these products are inconsistent with the composition of the monomeric unit of the phosphorus-containing PHMG salts, presented in the experimental.

With the PHMG : acid molar ratio raised to 1 : 4 and 1 : 5, the oligomer yield increases to 92%. The results of elemental analysis show that there is single acid molecule per monomeric unit of the macromolecule. The resulting PHMG becomes stable.

Table 2 presents the results of elemental analysis and conditions of synthesis of PHMG salts, performed by polycondensation of guanidinium carbonate with equimolar amount of HMDA at 110–165°C in an organic solvent in which the guanidinium salts are sparingly soluble [6]. Unlike the procedure performed in a melt [4, 5], the synthesis occurs in this case under a solvent layer with stirring of a rather low-viscous white resin, which allows preparation of polymers with M from 7000 to 8000 (n = 4–30) (Table 2). The carbonate anion in the resulting PHMG carbonate can be readily substituted with another anion by treatment with the corresponding acid. Unlike the procedure described in [4–6], the stage of PHMG base formation is absent. A pilot plant for production of PHMGP with an output of 5 t/year, based on this procedure for preparing PHMG salts, has been put in operation [10].

The protective properties of PHMGP, HPPG, and commercial inhibitors (Kurita company) of corrosion, salt deposition, and biological overgrowing are summarized in Table 3. The samples of PHMGP and HPPG have different molecular weights and were prepared by addition of different amounts of the acids.

A preliminary electrochemical study of PHMGP and HPPG showed that these salts are film-forming inhibitors of the mixed anodic-cathodic type. The films formed on the steel surface after 20 h of electrolysis have thickness within 0.1 mm and can be observed visually. These films are formed by reaction of the corrosion products of iron with the phosphorus-containing groups; they prevent access of corroding agents to the metal surface, thus decelerating the corrosion. In 0.01 g l^{-1} solutions of the examined PHMG salts, the steel corrosion is decelerated by a factor of 2.8 (Table 3) as compared with that in water. Raising the concentration of pure PHMGP-3 and HPPG-2 to 0.05 g l^{-1} and using 0.02 g l^{-1} solutions of PHMGP-5' and HPPG-6 with higher molecular weight lead to a sharp (to 97%) increase in the degree of protection. In the presence of these additives, the corrosion is appreciably slower than that in the presence of HPPG-1 and PHMGP-1 prepared with a smaller amount of the acid. In contrast to the last two salts, the growth of bacteria and microorganisms is aqueous solutions of the first four salts is completely suppressed. Further increase in the concentration of PHMG salts to 0.1 g l^{-1} or use of salts with higher molecular weights is unnecessary since the corrosion rate in solutions of these salts remains virtually the same.

The inhibiting powers of the Kurita preparations and PHMG solutions were compared at almost the same concentrations. The corrosion rate in the presence of PHMG salts is lower. At the inhibitor concentration of 0.02 g l^{-1} the protective effect of PHMGP-3 is 3 times higher than that of the Kurita preparations. As the PHMGP concentration is increased to 0.05 g l^{-1}, the protective effect increases by a factor of 26.

Although PHMGP inhibits corrosion and biological overgrowing of metal, it does not protect the metal surface from salt deposition and in some cases even promotes this process (Table 3). At the same time, HPPG suppresses salt deposition already at the concentration of 0.01 g l^{-1}. Thus, HPPG salts can be used to protect

the metal surface from corrosion, salt deposition, and biological overgrowing in water-circulating systems.

CONCLUSIONS

(1) Polyhexamethyleneguanidinium salts with strong protective power were prepared in high yield by neutralization of guanidine with equivalent amount of appropriate acid. Polyhexamethyleneguanidinium salts with molecular weight from 7000 to 8000 were synthesized by polycondensation of guanidinium carbonate with hexamethylenediamine in solvents in which guanidinium salts are sparingly soluble.

(2) Corrosion and biological overgrowing of metal surface are effectively suppressed in presence of polyhexamethyleneguanidinium phosphate in the concentration from 0.01 to 0.05 g l^{-1}. The polymers with higher molecular weight exhibit the same protective effect at their lower concentration in the solution.

(3) Polyhexamethyleneguanidinium hydroxyethylibenebiphosphonate is a better inhibitor of corrosion, salt deposition and biological overgrowing than the commercial Kurita inhibitor.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thiokols Based on Wastes from Epichlorohydrin Production as Components of Rail Lubricants

Abstract—Preparation of solid polymers with varied content of sulfur by condensation of 1,2,3-trichloropropane-rich wastes from epichlorohydrin production with sodium polysulfide Na_2S_x (x = 1–4) generated by reductive dissolution of sulfur in the hydrazine hydrate–alkali system was studied.

Various organosulfur compounds are used as antiwear and extreme-pressure additives to lubricants [1, 2]. In contrast to other lubricants, formulations for rail lubrication at curved sections of railway lines operate in rather specific conditions, because nonstationary friction appearing at contact of the wheel flange and the lateral surface of the rail head is characterized by large specific loading and periodicity. At this contact, the pressure and temperature increase for short time [3], which can activate the molecules of lubrication formulations and improve their sorption on the rubbing elements. Therefore, sulfur and alkali are added to some rail lubricants [4], because in the presence of surfactants they sulfidize and strengthen the wheel and rail surfaces. However, addition of alkali and surfactants impairs other operation properties of lubricants and increases their corrosion activity and environmental hazard.

Sulfur-containing polymers (thiokols) based on wastes from epichlorohydrin production are often used as additives to rail lubricants.

In industry, thiokols are prepared from dihalo derivatives [1,2-dichloroethane, di(β-chloroethyl) formal, and dichlorodiethyl ether] and sodium polysulfide. To obtain branched macromolecules, minor amounts of 1,2,3-trichloropropane (TCP) are often added [5–7]. As a rule, polymerization of the above components yields rubbery or liquid polymers. Solid polymers, prepared only in the presence of sodium monosulfide Na_2S, contain low-reactive C–S groups, and their use in lubrication formulations is rather difficult. Rubbery polymers are immiscible with other lubricant components, and liquid thiokols are mixed with them only upon prolonged vigorous stirring.

At the same time, the source of raw materials for thiokol production can be significantly expanded owing to chlorine-containing wastes from industrial organic synthesis. At present, utilization of these wastes is a complex environmental problem [8, 9]. In this study, we prepared sulfur-containing polymers from the wastes of epichlorohydrin production, which is the main component of epoxy resins. In industry, it is prepared from propylene in three stages [10], and each stage is accompanied by various side reactions. As a result, more than 500 kg of chlorine-containing wastes are formed per 1000 kg of commercial epichlorohydrin [11]. These wastes are enriched in 1,2-dichloropropane, TCP, dichloropropanols, or epichlorohydrin, depending on the sampling point. Thus, specific compositions of the wastes, which varies within a wide range, is determined by the process conditions and operation stability of industrial units.

EXPERIMENTAL

The polysulfide polymers were prepared using a TCP fraction containing (wt %): 76.6 TCP, 17.4 dichloropropanols, 2.0 1,2-dichloropropane, 2.1 dichloropropenes, and 1.9 other products.

The polymers can be prepared using two different procedures for sodium polysulfide Na_2S_n generation. In the first case (procedure 1), it was prepared by a common procedure used in industrial production of

* (PY) Polymer yield based on TCP, (S_{theor}) theoretical content of sulfur at complete chlorine substitution.

** Sodium polysulfide synthesized by procedure 1 (polymer no. 1) and procedure 2 using a tenfold molar excess of hydrazine hydrate with respect to sulfur (polymer nos. 2–5).

thiokols, namely, by dissolution of sulfur in 40% aqueous solution of sodium hydroxide [6]:

$$6NaOH + (2n + 1)S \rightarrow 2Na_2S_n + 3H_2O + Na_2SO_3. \quad (1)$$

The resulting sodium sulfite reacts with sulfur, yielding thiosulfate:

$$Na_2SO_3 + S \rightarrow Na_2S_2O_3. \quad (2)$$

In this case thiokols were prepared in the presence of magnesium hydroxide (dispersing agent).

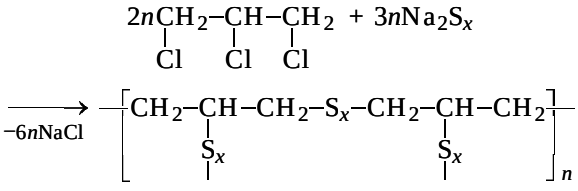
Using this procedure, we obtained from the TCP fraction at hand a dark brown elastomeric product. As seen from Table 1, the residual content of chlorine in the product is rather high, despite that we used the stoichiometric NaOH : S ratio, corresponding to the synthesis of Na_2S_4 by reaction (1).

In the second case (procedure 2), sodium polysulfide was generated by reaction of sulfur with the reductive system hydrazine hydrate–alkali [12]:

$$2nS + N_2H_4 \cdot H_2O + 4NaOH \rightarrow 2Na_2S_n + N_2 + 5H_2O. \quad (3)$$

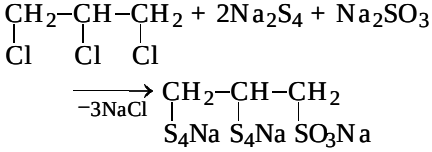
The last reaction yields no sulfur-containing byproducts (Na_2SO_3 and $Na_2S_2O_3$) and thus *n* is determined by the average sulfur:alkali ratio, so that *n* can be varied from 1 to 4 (Table 1). In this procedure, thiokols are prepared without dispersing agents.

At any *n*, we obtained solid polymeric products, which can be easily ground to a fine powder. The polymer preparation is represented by the following scheme:



The required polymers were obtained by the two above procedures in a reactor equipped with a stirrer. First, a solution of sodium polysulfide was prepared by reactions (1) or (3), and then TCP was added with stirring. The resulting polymer was filtered off, washed with dilute hydrochloric acid and organic solvent, and dried.

The difference in the composition and properties of the polymers prepared is probably due to the structure of the macromolecules formed and the surface layer of the drops of the monomer or oligomers in the system. Longer polysulfide chains S_3 and S_4 promote the reaction of chlorine atoms at the central carbon in TCP with S_n^{2-} anions, and thus the residual content of chlorine in the polymers prepared by procedure 2 decreases with increasing *n*. The high content of residual chlorine in the polymer prepared by procedure 1 is probably due to the presence of a dispersing agent and high salinity of the reaction mixture. The dispersing agent occurring at the surface of the organic phase drops hinders diffusion of S_n^{2-} anions and thus decreases the degree of TCP sulfuration. In the presence of SO_3^{2-} and $S_2O_3^{2-}$ in the reaction mixture, side reactions of chlorine substitution by these anions may proceed [7]:



(4)

As a result, we obtain a rubbery polymer with a smaller molecular weight and less developed macromolecular network. In contrast to the polymers prepared by procedure 2, the IR spectrum of the polymer prepared by procedure 1 contains additional bands at 1027 and 1200 cm^{-1}, which suggests the presence of SO_3H and S_2O_3H groups [8].

* Lubricant without thiokol (15 petroleum coke, 20 diesel oil, and 65% LMWP).

Using procedure 2, we prepared four polymers differing in the content of sulfur and chlorine. These polymers are easily ground and their hardness increases with increasing x.

In the dispersed state, these polymers are easily mixed with a formulation for rail lubrication, which is based on low-molecular-weight polyethylene (LMWP), finely dispersed petroleum coke, and spent locomotive diesel oil [13]. After mixing these four components, a stable lubricant grease is obtained. We used the following formulation, wt %: 60 LMWP, 10 petroleum coke, 20 spent diesel oil, and 10 sulfur-containing polymer.

As seen, the lubrication formulations studied are prepared from available and cheap components. Their antiwear properties were tested on an MI-1M friction machine [14] using the running (RR) and fixed (FR) rollers, whose friction and wearing conditions simulate the wheel-rail friction couple at curved sections of a railway line. The magnitude of the sample wear was determined by weighing the rollers on an analytical balance with an accuracy of 0.0001 g; the results are listed in Table 2.

In the absence of lubricant, the wear after 6 h was as large as 1.464 g for FR and 1.421 g for RR.

To evaluate the enhancing effect of the thiokol additive on the wear resistance of the roller surface, their wear was determined three times in the course of a single test. First the rollers operated for 6 h in the presence of lubricant, whose additional amounts were placed in the contact zone every 10 min. Then the lubricant was removed with acetone and rags, the wear was registered, and the test was continued for 3 h. The wear was registered, and additional treatment for 3 h was performed. The results are listed in Table 2.

As seen, upon polymer addition lubricant not only preserves high antiwear power, but enhances the wear resistance of the surface in the contact zone, because the protective effect is retained after removing the lubricant. This is probably due to the formation of surface iron sulfides or chlorides (at high residual content of chlorine in the polymer). In some cases, sulfuridizing is performed to enhance the surface strength [15]; this accounted for the function of sulfur in the rail lubricants [4] and the effect of sulfur- and chlorine-containing extreme-pressure additives [1].

CONCLUSIONS

(1) Procedures were developed for preparing solid thiokols with varied content of sulfur by reaction of wastes from epichlorohydrin production (enriched in 1,2,3-trichloropropane) and sodium polysuldfide Na_2S_x (x = 1–4) generated by reductive dissolution of sulfur in the hydrazine hydrate–alkali system.

(2) Rail lubricants containing thiokols were studied. These lubricants decrease the wear of the wheel flange and lateral surface of the rail head on passing the curved sections of railway lines not only in the presence of lubricant in the contact zone, but also after its complete removal.

Abstract—To control the structural contributions of the polycondensation and polymerization curing of epoxy resins, the curing kinetics of the composites diepoxide–tertiary amine and diepoxide–(primary + tertiary) amines is studied by the isothermal calorimetry.

A specific feature of products formed in curing of epoxy resins with primary amines by the polycondensation mechanism is the presence of tertiary amino groups fixed at the network junctions and of secondary alcohol groups in the hydroxy ether fragments of the interjunction chain [1, 2]. This affects not only the kinetics and mechanism of formation of the cross-linked structure in the course of curing [2, 3–6], but also characteristics of the resulting epoxy-amine cross-linked polymers (EACLPs) [1, 2, 7].

The latter is associated with the fact that these groups can serve as active sites in the physical network [6, 8], causing high cohesion strength of polycondensation (PC) EACLPs. At the same time, polymerization (PM) EACLPs prepared by the mechanism catalyzed by tertiary amines (TAs) demonstrate, unlike PC EACLPs, lower cohesion strength, but higher adhesion to the surface of glass fibers [9, 10].

These differences in the properties of PC and PM cross-linked polymer matrices (CLPMs) are probably due to the features of their structural organization at the chemical, topological, and supramolecular levels [11]. A particularly pronounced difference is observed in the structures of a network junction and an interjunction chain responsible to a significant extent for the mechanical characteristics of EACLPs [12]. In the case of PM EACLPs a more defective, less rigid crosslinked structure is realized, demonstrating higher flexibility [11, 13], which, evidently, facilitates relaxation of internal (thermal) strains, generally concentrated at the CLPM–fiber interface [14], thus increasing the adhesion resistance [9].

Therefore, it was of interest to obtain CLPMs with varied content of PC and PM fragments or the corresponding microvolumes with varied degree of cross-linking. The final purpose of the study is to obtain high-strength epoxy matrices with controlled structural microheterogeneity. As known [15–17], high-strength CLPMs can be designed by forming synthetically a faulted structure with microvolumes having lower degree of cross-linking, i.e., demonstrating lower local modulus of elasticity and higher molecular flexibility.

In this work, we studied the structural and kinetic features of curing of epoxy resins with primary aromatic amines in the presence of tertiary amines with varied reactivity by the combined polycondensation–polymerization mechanism, and also analyzed the structure and relaxation and mechanical characteristics of the resulting PM/PC polymer matrices.

EXPERIMENTAL

As starting materials we used resorcinol diglycidyl ether (RDE) purified by high-vacuum distillation and diaminopyridine (DAP) recrystallized from a methanol–heptane mixture.

As additives we used two types of tertiary amines: reactive TAs [dimethylbenzylamine (DMBA), dimeth-

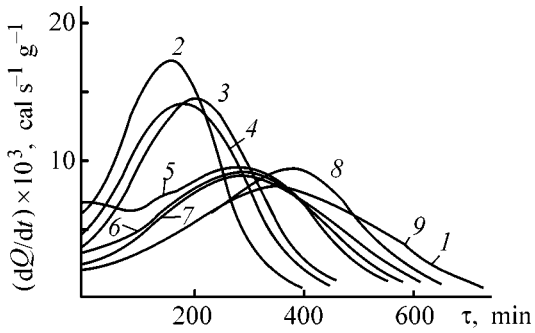

Fig. 1. Rate of heat release, d*Q*/d*t*, vs. the curing time τ at 80°C for RDE–DAP–TA composites. TA: (*1*) no, (*2*) LD, (*3*) DMA, (*4*) α-P, (*5*) DMBA, (*6*) β-P, (*7*) TEA, (*8*) CD, and (*9*) DEA.

ylaniline (DMA), α- and β-picolines (α- and β-P), triethanolamine (TEA), 2,4-lutidine (LD), 2,4,6-collidine (CD)] and inactive diethylaniline (DEA). All the tertiary amines were purified by vacuum distillation from KOH.

The curing kinetics was studied with an EK-2 isothermal fast microcalorimeter and a DAK-1-A microcalorimeter.

Relaxation characteristics of epoxy-amine composites cured according to the following schedule: 70°C, 18 h; 140°C, 6 h; and 160°C, 2 h, were studied in the range of α-relaxation by method of the bending resonance vibrations on a setup described in [18] and in the range of β-relaxation, with a torsion pendulum (free oscillations) [19].

The nuclear magnetic spin-lattice (T_1) and spin–spin (T_2) relaxation times were determined on a pulse coherent relaxometer [11] at a frequency of 17 MHz. The T_2 was measured by the free induction decay and Hahn's methods, and T_1, using 180°–90° pair pulses. Mechanical characteristics (tensile strength σ_t, Young's modulus E_t, and the rupturing deformation ε_t were determined on a 1231U tensile-testing machine at a clamp motion velocity of 1 mm min^{-1}. The total fracture energy A_f was estimated by integration of the area under the fracture curve. The surface fracture energy γ was determined by the procedure described in [20]. Electron micrographs were obtained as in [21].

Effect of TA additives on the kinetics and mechanism of curing. In this section we report on a kinetic study performed in attempt to control the relative contributions of the PC and PM mechanisms by varying the ratio of the corresponding rates of conversion of epoxy groups. This was realized by using TAs with different reactivities and by varying the TA amount and curing temperature.

The differential curves of heat release for the initial system RDE + DAP and the systems RDE + DAP + TA are presented in Fig. 1 (each point in the curves corresponds to a current rate of heat release). As seen, in all the systems curing develops as an autocatalytic process (the initial rate of curing is noticeably lower that the maximal value). The presence of 0.8–1.4 mol % reactive TAs (LD, DMA, α-P, DMBA, β-P, and TEA) noticeably accelerates curing: the initial and maximal rate of heat release increase, and the time in which the maximal rate τ_{max} is reached decreases. Addition of CD has virtually no effect on the initial stage of curing, only shifting the peak rate position to longer time. It should be pointed out that all the indicated TAs can themselves initiate PM conversion of the epoxy groups at the initial rate W_0^{PM} given in Table 1. At the same

* (W_0^{PM}, W_0^{PC+PM}) Initial rates for the systems RDE + TA and RDE + DAP + TA, respectively; $k_0 = W_0^{PC+PM}/(W_0^{PC} + W_0^{PM})$, where ($W_0^{PC} + W_0^{PM}$), is the estimated total rate for the systems RDE + DAP and RDE + TA; $k_{max} = W_{max}^{PC+PM}/W_{max}^{PC} \times \tau_{max}$ is the time in which the maximal rate is reached at 80°C.

time, addition of DEA, which does not promote polymerization of the epoxy groups, does not influence the curing kinetics at [DEA] < 2 mol %, and at higher concentrations the initial and maximal rates of heat release decrease and the peak rate position shifts toward longer time. Note that the inhibiting effect of DEA on polycondensation has been observed previously with primary aromatic and aliphatic amines [22]. Since addition of DEA does not change significantly the curing mechanism and, correspondingly, the topological structure of EACLPs, it acts as a typical plasticizer which, like DBP, decelerates chemical cross-linking and accelerates physical (relaxation) structurization of EACLPs [23].

A kinetic study to predict the particular contributions of PC and PM mechanisms of conversion of epoxy groups to the final chemical structure appeared to be difficult. The results obtained (Table 1) show that, firstly, there is no correlation between the basicity of TAs (pK_b) and the PM conversion rate, which is caused by the steric accessibility of the nucleophilic center at the nitrogen atom (in the case of DEA this is a crucial factor) [24]. Secondly, there is no correlation between the PM activity of TAs and the gain in the rate of the combined PC–PM curing. This is probably due to the dual behavior of TAs in the polycondensation system. On the one hand, TAs can act as electron donor capable of binding active protons of primary amino groups, thereby making lower the effective concentration of proton donors [22] and decelerating the PC process. On the other hand, primary amino groups, can in their turn, being proton donors, accelerate the PM process under the action of TAs [22]. The cross effect of the PC and PM processes must be strongly dependent on the reactivity and complexing power of the corresponding primary and tertiary amines. The relative rates of these processes are also influenced by the presence of other proton donors, especially of secondary alcohol hydroxy groups formed in opening of epoxy groups by various mechanisms (one OH group per epoxy group in the case of the PC mechanism and per 5–6 epoxy groups in the case of the PM mechanism [25]). Therefore, the PC to PM rate ratio may vary widely in the course of curing. It should be pointed out that combined action of different types of hardeners is not additive, but provides a synergistic effect. It follows from Table 1 that, for most of TAs, the initial rate W_0^{PC+PM} in the combined system RDE + DAP + TA exceeds the sum of the rates $W_0^{PC} + W_0^{PM}$ in separate systems RDE + DAP and RDE + TA. The synergistic effect makes it impossible to estimate from the kinetic data the structural contributions from

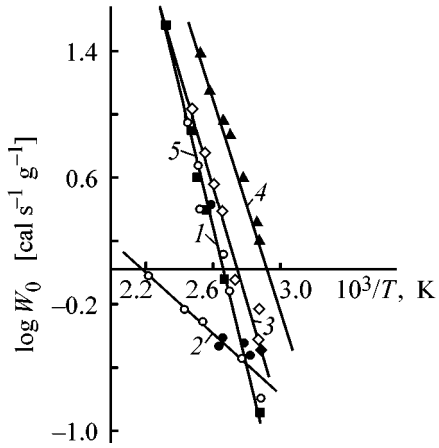

Fig. 2. Arrhenius plots of the initial curing rates in the systems (*1*) RDE + DAP, (*2*) RDE + β-P, (*3*) RDE + DAP + β-P, (*4*) RDE + DAP + DMBA, and (*5*) RDE + DAP + DEA. (W_0) Initial curing rate and (T) temperature.

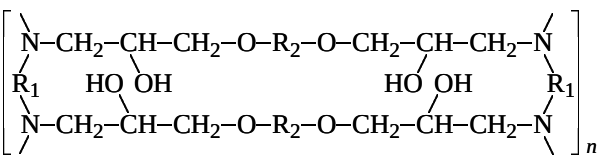
the PC and PM processes. Evidently, the only way to estimate these contributions adequately estimation is by IR spectroscopic study of the accumulation of OH groups (essentially by the PC mechanism) and C–O–C linear ether groups (PM process) [2, 26–28]. Note that, when using a combination of primary and tertiary amines, changing the curing temperature makes the situation even more complicated. It follows from the Arrhenius plots of the initial curing rates in the systems RDE + DAP, RDE + β-P, RDE + DAP + β-P, RDE + DAP + DMBA, and RDE + DAP + DEA (Fig. 2) that the activation energy of the purely PM process (curve *2*) is considerably lower than that for the PC process (curve *1*) (4.6 and 19.6 kcal mol^{-1}, respectively). Therefore, the activation energy of the combined process decreases too, being 16 kcal mol^{-1} for β-P and 15 kcal mol^{-1} for the more reactive DMBA. In the case of small additions of inactive DEA (curve *5*), the activation energy remains unchanged. The results show that, with increasing curing temperature, the contribution of the PM process must decrease, since W_0^{PC+PM} approaches W_0^{PC}. This should be taken into account in the case when curing proceeds step-by-step, since the PC to PM rate ratio will additionally change in the course of curing, depending on the temperature and treatment time in the corresponding step.

The PM contribution can be controlled by varying the TA concentration only to a limited extent, since the polycondensation kinetics is second-order with respect to a primary amine (T = 70°C), and the order of polymerization varies between 0.6 and 1.0. Therefore, the most effective factor controlling the PM contribution is the TA reactivity which can be varied within two orders of magnitude.

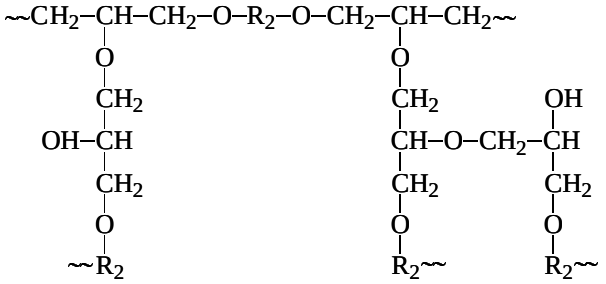
Analysis of the structural organization of EACLPs. (1) Chemically, addition of TA results in increased amount of unreacted secondary amino groups, decreased content of secondary alcohol groups, and formation of double vinylidene bonds via isomerization of the epoxy ring [2, 25, 26, 28]. Lowering the amount of secondary OH groups, serving as network junctions [1, 5, 6], must decrease to certain extent the cohesion resistance of EACLPs. It should be outlined that some of the amines studied, e.g., β-P, can enter the network, as demonstrated by data on its consumption in the course of curing (data were obtained using chromatographic analysis). Although the mechanism of this reaction is not understood exactly, one may suggest that such a behavior of β-P is caused by the possibility of pyridine ring opening with cleavage of the C–N bond [29]. In this case linear products having a system of conjugated bonds can be formed, as evidenced by the intense coloration of the system RDE + DAP + β-P. Therefore, this TA can additionally modify the network chemical structure.

(2) Topologically, addition of TA changes the nature and functionality of the junctions and interjunction chain. Note that, as considered below, the junction functionality can take an important part in formation of mechanical characteristics of cross-linked polymers. A network junction is a major kinetic unit of large-scale segmental motion in EACLPs (α relaxation) [30]. Therefore, the junction functionality must control the effective size of the kinetic unit, i.e., the degree of cooperativity of segmental motion and, correspondingly, the energy dissipated in the course of α relaxation. In the case of PC process (if it proceeds without a side reaction of epoxy groups with secondary alcohol groups and without cyclization), the nitrogen atom is the only branchpoint or junction. In this case, the functionality of EACLP network junction is controlled essentially by the structure of an amine hardener [1]. If the structure of the fragment connecting two primary amino groups has certain flexibility (e.g., in the case of the aliphatic fragment ~CH_2–CH_2~), the junction with a branchpoint at the nitrogen atom can be considered trifunctional. When the connecting fragment is an aromatic ring (pyridine ring in our case), we have a tetrafunctional junction. A typical fragment of a PC cross-linked structure is shown below:



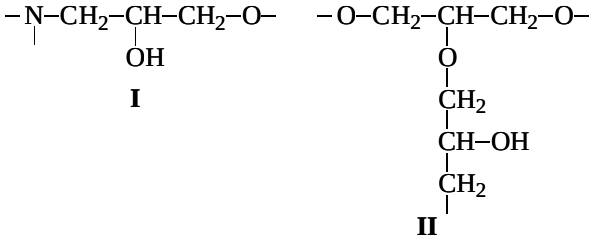
where R_1 and R_2 are aromatic residues of the corresponding diamines and diglycidyl ethers.

In the PM process with a bifunctional epoxy resin, a cross-linked structure with a trifunctional junction and a branchpoint at the nitrogen atom is formed. A typical fragment of PM crosslinked structure formed without side isomerization reactions can be represented as follows:



It follows from a comparison of the typical defect-free PC and PM structural fragments that, in the case of the PM network, the interjunction distance must be noticeably shorter than that in the PC network. It would be expected that such a PM cross-linked structure must have higher rigidity (degree of correlated motion of the network junctions) and more hindered segmental motion, resulting in a higher glass transition point T_g. However, our experiments showed that T_g of PM EACLPs (as a parameter characterizing the segmental mobility [31]) appeared to be lower as compared with PC, which is due to higher fault density in PM EACLPs [11]. Therefore, it may be suggested that, with addition of TA, the degree of topological faultiness of the combined EACLP structure must increase too. Indeed, the decrease in T_g with increasing TA content, which becomes more pronounced with increasing TA reactivity (W_0^{PM} in Table 1), supports this hypothesis.

Furthermore, comparison of the regular structural units of the PC and PM networks shows that the difference between them consists in that the interjunction chain contains two hydroxy ether groups (**I**) in the former case, and one or two ether groups (**II**) in the latter:



With increasing TA concentration in the system, the content of fragment **I** must decrease, and that of

fragment **II**, decrease. This trend can be revealed by studying the temperature dependence of the mechanical loss tangent tan δ, as a decreasing intensity of the β transition. Indeed, such a confirmation was obtained in [13]. A thorough analysis of β relaxation spectra can be found below. Therefore, addition of TA modifies significantly the topology of EACLPs, the effect being more pronounced with increasing TA reactivity and concentration. These parameters can be optimized on the basis of data on the structural and strain behavior of combined PC–PM EACLPs.

(3) At the supramolecular level of the EACLP structure one may expect increasing degree of microheterogeneity as a result of higher degree of the topological faultiness in the presence of TA. In fact, we observed increased microroughness of the chip surface in the electron micrographs of TA-modified samples. It should be pointed out that the effect of small addition of TAs on the supramolecular structure of epoxy-amine polymer matrices differs significantly from that in epoxy-phenol cross-linked polymer matrices [32]. In the latter case, a small amount of TA suppressed the side reaction producing ether fragments **II**. As a result, the degree of ordering at the topological and, correspondingly, supramolecular levels of the CLPM structure increased. Also, TA considerably affects the supramolecular packing of EACLPs. Figure 3 presents theoretical concentration dependence of the specific volume V_{theor}, obtained on the assumption of additivity of the polymer matrix and TA volumes:

$$V_{theor} = \varphi_{PM} V_{PM} + \varphi_{TA} V_{TA},$$

where V_{PM} and V_{TA} are the specific volumes of the polymer matrix and TA, respectively; φ_{PM} and φ_{TA} are their weight fractions. The same figure shows the experimental concentration dependence of the specific volume V_{exp} of the system RDE + DAP + TA for tertiary amines with different polymerization activities. The results show that the specific volume of the system with more active DMBA increases more rapidly as compared with the theoretical dependence, and with less active β-P and inactive DEA, more slowly, suggesting that DMBA loosens the network structure through its chemical modification, while β-P and DEA act essentially as typical plasticizers [33], filling voids of the free space or promoting relaxation of the excess free volume of the polymer matrix.

Relaxation properties of EACLPs. The TA effect on the EACLP structure is distinctly reflected in evolution of the relaxation properties of these polymers at the local (β process) and segmental levels of molecular mobility (α process). (1) Analysis of β-relaxation spectra of TA-modified EACLPs shows that local motion in PC–PM EACLPs significantly depends on both the TA activity and concentration. The temperature dependences of the dynamic shear modulus G' and mechanical loss tangent tan δ of EACLPs modified with various TAs (4 wt %) or without TA are presented in Fig. 4. In all cases, we

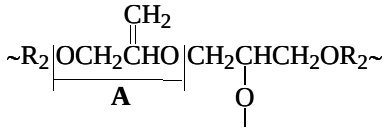
observed spectra typical of epoxy-based polymers [34]. The effect of TA, as expected, increases in the order of the TA activity: DEA < β-P < DMBA. This effect is reflected in the shift of the low-temperature β peak ($\tan\delta_{max}$) toward lower temperature, and, as seen from Table 2, in the decreasing intensity of this peak, decreasing total degree of relaxation $\Delta G/G$ in the vicinity of the β transition ($\Delta G/G = 1 - G_{280}/G_{140}$, where G_{140} and G_{280} are the shear modulus values at 140 and 280 K, respectively), and, finally, in decreasing activation energy of the β process (ΔH). Since β transition is caused by local mobility of the shaft crown type of the hydroxyether fragments **I** [35–37], the observed decrease in the transition parameters can be attributed to decreasing concentration of these structural units. This conclusion is also supported by measured relaxation characteristics of the system RDE + DAP + β-P, as influenced by the TA concentration. It is seen from Figs. 5, 6 that the increasing TA concentration has an effect similar to increasing TA activity. However, the concentration dependences of $\tan\delta_{max}$, $\Delta G/G$, and ΔH tend to level off (Fig. 6), which can be interpreted as follows. In the course of polymerization, the chain-terminating reactions produce polymer network fragments **A** [25]:



Such fragments are similar in structure to the hydroxy ether fragments responsible for β transition in the PC network. However, they contain no strongly polar OH group. Furthermore, they must demonstrate high flexibility, as containing no nitrogen atom forming a PC network junction. Therefore, it whould be expected that the relaxation of ether fragments **A** proceeds in the vicinity of β transition, but at lower temperature. Indeed, according to [11], the β peak is quite distinctly pronounced and shifted toward low-temperature region in the PM network formed in the system RDE + 5% TA. Similar results were obtained in the systems RDE + DAP + 4% DMBA (Fig. 4, curve *4*) and RDE + DAP + 10% β-P (Fig. 5, curve *5*). The formation of new, more flexible fragments in the PC–PM network is demonstrated by the decrease not only in the activation energy ΔH, but also in $K = \tan\delta_{max}/(\Delta G/G)$, observed with increasing TA activity (Table 2) or concentration (Fig. 6, curve *4*). Since for a purely Debye relaxation peak with a single relaxation time $K = 0.5$ [18], the deviation of the experimental K from the standard value can be regarded as evidence in favor of the occurrence of a spectrum of relaxation times. The decrease in K with increasing TA activity and concentration is an indication of the broadening of this spectrum, specifically, by virtue of the increasing fraction of flexible fragments **A**. Therefore, introduction of flexible PM fragments by

adding TA makes lower the rigidity of the network structure, thus reducing the intrachain cooperativity of local motion [38] and the mechanical energy dissipated at the local level in EACLPs.

At the same time, addition of inactive DEA, not changing the topological structure and not reducing the network rigidity, also decreases the β-peak intensity (peak area) and ΔH of the β process [39]. Such an effect of the inactive TA is due to its plasticizing action, resulting in a decrease in interchain cooperativity of local motion or in the effective size of the kinetic unit of motion [39]. In other words, molecules of low-molecular-weight fluids reduce the effective microviscosity of the medium, thus decreasing the specific mechanical loss.

To conclude, TAs act as chemical or (and) physical plasticizing agents for EACLMs, and, depending on their PM activity and concentration, they can reduce the degree of interchain cooperativity of local motion, thus decreasing the specific mechanical loss.

Note that, in certain cases [40, 41], the mechanical energy dissipated in β process (β-peak area) correlates with the specific impact resilience.

(2) Analysis of α relaxation in PC–PM EACLPs allows understanding of the effect of TAs on the long-range molecular mobility of the segmental type which, as known [42, 43], can play a significant part in static fracture of linear and network polymers. The main contribution of α relaxation consists in dissipation of mechanical load through afterflows at the mouth of a growing crack and relaxation of residual internal strains in the course of curing or of overstrains at the apex of crack in the initial stage of fracture of a cross-linked polymer matrix.

We analyzed the temperature dependences of the nuclear magnetic spin-lattice (T_1) and spin–spin (T_2) relaxation times, using pulse NMR in the vicinity of α transition [11]. A minimum in the temperature dependence of T_1 was found only for the system RDE + 5% TA (Fig. 7, curve *2*), but not for the initial system RDE + DAP (curve *1*). In the case of β-P, the minimum becomes pronounced at a TA concentration above 5 wt %, suggesting that the rigidity of the PC–PM network structure decreases in the presence of TA (in other words, the relaxation capacity of the system increases). An analysis of the decay of cross magnetization (Fig. 7) showed that the decay is described by a single time T_2 (curve *1*') in the case of PC network (initial system RDE + DAP), by two times: short T_{2a} (curve 2') and long T_{2b} (curve *2*") and in the case of PM network (RDE + 5 wt % DMBA) at a temperature above the glass transition point (T_g = 80°C).

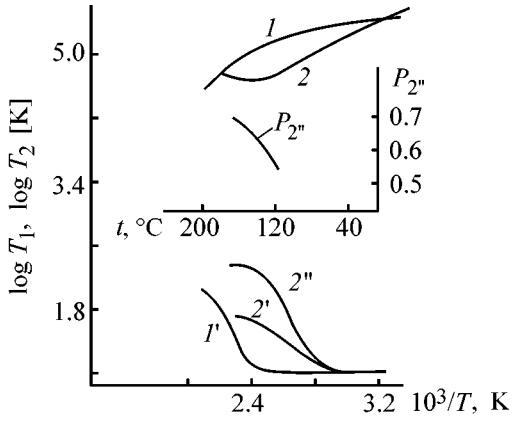


Fig. 7. (*1*, *2*) Nuclear magnetic spin-lattice relaxation time T_1 and (*1*', *2*', *2*") nuclear magnetic spin–spin relaxation time T_2 vs. the temperature T; and population of protons of the more mobile phase $P_{2"}$ vs. the temperature t. (*1*, *1*') PC EACLP and (*2*, *2*') PM EACLP.

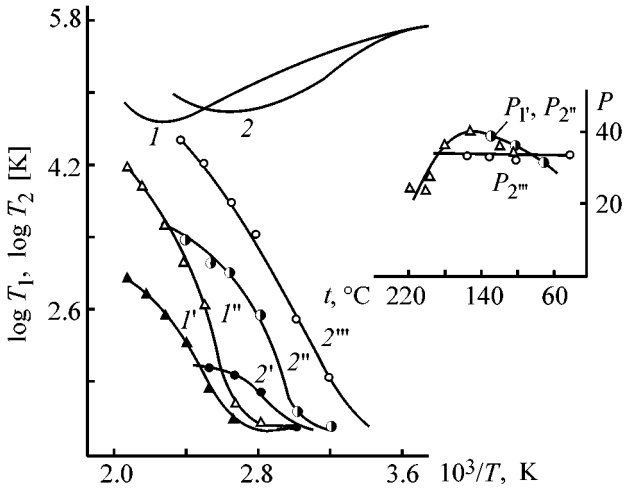

Fig. 8. (*1*, *2*) Nuclear magnetic spin-lattice relaxation time T_1 and (*1*', *1*", *2*', *2*", *2*"') nuclear magnetic spin–spin relaxation time T_2 of the temperature T for the hardened composite RDE + DAP + β-P; and population P of protons of mobile phases vs. the network $P_{1'}$ and $P_{2"}$, and of β-P itself $P_{2'''}$ vs. the temperature t. β-P concentration (wt %): (*1*, *1*', *1*") 10 and (*2*, *2*', *2*", *2*"') 30.

It has been demonstrated previously [11] that this is due to the presence of two kinetic phases formed by protons the PM network and the corresponding fragments (microvolumes) of different topological levels. The short (T_{2a}) and long times (T_{2b}) characterize the behavior of protons in rigid and labile faulty fragments of the PM network, respectively, whose occurrence is caused by the known specific features of the PM process. On varying the β-P concentration in the system RDE + DAP + TA over the range 0–10 wt %, we also found two time parameters T_2 (Fig. 8, curves *1*', *1*"). In this case the short time

Table 3. Effect of β-P concentration on parameters of β transition

Notes: (E'_{300}, E'_{he}) Dynamic modulus of elasticity at 300 K and in the hyperelastic state, respectively; (τ_α) effective relaxation time of α transition, (ν) cross-linking density, and ($\Delta_{1/2}$) half-width of α peak.

T_{2a} characterizes the behavior of protons in fragments of more rigid PM network, and the long time T_{2b}, the behavior of labile faulty fragments. At a β-P concentration above 30 wt % the cross magnetization decay is described by three time parameters: T_{2a} and T_{2b} (curves *2*' and *2*''), characterizing the relaxation of protons in rigid and flexible faulty fragments of the PC–PM network, and also the longest T_{2c} (curve *2*''') characterizing the behavior of protons of β-P itself, separated out in its own phase, as demonstrated by the coincidence of the estimated fraction of protons in β-P and the measured fraction (population P_c) of protons in the phase characterized by the time T_{2c}. Furthermore, the population of protons in the kinetic phases characterized by the parameters T_{2a} and T_{2b} (whose protons belong just to the network) changes with temperature; the temperature dependence having a maximum (Fig. 8, curves $P_{1'}$ and $P_{2''}$). This suggests that T_{2a} and T_{2b} are close, opening the door for temperature-induced transition of protons from one kinetic phase to another. At the same time, the population of protons in the kinetic phase, characterized by T_{2c}, does not change with temperature (curve $P_{2'''}$), suggesting that their behavior is independent of the polymer matrix (phase separation). To conclude, pulse NMR study of α relaxation shows that the use of TAs provides wide potentialities to control the molecular flexibility within the three modes, which is important in designing materials operating at various load frequencies.

The effects of β-P concentration on the temperature dependences of the dynamic modulus of elasticity E' and mechanical loss tangent tan δ were studied by the method of bending resonance vibrations. The effective number of cross-links decreases with increasing TA concentration, as demonstrated by the decrease in dynamic modulus of elasticity in the hyperelastic state E'_{he} and, correspondingly, in the cross-link density ν (Table 3). The effective ν was determined on assumption of the approximate equality of E'_{he} and the limiting modulus of elasticity E_∞ [18] which, according to the hyperelasticity theory [44], is related to the cross-link density

$$E_\infty = 3\nu RT,$$

where R is the gas constant and T is the absolute temperature.

Addition of TA also decreases other parameters of α relaxation, such as the peak temperature (mechanical glass transition point) T_α and effective time of relaxation of α transition τ_α.

All these trends suggest the decreasing degree of intra- and interchain cooperativity of segmental motion (decreasing effective size of the kinetic unit of this motion) and, as a result, decreasing mechanical loss at α peak ($\tan \delta_{max}$). At the same time, the observed increase in the α-peak half-width $\Delta_{1/2}$ is an indication of the increasing structural and, correspondingly, α-relaxation inhomogeneity in TA-modified EACLPs, which is well consistent with the NMR data. This causes an increase in the total energy dissipated in the course of the α process, determined as $\tan \delta_{max} \Delta_{1/2}$. The results demonstrate that the increasing molecular flexibility of the segmental type in TA-modified EACLPs makes larger the contribution of α relaxation under static load [43] and the energy dissipated in afterflows at the mouth of growing crack [45, 46].

Dilatometric analysis data showed that, in the case of addition of low concentration of inactive DEA or medium-active α-P and β-P, the glass transition point T_g of EACLPs decreases linearly with increasing TA concentration (Fig. 9, curve *1*). This result can be attributed to the essentially plasticizing effect of TAs, changing the interchain cooperativity of segmental motion. At the same time, the observed abrupt decrease in T_g upon addition of minor amounts of DMBA evidences in favor of the fact that TAs also affect on the intrachain cooperativity of long-range motion. It should be pointed out that, in the case of

DMBA, two breaks were detected in the dilatometric curves: the first at a temperature corresponding to T_g of the initial compound RDE + DAP and the second at a temperature decreasing with increasing TA concentration. This is probably due to formation of microheterogeneous PC–PM network structure consisting of microvolumes, rather than large fragments of the PM structure. This finding is consistent with the two different types of the kinetic behavior of protons in the network structure, demonstrated by NMR.

The structural analysis given above allows more adequate interpretation of the trends in the mechanical behavior of EACLPs having a combined PC–PM network structure.

Mechanical properties. Analysis of the experimental data on the effect of TAs on mechanical characteristics of EACLPs (tensile strength σ_t, rupturing deformation ε_t, and Young's modulus E_t) (Fig. 10) revealed the following major trends.

(1) In the case of addition of small amount of inactive DEA (or CD), the tensile strength σ_t remains virtually unchanged (curve *2*). With DMBA (active TA), σ_t decreases (curve *3*), and with β-P or α-P (medium active TAs), the curve passes through a maximum at a TA concentration of 0.5 wt % (curve *1*). In the latter case, the maximal σ_t exceeds the value characteristic of the TA-free compound by 10%.

(2) In the systems with β-P and DEA E_t is virtually constant (curves *1*', *2*') and in those with DMBA, E_t noticeably decreases (curve *3*'). The constancy of E_t in the former case is, evidently, due to the dominant plasticizing effect of small additions [33], when the intrinsic loosening effect of the low-molecular-weight additive is compensated for by the relaxation compaction of the polymer matrix. This is demonstrated by the trend in variation of the EACLP specific volume in the presence of these additives. The decrease in E_t in the presence of DMBA is caused by decreasing rigidity of the PC–PM network structure, as demonstrated by the relaxation data.

(3) At low TA concentrations, ε_t is virtually constant in the case of DEA and DMBA (curves *2*'', *3*'') and passes through a maximum with β-P (note that the peak positions of σ_t and ε_t coincide). It is worth noting that in the latter case a distinctly pronounced plateau of the yield point or hyperelasticity is seen in the deformation failure curves. In this case, the predominance of rough areas is observed in EACLPs on the surface of failure, which is typical of plastic fracture in glassy polymers [47], indicating that the nature of fracture in the combined EACLPs is

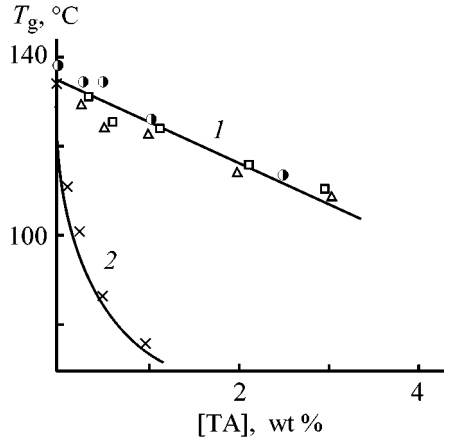

Fig. 9. Glass transition point T_g of the compound RDE + DAP + TA vs. the TA concentration [TA] (wt %): (*1*) DEA, β-P, or α-P; (*2*) DMBA.

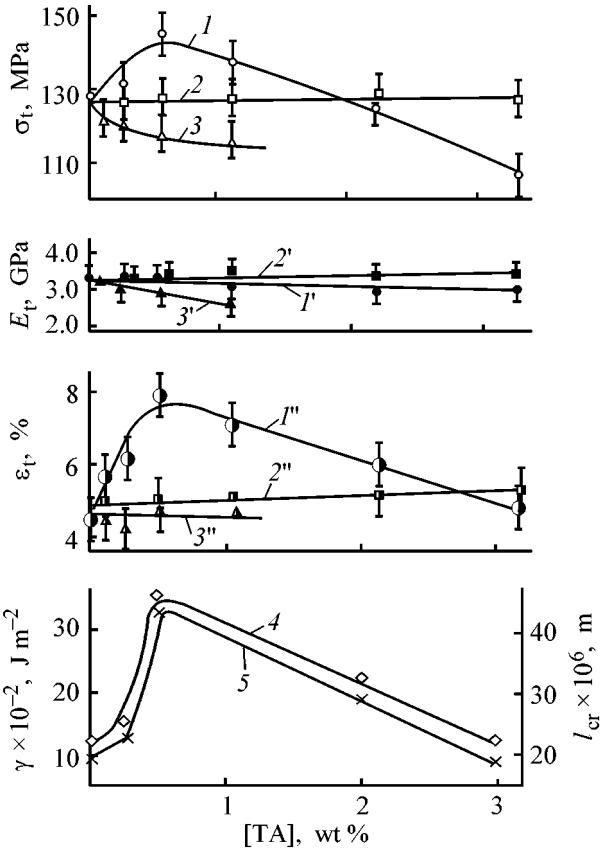

Fig. 10. Mechanical properties of the system RDE + DAP + TA vs. the TA concentration [TA] (wt %): (*1*–*3*) σ_t, (*1*'–*3*') E_t, (*1*''–*3*'') ε_t, (*4*) γ, and (*5*) l_{cr}.

changed. Note also that addition of β-P produces about 200% increase in the deformation characteristics. This is an important result of modification, since the gain in ε_t at constant E_t provides considerable increase in the work of deformation A_d (area under the deformation curve) reflecting the total energy

consumption for deformation and fracture of a material. The A_d value is an important criterion in selecting optimal binders [48] providing high performance of a composite [49].

Let us try to make a simplified analysis of the results obtained using the Griffits equation for the critical strength, relating the major structural parameters of hard materials to each other:

$$\sigma_{cr} = \sqrt{\frac{2E\gamma}{\pi l_{cr}}}.$$

Among these parameters are the modulus of elasticity E (elasticity parameter), surface fracture energy γ (dissipation parameter), and critical size of defect, l_{cr} (structural parameter).

It is seen from Fig. 10 that, with changing β-P concentration, γ also passes through a maximum at about 0.5 wt % TA.

Substituting the E_t, σ_t, and γ values in the equation, we estimated l_{cr} which, like γ, passes through a maximum.

The observed parallelism in the dissipation and structural parameters, which is similar to that reported in [20], suggests that l_{cr} reflects not the size of the critical structural defect in the initial material, but its size in the prerupture state. Therefore, addition of TA has an effect on the rupture initiation stage. Evidently, faulty microvolumes formed in the EACLP structure in the presence of TA favor local (in the mouth of incipient crack) microafterflows, possibly as shear zones observed in faulty EACLPs [51]. As a result of plastic deformation with participation of α relaxation, dissipation of mechanical energy takes place, which grows with increasing α-relaxation cooperativity. This mechanism of action of TA additives can be assigned to the effect of the structural factor. Furthermore, small concentrations of TAs, increasing the local and long-range (segmental) molecular flexibility, favor relaxation of stresses in the mouth of growing crack and delocalization of fracture. The local fracture process involves a large volume of material subjected to deformation [32]. This implies higher deformability of PC–PM EACLPs and, correspondingly, larger size of the prerupture critical defect.

To conclude, taking into account the observed improvement in the mechanical properties (tensile strength and, especially, rupturing deformation) through modification of EACLPs with TAs, and also in the adhesion to glass, TA additives can be recommended as modifiers for EACLPs of various purposes.

CONCLUSIONS

(1) Simultaneous operation of the polycondensation and polymerization curing mechanisms gives a synergistic effect whose intensity is controlled by the structure of a tertiary amine.

(2) The effect of tertiary amines of various reactivities on the local (α-process) and segmental (β-process) molecular flexibility in epoxy-amine cross-linked polymers is studied by the method of bending resonance vibrations, torsion pendulum method (free oscillations), pulse NMR spectroscopy, and dilatometry. The relaxation spectra of various modes of flexibility show that the structural microheterogeneity grows with increasing TA content and reactivity.

(3) The effect of TA additives on mechanical characteristics, such as the tensile strength, Young's modulus, rupturing deformation, and total and surface rupture energies, and also on the rupture mechanism is studied.

Received November 2, 2001

Abstract—Water-soluble *N*-vinylpyrrolidone–crotonic acid–2-hydroxyethyl methacrylate terpolymers, potential polymeric carriers for biologically active substances, were prepared. The composition of the terpolymers was determined, their chemical structure was confirmed, and their hydrodynamic characteristics and structural features in aqueous solutions were studied.

N-Vinyl-2-pyrrolidone (VP) terpolymers containing two types of monomeric units with reactive functional groups are of indubitable interest for development of polymeric carriers for biologically active substances (BASs) [1]. Such terpolymers can serve as a basis for preparing hydrophilic polymers with polyfunctional activity by covalent (or ionic and covalent) binding of two BASs with different mechanisms of the biological effect. It is interesting to consider in this respect VP terpolymers **I** containing carboxy and primary hydroxy groups.

In this work, we prepared and studied such terpolymers. These substances were synthesized by ternary radical copolymerization of VP with crotonic acid (CA) and 2-hydroxyethyl methacrylate (2-HEMA). The interest in 2-HEMA is due to the fact that polymers based on it (hydrogels) are biologically compatible with a living body and are used for immobilization of various BASs and fabrication of contact lenses [2–6]. At the same time, VP–CA copolymers are also used for modification of various BASs [7, 8]. Furthermore, CA acts as a chain-terminating agent in the polymerizing monomer mixture.

The kinetics of terpolymerization of VP (M_1) with CA (M_2) and 2-HEMA (M_3) was studied in ethanol at 343 K; the monomer molar ratio was $[M_1] : [M_2] : [M_3] = 65.5 : 14.5 : 20.0$, and the concentration of the initiator, azobis(isobutyronitrile) (AIBN), 1.5 wt %. The total initial concentration of the monomers was 20 wt %. For comparison, we studied under the same conditions the binary copolymerization of VP with 2-HEMA at the molar ratio $[M_1] : [M_2] = 80 : 20$. Copolymerization of VP with 2-HEMA under these

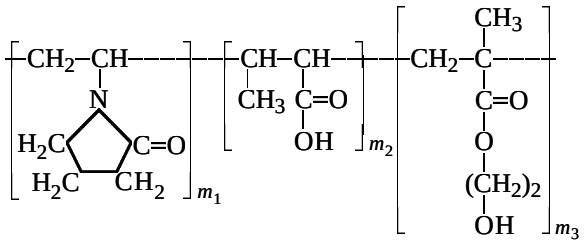
conditions is fast (Fig. 1, curve *1*). The copolymer yield is 63% in 3 h. A sharp self-acceleration of the copolymerization (gel effect) is observed in the conversion range 28–47%. The rate of ternary copolymerization of VP with CA and 2-HEMA is lower than the rate of binary copolymerization of VP with 2-HEMA (Fig. 1, curves *1*, *2*), which is due to the presence of CA, which is low-active and prone to degradation chain transfer. The results of preparative synthesis of VP–CA–2-HEMA terpolymers **I** are listed in Table 1. It is seen that at the molar ratio $[M_1] : [M_2] : [M_3] = 65.5 : 14.5 : 20.0$ the terpolymer yield is 45% in 3 h and reaches 90% in 48 h. The terpolymers are enriched, as compared with the initial monomer mixture, in 2-HEMA, which is the most active monomer in the system (Table 1, run nos. 1–13). With increasing content of CA, the yield of the terpolymer and its intrinsic viscosity decrease. An increase in the concentration of the monomer mixture at the same monomer ratio results in increased content of CA in the terpolymer (Table 1, run nos. 5 and 7, 6 and 8), which may be due to diffusion hindrance of the degradation chain termination. As seen from Table 1, it is possible to prepare, by varying the terpolymerization conditions, terpolymers **I** with the intrinsic viscosity ranging from 0.03 to 0.22 dl g^{-1}; CA unit content, from 10.0 to 30.6 mol %; and HEMA unit content, from 10.1 to 34.0 mol %.

Terpolymers **I** are typical anionic polyelectrolytes. They are titrated with alkalis, and their reduced viscosity in aqueous solutions increases with dilution:



The structure of terpolymers **I** ($m_1 + m_2 + m_3 = 100$ mol %) was confirmed by titration of carboxy groups, elemental analysis for nitrogen, and ^{1}H NMR spectra taken in DMF-d_7. The ^{1}H NMR spectrum of sample **I-2** contains, along with the proton signals of the VP unit, signals originating from the $–OCH_2–CH_2O–$ protons of the 2-HEMA unit (4.15 and 3.85 ppm) and from the methyl protons of the CA (1.15–1.20 ppm) and 2-HEMA (0.75–0.96 ppm) units (Fig. 2).

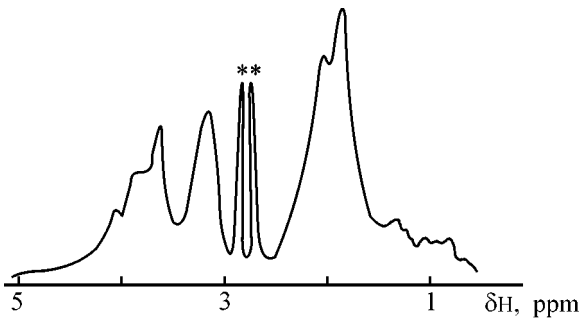


Fig. 2. ^{1}H NMR spectrum of terpolymer **I-2** in DMF-d_7. (δH) Chemical shift. The signals originating from impurities in the solvent are marked with asterisks.

* (*D*) Diffusion coefficient; (d*n*/d*c*) increment of the refractive index.

** M_{SD} was determined from sedimentation diffusion analysis.

As seen from Table 2, terpolymers **I** have low molecular weight with moderate polydispersity. Their forward diffusion coefficients, intrinsic viscosities, and molecular weights allow them to be classed with flexible-chain polymers [9]; the mean length of the Kuhn segment in them is 20×10^{-8} cm.

The viscometric data for VP–CA–2-HEMA terpolymers suggest occurrence of structural transformations in their aqueous solutions. Table 3 shows that, in going from sample **I-1** to **I-2** and **I-6**, the reduced viscosity of their aqueous solutions $\eta_{r,2}$ decreases, which suggests that, the macromolecular globules become more compact as the content of carboxy and hydroxy groups is increased. Because the hydrophobic interactions are enhanced with increasing temperature [10], $\eta_{r,2}$ at 310 K is lower than that at 298 K (macromolecules become more compact). In an aqueous urea solution, the intramolecular hydrogen bonds are broken, and the macromolecular globules unroll; therefore, $\eta_{r,1}$ is higher than $\eta_{r,2}$ for each terpolymer. In contrast to aqueous solutions, in aqueous urea solutions, $\eta_{r,1}$ grows with increasing content of carboxy groups, because mutual electrostatic repulsion of these charged groups causes the macromolecules to unroll to a greater extent. At 310 K, this trend is less pronounced because of the increased role of hydrophobic interactions in structure formation of the terpolymers.

Table 3. Viscometric study of VP–CA–2-HEMA terpolymers in aqueous solutions in the presence and in the absence of urea*

Terpolymer	$\eta_{r,1}$	$\eta_{r,2}$	$\eta_{r,1}$	$\eta_{r,2}$
	dl g^{-1}, 298 K		dl g^{-1}, 310 K	
I-1	0.256	0.169	0.232	0.143
I-2	0.270	0.160	0.252	0.120
I-6	0.423	0.146	0.377	0.107

* ($\eta_{r,1}$, $\eta_{r,2}$) Reduced viscosities of terpolymers in 1 M aqueous urea solution and in water, respectively (c_{terp} = 1.0 g dl^{-1}).

It is important that aqueous solutions of all the VP–CA–2-HEMA copolymers prepared in this work are transparent at "physiological" pH values and temperatures even at a concentration as high as 5 wt %. This fact predetermines the possibility of incorporation into terpolymers **I** of two BASs with different mechanisms of the biological effect. We confirmed this possibility by the example of two-stage fixation on terpolymer **I-2** of Acemin (agent stimulating reparative regeneration of tissues) by the ester bond and of Katamin AB (antiseptic) by the ionic bond stabilized by hydrophobic interactions of long alkyl chains of Katamin AB with macromolecules of the carrier [11]. As a result, we obtained a water-soluble VP copolymer exhibiting reparative and antimicrobial activity and showing promise for treatment of wounds and burns.

EXPERIMENTAL

VP and 2-HEMA were purified by vacuum distillation, and CA, by recrystallization from water with preliminary treatment of the solution with activated charcoal. The physicochemical constants of the monomers agreed with published data. Azobis(isobutyronitrile) was recrystallized three times from ethanol–chloroform (3 : 1); mp 376 K.

The kinetics of ternary copolymerization of VP, CA, and 2-HEMA, initiated with AIBN, in ethanol at 343 K was studied dilatometrically in ampules (4 mm in diameter, 250 mm high) sealed under argon. Variation of the reaction volume in the course of copolymerization was monitored with a KM-6 cathetometer. To determine the conversion, the VP–CA–2-HEMA terpolymer **I** formed was isolated by precipitation

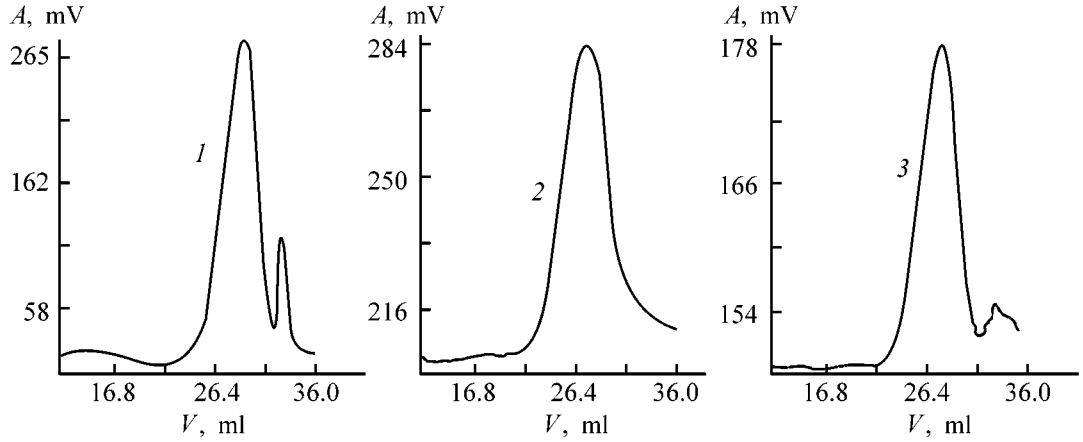

Fig. 3. Chromatograms of terpolymer **I-3**: (*A*) device readings and (*V*) retention volume. Detector: (*1*) refractometric, (*2*) of light scattered at an angle of 90°, and (*3*) viscometric.

into acetone. Preparative synthesis of **I** was performed in large ampules under the conditions indicated in Table 1. The compositions of terpolymers **I** were calculated from the results of analysis for nitrogen and from the content of carboxy groups, determined by titration with 0.1 N aqueous NaOH on a pH 340 titrator.

Terpolymer I-2. A glass ampule was successively charged with 0.1062 g of AIBN (1.5 wt % relative to the sum of monomers) and a solution of a monomer mixture consisting of 5 g (55 mol %) of VP, 0.80 g (15 mol %) of CA, and 1.2 ml (30 mol %) of 2-HEMA in 36 ml of ethanol. The ampule was purged with argon, sealed, and placed in a thermostat kept at 343 K. After heating for 48 h, the ampule was withdrawn, cooled, and opened. Terpolymer **I-2** was isolated by precipitation into diethyl ether, collected on a glass frit, and vacuum-dried. Yield 6.05 g (86.4%). Found, %: N 8.25, 8.47; COOH groups 5.2; m_1 = 6.67, m_2 = 12.9, m_3 = 20.4 mol %; intrinsic viscosity in 0.1 M sodium acetate solution at 25°C [η] = 0.14 dl g^{-1}; M_{SD} = 31000. The ^{1}H NMR spectrum of **I-2** was recorded on a Bruker AC 200 spectrometer in DMF-d_7.

Terpolymers **I** were studied by GPC using simultaneously three detectors [12] (Fig. 3): (1) a refractometric detector (Optilab 901/Wyatt Technology interference refractometer, the United States), (2) a detector recording scattered light of an He–Ne laser (5 mW, λ = 632.28 nm; Wyatt Technology, the United States); and (3) a viscometric detector of the hydrodynamic bridge type (similar to the Winston electric bridge) [13, 14]. The viscometric detector allows detection of the difference between the solution and solvent viscosities at very low concentrations, when the ratio $(\eta - \eta_0)/\eta_0 c$ can be fegarded as intrinsic viscosity. In the course of analysis, the injected volume (100 ml) passes through three series-connected analytical columns TSK G6000PW, G5000PW, and G4000PW (Anachem, UK), allowing separation of macromolecules of reference polyethylene oxide in the range of molecular weights 1×10^3–2×10^6. The eluent was fed at a rate of 0.8 ml min^{-1} at room temperature. The increments of the refractive index d*n*/d*c* were measured in independent experiments on an Optilab 901 interference refractometer. In GPC experiments, 0.05 M phosphate buffer solution was used as solvent.

Figure 4 shows the differential molecular-weight distribution of sample **I-5**, derived from chromatograms *1* and *2* (Fig. 3). The forward diffusion of terpolymer molecules was studied on a device equipped

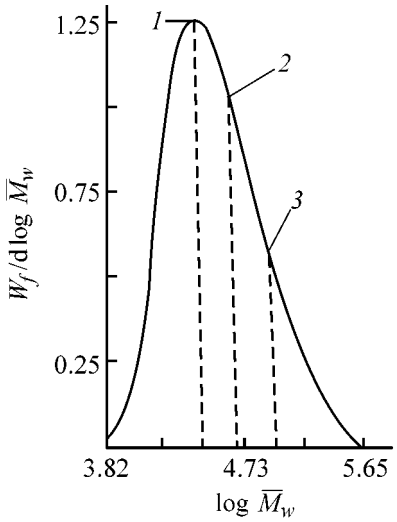

Fig. 4. Differential molecular-weight distribution of terpolymer **I-5**, derived from chromatograms *1* and *2* (Fig. 3). (*1*) $\overline{M}_n$ = 29800, (*2*) $\overline{M}_w$ = 50300, and (*3*) $\overline{M}_z$ = 93700.

with a Lebedev polarization interferometer as the detecting optical system. The Tsvetkov diffusometer and the procedure for calculaing the forward diffusion coefficients are described elsewhere [9, 15]. The solution–solvent boundary was formed in glass cells with optical path length of 3 cm. The diffusion boundary variance σ^2 was calculated from the maximal ordinate and the peak area. From the dependences

$$\sigma^2 = \sigma_0^2 + 2Dt,$$

we calculated the forward diffusion coefficient D (σ_0^2 is the initial variance characterizing the quality of formation of the diffusion boundary). Diffusion experiments were performed in 0.1 M KCl at 299 K. The intrinsic and reduced viscosities of copolymers **I** were determined in 0.1 M aqueous KCl solution at 298 K with an Ubbelohde viscometer.

CONCLUSIONS

(1) New water-soluble terpolymers *N*-vinylpyrrolidone–crotonic acid–2-hydroxyethyl methacrylate were prepared in 48.8–90.6% yield by radical ternary copolymerization in solution, initiated by azobis(isobutyronitrile). The ternary copolymerization kinetics was studied.

(2) The compositions and molecular-weight parameters of the resulting functional terpolymers were determined.

Abstract—The kinetics of acid hydrolysis of phenylpenicillins substituted in the benzene ring were studied at pH 3.0 and temperatures of 20, 25, and 30°C. A Hammett correlation analysis of the reaction was performed.

Antibiotics of the penicillin series significantly differ in stability in acid solutions. Among acid-resistant penicillins, which can be administered perorally, are phenoxymethylpenicillin, Oxacillin, Cloxacillin, etc. Benzylpenicillin, *p*-hydroxybenzylpenicillin, and Methicillin show poor acid resistance.

Penicillins contain a common bicyclic system consisting of fused β-lactam and thiazolidine rings and differ only in the structure of the side acyl group. All the differences between penicillins are largely due to structural features of this substituent, and, from this standpoint, it is appropriate to discuss the difference in acid resistance between penicillins.

Strukov *et al.* [1, 2] believe that the differences in acid resistance of penicillins are associated with the amide–imidol tautomerism of their side chain; however, no explanations for this hypothesis are given. Doyle *et al.* [3] showed that electron-withdrawing substituents in the side aliphatic acyl group enhance the acid resistance of penicillin, but they gave no explanations for this fact either. Therefore, it seemed appropriate to study the acid resistance of specially chosen penicillin derivatives differing in the nature of substituent in the aromatic ring of the side acyl group, with the aim to reveal a correlation between the structure of the side acyl droup, on the one hand, and the rate of penicillin acid cleavage, on the other, and also to find the reason for this correlation.

As objects for our study we chose phenylpenicillins substituted in the side chain. Their side acyl groups are structurally related to benzoic acids, for which the the dissociation constants strongly depend on the electronic effects of substituents. Hence, significant differences in acid resistance must be expected for substituted phenylpenicillins too.

The substituted phenylpenicillins were prepared by acylation of the core compound, 6-aminopenicillanoic acid, with various substituted benzoyl chlorides in aqueous acetone in the presence of sodium hydrogen carbonate [4]. The properties of the resulting sodium salts of substituted penicillins, which show high biological activity, are listed in Table 1. The purity

of phenylpenicillins, according to iodometric analysis, was 74–97%, which may be due to inactivation of these compounds in the course of isolation and purification. Purification of phenylpenicillins is very difficult because of their instability; therefore, substituted phenylpenicillins were additionally identified in the form of methyl esters. Furthermore, these derivatives appeared to be more convenient for a ^{1}H NMR study of phenylpenicillins than the salts. The properties of methyl esters of the phenylpenicillins substituted in the benzene ring are listed in Table 2. It is seen that these compounds were isolated pure.

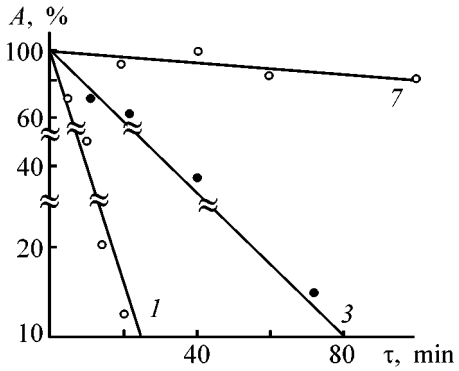

Fig. 1. Acid inactivation of phenylpenicillins. 25°C, pH 3.0; the same for Fig. 2. (*A*) Concentration of non-inactivated substituted phenylpenicillin and (τ) time elapsed from the start of the reaction. *Figures at curves* denote compound nos. in Table 1.

The kinetics of acid inactivation of the chosen penicillins were studied in a glycine buffer solution (pH 3.0) at 20, 25, and 30°C. The initial concentration of the antibiotic in solution was about 1000 units ml^{-1}. Under these conditions, hydrolysis of the amide bond in the β-lactam ring of substituted phenylpenicillins, resulting in their inactivation, is a pseudomonomolecular reaction and is described by a first-order equation, as in the case of other penicillins [5–7].

The parameter $\log[C_0/(C_0 - C_\tau)]$ is a linear function of τ (Fig. 1). The rate constants of acid inactivation of substituted phenylpenicillins and the activation energies of the reactions are listed in Table 3. It is seen that the rate constants of acid hydrolysis of phenylpenicillins differ considerably.

The large difference between the activation energies of hydrolysis of *p*-methoxyphenylpenicillin (5.06 kcal mol^{-1}) and *p*-nitrophenylpenicillin (21.5 kcal mol^{-1}) shows that at the instant of cleavage of the amide bond in the β-lactam ring the penicillin molecule is strongly polarized. The probability factors *PZ* also differ considerably. On the whole, the rate constants of acid inactivation of substituted phenylpenicillins vary in accordance with the polar effect of the substituent.

Examination of the applicability of the Hammett equation to the acid inactivation of phenylpenicillins (Fig. 2) shows that the logarithms of the rate constants of this reaction show a satisfactory linear correlation with the Hammett σ constants in the temperature range studied (in all cases we used common Hammett σ constants [8]). Thus, despite complex structure of penicillins, the description of their inactivation by the Hammett equation is quite adequate. The coefficients ρ at 20, 25, and 30°C, calculated from the slopes of the log *K*–σ straight lines, are –2.00 (r = 0.956), –1.76 (r = 0.996), and –1.65 (r = 0.994), respectively. The negative sign of ρ shows that the inactivation is promoted by donation of the electron density to the reaction center. The coefficients ρ are large in absolute value, which means that acid inactivation of substituted benzylpenicillins is highly sensitive to effects of substituents in the benzene ring of the side acyl group, despite their relatively large distance from the reaction center (amide bond in the β-lactam ring).

To understand why the effect of substituents on the cleavage of the relatively remote bond is so strong, it seemed important to study how the substituents affect the polarization of the amide bond in the β-lactam ring. Such information can be derived from the ^{1}H NMR spectra of the methyl esters of phenylpenicillins. Indeed, if the electronic effect of substituents in the benzene ring on the strength of the amide bond in the β-lactam ring were significant, it would alter the hybridization of the nitrogen atom and hence cause

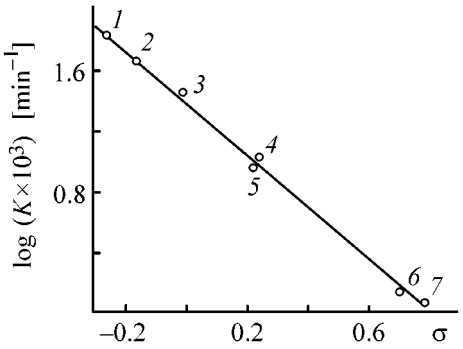

Fig. 2. Correlation between the logarithms of the rate constants *K* of acid activation of substituted phenylpenicillins and the Hammett σ constants of substituents in the benzoyl group. *Figures at curves* are compound nos. in Table 1.

appreciable changes in the coupling constant of the β-lactam protons and in the chemical shift of C^5H.

^{1}H NMR data for methyl esters of phenylpenicillins are given in Table 4. It is seen that for all the compounds the coupling constants $J(H^5–H^6)$ and the chemical shifts δ of the β-lactam protons are very similar. That is, there is no pronounced correlation between the ^{1}H NMR parameters of the lactam ring and the structure of the side chain. The lack of such a correlation suggests that either there is no specific interaction in an inert medium between the amide moiety of the β-lactam ring and the side chain, or this interaction is too weak to be detected by NMR. An increase in the chemical shifts of the C^5H protons with increasing electronegativity of the side chain (Table 4) suggests occurrence of a certain interaction, but this trend is very weakly pronounced. The effect of substituents in the benzene ring is apparently leveled out by the amide group of the side chain, which has a very low transmission factor π = 0.12 [8].

The high absolute values of ρ for the acid inactivation of substituted phenylpenicillins, taking into account the very weak transmission of the inductive ef-

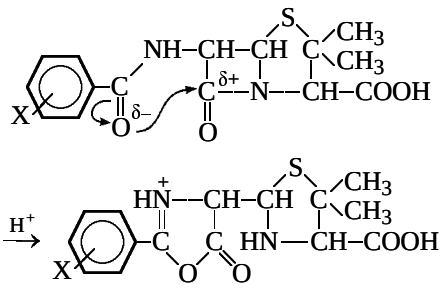
fects to the β-lactam ring by the mechanism of successive polarization of σ bonds, suggest direct participation of the side chain in the limiting stage of the acid inactivation:



In this case, the electronic effects of substituents are probably transmitted by the field effect mechanism via electrostatic interaction through space between the oxygen atom of the carbonyl group of the side chain and the carbonyl carbon atom of the β-lactam ring. In the process, the rate of formation of a new –O–C– bond with simultaneous cleavage of the amide bond in the β-lactam ring is determined by the electron density (δ– charge) on the oxygen atom of the side chain, which, in turn, strongly depends on the substituent in the benzene ring. Just this factor is responsible for the pronounced dependence of the rate of acid inactivation of phenylpenicillins on the polar effect of substituents in the benzene ring. The effect is similar to that observed in the series of benzoic acids, which is reflected in the linear correlation of $\log K$ with the Hammett σ constants.

The increased δ– charge on the amide oxygen atom of the side chain facilitates closure of the oxazolone ring with cleavage of the β-lactam ring; therefore, electron-donor substituents in the benzene ring noticeably accelerate the reaction. The negative sign of δ–, suggesting the promoting effect of electron donors, is consistent with this mechanism.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded at room temperature, relative to internal TMS, on a JEOL INM-C-60 spectrometer operating at 60 MHz. Samples were taken as 1–2 mol % solutions in $CDCl_3$. The IR spectra were recorded on a UR-10 spectrometer (KBr pellets). The specific optical rotation α_D^T of substituted phenylpenicillins and their methyl esters in solutions was determined with an EPL-1 polarimeter. The iodometric activity of phenylpenicillins and their methyl esters was studied as described in [9]. The TLC study of methyl esters of phenylpenicillins was performed as follows: solutions of the compounds in chloroform (1–1.5 mg ml^{-1}) were applied to plates coated with KSK silica gel (5 μg per spot). Ascending chromatography was performed in a closed chamber, with ethanol as eluent. After separation, the chromatograms were dried for 10 min at 20°C and for 15 min at 100°C, and then developed with iodine vapor. The target compounds gave rust-colored spots.

Phenylpenicillin sodium salt 3. A 0.2 g (0.00093 M) portion of 6-aminopenicillanoic acid was dissolved in a mixture of 20 ml of 0.1 M phosphate buffer solution (pH 6.6) and 4 ml of 10% $NaHCO_3$ solution. To the resulting mixture was added dropwise, with stirring and cooling on an ice bath, a solution of 0.197 g (0.0014 mol; 1.5-fold excess) of benzoyl chloride in 10 ml of acetone. Acylation was performed for 20 min, with addition of $NaHCO_3$ solution to maintain the neutral medium. After reaction completion, the unchanged benzoyl chloride was extracted with diethyl ether and discarded. The cooled aqueous solution was acidified with 1 N HCl to pH 2.0, and the phenylpenicillic acid formed in the process was extracted with 15 ml of diethyl ether. The extract was treated with 12 ml of 0.05 N $NaHCO_3$ to wash the acid back to the aqueous phase in the form of the sodium salt. The product was isolated by lyophilic drying and purified by reprecipitation from aqueous acetone into dry acetone. Yield of phenylpenicillin sodium salt 0.204 g (61%), iodometric activity 970 μg mg^{-1}. IR spectrum, ν, cm^{-1}: 1770 (C=O in β-lactam ring); 1400 (–O–C– in –C(=O)O$^-$ group); 1655, 1490 (C=O in –C(=O)–NH– group).

The sodium salts of phenylpenicillins substituted in the benzene ring were prepared similarly.

Phenylpenicillin methyl ester. A solution of 1.3 ml of diazomethane in 10 ml of diethyl ether was added with stirring to a solution of 0.5 g of phenylpenicillic acid in 50 ml of diethyl ether. The reaction was performed until the gas evolution ceased. Phenylpenicillin methyl ester was isolated by vacuum evaporation of the ether and purified by repeated reprecipitation from ethyl acetate into petroleum ether. Yield 0.208 g (40%); mp 116–117°C. IR spectrum, ν, cm^{-1}: 1770 (C=O in β-lactam ring); 1655, 1520 (C=O in –C(=O)–NH– group); 1720 (C=O in –C(=O)–O– group); 1170 (–O–C–).

Found, %: N 8.34, S 9.60.

$C_{16}H_{18}O_4N_2$.

Calculated, %: N 8.38, S 9.59.

Iodometric activity 960 μg mg^{-1}. Methyl esters of the other phenylpenicillins were prepared similarly.

Dioazomethane was prepared by Arndt's procedure [10].

CONCLUSIONS

(1) Phenylpenicillins substituted in the benzene ring were prepared and identified in the form of methyl esters.

(2) The rate constants of acid hydrolysis of substituted phenylpenicillins correlate with the Hammett σ constants of substituents in the benzene ring, with high (in absolute value) sensitivity coefficients ρ: –2.05, –1.76, and –1.65 for 20, 25, and 30°C, respectively. Contrasingly, the ^{1}H NMR spectra of the lactam moiety are weakly sensitive to the substituents in the benzene ring.

(3) The reaction mechanism, consistent with these facts, was suggested, in which the side acyl group takes an active part in the limiting stage.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Optical Properties of Semidilute Solutions of Poly-2-acrylamido-2-methylpropanesulfonic Acid at Varied Ionic Strength of the Medium

S. V. Valueva, I. G. Silinskaya, and A. I. Kipper

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 28, 2001

Abstract—Aqueous-salt semidilute solutions of a high-molecular-weight polyelectrolyte, poly-2-acrylamido-2-methylpropanesulfonic acid, were studied by flow birefringence and light scattering methods at varied ionic strength of the medium.

In [1], we studied the optical properties of solutions of a copolymer formed by 2-acrylamido-2-methylpropanesulfonic acid and acrylamide, P(AMPS–AA), with the degree of ionization of 20 %, as influenced by the ionic strength of the medium I and the polymer concentration c at $c > c^*$ (c^* is the solution concentration comparable with the average concentration of the units in the polymer coil and correlating with the parameter inverse to the intrinsic viscosity $[\eta]$ of this polymer in an appropriate solvent [2]). For P(AMPS–AA) in 1 M $NaNO_3$ solution we revealed an fluctuation network of engagements, and in 0.1 M $NaNO_3$ solution, disoriented anisotropic structural macroelements of the fluctuation nature. The macroelements have size comparable with the wavelength of light and are capable of mutual orientation in a gradient field.

The aim of this work was (1) to apply the flow birefringence (BR) and light scattering methods to study the structurization in semidilute solutions of high-molecular-weight flexible-chain polyelectrolyte poly-2-acrylamido-2-methylpropanesulfonic acid (PAMPS; 100% ionic groups) at ionic strength of solution I = 1 M (the case of suppressed electrostatic interactions) and I = 0.1 M {the case of long-range electrostatic interactions; the percolation effect is negligible; $A \sim$ const (A is the equilibrium rigidity of macromolecules) [3–5]} and (2) to compare the results with those for semidilute P(AMPS–AA) solutions reported by us in [1].

EXPERIMENTAL

Our study was concerned with high-molecular-weight ($M_w = 4.6 \times 10^6$) flexible-chain (A = 2 nm [6]) polyelectrolyte PAMPS. We described in detail the molecular and conformational parameters of this sample for the $c < c^*$ region in [7]. The PAMPS solutions were studied ionic strengths I of 1 and 0.1 M ($NaNO_3$).

The solutions and solvents were purified by centrifugation at 15000 rpm for 1.5 h.

We measured the flow BR Δn as dependent on the rotor rotation rate gradient g, polymer concentration c, and ionic strength I by the procedure described in [8]. We used a titanium dinamooptometer with a 4-cm-high internal rotor and a 3×10^{-2}-cm clearance between the rotor and stator. The measurements were conducted at $g < g_c$, where g_c is the rate gradient at which the flow becomes turbulent. Throughout the c and I ranges investigated, the PAMPS solutions exhibit positive BR. The $\Delta n = f(g)$ plots are linear and pass through the origin at all the c and I values studied, which suggests the lack of intermolecular association in the $c > c^*$ region.

Viscometric measurements were conducted on an Ostwald's capillary viscometer, the water outflow time being 120 ± 0.2 at 21°C.

Static light scattering for PAMPS solutions was studied on a Fica photogoniodiffusometer at the vertically incident polarized light with wavelength of 546.1 nm in the range $c \cong 0.01$–0.7% (herefrom, wt %) and angles (with respect to the incident light direction) $\theta = 30°$–$150°$. The results were interpreted in terms of the Debye-Simm theory [9]. The refractive index increment $\partial n/\partial c$ was derived from the results of refractometric studies on an IRF-23 instrument.

1070-4272/02/7502-0286 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The static light scattering was studied for PAMPS solutions on an FPS-3M instrument comprising a photoelectric system for recording the intensity of light scattered at an angle $\theta = 40°–140°$ (incident light wavelength 546.1 nm). The results obtained were interpreted in terms of the Bueche–Stein statistical theory [10].

The angular dependences of the vertically polarized component of the scattered light V_v were measured by a standard technique [9]. Based on the angular dependence of V_v in terms of the Bueche–Stein statistical theory, we determined the isotropic parameters of the structure: average squared fluctuation of the average polarizability of the scattering microvolume $\langle\langle\eta\rangle^2\rangle$ and the correlation radius of the polarizability fluctuations α_v. The isotropic structure parameters are related to the sizes of the macromolecules or associates α_v and to microheterogeneity, which is a function of the density fluctuation $\langle\langle\eta\rangle^2\rangle$.[1]

Based on the concentration dependence of the reduced viscosity η_{sp}/c ($\eta_{sp} \equiv \eta_r - 1$, where η_r is the relative viscosity) in dilute solutions, we determined the intrinsic viscosity $[\eta] \equiv (\eta_{sp}/c)_{c\to 0}$ ($[\eta]_1 = 5.0$ at $I = 1$ M and $[\eta]_2 = 9.0$ at $I = 0.1$ M [7]) and estimated Debye's concentration $c^* \sim [\eta]^{-1}$ above which the solution is semidilute: $c^* \sim 0.20$ % ($I = 1$ M) and $c^* \sim 0.11$ % ($I = 0.1$ M). The viscometric data suggest (1) fairly strong polyelectrolyte swelling of the poly ions with decreasing I ($[\eta]_2/[\eta]_1 = 1.8$) and (2) the existence in 0.1 M $NaNO_3$ solution, along with c^*, of additional critical points ($c \sim 0.2$ and $c \sim 0.5$%) at which the slope of the $\eta_{sp}/c = f(c)$ plot changes (Fig. 1).

The light scattering data for the PAMPS–1 M $NaNO_3$ solution system suggest that the angular dependences $(V_v - 4/3H_v)^{-1/2}$ are linear throughout the concentration range investigated, except at $c = c^* \cong 0.20$%. In this case, the experimental curve exhibits an inflection indicative of the existence in solution of additional, larger scattering elements typical of systems with suppressed polyelectrolyte effect, which are in a state of transition from dilute to semidilute solution and form a fluctuation network of engagements. For the PAMPS–0.1 M $NaNO_3$ solution system we

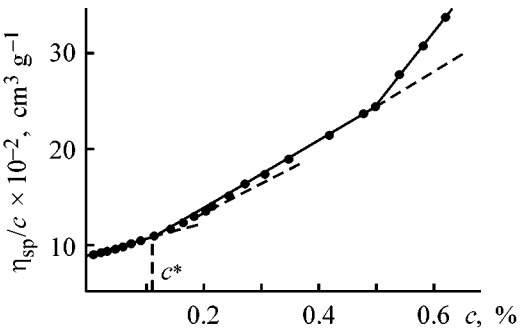

Fig. 1. Reduced viscosity η_{sp} vs. the polymer concentration c for PAMPS solutions at $I = 0.1$ M.

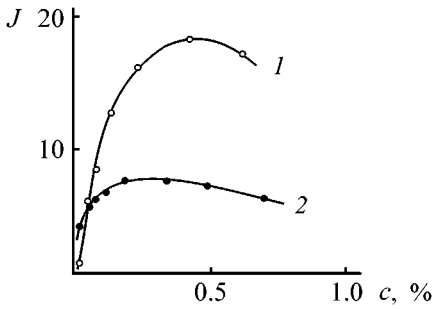

Fig. 2. Reduced intensity of the scattered light J vs. the polymer concentration c for PAMPS solutions at (*1*) $I = 1$ M and (*2*) $I = 0.1$ M.

observed at all the concentrations studied abnormally high light-scattering intensities at $\theta = 40–80°$. By extrapolation to zero scattering angle, we found that the size of the scattering formations is comparable with the wavelength of light. This is, evidently, accounted for by restriction of free fluctuations of the polymer coils in solution owing to incompletely suppressed polyelectrolyte interactions and, correspondingly, by an increase in the correlation radius of these fluctuations. It should be emphasized that the light scattering effects observed for PAMPS at $I = 1$ and $I = 0.1$ M are similar to those for P(APMS–AA) in 1 M and 0.1 M $NaNO_3$ solutions [1].

The concentration dependences of the reduced intensity of scattered light for PAMPS solutions at $I = 1$ and $I = 0.1$ M exhibit maxima in Debye's concentration range at $c^* \sim 0.20$ and $c^* \sim 0.11$%, respectively (Fig. 2). These maxima suggest a decrease in the fluctuation mobility at $c \geq c^*$ due to strong intermolecular interaction, namely, nonelectrostatic interaction at $I = 1$ M (owing to the formation of the fluctuation network of engagements) and polyelectrolyte interaction in 0.1 M $NaNO_3$ solution. It should be emphasized that the extremum in the $I = f(c)$ dependence also suggests the lack of aggregation in the solutions [9].

[1] Because of the lack of the angular dependence for the reduced intensity of anisotropic scattering (horizontal polarized component of the scattered light, H_v) for the systems PAMPS–1 M $NaNO_3$ solution and PAMPS–0.1 M $NaNO_3$ solution, the anisotropic structure parameters (squared average optical anisotropy $\langle\delta\rangle^2$ and the correlation radius of orientation of the optical axes of the scattering volume elements α_H) were not determined for these systems.

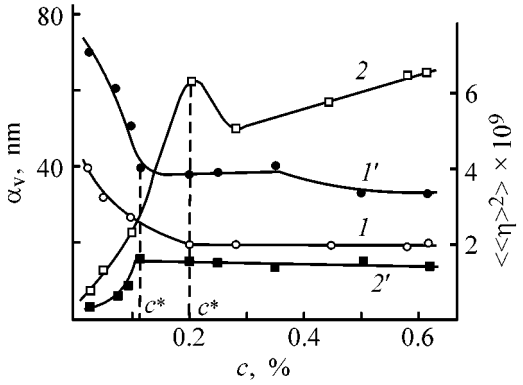

Fig. 3. Concentration dependences of (*1*, *1*′) the correlation radius of the polarizability fluctuations $\alpha\delta_v$, and (*2*, *2*′) the average squared fluctuation of the average polarizability of the scattering microvolume $\langle\langle\eta\rangle^2\rangle$ for PAMPS solutions at (*1*, *2*) I = 1 M and (*1*′, *2*′) I = 0.1 M.

As known, the average correlation radius of the polarizability fluctuations, α_v, for solutions of nonionic flexible-chain polymers initially tends to decrease with growing concentration up to Debye's concentration, to take a value $\alpha_{v,0}$ corresponding to the size of macromolecules $\langle R_g^2\rangle^{1/2}$, and then (at $c > c^*$) tends to increase owing to aggregation of the macromolecules [11].[2] For nonionic polymers with functional groups capable of strong specific interactions (this is, evidently, the case for PAMPS at I = 1 M) a significant increase in the parameter α_v for $c > c^*$ also reflects the intermolecular association in solution [12].

In contrast to nonionic polymer systems, the parameter α_v for PAMPS in 1 M and 0.1 M $NaNO_3$ solutions at $c > c^*$ (it should be mentioned that the c^* values estimated by light scattering studies coincide with Debye's concentrations obtained by viscometry) are significantly lower than the theoretically calculated values [$\alpha_{v,0}$ = 41 at I = 1 M ($[\alpha^2_{v,0} = 1/6\langle R_g^2\rangle$, $\langle R_g^2\rangle^{1/2}$ = 100 nm); $\alpha_{v,0}$ = 57 at I = 0.1 M ($\langle R_g^2\rangle^{1/2}$ = 140 nm)] and remain virtually unchanged at $c > c^*$ (Fig. 3, curves *1*, *1*′). This suggests the lack of intermolecular association in the region of semidilute solution. This is in agreement with the $\Delta n = f(g)$ dependence for PAMPS in 1 and 0.1 M $NaNO_3$ solution. The $\alpha_v = f(c)$ dependence for PAMPS at I = 1 and I = 0.1 M reproduces, on the whole, the analogous dependence for P(AMPS–AA) [1].

The parameter α_v for PAMPS in 0.1 M $NaNO_3$ solution, calculated for the linear section of the angular dependence $(V_v - 4/3H_v)^{-1/2}$, is 35–40 nm at $c > c^*$, which exceeds the analogous value for PAMPS in 1 M $NaNO_3$ solution (α_v = 20 nm). This is consistent with the viscometric data.

In view of the fact that a network of engagemenists probably formed in the system PAMPS–1 M $NaNO_3$ solution in the concentration range studied at $c > c^*$ [1, 13, 14], the parameter α_v evidently characterizes the correlation size of its interstice, and the parameter $\langle\langle\eta\rangle^2\rangle$ increasing at c > 0.3 % (Fig. 3, curve *2*), an increase in the number of engagements. In the case of 1 M solutions of $NaNO_3$ the $\langle\langle\eta\rangle^2\rangle = f(c)$ plot for PAMPS is analogous to that for P(AMPS–AA) [1]. This, probably, suggests a similar behavior of semidilute solutions of polyelectrolytes under depressed electrostatic interactions.

Of special interest is analysis of the concentration dependence of the reduced BR $[\Delta n/(g\eta_0 c)]_{g\to 0}$ (Figs. 4a, 4b; η_0 is the solvent viscosity).[3] High-molecular-weight flexible-chain polymers in dilute solutions with refractive index increment $\partial n/\partial c$ other than zero (in our case, $\partial n/\partial c$ = 0.133 $cm^3\ g^{-1}$) typically exhibit a steadily decreasing concentration dependence of reduced BR, which is due to a decrease in the macroform effect [8]. In our case, the dependence is nonmonotonic: For I = 1 M (Fig. 4, curve *1*) it has a critical point at $c = c^* \cong 0.20$ %; in 0.1 M $NaNO_3$ solution (Fig. 4b, curve *1*) critical points are observed at $c = c^* \cong 0.11$, $c \sim 2$, and $c \sim 0.5$ %. This correlates with the viscometric (Fig. 1) and light scattering (Fig. 3, curves *1*, *1*′) data.

Increase in the reduced BR for PAMPS in 1 M $NaNO_3$ solution at $c > c^*$, suggests similarly, to the light scattering data, formation of a fluctuation network of engagements. It should be noted that $[\Delta n/(g\eta_0 c)]_{g\to 0} = f(c)$ dependences for PAMPS and P(AMPS–AA) in 1 M $NaNO_3$ solution at $c > c^*$ are, on the whole, virtually identical.

The lack, in the case of PAMPS, of an angular dependence of the reduced intensity of anisotropic light scattering in 1 M $NaNO_3$ solution suggests the following. There is no mutual orientation of the segments of macromolecules, while for P(AMPS–AA) with suppressed electrostatic interactions at $c > c^*$ the formation of the fluctuation network of engagements was accompanied by the appearance of microdomain structures, which are mutually oriented macromolecular segments

[2] The size of macromolecules, $\langle R_g^2\rangle^{1/2}$, in 1 M and 0.1 M $NaNO_3$ solutions was estimated using the data on the asymmetry of scattered light in the $c < c^*$ region [7].

[3] In view of the significant curvature of the $\eta_{sp}/c = f(c)$ plot (Fig. 1), we present in Figs. 4a and 4b, the $[\Delta n[g\eta_0 c)]_{g\to 0} = f(c)$ dependence, instead of the widely used $\{\Delta n[g\eta_0(\eta_r - 1)]\}_{g\to 0} = f(c)$ dependence.

[1]. The difference in network morphology of the between the homo- and copolymer is, evidently, due to the fact that in the former, the dipole–dipole interactions dominate, and in the latter case the structure of the solution is significantly affected by hydrogen bonds (e.g., of the $-NH_2...O=C<$ type [1]).

The fluctuation network of engagements is also formed in semidilute solutions with suppressed electrostatic interactions in the case of moderately rigid-chain (A = 6–7 nm) high-molecular-weight [M_w = (6.6–10) × 10^6] polyelectrolytes of various structures [15, 16] (Fig. 4, curves *2*, *3*).

For rigid-chain high-molecular-weight polyelectrolyte (A ~ 17 nm, $M_w = 6 \times 10^6$) [15] we did not record formation of fluctuation network of engagements by the flow BR method (Fig. 4a, curve *4*). Formation of the network in polyelectrolyte solutions is, probably, affected not only by the ionic strength of the medium [13, 14], but also by the equilibrium rigidity of poly ions.

It was shown in [1, 13] that, in semidilute solutions of polyelectrolytes with incompletely suppressed polyelectrolyte effect, the electrostatic repulsion forces between the similarly charged poly ion groups hinder not only formation of associates but also interpenetration of the coils and formation of the fluctuation network of engagements at Debye's point.

Thus, the "abnormal" behavior of the optical anisotropy at I = 0.1 M [increase at c ~ 0.11–0.35 % (Fig. 4b, curve *1*)] cannot be understood from the standpoint of the network structure of solution. As shown by the light scattering studies, the lack of mutual orientation of the segments of PAMPS macromolecules seems to be sufficient for eliminating from consideration also the "microdomain" structure of solution, as in the case of PAMPS in 1 M $NaNO_3$ solution. We can presume (similarly to [1]) the hydrodynamic field-induced orientation of separate polymer chains with respect to each other (formation of "macrodomains"). This once again brings about the macroform effect owing to an increase in the degree of the form asymmetry p of the macromolecule ($p >> p_G$, where p_G is the parameter p for the Gaussian coil [8]). It should be noted that, even at $c < c^*$, the parameter p for the PAMPS macromolecule in 0.1 M $NaNO_3$ solution exceeds that under suppressed electrostatic interactions [7]. The homopolymer studied is a weakly charged species (fairly high ionic strength); hence, macrodomains are evidently formed for the most part via ion pair formation [13, 17, 18]. It should be emphasized, however, that the lack of correlation in orientation of anisotropic elements (according to light scattering data) in the PAPMS–0.1 $NaNO_3$ solution (unlike the data on flow BR) may be due to methodological factors: In studying of polyelectrolyte solutions by the flow BR method, the solution is strongly affected by the gradient field, in contrast to the light scattering method. Also, the polyelectrolyte effect does not allow in the case of interest any unambiguous interpretation of the light scattering data. Thus, the orientation effects in this system can be revealed only by the flow BR studies. In view of the fundamental difference between the methods, flow BR and light scattering, we cannot completely rule out the microdomain structure of the PAMPS–0.1 M $NaNO_3$ solution.

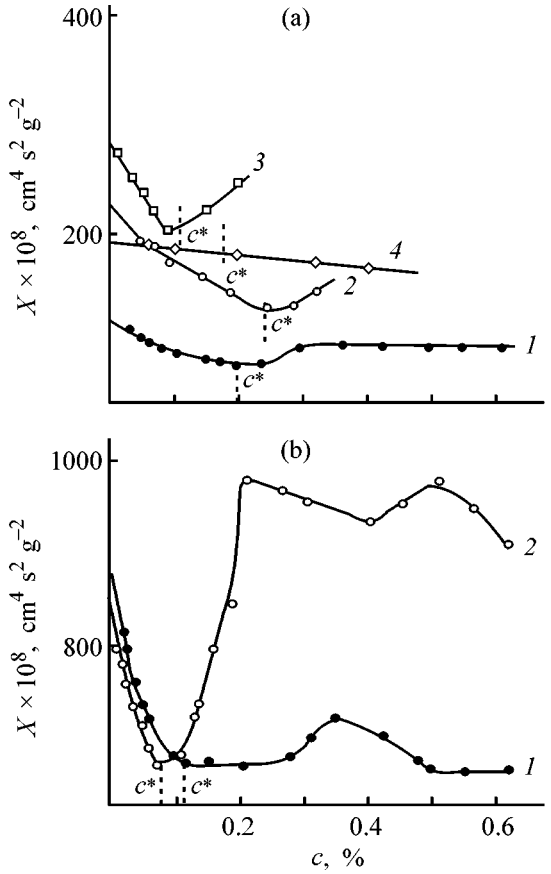

Fig. 4. Concentration dependence of reduced birefringence $[\Delta n/(g\eta_0 c)]_{g\to 0} = X$, for different solutions at (a) I = 1 M and (b) I = 0.1 M. Solution: (a) (*1*) PAMPS, (*2*) P(DMAEMA–AMPS) (DMAEMA is 2-dimethylaminoethyl methacrylate) [15], (*3*) P(DMAEMA–AAc) (AAc is acrylic acid) [16], and (*4*) P(DMAEMA · AMPS) [15]; (b) (*1*) PAMPS and (*2*) P(AMPS–AA).

Comparison of the $[\Delta n/(g\eta_0 c)]_{g\to 0} = f(c)$ dependences for systems PAMPS–0.1 $NaNO_3$ solution and P(AMPS–AA)–0.1 M $NaNO_3$ solution (Fig. 4b, curves *1*, *2*) shows that the effects are significantly stronger in the case of the copolymer, although the

amount of the ionic groups in PAMPS exceeds twofold that in the copolymer. The parameter *p* for PAMPS in 0.1 M $NaNO_3$ solution exceeds that for P(AMPS–AA) [7]. This contradicts the presumed macrodomain structure of the solution in the case of the system PAMPS–0.1 M $NaNO_3$ solution [7]. Evidently, this system is characterized by a microdomain structure of solution.

The morphological difference between the systems PAMPS–0.1 M $NaNO_3$ solution and P(AMPS–AA)–0.1 M $NaNO_3$ solution is clearly illustrated by the concentration dependence of the parameter $\langle\langle\eta\rangle^2\rangle$: In the case of the homopolymer, the $\langle\langle\eta\rangle^2\rangle = f(c)$ plot levels off at $c > c^*$ (Fig. 3, curve *2*'), and the $\langle\langle\eta\rangle^2\rangle = f(c)$ plot shows a clearly pronounced extremum in the case of the copolymer at $c \sim 0.2–0.4$ % [1].

The decrease in the optical anisotropy, suggested by the flow BR studies for PAMPS in 0.1 $NaNO_3$ solution at $c \sim 0.35–0.50$ % and the subsequent attainment of saturation (Fig. 4b, curve *1*) may be due to a greater hindrance to the mutual orientation of the segments at increased polymer concentration.

Our data on the flow BR for the systems PAMPS–0.1 M $NaNO_3$ solution and P(AMPS–AA)–0.1 M $NaNO_3$ solution suggest that the second extremum in the $[\Delta n/(g\eta_0 c)]_{g\to 0} = f(c)$ plot for P(AMPS–AA) (Fig. 4b, curve *2*) is due to the copolymeric nature of the polyelectrolyte.

CONCLUSIONS

(1) The flow birefringence, light scattering, and viscometric studies revealed the structural features of semidilute solutions of high-molecular-weight rigid-chain polyelectrolyte, poly-2-acrylamido-2-methylpropanesulfonic acid, at varied ionic strength of the medium and polymer concentration.

(2) In the case of suppressed electrostatic interactions (I = 1 M) in PAMPS solutions at $c > c^*$, a fluctuation network of engagements is formed. Its morphology differs from that of the fluctuation network forming in solutions of copolymer of 2-acrylamido-2-methylpropanesulfonic acid with acrylamide. In the latter case, the network formation is accompanied by formation of microdomain structures that are, essentially, mutually oriented macromolecular segments.

(3) Comparison of the results of the flow birefringence studies for semidilute solutions of high-molecular-weight polyelectrolytes of different structures in 1 M $NaNO_3$ solution showed that the network formation in polyelectrolyte solutions is affected by the equilibrium rigidity of poly ions.

(4) An assumption is made that, at I = 0.1 M and $c > c^*$, disordered fluctuation microstructures (microdomains) are formed in solutions of poly-2-acrylamido-2-methylpropanesulfonic acid which are capable of hydrodynamic field-induced orientation.

(5) The flow birefringence studies revealed the morphological differences for the systems poly-2-acrylamido-2-methylpropanesulfonic acid–0.1 M $NaNO_3$ solution and copolymer of 2-acrylamido-2-methylpropanesulfonic acid with acrylamide–0.1 M $NaNO_3$ solution. These differences are due to the structural features of the polymers.

Abstract—The reaction of fullerene C_{60} with polyamido acid in the stage of its conversion into polyimide was studied by complex thermal analysis. The thermal and kinetic characteristics of this reaction and its probable mechanisms are discussed.

Fullerenes attract the researchers' attention from not only theoretical, but also applied standpoints. Addition of fullerenes C_{60} and C_{70} or their mixtures to finished polymer or in the stage of its formation significantly affect the product characteristics and the polymerization mechanism [1–7]. The effects revealed suggest a polyfunctional role of fullerenes in polyolefin formation.

To proceed with these studies, we examined the effect of fullerenes on the formation of polymers of the polycondensation type, for the example of well-studied polyimides. It is well known that polyimides are formed in two stages. In the first stage, the starting compounds, tetracarboxylic acid dianhydrides and diamines, react in an aprotic polar solvent to form polyamido acid (PAA). In the second stage, dehydration and polycondensation occur under the action of various reagents or upon heating. These reactions are usually monitored by spectral or thermal analysis [8, 9]. These methods are fairly sensitive to quantitative or qualitative changes in the reaction system under the action of any external factors.

In this study, we mainly used calorimetry (differential scanning calorimetry, DSC) and thermal gravimetric analysis (TGA), with account of the kinetic and diffusion factors of polyimide formation.

EXPERIMENTAL

Pyromellitic dianhydride and diaminodiphenyl ether were used as the starting compounds. These reagents were purified by the standard procedure [8].

Since the aim of this work was to determine the time parameters of stabilization of PAA solutions [10], samples were withdrawn for analysis in the first 6–8 days of keeping the initial PAA solution of PAA under the identical conditions at room temperature.

As modifying additives to PAA solution we used fullerene C_{60} purified to 99% and partially cyclized polyacrylonitrile (*m*-PAN) [10], in which 40% of nitrile groups were converted to imine groups to form short ladder structures along the macromolecule. To prepare mixtures, a calculated amount (by weight) of C_{60} powder or jointly ground dry mixture of *m*-PAN and C_{60} in a required ratio was added to a DMF solution of PAA as polyimide (20%) precursor. After stirring for 10 min, the homogeneous mixtures were kept for a certain time (3 h, 1 day, etc. up to 8 days) at room temperature for stabilization and from subjected to thermal analysis. Each experimental series was completed by analysis of films produced from the solution of the mixture with finite aging time. For the system PAA + *m*-PAN + C_{60} (79 : 20 : 1, %) a thermogram of the film produced from the freshly prepared mixture was obtained. In parallel, the thermal behavior of *m*-PAN in solution was studied.

Thermal analysis was carried out on a Noetsch complex thermal analyzer (Germany) at a heating rate of 10 deg min^{-1} and weighed portion of 5 mg; and thermovolumetric analysis, on a TVA installation, heating rate 10 deg min^{-1}, pressure 5×10^{-3} mm Hg, and weighed portion 20 mg.

As shown previously [11, 12], thermal analytical study of a series of thermal and thermochemical processes of PAA formation and its conversion to poly-

imide gives the greatest body of data when quantitative and qualitative measurements are performed directly in the cell of the corresponding device. The DSC curves of PAA solution in DMF, measured in during PAA stabilization in the temperature range 20–400°C, are shown in Fig. 1. The general shape of these curves reflects the main features of thermal effects accompanying the transformation of PAA solutions, up to the temperature of thermal degradation of the resulting polyimide. At the beginning of solution heating, the heat capacity of the sample decreases owing to evaporation of the "free" solvent (unbound to PAA). The inflection in the curve at 60–70°C corresponds to the onset of solvent removal from the solvate shell of PAA, whose formation mechanism has been discussed previously [13, 14]. Subsequent thermal degradation of the solvate complex and imidization of PAA, accompanying this process, are manifested in the DSC curve as an asymmetrical endothermic peak in the range 105–111°C. The pattern observed in this range depends on the time of solution stabilization. Sample no. 1 differs from the other samples in the lack of an inflection in the DSC curve at 60–70°C and presence of a noticeable endothermic peak of water evolution at 133°C. These distinctions suggest that the formation of the stable solvate shell of PAA is complete within 2 days. An interesting feature of the thermal processes in the temperature range studied is the presence of significant endothermic effects for all PAA samples (curves *1*–*5*) with peaks in the range 287–292°C. Since, after heating to 160°C no weight loss is observed, according to the TGA data, up to 500°C, the above endothermic effects can be assigned to the melting of ordered domains of the resulting polyimide. It is most likely that there are mesomorphic structures extremely sensitive to the conditions of sample heating, which is confirmed by the absence of this effect in the case of a film of the same PAA, prepared under some other conditions (curve *0*), and also by noticeably different height and temperature of the peak in the DSC curves for a similar sample kept for 8 days (curve *6*).

The above distinctions show that the structure of PAA and its complexes with solvent is fairly labile and depends on the conditions of PAA synthesis and storage. These factors also have a pronounced effect on the characteristics of the resulting polyimides and their conversion at elevated temperatures [15]. In this connection, PAA solutions have been repeatedly used in practice as reactive components for synthesis of new heat-resistant composite materials. Their reactions with various monomers and polymers were confirmed by complex methods of thermal and spectral

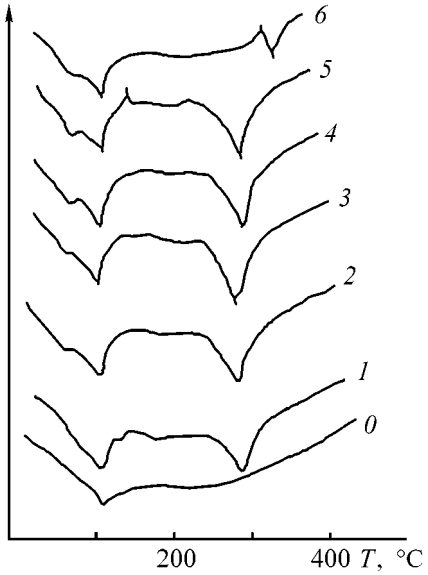

Fig. 1. DSC curves of PAA solution in DMF. (*T*) Temperature; the same for Fig. 3. Keeping time at room temperature, days: (*1*) 3 h, (*2*) 2, (*3*) 3, (*4*) 4, (*5*) 5, and (*6*) 8; (*0*) PAA film.

analysis [16]. In this study, we used as additional components fullerene C_{60} and modified PAN with partial cyclization along the chain.

We first studied the effect of fullerene C_{60} added to PAA solution in amounts of 0.3 and 5.0 wt %. Comparison of the DSC curves obtained under conditions similar to those for analysis of straight PAA did not reveal any significant changes. Irrespective of the C_{60} amount, the same endothermic effects in the temperature ranges 60–70°C and 105–110°C are observed, characterizing the evaporation of the solvent, decomposition of the solvate complex, and release of water with conversion of PAA to polyimide. Small variations of the peak temperatures and areas are independent of fullerene addition. The same is true for the parameters of peaks at approximately 300°C, which are less pronounced than those for straight PAA and do not allow any conclusions about the effect of C_{60} on the structural rearrangements of the polyimide.

When considering the kinetics of evolution of volatile products formed in heat treatment of PAA solution with and without fullerene (Fig. 2), monitored by thermal volumetric analysis (TVA), we can follow a regular trend in the removal of the solvent, bound and unbound to PAA macromolecules. With C_{60}-containing PAA solutions kept for more than 2 days, a splitting of the solvent evolution peak is clearly pronounced. According to calculation of the matter balance, the first peak in curves *2*′ and *3*′ at 60–70°C

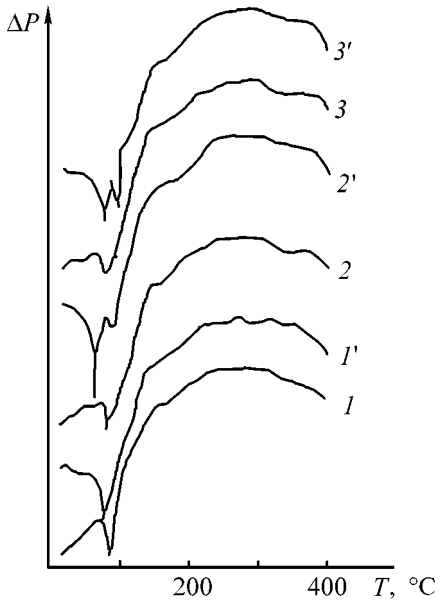

Fig. 2. TVA curves of the solution of PAA in DMF. (ΔP) Rarefaction and (T) temperature. Time of keeping at room temperature (days): (*1*, *1*') 3 h, (*2*, *2*') 2, and (*3*') 3. (*1*'–*3*') In the presence of 5% C_{60}.

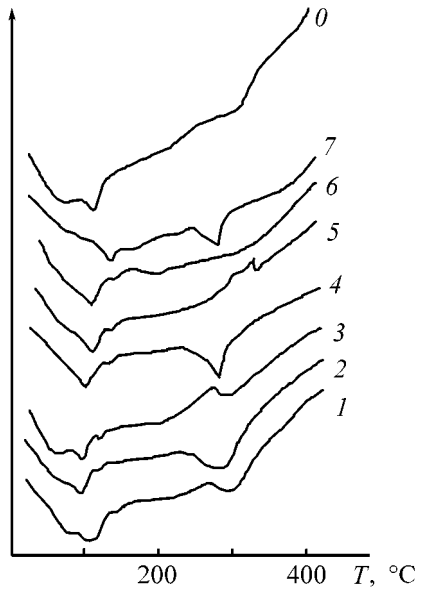

Fig. 3. DCS curves of solution of PAA in DMF + 1.0% C_{60} + 20% *m*-PAN. Time of keeping at room temperature (days): (*1*) 3 h, (*2*) 2, (*3*) 3, (*4*) 4, (*5*) 5, (*6*) 6, and (*7*) 10; (*0*) solution of *m*-PAN.

is assigned to evolution of the solvent unbound to PAA, and the second peak at 85–90°C, to evolution of DMF from its complex with PAA. It is evident that, under conditions of thermal decomposition in a vacuum, fullerene exerts a certain effect on the structural rearrangement of the PAA–solvent complex. A splitting of the peak is observed for curves *1*'–*3*' and not observed for curves *1*–*3*. It should be noted that solvent removal begins immediately after the start of heating. Without special crystallographic studies we cannot explain the mechanism of the effect of fullerene in this stage, but the occurence of this effect is an indisputable fact. As regards the cyclodehydration of PAA, in which water is evolved, the maximum effect is observed as evidenced by calorimetric data (Fig. 1) and the matter balance (Fig. 2),, at approximately 150°C. However, there are certain distinctions in this case, too, especially in the TVA curves. For example, according to DSC analysis, the endothermic effect of cyclodehydration after 2 days of stabilization of PAA solution almost coincides with the endothermic effect of decomposition of the solvate complex PAA-DMF, whereas TVA shows that these processes noticeably differ in temperature. In addition, it is seen that the presence of C_{60} shifts the cyclodehydration peak to higher temperatures by approximately 20–30°C. Under these conditions, fullerene is able not only to form complexes with CO and NH_2 groups of PAA but also to react with carboxy groups. The complexation promotes evolution of the solvent in thermal treatment of PAA in the presence of C_{60}, and chemical reaction of fullerene with carboxy groups hampers imidization.

The parameters of thermal conversion of PAA to polyimide change to a greater extent when *m*-PAN is added, along with C_{60}, to PAA solution. Typical DSC curves of the PAA + *m*-PAN + C_{60} mixture are shown in Fig. 3. When comparing DSC curves in Figs. 1 and 3, we can conclude that addition of partially cyclized PAN to PAA solution affects the activity of the system in both the first and second stages. It is likely that the differences observed are caused by the formation of PAA–*m*-PAN compositions whose activity in complexation has been demonstrated previously [17]; they react with C_{60} to form additional bonds.

CONCLUSION

The effect of fullerene C_{60} added to the polyamido acid derived from pyromellitic anhydride and diaminodiphenyl ether on its thermal conversion to polyimide was studied by complex thermal analysis. It was found that C_{60} affects some kinetic parameters of this reaction, especially when it is activated with modified polyacrylnitrile.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Plasticization of Polyvinyl Chloride with Reclaimed Polyvinyl Chloride–Polyurethane Mixture

O. P. Grigor'eva, L. V. Stepanenko, and L. M. Sergeeva

Institute of Chemistry of Macromolecular Compounds, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received July 13, 2001

Abstract—The feasibility was studied of plasticization of rigid polyvinyl chloride with a reclaimed polyvinyl chloride–polyurethane mixture yielded by thermomechanochemical degradation of wastes of polyurethane foam coated with a polyvinyl chloride film. The molecular-weight distribution of the polyurethane component, temperatures of phase transitions, and physicomechanical properties of the polymer systems were studied as influenced by the preparation temperature of the reclaim.

It is well known that polyvinyl chloride (PVC) is for the most part used in the plasticized form. The most widely used plasticizers are low-molecular-weight polar substances of the ester nature, such as, e.g., dioctyl phthalate (DOP), dioctyl sebacate, (DOS), etc. However, low-molecular-weight plasticizers make the properties of the resulting PVC unstable owing to migration of the plasticizer in the bulk of the material and its gradual exudation. In this context, much attention has been recently given to plasticization of PVC with high-molecular-weight compounds and polyurethanes (PUs), in particular, [1–6]. Even in the case of fast segmental diffusion, the polymer plasticizer molecule cannot leave the material surface, which ensures more stable properties of the material. The structural features and the properties of a number of compositions based on PVC/PU mixtures were studied in [2–6]. Also, plasticization of PVC with reclaimed PU was attempted with the aim of preparing materials suitable for sound proofing, pipeline facing, shoemaking, medicine, house-building, etc. [1].

The previous studies of the degradation of secondary PUs in an extruder showed that the products of inexhaustive degradation can be used for preparing polymer materials suitable for diversified applications [7–10]. These studies were concerned with individual polyurethane foams (PUFs) differing in degree of cross-linking (wastes from PUF production, automobile parts, furniture, shoes, etc.).

In this study, we analyzed the possibility of reclaiming a secondary PUF coated with a PVC film (wastes of sound-proofing materials) by thermomechanochemical degradation in an extruder, and also the suitability of the polymer mixture yielded by degradation (PVC/PU reclaim) for plasticizing rigid PVC. We also studied the properties and the phase structure of the plasticized PVC as influenced by the preparation conditions and the concentration of the PVC/PU reclaim introduced.

EXPERIMENTAL

We studied crushed wastes of elastic PUFs coated with a PVC film (10 × 10 × 10 mm crumb). Polyurethane foam was essentially polyesterurethane prepared from an ester (molecular weight M = 2200) and toluylene diisocyanate (TDI, a 65/35 isomer mixture). The trifunctional nature of the initial ester (based on adipic acid, diethylene glycol, and trimethylolpropane) and proper reactant ratio afforded sufficient degree of PUF cross-linking. The PVC film for PUF coating was prepared from rigid PVC (resin) plasticized with commercial plasticizers DOP and DOS. The degrading agent was a mixture of monoethanolamine (MEA) and potassium acetate (PA). The composition and the component ratio for the polymer systems are presented in Table 1.

For thermomechanochemical degradation of PVC–PUF wastes we utilized a mixture of degrading agents in a single-worm laboratory extruder. Prior to being fed into the charging bin of the extruder, the crushed wastes were treated with a mixture of degrading agents. The specially chosen parameters, namely, the geometry of the worm, the temperature gradient

1070-4272/02/7502-0296 $27.00 © 2002 MAIK "Nauka/Interperiodica"

along the worm, and the type and concentration of the above mixture allowed simultaneously partial thermomechanochemical degradation, homogenization, and plasticization of the material being processed. The temperature gradient $T_{in} - T_{end}$ along the worm was varied from 130–170 to 180–200°C. The worm rotation rate was set constant at 35 rpm. The time of material processing in the extruder was 2–4 min. The resulting PVC/PU reclaim was a homogeneous thermoplastic mixture of PVC and PU suitable for subsequent use without further purification or fractionation.

Plasticization of PVC was effected by mixing rigid PVC with commercial plasticizers (DOP : DOS = 2 : 1) and/or PVC/PU reclaim in certain proportions in dimethylformamide solution (10% solution). Films were prepared by casting the polymer solutions onto Teflon supports, followed by solvent evaporation and vacuum treatment of the films to constant weight.

The molecular weights and molecular-weight distributions for PU in the reclaim obtained under various temperature gradients in the extruder were determined by exclusive chromatography on a Du Pont (USA) installation for liquid chromatography in the UV region, with tetrahydrofuran as the solvent. A reference PU sample was synthesized from the same initial polyester P-2200 and excess TDI; the terminal isocyanate groups of the resulting PU were converted to urethane groups by reaction with methanol.

We studied the viscoelastic properties of the films of polymers and polymer blends by DMTA. The measurements were carried out for samples stretched at a frequency of induced sinusoidal vibrations equal to 100 Hz in the temperature range from –130 to +100°C at sample heating rate of 1 deg min^{-1}. The sample size was $5 \times 50 \times 1.0$ mm.

The thermal properties of the samples were studied by DSC on a Mettler TA 4000 calorimeter in the range from –100 to +250°C under nitrogen at sample heating rate of 20 deg min^{-1}.

The tensile strength and relative elongation of the films were measured on an FU-1000 tensile-testing machine at 25°C and sample stretching rate of 50 mm min^{-1}. The sample size was $5 \times 40 \times 1.0$ mm.

The intrinsic viscosity of PVC in cyclohexanone [η] was determined at 25°C.

It is known that, in thermal degradation of densely cross-linked PUF (e.g., semirigid PUF) in the absence of degrading agents, the secondary and main chemical bonds of the polymer chains in PUF are ruptured at high temperatures, 230–250°C [7]. Thermal oxidative degradation of PVC begins upon heating to 120–140°C and is accompanied by partial dehydrochlorination and formation of a conjugated double bond system in the main chain. This substantially improves the thermal stability of PVC, but deteriorates the physicomechanical properties of the polymers [6]. Bowden *et al*. [6] found that, in the case of thermal degradation of PUF coated with a PVC film, dehydrochlorination to give polyenes in PVC at the PUF–PVC interface proceeds at a rate exceeding 6–8-fold that at the air–PVC interface, and this process is accelerated by the residual amine catalyst utilized in synthesis of PUF.

Table 1. Initial materials

Composition	Component content, wt fraction
PVC/PUF composite (sound-proofing material wastes)	46/54
PVC film [0–55 brand, GOST (State Standard) 5960–72–PVC resin	100
Plasticizer:	
DOP	27
DOS	14
Special additives (carbon black, antioxidants, thermostabilizers, etc.)	9
PUF (EShZ brand, TU (Technical Specifications) 6-55-50–90:	
polyester P-2200	100
TDI	38
special additives (catalyst, foam stabilizer, etc.)	7
Formulation for extrusion, PVC/PUF composite	100
Mixture of degrading agents:	
MEA	6
PA	1

Of great importance in this regard is the proper selection of conditions for extrusion of the PVC : PUF composite, so as to ensure cleavage of cross-links in PUF with minimal degradation of the main polymer chains of both polymers (worm design, temperature condition, extrusion rate, chemical nature and concentration of the degrading agents).

Being thermoplastic, the PVC film contained in the PVC/PUF composite studied is easily processed in extruders, and thermostabilizers and antioxidants from the initial formulation favor preservation of the service properties of PVC subjected to energy

Table 2. Influence of extrusion conditions on the intrinsic viscosity of PVC film

PVC : DAM ratio, wt fraction : wt fraction	T_{in}–T_{end}, °C	[η], dl g^{-1}
100 : 0	–	0.56
100 : 0	160–175	0.61
100 : 7	160–175	0.58
100 : 7	170–190	0.57

Table 3. Molecular-weight distribution for PU in the reclaim under different temperature conditions of PVC/PUF composite extrusion

T_{in}–T_{end}	M_n	M_w	M_z	M_w/M_n
130–175	89 100	94 200	108 000	1.06
160–175	81 500	92 600	96 100	1.13
170–180	35 300	46 700	64 100	1.32
180–200	34 000	35 800	37 800	1.05

impact in the extruder for relatively short time. The presence of PUF and degrading agents can accelerate PVC degradation. Table 2 presents the intrinsic viscosities of PVC measured after extrusion under different conditions; it is seen that the intrinsic viscosity of PVC and, hence, its molecular weight, are virtually unaffected by the process temperature and the presence of degrading agents. Certain increase in the intrinsic viscosity of PVC after extrusion may be due to loose cross-linking of its chains, in agreement with the DMTA results.

Let us consider how the extrusion conditions for the PVC/PUF composite affect the properties of its second component, elastic PUF. The composition and the reactant ratio of the composite are such that it has a looser network of cross-links compared with semirigid and rigid PUFs [11]. This allows partial thermal degradation of the composite under the actual conditions at moderate temperature, which yields a soluble polymeric product suitable for processing.

Table 3 presents the molecular-weight distribution for PU in the reclaim as dependent on the extrusion temperature for the PVC/PUF composite. It is seen that the products obtained are linear polymers with fairly high molecular weights. With increasing processing temperature, the absolute values of M_n, M_w, and M_z tend to decrease. Table 3 shows that all the PU samples obtained are polydisperse ($M_w/M_n > 1$). It is seen that the polydispersity of PU tends to grow with increasing the processing temperature initially, but at the maximal processing temperature (180–200°C) it takes the minimum value. This involves, however, a decrease in the molecular weight by a factor of 2.6–2.8, and the parameters M_n, M_w, and M_z become virtually identical. The high molecular weights of PU (M_n, M_w, and M_z) and its narrow molecular-weight distribution ($M_w/M_n \approx 1$) must impart good mechanical properties of the materials on their base.

Thus, data in Tables 2 and 3 suggest that, under the actual extrusion conditions, the main chemical transformations in the PVC/PUF composite involve elastic PUF. Thermal degradation of semirigid PUF occurs primarily at 230–250°C (in extruder). When degrading agents are used, the temperature for degrading the PUF polymer chains is decreased to 200–220°C, which yields oligomeric reactive products (viscous liquids or pastes). These are essentially mixtures of oligocarbamateureas with the initial oligoester, from which PUF was obtained [10].

Extrusion of elastic PUF under the actual conditions yields, even at 130–175°C, linear polyurethaneureas with fairly high molecular weights which are compatible with other polymers and suitable for conventional processing. Table 3 shows that, with the extrusion temperature increasing from 180 to 200°C, the degradation of elastic PUF gets somewhat more profound. The inexaustive degradation products are, most probably, of polyesterurethane nature and contain carbamateurea moieties in the chain [12].

We also analyzed the suitability of the PVC/PU reclaim as plasticizer for rigid PVC. As known, the main effect exerted by plasticizers, both low-molecular-weight and polymeric, consists in their interaction with segments of macromolecules of the main polymer, which ensures a prompter viscoelastic response of the polymer to mechanical impact [13]. Thus, plasticizers increase the molecular mobility of polymer chains and decrease the glass transition point T_g. Therefore, it was of interest to study how the conditions of preparation of the PVC/PU reclaim affect the segmental mobility and the phase transition temperatures of the reclaim constituents, PVC and PU. The DMTA and DSC methods provide exhaustive information about specifically these changes in polymer blends.

Figure 1 presents the temperature dependences of the tangent of the mechanical loss angle tan δ and the elasticity modulus E' of the samples of the initial and extruded PVC, and those of the PVC/PU reclaim obtained at various temperature gradients in the extruder. Table 4 presents the phase transition temperatures for these samples.

The initial PVC has a single T_g (53°C), as judged from the single broad maximum of the mechanical loss angle in the temperature dependence of tan δ (Fig. 1, curve *1*) and the single transition observed in the $E' = f(T)$ plot. The significant width of the tan δ maximum and the decrease in the T_g, compared with nonplasticized PVC ($T_g \cong 80$°C [13]), is known to be due to the presence of the plasticizer in PVC. Also, a secondary relaxation transition is observed in the range from –80 to –30°C, whose mechanism remains to be fully elucidated. It is believed, e.g., that it is due to degradation of the interchain hydrogen bonds [14]. The temperature dependence of tan δ for PVC processed in the extruder (Fig. 1, curve *2*) is virtually identical to that for the initial PVC with only T_g somewhat increased (Table 4), which is probably due to loose cross-linking of PVC during processing.

The temperature dependences of tan δ for the PVC/PU reclaim exhibit three partially overlapping maxima (Fig. 1, curves *3*, *4*). The temperature dependences of the elasticity modulus are indicative of the corresponding transitions. The first low-temperature maximum of tan δ corresponds to T_g of PU, and the second and third maxima, to temperatures intermediate between the glass transition points for PU and PVC. The last fact suggests formation of mixed microphases enriched in PU and PVC, respectively (Table 4). It was impossible to determine T_g for the PVC component by DMTA, as the PVC/PU reclaim samples investigated soften upon stretching and rupture at $T \geq 40$°C. Therefore, we conducted DSC studies and found that T_g of the PVC component tends to decrease (unlike individual PVC, Table 4). Thus, the glass transition points for PU and PVC components tend to approach each other. This suggests a better compatibility of PVC and PU in the PVC/PU reclaim.

Figure 1 (curves *3* and *4*) also suggests that the temperature corresponding to the tan δ maximum remains virtually unchanged with increasing temperature of PVC/PU reclaim preparation. However, the kinetic mobility of the macromolecular segments, especially in the microphase enriched in PU, grows, as evidenced by a significant increase in the tan δ peak height (Fig. 1, curve *4*). This is due to a decrease in the molecular weights and widening of the molecular-weight distribution for the polyurethane component of the reclaim owing to a higher degree of PUF degradation (Table 3).

Figure 2 presents thermograms (DSC data) for the initial PVC film and for PVC/PU reclaim obtained under varied temperature conditions. Table 4 presents the phase transition temperatures for these samples. The thermogram of the initial PVC film (curve *1*) is indicative of two main transitions, one corresponding to T_g of PVC (63°C) and the other, to the melting point of PVC (236°C).

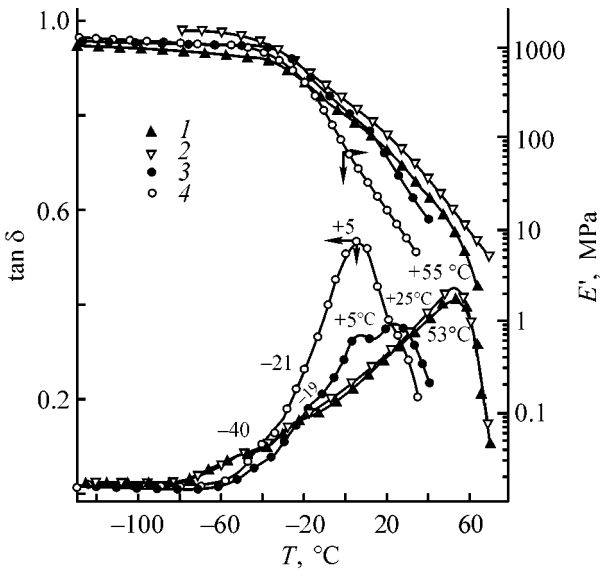

Fig. 1. Temperature dependences of the tangent of the mechanical loss angle tan δ and the elasticity modulus E', of (*1*) initial PVC, (*2*) PVC after extrusion at 130–175°C, and (*3*, *4*) PVC/PU reclaim. Temperature gradient in the extruder, °C: (*3*) 130–175 and (*4*) 160–175.

Let us analyze the thermograms of the PVC/PU reclaim obtained under varied temperature condi-

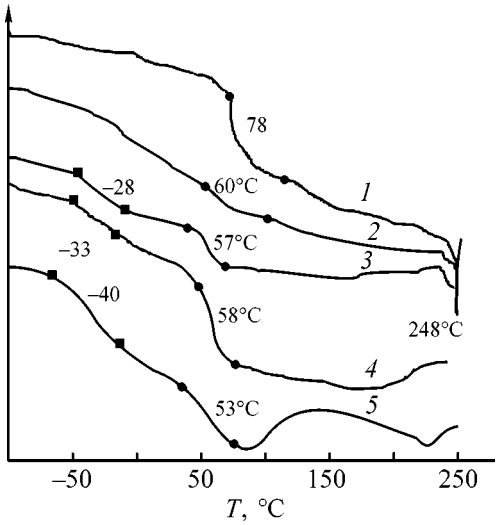

Fig. 3. Thermograms of plasticized PVC. Rigid PVC : polymer reclaim : DOP/DOS ratio: (*1*) 100 : 0 : 0, (*2*) 100 : 0 : 40, (*3*) 100 : 20 : 20, (*4*) 100 : 40 : 0, and (*5*) 0 : 100 : 0.

tions (Fig. 2, curves *2*, *3*). Both curves are indicative of two main transitions corresponding to the glass transition points of the PU and PVC components (Table 4). Also, graphical differentionation of the curves allows identification of less pronounced transitions corresponding to the glass transition points of mixed microphases enriched in the PU and PVC components (Table 4). These results reasonably agree with the DMTA data, and the difference in the absolute values of the glass transition points may be due to different heating rates of the samples (1 and 20 deg min^{-1} for DMTA and DSC, respectively).

Raising the temperature of the PVC/PU reclaim preparation virtually does not affect the T_g of PU, but lowers that of PVC from 59 to 53°C. Thus, the DSC data confirm the conclusion, made on the basis of the DMTA data, about partial mixing of the PVC/PU reclaim components during its preparation and improved compatibility of PU and PVC in the reclaim after rising temperature of its preparation.

Table 5. Glass transition point for the polymer components (DSC data) and physicomechanical properties of plasticized PVC

Rigid PVC : PVC/PU reclaim : DOP/DOS ratio	T_g, °C		Tensile strength, MPa	Relative elongation, %
	PU	PVC		
100 : 0 : 0	–	78	83.1	50
100 : 0 : 40	–	60	65.0	480
100 : 20 : 20	–28	57	68.6	490
100 : 40 : 0	–33	58	80.1	380
0 : 100 : 0	–40	53	16.2	350

Also, the thermograms of the PVC/PU reclaim suggest the following. First, the lack of a peak corresponding to the melting point of the crystalline phase of PVC in both the thermograms may be due to retardation of crystallization by the microphase structure formed in the PVC/PU reclaim because of a limited compatibility of its components and by formation of mixed microphases enriched in PVC or PU. Second, at $T \geq 100$°C the system undergoes afterpolymerization, as evidenced by ascending exothermic curves. Probably, this is due to polymerization of reactive oligomers yielded by thermomechanochemical degradation of the PVC/PU composite.

As known [13], to be suitable as polymer plasticizer for rigid PVC, the PVC/PU reclaim must (i) have $T_g << T_g$ of PVC, (ii) have a sufficiently high molecular weight so as to be classed as "polymer" ($M_n >$ 5000), and (iii) mix well with PVC (at the molecular or segmental level). Our experimental data suggest that the PVC/PU reclaim prepared by us satisfies all these requirements. Also, it contains impurity low-molecular-weight plasticizers DOP/DOS (entering into composition of the initial composite), which improves the miscibility of the components and the material processed.

Figure 3 presents the thermograms, and Table 5, the characteristics of the plasticized PVC (sample of

the PVC/PU reclaim prepared at 160–175°C). The concentrations of the plasticizers DOP and DOS do not include their content in the reclaim. It is seen that the PVC/PU reclaim lowers the T_g of PVC similarly to low-molecular-weight plasticizers DOP/DOS. The fact that the glass transition points for PU and PVC approach each other in the plasticized PVC suggests a decreased degree of segregation in the system. Table 5 shows that addition of reclaimed polymer plasticizers to rigid PVC improves the physicomechanical properties of the resulting material.

CONCLUSIONS

(1) The feasibility is demonstrated of reclaiming secondary polyurethane foam coated with polyvinyl chloride film by thermomechanochemical degradation in extruder. This yields a homogeneous reclaimed polymer mixture polyvinyl chloride–polyurethane, suitable as thermoplastic.

(2) The resulting mixture is both an efficient plasticizer and a modifier of the properties of rigid polyvinyl chloride. By varying the extrusion conditions for the initial material it is possible to modify the microphase structure and to achieve the desired mechanical properties of the reclaimed polyvinyl chloride–polyurethane mixture and, hence, those of plasticized polyvinyl chloride.

(3) Our results can be used not only for utilizing the wastes of polyurethane foam coated with polyvinyl chloride film, but also for saving the initial materials and improving the properties of polymer materials.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymerization of Methyl Methacrylate in the Presence of *N*-Acetyl-ε-aminocaproic Acid Acetylamide

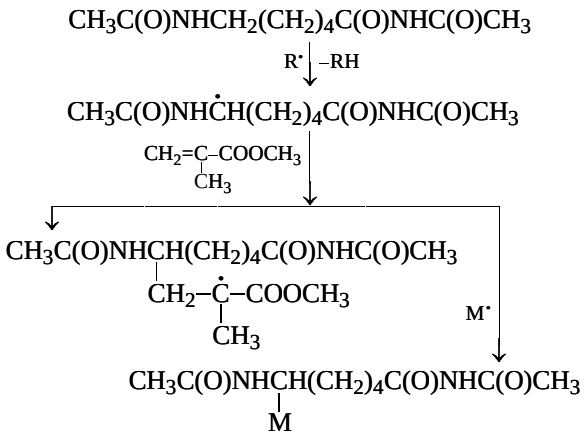
Abstract—The effect of *N*-acetyl-ε-aminocaproic acid acetylamide on radical polymerization of methyl methacrylate initiated with lauroyl peroxide was studied.

To impart new service properties, vinyl polymers are often modified with polymeric fragments containing heteroatoms. One of such modifying agents is polycaproamide (PCA), which is widely used in the fiber production. Upon prolonged storage in air, especially at elevated temperatures and on treatment with ozone, PCA is oxidized to form peroxy groups. Through these groups various vinyl monomers can be grafted to PCA, giving polymers with new service properties [1, 2].

To evaluate the mechanism of graft polymerization, we studied the effect of compounds with amide-containing fragments, namely *N*-acetyl-ε-aminocaproic acid acetylamide (DAPAC), on the polymerization kinetics and properties of vinyl monomers for the example of methyl methacrylate (MMA). DAPAC was prepared according to [3] by successive transformation of *N*-acetyl-ε-aminocaproic acid into acid chloride, amide, and then DAPAC. It is known that addition of some polar fragments to polymethyl methacrylate allows preparation of polymers with high thermal stability and light fastness [4].

The kinetic features of MMA radical polymerization in the presence of DAPAC with lauroyl peroxide initiator were studied by dilatometry [5]. Polymerization did not occur on heating of the reaction mixture at 333–353 K for 2–6 h at DAPAC concentration of $(1.75–43.3) \times 10^{-4}$ mol dm^{-3}, but occurred at DAPAC content decreased to $(0.5–1.7) \times 10^{-4}$ mol dm^{-3}.

The presumed role of DAPAC in polymerization can be illustrated by the following scheme:



In the presence of oxygen, formation of peroxy radicals and their participation in chain polymerization reactions are possible [6].

The kinetic parameters of MMA polymerization in the presence of lauroyl peroxide and DAPAC are listed in Table 1. Our data show that the initial rates of formation of modified PMMA are higher than those in the absence of DAPAC. The apparent rate constants of MMA polymerization in the presence of DAPAC at low (7.6%) and high (51.9%) conversions can be described by the following equations:

$$K_1 = 6.1 \times 10^{-3}\exp(-75\,000/RT), \quad (1)$$

$$K_2 = 2.0 \times 10^{-3}\exp(-122\,000/RT), \quad (2)$$

where R is the universal gas constant, 8.314 J mol^{-1} K^{-1}.

The apparent rate constants and activation energies at low conversions are similar to those determined

1070-4272/02/7502-0302 $27.00 © 2002 MAIK "Nauka/Interperiodica"

previously. At higher MMA conversion the process decelerates and its activation energy increases. Polymerization of MMA in the presence of DAPAC proceeds more uniformly, and the gel effect V_{max}/V_0 decreases nearly tenfold.

As seen from Table 1, polymerization of MMA in the presence of DAPAC proceeds in the initial stage at higher rates, and the induction period of this process (τ = 720 s) is significantly smaller as compared with that in MMA polymerization without additive (τ = 1020 s) (Table 2). It should be noted that, with increasing DAPAC concentration, the induction period decreases to 60 s. This is probably due to an increase in the concentration of free radicals initiating polymerization. Free radicals can arise in oxidation of DAPAC by oxygen to form peroxy groups. This reaction readily occurs at elevated temperatures due to the presence of labile hydrogen atom in ε-aminocaproic acid. These peroxy groups readily decompose, yielding active radicals [6].

As seen from Table 2, the molecular weight of polymers decreases from 7×10^5 to 0.9×10^5 with the content of DAPAC increasing from 0 to 1.7×10^{-4} mol dm^{-3}. This decrease in the molecular weight of polymers with increasing DAPAC concentration is probably due to the fact that at higher conversions there occurs chain transfer to the DAPAC molecule with the formation of a less-reactive radical (as compared with primary radicals), which decelerates polymerization. In this case, the ratio of the rate constants of chain termination K_t and chain propagation K_p decreases nearly twofold (K_t/K_p = 0.025 [6–8]).

The presence of DAPAC fragments in the polymer macromolecule is confirmed by the presence of the absorption bands typical of amide groups in the IR spectra [9], whereas in the IR spectrum of unmodified PMMA such bands are absent.

The parameters characterizing the thermal stability of PMMA prepared are listed in Table 3.

As seen from Table 3, addition of DAPAC to the polymerization mixture increases the temperature of the polymer degradation by 5–29°C at concentrations of $(0.5–1.7) \times 10^{-4}$ mol dm^{-3}, respectively.

EXPERIMENTAL

The effect of DAPAC on the polymerization of vinyl radicals was studied by dilatometry. Methyl methacrylate was washed with 2–3% sodium chloride solution to remove hydroquinone and with distilled water to neutral reaction for at least 2 h, and dried

over zeolites calcined at 623 K. Immediately before polymerization, methyl methacrylate was distilled in an argon atmosphere. Then lauroyl peroxide (0.4 wt %) and DAPAC [$(0.5–1.7) \times 10^{-4}$ mol dm^{-3}] were added to the freshly distilled monomer. Nitrogen was bubbled through the resulting solution and the ampules were sealed and placed in a thermostat heated to a required temperature. The kinetics of MMA polymerization was studied by dilatometry in 5-cm^3 glass ampules in the 333–353 K range; the temperature was maintained with an accuracy of 0.1 K. The measurements were performed using a KM-6 cathetometer.

The intrinsic viscosity of polymers η was determined in chloroform at 293 K using a viscometer. The viscosity-average molecular weight was calculated using the following equation [10]:

$$\eta = 0.60 \times 10^4 M^{0.79}.$$

The thermal oxidative degradation of the resulting copolymers was studied by thermal analysis using an MOM derivatograph (100 mg sample, Al_2O_3 reference, 10 deg min^{-1} heating rate, 1/5 DTA sensitivity).

The IR spectra in chloroform were recorded on a Specord M-82 spectrometer.

CONCLUSION

In the initiation stage of methyl methacrylate polymerization, addition of *N*-acetyl-ε-aminocaproic acid acetylamide sharply raises the process rate owing to generation of a large amount of free radicals, which is accompanied by a decrease in the induction period. The ratio of the rate constants of chain termination and chain propagation in the presence of *N*-acetyl-ε-aminocaproic acid acetylamide decreases by half as compared with the reaction without the additive. The resulting polymethyl methacrylate is characterized by smaller molecular weight and higher thermal stability.

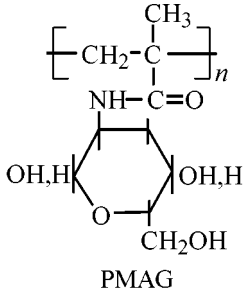
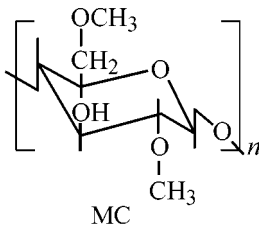
Abstract—The characteristics of dilute (0.1%) and moderately concentrated (2%) aqueous solutions of methyl cellulose, polymethacrylamidoglucose, and their blends, and also the composition of films based on them were studied by viscosimetry, rheology, and IR spectroscopy. The effect of the mixture composition on the conditions of gel formation in methyl cellulose solutions was studied.

Structural modification of polymers by combining two polymers with different structures in the same solvent is used for production of polymer blends with controllable characteristics. Depending on the chemical composition, rigidity of macromolecular chain, degree of polymerization, and solvent type, the polymers to be blended can form in solution stuctures of various organizations and stabilities. Data are available on the formation of intermolecular structures in polymer systems with components differing in the thermodynamic rigidity of chain: polyacryl acid + methyl cellulose (MC) and polyacrylamide + hydroxyethyl cellulose in aqueous solutions [1, 2]. These data suggest the possibility of purposeful modification of characteristics of cellulose ethers.

In this work, we studied the intermolecular interactions of semirigid-chain MC with flexible-chain polymethacrylamidoglucose (PMAG) in dilute and moderately concentrated aqueous solutions of their blends. The interactions of polymers in solutions were studied by viscosimetry and rheology, and in films, by IR spectroscopy. The structural formulas of monomeric units of MC and PMAG are shown below:



PMAG



MC

MC is used as a thickening agent or filler in textile, paper, food, and pharmaceutical industry and in agriculture [3]. Polymethacrylamidoglucose belongs to relatively new class of hydrophilic polymers, polyvinylsaccharides, and contains residues of glucosamide structure in the side chain. Such polymers exhibit immunostimulating properties [4] and can be used for modification of polymeric carriers [5]. This study is stimulated by the demand for new modifying agents for MC.

EXPERIMENTAL

The objects of study were commercial sample of MC with degree of substitution DS = 1.7 and degree of polymerization DP_η = 740, and also $PMAG_I$ and $PMAG_{II}$ with DP_η 3600 and 2300, respectively. The MC sample was dissolved in water, and the solution was filtered under a pressure and then subjected to lyophilic drying. The molecular weight and DP_η were determined viscometrically using the Mark–Kuhn–Houwink equation for MC in water [6]:

$$[\eta] = 2.8 \times 10^{-3} M^{0.63}.$$

The PMAG samples were synthesized by radical polymerization of methacrylamidoglucose in water in the presence of 2,2-azobis(2-methylpropanediamine) dihydrochloride as initiator [5].

The molecular weights and DP_η were evaluated using the constants in the Mark–Kuhn–Houwink equation for PMAG in water [5]:

$$[\eta] = 2.3 \times 10^{-3} M^{0.772}.$$

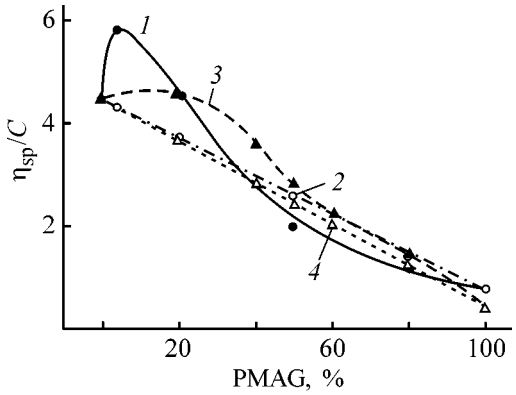

Fig. 1. Reduced viscosity η_{sp}/C of mixtures of dilute (0.1%) solutions of (*1*, *2*) MC–$PMAG_I$ and (*3*, *4*) MC–$PMAG_{II}$ vs. the amount of PMAG. (*1*, *3*) Experimental and (*2*, *4*) calculated.

In aqueous solutions of PMAG, no polyelectrolytic effects were observed [5]. Comparison of the constants α in the Mark–Kuhn–Houwink equations for MC (0.63) and PMAG (0.772) suggests that the shape of MC macrochains in water approaches the statistical Gaussian globule to a greater extent than that of macromolecules of flexible-chain PMAG. This fact can be accounted for by possible formation of intramolecular hydrogen bonds in PMAG macrochains in aqueous solutions [5].

Distilled water was used as solvent. The solutions of polymer mixtures were prepared by mixing equiconcentrated solutions of the initial components in various ratios.

The viscosity characteristics of dilute solutions were measured on a Ubbelohde capillary viscometer at 20°C. The rheological characteristics of the solutions were studied with a Rheotest 2.1 rotation viscometer with the cylinder-cylinder working unit in the range of shear streses 3–600 Pa at 20–50°C. The conditions of gel formation in the solutions were studied, depending on temperature, with a Hoeppler viscometer.

The IR spectra of the samples were recorded on a Bruker IFS-88 Fourier spectrometer. For this purpose, the films were formed from aqueous solutions of the initial MC and $PMAG_I$ and a mixture containing 20% $PMAG_I$. The films were also formed from the upper and lower phases after phase separation of the blend solution. The films were produced by applying the solutions to glass plates with subsequent evaporation of the solvent at room temperature. From the resulting films, KBr pellets were prepared.

Interactions of two different polymers in a common solvent are often studied by viscometry [7–9]. Namely, deviations are recorded of the experimental viscosity of the solutions of polymer blends from the ideal value, evaluated as weight-average viscosity of two components taken separately in the same concentrations. These deviations can be considered a measure of intermolecular interactions of polymers.

In this work, to study interaction of MC and PMAG molecules in aqueous solutions, we determined the reduced viscosity η_{sp}/C of separate components and their blends of various compositions by the formula

$$\frac{\eta_{sp}}{C} = \left(\frac{\eta_{sp}}{C}\right)_1 \frac{C_1}{C} + \left(\frac{\eta_{sp}}{C}\right)_2 \frac{C_2}{C}, \qquad (1)$$

where subscript 1 denotes MC, and subscript 2, PMAG; C is the total concentration of the polymer blend, C_1 and C_2 are concentrations of components 1 and 2, respectively, $C = C_1 + C_2$; $(\eta_{sp}/C)_1$ and $(\eta_{sp}/C)_2$ are the reduced viscosities of components 1 and 2, respectively, at concentration $C = C_1 + C_2$.

The experimental and calculated dependences of the reduced viscosity on the composition of MC–$PMAG_I$ and MC–$PMAG_{II}$ blends are presented in Fig. 1. For the MC–$PMAG_I$ blend, the deviations of the experimental curve from the calculated curve are positive at $PMAG_I$ content of 4 and 20% and negative at $PMAG_I$ content of 50 and 80%. For the MC–$PMAG_{II}$ blend, in which the second component has lower molecular weight, the deviations of the experimental curve from the calculated curve are positive for all the compositions studied. Both positive and negative deviations suggest the occurrence of intermolecular interactions in the systems in hand. The positive deviations can be caused by formation of intermolecular structures whose hydrodynamic volume is greater than that of the separate components. These structures can be formed via interaction of the functional groups of solvated MC and PMAG macromolecules through hydrogen bonds. With increasing fraction of $PMAG_I$ in a mixture, the deviations of the reduced viscosity from the calculated values became negative, which can be caused by formation of more compact structures than those in the case of separate components. Formation of these structures can be caused by weakening of interaction of polymers with the solvent (deterioration of solubility) and by incompatibility or partial compatibility of polymers, i.e., by phase separation in mixtures. This suggestion is confirmed by the increased turbidity of the mixtures of 2% solutions in comparison with the solutions of straight components. Upon storage of these

solutions for 10 days and more, the systems separate into two phases.

The phase composition was analyzed by IR spectroscopy. The IR spectra of the initial components, a mixture of MC with 20% $PMAG_I$, and components of the upper and lower phases of this mixture are shown in Fig. 2. In the IR spectrum of straight MC, there are absorption bands at 2897, 2839, and 942 cm^{-1} characteristic of stretching and bending modes of the CH groups of MC. The spectrum of straight $PMAG_I$ contains absorption bands in the region of 1643 and 1533 cm^{-1} characteristic of C=O groups of PMAG. In the IR spectrum of the film produced from the blend containing 20% $PMAG_I$, there are absorption bands characteristic of MC and PMAG. The spectrum of the film produced from the upper phase suggests that the dominant component of the blend is MC. The upper phase also contains PMAG as suggested by the absorption band at about 1535 cm^{-1} and by the altered shape of absorption band at 1643 cm^{-1}. The lower phase contains PMAG with a certain amount of MC, which is confirmed by the absorption band in the region of 2838 cm^{-1}. It is seen that, in phase separation of the mixed solution, one of the components is dominant in each phase. It is believed that MC and PMAG may be partially compatibile in moderately concentrated solutions of the MC–$PMAG_I$ blend, despite phase separation. This is suggested by significant changes in the systems of intra- and intermolecular hydrogen bonds, as judged from the absorption of hydroxy groups at 3200–3600 cm^{-1}. For example, the peak in the range of absorption of hydroxy groups in the IR spectrum of the film produced from the upper phase is shifted to higher frequences, and the band becomes more asymmetric and narrower. This may be due to the fact that PMAG macrochains appearing in the MC film matrix hinder formation of hydrogen bonds characteristic of MC. The high-frequency shift of the OH band reflects the tendency toward an increase in the fraction of free OH groups or OH groups bonded by weaker hydrogen bonds. In the IR spectrum of the film prepared from the lower phase, the absorption band of the OH groups is broadened, which reflects the significant rearrangement of the system of hydrogen bonds characteristic of straight PMAG. This band is broadened and shifted to lower frequencies, which suggests the formation of stronger hydrogen bonds in comparison with straight MC and $PMAG_I$.

It seems appropriate to study the effect of intermolecular reactions of two polymers in moderately concentrated solutions. For this purpose, we studied rheological characteristics of 2% solutions of MC–$PMAG_I$ and MC–$PMAG_{II}$. The flow curves of solutions of MC, $PMAG_I$, and blends of MC with $PMAG_I$ and $PMAG_{II}$ at 20°C are presented in Fig. 3. The flow curve of MC solution is an incomplete flow curve of a non-Newtonian liquid: the branch of structural viscosity becomes noticeable at a shear stress higher than $\log\tau = 2.4$. The flow curve of $PMAG_I$ solutions in the shear stress range studied suggests non-Newtonian flow of the solutions. This abrupt variation of viscosity with the shear stress is characteristic of structured systems [10]. The viscosity of $PMAG_I$ solution is considerably lower than that of MC solution, which may be due to differences in the behavior of macromolecules of flexible-chain and semirigid-chain polymers in solutions [11]. It can be assumed that in solution of $PMAG_I$ there is a system of hydrogen bonds between solvated macromolecules, which is more sensitive to external effect as compared with MC

solution. With increasing molecular weight of PMAG (Fig. 3, curves *6* and *7*), the external effect on solution viscosity becomes more pronounced.

The rheological behavior of solutions of the initial components and their blends was studied in the temperature range 20–50°C. Based on the temperature dependences of the solution viscosity, we evaluated the activation energies of viscous flow E_a, which reflect the strength of the solution structure [12]. The dependences of the solution viscosity and E_a on the composition of the MC–PMAG$_I$ blend are shown in Fig. 4. It is evident that the viscosity and E_a of the blends are higher than those of the initial MC and PMAG. The positive deviation of viscosity from the additive values may occur for several reasons. On the one hand, as noted in the discussion of the IR spectra, new systems of stronger hydrogen bonds, compared with straight MC, can be formed in the mixtures, which should affect E_a and viscosity. On the other hand, at phase separation the flow mechanism differs from that in a homogeneous solution. The viscosity and E_a can be affected by the shape, number, and stability (strength) of microparticles of the disperse phase, occurring in the solution of the other phase, serving as matrix. Deviations from the additive values may be both negative and positive. Finally, it should be noted that addition of the other polymer, PMAG, to the solution of MC can affect the thermodynamic quality of water as a solvent with respect to MC. Deterioration of the solvent quality will be accompanied by an increase in the viscosity of concentrated solutions and their structurization. This variation of the rheologic characteristics of concentrated solutions with deterioration of the solvent quality is characteristic of cellulose and its derivatives [11].

It is well known that physical thermally reversible gels can be formed upon heating of aqueous solutions of MC. The gelation conditions are affected by many factors, including molecular weight of MC, degree of substitution, and uniformity of distribution of substituents along the macrochain and within glucopyranose units [13–15]. Heating of aqueous solutions of MC is accompanied by gelation, and the shape of the flow curves is changed substantially (Fig. 5). The shapes of the flow curves for MC and MC–PMAG$_I$ blends, except straight PMAG$_I$, are characteristic of physical gels [16, 17]. The viscosity depends critically on the shear stress. The shape of the viscosity–temperature curves depends critically on the chosen shear stress (Fig. 6). At low shear stresses and temperatures above 40°C the viscosity of solutions of MC and MC–PMAG blends increases, which is caused by gelation in the systems. At higher shear stresses this effect is not manifested, since at high shear stresses the structure of thermoreversible gels can be destroyed. It is appropriate to study the gelation conditions on a Hoeppler viscosimeter.

Previously, it has been shown that addition of small amounts of hydrophobic and strongly polar substituents decreases the gel point of aqueous solutions T_{gel} [16, 17]. Decrease in T_{gel} is due to deterioration of interaction of the solvent with polymer owing to an increase in the amount of hydrophobic groups in macro-

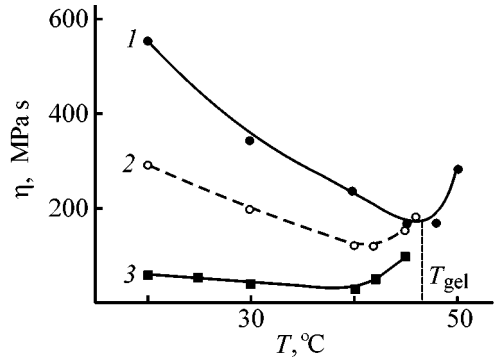

Fig. 7. Vuscosity of solutions of (*1*) MC, (*2*) MC with 20% $PMAG_I$ and (*3*) MC with 50% $PMAG_I$ vs. temperature *T*. (η) Viscosity.

chains. Low-molecular-weight salts added to MC solutions destroy the solvate shell of MC macromolecules, which also leads to a decrease in T_{gel} [18]. It can be expected that addition of another polymer, PMAG, to MC solution can affect the thermodynamics of interaction of MC with water and the gelation conditions. The results of determination of T_{gel} of solutions of MC and MC–PMAG blends are presented in Fig. 7. It is evident that, with increasing weight fraction of PMAG in the mixture, T_{gel} decreases. This trend can be accounted for by the fact that, in the case of incompatibility of polymers in the common solvent, PMAG macromolecules can destroy the hydrate shells of MC macrochains and accelerate their association, with subsequent aggregation. In the case of partial compatibility of the polymers, different macromolecules interact through hydrogen bonds, and mixed associates are formed. The mechanism of aggregation of mixed associates and their physicochemical characteristics may differ from the mechanism of gelation in solutions of straight MC. Thus, addition of PMAG macromolecules to MC solution promotes gelation in solutions at lower temperatures, which suggests the possibility of using PMAG as modifying polymer for control of the structure formation in MC solutions.

CONCLUSIONS

(1) In dilute solutions of methyl cellulose and polymethacrylamidocellulose blends, the experimental values of viscosity differ from the calculated values, which is caused by intermolecular reactions of different polymers.

(2) In moderately concentrated solutions of the above blends, the deviations of viscosity and activation energy from the additive values are positive, which is due to variations in the strength of the solution structure, intermolecular interactions, and phase separation in the systems.

(3) The IR spectra show that after phase separation in the solutions of polymer blends one of the initial polymers prevails in each of the phases, which is characteristic of partial compatibility of polymers.

(4) Addition of polymethacrylamidoglucose to methyl cellulose solutions decreases the gelation point of the systems.

Abstract—The reactions of α-pinene with chloro-, bromo-, and trichloroacetic acids, accompanied by isomerization of α-pinene, were studied.

α-Pinene **I**, one of the major components of turpentine, is an important representative of unsaturated monoterpene hydrocarbons. Esters derived from α-pinene show a wide spectrum of scents [1] and are used as components of diverse perfume formulations. Also, these compounds are components of plastics, rubbers, drugs, cosmetics, and disinfectants [2]. Monoterpene esters show particular promise in production of detergents to impart to them pleasant odor and to mask the odor originating from petroleum raw materials used for detergent manufacture [3].

Esters derived from α-pinene are widely used as intermediates in synthesis of biologically and physiologically active substances [2, 4, 5]. Of most interest in this respect is the report [5] on synthesis of borneol with high yield and selectivity by reaction of α-pinene with chloroacetic acid, followed by saponification of the reaction mixture with NaOH. According to other papers [6–8], the yield of borneol esters in reactions of α-pinene with some haloacetic acids does not exceed 20%, with low reaction selectivity.

In this work, we studied the reaction of α-pinene with chloro-, bromo-, and trichloroacetic acids. The results are given in the table and in Figs. 1 and 2.

We found that addition of haloacetic acids to α-pinene is accompanied by its isomerization and yields both mono- and bicyclic terpenoids. As seen from the table, the qualitative composition of the isomerization products is similar in all cases: camphene **II**, dipentene **III**, α-terpinene **IV**, β-terpinene **V**, terpinolene **VI**, and fenchene **VII** are detected. With chloro- and bromoacetic acids, the corresponding fenchol, borneol, and α-terpineol esters are formed, and with trichloroacetic acid, a minor amount of the isoborneol ester is also detected. Furthermore, with

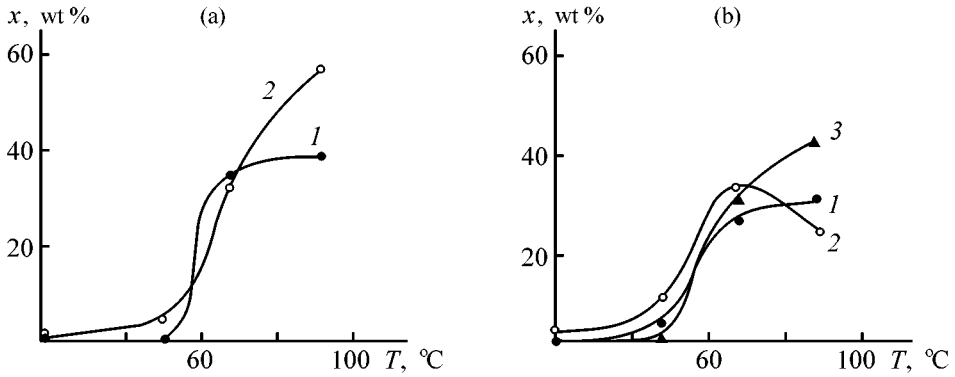

Fig. 2. Influence of temperature *T* on the composition of products formed in reactions of α-pinene with (a) chloroacetic and (b) trichloroacetic acids (1 h, molar ratio α-pinene : acid = 1 : 1).

trichloroacetic acid, oligoterpenes are formed along with the addition and isomerization products.

The yield of products in reactions of α-pinene with haloacetic acids largely depends on the reaction conditions and on particular acid.

Figure 1 illustrates the difference in the rates of accumulation of terpene esters and terpene hydrocarbons in reactions with different acids. In reaction of α-pinene with chloroacetic acid at 70°C, the yields of esters and isomeric terpene hydrocarbons in 0.5 h are 35 and 30%, respectively, with 35% of α-pinene remaining unchanged. After 3 h, the content of terpene hydrocarbons is almost doubled (55%), whereas the content of esters changes insignificantly (Fig. 1a).

Isomerzation of α-pinene into other terpene hydrocarbons is the major transformation pathway in its reaction with bromoacetic acid at the same temperature (Fig. 1c). However, in contrast to chloroacetic acids, the accumulation curves of terpene hydrocarbons and terpene esters are smoother, and even in 4 h the content of these products does not exceed 31 and 20 wt %, respectively, with approximately 50% conversion of α-pinene.

In the reaction of α-pinene with trichloroacetic acid (Fig. 1b), changes in the composition of the reaction products with time are the sharpest. The content of terpene hydrocarbons passes through a maximum. It is seen that the highest (57%) content of isomeric terpene hydrocarbons is attained in 0.5 h, after which it gradually decreases, reaching 43% in 4 h, with simultaneous increase in the content of oligoterpenes. The accumulation pattern of terpene esters is similar to that observed with monohaloacetic acids.

The influence of temperature on the composition of reaction products, examined with chloro- and trichloroacetic acids, is also significant. As seen from Fig. 2, the patterns for terpene esters are similar with both acids. Below 50°C, formation of terpene esters is negligible, and at 65–70°C their content sharply increases. With the temperature rising further, the curve of the ester content flattens out. For α-pinene isomerization products, the patterns observed with chloroacetic and trichloroacetic acids are different. In the first case, the content of terpene hydrocarbons increases steadily with temperature, whereas in the second case their content passes through a pronounced maximum (33–35%) at 70°C. Also, oligoterpenes are formed with trichloroacetic acid, and their content considerably increases with temperature.

It should be noted that oligoterpenes are formed from α-pinene only in the presence of trichloroacetic acid. Furthermore, a distinctive feature of this reaction, as compared witho the reaction with monohaloacetic acids, is its sensitivity to the temperature of reactant mixing (see table). When the starting compounds, α-pinene and CCl_3COOH, are cooled to –5°C, carefully mixed with warming up avoided, and then kept in a thermostat at the required temperature for 1 h, the resulting mixture contains 33% terpene esters, 54% terpene hydrocarbons, and 2% oligoterpenes. When α-pinene is slowly added with stirring to trichloroacetic acid preheated to 70°C and then the mixture is kept at this temperature for 1 h, the content of oligoterpenes sharply increases (to 35%), and the content of terpene hydrocarbons decreases to 36%. The content of terpene esters changes only slightly. Presumably, when α-pinene is mixed with trichloroacetic acid without controlling the temperature, local overheatings due to the heat of reaction cause secondary transformations of terpene hydrocarbons with accumulation of oligoterpenes. A similar assumption was made in [6, 9]. In reactions of α-pinene with chloro- and bromoacetic acids, the temperature of reactant mixing has no effect on the product composition.

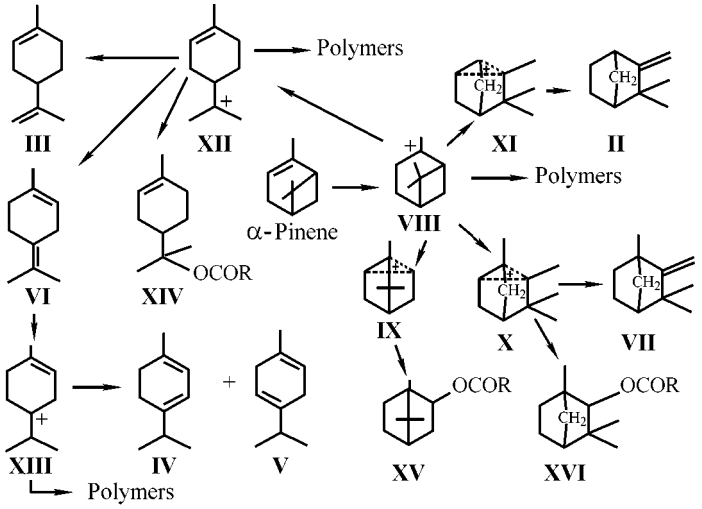
* The reaction was performed without preliminary cooling of the reactants.

As already mentioned, the reaction products formed from α-pinene contain both mono- and bicyclic terpenoids. Terpenoids with various structures of the carbon skeleton are present both in isomerization products and in the esters. Our results are well consistent with the well-known and generally accepted carbocation mechanism of α-pinene isomerization in the presence of acid catalysts [4] (see scheme).

Scheme of α-pinene transformations in the presence of α-haloacetic acids.



(**II**) Camphene, (**III**) dipentene, (**IV**) α-terpinene, (**V**) γ-terpinene, (**VI**) terpinolene, (**VII**) fenchene, (**VIII**) pinyl cation, (**IX**) bornyl cation, (**X**) fenchyl cation, (**XI**) isocamphyl cation, (**XII**) terpenyl cation, (**XIII**) isomeric terpenyl cation, (**XIV**) terpineol ester, (**XV**) borneol ester, and (**XVI**) fenchol ester.

Protonation of α-pinene gives pinyl cation **VIII**, which undergoes Wagner–Meerwein rearrangement to give carbocations **IX**–**XI**, subsequently transforming into bicyclic terpenoids of the bornane, fenchane, and camphane series. Namely, deprotonation yields hydrocarbons (camphene, **II**; fenchene, **VII**), and addition of the acid anion to carbocations **IX** and **X** gives the corresponding bornyl and fenchyl haloacetates.

Monocyclic terpenoids, such as dipentene **III** and terpinolene **VI**, are formed via terpenyl cation **XII**, which is, in turn, formed by ring opening in pinyl cation **VIII**; α- and γ-terpinenes are formed via carbocation **XIII**.

Transformations occurring in the presence of trichloroacetic acid yield, along with isomeric terpene hydrocarbons and terpene esters (via carbocations **VIII**, **XII**, and **XIII**), also oligoterpenes.

The ratio between the products of α-pinene isomerization and addition of haloacetic acids, and also the ratio between the mono- and bicyclic terpenoids, governed by the rates of the competing isomerization and addition reactions, depend on the reaction conditions and particular haloacetic acid.

It should be noted that, when studying the reactions of α-pinene with chloro- and trichloroacetic acids under similar conditions Markevich *et al*. [6], have not detected the corresponding α-terpineol esters. This could be due to inefficient GLC procedure used in [6] for identification of terpenoids. A packed GLC column with tricresyl phosphate as liquid phase does not provide separation of borneol and α-terpineol esters of haloacetic acids, as shown by our experiments with the corresponding reference compounds under the similar conditions. Therefore, we chose conditions for more efficient GLC analysis.

To confirm the formation of α-terpineol esters of haloacetic acids, the products of the reactions of α-pinene with chloro- and trichloroacetic acids were treated with a 10% solution of NaOH in ethanol. In the resulting mixture, we detected, along with fenchol and borneol formed by saponification of the corresponding haloacetates, also α-terpineol, and the ratio of the alcohols fully coincided with the ratio of the corresponding esters in the initial mixture. All the alcohols were also identified by GLC using the reference compounds. Thus, we can conclude with certainty that α-terpineol haloacetates are major products of the reactions of α-pinene with haloacetic acids.

EXPERIMENTAL

α-Pinene and haloacetic acid were cooled to –5°C and then carefully mixed, with warming up avoided, and transferred to a temperature-controlled reactor equipped with a heated jacket, a stirrer, and a reflux condenser. The temperature in the reactor was maintained constant to within ±0.5°C. The stirrer rotation rate was controlled with a tachometer. After a certain time, the mixture was rapidly cooled, the reaction products were washed with water, excess acid was neutralized with 10% aqueous Na_2CO_3, and the mixture was again washed with water to pH 7 and dried over $MgSO_4$, after which the products were analyzed by GLC. In experiments without preliminary cooling of the reactants, the acid was charged into the reactor and heated with stirring to a certain temperature, after which α-pinene was added, which was regarded as the start of the reaction.

Sodium hydroxide treatment of the product mixtures from reactions of α-pinene with chloro- and trichloroacetic acids was performed as follows. After washing with water to pH 7 and drying over $MgSO_4$, the mixture was charged into a reactor. A twofold excess amount (by volume) of a 10% solution of NaOH in ethanol was added. The mixture was refluxed for 2 h and cooled; the reaction products were extracted with two portions of hexane. The combined extract was washed with water to pH 7 and dried over $MgSO_4$. The solvent was removed, and the products were analyzed by GLC.

The chromatographic analysis was performed on a Chrom-5 chromatograph (flame ionization detector; 3-m stainless steel column; stationary phase 15% PFMS-4 silicone oil on Chromaton N-AW-DMSC, 0.20–0.25 mm; column temperature 110–180°C; vaporizer temperature 250°C; carrier gas nitrogen, flow rate 60 ml min^{-1}). Also, we performed analysis under the same conditions as in [6]: column length 3 m; stationary phase tricresyl phosphate; column temperature 110–180°C; vaporizer temperature 250°C; carrier gas nitrogen, flow rate 60 ml min^{-1}. Tridecane was added as internal reference. The products were identified by comparison with the corresponding reference compounds or by using data on relative retention of terpenoids [4]. The relative error of single analysis at a confidence level of 0.95 was within ±2%. With each sample, five chromatograms were recorded, and the results were averaged.

CONCLUSION

Reactions of α-pinene with chloro-, bromo-, and trichloroacetic acids yield terpene alcohols and esters, which can be used as components or intermediates in syntheses of active substances.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Pore Structure of Film Materials Based on Ultra-High-Molecular-Weight Polyethylene

E. V. Nazarova, T. A. Anan'eva, and S. F. Grebennikov

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received October 31, 2001

Abstract—The pore structure of xerogel films of ultra-high-molecular-weight polyethylene, prepared by the gel process, was studied by mercury porosimetry and water vapor sorption. Data on the pore size distribution and on the volume and surface area of sorbing pores were obtained.

The majority of commercially produced film materials are solid (monolithic) uniform films. By now, new promising products have been developed, among which a particular place is occupied by porous film materials. Such materials find growing use for filtration and separation of liquid media, and also as separators for chemical power sources, as diaphragms for electric capacitors and electrolytic membranes, and in devices for environmental protection [1, 2].

A versatile procedure for preparing porous polymeric materials is treatment of crystallizing polymers with organic solvents at elevated temperatures [3–5]. These materials can also be prepared by conventional extrusion of gas-filled materials with the formation of a film fabric in the die head [6] or by extrusion of a polymer melt at high flow velocity, followed by annealing of samples crystallized at room temperature, uniaxial drawing of the annealed films, and their thermofixation. This procedure allows preparation of films with various ratios of open and closed pores [2, 7]. One of procedures for preparing porous film materials involves condensation cross-linking and is based on physicochemical processes spontaneously occurring in polymer melts [8]. A promising line in polymer processing is the gel technology, which has recently led to a considerable success in forming highly porous film materials based on ultra-high-molecular-weight polyethylene (UHMWPE) [9–12]. The first stage of the gel process is transfer of a polymer into solution. Suitable solvents are aliphatic, cycloaliphatic, and aromatic hydrocarbons boiling above 100°C, such as octane, nonane, decane, their isomers, higher linear and branched hydrocarbons, petroleum fractions boiling above 100°C, and halogenated hydrocarbons. The main requirement to a solvent is that its evaporation under the process conditions must not be significant. This is necessary to maintain the constant solution concentration and prevent nonuniform distribution of the liquid in the gel. The next stage after polymer dissolution is solidification of the initially liquid solution. In the gel process, as applied to UHMWPE, this is provided by decreasing temperature, rather than by varying the solution composition. The gel formed in the process is a macroscopically connected, three-dimensionally cross-linked system containing significant amounts of a low-molecular-weight liquid and exhibiting elastic properties. In contrast to systems with chemical cross-links, UHMWPE gels are loosely packed systems linked by crystalline junctions [13].

Removal of the solvent from a UHMWPE gel yields a xerogel exhibiting a high total porosity and a uniform structure throughout the volume. Owing to this feature, it is feasible to prepare from UHMWPE xerogels highly porous materials with properties largely depending on the pore structure features [14]. However, data on the pore-size distribution, the presence of pores of a definite size, and the volume and surface area of sorbing pores are virtually lacking.

In this work, we studied experimentally using mercury porosimetry and water vapor sorption, the porosity of UHMWPE xerogel films.

EXPERIMENTAL

Xerogel films were prepared from UHMWPE (average molecular weight 1.5×10^6, UHMWPE-1; or 4.0×10^6, UHMWPE-2) solutions in paraffin. The

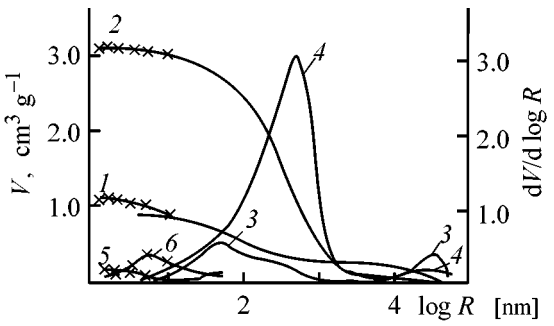

Fig. 1. (*1*, *2*) Integral and (*3*–*6*) differential curves of (*2*, *4*, *5*) UHMWPE-1 and (*1*, *3*, *6*) UHMWPE-2 samples. (*V*) Volume of pressed-in mercury and (*R*) pore radius. Curves *5* and *6* were plotted on the basis of data on water vapor sorption.

UHMWPE solutions were prepared as described in [15]. The choice of the solvent is explained in detail in [11, 12].

Films were cast onto a smooth polished metallic table heated to 60°C, with a heated metallic cover. The table was cooled to room temperature at a rate of 1.6 deg min^{-1}. Solid paraffin was extracted from the gel films in the fixed state with heptane at 70–75°C. After extraction, the films were dried at room temperature to constant weight to obtain porous UHMWPE xerogel films.

To measure the water vapor sorption isotherms, film samples were dried to constant weight at 50°C, cooled in a desiccator over silica gel, and transferred into desiccators with saturated salt solutions.

The drying temperature was chosen taking into account the possible α-relaxation transition at 50–60°C, which consists of several independent relaxation processes. It is believed that at these temperatures the macromolecular chains become mobile, and folds on the plate surfaces in crystals and macromolecules in defective regions can undergo reorientation [16].

The pore structure of xerogel films was studied on Macropores Unit 120 (low pressure) and Porosimeter 2000 Carlo Erba Strumentazions (high pressure) devices. A sample of UHMWPE xerogel film, preliminarily dried at 50°C, was placed in a dilatometer, which was then transferred into a low-pressure porosimeter. After evacuation, the dilatometer was charged with mercury, and air was admitted to atmospheric pressure to fill the coarsest pores with mercury. After that, the dilatometer with the sample was transferred into a high-pressure porosimeter. The pressure in the dilatometer was set by means of in the range from 0.1 to 200 MPa oil in a capillary. As the pressure is increased, pores with the size decreasing from 43000 to 5 nm are filled.

Figure 1 shows the integral structural curves of xerogel film samples prepared from UHMWPE-1 and UHMWPE-2. As seen, for the UHMWPE-1 sample the integral curve ascends more steeply. The maximal volume of pressed-in mercury was 3.04 $cm^3 g^{-1}$ for UHMWPE-1 and 0.92 $cm^3 g^{-1}$ for UHMWPE-2. This is due to the fact that the polymers significantly differing in molecular weight form xerogel films with different pore structures.

The differential curves of pore volume distribution with respect to the pore radius for UHMWPE-1 and UHMWPE-2 samples (Fig. 1) show that the major volume of macropores in the UHMWPE-1 sample corresponds to the pore radius range 70–1250 nm. The UHMWPE-2 xerogel film has a bidisperse pore structure, with maxima at about 47 and 29000 nm. The specific features of the pore structure of these film samples are probably due to different courses of gelation and crystallization of polymer solutions, depending on the UHMWPE molecular weight.

In crystallization from semidilute solutions ($c \geq$ 1%), the morphology of the forming crystals largely depends on the rheological history of the solution. If a solution was subject to shear stresses, knotted fibrillar chains of a shish-kebab structure may form along with lamellar crystals. The shish-kebab structures arise on peculiar precursor structures which are developed in a polymer solution in the course of its flow through a die channel or onto a metallic support. These "flow units" can be represented as alternating "bundles" of stretched macromolecules and clusters of strongly knotted chains. The bundles can crystallize at high temperatures even in the flow field, because of the considerably decreased, owing to stretching, conformational entropy of the molecules composing them [13]. On this basis, it can be assumed that in a solution of the higher-molecular-weight polymer sample, UHMWPE-2, more bundles are formed than in a UHMWPE-1 solution, which ultimately affects the pore structure of the UHMWPE gel and xerogel.

From the porosimetric data, we calculated the specific surface areas of the xerogel samples, assuming the cylindrical shape of the pores, by the formula

$$S = \Sigma \Delta S_i = \Sigma 2 \frac{\Delta V_i}{R_{\text{av}\,i}}, \qquad (1)$$

where S is the specific surface area of the solid ($m^2 g^{-1}$), ΔV_i is the width of an interval of pore radii ($m^3 g^{-1}$), and $R_{\text{av}\,i}$ is the average pore radius in the interval ΔV_i (m).

The specific surface area of the pores with radii larger than 5 nm in UHMWPE-1 and UHMWPE-2 xerogel samples was 50 and 13 $m^2 g^{-1}$, respectively.

The isotherms of water vapor sorption by the UHMWPE-1 and UHMWPE-2 xerogel films are shown in Fig. 2. It is seen that the sorption value is strongly influenced by the molecular weight of a polymer. The sorption by the UHMWPE-2 xerogel film is higher than by the UHMWPE-1 xerogel film. From the sorption isotherms we calculated, using the Kelvin equation, the pore radii:

$$R_{\text{pore}} = \frac{2V_{\text{m}}}{RT\ln(p_s/p)}, \quad (2)$$

where R_{pore} is the pore radius (m), σ is the surface tension of water (71.96×10^{-3} N m^{-1}), V_{m} is the molar volume of water (m^3 mol^{-1}), R is the universal gas constant, T is temperature (K), and p/p_s is the relative water vapor pressure.

Using these data, we supplemented the integral and differential porosimetric curves (Fig. 1) toward smaller pore radii; the curve continuations are marked with *crosses*.

As seen from Fig. 1, the UHMWPE-2 xerogel film has a more developed mesoporous structure (V_{me} = 0.32 cm^3 g^{-1}) as compared with the UHMWPE-1 xerogel film (V_{me} = 0.17 cm^3 g^{-1}). The major fraction of the mesopore volume in the UHMWPE-2 sample corresponds to the pore radius range 3–10 nm. At the same time, macropores prevail in the UHMWPE-1 sample (2.9 cm^3 g^{-1}, against 0.8 cm^3 g^{-1} for UHMWPE-2). This is due to the fact that a solution of UHMWPE with molecular weight of 4.0×10^6 is more viscous, and hence the polymer molecules in it are less mobile. In this case, gelation is accompanied by build-up of considerable internal stresses in the polymer network, which results in shrinkage of the xerogel after solvent removal. The shrinkage of UHMWPE gels is largely associated with crystallization processes in the enriched polymer phase, occurring differently depending on the molecular weight of the polymer.

By the BET procedure, we calculated from the sorption data the specific surface area of the porous xerogel films:

$$A = \frac{a_{\text{m}}}{18} N_{\text{A}} \sigma, \quad (3)$$

where A is the specific surface area (m^3 g^{-1}), α is the landing surface area for water molecule (0.105 nm^2) [17], a_{m} is the adsorption value (g g^{-1}), and N_{A} is the Avogadro number.

The specific surface area of the UHMWPE-1 and UHMWPE-2 xerogel samples was 157 and 98 m^2 g^{-1}, respectively, i.e., for UHMWPE with M 4.0×10^6 it is lower than for UHMWPE with M 1.5×10^6. This fact is due to differences in the course of crystallization of the polymer phase and in the shrinkage of the polymeric skeleton, affecting the features of the forming macro- and mesoporous structure of the xerogel samples.

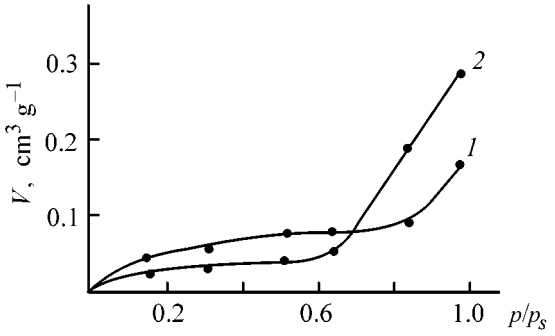

Fig. 2. Isotherms of water vapor sorption by (*1*) UHMWPE-1 and (*2*) UHMWPE-2 xerogel films. (V_s) Sorption value and (p/p_s) relative water vapor pressure.

CONCLUSIONS

(1) As shown by mercury porosimetry, the molecular weight of ultra-high-molecular-weight polyethylene affects the formation of the macroporous structure of the films.

(2) The differential curves of the pore volume distribution with respect to the pore radius were plotted. The specific surface areas of the xerogel films were calculated. This parameter decreases with increasing molecular weight of ultra-high-molecular-weight polyethylene.

(3) As shown by the isotherms of water vapor sorption and by the corresponding BET calculations, the molecular weight of ultra-high-molecular-weight polyethylene appreciably affects the sorption value, the mesopore volume, and the specific surface area of the xerogel films.

Institute of Surface Chemistry, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received April 12, 2001

Abstract—The structure of fine iron powders modified with cross-linked dextran was studied by X-ray diffraction analysis. The parameters of short-range ordering of dextran in the modifying coating were determined as influenced by dextran content. The parameters for quantitative phase analysis was proposed.

Preparation of high-performance magnetically targetable drugs of directional and prolonged action on the basis of fine iron powders (FIPs) with immobilized drugs [1–5] is impossible without creating a magnetic carrier having required capacity for the corresponding drug, controlled, in particular, by thickness or volume of a biocompatible polymeric coating. The polymeric coating formed on the surface of magnetic particles should be tested with respect to its phase state, structure, and composition [6–9]. Such compositions are untypical of quantitative X-ray diffraction (XRD) analysis, because they involve crystalline (iron) and amorphous (dextran) components of different chemical nature; moreover, the scattering power of iron powder is extremely higher [10–12].

The aim of this work was to perform the quantitative phase analysis of FIPs modified with cross-linked dextran and to elucidate the structural features of polymeric modifying coatings.

EXPERIMENTAL

We studied the FIP samples prepared by electrolytic procedure [13] and modified with cross-linked dextran by emulsion polymerization of dextran (molecular weight 70 000) on the powder particle surface in the presence of initiating and cross-linking agents [14] with varied content of the polymer. The concentration of dextran in the modified FIP samples was determined by chemical analysis; the results are listed in the table. We also studied the initial FIP, dextran cross-linked under the conditions similar to those used in modification, and mechanical mixtures of FIP with cross-linked dextran, having the same composition as the modified samples.

The diffraction patterns of the samples we recorded on a DRON-UM1 diffractometer using $Co_{K\alpha}$ radiation (iron filter) in the reflected beam focused according to Bragg–Brentano.

It should be noted that we studied in this work modified FIP samples in which the content of dextran was determined preliminarily by chemical analysis. The mechanical mixtures were prepared using the data of chemical analysis. Thus, comparison and analysis of the diffraction patterns of the modified FIP samples and mechanical mixtures of the same composition can be considered a model diffraction experiment.

The diffraction patterns of the initial FIP, cross-linked dextran, FIP samples modified with dextran at its varied content (solid lines), and mechanical mixtures of the same composition (dotted lines) are shown in Fig. 1. Despite the difference in scattering power between dextran and iron (curves *1*, *2*) and insignificant increase in the scattering of the polymer over the background in the diffraction patterns of the modified FIP samples, identification of the phases and evaluation of the short-range parameter of polymer ordering [10] are possible owing to different locations of the diffraction peak of dextran and diffraction lines of iron (curves *3*–*6*). As seen from these data, cross-linked dextran and dextran in modified FIPs are in the amorphous state. The parameters of the short-range ordering of dextran, calculated from the diffraction patterns, are listed in the table. With the dextran content in the modified samples increasing from 9.9 to 33.8% the short-range ordering parameter grows from 0.412 to 0.420 nm, which suggests a decrease in the packing density of the polymer chains.

Dextran content, wt %: (*3*) 9.9, (*4*) 15.4, (*5*) 25.2, and (*6*) 33.8. *Dotted lines* are the diffraction patterns of mechanical mixtures of the same composition as modified samples, shifted along both axes for clarity.

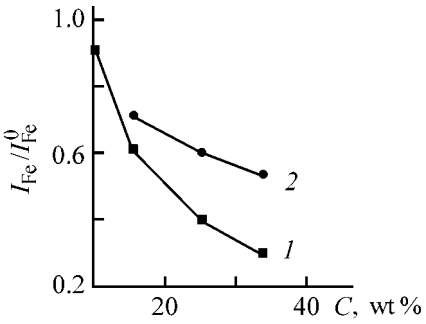

Fig. 2. Ratio of the intensity of the diffraction peak (110) of iron in (*1*) FIP modified with dextran and (*2*) mechanical mixture of FIP and dextran to the intensity of the diffraction peak (110) of iron in the initial FIP I_{Fe}/I_{Fe}^0 vs. the dextran content *C*.

The presence of cross-linked dextran on the FIP particle surface was judged from comparison with the diffraction data for mechanical mixtures of cross-linked dextran and FIP, having the same composition as modified FIP samples. It is known that the intensity of the diffraction lines of one component may decrease when its particles are coated with another component [15, 16]. As seen from our data, the intensity of the diffraction line in the patterns of modified FIPs is lower than that in the case of mechanical mixtures (Fig. 1, *dotted lines*). Thus, cross-linked dextran is present on the surface of the FIP particle.

As known, quantitative analysis is based on the dependence of the intensity of the diffraction peaks of a crystalline compound on its content in the mixture; it is carried out using calibration dependences (as a rule, linear) plotted by various procedures [16]. However, quantitative determination of the dextran content in modified FIPs and mechanical mixtures, using these calibration dependences, is rather difficult because of the small scattering power of dextran as compared with iron.

The content of dextran in the formulations in question can be evaluated from the calibration dependences of the intensity of the diffraction peak (110) on the dextran content in modified FIP samples and mechanical mixtures, using the external standard (unmodified initial FIP). Although these dependences are nonlinear (Fig. 2), they can be used in analysis of the dextran content in the samples studied. However, for more precise evaluation of the concentration dependence, the number of experimental points should be greater.

As seen from the diffraction patterns of modified FIPs and mechanical mixtures, the deviation of the background level from the additive value (determined by summation of the diffraction patterns of cross-linked dextran and unmodified FIP) grows with increasing diffraction angles. In these patterns, the background is about the same in the entire scanning range studied, which is illustrated in Fig. 3 for samples with dextran content of 25.2 wt %.

With increasing dextran content the intensity of the diffraction peak (110) and the background level decreased simultaneously with changes in the angular distribution of the background. This distribution can be quantitatively described with parameters *A*, *B*, and *C*, which characterize variations in the background scattering at the beginning and the end of the diffraction pattern with respect to the background scattering at the end of the diffraction pattern of the initial FIP:

Concentration *C* and short-range ordering parameter of cross-linked dextran *r* in modified FIP

Sample	*C*, wt %	*r*, nm	Sample	*C*, wt %	*r*, nm	Sample	*C*, wt %	*r*, nm
1	–	–	3	9.9	0.412	5	25.2	0.418
2	10.0	0.412	4	15.4	0.416	6	33.8	0.42

$$A = (I^0_{bb} - I_{bb})/I^0_{be}, \quad (1)$$

$$B = (I^0_{be} - I_{be})/I^0_{be}, \quad (2)$$

$$C = (I_{be} - I_{bb})/I^0_{be}, \quad (3)$$

where I_{bb} is the intensity of the background scattering of FIP modified with dextran and mechanical mixture at the beginning of the diffraction pattern, I_{be} is the is the intensity of the background scattering of FIP modified with dextran and mechanical mixture at the end of the diffraction pattern, and I^0_{bb} and I^0_{be} are the intensities of the background scattering of the initial FIP at the beginning and the end of the diffraction pattern.

The dependences of these parameters on the dextran content are shown in Fig. 4. As seen, parameters *A* and *B*, which have different initial values, grow with increasing dextran content, and the rate of this increase is greater for parameter *A*; parameter *C* simultaneously decreases. The dependences of parameters *A*, *B*, and *C* on the dextran content are nearly linear, which simplifies plotting of the calibration dependences, because smaller number of the model compositions is required for this procedure. The concentration dependences for mechanical mixtures with dextran content of up to 15 wt % are similar to those obtained for modified FIPs. With the dextran content increasing further, the dependences for mechanical mixtures deviate from the dependences for modified FIPs, so that the content of dextran in modified samples, determined from the calibration curves for mechanical mixtures, is overestimated. For example, at a dextran content in modified sample, determined by chemical analysis, of 25.2 wt % the value estimated from the calibration dependences for mechanical mixtures is greater by 28%, and at dextran content of 33.8 wt %, by 33%. The calibration curves given in Fig. 2 also give overestimated dextran concentrations. Thus, when using variations in the intensity of the diffraction peak (110) of iron and parameters *A*, *B*, and *C* for quantitative determination of the dextran content in the modified FIP samples, we should introduce appropriate corrections in the calibration dependences for mechanical mixtures.

The features of the diffraction patterns can be explained by assuming that at low content of dextran the polymer layer on the FIP particles is not solid because of the dendritic shape of the FIP particles, determined by the preparation conditions, and, hence, of their large specific surface area. In this case the diffraction patterns of modified FIPs are similar to those recorded for mechanical mixtures. With increasing

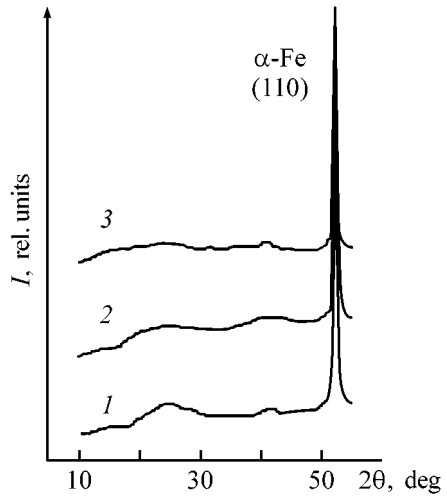

Fig. 3. Diffraction patterns of (*1*) FIP modified with dextran, (*2*) mechanical mixture of FIP with dextran, and (*3*) their additive curve; dextran content 25.2 wt %.

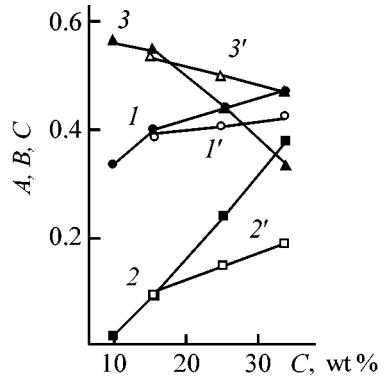

Fig. 4. Parameters (*1*, *1*′) *A*, (*2*, *2*′) *B*, and (*3*, *3*′) *C* for (*1*–*3*) FIPs modified with dextran and (*1*′–*3*′) mechanical mixtures of FIPs and dextran vs. dextran concentration *C*.

content of polymer, its layer on the particle surface becomes solid. Variation in the parameter of short-range ordering of cross-linked dextran in modified FIP does not contradict this assumption. Formation of a solid polymeric coating on the FIP particles with the dextran concentration increasing in the 15–33 wt % range affects the intensity of the diffraction peaks of iron in the modified samples more strongly as compared with mechanical mixtures.

Thus, quantitative phase analysis of modified FIP samples on the basis of the calibration dependences found for mechanical mixtures can be used at polymer concentrations of up to 15 wt %. At higher polymer content the dextran concentrations determined using the calibration curves for mechanical mixtures are overestimated by 20–30%. However, despite the above limitations, our analysis of the intensity of

the diffraction peak (110) and the angular dependence of the background scattering allow us to supplement conclusions concerning the qualitative detection of the dextran coating on the FIP particle surface. The dextran phase in the modified FIPs decreases the intensity of the diffraction peak of iron and affects the angular dependence of the background scattering as compared with those in the initial FIP, and this effect is the most pronounced at the beginning of the diffraction pattern.

CONCLUSIONS

(1) An X-ray diffraction study of a fine iron powder modified with cross-linked dextran showed the possibility of determining the spatial distribution of the polymer modifying the fine iron powder particles. The parameters are proposed, quantitatively describing how the background level in the diffraction patterns of fine iron powder modified with dextran and of the corresponding mechanical mixtures of these components change relative to those in the initial powder as influenced by the dextran concentration.

(2) Cross-linked dextran occurs on the surface of iron particles, and the coating state depends on the polymer content. At low dextran concentrations (up to 15 wt %) its layer is not solid; with the polymer content increasing to 33.8 wt % the coating becomes solid and less compact, which is confirmed by the increase in the short-range ordering parameter of cross-linked dextran in the modifying coating as compared with free cross-linked dextran.

(3) In determining the content of cross-linked dextran in modified fine iron powder from the calibration dependences plotted for mechanical mixtures of dextran and iron powder, appropriate correction parameters should be used.

BRIEF COMMUNICATIONS

Extraction-Conductometric Determination of Phenol and Cresol in Nonaqueous Concentrates

Ya. I. Korenman, E. A. Podolina, and L. A. Kharitonova

Voronezh State Technological Academy, Voronezh, Russia

Received June 21, 2001

Abstract—Extraction of phenol and cresols with hydrophilic solvents (acetone, acetoacetic ester, and diacetone alcohol) from aqueous-salt solutions [$MgSO_4$, $(NH_4)_2SO_4$, NaCl] was studied. Extraction-conductometric technique for determination of phenol and cresols was developed.

Hydrophilic solvents are widely used for extraction of phenol derivatives from aqueous solutions [1–3]. These solvents are chosen to ensure phenol determination by electrochemical methods directly in the organic extract (without preliminary backwashing).

In this work, we studied extraction of phenol and cresols with hydrophilic solvents from aqueous solutions to develop the technique for their selective determination directly in the nonaqueous concentrates.

EXPERIMENTAL

Phenol and *o*-, *m*-, and *p*-cresols used in our experiments were of pure grade. The extractants (acetone, acetoacetic ester, and diacetone alcohol) were purified prior to use [4]. These hydrophilic solvents form a separate phase upon contact with aqueous solutions of salts [5], e.g., $MgSO_4$, $(NH_4)_2SO_4$, and NaCl. The extraction procedure was similar to that described in [6]. The equilibrium phenol concentration was determined spectrophotometrically on an SF-46 spectrophotometer. The conductometric titration was carried out on a Tesla Semiautomatic Universal Bridge-BM-509 setup equipped with two platinum electrodes (S = 1 cm^2, l = 1 cm) at 20 ± 1°C. A 0.01 M NaOH solution in isopropyl alcohol was used as titrant. Intermolecular interactions between the infinitely water-soluble polar extractant and compounds being extracted involve van der Waals interactions, depending on the polarization of the O–H, C=O, and O–C=O bonds, and hydrogen bonding [7].

The distribution coefficients determined in the systems containing hydrophilic solvent and aqueous salt solution under identical conditions are given in Table 1.

It has been reported [8] that in the aqueous–acetone system solvates are formed in which the phenolic OH group is bound to the acetone carbonyl group through a water molecule. The highest distribution coefficients were observed in extraction of unsubstituted phenol, which is the most hydrophilic among the compounds tested. The hydrophobic CH_3 group in the cresol molecule decreases its affinity for hydrophilic solvents, which makes lower the extractability of cresols as

compared with phenol. The CH_3 group in the *ortho* position shields the phenolic OH group in cresol molecule and, therefore, hinders its hydration.

The extractive power of an organic solvent depends on the number of functional groups in its molecule [9]. For example, acetoacetic ester and diacetone alcohol molecules contain, along with the C=O polar group, also ester and alcohol groups. Acetoacetic ester in nonaqueous solvents exists as keto and enol tautomers [10].

Owing to intermolecular hydrogen bonding of the enol hydrogen atom and oxygen atom of the β-carbonyl group, a stable six-membered ring is formed. In this ring the proton is deshielded by the oxygen atoms of OH and anisotropic C=O groups. The ester group exhibiting the *I* effect decreases the electron density on the oxygen atom of the carbonyl group and thereby decreases the proton-acceptor power of acetoacetic ester. Therefore, the distribution coefficients of phenol and cresols in the systems consisting of acetoacetic ester and aqueous salt solution are considerably lower than those in a similar system with acetone and diacetone alcohol.

The C=O and OH functional groups of diacetone alcohol increase the efficiency of extraction of phenols from aqueous salt solutions. The highest distribution coefficient (~500) is reached in extraction with diacetone alcohol in the presence of ammonium sulfate.

The extraction involves combined recovery of phenol and cresols. Since the organic solvents suitable for extraction have high permittivity and differentiating power [11], phenols can be determined electrochemically directly in the extract. The best titration curves of phenol and cresols (isomer mixture) were obtained on addition of dimethyl sulfoxide.

The electrochemical determination of phenol and cresols is carried out as follows. Water (500 ml) containing phenol and cresols is placed in a separatory funnel and acidified with H_2SO_4 approximately to pH ~2. Next, ammonium sulfate is added till formation of a virtually saturated solution, diacetone alcohol (50 ml) is added, and the resulting mixture is shaken on a vibro mixer for 15 min. After phase separation, 10 ml of the extract is placed in a conductorymetric cell and titrated with NaOH solution in isopropyl alcohol. Phenol and cresol are determined in the extract using titration curve obtained. Their concentrations are calculated by the equation

$$C_w = \frac{V_a C_a \times 100}{V_{ex} R r},$$

where V_a is the volume of the NaOH solution in isopropyl alcohol, spent for titraration (cm^3); C_a the NaOH concentration in isopropyl alcohol (M); V_{ex} the extract volume (cm^3); R the degree of phenol recovery (%) in extraction with diacetone alcohol from aqueous salt solution; and r the ratio of the equilibrium volumes of the aqueous and organic phases.

The statistically processed data on separate determination of phenol and cresols in aqueous solutions are given in Table 2.

The technique developed by us allows fast extraction-conductometric determination of phenol and cresols.

CONCLUSION

The distribution coefficients of phenol and cresols in systems consisting of a hydrophilic organic solvent and an aqueous salt solution were determined. The highest distribution coefficients were attained in extraction with diacetone alcohol in the presence of ammonium sulfate. The conditions for acid-base conductometric titration of phenol and cresols in nonaqueous concentrates were found. The technique for extraction-conductometric determination of phenol and cresols in the extracts was developed.

Abstract—A method is proposed for obtaining copper-chromium-barium catalyst with the use of a nitrate ammonia solution of copper(II), obtained as a result of leaching of a spent copper-chromium-barium catalyst.

Copper-chromium-barium catalyst (CCBC) of general formula $x\mathrm{CuO} \cdot y\mathrm{Cr_2O_3} \cdot \mathrm{BaO}$, where x = 12–14, y = 6–7.5, is commonly used in hydrogenation of organic compounds. The catalyst is obtained by various techniques, with the highest-activity catalyst produced by thermal decomposition of a basic salt $\mathrm{NH_4(CuOH)CrO_4}$. With CCBC used as a suspension in a liquid raw material, e.g., in manufacture of higher alcohols, a waste is produced in the form of a paste consisting of an organic part (35–50%) and a mineral fraction including oxides CuO, $\mathrm{Cr_2O_3}$, BaO, and $\mathrm{SiO_2}$ [1]. A method has been proposed for utilization of spent CCBC by ammonia leaching [2]. It is advisable to use the forming $\mathrm{[Cu(NH_3)_4](NO_3)_2}$ solutions for obtaining fresh CCBC. A study of this possibility is the subject of the present work.

EXPERIMENTAL

Chromium(VI) oxide [GOST (State Standard) 2548–77], barium nitrate of chemically pure grade (GOST 3777–76), aqueous ammonia (GOST 9–77), and nitric acid (GOST 5.1187–72) were used in the study. $\mathrm{[Cu(NH_3)_4](NO_3)_2}$ solution containing (g $\mathrm{l^{-1}}$): Cu(II) 53, $\mathrm{NH_3}$ 29, and $\mathrm{NH_4NO_3}$ 139 was prepared by leaching of degreased spent CCBC. The content of the components and the catalyst activity (nominally 30–36% as regards the degree of acetone hydrogenation) were determined in conformity with TU (Technical Specification) 38-1325–74.

To obtain CCBC, to 200 ml of a nitrate-ammonia solution of copper(II) in a 500-ml vessel containing 10.6 g (0.165 mol) of Cu(II) was added 3.4 g (0.013 mol) of $\mathrm{Ba(NO_3)_2}$ and the mixture stirred at 70°C (solution 1). Into a 100-ml vessel was poured 15 ml of water, 16.5 g (0.165 mol) of $\mathrm{CrO_3}$ was introduced, and the mixture was stirred to complete dissolution (solution 2). A vessel with solution 1 was placed in a UT-15 thermostat at 74 ± 2°C and solution 2 was added. The excess of the sum of Cu(II) and Ba(II) with respect to Cr(VI) was 8.3%. Then, a 55% solution of $\mathrm{HNO_2}$ was added dropwise in the course of 0.5 h to pH 5.5 (about 22 ml). The suspension was stirred for 1 h, filtered under a vacuum, and washed with water (30 ml), with the filtrate and washing water collected separately. Found in the filtrate (g $\mathrm{l^{-1}}$): $\mathrm{NH_4NO_3}$ 365, Cu(II) 2.66, and Cr(VI) 0.027. At pH 6.4, no Cr(VI) and 2.6 g $\mathrm{l^{-1}}$ was found. The precipitate was dried for 30 min at 170°C and then calcined in a muffle furnace at 400°C for 1 h.

The main reaction of CCBC preparation [1] can be represented as

$$\mathrm{Ba(NO_3)_2 + (NH_4)_2CrO_4 \rightleftarrows BaCrO_4\downarrow + 2NH_4NO_3}, \quad (1)$$

$$\mathrm{Cu(NO_3)_2 + (NH_4)_2CrO_4 + NH_4OH} \xrightleftharpoons[65\text{–}80^\circ\mathrm{C}]{\mathrm{pH\ 5.5\text{–}6.2}} \mathrm{NH_4(CuOH)CrO_4\downarrow + 2NH_4NO_3}, \quad (2)$$

$$\mathrm{2NH_4(CuOH)CrO_4} \xrightleftharpoons{380\text{–}420^\circ\mathrm{C}} \mathrm{2CuO \cdot Cr_2O_3 + N_2 + 5H_2O}. \quad (3)$$

The precipitation was done at a 4–5 mol % excess of chromate ions with respect to the sum of Ba(II) and Cu(II) ions; the wastewater was purified to remove the major part of chromium(VI) by sorption of $\mathrm{Cr_2O_7^{2-}}$ on an AB-17 × 8 anion-exchange resin. Additional purification of wastewater to remove Cr(III)

1070-4272/02/7502-0326 $27.00 © 2002 MAIK "Nauka/Interperiodica"

and Cu(II) ions was done by addition of $Ca(OH)_2$; chromium(VI) was preliminarily reduced with iron(II) sulfate. A disadvantage of this method is the large volume of liquid waste (up to 20 m^3 per 1 ton of CCBC).

Let us compare five ways to obtain a fresh catalyst with the use of $[Cu(NH_3)_4](NO_3)_2$ solutions.

(1) Solution of a complex $[Cu(NH_3)_4](NO_3)_2$ was converted by acidification with HNO_3 into copper(II) and ammonium nitrate:

$$[Cu(NH_3)_4](NO_3)_2 + 4HNO_3 \rightleftarrows Cu(NO_3)_2 + 4NH_4NO_3. \quad (4)$$

This solution was used to obtain the catalyst by the method described in [1]. The CCBC activity was 30.1%. The disadvantages of the technique consist in that ammonium nitrate appears in wastewater in amount exceeding 3–3.2-fold that in wastes produced by the known technology and in increased loss of copper(II) into the filtrate (up to 6 g l^{-1}).

(2) To a nitrate-ammonia solution of copper(II) was added HNO_3 till basic salts were formed

$$[Cu(NH_3)_4](NO_3)_2 + 3HNO_3 + H_2O \rightleftarrows (CuOH)NO_3\downarrow + 4NH_4NO_3. \quad (5)$$

The precipitate was filtered off, dissolved in nitric acid, and $Cu(NO_3)_2$ was used to prepare the catalyst by the method described in [1]. The CCBC activity was 30.4%. The loss of copper(II) into the filtrate was diminished, with, however, a large amount of unused ammonium nitrate solution still formed.

(3) Basic salts obtained by variant 2 were added to a solution containing ammonium chromate and barium nitrate at $m_s : m_l \sim 1 : 3.3$. The precipitate was obtained in accordance with the equations

$$Ba(NO_3)_2 + (NH_4)_2CrO_4 \rightleftarrows BaCrO_4\downarrow + 2NH_4NO_3, \quad (6)$$

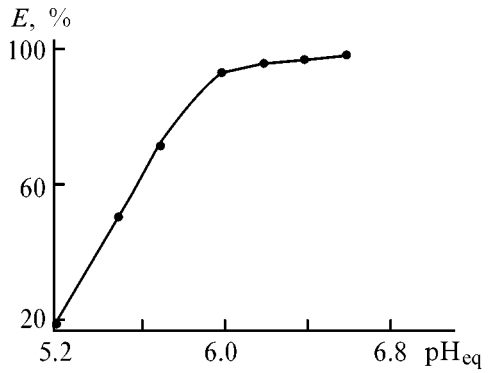
$$(CuOH)NO_3\downarrow + (NH_4)_2CrO_4 \rightleftarrows NH_4(CuOH)CrO_4\downarrow + NH_4NO_3. \quad (7)$$

Further, the precipitate was processed using the technique described in [1]. The activity of the obtained catalyst was 34.7%. Smaller amounts of wastewater were obtained, the amount of NH_4NO_3 exceeded that produced in the case of the technology reported in [1] only 2–2.2-fold.

(4) Variant 3 at $m_s : m_l \sim 1 : (1.3–1.5)$ was used. The obtained paste with 60% humidity was dried and calcined [1]. The CCBC activity was 30.0%. No wastewater was formed; however, ammonium nitrate remained in the precipitate, forming nitrogen(I) oxide in calcination

$$NH_4NO_3 \xrightarrow{>190°C} NO_2 + 2H_2O. \quad (8)$$

The method is promising if an effective system is available for waste gas purification to remove N_2O and other forming nitrogen oxides.



Degree E of copper(II) recovery with carboxylic acids of the C_7–C_9 fraction vs. pH_{eq} of solution obtained after separation of the precipitated catalyst. Concentration (g l^{-1}): Cu(II) 2.6 and NH_4NO_3 365 g l^{-1}; V_w = 25 ml, V_o = 5 ml; τ = 3 min.

(5) Into a nitrate-ammonia solution of copper(II) was introduced under heating a calculated amount of $Ba(NO_3)_2$. Then, an aqueous solution of CrO_3 was added. The pH value was adjusted to 5.8–6.2 by introduction of HNO_3; $m_s : m_l \sim 1 : (5–6)$. The occurring processes can be represented as

$$2Ba(NO_3)_2 + H_2Cr_2O_7 + 4NH_4OH \rightleftarrows 2BaCrO_4\downarrow + 4NH_4NO_3 + 3H_2O, \quad (9)$$

$$2[Cu(NH_3)_2](NO_3)_2 + H_2Cr_2O_7 + 5H_2O \rightleftarrows 2[Cu(NH_3)_2(H_2O)_2]CrO_4 + 4HNO_3, \quad (10)$$

$$[Cu(NH_3)_2](H_2O)_2]CrO_4 + HNO_3 \underset{70–80°C}{\overset{pH\ 5.8–6.2}{\rightleftarrows}} NH_4(CuOH)CrO_4\downarrow + NH_4NO_3 + H_2O, \quad (11)$$

$$[Cu(NH_3)_4](NO_3)_2 + 2HNO_3 + 2H_2O \underset{70–80°C}{\overset{pH\ 5.8–6.2}{\rightleftarrows}} Cu(OH)_2\downarrow + 4NH_4NO_3, \quad (12)$$

$$Cu(OH)_2 \overset{380–420°C}{\rightleftarrows} CuO + H_2O\uparrow. \quad (13)$$

The catalyst activity was 33.0%. The given way to use nitrate-ammonia solutions of copper(II) is the

most appropriate: 3 mol of NH_4NO_3 is produced per 1 mol of $NH_4(CuOH)CrO_4$, which is only 1.5 times that in the technique reported in [1]. At a small (4–8 mol %) excess of copper(II) with respect to Cr(VI) and pH 6.0–6.2, 20–30 mg l^{-1} of chromium(VI) passed into wastewater, and the content of copper(II) did not exceed 2–3 g l^{-1}. This makes unnecessary the ion-exchange purification of the filtrate to remove chromate ions and allows a 3–4-fold decrease in the volume of wastewater, with the NH_4NO_3 concentration simultaneously increased.

The filtrate obtained in variant 5 is a concentrated ammonium nitrate solution (300–370 g l^{-1}) containing 20–30 mg l^{-1} of Cr(VI) and 2–3 g l^{-1} of Cu(II). The solution can be used as recycle solution in ammonia leaching of copper(II) from spent CCBC or as a liquid nitrogen-containing fertilizer. To remove a major part of copper(II), liquid extraction with 100% carboxylic acids of the C_7–C_9 fraction was studied [3]. It can be seen from the figure that 98–99% of copper(II) was recovered at high NH_4NO_3 concentration in a single extraction stage at $V_w : V_o = 5 : 1$ and pH_{eq} 6.4–6.7; the residual content of copper(II) did not exceed 30–50 mg l^{-1}. The capacity of the organic phase with respect to Cu(II) was 15–20 g l^{-1}. Copper(II) was transferred from the organic into the aqueous phase under the action of mineral acids [4] and used to obtain CCBC. The amounts (milligrams) of Cu(II) and Cr(III) upon reduction of Cr(VI) remaining in the $(NH)_4NO_3$ solution are of interest as microelements. Also possible is additional purification of the obtained solution to remove Cu(II) and Cr(III), e.g., by ion floatation [5].

CONCLUSION

Nitrate-ammonia solutions of copper(II), obtained by ammonia leaching of a spent copper-chromium-barium catalyst, are suitable for obtaining a fresh catalyst. The most promising is the method of precipitation of $Cu(OH)_2$ and $NH_4(CuOH)CrO_4$ by treating a tetraammine(II) nitrate solution with HNO_3 at a 4–8 mol % excess of copper(II) with respect to chromate ions, which makes it possible to diminish 3–4-fold the volume of wastewater. The filtrate was purified to remove Cu(II) by extraction with carboxylic acids of the C_7–C_9 fraction. Wastewater containing 300–370 g l^{-1} of ammonium nitrate is proposed as a liquid nitrogen-containing fertilizer.

Abstract—X-ray structural analysis was applied to study recrystallization of the material of carbon fiber in high-speed high-temperature (up to ~3200°C) thermomechanical treatment. The time of heating of a fiber bundle is evaluated.

The unique physicomechanical properties of carbon fiber are due to its specific microstructure, including the size of coherent domains and the high degree of texturing of carbon ribbons (layers) with respect to the axis of fibers formed in high-temperature thermomechanical treatment [1–3]. In the course of treatment of a thermally stabilized polyacrylonitrile fiber at temperatures of up to 2300°C, heteroatoms are intensively removed and carbon layers (ribbons) mainly oriented along the filament axis are formed to give an ultradisperse, thermodynamically unstable structure. Subsequent thermomechanical treatment of such carbon fibers at 3000–3200°C leads to further recrystallization, with the result that the mean sizes of coherent domains, L_a and L_c, grow substantially, and the elasticity modulus of the material becomes as high as 500 GPa. It is believed that the structural transformation of carbon fibers in high-temperature thermal treatment is rather slow [3]. The present study is concerned with the effect of heating rate and duration of high-speed thermal treatment of a carbon bundle in the temperature range 3000–3200°C on microstructure formation and carbon fiber properties.

Carbon fiber samples were produced by high-speed high-temperature thermomechanical treatment in argon of 99.999% purity (temperature 3000–3200°C, elongation 5.5–7.6%) of a carbon fiber bundle preliminarily thermally treated at 2300°C in the atmosphere of nitrogen of 99.999% purity. To a fiber bundle comprising 7200 filaments about 8 μm in diameter was applied, in the course of thermal treatment at 3000–3200°C, a constant stretching force of 1.5 kg. The furnace temperature in each thermal treatment mode was controlled to maintain constant the relative elongation ΔL.

At a chosen mode of thermal treatment (see table), a fiber bundle was moved, from the input zone of the furnace, with a temperature of about 600°C, into the isothermal zone with temperature of 3000–3200°C in a time of 0.6 to 0.3 s, with the duration of residence, $\Delta\tau$, in the isothermal field of the furnace decreasing in this case from 2 to 1 s. With decreasing time of residence of the fiber bundle in the isothermal field of the furnace, the temperature was raised somewhat to values at which the relative elongation ΔL reached a prescribed value (the interval ΔT of temperature variation did not exceed 200°C).

X-ray structural studies of carbon fibers were carried out on rectangular black-reinforced plastic arms of 4 × 4-mm cross-section. To fabricate the arms, portions of fiber bundle were impregnated with epoxy resin, placed in parallel rows in a mold, with excess amounts of resin removed, and monolithized. The structural investigations were performed with filtered Cu_{K_α} radiation. The interplanar spacing in coherent domains of the carbon fiber was determined from the centers of gravity of the 002 and 110 diffraction peaks. The mean sizes L_c and L_a were calculated by the Selyakov–Scherrer formula.

According to X-ray structural data, the mean sizes L_c and L_a for initial fiber samples subjected to thermal

treatment at 2300°C are about 2.2 and 5.5 nm, respectively, with the interplanar spacings $d_{002} \cong 0.354$ and $d_{110} \cong 0.121$ nm. High-speed thermal treatment of such a fiber at 3000–3200°C initiates recrystallization of the ultradisperse carbon material (see table). Let us consider in more detail the influence exerted by modes of thermal treatment of a bundle in a high-temperature furnace on the structure and properties of high-modulus carbon fiber. It is noteworthy that effort was made to maintain constant the relative elongation Δ*L* of a bundle in the course of thermal treatment in each mode (~5.8–5.9%). However, fibers with somewhat shorter or longer Δ*L* were obtained in some modes because of technical difficulties.

The mean sizes L_c and L_a for bundle samples treated in modes 1 and 2 (temperature ~3000°C, residence time of the material in the high-temperature zone 2.2 s) are 6.6 and 22 nm, respectively. On decreasing the treatment duration to 1.8 s, the furnace temperature was raised somewhat to ensure a relative elongation Δ*L* = 5.8–5.9%. As a result of such a thermal treatment, the L_c and L_a of carbon fiber increased substantially to 8.4 and 26,5 nm, respectively. The elasticity modulus *E* also increased to become 500 GPa. During thermal treatment of the fiber bundle at the same Δτ, but somewhat higher temperature (Δ*L* increased to 7.1%), the mass transfer is markedly intensified. The mean sizes of coherent domains along the *c* and *a* axes become as large as nearly 10 and 30 nm, with the elasticity modulus equal to 510 GPa. The density γ of fiber obtained in modes 3 and 4 was the highest (≥1.9 g cm^{-3}).

The mean sizes L_c and L_a for bundle samples obtained upon thermomechanical treatment in modes 5–10 was 4–18% lower (see table, Fig. 1). In this case, the density γ and elasticity modulus *E* decrease. However, after treatment in mode 11 (time of bundle transfer into the isothermal field of the furnace, with temperature of about 3200°C, is approximately 0.3 s, and the duration of isothermal treatment, ~1 s), a certain increase in mean sizes of coherent domains and improvement of physicomechanical properties of fibers were again observed (Fig. 1). Thus, modes of carbon bundle treatment, in which the largest coherent do-

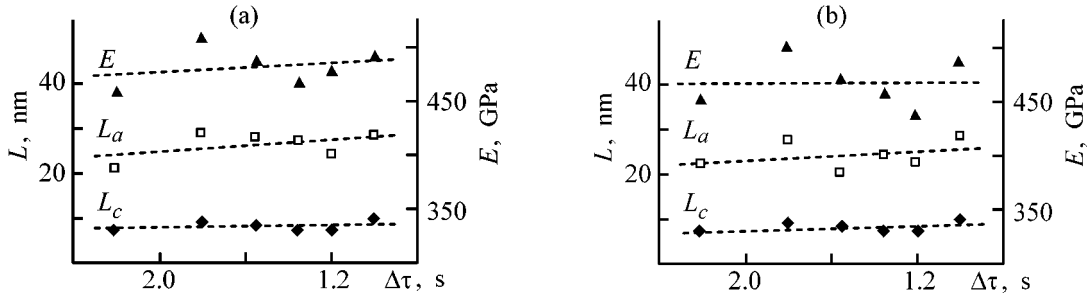

Fig. 1. Mean sizes L_c and L_a of coherent domains and Young's modulus *E* of carbon fiber samples vs. thermal treatment duration Δτ. Furnace temperature corresponds to (a) greatest and (b) smallest relative elongation.

mains are formed, can be distinguished in the temperature-time interval of thermal treatment, considered in this study.

It should also be mentioned that a certain increase in the bundle material treatment temperature in even modes of thermomechanical treatment always initiates a more pronounced mass transfer, compared with modes 1, 3, 5, 7, and 9, respectively. However, cutting down substantially the time of thermal treatment of fiber bundle, $\Delta\tau$, by more than a factor of 2 (to ~1 s) has no significant effect on mean sizes of coherent domains and physicomechanical properties.

The carbon bundle consists of a great number of filaments, its heat conductivity in radial direction is low (0.282 W m^{-1} deg^{-1}) [4]. An estimate of the time of bundle heating (Fig. 2) shows that the residence time of the carbon material in the central part of the bundle at temperatures of about 3200°C is actually shorter by nearly 0.5 s. Thus, depending on a treatment mode, structural transformations in carbon bundle fibers are complete in 1.7 to 0.5 s. It may be assumed that, as in other ultradisperse systems [5, 6], recrystallization centers are formed in microscopic volumes of carbon fiber upon an abrupt rise in material temperature (upon fast transfer of the bundle into a heated furnace). Apparently, further structural transformations develop rather intensively in such local microscopic volumes in a time significantly shorter than the treatment duration. In particular, the time of structural transformations in microscopic volumes of an amorphous carbon film is only 100–200 μs [5]. Therefore, structural transformations of the material of carbon fiber are the most strongly affected in high-speed thermomechanical treatment by the treatment temperature and heating rate, rather than by the duration of heating.

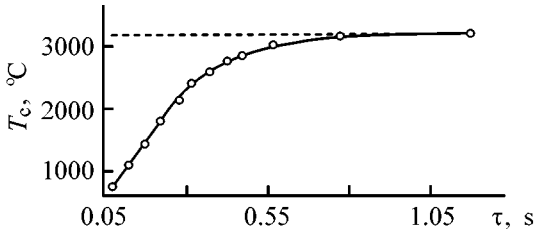

Fig. 2. Time of heating, τ, of a carbon bundle to a temperature T_c.

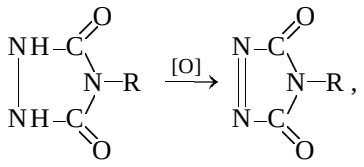
Received July 9, 2001

Abstract—4-Arylurazoles are selectively oxidized with $Fe_2(NO_3)_3 \cdot 9H_2O$ to the corresponding Δ^1-1,2,4-triazoline-3,5-diones.

Recently there has been growing interest in Δ^1-1,2,4-triazoline-3,5-diones, which are extremely active dienophiles and are successfully used in syntheses of fused and polysubstituted heterocycles [1–3]. Also, these compounds react with olefins to form the corresponding secondary amines [4, 5]. The most versatile and widely used route to Δ^1-1,2,4-triazoline-3,5-diones is oxidation of the corresponding urazoles (1,2,4-triazolidine-3,5-diones).

Along with the use of powerful oxidants, such as *tert*-butyl hypochlorite [6], trichloroacetyl isocyanate [7], or nitrogen dioxide [8], procedures have been developed for oxidation with *N*-bromosuccinimide [9, 10] and halogens [11]:



Ia–**Ic** **IIa**–**IIc**

where R = Ph (**a**), 4-ClC_6H_4 (**b**), 3,4-$Cl_2C_6H_3$ (**c**).

In addition to the known procedures, we found that 4-arylurazoles **Ia**–**Ic** can be oxidized to 4-aryl-Δ^1-1,2,4-triazoline-3,5-diones **IIa**–**IIc** with iron(III) nitrate under mild conditions in high yields (65–75%). The reaction occurs in the solid phase, which considerably simplifies the isolation and purification of the target diones **IIa**–**IIc**. A similar procedure has been used previously to prepare substituted semicarbazides [12].

EXPERIMENTAL

4-Aryl-Δ^1-1,2,4-triazoline-3,5-diones IIa–IIc. A mixture of triazolidinedione **Ia**–**Ic** with $Fe_2(NO_3)_3 \cdot 9H_2O$ (molar ratio 1 : 2) was ground in an agate mortar for 5–8 min. The mixture was transferred into dry acetone (15 ml per millimole of **Ia**–**Ic**), concentrated HCl was added to pH ≤ 2, and the resulting bright red liquid was diluted with an equal volume of ice-cold water. The precipitate was filtered off, washed with water, and vacuum-dried. Target compounds **IIa**–**IIc** were obtained in 65–75% yields; their constants agreed with published data [9, 10].

INFORMATION

XXII Danube Region Colloquium on Natural and Artificial Degradation of Polymers

The XXII Danube Region Colloquium on Natural and Artificial Degradation of Polymers was held from September 17 to 18, 2001, at the Federal Institute for Materials Research and Testing in Berlin (Germany). The Organizing Committee Chairman was Dr. P. Trubiroha. The Colloquium was sponsored by several German research centers. The Colloquium title is of purely historical origin: in the early 1960s, scientists from Austria, Germany, and Hungary organized the first colloquium and named it for the Danube River running across these countries. Now this is an all-Europe conference; however, the original title remained.

Among the conference participants were more than 500 scientists from nine European Countries (Austria, Czech Republic, Germany, Hungary, the Netherlands, Russia, Slovak Republic, Sweden, and Switzerland), representing 30 research centers. In all, there were given 25 lectures devoted to thermal, thermooxidative, photooxidative, biological, hydrolytic, and mechanically induced polymer degradation.

The subject of the report delivered by D. Kockott (Germany) was comparison of natural and artificial aging from the standpoint of using accelerated aging methods for prediction of useful life and shelf-life of polymer articles. J. Boxhammer (Germany) examined in his report accelerated photodegradation of polymers as a way to develop new methods for express evaluation of the photostability of polymer articles in use. The problem of fast test calibration for express evaluation of polymer stability was examined in the report presented by a group of authors [G. Pausch (Germany), R. Raymond, and P. Brennan (the United States)]. Much attention was given by the participants to a report by P. Trubiroha on the kinetic features and mechanism of polymer photodegradation and a search for methods for photostabilization of polymer articles. J. Boxhammer's second contribution concerned the use of various simulated-climate chambers for acceleration of polymer degradation and correlation of the data obtained with natural polymer degradation. The same problems were examined in the report by T. Raabe (Germany).

The effects of temperature and humidity on polymer photodegradation were considered by U. Schultz (Germany) who demonstrated that these factors considerably accelerate photodegradation. In the report presented by I. Jakubowicz (Sweden), special emphasis was placed on degradation and stabilization of polyvinyl chloride (PVC).

The problems of accelerated degradation of polymers used in the automobile industry were considered by T. Franz (Switzerland).

A series of the conference contributions were devoted to polymer biodegradation. Specifically, K.Z. Gumargalieva, G.E. Zaikov, and S.A. Semenov considered the interaction of fungi with polymer, particularly PVC, surface; and the report by I. Stephan (Germany) focused on preparation of biofilms through adhesion of microorganisms to the surface of various polymers.

The participants showed considerable interest in the results reported by a group of authors [J. Pospisil, S. Nespurek, Z. Horak, Z. Krulis (Czech Republic), and W.D. Habicher (Germany)] on the effects of polymer matrix and testing conditions on the behavior and useful life of stabilizers for polymers.

A series of contributions were devoted to the problems of environmental protection and interaction of polymers with polluted atmosphere. T.F. Reichert and U. Pohsner (Germany) reported the effect of the type of air pollution on selection of polymers sufficiently resistant against a given type of pollution. U. Schultz considered the part played by acid rains in polymer photodegradation, and V. Wachtendorf reported the development of new polymeric coatings stable in polluted environment (tests were performed in the US). P. Truberoha, U. Schultz, and V. Wachtendorf reported the effect of acid rains on degradation of polymer films for agricultural use. The effects of various additives on accelerated degradation of polymers were analyzed by M. Zah (Germany).

W. Bachleitner and L. Kranner (Austria) focused in their report on natural and accelerated degradation of polycarbonate, and G. Kalinka, on the study of de-

1070-4272/02/7502-0333 $27.00 © 2002 MAIK "Nauka/Interperiodica"

gradation of the surface of polymer articles. The condition of the surface of polymer articles upon their aging and development of quality control methods were considered by C. Van Teylingen (the Netherlands).

The topics of the latter five reports concerned the analysis and control of natural and accelerated polymer degradation. In particular, B. Ivan and T. Szakacs (Hungary) reported on a study of thermooxidative degradation of PVC by gel chromatography. The report by P. Meinlschmidt (Germany) and G.B. Pausch was devoted to determination of latent defects in polymeric coatings by high-resolution thermography. Three reports were devoted to the use of chemiluminescence for studying thermooxidative degradation of various polymers [L. Matisova-Rychla and J. Rychly (Slovak Republic); K. Germann (Germany); and D. Kockott and V. Wachtendorf].

The next, XXIII Colloquium is planned to be held in 2003. However, the place of the meeting has not been specified yet, since none of the organizers of the XXII Colloquium took an initiative to hold the next conference. So the place and date of the XXIII Colloquium will be decided in 2002. The Abstracts of Papers of the XXII Colloquium are available from the library of the Institute of Chemical Physics, Russian Academy of Sciences (Moscow, Russia).

Kontseptsiya razvitiya goreniya i vzryva kak oblasti nauchno-tekhnicheskogo progressa (The Concept of Development of Research into Combustion and Explosion as an Avenue of Scientific and Technical Progress), Chernogolovka: Territoriya, 2001, 176 pp.

The book is a collection of papers prepared by a group of leading specialists on the instructions of the Scientific Council on combustion and explosion of the Russian Academy of Sciences. The purpose of this collection is to reflect the present state of R&D in the field of combustion and explosion and to assess the prospects for their development.

In a brief introduction (pp. 6–12), the executive editor of the collection, Academician of the Russian Academy of Sciences A.G. Merzhanov emphasizes that combustion and explosion presently constitute an independent field of knowledge which has its own experimental and theoretical means of investigation. These are based on analysis of nonlinear direct and back couplings between the rates of chemical, phase, and structural transformations, on the one hand, and rates of energy (heat) and mass transfer, on the other. This approach gives insight into the nature of quite a number of specific phenomena that are typical of combustion and explosion. Despite the difference in outward manifestations, the combustion and explosion are processes which are close in their scientific essence and are characteristic of systems possessing a common feature—high energy capacity. The introduction notes the vast possibilities of the science of combustion and explosion and its real advances in practical applications.

The material of the collection is divided into five chapters, some of which contain actually independent sections written by different authors. The first chapter "Some Aspects of Fundamental Investigations into Combustion and Explosion" (pp. 13–77) contains evidence about the main directions of research, to which, in particular, belong initiation and propagation of combustion waves, effect of external physical fields on combustion and explosion, thermodynamics and kinetics of combustion and explosion, and their mathematical modeling.

The second chapter "Shock Waves and Detonation" (pp. 78–93) is concerned with the state and prospects of studies of shock wave and detonation phenomena. Computer simulation of explosion and high-speed impact, studies of states of substance at high pressure and temperature, technological applications of shock and detonation waves, and some other issues are considered.

The third chapter "Scientific Foundations of the Use of Combustion and Explosion in Technology" (pp. 94–131) discusses a variety of topical problems important for the national economy and energy safety of the country. To these belongs, in particular, the use of hydrogen, which is not only a high-energy ecologically safe fuel, but also a convenient energy carrier. It is noted that effective, corrosion-inactive, and ecologically safe inhibitors, capable of controlling the combustion, explosion, and detonation of hydrogen and its mixtures with carbon dioxide, have been developed at the Institute of Structural Macrokinetics and Problems of Materials Science, Russian Academy of Sciences. Another global problem is related to the necessity for eliminating, processing, or utilizating industrial and domestic wastes. According to the authors' data, use of filtration combustion in modes with superadiabatic heating is among the most efficient ways to solve the problem. The essence of the method and results of tests with reactors intended for various purposes are discussed. Of particular interest is the part of the chapter which is devoted to the analysis of heat-and-power facilities of Russia. The part played by Russia in the world's power engineering in the 21st century is very important—more than 13% of the world's oil reserves, 33% of proven natural gas resources, 16% of coal reserves, and 14% of uranium reserved are concentrated in its territory covering approximately 10% of the Earth's land surface, together with a vast economical potential of unconventional power sources and local reserves of organic fuel. In 1999, Russia occupied the third place in the world, after Saudi Arabia and the US, in oil production (304.2 million ton). Production of gas (591 billion m^3)

1070-4272/02/7502-0335 $27.00 © 2002 MAIK "Nauka/Interperiodica"

was approximately 25%, and that of coal (250 million ton), 5.3% of the respective world's figures.

At the same time, the authors mentioned some negative tendencies in the heat-and-power complex of Russia—decline in gas production at the existing deposits, and decrease in production and, especially, refining of oil at domestic refineries, and the resulting reduction of fuel oil resources, and ecological problems. The authors are of the opinion that, in Russia, it is advisable to use coal whose resources will last for 300–500 years. Directions of investigations that could favor a wider and more efficient use of solid fuel and improve the ecological characteristics of its burning are outlined.

The same chapter considers prospects for development of scientific investigations of combustion processes in internal-combustion engines and points to the necessity for increasing the number of energy carriers that can be used in these engines.

The fourth chapter "Technological Processes of Combustion and Explosion" (pp. 132–156) pays much attention to self-propagating high-temperature synthesis (SHS)—a process in which practically valuable solid substances are formed. The technological advantages of SHS lie in its operation principle—use of heat released in chemical reactions instead of heating a substance by means of an external source. SHS processes have found a wide variety of applications (the problem of SHS is being studied in 47 countries all over the world), but there exist even wider prospects. Use of SHS processes in metallurgy is considered.

Among other promising combustion-related technologies discussed in the chapter are oxypyrolysis and production of synthesis gas (mixture of carbon oxide and hydrogen), and preparation of technical-grade carbon (carbon black) and sulfur in incomplete combustion of aromatic hydrocarbons and hydrogen sulfide, respectively. In the industry of Russia, the annual manufacture of synthesis gas constitutes tens of millions of cubic meters, and, therefore, laying scientific foundations of an energy-saving technology of its production is of primary economical importance. A separate section of the chapter is devoted to explosive technologies. They are based of physicochemical and physicomechanical processes occurring in a substance under the action of shock waves. Irrespective of the method used to generate the waves, a pressure surge ($\sim 10^{10}$ Pa) appears in a material, propagating in it at high speed ($\sim 10^3$ m s^{-1}). The response of materials to an extremal action of this kind may vary. This section of the chapter analyzes the history, present state, and prospects for the development of explosive technologies. Of particular interest is the shock-wave impact upon substances and their mixtures that are apt to undergo chemical and phase transformations.

The fifth chapter "Safety and Ecology" (pp. 157–171) gives general consideration to problems associated with safety and reduction of the technological risk for quite a number of branches of national economy. Analysis of the known emergencies shows that more than 60% of these have been accompanied by inflammation and explosion. Special attention is given to such widely occurring natural ecological catastrophes as forest fires, leading to burning-out of vast forest tracts and contamination of the atmosphere, up to its upper layers, with carbon black particles. The authors of the chapter formulate the main lines of studies of safety and ecology in terms of the presently considered concept of development of research into combustion and explosion as an avenue of scientific and technical progress.

Despite the large number of authors and some differences in the presentation styles, the book is rather well written and is of much interest for a wide variety of specialists in various fields.

The concept in question is based on fundamental investigations requiring considerable funds and commitment of the state and major financial and industrial companies. As noted by one of the authors (p. 156), a decline in basic and applied research in all fields of science has been observed since the early 1990s. Insufficient financing, low pay, lack of inflow of young scientists, and difficulties with scientific exchange—all these factors tell on the rate of development and level of scientific investigations. It only remains to hope that the negative tendencies in science and science-intensive industries, associated with the economic recession in Russia, will be overcome and works in the field of combustion and explosion will receive appropriate support.

BOOK REVIEWS

Petrov, G.V., Greiver, T.N., and Lazarenkov, V.G., *Sovremennoe sostoyanie i tekhnologicheskie perspektivy proizvodstva platinovykh metallov iz khromitovykh rud* (Present State and Technological Prospects of Manufacture of Platinum Metals from Chromite Ores), St. Petersburg: Nedra, 2001, 200 pp.

In the 19th century, Russia was the major manufacturer of platinum extracted from gravel deposits of Urals, which had been exhausted long ago and were replaced in the middle of the 20th century by sulfide copper-nickel ores of the Noril'sk–Talnakh region, containing no less than 40% of the world's reserves of platinum metals. This allows Russia to remain a major manufacturer of platinum metals in the 21st century. Even though chromite ores (chromites are spinel minerals with Cr_2O_3 content ranging from 18 to 62%) are unconventional source of platinum metals, they are of interest in view of the growing demand for platinum and its accessories.

Among the authors of this monograph are specialists with many years of experience both in the geology of platinum metals (V.G. Lazarev) and in the development of methods for their dressing in integrated use of the raw material (T.N. Greiver, G.V. Petrov). This allowed discussion of a wide variety of problems.

The book comprises eight small chapters and a reference list including 193 references to publications by mainly Russian authors. The first chapter (pp. 7–28) characterizes the world's mineral resources of platinum metals and the state of their manufacture and consumption. The most prominent exporters of home-manufactured platinum metals are Republic of South Africa, Russia, Canada, and Australia. The first place in manufacture of platinum is occupied by the Republic of South Africa, the largest manufacturer of palladium is Russia.

The second chapter (pp. 29–46) is concerned with chromite ores, their deposits, resources, mining, and dressing, structure of chromite ore consumption, and state of the world's market of ferrochromium. The third chapter (pp. 47–64) considers the processes of concentration of platinum metals in dressing of ores from deposits in the territory of the Republic of South Africa (Bushweld massif). The fourth chapter (pp. 65–106) discusses problems associated with the recovery of platinum metals in dressing of chromite ores from another kind of deposits—zonal massifs characteristic of the platinum-bearing belt of Urals. Specific features of the behavior of chromium and platinum metals in dressing of ores from the Nizhni Tagil deposit and also from deposits of the southeastern part of the Siberian platform are described. The fifth chapter (pp. 107–126) considers the prospects for dressing of platinum-containing chromite ores from other deposits in the territory of the CIS.

The following chapters—sixth (pp. 126–147), seventh (pp. 148–169), and eighth (pp. 170–187), are concerned with various kinds of technological schemes for processing of the platinum-containing concentrates obtained. Combination of various dressing methods under industrial conditions may yield concentrates with content of the sum of platinum metals in the range from 100 to 1000 g per 1 ton. In choosing a technology, the central issue is the method for stripping the concentrate in order to transfer platinum metals into solution, wherefrom they can be extracted by various techniques (sorption on anion-exchange resin, cementation).

In a brief conclusion (pp. 188–189), the authors emphasize that improving the sensitivity and accuracy of analytical determination of platinum metals made it possible to reveal their presence in many kinds of raw materials that are unconventional for the extraction of platinum metals. Particularly topical for Russia is the processing of the chromite ore which is already an important source of platinum metals in foreign countries.

The monograph is marked by high scientific level and is of interest for engineers and researchers in the field of integrated processing of various kinds of complex mineral raw materials.

BOOK REVIEWS

Ni, L.P., *Fizicheskaya khimiya gidroshchelochnykh protsessov polucheniya oksida alyuminiya* (Physical Chemistry of Hydroalkaline Processes for Production of Aluminum Oxide), Almaty: KazgosINTI, 2001, 148 pp.

This monograph is concerned with an issue that is rather topical for Russia and Kasakhstan. It was written by a known specialist in alumina production and is largely based on results of his many years' investigations. The author made a major contribution to the development of technological schemes for processing of high-silica and high-iron alumina-containing substances and other low-grade aluminum raw materials.

The book comprises five chapters and a list of references to 82 titles. The first chapter (pp. 6–19) gives a general characteristic of the main kinds of aluminum raw materials—bauxites and alkaline and alkali-free aluminosilicates. It briefly describes hydroalkaline methods for alumina production. The second chapter (pp. 20–70) is devoted to the analysis of physicochemical properties of systems, underlying hydroalkaline processes. Much attention is given to the systems containing silicon dioxide and iron(III) oxide. The third chapter (pp. 71–111) occupies the central place in the monograph. The author briefly considers the classical scheme of alumina production by the Baeyer method; various modifications of this method, depending on the type of raw materials being processed; and ways to improve the technology of autoclave leaching of bauxites. The primary aim of improving the autoclave processing in the Baeyer method is to reduce the expenditure of the high-priced caustic alkali. This can be achieved by either raising the temperature of autoclave leaching or replacing sodium hydroxide with soda ash. The monograph analyzes both possible ways. Specific features of processing of high-silica and high-iron bauxites are discussed in detail.

The fourth chapter (pp. 112–133) is concerned with the theory and technology of chemical dressing of high-silica aluminum raw materials. The process is based on the decomposition of high-silica raw materials under the action of acids to give a silicate solution and aluminum-enriched concentrate. Chemical dressing of alkali-free aluminosilicates (kyanite, kaolins and clays, mineral fraction of coals), nepheline ores, and high-silica bauxites is considered. Special attention is given to the processing of silicate solutions. The cost-effectiveness of the technology of chemical dressing is determined largely by the cost and sales volume of products obtained in utilization of silicate solutions. The final fifth chapter (pp. 134–140) contains brief information about autoclave desiliconization of aluminate solutions.

According to the available data, Russia manufactured 3.24 million tons of aluminum in 2000, and the country holds the second place in the world being surpassed only by the United States (3.67 million tons). However, it is known that a considerable part of raw materials is imported. The topicality of using various kinds of low-grade aluminum-containing raw materials in Russia was noted as far back as the 1930s by A.A. Yakovkin (1860–1936), an outstanding physical chemist and technologist.

The book written by L.P. Ni is of indubitable interest for a wide audience of specialists in manufacture of alumina. It can be used as a textbook in chemical-engineering and metallurgical higher-school institutions. The monograph has a clear-cut technological purpose, is well written, and gives a clear picture of the important technological problem.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Properties of Modified Fillers Based on Calcium and Magnesium Carbonates

I. L. Shashkova, A. I. Rat'ko, V. D. Koshevar, N. V. Kitikova, and A. G. D'yachenko

Institute of General and Inorganic Chemistry, State Scientific Institution, National Academy of Sciences of Belarus, Minsk, Belarus

Received April 24, 2000; in final form, December 2001

Abstract—A possibility of modifying natural carbonate fillers for paint and varnish industry by solutions of salts of some nonferrous metals was studied. Reactions of carbonates with metal ions and physicotechnical properties of the resulting materials were considered.

Paints and paint coatings to approximately 70% consist of fillers: natural or synthetic inorganic powders used in combination with chromatic or achromatic pigments to reduce the cost of paint-and-varnish compositions [1]. Colorless substances are used as fillers, but these components of paints and enamels are not inert. A proper choice of fillers makes it possible to improve physicochemical and physicomechanical properties of the painting systems. Fillers based on alkaline-earth metal carbonates gained the widest acceptance owing to their availability and relatively low price. In recent years, a cycle of studies on using natural carbonates as sorbents of such heavy and nonferrous ions as Cu(II), Fe(III), Cr(III), Pb(II), Ni(II), Co(II), etc., has been carried out and summarized in [2]. It was found that solid carbonates, when in contact with solutions of salts of the above metals, react with them to give difficultly soluble colored compounds with solubility products lower than those of the starting compounds [2–4]. These compounds are M(II) and M(III) carbonates, subcarbonates, or hydroxides.

The carbonates can be partially transformed by a two-stage treatment into other colored chemical compounds of M(II) and M(III), which are also high-quality pigments, for example, hexacyanoferrates(II) or phosphates [5, 7]. Moreover, the phosphates are thermostable up to 1000°C and higher.

According to the obtained data, 30–40% transformation of the starting carbonates into reaction products ensures an intense color of the materials.

The capability of alkaline-earth metal carbonates to selectively sorb ions of nonferrous metals from various solutions offers possibilities of utilizing various metal-containing wastes, including wastes of electroplating productions and of metal working, to produce colored materials.

Here we report on the modification of natural chalk and dolomite[1] with solutions of M(II) and M(III) salts and of $K_4[Fe(CN)_6]$, including modification in the presence of phosphate anion, and on the physicochemical properties of the resulting compounds.

EXPERIMENTAL

We used natural dolomite and chalk as the base of pigments and fillers. According to the differential thermal analysis (DTA) data, dolomite contains 84% calcium–magnesium carbonate, and chalk, 96% calcite $CaCO_3$. To prepare modifying solutions, we used the following salts: $CuCl_2 \cdot 2H_2O$ (pure grade), $CuSO_4 \cdot 5H_2O$ (pure grade), $Cu(NO_3)_2 \cdot 3H_2O$ (chemically pure grade), $Co(NO_3)_2 \cdot 6H_2O$ (pure grade), $Cr(NO_3)_3 \cdot 9H_2O$ (pure grade), $Fe(NO_3)_2 \cdot 9H_2O$ (analytically pure grade), $FeSO_4 \cdot 7H_2O$ (analytically pure grade), $K_4[Fe(CN)_6] \cdot 3H_2O$ (chemically pure grade), and also copper-containing wastes $3Cu(OH)_2 \cdot CuCl_2 \cdot xH_2O$ (x = 1–3) and copper shavings, which were dissolved in nitric acid.

We modified natural carbonates with solutions of M(II) and M(III) salts under static conditions at room temperature. A 100-g portion of natural chalk or dolomite was added to 350 ml of 0.9–1.8 N solution of an M salt [M = Cu(II), Fe(III), Cr(III), Co(II)] and allowed to stand for a day at room temperature with intermittent stirring. Then the solid phase was separated, washed with distilled water, dried in air, and ground

[1] Both are industrially mined in the Vitebsk oblast, Belarus'.

in a mortar. To study physicochemical properties, we used the fraction of less than 0.05 μm.

To obtain hexacyanoferrate modifications, we first treated natural carbonates with 0.9 N solutions of $CuCl_2$ and $FeSO_4$ [the solid-to-liquid ratio (g : ml) was $M_s : V_l = 100 : 350$] and then, after washing with distilled water, with a 0.1 N solution of $K_4[Fe(CN)_6]$ ($M_s : V_l = 100 : 750$). The resulting intermediate compounds were treated with potassium dichromate to oxidize Fe(II) by the procedure given in [1].

When obtaining the phosphate modification, we used the product of treating dolomite with a solution of phosphoric acid, which consisted of a mixture of calcium and magnesium hydrophosphates [5]. We colored this mixture with solutions of M(II) and M(III) salts.

We treated carbonates with metal salt solutions for 1 day, though kinetic studies showed that the chemical processes are 80% complete within several hours [3–7].

The concentrations of the modifying salt solutions (0.9–1.8 N) and the ratio between the solid and liquid phases were chosen on the basis of the data on the adsorption of M(II) and M(III) ions by carbonates and phosphates [3–7] in such a way as to ensure partial transformation of the starting phases into the reaction products. The amount of metal ions absorbed from the solution was determined by photometry or by complexometric titration [3, 4, 6, 7] as the difference between their concentrations in the starting solution and in the solution after a contact with a carbonate.

The samples of modified carbonates were heat-treated at 200–800°C.

We determined the specific surface area of the samples S_{sp} ($m^2\ g^{-1}$) by the air adsorption at the liquid nitrogen temperature [8].

The differential thermal analysis (DTA) was carried out with an MOM (Hungary) derivatograph by heating in air at a rate of 10 deg min^{-1} in an open conical crucible. The sample weight was 600 mg.

We determined the phase compositions of the starting carbonates and products of their chemical treatment by the X-ray phase analysis on a DRON-2 diffractometer with the CuK_α radiation.

We determined pH of the aqueous extract, the bulk density, and the oil absorption of modified colored carbonates by the procedures designed for inorganic pigments [9, 10]. The covering power was determined by the visual procedure designed for pigmented paint and varnish materials (relative error ±5%) [9].

The color properties of the materials obtained by the chemical and thermal treatment of natural carbonates are given in Table 1. The combination of chemical and thermal methods for modifying carbonates allowed a wide variety of colored materials to be obtained on their basis. The color intensity of the obtained materials is a function of the modifying solution concentration and is determined by the nature of the modifying agent. A copper chloride solution gave a brighter color than copper nitrate and sulfate solutions.

With the aim to study in detail the physicochemical properties of the colored materials obtained on the basis of chalk $CaCO_3$, dolomite $CaMg(CO_3)_2$, and phosphated dolomite $CaMg(CO_3)_2 \cdot H_3PO_4$, we selected several samples modified in the systems $CaCO_3$–$CuCl_2$, $CaCO_3$–$CuCl_2$–$K_4[Fe(CN)_6]$, $CaCO_3$–$FeSO_4$–$K_4[Fe(CN)_6]$, $CaMg(CO_3)_2$–$Fe(NO_3)_3$, $CaMg(CO_3)_2$–H_3PO_4–$Co(NO_3)_2$, $CaMg(CO_3)_2$–H_3PO_4–$CuCl_2$, and $CaMg(CO_3)_2$–H_3PO_4–$Cu(NO_3)_2$. In the latter case we prepared a solution of copper nitrate from both the reagent-grade salt, $3Cu(OH)_2 \cdot CuCl_2 \cdot xH_2O$ wastes, and copper shavings.

The phase composition, covering power, pH of aqueous extract, density, specific surface area, and oil absorption of the compounds obtained in the listed systems are given in Table 2. Similar properties of the starting nonmodified carbonates are also given there for comparison.

The X-ray phase analysis showed that the products of the reaction of $CaCO_3$ with Cu^{2+} ions and of $CaMg(CO_3)_2$ with Fe^{3+} ions are amorphous: the X-ray patterns contain no reflections of new phases, but involve only the diffraction peaks of the starting $CaCO_3$ or $CaMg(CO_3)_2$ phases. The examination of published data points to the fact that the product of the reaction of the carbonates with iron ions is $Fe(OH)_3$, as Fe(III) does not give carbonates [11]. The reaction is described by the equation

$$3CaMg(CO_3)_2 + 4Fe^{3+} + 6HOH \rightarrow 4Fe(OH)_3 + 3Ca^{2+} + 3Mg^{2+} + 6CO_2. \quad (1)$$

Reactions of chalk with solutions of copper salts can yield various compounds: carbonate, basic carbonates and chlorides, or copper hydroxide. The published information on this problem is rather ambiguous. We used for modification a 1.8 N solution of copper chloride with pH 2.7. After the reaction with calcium carbonate pH of the mother liquor increased to 5.7. It is most probable that under the conditions in

hand the amorphous product is copper hydroxocarbonate.

When phosphated dolomite was treated with salt solutions, the reflections of new phases resulting from the reaction with Cu^{2+} and Co^{2+} ions were identified in the X-ray pattern of the end products, whereas the peaks of the starting phases (calcium and magnesium hydrophosphates $CaHPO_4 \cdot 2H_2O$ and $MgHPO_4 \cdot 3H_2O$) were, as a rule, absent from the patterns of the modified samples.

According to the X-ray data, the products of the reaction of phosphated dolomite with solutions of cobalt(II) and copper(II) salts are $Co_3(PO_4)_2 \cdot 8H_2O$ and $Cu_3(PO_4)_2 \cdot 3H_2O$. Their formation can be expressed by the equations

$$CaMg(CO_3)_2 + 2H_3PO_4 + 3Co^{2+} + 6H_2O \rightarrow Co_3(PO_4)_2 \cdot 8H_2O + Ca^{2+} + Mg^{2+} + 2CO_2 + 2H^+, \quad (2)$$

$$CaMg(CO_3)_2 + 2H_3PO_4 + 3Cu^{2+} + H_2O \rightarrow Cu_3(PO_4)_2 \cdot 3H_2O + Ca^{2+} + Mg^{2+} + 2CO_2 + 2H^+. \quad (3)$$

The products of chalk modification with potassium hexacyanoferrate(II) exhibit reflections of calcium carbonate and of copper and iron hexacyanoferrates(II).

The content of the starting phase, i.e., of an unreacted carbonate, in colored samples is 54–69%, as calculated from the amount of metal ions absorbed from solutions according to the equations of the corresponding chemical reactions (Table 2). Despite this fact, the synthesized materials are fairly uniformly colored without markedly contrasting disseminations of unchanged carbonates. This fact suggests that particles of unchanged phases are colored at the expense of surface processes: either owing to chemical reactions occurring on their surface or owing to the adsorbed metal ions.

Partial transformation of the carbonate phase into new chemical substances results in a characteristic change in the thermogravimetric parameters of the material. The data of differential thermal analysis of carbonates before and after their modification with M(II) and M(III) solutions are given in the Figs. 1a–1c, which show, in particular, that the starting car-

bonates do not undergo thermal decomposition up to 800–900°C. The materials prepared by modifying dolomite and chalk with $Fe(NO_3)_3$ and $CuCl_2$ solutions, respectively, have quite different thermogravimetric characteristics. As seen from Fig. 1, two ranges of thermal transformations can be distinguished. The first range is 117–550 (Fig. 1a) and 106–567°C (Fig. 1b), and the second range covers higher temperatures. The major process in the second range is carbonate decomposition, whereas the first stage, with endothermic effects at 150–300°C, corresponds to the release of water contained in the chemical compounds, in particular, in iron(III) hydroxide (Fig. 1a) and in unidentified amorphous copper(II) compound (Fig. 1b).

When phosphated dolomite is treated with solutions of copper and cobalt salts, hydrated phosphates of alkaline-earth metals partially transform into hydrated copper and cobalt phosphates, the weight loss substantially decreases, but the temperature range of the substance decomposition does not change appreciably (Fig. 1c).

The modification of natural carbonates with acid solutions of metal salts changes not only their color, but also the other physicochemical characteristics (Table 2). The bulk volume of the materials obtained is 0.61–1.47 $cm^3 g^{-1}$. For the initial chalk and dolomite these values are 0.83 and 0.56 $cm^3 g^{-1}$, respectively. The modified fillers are characterized by pH of aqueous extract of 5–8, whereas the initial carbonates have basic properties, pH of their aqueous extract is 8.0–8.9.

The transformation of natural carbonates in solutions of salts with double- and triple-charged metal ions substantially increases the material surface area owing to two factors. First, compounds with a smaller particle size than in the initial carbonate are formed in the reaction with metal ions and, second, unchanged particles of natural carbonates decrease in size on treating with acid solutions of metal salts owing to their partial dissolution. Thus, the specific surface area of the initial materials, which does not exceed 1 $m^2 g^{-1}$, increases after the modification by more than an order of magnitude: to 12–83 $m^2 g^{-1}$.

The oil absorption of the colored fillers obtained is 12–49 g/100 g, which allows them to be classed with readily dispersible substances. One of the most important characteristics of pigments is their covering power. It is seen from Table 2 that cyanoferrate modifications of carbonates have the best covering power: 12 and 25 g m^{-2}. The material obtained from dolomite modified with $Fe(NO_3)_3$ has the covering power of 117 g m^{-2}, which is fairly close to the value given in [1] for natural iron oxide pigments. For blue, light green, and pink fillers obtained from phosphated dolomite and various copper and cobalt solutions, the covering power is 206–342 g m^{-2}. Therefore, many of the obtained modified samples based on natural carbonates have a satisfactory covering power close to that of commercial pigments.

CONCLUSION

(1) Chemical treatment of alkaline-earth metal carbonates in solutions of copper(II), iron(III), chromium(III), and cobalt(II) salts and of potassium hexacyanoferrate(II) results in their transformation into the corresponding transition metal carbonates, basic carbonates, and hexacyanoferrates(III), and in the presence of phosphate anions, into transition metal phosphates. The process is accompanied by substantial changes not only in color, but also in physicochemical characteristics of the materials.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Study by Methods of Electron Spin Resonance and Model Oxidation Reaction of Nanosize Metal Powders Obtained in Electric Explosion of Conductors

T. A. Fedushchak and A. P. Il'in

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received October 17, 2000

Abstract—Paramagnetic properties of nanopowders obtained by electric explosion of copper, aluminum, cobalt, and platinum conductors have been studied. The possibility of using ESR and model reaction of isopropylbenzene for testing the electric-explosion powders as chemical reagents is discussed.

Nanosize metal powders obtained by electric explosion of a conductor are comparatively new and poorly studied objects. They possess a number of specific properties [1–7]. The electric explosion is a phenomenon consisting in explosive disintegration of a metallic conductor through which a current pulse of high density is passed. The most important characteristics of the electric explosion, determining the grain size and nature of the forming metallic dispersions, are the density of energy introduced into a substance (ratio of energy introduced into a conductor to the sublimation energy of this conductor, ω/ω_s), rate of its introduction, its distribution along and across a wire, chemical composition of the medium in which explosion occurs, etc. [8, 9]. The properties of nanopowders produced by electric explosion (NPEE) are strongly affected by the explosion chamber design, which influences the dynamics of particle dispersion in explosion, and by the mode of nanopowder passivation [10]. Use of NPEEs as chemical reagents or catalysts may be efficient if reproducibility of their properties is ensured in the course of preparation and their reactivity in the corresponding chemical transformations can be prognosticated. The conventional approach relying upon "exit" test of NPEEs by means of low-temperature adsorption of inert gases and differential-thermal (DTA), X-ray phase, elemental, and calorimetric analyses proved to be insufficient. Additional diagnostic studies aimed at adaptation of NPEEs as novel chemical objects are necessary. It seems appropriate in this connection to study the paramagnetic properties of NPEEs. The paramagnetic properties of finely dispersed metallic media have been mentioned in the literature. For example, superparamagnetism is exhibited by nanosize ensembles of ferromagnetic nickel in ultradisperse powders obtained by the method of pulsed plasma channel [11, 12]. The authors attributed this phenomenon to distortion of the domain structure of compact nickel. A conclusion that the observed ferromagnetism has impurity nature was made in [13] on the basis of magnetochemical studies of highly dispersed spherical particles of powdered copper and aluminum. Ushakov *et al*. [14] reported the possibility of concentrating various kinds of impurities, including those of paramagnetic nature, either on the surface of particles of nanopowders produced by electric explosion or in the bulk, depending on preparation conditions. In this case, as shown in [15], NPEEs frequently do not absorb the microwave radiation of the ESR spectrometer.

The aim of this study was to analyze the properties of copper, aluminum, platinum, and cobalt powders obtained under varied electric-explosion conditions by the methods of electron spin resonance (ESR) and model reaction of isopropylbenzene (IPB) oxidation.

As objects of study served numerous samples of metals obtained under varied conditions of electric explosion in various gas media: NPEEs of copper, platinum, cobalt, and aluminum (set 1) and NPEEs of copper (sets 2 and 3). The table lists characteristics and preparation conditions of nanopowders belonging to set 1. For comparison, aerosol and plasmochemical nanopowders of copper and PMS-1 powder were studied under similar experimental conditions.

Here we discuss the basic problem of manifestation of paramagnetic properties in the series of the objects under study. The ESR spectra of copper NPEEs of

* D_S is the surface-average particle diameter; $D_S = 6/\rho S$, where ρ is particle density (g cm^{-3}), S is the specific surface area (m^2 g^{-1}) determined by BET; C_{PMC} is the concentration of paramagnetic centers; T_{on}^{ox} is the temperature of oxidation onset, as indicated by DTA; V_{in}, V_{fin} are the gas absorption rates at the initial and final instants of observation; Q is the amount of O_2 taken up in 10 min; and AIBN is azobis(isobutyronitrile).

sets 2 and 3, plasmochemical and aerosol nanopowders of Cu, and PMS-1 powder show no signals. At the same time, nearly all samples of set 1 (nanopowders of copper, aluminum, cobalt, and platinum) are characterized by high intensity of absorption of microwave radiation. Spectra recorded in the form of a first derivative of the absorption intensity function have the form of irregular, broad, asymmetric lines. Typical ESR spectra are shown in Fig. 1. Their line shape corresponds to the Dyson line, which reflects the presence of conduction electrons [16, 17]. The spacing between the absorption peaks H_{max} is 36–37 mT, and the g factor values vary within the range 1.9–2.2. At liquid nitrogen temperature the spectra are even more broadened and, with temperature increasing from 20 to 100°C, the signal becomes narrower without change in the total area under the spectral curve. Placing solid samples in a high vacuum (with residual pressure of 10^{-4} torr) has no effect on this characteristic, either. The concentration range of paramagnetic centers in nanopowders is (spin g^{-1}) $(3–37) \times 10^{20}$ for copper powders, $(3–18) \times 10^{20}$ for aluminum, $(40–316) \times 10^{20}$ for platinum, and $(57–68) \times 10^{24}$ for cobalt. In aluminum powders Al60–Al65, the concentration of paramagnetic centers decreases by a factor of 2 and more already after 3 months, whereas the paramagnetism of copper nanopowders Cu7–Cu12 remains unchanged. In this case, nanopowders obtained in argon medium degrade at much lower rate, compared with powders obtained in nitrogen.

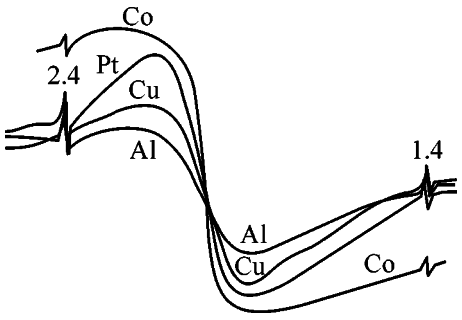

Fig. 1. ESR spectra of Cu, Al, Pt, and Co nanopowders. 2.4 and 1.4 are the g factors of ruby reference.

Previously, the relationship between the energy introduced and dispersity of explosion products has been repeatedly demonstrated. All other conditions being the same, raising the amount of introduced energy leads to higher dispersity of the obtained powders [1]. Comparison of the data presented in the table for Cu8 and Cu10; Cu 11, Cu7, and Cu9; Al60 and Al61; and Al63 and Al66, not only confirms the aforesaid, but also reveals a difference between the initial temperatures of nanopowder oxidation, as indicated by DTA, and between the paramagnetic center concentrations.

ESR analysis characterizes the overall concentration of paramagnetic centers in a sample. Meanwhile, the fundamental questions are those concerning the nature of the powder surface and distribution of paramagnetic centers over this surface and throughout the bulk.

It is known that heterogeneous chemical reactions are highly sensitive to the state of the surface at which they occur. In recent 15 years, an efficient method has been successfully used for studying the surface of solid substances. This method is based on comparison of a thoroughly studied kinetics of the model reaction of IPB oxidation in the case of its homogeneous initiation, on the one hand, and in the presence of heterogeneous surfaces, on the other [18, 19]. It has been established previously in numerous experimental studies that the rate of liquid-phase oxidation of hydrocarbons changes upon introduction into solution of various kinds of solid surfaces (oxides, metals, metal salts, minerals). This effect has been attributed to catalytic and initiating action of the additives. It has been shown that cobalt and manganese oxides affect the stages of not only chain initiation, but also chain termination, whereas metallic copper (micrometer size powders, shavings) affects only the reaction initiation, followed by transfer of radicals into the liquid bulk [18]. As applied to NPEEs, the method of model reactions of liquid-phase oxidation has not been tested as yet.

In this work, we used as a model the low-temperature (60°C) liquid-phase oxidation of IPB initiated by free radicals formed in AIBN decomposition [19]. Nanopowders of Al, Cu, Pt, and Co were used in this reaction together with, and instead of the conventional initiating agent (AIBN).

A 1.5–4.0-fold decrease in paramagnetic center concentration was observed for all of the paramagnetic powders after their being placed in IPB for 10 min and then isolated. For example, the concentration of paramagnetic centers in the system Cu10 + IPB is

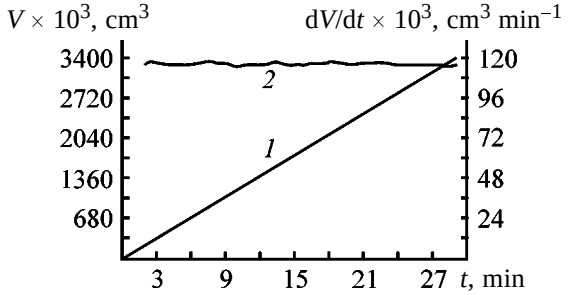

Fig. 2. Kinetics of oxygen uptake in the model reaction of IPB oxidation with oxygen in the presence of AIBN homogeneous initiator. (V) Oxygen uptake, (dV/dt) rate of gas absorption, and (t) time; the same for Figs. 3–5. (*1*) Kinetic curve of oxygen uptake and (*2*) variation of the rate of gas absorption with time; the same for Figs. 3–5.

64×10^{20} spin g^{-1} (see table), being by a factor of 20 higher than that in the initial Cu10 nanopowder, which indicates the development of free-radical processes in this system. For Cu10 isolated from the reaction mixture after being brought in contact with IPB, the corresponding concentration decreases to 1.5×10^{20} spin g^{-1}, i.e., falls by a factor of 2 relative to the initial value. The results obtained confirm the assumption that active centers on the surface of NPEE of set 1, which can initiate the radical reaction of IPB oxidation, have paramagnetic nature. The nature of the surface was studied in more detail by carrying out appropriate kinetic measurements.

The rate of free radical formation in the model reaction of IPB oxidation is commonly found in two ways: from the rate of oxygen uptake and from the rate of inhibitor consumption [19]. In this study, the first method was used on a gasometric installation described in [20].

Figure 2 presents the kinetic curve of oxygen uptake and its derivative, corresponding to the rate of IPB oxidation in the presence of a standard initiating agent (AIBN, 117×10^{-3} cm^3 min^{-1}). The process of gas uptake by all the samples in the initial stage of the reaction was characterized by different observed rate functions and amounts of oxygen taken up. It follows from the table that powders Al61–Al65 of set 1, taken together with IPB but without initiating agent, ensure oxygen uptake on a level not exceeding the standard values. Powder Al66 is nonparamagnetic and remained inert under the conditions of the model reaction. For other nanopowders of copper, platinum, and cobalt, the rate of oxygen uptake by IPB much exceeds the standard value, both with and without initiating agent, which is reflected in Figs. 3 and 4 for the example of Cu10. No definite relationship between the concentration of paramagnetic centers, process

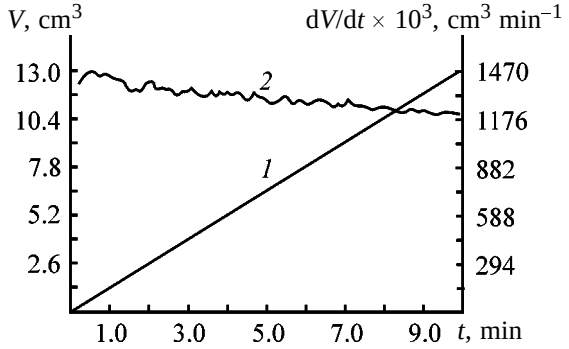

Fig. 3. Kinetics of oxygen uptake by dispersion of Cu10 in IPB in the presence of AIBN initiating agent.

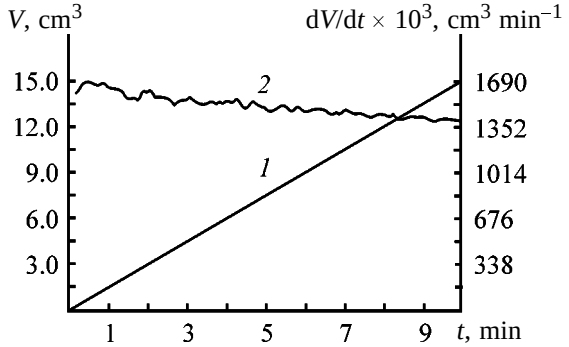

Fig. 4. Kinetics of oxygen uptake by dispersion of Cu10 in IPB. The curve shape is typical of nanopowder nos. 1–14.

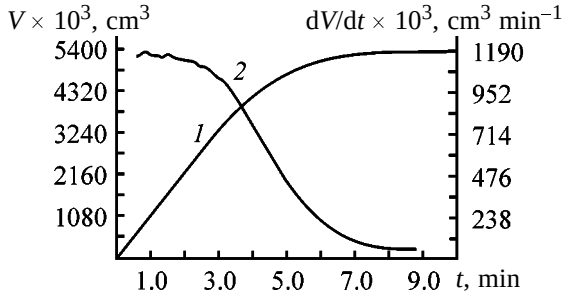

Fig. 5. Typical shape of curves characterizing oxygen uptake by IPB in the presence of nanopowder nos. 15–20.

rate, and amount of absorbed oxygen is observed. For example, nanopowder of platinum (see table, sample no. 13) with a high concentration of paramagnetic centers (40×10^{20} spin g^{-1}) is characterized by a medium, and constant in time, rate of 568×10^{-3} cm^3 min^{-1}. The oxygen uptake is the most intensive on a cobalt powder. These results suggest different concentrations of reactive centers on the particle surface.

According to shapes of the kinetic curves of oxygen uptake by the systems IPB + AIBN + nanopowder and IPB + nanopowder, nanopowders can be classed into two groups. For the first group, a hyperbolic dependence is observed (Fig. 5, curve *1*), adequately reflecting the fast saturation of the system with oxygen (see table, sample nos. 15–20). The second is characterized by gas absorption linearly growing at a constant, comparatively high rate (see table, sample nos. 1–14; typical kinetic curve is shown in Fig. 4, curve *1*). For powders of the first group, the active surface centers are saturated, on the average, in the course of 10 min. Therefore, for all samples the rates and amounts of absorbed oxygen in the table refer just to this time interval. Cu10 and Cu12 samples obtained under similar conditions have different temperatures of oxidation onset (111 and 159°C, respectively). In accordance with the shapes of the kinetic curve, they also belong to different groups. For Cu8, Cu10, and Cu11 powders, the rate of oxygen uptake by the nanopowder dispersion in IPB is the higher, the lower the onset temperature of sample oxidation in air, according to DTA. An analysis of the reaction medium of nanopowders with hyperbolic kinetics of oxygen uptake revealed no products of IPB oxidation. In parallel, oxygen uptake by a suspension of cobalt nanopowder was recorded, even if at low rate [$(28–32) \times 10^{-3}$ cm^3 min^{-1}], in heptane and isooctane, i.e., in a liquid medium stable against oxidation. This possibly means that there is no initiation of IPB oxidation with radicals passing into the bulk of the liquid, during the time interval monitored, and threshold sorption processes occur. Switching the reaction mixture for several minutes into the mode of oxygen bubbling through nanopowder dispersions in IPB results in that the system under study again gains the capacity for short-time gas absorption. Such a cyclic recurrence was verified for all powders of the second group in five cycles. It may be assumed that, under the given particular conditions, activity is exhibited by oxygen-containing surface paramagnetic centers. For nanopowders belonging to the group with hyperbolic kinetics of oxygen uptake, there appears a possibility of separately determining paramagnetic centers on the surface and in the bulk of powder nanoparticles from the difference between the paramagnetic center concentrations in a nanopowder before and after its being brought in contact with IPB and oxygen. In addition, it was found that, upon preliminary evacuation of air, the kinetic behavior of the given powders in the system nanopowder + IPB under conditions of high vacuum (residual pressure 10^{-4} torr) becomes similar to that of powders of the first group, and similar oxidation products are formed.

According to liquid chromatography, the products of IPB oxidation with oxygen in the presence of NPEEs of copper, cobalt, and platinum are composed of a (1–2) : 20 mixture of IPB hydroperoxide and dimethylphenylcarbinol in amount corresponding to 3% IPB conversion. Contrary to published data [18]

concerning IPB oxidation in the presence of micrometer-size copper powders, nanopowders of sets 1 and 3, and aerosol and plasmochemical powders, including coarsely dispersed PMS-1 powder, were inert in the model reaction. This may indicate a different state of their surface.

EXPERIMENTAL

Nanosize powders of copper, platinum, cobalt, and aluminum, produced by electric explosion, were supplied by the Institute of High-Current Electronics, Siberian Division, Russian Academy of Sciences (Tomsk). For the example of set 1, Valevich and Sedoi [8] developed the conditions for uniform volume heating at current densities in the range 5×10^6–5×10^8 A cm^{-2}. This ensured production of powders with increased dispersity, narrow size distribution of particles, and small mass of the coarse fraction (2–3%). Copper nanopowders produced by electric explosion (set 2, explosion in argon, ω/ω_s = 1.2–1.4) were obtained at the Research Institute of High Voltages and at the Russian Center of Science and Engineering, Siberian Division, Russian Academy of Sciences (Tomsk; set 3, argon, ω/ω_s = 1.1–1.5) [9, 10]. The aerosol powder of copper (surface-average diameter of particles of a freshly produced nanopowder from 4 to 6 nm) was supplied by the Krasnaya Zvezda State Enterprise (Moscow), and the plasmochemical nanopowder of copper (200 nm), by the Siberian Chemical Combine (Seversk). An industrial copper powder with micrometer grain size, PMS-1, was obtained by atomization of a melt with subsequent fractionation of particles (40 μm). All powders produced by electric explosion were obtained on installations with electric circuit based on capacitor discharge. A wire 0.3 mm in diameter was fed into the working chamber under lowered pressure of the gas medium (xenon, argon, helium, nitrogen). After a certain amount of powder was produced, the settled powder was collected and studied.

Differential-thermal analysis was made on a Q-1500D derivatograph (Hungary) by the standard procedure (heating rate 10 deg min^{-1}, weighed portion 1×10^{-4} kg). ESR spectra were recorded on a Radiopan SE/X 2544 spectrometer (Poland, Q range) at liquid nitrogen temperature and in the range 20–100°C. The recording was done at a frequency of 9.3 GHz with scanning in the range 0–700 mT in a cylindrical quartz ampule 2 mm in diameter at modulation amplitude of 0.25 mT, scanning time of 16 min, and time constant of 0.3 s. The device was equipped with an attachment for varying the ampule and sample temperature directly in the resonator. The concentration of paramagnetic centers was found by comparing the intensities of ESR signals from the powders under study (area under the curves of microwave absorption derivatives) with that from a reference sample of ruby [17, 21]. The table lists average values of the paramagnetic center concentrations for each sample, calculated from no less than five measurements. The reproducibility was no worse than 5%.

The model reaction of oxidation was studied on a gasometric setup [20] at 60°C in a duck-shaped reactor under standard conditions: 10 cm^3 IPB + 11.2 mg initiating agent [azobis(isobutyronitrile), AIBN] + nanopowder. The initiating agent AIBN was preliminarily purified by recrystallization from ethanol, benzene, and acetone. The kinetic features of gas absorption processes were recorded for various samples and compared for the initial 10-min period of the reaction. The reaction mixture was analyzed on an ELWRO liquid chromatograph (PEG-25M column) and MK-40 IR spectrometer.

CONCLUSIONS

(1) Under certain conditions of electric explosion of such conductors as copper, aluminum, platinum, and cobalt, the forming nanopowders may acquire paramagnetic properties. Paramagnetic centers are distributed over the surface and throughout the volume of nanoparticles, with the concentration of these centers on the surface of copper, cobalt, and platinum nanopowders being higher than in the case of aluminum. The ability of nanopowders to retain paramagnetism in the course of time depends on the chemical composition of the gas medium in which the explosion occurs, with nanopowders obtained in argon being more stable.

(2) The method of a model reaction of isopropylbenzene oxidation reveals surface paramagnetic centers in nanopowders produced by electric explosion and distinguishes even powders of the same type, obtained under similar conditions. The lower the temperature of oxidation onset, the higher the rate of oxygen uptake. In accordance with the nature of gas uptake, powders are divided into two groups. The oxidation reaction occurs only in powders with linear time dependence of the intensity of oxygen uptake. The surfaces of copper and cobalt nanopowders, originally not initiating the model reaction, can be activated by vacuum treatment.

Abstract—Methods of silicon planar technology and pulsed laser deposition were applied to fabricate fully solid-state chemical sensors for determining ions of copper, lead, cadmium, thallium, and also sulfide and chloride ions on the basis of thin chalcogenide films as ion-sensitive membranes.

Development and study of new types of chemical sensors is presently associated with the achievements of new technologies and, in particular, with advances in the technology of integrated microcircuits. In developing microsensors and single-chip sensor systems, a problem arises of obtaining thin-film membranes by techniques compatible with the technology of microelectronics. It is rather difficult to obtain films of required composition by using the previously known methods of CVD, vacuum evaporation, or irradiation-induced deposition. At the same time, physical and electrochemical characteristics of films, affecting the chemical sensitivity of these films as membranes in chemical sensors, are composition-dependent.

Recently, a new method has appeared, pulsed laser deposition (PLD) [1, 2]. This method has been employed to deposit films of superconducting and magnetic materials. The main distinction of the technique is that the sample stoichiometry is preserved even in the case of multicomponent materials. Previously, the PLD method has been specially developed for obtaining thin films of materials that can be used to fabricate membranes of chemical sensors based on silicon structures [3–5].

The aim of this study was to prepare by PLD onto silicon new thin-film sensors for determining ions of copper, lead, cadmium, and thallium, and also sulfide and chloride ions. With positive results obtained, these sensors could be used in developing multisensor systems of the "electronic tongue" type on a single chip [6, 7].

EXPERIMENTAL

The PLD installation shown schematically in Fig. 1 included a Lambda LPX305 KrF excimer laser with pulse width and energy of, respectively, 20 ns and 1 J pulse^{-1} and wavelength λ = 248 nm. Deposition cycles were performed at room temperature and partial pressure of N_2 of about 0.2 mbar to prevent oxidation of the forming thin films. The process duration was varied between 300 and 600 s. At energy density of 5 J cm^{-2} and pulse repetition frequency of 10 Hz, the thickness of the obtained films varied within 380–1500 nm.

In the installation in question, a focused beam of a KrF excimer laser is used as external energy source to evaporate the material from the target surface and deposit it in the form of a thin film onto a substrate, The interaction between the laser beam and the target,

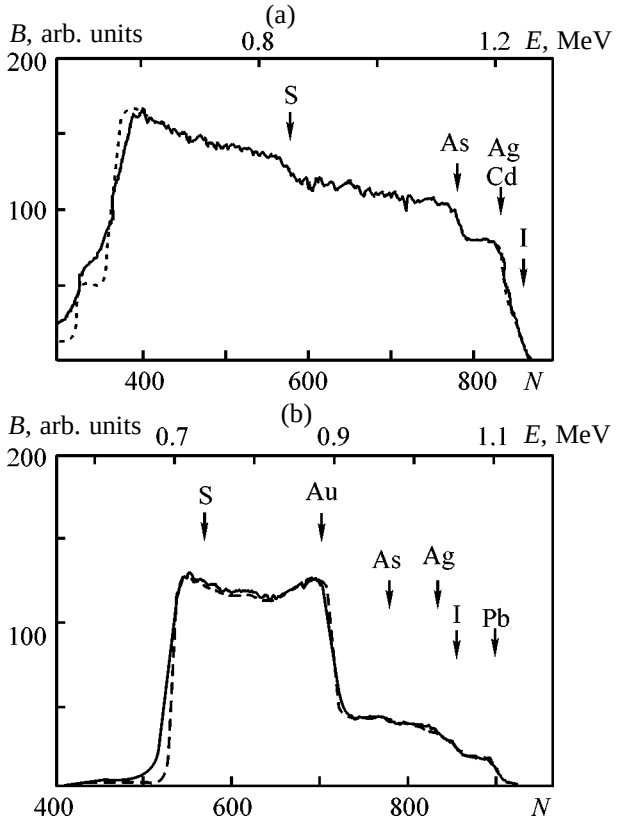

Fig. 2. RBS data for (a) Cd–Ag–I–As–S and (b) Pb–Ag–As–I–S films deposited by PLD onto a gold layer 300 nm thick. (*B*) Normalized output signal, (*N*) channel number, and (*E*) energy. Film thickness (nm): (a) 870 and (b) 300. Solid line: measured data; dashed line: result of their processing by RUMP software [11]; arrows show the corresponding elements.

with duration estimated at several tenths of a second, is divided schematically into four stages [1]: (I) optical irradiation of the target with a short pulse leads to heating of the target surface; (II) the heating is accompanied by melting of the target surface; (III) then substance evaporates from the target surface and multiphoton ionization leads to plasma formation; and (IV) the plasma absorbs laser radiation and controls its further interaction with the surface.

The composition, structure, and thickness of the thin films obtained was studied by Rutherford backscattering spectroscopy (RBS) with the use of He^+ ions with initial energy E_0 = 1.4 MeV and by electron microscopy (JEOL FX4000).

Chalcogenide glasses and polycrystals were used as targets in PLD for fabrication of thin-film membranes of chemical sensors. The targets were 10–12 mm in diameter and 10–12 mm long.

Chalcogenide glasses in the systems Cu–Ag–As–Se–Te, Cd–Ag–As–I–S, Tl–Ag–As–I–S, Pb–Ag–As–I–S, Ag–I–As–S, Ag–I–As–Se, and Ag–As–Te–Se were synthesized from element substances of semiconductor purity in quartz ampules evacuated to residual pressure of 0.1–0.01 Pa in a furnace heated to 1000–1200 K for 5–10 h. Ampules with melt were quenched in air in the temperature range 400–600 K at average cooling rate of 4–6 deg s^{-1}. Ag_2S and AgCl–Ag_2S polycrystals were synthesized by, respectively, precipitation and coprecipitation. The obtained crystalline deposits were compacted under a pressure of 8–10 t cm^{-2}.

Wafers of single-crystal phosphorus-doped *n*-Si with ⟨100⟩ surface orientation, resistivity of 1000–5000 Ω cm, and thickness of 350 ± 40 μm were used as substrates for fabricating chemical sensors. The functional layers of the sensors were structured on the substrates and produced by means of thin-film technology [8]. Ti/Pt, Ti/Pt/Au, and Cr/Au metal contact layers were structured by means of photolithography [4, 5].

The substrates with contact layers were divided into separate elements, and thin-film chalcogenide membranes were prepared by PLD [3–5], using chalcogenide glasses and polycrystals as targets, as described above. The obtained sensors were assembled on printed-circuit boards with appropriate waterproofing.

The electrochemical behavior of the sensors was studied potentiometrically in an electrochemical cell with double liquid junction

Ag	AgCl	KCl (0.1 M)	KNO_3 (0.1 M)	Solution under study	Sensor

The electrode potential of the cell was measured with a V7-23 general-purpose digital voltmeter with accuracy of 0.1 mV. The solution pH was monitored using Ionomer I-130 device with ESL-43-07 glass indicator electrode, calibrated against standard buffer solutions, and silver chloride reference. All measurements were done at room temperature. The ionic strength of the solutions used was maintained constant with 0.1 M KNO_3. The sensor response was studied in solutions containing metal cations (Cd^{2+}, Cu^{2+}, Tl^+, Pb^{2+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, Ca^{2+}, and Mg^{2+}) in the concentration range 10^{-7}–10^{-2} M. The selectivity coefficients were determined using the method of mixed solutions [9, 10].

The effect of the solution pH on the sensor response was studied in solutions with constant concentration of the potential-determining ion, with the pH

varied by adding solutions of nitric acid and potassium hydroxide and the ionic strength of the working solutions maintained constant with a 2 M KNO_3 buffer solution. To monitor the solution pH in the process, the pH was simultaneously measured with a glass pH electrode preliminarily calibrated against standard buffer solutions. All the solutions were prepared using distilled water. The starting solutions of Cd^{2+}, Cu^{2+}, Tl^{+}, Pb^{2+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, Ca^{2+}, and Mg^{2+} nitrates were prepared by dissolving weighed portions of the corresponding nitrates in distilled water acidified with nitric acid. The concentrations of the thus obtained solutions were found by complexometric titration with potentiometric indication of the end point [9]. Individual solutions of Cd^{2+}, Cu^{2+}, Tl^{+}, Pb^{2+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, Ca^{2+}, and Mg^{2+} nitrates with concentrations in the range 10^{-5}–10^{-1} M were produced by tenfold dilution of the starting solutions. Solutions with lower concentrations (10^{-8}–10^{-5} M) were prepared immediately before the measurements in a Teflon cell by the addition method. Reagents of analytically pure grade were used in the study.

The correspondence between the chemical composition of multicomponent thin films deposited by PLD and that of the corresponding targets was checked by RBS spectroscopy. The results obtained are presented in Fig. 2 for films of Cd–Ag–I–As–S (Fig. 2a, 870 nm) and Pb–Ag–As–I–S (Fig. 2b, 300 nm) deposited onto a 300-nm-thick layer of gold by the PLD technique. The comparative data are given in Table 1. It can be seen that a strong deviation of the thin film composition from the composition of the corresponding bulk target was observed only for the Ag–As–Se–Te system. Thus, there is good correspondence between the component composition of multicomponent thin layers deposited by the PLD method and that of the targets used.

The structure and thickness of the obtained films were analyzed by electron microscopy. The study revealed the presence of crystalline nanophases (with size of about several micrometers), compared with the amorphous nature of chalcogenide glass targets. The film thickness was in the range from 380 to 1500 nm (Table 1).

In order to achieve a transition from the ionic (Ag^{+}) conductivity of the sensitive membrane to the electronic conductivity of a metallic contact and to obtain better adhesion of the thin chalcogenide film to the metallic contact layer, which improves the reproducibility and stability of the sensor response and prolongs its service life, various compositions of metallic contact layers were studied. The composition and thickness of the contact layers were as follows: Ti/Pt (25/175 nm), Ti/Pt/Au (30/50/200 and 30/50/300 nm),

and Cr/Au (25/175 nm). Measurements carried out in the course of 3 months demonstrated that sensors with Cr/Au contact layers are characterized by poorer stability and reproducibility.

(1) Cu sensor. A typical curve describing the dependence of the potential difference across the electrochemical cell, E, on the logarithm of the concentration of the potential-determining ion is presented in Fig. 3, curve *3*. It can be seen that the developed fully solid-state sensors sensitive to copper(II) ions (Cu–Ag–As–I–S system) are characterized by Nernst response in the concentration range 3×10^{-5}–1×10^{-1} M, with the slope of the electrode function equal to 27–29 mV/pCu, and a hyper-Nernst response of the sensor is observed in the range of more dilute solutions. This fact may be due to the influence of redox processes occurring at the membrane|solution interface in the case of a low concentration of the potential-determining ion, which was studied, in particular, for Cu ion-selective electrode with a bulk membrane based on a Te-containing chalcogenide glass [12, 13]. Owing to the strong influence of redox processes at low concentrations of the potential-determining ion, a mixed potential is formed at the membrane|solution interface. However, this behavior of the sensor is reproducible, which allows its use in dilute solutions, too. The detection limit of the sensor was 1×10^{-7} M. The main characteristics of the sensors developed, such as the composition of the thin-film membrane, detection limit, slope S of the electrode function, working pH range, and selectivity coefficients, are presented in Table 2.

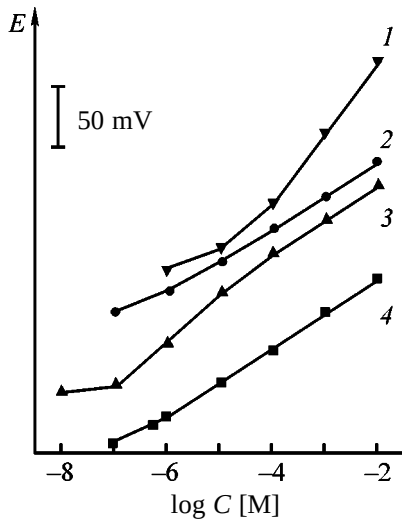

Fig. 3. Calibration curves of (*1*) Tl sensor (Tl–Ag–As–I–S) in $TlNO_3$ solution, (*2*) Cd sensor (Cd–Ag–As–I–S) in cadmium nitrate solution, (*3*) Cu sensor (Cu–Ag–As–Se–Te) in copper nitrate solution, and (*4*) Pb sensor (Pb–Ag–As–I–S) in lead nitrate solution. (*E*) Potential and (*C*) concentration of the potential-determining ion; the same for Fig. 5. (*1*) Solution pH 1.5 adjusted with nitric acid.

The response time of the sensors in stirred solutions does not exceed 30 s in the Cu(II) ion concentration range 1×10^{-4}–1×10^{-1} M, and is about 1–2 min in more dilute solutions.

The effect of the solution pH on the potential of Cu sensors is illustrated in Fig. 4a for two copper(II) ion concentrations, 10^{-4} and 10^{-3} M.

The characteristic rise in the electrode potential, observed with increasing acidity of solutions (pH ≤ 2),

is due to slow membrane dissolution. With the solution acidity lowered, the activity of copper(II) ions decreases because of the formation of hydroxo complexes by metal ions, which accounts for the decrease in the electrode potential and limited applicability of the sensor to direct potentiometric determinations in the alkaline range.

The extent of the hindering influence of foreign ions, i.e., ions different from that determining the potential for a given sensor, in multicomponent solutions on the sensor response was quantitatively evaluated by means of the selectivity coefficients $K_{ij/j}$. Table 2 lists the potentiometric selectivity coefficients found by the method of mixed solutions. As seen from the presented data, a 10^4–10^5 M excess of Pb^{2+} and Cd^{2+} ions and a 10^6–10^5 M excess of Zn^{2+}, Ni^{2+}, Co^{2+}, Ca^{2+}, or Mg^{2+} ions over the Cu^{2+} ion do not hinder analysis for the potential-determining ion.

Experiments concerned with the stability and reproducibility of the behavior exhibited by a Cu-selective sensor were carried out in the course of 8 months. During this period of time, the electrode function, selectivity coefficients, and linearity range remained unchanged, but a drift of the standard potential E_0 was observed, constituting ±5 mV for 10^{-6} M solutions and ±3 mV for 10^{-4} solutions of Cu^{2+} ions. This drift may be due to surface oxidation of the film membrane and gradual change in the surface composition.

(2) Tl, Cd, Pb, Cl, and S sensors. The calibration curves of Tl, Cd, Pb, Cl, and S sensors are presented in Fig. 3 (curves *1*, *2*, and *4*) and Fig. 5 (curves *1* and *2*), respectively. The slopes of the electrode functions and the detection limits were, e.g., 55–59 mV/pTl in the concentration range 5×10^{-5}–10^{-1} M, with detection limit of 3×10^{-5} M, for the Tl sensor (Tl–Ag–I–As–S); 26–28 mV/pCd in the concentration range 10^{-6}–10^{-1} M, with detection limit of 4×10^{-7} M, for the Cd sensor (Cd–Ag–I–As–S); and 56–57 mV/pCl in the concentration range 3×10^{-5}–10^{-1} M, with detection limit of 1×10^{-5} M, for the Cl sensor (Ag_2S–AgCl). All the data are summarized in Table 2.

Unfortunately, it was impossible to fabricate, with the use of chalcogenide glass targets, Ag-selective sensor with stable and reproducible potentiometric response. Possibly, this fact can be accounted for by the high rate of silver ion diffusion in the film, leading to a change in its properties.

The response time of the sensors in agitated solutions of a potential-determining ion does not exceed 30 s at high concentrations and is about 1–2 min in more dilute solutions. The potentiometric selectivity coefficients, and also the working pH ranges, were determined as in the case of the copper-selective electrode and are listed in Table 2. The developed sensors

exhibit high selectivity with respect to the potential-determining ion in the presence of alkali and alkaline-earth metal ions, and also Ni(II) and Co(II).

The stability and reproducibility of the behavior exhibited by the sensors was inspected during 6 months, with no changes in sensor response parameters observed.

The advantage of the developed thin-film sensors over those with bulk membranes is that their technology is compatible with the technology of integrated microcircuits, which enables mass production of lower-cost and reliable sensors and analytical microsystems based on them. In addition, thin-film sensors can be used in small-size flow-through systems with small volume of solutions to be studied.

The results obtained indicate that the employed method may favor further miniaturization, and multisensor systems can be fabricated with sensor membranes having prescribed composition and, consequently, definite sensor characteristics, which is particularly important in creating such analyzers as "electronic tongue."

CONCLUSIONS

(1) Fully solid-phase chemical sensors were developed in the form of ion-sensitive membranes for determining ions of copper, lead, cadmium, and thallium, and also sulfide and chloride ions on the basis of chalcogenide thin films (300 to 1500 nm).

(2) The membranes were fabricated by the methods of silicon planar technology and pulsed laser deposition. The use of the latter allowed fabrication of membranes with prescribed composition and electrochemical characteristics.

Abstract—The effect of swelling conditions on the vermiculite pore structure was studied by X-ray diffraction analysis, mercury porosimetry, and scanning electron microscopy. The closed porosity of the samples was estimated. A possibility for purposeful modification of vermiculite pore structure by varying the swelling temperature and heating rate was evaluated.

Vermiculites belong to minerals of hydromica group, which are formed in the course of hydration and other secondary changes in some micas, particularly in phlogopite and biotite. Two elementary layers of silicon–oxygen tetrahedra, in which silicon is partially replaced by aluminum, and a layer of OH^- groups and magnesium ions form a strongly bound mica stack. A hydrate layer is located between the stacks. This layer consisits of hydrated ions of double-charged metals (mainly Mg^{2+} and Ca^{2+}) [1, 2]. On fast heating (calcination) vermiculites swell, with their volume increasing by a factor of 10–20 owing to vaporization of water from hydrate interstack layers. Swollen vermiculite is used as a construction material because it is a porous material with a low bulk density, high heat-insulating and sound-proof properties, and a high flame resistance. In this regard, a low bulk density of vermiculite is the most important feature; therefore, the influence of the calcination conditions on the bulk density was studied in detail [1, 3].

Recently vermiculite became more attractive for using also in other fields. In particular, it was shown [4] that a composite sorbent based on swollen vermiculite with calcium chloride contained in its pores is capable to absorb a large amount of water (more than 1 g g^{-1}) under static conditions. This property can be important for systems destined for air dehydration and heat accumulation. In view of the fact that the sorption properties of "salt in porous host matrix" composites substantially depend on the pore structure of a matrix [5], we studied in this work in detail the vermiculite pore structure and regular trends in its formation upon calcination.

EXPERIMENTAL

Vermiculites of Kovdor field (KVK-2, fraction 2 ± 0.71 mm) and of Kramer Progetha Basalt-Feuerfest GmbH (Rohvermikulite no. 1, KR-1) were used in the work. The chemical composition of the starting samples is shown in Table 1 [2].

Samples were swollen as follows. A preliminarily dried 0.5-g sample of the initial vermiculite was placed in a furnace heated to 200°C. The furnace temperature was monitored with a thermocouple placed directly over the sample. Then the temperature was linearly increased to 700–1200°C; the sample was kept at a required temperature for 30–60 s and

taken out of the furnace. The heating rate was 40–200 deg min^{-1}. The maximal heating rate was reached by placing a sample in a furnace preheated to 1000°C. In this case the heating was not linear, and the average heating rate reached 1000 deg min^{-1}.

The phase composition of the initial and swollen samples was studied by X-ray diffraction analysis (XRD) on an HZG-4C diffractometer with a graphite monochromator using CuK_α irradiation. The phase composition was determined using the JCPDS data base [6] and the data [7–9] for reference samples of separate minerals. The relative contents of phases were calculated from the integral intensities of their diffraction peaks, and the crystallite sizes, from the diffraction peak broadening. The pore size distribution was determined on a Micromeritics ASAP 1400 automatic volumetric installation from the nitrogen adsorption isotherms at 77 K and by mercury porosimetry on a Micromeritics Pore Size 9300 apparatus. Electron photomicrographs of samples were taken on an REM-100U scanning electron microscope with a digital image output at accelerating voltage of 30 kV. To create a surface conductive layer, a thin layer of gold was preliminarily deposited on the sample surfaces by thermal vacuum dispersion.

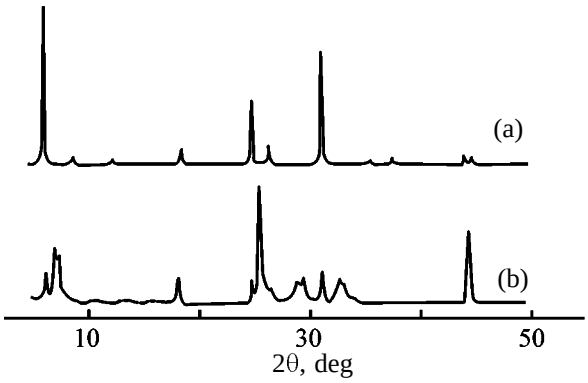

Fig. 1. Diffraction patterns of the initial (a) KVK-2 and (b) KR-1 vermiculites. (2θ) Bragg angle.

According to the XRD data, KVK-2 and KR-1 vermiculites significantly differ in the phase composition (Fig. 1). The former consists mainly of the Mg-vermiculite mineral with pronounced basal reflections (002, 004, 006, 008, 0010, 0012, and 0014). It contains hydrophlogopite as an impurity, which alternates with vermiculite layers with a probability $w \approx 0.06$. Hydrated mica (biotite or phlogopite) is the main phase of the KR-1 sample ($w \approx 0.46$), and Mg-vermiculite is its impurity phase. Thus, both samples contain both vermiculite and hydrated mica layers. However, these layers alternate more uniformly in the KR-1 sample. The difference in the phase composition of the initial samples determines their distinctions in the swelling process. The calcination of the KVK-2 sample at 700°C results in disintegration of Mg-vermiculite (Table 2). The sizes of hydrophlogopite crystallites remain unchanged in the course of the heat treatment, because low-hydrated hydro-

phlogopite undergoes only insignificant changes, which do not lead to its disintegration. Heating of the KR-1 sample to 700°C results in the disintegration of both the Mg-vermiculite (Table 2) and hydrobiotite (hydrophlogopite) phases. The biotite phase appears in the course of the heat treatment. The amounts of the crystallite phases decrease in both samples. The interplanar spacings remain unchanged, because the dehydration at 700°C is reversible [10]. Aluminosilicate layers are destroyed on heating above 1200°C, and the samples become X-ray amorphous [10].

The electron-microscopic patterns of the initial samples are similar (Fig. 2). The samples have a pronounced layered structure. They consist of parallel plates 5–20 μm thick, which are, as it will be clear later, secondary formations. These plates are separated by 0.5–10 μm thick cracks.

On heating, the samples are delaminated under the action of vapor formed in vermiculite hydrate layers (Figs. 3, 4). In this case, two parallel processes occur: (*1*) broadening of the cracks separating secondary plates (Figs. 3a, 3b) and (2) delamination of secondary plates into thinner (primary) layers with a thickness of 0.1–3 μm (Fig. 3b). On heating with a rate less than 200 deg min^{-1} the resulting vapor seems to escape mainly through cracks already available in the initial samples, which leads to the separation of secondary plates. Broadening of the plates at the expense of their delamination into primary layers occurs to a small extent (to 10–50 μm) (Fig. 3c). The structures of swollen vermiculites KVK-2 and KR-1 somewhat differ: secondary plates in KR-1 are delaminated less intensively (especially on edges), and consequently they are of more compact structure (Figs. 3b, 3c).

An increase in the vermiculite heating rate results in more intense delamination of secondary plates into primary layers, and their structure becomes looser (Fig. 4a). Samples obtained by fast heating consist of thin layers with sizes of 0.1–3 μm, which are separated by pores. Some plates take the form of pillows inflated from the inside and linked along the sample perimeter to form closed porosity (Fig. 4b). Samples of both vermiculites, owing to heterogeneity of their structures, have both "cleaved" and "inflated" parts. However, the formation of pillows is more typical for KVK-2 vermiculite. Data on the specific volume of pores and bulk weight of the samples allow us to estimate the volume of closed pores. The bulk weight (ρ_b) of a sample is expressed as the quotient:

$$\rho_b = m/(V_{op} + V_{cl} + V_s + V_t),$$

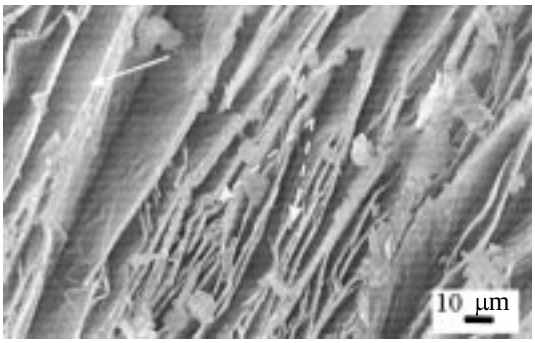

Fig. 4. Samples of (a) KVK-2 and (b) KR-1 swollen by heating to 1000°C at a rate of 1000 deg min^{-1}. Solid arrows indicate areas of closed pores or pillows, and dashed arrows show areas with open pores.

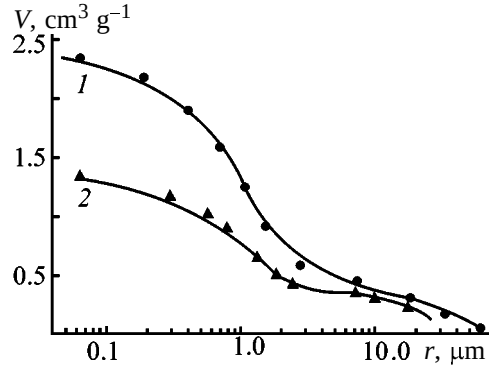

Fig. 5. Influence of the rate of heating to 1000°C on the pore structure of KR-1 vermiculite. (*V*) Pore volume and (*r*) pore radius. Heating rate (deg min^{-1}): (*1*) 1000 and (*2*) 38.

where m is the sample weight (g), V_{op} is the volume of open pores, V_{cl} is the volume of closed pores, V_s is the volume of intergranular space in a sample, $V_t = 1/\rho_t$ is the volume of the solid phase, and ρ_t is the true sample density.

The porosity ε of a layer of granules of different shapes and of the size varying in a wide range is known to be 0.35–0.45 [11]. Taking into account the fact that KVK-2 and KR1 vermiculites swollen by industrial technique have ρ_b of 0.12 and 0.11 g cm^{-3}, V_{op} of 2.6 and 3.5 cm^3 g^{-1}, respectively, and ρ_t of 2.6 g cm^{-3}, we find that the closed pore volume is in the range of 1.5–2.5 for KVK-2 and 0.8–1.8 cm^3 g^{-1} for KR-1. Thus, vermiculite swelling in fact results in formation of a large number of closed pores in addition to open pores, this process occurring to a greater extent in KVK-2 vermiculite.

The volumes of mesopores in both the initial and swollen samples are very small (0.036 and 0.066 cm^3 g^{-1}, respectively). In the course of swelling, numerous macropores with a broad size distribution are formed (Fig. 5). There are macropores of two predominant sizes: pores formed between primary layers, which seem to lie in the range 0.1–1 μm, and pores separating secondary plates from each other, of size in the range 5–50 μm. The specific pore volume increases with increasing heating rate. The volume of large pores (between plates) changes only slightly. The total pore volume increases mainly at the expense of relatively small pores separating layers inside the plates, which is in good agreement with the electron microscopy data. The increase in the calcination temperature from 700 to 1200°C results in a certain decrease in the pore volume (Fig. 5), which seems to be attributable to partial sample sintering. The maximal specific pore volume (2.5 cm^3 g^{-1}) is attained upon heating to 1000°C at a rate of 1000 deg min^{-1}.

CONCLUSION

Swollen KVK-2 and KR-1 vermiculites are characterized by the existence of closed and open pores. Open pores are characterized by a broad size distribution with two predominating pore sizes in the ranges 0.1–1 and 5–50 μm. The structure of open pores depends on the swelling conditions. An increase in the heating rate leads to more uniform swelling and favors the growth of relatively small pores, with the volume of large pores being preserved. The increase in the calcination temperature from 700 to 1200°C results in a decrease in the pore volume. Thus, the pore structure of the resulting samples can be purposefully modified by variation of the vermiculite calcination conditions.

Abstract—Data on the phase equilibria and thermodynamic properties of alloys in the calcium–antimony system are analyzed.

The component interaction in the calcium–antimony system plays an important role in refining of crude lead with calcium [1, 2]. In this work, we consider and compare data on the phase diagram and thermodynamic properties of the Ca–Sb system and, with due regard to these data, discuss the phase equilibrium in the system Ca–Pb–Sb. The phase diagram and thermodynamic properties of alloys of the Ca–Pb system in the solid and liquid states were considered in detail previously [3].

Data on the compositions of compounds forming in the Ca–Sb system are controversial. In handbooks [4, 5], the phase diagram of this system is taken from [6]. That work reports the congruently melting compound CaSb (mp 985 ± 5°C) and the compounds Ca_3Sb_2 and $CaSb_3$ melting with decomposition, with the respective peritectic horizontals lying at 825 ± 5 and 730 ± 5°C. However, in [7–9] compounds of a different composition were reported. According to a summary of published data made by Okamoto [10], in the system Ca–Sb there are the congruently melting compound $Ca_{11}Sb_{10}$ (mp 1123°C) and three compounds melting with decomposition: Ca_2Sb, Ca_5Sb_3, and $CaSb_2$. The peritectic horizontals corresponding to these compounds lie at 827, 996, and 597°C (Fig. 1).

The thermodynamic characteristics of compounds formed in the Ca–Sb system were studied repeatedly by various methods. However, the results are not always consistent. Certain difficulties arising when comparing data of various researchers are associated with different estimated compositions of the forming compounds. Kubaschewski and Villa [11, 12] give for Ca_3Sb_2 the standard enthalpy of formation ΔH^0_{298} = –728 ± 37.7 kJ mol^{-1} and the standard entropy, S^0_{298} = 157.3 J mol^{-1} K^{-1}. Shchukarev *et al.* [13], using solution calorimetry, obtained for Ca_3Sb_2 ΔH^0_{298} = –477 ± 4 kJ mol^{-1}. From the authors' viewpoint, the exothermic effects studied by the method used in [11] are overestimated.

Min and Sano [14], based on the chemical equilibrium data, estimated the Gibbs energy ΔG^0_T for the reaction

$$3Ca(l) + 2Sb(l) = Ca_3Sb_2(s). \quad (1)$$

In the range 1273–1573 K, the temperature dependence of ΔG^0_T (J mol^{-1}) is expressed by the equation

$$\Delta G^0_T = -726\,300 + 159.3T \pm 24\,600. \quad (2)$$

According to a handbook [15], the dependence $\Delta G^0_T = f(t)$ for reaction (1) in the same temperature range has the following form (J mol^{-1}):

$$\Delta G^0_T = -840\,000 + 176.4T. \quad (3)$$

At 1273 K, the ΔG^0_{1273} values for reaction (1),

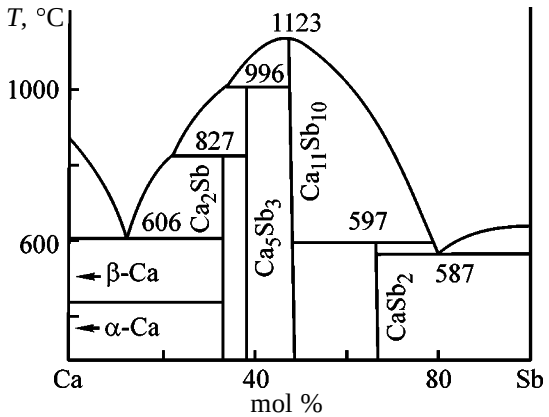

Fig. 1. Phase diagram of the system calcium–antimony [10]. (*T*) Temperature.

1070-4272/02/7503-0362$27.00 © 2002 MAIK "Nauka/Interperiodica"

calculated using Eqs. (2) and (3), are different (–523.5 and –615.4 kJ mol^{-1}). It should be noted, however, that data from [15] are largely based on the results of [11]. It seems appropriate to use Eq. (2).

Ustimov *et al.* [16] measured the solubilities of intermetallic compounds in liquid lead in large-scale experiments (tanks with 400 and 4000 kg of lead) and calculated the Gibbs energy of formation of the compound Ca_3Sb_2 in the solid state at temperatures of up to 714 K. In [16], the following dependence (J mol^{-1}) is presented without reference to calculation details:

$$\Delta G_T^0 = -421\,977 - 210T. \quad (4)$$

Equation (4) differs from Eqs. (2) and (3) primarily in the sign of the temperature coefficient, i.e., in the sign of the reaction entropy.

The cathodic polarization of solid antimony in nitrate (443 K) and chloride (800 K) melts containing calcium was studied in [17]. As will be shown below, interpretation of the results obtained depends on identification of the compounds forming in the system.

The thermodynamic properties of the Ca–Sb system in the middle region of compositions in a wide temperature range (933–1699 K) were studied in detail by Knudsen effusion mass spectrometry [18, 19]. Owing to the limitations of the method, the partial vapor pressure of both components was measured solely in the range of a two-phase equilibrium of $Ca_{11}Sb_{10}$ with Ca–Sb melts at the overstoichiometric content of calcium. This made it possible to calculate the Gibbs energy of formation of $Ca_{11}Sb_{10}$ from the solid components (kJ mol^{-1}):

$$\Delta G_T^0 = -(2184 \pm 15) - (43.5 \pm 12.3) \times 10^{-3} T. \quad (5)$$

In [18, 19], the activity of calcium and antimony in the liquid phase was also determined ($0.502 \le x_{Ca} \le 0.604$, x_{Ca} is mole fraction of calcium in the alloy), with the pure liquid components chosen for standard state. The whole set of the data on the component activity was treated by the authors in terms of the ideal associated solution model with consideration of the CaSb, Ca_2Sb, Ca_3Sb, and Ca_3Sb_2 groups. None of the associates can be considered dominating in a liquid phase, and their enthalpies of formation are comparable (–193.6, –280.8, –316.4, and –562.9 kJ mol^{-1}).

Data on the calcium activity in melts ($0.604 \le x_{Ca} \le 0.635$) in equilibrium with the compound Ca_5Sb_3 allowed estimation of the free energy of formation ΔG_T^0 of this compound from solid antimony and calcium (kJ mol^{-1}):

$$\Delta G_T^0 = -(919 \pm 5) + (34.2 \pm 4.7) \times 10^{-3} T. \quad (6)$$

The results of recent reviews and experimental studies [9, 10, 18, 19] show that, at 443 K, the existence of three phase regions, Sb + $CaSb_2$, $CaSb_2$ + $Ca_{11}Sb_{10}$, and $Ca_{11}Sb_{10}$ + Ca_5Sb_3, is the most probable. In this case, ΔG_{443}^0 of formation of $CaSb_2$, $Ca_{11}Sb_{10}$, and Ca_5Sb_3 from the solid components is –191.1, –1858.6, and –642.2 kJ mol^{-1}, respectively [17]. These values, recalculated to kJ (mol at.)$^{-1}$, are as follows: –63.7 for $1/3\,CaSb_2$, –88.5 for $1/21\,Ca_{11}Sb_{10}$, and –80.8 for $1/8\,Ca_5Sb_3$. Extrapolation of data of [18] to 443 K yields the following ΔG_{443}^0 values (kJ mol^{-1}): –104.9 for $1/21\,Ca_{11}Sb_{10}$ and –113.0 for $1/8\,Ca_5Sb_3$. Unfortunately, the temperature dependences of the Gibbs energy in [18] are given without discussion and comparison with the data of the other researchers [14, 16]. The experimental temperature dependence of ΔG_T^0 is described by the equation [14, 16, 18, 19]

$$\Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0, \quad (7)$$

where ΔS_T^0 is the entropy of formation of a compound from the pure components in the corresponding aggregation state.

Data on this quantity are controversial. As a rule, for the intermetallic compounds formed with a large exothermic effect, ΔS_T^0 is negative. All the calcium and antimony compounds being discussed, existing or hypothetical, are listed below:

Type	$x_{Ca} : x_{Sb}$	x_{Ca}
$CaSb_3$	1 : 3	0.250
$CaSb_2$	1 : 2	0.33
CaSb	1 : 1	0.500
$Ca_{11}Sb_{10}$	11 : 10	0.524
Ca_3Sb_2	3 : 2	0.600
Ca_5Sb_3	5 : 3	0.625
Ca_2Sb	2 : 1	0.667

As noted above, the main object of the initial thermodynamic studies of the Ca–Sb system was the hypothetical compound Ca_3Sb_2, in which the calcium content is intermediate between the compounds $Ca_{11}Sb_{10}$ and Ca_5Sb_3. The entropy of Ca_3Sb_2 formation from the pure components in a wide temperature range can be estimated using the data of a handbook [15] (Fig. 2). The quantity ΔS_T^0 strongly dependens on the aggregation state of the initial components, taking,

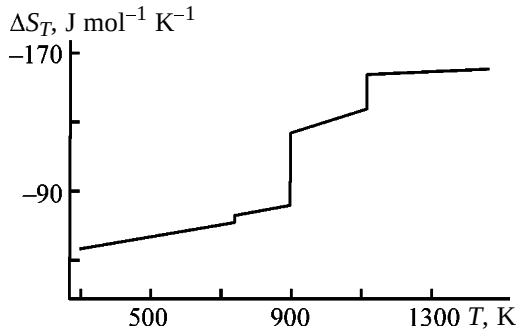

Fig. 2. Entropy of formation ΔS_T^0 of the compound Ca_3Sb_2 vs. temperature T.

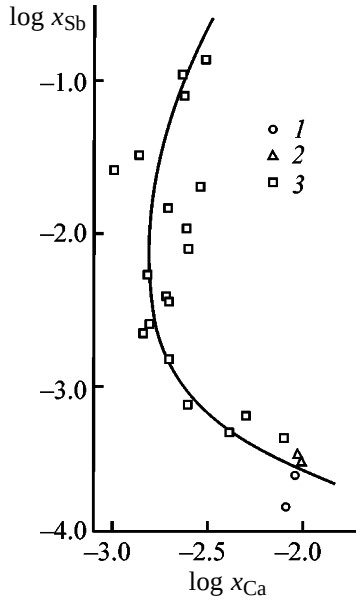

Fig. 3. Composition of the liquid phase in equilibrium with the solid phase in the lead-rich part of the Pb–Ca–Sb system at 400°C [22]. Solid phase: (*1*) $CaPb_3$, (*2*) $CaPb_3$ + Ca_3Sb_2, and (*3*) Ca_3Sb_2.

however, fairly large negative values at all temperatures. Its is reasonable to suggest that at comparable temperatures the ΔS_T^0 values per mole of atoms of the compounds close in the composition ($Ca_{11}Sb_{10}$ and Ca_5Sb_3) should not differ appreciably from the values given in Fig. 2. At the same time, Zaitsev *et al.* [18, 19] give for $1/21\,Ca_{11}Sb_{10}$ $\Delta S_T^0 > 0$ [2.07 J mol^{-1} K^{-1} (1110–1255 K)]. According to the same papers, for the compound $1/8\,Ca_5Sb_3$ $\Delta S_T^0 < 0$ [though it is as small as –4.28 J mol^{-1} K^{-1} (933–1187 K)]. Such discrepancies between the ΔS_T^0 values prevent comparison of experimental data and their recalculation from one temperature to another.

The thermodynamic properties of liquid alloys of the Ca–Sb system ($0.10 \le x_{Ca} \le 0.50$, 800°C) were studied for the first time by the emf method with single-crystalline CaF_2 solid electrolyte. The composition of the alloys was varied coulometrically [20]. The authors showed that, as the mole fraction of calcium is increased from 0.10 to 0.50 at 800°C, its activity changes from 3.16×10^{-10} to 3.50×10^{-9}. In [18, 19], a value of 3.43×10^{-8} was reported for the calcium activity in a liquid alloy with antimony at $x_{Ca} = 0.502$ and 986°C. Taking into account the temperature difference, these data on the calcium activity are in reasonable agreement.

Data on the enthalpy of mixing for liquid alloys in the Ca–Sb system at 1078 K are given in [21]. The extremum in the $\Delta H^0 = f(x_{Ca})$ curve is –67.2 kJ mol^{-1} at $x_{Ca} = 0.52$. The concentration dependence of the thermodynamic functions was described and the short order was estimated using the regular associated solution model. Bouhajib *et al.* [21] postulated formation of only one associate, CaSb, and took into account its interaction with excess pure components (CaSb–Ca and CaSb–Sb) and interaction between the free components. The association is characterized by ΔH_{as} = –158 kJ mol^{-1} and ΔS_{as} = –71 J mol^{-1} K^{-1}. The maximal number of associates was formed close to the composition corresponding to $Ca_{11}Sb_{10}$. The calculated entropy of formation of the CaSb associate in liquid alloys indirectly confirms that the ΔS_T^0 data from [18, 19] for the compounds $Ca_{11}Sb_{10}$ and Ca_5Sb_3 are hardly correct.

From the viewpoint of industrial practice, interaction of calcium with antimony dissolved in liquid lead is of particular interest. No data are available on the thermodynamic properties of Ca–Pb–Sb alloys. In the system Ca–Sb the component interaction is strong [3, 9]. The system Pb–Sb is eutectic, and its properties were repeatedly studied by emf, saturated vapor pressure, and calorimetric methods [2]. The system is characterized by insignificant deviations from the ideal behavior and by a nearly zero enthalpy of mixing.

Fedorov and Shachnev [22] experimentally studied the mutual solubility of calcium and antimony in liquid lead at 400°C. At a very low content of antimony (less than 0.015 wt %) in the solid phase, in equilibrium with the liquid alloy is the compound $CaPb_3$. At higher antimony concentrations (0.020 wt %), two solid compounds are detected: $CaPb_3$ and Ca_3Sb_2. With the antimony concentration increased further, only one compound, Ca_3Sb_2, exists in the solid phase (Fig. 3). No thermodynamic support is given for these results.

As shown previously [3], a value of –118.4 kJ can

be accepted for the Gibbs energy, $\Delta G^0_{673,}$ of the reaction

$$Ca(liq) + 3Pb(liq) = CaPb_3(sol) \quad (8)$$

at 400°C. Correspondingly, the equilibrium constant K_{673} for reaction (8) is 1.55×10^9. Taking into account that

$$K_{673} = a_{CaPb_3}/(a_{Ca} a^3_{Pb}), \quad (9)$$

that $CaPb_3$ is a separate phase, and that the lead activity is nearly unity ($x_{Pb} \sim 0.99$), we obtain a value of 6.45×10^{-8} for the calcium activity in the lead–calcium alloy in equilibrium with $CaPb_3$. In this case, the calcium content in the liquid phase lies within 0.16–0.18 wt % ($x_{Ca} = 0.008$–0.009).

The equilibrium constant for reaction (1) can be written as follows:

$$K_{673} = a_{Ca_3Sb_2}/(a^3_{Ca} a^2_{Sb}). \quad (10)$$

Since Ca_3Sb_2 is a separate solid phase, $a_{Ca_3Sb_2} = 1$, and Eq. (10) takes the form

$$K_{673} = [a^3_{Ca} a^2_{Sb}]^{-1} = K_x K_\gamma, \quad (11)$$

In its turn, $K_x = \prod_x^{-1}$, where K_x is the equilibrium constant expressed via mole fractions, and $\prod_x^{-1}$ is the solubility product, also expressed in mole fractions. In [22], the ratio $x_{Ca} : x_{Sb}$ in the liquid alloys in equilibrium with the solid phase was varied within the wide range: from 33.8 to 0.02. In the process, $\prod_x$ value varied from 1.0×10^{-14} to 1.1×10^{-10} (Fig. 4). To stoichiometry of the forming solid compound corresponds the ratio $x_{Ca} : x_{Sb} = 1.5$.

As noted previously, extrapolation of the ΔG^0_T values, necessary for calculating the equilibrium constant, to relatively low temperatures is difficult. The ΔG^0_{673} value obtained by extrapolation of Eq. (2) to 673 K is –619.1 kJ mol^{-1}. Then, the equilibrium constant of reaction (1) is 1.13×10^{48}. If, according to the equilibrium data, we accept $K_x = 10^{14}$, then K_γ will be $1.13 \times 10^{34.}$ When calcium is present in liquid lead in excess compared to antimony, the activity coefficient of calcium (γ_{Ca}) is mainly determined by the interaction of calcium with lead. As shown in [3], a value of 6.45×10^{-8} for γ_{Ca} can be accepted under these conditions at 400°C. Taking into account K_γ, we obtain the activity coefficient of antimony of 5.7×10^{-7}. However, estimation of ΔG^0_{673} based on the data of [9] gives a different result. For reaction (1) ΔG^0_{673} is

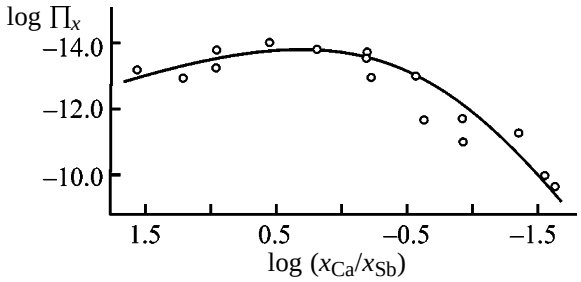

Fig. 4. Solubility product $\prod_x$ (expressed via mole fractions) of the compound Ca_3Sb_2 in the liquid lead at 400°C vs. the ratio of calcium to antimony mole fractions.

–705.9 kJ mol^{-1}. In this case, $K_{673} = 6.17 \times 10^{54}$, $K_\gamma = 6.17 \times 10^{40}$, and the activity coefficient of antimony is 2.46×10^{-10}.

To conclude, the experimental data on the thermodynamic properties of compounds in the system calcium–antimony differ appreciably, which makes any reliable optimization infeasible. This is, to a certain extent, due to the fact that in previous works the central place was given to the compound Ca_3Sb_2, whose existence seems doubtful. The most inconsistent are data on the temperature dependence of the standard Gibbs energy of formation, i.e., on the entropy of alloying.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Analysis of Alloys of the Lithium–Antimony System

A. G. Morachevskii

St. Petersburg State Technical University, St. Petersburg, Russia

Received December 13, 2001

Abstract—Data on the thermodynamic properties of alloys in the lithium–antimony system are compared and analyzed.

The phase diagram of the lithium–antimony system, according to handbooks [1, 2], has not been established. Only data on the crystal lattice parameters of Li_2Sb and Li_3Sb are reported [1]. The melting point of Li_3Sb lies between 1150 and 1300°C [1] or slightly above 950°C [2].

According to [3], the compound Li_3Sb melts congruently at temperature of about 1150°C; at about 650°C α-Li_3Sb transforms into β-Li_3Sb. Li_2Sb melts with decomposition, and the peritectic horizontal lies at about 825°C. On the lithium side, the eutectic is degenerated, and on the antimony side, the eutectic point lies at 89 mol % Sb and about 590°C. The phase diagram, according to [3], is shown in Fig. 1.

An essentially different phase diagram of the Li–Sb system was obtained in [4]. The author pointed out that the diagram could not be considered completely equilibrium, because preliminary annealing was not performed. The alloys were obtained by electrolysis of a molten eutectic mixture LiCl–KCl with liquid antimony as cathode. The probability of potassium incorporation into the alloy was not discussed in that work. In the Li–Sb system, two congruently melting compounds are formed, Li_3Sb_2 and Li_3Sb (mp 700°C and above 1000°C, respectively) [4]. To lithium antimonide Li_3Sb corresponds a very narrow and intense peak similar to that of the intermetallic compound Mg_3Bi_2 [4]. In addition, incongruently melting compound, $LiSb_2$, with the peritectic horizontal at 610°C, is also formed in the Li–Sb system [4]. The compound Li_3Sb_2 is not revealed on the liquidus curve. Thus, the comparison of the phase diagrams reported in [3, 4] calls for a further study of the system.

Some additional information on the compound compositions and other features of the lithium interaction with antimony can be obtained by comparing and analyzing the results of the thermodynamic studies of the system. In [5], a value of –325.5 and –335.0 kJ mol^{-1} was obtained by solution calorimetry for the enthalpy of formation ΔH^0_{298} of Li_3Sb from the solid elements and from liquid lithium and solid antimony, respectively.

The first data on the Gibbs energy of alloy formation in the Li–Sb system were obtained by Weppner and Huggins [6]. The authors varied the alloy composition coulometrically and measured the potential of the Li–Sb solid alloy in a liquid eutectic mixture LiCl–KCl. The study was performed in a wide temperature range (355–600°C). The reference electrode was the Li–Sb alloy in the two-phase region. Two compounds, Li_2Sb and Li_3Sb, were clearly detected in the potential vs. composition curves in [6]. The solubility of lithium in solid antimony is negligible. Passage from the two-phase region Sb + Li_2Sb to the region Li_2Sb + Li_3Sb at 360°C is accompanied by a very small potential drop. The homogeneity region of Li_3Sb at this temperature is small. Nonetheless, in going from x_{Li} = 0.74990 to x_{Li} = 0.75030 [x_{Li} is lithium mole fraction in the alloy] the lithium activity at 360°C changes from 1.04×10^{-7} to 0.438, and the

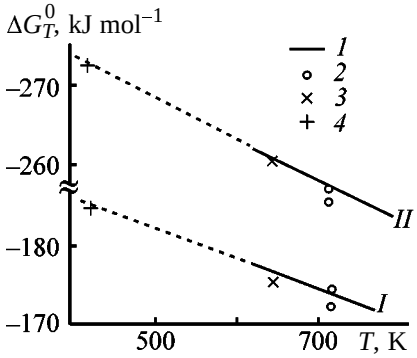

Fig. 2. Gibbs energy ΔG_T^0 of formation of compounds (*I*) Li_3Sb and (*II*) Li_3Sb from pure components, according to the data of various studies. (*T*) Temperature. References: (*1*) [6], (*2*) [7], (*3*) [8], and (*4*) [9].

antimony activity, from 0.297 to 2.78×10^{-22}. Weppner and Huggins [6] obtained the following results: for the reaction 2Li + Sb = Li_2Sb (355–500°C), ΔG_T^0 = = –197.3 + 0.0319*T*, kJ mol^{-1}. Correspondingly, in the given temperature range ΔH_T^0 = –197.3 kJ mol^{-1} and ΔS_T^0 = –31.9 J mol^{-1} K^{-1}. Similarly, for the reaction 3Li + Sb = Li_3Sb (355–500°C), ΔG_T^0 = –293.3 + 0.0492*T* kJ mol^{-1}, ΔH_T^0 = –293.3 kJ mol^{-1}, and ΔS_T^0 = –49.2 J mol^{-1} K^{-1}.

In [7], the polarization curves in the pulsed galvanostatic mode were taken, and switch-off curves were subsequently recorded to study the lithium deposition on liquid and solid antimony electrodes from the liquid electrolytes LiCl (650°C), LiCl–LiF (527°C), and LiCl–KCl (450, 527, and 650°C). The most appropriate temperature for estimating the thermodynamic properties of lithium–antimony compounds is 450°C. A special thermal analysis of the antimony-rich part of the Li–Sb system revealed an eutectic at 472 ± 3°C, which is close to the value of 466°C from [4]. Thus, at 527°C solid antimony is in equilibrium with a liquid alloy. At 450°C, the alloys are in the solid state in the phase regions studied.

The potential of the two-phase region, clearly defined in the polarization curves, is equal to 0.904 ± 0.002 V for the Sb + Li_2Sb system and 0.858 ± 0.002 V for the Li_2Sb + Li_3Sb system. The delays of the potential decrease in the switch-off curves at 450°C for the LiCl–KCl melt are 0.857 ± 0.002 and 0.895 ± 0.002 V. The Gibbs energy of formation of Li_2Sb from liquid lithium and solid antimony is ΔG_{723}^0 = –174.5 kJ mol^{-1}, as calculated from the polarization curve, and –172.7 kJ mol^{-1}, as calculated from the switch-off curve. In [6], the value of –174.2 kJ mol^{-1} is reported.

The Gibbs energy of formation of Li_3Sb from the pure components is ΔG_{723}^0 = –257.3 and –255.4 kJ mol^{-1}, as calculated from the polarization and switch-off curves, respectively. According to [6], ΔG_{723}^0 = –257.7 kJ mol^{-1}.

In a later work [8], the polarization curves in the course of lithium deposition on a solid antimony cathode were taken similarly at 650 K in heterocationic (LiCl–KCl) and homocationic (LiF–LiCl–LiI) electrolytes. At this temperature, the cathode potential relative to the lithium reference electrode in the phase region Sb + $LiSb_2$ was similar in both electrolytes (0.915 ± 0.002 V). This corresponds to the Gibbs energy ΔG_{650}^0 = –176.6 kJ mol^{-1}. With the two-phase system Li_2Sb + Li_3Sb system present at the surface, the electrode potential is 0.879 ± 0.003 V in the LiF–KCl electrolyte and 0.882 ± 0.001 V in the LiF–LiCl–LiI electrolyte. Correspondingly, ΔG_{650}^0 is –261.4 kJ mol^{-1} in the first case and –261.7 kJ mol^{-1} in the second case. The obtained ΔG_{650}^0 values are in good agreement with the data of [6].

At lower temperatures, the alloy formation in the course of lithium deposition on antimony cathode was studied using low-melting electrolytes $LiNO_3$–$LiNO_2$–LiOH and $LiNO_3$–KNO_3 [9].

In this case, the effect of potassium ions on the discharge potential of lithium ions was not revealed. At 150°C, the discharge potential relative to a solid lithium electrode is equal to 0.961 ± 0.003 V for the first phase region (Sb + Li_2Sb) and 0.901 ± 0.002 V for the second phase region (Li_2Sb + Li_3Sb). Correspondingly, the Gibbs energy ΔG_{423}^0 is –185.4 and –272.3 kJ mol^{-1} for Li_2Sb and Li_3Sb, respectively. In going to liquid lithium reference electrode at this temperature, these values change insignificantly (–185.8 and –272.9 kJ mol^{-1}). As seen from Fig. 2, the results of [6–9] are mutually consistent for both compounds of lithium with antimony. The dependence of the Gibbs energy of the Li–Sb solid alloys on the composition at 700°C is shown in Fig. 3.

Data are available on the potentials of lithium deposition from liquid electrolytes on a liquid antimony cathode, indirectly characterizing the component interaction in the liquid state. The polarization curves, reflecting the dependence of the potential of lithium deposition from LiCl and LiCl–KCl liquid electrolytes at 650°C on the logarithm of the current density, are linear in the current density range 2.5×10^{-3}–1.0 A cm^{-2}. In this case, the lithium deposition potential relative to a lithium reference electrode is shifted from 1.6 to 1.0 V [7, 10].

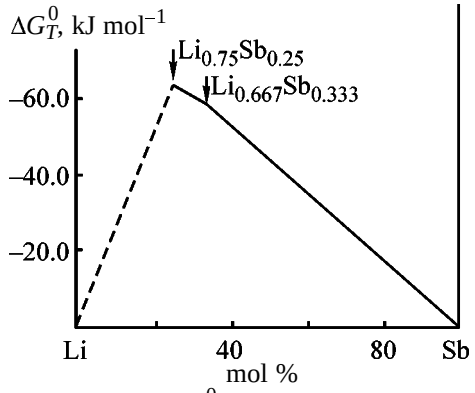

Fig. 3. Gibbs energy ΔG_T^0 vs. composition of the Li–Sb system at 700 K.

In [10], we summarized data on the potentials of lithium deposition from a liquid eutectic mixture LiCl–KCl on various liquid cathodes at a polarizing current density of 0.1 A cm^{-2}. A potential of 0.94 V vs. lithium reference electrode is reported for lithium deposition on a liquid bismuth cathode at 400°C. In [7, 10] we reported a potential of 1.14 and 1.23 V for lithium deposition on liquid bismuth and liquid antimony electrodes, respectively, under similar conditions at higher temperature (650°C). As expected, these values are considerably higher than the potentials of lithium deposition at a similar current density on tin (0.78 V, 400°C) or lead (0.68 V, 400°C).

CONCLUSIONS

(1) Analysis of the whole set of electrochemical data on solid alloys in the lithium–antimony system confirms formation of only two intermetallic compounds: Li_2Sb and Li_3Sb.

(2) The results of electrochemical studies with various liquid electrolytes in a wide temperature range are mutually consistent and allow estimation of the Gibbs energy of formation of Li_2Sb and Li_3Sb from the pure components.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Density of Liquid Halogermanes

I. B. Sladkov

St. Petersburg State Technical University, St. Petersburg, Russia

Received June 26, 2001

Abstract—The density of liquid bromo- and iodogermanes was calculated by four independent methods at temperatures between the melting and boiling points. The coefficients of a temperature series of density were established and the accuracy of the results obtained was analyzed. The reliability of the obtained data was confirmed by variation of the molar volume of a liquid substance in the series of halogermanes and halosilanes.

Germanium compounds containing hydrogen and chlorine atoms (chlorogermanes) are widely used for preparing single-crystalline germanium and for manufacturing semiconductor devices. The procedures commonly involve reduction of chlorogermanes with hydrogen. The germanium compounds with hydrogen and bromine (bromogermanes) and those with hydrogen and iodine (iodogermanes) are reduced with hydrogen more readily than chlorogermanes. Therefore, it may be appropriate to use them when the lower process temperature is the decisive factor.

At the same time, bromo- and iodogermanes are studied considerably less than chlorogermanes; presently, many of their physicochemical properties remain unknown. For example, data are lacking on the temperature dependence of the density in the liquid state.

In this work we obtained, using approximate procedures of the thermodynamic similarity principle, the lacking data on the density of these compounds. The reliability of the methods used was tested on related compounds for which experimental data on the density were available.

To calculate the density of liquid bromo- and iodogermanes, we used four independent procedures. Procedure 1 is based on the law of respective states. According to this law, thermodynamically similar substances must have similar reduced volumes in the liquid state at the same reduced temperature. Calculation of the density by procedure 1 involves a choice of a few compounds that are thermodynamically similar to the compounds under consideration, for which the density in the liquid phase, critical temperature T_{cr}, and critical volume V_{cr} are known from the literature. The reduced volumes, $V_{red} = V/V_{cr}$, of these substances in the liquid state, as calculated for a given reduced temperature $T_{red} = T/T_{cr}$, should be close. Their average value can be accepted as the reduced volume of the substances under consideration at a given reduced temperature.

The thermodynamically similar substances should be chosen so as to ensure close values of the complexity factor of intermolecular interaction (ψ-factor) [1], which is the determining criterion of thermodynamic similarity of inorganic molecular compounds. Therefore, we chose chloro- and bromogermanes GeH_2Br_2, $GeBr_4$, GeH_3Cl, GeH_2Cl_2, $GeHCl_3$, and $GeCl_4$, for which data on the density in the liquid state are available from the literature [1]. Tables 1 and 2 present, according to [1], the physicochemical properties necessary for the calculation. In Table 1 the properties of the substances studied (nos. 7–11) are given along with those of the thermodynamically similar compounds (nos. 1–6).

Evidently, the chosen reduced temperatures for calculating the reduced volumes of the substances should correspond to their liquid state. It is infeasible to estimate the lower temperature boundary of the liquid state without data on the melting point. However, the melting point of iodogermanes is unknown. To determine it, we used a correlation between the melting and boiling points for this class of substances (Fig. 1).

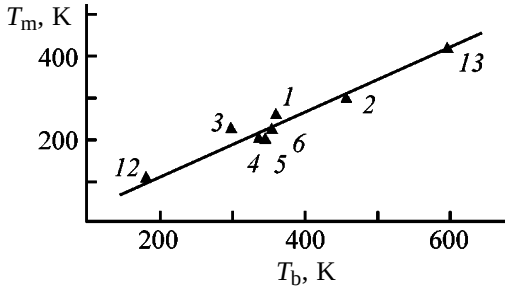

Fig. 1. Correlation between the melting T_m and boiling T_b points of halogermanes. Figures at curves are substance nos. in Table 1; (*12*) SiH_4 and (*13*) SiJ_4.

11	$GeHI_3$	0.014	5.84	338*	500	153.0	775	419

* Calculated by Eq. (1).

As seen, this is a clear linear correlation (correlation coefficient 0.9789, root-mean-square error ±8%) described by the equation

$$T_m = 0.735T_b - 29.6. \quad (1)$$

Using Eq. (1), we estimated the melting points of iodogermanes (Table 1).

Then, we found that the liquid state range for halogermanes corresponds to the condition $T_{red} > 0.42$. On the other hand, for halogermanes the reduced temperature corresponding to the boiling point lies within 0.62–0.65. Therefore, we chose three reduced temperatures (0.50, 0.55, and 0.60) at which any of the indicated compounds would be in the liquid state.

The temperature $T = T_{red}T_{cr}$ can be calculated for each reduced temperature and, using the data of Table 2, the density of a liquid substance, its molar volume $V = M/\rho$, and then the reduced volume $V_{red} = V/V_{cr}$ can be determined for this temperature. The results of the calculations for one of the reduced temperatures are listed in Table 3.

As seen from Table 3, the reduced volumes of different substances differ insignificantly. Thus, they can be averaged. As a result, the following averaged values of the reduced volume were obtained at indicated reduced temperatures (in parentheses): 0.332 (0.50), 0.345 (0.55), and 0.359 (0.60). Then for each reduced temperature we determined the temperature $T = T_{red}T_{cr}$, the molar volume of the liquid substance $V = V_{red}V_{cr}$, and its density $\rho = M/V$ (Table 4).

Calculation procedure 2 is based on the linear correlation between the volume of a liquid substance and the parachor Π, existing for related compounds. It is known that the parachor is a complex physicochemical property of a liquid substance relating its molar weight, surface tension, and density. One of the main properties of the parachor is additivity. Thus, it can be calculated for each substance as the sum of the atomic fractions of the constituent elements, taking into account the molecular stoichiometry [1]. Another im-

* Method of: (1) law of respective states, (2) volume–parachor correlation, (3) Mathias–Goldhammer equation, and (4) Rackett equation.

portant property of the parachor is its correlation with many physicochemical properties.

For example, for related substances the parachor correlates well with the molar volume of a liquid. Taking into account the thermodynamic similarity principle, the volumes as functions of parachor must be compared at the same reduced temperatures. The related substances for bromo- and iodogermanes are chlorogermanes.

Using the parachor values calculated by the procedure described in [1], the data of Table 1, and the volumes of the substances at the three above-indicated reduced temperatures, we constructed the V–∏ plots

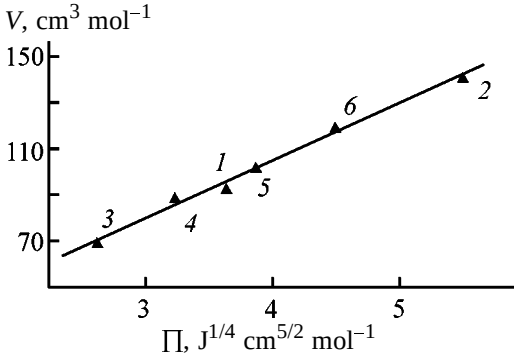

Fig. 2. Correlation between the molar volume of liquid substance *V* and parachor ∏ for T_{red} = 0.6. Figures at curves are substance nos. in Table 1.

for the related substances. Indeed, there is a clear linear correlation between the volume of a liquid substance and parachor (Fig. 2).

Thus, the volume can be calculated from the relation

$$V = A\prod + B. \quad (2)$$

The parameters of relation (2), along with the correlation coefficient *R* and the root-mean-square error *S*, which were determined by the least-squares method, are listed in Table 5. By substituting the parachor values of the substances under consideration into relation (2), we calculated the volumes of these substances and then their density in the liquid state ρ = *M*/*V*. The calculated densities of liquid bromo- and iodogermanes are presented in Table 4.

Procedure 3 uses the Mathias–Goldhammer equation [1]:

$$\rho = \alpha + \alpha(1 - T/T_{cr}) + \beta(1 - T/T_{cr})^{1/3},$$

where

$$\alpha = \rho_b/[2(2 - T_b/T_{cr})],$$

$$\beta = \rho_b/[2(1 - T_b/T_{cr})^{1/3}].$$

The densities calculated by this method are listed in Table 4.

Procedure 4 is based on the Racket equation [1]:

$$\rho = \rho_{cr}B^{y},$$

where

$$y = -(1 - T/T_{cr})^{2/7}.$$

The individual constant B was found using the boiling point parameters:

$$B = (\rho_{cr}/\rho_{b})^{z},$$

where

$$z = 1/(1 - T_{b}/T_{cr})^{2/7}.$$

The densities of liquid bromo- and iodosilanes as calculated by four independent procedures are given in Table 4. As seen, the values obtained by different procedures are in good agreement. Therefore, these values can be averaged to calculate the parameters of a temperature series of density.

To broaden the temperature range, we used the published data for the boiling point (Table 1). As seen from Fig. 3, all points are fitted well by straight lines

$$\rho = a - 10^{-3}bT.$$

The parameters of this dependence for bromo- and iodogermanes, found by the least-squares treatment, are listed in Table 6.

Let us now estimate the accuracy of our results. The root-mean-square error is ±2.5% for method 1 and ±2.4% for method 2 (Table 5). To estimate the accuracy for methods 3 and 4, we calculate the accuracy of the Mathias–Goldhammer and Racket equations for the related substances for which experimental densities are available (Table 2).

To do this, the temperature range between the melting and boiling points was divided in five sections, and the density was calculated for six temperatures, starting from the melting point and completing with the boiling point. The root-mean-square error of the Mathias–Goldhammer and Racket methods calculated for six substances using these data is, respectively, as follows (%): 2.7 and 3.3 for GeH_2Br_2, 0.4 and 0.4 for $GeBr_4$, 0.5 and 0.4 for GeH_3Cl, 0.2 and 0.4 for GeH_2Cl_2, 4.5 and 5.3 for $GeHCl_3$, and 0.8 and 0.2 for $GeCl_4$.

Thus, the overall root-mean-square error of methods 3 and 4 is ±1.7 and ±1.6%, respectively. If the parameter is calculated by several independent methods, and for each method the root-mean-square error is known (as in the case of estimating the densities of the compounds under consideration at each temperature), then the error of the arithmetic mean can be calculated by the method described in [1]. The calculation performed shows that in this work the accuracy in determining the density of liquid bromo- and iodogermanes is ±1.5%.

Table 5. Parameters of the $V = A\prod + B$ dependence

T/T_{cr}	A	B	R	$\pm S$, %
0.50	23.30	4.71	0.9942	2.8
0.55	23.98	5.78	0.9959	2.4
0.60	24.75	6.83	0.9971	2.0

Table 6. Coefficients for calculating the density ρ, g cm^{-3}, of liquid bromo- and iodogermanes at various temperatures, $\rho = a - 10^{-3}bT$

Substance	a	b	R	$\pm S$, %
GeH_3Br	3.01	2.83	0.9925	0.5
GeH_2Br_2	3.78	3.03	0.9999	0.1
GeH_3I	3.446	2.995	0.9923	0.5
GeH_2I_2	4.039	3.06	0.9986	0.2
$GeHI_3$	4.330	2.74	0.9974	0.3

Another way to test the reliability of our data is the method of comparative calculation. To do this, it is necessary to compare the volume variation in a series of related compounds of germanium and silicon. Bromo- and iodosilanes are studied better than the corresponding germanium compounds: for them the parameters for the boiling and critical points and data on the density in the liquid state in the temperature range between the melting and boiling points are available from the literature [1]. Based on these

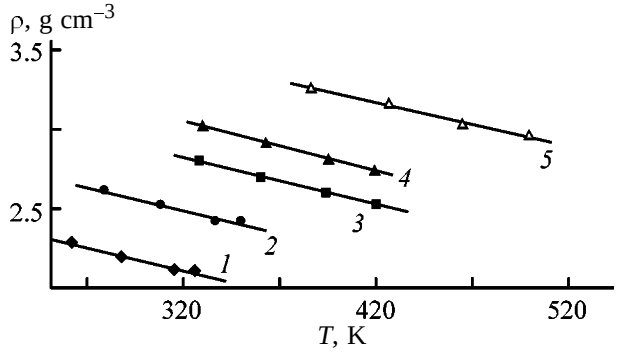

Fig. 3. Density ρ vs. temperature T for liquid bromo- and iodogermanes: (*1*) GeH_3Br, (*2*) $GeHBr_3$, (*3*) GeH_3I, (*4*) GeH_2I_2, and (*5*) $GeHI_3$.

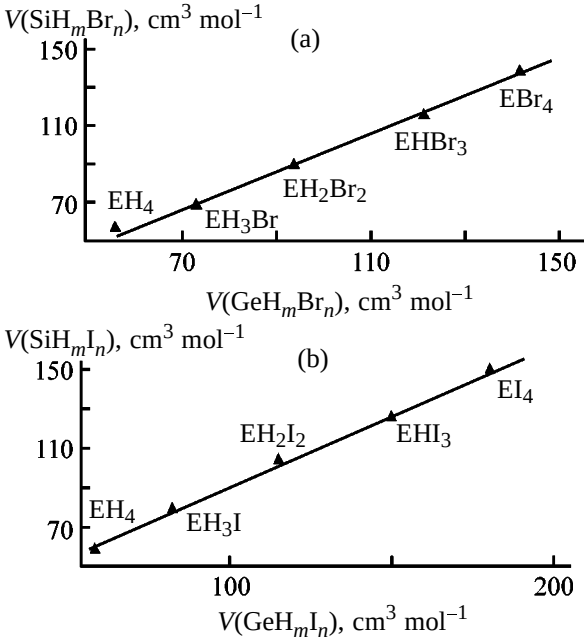

Fig. 4. Variation of the molar volume V of liquid substance for T_{red} = 0.6 in the series of (a) bromogermanes and bromosilanes and (b) iodogermanes and iodosilanes.

data, let us calculate the volumes of liquid bromo- and iodogermanes at a particular reduced temperature, for example, at T_{red} = 0.6. The variation of the volume is shown in Fig. 4a for a series of bromogermanes and in Fig. 4b for a series of iodosilanes and iodogermanes. As seen from these plots, a clear linear correlation exists in both cases. The correlation coefficients are as high as 0.9957 and 0.9989, respectively, and the root-mean-square errors, as low as ±0.7 and ±1.2%, respectively. This fact additionally confirms the high reliability of our results.

CONCLUSIONS

(1) The data on the density of liquid bromo- and iodogermanes, which are lacking from the literature, are obtained by four independent calculation procedures for the temperature range between the melting and boiling points.

(2) The reliability of the data obtained is confirmed by variation of the molar volumes of liquid substances in the series of halogermanes and halosilanes.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility of 1-Amino-4-Hydroxyanthraquinone in Water–Amide Mixtures

S. M. Prusova and A. V. Baranov

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received June 23, 1999; in final form, May 2000

Abstract—The solubility of a C.I. Disperse Red 15 dye in water and concentrated aqueous solutions of urea and acetamide was studied by isothermal saturation within the 313–353 K temperature range The thermodynamic characteristics of the dye solution were calculated, and the results were analyzed.

The state of a dye in intensifier, which is used in high-speed, high-temperature fixation of disperse dyes on a textile, is poorly studied. This is caused by partial decomposition of intensifiers at high temperatures and low solubility of disperse dyes. At the same time, the state of disperse dyes in water–amide solutions is of interest in terms of fixation of dyes on textile and development of high-speed high-temperature dyeing technology.

The goal of this work was to study the solubility of purified C.I. Disperse Red 15 dye (1-amino-4-hydroxyanthraquinone) in water and mixtures of water with urea and acetamide (water content 30–50%) within the 313–353 K temperature range by isothermal saturation method in order to obtain the thermodynamic parameters of dye solution.

EXPERIMENTAL

To determine the solubility of 1-amino-4-hydroxyanthraquinone, we used a special temperature-controlled device, which is a hermetically sealed tube equipped with a filtering attachment for sampling solid-phase-free solution. The concentration of the dissolved dye in the saturated aqueous solution was determined spectrophotometrically after its extraction with carbon tetrachloride. The relative error of determination of the dye solubility was 1.44%.

1-Amino-4-hydroxyanthraquinone used was prepared from commercial-grade Disperse Red 2C dye as follows. The dye was extracted with acetone and then precipitated with a large excess of distilled water, filtered, washed with water, and dried. The procedure was repeated several times to attain the constant molar absorption coefficient of the dye in the solution. The further purification was performed by the chromatography [1] on a column packed with 100/40 silica gel with toluene as an eluent. Four fractions were isolated, and only the fraction whose electronic spectrum contained the long-wave band with two maxima at 530 and 560 nm was used in the study. These maxima are characteristic of the charge-transfer band of 1-amino-4-hydroxyanthraquinone in toluene [2]. The dye was crystallized from toluene and dried under vacuum. Analytically pure grade amides were used.

The thermodynamic characteristics of solution of the nonionic dye were calculated using phase equilibrium equations. For poorly soluble nonelectrolytes, the activity coefficients are close to unity. Therefore, the concentration can be used instead of activity. The dye solubility was varied within the 0.4×10^{-5}–7×10^{-5} M range depending on the temperature and solvent composition. From data on solubility, the Gibbs energy was calculated:

$$\Delta G^0 = -RT \ln C, \quad (1)$$

where C is the dye concentration in the saturated solution.

As a rule, within a small range of temperature variation the heat of solution ΔH^0 varies weakly, and hence it can be taken as constant. With this assumption, the integration of the isobar equation $d\ln C/dT = \Delta H^0/RT^2$ gives

$$\ln C_2/C_1 = \Delta H^0(T_2 - T_1)/RT_2T_1, \quad (2)$$

where C_2 and C_1 are the dye solubilities at temperatures T_2 and T_1, respectively. Using Eq. (2), we calculated ΔH^0.

Water	31.9	56.0	–20.2	–	–	–	–	–	–

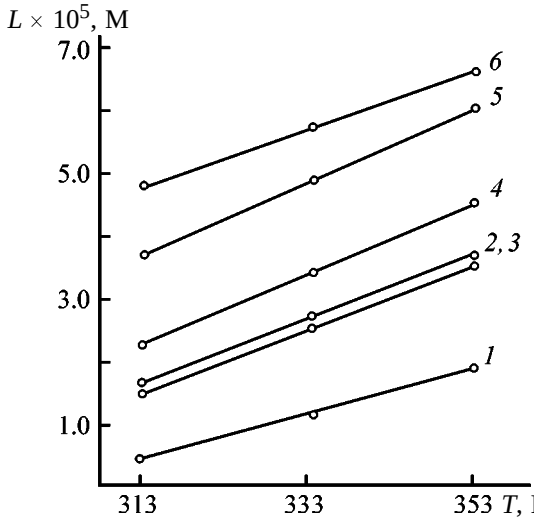
The entropy of solution can be determined from the relation

$$\Delta G^0 = \Delta H^0 - T\Delta S^0. \quad (3)$$

As the standard state of the substance dissolved in the real solution, we take its state in a hypothetical ideal solution with unit concentration, in which the partial molar volumes, enthalpy, and heat capacity are the same as in infinitely dilute solution. For the solvent in the real solution, the state of pure solvent under standard conditions is taken as the standard state.

The relative errors of the thermodynamic parameters calculated by differentiation of the corresponding equations are ±0.1% for ΔG^0 and ±3% for ΔH^0 and ΔS^0.

Data on the solubility of the dye in various solvents at various temperatures are shown in the figure. As seen, the temperature dependences are linear; the correlation coefficient is 0.999 from the least-squares treatment. Water–amide mixtures dissolve the dye better (curves *2*–*6*) than water (curve *1*).



Solubility L of 1-amino-4-hydroxyanthraquinone in (*1*) water, (*2*, *3*) water–urea, and (*3*, *4*) water–acetamide mixtures as a function of the temperature T. Water content (wt %): (*2*, *5*) 40, (*3*, *6*) 50, and (*4*) 30.

Dissolution of 1-amino-4-hydroxyanthraquinone in each water–amide mixture is specific. The solubility of the dye in the mixture with acetamide is higher than in the mixture with urea and noticeable depends on the amide : water ratio.

The calculated thermodynamic characteristics of solution of the dye in water and water–amide mixtures are listed in the table. As seen, the entropy factor largely governs the dissolution of the dye in water. The enthalpy of solution in water is highly positive, which prevents dissolution. In water–amide mixtures, the role of the enthalpy factor in dissolution increases. The enthalpy of solution is independent of water content within the 40–50 wt % range for water–urea mixtures and decreases for water–acetamide mixtures with increasing water content. We believe that it is due to lower structurization of water–acetamide solution as compared to water–urea solution, owing to the structure-breaking effect of the alkyl substituent. This increases the dye dissolvation (see table). The enthalpy contribution to dye solution increases with increasing water content in the water–acetamide mixture. The role of entropy in dye dissolution decreases from water to water–amide mixtures: the entropy becomes negative.

On the whole, dissolution of the dye in water–amide mixtures is less endothermic than in water, and this is due not only to specific interaction of amide molecules with water, but also to the effect of hydrophobic hydration, i.e., liberation of the additional energy as a result of increasing number and strength of H bonds between water and amide molecules surrounding the dye molecules. Hydrophobic hydration, in turn, favors strengthening of associates of organic substances in the solution [3, 5].

CONCLUSIONS

(1) The solubility of 1-amino-4-hydroxyanthraquinone in water and aqueous amides was studied by isothermal saturation within the 313–353 K range. The dissolving power of water–amide mixtures with the 30–50 wt % water content with respect to the dye is higher than that of water. The solubility of 1-amino-4-hydroxyanthraquinone in water–acetamide mixture depends of the mixture composition and is higher than the solubility in water–urea mixture.

(2) The main factor of dissolution of the dye in water is the entropy change. Dissolution of the dye in water–amide mixtures is characterized by increasing enthalpy contribution to the free energy of solution.

SORPTION AND ION-EXCHANGE PROCESSES

Lead(II) Sorption by Magnesium Phosphates

N. B. Shul'ga and V. V. Samusevich

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received May 4, 2000; in final form, July 2001

Abstract—Lead(II) sorption from aqueous solutions by various magnesium phosphates was studied. The sorption kinetics was studied. Magnesium phosphates show high performance in treatment of lead-containing solutions under static and dynamic conditions.

Recently the interest in phosphate sorbents increased again. The sorption of heavy metal ions, including lead, from solutions by zirconium [1, 2] and calcium [2–4] phosphates was studied. It is presumed in these papers that the sorption occurs by the ion-exchange mechanism; however, in certain cases the release of exchanging ions into the solution was out of equivalent stoichiometry [5], which suggests that the process can be complicated by side chemical reactions. Previous data [6] showed that the lead(II) sorption by hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ is accompanied by complicated topochemical transformations affecting the sorption parameters.

The ion-exchange properties of magnesium phosphates are poorly understood. Vol'khin *et al.* [7, 8] studied the ion exchange of alkali metals on $MgHPO_4 \cdot 3H_2O$, $Mg_3(PO_4)_2 \cdot 22H_2O$, and $MgNH_4PO_4 \cdot H_2O$. In [9, 10], it was shown that acid magnesium hydrophosphates can be used to sorb copper(II) and also other heavy metal (cadmium, nickel, cobalt, and mercury) ions from solutions. These facts suggest that magnesium phosphates can exhibit a sorption activity toward lead(II).

In this work we studied sorption of lead(II) by various magnesium phosphates. To optimize the sorption process, we have studied the kinetics of lead(II) sorption from dilute (0.1–0.0005 M) solutions of nitrates at 20°C under static conditions. The sorption isotherms were obtained, and the characteristics of magnesium phosphates under study were determined. Based on these data, the optimal sorption conditions were found and solutions contaminated with lead(II) were purified under dynamic conditions.

EXPERIMENTAL

Samples were synthesized by known procedures. Magnesium ammonium phosphate monohydrate $MgNH_4PO_4 \cdot H_2O$ was prepared by combining 1 M solutions of magnesium chloride (chemically pure grade) and ammonium hydrophosphate (analytically pure grade) in a 1 : 3 ratio at 90°C [11]. Crystalline magnesium hydrophosphate trihydrate $MgHPO_4 \cdot 3H_2O$ was prepared by the reaction of a 35% solution of magnesium sulfate (chemically pure grade) and 50% orthophosphoric acid (chemically pure grade), taken in an equimolar ratio, at 40°C [12]. The resulting crystalline samples were analyzed for the contents of lead(II) and magnesium(II) (by complexometric titration with xylenol orange and eriochrome black, respectively, as indicators), phosphorus (photocolorimetrically after formation of molybdenum blue), and nitrogen (by the Kjeldahl method) [13]. The water content was determined by the weight loss of samples on calcination (minus gaseous ammonia in the case of $MgNH_4PO_4 \cdot H_2O$).

Samples prepared for the analysis were dissolved in hydrochloric acid, as the use of, e.g., nitric acid can noticeably distort the results of phosphorus determination. The anlytical data were consistent with the above-given formulas. The X-ray patterns of the crystalline products coincide with published data [14] for the corresponding salts.

Magnesium orthophosphate was prepared by the reaction of solutions of magnesium sulfate (chemically pure grade) and sodium hydrophosphate (analytically pure grade) at pH 9 [15], maintained by adding sodium hydrocarbonate. At 40°C, an X-ray amorphous product is formed, identified by chemical analysis as $Mg_3(PO_4)_2 \cdot 6H_2O$.

When studying lead(II) sorption under static conditions, 0.2 g of a sample under study (from the sieved 100–200-μm fraction) was brought in contact at room temperature with 5×10^{-4}–0.1 M solutions of $Pb(NO_3)_2$ at a certain ratio R between the liquid (ml)

and solid (g) phases. To determine the sorption capacity, R was varied from 150 to 28000 (from 30 to 5600 ml of solution per 0.2 g of sorbent), and in kinetic experiments it was chosen in each particular case so as to ensure a constant (1.5-fold) excess of lead(II) at complete transformation of the initial sorbent into the product, irrespective of solution concentration. The resulting water–salt systems were kept at 20°C for various periods (0–48 h) with intermittent stirring. Then the precipitates were separated from the solution, washed with water, and dried in air to constant weight, after which the contents of lead, magnesium, and phosphorus were determined by the above-described techniques. The equilibrium liquid phases were analyzed similarly. The solution pH during sorption was monitored with an EV-74 ionometer in a parallel series of experiments.

When studying sorption under dynamic conditions, we stirred 0.1 g of a sorbent in aqueous suspension with silica in a 1 : 20 ratio and filled with this mixture a column 0.5 cm in diameter and 5 cm high. A dilute 5×10^{-4} M solution of lead nitrate was passed through the column at a constant rate (~1 ml min^{-1}). Eluate samples were taken at regular intervals, and the lead(II) and magnesium(II) contents were determined therein. On this basis, the output curves were plotted and the performance of the column was evaluated with respect to both the degree of solution concentrating and the degree of the sorbent exchange. The phase composition of the sorption product was also

determined. The dilution of the phosphate sorbent with silica (which is almost inert in the process under study) allows the experiment to be carried out much faster. With neat $Mg_3(PO_4)_2 \cdot 6H_2O$, at the same concentration of the initial solution and the same elution rate, the lead(II) breakthrough would occur only after several months.

The X-ray phase analysis of the initial samples and solid products formed in various stages of the sorption was carried out on a DRF-2.0 diffractometer (CuK_α radiation).

The data on the lead(II) sorption under static conditions [24-h contact of $MgHPO_4 \cdot 3H_2O$, $Mg_3(PO_4)_2 \cdot 6H_2O$, and $MgNH_4PO_4 \cdot H_2O$ with solutions of lead(II) nitrate at 20°C] are given in Tables 1 and 2. These data show that, as the lead(II) content in the initial solution per gram of the sorbent (a_0) increases, the amount of the sorbed lead(II) regularly increases irrespective of whether this increase is reached at the expense of increasing solution concentration at a constant volume (Table 1) or at the expense of changing R (Table 2). If the a_0 value is fixed, variation of the concentration of the initial solution (and, correspondingly, of R) only slightly affects the value of sorption. Only with $MgNH_4PO_4 \cdot H_2O$ an anomaly is observed, namely, at R = 150 the increase in the solution concentration from 0.05 to 0.1 M results in a sharp reduction in the amount of the sorbed lead(II) (Table 1). As will be shown below, this unexpected effect is due to the arising diffusion hindrances in delivery of lead(II) ions to the sorbent surface through a layer of the forming sorption product.

The sorption capacities of $Mg_3(PO_4)_2 \cdot 6H_2O$, $MgHPO_4 \cdot 3H_2O$, and $MgNH_4PO_4 \cdot H_2O$, determined from the corresponding isotherms, are as high as 18.8, 22.6, and 21.8 mg-equiv g^{-1}, respectively, whereas one of the best known inorganic sorbents (zirconium phosphate [1]) sorbs no more than 5 mg-equiv (2.5 mmol) of Pb^{2+} per gram. The isotherms in Fig. 1 almost coincide with the ordinate up to high sorption values, which means that high exchange capacity of magnesium phosphates can be reached even at low equilibrium concentrations of lead(II) in solution. This fact makes magnesium phosphates suitable for the purification of both concentrated and very dilute solutions. The data on lead(II) sorption from 0.001–0.1 M $Pb(NO_3)_2$ solutions by various phosphate sorbents at R = 150 (30 ml of solution per 0.2 g of sorbent) are shown in Fig. 2a. Under these conditions, $Mg_3(PO_4)_2 \cdot 6H_2O$ and $MgNH_4PO_4 \cdot H_2O$ completely remove lead(II) from its solutions with an initial concentration of up to 0.05 M, and magnesium hydrophosphate sorbs 95% of lead(II) from 0.05 M solutions. At the same time, zirconium hydrophosphate under these conditions sorbs less than a half of the initial lead(II). With this sorbent, the 100% purification is reached only with 0.005 M and less concentrated solutions.[1]

The initial solution concentration at which lead is completely removed depends on the liquid : solid

[1] The A values for zirconium phosphate were calculated from the sorption isotherms given in [1] for the liquid phase : sorbent ratio of 100 used in that work.

ratio; however, the experimental data obtained at different R values are well fitted by the curves in the coordinates degree of purification–total amount of lead(II) in the initial solution per gram of sorbent (Fig. 2b). This fact allows us to calculate easily in each particular case the amount of the sorbent required for exhaustive purification of the solution. Later, when discussing the kinetic data, we shall consider several cases of deviations of the above-mentioned trend (Fig. 2b, outlying points of curves *1* and *3*), which result from a change in the sorption mechanism.

The sorption rate is of considerable practical importance for the use of sorbents for treatment of solutions to remove heavy metal ions. In the case of inorganic sorbents it can depend in a complicated way on the sorption conditions, sorbent structure, and the concomitant chemical and phase transformations. Let us consider the kinetic features and mechanism of lead(II) sorption by various magnesium phosphates.

If the sorption occurs by the ion-exchange mechanism

$$MgNH_4PO_4 \cdot H_2O + Pb^{2+} \rightarrow PbNH_4PO_4 \cdot H_2O + Mg^{2+}, \quad (1)$$

1 mol of magnesium ammonium phosphate can sorb 1 mol of lead(II). The maximum amount of lead(II) that can be sorbed in the system obtained by mixing 200 mg of the monohydrate and 60 ml of a 0.05 M solution of lead nitrate is 1.29 mmol. At the same time, it was found that the lead(II) concentration in such solution decreases within a day to 0.015 M, which corresponds to the sorption of 2.1 mmol of Pb^{2+}. The excess sorption can result from chemical transformation of magnesium ammonium phosphate either to lead orthophosphate [reaction (2)] or to pyromorphite [reaction (3)]:

$$3MgNH_4PO_4 \cdot H_2O + 3Pb^{2+} \rightarrow Pb_3(PO_4)_2 + 2Mg^{2+} + 2NH_4^+ + H_2O, \quad (2)$$

$$3MgNH_4PO_4 \cdot H_2O + 5Pb^{2+} \rightarrow Pb_5(PO_4)_3OH + 3Mg^{2+} + 3NH_4^+ + H^+. \quad (3)$$

The X-ray phase analysis of the sorption product shows that the process develops according to (3). This equation is also consistent with the experimental molar ratio of the sorbed lead(II) and released magnesium(II), $Pb^{2+} : Mg^{2+}$, which is close to 5 : 3 (Table 1).

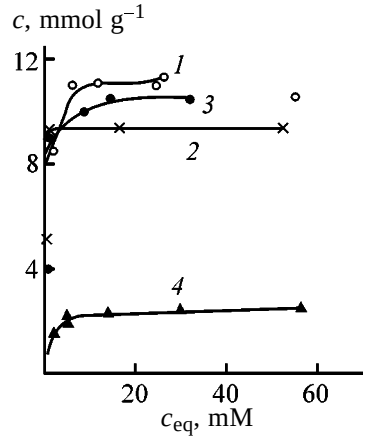

Fig. 1. Isotherms of lead(II) sorption by samples of magnesium phosphates: (c) $\overline{Pb}^{2+}$ concentration in the sorbent and (c_{eq}) Pb^{2+} concentration in the equilibrium solution. Sorbent: (*1*) $MgHPO_4 \cdot 3H_2O$, (*2*) $Mg_3(PO_4)_2 \cdot 6H_2O$, (*3*) $MgNH_4PO_4 \cdot H_2O$, and (*4*) $ZrHPO_4$ [1]; the same for Fig. 2.

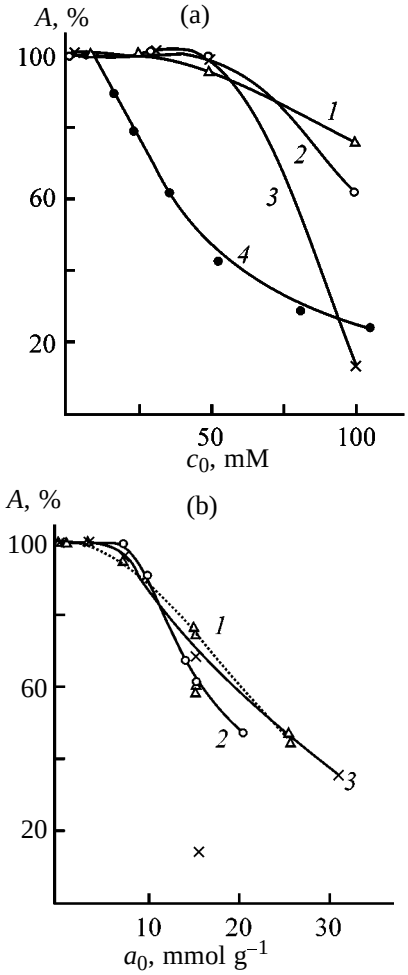

Fig. 2. Plots of the degree of lead removal A from $Pb(NO_3)_2$ solutions by magnesium phosphate samples vs. (a) the initial solution concentration c_0 and (b) total lead(II) content a in the initial solution.

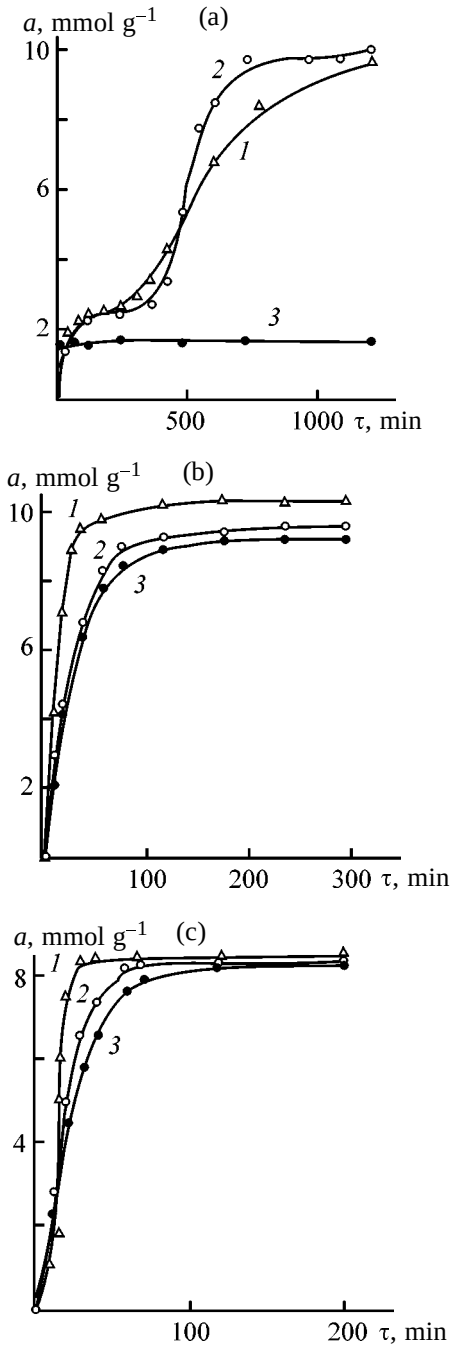

Fig. 3. Kinetic curves of lead(II) sorption by samples of (a) $MgNH_4PO_4 \cdot H_2O$, (b) $Mg_3(PO_4)_2 \cdot 6H_2O$, and (c) $MgHPO_4 \cdot 3H_2O$ from $Pb(NO_3)_2$ solutions. (*a*) Amount of sorbed Pb^{2+} (mmol per gram of sorbent) and (τ) time. Initial solution concentration (mM): (a) (*1*) 25.0, (*2*) 50.0, and (*3*) 100.0; (b) (*1*) 50.0, (*2*) 5.0, and (*3*) 0.5; (c) (*1*) 50.0, (*2*) 5.0, and (*3*) 2.5.

The kinetic curves of lead(II) sorption by magnesium ammonium phosphate from solutions of various concentrations are shown in Fig. 3 [complete transformation of $MgNH_4PO_4 \cdot H_2O$ into pyromorphite $Pb_5(PO_4)_3OH$ corresponds to the sorption of 10.7 mmol of lead(II) per gram of the sorbent]. The process starts at a maximal rate for all concentrations, but then it sharply decelerates at relatively low conversions. The X-ray phase analysis of the products formed in this stage suggests that the plateau in the kinetic curves is due to the formation of an amorphous product preventing the delivery of lead ions to the unchanged sorbent surface. When the system is kept at a constant temperature, the product crystallizes, the hindering layer is destroyed, and the sorption rate increases again. The time required to activate the sorption process is 3.5 and 5 h for 0.025 and 0.05 M solutions of $Pb(NO_3)_2$, respectively. When lead(II) is sorbed from 0.1 M solution of $Pb(NO_3)_2$, after the initial fast sorption (a = 1.8 mmol g^{-1}) the process practically stops, resuming only after 4–5 days. As a result, when $MgNH_4PO_4 \cdot H_2O$ is kept at R = 150 for a day in contact with solutions to be purified, in the plot of the degree of purification A vs. the initial concentration c_0 (Fig. 2a, curve *3*) the point corresponding to c_0 = 0.1 M lies much lower as compared to not only other magnesium phosphates, but also zirconium hydrophosphate. The sorption features are even more pronounced at c_0 = 0.1 M in the plot of A vs. total lead(II) amount in the initial solution a_0, in which the data obtained at different R values are summarized (Fig. 2b). As the contact time τ is varied, the shapes of the concentration dependences of the sorption capacity and degree of purification noticeably change, and, taking into account the kinetic features revealed, we can always choose such a value of τ at which the sorption capacity of the sorbent would be realized to a full extent (in case of the 0.1 M solution it takes more than 10 days).

Thus, when using $MgNH_4PO_4 \cdot H_2O$, the course of sorption is determined by the conditions of diffusion of exchanging ions, which, in their turn, depend on the rate of crystallization of the forming product.

The lead(II) sorption by magnesium phosphate $Mg_3(PO_4)_2 \cdot 6H_2O$ also involves the pyromorphite formation:

$$3Mg_3(PO_4)_2 \cdot 6H_2O + 10\,Pb^{2+} \rightarrow 2Pb_5(PO_4)_3OH + 9Mg^{2+} + 2H^+ + 4H_2O. \quad (4)$$

In this case, the maximal sorption capacity (18.0 mg-equiv per gram of the sorbent) calculated taking into account Eq. (4) is reached in the experiment. Such a reaction pattern is also proved by X-ray phase analysis, $Pb^{2+} : Mg^{2+}$ ratio, and also by a pronounced decrease in the solution pH (Table 1).

Lead(II) sorption from solution by magnesium orthophosphate proceeds with a high rate, which only slightly depends on the concentration of the solution to be purified (Fig. 3b). It should be noted that, in spite of high rates of orthophosphate conversion to pyromorphite, the latter is well crystallized. This seems to be due to the orientating effect of the support; therefore, a dense hindering layer is not formed in this case as it takes place when lead(II) is sorbed on magnesium ammonium phosphate. Only at a 0.05 M lead(II) concentration in the initial solution a small bend appears in curve *1*, indicating diffusion hindrance in the initial process stages.

The lead(II) sorption by crystalline magnesium hydrophosphate $MgHPO_4 \cdot 3H_2O$ is accompanied, as is the case with the other sorbents studied in this work, by the pyromorphite formation

$$3\,MgHPO_4 \cdot 3H_2O + 5Pb^{2+} \rightarrow Pb_5(PO_4)_3OH + 3Mg^{2+} + 4H^+ + 2H_2O, \quad (5)$$

with the theoretical sorption capacity of 19.1 mg-equiv g^{-1} being reached.

The kinetic curves of lead sorption at 20°C and various concentrations of $Pb(NO_3)_2$ solution are shown in Fig. 3c. At concentrations of ≤0.005 M the theoretical capacity is reached within 2 h; however, as the concentration increases, it becomes higher than the value corresponding to scheme (5). The X-ray phase analysis shows that final products formed at low and high concentrations of $Pb(NO_3)_2$ solution are different. When lead is sorbed from 0.05 M $Pb(NO_3)_2$ solution, pyromorphite formed in the initial stages transforms further into crystalline lead nitrate phosphate:

$$Pb_5(PO_4)_3OH + H^+ + 3NO_3^- + Pb^{2+} + 2H_2O \rightarrow 3Pb_2PO_4NO_3 \cdot H_2O. \quad (6)$$

Observation of the crystals in this stage of sorption shows that, as opposed to reactions (1)–(5), the transformation of pyromorphite to nitrate phosphate [Eq. (6)] occurs as spontaneous recrystallization rather than by a topochemical mechanism. As this case can be hardly described as sorption, it is necessary to clearly distinguish the areas of solid-phase (5) and liquid-phase (6) processes.

As found in [16], pyromorphite recrystallizes to nitrate phosphate when the solution pH becomes less than 2.5 as a result of reaction (5). We have calculated that, for the solid-phase sorption mechanism to become operative, the amount of the lead nitrate solution

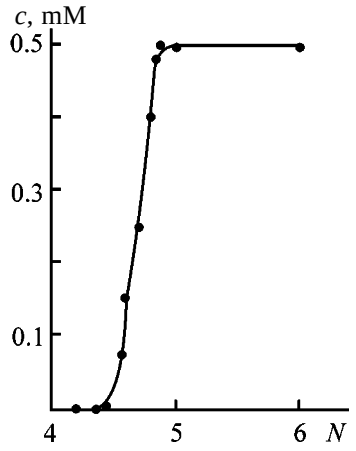

Fig. 4. Output curve of Pb^{2+} sorption on $Mg_3(PO_4)_2 \cdot 6H_2O$ from 5×10^{-4} M solution of $Pb(NO_3)_2$: (c) Pb^{2+} concentration in the purified solution and (*N*) amount of the solution passed through the column (thousand column volumes).

should be more than 300 ml per 0.2 g of magnesium hydrophosphate ($R > 1500$). In this case, the solution concentration is not of crucial importance, it should only be sufficient for the complete transformation by scheme (5). A similar calculation for partial sorption shows that the solid-phase sorption mechanism can become operative also at $R < 1500$. These data give insight into the above-mentioned anomaly, when the use of magnesium hydrophosphate as a sorbent results in the fact that the degree of solution purification *A* takes different values at the equal initial lead(II) content $a_0 = 15$ mmol g^{-1} (Table 2; Fig. 2b, curve *1*). The point is that two of four points were obtained at *R* 300 and 600, and the other two points, at *R* 3000 and 15 000. These latter points lie out of the A–a_0 curve, as, unlike the other points in this curve corresponding to the recrystallization by scheme (6), they reflect the solid-phase transformation by scheme (5).

Thus, it is desirable to carry out lead(II) sorption by $MgHPO_4 \cdot 3H_2O$ at high *R*, which in actual practice corresponds to the treatment of very dilute solutions. However, in this case it is necessary to take into account the possibility of partial dissolution of the sorbent, which prevents its use under dynamic conditions. The solubility of magnesium ammonium phosphate $MgNH_4PO_4 \cdot H_2O$ in dilute solutions is minimal, but the induction period characteristic of this sorbent (the possibility of diffusion hindrance of the process, at least in sorption from concentrated solutions) can also lead to complications in the implementation of the column version of the lead(II) sorption.

Thus, magnesium orthophosphate $Mg_3(PO_4)_2 \cdot 6H_2O$ is the best lead(II) sorbent under dynamic conditions. Figure 4 shows the output curve obtained on

passing a 5×10^{-4} M solution of lead nitrate through a column packed with magnesium orthophosphate deposited on silica of the same particle size as the sorbent. Breakthrough of lead (II) was observed only on passing more than 4000 column volumes of the solution. It should be noted that more than 50% of the theoretical column sorption capacity calculated by Eq. (4) is utilized in this case.

CONCLUSIONS

(1) Magnesium phosphates $MgHPO_4 \cdot 3H_2O$, $Mg_3(PO_4)_2 \cdot 6H_2O$, and $MgNH_4PO_4 \cdot H_2O$ show high performance in the purification of lead-contaminated solutions under static conditions (sorption capacity 22.6, 18.8, and 21.8 mg-equiv g^{-1}, respectively).

(2) Lead(II) sorption by magnesium phosphates from solution is accompanied by complicated topochemical transformations of the sorbents. Proper account of these transformations allows optimization of the sorption process.

(3) The best sorbent for lead(II) under dynamic conditions is magnesium orthophosphate, which allows 4000 column volumes of a 5×10^{-4} M solution to be completely purified; in this case, more than 50% of the theoretical sorption capacity is utilized.

SORPTION AND ION-EXCHANGE PROCESSES

Polyfunctional Anion Exchanger as Sorbent of Copper(II) and Vanadium(V) Ions

E. E. Ergozhin, N. A. Bektenov, and A. M. Akimbaeva

Bekturov Institute of Chemical Sciences, Almaty, Kasakhstan

Received February 12, 2001

Abstract—Sorption of copper and vanadium ions from aqueous solutions by cross-linked anion exchanger based on a copolymer of glycidyl methacrylate with styrene and polyethylenimine was studied. The effect of the solution pH on the completeness of sorption is considered.

The continuous and impetuous expansion of the application fields of synthetic polyelectrolytes is stimulating the growing interest in synthesis of ion-exchange polymers. Particular attention is attracted by sorption recovery of metals from aqueous solutions and metal separation, widely used in hydrometallurgy, chemical technology, environmental protection, and analytical chemistry [1, 2]. To enable these applications, a wide variety of ion-exchange resins, membranes, and fibers based on polymer ion exchangers of cation- and anion-exchange type are being manufactured at present. Of much interest for obtaining various ion-exchange polymers are copolymers of glycidyl methacrylate, exhibiting a high reactivity and a number of valuable physicochemical properties. The known methods for preparing ion exchangers of the styrene type are multistage and involve the use of toxic and sometimes difficultly available monomers. Therefore, a promising direction in the field of synthesis of ion exchangers is the use of a copolymer of glycidyl methacrylate and styrene, which allows synthesis of polyelectrolytes with high chemical and thermal stability and mechanical strength and makes it possible to perform reactions under mild conditions with the possibility of controlling the composition and properties of the obtained products [3, 4]. In radical homo- and copolymerization of glycidyl esters, the double bond is cleaved and the epoxy group, whose presence in a macromolecule allows synthesis of infusible and insoluble cross-linked products, is preserved.

In this work, we tested for sorption of metal ions an anion exchanger prepared by modifying with polyethylenimine a copolymer of glycidyl methacrylate and styrene (GMA–ST–PEI) [3].

EXPERIMENTAL

The polyfunctional anion exchanger GMA–ST–PEI was synthesized by the procedure reported in [3]. The IR spectra of the initial and metal-containing anion exchangers were measured in KBr pellets on a UR-20 spectrophotometer. Polymer samples were dried in a vacuum drying box to constant weight prior to each set of experiments. The static exchange capacity (SEC) was determined using the technique described in [5]. A weighed portion (1 g in terms of dried substance) of anion-exchange resin in the OH form was placed in 200 ml of 0.1 N HCl solution. The mixture was kept for 24 h with intermittent stirring. After that the ion exchanger was filtered off, and 25 ml of the filtrate was taken with a pipette and titrated with 0.1 N NaOH solution in the presence of phenolphthalein. The SEC of the anion exchanger (mg-equiv g^{-1}) was calculated by the formula

$$\mathrm{SEC} = \frac{[200F - (200/25)VF_1] \times 0.00365 \times 1000}{36.5g} = \frac{200F - 8VF_1}{10g},$$

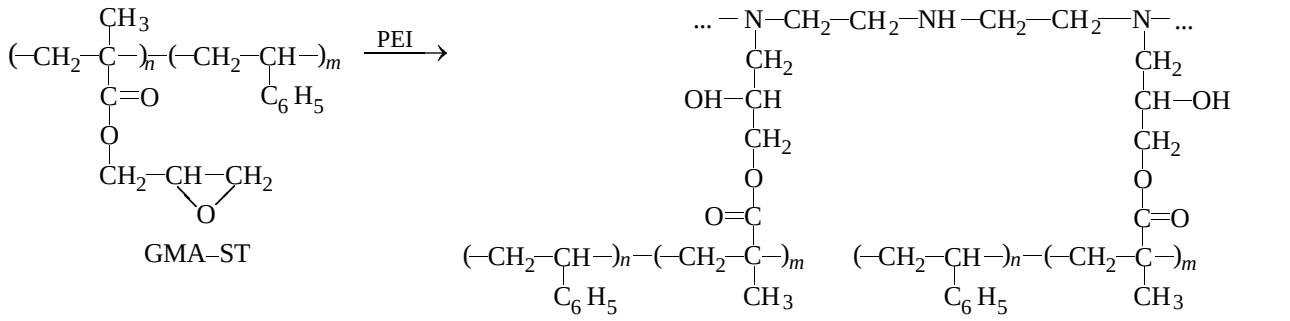
where F is the correction factor for 0.1 N HCl solution, V is the volume of 0.1 N NaOH solution (ml), F_1 is the correction factor for 0.1 N NaOH solution, 0.00365 is the titer of 0.1 N HCl solution, 36.5 is the molecular weight of HCl, and g is the weighed portion of anion exchanger (g).

The sorption of copper and vanadium ions was done under static conditions from copper sulfate solution (initial concentration of $CuSO_4 \cdot 5H_2O$ 6.24 g l^{-1})

1070-4272/02/7503-0385$27.00 © 2002 MAIK "Nauka/Interperiodica"

and sodium vanadate (initial concentration of $Na_3VO_4 \cdot 2H_2O$ 6 g l^{-1} in terms of V_2O_5) [6]. To determine the sorption capacity (SC) of the anion exchanger for ions in relation to the solution pH, weighed portions of the polymer (SEC 8.09 mg-equiv g^{-1}, grain size 0.25–0.50 mm, weight 0.10–0.12 g) were placed in six vessels and brought in contact for 6–7 days [6] with a solution containing 20 ml of a solution of a salt of the corresponding metal, sulfuric acid (for maintaining constant the solution pH) in amount of 0 to 12 ml, and water to make the total volume of solution in each vessel equal to 40 ml. The solution pH was measured with an EV-74 pH-meter with the accuracy $\Delta = 0.02$. The content of vanadium ions was found by titration with Mohr's salt in the presence of phenylanthranilic acid. The concentration of copper cations was determined by atomic-absorption spectroscopy.

Chemical modification of the starting polymer GMA–ST, containing active epoxy groups, with aliphatic polyamine PEI was carried out in toluene by the scheme



The practical use of ion exchangers involves their prolonged contact with water and aqueous solutions, occurring at elevated temperatures. In the process, physicochemical and technical properties of ion exchangers undergo irreversible changes associated with degradation of the polymer matrix or functional groups. Therefore, the thermal stability is an important factor for these materials. The recent success in studies of the mechanism and kinetics of thermal degradation of ion exchangers allows, in some cases, proper choice of ion exchanger and prediction of the service life and direction of changes in physicochemical properties of ion exchangers [7]. It has been established that two mechanisms of thermal degradation of anion exchangers are possible:

deamination

$$R\text{–}CH_2\text{–}N^+(CH_3)_3OH^- \xrightarrow[\Delta]{H_2O} RCH_2OH + N^+H(CH_3)_3OH^- \quad (1)$$

and dealkylation

$$R\text{–}CH_2\text{–}N^+(CH_3)_3OH^- \xrightarrow[\Delta]{H_2O} RCH_2\text{–}N^+H(CH_3)_2OH^- + CH_3OH. \quad (2)$$

Degradation by the first scheme is accompanied by complete loss of capacity with the formation of nonionic alcohol groups. The second way assumes conversion of functional groups with higher basicity into low-basic groups, with possible insignificant change in the ion exchanger capacity.

The thermal stability of anion exchangers depends not only to the structure of amino groups, but also on the structure of the ion exchanger skeleton. Of three constituents of a swollen ion exchanger (polymer matrix, functional groups, and water), the functional groups are the least stable [7]. Therefore, decomposition of ion exchangers commonly starts with functional groups and primarily affects the exchange capacity (after tests of ion exchangers), which is the quantitative criterion of thermal stability. According to some studies [7, 8], the ion exchanger is more stable in the salt form, compared with the basic form. The anion exchanger in the salt form is characterized by reactions described for an anion exchanger in the hydroxide form, with the exception of dealkylation to give methanol [Eq. (2)]. Therefore, experiments were carried out with samples in the OH form, boiled in water for 48 h. On heating the synthesized anion exchanger in water, its exchange capacity changes somewhat (6.02% loss of capacity). A different behavior is observed for EDE-10P and AV-18 commercial anion exchangers. Their loss of capacity on heating in water

to 100°C for 48 h is 23%, which is nearly 4 times that for the anion exchanger under study. Presumably, the matrix degrades, with decrease in the cross-linking density and elimination of the functional groups of the ion exchanger.

Polyfunctional cross-linked and linear ion exchangers with primary, secondary, and tertiary amino groups exhibit donor properties and, when brought in contact with substances whose molecules have acceptor groups or ions, form coordination compounds via unshared electron pairs at ionogenic groups [9]. It is known that the higher the content of protonated amino groups in the polymer phase, the smaller the number of active centers coordinated with metal. Protonated ligands of coordinated compounds form no coordination compounds with metal ions. In weakly acidic, neutral, or alkaline medium, the unprotonated form of the ion exchanger is in the undissociated state; under these conditions, the interaction of the polymer with metals occurs via coordination bonding. On the whole, it was noted [8] that the sorption capacity of ion exchangers for transition metal ions grows with decreasing acidity of the medium. However, in alkaline solutions metal hydroxides can precipitate, and, therefore, copper ions were recovered with a polyelectrolyte based on GMA–ST–PEI at pH 2–5 (see table).

At pH 4.94, the capacity of the polymer for copper ions is 380 mg g^{-1}. It can be seen from the table that the sorption capacity of the polymer grows with increasing solution pH. The change in the solution color suggests occurrence of complexation.

It is known [6, 8, 10] that many polyfunctional anion exchangers well recover vanadium(V) ions from solutions of its salts. The figure shows the sorption capacity of the anion exchanger under study as a function of the solution pH. For comparison, the figure presents the curve describing the sorption of vanadium ions by a commercial polyfunctional anion exchanger of the EDE-10P brand.

The strong influence of the solution pH on the sorbent capacity is due to the influence of the ionic state of vanadium in solution [11]:

Ionic state of V	pH
VO_4^{3-}	>13
HVO_4^{2-}	8–3
$V_3O_9^{3-}$	8.0–6.6
$V_{10}O_{28}^{6-}$	6.5–6.0
$HV_{10}O_{28}^{5-}$	6.0–3.5
$H_2V_{10}O_{28}^{4-}$	3.2–2.0
VO_2^+	<2

Change in sorption capacity of anion exchanger based on GMA–ST–PEI for copper(II) ions in relation to solution pH

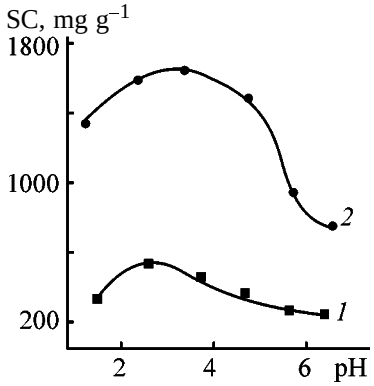
pH_{in}	pH_{eq}	SC, mg g^{-1}	Color of solution after sorption
4.94	5.93	380	Dark blue
2.49	4.42	118	Blue
2.04	3.12	82	″

As a result, the sorption capacity of the anion exchanger grows dramatically in the acid range and decreases with the solution pH growing further. The sorption capacity is as high as 1674 mg g^{-1} (pH 3.30) for the GMA–ST–PEI sorbent and 520 mg g^{-1} for EDE-10P.

The formation of metal ion complexes with anion exchangers was studied by IR spectroscopy. An analysis of the IR spectra of a polymer containing bound copper revealed broadening of bands associated with stretching vibrations of the N–H bond (3000–3400 cm^{-1}) and appearance of absorption in the range 200–360 cm^{-1}, attributable to a coordination bond between metal ions and amino groups. In the spectrum of the anion exchanger saturated with vanadium ions, an absorption band related to decavanadate ion appears at about 960 cm^{-1}.

CONCLUSION

An anion exchanger based on a copolymer of glycidyl methacrylate with styrene and on polyethylenimine can be effectively used for sorption of copper(II) and vanadium(V) ions from weakly acidic solutions.



Sorption capacity SC of GMA–ST-based anion exchanger for V_2O_5 vs. solution pH. Sorbent: (*1*) EDE–10P and (*2*) GMA–ST–PEI.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of M(III) with KFP-12 Phosphonic Cation Exchanger from Chloride Solutions

L. A. Pimneva and V. S. Pakholkov

Tyumen State Architectural Academy, Tyumen, Russia

Received May 10, 2001

Abstract—Sorption by KFP-12 phosphonic anion exchanger of ions of triply charged metals, such as indium, gallium, yttrium, and iron, from chloride solutions was studied. The nature of bonding between sorbed cations and functional groups of the cation exchanger and the mechanism of the ion exchange reaction were elucidated.

This study is a continuation of previous investigations of the phosphonic cation exchanger KFP-12 [1–5]. It is known that phosphate cation exchangers can sorb metal ions via not only ion exchange, but also complexation. It has been established [6] that, owing to the increased electron density on the phosphoryl oxygen atom, the phosphonic cation exchanger KFP-12 via its P=O groups forms strong coordination bonds with metals having unoccupied orbitals.

EXPERIMENTAL

This study is concerned with sorption of gallium, indium, yttrium, and iron ions from 0.3 M MCl_3 solutions containing 0 to 2.0 M HCl by a macroporous phosphonic cation exchanger with exchange capacity of 7.5 mg-equiv g^{-1}. In the ammonium form, the cation exchanger has exchange capacity of 9.9, 7.6, 7.4, and 7.2 mg-equiv g^{-1} (29.6, 22.8, 22.2, and 21.5 mmol g^{-1}) for indium, iron, gallium, and yttrium ions, respectively. The cation exchanger dissociates in two stages, with the apparent dissociation constants pK_1 3.5 and pK_2 8.9, respectively (calculated for α = 0.5). The sorption capacity of the KFP-12 cation exchanger depends on the state of ionic groups, form of the cation exchanger (H^+ , NH_4^+), and pH of the equilibrium solution. The maximum sorption capacity is characteristic of the KFP-12 cation exchanger in the completely ionized state (pH > 3). Under such conditions, metal sorption occurs via not only ionic, but also coordination bonding.

The initial solutions, their preparation, analytical techniques, and experimental procedure were the same as those described in [1–4]. All experiments were carried out at room temperature under static conditions.

The mechanism of sorption of triply charged indium, gallium, yttrium, and iron ions was studied by IR spectroscopy. The IR spectra were recorded on a UR-20 spectrometer in the frequency range 700–1600 cm^{-1}, using the KBr technique. The IR spectra of KFP-12 cation exchanger with sorbed indium, gallium, yttrium, and iron ions were analyzed in comparison with the spectra of the cation exchanger in the H^+ form.

A study of the behavior of triply charged ions of indium, gallium, yttrium, and iron in chloride solutions demonstrated that the ions exist in the form of positively and negatively charged chloride and hydroxo complexes, and also as neutral molecules. It is this factor that governs cation sorption on the phosphate cation exchanger. The sorption strongly depends on the solution acidity and on the ionic form of the cation exchanger. Figure 1 shows how the HCl concentration affects the sorption of Ga, In, Fe, and Y ions by the KFP-12 cation exchanger. The dramatic decrease in the sorption capacity is due to the fact that the fraction of neutral MCl_3 molecules and negatively charged chloride complexes $[MCl_4]^-$, $[MCl_5]^{2-}$, and $[MCl_6]^{3-}$ increases in acid solutions.

The amount of sorbed ions largely depends on the ionic form of the cation exchanger. The sorption capacity of the NH_4^+ form exceeds that of the H^+ form. This is due to the fact that in the course of sorption by the cation exchanger in the NH_4^+ form ammonium ions are displaced by cations of metal and hydrogen. The ion exchange is described by the following reactions:

$$R\text{–}PO(ONH_4)_2 + MCl_2^+ = R\text{–}PO(ONH_4^+)(OMCl_2) + NH_4^+,$$

$$R\text{–}PO(ONH_4)_2 + MCl^{2+} = R\text{–}PO(O_2MCl) + 2NH_4^+,$$

1070-4272/02/7503-0389$27.00 © 2002 MAIK "Nauka/Interperiodica"

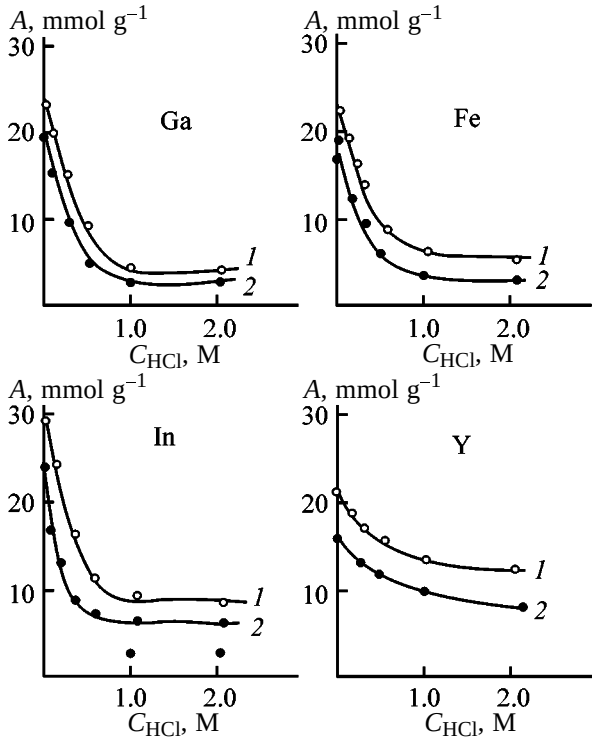

Fig. 1. Effect of HCl concentration C_{HCl} on sorption A of indium, gallium, yttrium, and iron ions from 0.3 M MCl_3 solution. Form of KFP-12 cation exchanger: (*1*) NH_4^+ and (*2*) H^+.

$$2R\text{–}PO(ONH_4^+)_2 + MCl_3 = 2R\text{–}PO(ONH_4^+)(OMCl) + 2NH_4Cl,$$

$$R\text{–}PO(ONH_4)_2 + HCl = R\text{–}PO(OH)_2 + 2NH_4Cl.$$

In sorption of triply charged metal ions from stoichiometric solutions and solutions with a low HCl concentration (up to 0.3 M), the sorption exceeds the total exchange capacity of the KFP-12 cation exchanger for ions of the corresponding metals. Such a behavior of the elements indicates that they are sorbed not only as simple triply charged cations, but also as chloride (MCl^{2+}, MCl_2^+) and hydroxo complexes. The very high sorbability of the triply charged metal ions and hence the high selectivity of the resins with respect to these ions are due to the interaction of metal ions with the ionic groups to form polymeric complexes.

Figures 2 and 3 present the IR spectra of the phosphonic cation exchanger KFP-12 with indium, gallium, yttrium, and iron(III) ions sorbed from chloride solutions. Analysis of the spectra allows conclusions about the nature of bonding between the sorbed ions and ionic groups of the cation exchanger. The spectra of the cation exchanger with sorbed metal ions differ from the spectrum of the initial cation exchanger in

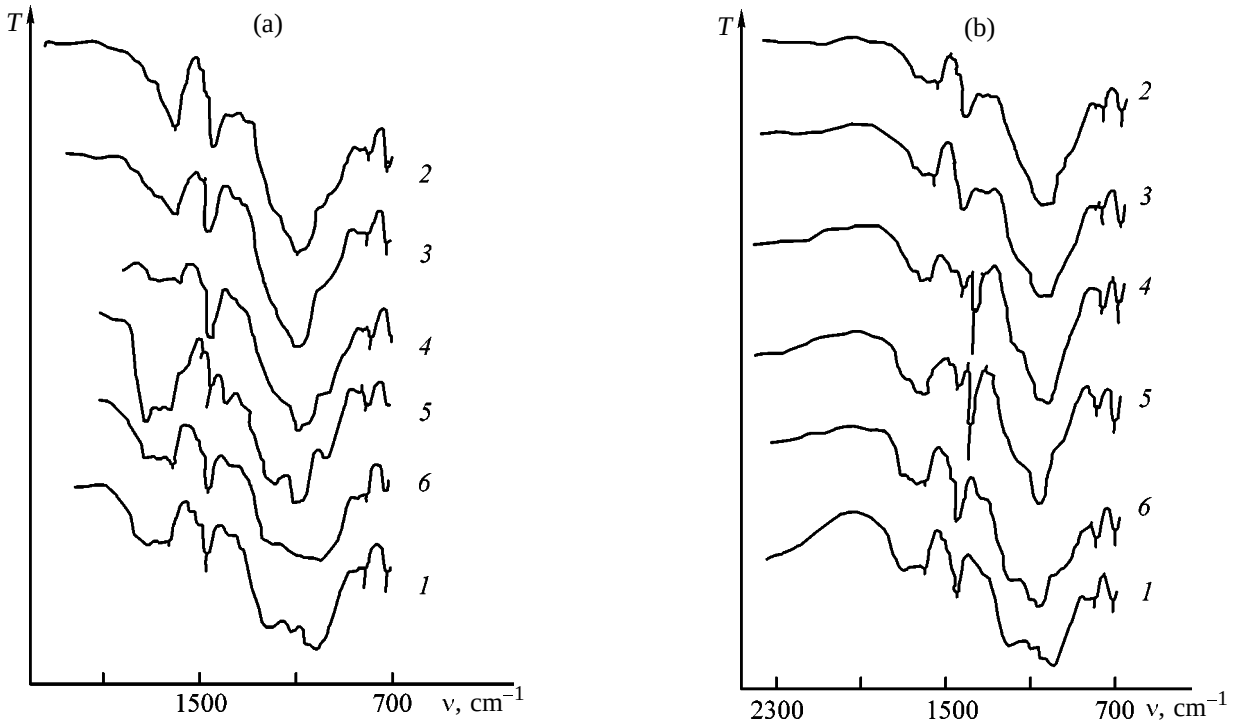

Fig. 2. IR spectra of KFP-12 cation exchanger (*1*) in the H^+ form and (*2*–*6*) after sorption of (a) indium and (b) iron ions. (*T*) Transmission and (ν) wave number; the same for Fig. 3. M^{3+} concentrations (M): (*2*) 0, (*3*) 0.1, (*4*) 0.3, (*5*) 0.5, and (*6*) 1.0.

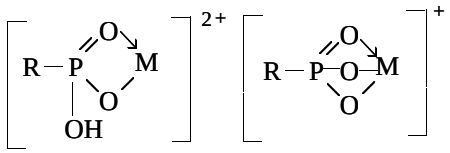
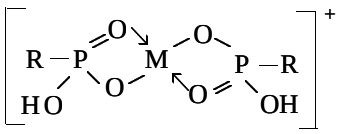
the H^+ form in that they contain absorption bands at 980 and 1060 cm^{-1}, associated with symmetric and antisymmetric vibrations of the R–PO_3^{2-} group [6–8]. Characteristically, absorption bands at 980 and 1060 cm^{-1} are observed even at minor loading of the cation exchanger (to 15–30%) with metal ions (Fig. 2, curves *5* and *6*). This indicates that hydrogen is replaced by metal in both the hydroxo groups of the phosphonic cation exchanger simultaneously.

The presence of phosphoryl oxygen with increased electron density in the P=O group is responsible for the ability of phosphonic cation exchangers to form strong coordination bonds with metals having unoccupied orbitals. In the spectra of the cation exchanger, the intensity of the absorption band at 1210 cm^{-1} (vibrations of the P=O group) decreases with filling of the cation exchanger and nearly disappears when all ionic groups are replaced (Fig. 2, curves *2* and *3*). The decrease in the intensity of this band points to rupture of hydrogen bonds [7] and to involvement of phosphoryl oxygen in the coordination with the metal ion. It should also be noted that the P=O stretching vibration band at 1210 cm^{-1} in the spectra of the cation exchanger with sorbed metal ions is shifted by 20–30 cm^{-1} to lower frequencies, and just this is observed in complexation [8].

In sorption of gallium and yttrium ions (Fig. 3), protons are replaced in both hydroxy groups of the cation exchanger. This is confirmed by the appearance of a broad absorption band at 1070 cm^{-1}, associated with stretching vibrations of the R–PO_3^{2-} ion, and disappearance of bands at 950, 1100, and 1175 cm^{-1}. The spectra of the cation exchanger saturated with yttrium and gallium ions show the same characteristic absorption bands as the spectra of the indium- and iron-saturated resin.

Thus, the following structural forms are possible in sorption of triply charged metal ions:





The formation of polymeric complexes is preceded by disintegration of chloride anionic complexes. This is evidenced by the observed sequence of decreasing sorbability, corresponding to the stability series of

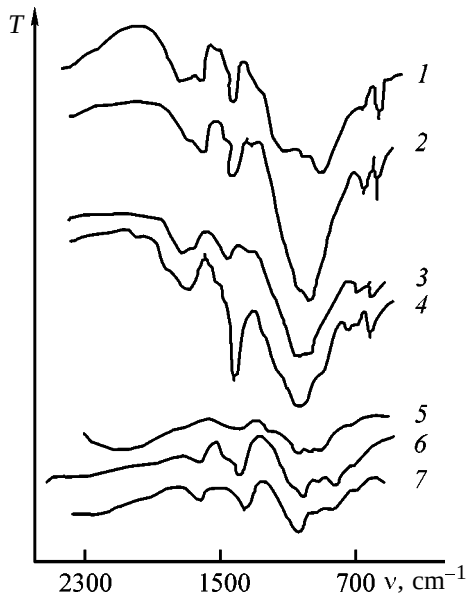


Fig. 3. IR spectra of KFP-12 cation exchanger (*1*) in the H^+ form and after sorption of (*2–4*) gallium and (*5–7*) yttrium ions. M^{3+} concentration (M): (*2*, *5*) 0, (*3*, *6*) 0.1, and (*4*, *7*) 1.0.

chloride complexes of elements (with the exception of indium): In > Fe ≫ Ga > Y. The main reason for the exceptional selectivity of KFP-12 is the interaction of indium with ionic groups to give stronger polymeric complexes.

To conclude, it should be noted that the difference in behavior between In^{3+}, Fe^{3+}, Ga^{3+}, and Y^{3+} in their sorption by the KFP-12 cation exchanger from chloride solutions can be widely used for solving various problems of analytical, preparative, and applied chemistry and technology. The cation exchange can be successfully applied in fine purification of elements forming stable anionic chloride complexes to remove impurities of other elements present in starting solutions as positively charged species.

CONCLUSIONS

(1) The sorption of triply charged gallium, indium, yttrium, and iron ions from chloride-containing solutions with the KFP-12 cation exchanger was studied. The sorption is influenced by the ionic form of the cation exchanger (H^+ and NH_4^+) and the concentration of hydrochloric acid. Metal ions are sorbed from solutions by the cation exchanger in the form of simple and complex positively charged ions.

(2) On the basis of data on sorption and the results of chemical analysis and IR spectroscopy, conclusions

are made concerning the mechanism of ion exchange and nature of bonding between the sorbed cations and functional groups. The complexation between triply charged metal ions and the cation exchanger was revealed.

SORPTION AND ION-EXCHANGE PROCESSES

Regeneration of VA-212 Cationic Polyelectrolyte Exhausted in Rhenium(VII) Recovery from Aqueous Solutions by Complexation–Ultrafiltration Technique

A. B. Maiboroda, D. G. Petrov, and I. D. Troshkina

Mendeleev Russian Chemical Engineering University, Moscow, Russia

Received January 20, 2001; in final form, September 2001

Abstract—A procedure was developed for regeneration of VA-212 cationic polyelectrolyte exhausted in recovery of rhenium(VII) from aqueous solutions by complexation–ultrafiltration technique. The regeneration includes polyelectrolyte coagulation by displacement of perrhenate by nitrate anions, ultrafiltration, and dissolution of the filtered sediment with reducing agent.

Water-soluble macromolecular compounds containing ionogenic groups are used for metal ion recovery from aqueous solutions [1]. This technique is preferable as compared to ion-exchange sorption on granulated ion exchangers, mainly because of high rates of sorption of the target ions and their subsequent displacement in the desorption stage.

The complexation–ultrafiltration technique (COUF) is suitable for metal recovery from dilute aqueous solutions. This technique includes binding of the target metal to water-soluble polyelectrolyte, displacement of this metal from the metal–polyelectrolyte complex, and separation of the precipitated polyelectrolyte by ultrafiltration. The term complexation takes into account all types of interactions capable of binding metal to polyelectrolyte, including anion–cation and donor–acceptor contacts. The polyelectrolyte is regenerated by displacement of target metal from metal–polyelectrolyte complex, followed by separation of the coagulated polyelectrolyte by ultrafiltration and, if required, transrformation of the polyelectrolyte to the form suitable for reuse.

The aim of this work was to determine the conditions ensuring the regeneration of VA-212 cationic polyelectrolyte used for anion-exchange recovery of perrhenate anions by the COUF technique.

EXPERIMENTAL

Our experiments were carried out on a laboratory ultrafiltration setup equipped with a membrane flow unit manufactured from hollow polysulfonic fibers [2]. These membranes retain species with the molecular weight exceeding 40 000. VA-212 cationic flocculant containing quarternary ammonium base groups was introduced into aqueous solution to bind perrhenate anions [3]. Prior to further procedures, this solution was concentrated threefold by ultrafiltration.

The IR spectra of the polyelectrolyte (KBr pellets) were recorded on a UR-20 IR spectrometer. The rhenium(VII) content in aqueous solutions was determined by kinetic analysis [4]; variations in the rhenium content in the course of COUF were monitored with short-lived ^{188}Re tracer prepared with an isotope generator [5].

The relationships of rhenium(VII) recovery from process solutions of copper production by the COUF technique were reported in [2, 6]. Data on the aggregative stability of a series of polyelectrolyte solutions, including those of VA-212, in the presence of salts were published in [6]. Displacement of rhenium(VII) from the rhenium–polyelectrolyte complex was studied in [2]. In that work it was found that addition of a nitrate-containing solution causes coagulation of the polyelectrolyte. The coagulation of a polyelectrolyte in the presence of lower electrolytes (salting-out agents) is characterized by a certain coagulation threshold depending on the salting-out agent. As a rule, sodium nitrate is used as the salting-out agent. In this case, the coagulation threshold is equal to 4.84×10^{-2} M at VA-212 polyelectrolyte concentration of 1 g l^{-1} [6].

Displacement of ReO_4^- from its complex with the polyelectrolyte was studied at different sodium nitrate

concentrations which were attained by adding the required amount of 4 M sodium nitrate. In the experiments we used rhenium(VII) concentrate containing 0.3 wt % of VA-212 and 4 mg l^{-1} of rhenium(VII) bound to the polyelectrolyte. The resulting suspension of the polyelectrolyte was subjected to ultrafiltration, and the rhenium content in the permeate (filtrate) was determined. The degree of polyelectrolyte regeneration φ_r was calculated by the equation

$$\varphi_r = \frac{C_p}{C_c} \times 100,$$

where C_p is the rhenium concentration in permeate (mg l^{-1}) after addition of $NaNO_3$ into the rhenium concentrate; C_c is the rhenium(VII) concentration in the concentrate (mg l^{-1}), corrected for the volume of the $NaNO_3$ solution added.

The degree of polyelectrolyte regeneration as a function of the sodium nitrate concentration is plotted in Fig. 1. These results show that 1 M is the optimal $NaNO_3$ concentration for regeneration of VA-212 polyelectrolyte. Under these conditions, the high degree of polyelectrolyte regeneration (98%) is reached. Furthermore, the resulting permeate can be processed by hydrometallurgical technique (e.g., by solvent extraction).

The regenerating solution (1 M $NaNO_3$) was continuously added to the concentrate circulating in the ultrafiltration unit. We found that, at the 3 : 1 volume ratio of the regenerating solution and initial concentrate, more than 90% of rhenium passes into the permeate.

To reuse the polyelectrolyte for further rhenium(VII) recovery, its filtered precipitate should be converted to the water-soluble state. We found that washing of this precipitate with distilled water did not lead to dissolution even at the NO_3^- concentration lower than the coagulation threshold. The fast and complete dissolution of VA-212 precipitate is reached on addition of hydrazine (0.005 M) or a mixture containing 0.05 M sodium sulfite and 0.10 M ammonia. The resulting solution was washed with distilled water in the ultrafiltration unit and reused for rhenium recovery.

The possibility of repeated rhenium(VII) recovery using the regenerated polyelectrolyte was studied with return solutions from a concentrating mill processing copper-containing sandstown. It was found [2] that, after five successive recovery–regeneration cycles using sodium nitrate for rhenium(VII) displacement and sodium sulfite for dissolution of the polyelectrolyte precipitate, the change in the degree of rhenium recovery was minor.

The regenerated sample of VA-212 polyelectrolyte was washed with water, separated from the aqueous phase, and characterized IR-spectroscopically. In the IR spectrum, a strong absorption band at 1389 cm^{-1} is due to $\nu_a(NO_3^-)$ vibrations. This band shows that the polyelectrolyte contains NO_3^- anions as the counterions. Comparison of spectra *1* and *2* (Fig. 2) shows also that IR spectrum of the precipitated polyelectrolyte (spectrum *1*) does not change noticeably after its dissolution in the presence of sodium sulfite (spectrum *2*). The precipitation–dissolution processes used by us for regeneration of water-soluble VA-212 polyelectrolyte are governed by interactions between the polyelectrolyte and inorganic electrolyte species. In aqueous solutions, polyelectrolytes form macromolecular globules with the size depending on the supporting electrolyte and its concentration. The internal and external surfaces of these globules are surrounded by

counterions which form an electrical double layer consisting of the dense and diffuse parts. With increasing counterion concentration, the polyelectrolyte ionogenic groups are neutralized. Under these conditions, the macromolucular globules agglomerate under the action of van der Waals forces into large aggregates, and polyelectrolyte coagulates [3]. In our system, polyelectrolyte coagulates owing to displacement of ReO_4^- by NO_3^- anions, with the NO_3^- anions being incorporated in the coagulate.

We found that the precipitated polyelectrolyte is dissolved on adding reducing agents. We believe that dissolution of the precipitated polyelectrolyte is caused by redox reactions occurring on the surface between the macromolecular globules. As seen from the standard electrode potentials of the reactions given below, nitrate anions can be reduced by sulfite anions in alkali solution [7]:

$$NO_3^- + H_2O + 2e \rightarrow NO_2^- + 2OH^-, \quad E^0 = +0.01 \text{ V};$$

$$SO_4^{2-} + H_2O + 2e \rightarrow SO_3^{2-} + 2OH^-, \quad E^0 = -0.93 \text{ V}.$$

Combination of these reactions shows that reduction of nitrate by sulfite anions is characterized by increase in the standard electrode potential: $\Delta E_0 > 0$. Since $\Delta G = -zF\Delta E^0$ (z is the number of electrons participating the redox reaction, F is the Faraday constant), the change of the Gibbs energy in nitrate reduction with sulfite is negative. This fact suggests that nitrate ion can be efficiently reduced with sulfite anions. Taking into account that the reducing power of sulfite anion increases in alkali media, the polyelectrolyte solutions in our experiments were alkalized with ammonia. Ammonia is a convenient agent since it can be removed into the gas phase in hydrometallurgical processing of the permeate.

Our preliminary experiments [6] showed that, at the polyelectrolyte concentration of 1 g l^{-1}, the coagulation threshold of VA-212 is reached at the sulfite concentration equal to 3 M, which by more than two orders of magnitude exceeds that for nitrate anions. Introduction of SO_3^{2-} anions into an aqueous suspension of the coagulated polyelectrolyte results in reduction of NO_3^- to NO_2^-. This reaction apparently occurs in the diffuse part of the electrical double layer of the macromolecules. The decrease in the NO_3^- concentration in the diffuse part of the electrical double layer due to its partial displacement by nitrite anions, characterized by a higher coagulation threshold, causes disaggregation of macromolecular globules and, as a result, their dissolution. Our IR data show that nitrate anions localized in the internal part of globules are not reduced.

Polyelectrolyte can be dissolved also with hydrazine which is capable of reducing nitrate anions. However, taking into account toxicity of hydrazine and its gradual decomposition in aqueous solution, the use of sodium sulfite as the reducing agent is preferable.

CONCLUSIONS

Rhenium(VII) is efficiently recovered from aqueous solution by multistage technique including rhenium binding with VA-212 polyelectrolyte, its coagulation with nitrate anions, and ultrafiltration. The precipitated polyelectrolyte can be reused after dissolution in the presence of a reducing agent.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Acid Modification on the Structure and Catalytic Activity of Aluminum Oxide

A. A. Lamberov, R. G. Romanova, I. G. Shmelev, and V. F. Sopin

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 6, 2001

Abstract—The effect of acetic acid introduced as modifying additive into active aluminum oxide on its structural characteristics is considered. A relationship is established between the structural characteristics, content and features of aprotic acid centers, and catalytic activity of the obtained catalysts in dehydration of methylphenylcarbinol.

One of industrial methods for styrene production is based on dehydration of methylphenylcarbinol (MPC). The main disadvantage of the process is its high energy consumption, resulting from the fact that the reaction is endothermic and proceeds in the gas phase. In this connection, development of effective catalysts making it possible to reduce the energy consumption by lowering the process temperature is a topical problem. It is known that active aluminum oxide (γ-Al_2O_3, AAO) is used as catalyst for dehydration of aromatic alcohols, and the process occurs by the acid–base mechanism [1]. Consequently, the catalyst activity will depend on structural characteristics and distribution of acid–base centers over the surface. It has been shown previously that dehydration proceeds the most efficiently on an AAO surface with the pore diameter distribution peaked at about 150 Å [2]. One of promising ways to change the structure and surface distribution of active centers is to introduce modifying agents into the catalyst composition.

In this paper we analyze the effect of modification with acetic acid on the structure and activity of the catalyst in MPC dehydration to give styrene.

EXPERIMENTAL

Commercial AAO manufactured by the aluminate–nitrate method was modified by impregnation [3]. The thus treated aluminum oxide was dried to constant weight at 110°C and then calcined at 550°C for 2 h.

MPC dehydration was performed in an isothermal reactor at 220°C in the presence of water vapor (MPC : H_2O = 1 : 1) under conditions of incomplete conversion, since only in this case the catalyst activities can be compared. The temperature was maintained constant to within ±5°C, the space velocity of the raw material and water was 5.4 h^{-1}, and the catalyst volume, 50 cm^3.

Liquid catalyzate was analyzed on a Tsvet chromatograph with a thermal conductivity detector and a steel column 2 m long and 3 mm in diameter, stationary phase 12% PEG-20 000 on Porokhrom support (0.25–0.315 fraction), carrier gas helium. The columns and the detector were thermostated at, respectively, 150 and 180°C; the vaporizer was heated to 250°C.

Adsorption measurements aimed at determining the specific surface area, pore volume, and pore diameter distribution were performed by the method of nitrogen desorption on a Micromeritics ASAP-2400 installation. Adsorption isotherms were measured at 200°C, and degassing was done at 500°C to a residual pressure of 10^{-4} mm Hg. The model of slit-like pores open on all sides was used in calculations.

The crystal structure was studied on a DRON-3M diffractometer with FeK_α radiation and secondary beam passed through a graphite monochromator. Diffraction patterns were processed using RIETQUAN 2.3 software [4, 5] applicable to both crystalline and amorphous structures. As reference were used structures represented in the Inorganic Crystal Structure Database (ICSD for WWW).

The acid-base properties of the aluminum oxide surface were studied by IR spectroscopy.[1] The IR

[1] Investigations were carried out under supervision of E.A. Paukshtis (Boreskov Institute of Catalysis, Siberian Division, Russian Academy of Sciences, Novosibirsk).

spectra were recorded at the adsorption temperature, using a Shimadzu 8300 Fourier spectrometer with a resolution of 4 cm^{-1} and a spectrum accumulation factor of 50. The spectra were recorded at –170°C. The detection limit of the concentration of Lewis acid centers was 0.2 μmol g^{-1}. As probes in determining the acid and base centers were used carbon monoxide and deuterochloroform. The concentration of Lewis acid centers was found from the integral intensity of the corresponding bands in the spectrum of adsorbed CO with the use of integral absorption coefficients [6] which depend on the position of the absorption band of CO complexes in the range 2180–2240 cm^{-1}, in accordance with the formula $A_0 = (\nu_{CO} - 2130)$.

The strength of Lewis acid centers was characterized by the heat of CO adsorption, Q_{CO}, found using the correlation equation [6]

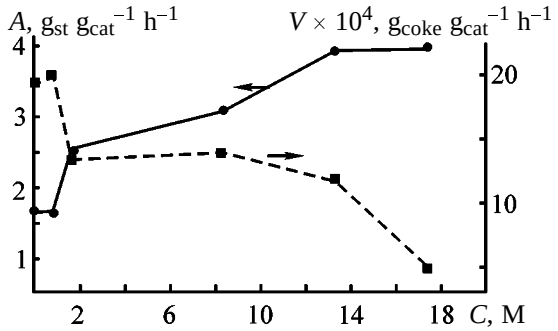
$$Q_{CO} = 10.5 + 0.5(\nu_{CO_i} - 2143),$$

where ν_{CO_i} is the vibration frequency of CO adsorbed on ith Lewis center.

The surface OH groups were characterized by the vibration frequency ν_{OH} (cm^{-1}) and the strength on the proton affinity (PA) scale (kJ mol^{-1}). In determining base centers, spectra of a pretreated sample were measured in the ranges 2000–2300 and 3000–3900 cm^{-1} at room temperature, and then adsorption of $CDCl_3$ was performed at the same temperature under saturated vapor pressure of deuterochloroform to completely saturate the base centers.

The catalytic activity of commercial aluminum oxide modified with solutions of acetic acid of various concentrations was studied in MPC dehydration. The catalyst activity was evaluated on the basis of the MPC conversion, specific rate of styrene formation, selectivity of the reaction with respect to styrene, and reduced deactivation rate. As shown in Table 1, the catalyst activity grows with increasing concentration of acetic acid taken for modification. The dependence of the specific rate of styrene formation on the acid concentration (see figure) indicates that the catalyst activity increases dramatically, compared with unmodified AAO, on treating AAO with acetic acid solutions with concentrations of up to 1.67 M. With the concentration of the modifying agent increasing to more than 13.3 M, the catalyst activity grows to a lesser extent. The selectivity of modified samples with respect to styrene is commonly higher.

The dependence of the reduced rate of catalyst deactivation on the concentration of acid taken for modification (see figure) is complex. At low acetic acid concentrations the modified catalyst is deactivated even faster than the initial sample. The rate of catalyst deactivation falls markedly (by 30%) with the



Specific rate A of styrene formation and specific rate V of catalyst deactivation vs. the acetic acid concentration C.

Table 2. Texture characteristics of modified AAO samples

acid concentration, increasing from 0.83 to 1.67 M, the decrease in the range from 1.67 to 13.3 M is insignificant, and for a sample modified with glacial acetic acid the rate of deactivation again decreases dramatically. For example, in a sample impregnated with glacial acetic acid the rate of deactivation is approximately 4 times smaller than that in the initial AAO. Thus, the maximum catalytic activity and minimum rate of deactivation under the reaction conditions are observed for a sample obtained by impregnation with glacial acetic acid.

The catalyst performance is strongly affected by conditions of its thermal treatment after modification. For example, a catalyst prepared by treatment with a 1.67 M solution of acetic acid and subsequent drying to constant weight at 100°C failed to show high activity in MPC dehydration, despite the fact that the MPC conversion into styrene was rather high during the first hours of operation. Probably, in the case of this treatment procedure, dehydration involves, during the first hours, acid centers formed on the AAO surface as a result of adsorption of acetic acid, which is not removed completely at 100°C. Subsequently, acid molecules are gradually removed from the surface, which is also indicated by the fact that the catalyst mass gain after 8 h of operation is negative, despite the observable indications of coking. The change in the nature of active centers is also evidenced by the decreasing selectivity with respect to styrene.

To reveal the fundamental aspects of processes occurring in acid modification of AAO, the structural and acid–base characteristics of the catalysts obtained were studied. The isotherms of adsorption belong, for all the samples, to type IV by BDDT classification [8], and, consequently, mesopores prevail in the pore structure of the systems under study. The type of the hysteresis loop (H2 according to IUPAC classification) indicates that the mesoporous system consists of parallel-sided particles with slit-like pores open on all sides [9]. The pore structure of AAO is characterized by mesopores with the size distribution peaked at around 40 and 165 Å. These samples of commercial aluminum oxide were prepared by mixing hydroxides (AH) produced by cold and hot precipitation. The former, as a rule, have finely porous structure and virtually totally determine the left-hand side of the pore-size distribution pattern. The structure of the latter is characterized by larger pores, responsible for the right-hand part of the pattern. In AH mixing, the finely porous hydroxides (cold precipitation) are arranged in larger pores of hot-precipitated AH, making lower their true porosimetric volume.

As shown in [9], contacts between primary particles of finely porous AH, resulting from weak van der Waals interaction, are rather labile and are broken under the action of acids. The contacts between hot-precipitated particles are similar to those in crystals and are broken under the action of acids to a much lesser extent. Probably, similar behavior must be observed for AAO, too.

As seen from Table 2, the action of acetic acid on the AAO structure makes the intensity of the peak at 42 Å in the pore size distribution lower, from 0.0076 to 0.0048 $cm^3\ g^{-1}$, whereas the intensity of the broad peak at 140–150 Å grows from 0.0040 to 0.0044 $cm^3\ g^{-1}$. The observed behavior can be accounted for by deaggregation of finely porous oxides responsible for the peak at 42 Å. As a result, the height of the peak at 42 Å decreases, and the porosimetric volume of larger pores increases owing to the breakdown of finely porous oxides present within these pores. This leads to a decrease in the specific surface area and an increase in the total pore volume. Raising the concentration of the acid to 8.33 M makes this tendency more pronounced.

Since changes in the nature of pore distribution are related to the AAO structure, we studied how the

Table 3. Phase analysis data for AAO samples modified with acetic acid

Phase content, wt %		Crystallite size, Å		Lattice constants, Å		
				β-Al_2O_3		η-Al_2O_3, *a*

35.7	64.3	6.08	31.68	6.08	25.46	7.90

crystal structure of catalyst samples changes upon their modification with acetic acid. According to [10], AAO is composed of aggregates (more than 1000 Å in size) constituted, in their turn, by finely dispersed (~20 Å) oxide particles. The large number of layer displacement defects leads to anisotropic broadening of diffraction peaks. Therefore, the diffraction pattern of X-ray scattering by commercial γ-Al_2O_3 significantly differs from that observed for well-crystallized γ-oxide whose crystal structure is in agreement with reference data (*Fd*3*m* space group, lattice constant 7.9 Å, crystallite size 27 Å). Attempts to use diffraction patterns of the standard γ-Al_2O_3 structure for identification purposes failed to produce satisfactory results even in the case of arbitrary filling with Al^{3+} ions of octahedral and tetrahedral voids formed in the γ-Al_2O_3 structure by O^{2-} ions. That is why the η-Al_2O_3 structure was chosen, making it possible to formally consider the spinel structure with large number of cationic vacancies [11]. The use of the η-Al_2O_3 structure allowed a sufficiently good description of clearly pronounced crystalline diffraction peaks, but failed to do so for broad diffuse peaks. The trial-and-error method revealed that the diffuse component of the diffraction pattern is best described with the use of the β-Al_2O_3 structure. Only this phase, combined with η-Al_2O_3, enables a satisfactory description of the peak of complex shape in the angle range 32°–54°. The proposed two structures were optimized by the least-squares technique, with primary attention given to fitting of parameters characterizing filling with Al^{3+} ions of vacancies between O^{2-} ions and to crystallite sizes. The results obtained in determining the crystallographic parameters are listed in Table 3, whence follows that acetic acid treatment increases the relative content of the finely crystalline phase β-Al_2O_3, and its content grows with increasing acid concentration. Correspondingly decreases the content of the coarsely crystalline phase.

Thus, modification with acetic acid leads to a decrease in the prevalent pore diameter through breakdown of secondary aggregates. As shown previously [2], the optimal pore diameter for dehydration is 150 Å. Modification with acetic acid solutions with concentrations of up to 8.33 M increases the volume of pores with the diameter close to this value, which enhances the catalyst activity.

However, the substantial increase in the reaction rate for the catalyst obtained by modification with glacial acetic acid cannot be accounted for by changes in structural characteristics. Acid modification of AAO leads, in addition to structural changes, to changes in its hydroxyl cover and, consequently, in the distribution of acid and base centers on the surface. Data on the acid–base properties of the catalysts are presented in Table 4. The AAO Lewis centers in the form of complexes with carbon monoxide are characterized by intense bands in the range 2158–2240 cm^{-1}, characteristic of γ-Al_2O_3 [6]. There are four main types of Lewis acid centers on the surface of the aluminum oxides under study: strong (type 1, Q_{CO} = 58–59 kJ mol^{-1} and ν = 2238–2240 cm^{-1}), two types of medium strength (type 2, Q_{CO} = 41–42 kJ mol^{-1} and ν = 2203–2207 cm^{-1}; type 3, Q_{CO} = 33–33.5 kJ mol^{-1} and ν = 2189–2191 cm^{-1}), and weak (type 4, Q_{CO} = 27–27.5 kJ mol^{-1} and ν = 2177–2180 cm^{-1}). In addition, OH groups exhibiting weakly acid properties are identified on the surface (Q_{CO} = 18–18.5 kJ mol^{-1}, ν = 2157–2162 cm^{-1}); upon modification they remain virtually unchanged. It should also be noted that the number of strong centers and medium-strength Lewis acid centers (type 2) is insignificant and constitutes 4.3–4.5% of the total number of aprotic centers. These centers also change only slightly upon modification with acetic acid. The most pronounced changes are observed for centers with medium (type 3) and weak (type 4) strength. For example, upon treatment with 1.67 M acetic acid, the content of type 4 centers decreases from 0.700 to

Table 4. Acidity of the initial catalyst samples and samples modified with acetic acid

$[CH_3COOH]$, M	Lewis centers (L)		OH groups		Base centers			Σ_L/Σ_{base} ratio

* (*n*) Number of centers.

0.467 μmol m^{-2}, and that of type 3 centers increases from 1.93 to 2.08 μmol m^{-2} (i.e., by approximately 8%). By contrast, modification with glacial acetic acid increases the content of Lewis acid centers of types 4 and 3, from 1.93 and 0.700 to 2.83 and 0.870 μmol m^{-2}, respectively, which constitutes 46.6 and 24.3%. The total content of Lewis acid centers decreases by 4.3% upon treatment with 1.67 M acetic acid and markedly increases, by 39.6%, upon impregnation with glacial acetic acid.

The spectra of catalysts with deuterochloroform reveal two types of base centers: weak and strong at around 2253 and 2230 cm^{-1}, respectively. The total content of base centers varies within the range 679–797 μmol g^{-1} (3.50–3.17 μmol m^{-2}). Treatment with 1.67 M acetic acid decreases the total number of base centers by approximately 9%. In the process, the ratio of the contents of the strong and weak centers changes from 1.85 to 19.6, i.e., by a factor of more than 10. Upon modification with glacial acetic acid, the total content of base centers decreases by 5%, with the strong/weak center ratio increasing from 1.85 to 2.19. It should also be noted that the vibration frequency ν(C=O) is shifted from 2234 to 2242 cm^{-1}. The ratio between the total contents of Lewis acid and base centers, Σ_L/Σ_{base}, increases upon treatment with 1.67 and 17.4 M solutions of acetic acid from 0.794 for the initial sample to 0.838 and 1.16 (by 5.5 and 46%), respectively.

The change in the distribution of acid–base centers on the aluminum oxide surface is probably due to chemical reaction of the acid with aluminum oxide, resulting in the formation of insoluble base salts of aluminum in the stage of thermal treatment. The presence of the acetate ion is confirmed by the IR spectra containing, for the catalysts modified with acetic acid, two weak absorption bands at 1380 and 1580 cm^{-1}, assigned to symmetric and asymmetric stretching vibrations of the carboxylate ion [12]. It is noteworthy that raising the concentration of the modifying acid results in higher intensity of these absorption bands.

Comparison of the activities of the catalyst and surface acid centers shows that the rate of styrene formation grows in parallel with the increasing content of medium-strength Lewis acid centers (type 3) and increasing ratio between the total contents of Lewis acid and base centers. The revealed pattern suggests that MPC dehydration occurs on medium-strength Lewis acid centers.

CONCLUSIONS

(1) Modification of active aluminum oxide with acetic acid leads to changes in the pore structure and

acid–base properties of the surface, with the type of changes depending on the acid concentration and modification method.

(2) A relationship was established between the structural characteristics, amount and strength of aprotic acid centers, and the catalytic activity of the catalysts obtained.

(3) The maximum activity in dehydration of methylphenylcarbinol is exhibited by catalysts in which modification leads to an increase in the amount of medium-strength Lewis acid centers and in the volume of pores with a size of 130–150 Å.

SORPTION AND ION-EXCHANGE PROCESSES

Recovery of Platinum with Calcium Oxide Sorbent in Ammonia Oxidation

N. I. Zakharchenko

Zhukovsky Aerospace University, Kharkov, Ukraine

Received June 26, 2001

Abstract—The reaction of granulated CaO sorbent with platinum lost in high-temperature oxidation of ammonia was studied. Physicochemical properties of the product and conditions and mechanism of its formation are considered.

Catalytic oxidation of ammonia to nitrogen(II) oxide is the key stage in industrial synthesis of nitric acid [1]. Commercial catalysts (Pt, Rh, and Pd alloys) undergo physicochemical transformations in the process, with their surface structure and chemical composition changed [1–6]. A set of transformations of this kind results in loss of deficient and expensive platinum-group metals. An effective way to reduce the loss of platinum metals is their partial recovery by sorbents mainly based on calcium oxide [1, 7–15].

The mechanism of platinum recovery by calcium-containing sorbents and the chemical aspect of the process are debated in the scientific literature. Atroshchenko *et al*. [9] came to a conclusion that platinum is bound on the surface of the oxide sorbent to form an $x\mathrm{CaO}\cdot y\mathrm{Pt}$ compound. In other studies [10, 11], platinum was found in the sorbent bulk as $4\mathrm{CaO}\cdot\mathrm{PtO_2}$ and $\mathrm{CaO}\cdot\mathrm{Pt_2}$ compounds. In [12, 16], platinum compounds in the sorbent bulk were identified as $\mathrm{Ca_4PtO_6}$ and PtO.

This study is concerned with recovery by calcium oxide of platinum lost in high-temperature oxidation of ammonia and with identification of products formed in the reaction of the lost platinum with calcium oxide.

The calcium oxide sorbent was prepared as follows. As starting compound served calcium oxide of chemically pure grade, which was treated with 80% ethanol (2–3% relative to sorbent weight) and compacted into pellets under a pressure of 150 MPa. Step-like thermal treatment of the sorbent was done in a muffle furnace in air at 473, 673, 873, and 1073 K (for 2 h in each stage). The sorbent was crushed into grains, and fraction with a grain size of $(2–3)\times 10^{-3}$ m was selected.

Since the lost platinum is mainly caught by the surface layer of sorbents [1, 7–14, 17], sorbent grains were ground and subjected to additional forming and thermal treatment in inert medium (argon) following the above scheme in order to intensify the process and raise the yield of the chemical compounds obtained.

The processes of platinum recovery were studied on a flow-through installation with a quartz reactor 5×10^{-1} m in diameter. As catalyst was used platinum in the form of a package of five meshes with a wire diameter of 7.5×10^{-5} m (industrial platinoid alloy nos. 1 and 5 were not used, because Rh and Pd contained in these alloys in addition to Pt would complicate the interpretation of the experimental results). A bed of sorbent grains, of height 1.7×10^{-1} m, was placed directly after the catalyst meshes at a distance of 8.0×10^{-3} m from them.

The temperature of catalytic oxidation of ammonia was maintained at 1073 K, and the pressure in the system, at 0.101 MPa. The content of ammonia in the air–ammonia mixture (AAM) was about 11.5 vol %. The linear flow velocity of AAM was 0.40 m s^{-1} (normal conditions).

X-ray phase analysis of the compounds obtained was carried out on a Siemens D-500 diffractometer with $\mathrm{Cu}K_\alpha$ radiation and graphite monochromator used to analyze the diffracted beam. The phases observed in the diffraction patterns were identified using the JCPDS file contained in the mathematical software package of the diffractometer; some X-ray diffraction pattern were compared with the data of the ASTM file [18].

IR absorption spectra were measured on a Perkin–Elmer 577 spectrometer in the range 200–2000 cm^{-1} with CsI pellets used as matrices.

Differential thermal analysis was made on an

1070-4272/02/7503-0402$27.00 © 2002 MAIK "Nauka/Interperiodica"

MOM Q-derivatograph (Hungary). The temperature was raised at a rate of 300 deg h^{-1} in the interval 293–1273 K, the sample weight was 1×10^{-4} kg, and the duration of catalyst operation and of tests with absorption mass constituted 500 h.

During reactor shutdowns (especially in the final stage of a prolonged experiment), measures were taken for preventing to the maximum possible extent the moisture absorption by the sorbent, leading to its conversion into $Ca(OH)_2$, by purging the reactor at high temperature with dried argon and isolating the argon-filled reactor from humid air by means of moisture absorbents. After being discharged from the reactor, the sorbent was stored in a hermetically sealed vessel filled with dried argon.

X-ray phase analysis of used up sorbent demonstrated that it contained calcium oxide, platinum, and a compound of unknown composition with low line intensities (Fig. 1); no platinum dioxide PtO_2 was found. To confirm the results of X-ray phase analysis, sorbent samples were treated with a 48% solution of HBr at 293 K (PtO_2 dissolves in this reagent, whereas Pt and other its compounds do not [5]). The presence of platinum in solution was determined by the atomic absorption method. Experiments demonstrated that, indeed, there was no platinum dioxide in the sorbent.

Identification of X-ray patterns of a multicomponent mixture is difficult (especially in the cases when lines are closely spaced or insufficiently intense at low concentrations of substances). For this reason, the system was separated into components, with their subsequent identification.

To eliminate the influence of unchanged sorbent on the X-ray patterns of a complex system, the formulation was dissolved in HNO_3 (25 wt %, chemically pure grade) at 308 K. In doing so, account was taken of the fact that neither Pt nor its compounds dissolve at moderate temperatures [5, 19, 20]. The liquid phase was separated from solids and discharged. The solid phase was thoroughly and repeatedly washed with hot double-distilled water (to absence of Ca^{2+} and NO_3^- ions in washing water) and subjected to thermal treatment in inert medium (Ar) at 473–523 K to constant weight.

The X-ray patterns of the solid residue (after dissolution and removal of the unchanged part of the sorbent) contained only line sets with interplanar spacings characteristic of platinum, and less intense lines of a compound of unknown composition (Fig. 1). Based on characteristics of the lines, an assumption was made that the unknown compound belongs to the structural type $M_xPt_3O_4$, where M is Ca, i.e.,

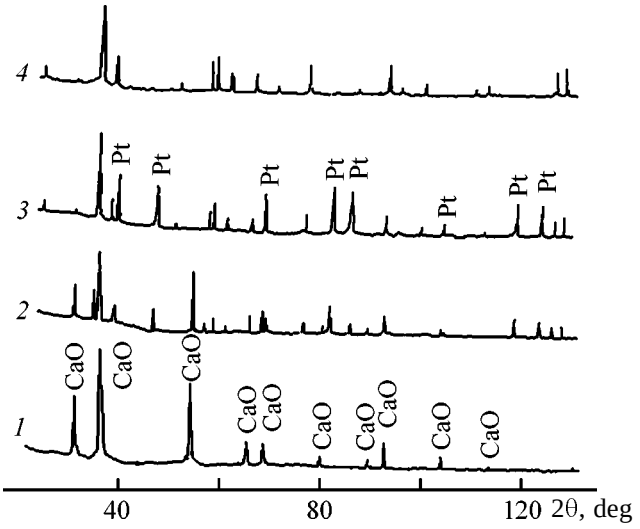

Fig. 1. X-ray patterns of the sorbent and products of platinum recovery. (2θ) Bragg angle. Sorbent: (*1*) starting, (*2*) after 500 h of catalyst operation, and (*3*) after treatment with HNO_3; (*4*) product of sorbent reaction with Pt compounds.

$Ca_xPt_3O_4$. Since this compound does not dissolve even in boiling aqua regia [19], the following analytical procedure was used to isolate it as individual phase. The residue after dissolving CaO was treated with aqua regia at 318 K to recover platinum dissolving under these conditions [5, 19, 20]. The liquid phase was separated, and the solid phase was thoroughly washed in hot double-distilled water (to absence of Ca^{2+} and NO_3^- ions in washing water) and subjected to thermal treatment by the scheme described above. Characteristics of X-ray patterns of the given compound are presented in Table 1.

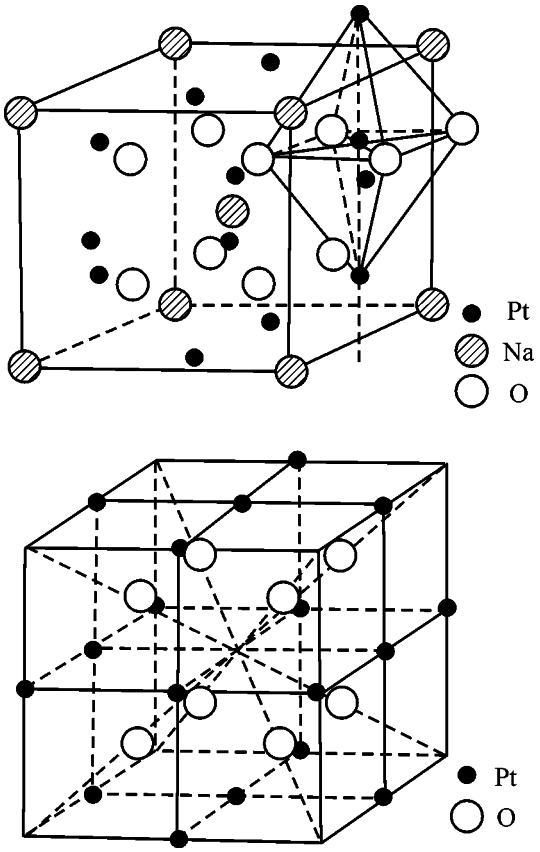

Fig. 2. $Na_xPt_3O_4$ structure by Muller and Roy [21].

The set of lines in X-ray patterns (interplanar spacings, intensities), which is in good agreement with the data of [19] and JCPDS and ASTM files [18], indicates the formation in the sorbent of a chemical compound, $Ca_xPt_3O_4$, having a simple cubic lattice (a = 0.5739 nm) with space group $Pm3n$–O_h^3. The compound $Ca_xPt_3O_4$ belongs to the structural type $Na_xPt_3O_4$ (with x varying between 0 and 1) and is a nonstoichiometric intercalation compound of platinum oxide (Pt_3O_4) [19, 21]. The cubic structure of Pt_3O_4 is constituted by square oxygen prisms occupied by Pt atoms and arranged perpendicularly to one another (Fig. 2). Oxygen atoms occupy cube vertices. Pt atoms center each oxygen face in these prisms. Cubic voids formed by prism intersection are empty. This structure corresponds to the ideal composition $PtO_{1.33}$ [21]. Deviations from the ideal composition Pt_3O_4 can be attributed to formation of interstitial solid solutions. Excess, with respect to the $PtO_{1.33}$, platinum atoms, and also impurity ions Na^+, K^+, Ca^{2+}, and Mg^+, may be introduced into cubic voids of the structure, forming stable nonstoichiometric intercalation compounds of the structural type $Na_xPt_3O_4$ [19, 22, 23]. Compounds with this structure are stable even at a very small number of atoms introduced [19, 22, 23]. In the given case, the compound $Ca_xPt_3O_4$ of the same structural type was formed when Ca^{2+} ions were present in excess.

Table 2. Analytical data for the composition of $Ca_xPt_3O_4$ (x = 1) found in the sorbent

* Determination method: (*1*) gravimetric, (*2*) volumetric, (*3*) thermogravimetric, (*4*) atomic-absorption, and (*5*) chemical.

The IR spectrum of the compound contains absorption bands at 707, 683, 599, 479, 367, and 230 cm^{-1}, characteristic of the compound of this structural type [24]. The absorption bands at 707 and 599 cm^{-1} can be assigned to Pt–O stretching vibrations, and those at 683 and 479 cm^{-1}, to Ca–O stretching vibrations. The absorption bands at 367 and 230 cm^{-1} characterize O–Pt–O bending vibrations.

To confirm the quantitative composition of nonstoichiometric $Ca_xPt_3O_4$, this compound was analyzed for the content of all the constituent elements by various techniques. The results obtained are presented in Table 2.

The stoichiometric compound $Ca_xPt_3O_4$ (x = 1) must contain (wt %): Pt 84.90, Ca 5.82, and oxygen 9.28. The content of oxygen was determined as an average of the values yielded by three analytical methods: gas-volumetric, thermogravimetric (decomposition of the compound), and from the difference when determining the content of platinum and calcium.

A thermogravigram of the compound $Ca_xPt_3O_4$ is shown in Fig. 3. Heating of the substance (in argon, to prevent high-temperature oxidation of platinum and its sublimation as platinum dioxide vapor [1–5, 20]) in the interval 1183–1223 K leads to the weight loss (6.96%), associated with endothermic decomposition

of the compound in accordance with the equation

$$2Ca_xPt_3O_4 = 2xCaO + 6Pt + (4 - x)O_2. \quad (1)$$

The products of dissociation of the compound are calcium oxide, metallic platinum, and oxygen, which is characteristic of double oxides including a noble metal [25]. The endothermic peak in the DTA curve lies at 1203 ± 5 K.

The X-ray patterns of products of $Ca_xPt_3O_4$ decomposition, cooled in inert medium (Ar), contain, in addition to reflections associated with calcium oxide (0.276, 0.239, 0.169, 0.1447, 0.1383, 0.1203, 0.1072, and 0.0980 nm), also those associated with metallic platinum (0.227, 0.1957, 0.1386, 0.1179, 0.1132, 0.0979, 0.0898, 0.0875, 0.0799, and 0.0754 nm).

For the compound $Ca_xPt_3O_4$, the weight loss in decomposition virtually did not exceed the expected value calculated by Eq. (1) at $x = 1$, which indicates that the influence of platinum sublimation in the form of dioxide

$$Pt(c) + O_2(g) = PtO_2(g) \quad (2)$$

is eliminated in the inert medium. A chemical analysis of the solid residue after $Ca_xPt_3O_4$ decomposition was made by dissolving the mixture in boiling aqua regia and then determining the platinum content in solution by the atomic-absorption method [26]. The content of calcium(II) was found gravimetrically by a standard procedure in the form of calcium carbonate after solution neutralization.

The oxygen content in $Ca_xPt_3O_4$ was determined volumetrically by thermal decomposition of a sample in a sealed ampule placed in a muffle furnace (1273 K, 1.5 h). After fast cooling of the ampule to room temperature, the volume of evolved oxygen was measured with a gas burette. The gas-volumetric analysis confirmed the data of thermogravimetric and chemical methods as regards the content of oxygen in a $Ca_xPt_3O_4$ sample at $x = 1$ (Table 2). Thus, chemical analysis of condensed products of $Ca_xPt_3O_4$ decomposition, and also analysis for the content of oxygen by various techniques, made it possible to determine unambiguously the composition of the compound obtained: $CaPt_3O_4$, i.e., $x = 1$.

The formation of $Ca_xPt_3O_4$ in the sorbent can be accounted for on the basis of a comparative analysis of the conditions of platinum recovery and synthesis of this compound. In [19], $Ca_xPt_3O_4$ ($x = 1$) was synthesized upon prolonged heating in air (823–973 K, $P = 0.101$ MPa) of a mixture of platinum dioxide and

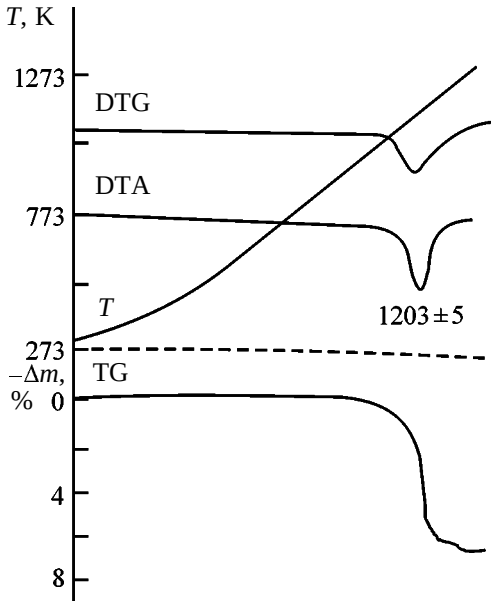

Fig. 3. Thermogravigram of $CaPt_3O_4$. Substance weight 1×10^{-4} kg, heating rate 300 deg h^{-1}. (T) Temperature and (Δm) weight change.

calcium nitrate. In [27], the same compound was obtained by heating a mixture of platinum dioxide, platinum black, and calcium oxide (673–773 K, $P = 0.202$–0.808 MPa) for 300–340 h. $Ca_xPt_3O_4$ was synthesized by introducing calcium ions into voids of the cubic lattice of Pt_3O_4 of the structural type $Na_xPt_3O_4$ [19, 21–23], which is stable at $T \leq 1073$ K. Consequently, formation of $Ca_xPt_3O_4$ assumes the presence of platinum oxide Pt_3O_4 in the starting reaction mixture or formation of this substance in some stage of a complex process.

Introduction of platinum atoms or calcium ions (and also, according to [19, 21–23], of microscopic amounts of Na^+, K^+, Mg^{2+}, Zn^{2+}, and Li^+) leads to formation of a thermally stable nonstoichiometric compound $Ca_xPt_3O_4$ of the structural type $Na_xPt_3O_4$. The composition of $Ca_xPt_3O_4$ varies depending on the concentration of ions introduced into the substance structure (this concentration grows, at constant temperature and pressure, with increasing process time).

Platinum oxide Pt_3O_4 can be obtained by various methods [24, 28]; in particular, by thermal decomposition of platinum dioxide in accordance with the equation

$$3PtO_2 = Pt_3O_4 + O_2. \quad (3)$$

The optimal decomposition temperature is 923–953 K; at higher temperature, platinum dioxide inten-

sively dissociates into platinum and oxygen (at 1173 PtO_2 dissociates completely [28]).

Platinum oxide Pt_3O_4 can also be obtained by oxidation of highly dispersed platinum (platinum black) in oxygen [24, 27] (especially under elevated pressure):

$$3Pt + 2O_2 = Pt_3O_4. \quad (4)$$

In the course of high-temperature oxidation of ammonia, the platinum catalyst undergoes a number of physicochemical transformations [1–6, 20]; in particular, platinum and platinum dioxide appear in the gas phase:

$$Pt(c) = Pt(g), \quad (5)$$

$$Pt(g) + O_2(g) = PtO_2(g). \quad (6)$$

To this should be added sublimation of platinum as platinum dioxide in accordance with Eq. (2).

The products of reactions (2), (5), and (6), Pt and PtO_2, are starting substances in processes used to obtain Pt_3O_4 (in gas phase or on the sorbent surface). Introduction of atoms (ions) of platinum and calcium (or microscopic amounts of K^+, Na^+, Mg^{2+}, and Zn^{2+}, present in the sorbent as impurities and, in part, coming from AAM as contaminants, despite the reagent purification to remove them) into voids in platinum oxide Pt_3O_4 stabilizes a compound of the structural type $Na_xPt_3O_4$ and improves its thermal resistance. The temperature of PtO_2 dissociation should not be exceeded only in the initial stage of synthesis. In later stages, this limitation is lifted since a higher-temperature process of Ca^{2+} ion introduction into the crystal lattice of a compound of the structural type $Na_xPt_3O_4$ occurs, i.e., $Ca_xPt_3O_4$ is formed in accordance with the equation

$$Pt_3O_4 + xCa^{2+} = Ca_xPt_3O_4, \quad (7)$$

where $0 \le x \le 1$.

Analysis of the conditions for absorption by the CaO sorbent of products formed in conversion of the platinum catalyst leads to the following important practical recommendations.

(1) It is necessary to satisfy certain temperature conditions of sorbent operation. The sorbent should be placed at a distance from the catalyst meshes at which its temperature does not exceed the temperature of complete PtO_2 dissociation ($T \le 1173$ K) or the temperature of Pt_3O_4 dissociation. Beginning with the instant of time when a nonstoichiometric compound $Ca_xPt_3O_4$ is synthesized in the sorbent, the sorbent temperature should not exceed the dissociation temperature of this compound (1183–1203 K).

(2) Since the nonstoichiometric compound $Ca_xPt_3O_4$ is formed in the sorbent at the phase boundary CaO–Pt_3O_4, it is necessary to have well-developed interface for accelerating the process. Low rate of the topochemical process leads to accumulation on the sorbent surface of products formed in transformations of the platinum catalyst [Eqs. (2), (4)–(6)]. Dissociation of these compounds enriches the sorbent surface with platinum, and the rate of $Ca_xPt_3O_4$ formation falls. Consequently, the sorbent taken in the form of pellets, coarse grains, or cylinders is inefficient in chemical recovery of products of platinum conversion, since only a small part of its outer surface is used in reaction (7), with deep layers of the sorbent virtually not involved in sorption at all.

(3) To make faster the chemical absorption of platinum-containing components by the sorbent, it is necessary to stabilize platinum oxide Pt_3O_4, i.e., to obtain a nonstoichiometric intercalation compound of the type $Na_xPt_3O_4$. Consequently, the presence in the calcium-containing sorbent of even minor concentrations of ions with small radius and high mobility (e.g., Li^+, Na^+, Mg^{2+}, Zn^{2+}, etc.), which readily penetrate into voids of the cubic lattice of Pt_3O_4 and stabilize it, must exert positive influence on the efficiency of platinum recovery in the form of the chemical compound $Ca_xPt_3O_4$ ($0 \le x \le 1$). When present in the sorbent, ions with larger radius (e.g., Ba^{2+}, Sr^{2+}, Cs^+, Rb^+, etc.) will adversely affect the efficiency of platinum recovery.

(4) In recovery of platinum from a calcium-containing sorbent, account should be taken of the high thermal and chemical stability of the compound $Ca_xPt_3O_4$, and appropriate temperature ($T \ge 1223$ K) and reagents should be used.

CONCLUSIONS

(1) It is established that conversion products of platinum lost in high-temperature oxidation of ammonia are bound chemically by a calcium-containing sorbent to give a nonstoichiometric compound $Ca_xPt_3O_4$ ($0 \le x \le 1$). The extent to which the compound is nonstoichiometric depends on the time of sorbent operation and process parameters.

(2) Data on chemical mechanisms of recovery of platinum lost in high-temperature oxidation of am-

monia by a calcium-containing sorbent can be used to develop theoretical prerequisites for synthesis of effective sorbents.

Abstract—The influence exerted by the nature and concentration of a number of organic and mineral acids on the composition of products formed in electric-spark dispersion of aluminum was studied.

Being a continuation of [1–3], this study is concerned with the effect of organic and mineral studies on the composition of products formed in electric-spark dispersion of aluminum. The experiments were carried out on a setup, and using a procedure, described in [1].

The results obtained in studying the influence exerted by the concentration of working solutions of nitric, hydrochloric, and acetic acids on the composition and amount of spark-erosion products are presented in Fig. 1. Among the products are identified aluminum powder and boehmite and bayerite forms of aluminum hydroxide (AH). As seen, the ω–*C* dependences show different behavior in two ranges. With the concentration of acid solutions increasing in the first range, the content of aluminum powder in spark-erosion products grows steeply (ω_1–*C* dependence). Correspondingly, the fraction of AH decreases (ω_2–*C* dependence). The stronger the acid, the steeper the increase in the content of metal powder in the product. Further increase in the acid concentration affects the amount of metal powder in the product only slightly (portion II of the ω_1–*C* dependence). The observed run of the ω–*C* curves is apparently due to the fact that, as the acid concentration in solution is increased, the mechanism of oxide film formation on the surface of dispersed aluminum particles changes. It has been suggested previously [2, 3] that the energy released in the spark discharge zone is sufficient for atomization of oxygen from oxygen-containing acid residues. The released oxygen may be involved in aluminum oxidation to give a protective oxide film. However, a steep rise in the content of powdered aluminum in the product formed in spark erosion is observed in the first range in a narrow interval of concentrations also in that case when one of acids (hydrochloric) has no oxygen-containing acid residue. Hence, oxygen that oxidizes aluminum originates from sources other than the acid residue of an acid. It is known that hydrogen ions in dilute aqueous solutions of acids are in the hydrated state in the form of hydroxonium H_3O^+.

*** (AH) Content of aluminum hydroxides: (numerator) bayerite and (denominator) boehmite; (Σ) total content of all AH forms.

Presumably, either water or H_3O^+ may serve as a source of oxygen. The mass fraction of aluminum in products of thermal-electric decomposition strongly depends on the nature and concentration of acid in a working solution. In the first range, the stronger the acid, the greater the amount of atomic oxygen formed via thermal-electric decomposition of H_3O^+ ions and, correspondingly, the higher the fraction of aluminum powder in the products. In the second portion of the ω_1–C dependence, the content of metal powder varies slowly with increasing acid concentration. The possible reason is that oxygen produced in thermal decomposition of the oxygen-containing acid residue is involved, together with oxygen formed in decomposition of the hydroxonium ion, in aluminum oxidation in the second range of the dependence. Consequently, the oxidation of aluminum in the given range of concentrations is the slowest and the most incomplete in the case of hydrochloric acid solutions.

Experimental and calculated data for a number of the acids studied are presented in the table. Addition of acid nos. 4–7 to the working solution leads to preferential formation of an oxide film on the aluminum surface. The observed phenomenon is virtually independent of the type of anion. However, this contradicts the conventional concepts of how acids act upon aluminum under nearly standard conditions. The protective oxide film is formed on aluminum in sufficiently concentrated nitric acid solutions. No protective film is formed in hydrochloric acid solutions [4]. At the same time, under conditions of electric-spark dispersion of aluminum in hydrochloric acid solutions, there occurs, at the initial instant of time, even more intensive formation of a protective film than that with nitric and weaker acids. In this case, the experimentally obtained series of influence exerted by the nature and concentration of acids on the intensity of oxide film formation is in good agreement with data on acid protolysis constants [5] (see table).

The composition of products formed in spark dispersion of aluminum is in qualitative agreement with the energy ΔE of atomic oxygen formation from molecules of solution components, calculated by quantum-chemical methods AM1 [6] and PM3 [7]. The table lists the energies necessary for removing an oxygen atom from a molecule to give independent fragments (or a fragment) of the molecule. In calculations, the geometry of fragments was optimized.

On the whole, the observed experimental data are in satisfactory agreement with the individual properties of the components introduced into the working solution, if their acid properties and the energy of atomic oxygen formation are considered simultaneously. In all probability, the acid properties of a component affect the total concentration of the atomic oxygen being formed to even greater extent. Such a conclusion follows not only from the fact that water is the dominant component of the working solution. Free electrons with rather high kinetic energy appear in the spark discharge zone; and these electrons can be involved in reactions. Calculations show that the reac-

tion of formation of atomic oxygen from a hydroxonium ion, proceeding with electron of capture, requires much less energy than formation of atomic oxygen from water:

$$H_3O^+ + e \rightarrow 3H + O, \quad \Delta E = 210 \text{ kJ mol}^{-1}. \quad (1)$$

A calculation in terms of scheme (1) assumed that the electron energy is zero. The energy consumption in formation of atomic oxygen by reaction (1) is much lower than that in reactions of its formation from water or acid residues. Thermodynamic calculations employing data of [8] show that the entropy-related contribution to the total energy in decomposition of a hydroxonium ion is approximately 1.55 times that in decomposition of a water molecule. At a temperature of about 1000 K this quantity is approximately 310 and 200 kJ mol^{-1} for the hydroxonium ion and water molecule, respectively. Consequently, the entropy factor dominates over the enthalpy factor in decomposition of a hydroxonium ion. In decomposition of a water molecule, such a condition is not satisfied at the given temperature. Therefore, one would expect that atomic oxygen is formed in thermal-electric dissociation of just the hydroxonium ion.

Atomic oxygen may also appear in decomposition of acid molecules. However, the decomposition energy proved to exceed by, on the average, a factor of 2 and more that required for atomization of oxygen from water (see table). The concentration of acid molecules in aqueous solutions of weak acids is much higher than that of hydroxonium ions. However, the influence exerted by thermal decomposition of oxygen-containing acid residues to give atomic oxygen on the composition of products of spark erosion of aluminum should also be taken into account for weak acids.

As seen from the table, virtually 100% boehmite is formed when solutions of boric acid and hydrogen peroxide are used. In view of the fact that the protolysis constants of these acids have values intermediate between the constant of water and those of the acids under study, such a composition of the products is as it would be expected. Indeed, the boehmite phase of AH is, formally, also intermediate between the bayerite AH phase (obtained in water) and the oxide phase of aluminum (formed in solutions of stronger acids). Judging from the decomposition energy ΔE of orthoboric acid, it would be expected that decomposition to give atomic oxygen is hindered. However, boric acids are easily dehydrated on heating to form metaboric and other acids. In the end, boric acids completely pass into the gas phase at a temperature of about 2250°C (reached in the spark discharge zone) in the form of monomeric boron oxide B_2O_3. The ΔE value is close to the decomposition energies of the acids, listed in the table. The energy of oxygen atomization for the monomeric form of metaboric acid is close to the atomization energy of oxygen from B_2O_3. Moreover, boric acid markedly differs in nature from the other acids represented in the table: its acid function is associated with protolysis of water bound to boron to form a complex, rather than with protolysis of the acid itself. This circumstance may affect processes occurring in the solution bulk. The case of hydrogen peroxide is characterized by disproportionation with evolution of oxygen. This oxygen may favor formation of AH containing increased fraction of oxygen, namely, boehmite AH (see table).

CONCLUSION

Mineral and organic acids introduced into the working solution markedly affect oxidation of aluminum in the course of its electric-spark dispersion. The possible mechanism of formation of a protective oxide film on the surface of dispersed aluminum is associated with the occurrence of thermal-electric decomposition of the hydroxonium ion and acid molecules to give atomic oxygen under spark discharge conditions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution, Passivation, and Methods for Electrochemical Polishing of Nb, Ta, and Ti in Low-Temperature Urea–Halide Melts[1]

N. Kh. Tumanova

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received April 11, 2001

Abstract—Processes of anodic dissolution of Nb, Ta, and Ti in low-temperature urea–NH_4Cl and urea–NH_4F melts were studied. Methods for electrochemical polishing of metals were developed.

The electrochemical behavior of niobium, tantalum, and titanium, oxidation levels of metal ions formed in melt as a result of anodic dissolution, and equilibrium of metals with their ions in chloride, fluoride, and mixed chloride–fluoride melts have been extensively studied [1–10]. Despite the considerable number of publications, the relevant scientific concepts and results are subject of discussion. The ambiguity of mechanisms of processes at electrodes, described in the literature, is associated with the complexity of multielectron processes occurring in anodic dissolution and deposition of metals and with the formation and stability of poorly soluble intermediate oxyhalides and oxides.

Passing to low-melting ion–organic electrolytes (consisting of an organic compound and an ionic compound) is of interest for solving a number of scientific and applied problems. The scientific interest is primarily associated with the need to reveal the fundamental aspects of the electrochemical behavior of Nb, Ta, and Ti in low-temperature melts containing organic compounds and its general (common to all molten media) and specific features. Another important thing is to determine the stable oxidation states of metals and the structure of complexes formed by niobium, tantalum, and titanium with melt components.

The expediency of practical use of low-temperature melts for electropolishing of Nb, Ta, and Ti is governed by the problem of environment protection. The electrolytes presently used for electropolishing of these metals are based on corrosive acids: hydrofluoric and sulfuric [11]. Use of urea-based melts will improve the environmental and labor conditions and make simpler and less expensive the equipment to be used. No published data on use of low-temperature ion–organic melts for studying the electrochemical behavior of high-melting metals could be found in the literature, except for [12–15].

EXPERIMENTAL

The electrochemical behavior of Nb, Ta, and Ti in urea–halide melts was studied by cyclic voltammetry with the use of a PI-50-1 potentiostat. The surface area of the indicator electrode (Nb, Ta, Ti) was $(5–8)\times10^{-3}$ cm^2. As auxiliary electrode served platinum plate. The electrode potential was measured relative to a silver reference electrode $Ag/AgNO_3$ (0.07 mol kg^{-1})–urea–NH_4NO_3 (16 mol %). Experimental data were obtained in the temperature range 120–140°C in an argon atmosphere. The oxidation states of metal ions passing into melt in electrochemical dissolution were determined by gravimetry and spectroscopically: by electronic (Specord UV/VIS and IKS-14), Raman (DFS-24), and IR (Specord M-80) spectroscopies. The electronic spectra were measured in the course of anodic dissolution of metals, quenched melts were studied by Raman and IR methods. The electrode surface was analyzed with a 09 IOS-1 Auger spectrometer. A layer-by-layer analysis of samples was made in a vacuum, with a beam of Ar^+ ions with an energy of about 3000 eV. The melts were prepared from salts of chemically pure grade, recrystallized and dried in a vacuum.

Two sets of melts were studied: urea–MCl (M =

NH_4^+, K^+, Na^+, Cs^+) and urea–NH_4Cl (Br^-, I^-, F^-). The results of electrochemical studies of the given melts with the use of inert (platinum, glassy carbon) electrodes were reported in [12, 13].

A study of urea–chloride melts of varied composition revealed distinctive features of melts containing ammonium ions. Formation of a compound present both in the gas phase and, in lesser amount, in the melt was revealed in a urea–NH_4Cl melt in anodic polarization of a Pt (glassy carbon) electrode to potentials exceeding that at which the electrolyte decomposes (0.9 V), i.e., under conditions of joint oxidation of Cl^- ions and urea. This compound is reduced at 0.1 V (Fig. 1a, curve *1*); according to chronopotentiometric data (Fig. 1b), the reduction proceeds from an adsorbed layer [13]. The results obtained in an IR study of the anolyte and anode gases, and their comparison with published data [16], made it possible to identify this compound as NCl_3. In the urea–K(Na, Cs)Cl melts, there is no cathodic peak of current, corresponding to NCl_3 reduction, in the reverse portion of the voltammetric curve measured in the first cycle (Fig. 1, curve *2*), and free chlorine is present in the gas phase. Preliminary electrolysis in melts containing alkali metal chlorides, during which urea is isomerized, leads to accumulation of NH_4^+ ions [12]. Simultaneously, a cathodic current peak appears in voltammograms, similar to that observed in urea–NH_4Cl melts (Fig. 1a, curve *3*). In the process, the peak corresponding to Cl_2 gradually disappears from the spectra of the gas phase, and signal indicating formation and accumulation of NCl_3 appears. The fact that the occurring processes and voltammograms obtained on Pt electrodes in urea–NH_4Cl and urea–(alkali metal chloride) melts are identical after 30–40 min of electrolysis indicates that the use of the urea–NH_4Cl melt as solvent is preferable.

A study of systems comprising urea and ammonium salts of varied anionic composition revealed that electrolysis of bromide and iodide melts is accompanied by liberation of free bromine and iodine, imparting, respectively, yellow and brown-yellow color to the melts, which hinders interpretation of the results of electrochemical and, especially, spectroscopic studies. Therefore, the urea–NH_4Cl (16.8 mol %) and urea–NH_4F (10 mol %) melts were chosen for studying the mechanism of anodic dissolution of metals and solving applied problems.

A study of Nb, Ta, and Ti dissolution in the urea–NH_4Cl melt demonstrated that all the metals are passive, but to varied extent.

Niobium is passive in a rather wide range of potentials. Its surface is activated only in the transpassive region at potentials more positive than 1.0 V (Fig. 2a, curve *1*). After activation, the wave of niobium dissolution current can be observed in the reverse portion of the voltammetric curve. Recycling leads to appearance in the forward portion of an anodic current peak (curve *2*), with the current increasing in cycling (curves *3* and *4*) if the electrode polarization reaches the transpassive region. That is, the increase in niobium dissolution current is proportional to the rise in the concentration of NCl_3, which is formed in the transpassive region and activates the surface of the Nb electrode. If the polarization is switched off and the electrode is kept in the melt for a certain time, the voltammetric curve retraces the curve obtained in the first cycle, reflecting the complete passivation of the electrode. Auger spectroscopy was applied to study the surface of the Nb electrode in the steady state and in the case of anodic polarization. In the steady state, the electrode is covered with a passive film mainly composed of urea; with increasing positive potential, the content of Cl^- in the film markedly increases.

According to gravimetric data, niobium passes into

the melt in anodic dissolution as pentavalent ions. The calculated oxidation state n is 5–5.2 for all portions of the anodic curve. The metal is dissolved by the solid-phase mechanism of dissolution of high-melting metals [17]. According to this mechanism, compounds with varied metal oxidation state are formed in the passive film, and the oxidation state increases in going from metal to the film–melt interface. The fact that ions with the highest oxidation state [Nb(V)] are formed in dissolution of Nb is an indirect evidence in favor of the formation of a sufficiently stable passive film on the metal surface. The formation and accumulation of Nb(V) ions in the urea–NH_4Cl melt was indicated by the shift of charge-transfer bands in the UV part of the electronic spectra in the course of anodic dissolution of the metal (at current densities i = 5–50 mA cm^{-2}). The position (36 000, 32 500, and 28 500 cm^{-1}) and the nature of the absorption bands indicate formation of octahedral chloride complexes of niobium, $[NbCl_6]^-$ [18]. A study of quenched melts by other spectroscopic methods confirmed this conclusion. The peaks in Raman spectra at 370, 290, and 180 cm^{-1} are characteristic of $[NbCl_6]^-$ [16]. The IR spectra of melts solidified before and after metal dissolution demonstrated that the frequencies of stretching vibrations of the C–O and N–H bonds remain unchanged. This means that urea is not involved in complexation.

The mechanism of tantalum dissolution in the urea–chloride melt also corresponds to the solid-phase mechanism of dissolution of high-melting metals. The passivation of Ta in the melt is even more pronounced, compared with that of niobium. In the case of Ta, electrode polarization into the transpassive range does not depassivate the surface of the metal surface and lead to its dissolution (Fig. 2b). The dissolution of tantalum requires accumulation of a much greater amount of the depassivating agent than that formed while the electrode is in the transpassive region during a single cycle at potential sweep rate of 10^{-1} V s^{-1}. For a sufficient amount of depassivating agent to be accumulated, the time of electrode polarization in the transpassive region is to be extended. For this purpose, it is necessary to either perform multiple cycling (3–5 cycles, Fig. 2b) or reduce the potential sweep rate to 10^{-2} V s^{-1}. The peak of tantalum dissolution current can also be observed in the voltammetric curve after preliminary electrolysis of the melt for 20–30 min at voltages exceeding 1 V. In reverse portions of the voltammetric curve, the dissolution wave occasionally appears even in those cases when it is absent in the forward portion of the curve. When

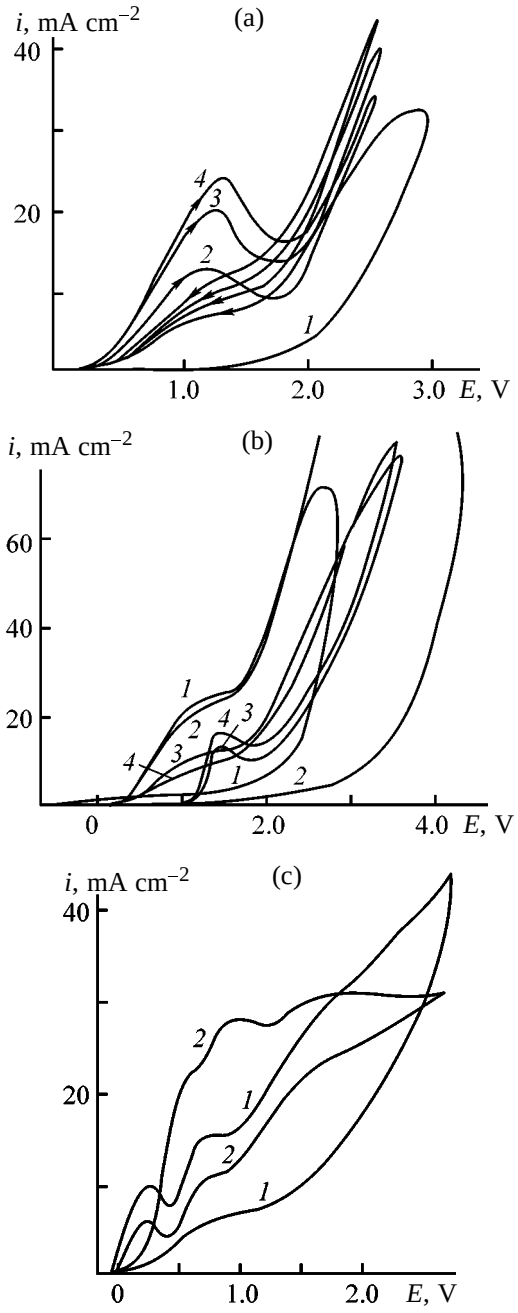

Fig. 2. (*1–4*) Anodic portions of voltammograms obtained successively on (a) Nb, (b) Ta, and (c) Ti electrodes in a eutectic urea–NH_4Cl melt. Potential sweep rate 0.1 V s^{-1}; the same for Fig. 3. (*i*) Current density and (*E*) potential; the same for Fig. 3.

the electrode is placed in the melt, the dissolution peak current decreases in the course of time, to the point of its complete disappearance. This indicates the gradual passivation of the electrode. The stable passivation of the Ta electrode is due to the fact that the urea film formed on the electrode in the melt in

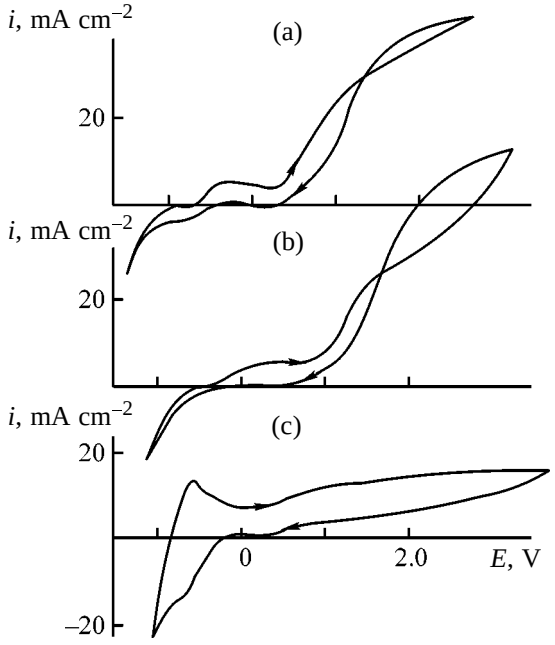

Fig. 3. Voltammograms obtained on (a) Nb, (b) Ta, and (c) Ti electrodes in eutectic urea–NH_4F melt.

the steady state is saturated with oxygen as the electrode is polarized. This leads to formation on the tantalum surface of an oxide film (according to Auger spectroscopy) whose disintegration requires a substantial activity of the depassivating agent.

The formation of tantalum ions with the highest oxidation state, Ta(V), was established gravimetrically and spectroscopically. Electronic spectra were measured during electrolysis in the course of 15–60 min in a wide range of current densities, 5–150 mA cm^{-2}. The peaks in the spectrum (27000, 31000, and 38000 cm^{-1}) correspond to formation of octahedral chloride complexes $[TaCl_6]^-$ [18, 19]. Raman spectra of quenched melts also confirm this conclusion (frequencies 380, 300, and 183 cm^{-1}) [16]. No tantalum ions with lower oxidation states were formed.

Depassivation of the urea film on titanium proceeds rather easily. A region of Ti dissolution is observed in the forward portion of the voltammetric curve in the first cycle (Fig. 2c). This means that the depassivating action of the Cl^- ion is sufficient for disruption of the passive film and dissolution of titanium to give Ti(II) ions in the melt. The electronic spectra obtained after 30 min of electrolysis at current densities in the range 5–20 A cm^{-2} confirm the formation of urea complexes with Ti(II) $Ti[CO(NH_2)_6]^{2+}$, with coordination via oxygen. The IR spectra of quenched melts before and after dissolution of titanium show a decrease in the frequency of vibrations of the C–O bond from 1683 to 1615 cm^{-1}, with the frequencies corresponding to the N–H bond remaining unchanged.

However, with increasing anodic polarization Ti(II) ions are not oxidized further to higher oxidation state (Fig. 2c, curve *1*). According to Auger spectroscopy, the urea film is gradually saturated with oxygen and chlorine. Apparently, an oxychloride film shielding the electrode surface is formed on the titanium surface. If the electrode is polarized into the transpassivation region, two new waves appear in the reverse portion of the voltammetric curve, retained in the forward portion of the curve. These waves reflect the formation of Ti(III) and Ti(IV) ions (as indicated by gravimetry). The formation of Ti(III) ions was also revealed in measuring electronic spectra at current densities of 30–50 A cm^{-2}. The peaks in the spectrum (23000 and 19000 cm^{-1}) correspond to formation of four-coordinate complexes of Ti(III) with urea, $[Ti(CO(NH_2)_2)_4]^{3+}$, coordinated via nitrogen. The IR spectra measured before and after dissolution of titanium at the current densities specified show an increase in vibration frequencies from 1683 to 1720 cm^{-1} for the C–O bond, and a decrease from 1471 to 1400 and from 3400 to 3200 cm^{-1} for, respectively, the C–N and N–H bonds. For Ti(IV) the spectra could not be obtained because of the possible overlapping of the charge-transfer spectrum for Ti(IV) and the spectra of *d–d* transitions in Ti(II) and Ti(III). The formation of Ti(IV) in the third wave of the cyclovoltammograms was confirmed qualitatively, by introducing $TiCl_4$ into the melt.

It follows from the results obtained in studying the electrochemical dissolution of metals in the urea–chloride melt that the electrochemical activity of the metals decreases in the order Ti > Nb > Ta, which is due to the formation of a passive film and is determined by its composition, stability, and solubility in the melt. The electrochemical activities of the metals being different, the methods for electropolishing of Nb, Ta, and Ti in the urea–chloride melt differ in the electrolyte composition and electrolysis conditions: the quality of a treated surface decreases in the order Ti > Nb > Ta.

For obtaining a lustrous metal surface, the electrode polarization is to be performed with the use of reversing current, $i_a/i_c = 3:1$, at total time of a cycle equal to 1 s. For the same purpose, organic surfactants of various kinds (neutral, cationic, and anionic, which are thermally, chemically, and electrochemically stable under the electrolysis conditions) are to be introduced into the urea–NH_4Cl melt.

The treatment can be done in the easiest way, and with the best results obtained, in polishing of titanium. After electrochemical treatment for 5 min in a urea–NH_4Cl melt, the degree of surface finish increases by three points, and the luster reaches a value of 84% [20]. In treatment of niobium, the degree of surface finish can be increased by two points, and the luster becomes 74% upon electrolysis for 10 min [21]. The most difficult is polishing of tantalum. The time of treatment is, in this case, 15 min, the degree of finish increases by one point, and the luster does not exceed 70% [22].

The quality of the metal surface after treatment can be much improved if electrochemical polishing is carried out in urea–fluoride melts.

The mechanism of metal dissolution in a fluoride-containing $CO(NH_2)_2$–NH_4F melt differs from that in a chloride-containing melt. The depassivating agent in the chloride melt is NCl_3 formed in electrolysis of the $CO(NH_2)_2$–NH_4Cl melt, whereas in the fluoride melt this part is played by the F^- ion.

The dissolution of Nb and Ta occurs immediately after the beginning of polarization (Fig. 3). The first wave corresponds to formation of ions with the lower oxidation state (IV), and the second, to their oxidation to Nb(V) and Ta(V) (gravimetry). Polarization of the electrode into the transpassive region does not lead to any significant changes in the shape of the curves. This may indicate that no compound with depassivation action stronger than that of the F^- ion is formed in the given range of potentials.

The formation of pentavalent ions of Nb and Ta in electrochemical dissolution of metals at current densities in the range 5–10 A cm^{-2} was confirmed by electronic and Raman spectroscopies. The shift of the charge-transfer bands in the electronic absorption spectra (from 42 000 to 32 000 cm^{-1} for Nb and from 39 000 to 34 000 cm^{-1} for Ta) is in agreement with the data of Raman spectroscopy for quenched melts (280, 560, and 682 cm^{-1} for niobium and 290, 590, and 694 cm^{-1} for Ta) and corresponds to formation of octahedral complexes of Nb(V) and Ta(V), $[MF_6]^-$.

The wave of Ti dissolution in the urea–fluoride melt (Fig. 3) also appears in the forward portion of the voltammetric curve in the first cycle. However, measurements of the reverse portion of the curve show that poorly soluble compounds of titanium are formed on the metal surface. Auger spectroscopy revealed the formation of titanium oxyfluoride on the anode surface during polarization. The formation of a deposit on the electrode surface can be observed visually in electrolysis for 1 h. After the current is switched off, the deposit gradually dissolves in the urea–NH_4F melt to give octahedral complexes of Ti(III) of the type $[TiF_6]^{3-}$. This indicates that the rate of Ti oxyfluoride formation in polarization exceeds the rate of its dissolution.

The urea–fluoride melt was used as electrolyte for Ta electropolishing as the metal most difficultly treated in the chloride melt. Introduction of even minor amounts of NH_4F (5 mol %) into the eutectic melt urea–NH_4F markedly changes the results of electrochemical treatment. The degree of finish increases by unity, with the luster reaching a value of 80% (in chloride melts the luster does not exceed 70%).

With account of the toxicity of fluoride melts, their practical use is possible, but inexpedient, since the main parameters characterizing the quality of the Nb, Ta, or Ti surface conform to the requirements to a polished surface after electrochemical treatment in the urea–chloride melt.

CONCLUSIONS

(1) A study of the anodic dissolution of Nb, Ta, and Ti in urea–NH_4Cl and urea–NH_4F melts demonstrated that all these metals are passive in urea-based melts and the dissolution mechanism corresponds to the solid-phase mechanism of dissolution of high-melting metals.

(2) The electrochemical dissolution of metals occurs under the action of the depassivating agent, NCl_3, formed in electrolysis of the urea–NH_4Cl melt at potentials exceeding 1.0 V, and of the F^- ion in urea–NH_4F melts. The electrochemical activity of the metals decreases in the order Ti > Nb > Ta in the urea–chloride melt and is about the same in the urea–NH_4F melt. Titanium virtually does not dissolve in the urea–fluoride melt because of the formation of poorly soluble titanium oxyfluoride on the metal surface.

(3) The study of the electrochemical dissolution of Nb, Ta, and Ti in urea-based melts made it possible to develop methods for electrochemical polishing of the metals. The basic parameters characterizing the metal surface quality (degree of finish, luster) conform to the requirements to a polished surface for all the metals studied.

Received April 11, 2001

Abstract—Nanostructural titanium dioxide, TiO_2(E), synthesized by the emulsion method, was studied as cathode and anode of a lithium current source.

Titanium dioxide, TiO_2, is used in lithium current sources [1, 2], electrochromic systems [3], and in photocatalysis [4].

Among structural modifications of titanium dioxide, anatase is the most extensively studied as electrode of lithium sources. Nanostructural anatase is a promising cathode [2]; also, it was tested as anode of a lithium-ion battery [1].

The discharge–charging cycle of a TiO_2 electrode in aprotic Li-containing medium is accompanied by a topotactic reaction of lithium ion intercalation into the titanium dioxide lattice:

$$TiO_2 + xLi^+ + xe \rightarrow Li_xTiO_2. \quad (1)$$

The service life of a lithium battery based on TiO_2 is determined by the reversibility of reaction (1), which depends, to a considerable extent, on the procedure for titanium dioxide synthesis. In cathodes based on the anatase [TiO_2(A)], the intercalation of lithium ions is reversible at $x \leq 0.5$. The discharge capacity of the lithium-ion system with TiO_2(A) anode and $TiCoO_2$ cathode in 1 M solutions of $LiN(CF_3SO_2)_2$, EC (ethylene carbonate), and DME (dimethoxyethane) is 50 mA h g^{-1} [1].

To improve the relative discharge characteristics of the TiO_2(A) electrode, various methods were developed for anatase preparation. It was synthesized in the mesophase form and also by applying a thin layer to a conducting substrate for use in thin-film chemical current sources (CCSs) and electrochromic systems. For example, the electrochemical intercalation of lithium ions was studied in TiO_2(A) synthesized by the following methods: cathodic electrodeposition from aqueous solution containing TiO^{2+} ions [5], electrophoresis in organic electrolyte, electron-beam evaporation [6], reaction of titanium carbide with hydrogen peroxide [4], anodic dissolution of titanium in acetonitrile [7], sol–gel formation from titanium alcoholates [8], nanocomposite formation [2], and by other methods.

However, the electrochemical potentialities of TiO_2(A) in the synthesized materials during cycling of lithium batteries are not exhausted to a full measure. This fact stimulates a search for new ways to improve the electrochemical performance of TiO_2(A), including development of new synthesis procedures.

In this work, we studied the electrochemical intercalation of lithium ions into nanostructural TiO_2(A) synthesized by the emulsion method [TiO_2(E)].

The emulsion method for synthesizing TiO_2(E) was proposed and described in detail in [9]. Finely dispersed titanium dioxide was prepared in reverse emulsion from titanium tetrachloride. For this purpose, a 1% solution of oxyethylated lard (surfactant) in benzene, placed in a glass cap, was added to aqueous ammonia without mixing the layers. Then, a conical head of an ultrasonic disperser was plunged into the aqueous phase, and the generator adjusted to a frequency of 22 kHz was switched on. After the emulsification was complete, a titanium tetrachloride solution in benzene was added to the emulsion, with the ultrasonic treatment continued. In the process, titanium tetrachloride diffused into the dispersed phase and was hydrolyzed in the emulsion droplets. The hydrolysis product was centrifuged, dried, and calcined at 350–400°C to remove ammonium chloride and organic substances.

The synthesized products were studied by IR spectroscopic, X-ray diffraction, thermal, and electrochemical analyses. X-ray diffraction patterns were taken on a DRON-2 diffractometer. The IR absorption

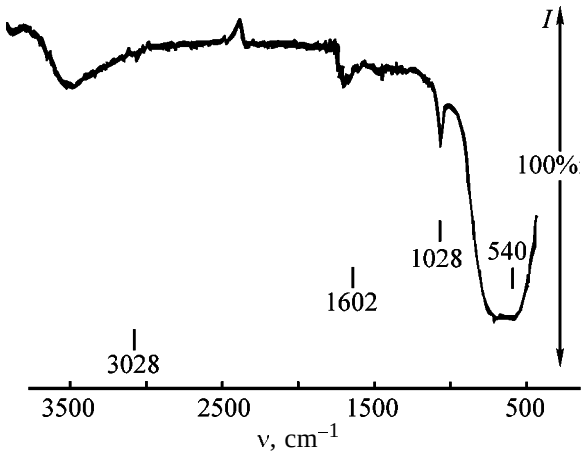

Fig. 1. IR absorption spectrum of TiO_2(E). (*I*) Transmission and (ν) wave number.

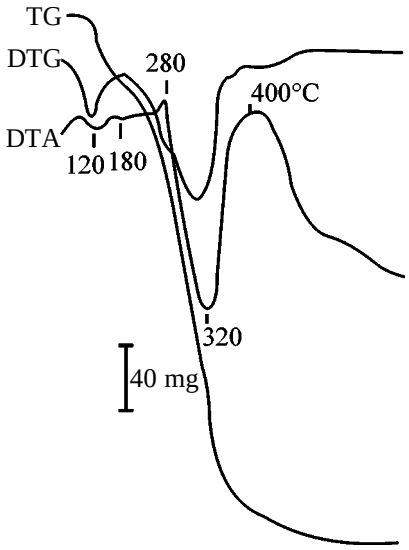

Fig. 2. Thermogravimetric curve of the hydrolysis product of the composition $Ti(OH)_4$ + NH_4Cl.

spectra were recorded on a Specord IR-75 spectrophotometer in the range 400–4000 cm^{-1} using KBr technique. The thermogravimetric curves of 200–300-g TiO_2 samples were obtained on a Q1500-D derivatograph (heating rate 10 deg min^{-1}).

The electrochemical characteristics of TiO_2 were determined in composite electrodes prepared from a grid of 18Cr12Ni10Ti stainless steel, to which the active component containing additives of carbon black and fluoroplastic binder (10 wt % each) was applied as paste, with subsequent drying at 250°C for 2.5–5 h.

The TiO_2 electrode and counterelectrode were assembled as sandwich in commercial KhIT 2325 cells, in which 1 M $LiClO_4$ solution in PC (propylene carbonate) and DME was the electrolyte and a two-layer 110-μm-thick fiber glass was the separator.

The cyclic voltammograms were taken in a sealed three-electrode cell with Li auxiliary electrode and Li/Li^+ reference electrode. The cell was assembled in a glove box under argon.

In study of lithium battery TiO_2 was the cathode and lithium foil, the anode, and in study of lithium-ion current source TiO_2 was the anode and $LiCoO_2$, the cathode. The layered $LiCoO_2$ was synthesized by the thermal method, i.e., by sintering a mixture of dry Li_2CO_3 and Co_3O_4 (Li : Co = 1.05 : 1) at 750°C for 20 h.

The galvanostatic charging–discharge curves of the CCSs and the volt–ampere characteristics of the TiO_2(E) electrode were obtained on a computer-controlled electronic testing bench, at I_{dis} = 0.2 mA and I_{ch} = 0.1 mA. The TiO_2(E) electrode was cycled in the potential range 4.0–0.9 V and then in the narrower range 2.8–0.9 V, with the results changed inappreciably. The cycling range of the $LiCoO_2$ electrode was 3.0–1.1 V.

The X-ray diffraction patterns of TiO_2(E) contain weak diffuse reflections, indicative of finely dispersed powder. The crystallite size estimated from the diffraction patterns is 60 nm. According to the data [9] of transmission electron microscopy, the grain size of TiO_2(E) is 40–60 nm. The emulsification product is a mixture of the TiO_2 structural modifications with anatase as predominant phase [88–90%; *d* (Å): 3.50, 2.47, 2.37, 1.88, 1.68, 1.61, 1.48, 1.36, 1.34, 1.26, and 1.24]. The remainder is rutile [*d* (Å) 3.25 and 1.88] and insignificant amount of orthorhombic titanium oxide [*d* (Å) 2.92 and 2.47].

The physicochemical and electrochemical properties of titanium dioxide depend on the moisture content. The IR spectrum of the synthesized TiO_2(E) confirmed its hygroscopicity (Fig. 1). The absorption spectrum of titanium dioxide, kept in air and then over P_2O_5, has absorption bands attributable to the OH stretching (3440 cm^{-1}) and H–O–H bending vibrations of coordinated water molecules (1640 cm^{-1}). In a humid atmosphere, the titanium–oxygen bonds are not clearly resolved. Only one broad absorption band between 900 and 400 cm^{-1} is present, resembling that in the TiO_2 IR spectrum from [10].

The thermal analysis curves of the heated hydrolysis product of the composition $Ti(OH)_4$ + NH_4Cl have several peaks (Fig. 2). The weight loss (TG and DTG curves) occurs in three stages (at 40–200°C, 200–350°C, and 350–500°C). The DTA curve has three endothermic peaks. The first peak at 110–120°C is due to the water evaporation, the second at 160–

180°C is of uncertain origin, and the third at 320°C is due to NH_4Cl decomposition. The fourth peak at 400–550°C, evidently caused by the decomposition of organic substances, overlaps with the exothermic peak of TiO_2 crystallization at 400–430°C. Above 500°C the weight loss ceases, which confirms the removal of volatile impurities and stabilization of TiO_2.

Thus, the product synthesized by sintering at 400°C is contaminated with organic impurities.

The discharge capacity of the TiO_2(E)/Li system in the first cycle is 600–670 mA h g^{-1}. The discharge curve has two inclined potential plateau: at 1.80–1.60 (*I*) and 1.20–0.9 V (*II*) (Fig. 3a, curve *1*). To them correspond two plateau of the open-circuit potential (OCP): 1.90–1.60 and 1.45–1.35 V (Fig. 3a, curve *2*). The OCP was determined after switching off current, when the change of potential with time did not exceed 1 mV h^{-1}. In charging a TiO_2(E) electrode charged to 0.9 V, the process corresponding to potential plateau *I* is reversible and that corresponding to potential plateau *II*, irreversible (Fig. 3a, curve *3*).

In the second cycle, the discharge capacity of the TiO_2(E) electrode sharply decreases (to 250–270 mA h g^{-1}) (Fig. 3a, curve *4*). The discharge plateau *II* (1.2–0.9 V) in the galvanostatic curve disappears since the second cycle.

In the third cycle, the charging–discharge curve of the TiO_2(E) electrode has the charging (1.80 V) and discharge (1.65 V) potential plateaus (Fig. 3b). The change in the discharge capacity upon TiO_2(E) cycling is reflected in Fig. 3c. Upon subsequent cycling, the discharge capacity decreases, reaching 90 mA h g^{-1} on the 100th cycle.

The cycling voltammetry also shows that the electrochemical intercalation of lithium ions into TiO_2(E) is irreversible. This is seen from Fig. 4: (1) the maximum of the cathode current is smaller than of the anode current, although the total amount of electricity in intercalction is similar to that in Li^+ extraction (Q_{dis}/Q_{ch} = 1.04); (2) the potential difference between the cathode and anode current maxima at the potential scan rate $V = 5 \times 10^{-4}$ V s^{-1} is 0.45–0.55 V. With decreasing scan rate, the potential difference of these maxima decreases (to 0.40–0.50 V at $V = 2 \times 10^{-4}$ V s^{-1} and to 0.32–0.40 V at $V = 1 \times 10^{-4}$ V s^{-1}).

It was determined that the discharge characteristics of TiO_2(E) differ insignificantly from those of TiO_2(BH)-anatase synthesized by traditional base hydrolysis. The discharge curves of TiO_2(BH) are similar to those of TiO_2(E). In the first cycle, the discharge capacity of TiO_2(BH), 550–580 mA h g^{-1}, is

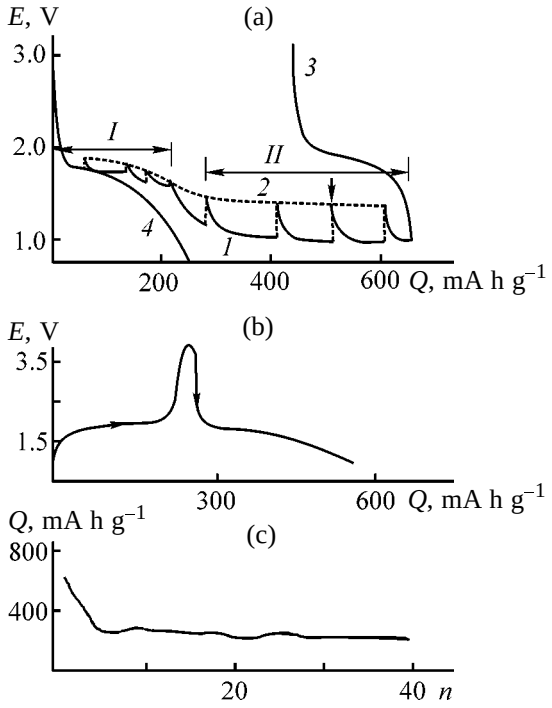

Fig. 3. KhIT 2325 TiO_2(E)/Li current source. I_{dis} = 0.2 mA cm^{-1}, I_{ch} = 0.1 mA cm^{-1}. (*E*) Potential, (*Q*) capacity, and (*n*) cycle number. Curve: (a) (*1*) initial discharge, (*2*) change in OCP upon discharge, (*3*) charging, and (*4*) discharge in the second cycle; (b) charging–discharge in the third cycle; and (c) change in the discharge capacity upon cycling. (a) Vertical arrow indicates the moment of switching on the current.

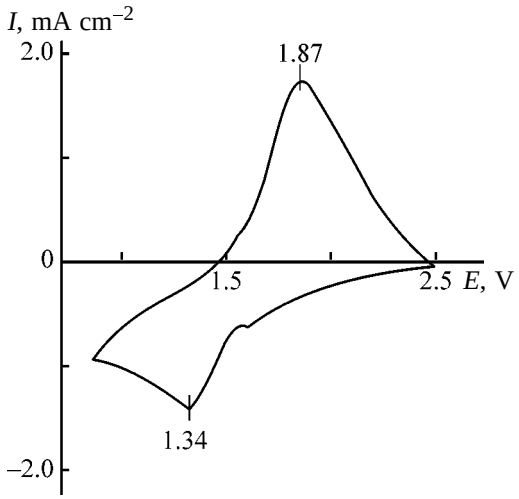

Fig. 4. Cyclic voltammogram of TiO_2(E) for the second cycle. Weight of the cathode active paste 3 mg cm^{-2}, potential scan rate $V = 5 \times 10^{-4}$ V s^{-1}. (*I*) Current and (*E*) potential.

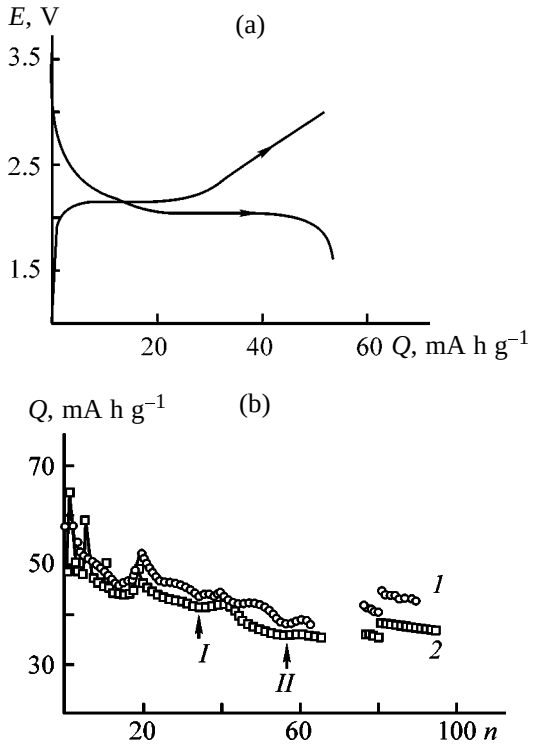

Fig. 5. KhIT 2325 $LiCoO_2/TiO_2$(E) current source. (*E*) Potential, (*Q*) capacity, and (*n*) cycle number. (a) Charging–discharge curve (fifth cycle); (b) change in (*1*) charging and (*2*) discharge capacity upon cycling. Discharge current (mA): (*I*) 0.2 and (*II*) 0.4.

lower than that of TiO_2(E). However, the reversible discharge capacity of titanium dioxide obtained by base hydrolysis is similar to that determined for TiO_2(E).

Our data on the electrochemical intercalation of lithium ions into TiO_2(E) are compared with the published data for TiO_2(A). The open-circuit potentials corresponding to process *I* on the discharge galvanostatic curve of TiO_2(E) lie within the range of the published data: 1.75 [11–13] and 1.80 V [14, 15]. The discharge plateau *II*, which, according to the published data, also disappears at cycling TiO_2(A), is assigned to the film forming at the interface owing to the reaction of titanium dioxide with the electrolyte. In the course of the intercalation of lithium ions, tetragonal TiO_2(A) transforms into orthorhombic Li_xTiO_2, with a maximal value of x differing from the published data: $x = 0.7$ [13] and $x = 1$ [3, 12, 16]. The value $x = 1$ obtained from the X-ray diffraction data is questionable. It is more reasonable for the electrochemical intercalation of lithium ions into TiO_2(A) at room temperature to accept $x = 0.5$ [15, 17, 18]. Our data give $x = 0.60–0.62$ for the maximal degree of lithium ion intercalation on the 30th–40th cycle.

For practical use of electrode materials, the high reversibility of electrochemical conversion and the high rate of lithium intercalation are the necessary conditions. Attempts are made to solve these problems using nanostructural or thin-film materials. However, even for TiO_2(A) thin films, the potential difference between the maxima of the cathode and anode currents exceeds 0.2 V, according to the cyclic voltammogram taken at a scan rate of 2.5×10^{-5} V s^{-1}, i.e., process is irreversible [15]. In thicker porous films, being the objects of our study, the degree of irreversibility is still higher.

It should be taken into account that our results concern anatase containing impurities of other titanium dioxide modifications, including rutile. It was found that the intercalation potential of Li^+ ions into rutile is lower by 0.4 V than into anatase [19]. According to our data, TiO_2-rutile synthesized by thermal hydrolysis showed a 480–500 mA h g^{-1} capacity during the first cycle, when discharged to 0.90 V. Its maximal reversible capacity was 95–100 mA h g^{-1}. Therefore, the specific discharge characteristics of TiO_2(E) with a pure anatase structure can be better.

TiO_2(A) is used as anode of rechargeable lithium-ion batteries [1, 20]. Its theoretical charging capacity is 168 mA h g^{-1}. We tested the TiO_2(E) anode in the lithium-ion system $LiCoO_2/TiO_2$(E). The tests were performed with the applied composite electrodes (active paste weight 10–20 mg cm^{-2}).

The structure of the cathode material $LiCoO_2$ synthesized for the lithium-ion system was confirmed by X-ray diffraction analysis (*d*, Å: 4.67, 2.40, 2.34, 2.20, 2.00, 1.84, 1.55, 1.42, 1.40, 1.34, and 1.22).

The open-circuit potential of the uncharged current source $LiCoO_2/TiO_2$(E) is 0.033–0.040 V. It was charged by intercalating lithium ions into TiO_2(E) and by extracting them from $LiCoO_2$ in the potential range 3.0–1.1 V. The charging-discharge curves are plotted in Fig. 5a. The reversible discharge capacity, as calculated per unit weight of the anode active paste, reached 70–60 mA h g^{-1}, which exceeds the results of [1]. The change in the discharge capacity upon cycling, as calculated per unit weight of the anode active paste, is shown in Fig. 5b. The lithium-ion system studied was not optimized. Its discharge capacity can be enhanced taking into account the material balance of the system.

CONCLUSIONS

(1) Titanium dioxide prepared by emulsion hydrolysis, which is a mixture of TiO_2 structural modi-

fications with anatase prevailing (90%), when used as cathode of a lithium current source, exhibits the initial discharge capacity of 600–650 mA h g^{-1} and the reversible capacity of about 200 mA h g^{-1} on the 30th–40th cycles. The initial discharge capacity of TiO_2(E) anode in the lithium-ion system $LiCoO_2/TiO_2$ is 67–70 mA h g^{-1}, and its reversible capacity after 10 cycles, about 50 mA h g^{-1}. The specific discharge characteristics of TiO_2(E) are similar to those of TiO_2(A) prepared by various procedures.

(2) Compared to titanium dioxide prepared by base hydrolysis, the TiO_2(E) cathode exhibits the higher discharge capacity on the first cycle. The relative discharge characteristics of the TiO_2(E) electrode in a lithium current source can be improved after preparing 100% anatase. In this case, TiO_2(E) will compete with titanium dioxide of anatase structure synthesized by traditional procedures.

Abstract—The Stokes and Hadamard–Rybchinsky formulas are generalized, making it possible to take into account the temperature dependence of viscosity in a wide range of temperatures and to calculate the force of resistance to motion and velocity of gravitational fall at arbitrary temperature differences between the particle surface and a remote region.

Determining the granulometric composition of disperse systems via their sedimentation is one of the most practicable and widely used methods of dispersion analysis [1]. In cleaning of liquids to remove contaminating particles and dressing of minerals, it is important to accelerate sedimentation. This is commonly achieved in various ways, depending on the kind of particles and their environment. Sedimentometry is based on the relationship between the velocity of particle motion in a viscous medium and the particle size. The velocity of particle motion can be markedly raised by heating the particle surface, since the viscosity of a fluid decreases exponentially with increasing temperature. Of practical and theoretical interest in this regard is description of the gravitational motion of a heated particle in a viscous fluid.

Let us consider the gravitational motion of a uniformly heated hydrosol particle in another, viscous incompressible fluid, which is immiscible with the former and fills the entire space. At infinity, the fluid is at rest. By heated (cooled) particle is understood a particle whose surface temperature differs from that at a distance from the particle. The temperature difference between the particle and the viscous fluid can be maintained steadily via, e.g., heat release in chemical reactions at the particle surface, radioactive decay of the drop substance, external irradiation, etc. In particular, if a flux of electromagnetic radiation (wavelength λ_0, intensity I_0) is incident on the drop, then the energy absorbed by the drop is $\pi R^2 I_0 K_a$, where R is the drop radius and K_a is the absorption factor [2]. If the heat conductivity of the drop much exceeds that of the external medium and $\lambda_0 \gg R$, then the absorbed energy is evenly distributed over the drop surface and, consequently, the drop can be considered uniformly heated.

The heated particle surface affects the heat-transfer properties of the ambient fluid and, in the end, the distribution of the velocity and pressure fields in the vicinity of the particle.

In contrast to previous investigations [3–7], the present study generalizes the Stokes and Hadamard–Rybchinsky formulas to the case of uniformly heated spherical drop in a viscous incompressible fluid at arbitrary temperature difference between the particle surface and remote region with account of the temperature dependence of viscosity.

Of all fluid transfer parameters, the viscosity coefficient depends on temperature most strongly [8]. To take into account the temperature dependence of the dynamic viscosity, we use a formula that describes changes in the viscosity of a fluid in wide range of temperatures with any required accuracy (at $F_n = 0$ this formula can be reduced to the known Reynolds relation [8]):

$$\mu_e = \mu_\infty [1 + \sum_{n=1}^{\infty} F_n (T_e/T_\infty - 1)^n] \exp [-A(T_e/T_\infty - 1)], \quad (1)$$

where A and F_n are constants, $\mu_\infty = \mu_e(T_\infty)$, and T_∞ is the fluid temperature far away from the particle.

Hereinafter the indices e and i refer, respectively, to viscous fluid and heated particle; index ∞ denotes fluid parameters at infinity in an unperturbed flow; and index s refers to values of physical quantities at average surface temperature T_s.

It is known that the fluid viscosity decreases exponentially with increasing temperature [8]. An analysis of the available semiempirical formulas demonstrated that expression (1) describes the variation of

1070-4272/02/7503-0422$27.00 © 2002 MAIK "Nauka/Interperiodica"

viscosity in a wide temperature range in the best way, with any required accuracy. For example, we have $A = 5.779$, $F_1 = -2.318$, $F_2 = 9.118$ for water in the temperature range 0–90°C, with relative error not exceeding 2% ($T_\infty = 273$ K).

It is assumed that the densities, heat conductivities, and specific heats of the fluid and particle are constant, the heat conductivity coefficient of the particle much exceeds that of the medium, and particle motion is rather slow (small particles by Reynolds and Peclet).

It is convenient to introduce a reference system associated with the center of a moving particle (the problem is reduced to analysis of how an infinite plane-parallel flow, whose velocity U_∞ is to be determined, moves past a particle). The distributions of velocity and temperature is axially symmetric with respect to the 0Z axis passing through the drop center in the direction of the velocity vector of the incident flow. Therefore, the analysis uses a spherical system of coordinates in which radius is reckoned from the drop center, and angle θ, from the velocity direction of the incident flow.

In terms of the assumptions made, the equations and boundary conditions for the velocity, pressure, and temperature inside and outside a drop can be written in Stokes approximation in the spherical system of coordinates r, θ, η in the form [9]

$$\nabla P_e = \mu_e \nabla^2 U_e + 2(\nabla \mu_e)\nabla U_e + (\nabla \mu_e) \times (\nabla U_e), \quad \mathrm{div} U_e = 0, \tag{2}$$

$$\mu_i \Delta \mathbf{U}_i = \nabla P_i, \qquad \mathrm{div}\, U_i = 0, \tag{3}$$

$$\Delta T_e = 0, \tag{4}$$

$$r = R, \quad U_r^e = U_r^i = 0, \quad U_\theta^e = U_\theta^i, \quad T_e = T_s, \tag{5}$$

$$r \to \infty, \ \mathbf{U}_e \to U_\infty \cos\theta \mathbf{e}_r - U_\infty \sin\theta \mathbf{e}_\theta, \ T_e \to T_\infty, \ P_e \to P_\infty, \tag{6}$$

$$r \to 0, \quad |\mathbf{U}_i| \neq \infty, \quad P_i \neq \infty, \tag{7}$$

where μ and λ are, respectively, the dynamic viscosity and heat conductivity; P is the pressure; U_r and U_θ are the radial and tangential components of the mass velocity of the fluid, $\mathbf{U}$, in the spherical system of coordinates; $U_\infty = |\mathbf{U}_\infty|$, U_∞ is the velocity of the incident flow, which is to be determined from the condition of vanishing total force acting on the particle ($U_\infty > 0$ if this velocity is directed along the z axis, and $U_\infty < 0$ otherwise); $\mathbf{e}_r$ and $\mathbf{e}_\theta$ are the unit vectors in the spherical system of coordinates; and T_s is the mean temperature of the drop surface.

Conditions (5), assuming impermeability and continuity of the normal and tangential components of the mass velocity and constant particle surface temperature, are taken for the particle surface. As boundary conditions at infinity, i.e., far away from the particle, are taken conditions (6), and the finiteness of the physical quantities characterizing the drop at $r \to 0$ is accounted for by conditions (7).

To obtain a closed problem, the boundary conditions on the surface of a uniformly heated drop are supplemented with the condition of continuity of the stress tensor components (normal and tangential) on the drop surface [9]:

$$-P_e + 2\mu_e \frac{\partial U_r^e}{\partial r} = -P_i + 2\mu_i \frac{\partial U_r^i}{\partial r}, \tag{8}$$

$$\mu_e\left(\frac{1}{r}\frac{\partial U_r^e}{\partial \theta} + \frac{\partial U_\theta^e}{\partial r} - \frac{U_\theta^e}{r}\right) = \mu_i\left(\frac{1}{r}\frac{\partial U_r^i}{\partial \theta} + \frac{\partial U_\theta^i}{\partial r} - \frac{U_\theta^i}{r}\right). \tag{9}$$

The boundary conditions (5)–(9) make it possible to separate variables and reduce the system for perturbed quantities to a system of ordinary differential equations. Solving Eqs. (2)–(4) with boundary conditions (5)–(9) gives the distribution of velocities, pressures, and temperature in the fluid and the drop. After these distributions are found, we can calculate the force acting on a uniformly heated drop and the velocity of its drift.

At $\mathrm{Re}_\infty = \pi_e R U_\infty / \mu_\infty \ll 1$, the incident flow exerts only perturbing influence, and, therefore, the solution to the equations of hydrodynamics and heat transfer is to be sought for as an expansion in the Reynolds number Re_∞. In determining the force acting on a uniformly heated drop and its drift velocity, we restrict the consideration to corrections of the first order of smallness. To find these corrections, it is necessary to know the fields of velocity, pressure, and temperature in the vicinity of the particle. The general solution to the heat conduction equation (4), satisfying the relevant boundary conditions, has the form

$$t_e = 1 + \gamma / y, \qquad \gamma = (T_s - T_\infty)/T_\infty, \tag{10}$$

where γ is a dimensionless parameter characterizing the temperature difference between the particle surface and remote region; $t_e = T_e/T_\infty$, $y = r/R$.

Substituting (10) in (1), we obtain

$$\mu_e = \mu_\infty[1 + \sum_{n=1}^{\infty} F_n(\gamma^n/y^n)]\exp(-A\gamma/y). \quad (11)$$

Formula (11) is further used for determining the velocity and pressure fields in the vicinity of a uniformly heated drop.

Since the viscosity depends only on the coordinate y, the equations of hydrodynamics are solved by separation of variables, with the velocity and pressure fields expanded in Legendre and Gegenbauer polynomials [10]. In particular, the following expressions were derived for the components of the mass velocity U:

$$U_r^e(y,\theta) = U_\infty\cos\theta[1 + A_1G_1(y) + A_2G_2(y)], \quad (12)$$

$$U_\theta^e(y,\theta) = -U_\infty\sin\theta[1 + A_1G_3(y) + A_2G_4(y)], \quad (13)$$

$$U_r^i(y,\theta) = U_\infty\cos\theta(A_3 + A_4y^2), \quad U_\theta^i(y,\theta) = -U_\infty\sin\theta(A_3 + 2A_4y^2), \quad (14)$$

where

$$G_1(y) = -y^{-3}\sum_{n=0}^{\infty}\Delta_n^{(1)}[(n+3)y^n]^{-1},$$

$$G_1^I = dG_1/dy, \quad G_2^I = dG_2/dy,$$

$$G_2(y) = -y^{-1}\sum_{n=0}^{\infty}\Delta_n^{(2)}[(n+1)y^n]^{-1} - \alpha y^{-3}\sum_{n=0}^{\infty}[(n+3)\ln y^{-1} - 1]\Delta_n^{(1)}[(n+3)^2y^n]^{-1},$$

$$\Delta_n^{(1)} = [n(n+5)]^{-1}\sum_{k=1}^{n}\{(n+4-k)[\alpha_k^{(1)}(n+5-k) - \alpha_k^{(2)}] + \alpha_k^{(3)}\}\gamma^k\Delta_{n-k}^{(1)} \quad (n \geq 1). \quad (15)$$

$$G_3(y) = G_1(y) + 0.5yG_1^I, \quad G_4(y) = G_2(y) + 0.5yG_2^I,$$

$$\Delta_n^{(2)} = [(n+3)(n-2)]^{-1}[-6\alpha_n^{(4)}\gamma^n + \sum_{k=1}^{n}\{(n+2-k) \times [\alpha_k^{(1)}(n+3-k) - \alpha_k^{(2)}] + \alpha_k^{(3)}\}\gamma^k\Delta_{n-k}^{(2)} + \alpha\sum_{k=0}^{n}[(2n+5 - 2k)\alpha_k^{(1)} - \alpha_k^{(2)}]\gamma^k\Delta_{n-k-2}^{(1)} \quad (n \geq 3). \quad (16)$$

In calculating the coefficients $\Delta_n^{(1)}$, $\Delta_n^{(2)}$ by means of recurrence formulas (15) and (16), account should be taken that

$$\Delta_0^{(1)} = -3, \ \Delta_0^{(2)} = -1, \ \Delta_2^{(2)} = -1, \ \alpha_0^{(1)} = \alpha_0^{(4)} = -1,$$

$$\alpha_0^{(2)} = 4, \ \alpha_0^{(3)} = -4, \ \alpha_n^{(1)} = F_n, \ \alpha_n^{(2)} = (4-n)F_n + AF_{n-1},$$

$$\alpha_n^{(3)} = 2AF_{n-1} - 2(2+n)AF_n, \ \alpha_n^{(4)} = A^n/n!,$$

$$\alpha = -\gamma\{6\gamma^2\alpha_2^{(4)} - [3(4\alpha_1^{(1)} - \alpha_1^{(2)}) + \alpha_1^{(3)}]\Delta_1^{(2)} + [2(3\alpha_2^{(1)} - \alpha_2^{(2)}) + \alpha_2^{(3)}]\gamma\}/15,$$

$$\Delta_1^{(2)} = -\gamma[6\alpha_1^{(4)} + 2(3\alpha_1^{(1)} - \alpha_1^{(2)}) + \alpha_1^{(3)}]/4.$$

The integration constants A_1–A_4, appearing in Eqs. (12)–(14), are found upon their substitution in the corresponding boundary conditions on the drop surface. With this done, the force acting upon the particle is found by integration of the stress tensor over its surface [9] and has the following form:

$$\mathbf{F} = -4\pi R\,\mu_\infty U_\infty A_2\exp\{-A\gamma\}\mathbf{n}_z, \quad (17)$$

where

$$A_2 = -(N_3 + N_4\,\mu_e^s/3\mu_i^s)/\Delta, \quad \Delta\Big|_{y=1} = N_1 + N_2\,\mu_e^s/\mu_i^s,$$

$$N_4\Big|_{y=1} = 2G_1^I + G_1^{II},$$

$$N_2\Big|_{y=1} = G_2(2G_1^I + G_1^{II}) - G_1(2G_2^I + G_2^{II}),$$

$$N_1\Big|_{y=1} = G_1G_2^I - G_2G_1^I, \quad N_3\Big|_{y=1} = G_1^I,$$

The index s denotes the values of the physical quantities for the mean surface temperature of a uniformly heated drop, T_s; $\mathbf{n}_z$ is the unit vector in the direction of the z axis.

It is noteworthy that the force **F** is calculated on the assumption of a uniform drop motion, which is only possible if the total force acting upon the particle is zero. Since the force (17) is proportional to the velocity and vanishes together with the latter, then, for uniform motion of a heated drop to occur, it is necessary to assume the presence of a certain extraneous force counterbalancing the force (17).

Substituting the explicit form of coefficient A_2 in (17), we obtain the expression

$$\mathbf{F} = 6\pi R\,\mu_\infty U_\infty f_\mu\mathbf{n}_z, \quad (18)$$

$$f_\mu = 2\exp\{-A\gamma[N_3 + N_4\mu_e^s/(3\mu_i^s)]\}/[3(N_1 + N_2\mu_e^s/\mu_i^s)].$$

Let us consider as an example the gravitational fall of a uniformly heated drop. A spherical drop falling under the action of gravitational force in a viscous medium ultimately starts to move at a constant velocity at which the action of the gravitational force is counterbalanced by hydrodynamic forces. The gravitational force acting upon a particle is given, with account of the buoyancy force, by

$$\mathbf{F} = (\rho_i - \rho_e)g\pi R^3\mathbf{n}_z \times 4/3, \quad (19)$$

where g is the gravitational acceleration.

Equating expressions (18) and (19), we obtain the fall velocity of a uniformly heated spherical particle (analog of the Hadamard–Rybchinsky formula):

$$\mathbf{U} = h_\mu \mathbf{n}_z, \quad (20)$$

where

$$h_\mu = \frac{2}{9}R^2\frac{\rho_i - \rho_e}{\mu_\infty f_\mu}g.$$

If $\mu_e^s/\mu_i^s \to 0$ in expressions (18) and (20), then we obtain a formula for the resistance force and the velocity of gravitational fall of a solid uniformly heated particle (analog of the Stokes formula).

Thus, formulas (18) and (20) allow evaluation of the force acting upon a uniformly heated drop and the velocity of its gravitational fall with account of the temperature dependence of viscosity, represented as an exponential-power series at arbitrary temperature differences between the particle surface and a remote region.

In the case when the drop surface is heated to a relatively low extent, i.e., the mean surface temperature differs only slightly from the temperature of the ambient at infinity [$\gamma = (T_s - T_\infty)/T_\infty \to 0$], the temperature dependence of the dynamic viscosity coefficient can be neglected and $G_1 = 1$, $G_1^I = -3$, $G_1^{II} = 12$, $G_2 = 1$, $G_2^I = -1$, $G_2^{II} = 2$, $N_1 = 2$, $N_2 = 6$, $N_3 = 3$, and $N_4 = 6$. In this case, formulas (18) and (20) are transformed into the known expression for a sphere [9, 10].

Mention should be made of some problems concerning the motion of a uniformly heated spherical drop, whose solutions can be found directly from the results obtained here. Let us consider motion of a particle containing uniformly distributed heat sources (drains) with constant power and density q_1, i.e., the motion of a particle with uniform internal heat release. In this case, it is necessary to supplement Eqs. (2)–(4) with an equation describing the distribution of temperature within the drop ($\Delta T_i = q_i/\lambda_i$) and to take into account the equality of temperatures and heat fluxes in the boundary conditions. Then the mean surface temperature of a uniformly heated drop is given by the relation

$$T_s/T_\infty = 1 + q_i R^2/(\lambda_e T_\infty). \quad (21)$$

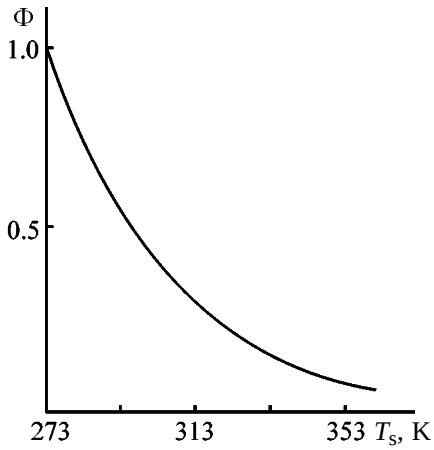

Fig. 1. Contribution to the resistance force, $\Phi = f_\mu/f_\mu\big|_{T_s = 273\ K}$, vs. the mean temperature T_s of the mercury drop surface.

It is noteworthy that, in formulating the problem, the boundary condition (8) for normal stresses, unnecessary in analyzing the flow around a uniformly heated drop, was left out. It can be shown that, upon substitution of the obtained solution for velocity and pressure components, the given boundary condition reduces to identity. This means that, in the approximation employed, the drop remains strictly spherical and its shape should be analyzed in terms of higher-order approximations.

To illustrate the contribution of particle surface heating to the resistance force and the fall velocity of a drop, i.e., to take into account the temperature dependence of viscosity, represented by formula (1), Figs. 1 and 2 show curves relating the values $\Phi = f_\mu/f_\mu\big|_{T_s = 273\ K}$ and $\Phi_1 = h_\mu/h_\mu\big|_{T_s = 273\ K}$ to T_s values for large mercury drops with radius $R = 2 \times 10^{-5}$ m, moving in water at $T_\infty = 273$ K. The curve Φ_1^* is plotted using the formula for small relative temperature differences ($\gamma \to 0$) [9, 10], but with the molecular transfer coefficients taken for $T_e = T_s$. As seen from the presented curves, the drop surface heating

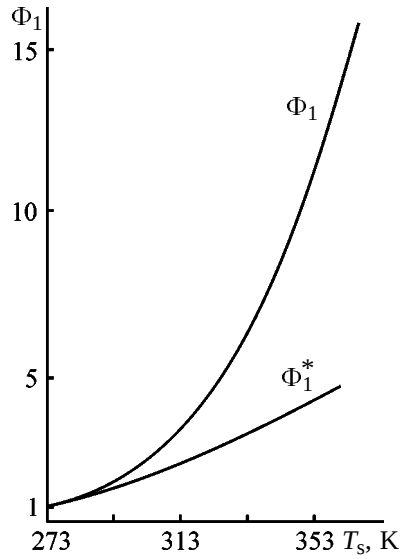

Fig. 2. Fall velocity of mercury drop, $\Phi_1 = h_\mu/h_\mu\big|_{T_S = 273\,\mathrm{K}}$, vs. the mean temperature T_S of the mercury drop surface.

strongly affects the resistance force and the velocity of gravitational fall of the drop. This result can be used in practice for accelerating the sedimentation process [11]. Let us consider selective sedimentation of coal particles in a water flow with temperature of 20°C in a rectangular chamber with length L = 100 cm, width d = 80 cm, and height h = 5 cm. In the absence of heating, the particle velocity in this chamber is 1.109×10^{-2} cm s^{-1}. To this velocity corresponds the volumetric flow rate of cleaned water Q = 0.319 m^3 h^{-1} [11]. The formulas derived in the present study yield Q = 0.356 m^3 s^{-1}, which corresponds to sedimentation accelerated by a factor of 1.12, and, with the particle surface heated to 50°C, we obtain Q = 0.588 m^3 s^{-1}, which already gives an acceleration by a factor of 1.84. Consequently, the use of the derived formulas enables acceleration of particle sedimentation.

CONCLUSIONS

(1) An analytical solution of the problem of a fluid flow around a uniformly heated particle at small Reynolds numbers is described. In solving the hydrodynamics equations, account is taken of the temperature dependence of dynamic viscosity, represented as an exponential–power-law series. The Stokes and Hadamard–Rybchinsky formulas are generalized, which makes it possible to calculate the resistance force and the velocity of gravitational fall at arbitrary temperature differences between the particle surface and a remote region. It is shown that particle surface heating markedly affects the resistance force.

(2) The results obtained can be used in evaluating the settling velocity of spherical hydrosol particles in channels, in designing experimental installations in which a directed motion of hydrosol particles is to be ensured, in developing methods for fine cleaning of fluids to remove hydrosol particles, etc.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Spectroturbidimetric Determination of the Size and Concentration of Terrestrial Particles in Potable Water

V. I. Klenin and N. A. Ivanova

Chernyshevsky Saratov State University, Saratov, Russia

Received October 12, 2001

Abstract—A method was proposed for determining the average size and mass-space concentration of terrestrial particles in potable water from the turbidity spectrum. This method was applied to a systematic study of a formazine suspension and potable water samples.

Turbidity of water is due to the presence of terrestrial particles having a colloidal degree of dispersion.

At the present time, GOST (State Standard) 3351–74 [1] is acting in Russia, which prescribes photometric determination of terrestrial particles, with a formazine suspension (prepared from hexamethylenetetramine and hydrazine sulfate) as the reference. The reaction goes to completion, which gives us information about the formazine content in a unit volume of the reaction medium. Several reference suspensions of different concentrations are prepared and their optical densities D are measured on an FEK-56 photocolorimeter with a light filter (λ = 540 nm) in 5-cm cells. The reference cell contains double-distilled water. The calibration plot of D vs. the formazine suspension concentration C, mg dm^{-3}, is constructed. From this plot, the concentration of terrestrial particles in potable water samples is determined. A similar method for determining the terrestrial particle concentration is practiced abroad [2]. This method cannot be treated *a priori* as a correct one, as the turbiidity of colloidal systems is not only a linear function of the concentration but also a complex function of the relative size (size-distribution pattern) and of the relative refractive index of the particles.

Light scattering theories describe the turbidity of a colloidal monodisperse system by the equation [3]

$$\tau = N_2 \pi r^2 K(\alpha, m). \quad (1)$$

Here, τ is the turbidity, cm^{-1}, N_2 is the number of particles in cm^3, r is the particle radius, $K(\alpha, m)$ is the light scattering efficiency factor as a function of the relative size α and the relative refractive index m:

$$\alpha = 2\pi\mu_1 r/\lambda, \quad (2)$$

$$m = \mu_2/\mu_1, \quad (3)$$

μ is the refractive index of the dispersed phase, μ_1 is the refractive index of the dispersion medium, and λ is the wavelength in vacuum.

The procedure prescribed by GOST [1] does not allow for the particle size and the difference between the μ_2 parameters for formazine and terrestrial particles.

The aim of this work was to elucidate the potentialities of the spectroturbidimetric method as applied to determining the mass-space concentration and the size of terrestrial particles in potable water.[1]

The spectroturbidimetric method showed a good performance in characterizing dispersed systems of different nature [3], in particular, in analyzing mineral suspensions in natural water basins [4]. For the latest data concerning disperse systems of different origin, see monograph [5].

EXPERIMENTAL

We found no explanations in published papers and patents why specifically formazine suspension was chosen as the reference for analysis of terrestrial particles in potable water. Thus, we began with studying the properties of the formazine suspension prepared according to the GOST mentioned [1].

Next, we systematically studied potable water samples by the spectroturbidimetric method and by the method prescribed by the GOST. Water samples were taken in various stages of purification, namely,

[1] Our study was concerned with potable water from the water supply systems in Saratov and Saratov oblast.

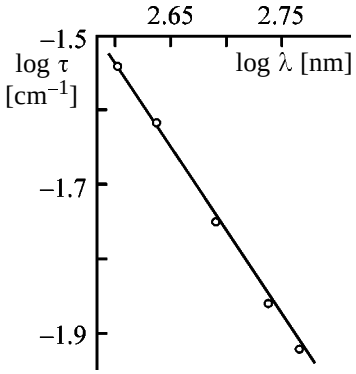

Fig. 1. Variation of the turbidity τ with the wavelength λ for water from the water manifold of the Smorodinka settlement, Perelyub raion.

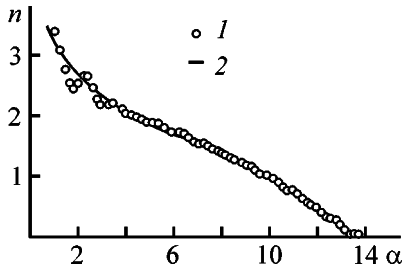

Fig. 2. Variation of $n(\alpha, m)$ with α for $m = 1.15$. System: (*1*) monodispersion and (*2*) polydispersion; the same for Fig. 3.

from the initial water (river, artesian well, water storage basin), from the potable water supply system, and from the water manifold (tap water cock). The optical density spectrum $D(\tau)$ was measured on an FEK-56 instrument at four wavelengths within 400–540 nm in a 5-cm cell. The reference cell contained double-distilled water.

Within a limited wavelength range $\Delta\lambda$, the spectral dependence of the turbidity is described by the Ångström equation [3]

$$\tau = A\lambda^{-n}. \quad (4)$$

Here, n is the wave exponent, or a wavelength index which is a complex function of the relative size α and relative refractive index m.

In log–log coordinates, Eq. (4) describes a straight line (Fig. 1):

$$\log\tau = \log A - n\log\lambda. \quad (5)$$

Thus, n is determined as the slope of the plot of (5). The turbidity, cm^{-1}, was determined by the formula

$$\tau = 2.3D/l, \quad (6)$$

where l is the cell length, cm.

In [3], the exponent $n(\alpha, m)$ was tabulated according to the Mie theory over a wide range of α and m values. For monodispersion particles, the characteristic light scattering functions have the oscillating character, and for polydispersion particles, smoothened approximation formulas are applied [6].

In [7], a routine was devised for processing the data derived by the spectroturbidimetric method on a mini-micro computer (calculators with minimal programming options) using the approximation formulas [6]. Processing of a large body of experimental data for water samples taken from oceans and rivers yielded $m = 1.15$ for terrestrial particles in water [8].

The parameter α for the experimentally determined n is derived from the calibration plot $n(\alpha, m) = f(\alpha)$. Figure 2 shows this dependence for $m = 1.15$.

The average particle size can be calculated by the formula

$$\bar{r} = \frac{\alpha\lambda_{av}}{2\pi\mu}, \quad (7)$$

where λ_{av} corresponds to the middle of the wavelength range where the turbidity was measured, in logarithmic coordinates, or $\lambda_{av} = (\lambda_1\lambda_2)^{1/2} = 469$ nm, where λ_1 and λ_2 are the smallest and the greatest light wavelengths in the working range for λ, respectively.

The mass-space concentration C, g dm^{-3}, of terrestrial particles in the formazine suspension was calculated by the formula [3]

$$C = Sv\tau, \quad (8)$$

$$s = \frac{10.61\rho_2\lambda_{av}}{\mu_1(m-1)}, \quad (9)$$

$$v(\alpha, m) = \frac{2\alpha(m-1)}{K(\alpha, m)} = \frac{2n(m-1)}{\partial K(\alpha, m)/\partial\alpha}, \quad (10)$$

where s is a parameter, g/100 cm^2, and ρ_2 is the particle density.

The wavelength exponent n and the structure factor v are functions of the same arguments, α and m, which allows plotting $v(\alpha, m)$ vs. $n(\alpha, m)$ (Fig. 3).

The above formulas suggest that measuring the disperse system parameters by the spectroturbidimetric method requires the knowledge of the density and refractive index of the substance in the dispersed phase.

The refractive index of the dispersed phase can be determined either directly with a refractometer or from

the refractive index increment for a solution of the substance, or by the spectroturbidimetric method [3, 5], provided that the concentration of the dispersed phase particles is known.

Attempts to prepare a solution of formazine failed, as this polymer is insoluble in most of organic solvents [9]. Therefore, the relative refractive index of the formazine particles was estimated spectroturbidimetrically.

When the mass-space concentration of the suspension is known, the measured turbidity τ can be used for determining by Eq. (8) the *vs* product, which in the $2 < n < 4$ range is strongly dependent on *m*. Using the tables from [5], it is possible to construct a tentative plot of *vs* vs. *m* for a given *n* value (Fig. 4). Then, using the $C/\tau = sv$ ratio and the plot from Fig. 4, it is possible to determine *m*.

The experiments with the formazine suspension showed that the experimental points are concentrated around $m = 1.07$ corresponding to the refractive index of the formazine particles $\mu_2 = 1.426$. Repeated preparations and spectroturbidimetric examinations of formazine suspensions showed good reproducibility of the size of formazine particles formed in independent preparations, namely, the average particle radius was 800 ± 50 nm. The particle size remained unchanged upon diluting the suspension within 230–0.6 mg dm^{-3}.

The formazine particles are fairly large, which allows determination of the formazine particle concentration by two independent methods, spectroturbidimetric and gravimetric.

The formazine dispersion was filtered through a Schott's filter whose pore diameter was *a fortiori* smaller than the formazine particle size. The mass of all the formazine particles in a given volume (0.05–0.5 dm^3) was determined from the Schott's filter mass before and after filtration, with the filter being dried to constant weight.

Below, we compare the particle concentration calculated from the turbidity spectrum C_1 with that determined gravimetrically, C_2, for a formazine suspension with the concentration *C* calculated from the concentrations of the initial substances, which were estimated according to GOST 3351–74.

C, mg dm^{-3}	232	23.2
V, ml	50	500
τ_{483}, cm^{-1}	3.2 ± 0.1	0.31 ± 0.01
n	1.68 ± 0.02	1.68 ± 0.02
$\bar{r}$, nm	800 ± 50	800 ± 50
C_1, mg dm^{-3}	220 ± 10	20.7 ± 0.4
C_2, mg dm^{-3}	215 ± 5	20.6 ± 0.1

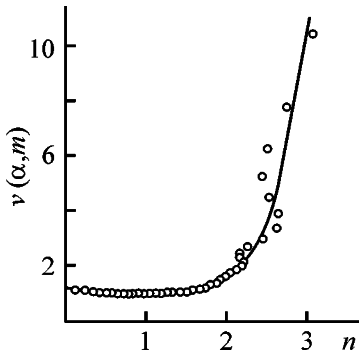

Fig. 3. Variation of the structure factor $v(\alpha, m)$ with the wavelength index *n* for $m = 1.15$.

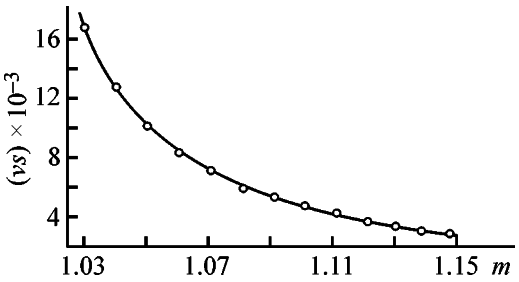

Fig. 4. Variation of the *vs* product with the relative refractive index *m* at *n* = const.

The data obtained by the two independent and absolute methods of determining the formazine concentration reasonable agree. Comparison of these experimental values with those calculated according to the chemical reaction shows that the reaction yield is actually 95%. The parameters were estimated by the methods of interest accurately to within 5% for formazine concentrations of 232 and 23.2 mg dm^{-3}.

The average particle radius for different samples of potable water, as determined spectroturbidimetrically, lies within 70–700 nm. As Eq. (8) incorporates the structure factor [described by Eq. (10)], which is a function of α and *m*, the difference in the mass-space concentrations of the particles determined spectroturbidimetrically and by the method prescribed by the GOST [1] must be the greater, the stronger the sample particle size differs from 800 nm.

The table presents the results of analysis for a number of potable water samples by both methods discussed. It is seen that the content of terrestrial particles in potable water widely varies. As expected, the concentrations determined spectroturbidimetrically and according to GOST [1] differ the stronger, the stronger the size of terrestrial particles differs from that of formazine particles.

Concentration of terrestrial particles as determined from the turbidity spectrum C_1, by the procedure prescribed by GOST [1] C_2, and calculated from the turbidity spectrum without taking into account the terrestrial particle size C_3

The procedure specified by the GOST neglects the size of terrestrial partciles. To clearly indicate one of the sources of the systematic error in this procedure, we intentionally introduced an error into the calculations involved in the spectroturbidimetric method: We eliminated from formula (8) the structure factor (10) which shows how the turbidity varies with the particle size. This calculation yielded the concentrations C_3 (see table). It is seen that these *a fortiori* erroneous concentrations are close to those estimated according to the GOST.

The plot in Fig. 4 indicates the systematic error in the method prescribed by GOST due to neglecting the difference in the relative refractive indices for formazine (m = 1.07) and terrestrial particles (m = 1.15). The parameters $C/\tau = sv$ for m = 1.07 and m = 1.15 differ by a factor of 2.5. Thus, neglecting the difference in the relative refractive indices is responsible for a 2.5-fold error in the data estimated by the GOST procedure, and, thereby, for overestimation of the concentration of terrestrial particles by a factor of about 2.5 (Fig. 4).

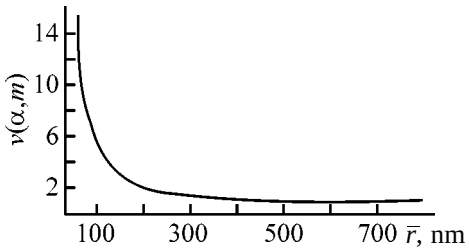

Fig. 5. Structure factor $\nu(\alpha, m)$ as a function of the average particle size $\bar{r}$ for m = 1.15.

Neglecting the difference in the sizes of terrestrial particles and formazine is responsible for underestimation of the concentration of terrestrial particles, the extent of overestimation being the greater, the larger the difference in size between the formazine and terrestrial particles (the latter are always smaller) (Fig. 5). Hence, in certain cases these two errors can compensate each other and, as a result, certain values of the parameters C_2 and C_3 become close to each other (see table).

Standard calibration plots of D vs. C for formazine make sense only for particles ca. 800 nm in size at m = 1.07. The real size of terrestrial particles for different water samples varies, however, within 70–700 nm, and real m is equal to 1.15. The concentration of terrestrial particles varies within 0.5–28.5 mg dm^{-3}. Therefore, the formazine suspension is not an adequate reference for determining the degree of potable water contamination.

The spectroturbidimetric method proposed by us compares advantageously with that prescribed by GOST 3351–74 [1] in that it is an absolute method based on rigorous theories of light scattering by colloidal systems and thus requires no preliminary, especially inadequate, calibrations.

CONCLUSIONS

(1) A spectroturbidimetric method was proposed which, as compared to the empirical method prescribed by GOST, is more rigorous and easier (no

preliminary calibration using absolutely different system is needed).

(2) The spectroturbidimetric method is suitable for determining the average size and concentration of terrestrial particles in potable water from urban water supply system.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Structural Changes of Aluminosilicate Materials in the Presence of *Rhodococcus sensu stricto*

Abstract—The influence of rhodococci on highly porous ceramics based on celsian and cordierite porcelain was studied by X-ray diffraction and IR spectroscopy.

The study of microorganisms involved in restoration of ecosystems affected by human activity is an urgent problem. One of these ecologically trophic bacteria oxidizing natural and man-made hydrocarbons is *Rhodococcus sensu stricto* [1]. Highly porous honeycomb ceramics (HPHC) combining developed macroporosity with the presence of channel micropores [4, 5] are promising supports for biogenic agents. However, even ceramics are affected by rhodococci [4, 5]. Previously we found that rhodococci catalyze not only degradation of aluminosilicate HPHC but also epitaxial processes increasing the weight and strength of the samples. The phase composition of the reprecipitation products formed in thin ceramic films of complex shape is difficult to determine.

In this work we studied structural transformation of aluminosilicate HPHC under the action of *Rhodococcus sensu stricto*.

EXPERIMENTAL

We used pure *R. ruber* IEGM 231 rhodococcus culture[1]. To determine the resistance of the ceramics to the bacterial action, HPHC samples were placed in mineral media containing 0.003% acrylamide as the carbon source and 4.0×10^9 rhodococcus cells per ml. The blank experiment was performed without bacteria. We studied highly porous honeycomb ceramics based on celsian and cordierite porcelain [2]. X-ray diffraction analysis was performed on a DRON-3M diffractometer using β-filtered cobalt radiation.

The IR spectra of ceramic samples kept in the bacterial media for 10 months were recorded on an IFS-66 Fourier spectrometer (Bruker, Germany) under the following conditions: Nujol mulls prepared in an agate mortar, KBr windows, resolution of 1 cm^{-1}, 100 scans. The spectra were brought to the zero baseline. The complex bands were resolved into the components whose location (ν), half-width, and peak (D_p) and integral (D_i) optical densities were determined. Since powders of multiphase ceramics are structurally nonuniform, the shape of separate bands was approximated by the Gaussian functions. Resolution of the complex bands of the initial cordierite porcelain into the components is shown in Fig. 1 as an example. The parameters of these bands are presented in Table 1.

Since the intensity of the absorption bands depends on the thickness of the absorption layer and the content of Nujol in the mull, which were not controlled,

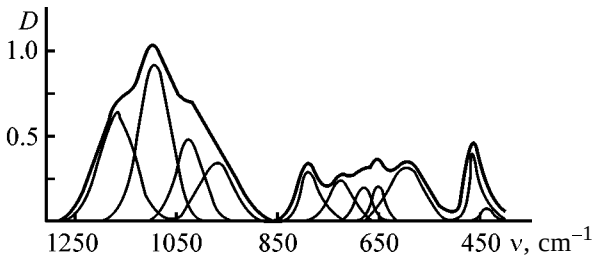

Fig. 1. Resolution of absorption bands of the initial cordierite porcelain into the components: (*D*) optical density and (ν) wave number.

Table 1. Parameters of IR bands of cordierite porcelain

ν, cm^{-1}	D_p	Half-width, cm^{-1}	D_i
431	0.15	25	4.0
468	0.43	30	13.7
594	0.32	82	27.6
650	0.22	31	7.2
680	0.20	35	7.5
724	0.24	58	14.8
789	0.31	44	14.5
965	0.35	88	32.9
1023	0.49	67	34.8
1089	0.93	75	74.8
1165	0.64	82	56.0
1376	0.23	16	3.9

we compared the relative band intensities calculated by the equation

$$A_{rel,j} = D_{i,j}/\Sigma D_i,$$

where $A_{rel,j}$ is the relative intensity, $D_{i,j}$ is the integral optical density of jth band, and ΣD_i is the total optical density.

As seen from Table 2, the absorption bands of celsian porcelain at 1173, 985, 787 cm^{-1} are shifted to lower frequencies after keeping in the aggressive media. The first band is shifted under the action of both the mineral solution (control) and the bacterial suspension (experiment); the second, only under the action of the mineral solution; and the third, only under the action of the bacterial suspension. The action of aggressive media on the bands of cordierite porcelain (1165, 1023, 965, and 680 cm^{-1}) is similar. However, the bands at 1165 and 680 cm^{-1} are shifted to the low frequencies, and the bands at 1023 and 965 cm^{-1}, to higher frequencies. Thus, rhodococci catalyze the processes occurring in cordierite porcelain also in their absence and have a complex effect on celsian porcelain.

The changes in the relative intensity of the absorption bands of the control and experimental samples of HPHC as compared to the initial porcelain are shown in Fig. 2.

The bands at 1160 and 1090–1095 cm^{-1} are in the range of the Si–O stretching vibrations typical for aluminosilicates (850–1250 cm^{-1}) [7, 8]. It should be noted that the bands of isolated SiO_4 tetrahedra appear in the range 800–1050 cm^{-1}, and the bands of silicate polymers, in the range 1000–1200 cm^{-1} [7].

The relative intensity of the characteristic absorption bands of isolated SiO_4 groups decreases and that of polymeric silicates increases after keeping celsian porcelain in the mineral solution. Rhodococci exert the opposite effect: the intensity of the bands of monomeric silicates slightly increases and that of the bands of polymeric silicates decreases appreciably. Thus, inorganic compounds favor glass crystallization, whereas rhodococci initiate structural transformations in the crystalline phases. The shift of the IR bands to the lower frequencies suggests isomorphous substitution of ions.

Fragments of the X-ray pattern of celsian porcelain kept for 10 months in the (*1*) mineral solution and (*2*) bacterial suspension are shown in Fig. 3. The first X-ray pattern is similar to that of the initial material:

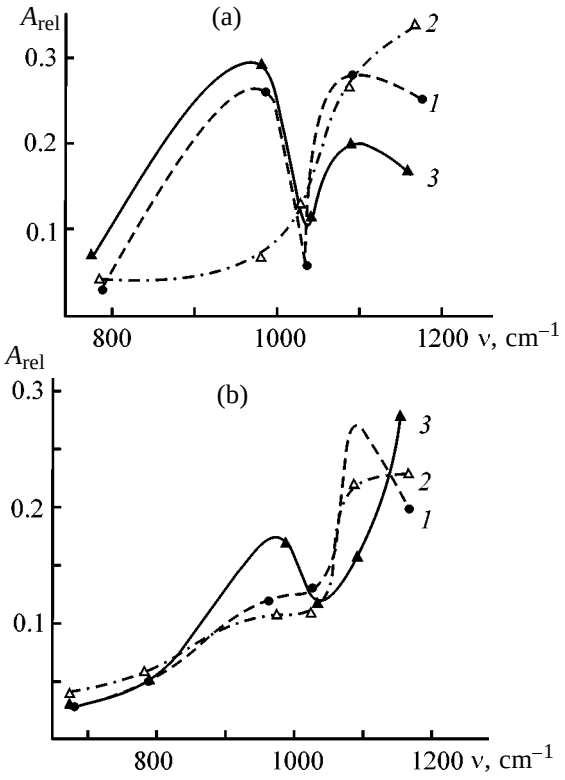

Fig. 2. Relative intensity of absorption bands of (a) celsian and (b) cordierite porcelain. (ν) Wave number. (*1*) Initial sample, (*2*) sample kept in the mineral solution (control), and (*3*) sample kept in a suspension of *R. ruber* IEGM 231 (experiment).

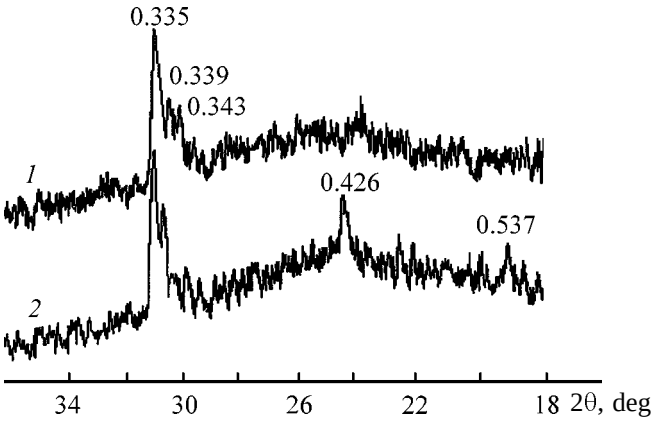

Fig. 3. Fragments of X-ray diffraction patterns of celsian porcelain kept in (*1*) mineral solution and (*2*) bacterial suspension. (2θ) Bragg angle. Interplanar spacings (nm) are given for the most intense reflections.

almost all reflections are assigned to orthorhombic mullite. The ratio of the most intense and closely located reflections of mullite (021), d_α = 0.399 nm and (120), d_α = 0.343 nm, is 1.1, which agrees with the ASTM data. A strong reflection with d_α = 0.335 nm is probably a superposition of the strongest quartz reflection (110), d_α = 0.335 nm, and celsian reflection (220), d_α = 0.335 nm. Probably sillimanite Al_2SiO_5 and hyalophane $0.57KAlSi_3O_8 \cdot 0.43BaAl_2Si_2O_8$ are also present.

After keeping celsian poreclain in the culture media, new reflections appear. In particular, relatively strong reflections with d_α = 0.537 and 0.426 nm are observed in the fragment shown in Fig. 3. The ratio of the most intense and closely located reflections of mullite (021), d_α = 0.399 nm, and (120), d_α = 0.343 nm, increases to 2, which can be due to formation of calcined mullite usually prepared by kaolinite calcination. The (120) reflection with d_α = 0.343 nm is absent in the X-ray pattern of calcined mullite, and the reflection with d_α = 0.537 nm is stronger than that of orthorhombic mullite. The reflection with d_α = 0.426 nm can be assigned to quartz. However, the ratio of the intensities of this reflection and the reflection with d_α = 0.426 nm is 2, differing from the tabulated value (*4*). This is probably due to superposition of the reflections of quartz and potassium barium feldspars of different compositions.

In the case of cordierite porcelain, strong reflections of crystalline α-Al_2O_3 contained in the sample mask weak reflections, which complicates the similar structural study.

CONCLUSIONS

(1) Structural transformations in celsian porcelain in the presence of rhodococci were studied by IR spectroscopy and X-ray diffraction. It was found that rhodococci strongly affect ceramics.

(2) Rhodococci intensify mainly isomorphous substitution in the SiO_4 and AlO_4 groups, thus affecting metamorphism of aluminosilicates.

(3) The kinetics of degradation and epitaxial processes occurring in ceramics in the presence of *rhodococci* can be studied by IR spectroscopy.

ACKNOWLEDGMENTS

We are grateful to V.N. Antsiferov for participation in discussion of the experimental results.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reduction of 4,4'-Dinitrostilbene-2,2'-disulfonic Acid with Hydrogen on Raney Nickel

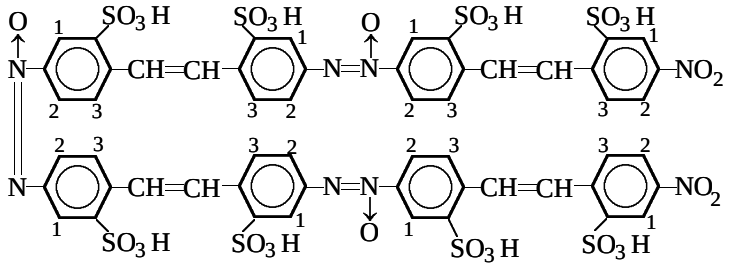
I. N. Bazanova, N. V. Kholodkova, and V. P. Gostikin

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received July 23, 2001

Abstract—Reduction of 4,4'-dinitrostilbene-2,2'-disulfonic acid with hydrogen in aqueous solution on Raney nickel yields a trisazo compound identical to Direct Yellow K dye.

In syntheses of some dyes and optical whitening agents, 4,4'-diaminostilbene-2,2'-disulfonic acid (DAS) is widely used as the diazo component. At present, this acid is prepared from 4,4'-dinitrostilbene-2,2'-disulfonic acid (DNS) by Bechaump reduction [1]. The drawbacks of this process are large amounts of wastewater, the necessity of utilizing the iron slime, and labor-consuming isolation of the target product; they make the process environmentally and economically unacceptable. Heterogeneous-catalytic reduction of DNS with hydrogen in the liquid phase (see scheme) is more efficient and economically feasible. However, this process is accompanied by formation of by-products and intermediates decreasing the yield and quality of DAS. The scheme of catalytic reduction of DNS suggested by Bizhanov and Zhubanov [2] does not reflect all the transformations that DNS undergoes under conditions of catalytic reduction. Bizhanov and Zhubanov proved the possibility of hydrogenation of the C=C double bond in the stilbene moiety with the formation of 4,4'-diaminodibenzyl-2,2'-disulfonic acid (DADB) and *p*-aminotoluenesulfonic acid; they also noted formation in solution of diazo compounds and unidentified unstable colored products. Formation of an unidentified red product in reduction of DNS was noted in [3, 4]. It was suggested that the compound imparting the red color to the reaction mixture in the course of DNS reduction contains an azoxy group [4]. At the same time, DAS can be prepared by hydrogenation of a mixture of azo dyes containing as major component the trisazoxy dye Direct Yellow K (DYK) of the following structure [7]:



According to the Haber–Lukashevich–Shmonina scheme, nitro compounds are reduced in steps, with the products of incomplete hydrogenation of the NO_2 group being capable to react with each other to form azoxy compounds [6, 7]. Therefore, presumably, heterogeneous-catalytic reduction of DNS can yield a product identical to DYK, imparting the red color to the catalyzate and the cream color to the isolated target product.

Papers concerning the DAS production process discuss the influence of various process conditions on the product quality. This influence cannot be understood without data on intermediates and by-products. Therefore, the goal of this work was to prepare and study intermediates and by-products arising in catalytic reduction of DNS. The results would allow us to suggest a more detailed scheme of DNS reduction with hydrogen on Raney nickel and to find conditions for preparing the purest target product.

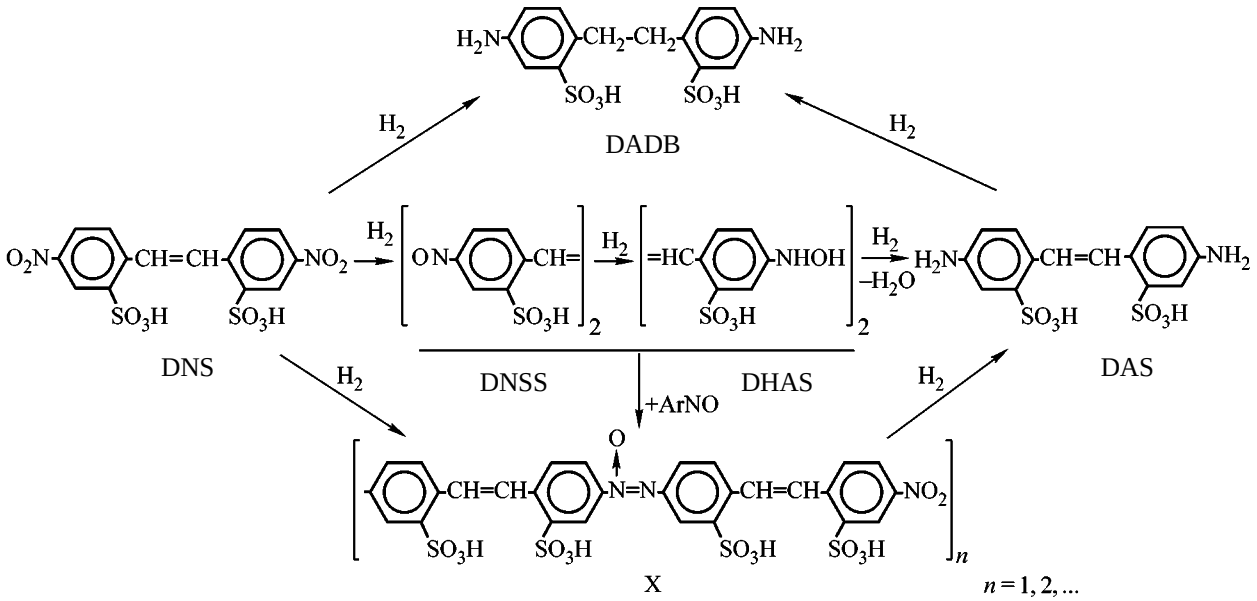
Scheme of heterogeneous-catalytic reduction of DNS



where DNSS is 4,4'-dinitrosostilbene-2,2'-disulfonic acid and DHAS is 4,4'-di(hydroxylamino)stilbene-2,2'-disulfonic acid.

EXPERIMENTAL

Catalytic reduction of DNS with hydrogen was performed at atmospheric pressure in a Vishnevskii apparatus with vigorous stirring of the liquid phase. Raney nickel was prepared by leaching nickel–aluminum alloy (1 : 1 by weight) with a 25% NaOH solution. Crude DNS was purified by double recrystallization, which yielded fine yellow needle-like crystals soluble in water and dimethyl sulfoxide. The intermediate, hereinafter denoted as X, was prepared by reduction of DNS. A reaction vessel was charged with 2 g of the catalyst washed to remove NaOH and with 100 ml of water. The vessel was purged with hydrogen, after which the catalyst was saturated with hydrogen at stirring (1000 rpm) for an additional 10 min. Then 7 g of DNS was added, and reduction was performed at 303 K for 5 min with stirring (4000 rpm). Under these conditions, the reduction yielded a red solution, which was filtered to remove the catalyst and evaporated. The residue was recrystallized from DMF. A red powder was obtained, soluble in water and DMF. Separate experiments showed that intermediate X can be reduced to DAS in the presence of Raney nickel.

The target product, DAS, was prepared by reduction of DNS (1 g) in citrate–phosphate buffer solution (pH 9.5) at 303 K on Raney nickel (1 g). The crude product was recrystallized from water. The resulting flesh-colored needle-shaped crystals were soluble in aqueous alkali. DADB was prepared by hydrogenation of DAS (1 g) in aqueous solution on Raney nickel and isolated by acidification with HCl to pH 2.35. The product was a white amorphous powder. DYK was prepared according to [5] from nitrotoluenesulfonic acid and purified by recrystallization from DMF. The product was a red powder soluble in water and DMF. All the products were sulfo derivatives; they decomposed without melting above 300°C.

To determine the structure of intermediate X, all the above substances were studied by IR and UV spectroscopy. For DYK and product X, we also recorded the ^{1}H NMR spectra and performed elemental analysis. The UV spectra were taken on an SF-46 spectrophotometer in the wavelength range 250–500 nm in aqueous solution (cell thickness 1 cm). The IR spectra were taken on a Specord M80/M85 spectrophotometer in the frequency range 4000–200 cm^{-1} using the KBr technique (0.002–0.0024 g of substance per 0.3 g of KBr, pressing at 6000–1000 atm with continuous evacuation to 10^{-3} mm Hg). The ^{1}H NMR spectra were taken on a Bruker AMX spectrometer (400.13 MHz, DMSO-d_6) relatve to internal TMS.

The C=C double bond was detected by iodination, and the amino group, by diazotization. Elemental analysis was performed by the standard procedure [8].

The UV spectra of DNS, DAS, DADB, product X, and DYK are shown in Fig. 1. The spectra of DNS

Table 1. IR spectra of DNS and its reduction products

Compound	ν, cm^{-1}						
	–CH=CH–	C=C (arom.)	C–H (arom.)	CH_2– (aliph.)	$–NO_2$	$–NH_2$	$–SO_3H$
DNS	1664 vs	1472, 1484, 1576	968, 976	–	752, 848, 876 1348, 1520–1568	–	628, 1080, 1296
DAS	1664	1496, 1568, 1576, 1584, 1608	912, 976	–	–	640, 660, 1256 1496, 3312–3400 3512	628, 1080, 1280
DADB	–	1436, 1508, 1584, 1620	968, 976	2624, 2712, 2960	–	672, 704, 796 908, 1272, 1508 1508, 3280, 3448	624, 1088, 1272
DYK	1664 vs	1472, 1568	976	–	–	–	624, 1128, 1288
X	1664 vs	1456, 1568	968, 976	–	–	–	624, 1128, 1288

and DAS differ insignificantly. The only absorption maximum in the spectrum of DNS (350 nm) corresponds to the π–π^* transition with the electron transfer to the NO_2 group [6]. In the UV spectrum of DAS, there is a maximum at λ = 340 nm, characteristic of aromatic amines [9]. Absorption in the visible range is insignificant. DADB has no absorption maxima in the examined range. The spectra of product X and DYK appeared to be virtually identical. The maximum at about 440 nm is assigned to the n–π^* transition.

The IR spectra of all the compounds listed in Table 1 contain bands assignable to vibrations of the sulfo group and aromatic CH group, skeleton vibrations of benzene rings, and out-of-plane bending vibrations of the C–H bonds in benzene rings. The spectrum of DNS also contains the NO_2 vibration bands, and the spectra of DAS and DADB, the vibration bands of the NH_2 group. Because DADB contains no –CH=CH– bond, in the spectrum of this compound the band at 1664 cm^{-1} is lacking, but bands assignable to stretching vibrations of the aliphatic CH_2 group are observed, which are absent in the spectra of the other substances.

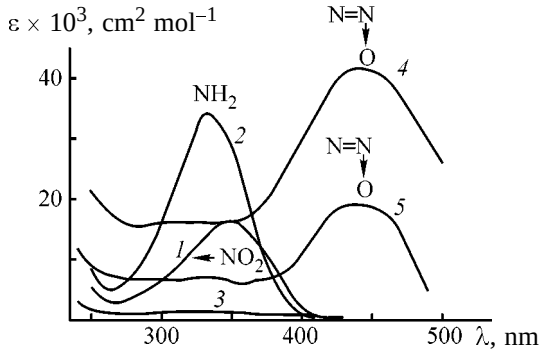


Fig. 1. UV absorption spectra of (*1*) DNS, (*2*) DAS, (*3*) DADB, (*4*) product X, and (*5*) DYK. (ε) Extinction coefficient and (λ) wavelength.

The spectra of product X and DYK contain a whole set of bands confirming the presence of the stilbene double bond, benzene rings, and sulfo group. A distinctive feature of the spectra of X and DYK, as compared to those of the other compounds, is the presence of a strong band at 1300–1304 cm^{-1} belonging to the azoxy group. The fine structure of the spectra of X and DYK in the range 1300–900 cm^{-1} is slightly different, which may be due to partial hydrogenation of double bonds between the benzene rings in the course of catalytic reduction. In other respects, the spectra of DYK and product X virtually coincide.

Comparison of the chemical shifts in the ^1H NMR spectra of product X and DYK (Table 2) shows that all the major fragments in these substances coincide. Insignificant differences are due to the presence of the aliphatic CH_2–CH_2 bond in product X.

Both X and DYK are neither iodinated nor diazotized. Elemental composition of X, found, %: C 42.3; N 7.2; H 2.8. Calculated for DYK, %: C 42.2; N 7.0; H 2.5. The difference between the spectra of DYK and product X may be due to simultaneous transformations of intermediates with different extents of reduction under the conditions of the heterogeneous-catalytic reaction. As a result of the reactions suggested in

Table 2. ^{1}H NMR spectra of DYK and product X

Compound	^{1}H NMR spectrum, δ, ppm					
	H^1 (arom.)	H^2 (arom.)	H^3 (arom.)	–CH=CH–	SO_3H	$–CH_2–CH_2–$
DYK	8.669 (8H)	8.165 d (8H)	6.832 d (8H)	5.390 (8H)	2.611 d (8H)	–
X	8.681 d (8H)	8.166 d (8H)	6.796 d (8H)	5.375 (8H)	2.611 d (8H)	2.337 s

[7], product X contains impurities of azo coupling products with similar properties. Apparently, reduction of DNS occurs via azo coupling of product X with other reaction participants. Thus, heterogeneous-catalytic reduction of DNS in aqueous solution follows a complex pattern involving much more species than it was suggested earlier [2].

We plotted a calibration chart to determine the concentration of X from the optical density of its solutions at 440 nm and, using these data, examined how the concentration of X in hydrogenation products varies with time in the course of DNS reduction (Figs. 2a, 2b). The concentration of X passed through a maximum in the initial period of the reaction. The maximal concentration of X depended on the weight ratio of DNS to the catalyst (the lower this ratio, the lower the maximal concentration of X) and on pH. The highest concentration of X was attained at pH 9.5–9.7. At this pH the reaction was also the most selective with respect to hydrogenation of the NO_2 group to form DAS (the stilbene double bond was not involved). Therefore, formation of X can be considered as a condition for selective formation of the target product.

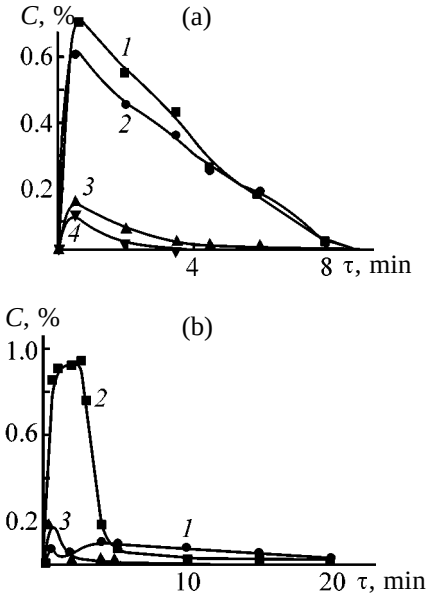

Fig. 2. Concentration of product X *C* as a function of time τ in (a) aqueous and (b) phosphate buffer solutions. 303 K; 0.5 g of DNS. (a) Catalyst weight, g: (*1*) 0.4, (*2*) 0.5, (*3*) 1.0, and (*4*) 2.0. (b) Catalyst weight 1 g; pH: (*1*) 5.64, (*2*) 9.68, and (*3*) 11.00.

We have shown previously [10] that at low weight ratios of DNS to the catalyst the DNS reduction occurs with an induction period. Comparison of the induction period to the time in which the concentration of X reaches a maximum shows that a low rate of hydrogen uptake is associated with formation of this intermediate. Apparently, rapidly forming product X blocks the catalyst surface and prevents further reduction. This is accompanied by partial reduction of X with the metal of the catalyst, primarily with residual aluminum.

The homogeneous stages of coupling of X with reactants play a major role under conditions when the amount of hydrogen on the catalyst surface is insufficient (Figs. 2a, 2b, curves *1*), i.e., at large DNS loads and deficiency of the catalyst. To improve the quality of DAS, such unfavorable conditions should be avoided.

CONCLUSIONS

(1) An intermediate of reduction of 4,4'-dinitrostilbene-2,2'-disulfonic acid in aqueous solution on Raney nickel was detected and studied; it is identical to Direct Yellow K trisazo dye.

(2) Formation of this intermediate explains the kinetic features of reduction of 4,4'-dinitrostilbene-2,2'-disulfonic acid and is the cause of the reaction deceleration. Incomplete reduction of this product results in decreased process selectivity.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Ethyl Benzoate by Ozonolysis of Styrene in the Presence of Ethanol

E. K. Gaifutdinova and V. V. Beresnev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 11, 2001

Abstract—Ozonolysis of styrene in the presence of ethanol was studied as a route to ethyl benzoate.

Thanks to the high reactivity of ozone and its selective action on C=C bonds, ozonolysis of unsaturated organic compounds shows promise for industrial synthesis of various compounds with oxygen-containing functional groups [1].

Recently the demand for benzoic acid and its derivatives increased. These compounds are widely used in various branches of the national economy. Benzoic acid esters are used in production of dyes [2], heat-resistant lubricants [3], herbicides [4], alkali-resistant polyester coatings [5], and also as plasticizers for synthetic resins, cellulose ethers and esters, rubbers, and paper, as additives for dyeing fabrics made from manmade fibers [5], as polymerization catalysts [3], drugs [6–8], active ingredients of plant growth regulators [9], and cosmetic means [10].

High selectivity of ozonolysis of unsaturated hydrocarbons gives reasons to hope that synthesis of benzoic acid esters by ozonolysis starting from styrene and alcohols would be commercially feasible.

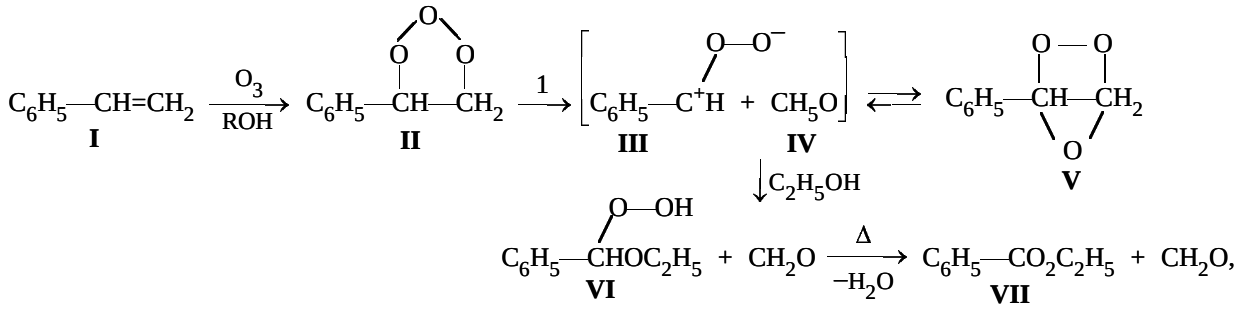
EXPERIMENTAL

Ozonolysis was performed in a glass bubbler with a porous bottom; it was charged with a styrene (**I**) solution. Ozone was generated by passing oxygen through a glow discharge at 10 kV. The ozone concentration was determined spectrophotometrically at 254 nm. Oxidation was performed to ozone breakthrough, which was detected by coloration of a 15% aqueous KI solution in a wash bottle placed at the reactor outlet (with starch as indicator). In the course of ozonolysis, we withdrew samples to determine the content of available oxygen [11] and of carboxy, carbonyl, and ester groups [12].

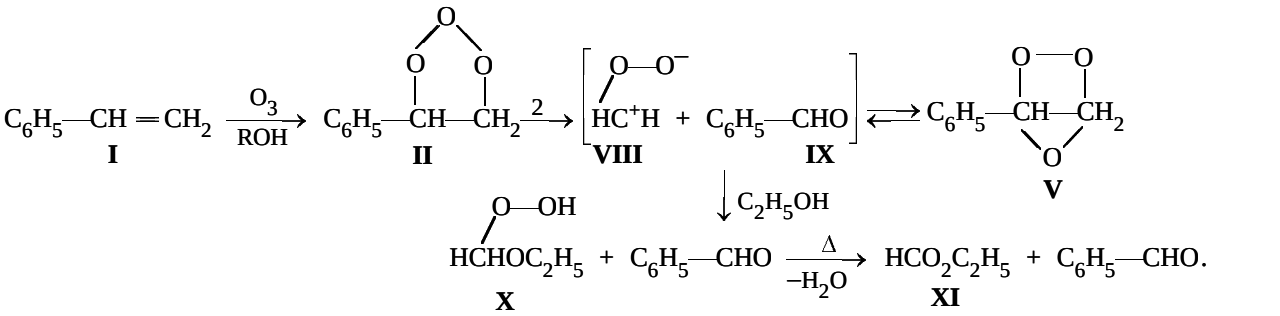
The thermal decomposition of ozonides was performed by heating the reaction solutions at 90–100°C for 2–4 h. In the resulting products, we determined the content of carboxy, ester, and carbonyl groups.

The IR spectra were recorded on an IFS-113V Fourier spectrometer in the range 400–4000 cm^{-1} with a resolution of 2 cm^{-1}; samples were prepared as films cast from solution on KBr plates, or as KBr pellets. The GC–MS study of ozonolysis products was performed with a Finnigan-MAT 212 device (INCOS 50 mass spectrometer, Varian 3400 gas–liquid chromatograph, capillary column with grafted SE-30, carrier gas helium, heating from 40 to 300°C at a rate of 15 deg min^{-1}, injector temperature 250°C). The ^{13}C NMR spectra of ozonolysis products were taken on a Bruker MSL 400 spectometer at 100.62 MHz; the chemical shifts were measured relative to TMS [13].

According to the experimental results, ozonolysis of styrene in the presence of ethanol can be described by the following scheme:



1070-4272/02/7503-0441$27.00 © 2002 MAIK "Nauka/Interperiodica"



According to this scheme, addition of ozone to the double bond in styrene **I** yields unstable molozonide **II**; in the presence of a terminal double bond the aromatic system remains intact [14]. Molozonide readily decomposes into two fragments: bipolar ion **III** or **VIII** and carbonyl compound **IV** or **IX**. Presumably, owing to the positive inductive effect of the phenyl ring in styrene **I**, formation of the bipolar ion at the phenyl-substituted carbon atom [reaction (1)] is preferable [15]. The pair bipolar ion–carbonyl compound arising in decomposition of molozonide rapidly recombines in the solvent cage to form ozonide **V**. Formation of this compound is preceded by a change in the mutual orientation of fragments **III** and **IV** [reaction (1)], or **VIII** and **IX** [reaction (2)] (turn by 180°). Decomposition of ozonide **V** also yields bipolar ion **III** or **VIII** and carbonyl compound **IV** or **IX**.

Bipolar ion **III** or **VIII** is stabilized by reaction with an added active compound (ethanol) to form ethoxy hydroperoxides **VI** and **X**. In pathway (1), which is apparently preferable (see above), the second reaction product is formaldehyde **IV**. However, its content in the reaction mixture was low, probably because of easy volatilization.

We found that the content of available oxygen increases with the progress of styrene oxidation. We found that at the molar ratio styrene : ethanol = 1 : 1.5 the yield of available oxygen reaches a maximum (8.14 wt %); at the ethanol content increased further, the content of available oxygen decreases.

The IR spectra of alkoxy hydroperoxides contain the following absorption bands (cm^{-1}): 2980 [$\nu(CH_3)$]; 2950 [$\nu(CH_2)$]; 2890 [$\nu(CH_3)$]; 1310 [δ(C–O)]; 1110 [ν(CO)]; 990, 910, and 840 [ν(O–O)] [15].

Alkoxy hydroperoxides are unstable and readily decompose even at room temperature [16]. After storage of a mixture of ethoxy hydroperoxides **VI** and **X** for 2 months at 20°C, the content of available oxygen decreased from 8.1 to 1.9%.

Thermal decomposition of alkoxy hydroperoxides **VI** and **X** was performed at 90–100°C. It is advisable to perform the reaction at elevated temperatures, because at low temperatures formation of esters is too slow. The reaction is accompanied by release of low-molecular-weight inorganic products (e.g., water, which is formed by hydrogen abstraction by the hydroxy radical).

The IR spectra of reaction products contain absorption bands at 1260 [ν(C–O)] and 1715 cm^{-1} [ν(C=O)], confirming the presence of ethyl benzoate. The bands at 1680 and 1690 cm^{-1} belong to benzoic acid, and the band at 1700 cm^{-1} is characteristic of aromatic aldehydes (in particular, benzaldehyde **IX**). The ^{13}C NMR spectrum of the reaction product (after vacuum distillation) confirms its identification as ethyl benzoate [δ_C, ppm: 166 (C=O), 125–135 (Ph), 61.4 (CH_2), 14.6 (CH_3)].

The major reaction products are ethyl benzoate **VII** [63.4 wt %, isolated by vacuum distillation (68°C at 15 mm Hg)] and ethyl formate **XI** (20.4 wt %); the by-products are formaldehyde (6.0 wt %), benzaldehyde (6.3 wt %), formic acid (1.8 wt %), and benzoic acid (2.1 wt %).

CONCLUSION

A procedure was suggested for preparing ethyl benzoate by ozonolysis of styrene in the presence of ethanol, followed by thermal decomposition of the intermediate ozonolysis products.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Radiation-Chemical Behavior of C_1–C_4 Alcohols and Their Binary Mixtures

M. M. Silaev

Moscow State University, Moscow, Russia

Received June 19, 2001

Abstract—Data on γ-radiolysis of C_1–C_4 alcohols, practically significant for related fields of chemistry, were summarized.

Studies of γ-radiolysis of C_1–C_4 alcohols and their binary systems gave numerous data significant for related fields of chemistry [1–4]. The kinetics of competing addition of free radicals to double bonds of molecules with formation of 1 : 1 adducts and inhibition with unsaturated substrate [5] was developed, and the applicability of this kinetics to radical-chain oxidation was demonstrated [6]. In this work, we summarize the results that can be used in related fields of research.

The dissociation energies of chemical bonds in alcohol molecules, as data required for preliminary estimation of the probability of radiolytic reactions in alcohol-containing systems, are listed in Table 1.

In [1] we compared γ-radiolysis of aliphatic monohydric C_1–C_3 alcohols and 2-methyl-2-propanol in a wide temperature range (195–503 K) to determine their relative radiation-thermal stability. Such data can be useful in forecasting radiolytic transformations at various temperatures of both individual alcohols whose radiolysis has not been studied experimentally and various mixtures of alcohols with other components. The logarithms of the total yields of the decomposition of C_1–C_3 alcohols at γ-radiolysis as functions of reciprocal temperature are shown in Fig. 1. The effective activation energies E_α of various radiolytic reactions in alcohols: alcohol decomposition, reactions involving rupture of C_α–C and C–O bonds, and α-diol formation (as a result of recombination of α-hydroxyalkyl radicals arizing from the rupture of C_α–H bonds in alcohols) at low temperatures (≤ 293 K), when the thermal decomposition is negligible, are also presented in [1]. The E_α(α-diol) values (equal to 1.3, 5.7, 2.7, and 4.4 kJ mol^{-1} for methanol, ethanol, 1- and 2-propanol, respectively) can be used to extrapolate to higher temperatures, using the Arrhenius equation [10], the initial radiation-chemical yields of α-hydroxyalkyl radicals in alcohols, known for room temperature from ESR data [11].

Addition of α-hydroxyalkyl radicals to olefins and their derivatives in the course of γ-radiolysis leads to formation of molecular products (mainly 1 : 1 adducts) by the chain mechanism [3–5]. It was found that the reactivity of saturated alcohols with respect to γ-diol formation in γ-radiolysis of 2-propen-1-ol in saturated C_1–C_3 alcohols [3] (Fig. 2) and formation of recombination α-diols in γ-radiolysis of individual saturated C_1–C_3 alcohols at low temperatures (before transition to the radiation-thermal mode [1]) increase in the series methanol < 1-propanol < ethanol <

Table 1. Dissociation energies *E* of bonds in the gas phase at 298 K [7]

Alcohol	*E*, kJ mol^{-1}			
	C_α–C	C_α–H	C–O	O–H
Methanol	–	383.7	383.3	428.4
Ethanol	356.1	377.4	381.2	424.7
2-Propen-1-ol	363.6	330.1*	334.7* [8]	
1-Propanol	342.7	381.2*	382.8	427.2
2-Propanol	339.3	379.1	389.1	437.6
2-Methyl-2-propanol	310.0 [9]	–	387.9	434.3

* Calculated using the ratio of the dissociation energies of single-type chemical bonds in the series of ROH/RX pairs (R is saturated or unsaturated hydrocarbon radical C_1–C_3, X is CH_3 or OCH_3 for C_α–H or C–O bonds, respectively); for each bond type these ratios are constant within the limit of relative deviations: no more than 2 and 8% for C_α–H and C–O bonds, respectively.

1070-4272/02/7503-0444$27.00 © 2002 MAIK "Nauka/Interperiodica"

2-propanol.[1] It was shown in [4] that this series correlates with the entropy of formation of H bonds in alcohols, ΔS^0_{298} (it is quantitative characteristic of alcohol association), and the energy $E_{\lambda max}$ corresponding to the wavelength of the absorption band maximum in the spectrum of solvated electrons in alcohols (i.e., energy of electron solvation in alcohols) and inversely correlates with the effective activation energy of the alcohol self-diffusion E_D (Table 2).

The dependences of the radiation-chemical yields of formation of γ-diols, molecular products of addition of α-hydroxyalkyl radicals to 2-propen-1-ol [3], and 1 : 1 adducts of any free saturated radicals with olefins [16] on the concentration of the unsaturated compound have maxima. Using the scheme with competing reactions (parallel reactions in which molecules of the saturated and unsaturated components compete for radical adduct) and the method of steady-state concentrations, we described such nonmonotonic dependences by a kinetic equation with a single parameter α to be determined [6, 17, 18]. This equation describes both the dependences (with a maximum) of the radiation-chemical yield (or formation rate) of the 1 : 1 adduct on the concentration of the unsaturated component in binary systems consisting of saturated and unsaturated components at their comparable concentrations and of the yield (formation rate) of peroxide and alcohol (with the same number of the carbon atoms as in the initial hydrocarbon) on the concentration of molecular oxygen in noncatalytic oxidation by unbranched radical-chain mechanism (when the yields of these products substantially exceed the yields of carbonyl compounds). The above equation also allows determination of the rate constant k_{ad} of addition of a free radical to a double bond:

$$G(1:1\ \text{adduct}) = \frac{\varepsilon G(R_{sat})\alpha l x}{x^2 + (\alpha l + x)x^2_{max}/\alpha l_{max}}, \qquad (1)$$

$$k_{ad} = \alpha l_{max}[2k\varepsilon G(R_{sat})P]^{0.5}/x^2_{max},$$

where ε is the electronic fraction of the saturated component, $G(R_{sat})$ is the initial radiation-chemical yield of α-hydroxyalkyl or any other free saturated radicals (initiation yield), P is the dose rate, l and x are the initial molar concentrations of the saturated and unsaturated initial components ($l > x$), l_{max} and x_{max} are l and x at the curve maximum, respectively, α is the ratio of the rate constants of competing reactions, and $2k$ is the rate constant of the decay of the identical chain-leading free saturated radicals by their collisions with each another.

The constants $2k$ of diffusion-controlled reactions of the mutual decay of the identical hydroxyalkyl

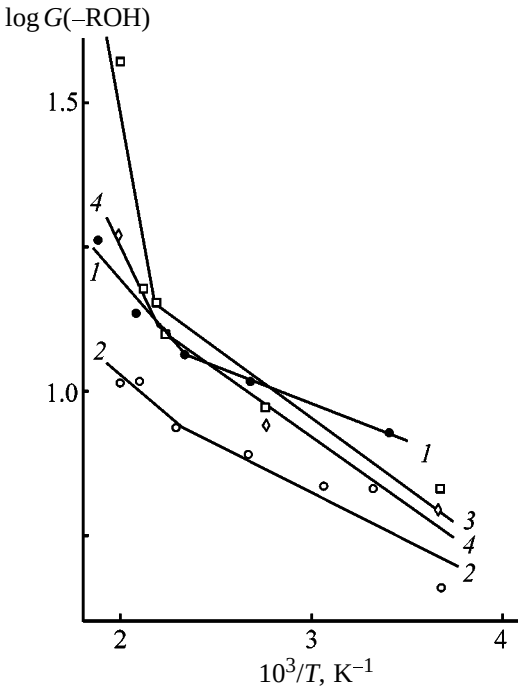

Fig. 1. Yields of alcohol decomposition G(–ROH) (molecules per 100 eV) as a function of temperature T in γ-radiolysis of (*1*) methanol, (*2*) ethanol, (*3*) 1-propanol, and (*4*) 2-propanol.

radicals enter into many kinetic equations combining the rates of formation of any alcohol-derived products with the concentrations of the reacting substances. Figure 3 shows how the experimental 2*k* values for hydroxyalkyl radicals C_2–C_3 in individual alcohols (neutral medium, room temperature), 2*k* values obtained from the self-diffusion coefficients of C_1–C_4 alcohols, and *k* values [10] for hydroxyalkyl radicals in 0.1 M aqueous solutions of C_2–C_4 alcohols with pH 6 (in this case, the use of *k* instead of 2*k* is associated with the lower viscosity of aqueous solutions of alcohols and higher alcohol diffusion coefficients [19, 20], which are practically the same as the diffusion coefficients of the corresponding hydroxyalkyl radicals [10]) correlate with the reciprocal viscosity (fluidity) of the corresponding alcohols. The correlation (a total of 12 points) is linear (correlation coefficient 0.995) and is described by the equation

$$2k = aD = b_{exp}/\eta, \quad (2)$$

where $a = (1.0 \pm 0.13) \times 10^{15}$ m mol^{-1} is the coefficient of Smoluchowski equation for identical species (C_1–C_4 saturated alcohols) at 298 K [20], *D* is the self-diffusion coefficient (m^2 s^{-1}), $b_{exp} = (1.27 \pm 0.05) \times 10^3$ N m mol^{-1}, and η is the viscosity (MPa s) [10].

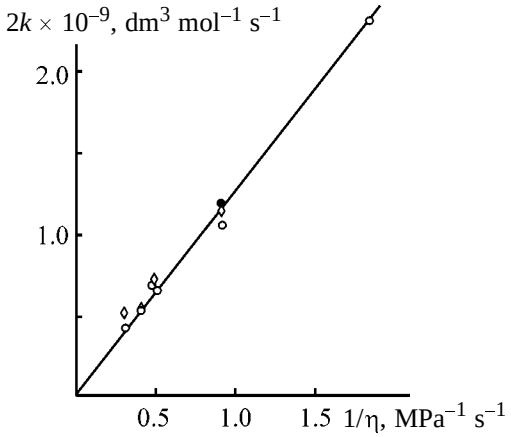

Fig. 3. Rate constant 2*k* of decay of hydroxyalkyl radicals in individual C_1–C_4 alcohols at room temperature as a function of the viscosity η of these alcohols. (*1*) $2k_{exp}$, (*2*) $2k = aD$, and (*3*) $2k = k_{0.1\ M}$.

This equation allows obtaining numeral estimation of unknown 2*k*. Due to the use of the empirical coefficient b_{exp}, the differences between the estimated and experimental (taken as 100%) values of the average alcohol self-diffusion coefficients $D = b_{exp}/a\eta$ and of 2*k* are small as compared to the experimental relative error (< 20%). Only for the self-diffusion coefficient of ethanol and 2*k* of hydroxymethyl radicals such differences are 12.5 and 18%, respectively.

The decay constants 2*k* of the identical hydroxyalkyl radicals at any taken temperature can be found from their room-temperature values by the Arrhenius equation using the known activation energies E_a of these reactions. For the majority of alcohols, within the experimental error, these quantities are approximately equal to the activation energies of self-diffusion E_D or viscous flow E_η [10]. The E_η values were calculated in [10] from the slope of the linear dependences of the logarithms of the viscosity on reciprocal temperature for the majority of C_1–C_8 aliphatic alcohols within the 273–373 K range.

Addition (under the action of γ-radiation) of α-hydroxyalkyl radicals to the carbon atom at the double bond of free (desolvated, monomeric) formaldehyde leads to the chain formation of α-diols [5, 21]. In these processes, the main role in the reactivity of alcohols belongs to desolvation of formaldehyde in alcohol–formaldehyde solutions. Neutral solutions of formaldehyde in alcohols at room temperature are mainly equilibrium mixtures of formaldehyde–alcohol oligomers of various molecular weights, described by the general formula $RO(CH_2O)_nH$, where $n = 1$–4 [22]. The concentration of free (unbound to solvent) formaldehyde (active species capable to accept free radicals) is as low as a fraction of percent of the total formaldehyde concentration [22]. The concentration of free formaldehyde was determined by high-temperature spectrophotometry at 335–438 K for solutions in water, ethandiol, methanol, ethanol, 1- and 2-propa-

nol, and 2-methyl-2-propanol with the analytical formaldehyde concentrations from 1.0 to 8.4 mol dm^{-3} [23]. The free formaldehyde concentration exponentially increases with increasing temperature and can reach several percents of the formaldehyde total concentration, i.e., 19.3% for 2-methyl-2-propanol (alcohol concentration 1.0 mol dm^{-3}, 398 K) (Fig. 4).

The treatment of 101 measurements gave empirical formula combining the free formaldehyde concentration x (mol dm^{-3}) with the temperature T (K) and total formaldehyde concentration in the solution c_0 (measured at room temperature):

$$\log x = -\alpha(10^3/T) + \beta + \gamma \log c_0, \quad (3)$$

where α and β, as parameters of the straight line equation, were calculated by the least-squares method from the dependences of $\log x$ on $1/T$ at c_0 = 1.0 mol dm^{-3} for various solvents; the coefficient γ was obtained as the average slope of the linear dependences of $\log x$ on $\log c_0$ at various fixed temperatures. The coefficients α, β, and γ for each solvent are listed in Table 3.

The deviation of x calculated by Eq. (3) from the experiment does not exceed 25%.

The alcohol concentrations l_T (mol dm^{-3}) in alcohol–formaldehyde solutions at any temperature can be estimated assuming linear dependence of the solution density on the formaldehyde concentration, similar to that for formaldehyde aqueous solutions (0–14 mol dm^{-3}, 291 K), by the formula

$$l_t = \frac{(10^3 d - 21.6 c_0) d_T}{(d + 8.4 \times 10^{-3} c_0) M}, \quad (4)$$

where c_0 is the total formaldehyde concentration (mol dm^{-3}); M is the solvent molecular weight (g mol^{-1}); d and d_T are the densities of the solvent at room temperature and given temperature T (g cm^{-3}), respectively; the dimension of the coefficient 8.4×10^{-3} is 10^3 g mol^{-1}, and that of coefficient 21.6 is g mol^{-1} [25].

We showed [23] that at constant temperature the concentration of free formaldehyde decreases with increasing the solvent dielectric constant (Fig. 4). Water, in which, in spite of its higher polarity, the concentration of free formaldehyde is abnormally high and close to its concentration in 2-propanol (Fig. 4), is an exception. This may be caused by the specific instability of hydrated formaldehyde species and their ready conversion into free formaldehyde at elevated temperatures. Hence, we can assume that the addition of a less polar solvent to more polar alcohol (and of water to methanol or ethanol) will increase the free formaldehyde concentration, similarly to heating of the solution.

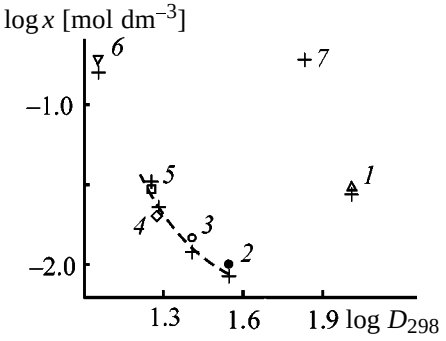

Fig. 4. Experimentally determined concentration x of free formaldehyde in (*1*) water, (*2*) methanol, (*3*) ethanol, (*4*) 1-propanol, (*5*) 2-propanol, and (*6*) 2-methyl-2-propanol as a function of dielectric constant D_{298} of these solvents. Total formaldehyde concentration C_0 1.0 mol dm^{-3}, temperature 395 ± 3 K. (*7*) Values of x in the above solvents calculated by Eq. (3).

CONCLUSIONS

(1) The relative radiation-thermal stability of C_1–C_3 alcohols within the 195–503 K range was determined.

(2) The general kinetic equation for unbranched radical-chain reactions of addition and oxidation, describing the experimental curves with a maximum, was obtained.

(3) An equation for quantitative estimation of the rate constants of reactions describing the decay of identical free hydroxyalkyl radicals at collision with each other from reciprocal viscosity (fluidity) of the corresponding alcohols was derived.

Table 3. Coefficients of empirical Eq. (3) for estimation of free formaldehyde concentration x in polar solvent–formaldehyde mixtures [23]

Solvent	α	β	γ
Water	2.36	4.45	0.80
Ethanediol	1.83	2.60	1.28
Methanol	3.11	5.58	$0.22c_0/\log c_0$
Ethanol	3.10	5.92	$1.10\ (10^3/T)$–1.44
1-Propanol	2.42	4.47	1.30
2-Propanol	2.42	4.64	1.05
2-Methyl-2-propanol	3.19	7.31	0.96

(4) Empirical equations for calculating concentrations of free (desolvated) formaldehyde and the alcohol in alcohol–formaldehyde systems at various temperatures and formaldehyde concentrations were found.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reaction of Dinitropolychlorobiphenyls with *O*- and *N*-Nucleophiles as a New Route of Reprocessing Polychlorobiphenyls

T. I. Gorbunova, A. Ya. Zapevalov, V. I. Saloutin, and O. N. Chupakhin

Institute of Organic Synthesis, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received October 29, 2001

Abstract—The reactivity of a mixture of dinitropolychlorobiphenyls in nucleophilic substitution of aromatic chlorine by polyethyleneoxy and amino groups was studied. New polychlorobiphenyl derivatives were obtained.

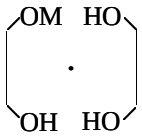
Rendering harmless polychlorobiphenyls (PCBs) used as dielectrics, plasticizers, materials for hydraulic devices, etc., remains an urgent problem. According to various sources [1–3], from 100 to 500 thousand tons of PCBs was produced in the former Soviet Union. Although production and use of PCBs was prohibited by WHO in 1990, in some industrial enterprises they are still in use, which increases environmental pollution with PCBs and their derivatives, dibenzodioxins and dibenzofurans [3], which are very stable organic pollutants.

This work continues a search for methods of PCB reprocessing alternative to incineration. As noted previously, an efficient procedure for cleaning transformers to remove residual PCBs (and possibly dioxins) is treatment of the inner surface of a transformer with polyethylene glycols (PEGs) in the presence of alkali metal hydroxides [4, 5] to substitute aromatic chlorine in PCBs by polyethyleneoxy groups. A necessary condition of this process is the use of higher solid PEGs.

We also studied the reaction of a crude mixture of pentachlorobiphenyls (PCB-5) with PEGs of various molecular weights (PEG-3, 13, 35, 65) in the presence of alkali metal hydroxides [6] and found that, under the reaction conditions, two chlorine atoms were substituted by the corresponding alkoxy groups. Alkoxylation occurred under relatively mild conditions (120–130°C, 3–6 h) with a high yield of the target products (95–99%).

However, attempts to perform similar reactions with lower polyethylene glycols, ethylene glycol (EG) and diethylene glycol (DEG), failed: no conversion of PCB-5 was observed. This fact is attributable to structural features of the alkali metal alcoholates formed in the reaction mixture.

It is known that, under common conditions, EG reacts with alkali metal hydroxides or alkali metals to form monoethylene glycolates containing a tightly bound EG molecule [7]:

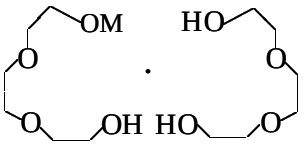


A

M = Na, K

According to [7], structure **A** is stable up to 150°C (at higher temperatures, the substance undergoes carbonization). Formation of such a structure is responsible for deactivation of monoethylene glycolate in nucleophilic substitution of aromatic chlorine. Apparently, with DEG a structure similar to **A** is formed also.

Alcoholates derived from PEG-3 (and from higher PEGs) probably form a similar adduct:



B

However, formation of structure **B** promotes rather than inhibits nucleophilic substitution of chlorine in PCB-5. Presumably, the PEG-3 molecule in **B** behaves as a podand [8]. Although PEG-3 contains no

1070-4272/02/7503-0449$27.00 © 2002 MAIK "Nauka/Interperiodica"

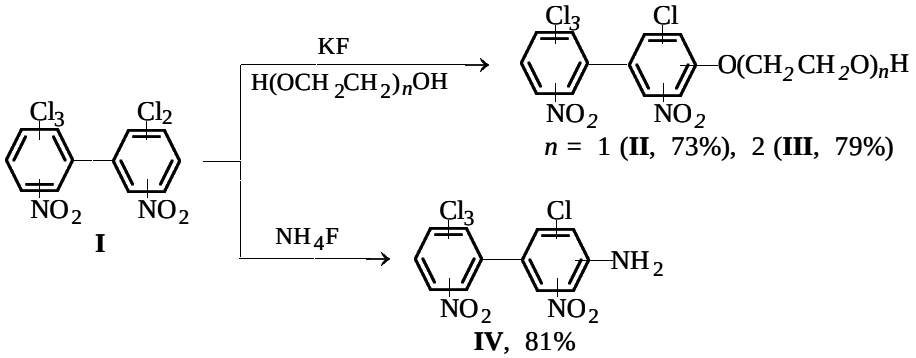
hard terminal donor groups enhancing complexation with metal ions, this molecule can form complexes via terminal hydroxy groups. These groups fulfil two functions simultaneously: coordination with metal ion and stabilization of the alkoxide ion by hydrogen bonding. As a result, interaction of the alkoxide oxygen with the metal cation is weakened, and the reactivity of this species is enhanced as compared to EG and DEG anions.

These data and our previous experimental results [6] suggest that alcoholate anions derived from EG and DEG are unsuitable for nucleophilic substitution of aromatic chlorine in PCB-5. At the same time, it is known that two acceptor substituents (e.g., nitro groups) introduced into *o*- and *p*-positions relative to halogen considerably facilitate substitution of halogen in aromatic compounds by alkoxy groups [9]. Furthermore, alcoholate anion appears to be more reactive when generated from alcohol and alkali metal fluoride [10] as compared to generation from alcohol and alkali metal or its hydroxide:

$$ROH + 2F^- \rightleftarrows RO^- + HF_2^-.$$

In the presence of weak hydrofluoric acid coexisting in solution with alkali metal alcoholates, the alkoxy groups are solvated relatively weakly.

We believe that for exchange of halogen by alkoxy groups derived from EG and DEG the most promising initial substance among the known PCB derivatives is a mixture of dinitropentachlorobiphenyls **I** described in detail in [11]. In this work, alkoxylation of **I** with alcoholates derived from EG and DEG in the presence of KF was performed at 110–130°C for 8–10 h. Analysis of the resulting mixtures **II** and **III** showed substitution of a single chlorine atom in **I** (see scheme). Incorporation of two alkoxy groups is apparently hindered sterically. The presence of such substituents as $O(CH_2CH_2O)_nH$ (n = 1, 2) makes mixtures **II** and **III** suitable initial substances for polycondensations.



A similar pattern is observed in reaction of PCB derivatives with amino groups. Synthesis of diaminopentachlorobiphenyls by reduction of mixture **I** was reported in [11]. Similar to [10], we performed nucleophilic substitution of aromatic chlorine by amino group. The reaction occurred on heating of **I** with excess ammonium fluoride at 110°C for 8 h and yielded a mixture of aminodinitrotetrachlorobiphenyls **IV** (see scheme). However, both kinds of amino derivatives derived from PCBs are of little promise for preparation of polymers, because the aromatic amino group is a weak ("masked") polymerization center. Apparently, further functional substitution of PCB amino derivatives is required.

EXPERIMENTAL

The IR spectra of **II**–**IV** were recorded on a Specord 75-IR spectrophotometer; samples were cast as films from toluene solution. The IR and analytical data are listed in the table.

(Oxyethylen-ω-ol)dinitrotetrachlorobiphenyls II. A three-necked flask equipped with a power-driven stirrer and a reflux water condenser was charged with 3.2 g (0.055 mol) of KF, 10 ml (11.2 g, 0.18 mol) of EG, and 10.4 g (0.025 mol) of **I**. The mixture was heated on a glycerol bath at 110–130°C for 8 h with vigorous stirring. Then the mixture was cooled, 25 ml of toluene was added, and the mixture was refluxed for 5–10 min. The toluene layer was separated and washed with water, the solvent was evaporated, and the transparent brown residue was dried in a vacuum (5–6 mm Hg) at 60–80°C for 10 min. A mixture of compounds **II** was obtained; yield 8.1 g (73%), mp 53–58°C.

Similarly, from 3.2 g (0.055 mol) of KF, 15 ml (16.5 g, 0.16 mol) of DEG, and 10.4 g (0.025 mol) of

IR and analytical data for **II**–**IV**

Substance	Found, %/Calculated, %				Empirical formula	IR spectrum, ν, cm^{-1}
	C	H	Cl	N		
II	37.97/38.04	1.49/1.82	32.56/32.08	6.49/6.34	$C_{14}H_8Cl_4N_2O_6$	3435 (OH); 1555, 1340 (NO_2); 1100 (C–O–C)
III	39.82/39.53	2.72/2.49	29.68/29.17	5.82/5.76	$C_{16}H_{12}Cl_4N_2O_7$	3380 (OH); 1540, 1320 (NO_2); 1110 (C–O–C)
IV	36.08/36.31	1.07/1.27	36.18/35.72	10.32/10.58	$C_{12}H_5Cl_4N_3O_4$	3490, 1620 (NH); 1550, 1345 (NO_2)

I, 9.6 g (79%) of a mixture of (dioxyethylen-ω-ol)dinitrotetrachlorobiphenyls **III** was obtained as a light brown viscous liquid.

Aminodinitrotetrachlorobiphenyls IV. A round-bottomed flask equipped with a reflux condenser with a $CaCl_2$ tube was charged with 4.1 g (0.01 mol) of **I** and 3.7 g (0.1 mol) of NH_4F. The mixture was heated on a glycerol bath at 110°C for 8 h, after which it was worked up similarly to synthesis of **II**. A mixture of products **IV** was obtained as a transparent brown solid; yield 3.2 g (81%), mp 46–56°C.

CONCLUSION

(1) Reactions of dinitropentachlorobiphenyls with alcoholates derived from ethylene glycol and diethylene glycol, performed in the presence of KF, gave the monoalkoxylation products in yields of 73 and 79%, respectively.

(2) New polychlorobiphenyl derivatives, aminodinitrotetrachlorobiphenyls, were prepared.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Cationic Surfactants on Association of Pinacyanol with Organic Counterions

S. A. Shapovalov and Ya. A. Svishcheva

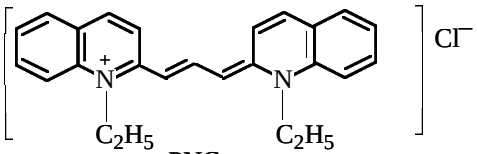
Research Institute of Chemistry, Karazin National University, Kharkov, Ukraine

Received November 23, 2001

Abstract—The absorption spectra of aqueous solutions containing associates of pinacyanol and organic counterions (tetraphenylborate, sulfophthalein, and oxyxanthene) were studied as influenced by cationic surfactants. The possibility of developing sensitive procedures for quantitative evaluation (test control) of the content of cationic surfactants in aqueous solutions using pinacyanol associates was analyzed.

At present, interaction of cyanine (polymethine) chromophores with organic ions is widely studied using various media such as aqueous and nonaqueous solutions [1, 2], polyelectrolyte systems [3], thin films [4], and photosensitive materials [5]. The spectral study of such association will furnish information on specific interactions (hydrophobic, van der Waals, and π-electron) of bulk chromophores [6]; it is also urgent for practical use of ionic associates for quantitative determination of the content of cationic surfactants (CSAs) in solutions [6, 7].

Among the cyanine dyes, pinacyanol (1,1'-diethylquino-2-carbocyanine chloride, PNC)



PNC

is of practical interest owing to its pronounced ability to form monomeric, dimeric, and more aggregated structures in aqueous solutions [8]. It was found that PNC forms ionic associates with bulky organic anions such as colorless single-charged tetraphenylborate anion (TPB) [9] and other organic anions including sulfophthalein and oxyxanthene chromophores [7, 10]. Thus, study of interaction of these PNC heteroassociates with ionic surfactants is of particular importance. In this work, we studied the interaction of PNC heteroassociates with CSAs.

EXPERIMENTAL

In this work, we used PNC chloride (Aldrich) and sodium TPB (Apolda, chloride content less than 0.01%); the other reagents (at least analytically pure grade) were used without additional purification. The CSAs [cetylpyridinium bromide (CPB), cetylpyridinium chloride (CPC), and cetyltrimethylammonium chloride (CTMA)] contained 98±1% of the main compound. The dye purity was monitored spectrophotometrically using the extinction coefficients and wavelengths of the absorption peak of the double-charged anions, and by the equilibrium dissociation constants in the case of oxyxanthenes. The required acidity of the solutions was adjusted using acetate buffers (for pH-metry) and hydrochloric acid and sodium hydroxide solutions. The solution pH was monitored with a glass electrode. The absorption spectra of the solutions were registered directly after their preparation at room temperature on Hitachi-U3210 and SF-46 spectrophotometers.

We used phenol red (PR), cresol red (CR), thymol blue (TB), bromothymol blue (BTB), bromocresol purple (BCP), bromocresol green (BCG), and bromophenol blue (BPB) sulfophthalein counterions and fluorescein (FL), eosin (EO), ethyleosin (EE), tetrabromophenylfluorone (TBPF), erythrosine (ER), and Rose Bengal B (RBB) oxyxanthene counterions.

At pH 4.5–9.5 and concentrations smaller than 7×10^{-7} M, PNC occurs in solutions as strongly absorbing single-charged cation (monomer, pK_a 3.5 [12]), which strongly decolorizes at pH ≥10 owing to hydrolysis. It is known [8] that PNC tends to self-associate. The absorption spectra of the PNC monomer exhibit the strongest band at 600 nm (Fig. 1, curve *1*), whereas the strongest band of the dimer ($c \approx 5 \times 10^{-5}$ M) is observed at 545 nm (Fig. 2, curve *1*). Moreover, at $c \geq 5 \times 10^{-4}$ M PNC forms H-aggregates with the absorption maximum at 510 nm.

(*A*) Absorption, (λ) wavelength, and (ν) wave number; the same for Figs. 2–6. c_{CPB}, M: (*1*) 0, (*2*) 10^{-6}, (*3*) 5×10^{-6}, (*4*) 10^{-5}, (*5*) 10^{-4}, (*6*) 3×10^{-4}, (*7*) 6×10^{-4}, and (*8*) 9×10^{-4}.

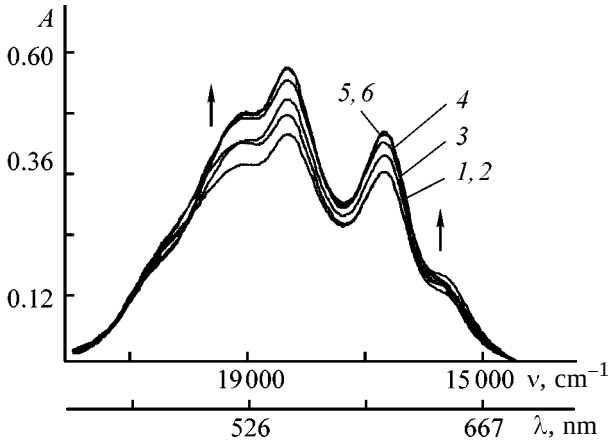

Fig. 2. Absorption spectra of dimeric PNC species (4.9×10^{-6} M) at various content of CPB in aqueous solutions. Water reference, layer thickness 0.20 cm, pH 6.9. c_{CPB}, M: (*1*) 0, (*2*) 5×10^{-6}, (*3*) 10^{-5}, (*4*) 5×10^{-5}, (*5*) 10^{-4}, and (*6*) 10^{-3}.

The premicellar and micellar contents of CSAs do not affect the shape of the absorption bands of both PNC monomer (Fig. 1) and dimer (Fig. 2), which suggests the absence of a strong interaction of the similarly charged chromophore and CSA ions. In contrast, the cationic PNC species readily interact with TPB anion and anionic chromophores listed above. As a result, the absorption of PNC (and in some cases of the chromophore) in solutions decreases by 40–65%, and new absorption bands appear in the spectra [2, 7, 9, 10]. These spectral changes observed at relatively low concentrations of the counterion ($c \geq 10^{-6}$) are similar to those occurring in aqueous solutions upon formation of ionic associates with cations of indopolycarbocyanines [13–15] and rhodamines [16–18].

It should be noted that the heteroassociates decompose in the presence of all the CSAs studied in this work, and the degree of decomposition is determined by the CSA concentration and is almost independent of its anionic component. For example, the ionic associate of PNC and TPB (Fig. 3, curve *1*) starts to decompose at a CTMA concentration of 3×10^{-6} M (Fig. 3, curve *2*). At further CSA addition, the solution absorption increases (Fig. 3, curves *3*–*7*), and at concentrations close to the micellar level $\{(1.0-1.8) \times 10^{-3}$ M [19]$\}$ the initial associate completely breaks down (Fig. 3, curve *8*). In the latter case, the solution spectra are similar to those of PNC in micelles of CTMA, CPC, and CPB (Fig. 1, curve *8*).

The breakdown of associates containing two chromophores (associates of PNC with sulfophthalein or oxyxanthene) is also accompanied by restoration of the absorption bands of their initial species. In these cases (Figs. 4–6), the absorption bands of each counterion are similar to those of the individual chromophores in CSA micelles. The band of the single-charged sulfophthalein anion undergoes a hypsochromic shift (≈ 8–12 nm) with respect to the CSA-free solution (absorption bands at 435 nm, e.g., PR^-, Fig. 4, curve *8*; BTB^-, Fig. 5, curve *6*), whereas in the case of the double-charged anions of sulfophthalein and oxyxanthene the bathochromic shift (≈ 15 nm,

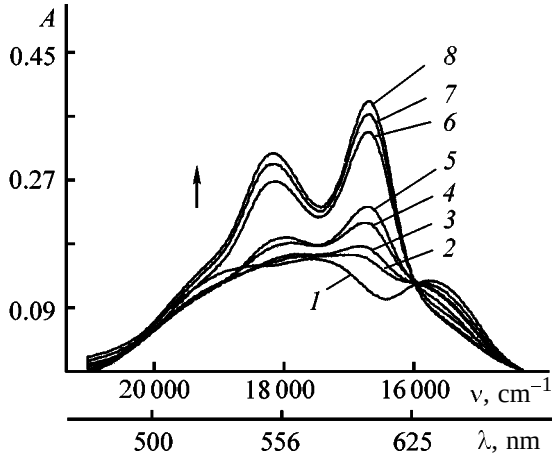

Fig. 3. Absorption spectra of the PNC (4.9×10^{-6} M) + TPB (5×10^{-6} M) system at various content of CTMA in aqueous solutions. c_{CTMA}, M: (*1*) 0, (*2*) 3×10^{-6}, (*3*) 5×10^{-6}, (*4*) 7×10^{-6}, (*5*) 10^{-5}, (*6*) 5×10^{-5}, (*7*) 10^{-4}, and (*8*) 6×10^{-4}.

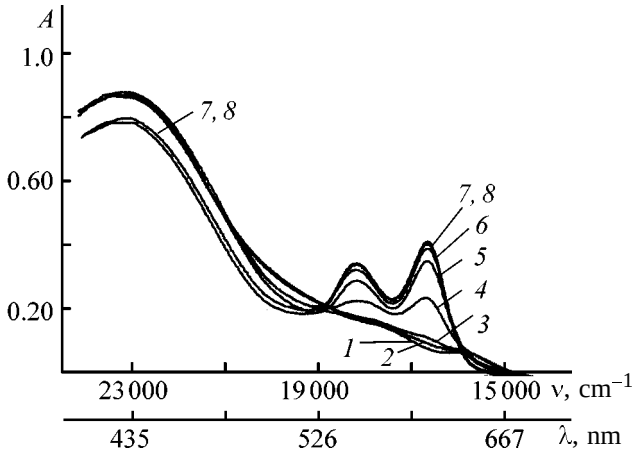

Fig. 4. Absorption spectra of the PNC (4.9×10^{-6} M) + PR (7.1×10^{-5} M) system at various content of CPB in aqueous solutions. Water reference, layer thickness 1.00 cm, pH 4.6. c_{CPB}, M: (*1*) 0, (*2*) 3×10^{-6}, (*3*) 10^{-5}, (*4*) 3×10^{-5}, (*5*) 6×10^{-5}, (*6*) 8×10^{-5}, (*7*) 6×10^{-4}, and (*8*) 9×10^{-4}.

absorption band at 530 nm, e.g. ER^{2-}, Fig. 6, curve *8*) is observed. It should be noted that similar spectral shifts, related to solubilization, were observed for the absorption bands of individual anions of a series of sulfophthalein and oxyxanthene dyes in the CSA micelles [20, 21]. As seen from the comparison of curves *1* and *8* (Fig. 1) and curves *1* and *6* (Fig. 2), in the case of PCN cation such shifts are absent.

Spectral changes observed in the PNC + TPB and PNC + chromophore systems suggest the equilibrium association. Using published analytical procedures [9, 13, 15, 16]; we found that the interaction of the ions can be presented by the following equations:

$$2Ct^+ + An^- \rightleftarrows (Ct^+)_2 \cdot An^- \text{ (for TPB anion);}$$

$$Ct^+ + An^- \rightleftarrows Ct^+ \cdot An^-,$$

$$2Ct^+ + An^{2-} \rightleftarrows (Ct^+)_2 \cdot An^{2-} \text{ (for chromophore anions),}$$

where Ct^+ is a monomeric PNC cation and An^- and An^{2-} are the single- and double-charged anions.

Taking into account the stoichiometric ratios observed, we calculated the thermodynamic equilibrium constants K_{as}. In the case of the PNC–TPB associate, K_{as} was 2.5×10^{13}. With increasing number of the halogen atoms and decreasing number of the alkyl substituents in the sulfophthalein molecule, K_{as} increases (its logarithm is given in parentheses) for both single-charged anions in the series CR^- (4.6) < TB^- (5.3) < PR^- (5.8) ≈ BTB^- (5.9) < BCP^- (6.7), and double-charged anions, CR^{2-} (11.0) ≈ BTB^{2-} (10.9) ≈ BCP^- (11.1) < PR^{2-} (11.8) < BCG^{2-} (12.1) < BPB^{2-} (13.7). Similar phenomenon is observed for oxyxanthenes: FL^- (4.6) < EE^- (5.5) < $TBPF^-$ (6.4), and especially for their double-charged anions: FL^{2-} (9.8) < EO^{2-} (11.3) < ER^{2-} (11.8) < RBB^{2-} (13.5).

Statistically significant differences in K_{as} suggest that the associate formation along with electrostatic factor strongly depends on the structural factor, which, in turn, is determined by specific interaction and thus affects the particle hydrophobicity [6, 11, 22]. As

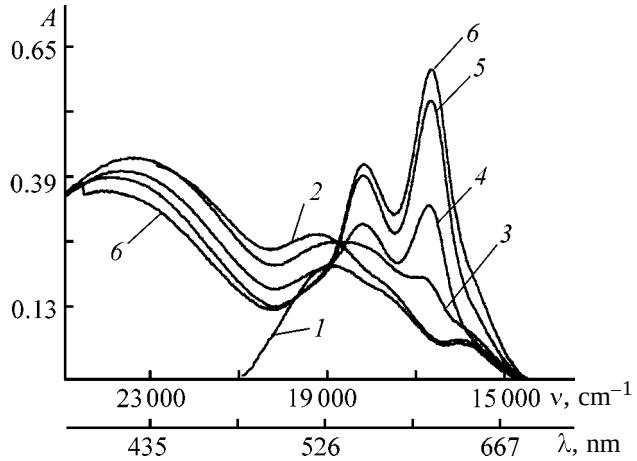

Fig. 5. Absorption spectra of the PNC (5.1×10^{-6} M) + BTB (2.5×10^{-5} M) system at various content of CPB in aqueous solutions. Layer thickness 1.00 cm, pH 4.6. c_{CPB}, M: (*1*) 0, (*2*) 3.1×10^{-6}, (*3*) 10^{-5}, (*4*) 4.8×10^{-5}, (*5*) 4×10^{-4}, and (*6*) 8.1×10^{-4}. Reference solution: (*1*) BTB, 2.5×10^{-5} M and (*2–6*) water.

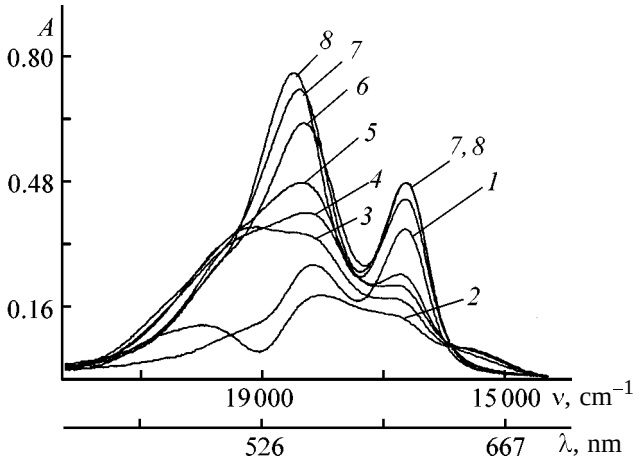

Fig. 6. Absorption spectra of (*1*) PNC (4.9×10^{-6} M), (*2*) PNC associate with double-charged ER, and (*3–8*) solution containing associate with addition of CPB. Layer thickness 1.00 cm, pH 9.2. c_{CPB}, M: (*1, 2*) 0, (*3*) 3×10^{-6}, (*4*) 6×10^{-6}, (*5*) 8×10^{-6}, (*6*) 6×10^{-5}, (*7*) 6×10^{-4}, and (*8*) 9×10^{-4}. Reference solution: (*1, 3–8*) water and (*2*) ER, 4×10^{-6} M.

seen, in the above series the strongest are the associates of BPB and RBB, which contain no alkyl substituents and have the greatest number of the hydrophobic halogen atoms.

The CSAs studied more easily break weaker associates: the breakdown of a stronger associate requires a higher concentrations of CSA, other conditions being equal (in particular, initial concentrations of counterions, relative excess of CSA with respect to counterions, etc.). Such a trend suggests that the surfactant cations (CSA^+) in the premicellar concentration range compete with PNC cations in the associate formation, replacing the latter from the associate with increasing CSA concentration:

$$Ct^+ \ An^- + CSA^+ \rightleftarrows Ct^+ + An^- \cdot CSA^+$$

or

$$(Ct^+)_2 \ An_2^- + CSA^+ \rightleftarrows 2Ct^+ + An^{2-} \cdot CSA^+.$$

In the micellar concentration range, the counterions are essentially separated from each other, but they are surrounded by CSA micelles:

$$Ct^+ \cdot An^- + (x+y)CSA^+ \rightleftarrows (Ct^+)_{xCSA^+} + (An^-)_{yCSA^+}$$

or

$$(Ct^+)_2 \cdot An^{2-} + (2x + y)CSA^+ \rightleftarrows 2[(Ct^+)_{xCSA^+}] + (An^{2-})_{yCSA^+},$$

Thus, in micellar solutions CSA acts both as competitor and medium for the associate component [23].

As seen from the calculated K_{as} values, the PNC associates are fairly strong and dominate in an aqueous solution at a 1.5–3.0-fold excess of an organic anion with respect to a cation. Nevertheless, even insignificant amounts of CSA can affect absorption of the aqueous solution containing associate. It should be noted that these changes occur in a wide range of CSA concentrations up to the micellar level. The optical density of the solution containing fixed amounts of PNC and counterions increases proportionally to the CSA concentration. Thus, the optical density at a given wavelength is a function of the CSA concentration in solution. For example, for PNC–TPB associate in the PCB concentration range 10^{-6}–10^{-4} M and at PNC and TPB concentrations of 4.9×10^{-6} and 10^{-5} M, respectively, the dependence of the optical density on the CSA concentration can be described as follows:

$$A_{600} = (0.098 \pm 0.009) + (2.22 \pm 0.18) \times 10^5 c_{CPB},$$

where A_{600} is the optical density at 600 nm and c_{CPB} is the concentration of CPB in the aqueous solution (M).

These relationships only slightly depend on the solution acidity; neither PNC nor TPB enter into protolytic reactions at pH 4.5–9.5. Therefore, quantitative determination of the CSA concentration using such dependences can exhibit high sensitivity to CSA (nearly 10^{-6} M) with the reliably determined concentrations ranging from 10^{-5} M to the micellar level in the solution pH range 4.5–9.5.

Moreover, some associates can be used for semiquantitative evaluation (test control) of the CSA concentration. In this case, we prepared a series of solutions containing fixed amounts of PNC and counterion (e.g., PNC and EE, both 5×10^{-6} M) and various amounts of CSA (10^{-6}, 5×10^{-6}, 10^{-5}, 5×10^{-5}, and 10^{-4} M). Each solution is characterized by its own color index, because the breakdown of the associate in each solution would be different. To evaluate the CSA concentration in a solution, its aliquot is added to a solution containing PNC and EE, and the color index of the resulting solution is compared with those of the reference solutions, after which the concentration is determined by interpolation.

CONCLUSIONS

(1) In aqueous solution, pinacyanol cation forms ionic associates with colorless (tetraphenylborate) and colored (sulfophthalein, oxyxanthene) anions. Irrespective of the composition, associates decompose in the presence of surfactants.

(2) The associate breakdown in the presence of various surfactants was studied. At the premicellar concentrations, the cationic surfactant competes with a pinacyanol cation, whereas at the micellar concentrations a specific medium is formed, which breaks associates.

(3) The properties of some associates can be used to develop new highly sensitive (up to 10^{-6} M) procedures for semiquantitative (test) and quantitative analysis of the content of cationic surfactants in aqueous solutions. These procedures are based on the proportional dependence of the optical density (coloring) of the solution on the concentration of cationic surfactants.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties and Application Prospects of 1-(Vinyloxyalkoxy)propylene 2,3-Oxide Copolymers

Abstract—Thermal stability, impact strength, folding resistance, and adhesion were studied for copolymers of vinyl chloride and 1-(vinyloxyalkoxy)propylene 2,3-oxides prepared in acetone and dimethyl sulfoxide.

Polyvinyl chloride (PVC) ranks among basic commercial polymers owing to its versatility and low cost. To almost 57% polyvinyl chloride consists of chlorine which is a cheap raw material whose world reserves are virtually unlimited. This specific polymer composition is responsible for both its advantages (strength and resistance to acids and solvents) and disadvantages (high viscosity of melt and low resistance to heat and light). One of the main disadvantages of PVC is that the temperature range of its conversion to the fluid state exceeds the degradation temperature. Therefore, the processing of PVC into articles requires, above all, introduction of stabilizing agents enhancing the thermal stability and plasticizing agents lowering the flow point [1].

However, many additives (especially the most efficient stabilizing agents based on lead, cadmium, and barium compounds) belong to hazard class 1 and 2 compounds [2]. Modern strict safety requirements to PVC composition components imply changing to new types of stabilizing agents free from the above-mentioned toxic metals.

The most widely used phthalate plasticizing agents are regarded as harmless [3, 4]. However, international environmental organizations regularly claim on unsafe application of these agents [5]. A possible reason is that the PVC–plasticizing agent system is metastable, and plasticizing agents can migrate from the composition during exploitation of articles, thereby taking away toxic stabilizing agents. Also, the introduced plasticizing agents inevitably decrease the softening point of the material; as a result, the deformation temperature of even rigid plastics based on PVC does not exceed 80°C.

The desired properties of the materials can be achieved by combining various chemical structures not only physically (by mixing appropriate composition components) but also chemically (copolymerization of the basic monomer with small amounts of a modifying comonomer). Therefore, an alternative line of improving the processability of PVC is copolymerization of vinyl chloride (VC) with a small amount of comonomers containing fairly bulky substituents ("internal" plasticization) and/or groups able of efficiently trapping the evolving hydrogen chloride (self-catalyst of the degradation process) and preventing oxidation processes (internal stabilization).

Vinyl ethers are often used as such comonomers [6–8]. In this case, stabilization is ensured by the specific structure of the copolymer macromolecules: Short blocks of VC units are separated by single vinyl ether units. The rate of elimination of hydrogen chloride is proportional to the length of VC blocks, which makes the copolymer containing no stabilizing groups more stable to thermal degradation than PVC [8]. The plasticizing efficiency of the polymer material is increased in the presence of fairly bulky side substituents in the vinyl ether molecule [9].

One of the main drawbacks of materials based on these copolymers is a lower (compared to PVC) softening point. Therefore, it is necessary to introduce into the monomer composition functional (e.g., epoxy) groups able of forming three-dimensional macromolecular networks and thereby increasing the softening point of the material.

In this connection, copolymers of VC and vinyl ethers containing an oxirane ring seem promising. These copolymers can efficiently trap hydrogen chloride, thereby significantly improving the resistance of copolymers to thermal degradation [10].

The aim of this work is to study the properties of

copolymers based on VC and 1-(vinyloxyalkoxy)propylene 2,3-oxides (VEP): 1-(vinyloxyethoxy)propylene 2,3-oxide (VEP_1), 1-(vinyloxydiethoxy)propylene 2,3-oxide (VEP_2), and 1-(vinyloxytriethoxy)propylene 2,3-oxide (VEP_3):

$$CH_2CHORCH_2\underset{\backslash\,O\,/}{CH}CH_2,$$

where R = $(CH_2–CH_2–O)$ in VEP_1, R = $(CH_2–CH_2–O)_2$ in VEP_2, and R = $(CH_2–CH_2–O)_3$ in VEP_3.

As shown earlier [10], the thermal stability of copolymers based on VC and VEP_1 increases owing to not only "internal" but also "structural" stabilization. The effect of the latter is manifested in the difference in the thermal stabilities of binary VC–VEP_1 and ternary VC–VEP_1–butyl vinyl ether (BVE) copolymers. The thermal stability of ternary copolymers significantly exceeds that of binary VC–VEP_1 copolymers (Table 1), despite lower content of VEP_1 and hence lower content of epoxy groups.

The thermal stability of VC–VEP_2 and VC–VEP_3 copolymers significantly exceeds that of binary VC–VEP_1 copolymers and is comparable with that of ternary VC–VEP_1–BVE copolymers (Table 1).

By contrast to the VC–VEP_1 system, in the VC–VEP_2 and VC–VEP_3 systems the thermal stability slightly decreases with increasing VEP fraction in the copolymers. Probably, lengthening of the side substituent intensifies degradation processes involving VEP and typical for poly(alkyl vinyl) ethers at temperatures around 250°C.

At the same time, lengthening of the side substituent should enhance the internal plasticization, which naturally increases the impact strength, folding resistance, and adhesion of coatings based on VC–VEP_2 and VC–VEP_3 copolymers. These coatings are formed from concentrated (40–50 wt %) solutions in available organic solvents, individual or mixed. Ordinary PVC is unable of forming lacquer coatings.

Coatings based on VC–VEP copolymers exhibit high impact strength (45–50 kg cm), the maximal folding resistance (1 mm), and high adhesion to metals, depending on the VEP content in copolymer (Table 2). High strength is characteristic for coatings based on copolymers containing over 4 mol % of VEP units. The coating strength is virtually unaffected by the length of the side VEP (VEP_2 or VEP_3) chain.

The adhesion of coatings based on these copolymers is also unaffected by the VEP content. When the VEP content in the copolymers is under 3 mol %, the adhesion of the coatings is moderate (2–3 points according to the lattice notch method), and it increases to a maximum (1 point according to the parallel notch method) with increasing VEP content in the copolymers.

These results can be explained by insufficient plasticizing effect exerted by VEP when in small amounts (up to 3 mol %) in copolymers, which is responsible for moderate strength and low adhesion of the coatings. With over 4 mol % of VEP units in the copolymer, internal plasticization is responsible for enhanced strength and adhesion.

The strength and adhesion characteristics of the coatings based on VC–VEP_2 and VC–VEP_3 copolymers significantly exceed those of coatings based on VC–VEP_1 copolymers (Table 2).

High strength and strong adhesion to various materials of uncured coatings are characteristic only for suspension or emulsion VC–VEP_1 copolymers, because such polymers contain hydroxy groups arising from partial hydrolysis of epoxy groups of VEP units in aqueous medium [10]. Also, the limiting impact strengths for coatings based on suspensions of VC–VEP_1 copolymers were achieved only after curing (Table 2).

The copolymers can be cured by virtually any curing agent suitable for epoxy resins. The thermal stability limit of the cured materials increases to 150–200°C. Moreover, by selecting appropriate curing agents it is possible to additionally increase the thermal stability of copolymers [11, 12]. For example, their modification with nitrogen-containing com-

* Method of lattice notches.
** After curing with polyethylenepolyamine, 1 wt fraction.

pounds, e.g., quinoxaline-2,3-dithiol or silicon-containing derivatives of ureas, *N*,*N*'-bis(trimethoxysilylmethyl)trimethylurea and *N*,*N*'-bis(dimethylchlorosilylmethyl)trimethylurea, increases the thermal stability of cured copolymers. Nitrogen in these compounds is the basic center, and it is able of accepting the hydrogen chloride evolving in degradation, thus transforming into ammonium cation. For example, the thermal stability limit of the VC–VEP_1 copolymer, which is initially stable up to 180°C, can be increased to 240–280°C by modifying with quinoxaline-2,3-dithiol [11]. Modification of the same copolymer with *N*,*N*'-bis(trimethoxysilylmethyl)trimethylurea makes it more resistant to thermal oxidative degradation, extending its stability range to 310°C [12].

High thermal stability of the copolymers make them suitable as stabilizing and costabilizing agents preventing degradation of PVC and exhibiting synergistic effect with the conventional barium stearates. The bulky side moieties in the VEP units significantly improve the processability of copolymers: The amount of the plasticizing agent consumed in extrusion of the compositions based on VC–VEP_1 copolymers decreases fivefold compared to PVC [10]. Of undoubted interest is the use of the copolymers as polymeric modifying agents for PVC-based plastics.

Thus, VC–VEP copolymers have a set of valuable operation and process characteristics which significantly improve the corresponding characteristics of PVC and make them versatile. These results can be achieved without adding any toxic compounds, which ensures high hygienic safety of the materials based on the copolymers studied.

Technologically, copolymerization is undoubtedly a more sophisticated process than polymerization, and introduction of a comonomer such as VEP will certainly increase the prime cost of the product. However, an easier and cheaper process of synthesizing PVC will inevitably complicate its processing and require expensive equipment for efficient mixing of various components.

EXPERIMENTAL

Both synthesis of the copolymers and their thermogravimetric studies followed the procedure described in [8].

The composition of the copolymers was calculated from the elemental analysis data. The content of chlorine was estimated by the Schoeniger's procedure [13].

The relative viscosity of the copolymers was determined in cyclohexanone at 25°C; it was recalculated to intrinsic viscosity as described in [14].

The characteristics of the coatings based on the copolymers were determined by conventional procedures [15].

CONCLUSIONS

(1) A study was made of the properties of copolymers based on vinyl chloride and 1-(vinyloxyalkoxy)-propylene 2,3-oxides. The thermal stability of all the copolymers significantly exceeds that of straight polyvinyl chloride; it increases with lengthening of the side moiety in 1-(vinyloxyalkoxy)propylene 2,3-oxides.

(2) The characteristics of coatings based on the copolymers (adhesion, folding resistance, and impact strength) are improved with lengthening of the side moiety in 1-(vinyloxyalkoxy)propylene 2,3-oxides.

Abstract—The amount of precipitated rubber in flocculation of SKS-30 ARK butadiene–styrene latex was studied as influenced by the concentration of poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride cationic polyelectrolyte at various temperatures and concentrations of the latex dispersed phase.

Recently, considerable attention has been given to the use of quaternary ammonium polymeric salts as coagulating agents for recovery of rubbers after emulsion copolymerization [1–5]. This is due to the fact that the amount of these salts required for recovery of rubbers from latexes is 50–100 times smaller as compared with the common coagulating agents (sodium chloride) [6]. As a result, environmental pollution with aqueous salt wastes, which is the main disadvantage in production of emulsion rubbers, can be significantly decreased, and thus utilization of quaternary ammonium salts in production of synthetic rubber is rather promising. At the same time, published data are insufficient for industrial use of these salts. For example, significant scattering in molecular weights and pH of their aqueous solutions can strongly affect the consumption of the reagent required for complete coagulation of the latex. Since under the real industrial conditions the recovery of rubber from a latex depends on such factors as concentration of the dispersed phase and temperature, study of the effect of these parameters is of particular importance.

In [5], we used ungraded commercial cationic polyelectrolyte poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride (PDMDAAC) as flocculating agent. It was found that the dependence of the fraction of the precipitated polymer on the concentration of the cationic polyelectrolyte passes through a maximum only at relatively small concentrations of the dispersed phase ($\approx$50 g l^{-1}). At higher rubber concentrations in the latex, the flocculation optimum is lost.

In this work, we studied the flocculating power of PDMDAAC of various molecular weights as influenced by the temperature and concentration of the dispersed phase.

We used SKS-30 ARK brand commercial butadiene–styrene latex containing soap emulsifiers based on disproportionated rosin and fatty and resin acids of tall oil.

In the first stage, PDMDAAC was subjected to fractional precipitation in the water–acetone system. The initial commercial PDMAAC sample ($\approx$ 40 wt % concentration) was diluted with water to nearly 10% concentration. Fractionation was performed by addition of acetone into the resulting PDMAAC aqueous solution with subsequent separation of the corresponding fractions. Then each fraction was dried in an oven at 90°C for 4–6 h to remove acetone. We studied three PDMAAC fractions with $\overline{M}_v$ of 172 000, 62 000, and 16 000. The molecular weights were calculated from the Mark–Kuhn–Houwink equation with the following constants: $K = 1.12 \times 10^{-4}$ and $\alpha = 0.82$ [7].

The coagulating power of PDMAAC samples with various $\overline{M}_v$ was evaluated gravimetrically (from the weight of the resulting coagulum) and visually (from the serum transparency).

Coagulation tests were performed as follows. A sample of the SKS-30 ARK latex with a given concentration of the dispersed phase (1.0, 1.5, 2.0, 3.0, 5.0, and 10 wt %) was charged into a vessel equipped with a stirrer and a thermometer and then placed in a thermostat heated to a required temperature. After heating for 10 min, the required amounts of a PDMAAC aqueous solution and 2% sulfuric acid were added with stirring. The content of the acidifying agent was constant (15 kg per ton of rubber). The resulting coagulum was separated from the serum and dried at 75–80°C.

The dependence of the degree of coagulum re-

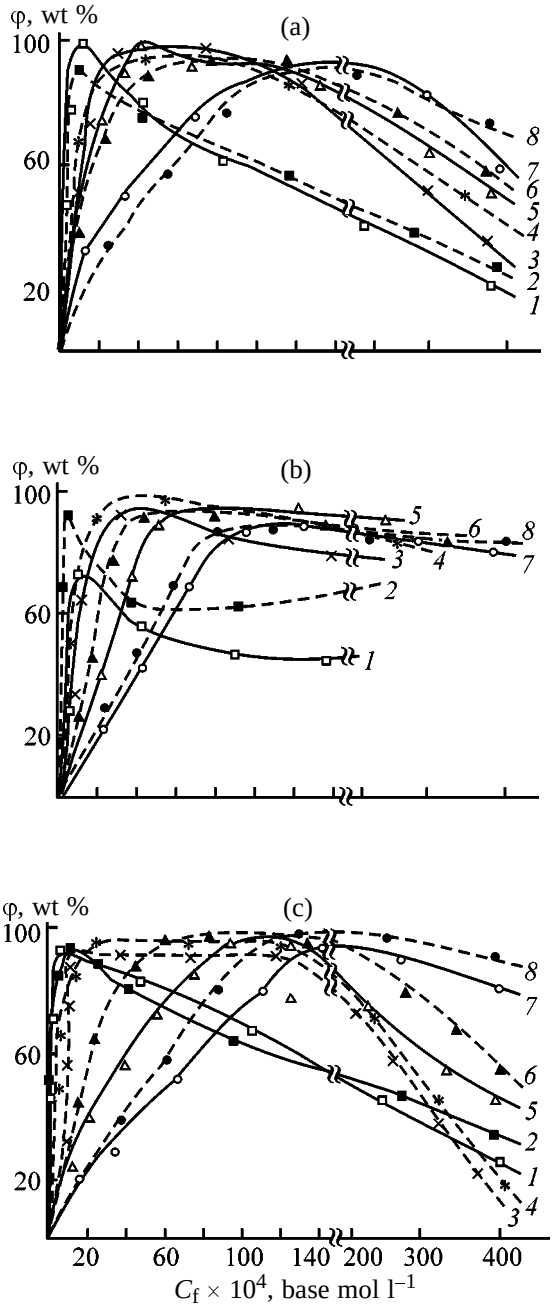

Fig. 1. Degree of coagulum recovery φ from the SKS-30 ARK latex as a function of PDMAAC concentration C_f. Dispersed phase concentration (wt %): (*1, 2*) 1, (*3, 4*) 3, (*5, 6*) 5, and (*7, 8*) 10. Temperature, °C: (*1, 3, 5, 7*) 20 and (*2, 4, 6, 8*) 80. Average molecular weight of PDMAAC, $\overline{M}_v \times 10^{-3}$: (a) 172, (b) 62, and (c) 16.

covery φ on the concentration of the PDMAAC fraction C_f at 20 and 80°C at various concentrations of the dispersed phase C_d are shown in Figs. 1a–1c. With increasing concentration of the dispersed phase, the curves of coagulum recovery $\varphi = f(C_f)$ shift monotonically toward higher concentrations of the flocculating agent. Moreover, with increasing C_d the shape of the recovery curves also changes, and the dependences with a maximum observed at small C_d transform into curves with a plateau or with a very broad maximum.

For dilute dispersions of the polystyrene latex [8], the precipitation curves $\varphi = f(C_f)$ showed a flocculation optimum typical for the flocculation with both charged and uncharged polymers. In all the cases, in the initial stage the flocculation efficiency strongly increased with increasing concentration of a cationic polyelectrolyte, passing through a well-defined maximum at low concentrations of the dispersed phase and flattening out or only slightly decreasing, without pronounced maximum, at high concentrations of the dispersed phase.

These different concentration dependences of the flocculation efficiency at low and high concentrations of the dispersed phase are presumably due to the features of the flocculating effect of the polymeric reagents [8]. The flocculation optimum in the sol flocculation with oppositely charged polymers can be considered as a resultant of two effects: destabilization due to neutralization of the particle surface charge and bridge binding mechanism, with subsequent restabilization due to the surface recharging and formation of a compact adsorption layer of a hydrophilic polymer on the particle surface [9]. These effects initiate the adsorption of the charged polymeric macromolecules on the particle surface, which provides neutralization of the surfactant anions with PDMAAC cationic groups to form an insoluble ionic complex. The flocculant excess promotes formation of a charged protective adsorption layer of the cationic polyelectrolyte macromolecules on the particle surface, which restabilizes the sol and decreases the amount of the recovered coagulum.

As seen from Fig. 1, irrespective of temperature and molecular weight of the polyelectrolyte, this effect is most pronounced for the dilute latex (C_d 1.0 wt %). At higher C_d, the maximum in the φ–C_f dependences becomes more diffuse or flattens out, i.e., the restabilization effect decreases or almost disappears, which is due to relaxation processes occurring in the adsorption layers of macromolecules at the particle surface [10]. With aging, the number of segments bound with the surface increases, whereas the length of the tails and loops of the polymer chain, which occur in the aqueous phase and provide bridging of the neighboring particles, decreases. At smoothening of the polymer macromolecules, the power to form

bridges decreases and a compact protective layer is formed, which decreases flocculation and hence the amount of the coagulum formed. These processes develop in time, and thus the operation period (aging of the adsorption layer) is a decisive factor.

With increasing content of the dispersed phase, the number of collisions between the particles increases and the relaxation time decreases, becoming insufficient for smoothening of the adsorbed molecules, so that they retain the bridging power. As a result, despite recharging, the cationic polyelectrolyte retains a high flocculating power due to the bridging mechanism of the particle binding. The recharging of the latex particles was observed experimentally in the study of the dependence of the electrokinetic potential of the particles on the concentration of the cationic polyelectrolyte added to the latex [5, 8, 9].

As seen from Fig. 1, with increasing temperature from 20 to 80°C the flocculation efficiency increases. This is also confirmed by the dependence of the optimal flocculation concentration (OFC) C_m on the dispersed phase concentration (Fig. 2). Due to the different shape of the precipitation curves at low and high C_d, as C_m we took the flocculant concentration either in a maximum or in a point corresponding to the beginning of the plateau. As seen, for both flocculation temperatures the $C_m = f(C_d)$ dependences are approximately linear, and the results for PDMAAC samples of different molecular weights are fitted by common curves. The slope of these dependence (calculated by the least-squares method) slightly decreases from 13.8×10^{-4} base mol g^{-1} at 20°C to 11.9×10^{-4} base mol g^{-1} at 80°C, which suggests certain decrease in the specific consumption of the flocculant in the flocculation optimum with increasing temperature. This is probably due to increased contribution of effective collisions at higher kinetic energy of the particles.

The above data suggest that temperature can affect the flocculation in the course of restabilization. Owing to the increase in the collision number and decrease in the free path of the particles with increasing temperature, their deactivation due to the smoothening of the adsorption layer should be suppressed, and both the flocculating power of the reagent and the trend toward flattening out of the flocculation curves should increase. However, as seen from Fig. 1, this is not the case. This trend is probably suppressed by the opposite factor: increase with increasing temperature in the mobility of macromolecular chains and in the rate of relaxation processes causing deactivation of the particles.

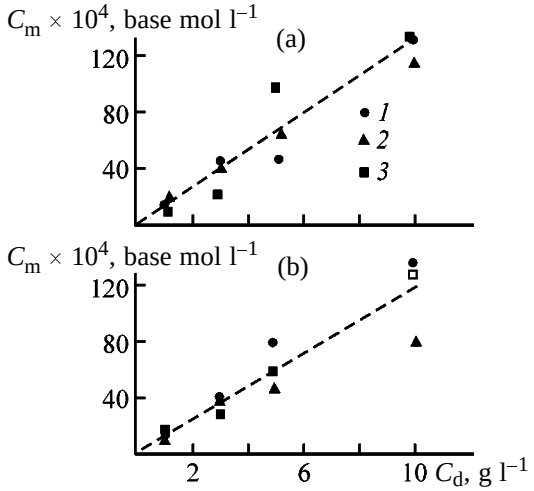

Fig. 2. Optimal flocculation concentration C_m as a function of the dispersed phase concentration in latex C_d. Temperature, °C: (a) 20 and (b) 80. Average molecular weight of PDMAAC fraction, $\overline{M}_v \times 10^{-3}$: (*1*) 172, (*2*) 62, and (*3*) 16.

In practice, the results obtained suggest that, in the course of SKS-30 ARK rubber recovery, the effect of the average molecular weight of PDMAAC flocculant and flocculation temperature is insignificant. This weakens the requirements to the control of the molecular weight of the flocculants and decreases power consumption in the rubber recovery.

Our study of the properties of rubbers, rubber stocks, and vulcanized rubbers showed that the properties of SKS-30 ARK rubber and vulcanized rubber based on it (see table) are almost independent of the molecular weight of PDMAAC and flocculation temperature.

The chemical composition of the rubbers recovered from the latex with PDMAAC aqueous solutions was close to that of the control samples of the rubber recovered with sodium chloride. However, in all the coagulum samples recovered from the latex with PDMAAC, the content of the organic acid soaps was minimal (absent or traces). At the same time, in the coagulum samples recovered from the latex with sodium chloride the soap content varied from 0.0 to 0.2%.

The properties of the vulcanized rubbers based on the rubbers recovered from the latex with cationic polyelectrolytes are similar to the properties of the reference sample. At the same time, the vulcanization rate of the rubber stocks based on SKS-30 ARK rubber recovered from the latex with PDMAAC is higher. As shown in [11, 12], vulcanization is probably accelerated with polymeric quaternary ammonium salt retained in the rubber after coagulation and(or)

products of its reactions with the emulsion system components.

CONCLUSIONS

(1) Flocculation of SKS-30 ARK butadiene–styrene latex at various concentrations of the dispersed phase is almost independent of temperature (20–80°C) and average molecular weight of poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride cationic polyelectrolyte. The flocculating power of the reagent (rubber yield) slightly increases with temperature.

(2) Utilization of poly-*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride cationic polyelectrolytes of various molecular weights does not require significant changes in the industrial flowsheet of rubber recovery and does not noticeably affect the properties of rubbers and vulcanized rubbers based on them.

Received October 10, 2001

Abstract—Spontaneous polymerization of 2-acrylamido-2-methylpropanesulfonic acid in the presence of inorganic and organic neutralizing agents in concentrated aqueous solutions is studied. The hypothesis of redox mechanism of the process initiation is discussed.

Water-soluble copolymers based on 2-acrylamido-2-methylpropanesulfonic acid (AMPSA) and its sodium salt are used in oil production and as effective flocculants and additives in paper production [1]. These products are prepared by free radical polymerization of the corresponding monomers using the traditional methods. For methacrylic monomers capable of association (containing ionogenic groups, e.g., *N*,*N*-dialkylaminoethyl methacrylates, or mobile hydrogen atoms, e.g., acrylamide), the methods for spontaneous polymerization in concentrated aqueous solutions are being extensively developed [2, 3]. The AMPSA molecule contains an acid group and a monosubstituted amide group and therefore should also be capable of spontaneous polymerization. Indeed, spontaneous polymerization of AMPSA in water was reported in [4]. At the same time, in the system *N*,*N*-dialkylaminoethyl methacrylate–AMPSA–water (no initiator) a homopolymer of amino methacrylate was obtained, i.e., AMPSA molecules were not involved in spontaneous polymerization [5].

It was demonstrated in preliminary experiments that spontaneous polymerization leading to consumption of C=C bonds and considerable increase in the viscosity of the system goes at a noticeable rate at a temperature above 20°C and pH <7 in concentrated aqueous AMPSA solutions. As the reaction proceeds by the free radical mechanism, it does not occur in the presence of sufficiently large amounts of inhibitors. Furthermore, the monomer solutions remain stable after total neutralization of AMPSA with NaOH and also in the case of excess NaOH.

In this work we studied the features of autoinitiated radical polymerization of AMPSA in acidic aqueous solutions. Figure 1 shows the kinetics of C=C bond consumption in spontaneous polymerization of AMPSA at various degrees of neutralization of the sulfonic acid groups with NaOH. In the absence of the neutralizing agent, the reaction proceeds slowly (curve *7*). The dependence of the initial polymerization rate on the degree of neutralization *K* passes through a maximum at *K* of about 50% (Fig. 2). At larger conversions, the effect of this factor becomes weaker: at the degree of neutralization of AMPSA varied within 10–95%, the conversion of the monomer after 4 h varies within a narrow range from 75 to 88% (Fig. 1). Considerably lower value was obtained only in the absence of NaOH.

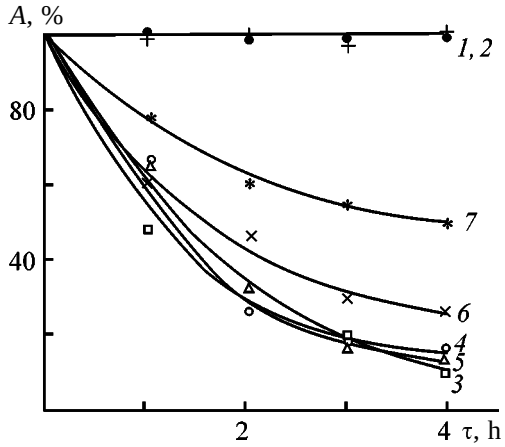

Fig. 1. C=C bond concentration *A* in the system AMPSA–NaOH–H_2O as a function of time τ. $[AMPSA]_0$ = 37 wt %, *T* = 50°C; the same for Fig. 2. Molar ratio AMPSA : NaOH: (*1*) 1 : 1.5, (*2*) 1 : 1, (*3*) 1.1 : 1, (*4*) 4 : 3, (*5*) 4 : 1, (*6*) 10 : 1, and (*7*) 1 : 0.

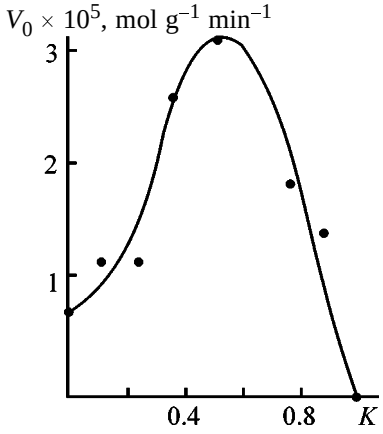

Fig. 2. Initial polymerization rate V_0 as a function of the degree of AMPSA neutralization *K*. Neutralizing agent NaOH.

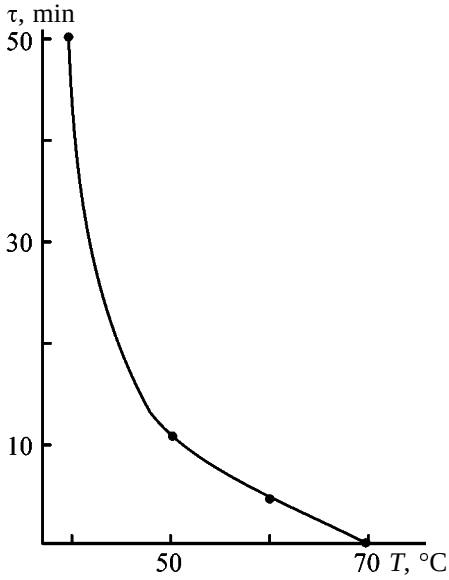

Fig. 3. Induction time of polymerization τ as a function of the temperature *T*. Molar ratio AMPSA : NaOH = 2 : 1, $[AMPSA]_0$ = 31 wt %; the same for Figs. 4 and 6.

Polymerization parameters are strongly influenced not only by the content of free acid groups, but also by the initial monomer concentration M_0. The effect of M_0 on the initial rate V_0 of spontaneous polymerization is illustrated below.

M_0, wt %	$V_0 \times 10^5$, mol g^{-1} min^{-1}
20.0	0
25.0	0.35
37.5	3.10
45.0	3.95
51.5	5.95

The experiments were carried out at the optimal AMPSA : NaOH molar ratio of 2 : 1, temperature of 50°C, and a monomer concentration of 10–50 wt % (the upper limit corresponds to the monomer solubility). The process rate abruptly increases with increasing concentration, which is typical of radical polymerization (either spontaneous and initiated) of associated monomers in water [6]. This is due to the fact that in concentrated solutions monomer associates are formed, facilitating generation of initiators and chain propagation. A significant role of association in autoinitiated polymerization is supported by large orders of the reaction with respect to the monomer. For example, in this work this parameter was determined to be 2.3 at $[AMPSA]_0$ = 50 wt %, AMPSA : NaOH = 1.2 : 1, and T = 70°C. In dilute solutions association of the monomers is hardly probable. Therefore, decreasing initial concentration abruptly decelerates polymerization of associating monomers [6]. In the presence of initiators, dilution considerably decelerates polymerization, and in the absence of initiators at $[AMPSA]_0$ < 20 wt %, spontaneous polymerization was not observed at all in 8 h (50°C), suggesting that the indicated conditions do not favor chain propagation as well as generation of a sufficient amount of radicals initiating polymerization. Therefore, it may be concluded that active species are formed in AMPSA monomer associates.

Additional information important for understanding the process mechanism can be obtained from the temperature dependences of τ (Fig. 3) and also from data on the effect of inhibiting admixtures. The induction time of polymerization at 40–70°C is given in Fig. 3. At 30°C τ ~ 16 h, and with increasing temperature to 50°C τ decreases to 10 min. At 70°C the induction time was too short to be detected. The induction time increases not only with decreasing temperature, but also with introduction of small amounts of inhibitors. For example, with introduction of 0.02 and 0.1 mol % *p*-methoxyphenol (against the monomer concentration) into the system, the induction time at 50°C is 40 and 120 min, respectively (for the experimental conditions, see the caption to Fig. 3). At higher inhibitor concentration (1.0 mol %), no polymerization occurred in the observation period (4 h). The occurrence of the induction time at low temperature in the absence of inhibiting additives can be attributed to the low rate of initiation and also to the presence of trace amounts of inhibiting admixtures in the tested samples of the monomers. However, these admixtures, even if occur, have no significant effect on the initial rate of polymerization after the end of the induction period, since the initial rates at 40–70°C (within this temperature range the induction time decreases from 50 to 0 min)

demonstrate a satisfactory linear correlation in the coordinates $\ln V_0 - 1/T$. This allowed determination of the overall activation energy of polymerization (21.7 ± 4.8 kJ mol^{-1} at $[AMPSA]_0$ = 31% and AMPSA : NaOH = 2 : 1). The activation energy of initiation is hence even lower, which is consistent with data on spontaneous polymerization in water of acrylamide [3] and *N*,*N*-dimethylaminoethyl methacrylate tertiary salts [2].

In many cases the fact that polymerization of methacrylic monomers proceeds without addition of initiators is attributed to formation of peroxy compounds from the initial monomers and oxygen [7, 8]. For the systems studied in this work, this is hardly probable. Thus, we observed no acceleration of polymerization after AMPSA was allowed to stand in air. Furthermore, the process does not occur in neutral and alkaline solutions, and, what is more, polymerization even accelerates after preliminary purging of the reaction mixture with nitrogen, i.e., oxygen has some inhibiting rather than initiating effect. All these findings are inconsistent with the concept of peroxide initiation.

It should be pointed out that the activation energy below 40 kJ mol^{-1} is typical of redox systems (with substance initiation), being considerably lower that those found in thermal homolytic breakdown of weak bonds of initiators (>60 kJ mol^{-1}) [7]. To check for consistency the hypothesis of redox initiation in spontaneous polymerization of AMPSA, we conducted experiments with addition in the system of such a strong reducing agent as sodium metabisulfite. This resulted in elimination of the induction period and acceleration of polymerization (Fig. 4), suggesting the presence in concentrated aqueous AMPSA solutions of some reactive centers acting as weak reducing agents. Evidently, as such reducing agents can serve heteroatoms having a lone pair (nitrogen or oxygen), and as oxidizing agents, electrophilic C=C bonds of the monomer. Initiation of polymerization of methacrylic monomers through electron transfer from a heteroatom to the C=C bond is known from the literature [9]. Possibly, association of monomers in concentrated aqueous solutions is the factor favoring such an initiation.

It is known that the rate of radical polymerization of AMPSA salts in water in the presence of initiators increases with increasing solution ionic strength (for example, with addition of NaCl [10]) and atomic radius of a neutralizing agent cation ($Li^+ < Na^+ < K^+$) [11]. Increasing radius of the cation facilitates its binding to the sulfonate anion, thus decreasing electrostatic repulsion between the growing macroradicals and the monomer molecules. Increasing ionic strength of the solution by adding a low-molecular-weight electrolyte also results in weakened electrostatic repulsion.

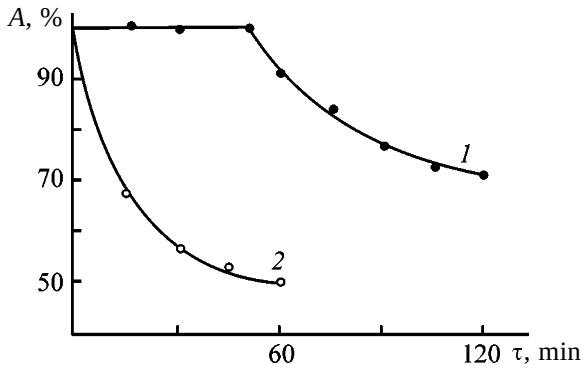

Fig. 4. Concentration of C=C bonds in AMPSA *A* as a function of the polymerization time τ (*1*) in the absence and (*2*) in the presence of $Na_2S_2O_5$. Temperature 40°C, $[Na_2S_2O_5]$ = 0.3 mol % against AMPSA.

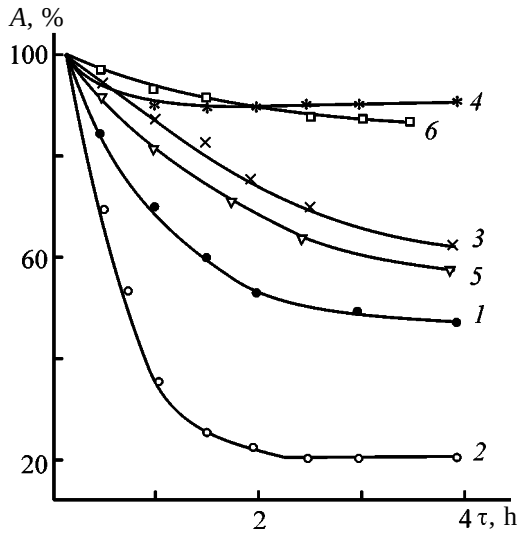

Fig. 5. Effect of neutralizing agent on spontaneous polymerization of AMPSA at 50°C: (*1*) NaOH, (*2*) KOH, (*3*) NH_4OH, (*4*) $N(CH_3)_3$, (*5*) $N(C_2H_5)_3$, and (*6*) $N(C_4H_9)_3$. AMPSA to neutralizing agent molar ratio 2 : 1, [AMPSA] = 31 mol %. (*A*) C=C bond concentration and (τ) time; the same for Fig. 6.

Figure 5 demonstrate data on spontaneous polymerization of AMPSA in the presence of various neutralizing agents. With alkalis, the polymerization rate increases with increasing radius of the cation ($Na^+ < K^+$). More complicated pattern is observed when the sulfonic acid is partly neutralized with ammonia or trialkylamines. Triethylamine, taking the intermediate position in the size of substituents between trimethylamine and tributylamine, is the most

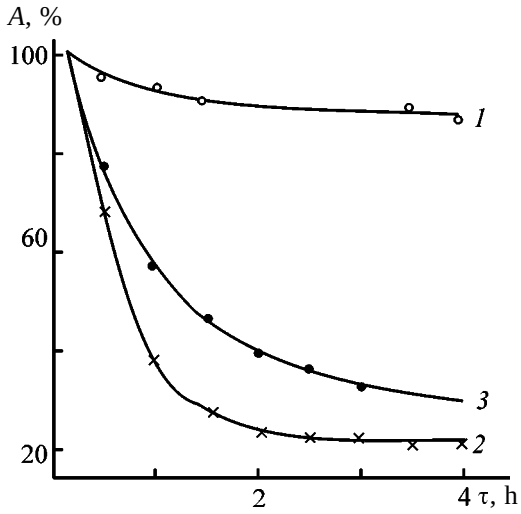

Fig. 6. Effect of electrolytes on spontaneous polymerization of AMPSA at 50°C: (*1*) NaCl, (*2*) Na_2SO_4, and (*3*) $NaNO_3$. [NaA] = 30 mol %.

active among the indicated amines, close in basicity (Fig. 5, curves *4*–*6*). In contrast to polymerization of AMPSA salts, increasing ionic strength of solutions by adding inorganic electrolytes does not necessarily accelerate the process. For example, addition of sodium sulfate or nitrate considerably accelerates polymerization, whereas addition of sodium chloride has the opposite effect (Fig. 6). Note that a noticeable effect of the anion was also observed in studying spontaneous polymerization in water of *N*,*N*-dimethylaminoethyl methacrylate salts with mineral acids, with the hydrochloride being considerably less active that the nitrate or sulfate [2]. The results obtained show that ions occurring in the system considerably affect spontaneous polymerization of AMPSA in aqueous solutions, which is probably due to the fact that different ions differently contribute to packing of the monomeric molecules in the associates.

Analysis of the rate of spontaneous polymerization of AMPSA as a function of the degree of neutralization of the monomer shows that increasing acidity, on the one hand, should facilitate electrophilic activation of the C=C bonds and increase their activity as oxidizing sites, and, on the other hand, should hamper association of the monomers. Furthermore, increasing degree of neutralization by adding a base increases the solution ionic strength, accelerating the process. The observed dependence of the polymerization rate on the monomeric acid to neutralizing agent molar ratio, having a maximum (Fig. 2), is a resultant of these oppositely directed trends. In the case of totally neutralized sulfonic acid groups, the key factor responsible for suppressing spontaneous polymerization is most likely the lack of protonated carbonyl groups. To gain a better insight into the process mechanism, further investigations are needed.

The results obtained in this work provide tools for control of spontaneous polymerization in aqueous AMPSA solutions. If needed (for example, in industrial synthesis of AMPSA copolymers), polymerization can be suppressed. Additionally, autoinitiated polymerization can be used for preparing AMPSA-based homopolymers. In this case, the molecular weight of the products can be controlled by varying the reaction temperature. Thus, the viscosity-average molecular weight of the polymers, determined by the Mark–Houwink equation [12], decreases from 3×10^6 to 1×10^6 with increasing temperature from 40 to 70°C.

EXPERIMENTAL

In the work, we used AMPSA recrystallized from acetic acid (mp 186°C). The polymerization kinetics of AMPSA in the presence of neutralizing agents was studied in water at 20–70°C and an initial AMPSA concentration of 10–50 wt %. Polymerization was monitored by two methods: by the concentration of C=C bonds and with separation of the reaction products by adding acetone. The resulting polymers were additionally washed with acetone and dried in a vacuum (20°C, 2 mm Hg) to constant weight.

The C=C bond concentration was determined by the bromide–bromate titration method. The ^{1}H NMR spectra were registered on a Varian Gemini-300 Fourier-transform spectrometer at a frequency of 75 MHz in D_2O with DMSO as a reference. Infrared spectra were registered on a Specord M-80 spectrometer using the KBr technique.

Poly(2-acrylamido-2-methylpropanesulfonic acid) sodium salt. To 2.25 g of AMPSA in 3.8 ml of water, 1.07 g of 20% NaOH was added, and the solution was allowed to stand at 50°C for 5 h. Then the same portion of 20% NaOH was added for total neutralization of the acid. The polymer was separated from the reaction system by adding 50 ml of acetone. The product was additionally washed with acetone and dried in a vacuum (20°C, 2 mm Hg). Yield 5.8 g (85%). No C=C bonds were detected in the product. ^{1}H NMR spectrum (δ, ppm): 2.9–3.6 ($-CH_2SO_3$), 1.7–2.3 (–CHC=O), and 0.9–2.3 (CH_3– and $-CH_2CH-$). IR spectrum (ν, cm^{-1}): 1668 (C=O), 1548 (amide II), 1220 (amide III), and 1046 and 632 (SO_3^-).

CONCLUSIONS

(1) In concentrated aqueous solutions, 2-acrylamido-2-methylpropanesulfonic acid spontaneously polymerizes at pH <7.

(2) The maximal initial rate of the process is observed at 50% neutralization of 2-acrylamido-2-methylpropanesulfonic acid and depends on the cations and anions occurring in the system.

(3) Experimental data on the effects of the initial concentration, temperature, electrolytes, inhibitors, and reducing agents can be interpreted assuming generation of radical initiators in the monomeric associates through redox reactions involving the C=C bonds and heteroatoms of 2-acrylamido-2-methylpropanesulfonic acid.

Abstract—A frost-resistant polyamidobenzimidazole-based polymer composite is synthesized from 3,3',4,4'-tetraaminodiphenyl oxide, diphenyl adipate or diphenyl sebacate, and hexamethylenediamine or ε-caprolactam. As stabilizers for the polymers were used 4-phenyl-2,2,5,5-tetramethyl-3-imidazoline-3-oxide-1-oxyl and carbon black.

It is known that, under conditions of distinctly continental climate with negative annual average temperature, polymeric materials and composites degrade considerably more rapidly than in temperate climatic zones [1]. Through simultaneous effects of solar radiation, moisture, and atmospheric oxygen and ozone, polymers are subject of photooxidative and hydrolytic degradation, resulting in significant decrease in their molecular weight, brittle failure, and rapid deterioration of performance characteristics.

It is obvious that the frost resistance of polymeric materials can be enhanced by modification of the polymer composition and structure [1]. Of particular interest in this context are resonance-stabilized rigid-chain heterocyclic polymers containing aromatic and heterocyclic fragments in their macrochains.

It was demonstrated in [2, 3] that polybenzimidazoles (PBIs) based on aromatic tetramines and diphenyl esters of aromatic or aliphatic dicarboxylic acids can be used as starting materials for preparation of glues and binders for glass fiber reinforced plastics which are capable to maintain high performance at cryogenic temperatures, despite high rigidity of their chain and high glass transition temperature. However, in most cases PBIs are infusible compounds poorly soluble in organic solvents, making it more difficult to process them into goods by modern industrial methods.

Polyamidobenzimidazoles (PABIs) reported in [4–6] are copolymers of PBI and a polyamide whose molecule contains benzimidazole rings and amide bonds. They were synthesized by solid-phase polycondensation from 3,3',4,4'-tetraaminodiphenyl oxide, diphenyl adipate or diphenyl sebacate, and hexamethylenediamine or ε-caprolactam.

Chemical modification of BPIs through introduction of aliphatic fragments in the macrochain increases the chain flexibility and free space of the macromolecule, which has a favorable effect on such properties as the solubility and plasticity. Commercial polyamides, which are low-resistant to the action of climatic factors [7], can be stabilized by introduction of benzimidazole rings [7].

It was demonstrated in preliminary tests of PABI-based films[1] that this class of copolymers show promise for exploitation under conditions of cold climate and strong UV radiation [8]. Good results obtained with the films in environmental tests stimulated study of degradation of pressed samples of such polymers. Shovel-shaped samples obtained by direct pressing of PABI molding powders were exposed for three years at the site of the Institute of Nonmetallic Materials, Yakut Scientific Center, Siberian Division, Russian Academy of Sciences (Yakutsk).

The initial polymer composite was as in [10] and contained (wt %): PABI 97.5–98.1, 4-phenyl-2,2,5,5-tetramethyl-3-imidazoline-3-oxide-1-oxyl 1.0–1.5, and carbon black 0.9–1.0.

The reduced viscosity at 25°C of 0.5% PABI in concentrated formic acid was found to be 2.53–

[1] Tests were conducted in cooperation with the Institute for Physical and Engineering Problems of the Russian North, Yakut Scientific Center, Siberian Division, Russian Academy of Sciences (Yakutsk).

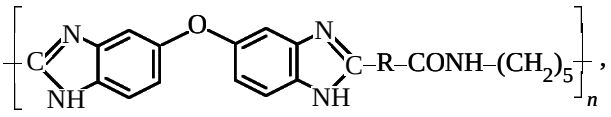
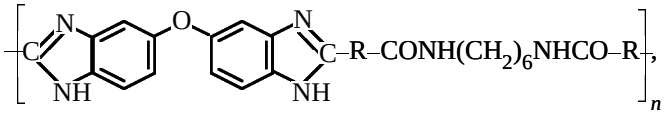
Polyamide**	–	–	630–950	240–450	–	–

* (η_r) Reduced viscosity of 0.5% aqueous polymer solution in formic acid, (σ_t) breaking tensile stress, and (ε_b) elongation at break.
** $NH(CH_2)_6NHCO(CH_2)_4CO$ [9].

4.76 dl g^{-1}. This copolymer is soluble in concentrated sulfuric and formic acids, amide solvents, and tricresol, being also sufficiently heat-resistant [11]. According to TGA data (air; heating rate 5 deg min^{-1}), for polymers **I** and **II** τ_0, τ_5, and τ_{10} are 210–300, 280–360, and 360–400°C, respectively, depending on the elementary unit composition. The latter, in its turn, depends on the starting monomer. The structure of elementary units is as follows:



I

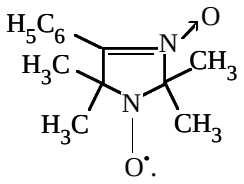


II

where R = –$(CH_2)_4$ (**I**); –$(CH_2)_8$–,  (**II**).

The environmental testing results for the investigated polymer films are summarized in Table 1.

The structure of the radical-type stabilizer 4-phenyl-2,2,5,5-tetramethyl-3-imidazoline-3-oxide-1-oxyl (ST) is as follows:



The well-known stabilizer, carbon black, absorbs solar radiation and, being an antioxidant by itself, enhances the inhibiting action of other antioxidants. Furthermore, oxygen-containing functional groups and free radicals present on the carbon black surface are capable to recombine with radicals formed in polymer degradation [12].

The results of 3-year environmental tests under conditions of cold climatic zone of the polymer composites studied in this work are summarized in Table 2. The polymeric materials obtained demonstrate a sufficiently high resistance to the factors of cold climate. Even after a 3-year exposure their elasticity remains at a 69–81% level, whereas for the samples of polyamide-6, ε_b decreased by about 90% after exposure to moderately cold climatic conditions [7]. The first cracks were found on the surface of the polyamide samples after 6–8 months, whereas the polymer composites proposed in this work maintain their surface appearance throughout the entire period of testing. Note that unstabilized PABIs are less stable.

If considering the PABIs studied as a modified polyamide, one may suggest that their increased aging stability is due to the positive effect of benzimidazole fragments in the macrochain. Furthermore, the presence of a radical stabilizer and carbon black also contribute to maintenance of mechanical properties in the course of long exposure.

The initial and exposed samples were characterized by infrared spectroscopy. The spectra show the absorption bands at 1680–1630 cm^{-1} due to vibrations of the >C=O groups of secondary amides (amide

Table 2. Elongation at break of PABI-based polymeric composites after various exposures

Composite no.	ST	Carbon black	ε_b, %, after indicated exposure, months				
	%		initial composite	6	12	24	36
1	–	–	5.0	3.3	1.9	0.9	–
2	1.0	1.0	4.0	4.2	4.0	4.0	3.2
3	1.5	1.0	4.5	4.0	3.7	3.7	2.8
4	1.0	0.9	3.5	3.0	2.7	2.7	2.5
5	1.6	1.0	4.5	4.5	4.0	3.5	3.1
6	1.0	1.0	4.0	4.2	3.7	3.6	3.1
7	1.5	1.0	3.5	3.3	3.2	3.2	2.9

Note: Polyamidobenzimidazoles in composite nos. 1–5 were prepared from 3,3',4,4'–tetraaminodiphenyl oxide, diphenyl adipate, and ε-caprolactam; and in nos. 6–7, from the same tetramine, diphenyl sebacate, and hexamethylenediamine.

I band) and at 1570–1515 cm^{-1} due to bending vibrations of >NH (amide II band). The bands at 800 and 1445 cm^{-1} are indicative of the presence of benzimidazole rings [13]. The intensity of the indicated bands in the stabilized samples only slightly changes with exposure as compared to the unstabilized samples.

For the stabilized pressed samples, TGA data showed that τ_{10} is 340–360°C, only slightly changing in the course of a 3-year exposure. The viscous characteristics, reflecting the molecular weight, decreased by 8–10% in two years, whereas for the unstabilized samples the decrease is 25–30% of the initial.

Finally, the stabilized PABI-based polymer composite demonstrate high resistance to factors of cold climate, moisture, oxygen, and solar radiation, showing promise for manufacture of goods designed for exploitation under inclement climatic conditions of the North and Siberia.

EXPERIMENTAL

Polyamidobenzimidazole was obtained by solid-phase polycondensation of equimolar quantities of 3,3',4,4'-tetraaminodiphenyl oxide, diphenyl adipate or diphenyl sebacate, and hexamethylenediamine or ε-caprolactam. A mixture of the indicated monomers in a reaction vessel was multiply purged with argon by multiple evacuation–admission cycles and then placed into a furnace heated to 200°C. After the reaction mixture fused, the temperature was raised to 260°C over a period of 1–1.5 h, and the mixture was allowed to stand at this temperature for 3.5–4.0 h. After 20–30 min of heating, the melt hardens, and the reaction goes in the solid phase with liberation of water and phenol. Then the reaction vessel was evacuated to 1–2 mm Hg, and polycondensation was continued for 1 h at the same temperature. Finally, the product was cooled to room temperature.

The resulting copolymer was dissolved in concentrated formic acid and separated by adding aqueous ammonia. The products with aliphatic fragments in the macrochain were intimately mixed with the radical stabilizer (1.0–1.6 wt %) and carbon black (0.9–1.0 wt %) and then pressed at 180–190°C and a pressure load of 80–100 MPa to obtain shovel-shaped samples according to GOST (State Standard) 11262–68. In the case of PABIs with aromatic fragments in the macrochain, the pressing temperature was 260°C, and no radical stabilizer was introduced in the composite, since it is unstable at this temperature.

The radical stabilizer was prepared at the Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences (Novosibirsk) by the procedure described in [14]; mp 103–105°C, decomposition temperature 170–190°C.

Infrared spectra were recorded on a Specord 75-IR spectrometer. Mechanical tests of the pressed samples for the breaking tensile stress and elongation at break were performed on an Instron 1195 general-purpose high-precision tensile-testing machine. Thermogravimetric analysis was carried out on a Q-1000 derivatograph at a heating rate of 5 deg min^{-1}.

CONCLUSION

Composites prepared from a polyamidobenzamidazole, a radical stabilizer, and carbon black by direct hot pressing demonstrate good stress–strain behavior, which is preserved during long-time exposure under conditions of cold climate. These composites outperform any commercial polyamides.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Role of the Structure of Polymer Melt in Thermal Oxidative Degradation of Heterochain Polyesters

G. V. Kozlov, G. B. Shustov, and G. E. Zaikov

Kabardino-Balkar State University, Nalchik, Kabardino-Balkaria, Russia

Received November 22, 2001

Abstract—A study was made of the fractal dimension of the macromolecular coil as a parameter characterizing the polymer melt structure.

It is generally recognized now that the thermal oxidative degradation of polymers is influenced by their structure [1–3]. However, this influence was quantitatively characterized only for solid-phase crystalline-amorphous polymers, namely, by the degree of crystallinity [3, 4]. Other models utilize semiempirical approaches such as the "cage" model [2], zone model [3], etc. This is due to the lack of a quantitative structural model for amorphous state of both amorphous glassy and polymer melts. This gap can be filled, however, by the recently developed fractal analysis methods [5, 6]. In particular, fractal analysis provides now essentially the only mathematical means for describing the structure of polymer melts [7].

The aim of this work was to elucidate the structure-related factor governing the thermal oxidative degradation of polymer melts.

We studied polyarylates (PArs) based on 1,1-dichloro-2,2-di(*p*-chlorocarbonylphenyl)ethylene and 4,4-isopropylidenediphenol, as well as block copolymers of poly(arylene sulfone oxide arylates) (PASOAs) synthesized from 4,4'-isopropylidenediphenol, a 1 : 1 mixture of tere- and isophthaloyl dichlorides, and dihydroxyl-containing oligo(arylene sulfone) oxide based on 4,4-isopropylidenediphenol and 4,4'-dichlorodiphenyl sulfone with the molecular weight of 4600. The polycondensation procedures utilized for preparing these polymers are presented in the table.

The glass transition point T_g of the polymers was determined by the dielectric method on a Tesla BM-560 coulometer at a frequency of 1 MHz at 293–573 K [8].

Thermal oxidation processes in air were studied by the ampule technique. The working volume of the ampules was 3×10^{-5} l. The initial oxygen content was, on the average, 2.5–3.0 mol O_2 per base mole of the polymer. The studies were carried out at 573–723 K [8]. The main characteristics of PArs and PASOAs are listed in the table.

Let us consider the parameters characterizing the polymer melt structure. Thermal oxidative degradation of PArs and PASOAs was studied at 573–723 K, and the glass transition points of these polymers lie within 463–491 K (see table). As known [9], the temperature of the so-called fluid 1–fluid 2 transition T_{II} can be estimated as

$$T_{II} = (1.20 \pm 0.05)T_g. \quad (1)$$

It follows from Eq. (1) and the table that $T > T_{II}$. At T_{II} the polymer melt transforms from "a fluid with a fixed structure" (exhibiting a residual structural ordering [9]) to a truly liquid state, or a "structureless fluid" [10]. However, the latter term means that the melt at $T > T_{II}$ exhibits no supramolecular structure, whereas the structure of the macromolecular coil in the melt is still an important structure factor (essentially, the only factor operating at $T > T_{II}$).

Polycondensation methods and main characteristics of the polymers

Polymer	Polycondensation method	T_g, K	$\overline{M}_w \times 10^{-3}$
PAr-1	Low-temperature	471	76
PAr-2	High-temperature	476	72
PAr-3	Phase-transfer	462	69
PASOA-1	Low-temperature	472	76
PASOA-2	High-temperature	474	64
PASOA-3	Phase-transfer	491	66
PASOA-4	Emulsion	489	58

The structure of supramolecular coil which is a fractal object [11] is most adequately described by its fractal ("Hausdorf") dimension Δ_f characterizing the spatial distribution of the coil elements [7]. The parameter Δ_f can be estimated as follows [12]. The formal kinetics of chemical reactions is described by the equation

$$dQ/dt = k_d(1 - Q). \quad (2)$$

Here, Q is the degree of conversion, t is the reaction time, and k_d is the reaction rate constant.

The general fractal relation which is also used for describing the kinetics of chemical reactions has the form [6]

$$Q \sim t^{(3 - \Delta_f)/2}. \quad (3)$$

By differentiating relation (3) with respect to the time t and equating the derivative dQ/dt to the analogous derivative in Eq. (2), we obtain [12]

$$t^{(\Delta_f - 1)/2} = \frac{C_1}{k_d(1 - Q)}. \quad (4)$$

Here, C_1 is the constant to be estimated from the boundary conditions [12]; the k_d values are taken from [8].

It was shown earlier [3] that the plots of $[N_{O_2}/(1 - K)]^{1/2}$ (N_{O_2} is the amount of the oxygen absorbed, and K is the degree of crystallinity) vs. the time t for polypropylene are straight lines. The parameter $(1 - K)$ determines the portion of the structure of crystalline-amorphous polypropylene which is the site of thermal oxidative degradation (amorphous phase). The structure of PAr and PASOA melts is characterized by the parameter Δ_f. As shown in [13], the processes occurring in fractal spaces (in fractal time) are described by the fractional differentiation and integration methods. In this case, the fractional exponent ν coincides with the fractal dimension of the Cantor set and characterizes the fraction of the states of the system retained within the evolution time t. It should be reminded that the Cantor set is considered in one-dimensional Euclidean space ($d = 1$), and for its fractal dimension holds $d_f < 1$ by definition of the fractal. For fractal objects in Euclidean spaces with higher dimensionalities ($d > 1$), one has to take as ν the fractional part of d_f (in our case, Δ_f):

$$\nu = \Delta_f - (d - 1). \quad (5)$$

Then the parameter ν will characterize the fraction of the fractal (macromolecular coil) preserved after

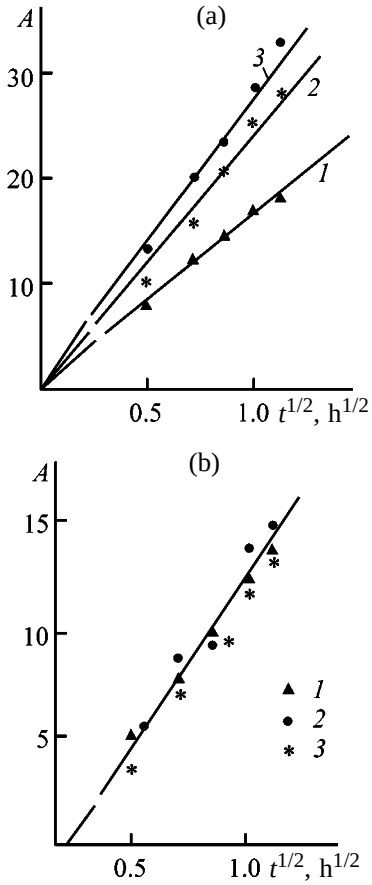

Fig. 1. Normalized amount of absorbed oxygen $N_{O_2}/(3 - \Delta_f)$ A, mole per base mole of polymer, as a function of the time $t^{1/2}$ for (a) PArs and (b) PASOA. Temperature, K: (a) (*1*) 623 (PAr-1), (*2*) 673 (PAr-3), and (*3*) 723 (PAr-3); (b) (*1*) 623 (PASOA-1), (*2*) 673 (PASOA-2), and (*3*) 723 (PASOA-3).

degradation. Evidently, the fraction of the macromolecular coil β breaking down in degradation is determined as

$$\beta = 1 - \nu = 1 - [\Delta_f - (d - 1)] = d - \Delta_f \quad (6)$$

or, taking into account that in this case $d = 3$, as

$$\beta = 3 - \Delta_f. \quad (7)$$

Thus, it should be presumed that specifically parameter β must be used for normalization of N_{O_2}, by analogy with the parameter $(1 - K)$ in the case of solid-phase crystalline-amorphous polymers. Figure 1 shows the plots of $N_{O_2}/(3 - \Delta_f)$ vs. t for PArs and PASOA. These plots can be linearized only with the parameter $t^{1/2}$ as abscissa. This means that the order of the chain termination reaction for PAr and PASOA melts is equal to 0.5. The slopes of the straight lines

in Fig. 1a differ because of different rate constants of the reaction [3].

The most important fact is that the plots shown in Figs. 1a and 1b were linearized using the fractal parameter $(3 - \Delta_f)$. This means that the fractal dimension Δ_f of the macromolecular coil is as unambiguous characteristic for a polymer melt structure as the degree of crystallinity for solid crystalline polymer [3].

The plots shown in Figs. 1a and 1b differ significantly in that the straight lines for PArs pass through the origin, while that for PASOA is shifted along the abscissa. Similar situation was observed in the case of atactic and isotactic polypropylene in [3]. The straight line for the latter is shifted by a certain time period t_0. This shift was explained by linear termination of the chain at the crystalline phase elements playing an important role in the very beginning of the reaction, when free radicals participating in the oxidation reaction are captured by crystalline formations containing no or insignificant amounts of oxygen. Too small, badly shaped crystallites cannot retain free radicals, but as their size and the degree of ordering increase they grow in importance as traps for free radicals. As a result, the oxygen absorption rate decreases and the induction period in the polymer oxidation increases [3]. For the polymers studied by us, this can be explained as follows. As shown in [14], PASOA exceeds PArs in the activation energy of thermal oxidative degradation for identical Δ_f's because of steric hindrances in the PASOA chain. These hindrances can be produced by various types of substituents, side branches, substituents in different positions (*para, ortho, meta*), etc. In this case, the degree of influence of this factor can be estimated using the Hammett's constant [15]. The sterically hindered moieties can serve as free radical traps, as in the case of polypropylene. This decreases the oxygen absorption rate and increases the induction period for oxidation of PAr and PASOA melts.

CONCLUSION

The parameter characterizing the structure of polymer melt is the fractal dimension of macromolecular coil. Sterically hindered moieties in the polymer chain can act as free radical traps, thereby exerting an effect similar to that of inhibitor.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Kinetics of Formation and Curing of Oligoether Urethane Allyl Ester

S. A. Kotel'nikov, V. S. Sukhinin, and A. S. Ermilov

Perm State Technical University, Perm, Russia

Received November 5, 2001

Abstract—Kinetic parameters of formation of P-9AD oligoether urethane allyl ester with terminal double bonds and of its curing with dinitrile oxide were determined. The dependence of the rate constant on the allyl alcohol concentration and temperature was studied. The mechanism of reaction of P-9A prepolymer with allyl alcohol was proposed. The kinetic and thermodynamic parameters of curing of oligoether urethane allyl ester with dinitrile oxide were determined. The mechanism of reaction of P-9AD oligoether urethane allyl ester with dinitrile oxide was proposed.

One of procedures for processing filled systems is cross-linking of oligomers via reactive terminal groups in the presence of active curing agents. To simplify the production process and to improve its efficiency and the quality of the product, low-temperature curing agents are developed. Among promising agents of low-temperature rubber curing are nitrile oxides. These agents accelerate polymer curing by a factor of 3–4 and decrease the curing temperature to 0–80°C [1]. Oligoether urethane esters derived from unsaturated alcohols can be cured at low temperatures with nitrile oxides. Although some properties of various unsaturated oligoether urethane esters are reported [2], the kinetics of their formation and curing was poorly studied. In this work we studied the kinetics of formation of P-9AD oligoether urethane ester (prepared from P-9A prepolymer and allyl alcohol) and its curing with dinitrile oxide.

EXPERIMENTAL

P-9AD oligoether urethane ester with terminal double bonds was prepared by reaction of P-9A prepolymer with allyl alcohol. The content of double bonds in the polymer is 3.3 wt %; the density at 25°C is 1.22 g cm^{-1}; the refractive index at 20°C is 1.5080. The kinetics of formation of P-9AD oligoether urethane ester (18–100°C) and of its curing (16–30°C) was monitored by variation with time of the optical density of the characteristic IR bands of the isocyanate groups –N=C=O at 2270 cm^{-1} and of the nitrile oxide groups –C≡N→O at 2290 cm^{-1}. The kinetic parameters of addition of allyl alcohol to P-9A prepolymer are presented in Table 1.

The activation energy (E = 59.1 kJ mol^{-1}) and preexponential factor of the Arrhenius equation (A = 6.09×10^5 l mol^{-1} s^{-1}) were calculated by the least-squares treatment of the data presented in Table 1. The activation enthalpy $\Delta H_0^{\neq}$ was calculated by the equation

$$\Delta H_0^{\neq} = E - RT, \quad (1)$$

where R is the universal gas constant, and T is the temperature, K; $\Delta H_0^{\neq}$ = 56.59 kJ mol^{-1}.

The activation entropy ΔS_0 calculated by the equation

$$\Delta S_0^{\neq} = R[\ln A - \ln(kT)/h - n] \quad (2)$$

(where k is Boltzmann's constant, h is Planck's constant, n is the reaction order) is –126.52 J mol^{-1} deg^{-1}.

Table 1. Kinetic parameters of addition of allyl alcohol to P-9A prepolymer

T, °C	K, l mol^{-1} s^{-1}	ln K
18	1.43×10^{-5}	–11.45
25	3.8×10^{-5}	–10.18
40	8.25×10^{-5}	–9.4
60	3.28×10^{-4}	–8.02
70	6.02×10^{-4}	–7.41
80	1.41×10^{-3}	–6.59
100	3.61×10^{-3}	–5.63

1070-4272/02/7503-0477$27.00 © 2002 MAIK "Nauka/Interperiodica"

Table 2. Dependence of the rate constant on the allyl alcohol concentration

[NCO]	[ROH]	K, l mol^{-1} s^{-1}	[ROH]/[NCO]
M			
1.5	0.94	6.97×10^{-6}	0.63
1.39	1.868	7.89×10^{-5}	1.34
1.35	2.23	1.59×10^{-4}	1.7
1.032	5.53	1.32×10^{-3}	5.16

The rate constant of the reaction of allyl alcohol with the prepolymer at 47°C increases with increasing allyl alcohol concentration, which is due to the catalytic influence of the alcohol (Table 2).

The reaction of allyl alcohol with the urethane prepolymer can be described by the equation [3]

$$RNCO + R'OH \xrightarrow{R'OH} [R-N=C(H-O-R')-O]$$

$$\rightarrow R-N(H-O-R')-C(H-O-R')-O \rightarrow RNHCOR' + R'OH,$$

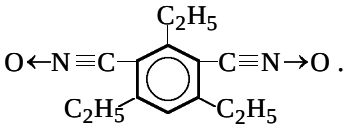
where R' = $-CH_2-CH=CH_2$.

We suggest that one isocyanate group reacts with two alcohol molecules, one of which is a catalyst. Up to the 75% conversion the dependence is linear, and then the reaction is accelerated, probably owing to catalysis by the urethane groups. The catalytic effect up to 75% conversion is weak, and the reaction is described by the second-order equation

$$-d[NCO]/d\tau = K[NCO]^2. \quad (3)$$

The activation energy E = 59.1 kJ mol^{-1} is slightly higher than that reported in [3] for the reaction of phenyl isocyanate with aliphatic alcohols, which may be due to the higher reactivity of these compounds. The high calculated activation entropy $\Delta S_0^{\neq}$ = –126.52 J mol^{-1} deg^{-1} suggests high ordering of the transition state, which confirms the proposed mechanism of reaction of allyl alcohol with the prepolymer.

P-9AD rubber was cured 3,4,6-triethylisophthalodinitrile di-*N*-oxide



The kinetics of curing in solvents with different dielectric constants was studied at the rubber : solvent volume ratio of 3 : 7. The activation energy and preexponential factor A were calculated by Arrhenius equation from data for two temperatures. The activation enthalpy and entropy (Table 3) were calculated by Eqs. (1) and (2), respectively.

As seen from Table 3, the rate of addition of nitrile oxide groups to the double bonds of the rubber is weakly dependent on the dielectric constant (polarity) of the solvent. This is typical for reactions of 1,3-dipolar cycloaddition [4] where the dipolarphile is the

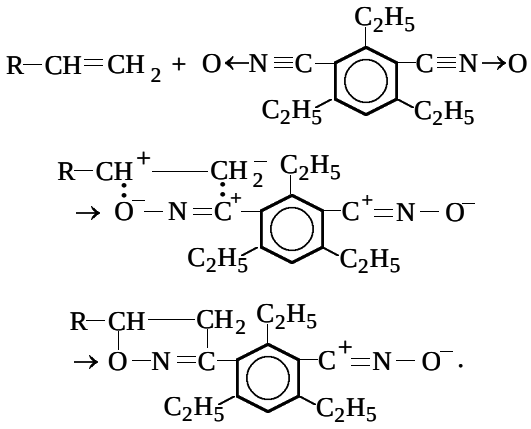
double bond of the rubber and the dipolar agents are the nitrile oxide groups of the curing agent. The negative entropy indicates high ordering of the transition state and concerted addition of nitrile oxide groups to the double bonds. The mechanism of this reaction can be described by the following scheme:



Reaction of P-9AD rubber with 3,4,6-triethylisophthalodinitrile di-*N*-oxide yields a five-membered isoxazoline ring.

CONCLUSIONS

(1) The rate of reaction of P-9A rubber with allyl alcohol at 18–100°C is described by the second-order equation. The acceleration of the reaction with increasing alcohol concentration is due to the catalytic effect of the alcohol.

(2) Reaction of P-9AD unsaturated rubber with 3,4,6-triethylisophthalodinitrile di-*N*-oxide is described by the second-order kinetic equation, with the rate constant being weakly dependent on the dielectric constant of the solvent.

(3) Reaction of P-9AD oligoether urethane ester with 3,4,6-triethylisophthalodinitrile di-*N*-oxide proceeds by the mechanism of concerted 1,3-dipolar cycloaddition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Vinyl Phenyl Ether and Its Use for Ammetric Titration of Silver(I)

S. E. Nurmanov, A. M. Gevorgyan, Sh. A. Matmuratov, O. Kasimova, T. S. Sirlibaev, and V. G. Kalyadin

National University of Uzbekistan, Tashkent, Uzbekistan

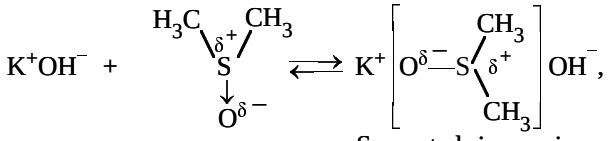
Received August 16, 2001

Abstract—Catalytic vinylation of phenol with acetylene at atmospheric pressure was studied. The yield of vinyl phenyl ether was determined as influenced by the solvent, reaction temperature, and catalyst amount. The mechanism of formation of vinyl phenyl ether was proposed. Ammetric titration of silver(I) with a solution of vinyl phenyl ether in nonaqueous acetic acid solutions was performed.

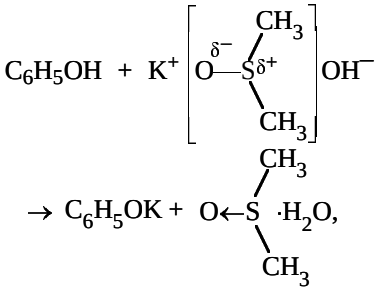
It is known [1, 2] that vinyl derivatives are widely used as monomers, cross-linking agents, pharmaceuticals, etc.. Among them vinyl ethers are the most used, since are synthesized from readily available reagents by simple procedures. Preparation of vinyl ethers by vinylation at atmospheric pressure was studied insufficiently.

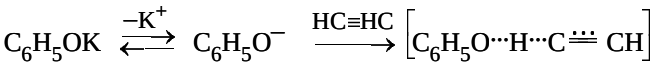
In this work we studied vinylation of phenol with acetylene at atmospheric pressure and different temperatures in different solvents in the presence of KOH as catalyst. This reaction was performed in benzene, water, and dimethyl sulfoxide (DMSO) (Table 1). In benzene, no vinyl phenyl ether (VPE) was formed, since this solvent is low-polar, has low boiling point, and does not dissolve the catalyst. In water, the VPE yield is low.

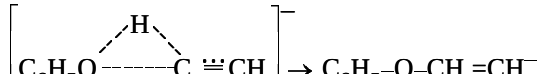
In DMSO, KOH–DMSO separated ion pairs are formed, which increases the basicity of the solvent. Phenol transforms into readily dissociating potassium phenolate, which promotes vinylation.



Separated ion pair







Thus, the VPE yield increases with increase in the dielectric constant and basicity of the solvent.

Since the solubility of gases in liquids decreases with increasing temperature, we studied the temperature dependence of the VPE yield in the presence of various amounts of KOH (3–15 wt % relative to phenol) (Table 2).

As seen from Table 2, no VPE is formed at temperatures below 75°C. At 95–100°C the yield is 17–19%, and at 145–150°C it reaches a maximum of 25–32%.

The structure of VPE was confirmed by IR spectroscopy and by its physicochemical parameters which coincided with the published values.

Thus, synthesis of PVE at atmospheric pressure

Table 1. Yield of VPE as influenced by the solvent (KOH catalyst : phenol weight ratio 0.1)

Solvent	*T*, °C	VPE yield, %
Benzene	76–79	–
H_2O	95–100	Traces
DMSO	95–100	17–19

1070-4272/02/7503-0480$27.00 © 2002 MAIK "Nauka/Interperiodica"

should be performed in DMSO at 145–150°C and the catalyst (KOH) : phenol weight ratio of 0.15.

Vinyl ethers are widely used as biologically active compounds in various branches of science, medicine, and agriculture [3]. However, no data are reported on analytical application of VPE. Its analogs are used as analytical reagents [4]; in this connection, we tested VPE as a titrating agent for determining various metal ions in nonaqueous and mixed solvents. For this purpose, we determined electrochemical properties of VPE.

Previously we found [5] that metal cations can be selectively titrated with VPE solutions in glacial acetic acid and its mixtures with various inert nonaqueous solvents (chloroform, tetrachloromethane, hexane, benzene, dioxane, methyl ethyl ketone, heptane, etc.). The equivalence point (EP) was determined ammetrically with a platinum working electrode.

This procedures can be used for determining metal ions in extracts formed in analysis of multicomponent inorganic materials and in organic materials readily soluble in nonaqueous and mixed solvents.

Preliminary experiments on titration of silver(I), mercury(II), palladium(II), platinum(IV), and other metals with VPE solutions in glacial acetic acid and its mixtures with inert solvents [6, 7] confirmed our assumptions about the shape of the titration curves and the accuracy of the analysis. Complexes of these metals with VPE are sufficiently soluble in nonaqueous and mixed solvents. In all cases the EP determined by extrapolation of the straight line sections of the titration curves to their intersection corresponds to formation of 1 : 1 and 2 : 1 complexes of the titrating agent with monovalent and bivalent metal cations, respectively. This was also confirmed by electrochemical and optical methods and by NMR spectroscopy [8].

To determine Ag^+ in the presence of large amounts of elements interfering with its determination and usually present in tested minerals, jewelries, alloys, and other objects, we proposed a procedure based on extractive separation of Ag^+ ions with subsequent ammetric titration of these anions in the extract with VPE.

An aliquot of a test solution containing no more than 200 mmol of Ag(I) was placed in a separatory funnel and acidified with $HClO_4$ and HCl to the concentration of about 0.2 M. A 0.1 M solution of ethylenediaminetetraacetic acid disodium salt (5 ml) and 1% solution of Thionalide (thioglycolic acid β-naphthylamide) were added. The resulting solution was stirred for 10 min and then silver(I) was extracted for 1–2 min with two 5-ml portions of chloroform [9]. To the combined extract placed in a titration vessel, glacial acetic acid (5 ml) was added. The solution was heated to boil and Thionalidate silver complex was decomposed by adding a saturated solution (30–40 drops) of potassium permanganate or chromium trioxide in glacial acetic acid until the solution became yellow–brown. Then 0.2 M solution (5 ml) of lithium chloride or lithium perchlorate in glacial acetic acid was added. The mixture was heated for several minutes to reduce completely colloidal manganese dioxide to Mn(II) [or Cr(IV) to Cr(III)] and Ag(I) to Ag(0), which was judged by decolorization of the solution. The solution was cooled to room temperature and was ammetrically titrated by the procedure in [6] with a standard (c = 0.0001–0.002 M) VPE solution using two platinum working electrodes.

Table 2. Yield of vinyl phenyl ether in DMSO as influenced by temperature and catalyst amount

c_{KOH}, wt % relative to phenol	T, °C	VPE yield, %
10	75–80	Traces
10	95–100	17–19
10	120–125	23
10	145–150	31
10	155–160	26
3	145–150	9
5	145–150	25
15	145–150	32

The results of silver(I) determination in five different artificial mixtures simulating natural and industrial objects are presented in Table 3. Statistical treatment of these data [10] shows that the procedure proposed allows reliable and selective determination of silver with a high accuracy.

CONCLUSIONS

(1) The best conditions (15% KOH, DMSO, 145–150°C) for preparing vinyl phenyl ether by reaction of phenol with acetylene at atmospheric pressure were determined.

(2) A procedure was developed for determining Ag^+ in systems simulating real objects by ammetric titration with a solution of vinyl phenyl ether in nonaqueous and mixed solvents.

Abstract—Reactions of dextran polyaldehyde with carboxylic and sulfonic acid amides were suggested for modification of polysaccharides with low-molecular-weight compounds. The influence of reaction conditions on the content of fragments incorporated into the polymer was examined.

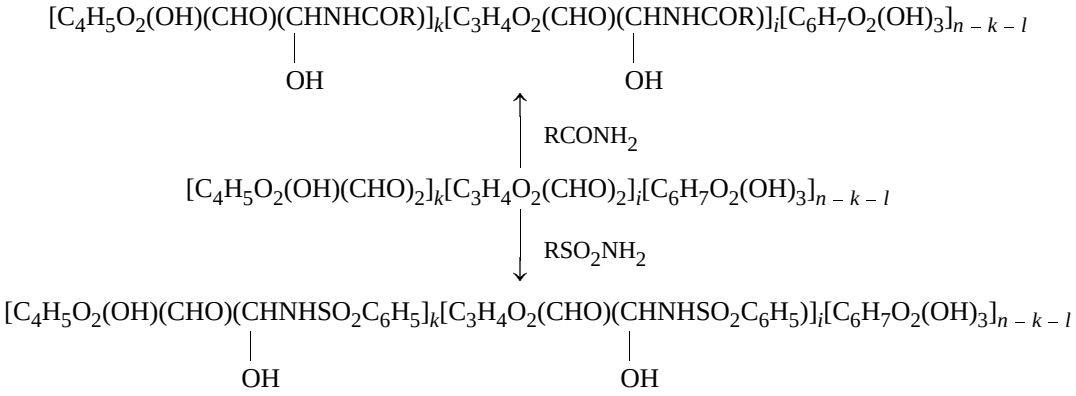
The majority of aliphatic and all aromatic aldehydes react with amides to form alkylidene- or arylidenebisamides. With diamides of oxalic, malonic, and alkylmalonic acids, cyclic bisamide derivatives are formed. With sulfamides, aldehydes react difficultly to give bisamides [1].

Reactions of polysaccharide polyaldehydes with carboxylic and sulfonic acid amides were not studied previously. Such reactions are of interest as routes to physiologically active polymers, in view of the fact that many biologically active substances are amides, and their conversion to polymeric derivatives would prolong their effect and decrease the toxicity. Therefore, it was interesting to study the reactions of polysaccharide polyaldehydes (with dextran polyaldehyde, DPA, as example) and carboxylic and sulfonic acid amides.

DPA was prepared by a common procedure of polysaccharide oxidation [2], so as to minimize formation of by-products. The oxidant consumption was monitored spectrophotometrically at 222.5 nm [2], and the amount of the released formic acid was determined by volumetric titration. After reaction completion, the mixture was concentrated in a water-jet-pump vacuum at 60°C, dialyzed against water to remove low-molecular-weight reaction products, and again concentrated in a vacuum; the product was precipitated with ethanol. The resulting DPA was a white amorphous powder soluble in water and insoluble in alcohol, acetone, ether, and other organic solvents.

The content of aldehyde groups in DPA was determined by photocolorimetric [3] and oxime [4] methods. The degree of substitution C_{sa} (the number of aldehyde groups in polysaccharide aldehyde per monosaccharide unit) of the DPA samples used in this work varied from 0.73 to 1.1.

Chemical modification of DPA was performed as follows:



where R = CH_3–, $C_6H_5CH_2$–, and C_5H_4N–.

Table 2. Degree of conversion of aldehyde groups C_{ca} in reaction of DPA with acetamide in aqueous solution, as influenced by temperature, time, and reactant ratio

Run no.	T, °C	τ, h	Molar ratio of amide to aldehyde groups	C_{ca}, %
1	90	2	5	6
2	90	3	5	9
3	90	4	5	13
4	90	6	5	20
5	90	10	5	24
6	40	4	5	1
7	60	4	5	2
8	80	4	5	9
9	90	4	5	13
10	100	4	5	24
11	90	6	2	11
12	90	6	3	13
13	90	6	5	19
14	90	6	7	30
15	90	6	10	38

The reactions of DPA with amides were performed in aqueous solution at 40 to 90°C for 1 to 10 h; the molar ratio of amide to aldehyde groups was varied from 2 to 10. After reaction completion, the products were precipitated with ethanol, filtered off, washed with ethanol and ether, and dried in a water-jet-pump vacuum at 60°C for 2 h. The resulting compounds are beige amorphous powders soluble in water and insoluble in alcohol, acetone, and ether.

The absence of the initial amide in the target product was confirmed by TLC.

The reaction products were studied by elemental analysis, conductometric titration, and IR and UV spectroscopy.

The IR spectra of the products contained absorption bands at 1660 cm^{-1}, lacking in the spectra of the initial amides and assignable to the C=O stretching vibrations in the amide group, and at 1570 cm^{-1}, characteristic of the NH bending vibrations in the amide group.

The products of reaction of DPA with benzenesulfamide were examined by elemental analysis and conductometric back-titration of amide NH groups. As seen from Table 1, the results obtained by both methods are quite consistent.

The reaction products were characterized by the degree of substitution C_s (number of low-molecular-weight fragments per monosaccharide unit). The reaction of DPA with amide was characterized by the degree of conversion of aldehyde groups C_{ca} (%), calculated as

$$C_{ca} = (C_s/C_{sa}) \times 100.$$

To determine the best conditions for the reactions of polysaccharides with carboxylic acid amides, we studied how C_{ca} depends on the reaction temperature, time, reactant ratio, and solvent, with acetamide as example. The results are listed in Table 2.

We found that the content of acetamide fragments in the polysaccharide aldehyde sharply increased as the reaction temperature was increased (run nos. 6–10). Therefore, the subsequent experiments were performed at 90°C. The reaction was virtually complete in 6 h (run nos. 1–5). As expected, C_{ca} increased with increasing amide-to-aldehyde molar ratio (run nos. 11–15) and reactant concentrations. However, too large excess of the amide is not appropriate, because its solubility in water is limited. Therefore, in the subsequent experiments we took the amide in a five-fold excess, and the concentration of aldehyde groups was approximately 1 M. When the reaction was performed in ethanol, the conversion decreased from 13 to 5%, because DPA is insoluble in ethanol and therefore the reaction was heterogeneous.

Thus, we chose the following conditions for the reactions of DPA with carboxylic and sulfonic acid amides: aqueous solution, 90°C, 6 h, and molar ratio of amide to aldehyde groups 5 : 1. Under these conditions, we performed the reactions of DPA with amides of acetic, phenylacetic, nicotinic, and thioacetic acids, acetanilide, phthalimide, and benzenesulfamide. This set of compounds includes primary and secondary amides of aliphatic and heterocyclic carboxylic acids, an imide, and a sulfonic acid amide. The degrees of conversion of aldehyde groups C_{ca} in the reactions of DPA with amides are listed below (90°C, 6 h, molar

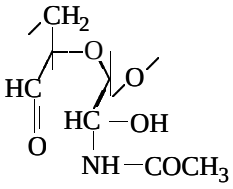
ratio of amide to aldehyde groups 5 : 1):

Compound	C_{ca}, %
Acetamide (CH_3CONH_2)	19 ± 1
Phenylacetamide ($C_6H_5CH_2CONH_2$)	22 ± 0.5
Thioacetamide (CH_3CSNH_2)	25 ± 1
Nicotinamide ($C_5H_4NCONH_2$)	14 ± 0.5
Benzenesulfamide ($C_6H_5SO_2NH_2$)	25 ± 2
Phthalimide [$C_6H_4(CO)_2NH$]	7 ± 0.5
Acetanilide ($CH_3CONHC_6H_5$)	0

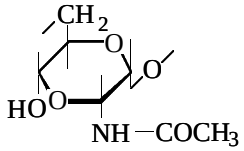
These results show that all the unsubstituted amides of monobasic acids, tested in this work, react with DPA to a similar extent, whereas the secondary amide (acetanilide) does not react with DPA. The low C_{ca} in the reaction of DPA with phthalimide is probably due to the low solubility of the imide in water.

To evaluate the lability of the bond between DPA and the amide fragment, we studied the hydrolytic stability of the acetamide and benzenesulfamide derivatives of DPA in strongly alkaline (pH 13.6) solutions at 18–20°C. We found that about 40% of amide fragments are eliminated in 4 days, and about 90%, in 7 days.

To obtain information on the product structure, we determined by the oxime procedure the content of aldehyde groups that remained unchanged in the reactions with acetamide and benzenesulfamide. We found that, on the average, two aldehyde groups are converted per mole of incorporated amide. These results, in combination with the IR and conductometric titration (for benzenesulfamide) data, suggest formation of a stable six-membered ring (structure **II**):



I



II

CONCLUSION

Polysaccharide aldehydes react with amides of aliphatic and heterocyclic carboxylic, thiocarboxylic, and sulfonic acids. The highest conversion of aldehyde groups in reactions of dextran polyaldehyde with unsubstituted carboxylic acid amides is attained in aqueous solution at 90°C, reaction time of 6 h, and molar ratio of amide to aldehyde groups of 5 : 1.

Abstract—The contribution of diffusion and transformation of macromolecules to the mechanism of delignification of cell wall in sulfite cooking of spruce wood was quantitatively estimated from variation of the parameters of the Kolmogorov–Erofeev–Avrami equation and hydrodynamic radii of lignosulfonate macromolecules found in the cooking liquor.

In topochemistry of sulfite cooking, it is assumed that an increase in the molecular size and the size of network fragments of lignin in the form of lignosulfonates diffusing into cooking liquor is caused by their sifting through capillaries with increasing sizes in the cellular structure of wood substance. However, actually the pore size was measured after delignification was stopped and wood residue was removed from the autoclave. In this case, the capillary size could be altered as a result of probable relaxation processes occurring after cooking, and also during experimental determination of the capillary volumes by standard procedures.

Spruce wood consists to 95% of long tubular cells (tracheids). The wall thickness in these cells is in the range of $(0.5–4.0) \times 10^{-6}$ m; therefore, the wall and wood as a whole can be considered as a membrane. In terms of its structure, the cell wall presents a layered porous membrane consisting of cellulose fibrils immersed in a lignocarbohydrate matrix subjected to various phase transitions with possible formation and destruction of interpenetrating physicochemical networks (bonds) in solid solutions (gels) in various stages of sulfite cooking [2–4]. Here, the main topochemical processes occurring initially in cooking and completed by formation of soluble lignosulfonates are followed by diffusion transfer of lignosulfonates predominantly in the transverse direction from the central plate into the cell body. For simplicity sake it can be assumed that the driving force of this process is the gradient of lignin concentration in various layers of the cell wall membrane and at its surface facing to the cooking liquor and in the cell capillaries. Therefore, the process kinetics can be described by the Fick diffusion model [5, 6].

Here we report the principle and procedure and analyze the results of quantitative estimation of the contribution of diffusion and relaxation processes in a cell wall in the topochemical stage, made directly in cooking without removal of wood residue from the autoclave. Our procedure involves comparing the variation of the topokinetic equation parameters of delignification and determining the hydrodynamic radii and transformations of lignosulfonate molecules in solutions during sulfite cooking of spruce wood.

EXPERIMENTAL

Delignification was studied by a conventional procedure of wood residue sampling at successive stages of the process. Spruce chips 2–3 mm thick were cooked using three process modes with the acid containing in total 7 wt % SO_2 and 1.1 wt % base (recalculated to Na_2O). In modes I and II, the temperature–time schedule was standard. Mode II differed from mode I in that samples of alkali liquors were taken at each stage with addition of the equal volume of fresh cooking acid to continue the process in subsequent stages. The temperature schedule was as follows: heating to 105°C for 60 min, keeping at 105°C for 90 min (stage 1); heating to 140°C for 90 min (stage 2); keeping at 140°C for 60 min (stage 3), 120 min (stage 4), and 180 min (stage 5). Mode III was based on mode II and differed from the latter in

1070-4272/02/7503-0486$27.00 © 2002 MAIK "Nauka/Interperiodica"

that after sampling of liquors the wood residue (without washing) was poured over with fresh acid and the successive stage of cooking was carried out until the process completion. The prescribed time and temperature were followed with an accuracy of ±1 min and ±1°C, respectively. The yield and content of lignin were determined by the standard procedures [7].

The kinetic curves of delignification in the coordinates α–τ are shown in the figure.

The kinetic constants were evaluated by the Kolmogorov–Erofeev–Avrami equation reflecting the topochemical nature and nonstationary course of the processes:

$$1 - \alpha = \exp(-kt^n), \quad (1)$$

where α is the fraction of lignosulfonates diffusing from the cell wall into cooking liquor; k is the rate constant of multistage topochemical delignification; t is the process time expressed in minutes as conventionally accepted in the delignification kinetics; and n is a parameter indicating variation of the rate constant of a nonstationary process.

By taking the logarithm, the equation is brought to a linear form:

$$\ln(1 - \alpha) = -kt^n, \quad \ln[-\ln(1 - \alpha)] = \ln k + n\ln t,$$

$$\ln\ln[1/(1 - \alpha)] = \ln k + n\ln t.$$

For practical calculations and plotting, it is preferable to use the logarithms to the base 10 rather than e:

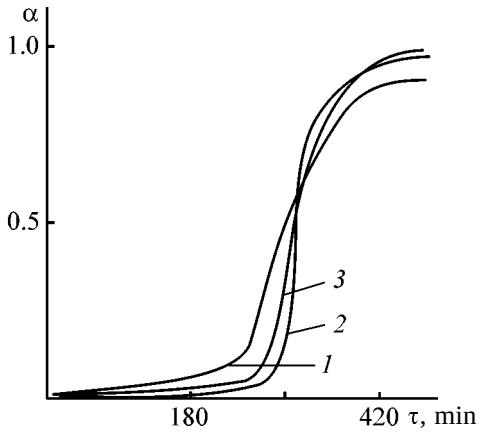
$$\log\log[1/(1 - \alpha)] = \log[-(1 - \alpha)]$$

$$= \log K + n\log t + \log\log e. \quad (2)$$

The latter term in Eq. (2), being small (–0.3623), is usually neglected.

At $\log t \to 0$ $\log K = \log K_0$ (this value is graphically determined by the portion intercepted on the ordinate at $\log t = 0$). The parameter K evaluated by this equation is the effective constant expressed in logarithms to the base 0 and in logarithmic coordinates of the Kolmogorov–Erofeev equation.

The advantage of this topokinetic equation is the possibility of describing the nonstationary delignification in the portion before and after the maximum rate by experimental determination of only one quantity, the residual content of lignin in the wood residue or of lignosulfonates in the cooking liquor. The linear feature of the equation in the logarithmic form allows us



Kinetic curves of delignification: (α) fraction of dissolved lignosulfonates and (τ) time. Cooking mode: (*1*) I, (*2*) II, and (*3*) III.

to find and select graphically the isokinetic linear portions with constant n and $\log K_0$ by the least-squares technique. In this case, it should be noted that K_0 can also be considered as a constant characterizing the relaxation state of the cell wall. The relation of the parameters of the topokinetic equation to the delignification mechanism was estimated from the well-known selection rules for information in topokinetic studies by the Kolmogorov–Erofeev–Avrami equation [8, 9], considering the mechanism of sulfite cooking of cellulose from spruce chips.

A remakable feature of the Kolmogorov–Erofeev–Avrami equation is the possibility of using it for description of the relaxation states of a polymer system [10] at varied process temperature and time. Any such variation of the system characteristics involves certain structural rearrangements depending not only on the temperature and time, but also on the rate of temperature variation in each specific temperature–time schedule.

The parameters n and $\log K_0$ of the logarithmic equation reflect the lifetime of a certain structure of the relaxing polymer system of a wood cell wall. Under the assumption that polymers of cellulose fibers are frozen in delignification processes at commonly used temperatures of cooking, the parameters n and $\log K_0$ characterize the state of the lignocarbohydrate matrix of cell wall. The delignification process is characterized quantitatively by the same constants. Variations of the molecular-weight characteristics of lignin in the process furnish quantitative information on variation of the pore structure of a relaxing cell wall without recovery of wood residue from the cooking liquor.

4	0.0	0.05	0.05–0.40	0.40–0.55	0.55–1.0

The results of calculations from the experimental data are presented in Table 1.

The hydrodymanic radii of lignosulfonate macromolecules R_h were determined by the laser correlation spectroscopy directly in cooking liquor. The procedure is based on the measurement of the halfwidth of the light scattering spectrum of laser beam from lignin macromolecules in dilute solutions and calculation from these data of the translation diffusion coefficient D and R_h by the well-known Einstein–Stokes formula [11, 12].

The molecular radii of lignosulfonates were measured in samples of the first liquor withdrawn 150 min, the second liquor, 240 min, the third liquor, 360 min, and the fifth liquor, 420 min after the beginning of cooking.

To evaluate the retention coefficient $\varphi(R_{hi})$, the liquor withdrawn in the final, fifth stage of cooking, containing the total set of sizes R_{hi}, was selected as a calibrating mixture. The calculation was carried out by the formula

$$\varphi(R_{hi}) = 1 - [\psi(R_{hi})/f(R_{hi5})] \quad (i = 1, 2, 3\ldots),$$

where $\varphi(R_{hi})$ is the retention coefficient of lignosulfonates with the radius R_{hi}; $\psi(R_{hi})$ is the fraction of the ith interval of radii of lignosulfonate molecules in first–fourth liquors; $f(R_{hi5})$ is the fraction of ith interval of radii of lignosulfonate molecules in the fifth liquor; and i is the number of intervals used for calculation of the retention coefficients.

The calculation results are presented in Table 2.

Variations of the average molecular weights M_w, hydrodynamic radii R_{hi}, the ratio R_{hi}/M_w reflecting branching of molecues in relation to the degree of delignification α, and the fraction of capillaries with the known interval of radii in the wood residue (from published data [1]) are listed in Table 3. The molecular weights M_w were determined on a centrifuge by the nonestablished equilibrium technique [13].

The kinetic curves of delignification in the coordinates α–τ (see figure), evaluated from the results of cooking in mode I (curve *1*) commonly used in industry, are compared with those for mode II, differing in addition of a new portion of fresh acid in each stage (curve *2*), and for mode III differing from cooking in mode II in that in each subsequent stage cooking is performed with the wood residue after cooking in mode II (curve *3*). In view of essential differences in the times and conditions of pretreatment, curves *2* and *3* are brought into coincidence for comparison in the inflection point $\alpha = 0.55$ corresponding to 315 min on the time axis of curve *1*. This procedure allowed us to determine already from the shapes of the primary kinetic curves that in cooking with sampling of liquors and addition of acid (modes II and III) delignification is significantly accelerated and occurs to a greater extent, and the highest rate of the process

Table 3. Characteristics of wood residue and macromolecules in cooking liquor

Stage of cooking	Wood residue				Lignosulfonates		
	yield, %	α	capillaries		$M_w \times 10^{-3}$	R_h, nm	$R_h/M_w \times 10^{-6}$
			radius, nm	% of the total amount			
1	87.7	0.02	1.8–2.4	40	10	2.2	2.2
2	64.2	0.105	1.8–6.0	45	15	2.4	1.6
3	58.9	0.54	2.2–8.0	53	26	3.4	1.3
4	52.6	0.85	2.2–8.0	67	35	4.2	1.2
5	42.5	0.98	2.2–8.0	70	55	4.4	0.8

is observed at $\alpha = 0.55$. This is characteristic of the rate of topochemical processes in solids and hence can be evidence of the topochemical nature of sulfite delignification of the polymeric lignocarbohydrate matrix of cell walls relaxing under conditions predetermined by the temperature–time schedule.

A quantitative distinction in the delignification mechanisms, caused by different sequence and duration of stages 1–3 of cooking in modes II and III, is governed by the numerical values of n and $\log K_0$ (Table 1). It is evident that the process can be divided in three stages: initial (n_1 = 0.75–1.20), active (n_2 = 2.40–5.76), and final (n_3 = 1.27–1.84). In the case of cooking in mode I (without stopping the process and adding fresh acid) all the stages are characterized by smaller numerical differences in the constants $-\log K_0$ and n. According to interpretation of parameters in topokinetic equations [7, 8] and well-known concepts of the delignification mechanism in sulfite cooking, low numerical values of n and $-\log K_0$ in the beginning (60–260 min) and in the end of dlignification (370–420 min) can be assigned to the diffusion mode of the process. The active stage of delignification in mode I at n = 2.40 and $-\log K_0$ = 6.80 substantially differs from those in modes II and III, characterized by n = 5.76–5.35 and $-\log K_0$ = 15.57 and 12.61. These significant differences suggest stronger effect of chemical processes in successive stages of delignification in modes II and III. As seen from comparison of the constants for successive stages of cooking in modes I–III, the relaxation states of the cell system in the active stage of delignification vary significantly. This is caused by differences in the stage-by-stage treatment of the wood residue removed from autoclaves, and hence in the relaxation states of lignocarbohydrate matrix of cell walls. As a result, the process should be considered in terms of molecular relaxation constants and chemical kinetics of delignification.

The effect of changes in pore structure of cell walls as a result of hydrolytic and delignification processes in the lignocarbohydrate matrix on the delignification mechanism in successive sulfite cooking of spruce chips can be estimated by comparing the retention coefficients (Table 2), charactersistics of lignosulfonate macromolecules in solutions, and sizes of capillary pores in wood residue in relation to the degree of delignification (Table 3).

Table 2 shows that at complete retention of macromolecules with the radius greater than 1.5 nm in the first stage of cooking, with increasing extent of delignification (stages 2–4) the retention coefficients of lignosulfonates φ_i gradually decrease for macromolecules with large hydrodynamic radii R_{hi}, up to 7 nm. Macromolecules with the radius greater than 8 nm are completely retained by cell walls in all the stages of cooking. Therefore, it can be concluded that, in the course of structural transformations in the matrix, pores with the size larger than 8 nm were absent or were not formed. In the first stage, retention of macromolecules is apparently caused by plugging or absence of pores in the nondegraded lignocarbohydrate gel in the wood residue. As a result, only low-molecular-weight lignosulfonates can pass into the cooking liquor by the mechanism of molecular diffusion [5, 6]. In stages 2–4, φ_i of molecules with the larger size significantly decreases, and only macromolecules with the radius greater than 8 nm are completely retained. This trend in variation of the sizes of coarse capillaries of the wood residue in particular stages of cooking [1], corresponding to variation of the retention coefficients of lignosulfonates depending on the average hydrodynamic radii R_h, is also followed in variation of the average molecular weight M_w and branching index R_h/M_w of lignosulfonate macromolecules detected in solutions (Table 3).

It was shown previously [5] that macromolecules

of lignosulfonates are separated by ultrafiltration with a synthetic membrane owing to their interaction with the membrane and formation of a gel layer at its surface and in capillaries, and the process itself proceeds in the mode of pre-gel polarization and is characterized by plugging of pores and operation of the molecular-diffusion mechanism of lignosulfonate transfer.

Comparison of data listed in Tables 2 and 3 and topokinetic parameters of delignification (Table 1) gives ground to the statement that, in the first stage of delignification, the process is diffusion-controlled owing to formation of a soft lignosulfonate gel and intramembrane deceleration of lignosulfonate molecules with $M_w < 10^3$, even the least branched (2.2×10^{-6}), and in the final stage it is also diffusion-controlled owing to thin cross-linking and formation of a macromolecular fraction of lignosulfonates with $M_w > 55 \times 10^3$ with the greatest branching (0.8×10^{-6}). It is possible that in the final stage a more rigid lignocarbohydrate gel is formed as a result of thin chemical cross-linking.

The relaxation state of the cellulose component of the cell wall membrane in all the stages does not govern the delignification mechanism in sulfite cooking of cellulose in the ranges of temperature–time schedules with heating and impregnation at 105°C. The delignification rate in this process is governed by modification of characteristics and degradation of the bond network of the lignocarbohydrate matrix relaxing in the process.

CONCLUSION

Variation of the parameters of the Kolmogorov–Erofeev–Avrami topokintic equation, hydrodynamic radii, and coefficients of retention and transformation of macromolecules can be used for quantitative estimation of the contribution of diffusion and mass-transfer to the mechanism of delignification and variation of the porosity of the relaxing matrix of cell walls in sulfite cooking of cellulose produced from spruce chips.

Abstract—The influence of temperature (75–100°C), ammonia concentration in solution (1–5%), and oxygen pressure (1–8 MPa) on the yield of the target product (insoluble residue) and nitrogen content in this product in treatment of pine bark with oxygen in aqueous ammonia (oxidative ammonolysis) was studied. The resulting samples were tested in agriculture as nitrogen-containing fertilizers.

In wood felling and processing, large amounts of bark wastes are formed, which are not yet properly utilized. The promising line of utilization of these wastes is their use as fertilizers. The process of production of fertilizers from bark, consisting of composting of the substrate with preliminary addition of nutrients, was considered in detail [1, 2]. The grave drawback of composting is that it is time- (1–4 months) and labor-consuming [2]. The process including treatment of raw materials with oxygen in aqueous ammonia (oxidative ammonolysis) was also proposed for production of nitrogen-containing fertilizers from bark [3]. However, oxidative ammonolysis of bark practically was not studied. In addition, data on the effect of the resulting fertilizer on plants are lacking.

The goal of this work was to study the influence of the process conditions on the yield and characteristics of a nitrogen-containing fertilizer produced from bark by oxidative ammonolysis (oxyammonolysis).

EXPERIMENTAL

The surface part of pine bark (*Pinus Sylvestris*) milled to a fraction of less than 5 mm was used as raw material. The target product of oxidative ammonolysis was the residue insoluble in the reaction medium and presenting a complex of partially oxidized macromolecular components of bark incorporating nitrogen-containing functional groups. The nitrogen content in the product was determined by the Kjeldahl method. The nitrogen content in the initial bark was 0.33%. Two series of the experiments were carried out. In series A, 50 g of bark and 500 ml of aqueous ammonia were placed in a flat-bottomed flask equipped with a reflux condenser, a bubbler, and thermometer. Air was bubbled through the reaction mixture at a flow rate of approximately 20 l h^{-1}. The flask was heated over a period of 1 h to 90 ± 1°C, and this temperature was maintained for 2 h. After completion of the process, the flask was cooled and the reaction mixture was filtered. The residue on the filter was washed with water to neutral reaction, dried at 100°C, and the product yield was determined.

In series B, the experiments were carried out in a rocking (53 s^{-1}) 1-l autoclave equipped with a pressure gage and a thermometer. A 50-g portion of bark and 500 ml of aqueous ammonia were placed into the autoclave, and, after its sealing, oxygen was fed. The autoclave was placed in a heater, stirring was started, and the autoclave was heated to a given temperature. In all runs the process duration was 3 h including the time of reaching the required temperature (1 h). After the process completion, the autoclave was cooled with water and the product was recovered by the same manner as in series A.

The plants were grown in 500 cm^3 vessels. Three tests were performed for each set of conditions. Soddy weakly podzolic medium-loamy soil with a humus content of 2.1–2.5% and pH 5.6–5.9 was used. The content of mobile compounds of phosphorus and potassium was 0.10 g P_2O_5 and 0.10 g K_2O per 1 kg of soil. The efficiency of the samples was determined from the amount of the resulting ground biomass. For monitoring we used (a) fertilizer-free soil and (b) soil with mineral fertilizers (ammonium nitrate, double superphosphate, and potassium sulfate): 0.15 g N, 0.10 g P_2O_5, and 0.10 g K_2O per 1 kg of soil. The samples of series A were tested in growing of corn (three plants per vessel). The samples were taken in the amount corresponding to 0.15 g N per 1 kg of

5A	5.5 ± 0.3	126.5

soil. The samples of series B were tested in growing of multimowing rye grass (*Lolium multiflorum*). The following amounts of the samples were used: B_1, 0.15 g N per 1 kg of soil; B_2, 0.30 g N per 1 kg of soil. The productivity was considered from three mowings.

In the first series of the experiments (series A), we examined the influence of the ammonia concentration on the characteristics of the resulting product. Table 1 shows that with increasing concentration of ammonia in solution the yield of the product (insoluble residue) decreases; in parallel, the nitrogen content in the product increases. One run was performed with addition of copper chloride $CuCl_2$. We used copper salt because of the fact that, as found in [4], addition of copper ions to the reaction mixture in oxyammonolysis of lignin results in increased nitrogen content in the product. It was assumed that in oxyammonolysis of pine bark, having fairly high content of lignin and other phenolic compounds [5], addition of copper chloride will result in increased nitrogen content in the product as well. However, Table 1 shows that copper(II) ions did not noticeably affect the yield of insoluble residue and the nitrogen content in this residue. Apparently, nitrogen-containing substances formed in this case have relatively low molecular weight and therefore are readily soluble in the reaction mixture.

In series B, we examined the influence of the process temperature and oxygen pressure on the product characteristics. Oxidative ammonolysis was carried out in a rocking autoclave, in which oxygen was fed to a certain pressure before the run. To prevent fast development of deep oxidation of the substrate, oxygen was taken in relatively low amounts. Table 2 shows that with increasing temperature from 75 to 81°C the product yield significantly decreases. This may be due to the presence of large amounts of alkali-soluble substances in the bark [5], which pass into aqueous-ammonia solutions under conditions of oxidative ammonolysis. With increase in temperature, the nitrogen content in the insoluble residue increases. With further increase in temperature, the yield of the product and the nitrogen content in the product do not vary noticeably, which is apparently caused by small amount of oxygen (1.5 wt % relative to the initial raw material) fed into the system and hence by a low extent of oxidation. Attention is drawn to the fact that in the runs of series B the yield of the insoluble residue is noticeably lower than the yield of the products obtained in series A. This distinction may be due to lower concentration of ammonia in the reaction mixture in series A, as a result of ammonia removal with the air flow in the runs of series A, which decreases the ammonia concentration in the solution by more than 30%.

An increase in the oxygen pressure from 0.1 to 0.5 MPa increases the product yield and the nitrogen content in the product (Table 3).

Table 5. Effect of nitrogen-containing fertilizers on the productivity of multimowing rye grass

Fertilizer	Weight of dry substance, g				Increase, %
	1st mowing	2nd mowing	3rd mowing	total	
None	1.09	0.56	0.10	1.75	
$N_{0.15}P_{0.10}K_{0.10}$	1.63	0.89	0.26	2.78	58.9
Initial bark	–	0.36	1.02	1.38	–21.2
$1B_1$	1.17	0.61	0.26	2.04	16.6
$3B_1$	1.11	0.77	0.25	2.13	21.7
$4B_1$	1.22	0.65	0.22	2.09	19.4
$5B_1$	1.32	0.77	0.26	2.35	34.3
$N_{0.30}P_{0.10}K_{0.10}$	2.43	1.32	0.32	4.07	132.6
$1B_2$	1.38	0.85	0.24	2.47	41.2
$4B_2$	1.51	0.76	0.27	2.54	45.2
$5B_2$	1.76	1.05	0.18	2.99	70.9

The results obtained can be explained by an increase in the amount of quinone structures formed from phenols, whose reactions with ammonia cause accumulation of nitrogen-containing functional groups apparently participating in condensation reactions and forming macromolecular products insoluble in the reaction medium. However, with increasing oxygen pressure to 0.8 MPa the yield of the insoluble residue decreases. This is apparently due to the fact that further increase in the oxygen amount in the system results in acceleration of oxidative degradation reactions yielding water-soluble substances. Since the whole of oxygen added to the system is consumed during the process, an increase in temperature does not affect substantially the product yield (Table 3, run nos. 5B and 6B).

The use of nitrogen-containing samples of series A as fertilizers in growing of corn showed their high performance (Table 4). The greatest positive effect was observed with fertilizers of run 5A, which may be due to the presence of copper ions, playing an important role in photosynthesis.

The experiments with rye grass showed that the initial bark exerts depressing effect on the plant growth. This is caused by the presence in the fresh bark of organic compounds toxic for plants. In oxyammonolysis these compounds are oxidized, react with ammonia, and lose the ability to inhibit the plant growth. Nitrogen-containing samples of series B exert a positive effect on the growth and development of plants (Table 5).

The performance of nitrogen-containing bark products increases with increasing nitrogen content. Since the specific consumption of nitrogen in fertilizers added to soils was the same, the above trend can be explained by an increase in the degree of oxidation of the samples in hand. Indeed, Table 3 shows that the oxygen consumption in preparation of nitrogen-containing fertilizers increases in the series 3B–7B.

Table 5 shows that the performance of organic fertilizers of series B, in contrast to those of series A, was lower than that of mineral fertilizers. The difference between samples of series A and B may be due to higher degree of condensation of organic compounds produced by oxidative ammonolysis under oxygen pressure. As a result, degradation of fertilizers with soil microflora is hindered, and liberation of chemically bonded nitrogen is decelerated. The indirect evidence of this assumption is an increase in the effect of organic fertilizers with increase in their expenditure.

CONCLUSIONS

(1) In treatment of pine bark with oxygen in aqueous ammonia, the bark components react with ammonia to form nitrogen-containing products. The yield of the product and its nitrogen content depend on the process conditions and vary in the ranges 68–87 and 1.10–3.50%, respectively.

(2) The amount of chemically bonded nitrogen in the samples produced by oxidative ammonolysis increases with increasing concentration of ammonia in solution, process temperature, and oxygen pressure in the system.

(3) The resulting nitrogen-containing samples

exhibit high performance as fertilizers in growing of corn and multimowing ray grass.

CHEMISTRY OF FOSSIL FUEL

Chemical Composition of the Organic Matter of Oil Shale (Kerogen-70) from Leningrad Oblast (Benzene–Ethanol Extract)

Abstract—Detailed data are reported on the chemical composition of the benzene–ethanol extract of oil shale (kerogen-70).

Among fossil fuels, oil shales occupy a particular position with respect to both origin and composition, on the one hand, and role as a chemical raw material and power source, on the other hand. The increased hydrogen content in the organic matter of shales (OMS) and, as a result, higher yield of liquid products make oil shales promising as a source of liquid fuel and raw materials for chemical industry.

Integrated processing of oil shales to obtain hydrocarbon raw materials can be set up only after detailed elucidation of the composition of OMS. Such studies will give insight into the composition of the initial biomaterial, its genetic relationship with various OMS compounds, and pathways of biogeochemical transformation of OMS in the course of shale formation and will facilitate development of a process for shale treatment to obtain a wide range of valuable products [1–12].

In this work we studied the chemical composition of the benzene–ethanol extract of shale oil (kerogen-70) from Leningrad oblast.

EXPERIMENTAL

Shale was extracted in a Soxhlet apparatus with a boiling benzene–ethanol (3 : 1 by volume) mixture. The yield of the extract was 6.4% relative to OMS. The molecular structures of the extract components were determined by a combination of methods including elemental, quantitative functional, emission spectrum, and structural-group analyses, cryoscopy, IR and UV/VIS spectroscopy, and capillary gas–liquid chromatography (CGLC).

The average molecular weight of the extract $\overline{M}$ was 298; elemental composition, %: C 73.6, H 10.5, N 0.7, and O + S 15.2; atomic ratio H/C 1.71; degrees of aromaticity 0.19, naphthenicity 0.53, and alkyl substitution 0.28; functional composition (groups, mg-equiv g^{-1}): phenolic (PG) 1.01, keto (KG) 1.33, quinoid (QG) 0.79, carboxy (CG) 0.22; ester groups (EG) and lactone rings (LR) 0.35; iodine number 0.14.

In the IR spectrum of the extract, we identified the absorption bands of the following fragments (ν, cm^{-1}). Fairly strong bands of aromatic rings (3010–3080, doublet 1500/1595, 1450, 675–900, 800–1200). The higher intensity of the low-frequency component of the doublet suggests that monocyclic aromatic structures prevail. Substitution in aromatic rings: monosubstituted compounds (735, 710) prevail, the content of disubstituted compounds (740–760, 820) is lower, and more highly substituted compounds are not detected. The spectra also contain bands of the CH_3 and CH_2 groups in alkanes and cycloalkane structures (2850, 2926–2980, 1370–1380, 1470, 1450), a broad strong band (3380) of alcoholic and phenolic hydroxyls, and some other bands characteristic of alcohols and phenols (1360, 1220, 1330–1420, 635–660). We also observed medium-intensity carbonyl bands characteristic of various compounds: ketones, mainly aliphatic (1690, 1700, 1710, 1720, 1100); α- and γ-pyrones (1720, 1735, 1600–1650, 1540); six- (1735, 750, present in larger amounts) and five-membered (1775, 1720) lactones; and cyclic anhydrides (1750, 1800). Also the spectra contain weak bands of esters with cycloalkane and alkane fragments (3450, 1735–1750, 1160–1210), furan (1570–1605, 1475–1510, 1380–1400, 820–885, 740–800) and pyrrole heterocycles (3490, 1565, 1500), and alkoxy groups (1200–1225, 812, 2990), including methoxy groups (2835).

* The yields of eluates are given in wt % relative to the OMS extract. (*M*) Molecular weight; (C, H, N, O, S) content of the respective elements, wt %; (H/C) H/C atomic ratio; (D_a, D_n, D_{alk}) degrees of aromaticity, naphthenicity, and alkyl substitution, respectively; groups: (PG) phenolic, (KG) keto, (QG) quinoid, (CG) carboxy, (EG) ester, and (LR) lactone rings; (IN) iodine number.

The conclusions made from the IR spectra are confirmed by the UV/VIS data. The main absorption maxima (λ_{max}, nm) in the UV/VIS spectra belong to unsaturated carboxylic acids and their derivatives (200), flavonols (250, 370), enols (220, 320), benzene rings (200, 260), steroid λ-diketones and their derivatives (280, 340), porphines (450, 480–494, 500–550), possibly nickel porphyrins; and chlorophylls b (456, 598, 646) and a (430, 617, 667).

By emission spectrum analysis, we detected in the extract Fe, Ni, V, Cu, Zn, Co, Mo, Si, Ge, Ga, Ti, Ca, Mg, and Al.

Thus, compounds from the benzene–ethanol extract have a relatively high molecular weight and polyfunctional composition; they contain unsaturated fragments.

To obtain more detailed data on the composition of the initial shale (kerogen-70) and benzene–ethanol extract, it was appropriate to separate the extract into a number of close-cut fractions by adsorption liquid chromatography on ASKM silica gel. This procedure in most cases does not alter the structures of the compounds being separated.

The following eluates were obtained (the eluents are given in parentheses): nos. 1 (C_6H_{14}), 2 (C_6H_{14}–C_6H_6, 1 : 1 by volume), 3 (C_6H_6), 4 ($CHCl_3$), 5 [$(CH_3)_2CO$], and 6 (C_2H_5OH). These eluates were studied by the same physicochemical methods as the initial benzene–ethanol extract (Table 1).

In the IR spectrum of eluate no. 1, we identified strong absorption bands (ν, cm^{-1}) of long alkyl chains and saturated rings (2930, 2970, 2860, 1450, 1460, 1470, 1380, 970, 725) and weak bands of aromatic rings (3060, doublet 1500–1600, a series of bands at 900–1200), unsaturated compounds (3060, 1675, 680, 880), possibly carotenoids, and aliphatic ketones (1695, 1710, 1650, 1720).

By UV/VIS spectroscopy (λ_{max}, nm), we detected unsaturated carboxylic acids and their derivatives (220), carotenoid pigments (440.5, 450, 480–494, 500–550), diketones of the diterpene series (318), flavonols (251, 370), and chlorophylls a (380, 418, 428, 510, 580, 700) and b (428, 465, 675).

By CGLC, we identified in eluate no. 1 *n*-alkanes, isoalkanes, and cycloalkanes (Table 2). The odd/even ratio is 0.99 for alkanes and 0.80 for isoalkanes, indicating that the major role in formation of OMS was played by algal material, although the contribution of terrestrial material is also significant. It should be noted that in diagenesis the reductive conditions prevailed. The distribution of *n*-alkanes has a maximum at C_{21}–C_{27}, on the whole typical of bacterial bioproduction.

The major bands in the IR spectrum of eluate no. 2 (ν, cm^{-1}) are those of long alkyl chains and, to a lesser extent, of saturated rings (2960, 2920, 2856, 2840, 1470, 1460, 1450, 1375, 970, 720) and aromatic (possibly naphthalene) rings (3000–3050, doublet 1500–1600, 750); bands are detected assignable to C=C bonds (3000–3050, 1675, 965, 730–885), keto groups (1695, 1705, 1715), ester groups (1730, 1755,

3470), primary and secondary amines, alcohols (sharp peak at 3400, 3250–3450, shoulder at 3200, 750–850, 1590–1650), and oxygen-containing heterocycles (1570–1605, 1475–1510, 1380–1400, 820–885, 740–800).

According to the UV/VIS spectrum (λ_{max}, nm), eluate no. 2 contains unsaturated carboxylic acids and their derivatives (220), λ-diketones (280, 350), carotenoids (440.5, 450, 480–494, 500–550), diketones of the diterpene series (318), porphyrin rings (520, 560), flavonols (251, 370), and chlorophylls a and b (380, 418, 428, 510, 580, 700, 428, 465, 675).

The IR spectrum of eluate no. 3 contains the bands (ν, cm^{-1}) of aromatic rings (3030–3070, doublet 1500–1600, series of bands at 900–1200), alkyl chains (2920, 2960, 2880, 1470, 1460, 1385 broad split, 730), keto groups (1700, 1715, 1725), ester groups (1750, 1730), and lactone rings (1770, 1785).

By UV/VIS spectroscopy (λ_{max}, nm), we detected in eluate no. 3 carotenoids (440.5, 450, 480–494), saturated and unsaturated ketones (280, 365–368, 380–390), unsaturated lactones, and unsaturated esters (200, 240).

The IR spectrum of eluate no. 4 contains the bands (ν, cm^{-1}) of aromatic rings (3050–3070, doublet 1605/1595, series of bands at 900–1200; impurity of hydroaromatic rings is possible), unsaturated rings (1470, 1270, 970), short aliphatic chains, substituted pyridines and quinolines (3030–3070, 1585–1620, 1570–1575, 1475, 1428), pyrrole rings (3490, 1565, 1500), keto groups (1705, 1715, 1725), ester groups and lactone rings (1730, 1745, 1765, 1785, 1795, 1805), aromatic ethers (990–1090 broad), and primary alcohols (3140–3600 broad).

The UV/VIS spectra (λ_{max}, nm) suggest the presence of unsaturated lactones and esters (222), saturated and unsaturated ketones (280, 365–368, 380–390), flavonol (246, 368) and coumarin (266, 282, 318) derivatives, chlorophyll c (444, 580, 630), bacteriochlorophyll (475), and nickel porphyrin (575, 550); the presence of nickel was confirmed by emission spectrum analysis.

Eluate no. 5 is characterized by a high content of sulfur and oxygen and a low H/C ratio.

Its IR spectrum (ν, cm^{-1}) contains the bands of aromatic rings (3050, doublet 1500/1600, 727), alkyl chains and unsaturated rings (2860, 2940, 2970, 1465, 1470, 1300, 1380 narrow, 1022, 970, 750–920), carboxy groups and ketones, mainly aliphatic (1690, 1715, 1725, 1050), esters and lactones (1735, 1745, 1250–1300, 1100–1150, 1765, 1780, 1790), with a possible impurity of chromone structures; alcoholic and phenolic hydroxyls (3100–3600, 1050 strong broad, 1200, 1310–1410), cyclic ethers (broad band of complex structure at 1180–1290), terpenes (1680, 1648, 890, 810, 680), unsaturated double bonds, and steroid structures (series of bands at 3390, 3200 shoulder, 1612, 1585, 1500, 1435, 1415, 1054, 870, 815).

Table 2. Content* of *n*-alkanes and isoalkanes in eluate no. 2

n-Alkane	Content, wt %	Isoalkane	Content, wt %

* Relative to the total weight of hydrocarbons in the eluate.

By UV/VIS spectroscopy (λ_{max}, nm), we detected in eluate no. 5 aliphatic ketones (300), diketones of the diterpene series (319), carotenoids (440, 450, 480–494, 500–550), chlorophyll a (380, 418, 428, 510, 580, 700), nickel and vanadium porphyrins (620, 565, 535, 500, 400), and chlorins (695).

Eluate no. 6 is characterized by a low content of nitrogen and hydrogen and a low H/C ratio.

In its spectrum, we identified the bands (ν, cm^{-1}) of alkyl chains and saturated rings (2980, 2930, 2815, 2826, 1475, 1455, 1380 split, 1260, 970, 720), traces of aromatic rings (3050, doublet 1500–1600, 725), alcohols and phenols (3620, 3400, 3170, 1200, 1155, 1310–1410), carboxy groups (2730, 1300, 1310, 1295), traces of sulfur compounds (1930, 1950), thio-

phenes (1050–1200, 1225–1260, 847, 549), sulfides (630, 680–700), and also skeleton vibration bands of heterocycles or metal complexes of oxygen-containing compounds (465–475).

According to the UV/VIS spectrum (λ_{max}, nm), eluate no. 6 contains chlorophylls a (380, 418, 428, 510, 580, 700) and b (456, 598, 646), saturated ketones (275–290), and polycyclic and aromatic compounds, mainly of the naphthalene series (220, 276, 311).

To conclude, the developed adsorption-chromatographic procedure allowed separation of the benzene–ethanol extract of oil shale (kerogen-70) into close-cut groups appreciably differing in the molecular weight, elemental composition, quantitative content of functional groups, degree of aromaticity, and H/C ratio. The benzene–ethanol extract consists mainly of cycloalkanes and alkanes. The OMS was formed not only from algal material, but also from terrestrial material of higher plants, bacterial bioproducts, animal material, and fungi. Detection of long-chain *n*-alkanes (C_{12}–C_{34}) proves participation of terrestrial higher plants in formation of OMS.

CONCLUSIONS

(1) An adsorption liquid chromatographic procedure was developed for separation of the benzene–ethanol extract of oil shale into a number of close-cut fractions appreciably differing in the molecular weight, elemental composition, and functional groups.

(2) Organic matter of shales was formed with the participation of algal and terrestrial material of higher plants, bacterial bioproducts, animal material, and fungi.

CHEMISTRY OF FOSSIL FUEL

Chemical Concept of Geodynamic Shocks in Coal Strata

Abstract—A chemical concept of geodynamic shocks in coal strata, accompanied by ejection of coal dust and gas, is suggested.

A dangerous phenomenon in coal mining is geodynamic shock in a coal stratum, accompanied by ejection of enormous amount of coal dust and gas enriched in H_2, CH_4, CO, CO_2, C_2H_6, C_3H_8, and other low-boiling hydrocarbons. This phenomenon causes severe damages and miners' death. Various theories explaining the origin of geodynamic shock mainly take into account the physical characteristics of coal and do not consider at all the features of chemical composition of the organic and mineral components of coal.

Studies of sudden ejections of coal and gas in mines revealed a correlation between ejection danger in coal strata and degree of disturbance of their structure [1–3]. Coals with different degrees of structure disturbance are characterized by different rates of release of adsorbed gaseous products. This fact can be used to reveal zones with ejection danger in coal strata [1, 2]. The capability of coals for fast gas release is associated with formation of a highly developed microporous structure in the course of their dispersion.

Published data concerning mechanical actions on various caustobioliths (lignites, coals, oil shales, peat) and also on graphite, quartz, and various metal oxides show that mechanical actions induce significant changes in the physical structure, enhance the reactivity, and cause release of a large amount of a gas enriched in hydrogen [4–17]. Dispersion of fossil fuels significantly affects the composition of both organic and mineral matter. The organic matter of fuels is hydrogenated, a "mobile molecular phase" appears, the yield of extracts, humic and fulvic acids, and neutral oils grows, the H/C atomic ratio in the residual coal decreases, but the degree of its aromaticity increases; various atomic groups are broken down or altered; the layer size, cluster height, number of layers *n* associated in the cluster, and the distance between aromatic layers decreases. Mechanical action on coals causes, along with increased yield of bitumens, also generation of gaseous products containing, along with O_2, CO_2, and CO, also significant amounts of H_2, CH_4, C_2H_6, C_3H_8, and C_4H_{10}. The composition of gaseous products depends on the origin of coal, grinding procedure (planetary mills, disintegrators, acoustic or ultrasonic treatment, etc.), and medium and time of mechanical activation.

The goal of this work was to study the chemical composition of the initial coals of various technological groups and of their geodynamic shock products, and also to develop a chemical concept of geodynamic shocks in coal strata in relation to the chemical composition of the organic and mineral matter of coals.

The investigation objects were coals of groups E, D, and G, and also the product of sudden ejections of coal and dust in Vostochnaya mine (Donetsk coal basin), the so-called "mad dust."

The results of technical analysis, elemental composition and yield of the benzene–ethanol extract, structural parameters, and elemental and quantitative functional composition of the initial coals and "mad dust" are listed in the table.

The table shows that the initial coals significantly differ in the yield of volatiles (24.8–41.2%), carbon (79.8–88.6%) and hydrogen (5.5–5.9%) content (wt%, daf), yield of the benzene–ethanol extract [2.10–3.52 wt % relative to organic matter of coal (OMC)], average molecular weight, elemental and functional composition, and structural parameters of the extract.

In the IR spectrum of the extracts, we identified the absorption bands (ν, cm^{-1}) of the following fragments: aromatic rings (3030–3100, CH stretching

* (W^a, A, V^{daf}) Moisture content, ash residue, and yield of volatiles, respectively, wt % relative to dry sample; (C, H, N, O, S) content of the respective elements, wt % daf; (D_a, D_n, D_{alk}) degrees of aromaticity, naphthenicity, and alkyl substitution, respectively; groups: (PG) phenolic, (CG) carboxy, (QG) quinoid, (KG) keto, (EG) ester, and (LR) lactone rings; (IN) iodine number, mg-equiv g^{-1}.

vibrations; 1575–1605 and 1480–1510, C=C in-plane vibrations; the components of the doublet at 1575–1605 have comparable intensity, which suggests low degree of fusion of aromatic rings; strong bands of the CH_3 and i-C_3H_7 groups (2975–2950, 2885–2860, 1380, 1410–1435); stretching and bending vibration bands of CH and CH_2 groups in aliphatic and cycloalkane fragments (2975–2950, 2850, 2875, 1460, 1260, 1470, 970); stretching vibration bands of O–H (2500–3500, 3500–3550, 955–890) and C–O (1230–1140, 1310–1410, 1395–1440) groups in carboxylic acids and phenols; bands of keto (1700–1725) and ester groups, six- (1795–1750, 1660–1210) and five-membered lactone rings (1760–1795); medium-intensity bands of quinoids groups (1645, 1675); and weak bands of ethers (2835–2878, 1125, 1210–1310) and oxygen-containing furan heterocycles (1570–1605, 820–880, 740–800).

The IR spectra of extracts from "mad dust" are characterized by increased concentration of absorption bands of epoxy groups (2990–3050, 1230–1280, 815), ester groups and lactone rings, especially of aliphatic esters, quinoid rings, and furan heterocycles; the content of carboxy and phenolic groups is also somewhat increased.

The yield of the benzene–ethanol extract from "mad dust" varies from 9.5 (E) to 16.4 (G); the average molecular weight, from 365 to 425; and the degree of aromaticity, from 0.30 (E) to 0.40 (G). The prevailing functional groups are quinoid, carboxy, phenolic, and ester (including lactone rings; see table).

The table shows that mechanochemical breakdown of OMC significantly increases the yield of the benzene–ethanol extract and the quantitative content of functional groups. The solid residue of the coal is enriched in the mineral component, the hydrogen content increases, but the carbon content and the yield of volatiles decrease. For example, for D6 coal the yield of volatiles decreased from 36 to 32.2, and the carbon content, from 82.4 to 80.2; the yield of hydrogen increased from 5.9 to 6.5 wt% daf; the yield of the benzene–ethanol extract increased from 3.1 to 12.4 wt % of OMC; the content of phenolic groups increased from 0.15 to 0.40, carboxy groups, from 0.16 to 0.40, quinoid groups, from 0.53 to 1.63, keto groups, from 0.05 to 0.20, and ester groups and lactone rings, from 0.13 to 0.45 mg-equiv g^{-1}. Similar trends were also observed with coals E and G (see table).

The organic matter of "mad dust" has increased content of hydrogen and oxygen and decreased content of carbon. Hence, mechanochemical breakdown of OMC is accompanied by significant enrichment in hydrogen, but after geodynamic shock the hydrogen content decreases as a result of oxidative processes in "mad dust" and of hydrodealkylation, dehydroxylation of phenols and alcohols, and hydrogenation of quinones and aromatic rings, catalyzed with the finely dispersed material. Thus, we can suggest that tectonic heaves of coal rocks containing organic and mineral matter are accompanied by significant mechanical processes causing primarily crushing of rocks and formation of a large amount of a finely dispersed mass. Cleavage of various chemical bonds is accompanied by release of hydrogen, which promotes hydrogenation of aromatic rings and their transformation into naphthenic rings, degrading more readily, and also hydrodealkylation, dehydroxylation, decarboxylation reactions, etc. Large amounts of hydrogen are adsorbed by finely dispersed coal. Accumulation of hydrogen and pathways of mechanical breakdown of the organic and mineral components of coal undoubtedly depend on their chemical composition.

Detailed studies of various coal products (extracts, semicoking tars, products of destructive thermal hydrogenation in hydrogen-donor solvents and oxidative degradation) show that a significant part of metals in fossil fuels are bound in metal porphyrins, phthalocyanines, phenolates, and carboxylates. Particular attention should be given to Fe, V, Ni, Zn, Cu, Co, and Mo porphyrins, which effectively catalyze release of hydrogen from water and its transfer to aromatic fragments of a coal macromolecule. The structure of metal porphyrins correlates with the degree of metamorphism of fossil fuels. Differences are observed in both the carbon skeleton of the tetrapyrrole macroring and in the central metal ion [18, 19].

Because metal porphyrins show a high catalytic activity in hydrogen release, they should be assumed to be the main hydrogen generators. This process is induced by profound mechanochemical transformations in OMC caused by tectonic forces. Fairly high degree of amorphization of the coal mass, formation of large amounts of reactive radical fragments, high performance of metal porphyrins, especially in the presence of acidic groundwater (typical for zones with a high ejection danger)—all these factors favor release of large amounts of hydrogen. The released hydrogen is accumulated by sorption in the amorphous coal mass. A significant part of hydrogen is involved in hydrogenation, hydrodealkylation, and saturation of low-molecular-weight radicals, yielding large amounts of CH_4, C_2H_6, and C_3H_8, which are also sorbed by the coal mass. Various reactions with hydrogen are also catalyzed with organometallic complexes, especially with complexes of metals with variable oxidation state. To understand processes occurring in OMC at tectonic heaves of coal rocks, it is appropriate to consider a correlation between the tendency of coals to destructive hydrogenation and the chemical composition of their organic mineral material.

It was found experimentally that hydrogenation of OMC is primarily determined by the features of structural organization of separate fragments of the coal macromolecule, their ratio, and structure and quantitative content of functional groups (phenolic, keto, carboxy, ether, ester, alcoholic; lactone and quinoid rings). Coals that are readily hydrogenated are characterized by a definite ratio of hydroaromatic and aromatic fragments, low content of humic acids, phenols, and carboxylic acids, and high content of quinoid, furan, and thiophene rings. Hydroaromatic structures like tetralin, hydroanthracene, dihydrophenanthrene, di- and tetrahydropyrene, dihydrofluoranthene, and dihydroquinoline are effective hydrogen donors. In turn, polycyclic aromatic hydrocarbons and thiophene, furan, and quinoid rings effectively transfer hydrogen to various radical products of OMC degradation [20–23].

Lignites are characterized by a high content of

hydrogen donors (hydroaromatic hydrocarbons, terpenes, azulenes, adamantanes, cycloalkanes), but the content of hydrogen-transfer agents in them is low. The high degree of substitution of structural fragments of the lignite macromolecule with phenolic, keto, ether, ester, carboxy, and alcoholic groups is a negative factor, because hydrogen is consumed for reduction of these groups. This fact suggests that in lignite strata mechanical breakdown of their structure under the action of tectonic forces will not be accompanied by accumulation of large amounts of free hydrogen, and hence the geodynamic shock will be impossible.

In coals containing 80–86% C, the content of hydrogen donors, and also of polycyclic aromatic fragments and of Fe, V, Ni, Cu, Co, and Ti porphyrins, which are effective hydrogen-transfer agents, is high. Furthermore, metal porphyrins are additional hydrogen generators and highly active catalytic systems easily effecting hydrogenation, dehydrogenation, hydrodealkylation, cyclization, and isomerization.

In the presence of hydrogen, polycyclic aromatic structures are hydrogenated to naphthenic structures, which readily degrade with release of large amounts of low-boiling hydrocarbons accumulating in the highly amorphized coal mass, producing a high pressure. It should be noted that accumulation in coal strata of large amounts of hydrogen, lower alkanes, CO, and CO_2 is also favored by low degree of substitution of OMC structural fragments by functional groups (carboxy, phenolic, ether, ester) reducible by hydrogen.

Thus, tectonic heaves of coal strata are accompanied by significant chemical transformations of OMC, with release of large amounts of hydrogen and its subsequent accumulation in the amorphous mass of coal. These processes occur especially actively at the sites of contact of OMC with mineral streaks, which, in turn, should be rich in Al, Fe, V, Co, Ni, Ti, and Si, i.e., in elements catalyzing hydrogenation, dehydrogenation, hydrodealkylation, etc. The main hydrogen generators are metal porphyrins and water.

Apparently, mining of coal strata is accompanied by admission of atmospheric oxygen to areas rich in hydrogen and lower alkanes. As a result, a detonating gas mixture is formed, which causes avalanche-like ejection of enormous amounts of coal dust that was formed in the course of tectonic heaves of coal mineral rocks.

It should be expected that the strength of a geodynamic shock and the amount of the ejected "mad dust" are largely determined by the mine working rate. At a low rate, the intrastratal gas pressure is relieved gradually, and avalance-like ejection of coal dust and gas can be avoided. It was noted that geodynamic shocks are characteristic of moderately amorphized coals and are virtually untypical of highly metamorphized coals (86% C). Highly metamorphized coals are characterized by a high content in their organic matter of polycyclic aromatic fragments, which are hydrogen-transfer agents, and a low content of hydrogen donos. These coals are very strong, so that the highly amorphous mass capable of accumulating hydrogen and alkanes is formed in a low amount. Owing to these factors, the probability of sudden ejections of "mad dust" and gas, associated with disturbance of the structural organization of coals under the action of tectonic forces, is low. It should be expected that the major gases sorbed in the bulk of these coals will be CH_4 and C_2H_6, which, when mixed with oxygen, are less reactive than hydrogen. Furthermore, CH_4 and C_2H_6 are bound with the coal matter more tightly; therefore, they are desorbed more slowly, and the drop of the intrastratal pressure is not so sharp.

When considering the tendency of coal strata to hydrodynamic shock caused by tectonic forces, we should also take into account the stratum porosity, making possible the access of water as a source of hydrogen to the mineral and organic components of coal. Dense rocks are impermeable for water, and virtually no hydrogen is formed.

Significant structural changes in both the organic and mineral components of coal cause generation of large amounts of radical products. They are localized in definite zones. This factor plays also a signifacnt role in subsequent processes occurring in the finely dispersed porous coal mass and capable of causing suddent ejection of coal dust and gaseous products. Probably, preliminarily boring of a coal block is necessary, with pumping of an electrolyte solution, e.g., of mine water enriched in metal ions (Fe^{2+}, Al^{3+}, Ca^{2+}, Mg^{2+}, Ni^{2+}, etc.); this procedure will be more efficient when using acidic ground water. It can be appropriate to use solutions of phenols (especially di- and trihydric). The content of trihydric phenols is fairly high in waters from peat, shale, lignite, and immature coal deposites, in which virtually no sudden ejections of dust and gas under the action of tectonic forces were observed.

It follows from the above consideration that the probability of geodynamic shock in a coal stratum with sudden ejection of finely dispersed coal and gas ("mad dust") under the action of tectonic forces is in-

fluenced by numerous factors. However, it is beyond doubt that the major factor is structural organization and chemical composition of both organic and mineral components of the coal macromolecule, the quantitative ratio of its structural fragments, e.g., hydroaromatic (hydrogen donors) and polycyclic aromatic (hydrogen-transfer agents). An important role is played by the structure of oxygen-containing functional groups substituting various hydrocarbon fragments of OMC, their ratio, structure of metal porphyrin complexes, chemical forms of inorganic and organic sulfur and nitrogen, composition of groundwater and surrounding mineral rocks, coal stratum porosity, and its sorption activity toward hydrogen and lower alkanes.

CONCLUSIONS

(1) Geodynamic shocks in coal strata under the action of tectonic forces have undoubtedly chemical origin and correlate with the composition of the organic and mineral matter of coals.

(2) Tectonic shifts in the bulk of a coal block induce profound mechanochemical transformations causing hydrogenation, dehydrogenation, hydrodealkylation, and thermal cleavage of various chemical bonds. These reactions are promoted by hydrogen, a number of metals, organomineral complexes like metal porphyrins and phthalocyanines, and acidic groundwater.

(3) One of the hydrogen sources is water reacting chemically with various compounds of the mineral matter of coal.

Abstract—It is demonstrated that the absolute age of osteological material from archeological sources can be determined using dynamic thermogravimetric analysis and pyrolysis gas chromatography.

Today, when each branch of science is highly specialized, the fundamental problems are commonly solved using interdisciplinary approaches. Among the humanities, this is especially true in regard to the archeology. As distinct from the history in its narrow sense, the archeology has at its disposal diverse materials which can be analyzed by methods typical of many disciplines, primarily the chemistry and physics [1].

Of vital importance for archeology is maximally exact determination of the period of being of one or another culture and archeological finds, and archeologists are making considerable efforts to determine the absolute and relative age of archeological sources in hand.

One of the basic chronological analysis methods is radiocarbon dating [2–4]. However, it requires development of such a method for synthesis of organic compounds that corresponds to a given radiocarbon registration procedure. In its turn, this requires a considerable amount of the material and increases the analysis time and cost. Furthermore, very sensitive radiometric systems are needed to register the radioactivity at a level of 10^{-11}–10^{-15} Ci [5].

In this work we examined the potentialities of absolute dating of osteological material from archeological sources by dynamic thermogravimetric analysis (DTGA) and pyrolysis gas chromatography. These methods are thought as tentative screening tests of field materials prior to exact dating by the standard methods.

EXPERIMENTAL

Characteristics of the initial osteological material are given in the table. Bone material was preliminarily mechanically cleaned to remove surface soiling. Humic acids were removed by treatment with 0.1–0.5 NaOH at room temperature for 20–24 h. Then the material was treated with ethanol in a Soxhlet apparatus for 4–6 h and dried in a vacuum drier at 60°C and a residual pressure of 1–2 mm Hg. The dry material was ground with a side milling cutter and on a vibrating grinder (agate mortar and ball) to a milling grade of 200 mesh. Dynamic TGA analysis was performed on an OD-103 derivatograph in a platinum crucible (sample 200 mg, air, heating rate 5 deg min^{-1}). Pyrolysis of osteological material was studied at 500°C in a flow pyrolysis cell. The procedure allowed controlled pyrolysis of the material (1–2-mg samples), followed by GC analysis of volatile products (CO_2) with a Chrom-4 chromatograph [1-m column, silica gel L 80–120 mesh, carrier gas (Ar) flow rate 60 mil min^{-1}]. A standard gas mixture (CO_2 + N_2) with a CO_2 concentration of 19.33 vol % was used for calibration.

Osteological material is an element of the skeleton of the vertebrates, characterized by a mineral to organic fraction ratio of 65 : 35. The mineral fraction represents calcium phosphate (85%) and carbonate (10%) containing small amounts of magnesium phosphate (1.5%) and calcium fluoride (0.5%). The organic fraction consists of collagen, protein, fats, etc. [6]. Long-term being of osteological material in buried condition is accompanied by fossilization and, as

a result, decrease in the organic fraction content. Despite numerous attempts made to correlate variations in different characteristics of collagen (nitrogen content, physical and optical properties, and amino acid content) in the course of fossilization, diagenesis of collagen is poorly understood yet. Nevertheless, a fairly simple conceptual model was proposed for collagen degradation, setting up a link between its content and the problem of dating of low-collagen bones [7, 8].

According to the primary classification, collagen is related to insoluble proteins (scleroproteins). It contains abnormally high amounts of glycine, proline, and hydroxyproline. One of every four units in the protein skeleton of collagen is proline or hydroxyproline bound to glycine. The elongated shape of the collagen spiral prevents intramolecular hydrogen bonding. However, the interchain hydrogen bonding is an important factor in collagen diagenesis, including kinetic and transport processes. Therefore, the time of osteological material being buried may be estimated from the amount of polypeptide fragments in the matrix. Knowing the trends of thermal and thermooxidative degradation of collagen in osteological material opens the door for dating this material using thermal analysis.

Since the major structural elements of the polypeptide chain of collagen are aliphatic fragments, its thermal decomposition should be similar to that of synthetic aliphatic polyamides (their thermal stability was studied in detail). It was demonstrated that they decompose even at 300°C, which is accompanied by considerable weight loss, liberation of volatile products, and formation of an insoluble coke-like residue [9]. The thermal decomposition of polyamides accelerates with temperature, especially in air [10].

The thermal analysis data obtained in this work with osteological material are consistent with the above-mentioned trends. For example, the maximal weight loss rate due to exothermic thermooxidative decomposition is observed at about 300°C. With increasing temperature to 400°C, the decomposition rate considerably decreases. Therefore, the weight loss over the temperature range 300–350°C can be used as a parameter characterizing the collagen content in osteological material. It is important that the mineral fraction of osteological material decomposes at much higher temperature (thermal decomposition of calcium carbonate with liberation of CO_2 occurs at 740°C [11]).

The DTGA results obtained for osteological material of various ages (see table) are presented in Fig. 1.

The results obtained demonstrate a clear correlation between the age of osteological material and the organic fraction content in it. The weight loss at 350°C was found to be 16–17, 11–12, and 8–9% for sample nos. 4, 2, and 3, respectively.

Even more illustrative are the results of pyrolysis gas chromatography. The volume of liberated CO_2 decreases linearly with increasing age of osteological material (Fig. 2).

The dependence plotted in Fig. 2 can serve as a calibration curve for determination of the absolute age of bone material from archeological sources.

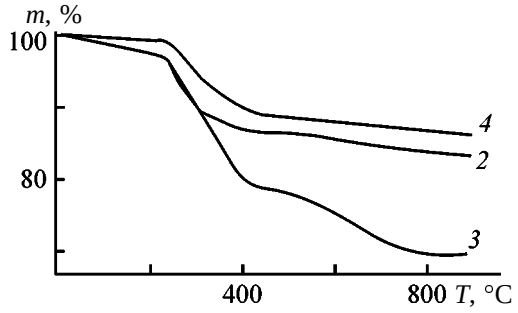

Fig. 1. Dynamic thermogravimetric analysis of osteological material of various ages: (*m*) residual weight and (*T*) temperature. Figures at the curves correspond to the sample numbers in the table.

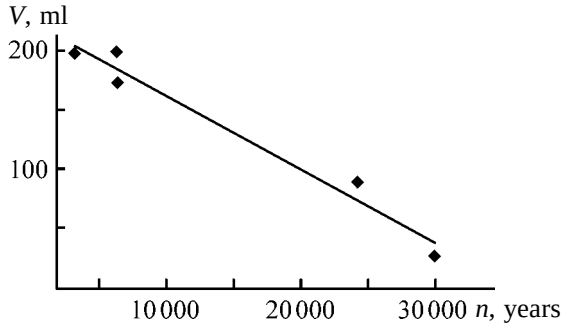

Fig. 2. Volume of CO_2 V liberated in pyrolysis of osteological material of various ages n.

CONCLUSION

Absolute dating of osteological material from archeological sources can be made by the dynamic TGA and pyrolysis gas chromatography methods. Collagen, the organic component of bones of the vertebrates, being buried for a long time, is subject to fossilization, resulting in its decreasing amount. At high temperatures, collagen undergoes thermal and thermooxidative degradation with the amount of the released products depending on the material age.

Correction for Fluctuations of Local Molecular Field in the Debye Method of Dilute Solutions

A. N. Bykov and S. M. Karabanov

Ryazan Plant of Metal–Ceramic Devices, Joint-Stock Company, Ryazan, Russia

Received June 28, 2001

Abstract—A simple method for evaluating the correction for the effect of solvent on the dipole moments of molecules, determined using the Debye method of dilute solutions, is proposed.

As shown by analysis of a vast body of experimental data [1], the properties of strongly polar molecules are poorly described by correlation dependences that well fit nonpolar molecules. The most important characteristic of a polar molecule is its dipole moment μ, which is frequently used in correlating the properties of polar substances [1].

However, this poses the problem of how to choose the dipole moment μ represented in the reference literature by rather widely varying values [2, 3], which is due not only to experimental errors. All correlation dependences for polar substances include the dipole moment μ_0 determined in the gas phase, in which case the influence of other molecules is negligible. At the same time, the main technique used for determining the dipole moments of molecules is the Debye method of dilute solutions. It is this method that has been used to find the majority of presently known dipole moments [3]. As shown by numerous experimental studies [2, 3], the dipole moments μ_s determined by the method of dilute solutions differ from μ_0.

To evaluate the influence exerted by solvent, we performed [4] a full statistical analysis of experimental data for all the 226 substances for which both μ_0 and μ_s are known (the latter was measured in solutions of benzene C_6H_6). Benzene was chosen as the solvent for which the most extensive data on dipole moments of dissolved molecules are available.

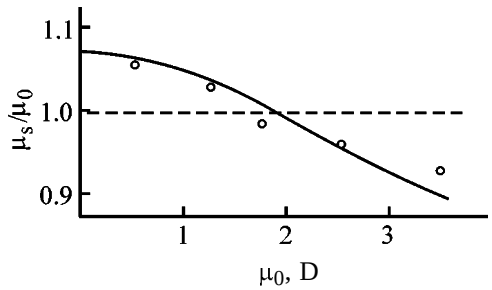
As seen from the figure, the μ_s/μ_0 ratio averaged over large groups of substances decreases monotonically with increasing μ_0. The thus obtained statistical dependence of μ_s on μ_0 can already be used to evaluate μ_0 on the basis of data on μ_s. This is all the more important since only data on μ_s are available for many chemical substances.

To evaluate the correction for the solvent effect more precisely, let us consider this issue in more detail. In the method of dilute solutions, the orientational polarizability a_{or} of molecules of a polar component x_2 in an external effective field $\mathbf{F}_{eff}$ is extrapolated to zero concentration of this component. In doing so, it is assumed that at $x_2 \to 0$ polar molecules are oriented in the external field as freely as this occurs in a gas, i.e.,

$$\lim_{x_2 \to 0} a_{or} = \mu_0^2/(3kT). \quad (1)$$

However, an important part may be played in nonpolar liquids by fields of molecular multipoles [5], with $\langle \mathbf{F}^2 \rangle \neq 0$, where $\mathbf{F}$ is the local molecular field at the center of an arbitrarily chosen particle.

In [4], analytical expressions for the μ_s/μ_0 ratio were derived in terms of a statistically substantiated discrete model of a nonpolar solvent. These expressions account for the influence exerted by fluctuations of local molecular fields on μ_s and describe satisfactorily the dependence of the μ_s/μ_0 ratio on μ_0, molecule size, and temperature T.



Effect of μ_0 on the μ_s/μ_0 ratio. Curve: theoretical dependence at quadrupole moment of benzene molecules $Q = 5.6 \times 10^{-26}$ CGS units cm^2; points: data obtained in statistical processing of experimental data.

1070-4272/02/7503-0507$27.00 © 2002 MAIK "Nauka/Interperiodica"

Here we propose a simpler method for evaluating the correction for the effect of fluctuations of the local molecular field in nonpolar solvents. Taking, in accordance with the theory of corrections for the effect of solvent [2], that

$$\lim_{x_2 \to 0} a_{or} = \mu_s^2/(3kT) \quad (2)$$

and assuming that

$$\lim_{x_2 \to 0} a_{or} = \lim_{x_2 \to 0} \langle a_{or} \rangle = \langle a_{or} \rangle_0 \quad (3)$$

(where $\langle a_{or} \rangle$ is the average orientational polarizability of polar molecules in an infinitely dilute solution in the presence of fluctuations of local molecular fields in the nonpolar solvent), we obtain for μ_s/μ_0

$$(\mu_s/\mu_0)^2 = [3kT\langle a_{or} \rangle_0]/\mu_0^2, \quad (4)$$

Calculating $\langle a_{or} \rangle$ in terms of the discrete model [4], we have

$$(\mu_s/\mu_0)^2 = \mu/(8.66\mu_0) \times \int_0^\infty (1 - \mathrm{cth}^2 a + a^{-1}\mathrm{cth}\, a - a^{-2})s^3 \exp(-s/1.1)ds, \quad (5)$$

$$a = \mu F/(kT) = \mu s Q\langle r^{-4} \rangle/(kT),$$

where F is the local molecular field strength, $F = sQ\langle r^{-4} \rangle$; r is the intermolecular distance; Q is the quadrupole moment of molecules of the nonpolar solvent; and s is the proportionality factor; $\langle r^{-4} \rangle$ can be readily found in terms of Kirkwood's model of rigid spheres [4].

The μ value can be obtained in the conventional approximation [6]

$$\mu = \mu_0 \frac{\varepsilon_\infty + 2}{3} \frac{2\varepsilon_\infty + 1}{2\varepsilon_\infty + \varepsilon_\infty}, \quad (6)$$

where $\varepsilon_\infty \approx 1.05 n_D$ and n_D is the refractive index of the nonpolar solvent.

The μ_s/μ_0 value can be easily found from (5) by graphical integration since the integrand has a relatively narrow maximum.

The figure presents the dependence of the μ_s/μ_0 ratio on μ_0, plotted theoretically for benzene solutions with the use of (5) and found experimentally by averaging data for all the 226 chemical substances for which data on μ_0 and μ_s in benzene are available [3].

As follows from the figure, the proposed relation (5) describes satisfactorily the dependence of μ_s/μ_0 on μ_0, which allows its use for evaluating the influence exerted by fluctuations of local molecular fields on the μ_s values found using the Debye method of dilute solutions.

BRIEF COMMUNICATIONS

Relationships of Sorption of Heavy Metals (Lead, Nickel, Cobalt) on Biomass Isolated from Production Waste of Megaterin Enzyme Preparation

N. N. Komarova and E. M. Sul'man

Tver State Technical University, Tver, Russia

Received April 18, 2001

Abstract—The biomass of *Bacillus megaterium* cells, containing polypeptides, polysaccharides, and lipids, isolated from production waste of Megaterin enzyme preparation, was tested for sorption recovery of heavy metals (lead, nickel, cobalt) from aqueous solutions. The sorption capacity of this biosorbent and the main relationships of the metal sorption were studied.

Modern processes for water decontamination from various impurities tend to wider use of sorbents prepared from bacterial waste of biotechnological productions [1]. The microbial biomass used as a raw material for preparation of biosorbents is formed in the course of microbial synthesis. This material consists of partly destroyed cells of microorganisms containing biopolymers rich in ionogenic groups [1]. It is known that heavy metal ions are toxic agents. At the same time, heavy metals incorporated in complexes lose toxicity. The biomass of microbial cells can be effective natural sorbent accumulating heavy metals on the cell surface. The aim of this work was to study the sorption capability of microbial biomass for heavy metals.

EXPERIMENTAL

The microbial biomass used in our experiments (*Bacillus megaterium*) was isolated from production waste of Megaterin enzyme preparation.[1] The sorption power of bacterial cells with respect to heavy metals and the optimal conditions for metal sorption were studied using aqueous solutions of cobalt chloride $CoCl_2$, nickel acetate $Ni(CH_3COO)_2$, and lead acetate $Pb(CH_3COO)_2$. The sample of dry biomass taken from the enzyme-producing plant was treated with acetone. Excess acetone was removed by vacuum filtration. Prior to use, the biomass was washed with distilled water to neutral reaction of wash water and dried [1, 2]. A portion of the resulting biomass was introduced into a model solution containing heavy metal ions. The sorption was carried out in a temperature-controlled reactor at stirring. After completion of a sorption experiment, the biomass was separated by centrifuging. The residual content of Co(II), Ni(II), and Pb(II) in the cenrifuged solution was determined spectrophotometrically and fluorometrically [3].

We found that at a constant metal concentration (0.1 g l^{-1}) in solution and a constant solution volume (250 ml) the residual metal content in solution continuously decreased with increasing sorbent weight. The results obtained in the sorption experiments showed that the sorption was maximal at the sorbent concentration of 80–90 g l^{-1}.

The sorption isotherm has a convex shape and is fairly well fitted by Langmuir's equation (Fig. 1). The metal ion concentration in the solution was varied from 0.01 to 0.2 g l^{-1}. Sorption was performed to

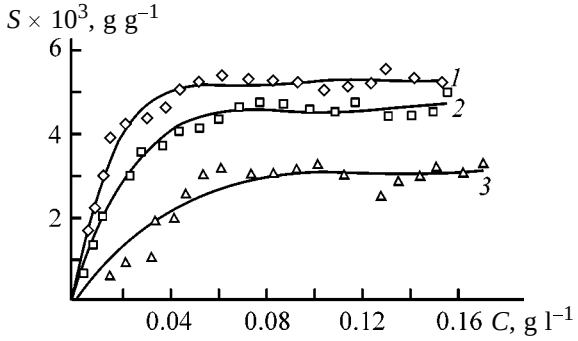

Fig. 1. Sorption isotherms of metals on microbial biomass: (*S*) sorption capacity and (*C*) equilibrium metal concentration in solution. Cation sorbed: (*1*) Pb^{2+}, (*2*) Ni^{2+}, and (*3*) Co^{2+}: the same for Fig. 2.

[1] The material was produced and submitted by the Vyshni Volochek plant of Enzymatic Preparations.

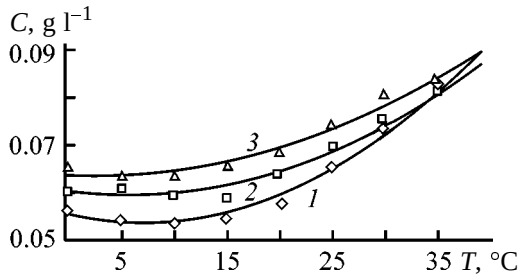

Fig. 2. Residual metal content in solution as influenced by temperature.

complete saturation of the sorbent. In obtaining the sorption isotherms, both the solution volume (250 ml) and the sample weight (80 g l^{-1}) were constant. Figure 1 shows that lead ions exhibit higher affinity for the biomass than nickel and cobalt ions. The sorption capacity of the biomass is 0.0042, 0.0029, and 0.0049 g g^{-1} for nickel, cobalt, and lead, respectively.

The sorption kinetics was studied at different contact times of the biosorbent and solution. A portion of solution was sampled at regular intervals and analyzed for metal. We found that the major fraction of the metals was sorbed within the first 15–20 min. The sorption equilibrium sorption was attained in 30 min. Under these conditions, the following degree of metal recovery was reached (%): Pb 42, Ni 34, and Co 27.

Figure 2 shows that with increasing temperature from 0 to 50°C the sorption of metals slightly decreases. The sorption of metals on the biomass is maximal in the temperature range 0–20°C.

CONCLUSIONS

(1) The biomass of bacterial cells prepared from production waste of Megaterin enzyme preparation is capable of recovering heavy metals (lead, nickel, and cobalt) from aqueous solutions.

(2) The residual metal content in solution decreases with increasing amount of the sorbent. The sorption is maximal at a biomass content of 80–90 g l^{-1}.

(3) The dependences of lead, nickel, and cobalt sorption on their concentration in solution are described by Langmuir's isotherm.

(4) The sorption equilibrium is attained within 30 min. The degree of metal recovery is 42, 34, and 27% for Pb, Ni, and Co, respectively.

(5) The degree of heavy metal recovery is maximal in the temperature range 0–20°C.

Our results show that the biomass of microbial cells prepared from Megaterin production waste is effective and inexpensive sorbent for purification of aqueous solutions to remove heavy metals.

Phase-Transfer Catalysis in Synthesis of Oximes

I. M. Osadchenko and A. P. Tomilov

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received September 25, 2001

Abstract—Perfluorinated higher carboxylic acids were tested as phase-transfer catalysts in synthesis of oximes.

The known synthetic routes to oximes are based on reaction of a carbonyl compound with an aqueous solution of a hydroxylamine salt [1–3] in the presence of inorganic compounds, e.g., of NaOH:

$$\underset{\underset{\|}{\mathrm{O}}}{\mathrm{RCR'}} + \mathrm{NH_2OH \cdot HX} + \mathrm{NaOH} \rightarrow \underset{\underset{\|}{\mathrm{NOH}}}{\mathrm{RCR'}} + \mathrm{H_2O} + \mathrm{NaX},$$

where R = Alk; R' = Alk, H, Ar, Ht; X is an inorganic anion.

Because carbonyl compounds, as a rule, are poorly soluble in water, the reaction is usually performed in aqueous alcohol. However, the reaction is slow (5–8 h) and does not go to completion even in the presence of excess hydroxylamine salt. The yield of the oxime based on the taken carbonyl compound usually does not exceed 80%.

To promote the reaction, various phase-transfer catalysts were tested without using an organic solvent. We found that the most effective phase-transfer catalysts for oximation are higher perfluorinated carboxylic acids exhibiting a high surface activity. Addition of these compounds (0.07–0.10 wt %) appreciably shortens the reaction time and allows preparation of oximes in high, sometimes almost quantitative yields. This can be illustrated by several examples.

Acetophenone oxime. (a) A 1-l reaction vessel equipped with a thermometer, a reflux condenser, a stirrer, and a dropping funnel was charged with a solution of 76.5 g (1.1 mol) of hydroxylamine hydrochloride in 200 ml of water and 120 g (1.0 mol) of acetophenone, and a 20% solution of 44 g (1.1 mol) of NaOH was added dropwise with stirring at 36°C until pH 7–8 was attained. The mixture was heated at 60–70°C for 5 h and then cooled to 0–3°C. The resulting crystalline precipitate was filtered off, washed with several portions of ice-cold water, and dried in a desiccator over $CaCl_2$ to constant weight; 100 g of acetophenone oxime was obtained, mp 57°C (published data [2, 3]: 57–58°C); yield 70%.

(b) The reaction was performed similarly to procedure (a) but in the presence of 0.61 g (1.7 mmol) of perfluoroenanthic acid with addition of a 20% NaOH solution at 60–70°C; the mixture was heated at this temperature for 3.5 h. Yield of acetophenone oxime 131.6 g (98%).

(c) The reaction was performed similarly to procedure (a) but in the presence of 0.61 g (2.3 mmol) of perfluorovaleric acid; time of heating at 60–70°C 3 h. Yield of acetophenone oxime 132.3 g (99%).

5-Methyl-3-hexanone oxime. A reaction vessel [the same as in procedure (a)] was charged with 57 g (0.8 mol) of 5-methyl-3-hexanone, 39 g (0.56 mol) of hydroxylamine hydrochloride, 100 ml of water, and 0.6 g (1.65 mmol) of perfluoroenanthic acid; 100 ml of 25% aqueous NaOH was added, keeping the temperature below 35°C, after which the mixture was heated to 67–68°C and kept at this temperature for 3 h. After cooling, the upper layer was separated, washed with three 20-ml portions of cold water, and distilled in a vacuum (10–12 mm Hg). A fraction boiling at 85–95°C was collected. Yield of 5-methyl-3-hexanone oxime 49.7 g (71%); n_D^{20} 1.4424 (published data [4]: n_D^{20} 1.4436).

Salicylaldoxime. Similarly to procedure (a), a 500-ml reactor was charged with 26 g (0.21 mol) of salicylaldehyde, 16 g (0.21 mol) of hydroxylamine hydrochloride, 40 ml of water, and 0.2 g (0.55 mol) of perfluoroenanthic acid; a solution of 9 g (0.225 mol) of NaOH in 30 ml of water was slowly added, after which the mixture was heated to 65–70°C and kept at this temperature for 3 h. After cooling to 5–10°C, the mixture was worked up similarly to procedure (a).

1070-4272/02/7503-0511$27.00 © 2002 MAIK "Nauka/Interperiodica"

Yield of salicylaldoxime 26 g (98%), mp 58°C (published data [5]: 57–59°C).

3-Thioxo-2-butanone oxime. Similarly to synthesis of salicylaldoxime, a reactor was charged with 25.2 g (0.247 mol) of 3-thioxo-2-butanone, a solution of 16 g (0.23 mol) of hydroxylamine hydrochloride in 210 ml of water, and 0.2 g (0.55 mol) of perfluoroenanthic acid, after which a solution of 9 g (0.225 mol) of NaOH in 30 ml of water was added dropwise at 30–35°C. The mixture was heated to 70°C and kept at this temperature for 3 h. After cooling, the mixture was worked up as described above. Yield of 3-thioxo-2-butanone oxime 20.8 g (74%); mp 105–106°C. The structure was confirmed by IR spectroscopy.

Thus, addition of perfluorinated carboxylic acids increases the yield of oximes, shortens the reaction time, and eliminates the necessity of using an organic solvent, which considerably simplifies the oximation process.

BRIEF COMMUNICATIONS

A Procedure for Synthesis of 3-Halomethyl-4-oxothiazolidine-2-thiones

A. I. Ginak and E. B. Aronova

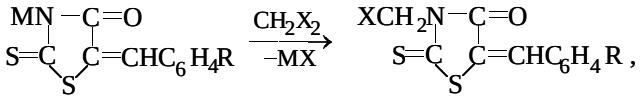
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 23, 2001

Abstract—Solid-phase synthesis of 3-halomethyl-4-oxothiazolidine-2-thiones was perforomed.

Halomethyl-4-oxothiazolidine-2-thiones, which are starting compounds for preparing biologically active substances [1], vulcanizing agents [2], and plant growth stimulants [3], are synthesized by a multistage procedure via intermediate hydroxymethyl-4-oxothiazolidine-2-thiones, with subsequent replacement of the hydroxy group in the methyl substituent under the action of $SOCl_2$, PBr_3, or HBr [4]. The procedure involves the use of corrosive media and expensive chemicals; the loss in each stage reaches 25%.

We have developed a single-stage solid-phase procedure for preparing 3-halomethyl-4-oxothiazolidine-2-thiones **IIa**–**IIf** by reaction of the vapors of the corresponding methylene dihalides with crystalline alkali metal salts of 4-oxothiazolidine-2-thiones **I**. It is known [5] that crystals of ambifunctional compounds exhibit anisotropic reactivity on various crystal faces. This property was used to develop a synthetic process. Lithium, sodium, potassium, and cesium salts of 4-oxothiazolidine-2-thiones were crystallized from organic solvents (methanol, acetone, acetonitrile, dimethylformamide), and the crystals that exhibited the strongest anisotropy in alkylation were selected. The reaction progress was monitored by TLC. We found that the most anisotropic were the lithium salts of 4-oxothiazolidine-2-thiones crystallized from methanol: the yield of the target products (see table) exceeded 95%.



I **IIa**–**IIf**

where M = Li, Na, R, Cs; X = Cl, R = H (**IIa**); X = Br, R = H (**IIb**); X = I, R = H (**IIc**); X = Cl, R = *p*-CH_3 (**IId**); X = Br, R = *p*-CH_3 (**IIe**); X = Cl, R = *m*-NO_2 (**IIf**).

BOOK REVIEWS

Buler, Peter, *Fiziko-khimicheskaya termodinamika veshchestva* (Physicochemical Thermodynamics of Substance),

St. Petersburg: Yanus, 2001, 192 pp.

The book is an author's translation of *Physicochemical Thermodynamics of Substance*, previously published in English (St. Petersburg: Yanus, 2000). The author, professor P. Buler, a metallurgist engineer by education, held the chair of chemical technology of glass and glass ceramics of the Ural State Technical University in Yekaterinburg, prior to moving to Germany in 1990. From 1991 till 2000, he had been a professor of the chair of glass and ceramics of Universität Erlangen (Nürnberg). At present, he is a consultant of the same chair. During the whole period of his activities, P. Buler's scientific interests have been associated with investigations into interaction of oxide melts with metals and gases.

The brief introduction and the first chapter, *Substance and Its Internal Energy*, point out the specific features of the author's approach to presentation of the fundamentals of chemical thermodynamics. In particular, doubt is cast on the correctness of using such a function as enthalpy ($H = U + PV$). The main reason is that, although the product PV has the dimensionality of energy, "this product does not come to be energy in the Nature" (p. 24). As seen from the summary (*Symbols and Definitions*) and the subsequent presentation, such notions as Gibbs energy and chemical potential are not used, either. Individual substances and mixing processes are mainly characterized by internal energy (U), free energy ($G = U - TS$), and peculiarly understood entropy. The author writes: "The entropy of a substance is the temperature coefficient of the free energy and cannot be interpreted in any other way" (p. 32).

The second, third, fourth, and fifth chapters consider relations describing changes in the internal energy, free energy, and entropy under various conditions. The author comes to conclusions that are difficult to comment. It is noted, in particular, that, changes in entropy being only associated with changes in energy, the entropy of mixing in the formation of an ideal gas mixture or ideal solution proves to be zero. Correspondingly, changes in free energy are also zero for these systems. The sixth chapter is concerned with phase equilibria in single-component systems, with no mention made of the phase rule.

The seventh chapter considers thermodynamic functions characterizing the formation of binary solutions from pure components. The concepts developed by the author rule out the notion of excess functions and thereby cause a certain confusion of terminology in describing processes of mixing. The eighth chapter discusses the equilibrium between condensed phases in two-component system, without, however, using the term "chemical potential." The ninth chapter is devoted to the liquid–vapor equilibrium, and the tenth considers the equilibrium in chemical transformations. The eleventh chapter presents results of some experimental studies carried out by the author.

One hundred and twenty-five years ago, J.W. Gibbs (1839–1903) published his major work *On the Equilibrium of Heterogeneous Substances*, which was of paramount importance for the development of chemical thermodynamics. The analytical method rigorously and consistently described in this paper was later named by P. Duhem (1907) the method of thermodynamic potentials. The possibilities of the method are manifested to full extent in calculation of phase and chemical equilibria. Any "revision" of this method or abandonment of other fundamental concepts of the classical chemical thermodynamics seems to be unproductive.

The freedom of press is generally accepted all over the world, but it should not be unconditionally extended to scientific publications. A book of such a controversial nature should have been prefaced with an explicit introduction written by a specialist of authority in chemical thermodynamics, with a detailed analysis of merits and demerits and specific features of a publication brought to reader's notice.

Abstract—Gelation in concentrated solutions of high-basicity aluminum hydroxychloride in the presence of inorganic salts was studied. Comparative evaluation of the coagulation activities of aluminum hydroxychloride and solid formulations on its base in water purification was made.

The scale on which aluminum hydroxychlorides are used in purification of natural and wastewater to remove suspended and colloid impurities [1] motivates the increasing interest in the problem of their performance and availability [2–4]. They can also be used for preparing new coagulants with improved properties [5].

Most of the known methods for production of aluminum hydroxychloride are based on hydrolysis of aluminum chloride formed in the preliminary stage of treatment of an aluminum-containing starting material. All stages of this process have been extensively studied (see reviews [6–8]), and a conclusion was made that various kinds of Al(III) hydroxo complexes can coexist in concentrated aqueous solutions. The composition of these complexes varies from monomeric to polymeric, depending on Al(III) concentration, solution pH, and other factors. As applied to studies aimed at developing new coagulants, it was found important that a new phase of polynuclear hydroxo complexes of aluminum appears in aluminum hydroxychloride solutions at high Al(III) concentration and $[Al^{3+}]/[Cl^{-}]$ ratio exceeding 2 and the solution becomes colloidal [9, 10]. This made it possible to determine conditions for aluminum hydroxychloride structuring with inorganic salts and to obtain on this basis new solid coagulant formulations showing higher performance than the initial aluminum hydroxychloride.

EXPERIMENTAL

The initial aluminum hydroxychloride solution was prepared by reacting granulated aluminum of AG brand [intermediate in manufacture of electrolytic aluminum, TU (Technical Specifications) 48-0107-95–90] with hydrochloric acid [11] and had the following characteristics: Al(III) content 13.2 wt %, dry residue 54.3 wt %, atomic ratio Al^{3+}/Cl^{-} = 2.18, pH 4.6, ρ = 1340 kg m^{-3}.

The electrical conductivity of dilute aluminum hydroxychloride solutions was measured in a conductometric cell with platinum electrodes (S = 1 cm^2, L = 1 cm) with an F-480 ac bridge. Double-distilled water was used.

The structuring was studied with an RV-8M rotation viscometer in the constant shear stress mode. The dynamic viscosity of aluminum hydroxychloride solutions was measured with a VPZh-2 viscometer with a capillary diameter of 0.88 mm.

Solid coagulant formulations were obtained by adding to an aluminum hydroxychloride solution a weighed portion of NaCl or $MgCl_2$ of analytically pure grade (or its solutions) with subsequent stirring with a spatula.

To study the performance of the coagulants, dispersions of kaolin (of "pharmaceutical" brand) were prepared by roiling 1 g of kaolin in 2 l of tap water

1070-4272/02/7504-0515 $27.00 © 2002 MAIK "Nauka/Interperiodica"

Table 1. Characteristics of low-turbid kaolin dispersions in water

Dispersion	Content of dispersed phase, mg l^{-1}	Particle size, nm	pH of medium
1	88	78	7.7
2	16	77	7.6
3	7	47	7.6

(pH 7.6–7.7) and subsequent settling for 12, 24, or 48 h. The thus prepared dispersion was decanted, its upper part was sampled, and the sample was analyzed for the content of the dispersed phase by filtering through a membrane filter. The particle size of the dispersed phase (the most probable value) was found turbidimetrically (Table 1).

The coagulant performance was studied as follows: a freshly prepared kaolin dispersion of prescribed concentration was poured in 12 250-ml cylinders.

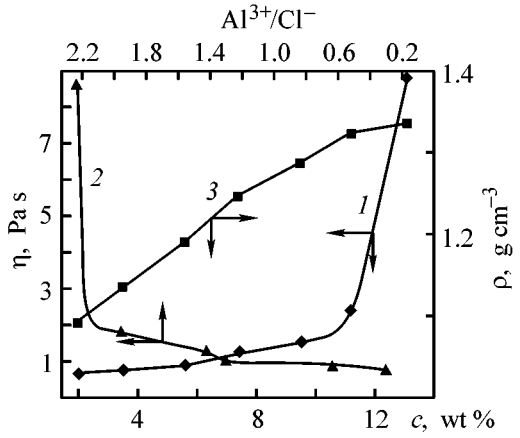

Fig. 1. Dynamic viscosity of the reaction mass, η, vs. (*1*) aluminum concentration *c* and (*2*) Al^{3+}/Cl^{-} ratio, and density ρ vs. aluminum concentration. Reaction temperature 85°C.

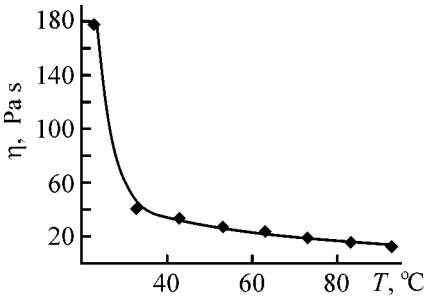

Fig. 2. Dynamic viscosity of aluminum hydroxychloride solution, η, vs. temperature *T*. Dispersed phase concentration 730 g l^{-1}.

A certain volume of a coagulant with a known concentration was introduced into each cylinder. After 12-fold tilting, the dispersion was allowed to settle for 1 h and the upper, over-sediment layer of the dispersion was sampled and its optical density was determined on a Spekol spectrophotometer in a cell with a layer thickness from 1 to 5 cm at incident light wavelength of 640 nm.

The kinetics of sedimentation of coagulant-treated dispersions was studied with an FET turbidimeter. Low-turbid kaolin dispersion was placed in a temperature controlled glass cell (V = 100 cm^3), and a coagulant dose was introduced at working magnetic stirrer (n = 120 rpm). In 5 s the stirrer was switched off, and the optical density of the dispersion was measured in transmitted light (λ = 540 nm) in the course of 1 h. Using the preliminarily constructed calibration plots [12], the optical densities of the dispersion were recalculated into turbidity (mg l^{-1}).

As already noted, the composition and properties of aqueous aluminum hydroxychloride solutions are governed by a number of factors: Al(III) concentration, pH value, etc. These factors largely depend on the conditions of aluminum hydroxychloride preparation. It was found that, when aluminum hydroxychloride is obtained by reacting aluminum with a 10% solution of hydrochloric acid, the properties of the reaction system change dramatically in the course of reaction. For example, on raising the Al(III) content in the reaction mass to more than 10 wt %, the viscosity of the reaction mass grows steeply (Fig. 1, curve *1*). At this Al(III) content the Al^{3+}/Cl^{-} atomic ratio reaches a value of 1.91 (curve *2*). The solution density grows virtually linearly in the course of the reaction (curve *3*). The occurring changes are presumably due to variation of the phase composition of the reaction mass. It is known that aluminum pentahydroxychloride is the final, and the most stable product of hydrolysis of aluminum salts in concentrated solutions [7]. The elemental composition of the product under study in its final state corresponds to this compound.

As shown by viscosity measurements with a concentrated aluminum hydroxychloride solution, the temperature dependence of the dynamic viscosity is nonlinear (Fig. 2). With the temperature increasing to above 23°C, the viscosity falls dramatically. At 80°C, the viscosity is only 10% of its initial value, and it remains virtually unchanged with temperature elevated further. Such a behavior of the system suggests structural interactions in the initial aluminum hydroxychloride solution. With increasing temperature, this structure disintegrates and the system becomes a sol.

The heterogeneous nature of aluminum hydroxychloride solutions is also evidenced by the dependence of the equivalent electrolytic conductivity of the solutions on the Al(III) concentration in these solutions (Fig. 3, curve *1*). The curve for the $\lambda = f(\sqrt{c})$ dependence shows an apparent break at $c = 1.25 \times 10^{-3}$ M. For colloidal solutions such a point characterizes the critical micelle concentration (CMC). Micelle formation in a hydrolytic interaction of aqua hydroxo complexes of Al(III) in aqueous dispersed systems is regarded as an intermediate stage in heterocoagulation with basic salts of aluminum [1]. Measurements of the optical density of an aluminum hydroxychloride solution diluted in the presence of a dye (solubilization technique) gives a CMC of 1.15×10^{-3} M (Fig. 3, curve *2*), i.e., a value close to that found from electrolytic conductivity measurements. Thus, the results of the investigations performed, combined with published data, suggest that a concentrated aluminum hydroxychloride solution is a dispersed system partly structured under standard conditions.

In water treatment technology, the customer's requirements to coagulants frequently refer not only to the performance of coagulants, but also to their aggregative state, storage conditions at low temperature, transportation problems, etc. The liquid form of reagents fails to always satisfy these requirements. The revealed specific features of concentrated aluminum hydroxychloride solutions, and also the known patterns of gelation of silica dispersions [13] close to aluminum hydroxychloride dispersions in particle size in water sols {$(0.12–0.6) \times 10^{-6}$ m for silica [14] and $(0.1–1.5) \times 10^{-6}$ m for particles of sols of aluminum complexes [3, 15]}, suggest that a concentrated aluminum hydroxychloride solution, which is actually a sol, may transform under certain conditions into a gel.

It is known that structuring in dispersed systems is largely influenced by electrolytes [16]. The gelation in aqueous dispersions of aluminum hydroxychlorides was studied upon introduction into these dispersions of a number of inorganic salts in solid state or as solutions. On adding an electrolyte, the dispersion was stirred with a spatula and its viscosity was measured on a rotation viscometer. The gelation time was found as the time elapsed from the instant of electrolyte introduction till the onset of viscosity rise [17]. Table 2 presents the time of gelation, τ_{gel}, in structuring of aluminum hydroxychloride dispersions with various salts.

The mass ratios aluminum hydroxychloride : salt, listed in Table 2, correspond to the minimum gelation time for a respective salt. It should be noted that no gel is formed with aluminum and iron chlorides even after 24 h. It is shown for the example of sodium chloride solution that the gelation time strongly depends on the concentration of the aqueous electrolyte solution (Table 3) introduced into the aluminum hydroxychloride dispersion (volume ratio aluminum hydroxychloride : solution = 10 : 1):

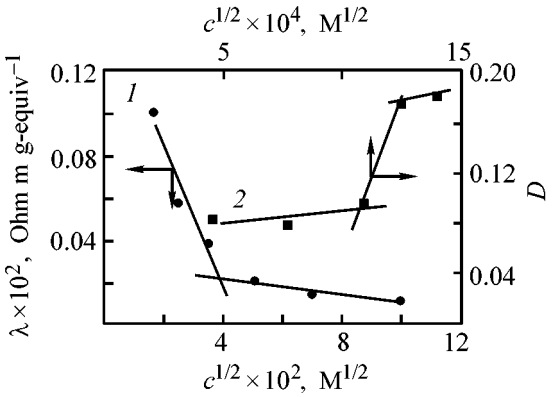

Fig. 3. (*1*) Equivalent electrolytic conductivity λ and (*2*) optical density *D* vs. aluminum hydroxychloride concentration *c*.

c_{NaCl}, %	6.6	10.0	12.0	13.2	16.0	20.0
τ_{gel}, min	60	10	1.5	1.2	0.8	0.5

These data were obtained for an aluminum hydroxychloride dispersion containing 54.3% main substance or 730 g l^{-1} in terms of aluminum pentahydroxychloride.

Table 2. Time of structuring of aluminum hydroxychloride dispersion with inorganic salts at 180°C

	Al(III)	NaCl	$MgCl_2$
Aluminum hydroxychloride	1.32	–	–
Formulation 1	1.12	0.91	–
Formulation 2	0.92	–	1.24

As is known, the concentration of the dispersed phase markedly affects the process of sol structuring [17]. Table 3 presents data on the dependence of the time of structuring of an aluminum hydroxychloride dispersion on the content of the dispersed phase in the dispersion. To make the nature and structure of the solutions identical, the following procedure was used. Instead of diluting an aluminum hydroxychloride solution with the maximum content of the main substance, dispersions were prepared by synthesis of aluminum hydroxychloride at varied process duration under conditions ensuring the required Al^{3+}/Cl^- ratio, i.e., leading to formation of aluminum pentahydroxychloride. The concentration of salts (per the whole dispersion volume) was chosen in such a way that the gelation time was minimal and equal for the most concentrated dispersion with different salt added.

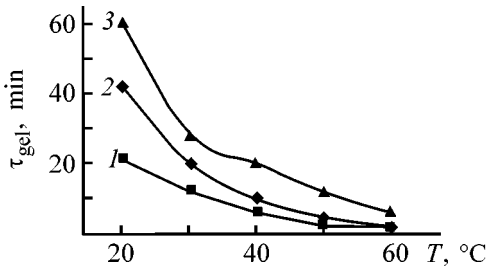

Fig. 4. Gelation time τ_{gel} vs. temperature T of aluminum hydroxychloride mixing with salts. Concentrations: dispersed phase 680 g l^{-1} and salt 1.6 M. Salt: (*1*) NaCl, (*2*) $MgCl_2 \cdot 6H_2O$, and (*3*) $Al_2(SO_4)_3 \cdot 18H_2O$.

As seen from Table 3, the gelation time increases steeply when the concentration of the dispersed phase is made lower than 680 gl^{-1}.

The transition from sol to gel and back is strongly affected by the pH of the medium. To obtain an aluminum hydroxychloride dispersion with the lowest possible pH, gaseous HCl was bubbled through the dispersion. Structuring of such dispersions with various electrolytes demonstrated that, irrespective of the type of salt, the gelation time is virtually the same and does not exceed 1 min at pH 3.7 and higher. Beginning with pH 3.6, the gelation time grows steeply, and no gel at all is formed at pH below 3.0.

As would be expected, the gelation time depends on temperature at which a salt is introduced into the aluminum hydroxychloride dispersion (Fig. 4). With the temperature increasing from 20 to 60°C, the gelation time decreases 10–20-fold.

The gels obtained in aluminum hydroxychloride structuring with electrolytes are X-ray amorphous and possess no thixotropic properties. When dried in air, they crack and are easily powdered mechanically. In gels obtained in the presence of sodium chloride, the strengthening of the coagulation structure results in their spontaneous transformation into a powder. A similar phenomenon was observed in formation of gels of silicic acid [18].

To evaluate the coagulant performance, aqueous dispersions of kaolin with varied content of the dispersed phase (Table 1), close to that in natural water, were subjected to coagulation. The efficiencies of the coagulating action of aluminum hydroxychlorides and gels obtained in the presence of NaCl (formulation 1) and $MgCl_2 \cdot 6H_2O$ (formulation 2) were compared. The working solutions were prepared by dissolving a weighed portion of a reagent (~1 wt %) in 100 ml of distilled water (Table 4).

Preliminarily, a comparative analysis of coagulant hydrolysis was made on the basis of changes in the turbidity of the medium, in which flakes of aluminum hydroxide were formed. For this purpose, the working solution of a coagulant (6 ml) was introduced into a cell with distilled water (V = 100 cm^3) with pre-

Table 5. Rates of hydrolysis of coagulants and sedimentation of hydrolysis products in water with alkalinity of 7.5 mg-equiv l^{-1}*

* 1 and 2 are formulation numbers.

scribed (hydrocarbonate) alkalinity of 7.5 mg-equiv l^{-1}. After short mixing (5 s), the optical density of the cell content was measured at certain intervals of time. The values obtained were recalculated (using a preliminarily plotted calibration graph) to dispersion turbidities (mg l^{-1}). The rate of hydrolysis was expressed as the slope of a tangent to the ascending portion of the turbidity curve. Similarly, the rate of sedimentation was found from the descending portion of the turbidity curve. The thus obtained rates of hydrolysis and sedimentation of hydrolysis products, presented in Table 5, suggest a higher coagulation activity of binary coagulants. Characteristically, the sedimentation rate of products formed in hydrolysis of formulation 2 (aluminum hydroxychloride + $MgCl_2$) much exceeds that of aluminum hydroxychlorides.

Figure 5 presents typical curves describing changes in dispersion turbidity upon introduction of certain doses of aluminum hydroxychloride and formulation 1 (aluminum hydroxychloride + NaCl). Similar curves were obtained for formulation 2 (aluminum hydroxychloride + $MgCl_2$). The same behavior is observed for all the three types of dispersions: equal degrees of clarification of the dispersions are obtained with a dose of binary coagulant that is much lower than that of aluminum hydroxychloride. Table 6 presents the results obtained in tests of the coagulants under study in purification of river water (Volzhskoe reservoir). The tests were done in conformity with GOST (State Standard) 3351–74.

The results of the tests confirm the enhanced, compared with aluminum hydroxychloride, coagulation activity of binary coagulants.

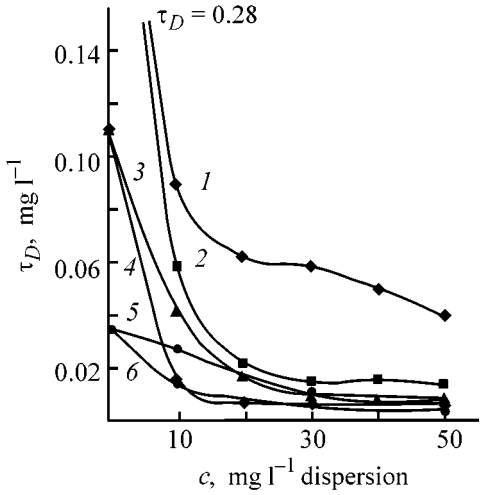

Fig. 5. Turbidity τ_D of kaolin dispersions vs. coagulant dose c in terms of Al(III). (*1, 3, 5*) Aluminum hydroxychloride and (*2, 4, 6*) formulation 1. Dispersion: (*1, 2*) 1, (*3, 4*) 2, and (*5, 6*) 3 (see Table 1).

CONCLUSIONS

(1) The results of the rheological and conductometric studies of concentrated solutions of aluminum hydroxychloride indicate the structuring of these solutions. Introduction of inorganic salts leads to gelation whose rate depends on the concentration of aluminum hydroxychloride, type of salt and its concentration, pH value, and temperature.

(2) The obtained solid formulations of aluminum hydroxychloride with NaCl and $MgCl_2$ exhibit higher coagulating activity in water purification as compared with the starting aluminum hydroxychloride.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determining the Activity Coefficients of Copper and Nickel Oxides in Melts of the System Cu_2O–NiO

N. A. Fedorova, L. B. Tsymbulov, and L. Sh. Tsemekhman

Gipronikel' Institute, Joint-Stock Company, St. Petersburg, Russia

Received December 14, 2001

Abstract—Equilibria between a copper–nickel alloy and oxide melt of the binary system Cu_2O–NiO were studied and the activity coefficients of copper and nickel oxides at 1573 K in the homogeneity region of the oxide melt (up to 11.6 mol % NiO) were determined. Similar values were also found by calculation from the phase diagram of Cu_2O–NiO.

Autogenous smelting of high-grade nickel containing copper sulfide concentrates obtained by floatation separation of converter matte gives metallic (0.5 to 6 wt % Ni, 0.01 to 1.5 wt % S) and oxide (slag) phases [1, 2]. The distribution of nickel between these phases is largely determined by the exchange reaction

$$(Cu_2O) + [Ni] = (NiO) + 2[Cu], \qquad (1)$$

where parentheses and square brackets designate components of, respectively, the oxide and metallic phases.

Since the interaction of components of the metallic and oxide phases in pyrometallurgical units can be considered from the standpoint of thermodynamic equilibrium, a knowledge is necessary of the activities of these components in melts.

However, detailed data are scarce, especially for oxide melts. With account of difficulties encountered in determining the activities of metal oxides in real multicomponent slag systems (to which may be referred slag formed in smelting of copper concentrates), it is appropriate first to find the activities of copper and nickel oxides in the binary system Cu_2O–NiO. A temperature of 1300°C, characteristic of the industrial processes considered, was chosen for the study.

The required activity coefficients can be determined experimentally by establishing an equilibrium between a copper–nickel alloy and an oxide melt of the system Cu_2O–NiO. Knowing the equilibrium constant of reaction (1), component concentrations in the oxide melt and metal, and the activities of copper and nickel in the metal alloy, we can find the ratio of the activity coefficients of the oxides

$$K_a = \frac{a_{Cu}^2 a_{NiO}}{a_{Ni} a_{Cu_2O}} = \frac{x_{Cu}^2 x_{NiO}}{x_{Ni} x_{Cu_2O}} \frac{\gamma_{Cu}^2}{\gamma_{Ni}} \frac{\gamma_{NiO}}{\gamma_{Cu_2O}}, \qquad (2)$$

where a_i, x_i, and γ_i are the activity, mole fraction, and activity coefficient of component i (i = Ni, Cu, NiO, Cu_2O) in the equilibrium phases, respectively.

From Eq. (2) follows that

$$\gamma_{NiO}/\gamma_{Cu_2O} = K_a(\gamma_{Ni}/\gamma_{Cu}^2)(x_{Ni} x_{Cu_2O}/x_{Cu}^2 x_{NiO}). \qquad (3)$$

Further, it will be shown that, according to the Gibbs–Duhem equation, this ratio can be used to find the activity coefficients of NiO and Cu_2O.

As starting materials served electrolytic copper, powdered metallic nickel produced by the carbonyl technique, and copper(I) oxide of analytically pure grade. A magnesium oxide crucible with a 15-g portion of the charge, comprising 5 g of metallic copper and nickel (with Cu : Ni ratio varied from 99.7 : 0.3 to 88 : 12) and 10 g of copper oxide, was placed in a hermetically sealed alundum reactor in a cold furnace with graphite heater. The charge was heated to the working temperature; the melt was kept at this temperature for 120 min and cooled under argon. After cooling, the alloy and slag were separated, weighed, and analyzed chemically for the content of copper and nickel. Additionally, the alloy was analyzed for the content of oxygen (on LECO analyzer), and the oxide phase, for magnesium (chemically). The content

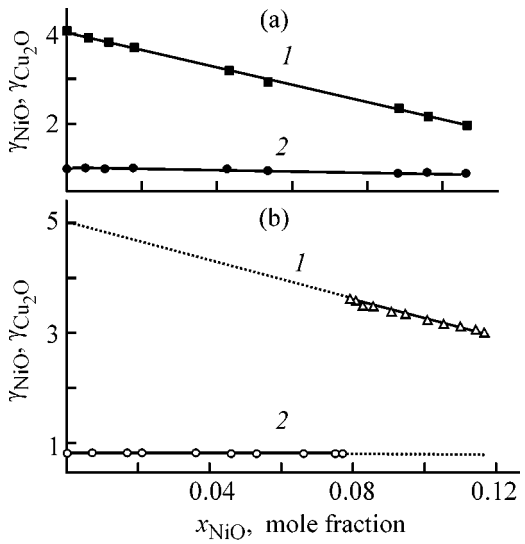

Fig. 1. Activity coefficients (*1*) γ_{NiO} and (*2*) γ_{Cu_2O} vs. nickel oxide content x_{NiO}. (a) Experimental data for 1573 K and (b) calculation on the basis of the phase diagram of the system Cu_2O–NiO.

of magnesium in the oxide melt was in the range 0.2–0.4 wt % in all the experiments, which well allows the influence of magnesium oxide on the equilibrium in the system under study to be neglected.

The time of keeping was chosen on the basis of a set of preliminary experiments carried out at 1300°C for 5 to 240 min, with metallic components taken in the ratio Cu : Ni = 90 : 10. It was found that equilibrium is attained in the system in about 50 min.

The compositions of alloys and oxide melts were varied by gradually increasing the Ni content relative to Cu. The Cu : Ni ratio in the initial charge was decreased until the oxide melt became saturated with respect to NiO. The nickel contents in the alloy and oxide melt, as influenced by the Cu : Ni ratio in the charge, are given below.

Initial Cu : Ni ratio	99.7 : 0.3	98.9 : 1.1	98.3 : 1.7
Ni content in alloy, wt %	0.085	0.16	0.259
Ni content in oxide phase, wt %	0.19	0.42	0.72
Initial Cu : Ni ratio	95.6 : 4.4	92.0 : 8.0	90.0 : 10.0
Ni content in alloy, wt %	0.59	1.29	0.9
Ni content in oxide phase, wt %	1.79	4.12	3.77
Initial Cu : Ni ratio	89.3 : 10.7	88.0 : 12.0	
Ni content in alloy, wt %	1.09	0.88	
Ni content in oxide phase, wt %	4.6	5.3	

On the basis of the thus determined contents of components in the alloy and the oxide melt, the equilibrium constant of reaction (1) [calculated with account of NiO overcooling (K_a = 8.16)], and the activity coefficients of copper and nickel, the ratio $\gamma_{NiO}/\gamma_{Cu_2O}$ was obtained in the NiO content range 0.5–10.6 at. % by means of Eq. (3):

x_{NiO}	0.005	0.010	0.017	0.043
$\gamma_{NiO}/\gamma_{Cu_2O}$	3.86	3.74	3.57	3.05
x_{NiO}	0.05	0.09	0.10	0.106
$\gamma_{NiO}/\gamma_{Cu_2O}$	2.81	2.18	2.04	1.87

Since the alloy was in equilibrium with the oxide melt, it contained, in addition to copper and nickel, also considerable amounts of oxygen (2.7–3.1 wt %), which is close to the solubility limit. Therefore, we calculated the activity coefficients of copper and nickel in the alloy, using the data of [3], where the activities of copper and nickel in oxygen-saturated alloys are presented. It should be noted, however, that the activities of copper and nickel in such alloys virtually coincide with those in oxygen-free alloys [4].

On the basis of the calculated ratios of the activity coefficients, let us find the activity coefficients, using the Gibbs–Duhem equation. For this purpose, let us define the function $\gamma_{NiO}/\gamma_{Cu_2O} = f(x_{NiO})$.

The activity coefficient of NiO is given by

$$\gamma_{NiO} = \gamma_{Cu_2O} f(x_{NiO}). \quad (4)$$

According to the Gibbs–Duhem equation,

$$x_{NiO}\, d\ln\gamma_{NiO} + x_{Cu_2O}\, d\ln\gamma_{Cu_2O} = 0. \quad (5)$$

Substituting (4) in Eq. (5), we obtain

$$x_{NiO}\, d[\ln f(x_{NiO}) + \ln\gamma_{Cu_2O}] + x_{Cu_2O}\, d\ln\gamma_{Cu_2O} = 0,$$

$$x_{NiO}\, d\ln[f(x_{NiO})] + x_{NiO}\, d\ln\gamma_{Cu_2O} + x_{Cu_2O}\, d\ln\gamma_{Cu_2O} = 0,$$

$$(x_{Cu_2O} + x_{NiO})\, d\ln\gamma_{Cu_2O} = -x_{NiO}\, d\ln[f(x_{NiO})],$$

$$d\ln\gamma_{Cu_2O} = -x_{NiO}\, d\ln[\gamma_{NiO}/\gamma_{Cu_2O}].$$

Integrating this equation over the interval 0–x_{NiO}, we obtain the following values of the activities

x_{NiO}	0.005	0.010	0.017	0.043
γ_{NiO}	3.89	3.79	3.65	3.22
γ_{Cu_2O}	1.007	1.014	1.024	1.056
x_{NiO}	0.05	0.09	0.10	0.106
γ_{NiO}	3.00	2.41	2.26	2.09
γ_{Cu_2O}	1.068	1.104	1.111	1.119

The composition dependence of γ_{NiO} and γ_{Cu_2O}, found from experimental data, is presented in Fig. 1a.

Let us compare the activity coefficients obtained from experimental data with the calculated values found on the basis of the phase diagram of Cu_2O–NiO. The procedure for calculating the activities on the basis of the phase diagram has been described in numerous manuals [5, 6] and is widely used in practice. The activity of a component is calculated along the line of its primary crystallization in the phase diagram. Among disadvantages of this method are its not always sufficient accuracy and necessity for making certain assumptions in recalculation of data to a single temperature. Despite these disadvantages, such a calculation can be rather useful for comparison purposes.

The phase diagram of the system Cu_2O–NiO was taken from [7] (Fig. 2). It can be seen from the diagram that the system is simple eutectic. Since the phase diagram of the system Cu_2O–NiO has not been found over the entire range of concentrations, it cannot be stated with full confidence that there is no range of solid solution formation for NiO. However, we assume in calculations that pure NiO crystallizes.

The melting points of Cu_2O and NiO are, respectively, 1502 and 2228 K, and the heats of melting, 65.6 and 42 kJ mol^{-1}. In all calculations, the heat of melting was taken to be temperature-independent.

For any point of the curve of primary crystallization of NiO ($T < T_m$), we can write the equilibrium equation

$$\mu_l = \mu_s,$$

$$\mu_{0,l} + RT\ln a_{NiO} = \mu_{0,s}, \quad \mu_{0,l} = \mu_{0,s} + \Delta\mu_m,$$

$$\Delta\mu_m = \Delta G_m = \Delta H_m - T\Delta S_m = T_m\Delta S_m - T\Delta S_m$$
$$= \Delta S_m(T_m - T) = (42\,000/2228)(2228 - T).$$

At T = 1573 K and x_{NiO} = 0.116, ΔG_m = 12 437.4 J mol^{-1}.

Let us consider the following scheme:

$$\begin{array}{ccc} \mathrm{NiO\,(s,}\ x_{NiO}=1) & \xrightarrow{\ \mathrm{I}\ } & \mathrm{NiO\,(l,}\ x_{NiO}=0.116) \\ & \searrow^{\mathrm{II}} \quad \nearrow_{\mathrm{III}} & \\ & \mathrm{NiO\,(l,}\ x_{NiO}=1) & \end{array}$$

The change in the Gibbs energy is zero for process I. Process II corresponds to melting of pure nickel oxide at $T < T_m$ and $\Delta G \neq 0$. Process III corresponds to transfer of nickel oxide from pure liquid phase to an alloy of the corresponding composition. In this case, the change in the Gibbs energy corresponds to

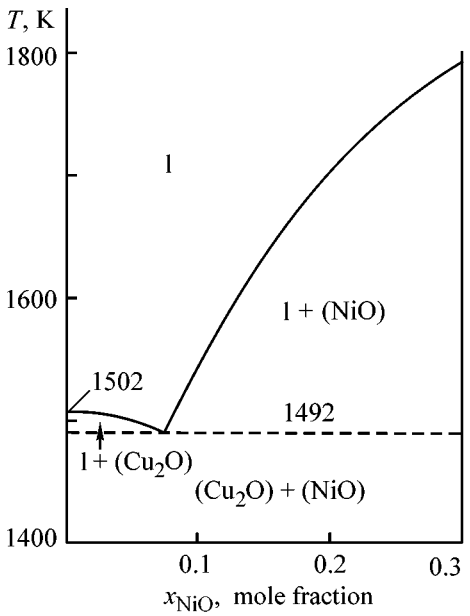

Fig. 2. Fusion diagram of the system Cu_2O–NiO. (T) Temperature.

partial molar energy of NiO in the liquid alloy, $\Delta\bar{G}_{NiO}$, with $\Delta G^{I} = \Delta G^{II} + \Delta G^{III}$. Thus,

$$\Delta\bar{G}_{NiO} = RT\ln a_{NiO} = -\Delta G_{m\,NiO}$$
$$= -(42\,000/2228)(2228 - T). \quad (6)$$

The activities of nickel oxide, calculated along the liquidus line from 1573 to 1492 K (eutectic point), and activity coefficient recalculated to 1573 K over the entire homogeneity region as far as the eutectic point on the assumption of regular solutions are presented in Table 1. To obtain the activity coefficients of NiO for compositions beyond the eutectic point, it is necessary to extrapolate the curve for the activity coefficient of nickel oxide from the initial to zero content (Fig. 1b).

The portion of the liquidus curve along which Cu_2O crystallizes is short (Fig. 2); however, in this case too, the thermodynamic characteristics of Cu_2O in liquid alloys can be calculated along the curve portion in a similar way:

$$\Delta\bar{G}_{Cu_2O} = RT\ln a_{Cu_2O} = -\Delta G_{m\,Cu_2O}$$
$$= -(65\,600/1502)(1502 - T). \quad (7)$$

It should be noted that the region in which solid solutions are formed is negligibly narrow for Cu_2O, with virtually pure component crystallizing. To obtain the activity coefficients of Cu_2O for compositions beyond the eutectic point, it is necessary to extrapolate the curve describing the dependence of the activity

Table 1. Activity coefficients of nickel and copper(I) oxides at 1573 K, calculated for compositions with 7.5–11.6 mol % NiO and 88.4–100 at.% Cu_2O with the use of the phase diagram of Cu_2O–NiO

coefficient of copper(I) oxide from pure Cu_2O to the line of NiO crystallization (Fig. 1b). The activities of copper oxide, calculated along the liquidus line from 1492 (eutectic point) to 1502 K and activity coefficients recalculated to 1573 K over the entire homogeneity region as far as the NiO crystallization line are presented in Table 1.

Because of the very gradual slope of the liquidus line, the activity coefficient of Cu_2O determined from the fusion diagram may be less accurate than the activity coefficient of NiO. For comparison, we calculated γ_{Cu_2O} from the Gibbs–Duhem equation. Contrary to expectations, the activity coefficients of copper oxide, calculated from the fusion diagram, and

those found by integration of the Gibbs–Duhem equation virtually ideally coincide.

Table 2 presents the activity coefficients of both components of the system Cu_2O–NiO and their ratio at 1573 K for the entire homogeneity region to the line of primary crystallization of NiO (0–11.6 at.% NiO).

Thus, we obtained calculated and experimental activity coefficients of the oxide melt components. Comparison of the values obtained shows that both the results are in good agreement. Figure 3 presents the composition dependence of the ratio of the activity coefficients, $\gamma_{NiO}/\gamma_{Cu_2O}$, obtained on the basis of experimental and calculated data. It can be seen that the experimental values are lower than those calculated. This minor discrepancy can be accounted for by the fact that, in contrast to the calculation based on the phase diagram, the estimate using experimental data is made without any assumptions.

It should also be noted that the experimentally obtained limiting activity coefficient γ_{NiO} = 3.96 is in good agreement with the limiting activity coefficient of nickel oxide found to be 3.2 in [8].

CONCLUSIONS

(1) The activity coefficients of copper and nickel oxides at 1573 K in the homogeneity region of the oxide melt (0 to 11.6 mol % NiO) were found on the basis of a study of the equilibrium between a copper–nickel alloy and an oxide melt of the system Cu_2O–NiO. γ_{Cu_2O} varies between 1.0 and 1.11, and γ_{NiO}, between 2.09 and 3.96.

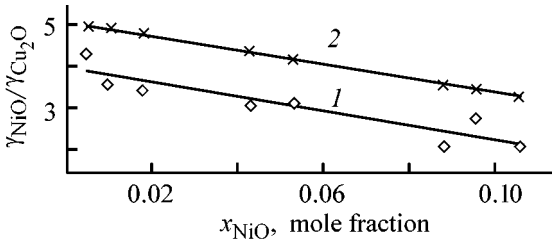

Fig. 3. Ratio of activity coefficients, $\gamma_{NiO}/\gamma_{Cu_2O}$, vs. nickel oxide content x_{NiO} at 1573 K. (*1*) Experimental data and (*2*) calculation.

(2) A conclusion that melts of the system Cu_2O–NiO belong to regular solutions was made on the basis of the data obtained.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Effect of Ultrasonic Field on the State of Starch Hydrogels

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received December 10, 2001

Abstract—Some fundamental aspects of how the primary structure of starch hydrogels with concentration of 1 to 8 wt % disintegrates in an ultrasonic field are discussed. The effect of ultrasonic vibrations on the basic characteristics of starch hydrogels: degree of grain cleavage, viscosity, transparence, and phase composition, is analyzed.

Water–starch gel-like materials are widely used in various industries (textile, food, paper, building, etc.). To ensure the technological usability, starch hydrogels are subjected to thermal, thermochemical, or intensive mechanical treatment [1] in order to destroy their primary structure. The conventional way to prepare gel-like materials from unmodified starches, still employed at domestic plants, is either prolonged cooking (glues, thickeners) or boiling under pressure (size). Both these techniques require much time and thermal energy.

The power intensity and duration of the process can be reduced dramatically by employing mechanical methods [1–3] of preparation of highly dispersed gel-like starch materials, including those with the use of ultrasound. Ultrasonic fields have not found wide application in industry for starch cleavage because of the complexity and poor reliability of the necessary equipment. More promising, in our opinion, is use for these purposes of continuous high-speed rotary-pulsed apparatus (RPA) in which the material treated is subjected to simultaneous action of high-rate shear deformations and ultrasonic field. The influence exerted by conditions of mechanical treatment of starch hydrogels in RPA on disintegration of their primary structure was studied previously [4, 5]. Particular attention was given to dynamic structuring in starch hydrogels under simultaneous action of shear stresses and ultrasonic vibrations in RPA.

The aim of this study was to evaluate the contribution of ultrasonic vibrations to mechanochemical cleavage of starch hydrogels in their treatment in RPA. To solve the problem in hand, disintegration of the primary structure of starch hydrogels under the action of only ultrasound, without shear deformations present in RPA, was studied.

EXPERIMENTAL

As object of study served corn starch [GOST (State Standard) 7697–82]. Starch hydrogels for subsequent ultrasonic treatment were prepared by cooking of a starch suspension on a water bath at 90°C for 15 min.

Starch hydrogels with starch concentration in the range 1–8 wt % were subjected to ultrasonic treatment in a UZDN-2T disintegrator at a frequency F = 22 kHz. The exposure time was 5 to 60 s; the volume density of acoustic energy, found calorimetrically, was 1.34 W cm^{-3}.

The degree of starch grain cleavage (DC, %) was found by centrifugation [6]; the content of the water-soluble fraction of starch, A (%), by the method of hot extraction; and the composition of extracts, spectrophotometrically, using complexation with iodine [7].

The optical densities of solutions were measured on a Spekol-221 spectrophotometer at a wavelength λ = 400 nm.

The starting starch hydrogels are in the form of a dispersion in which swollen starch grains are distributed in a solution of the water-soluble fraction. In starch cleavage by any of the known methods, starch grains disintegrate to a necessary level of dispersity,

1070-4272/02/7504-0526 $27.00 © 2002 MAIK "Nauka/Interperiodica"

determining the technological properties of the gel-like starch material.

The disintegration of the primary structure of starch hydrogels under the action of ultrasonic vibrations is, in fact, the process of dispersion. The term "dispersion" is referred to two different processes: dispersion proper, i.e., disintegration of monolithic particles, and deagglomeration, i.e., rupture of bonds between particles in the agglomerate [8]. Cleavage of starch hydrogels cannot be related with confidence to any of these processes. The specificity of starch hydrogels as microheterogeneous systems consists in that the colloid-disperse phase in these systems is composed on starch grains, which are, in their turn, natural formations with complex morphology. Swollen starch grains can be referred neither to monolithic particles nor to agglomerates, since, on the one hand, they contain finer structural units (fibrils, crystallites), and, on the other, each grain is a unified system with a nucleus and a lipid–polysaccharide shell. One more specific feature of starch dispersions is that the composition and, correspondingly, the viscosity of the dispersed medium change in the course of grain cleavage as a result of partial diffusion of starch macromolecules into solution. For the above reasons, the known procedures for calculating parameters of the dispersion process, developed for common dispersions and, as a rule, based on quite a number of assumptions and limiting conditions including, in particular, the invariable viscosity of the medium, are inapplicable to the case of starch hydrogels [9].

The disintegration of the initial structure of starch hydrogels is accompanied by a decrease in their viscosity, increase in the transparency, and rise in the content of the water-soluble fraction. Analysis of how these parameters vary with increasing time of ultrasonic treatment allows some conclusions on the mechanism of ultrasonic cleavage of starch hydrogels. As seen from Fig. 1, the viscosity reaches a certain maximum value in the very beginning of treatment (τ = 5 s) and then decreases abruptly, with the decrease in viscosity becoming slower after 15 s of ultrasonic treatment. Such a run of the curve describing the decrease in viscosity is in agreement with the run of the curves describing the increase in the degree of cleavage and in the content of the water-soluble fraction. The peak in the viscosity curve is accounted for by the stage of additional swelling which occurs before disintegration of grains because of the removal of their lipid shell limiting the swelling.

It was of interest to compare the rates and mechanisms of grain disintegration in ultrasonic and thermal treatment. For this purpose, one part of the same initial starch hydrogel was subjected to ultrasonic treatment, and another part, to thermal treatment in a closed vessel at a temperature of 105°C and pressure of 1.1 atm without stirring. It was found that the rate of cleavage of starch grains under the action of ultrasound at the volume density of acoustic energy used in the study exceeds by two orders of magnitude and more that in cooking without chemical cleaving agents. For example, an 80% cleavage of grains of a 5% starch hydrogel in cooking without stirring is achieved in 2 h, whereas in the case of ultrasonic treatment the same degree of cleavage is achieved in only 40 s.

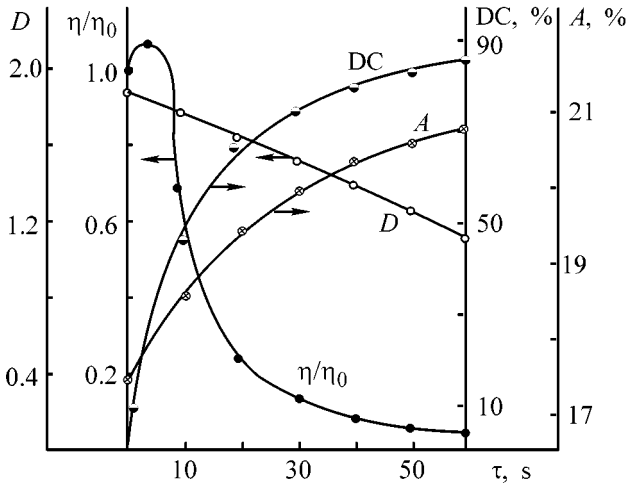

Fig. 1. Optical density D (λ = 400 nm), relative viscosity η/η_0, degree of cleavage DC, and content of water-soluble fraction, A, of starch hydrogels vs. time τ of ultrasonic treatment.

In both cases, the viscosity of hydrogel samples was measured at 80°C to reduce the contribution from the structural component of the viscosity. The viscosity of the hydrogels at this temperature is determined by the content of the water-soluble fraction and the particle size of the colloid-dispersed phase. The same refers to the optical density. As seen from Fig. 2, to the same content of the water-soluble fraction correspond, in the case of ultrasonic cleavage, much lower viscosities and optical densities as compared with those in thermal cleavage, which points to much smaller particle size in ultrasonically treated hydrogels. In thermal cleavage without stirring, the process dominating after the stage of swelling, which also occurs in this case, is diffusion of amylose macromolecules into solution, caused by thermal motion and concentration gradient. Grains weakened by the diffusion start to gradually disintegrate in cooking.

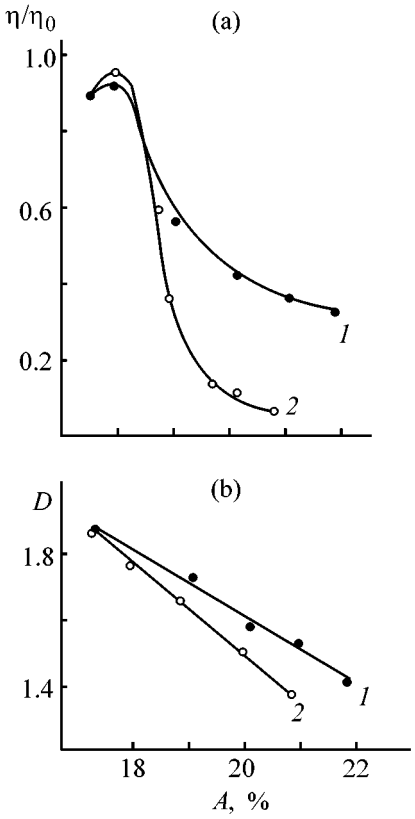

Fig. 2. (a) Relative viscosity η/η_0 and (b) optical density D vs. content A of the water-soluble fraction in cleavage of starch hydrogel (C = 5 wt %). Cleavage: (*1*) thermal (T = 105°C, P = 1.1 atm) and (*2*) ultrasonic (F = 22 Hz, T = 40°C).

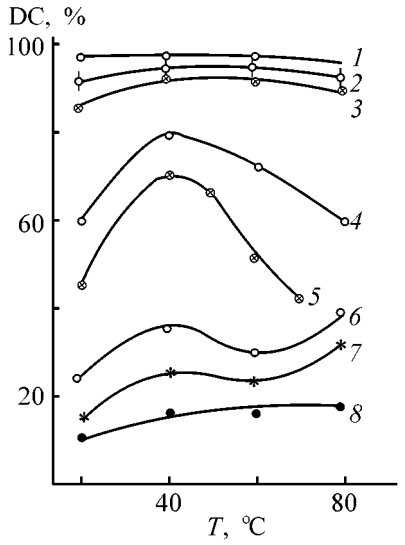

Fig. 3. Degree of cleavage, DC, of starch hydrogels vs. temperature T of ultrasonic treatment. F = 22 kHz, τ = 20 s. Starch concentration C (wt %): (*1*) 1, (*2*) 2, (*3*) 3, (*4*) 3.5, (*5*) 4, (*6*) 5, (*7*) 5.5, and (*8*) 6.

In this connection, a gradual and steady decrease in viscosity is observed.

As is known, the main reason for the high viscosity of uncleaved starch hydrogels is the hydrodynamic effect of swollen grains. Thus, the abrupt decrease in viscosity under ultrasonic treatment indicates disintegration of the majority of swollen starch grains already in the first seconds of ultrasonic treatment.

The key factor in the action of ultrasound on particles of the dispersed phase in a dispersion process is cavitation. In the case of cavitation, dispersion particles mainly disintegrate under the action of impact waves and microjets of liquid, generated by imploding cavitation bubbles. The domination of one or another mechanism in acoustic dispersion is determined by the relative size of cavitation bubbles and particles of the phase [8]. In the case when the particle is much smaller in size than the bubble, no particle fragmentation occurs, but the external layers of the particle as if peel under the action of impact waves. If the particle much exceeds in size the bubble, the initial spherical shape of the latter is distorted and the imploding process is accompanied by formation of high-velocity microjets of the liquid. In this case, the particle disintegration is dominated by the mechanism of wedging at weakened bonds between the structural units.

According to microscopic studies, the size of swollen grains of corn starch is 40–80 μm. The size of cavitation bubbles in water under atmospheric pressure for frequencies of several tens of kilohertz does not exceed tens of micrometers [9], i.e., is of the same order of magnitude as the grain size. There is no reason to expect a noticeable change in this value on passing from pure water to starch hydrogels, since the bubble size is mainly determined by the internal and external pressure, and also by surface tension, which is about the same for water and starch hydrogels [5]. Thus, it would be expected, on the basis of the relative sizes of grains being disintegrated and cavitation bubbles, that both the disintegration mechanisms are operative. Presumably, larger grains are the first to disintegrate. This is due not only to their lower strength [10], but also to the fact that, near the surface of large grains, the spherical shape of cavitation bubbles may be distorted and microjets may form on their implosion, which enhances the wedging effect. In the stage when fragments of large grains and more stable fine grains remain in the volume being treated, the part played by microjets becomes less important because of a change in the relative size of bubbles and particles and the process of cleavage as a whole is slowed down.

We also examined, the influence of the ultrasonic treatment temperature and concentration of starch hydrogels on the efficiency of their ultrasonic cleavage (Fig. 3). For starch concentration of 1 wt % complete cleavage is achieved at any treatment temperature. At other starch concentrations, the efficiency of ultrasonic cleavage increases at 40°C. Because of the multifactor nature of the process of cavitation dispersion, it is difficult to account for this result. In processes of this kind, the optimal temperature is to be found experimentally for each system. The degree of cleavage of starch grains decreases steadily with increasing hydrogel concentration (Fig. 3). This is presumably due, in the first place, to the fact that, at the same density of acoustic energy, its amount per particle being disintegrated decreases with increasing content of these particles in unit volume, i.e., with increasing hydrogel concentration in the case in question. Moreover, account should be taken of the fact that, at the same amount of ultrasonic energy imparted to a given volume of the liquid material, the effectiveness of disintegration of dispersed particles is determined by the erosion activity.

The erosion activity was determined by measuring the mass loss of standard samples of thin (50 μm) aluminum foil submerged in starch hydrogels and placed in parallel to the emitter surface at a distance of 5 mm. The time of exposure was 20 s. Figure 4 shows the erosion activity and degree of starch grain cleavage as a function of the starch concentration. It can be seen that the erosion activity changes only slightly with the concentration varying between 1 and 7%. For gels with concentration of 8%, a much lower damage to the foil was obtained. Thus, in the concentration range 1–7 wt %, both the energy per particle and the erosion activity decrease monotonically with increasing hydrogel concentration. Therefore, it would be, seemingly, expected that the degree of grain cleavage in an ultrasonic field should also decrease monotonically. However, the efficiency of cleavage falls stepwise at starch concentration of 4–4.5%. This behavior is confirmed by concentration dependences of the optical density and content of the water-soluble fraction (Figs. 5a and 5b). It can be seen that, for ultrasonically treated hydrogels, the characteristics mentioned do not vary monotonically with increasing starch concentration, but exhibit a bend at about 4–4.5%. These experimental data can presumably be accounted for as follows. As established previously [5], the curve describing the dependence $\log\log \nu = f(\log C)$ for starch has a clearly pronounced bend at a concentration of 4.5%, indicating a change of the mechanism of viscous flow

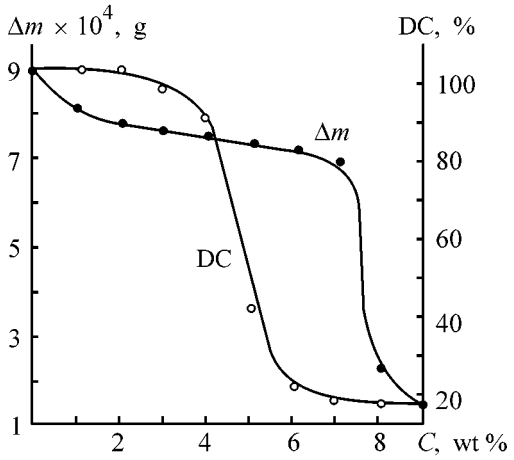

Fig. 4. Erosion activity Δm (F = 22 kHz, τ = 20 s) and degree of cleavage DC of starch hydrogels vs. starch concentration C.

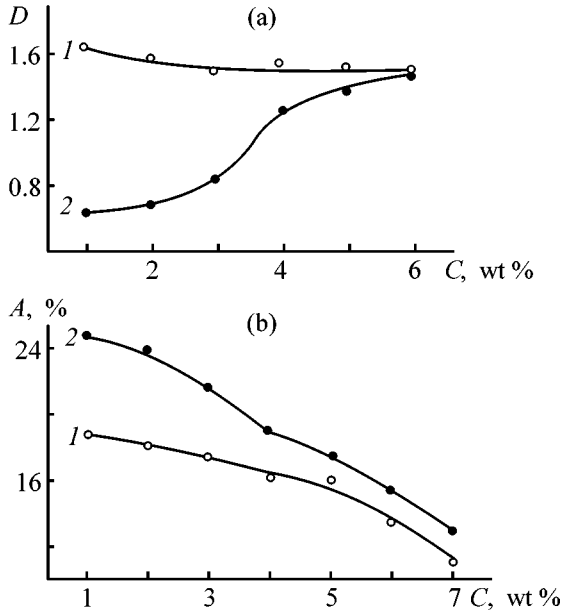

Fig. 5. (a) Optical density D and (b) content A of the water-soluble fraction of starch hydrogels vs. starch concentration C. Sample: (*1*) initial and (*2*) ultrasonically treated (F = 22 kHz, τ = 20 s).

on passing from one concentration range (C < 4.5%) to another (C > 4.5%). Presumably, the presence of a physical network stabilizing the initial structure in hydrogels with C > 4.5% is an additional factor reducing the cleavability of grains.

The most complicated problem encountered in studying the mechanical and, in particular, ultrasonic cleavage of starch is that concerning the degradation of its macromolecules. Determining the molecular weight to monitor the degradation is complicated by

Influence exerted by the time of ultrasonic treatment of starch hydrogels on the peak position in absorption spectra of I_2-amylose complex

* C is the starch concentration

the fraction and phase inhomogeneity of starch hydrogels. To study the extent of degradation of starch hydrogels, we used the method described in more detail in [4]. With this method, changes in the degree of polymerization of starch macrochains can be judged without determining the molecular weight. The method is based on the dependence of the position λ_{max} of the peak in the absorption spectrum of the I_2–amylose complex on the degree of amylose polymerization. In agreement with published data [11], a decrease in the degree of amylose polymerization causes a hypsochromic shift of the absorption peak in the spectrum of the I_2–amylose complex. The watersoluble fraction of starch, mainly composed of amylose judging from λ_{max}, ws used for analysis. The table lists λ_{max} values for the water-soluble fraction, corresponding to the initial and ultrasonically treated samples of hydrogels with various concentrations.

It can be seen from the table that ultrasonic treatment causes a hypsochromic shift of the absorption band of the I_2–amylose complex. Such a shift indicates a decrease in the average degree of amylose polymerization. As shown by analysis, ultrasonic treatment of starch hydrogels for 20 s does not change the concentration of reducing groups. This means that there occurs no degradation of linear macromolecules of amylose with rupture of α-1,4-glucoside bonds. In the case under study, the shift of the absorption band of the I_2–amylose complex is presumably due to accumulation of short amylose fragments formed as a result of amylopectin debranching with rupture of mechanically strained α-1,6 bonds. A similar result was obtained in studying the mechanochemical degradation of starch in treatment of starch hydrogels in RPA [4].

CONCLUSIONS

(1) A fundamental difference between the mechanisms of ultrasonic and thermal cleavage of starch grains in hydrogels was established. This difference consists in that in the former case cavitation cleavage of these grains into fine fragments occurs, and in the latter case grain disintegration is preceded by prolonged period of grain weakening by diffusion.

(2) The highest efficiency of ultrasonic cleavage of starch grains in hydrogels is achieved at a treatment temperature of 40°C.

(3) It was found that, with the content of starch in ultrasonically treated hydrogels becoming higher than a certain critical concentration corresponding to appearance of a physical fluctuation network, the cleavability of starch decreases dramatically.

SORPTION AND ION-EXCHANGE PROCESSES

Ceramic Cation Exchangers in Ion-Exchange Chromatography

Yu. A. Aleksandrov, A. A. Lukuttsov, A. E. Drabovskaya, I. I. Didenkulova, and E. I. Tsyganova

Abstract—The kinetics of attainment equilibrium in sorption and desorption of sodium and potassium ions with foam ceramic cation exchangers with chemically bound phosphate and vanadate groups was studied.

Ionic chromatography is an effective method for analysis of ions. Researchers' efforts are aimed at extending the possibility of the analysis, especially in determining cations. The problem of synthesis of new sorbents for ion-exchange chromatography remains urgent [1].

Small exchange capacity (10^{-3}–5×10^{-2} mmol g^{-1}), resistance to aqueous acids and alkali, and mechanical strength are characteristic of such sorbents.

Transformation of anion exchangers into cation exchangers by modification with phosphoric acid salts was described in [2]. A drawback of a thus obtained cation exchanger is that functional phosphate groups are fixed on the anion exchanger surface by Coulombic forces only, and they are gradually washed away during the process, which decreases the sorbent exchange capacity. Therefore, sorbents with strongly bound functional phosphate groups would be more promising.

In this study, a hydrothermally stable foam ceramic KhIPek [TU (Technical Specifications) 5759-010-10657190–97] [3] was used as a cation exchanger. It was synthesized from alumina with addition of metal oxides. Polymeric aluminosilicate chains were chemically cross-linked with salts of phosphoric acid (sorbent 1) and those of a mixture of phosphoric and vanadic acids (sorbent 2). This exothermic process is accompanied by foaming. The structure of the resulting ceramic is a cellular three-dimensional skeleton similar to that of natural zeolites [4].

The strength of binding of functional groups to the foam ceramics was monitored by the reaction with ammonium molybdate in nitric acid solutions, which is a sensitive and specific test for phosphate ions.

In this study, we examined the possibility of using cation exchangers based on a hydrothermostable foam ceramics with phosphate and vanadate functional groups in ion-exchange chromatography.

EXPERIMENTAL

The sorbents studied were compared with cation exchangers KU × 2-8 (exchange capacity 3–5 mmol g^{-1}) and KANK-KST (0.022 mmol g^{-1}) taken as references.

Foam ceramic sorbents were crushed in a porcelain mortar, and the required fraction was separated by sedimentation.

The sorbent dried in an oven was charged into a 6 × 50 mm standard column of a Tsvet-3006 chromatograph connected to a sample inlet unit and a conductometric detector. Through the column with the sorbent in the H^+ form, washed with water to neutral reaction, we passed aqueous solutions of potassium or sodium nitrate (10^{-4} M) at a flow rate of 6 ml min^{-1}. During the ion exchange, hydrogen ions were liberated, and the conductometric detector recorded the signal as the output sorption curve.

After the attainment of the equilibrium, deionized water was passed through the column at a rate of 6 ml min^{-1} until the stable minimal signal was obtained (the curve of elution of salts from the sorbent intergrain area). After replacing water with 10^{-4} M nitric acid solution, the sodium or potassium ions were eluted from the sorbent at the same flow rate (desorption curve).

The curves of sodium ion sorption are shown in Fig. 1. As seen, they differ in both the equilibrium

signal value and the retardation time τ_0 and time of attainment of the equilibrium t_0. It is more convenient to monitor the differences in the behavior of the sorbents studied by elution curves normalized to the same value of the equilibrium signal. The normalized curves of desorption of sodium or potassium ions from the sorbents studied are shown in Fig. 2. We found that, with the sodium ion, the equilibrium in sorption, washing with water, and elution with nitric acid solution is attained faster then that with the potassium ion. For sorbent 1 containing only phosphate functional groups, the desorption curve of the potassium ion exhibits a step (Fig. 2). The above differences in behavior between sodium and potassium can be accounted for by the fact that hydrated potassium ions, which are smaller by a factor of 1.46 [5], penetrate into the sorbent cells and are retained on phosphate groups, while sodium ions are mainly fixed by the functional groups of the sorbent surface. Therefore, in sorption of potassium ions with sorbent 1, the exclusion mechanism is along with the ion exchange mechanism operative. The possibility of exclusion on cellular sorbents or on cross-linked polymers is mainly determined by matching between the sizes of cells and hydrated ions or molecules. At low concentrations of the substance (10^{-4} M), the exclusion mechanism can be revealed by conductometry based on equivalent exchange of ions with low specific electrolytic conductivity for hydroxonium ions whose conductivity is an order of magnitude higher.

The output curves allow evaluation of the compactness of sorbent packing in the column from both the retardation time τ_0 and the rate of equilibrium attainment. It was found that the denser the packing, at a lower rate the equilibrium is attained.

Since the packing compactness is related to the size of sorbent grains and to the rate of the equilibrium attainment, we plotted the nomogram

$$\Delta E/\Delta t = 3.12 \times 10^{-2} d - 0.144, \quad (1)$$

where $\Delta E/\Delta t$ is the rate of equilibrium attainment for the output curves (Fig. 1), i.e., the variation of the recorder signal in unit time, and d is the sorbent grain diameter within the 20 (KANK-KST)–1500 μm (KU × 2-8) range.

Using the experimental rates of equilibrium attainment (Fig. 1) and Eq. (1), we calculated the grain sizes of sorbent 1 and sorbent 2 to be 290 and 420 μm, respectively.

The compactness of the sorbent packing can also be quickly estimated from the correlation between the pressure in the column and the retardation time of the sorption curve (Fig. 3). The denser the packing, the slower the flow of the mobile phase through the

column, and hence the longer the retardation time. On the other hand, the packing compactness increases with decreasing sorbent grain size. Correspondingly, a higher pressure is required to press the mobile phase through the column at a definite rate. For sorbents 1 and 2, this pressure does not exceed the level of 6–9 MPa, which is acceptable for liquid chromatography.

One of the main characteristics of any ion exchanger is its exchange capacity. The sorption and desorption output curves allow estimation of this parameter. The height of the step of the output curve, corresponding to the equilibrium signal, is proportional to the sorbent exchange capacity. The nomogram of the logarithm of the exchange capacity as a function of the equilibrium signal (Fig. 1) within the range from 0.022 mmol g^{-1} for KANK-KST sorbent to 4 mmol g^{-1} for KU × 2-8 sorbent is described by the equation

$$\log S = 5.6 \times 10^{-3} h - 1.99, \qquad (2)$$

where S is the sorbent exchange capacity (mmol g^{-1} sorbent), and h is the equilibrium signal of the sorption (desorption) output curves.

For sorbents 1 and 2, the exchange capacities estimated by Eq. (2) amount to 0.06 and 0.09 mmol g^{-1} sorbent, respectively.

To confirm these results, we used potentiometric titration. From the dependence of pH on the volume of alkali solution spent for titration of a sorbent sample in the H^+ form, we calculated the sorbent exchange capacity. The foam ceramic sorbents studied differ in exchange capacity only slightly (by t-test); its average value was 0.040 ± 0.004 mmol g^{-1} sorbent.

Thus, we showed by both potentiomentric titration and calculation by Eq. (2) that the exchange capacities of sorbents 1 and 2 are close to that of KANK-KST and amount to several hundredths of mmol g^{-1}. This level is acceptable for using foam ceramic sorbents to separate cations by ion-exchange chromatography.

The above method allows chromatographic separation of ion mixtures, using a single column without modifying the installation design.

It follows from Fig. 4 that both sorbents allow separation of sodium and potassium ions. In the chromatogram of sorbent 1 (Fig. 4a), two peaks correspond to potassium ions. This fact confirms specific features of the ion exchanger, revealed in dynamic studies of potassium sorption.

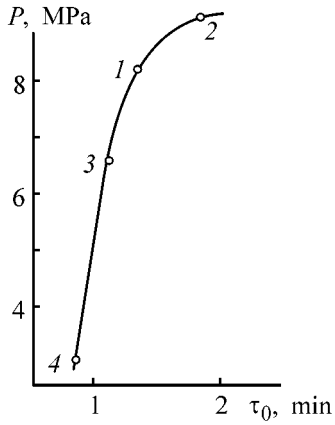

Fig. 3. Correlation between the pressure P in the column and the retardation time τ_0 (see Fig. 1), for the case of a sodium nitrate aqueous solution passed through the column.
