Fig. 4. Chromatogram of NaCl and KCl separation on sorbents (a) 1 and (b) 2. Eluent: aqueous solution of nitric acid. Conductometric detector (Tsvet-3006 chromatograph). (*E*) Detector signal and (*t*) time. (*1*) Cl^-, (*2*) Na^+, and (*3*) K^+.

Comparison of chromatograms in Figs. 4a and 4b shows that sorbent 1 separates ions better than sorbent 2. Since the separation efficiency depends on packing compactness in the column, which, in turn, depends on the grain size, we can conclude that the experimental chromatogram is in good agreement with the grain size of the sorbents calculated on the basis of dynamic studies.

CONCLUSIONS

(1) In sorption with foam ceramic sorbents, sodium ions are sorbed, washed with water from intergrain

space, and desorbed faster than potassium ions. In sorption of potassium ions on sorbent 1, both exchange and exclusion mechanisms are imported.

(2) Foam ceramic sorbents 1 and 2 with low exchange capacity, 0.06–0.09 mmol g^{-1} sorbent, are similar in sorption properties to cation exchangers for ion-exchange chromatography.

(3) Single-column chromatographic separation of potassium and sodium ions was performed, and a possibility was demonstrated of using foam ceramic cation exchangers with chemically fixed phosphate and vanadate groups in the ion-exchange chromatography.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Eremomycin on Carboxylic Cation Exchangers

Abstract—The relationships of sorption of antibacterial antibiotic eremomycin on carboxylic cation exchangers were studied. The difference between gel-like and structurally segregated carboxylic cation exchangers were analyzed by potentiometric titration. The optimal conditions for sorption and desorption of eremomycin were found.

Eremomycin, a modern antibiotic belonging to the group of polycyclic glycopeptides (dalbaheptides), was recovered from a culture broth of INA-238 actinomycetes. This antibiotic produces strong bactericidal effect on Gram-positive microorganisms. At the same time, it does not influence the growth and development of animals and does not change the morphology of internal organs [1].

Eremomycin is a *zwitter*-ion containing three primary amino groups (pK^1_{a1} 6.9, pK^2_{a1} 7.9, and pK^3_{a1} 9.0), phenyl groups (pK^1_{a2} 9.7, pK^2_{a2} 10.4, and pK^3_{a2} 11.35), and a terminal carboxy group (pK_a 3.1). The molecular weight of eremomycin $C_{73}H_{89}N_{10}O_{20}Cl$ is 1540 [2]. Owing to its amphoteric nature, eremomycin can be sorbed on both cation and anion exchangers.

At present, eremomycin is obtained biosynthetically. The initial preparation is purified by multistage extraction and then subjected to chemical modification. Production of eremomycin involves problems associated with the low yield of the target product, toxicity of the by-products, and detrimental environmental effect of the organic solvents [2].

Comparison of sorption characteristics of eremomycin *zwitter*-ion on sorbents of different types and structures is of interest from both scientific and practical viewpoints. Such a comparative study, on the one hand, extends the set of experimental data on sorption of such complicated substances as zwitterions, and, on the other, allows the development of a technique for recovery of this antibiotic from the native solutions containing products of the microbial metabolism.

EXPERIMENTAL

In our experiments, we used crystalline samples of eremomycin sulfate.[1] The content of the main substance, as determined by HPLC analysis, was 98.5%.

The following sorbents were tested: Polysorb [nonionic macroporous sorbent with poly(styrene–divinylbenzene) matrix], polydextran T70, AV-17 × 8 [highly basic anion exchanger based on poly(styrene–divinylbenzene) copolymer], sorbents of BDM type (carboxylic cation exchangers produced by radical copolymerization of methacrylic acid MAA and ethylene glycol dimethacrylate DMEG [3]), and MN-500 {isoporous sulfonated poly(styrene–divinylbenzene) copolymer prepared in the presence of cyclohexane as porophore [4]}.

Potentiometric titration of the sorbents was carried out by the technique of separate weighed samples [5]. A 0.1–0.2-ml portion of distilled water was added to 50 mg of sorbent and stirred for 20 min to completion of swelling. To provide different degrees of ionization of the sorbent α, a calculated volume of a titrated NaOH solution was added. The degree of ionization α was calculated by the equation:

$$\alpha = c_{NaOH} V_{NaOH} \times 1000 / E m_{sorb}, \quad (1)$$

where c_{NaOH} and V_{NaOH} are the concentration (mg-equiv ml^{-1}) and the volume (ml) of the titrant,

[1] The material was prepared in the Scientific Research Institute for New Antibiotics, Russian Academy of Medical Sciences, Moscow, Russia.

respectively; E, the total exchange capacity of the sorbent (mg-equiv g^{-1}); and m_{sorb}, the sorbent weight (mg).

After the attainment of equilibriium, the pH of the solution was measured and the curve of potentiometric titration in the Henderson–Hasselbach coordinates

$$pH = f\{\log[(1 - \alpha)/\alpha]\}. \quad (2)$$

was constructed.

The experiments on sorption of eremomycin were carried out in 0.2 M ammonium acetate [6]. The pH was adjusted with HCl (1 M) and NH_4OH (25%). The eremomycin concentration ranged from 0.2 to 1.5 mg ml^{-1}. Such levels are attained in the culture broth due to metabolism of INA-238 actinomycetes.

* pK determined by extrapolation of the linear plot of pH vs. log[(1 – α)/α] to interseption with the abscissa; n the slope of this plot.

** The figure in the sorbent brand refers to the content of the cross-linking agent (mol %).

The sorption kinetics of eremomycin was studied as follows. Distilled water (0.1–0.2 ml) was added to a dry sample of the ion exchanger (50 mg), and the mixture was stirred for 20 min to sorbent swelling. Then, 20 ml of the eremomycin solution in 0.2 M ammonium acetate with eremomycin concentration of 1 mg ml^{-1} was added to the swollen ion exchanger at the prescribed pH. In the course of the kinetic experiment performed at continuous stirring, 0.2-ml samples were taken at regular intervals. The eremomycin concentration in the solution was determined spectrophotometrically at λ = 280 nm, using a calibration curve. In preliminary experiments, we found that the rate of eremomycin sorption is independent of the antibiotic concentration and stirring rate. These experiments also showed that the limiting stage of eremomycin sorption on the cation exchanger is its diffusion into the sorbent granule. The pore-diffusion mechanism of kinetics of eremomycin sorption on the carboxylic cation exchanger was also confirmed in sorption experiments with intermittent separation of the cation exchanger and aqueous phases. In these experiments, sorbent granules were separated from the solution, kept for 20 h, and then returned into the same solution. We found that, on repeated contact of the cation exchanger and solution, the sorption rate increases as compared to that before phase separation. This fact shows that the cation pore-diffusion is the limiting stage of sorption. The internal diffusion coefficient was calculated by the Boyd equation [5]

$$\overline{D} = 0.087 \tan^2 \beta R^2, \quad (3)$$

where $\overline{D}$ is the effective diffusion coefficient ($cm^2 s^{-1}$); R, the radius of the swollen cation exchanger granule (μm); β, the slope the linear part of the plot F vs. $t^{1/2}$; $F = m_t/m_\infty$, the fraction of the total sorption capacity of the sorbent consumed by the sorbate; m_t, the sorption capacity in a time t; and m_∞, is the equilibrium sorption capacity.

The half-saturation time of the sorbent with the antibiotic (F = 1/2) was calculated from the plot of F vs. t.

Figure 1 shows the curves of potentiometric titration of the cation exchangers of BDM type and sulfonic cation exchanger MN-500 in the Henderson–Hasselbach coordinates. The parameters the Henderson–Hasselbach equation for different sorbent types are listed in Table 1.

With increasing degree of cross-linking, the total exchange capacity E of ion exchanger of the BDM type falls because of a decrease in the carboxy group content. The mobility of protons of the carboxy groups of cation exchanger depends on the content of the hydrophobic ethylene glycol dimethacrylate cross-linking units (DMEG) in the cation exchanger matrix. By the character of the influence exerted by the cross-linking agent on pK_a, the carboxylic cation exchangers can be subdivided into two groups: gel-like with DMEG content less than 5 mol % and structurally segregated cation exchangers with DMEG content exceeding 5 mol % [3]. For gel-like cation exchangers, the acidity of the cation exchanger decreases with increasing the DMEG content. As seen from Table 1, this decrease in acidity correlates with the decrease in the swelling coefficient. As the DMEG content is decreased, the sorbent swelling increases owing to the enhancement of the intrapolymeric hydration and increase in the entropy of the expanded matrix. Although these factors facilitate ionization of the carboxy groups, the irreversible sorption of biologically active compounds on these sorbents hinders their effective recovery by preparative-chromatographic technique [6].

The structurally segregated cation exchangers in the H form are characterized by an abnormally strong rise in swellability with increasing content of the cross-linking agent. The enhanced swelling may be due to the loose network structure formed because of the isolation of the double bonds of the cross-linking agent [7, 8]. One of the possible factors hampering cross-linking are hydrophobic interactions between methacrylic acid molecules, resulting in additional structurization of microgel sites in the polymeric network. This is the reason for the rise in acidity of BDM-9 and BDM-12 cation exchangers with increasing DMEG content.

The n term in the Henderson–Hasselbach equation characterizes the influence exerted by the degree of carboxy group ionization on the apparent ionization constant of the cation exchanger. The larger the difference between n and unity, the stronger the effects of ionized carboxy groups on the ionization of non-ionized carboxy groups in the sorbent. This means that, with increasing degree of ionization, the density of distribution of the ion-exchange sites in the polymeric matrix grows. In the absence of mutual effects of the ionized and unionized carboxy groups, the ideal ionization occurs (n = 1). In passing from BDM-1 to BDM-5 gel-like cation exchangers, n increases. This effect is due to the lower concentration of carboxy groups in the loosest BDM-1 cation exchanger, compared to that in BDM-5 gel-like sorbent with strongly cross-linked structure. The segregated sorbents with similar structure have close n. It is of interest that n of BDM-12 cation exchanger, belonging to the structurally segregated sorbent type, is virtually equal to that of BDM-1 gel-like sorbent. This fact shows that these sorbents have approximately the same densities of distribution of ionizable carboxy groups. MN-500 sulfonic cation exchanger exhibits a higher acidity. The n parameter of this sorbent is close to those of structurally segregated cation exchangers, which reflects the similarity in cooperative interaction between the carboxy groups in ionization of these sorbents.

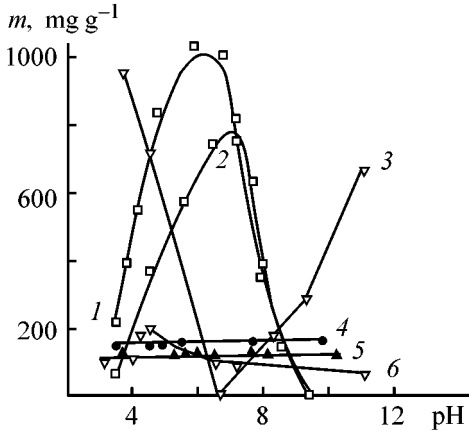

Fig. 2. Specific sorption of eremomycin m vs. pH: (*1*) BDM-3, (*2*) BDM-12, (*3*) MN-500, (*4*) Polysorb, (*5*) dextran T-70, and (*6*) AV-17 × 8.

The potentiometric titration gives insight into the correlation between the sorption capacity of the cation exchanger for eremomycin and the equilibrium pH of the sorbate solution (Fig. 2). The plots of the sorption capacity of carboxylic cation exchangers for eremomycin vs. pH show a sharp maximum at pH ~7 (curves *1* and *2*). We believe that this maximum is due to competition between the electrostatic attraction of the sorbent and antibiotic molecules and the repulsion between their likely charged functional groups. The ionization of carboxy groups of the cation exchanger strongly depends on pH of the sorbate solution. The ascending portion of sorption curves *1* and *2* (Fig. 2) corresponds to gradual dissociation of the carboxy groups and their association with the positively charged amino and phenyl groups of eremomycin (at pH < 7). At pH 3.5, the carboxylic cation exchanger is completely converted to the H form exhibiting some sorption capacity for eremomycin (~100–200 mg g^{-1}). Under these conditions, sorption occurs by the mechanism of hydrophobic interactions between the sorbent and antibiotic [8]. After the maximal sorption is reached at pH close to neutral re-

Table 2. Effect of cross-linking agent content on the sorption characteristics of eremomycin on carboxylic cation exchangers at pH 6.95

Sorbent	$t_{0.5}$, min	$\overline{D} \times 10^4$, $cm^2\ s^{-1}$
BDM-3	1.84	3.82
BDM-5	14.4	0.2
BDM-9	9.4	1.74
BDM-12	1.7	5.62

action, the sorbability of eremomycin gradually decreases with increasing pH, and at pH 9.5–10 the carboxylic cation exchangers lose their sorption power with respect to eremomycin. These data suggest that interaction between eremomycin and carboxylic cation exchanger in the pH range corresponding to the descending portion of sorption curves *1* and *2* is controlled by both transformation of the amino and phenyl groups to the nonionized state and ionization of the eremomycin carboxy groups. In contrast to the acidic pH range corresponding to partial ionization of the carboxy groups of the antibiotic molecule, the carboxy groups of both cation exchanger and antibiotic are completely ionized in the alkaline pH range. Under these conditions, the repulsion between the ionized sorbing sites and antibiotic molecules prevails over the hydrophobic interactions, and, therefore, the cation exchanger loses its sorption power with respect to eremomycin. Thus, eremomycin exhibits in the alkaline pH range a sorption behavior similar to that in the acidic region.

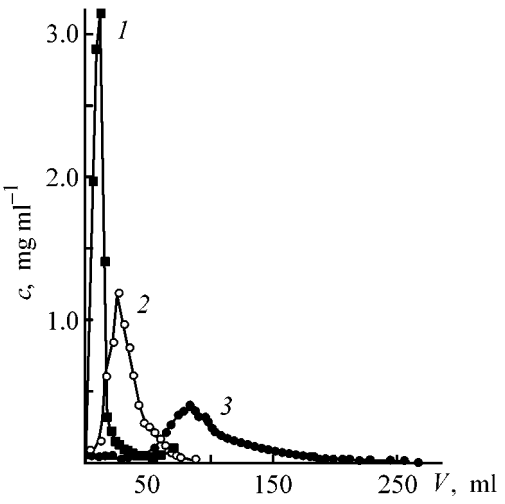

Fig. 3. Elution of eremomycin from structurally segregated BDM-12 cation exchanger. Eluent 0.2 M ammonium acetate. (*c*) Eremomycin concentration in eluate and (*V*) eluent volume. pH: (*1*) 8.6, (*2*) 9.5, and (*3*) 10.5.

The sorption of eremomycin on molecular sorbents and anion exchanger as influenced by pH is shown in Fig. 2 (curves *4*–*6*). These sorption curves are similar: the sorption of eremomycin is virtually independent of pH in the range 3.5–11.5, and its value is lower than that on cation exchangers. The insensitivity of sorption of amphoteric eremomycin molecules to pH and its sharp decrease in the presence of organic solvents [9] suggest that eremomycin is sorbed on the molecular sorbents and anion exchangers mainly by the mechanism of hydrophobic interactions.

A different pattern occurs in sorption of eremomycin on MN-500 sulfonic cation exchanger (Fig. 2, curve *3*). The degree of ionization of sulfonic cation exchanger considerably exceeds that of the carboxylic cation exchanger. Therefore, even at pH 3.5 the ionized sulfo groups of the sulfonic cation exchanger can bind the amino and phenyl groups of the antibiotic, and this sorbent exhibits the maximal sorption capacity for eremomycin zwitterion. With pH increasing to 6–7, the amino and phenyl groups of eremomycin are partially converted to the nonionized state, whereas the carboxy groups become completely ionized. Thus, the sorption of eremomycin on the cation exchanger ceases even in the neutral pH region. The ascending portion of curve *3* (Fig. 2) shows further increase in the eremomycin sorption due to enhancement of hydrophobic interactions between eremomycin and MN-500 cation exchanger at pH ~11.0–11.5.

Since the natural aqueous medium populated with INA-238 actinomicetes has pH ~7, the sorption kinetics of eremomycin on carboxylic cation exchanger was studied at pH 6.95 corresponding to the maximal sorption.

Table 2 shows that for gel-like cation exchangers the half-saturation period becomes longer with increasing content of the cross-linking agent. According to these data, the eremomycin diffusion coefficient and the rate of its sorption decrease with increasing cross-linking of the sorbent. The eremomycin diffusion in BDM-9 and BDM-12 structurally segregated sorbents occurs by a different mechanism. At the DMEG content in the cation exchanger higher than 5 mol %, the antibiotic can diffuse within cation exchanger granules not only through transport channels located in the structural sites with loose network but also through more strongly cross-linked sites surrounding the transport channels [3]. In the cation exchangers with denser polymeric network and rigid channels, eremomycin diffuses only through sites with loose structure and is anchored at the channel walls.

Therefore, the sorption rate of eremomycin on such sorbents grows with increasing content of the cross-linking agent.

Our studies of eremomycin desorption from carboxylic cation exchangers under dynamic conditions were aimed at finding the conditions providing effective desorption of eremomycin at its high concentration in the eluate. We found that eremomycin can be quantitatively desorbed with aqueous acid solution, commonly used for antibiotic elution, only upon addition of an organic solvent. In this procedure the cation exchanger is converted to the H form, whereas eremomycin occurs as the zwitterion.

In elution of eremomycin from BDM-12 cation exchanger with more alkaline aqueous solutions, the elution curve becomes sharper, and desorption of eremomycin becomes more complete (up to 95%) (Fig. 3). Under these conditions, eremomycin is converted from zwitterionic to carboxylate anionic form.

CONCLUSIONS

(1) Combined analysis of data on potentiometric titration and swelling of carboxylic cation exchangers shows that the structural organization of the polymeric matrix considerably affects the ionization constant of the carboxy groups pK_a and the parameter n. The strongest mutual effect of the ionized and nonionized carboxy groups is observed in gel-like cation exchangers.

(2) The opposite effects of ionization of the carboxy groups of cation exchanger, on the one hand, and dissociation of amino, phenyl, and carboxy groups of eremomycin, on the other, on the eremomycin sorption result in a peak in the plot of the eremomycin sorption vs. equiblibrium pH of the sorbate solution.

(3) The equilibrium sorption of eremomycin on cation exchangers is reached sufficiently fast.

(4) Complete elution of eremomycin from BDM-12 carboxylic cation exchanger at high antibiotic concentration in the eluate can be reached by conversion of eremomycin from the zwitterion to the carboxylate anion.

SORPTION AND ION-EXCHANGE PROCESSES

ESR Characterization of Vegetable Carbon Materials

O. V. Kravchenko, D. I. Shvets, V. V. Strelko, and T. I. Mironyuk

Institute of Sorption and Endoecological Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received December 4, 2001

Abstract—Paramagnetic centers arising in carbonization of vegetable raw materials at 290–450°C were studied.

Preparation of selective carbon-containing sorbents of new generation for solving ecological, medicinal, and other problems requires use of new methods for stage-by-stage monitoring of their production. One of such methods is electron spin resonance (ESR), which is highly sensitive and allows monitoring of variation of paramagnetic characteristics in process optimization and commercial production of the required materials.

For example, the mechanism of formation and the nature of paramagnetic centers (PMCs) in carbon materials have been studied previously [1–6]. The main attention in [3–6] was given to analysis of ESR signals of carbons produced by high-temperature heat treatment.

Here we report on an ESR study of paramagnetic characteristics of intermediate carbon materials produced by power-saving low-temperature carbonization of various vegetable raw materials (wood sawdust, leaves, straw, husk, grape sprat, etc.). Some features of these low-temperature processes were discussed in [5, 6] for the case of carbonization of coke and pitches in oxygen-free medium. In so doing, it was found that the ESR spectra of carbons are complicated and depend on many factors, among them sensitivity to oxygen in thermal treatment. Contrary to these studies, we studied here the nature of active PMCs of carbon materials in carbonization of raw materials in oxygen. The emphasis was placed on a study of this process in the intermediate stages of removal of water and organic substances from the matrix structure.

Finely divided vegetable raw materials were heat treated in air in the range 290–450°C. The ESR spectra were recorded on a computerized upgraded RE-1306M spectrometer. α,α'-Diphenyl-β-picrylhydrazyl and also Mn^{2+} ions in a MgO matrix were used as reference. The spectra were processed as described in [7].

The ESR spectra and variation of the width and intensity of PMC signals with carbonization temperature are shown in Figs. 1 and 2. The results obtained allow the following conclusions.

(1) Contrary to the generally accepted views that the intensity of ESR signal depends linearly on the temperature of heat treatment, we found that, in low-temperature carbonization in the intermediate single-stage mode, there is a clearly pronounced increase in the intensity of the ESR signal in the range 300–350°C.

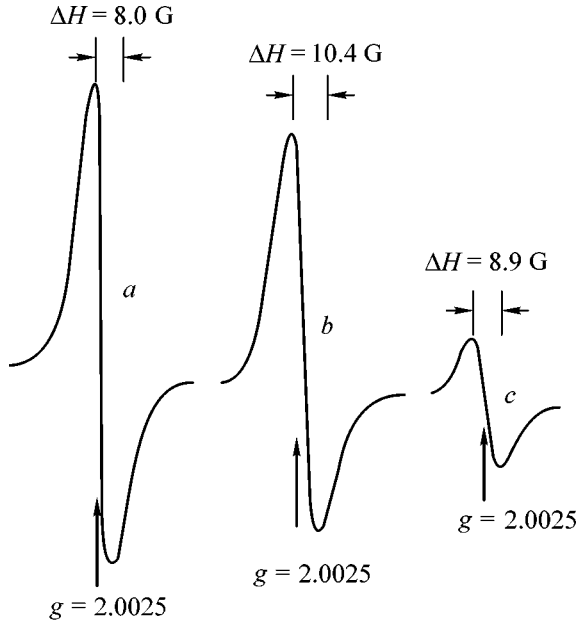

Fig. 1. Influence of the type of raw materials to be carbonized on the ESR signal. (*a*) Pine sawdust, (*b*) straw, and (*c*) leaves.

1070-4272/02/7504-0540 $27.00 © 2002 MAIK "Nauka/Interperiodica"

(2) In the initial (ascending) portion of the curve, a clearly pronounced change in the width of the ESR signals occurs (drop to ΔH = 4 G), which correlates with the weight loss in this temperature range.

(3) With further heating, in the descending portion of the curve (after passing of the maximum), changes are observed both in the line widths of ESR signals (further narrowing to ΔH = 3 G) and in the line shapes (the symmetric line becomes asymmetric, and the degree of asymmetry reaches 1.5–1.6). In this case, the signal asymmetry is retained in a wide temperature range (290–450°C).

The characteristics of PMCs of carbon materials obtained under the optimum conditions of single-stage heat treatment of raw materials substantially differ from the characteristics of samples prepared by two-stage carbonization: the ESR signal is narrowed still further to ΔH = 1.5–2.0 G. In addition, the shape of the ESR signal also depends on the type of a raw material being carbonized.

Hence, the characteristics of the ESR signals of materials produced in the low-temperature intermediate regime of carbonization substantially differ from the characteristics of signal from PMCs typical of high-temperature samples of carbon materials.

In turn, the results obtained suggest that complicated and diverse transformations take place in this temperature range, including those accompanied by formation of structural-sorption parameters of carbon materials, i.e., by transformations of the phase transition type. This is confirmed by the fact that, when the intensities of ESR signals reach a maximum, both the widths (narrowing) and the shapes (appearance of asymmetry) of the ESR signals change simultaneously, which is apparently caused by structural rearrangements and by ordering of interphase structures. It should be noted that the degree and rate of structural-chemical transformations attain a maximum in this temperature range, which can be accounted for by the presence of an extremum corresponding to a phase transition. At the same time, subsequent deceleration of the rise in intensity of the narrowing ESR signal suggests completion of the stage of structural rearrangement, which is confirmed by the appearance of a narrower ESR signal (ΔH = 3.5 G). The appearance of this signal may be due to further ordering of the structures formed in the course of phase transition. However, this phase transition is not completed, as suggested by the fact that the ESR signals become more asymmetric.

If this is the case, we can suggest that qualitative and quantitative changes in the structure of ESR signals reflect both physicochemical and phase transformations in total. Therefore, it can be expected that unusual paramagnetic characteristics should be manifested in atypical behavior of these carbon materials in sorption, desorption, etc. Indeed, studies of carbon materials produced under optimal conditions of carbonization (Fig. 3) revealed their abnormally high sorption capacity [(in particular, for petroleum, up to 12 g g^{-1}; maximum SEC (static exchange capacity) 3.5–4.0 mg-equiv g^{-1}] and nearly absolute hydrophobicity, preserved for a long time (5–6 months). At the same time, samples of carbon materials produced in regimes different from the optimum have nearly opposite characteristcs (low sorption capacity, extremely high moisture capacity, irreproducible SEC, etc.)

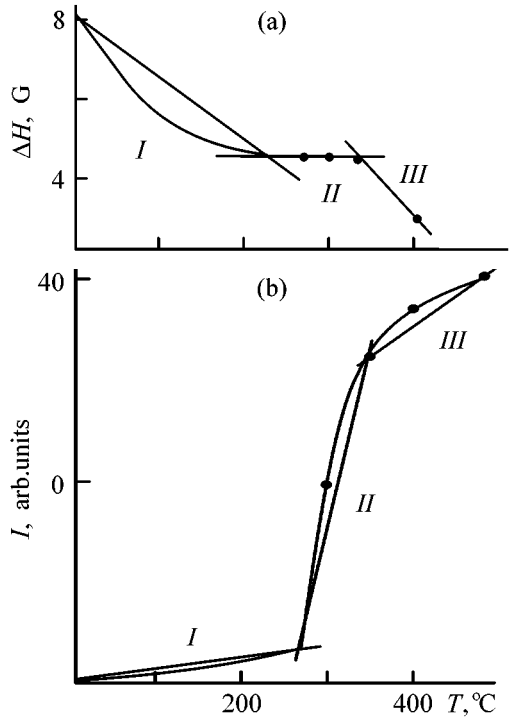

Fig. 2. (a) Width ΔH and (b) intensity I of the ESR signal from carbon materials (sawdust) vs. carbonization temperature T. (*I*) Temperature range in which water is removed; (*II*) intermediate range in which water removal is complete and removal of organic compounds begins; and (*III*) the range in which organic fractions are removed; the same for Fig. 3.

Thus, we can suggest that the abnormal paramagnetic characteristics of carbon materials in the range of transition stage (phase transition) must also be accompanied by abnormal physical and biochemical characteristics. This is confirmed, e.g., by high affinity in immobilization of microorganism strains on these matrices and abrupt variation of the Z-potential in the optimal mode.

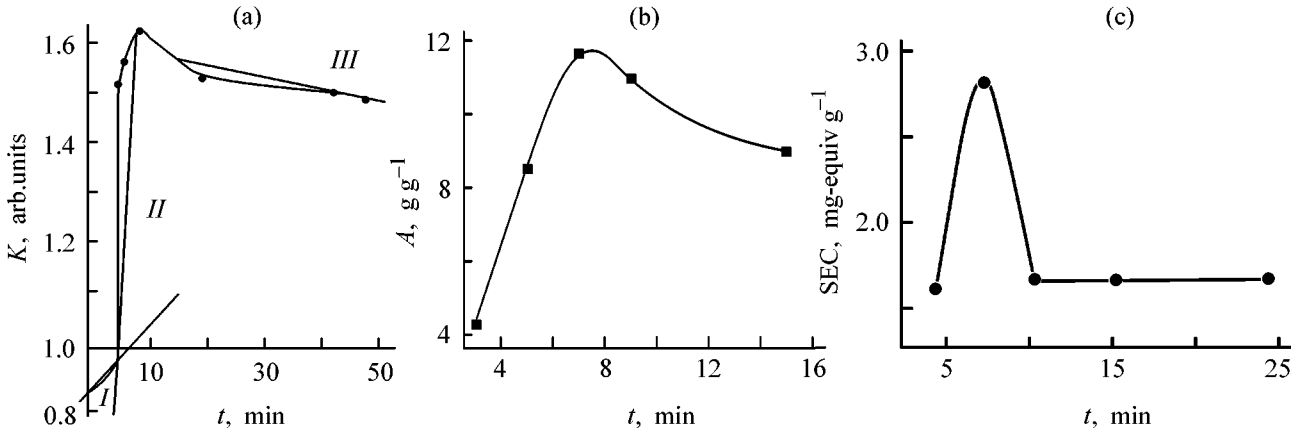

Fig. 3. (a) Degree of asymmetry of ESR signals, *K*, (b) oil capacity, *A*, and SEC of carbon materials (sawdust) vs. carbonization duration *t*.

Data on breaking of the symmetry of ESR signals in a relatively narrow temperature range (290–320°C) deserved special attention. This can be accounted for by a structural rearrangement of the matrix. Hence, the assumption that a phase transition occurs in the course of low-temperature carbonization of the material is confirmed. In addition, analysis of the whole set of varying characteristics of the ESR spectra furnishes valuable data on the specific nature of phase transitions. This opens up new avenues for understanding of processes occurring in phase transitions and also allows the use of new methods for monitoring and control of production of carbon materials with prescribed characteristics and well-defined structural-sorption parameters (pore type and size).

Thus, the study of paramagnetic characteristics of carbons produced by low-temperature carbonization furnishes valuable data on the specific nature of energy-controlled transformations in carbon-containing composites (phase transitions, formation of structural and sorption parameters, energy state of the surface, etc.) and, hence, allows prediction of the characteristics of the newly developed materials.

Received June 26, 2001

Abstract—Principles of designing of ultrahigh-power batteries and their electrodes are formulated on the basis of a theoretical analysis of phenomena limiting the rate of battery discharge. Experimental evidence in favor of the possible practical implementation of the principles proposed is presented.

Modern alkaline batteries have the maximum discharge current of 10 C [A (A h)$^{-1}$] [1]. This means that they can be effectively used at discharge duration more than 100 s. At shorter pulses of discharge current, batteries put out only a minor fraction of the energy stored and, therefore, lose their main advantage, high specific energy, and become inferior to their competitors, electrochemical capacitors. The most widely occurring type of the latter are capacitors with electrodes made of high-porosity carbon materials and electrolyte based on organic solvents. These capacitors operate on the principle of charging–discharge of the double layer. Recently, the demand for energy storage devices for 0.2–100-s pulses has been increasing continuously, which stimulates the rise in manufacture of electrochemical capacitors (in both quantity and quality) [2]. However, this type of energy storage devices has its own disadvantages: low energy storage capacity (only up to 5 W h kg^{-1}), high cost, fire risk, and explosion hazard.

It can be expected that, on changing fundamentally the technology of electrode fabrication and design of batteries, their specific power can be made tens and hundreds of times higher, so that they would compete successfully with electrochemical capacitors in numerous important applications.

(1) Conditions for achieving a high specific power of batteries. The discharge current of battery is limited by four interrelated quantities: internal resistance of electrolyte and current leads, rate of electrochemical processes on electrodes, rate of equalization of charges and potentials across the electrode thickness, and rate of equalization of electrolyte concentration in electrodes and separator.

Each of the quantities mentioned may become rate-determining under certain conditions and limit the discharge current and, consequently, the power of a battery.

The internal resistance of the electrolyte depends on the electrolyte resistance and on the thickness and porosity of the separator:

$$R_e = \rho_e \delta_s \varepsilon^{-\nu}, \quad (1)$$

where R_e is the internal resistance of the electrolyte in separator pores per unit geometric surface area (Ω cm^2), ρ_e the electrolyte resistivity (Ω cm), δ_s the separator thickness (cm), ε the separator porosity, and ν a constant dependent on the shape of separator pores.

At $\nu = 1.5$, the R_e value calculated using formula (1) has an intermediate value obtained using the known formulas of Fricke [3] and Mashovets [4]. Formula (1) shows that the separator must be thin and highly porous.

The internal resistance of a current lead (collector) depends on the collector thickness, resistivity of the material used, and electrode length in the direction of current supply:

$$R_c = \rho_c L^2 / 2\delta_c, \quad (2)$$

where R_c is the collector resistance per unit geometric surface area (Ω cm^2), ρ_c the resistivity of the material (Ω cm), δ_c the thickness (cm), and L the length in the direction of current supply (cm).

From formula (2) follows a quadratic dependence of the resistance of collector on its length. Thus, the electrode length in high-power batteries is limited by the admissible value of the internal resistance.

The rate of electrochemical processes is determined by temperature and specific surface area of particles

1070-4272/02/7504-0543 $27.00 © 2002 MAIK "Nauka/Interperiodica"

of the active paste, which are in contact with the electrolyte and in electronic contact with the collector. The large the total surface area of particles in contact with the collector, the lower the polarization resistance. Consequently, all particles of the active paste in high-power batteries must have reliable electrical contact with the collector, and their total surface area must be as large as possible.

The rate of charge and potential equalization across the electrode thickness is determined by the thickness and effective capacity of the active paste and effective electrolyte resistivity in pores. To a first approximation, the process of potential equalization across the active paste thickness can be regarded as discharge of a volume-porous capacitor through the resistance of electrolyte in pores. The discharge of such a capacitor can be described by an equation similar to the heat conduction or diffusion equation [5]:

$$\frac{\partial E}{\partial t} = a\frac{\partial^2 E}{\partial x^2}, \quad (3)$$

$$a = (C_V \rho_{\text{eff}})^{-1}, \quad (4)$$

$$C_V = \frac{1}{V}\frac{\mathrm{d}Q}{\mathrm{d}E}, \quad (5)$$

where a is a constant similar to the thermal diffusivity coefficient in the heat conduction equation ($\text{cm}^2\ \text{s}^{-1}$), ρ_{eff} the effective electrolyte resistance in the pores of the active paste (Ω cm), and C_V the effective capacity of the active paste per unit volume V (F cm^{-3}).

For example, at a typical specific charge of the active paste equal to 1000 C cm^{-3}, potential ?shift in the course of discharge by 0.2 V, $C_V \approx 5000$ F cm^{-3}, and $\rho_{\text{eff}} \approx 5\ \Omega$ cm the a value is about 4×10^{-5} $\text{cm}^2\,\text{s}^{-1}$.

The time constant τ of discharge of the volume-porous electrode depends on thickness δ_e and a:

$$\tau = \delta_e^2/a. \quad (6)$$

The thinner the electrode, the lower the time constant of discharge, and the faster the equalization of charge and potential within the electrode. In the above example, $\tau \approx 250$ s for an electrode of thickness 1 mm and $\tau \approx 2.5$ s for a 0.1-mm-thick electrode. Consequently, high-power batteries with discharge time constant of less than 100 s must have electrodes with thickness not exceeding several tenths of millimeter.

The rate of equalization of the electrolyte concentration in electrode and separator pores is determined by migration and diffusion of ions and, therefore, is described by an equation of the type (3). The diffusion coefficients of ions in aqueous solutions are on the order of 10^{-5} $\text{cm}^2\ \text{s}^{-1}$, which is comparable with the value of coefficient a in Eq. (3). Hence follows that the time constant of concentration equalization is close to the time constant of potential equalization, found from formula (6), with the principal requirement, small thickness of the electrode, remaining in force.

(2) Possible, in principle, ways to satisfy requirements to design of ultrahigh-power batteries. The design of modern alkaline batteries satisfies none of the four requirements considered above. The contact of active paste particles is ensured by pressure. The collector is, as a rule, a volume-porous body (sintered body, metallic felt, etc.) whose pores are filled with the active paste: particles of oxides, hydroxides, and hydrides mixed with electrolyte, and particles of electronic conductors (metals, carbon). In any case, the electronic contact is far from being ensured for all particles of the active paste. The electrode thickness, as a rule, exceeds 0.5 mm, and, occasionally, even 1 mm. As a result, even the best of modern alkaline batteries for fast discharge (e.g., SANYO no. 1000SCR [1]) have admissible discharge current of 8–10 C.

A radical way to raise the discharge rate is to abandon the active paste in its classical understanding. It was proposed in [6] to use as active paste thin passivating oxide (hydroxide) films formed on the surface of metals, such as, in particular, cadmium, nickel, or their alloys. At film thickness of several nanometers to tens of nanometers, the diffusion path of redox reactions decreases by orders of magnitude. This leads to an increase in the rate of discharge by orders of magnitude. At such a thickness of the active paste, metal particles on which passivating films are formed must have size comparable with the film thickness, i.e., several to tens of nanometers, and large specific surface area, at least several square meters per 1 gram.

With this principle of electrode formation, each particle of the active paste is involved in the redox process, and contact with the collector is conditioned by chemical bonding between the metal and the passivating film, ensuring full use of the "active paste."

One of universal and effective methods for fabricating such electrodes is porous oxidation of metal foils with subsequent electrochemical or chemical reduction of the porous oxide film to metal [7]. This method can be used to obtain cadmium or iron negative electrodes or silver positive electrode. Unfortunately, no satisfactory technology for porous oxidation of nickel could be developed.

Table 1. Specific capacity of electrodes of various batteries

Electrode no.	Electrode	Preparation method	Specific capacity, A h g^{-1}		
			theoretical	battery	
				modern	ultrahigh-power
1	$Fe/Fe(OH)_2$	Porous oxidation	0.596	0.2–0.25	0.05
2	$Cd/Cd(OH)_2$	"	0.417	0.2–0.25	0.07
3	MH*	Electrolytic	–	0.3–0.4	0.08
4	$Ni(OH)_2/NiOOH$	"	0.292	0.2–0.25	0.17
5	$Ni(OH)_2/NiOOH$	Raney nickel technology	0.292	0.2–0.25	0.11
6	Ag/Ag_2O	Porous oxidation	0.231	0.1–0.15	0.08

* MH fabricated by the technology described in [9]; collector, nickel foil.

Table 2. Characteristics of electrodes of various prototypes

Electrode no.	Electrode	Characteristics of electrodes				
		thickness, mm		mass, g		Capacity, C
		collector	active layer	active layer	electrode	
1	Negative cadmium	0.050	0.07	0.112	0.285	28
	Positive nickel oxide (Raney)	0.025	0.067	0.067	0.149	23.7
2	Negative metal hydride	0.030	0.220	0.2	0.307	57
	Positive nickel oxide (electrolytic)	0.030	0.082	0.082	0.189	49

A nickel electrode with highly developed surface, coated with a passivating film and able to work as nickel oxide positive electrode of a battery, was fabricated in two ways. The first method is formation of a nickel–aluminum alloy on the surface of nickel foil by diffusion with subsequent electrochemical or chemical leaching of aluminum from the alloy. This yields a layer of Raney nickel, firmly adhering to a layer of smooth nickel (collector) [6].

The second method, electrolytic, was described in a patent [8]. Both these techniques yield nickel positive electrodes with nickel foil or nickel grid as collector, in which nickel hydroxide ("active paste") has the form of a thin (several to tens of nanometers) layer on the surface of fine nickel particles bound to the collector by strong metallic bonds.

Both the positive (silver oxide, nickel) and the negative electrodes (iron, cadmium, metal hydride) fabricated by the above methods markedly differ from the electrodes of conventional batteries: the mechanical and electrical contact of highly porous metal layers covered with oxide (hydroxide) films (active layers) with the collector is ensured by strong chemical bonds, rather than by mechanical pressing. The contact resistance between the active layers and the collector is so small that it could not be measured.

The specific capacities of the active material of various electrodes are presented in Table 1. The capacity was found from curves of galvanostatic discharge at current density of 0.1 A cm^{-2} (30–60°C). As reference served mercury oxide electrode. For comparison, Table 1 also lists theoretical specific capacities of the same electrodes and the specific electrode capacity of modern batteries.

As follows from Table 1, the specific capacity of electrodes of ultrahigh-power batteries is 2–5 times lower than that of the electrodes of modern batteries. This is due to a much larger fraction of metal in the active material of the electrodes used. Possibly, further improvement of the technology will make the electrode capacity of ultrahigh-power batteries closer to the level of modern batteries. As an example may serve the nickel oxide electrode (Table 1, no. 4).

(3) Characteristics of prototype ultrahigh-power batteries. To assess the feasibility of new ways of battery design, simplest prototype batteries, nickel–metal hydride and nickel–cadmium, were fabricated.

The prototypes had electrodes 20 × 20 mm in size and Lavsan (Russin equivalent of Dacron) fabric with thickness of about 0.1 mm as separator. The characteristics of the electrodes used are presented in Table 2.

Table 3. Characteristics of prototypes of ultrahigh-power batteries

Prototype no.	Mass of prototype without case, g	Discharge current		Voltage, V		Discharge time, s	Specific capacity, A h kg^{-1}	Specific energy, W h kg^{-1}	Average specific power, kW kg^{-1}
		A	A (A h)$^{-1}$, C	initial	final				
1	0.50	0.4	53	1.3	0.8	67.5	15	15.7	0.84
		1.0	133	1.2	0.7	20	11	10.4	1.90
		2.0	266	1.0	0.6	4	4.4	3.5	3
2	0.58	0.4	31	1.3	0.8	115	22	23	0.72
		1.0	78	1.2	0.7	35.5	17	16	1.6
		2.0	157	1.0	0.6	8.5	8.2	6.5	2.7

The electrode capacity was measured at a current density of 0.1 A cm^{-2}.

The characteristics of two prototypes with pairs of electrodes no. 1–no. 3 and no. 2–no. 4 (Table 1) are presented in Table 3. The specific energy and power were calculated per total mass of the electrodes, separator, and electrolyte. The mass of the case and contact units was ignored. Figure 1 presents discharge characteristics of prototype no. 2.

As follows from Table 3 and Fig. 1, prototypes of ultrahigh-power batteries designed on the basis of the principles described above are characterized by sufficiently high power characteristics, exceeding those of modern batteries by an order of magnitude. True, this is achieved with a 3–4-fold loss of specific energy. For example, the best Cd batteries have a specific energy of up to 40 W h kg^{-1}, and the best NiOOH–MH batteries, a specific energy of up to 75 W h kg^{-1}.

A systematic study of the stability of ultrahigh-power batteries in cycling is incomplete as yet. Data are only available for the conditions of "fast" charging–discharge, when 10–30% of the total charge is taken from a prototype, and charging continues for no more than 100 s. Under these conditions, prototype no. 1 endures 1500–2000 cycles, and prototype no. 2, 8000–15 000 cycles.

(4) Technical application and ways to improve ultrahigh-power batteries. To determine the possible fields of application of ultrahigh-power batteries, Fig. 2 presents, in the specific power–specific energy diagram, the areas occupied by the already known energy storage devices. It can be seen that "gaps" corresponding to an order of magnitude in energy and power exist between the electrolytic and electrochemical capacitors and between electrochemical capacitors and batteries. The region corresponding to characteristics of ultrahigh-power batteries fills nearly entirely one of the gaps: that between electrochemical capacitors and batteries. The region between the electrolytic and electrochemical capacitors remains free for the time being. Probably, this gap will be filled in the course of improvement of the technology and design of both of these types of devices [2].

The principal conclusion following from an analysis of Fig. 2 is that ultrahigh-power batteries are energy storage devices with their own field of application. Their nearest competitors are "classical" batteries (having higher specific energy) and electrochemical capacitors (higher specific power). In the application

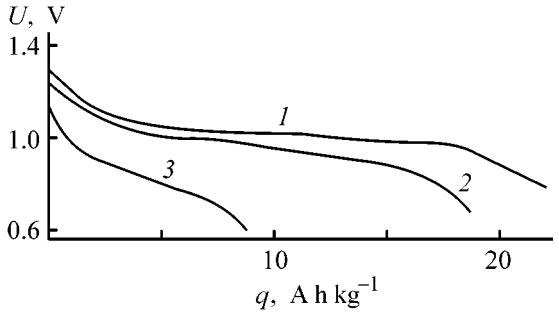

Fig. 1. Discharge characteristics of a prototype ultrahigh-power MH–NiOOH battery. (*U*) Voltage and (*q*) specific capacity. Discharge current (C): (*1*) 31, (*2*) 78, and (*3*) 157.

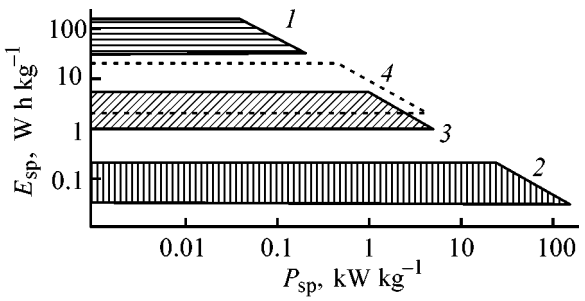

Fig. 2. Relationship between specific energy E_{sp} and specific power P_{sp} of various energy storage devices. Battery: (*1*) modern and (*4*) ultrahigh-power. Capacitor: (*2*) electrolytic and (*3*) electrochemical.

fields requiring specific power higher than 1 kW kg^{-1}, specific energy exceeding 10 W h kg^{-1}, and discharge time of up to 100 s, the ultrahigh-power batteries are the most efficient.

An important field of application of ultrahigh-power electrochemical batteries is the hybrid automobile equipped with both an electric motor and an internal combustion engine. The hybrid automobile allows a 20–25% decrease in fuel consumption and an order-of-magnitude decrease in the amount of hazardous substances in the exhaust gases, which is due to "electric" speeding and energy recuperation in braking. As is known [9], the hybrid automobile requires energy storage devices producing a power of up to 50 kW during an acceleration time of about 10 s, i.e., an energy of more than 500 kJ (more than 150 W h). With account of the fact that repeated starts are possible in real practice, there must be a 2–3-fold energy reserve. The required characteristics can be ensured by using electrochemical capacitors with mass exceeding 100 kg or classical batteries (>200 kg). Both these variants are of little use for economic and technological reasons. Use of ultrahigh-power batteries will allow a substantial decrease in the mass and cost of storage devices, thus creating prerequisites for transition from prototypes of hybrid automobiles to their full-scale production.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Antimony-free Alloys for Unattended (Sealed) Lead Batteries

Scientific and Technical Center Elektrotyaga Private Joint-Stock Company, St. Petersburg, Russia

Received October 4, 2001

Abstract—The effect of tin concentration on major characteristics of the Pb–0.08% Ca alloy was studied.

The creation of unattended sealed batteries requires alloys for manufacturing antimony-free positive electrodes. Antimony is known to be able to pass onto a negative electrode through corrosion of current leads, which results in a considerable increase in gassing because of the low overvoltage of hydrogen evolution. In the case of sealed batteries, the gas evolution leads to irreversible loss of water, dehydration of separators, increase in the internal resistance, and, in the end, to a decrease in the battery service life.

The number of publications in the technical literature, concerned with one or another alloy, can be considered a criterion of whether or not the alloy is promising. An analysis covering the period 1960–1995, carried out by the ALABC association (project Pb-001) [1], demonstrated that the Pb–Ca–Sn alloy was most frequently considered among antimony-free alloys (55% of the total number of publications concerned with antimony-free alloys).

We made a similar analysis covering the period 1995–2000, which demonstrated that the Pb–Ca–Sn alloy was the subject of 64.8% of publications in the field in question. There is virtually a consensus on the optimal calcium content (0.07–0.08%). As for the content of tin, opinions of researchers differ widely (0.3–1.8%). In this study, we analyzed the effect of tin concentration in the Pb–0.08% Ca alloy on its main characteristics: ultimate strength σ_S, creep limit σ_C, maximum hardness H_{Smax}, and hardness variation during aging of alloys after casting, afterflow (susceptibility to plastic deformation under static loads less than the ultimate strength), fluidity L, cracking susceptibility in casting CS, corrosion resistance CR, and conductivity of a contact corrosion layer (CCL) at the interface between the current lead and the active paste.

Pb–0.08% Ca alloys containing 0.5, 1.0, and 1.5% Sn served as objects of study. To prevent calcium oxidation during preparation and casting of the alloys, we added 0.010–0.015% aluminum to the alloys [2].

The ultimate strengths and creep limits of the alloys under study, measured 1, 8, and 41 days after sample casting are given in Table 1.

It follows from these data that addition of tin raises the strength of the alloys, especially at tin concentration of 1.5%. It is necessary to note that the increase in the alloy strength takes a long time. This is indicative of the prolonged character of the stabilization process after casting. It was shown in [3] that the strength of the Pb–Ca–Sn alloy continues to increase even after 90 days. The stabilization process can be accelerated either by optimization of the alloy cooling process or by additional heat treatment of samples after casting.

Table 1. Ultimate strengths and creep limits of Pb–Ca–Sn alloys (Ca content in alloy 0.08%)

Sn, %	Aging, day	σ_S	σ_C
		kg mm^{-2}

The hardness of the alloys under study, measured 1, 2, 8, 15, 37, and 90 days after casting, is given in Table 2. It can be seen that both the hardness and the strength grow steadily with increasing tin content in an alloy or shelf life of samples after casting.

The aging dynamics can be represented more visually by differential curves $dH_B/d\tau = f(\tau)$ showing how the hardness growth rate varies with time (Fig. 1). Three ranges of growth rate variation can be distinguished in the $dH_B/d\tau = f(\tau)$ curve. The highest rate is observed during the first two days. Then, between the 2nd and 37th day it changes insignificantly, and, finally, during the 37th–90th day it is virtually constant and extremely low. Addition of tin makes the hardness growth rate higher in the second portion of the $dH_S/d\tau = f(\tau)$ curves.

This behavior is in agreement with the modern theory of Pb–Ca alloy hardening [4]. According to this theory, the aging of these alloys after casting occurs in four successive stages of structural transformation, with the corresponding changes in hardness. The first stage, which is about 30 min long, is characterized by an almost twofold increase in hardness. In this stage, the macrocrystalline structure of an alloy becomes finer as a result of formation of new linear grain boundaries. It may be assumed that the reason for the development of new boundaries is that the alloy (supersaturated solid solution α-Pb) tends to make lower its internal energy. In the second stage of structural transformations, grains also become finer, but the boundaries have in this case a sinuous shape owing to minor Pb_3Ca precipitation. The duration of the second stage is 40–50 h. The third stage, beginning approximately 50 h later, is associated with precipitation of thin layers of such compounds as Pb_3Ca at grain boundaries. In this stage, the hardness growth slows down. In the fourth stage, which begins after 25–30 days, Pb_3Ca particles become coarser, with changes in hardness either ceasing or decreasing somewhat (superaging).

An analysis with the $dH_S/d\tau = f(\tau)$ curves in Fig. 1 in terms of this briefly described theory led us to conclude that the first portion of these curves is associated with the first and second stages of structural transformation of the alloy, the second portion, with the precipitation of Pb_3Ca compounds, and the third, with their coagulation. Addition of tin has virtually no effect on the mechanism of hardness growth, but influences the kinetics of its separate stages. The addition of tin is known to decelerate the first and the second transformations, which results in alloy grain coarsening. In addition, Fig. 1 shows that tin accelerates the third transformation stage owing to precipitation, along with Pb_3Ca, of new compounds Pb_3Sn and $(Pb,Sn)_3Ca$. These compounds increase the alloy hardness which depends on the total number of secondary phases.

Table 2. Hardness of Pb–Ca–Sn alloys (Ca content in alloy 0.08%)

Sn, %	H_{Smax}, kg mm^{-2}					
	1 day	2 days	8 days	15 days	37 days	90 days
0.5	15.32	15.75	16.08	16.34	16.88	16.50
1.0	15.45	15.88	16.31	16.78	17.42	17.61
1.5	15.49	15.92	16.52	17.17	17.98	18.45

The effect of tin addition on the alloy creep is shown in Fig. 2. To estimate the creep, we loaded statically cylindrical samples 2.5 mm in diameter at 27.5 MPa and measured the time elapsed till their rupture, which served as a creep parameter. It is seen from Fig. 2 that the alloy resistance to dead loads grows steadily with increasing tin content.

The effect of tin on the fluidity of an alloy and its cracking susceptibility in casting are presented in Fig. 2, which shows that tin makes the fluidity higher and reduces the tendency toward hot cracking. The alloy was cast into a mold with 15 channels 2.5 mm in diameter, hindering its shrinkage in hardening.

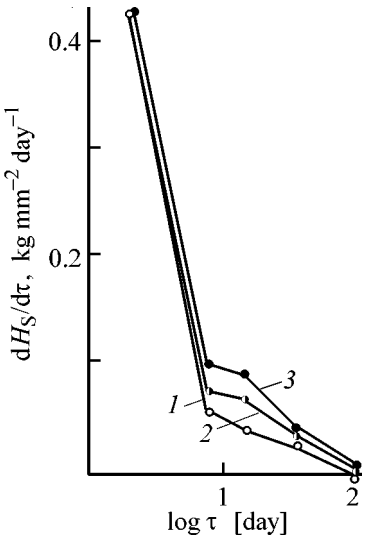

Fig. 1. Hardness growth rate $dH_S/d\tau$ for Pb–0.08% Ca–Sn alloys vs. the duration of alloy aging after casting τ. Sn content in alloy (%): (*1*) 0.5, (*2*) 1.0, and (*3*) 1.5.

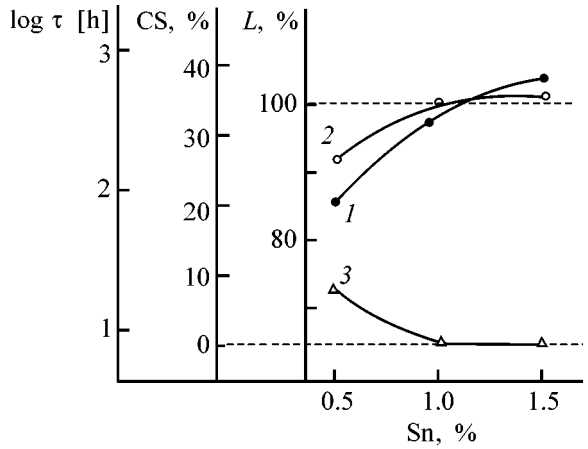

Fig. 2. (*1***)** Creep log τ, (*2*) fluidity *L*, and (*3*) cracking susceptibility in casting CS of the Pb–0.08% Ca alloy vs. the tin content in the alloy.

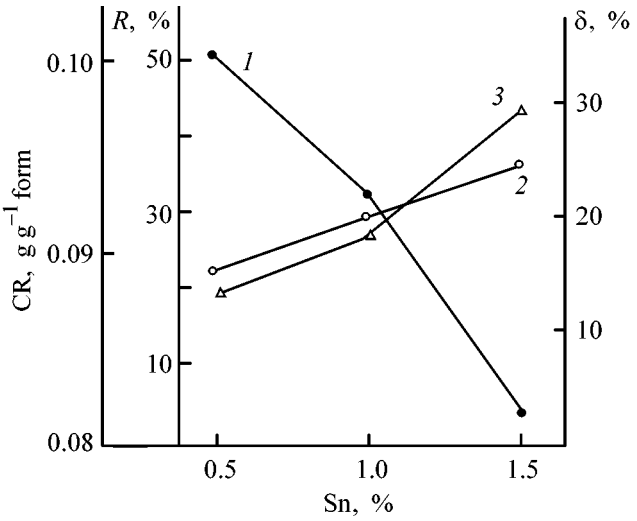

Fig. 3. (*1***)** Corrosion resistance CR, (*2*) fraction of the dense part of the oxide corrosion layer *R*, and (*3*) CCL conductivity δ of the Pb–0.08% Ca alloy vs. the tin content in the alloy.

As a criterion of cracking susceptibility was accepted the ratio of the number of broken veins to their total number in the mold.

We estimated the corrosion rate of the alloys from sample weight losses upon prolonged (300 h) anodic polarization in a sulfuric acid solution of density 1.28 g cm^{-3}. During oxidation, the alloy is covered by an oxide film consisting of two layers: one tightly adjacent to the surface and the other friable, falling off under the action of the evolving oxygen. It is evident that the dense film plays the part of a protective layer ensuring stable existence of passivating clusters [5]. We estimated the fraction of the dense oxide layer, along with the general corrosion losses. For this purpose, we determined the total amount of the oxide formed, P_Σ, and the weight of the dense noncrumbling part of the oxide layer, P_d, using the following formulas:

$$P_\Sigma = (M_{PbO_2}/A_{Pb})\Delta Pb = 1.15\Delta Pb,$$

$$P_d = P_1 - P_2.$$

Here, M_{PbO_2} is the molecular weight of PbO_2, A_{Pb} the atomic weight of Pb, ΔPb the sample weight loss, P_1 the weight of a sample directly after tests (with an oxide layer on the surface), and P_2 the weight of a sample after dissolution of the oxide layer in a hot alkaline solution of sugar.

After that, we calculated the fraction of the dense part of the corrosion layer, *R* (%), from the ratio

$$R = (P_d/P_\Sigma) \times 100.$$

The results of corrosion tests are presented in Fig. 3, which shows that addition of tin decelerates the alloy corrosion and increases the fraction of the dense part of the oxide layer.

A metallurgical study of the samples after corrosion tests demonstrated that the corrosion of the Pb–Ca–Sn alloy has local intercrystallite nature, which determines the dependence of the corrosion rate on the alloy structure. Alloys with low tin content have a finely crystalline structure with large grain boundary area, which predetermines rather high weight losses upon corrosion. As mentioned above, addition of tin noticeably increases the size of alloy grains by hindering the first and the second stages of its structural transformation. In the process, the total surface area of the boundaries decreases, which decelerates the corrosion. Furthermore, as seen from Fig. 3, tin favors an increase in the fraction of the dense part of the passivation film, which must also result in lower corrosion of the alloys.

One of the most important characteristics of alloys is the conductivity of CCL at the interface between the current lead and active paste, since it is across this interface that the overall current generated in electrochemical processes flows. The area of this surface is 10^{-6} of the surface area of the active paste, and any changes in its characteristics will strongly affect the efficiency of the positive electrode and the battery as a whole. If CCL is reduced faster than the active mass in battery discharge, then, when it reaches the oxidation state of $PbO_{1.5}$, it will create a nonconducting barrier in the path of the electron transfer from the active paste into an external circuit and thus

will stop the discharge. It is known [6] that Pb–Ca alloys have CCL that severely constrains the battery capacity, and that addition of tin can raise its conductivity significantly. In this study, we determined the conductivity of CCL formed on alloys from changes in the rate of Fe^{2+} oxidation on a preliminarily oxidized sample surface. Apparently, the rate of this reaction is determined by the rate of electron transfer across the CCL. We polarized the samples of the alloys under study (shaped as disks with smooth surface) at a potential of 700 mV (relative to an Hg/Hg_2SO_4 reference electrode) for 5 min in a vigorously stirred solution of sulfuric acid with density of 1.28 g cm^{-3}. In this case, a film similar to that formed in discharge of the positive active mass appeared on the surface. Then we introduced a $FeSO_4$ solution into the cell and recorded a current step in the current–time curves, resulting from iron(II) oxidation. This step served as a criterion for estimating the conductivity of CCL formed on the alloy under study. The dependence of this parameter on the tin content in the alloy is presented in Fig. 3, which shows that addition of tin leads to an increase in the CCL conductivity in the entire range of concentrations under study. This results from the formation of corrosion films composed of spinel-type double oxides $Pb_{1-x}Sn_xO_2$ with increased *n*-type conductivity [7] and with the known inhibiting effect of tin on the reduction process $PbO_2 \rightarrow PbO_x$ [6].

CONCLUSION

A study of the influence exerted by tin on the major characteristics of the Pb–0.08% Ca alloy, in many respects determining the performance of the positive current leads of batteries, has shown that the alloy containing 1.5% of tin has the best characteristics and can be recommended for use in unattended (sealed) batteries.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Joint Electrolytic Deposition of Vanadium and Manganese Oxides

Abstract—The electrolysis conditions and the character of the anodic processes were studied at the joint anodic deposition of vanadium and manganese oxides from mixed sulfate solutions in the form of double oxide systems, which are promising cathode materials of lithium batteries.

Complex multicomponent oxide systems of the type $LiCo_xMn_{2-x}O_4$, $LiCr_yMn_{2-4y}O_4$, and $Co_2V_2O_7 \cdot xH_2O$, prepared by doping of traditional electrochemically active oxides of manganese, vanadium, etc., are interesting cathode materials of lithium batteries, as they have considerably higher electrolytic characteristics compared to basic materials [1–4]. Basically, such systems are mainly prepared by thermal synthesis from stoichiometric mixtures of metal salts. At the same time, there is a great interest in electrochemical synthesis of complex oxide materials by the anodic deposition from mixed aqueous solutions of salts of codeposited metals [5, 6]. The advantage of the electrolytic synthesis is the possibility of preparing uniform structured systems, whose components, unlike simple mechanical mixtures, can interact at the molecular level. This allows ballast-less cathodes to be prepared by the direct deposition of compact oxide coatings onto a smooth or gauze stainless-steel support. Complex vanadium–manganese oxides prepared by the electrolytic deposition from aqueous solutions have the higher electrochemical activity compared to individual components [7]. It was appropriate to study the conditions of joint electrodeposition of the vanadium and manganese oxide compounds from mixed solutions of their salts to obtain on anode in a quantitative yield the complex oxide systems with a controllable phase composition, depending on solution concentrations and electrolysis parameters.

In study, we used mixed solutions of oxovanadium and manganese(II) sulfates of the overall average concentration of 0.3–0.35 M at a concentration ratio (hereinafter, V : Mn) of 5 : 1–1 : 5. Here, the first figures stand for the main component, i.e., for oxovanadium sulfate, and the second, for the doping component. Solutions were prepared from pure and analytically pure grade reagents and distilled water. The electrolysis was performed in a temperature-controlled glass cell 250-ml capacity. The compact coatings were deposited onto gauze and smooth platelike two-side anodes made of 12Cr18Ni9Ti steel of $10 \times 10 \times 0.15$ and $10 \times 10 \times 0.3$ mm size, respectively. Smooth plates of VT-1 commercial titanium with a ratio $S_a : S_c = 1 : 5$ of the anode and cathode surfaces served as cathodes. The tests were performed at 85°C and pH 1.8–2.2. These values were chosen based on the preliminary experimental test and the published data [5, 8] on the electrolytic deposition of vanadium and manganese oxides.

The electrolysis efficiency was estimated from the deposition rate V_{dep} (mg cm^{-2} h^{-1}) and the conventional current efficiency CE_{con} (wt %) by the anodic product, assuming that the whole efficient current is spent for formation of vanadium oxide V_2O_5 [electrochemical equivalent 3.4 g $(A\ h)^{-1}$]. The calculation of the electrochemical equivalent of the anodic product for each value of I_a and V : Mn, and, consequently, the true value of current efficiency is difficult. Despite the arbitrary assumption, the variations of electrolysis efficiency with electrolysis conditions can be, however, judged from correlation of the conventional current efficiency with the deposition rate.

The current efficiency was measured with a copper coulometer. The deposition rate was determined from the mass gain of the anode after electrolysis, which was recalculated per unit surface and unit time.

1070-4272/02/7504-0552 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The polarization curves were taken in a three-chamber cell on a 12Cr18Ni9Ti steel anode polished to a class V 7–8 finish with S_a = 1 cm^2 at I_a = 0.5–50 mA cm^{-2} and the above-indicated temperature and pH values. The potentials were measured relative to a silver chloride reference electrode (E = +0.225 V) with a ShCh-4315 digital voltmeter and then were recalculated to hydrogen scale.

A qualitative phase composition of deposits, along with its approximate quantitative composition (for a few samples), was estimated from comparison of the X-ray diffraction patterns (DRON-2 diffractometer, Cu_{K_α}-radiation) with the calibration graph obtained under the standard conditions [9]. Preliminarily, the "doping" phase (in wt %) in deposits was estimated qualitatively by simple chemical analysis involving dissolution in a hydrogen peroxide solution, which was adjusted to pH 9 with sodium hydroxide, sedimentation (for 24 h), separation, washing, drying at 125°C, weighing of the forming $MnO(OH)_2$, and recalculation to MnO_2. The microstructure and morphology of the surface of deposits (1.5–2.5 μm thick films) was studied with a digital nanoscope (Nona Scope IIIa, Digital Instruments).

Figure 1 shows the deposition rate V_{dep} of the double oxide V–Mn vs. a concentration ratio of the codeposited metal salts in solution. At a low concentration of manganese(II) ions in solution, the deposition rate of the anodic product is somewhat higher than upon deposition from the "straight" oxovanadium sulfate solution and reaches the maximal value at V : Mn = 7 : 1. At further increase in the manganese(II) concentration, the deposition rate decreases sharply, and then the gradual decrease is observed after the ratio V : Mn = 4 : 1 is attained. At V : Mn = 1 : 5, the deposition rate attains the minimal value and virtually passes to the region of zero effect. The specific feature of this process is that the rate of the manganese oxide deposition from the individual solution is higher several-fold than that of the vanadium oxide formation under the comparable electrolysis conditions (20–25 and 5.0–5.5 mg cm^{-2} h^{-1}). This shows that the joint deposition of vanadium and manganese oxides under the conditions studied is a set of complex anodic processes. The kinetics of these processes is to a considerable degree determined by the concurrent redox reactions of ions participating in the electrode process and by the products forming in the different stages of anodic oxidation. The standard electrode potentials of the anodic reactions [10]

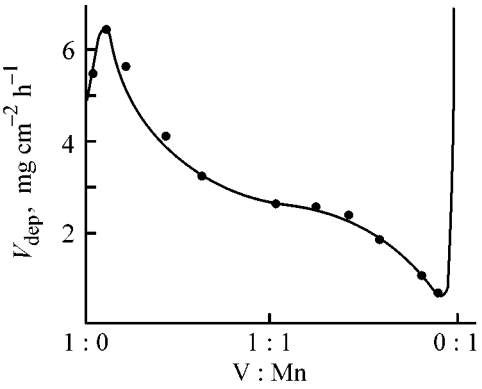

Fig. 1. Rate of deposition V_{dep} of the V–Mn double oxide on anode during the electrolysis of mixed solutions of oxovanadium and manganese(II) sulfates vs. concentration ratio V : Mn. c_Σ = 0.3–0.4 M, I_a = 10 mA cm^{-2}, 85°C, pH 1.9–2.2; the same for Fig. 2.

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+,\ E^0 = 1.10\ V; \quad (1)$$

$$Mn^{2+} + 2H_2O - 2e \rightarrow MnO_2 + 4H^+,\ E^0 = 1.23\ V; \quad (2)$$

$$2H_2O - 4e \rightarrow O_2 + 4H^+,\quad E^0 = 1.23\ V \quad (3)$$

are close. Therefore, the given redox reactions can occur in the intermediate and final stages of the electrolysis, when the equilibria are shifted to one side or another owing to the change in the concentration ratio of the initial components. For example, at the low concentrations of manganese(II) ions in a solution, reaction (2) in one of the intermediate oxidation stages is probably complete, yielding an active manganese oxide complex, which can catalyze formation of vanadium(V) oxide:

$$2VO_2^+ + H_2O \rightarrow V_2O_5 + 2H^+.$$

On the contrary, an increase in the manganese ion concentration in solution impedes formation of vanadium(V) oxide and decreases the yield of the total anodic product. This can be ascribed to the increased contribution of the redox reactions, which are responsible for the enhancement of nonproductive energy consumption and the decrease in the efficiency of the electrode reactions. This is supported, in particular, by the fact that, with manganese(II) concentration increased considerably (V : Mn < 1), the deposit color changes to brown owing to the presence of manganese dioxide. The degree of deposition from the solutions at indicated ratio of the component concentrations decreases as the electrolysis time increases (c_Σ = 0.35 M, V : Mn = 1 : 3, 85°C, I_a = 10 mA cm^{-2}, and pH 2.0):

τ, min	15	30	45	60	75	90	100
V_{dep}, mg cm^{-2} h^{-1}	0.04	0.03	0.025	0.02	0.015	0.015	0.013

Deposition rate of anodic product at T = 85°C, I_a = 10 mA cm^{-2}, and pH 2.0

Total concentration of $VOSO_4$ and $MnSO_4$, M	V_{dep} (mg cm^{-2} h^{-1}) at indicated V : Mn ratio		
	3 : 1	1 : 1	1 : 3
2.0	3.0	2.5	2.0
0.35	3.3	2.8	2.4
0.5	3.2	2.3	1.8

For example, after 1 h of electrolysis the anodization rate decreases twofold compared to the initial rate (after the first 15 min). After the solution is stored for 1 day, the initial rate slightly increases (to 0.05 mg cm^{-2} min^{-1}) and then decreases again to the given lower value.

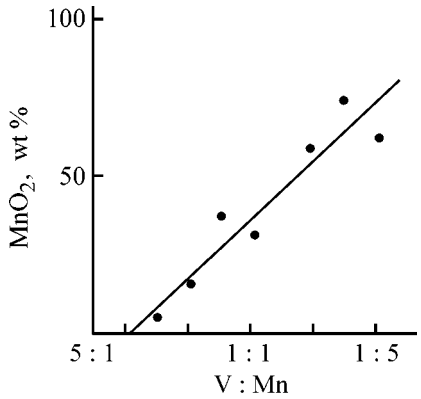

Fig. 2. The concentration of the MnO_2 doping phase in the anodic deposits vs. a ratio V : Mn of the oxovanadium and manganese(II) sulfate concentrations during the electrolysis from solutions.

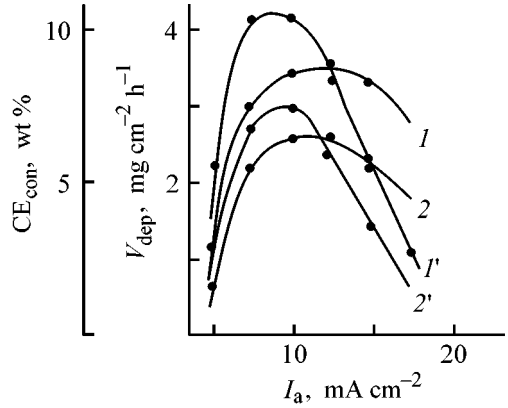

Fig. 3. Dependences of (*1*, *2*) deposition rate V_{dep} and (*1*', *2*') conventional current efficiency by the anodic product CE_{con} on current density I_a during the electrolysis from solutions of oxovanadium and manganese(II) sulfates. c_Σ = 0.3–0.4 M, 85°C, pH 1.9–2.2. V : Mn concentration ratio: (*1*, *1*') 3 : 1 and (*2*, *2*') 1 : 3.

The V_{dep} value and the appearance of deposits are also affected by the total concentration of components in a solution at their different ratios (see table). The decrease in the total concentration decreases the deposition rate and does not affect the character of its dependence on the V : Mn ratio at the optimal total concentration. At higher total concentrations, the electrolysis becomes unstable (the measured V_{dep} values are not reproduced, and the separated deposits have inhomogeneous structure and color). These deviations, along with the intensification of the above side reactions, are also caused by the increased contribution of the cathodic reactions, manifested in formation of loose dark brown films on the cathode.

A decrease in the anodization rate with increasing manganese(II) concentration can be explained by high adsorption activity of vanadium oxide compounds. As a result, adsorption layers rather strongly attached to a substrate can appear on the initial surface of electrode and on the surface of anodic deposit, which would increase the energy barrier of discharge of the manganese(II) ions. In this case, increasing the manganese(II) concentration simultaneously increases the concentration of manganese oxide in the deposit. At V : Mn = 1 : 3, the "doping" phase concentration of more than 50 wt % is attained (Fig. 2). However, its limiting value does not exceed 60 wt %, even at V : Mn = 1 : 5.

The analysis of the dependences of the deposition rate V_{dep} and conventional current efficiency CE_{con} on the current density at various V : M ratios in a solution leads to the similar conclusions (Fig. 3). Evidently, at low and medium current densities (5–10 mA cm^{-2}) the rate of the oxovanadium(IV) ion oxidation by reaction (1) is higher than that of manganese(II) oxidation, irrespective of the V : M ratio. This may be ascribed to the less electropositive standard electrode potential of reaction (1). For this reason, the latter reaction becomes rate-determining in the total anodic process. As a result, with the current density increasing to the optimal value, the deposition rate and the current efficiency by anodic product will increase. The corresponding extremal points on the V_{dep}–I_a curves (Fig. 3, curves *1*, *2*) coincide with the analogous points on the dependence of the deposition rate on the V : Mn ratio (Fig. 1). At current densities above 10 mA cm^{-2}, the manganese(II) oxidation by reaction (2) is predominant: the efficiency of the total process drastically decreases, and the sharp drop of the deposition rate and current efficiency is observed on the V_{dep}–I_a and CE_{con} curves (Fig. 3). It should be noted that the probable contribution of the man-

ganese oxide formation by reaction (2) [electrochemical equivalent 1.62 g $(A\ h)^{-1}$] to the total current efficiency by anodic product (Fig. 3, curves *1*', *2*') does not affect the main character of the dependences considered.

The data presented are confirmed by comparison of the volt–ampere characteristics for individual and joint deposition of vanadium and manganese oxides (Fig. 4). The curves of individual deposition (Fig. 4, curves *1, 2*) form two ascending branches separated with a transition plateau, being more pronounced for vanadium oxide. According to the data of [5], this plateau is of diffusion origin and arises from transition of the anodic process to the region where oxide deposition and oxygen evolution occur jointly. The I_a–E curve of the anodic deposition of manganese oxide has the traditional character (Fig. 4, curve *1*): after the limiting current of the oxidation reaction $Mn^{2+} \rightarrow Mn^{3+}$ is attained, the transition plateau (lower segment of curve) and then the second stage (upper segment) corresponding to the $Mn^{3+} \rightarrow Mn^{4+}$ reaction are observed [8]. The volt–ampere characteristics of the joint separation of vanadium and manganese oxides (Fig. 4, curves *3*–*6*) have another transition plateau owing to the change in the rate ratio of the simultaneous anodic reactions. The corresponding dependences at V : Mn < 1 lie at more positive potentials with respect to those at V : Mn > 1 (Fig. 4, curves *3*, *4*). This shows that the anode overvoltage significantly increases at higher concentrations of the manganese(II) ions in a solution. Correspondingly, the limiting current of the transition plateaus decreases, which agrees with the considered dependence of the rate of the double oxide deposition on the V : Mn ratio (Fig. 1).

The comparison of the I_a–E dependences for individual and joint anodic deposition of vanadium and manganese oxides shows that the lower ascending segments corresponding to them are mainly due to the discharge of oxovanadium ions and formation of the corresponding anodic oxide, which are accompanied by manganese(II) oxidation and oxygen evolution. Probably, the second ascending segment is ascribed to the change in a rate ratio of the concurrent reactions at the increasing rate of manganese(II) oxidation. In the regions of the upper ascending segments, the oxygen evolution, accompanied by intense oxidation of oxovanadium and manganese(II) ions, becomes the potential-determining process.

The nature of the structural and molecular correlation in the bulk of the deposits studied remains controversial. A certain information can be obtained from

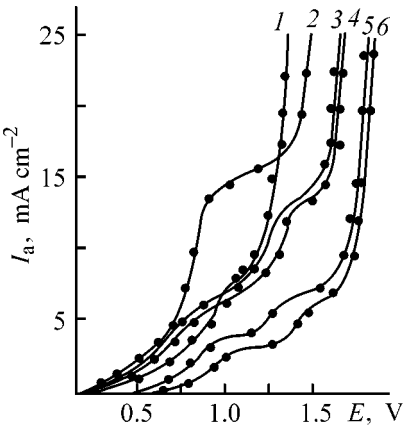

Fig. 4. Volt–ampere curves I_a–E of the anodic deposition of the binary V–Mn oxide from the solutions of oxovanadium and manganese(II) sulfates. c_Σ = 0.3–0.4 M, 85°C, pH 1.9. V : Mn ratio: (*1*) 0 : 1, (*2*) 1 : 0, (*3*) 5 : 1, (*4*) 3 : 1, (*5*) 1 : 5, and (*6*) 1 : 3.

The microstructure of the surface of thin-film anodic deposits of vanadium(V) and manganese(IV) oxides from sulfate solutions of (a) oxovanadium, (b) manganese(II), and (c) of double oxide obtained from mixed solution with a V : M concentration ratio of 1 : 2. I_a = 10 mA cm^{-2}, 85°C, pH 1.9. Deposits were dried in air at 0°C.

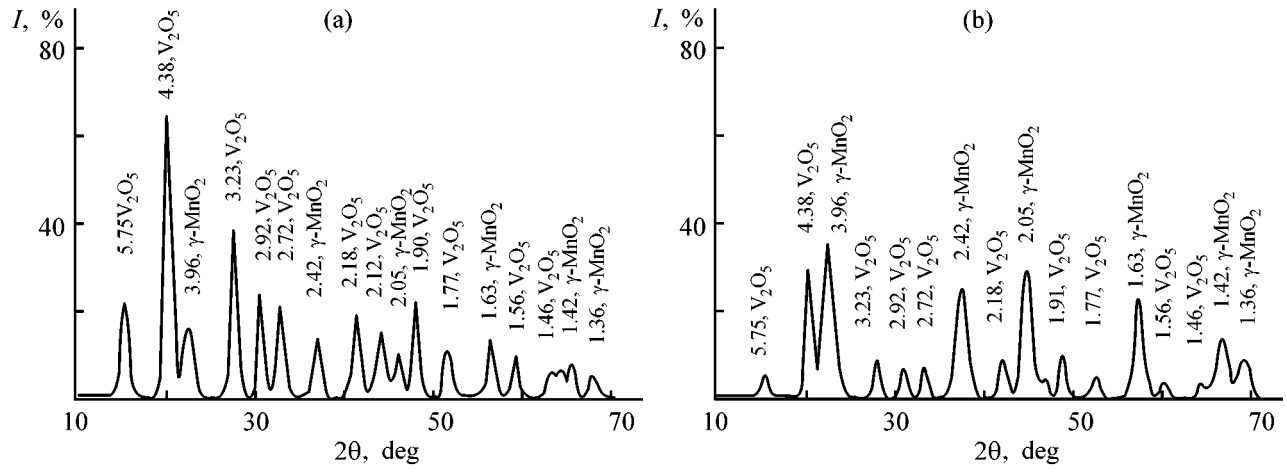

Fig. 6. X-ray diffraction patterns of the double V–Mn oxides, obtained by anodic deposition from solutions. c_Σ = 0.3–0.4 M, I_a = 10 mA cm^{-2}, 85°C, pH 1.9–2.2. Deposits were dried in air at 0°C. (*I*) Intensity and (2θ) Bragg angle. V : Mn ratio: (a) 3 : 1 and (b) 1 : 3. Interplanar spacing are given in Å.

comparison of the microstructure and microrelief of a surface of thin-film deposits of individual vanadium and manganese oxides with the binary oxide V–Mn (Fig. 5). The analysis of the data obtained shows that their nature, determined by electrolysis conditions and solution composition, differs qualitatively. The vanadium oxide deposits are amorphous with a rather developed specific surface area (Fig. 5a). The deposits formed at its joint anodic deposition with manganese oxide have evident crystalline structure (Fig. 5c) nearly similar to block crystalline structure of manganese dioxide deposits (Fig. 5b). Apparently, the structure of deposits of the double oxide system is determined by the fact that manganese dioxide (molecules) tend to form crystalline structures, as it is the energy profitable process (heat of formation of MnO_2 and V_2O_5 is –518 and –1560 kJ mol^{-1}, respectively [11]). The closeness of the crystal systems of rhombic V_2O_5 and γ-MnO_2 can also facilitate this process. Evidently, the mutual influence of originating and growing nuclei of a new phase, which are separated jointly with the oxides, disturbs a regular growth of a part of forming crystalline grains and facilitates formation of deposits with a rather developed surface.

The X-ray diffraction patterns of the double oxides studied, obtained from the solutions differing in the V : Mn ratios, showed that they clearly correspond to the double oxide systems containing both the codeposited oxides as individual phase and the oxide compounds of the type $MnO_2 \cdot V_2O_5$ and $MnO_x \cdot V_2O_{5-x}$. The number of the reflections due to the MnO_2 phase increases proportionally to the manganese(II) ion concentration in a solution (Fig. 6). These data show that, from the energy standpoint, the studied deposits of the double V–Mn oxide system are a certain intermediate system between homogeneous mechanical mixture and single-phase chemical compound.

CONCLUSION

Upon the electrolysis of mixed solutions of oxovanadium and manganese(II) sulfates, vanadium and manganese oxides are jointly deposited on the anode in the form of the double V–Mn oxide system. Such deposits with approximately controllable composition of the codeposited phases can be obtained from the above solutions at the oxovanadium to manganese(II) concentration ratio of 5 : 1–1 : 5, the total concentration of 0.3–0.4 M, 80–85°C, pH 1.9–2.2, and the anodic current density of 7–15 mA cm^{-2}.

Abstract—Electrochemical separation of lead–silver alloys into the constituents by thin-layer electrolysis in molten electrolytes, with bismuth as metal separator, is studied. It is proposed to determine the extent of component recovery by potentiometry.

Presently, up to 70–80% of silver manufactured in the world is recovered in integrated processing of raw materials containing nonferrous metals. About half of the total output of silver is recovered from lead–zinc ores [1].

At present, the only industrial method used to recover silver and gold from lead and its alloys, obtained from these raw materials, is the so-called Parkes process [2]. This method is based on the ability of silver to react with zinc to form intermetallic compounds characterized by limited solubility in lead. The technique is rather labor-consuming and involves a large amount of recycle products. In this connection, attempts have been repeatedly made to improve the method of silver recovery from intermediates of lead-and-zinc production [3–9]. It has been shown [3–5] that significant progress in improving the given process can be achieved by using electrolysis of molten salts and, in particular, by means of cathode–anode refining [3]. Electrolysis of molten salt mixtures containing zinc compounds makes it possible to combine in the same reactor the silver recovery from lead alloys in the form of its intermetallic compounds with zinc (at the cathode) and decomposition of these compounds to give silver-rich alloys (at the anode). This technique enables a significant decrease in the number of operations and in the amount of recycle products and, consequently, an increase in the extent of silver recovery.

In molten electrolytes, silver has more positive oxidation potential than lead [3], which allows concentration of silver at the anode in the course of electrolysis [3, 6–9]. The accumulation of silver in the anode alloy is 92–95% [9]. However, it should be noted that direct separation of lead–silver alloys into the components in molten salts is complicated by the fact that, when the anode alloy is enriched with silver in the course of electrolysis, the melting point of the alloy grows. This circumstance impairs the efficiency of alloy separation into components and requires that the electrolysis temperature should be raised. The high extent of enrichment with silver under the given conditions of electrolysis of the anodic alloy is achieved when the alloy is in the liquid state [9]. Consequently, there is good reason to believe that alloying of the initial silver-containing lead with a metal that forms sufficiently low-melting and homogeneous alloys with silver and has much more positive oxidation potential, compared with those of lead and silver, can create conditions for successive electrochemical recovery of these metals from the anode to the cathode. A metal possessing the whole set of the above properties is bismuth. In addition, it has been shown [10] that, owing to its ability to form compounds in different oxidation states, bismuth under appropriate conditions is virtually not involved in mass exchange between the electrodes in thin-layer electrolysis.

The present communication reports the results obtained in studying the electrochemical separation of a bismuth-containing Pb–Ag alloy.

EXPERIMENTAL

A Pb–Ag alloy containing 6.2% silver was subjected to electrochemical separation into components. Silver-containing lead was alloyed with bismuth in amount ensuring an Ag : Bi ratio in the ternary alloy

1070-4272/02/7504-0558 $27.00 © 2002 MAIK "Nauka/Interperiodica"

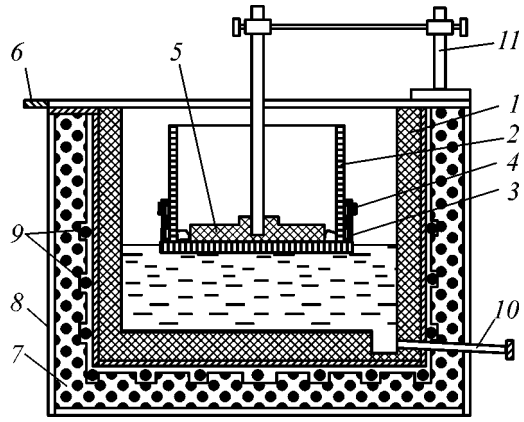
of 1 : (3.7–4.0). At this ratio of the components, the crystallization point of the anode alloy does not exceed (410 ± 10)°C. This allows electrolysis to be performed at a constant temperature, in contrast to electrolysis without adding Bi, when the temperature should be gradually increased because of the growth of the melting point of the alloy.

The ternary alloy obtained was separated in two stages by thin-layer electrolysis [11]. The method consists in that mass exchange between the electrodes occurs through a thin layer of a porous dielectric material containing molten electrolyte in its pores, with the anode–cathode spacing equal to the thickness of this layer [$(0.5–1.0) \times 10^{-3}$ m]. As molten electrolyte served a mixture of the following composition (mol %): NaCl 20, KCl 20, and $ZnCl_2$ 60, with the melting point of 203°C.

In the first stage of electrolysis, lead was extracted from the anode alloy.

A schematic of the electrochemical cell is presented in the figure. A graphite crucible *1*, simultaneously serving as anode current lead, was charged with a ternary alloy to be separated. On the surface of the ternary alloy was placed cathode vessel *2* whose bottom was made of a porous dielectric material *3*. Prior to being placed in the cell, the porous material was impregnated with a molten salt mixture of the composition specified above. The cathode vessel was made of quartz or corundum. As the material of the cathode current lead *5* served graphite or molybdenum. The prescribed temperature mode was provided by heaters *9*. In recovery of lead from cathode to anode, the cathode vessel was additionally charged with lead and electrolysis was carried out with a liquid lead cathode. The electrolyte mixture contained no compounds responsible for the mass transfer between the electrodes. In the first stage of electrolysis, such a compound is lead chloride. It was established experimentally that the concentration of this salt in thin-film electrolysis is as high as 20 wt % even after passing no more than 0.2–0.3 A h of electricity. This concentration is sufficient for ensuring a stable mass exchange between the electrodes. In the process, no zinc is deposited at the cathode from the electrolyte mixture.

The electrolysis was carried out in the temperature range 410–420°C until an anode potential of 0.35–0.40 V relative to a lead reference electrode was reached by the instant when the current was switched off. Composition of electrolyte in the reference electrode (wt %): $PbCl_2$ 20.0, NaCl 8.6, KCl 11.0, $ZnCl_2$ 60.4. It was established that the best characteristics of lead and silver separation are achieved under these



Electrolyzer for silver recovery from its alloys with lead in chloride melts: (*1*) electrolyzer bath (graphite), (*2*) cathode vessel made of a dielectric material, (*3*) membrane made of a porous dielectric material, (*4*) clip for membrane fixation, (*5*) disc-shaped cathode, (*6*) current lead, (*7*) refractory material, (*8*) casing, (*9*) heaters, (*10*) discharge, and (*11*) holder of the cathode current lead.

conditions. This is, to a certain extent, also favored by the fact that the ionization potential of silver is shifted to more positive values upon alloying of silver-containing lead with bismuth, and this shift diminishes silver transfer from anode to cathode. The characteristics of lead recovery from the ternary alloy are listed in Table 1. It can be seen that the conditions of lead recovery from the anode alloy are the most favorable at current densities i $(2–3) \times 10^3$ A m^{-2}. At higher current densities (5×10^3 A m^{-2}) there occurs joint ionization of silver and bismuth, with the content of these components in the cathode metal becoming as high as, respectively, 0.48 and 0.35%. Electrolysis at the optimal current densities (e.g., 3×10^3 A m^{-2}), but during a time in which the potential of the anode alloy reaches values exceeding 0.40 V relative to the above reference electrode potentials, also leads to dissolution of silver and bismuth at the anode and their joint deposition at the cathode. If lead recovery is terminated before the anode potential reaches the values specified above, lead cannot be recovered completely from the anode alloy (Table 1).

Thus, the potential of the anode alloy at the instant of current switching-off is a criterion of lead recovery.

In the second stage of electrolysis, the cathode vessel *2* was extracted from the cell, lead was poured out, the bottom part of the vessel was replaced with a new porous insulator, the insulator was impregnated with molten electrolyte, and the vessel was again placed on the surface of the alloy remaining after lead recovery. As a cathode was used, in the given case, a material not interacting with molten electrolyte and

* Silver from the anode residue of Bi–Ag–Pb (3.5%) alloy (Table 1, run no. 1).

forming no alloys with silver. For this purpose, graphite, nickel, molybdenum, and silver were tested. The best (as regards recovery, specific electric energy expenditure, current efficiency) results were obtained with a silver cathode.

As also in the first stage, the initial electrolyte contained no electromotive substance ensuring mass exchange between the electrodes. A stable electrolysis mode was attained immediately after switching on the current. The concentration of silver chloride in the electrolyte layer was no less than 15 wt % after passing 0.2–0.3 A h of electricity. It was established experimentally (Table 2) that the optimal range of current densities in the given stage of electrolysis is $(0.5–1.0) \times 10^3$ A m^{-2}, and temperature, 410–420°C. The electrolysis was carried out till the potential of the anode alloy reached a value of 0.60–0.62 V relative to the lead reference electrode. Under these electrolysis conditions, a finely crystalline silver deposit is obtained at the cathode. At higher current densities, a coarsely crystalline deposit is formed, the current efficiency decreases, and silver purity is impaired. To prevent penetration of silver through the layer of porous dielectric material separating the electrodes, the metal was removed from the cathode at regular intervals. If silver recovery is terminated in the second stage before the necessary anode potential is reached, high silver recovery characteristics cannot be ensured (Table 2, run no. 2). After the potential of the anode residue reaches a value of 0.62 V, the potential becomes virtually independent of the electrolysis duration since only a single potential-determining component, bismuth, remains on the anode. If the electrolysis is continued, the specific electric energy consumption grows (Table 2, run no. 5).

Thus, in the second stage of electrolysis, too, the potential of metal at the anode is the criterion of whether the process should be terminated.

After silver is recovered, bismuth obtained at the anode is used in subsequent operations of alloying with silver-containing lead and in repeated electrolysis.

Since the electrolysis in both the first and the second stages is carried out at exceedingly short interelectrode spacings [$(0.5–1.0) \times 10^{-3}$ m], the proposed

method is characterized by low specific consumption of electric energy and components. The average specific consumption of electric energy is estimated to be 0.12–0.15 and 0.3–0.4 kW h kg^{-1} in the stages of recovery of, respectively, silver and lead.

CONCLUSIONS

(1) An electrochemical method for separation of lead–silver alloys into components in molten electrolytes was proposed. The process is based on thin-film electrolysis with the use of bismuth as a metal separator. The method ensures high degree of alloy separation into components at low specific consumption of electric power and electrolyte.

(2) The extent of recovery of the components from the alloy can be monitored by the potential of the anode residue at the instant of current switching-off.

Abstract—The optimal conditions of electrochemical synthesis of silicon carbide in carbonate melts containing silicon oxide were determined on the basis of thermodynamic calculations and data of cyclic voltammetry.

Carbonate melts have found wide use as electrolytes for fuel cells [1] and for treatment of castings. The behavior of molten carbonates has been studied extensively. At the same time, use of carbonates as supporting molten electrolytes in electrolysis aimed to obtain solid deposits is poorly studied. In [2, 3], the possibility of carbon deposition at the cathode in these media was examined.

Alkali metal carbonates react rather well with a number of metals [4] and dissolve oxides of refractory metals and *p* elements (B, Al, Si, Ge, etc.) [5]. The range of potentials in which carbonate melts do not decompose is 1.6-V-wide, but cathodic depolarization of electrochemical synthesis is possible because of the low energy of formation of silicon and titanium carbides [6] (ΔG_f^0 = –65 kJ mol^{-1} for SiC and ΔG_f^0 = –173 kJ mol^{-1} for TiC at 1000 K). Synthesis of carbides in molten carbonates may occur in the given range of potentials. Therefore, it may be considered promising to use carbonate melts to synthesize carbides. Commonly, a binary K_2CO_3–Li_2CO_3 (mp 492°C) or ternary eutectic K_2CO_3–Na_2CO_3–Li_2CO_3 (mp 397°C) are used [7]. However, lithium carbonate is poorly soluble in water [8], and, therefore, a binary eutectic K_2CO_3–Na_2CO_3 (mp 720°C) was chosen as object of study [7].

Potassium and sodium carbonates are well soluble in water, which makes unnecessary use of acid for washing of the cathode product. In [9], silicon carbide was obtained from an SiO_2 (20%)–Li_2CO_3 melt at 1050°C. However, the synthesis mechanism was not studied. Electrolysis was performed at elevated temperature because of the high concentration of the higher-melting component, silicon oxide. Silicon carbide is widely used in the industry, since its exhibits high hardness, refractoriness, oxidation resistance, and semiconducting properties.

The aim of this study was to analyze the ?interaction of molten alkali metal carbonates with silicon oxide and the electrochemical behavior of this system, and to choose the optimal conditions of electrochemical synthesis of silicon carbide.

To prognosticate processes occurring in the systems, the Gibbs energy, ΔG^0, were calculated for a number of chemical reactions possible in molten carbonates at 750°C. The results obtained are presented in the table. It can be seen that silicon oxide is infinitely soluble in molten carbonates because of exchange reactions (4)–(6). The solubility of carbon dioxide in molten carbonates at 750°C is 10^{-4} mol cm^{-3} (~0.22 wt %) [10]. Carbon dioxide dissolves in molten carbonates without chemical reaction, and, consequently, its solubility is directly proportional to pressure, i.e., is described by the Raoult law. Having positive Gibbs energies, molten carbonates of potassium, sodium, and lithium are not susceptible to decomposition [reactions (2) and (3)]. Introduction of silicon oxide into a melt leads in all cases to formation of free carbon dioxide. Consequently, to stabilize carbonate melts containing silicon oxide, it is necessary to create an excess pressure of carbon dioxide. Redox reactions (7)–(22) have positive Gibbs energies and do not occur under the given conditions. Thus, it may be suggested on the basis of thermodynamic calculations that electrochemical synthesis of silicon carbide from carbonate melts containing silicon oxide is possible.

* The electromotive force V in a circuit in which a given current-forming reaction proceeds is given in parentheses.

pressure of carbon dioxide at 750°C. In one case, a platinum crucible served as a container for the melt and an auxiliary electrode, with platinum wire (S = 0.2 cm^2) as working electrode and oxygen–platinum reference electrode in air. In the other, glassy carbon crucible with working electrode (S = 0.8 cm^2) and reference electrode made of glassy carbon rods were used. Prior to experiments, reagents of chemically pure grade were recrystallized and silicon oxide was dried at 300°C. As cathode materials in electrolysis were used platinum and stainless steel. After electrolysis, cathode deposits were analyzed by X-ray diffraction analysis, Auger spectroscopy, and electron microscopy.

The rise in current observed in the anodic range of potentials in voltammetric curves obtained on a glassy carbon electrode in carbonate melts containing no SiO_2 is due to oxygen evolution, and the rise in the cathodic region, to deposition of carbon and alkali metal (Fig. 1a). The range of potentials in which there are no redox reactions is 0.5 V narrower in the case of glassy carbon electrodes, compared with that for platinum electrodes. This is due to the formation of carbon oxides on glassy carbon subjected to anodic polarization. In titration of the melt with silicon oxide to a concentration of 5×10^{-4} mol cm^{-3}, which corresponds to the limiting solubility of carbon dioxide, the rise in current observed in the cathodic range of potentials in the voltammetric curves obtained on a platinum electrode is due to discharge of carbon dioxide dissolved in the melt to elemental carbon (Fig. 1b). A peak of anodic current, associated with oxidation of carbon, is observed in the reverse run. No anodic current peak is observed on the glassy carbon electrode.

Stable platinum monocarbide exists only in the gas phase [11]. Thermodynamic characteristics of platinum carbide cannot be found in the literature, and, therefore, it is impossible to assess the possibility of formation of a compound of platinum and carbon at 1023 K. With increasing silicon oxide concentration in the melt, a new peak of anodic current appears in voltammetric curves (Fig. 1c) on both platinum and glassy carbon electrodes. The potential at which this current peak is observed is independent of silicon ox-

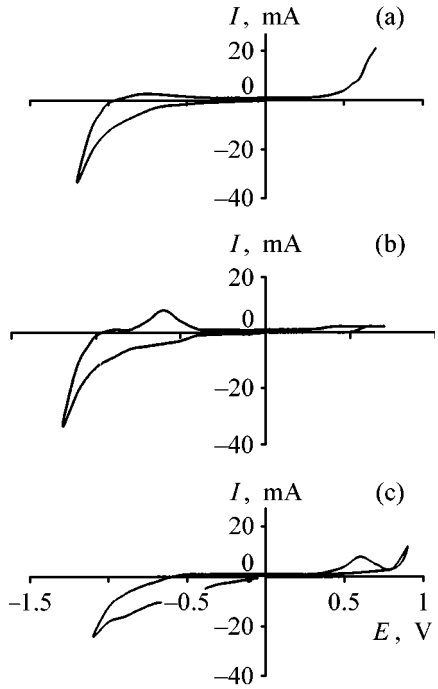

Fig. 1. Cyclic voltammetric curves obtained in (a) carbonate melt and (b, c) in carbonate melt containing SiO_2. Temperature 750°C, potential sweep rate 0.1 V s^{-1}. (I) Current and (E) potential. Electrode: (a, c) glassy carbon and (b) platinum. SiO_2 concentration (mol cm^{-3}): (b) 1×10^{-5} and (c) 9×10^{-5}.

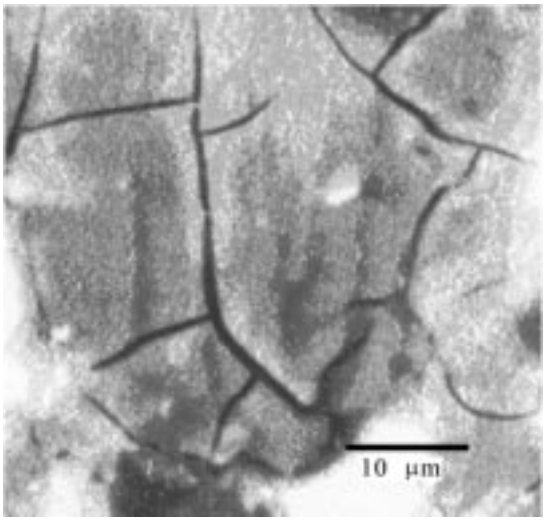

Fig. 2. Electron micrograph of the surface of a silicon carbide film obtained by electrolysis. Magnification 1500.

ide concentration and potential sweep rate at silicon oxide concentrations exceeding 5×10^{-4} mol cm^{-3}. The cathodic process corresponding to the appearance of a new peak of anodic current in the reverse run proceeds at potentials corresponding to residual currents and merges with the background. To shift the potential corresponding to the cathodic process by 24 mV, the carbon dioxide pressure is to be raised to 10 atm.

The results of voltammetric studies suggest that electrochemical synthesis of silicon carbide occurs on glassy carbon and platinum electrodes in molten carbonates containing silicon oxide under elevated carbon dioxide pressure and cathodic polarization.

To confirm the results obtained, electrolytic experiments were performed. By electrolysis of an Na_2CO_3–K_2CO_3–SiO_2 (5%) melt at 750°C, CO_2 pressure of 1 atm, and current density not exceeding 0.2 A cm^{-2}, carbon coatings were produced on steel and platinum, with a glassy layer of 20% carbon and 80% platinum formed on the latter. Under certain electrolysis conditions, coatings of black α-SiC (with increased carbon content) were obtained on steel. Figure 2 illustrates the surface morphology of an SiC coating obtained on steel by means of electrolysis. The coating had block structure with a grain size of 10–20 μm. The carbide coating was dense, had high hardness, easily scratched glass, and possessed semiconducting properties.

CONCLUSIONS

(1) Carbonate melts containing silicon oxide are unstable because of the occurrence of an exchange reaction to give carbon dioxide. This process can be stabilized by creating a carbon dioxide atmosphere with elevated pressure over the melt.

(2) The optimal conditions of electrochemical synthesis of silicon carbide in carbonate melts containing silicon oxide are found.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Physical, Chemical, and Electrochemical Behavior of Boron Oxide in Cryolite–Alumina Melts

S. V. Devyatkin and G. Kaptay

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine
University of Miscolc, Miscolc, Hungary

Received January 26, 2001; in final form, July 2001

Abstract—Preparation of aluminum alloys in an aluminum electrolyzer considerably reduces the cost price of the resulting ligatures. Introduction of new oxides into molten cryolite frequently disturbs the electrolyzer operation. The behavior of boron oxide in molten cryolite and the possibility of stabilizing the electrolyzer operation were studied.

Introduction of boron-containing compounds in the course of aluminum electrolysis is used to remove impurities of heavy metals, inhibit carbon anode combustion, and obtain boron-containing aluminum ligatures [1–3]. Introduction of boron-containing compounds into a cryolite–alumina bath leads, in some cases, to a rise in the process temperature and to deviation from the optimal process parameters of the electrolyzer. It has been shown [4–6] that boron(III) is irreversibly reduced in chloride and fluoride melts to elemental boron in a single stage. The data of [7] are indicative of a single-stage reduction of boron oxide in cryolite. However, the problem of increasing vapor pressure upon introduction of boron oxide into molten cryolite and possible ways to overcome this difficulty were not considered in [7]. Therefore, the aim of this study was to analyze the physical, chemical, and electrochemical behavior of boron oxide and its compounds in an aluminum electrolyzer.

EXPERIMENTAL

Voltammetric studies were carried out in two cells: a platinum crucible with platinum wire as working electrode (S = 0.2 cm^2) and oxygen–platinum reference electrode in air and also a glassy carbon crucible (auxiliary electrode) with glassy carbon working and reference electrodes in argon at 1000–1020°C. We used in our experiments the Greenland cryolite Na_3AlF_6, boric acid, and α- and γ-Al_2O_3 (alumina).

Among the components of a cryolite–alumina–boron oxide melt at 1000°C [8] boron oxide has the lowest density ρ and surface tension γ:

Melt	ρ, g cm^{-3}	γ, mN cm^{-1}
B_2O_3(l)	1.518	830
Al_2O_3(l)	3.03	10 000
Na_3AlF_6(l)	2.095	1360

The density and the surface tension of the higher-melting compound Al_2O_3 in liquid state were extrapolated to 1000°C. These data suggest that, when boron oxide is introduced into a cryolite–alumina bath, a boron oxide film will cover the melt surface with the subsequent formation of gaseous boron trifluoride:

$$2AlF_3(l) + B_2O_3(l) = Al_2O_3(l) + 2BF_3(g). \quad (1)$$

This can account for the unlimited solubility of boron oxide in molten cryolite [1]. The Gibbs energy of the exchange reaction (1) is –77 kJ, as calculated using reference data [9]. The voltammetric curves of cryolite–alumina melt, measured upon introduction of boron oxide, show peaks characteristic of a cryolite–alumina melt. Therefore, boron passes in a gas phase instead of being accumulated in the melt.

This problem can be solved by creating conditions for dissolution of boron oxide in the bulk of the melt, by decreasing the boron oxide activity, and by shifting the equilibrium of reaction (1) to the left. For this purpose, it is necessary to add a complex compound of boron and aluminum to the melt. We studied the formation of a compound from boric acid and γ-Al_2O_3 by thermogravimetry (Fig. 1). Water-containing components were specially selected so that the particle

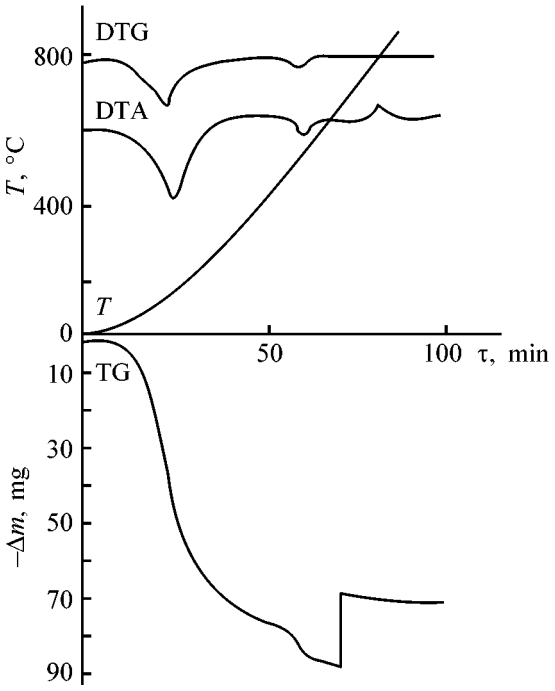

Fig. 1. Thermogravigram of an H_3BO_3–γ-Al_2O_3 sample (500 mg). (*T*) Temperature, (μ) weight change, and (τ) time.

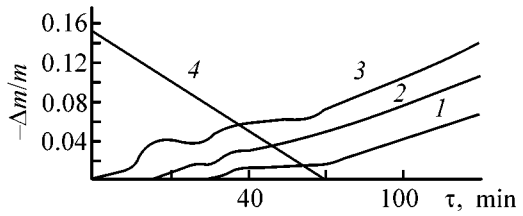

Fig. 2. (*1*)–(*3*) Sample weight $\Delta m/m$ and (*4*) temperature *T* vs. time τ. Sample: (*1*) cryolite, (*2*) cryolite + 10 wt % (B_2O_3 : 2γ-Al_2O_3) mixture, (*3*) cryolite + 10 wt % B_2O_3 : *n*Al_2O_3 compound.

surface was activated by water evaporation upon heating. The DTA curve in Fig. 1 exhibits two endothermic peaks related to water vaporization from boric acid and γ-Al_2O_3 [10] and an endothermic peak at 770°C corresponding to the formation of a compound by the reaction

$$n\mathrm{Al_2O_3} + m\mathrm{B_2O_3} = n\mathrm{Al_2O_3} \cdot m\mathrm{B_2O_3}. \quad (2)$$

This was confirmed by X-ray analysis and IR spectroscopy. A favorable property of this compound is its nonhygroscopicity, in contrast to boron oxide transforming into boric acid in air.

In the phase diagram of the Al_2O_3–B_2O_3 system, there are two incongruently melting compounds: $Al_4B_2O_9$ (mp 1308 K) and $Al_{18}B_4O_{33}$ (mp 2223 K) [11]. Formation of boron oxyfluoride compounds in a cryolite–alumina melt is also possible:

$$\mathrm{NaF} + n\mathrm{B_2O_3} = \mathrm{NaF} \cdot n\mathrm{B_2O_3}. \quad (3)$$

The phase diagram of the NaF–B_2O_3 system was presented in [12]. In this system, there are two compounds: $NaF \cdot B_2O_3$ (mp 913 K) and $NaF \cdot 2B_2O_3$ (mp 933 K). Th thermodynamic characteristics of boron oxyfluoride compounds are unknown, and, therefore, it is impossible to assess the probability of their existence in the melt.

In a number of works [13, 14], it was proposed to introduce sodium tetraborate $Na_2B_4O_7$ into cryolite, but the increasing activity of the alkali metal in the melt makes higher the probability of cathode bottom failure through incorporation of sodium.

Below are presented the results of thermodynamic calculations [9] of possible electrochemical reactions in a cryolite–alumina melt containing boron oxide and its compounds with aluminum and sodium oxides at 1273 K:

Reaction	Δ*G*, kJ	Δ*E*, V
$Al_2O_3 = 2Al + 3/2O_2$	1219.082	–2.106
$B_2O_3 = 2B + 3/2O_2$	960.740	–1.660
$Al_4B_2O_9 = 2Al_2O_3 + 2B + 3/2O_2$	1002.114	–1.731
$Al_4B_2O_9 = 4Al + 2B + 9/2O_2$	3546.438	–2.042
$Na_2B_4O_7 = Na_2O + 4B + 3O_2$	2208.673	–1.908
$Na_2B_4O_7 = 2Na + 4B + 7/2O_2$	2444.506	–1.809
$Na_2B_4O_7 = 2NaBO_2 + 2B + 3/2O_2$	978.817	–1.690
$2NaBO_2 = Na_2O + 2B + 3/2O_2$	1229.856	–2.124
$NaBO_2 = Na + B + O_2$	732.844	–1.899

Comparison of the decomposition potentials of boron, aluminum, and sodium oxides and their compounds shows that the potential of sodium tetraborate decomposition into boron and sodium is more electropositive than the potential of alumina decomposition, which may lead to an increase in the concentration of the alkali metal in aluminum. Correspondingly, the probability of graphite failure upon incorporation of sodium increases. Therefore, it is preferable to introduce a compound of boron and aluminum oxides into the melt.

The weight loss of pure molten cryolite and molten cryolite containing a mixture of boron and aluminum oxides and also their compounds was monitored by thermogravimetry (Fig. 2). It is seen from the figure that introduction of boron oxide as a compound with aluminum oxide diminishes the weight loss resulting from boron trifluoride formation. Therefore,

voltammetric studies were carried out by titration of the cryolite–alumina melt with a preliminarily prepared compound $2Al_2O_3 \cdot B_2O_3$.

Glassy carbon cell. When the compound $2Al_2O_3 \cdot B_2O_3$ is introduced into a cryolite melt, a new more electropositive peak, compared with the background curve characteristic of the cryolite–alumina melt, appears in the cathodic part of the cyclic voltammetric curve (Fig. 3). In the concentration range under study, the peak height linearly depends on the boron oxide content in the melt. A sharp fall of the cathode current after the peak and also the linear dependence of the peak current and potential on the polarization rate indicate the cathode passivation through formation on its surface of a layer having electrical conductivity different from that of the electrode. In this case, a semiconductor material, boron, is formed, which has electrical conductivity lower than that of glassy carbon, but higher than that of the melt [15]. Since the cathodic peak is not of diffusion nature, it is impossible to calculate the kinetic parameters of this electrochemical process. No anodic peak was observed in the entire range of polarization rates, which is also due to passivation of the working electrode.

Platinum cell. In the case of a cryolite–alumina melt, we observed three cathodic and anodic peaks, which are more electropositive than the background rise. These peaks correspond to reduction of aluminum on platinum with the formation of Pt–Al intermetallic compounds. The calculated potentials of depolarization of aluminum reduction through formation of intermetallic compounds [16] are close to the potentials obtained from the voltammetric curves (Fig. 4a):

Peak *I*:	$3Pt + Al = Pt_3Al$,	$\Delta E = +0.98$ V;
Peak *II*:	$Pt_3Al + Al = Pt_3Al_2$,	$\Delta E = +0.66$ V;
Peak *III*:	$Pt_3Al_2 + Al = 3PtAl$,	$\Delta E = +0.43$ V.

A new cathodic peak *B* appear on the top of peak *I* in the cyclic voltammetric curves (Figs. 4b and 4c) recorded in an Na_3AlF_6–Al_2O_3–B_2O_3 melt. The limiting current of this peak linearly depends on the concentration of boron oxide in the melt. The peak potential is shifted to the electronegative side with increasing boron oxide concentration and potential sweep rate. A forewave of boron reduction yielding a Pt–B compound was observed in voltammetric curves measured in an LiF–KF–B_2O_3 melt at 700°C on a Pt electrode [17]. In our case, we did not observe the forewave corresponding to the formation of a Pt–B compound. The aforesaid suggests that the new peak is attributable to irreversible three-electron reduction of boron.

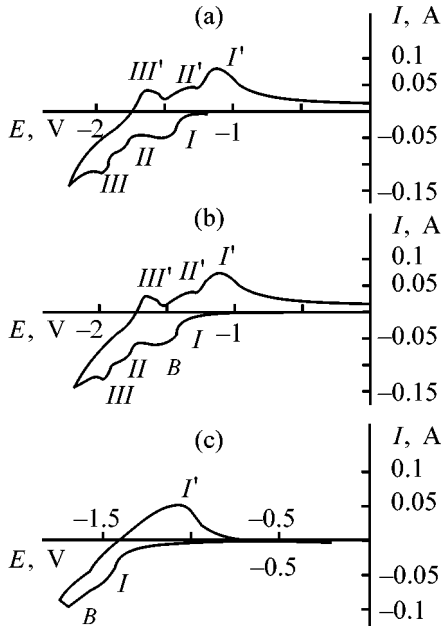

Fig. 4. Cyclic voltammetric curves for the systems: (a) Na_3AlF_6–Al_2O_3 (2×10^{-4} mol cm^{-3}), (b) Na_3AlF_6–Al_2O_3 (1.12×10^{-3} mol cm^{-3})–B_2O_3 (3.8×10^{-5} mol cm^{-3}), and (c) Na_3AlF_6–Al_2O_3 (1.12×10^{-3} mol cm^{-3})–B_2O_3 (1.9×10^{-4} mol cm^{-3}). Temperature 1020°C, $V = 0.5$ V s^{-1}, Pt working electrode ($S = 0.2$ cm^2), reference electrode O^{2+}/O_2 (Pt). (*I*) Current strength; (*E*) potential.

Introduction of boron oxide as a compound with aluminum oxide into molten cryolite does not result in its considerable losses, since the electrochemical reduction of boron is the most electropositive process.

CONCLUSION

A study of the physical, chemical, and electrochemical behavior of boron oxide and its compound with aluminum oxide in molten cryolite enabled stabilization of the melt. Boron oxide, when added to molten cryolite in the form of a compound with aluminum oxide, is reduced in a single stage to elemental boron. This process occurs at less negative potentials than aluminum reduction.

Abstract—The effect of oxidation conditions, temperature and concentration of the electrolyte, and its transformation from the true to colloidal solution on the phase composition and electrical resistance of coatings was studied.

Titanium and other rectifying metals are commonly anodized to prepare various coatings, for example, catalytic, catalyst supporting, and anticorrosion coatings. Controllable synthesis of films of a prescribed composition and crystalline structure is necessary for development of efficient protective coatings and new materials. One of promising methods of their synthesis is microarch oxidation (MAO), i.e., the formation of oxide coatings on metals and alloys in the regime of electrical breakdowns in aqueous and nonaqueous electrolytes. The method allows the chemical and phase composition, and, consequently, physicochemical properties of the anodic coatings on rectifying metals to be varied within wide range [1–3].

The conditions appearing in breakdowns (high temperature and considerable pressure drop) should result in the formation of anodic titanium oxide of rutile modification, which is a more thermodynamically stable phase highly resistant to chemical aggressive media. At the same time, previous experimental data showed that anatase, rutile, and amorphous inclusions in various combinations are formed in various electrolytes [2–7].

All the mentioned titanium dioxide modifications possess different physicochemical and corrosion–mechanical properties. For this reason, controllable synthesis of prescribed oxide structures is an urgent problem.

A few assumptions exist concerning the formation of anatase and rutile modifications of titanium oxide upon anodization: Koche *et al.* [8] believe that the transition anatase→rutile is temperature-induced; according to [2, 3, 5, 7], formation of one or another modification of TiO_2 is influenced by the anionic composition of the electrolyte.

The electrolyte anions can affect the phase composition of MAO films via generation of nuclei of the corresponding titanium oxide modification, similarly to a way in which the anionic composition of aqueous titanium salts used for titanium oxide deposition predetermines the polymerization type [2, 3]. Moreover, the ratio of these phases can be varied within a rather wide range owing to variations of the amount of the certain electrolyte components selectively dissolving anatase or rutile [7]. The phase composition of MAO coatings is largerly dependent on the formation conditions [1–3].

The elemental composition of MAO coatings sharply varies on passing from the colloidal to true solution [9, 10]. Under these conditions, the phase composition should vary.

In this work, we study the phase composition and electrical resistance of the coatings obtained by oxidation under different conditions of electrical breakdowns in an electrolyte containing sodium tetraborate. Also, we determined the change in the phase composition on passing from the colloidal to true electrolyte.

EXPERIMENTAL

Prior to anodizing, VT1-0 titanium samples ($2.5 \times 0.5 \times 1$ cm) were polished mechanically. Then, chemical polishing in a mixture of concentrated acids (HF : HNO_3 = 3 : 1) was done at 60–80°C for 2–3 s to remove the surface metal layer and obtain a standard state of the surface [11]. After that, samples were washed with distilled water and dried in air.

Oxide films on titanium were obtained by microarch oxidation in an electrolyte containing sodium tetraborate. Solutions were prepared from chemically pure grade reagents. True solution was prepared by dissolving sodium tetraborate in a solution heated to 60°C and then gradually cooling to a required temperature.

The coatings were formed in the galvanostatic mode (i = 0.05–0.2 A cm^{-2}, oxidation time 10 min). As power supply served a TER4-100:46ON thyristor transducer delivering a pulsed current of positive polarity. The MAO was performed in a 250-ml heat-resistant glass vessel with a spiral hollow cathode of Cr18Ni9Ti stainless steel cooled with tap water. The electrolyte temperature was varied within 10–50°C. The electrolyte was continuously stirred with a magnetic stirrer. After oxidizing, samples were washed with distilled water and dried in air.

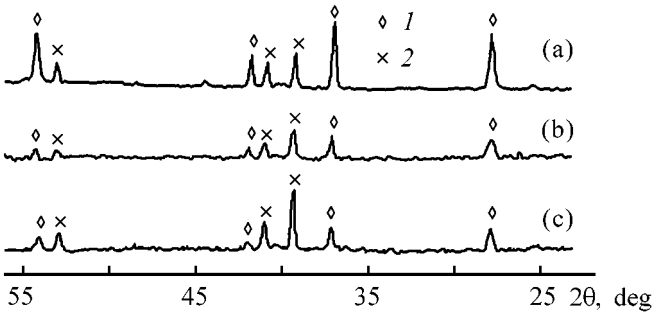

Fig. 1. Diffraction patterns of the MAO coatings formed in a tetraborate electrolyte under the different oxidation conditions. $Na_2B_4O_7$ concentration (M): (a, b) 0.3 and (c) 0.1; Current density (A cm^{-2}): (a, b) 0.1 and (c) 0.05. Temperature (°C): (a) 34, (b) 19, and (c) 12. (*1*) TiO_2 (rutile) and (*2*) Ti.

The phase composition of coatings was determined on a DRON-2.0 diffractometer (Cu_{K_α} radiation). The elemental composition of the surface was determined on a JXA-5A X-ray spectral microprobe analyzer. The electrical resistance of the films was measured with an R5021 alternating current bridge in a 3% NaCl solution. The counter electrode was platinum gauze. The measurements were made within a 1 cm^2 surface; the remaining surface and the edges of coating were insulated with lacquer.

The state of the solutions prepared is dependent on the electrolyte concentration and temperature. Transparent solutions, true over the entire temperature range studied, contain 0.1 M sodium tetraborate. In solutions containing 0.2 and 0.3 M sodium tetraborate, colloidal and suspended particles are formed at low temperature. With increasing temperature, the particle size decreases, and the colloidal solution transforms into true solution (a 0.2 M solution at 28–30°C and a 0.3 M solution at 32–38°C).

The table and Figs. 1 and 2a show how the concentration of tetraborate electrolyte and its state, dependent on temperature and MAO conditions, affect the phase composition of the coatings. As seen, the films obtained in borate electrolyte contain only the rutile modification of TiO_2, irrespective of the oxidation conditions. The relative amount of rutile, I_r, was estimated from the ratio of the reflection intensity of the studied sample (for three intense reflections) to the intensity of the sample anodized at i = 0.05 A cm^{-2}, c = 0.1 M, and T = 12°C (Fig. 1c). The amount of the rutile modification depends on the electrolyte state and oxidation conditions. In the electrolyte containing 0.1 M sodium tetraborate, the rutile amount increases with increasing current density. Anodization in a more concentrated electrolyte is influenced to a greater extent by the electrolyte state.

The content of the rutile modification in a coating and the electrical resistance of coatings formed in 0.3 M $Na_2B_4O_7$ solutions at i = 0.1 A cm^{-2} are presented in Fig. 2 as functions of electrolyte temperature. With increasing temperature, the rutile content increases, attaining the maximal value in the transition region with respect to the state of tetraborate solution of the given concentration (32–38°C). The amount of the crystalline phase in the coating formed at higher temperatures in the unsaturated solution sharply decreases. The rutile content is maximal on passing from the colloidal to true solution (Fig. 2a). In

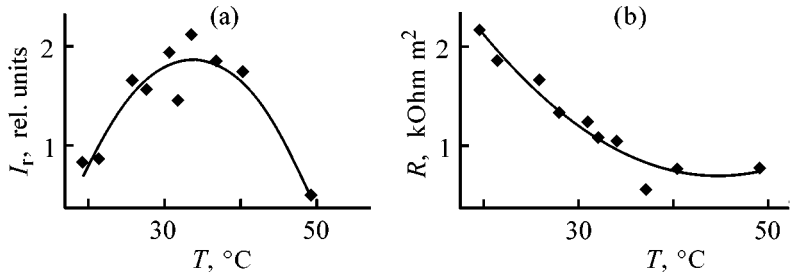

Fig. 2. Influence of temperature T on (a) rutile amount I_r and (b) electrical resistance R of the coatings formed in the electrical breakdown mode in a 0.3 M $Na_2B_4O_7$ electrolyte at current density of 0.1 A cm^{-2}.

the process, the elemental composition of the films varies insignificantly. For example, the titanium content changes from 60.6 to 60 wt %, and the sodium content, from 0.06 to 0.11 wt %. It should be noted that the method used for elemental analysis of coatings does not allow determination of light elements, boron in particular.

In a transition range from the colloidal to true solution, the content of the rutile modification in the coating and the electrical resistance of coatings show a certain correlation (Fig. 2). The increase in the rutile amount decreases the electrical resistance. However, in unsaturated electrolyte, no correlation was observed.

As known, titanium and other rectifying metals are anodized in an electrolyte containing borate and fluoride ions [12]. In this connection, we studied how addition of 0.5 M NaF to an electrolyte containing 0.1 M sodium borate affects the phase composition of coatings:

i, A cm^{-2}	0.05	0.1	0.2	0.2
I_r/I_a	1.02	0.85	1.32	2.43
T, °C	12	13	18	65

With NaF additive, the phase composition of the forming coatings is changed: titanium dioxide of the anatase modification is formed, with the rutile to anatase ratio dependent on oxidation conditions. A ratio I_r/I_a of the rutile to anatase amounts in the analyzed sample was calculated from the corresponding reflection intensities (for the three most intense reflections) and compared to the sample obtained at i = 0.05 A cm^{-2} and T = 12°C. The anatase amount is larger in coatings oxidized at i = 0.1 A cm^{-2} than in those oxidized at i = 0.05 A cm^{-2}. However, at i = 0.2 A cm^{-2} this ratio is changed, i.e., the rutile modification of titanium dioxide becomes predominant. This can be ascribed to the increased temperature, and, consequently, enhanced chemical interaction between the coating and electrolyte, which occur at higher current densities in the region adjacent to the electrical breakdown channels. As a result, anatase, as a less stable titanium dioxide modification, dissolves. This result is confirmed by the fact that, as the electrolyte temperature at i = 0.2 A cm^{-2} increases, the content of the rutile modification of TiO_2 grows.

Only rutile modification of titanium oxide is present in the MAO coatings obtained in the tetraborate electrolyte. This result can be explained using Gordienko's assumptions [2, 3]. It is evident that in the tetraborate electrolyte the borate ions enter the coordination sphere of titanium(IV) in a solution or on the anode surface with distortion of its octahedral surrounding. As a result, the nuclei of the rutile modification of titanium oxide are preferentially formed. The influence of the current density on the phase composition of a coating can be explained by the fact that, with increasing current density, the sparking power and, consequently, both the local temperature and the electrolyte temperature increase, thus facilitating formation of the rutile phase, a high-temperature titanium oxide modification.

Apart from the current density, the electrical resistance and the phase composition of coatings are also affected by the electrolyte concentration, which can be explained by a specific action of boron oxide. Boron oxide, B_2O_3, melts at 450°C [13] and in molten state can dissolve many oxides, with the oxide crystal lattice passing to the active state owing to deformation. Moreover, the energy of the B–O bond (18 254.45 kJ mol^{-1}) is higher than that of the Ti–O bond (12 158.47 kJ mol^{-1}). For this reason, boron oxide can loosen the crystal lattice of titanium oxides and facilitate defect formation, intensifying of the solid-state reaction at lower temperatures [14]. Thus, the higher the sodium tetraborate concentration, the stronger the influence exerted by it on the coating characteristics. The change in the rutile amount in the range 18–38°C can be largely associated with the electrolyte state.

A 0.3 M concentration of $Na_2B_4O_7 \cdot 10H_2O$ is attained at 38°C [15]. It is found experimentally that

the colloidal solution cooled with a stainless steel spiral starts transforming into true solution within 32–38°C, i.e., in the region where the maximal amount of the rutile modification is formed. In the transition region, the colloid size decreases gradually with increasing temperature. The increase in the number of colloids participating in microplasma-assisted anodic reactions results in the fact that colloids, while entering reaction zone, form the B_2O_3 phase, which affects the phase composition of the coatings. Probably, a drastic decrease in the amount of the crystalline phase in coatings formed at an electrolyte temperature above 38°C is due to transformation of the colloidal solution into true solution and to disappearance of colloids of a certain size.

As noted above, in the temperature range corresponding to transformation of the colloidal solution into true solution the rutile content in the coatings correlates with their electrical resistance. For films formed at higher temperature, the electrical resistance is constant. Probably, the growth of the crystalline phase in this temperature range produces a more defective structure, thus decreasing the electrical resistance.

CONCLUSIONS

(1) Coatings on titanium obtained in borate electrolyte by microarch oxidation contain solely the rutile modification.

(2) The rutile amount depends on the electrolyte state and is maximal in the range of transformation of the colloidal solution into true solution.

(3) The electrical resistance and the phase composition of the coating correlate.

(4) Titanium oxide of anatase modification is present in borate electrolyte containing NaF.

Abstract—The effect of Na_2WO_4 concentration, electrolyte depletion, and replacement of sodium tungstate by ammonium paratungstate on the specific features of formation and on the phase and elemental composition of coatings formed on AMtsM aluminum alloy in anodic-spark oxidation was studied.

Tungsten-containing oxide layers deposited on metallic surfaces are of interest because of their semiconducting, corrosion-resistant, catalytic, and decorative properties. As shown previously [1], even prespark oxidation of aluminum in tungstate electrolytes leads to incorporation of tungsten into anodic oxide films. In the process, tungsten is concentrated in the outer layer of the coatings, with its content being about 0.72 ± 0.05 at.%. The WO_3 phase was revealed in coatings upon anodic-spark oxidation of rectifying metals in 0.05 M Na_2WO_4 [2]. When 0.1 M Na_2WO_4 is used as electrolyte [3], coatings containing aluminum tungstates appear on AD-1 aluminum alloy in the initial stage, and then, as the electrolyte is being depleted and the quantity of electricity expended for coating formation grows, tungsten oxides and tungsten bronzes are formed. Thus, analysis of published data shows that the coating composition in the first place depends on the electrolyte concentration. The present study is aimed to reveal the effect of concentration and the depletion of the tungstate electrolyte on the composition and parameters of coatings on aluminum alloy.

EXPERIMENTAL

Electrolytes were prepared using distilled water and analytically pure grade $(NH_4)_{10}[H_2W_{12}O_{42}] \cdot 10H_2O$ and $Na_2WO_4 \cdot 2H_2O$. Ammonium paratungstate was dissolved with heating to 70°C. The electrochemical cell and the method of pretreatment of aluminum samples have been described previously [4]. Oxide layers on AMtsM alloy samples $40 \times 10 \times 1$ mm in size were formed in the galvanostatic mode at current densities i 3 and 5 A dm^{-2} in the course of t 10, 30, and 60 min. The process temperature did not exceed 20°C. After treatment, samples with coatings were thoroughly washed first with tap and then with distilled water and dried in air at room temperature.

The sparking voltage was evaluated by the appearance of the first visually observed sparks on the anode surface or by analyzing the forming curves $U = f(t)$ (from the beginning of deviation of the time dependence of the voltage across electrodes from linear behavior). As the electrolyte depletion Q^* (C l^{-1}) was taken the quantity of electricity, normalized to solution volume, passed through the electrochemical cell before the beginning of oxide layer formation on the electrode.

The phase composition of the coatings was studied by X-ray phase analysis (XPA) on a DRON-2.0 diffractometer (Cu_{K_α} radiation). The elemental composition of the coatings was determined on a JEDE JXA-5A X-ray spectral analyzer. The film thickness was measured with an MBI microscope in reflected light on coating cross sections as an average of 10–15 measurements with accuracy of ±2 μm.

Table 1 presents the concentrations of Na_2WO_4 solutions, pH values, electrical resistivities α of initial solutions and those after anodic-spark oxidation, and phase composition of coatings formed on aluminum alloy at i = 3 A dm^{-2} and varied duration of anodic-spark treatment, and also at different extents of electrolyte depletion Q^*. All the electrolytes exhibit weakly alkaline reaction due to hydrolysis of tungstate ions. Raising the Na_2WO_4 concentration leads to a change in the pH of the initial solutions, increase in electrical conductivity, and lowering of the sparking

Note: Oxidation mode: (1) t = 10 min, undeveloped electrolyte; (2) t = 10 min, Q^* = 1440–1800 C l^{-1}; and (3) t = 30–60 min, Q^* = 1800–5040 C l^{-1}; "?" denotes possible presence of the indicated phases.

voltage U_s and final voltage U_f of forming (Fig. 1a). For an undepleted electrolyte, the dependence $U_s = f(c)$ is linear, and $U_f = f(c)$, nonlinear. Moreover, the concentration affects the thickness h of the coatings formed and their elemental and phase composition (Figs. 1b and 1c, Table 1), and also their outward appearance (Fig. 2).

Figure 1c presents only the content of W, Al, and O in the coatings, with the content of other elements (Na, Mn, Fe) not exceeding 0.5 wt %. From data in Fig. 1 and Table 1, three ranges of the Na_2WO_4 concentration (M) influencing on the composition of the coatings can be distinguished: (I) 0.01–0.04, (II) 0.05–0.06, and (III) 0.07–0.1. In electrolytes with low sodium tungstate concentrations (region I), thin (3–4 μm) moire coatings (with light and dark areas) containing aluminum oxides and hydroxides are formed (Table 1). The content of tungsten in such coatings is 12–19 wt %.

The composition of coatings formed at intermediate concentrations (region II) is affected by the extent of electrolyte depletion. At $Q^* < 720$ C l^{-1}, green

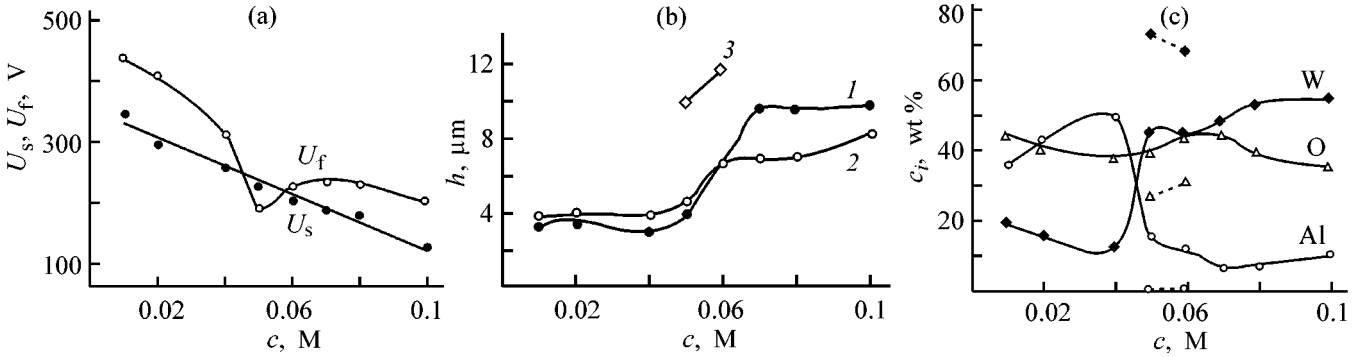

Fig. 1. (a) Sparking voltage U_s and final voltage U_f across electrodes, (b) coating thickness h, and (c) content c_i of main elements in coatings vs. concentration c of sodium tungstate. Current density i = 3 A dm^{-2}, t = 10 min. (b) (*1*, *2*) Dark parts of coatings, formed in, respectively, undepleted and depleted electrolyte; (*3*) green coatings. (c) Oxygen content in the coatings was determined from the difference; *dashed lines*: content of elements in green coatings.

10–12-μm-thick coatings are formed. WO_3 and $WO_{2.9}$ phases are present in their composition (Table 1). Formation of tungsten oxides on rectifying metals has been observed previously [2] in a 0.05 M Na_2WO_4 solution, but at higher current density (i = 16 A dm^{-2}). In the case under study, tungsten oxide layers are formed on the anode surface at Na_2WO_4 concentrations of 0.05–0.06 M by the linear discharge mechanism [5]. At Q^* > 720 C l^{-1}, green areas disappear, aluminum tungstate is formed, and the concentration of tungsten in the coatings decreases from 70 to 45 wt %.

At high Na_2WO_4 concentrations (region III), black coatings with thickness of up to 10 μm were obtained. The $Al_2(WO_4)_3$ phase was detected in them, although presence of sodium polytungstates is not impossible since the content of sodium is as high as 0.35 wt %. The concentrations of tungsten and aluminum in such coatings are 44–55 and 6–15 wt %.

Over nearly the entire range of Na_2WO_4 concentrations studied (0.02–0.08 M), making longer the duration of anodic-spark oxidation of an aluminum alloy (or raising the quantity of passed electricity $Q = it$) in depleted electrolytes gives coatings with identical composition, which contain the $Al_2(WO_4)_3$ phase (Table 1). In region III, raising the Q value favors formation of three-layered coatings. A black film with greenish tint is formed on a gray film and is overgrown by a green film of tungsten trioxide (Fig. 2).

Electrolyte development affects not only the outward appearance and composition of coatings (especially noticeable for coatings obtained in region II), but also the parameters of their formation (Fig. 3). In the first place, the ionic composition of the electrolytes is changed. With increasing Q^*, first colloids and then WO_3 precipitates are formed, the concentration of WO_4^{2-} ions decreases, and pH grows. The depletion of an electrolyte containing 0.1 M Na_2WO_4 leads, already at Q^* = 360 C l^{-1}, to a change in pH value by more than 3 units (Fig. 3b).

To account for the rise in pH on the basis of the results of [3, 6], the following scheme of chemical and electrochemical processes in anodic-spark oxidation of aluminum and its alloys in tungstate electrolytes may be suggested.

Hydroxide ions are formed at the cathode through electrochemical discharge of water molecules:

$$2H_2O + 2e \rightarrow 2OH^- + H_2\uparrow. \quad (1)$$

A film of aluminum hydroxide grows on the anode, and hydroxonium ions are generated:

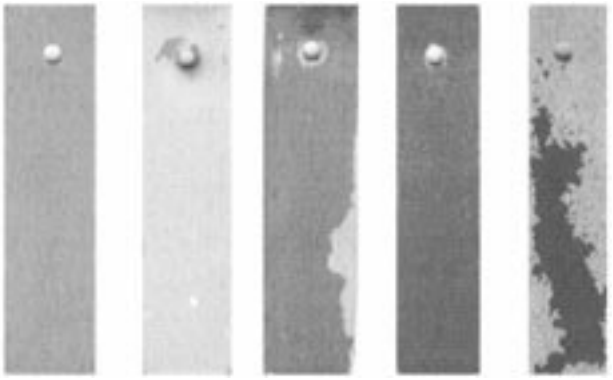

Fig. 2. Effect of Na_2WO_4 concentration on the outward appearance of coatings obtained in the course of anodic-spark treatment in (*1–4*) undepleted and (*5*) depleted electrolytes. Current density i = 3 A dm^{-2}. Time t (min): (*1–4*) 10 and (*5*) 30. Na_2WO_4 concentration (M): (*1*) 0.02, (*2*) 0.05, (*3*) 0.06, (4) 0.07, and (*5*) 0.1.

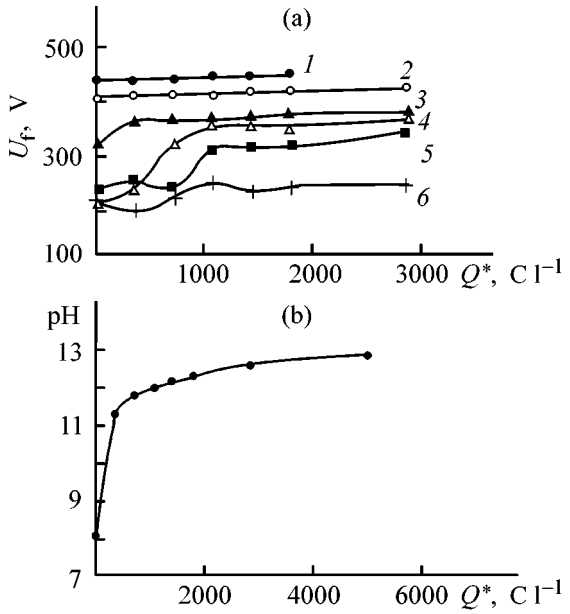

Fig. 3. Effect of electrolyte depletion Q^* on (a) final voltage of coating formation U_f and (b) pH value of 0.1 M Na_2WO_4. (a) Na_2WO_4 concentration (M): (*1*) 0.01, (*2*) 0.02, (*3*) 0.04, (*4*) 0.05, (*5*) 0.06, and (*6*) 0.1.

$$2Al + 9H_2O \rightarrow Al_2O_3 + 6H_3O^+ + 6e. \quad (2)$$

A decrease in pH in the near-anode layer promotes formation of isopolyanions (IPA) [7]:

$$nWO_4^{2-} + pH^+ \rightleftarrows H_xW_nO_{[4n-(1/2)(p-x)]}^{(2n-p)-} + 1/2(p-x)H_2O. \quad (3)$$

It is noteworthy that decomposition of tungsten IPA in the solution bulk would be expected at pH > 8 [8].

Table 2. Characterization of anodizing electrolytes containing 0.1 M tungsten(VI) and phase composition of precipitates

Electrolyte no.	Composition	Characteristics of electrolyte				Phase composition of precipitates	
		initial		after anodizing			
		pH	$\alpha \times 10^3$, $(\Omega\ \mathrm{cm})^{-1}$	pH	$\alpha \times 10^3$, $(\Omega\ \mathrm{cm})^{-1}$	from initial electrolyte	from electrolyte after anodizing
1	Na_2WO_4	8.11	12.4	12.80	13.4	–	$Na_{10}[H_2W_{12}O_{42}] \cdot 12H_2O + WO_3$
2	$Na_2WO_4 + (NH_4)_{10}[H_2W_{12}O_{42}]$	6.71	7.5	7.65	8.2	$Na_2(NH_4)_8[H_2W_{12}O_{42}] \cdot 12H_2O$	$Na_2(NH_4)_8[H_2W_{12}O_{42}] \cdot 12H_2O + WO_3$
3	$(NH_4)_{10}[H_2W_{12}O_{42}]$	6.45	3.2	6.91	3.2	$(NH_4)_{10}[H_2W_{12}O_{42}] \cdot 10H_2O$	$(NH_4)_{10}[H_2W_{12}O_{42}] \cdot 10H_2O + WO_3$

Reaction (3) may give sodium polytungstates which are retained on the surface of anodic films by capillary forces or by adsorption. The final product of polycondensation is tungstic acid. Formation of gel layers of hydrated tungsten oxide already in prespark anodizing of aluminum in tungstate electrolytes was observed in [6]. Dehydration of $WO_3 \cdot nH_2O$, initiated by microdischarges in the near-anode space, leads to appearance of tungsten oxides in the composition of coatings (region II).

Formation of aluminum tungstate in the coatings was attributed in [3] to solid-phase interaction of the anodic aluminum oxide with negatively charged hydrosol of tungsten(VI) oxide. Also possible is another mechanism of its formation. When sparks appear at the anode surface, metal ions pass into solution more intensively [9]. Interaction of aluminum ions with tungstate ions may lead to deposition of a difficultly soluble compound $Al_2(WO_4)_3$ [10] at the anode–electrolyte interface. Aluminum ions may be present in solution at the given pH values in the form of hydroxoaluminate anionic complexes. With aluminum ions accumulated in the electrolyte, formation of aluminum tungstate can also be observed on the anode surface. The formation of this compound in anodic-spark oxidation of titanium in aluminate–tungstate electrolytes has also been reported [11].

Irrespective of what tungsten-containing compound, WO_3 or $Al_2(WO_4)_3$, is formed, consumption of WO_4^{2-} anions at the anode and generation of OH^- at the cathode make higher the pH of electrolyte possessing no buffer properties.

Replacement of tungstate ions by hydroxide ions would have resulted in higher electrolytic conductivity of a solution, since the mobility of OH^- is higher [at 20°C the limiting electrical conductivity at infinite dilution $\lambda_{20}^{\infty}(OH^-) = 217.73$, $\lambda_{20}^{\infty}(1/2WO_4^{2-}) = 76.34\ \Omega^{-1}\ \mathrm{g\text{-}equiv^{-1}\ cm^2}$] [12]. The constant (within experimental error) electrolytic conductivity can be accounted for by changes in the number and mobility of carriers, including those caused by formation of IPA and colloid particles.

Changes in the coating composition may be due to the influence of concentration and depletion of electrolyte on the pH value. At pH > 11.2, gel layers of hydrated tungsten(VI) oxide cease to form on the surface of the aluminum anode, and transfer of aluminum ions to solution is enhanced [6]. After the depletion of the electrolyte, pH is lower than 11.2 at $c \le 0.04$ M and exceeds this value at c 0.05 M (Table 1). Consequently, it would be expected that the concentration of aluminum ions in the electrolyte decreases and aluminum tungstate is formed in the coatings beginning with $c \ge 0.05$ M. Indeed, formation of $Al_2(WO_4)_3$ in coatings deposited in the course of 10 min from depleted electrolytes onsets just at this concentration; however, in undepleted electrolytes $Al_2(WO_4)_3$ is only formed at $c \ge 0.07$ M. It is known [11] that the near-anode layer is acidified in anodic spark electrolysis. Possibly, changes in the composition of coatings are associated with changes in the electrolyte pH, concentrations of tungstate ions, and forms in which these ions are present in the near-anode space. Presumably, the amount of tungsten IPA appearing in the near-anode layer is insufficient for tungsten oxide coatings to be formed in region I, and sufficient in region II. In region III, dissolution of Al_2O_3 is enhanced because of the increasing pH of the depleted electrolyte, and coatings of different composition are formed.

To verify the assumption that the forms of occurrence of tungstate ions affect the composition of forming coatings, sodium tungstate was completely or partly replaced by ammonium paratungstate in such a way

Table 3. Phase composition of coatings formed in electrolytes nos. 1–3 containing 0.1 M tungsten(VI)

Electrolyte no. (Table 2)	Phase composition of coatings at indicated formation time, min			
	10		30	
	1	2	3	4
1	$Al_2(WO_4)_3$	$Al_2(WO_4)_3$	$Al_x(WO_4)_3 + H_{0.33}WO_3 + Na_2W_4O_{13}$	æ-Al_2O_3 + Al_xWO_3
2	$WO_3 + WO_{2.9}$	〃	$WO_3 + WO_{2.9}$	$Al_2(WO_4)_3$
3	WO_3	WO_3	WO_3	WO_3

Note: Oxidation mode: (1) i = 3 A dm^{-2}, Q = 18 C cm^{-2}; (2) i = 5 A dm^{-2}, Q = 30 C cm^{-2}; (3) i = 3 A dm^{-2}, Q = 54 C cm^{-2}; and (4) i = 5 A dm^{-2}, Q = 90 C cm^{-2}.

that the total concentration of tungsten in the electrolyte remained constant. The composition, pH value, and electrolytic conductivity of the initial electrolytes and those after anodizing are presented in Table 2.

Replacement of sodium tungstate with ammonium paratungstate changes the outward appearance and phase composition of coatings (Table 3). Coatings obtained in 0.1 M Na_2WO_4 contain aluminum tungstate, and aluminum–tungsten and (or) hydrogen bronzes are formed with increasing current density and time of anodic-spark treatment. The composition of coatings obtained in electrolyte no. 2 depends on the current density. The coatings contain tungsten oxides at i = 3 A dm^{-2}, and aluminum tungstate is formed at i = 5 A dm^{-2}. Coatings formed from the paratungstate electrolyte are identical in composition to those formed in a 0.05–0.06 M solution of Na_2WO_4 and contain tungsten trioxide.

Table 2 presents the compositions of precipitates formed in electrolytes obtained upon storage of both depleted and undepleted solutions for 1 month in sealed glass vessels. Tungsten(VI) oxide is formed after anodic-spark electrolysis in all the three electrolytes. Precipitates of double ammonium sodium paratungstate are formed in both undepleted and depleted electrolytes nos. 2 and 3, respectively. Precipitation of sodium paratungstate from electrolyte no. 1 at pH > 12 contradicts published data [7, 8, 10]. At such pH values, tungsten IPA can be only formed in the course of electrolysis, the more so as no precipitate was formed in undepleted electrolyte no. 1.

The formation of tungsten trioxide in the coatings upon replacing the tungstate electrolyte with a paratungstate one and precipitation of sodium paratungstate from a 0.1 M solution of Na_2WO_4 subjected to electrolysis confirm the assumption that tungsten IPA are formed in the near-anode layer and their concentration affects the coating composition.

Formation of bronzes and nonstoichiometric tungsten oxides (Tables 1, 3) at the anode has been attributed previously [3] to the action of hydrogen which is a product of water thermolysis under the action of microbreakdowns [13, 14]. A decrease in the oxidation level of elements contained in oxide coatings that are formed on aluminum in anodic spark treatment, compared with their oxidation level in the electrolyte, was also reported in [5] for vanadate–phosphate electrolytes. Bronze-containing coatings may be of interest for further study of their electrical and catalytic properties.

CONCLUSIONS

(1) Three ranges of the Na_2WO_4 concentration affecting formation and composition of oxide layers formed on aluminum alloy in its anodic-spark treatment are distinguished.

(2) It is shown that raising the Na_2WO_4 concentration and making longer the time of anodic-spark oxidation in depleted electrolyte lead to formation of coatings with identical compositions, containing the $Al_2(WO_4)_3$ phase.

(3) Anodic-spark oxidation of aluminum at sodium tungstate concentrations of 0.07–0.1 M in solution and $Q \geq 54$ C cm^{-2} leads to formation of tungsten oxide bronzes $H_{0.33}WO_3$ and Al_xWO_3 in the coatings.

(4) Tungsten trioxide is formed in coatings in an undepleted electrolyte only in a narrow range of Na_2WO_4 concentrations. An assumption is made that WO_3 formation is associated with the presence of isopolytungstate anions in the near-anode region. This is confirmed by the formation of similar layers on replacing sodium tungstate in the electrolyte with ammonium tungstate and by the results of studies of the precipitates formed in the electrolytes.

Received April 17, 2001

Abstract—The corrosion activity of chloride-containing solutions formed in production of ternary nitrogen–phosphorus–potassium fertilizers was studied. The inhibiting effect of hydroxide ions on the corrosion of 12Cr18Ni10Ti steel during the evaporation of solutions of nitrogen–phosphorus–potassium fertilizers was evaluated.

Production of complex ternary fertilizers (NPK) involves the use of potassium chloride, which significantly enhances the corrosion activity of the working medium. Therefore, introduction of potassium chloride into NP-containing solutions before evaporation is unacceptable. The structural material of evaporators is 12Cr18Ni10Ti steel. In the presence of chloride ions, the steel is subject to local forms of corrosion, i.e., point corrosion (pitting) and corrosion cracking under the action of stress. To avoid these and other undesirable phenomena, potassium chloride is introduced into evaporated NP-containing pulp before granulation.

In the course of drying, grinding, sorting, and packing of ternary fertilizers, a considerable amount of dust is formed, which should be returned to the process cycle to make the process economically and environmentally acceptable.

A portion of dust is catched by scrubbers sprayed with condensed process steam. The resulting dilute solutions of fertilizers should be evaporated prior to returning to the process cycle.

Therefore, it is necessary to examine whether 12Cr18Ni10Ti steel evaporators used for preparing binary nitrogen–phosphorus (NP) fertilizers can be used for the evaporation of dilute solutions containing NPK and chloride ions.

In this work, we studied the corrosion of 12Cr18Ni10Ti steel in multicomponent media of various compositions containing chloride ions.

As known, chloride ions inevitably enhance the corrosion activity of solution. This is especially true for pitting corrosion of stainless steels [1–3], which can also undergo a fast corrosion cracking under a stress [4, 5]. For example, solutions containing 0.01, 0.1, and 3.0 wt % sodium chloride at 245–250°C and a 32 kgs mm^{-2} load cause Cr18Ni10B steel samples to degrade in 49.4, 0.6, and 0.8 h, respectively [6]. Other types of anions (phosphate, nitrate, and hydroxide ions) makes solutions less corrosive. For example, 12Cr18Ni10Ti steel evaporators can operate for 8–10 years without repair under the following conditions: reaction mixture containing (g l^{-1}) 120–180 NaOH, 180–200 NaCl, and 0.15–0.25 $NaClO_3$, T = 140–150°C, and P = 4.0–5.0 atm; reaction mixture containing (g l^{-1}) 180–260 NaOH, 140–210 NaCl and 0.35–0.40 $NaClO_3$, T = 120–130°C, and P = 2.5–3.0 atm; reaction mixture containing (g l^{-1}) 230–340 NaOH, 210–75 NaCl, and 0.40–0.80 $NaClO_3$, T = 90–95°C, and P = 620–650 mm Hg [7].

Gorodnichii *et al.* [8] established the boundaries of stability of high-alloy steels (12 compositions) in boiling chloride–nitrate, chloride–sulfate, and chloride–phosphate solutions. These boundaries are mainly determined by the ratio of anion concentrations in a solution and by solution pH. The studied anions were arranged in the following order with respect to the inhibiting effect: PO_4^{3-}, NO_3^-, and SO_4^{2-}.

Uhlig and Revie [1] reported the similar data on the inhibiting effect of different anions. According to the authors' data, the inhibiting effect of the anions decreases in the following order: OH^-, NO_3^-, SO_4^{2-},

and ClO_4^-. However, the combined effect of the three anions, PO_4^{3-}, NO_3^-, and Cl^-, has not been studied yet.

EXPERIMENTAL

Initially, corrosion of 12Cr18Ni10Ti steel was studied electrochemically by the method of polarization curves [GOST (State Standard) 9.912–89]. The test samples were polarized in the potentiodynamic mode from the steady-state corrosion potential in the solutions under consideration to determine the bases of pitting resistance.

The 2-mm wires of 12Cr18Ni10Ti steel were glued to a polyvinyl chloride mounting with epoxy resin. The samples were finished with abrasive papers at the grain size decreased gradually to 7–10 μm in final finishing. After finishing, samples were washed with water, degreased with ethyl alcohol, and dried on a filter paper.

The test were performed in a glassy three-electrode cell thermostated at 90°C. Platinum was auxiliary electrode, and a saturated silver chloride electrode was reference (E = 0.201 V relative to standard hydrogen electrode). The polarization curves were taken with a P-5827M potentiostat and a PDP-4-002 two-coordinate plotting potentiometer.

A steel sample was kept in a test solution for 1 h to establish the steady-state corrosion potential E_{cor} and then was anodically polarized at a potential scanning rate of 1 mV s^{-1}. The potential was scanned in the opposite direction after the anode current density reached 0.1 A cm^{-2}.

The pitting potential E_{pp} and the repassivation potential E_{rp} were determined from the direct and inverse polarization curves plotted in the E–log i coordinates [GOST 9.912–89]. The E_{cor}, E_{pp}, and E_{rp} values obtained in three parallel measurements were averaged.

The pitting resistance bases, ΔE_{pp} and ΔE_{rp}, were calculated by the formulas $\Delta E_{pp} = E_{pp} - E_{cor}$, and $\Delta E_{rp} = \Delta E_{rp} - E_{cor}$. The values of the pitting resistance bases allowed determination of the susceptibility of steel to pitting corrosion.

In this work, we used solutions that are formed upon washing of evaporators and treatment of gases to remove dust. The resulting dulite solutions contain all components of complex NPK fertilizers. Evaporation of such solutions yields a valuable ternary fertilizer.

We tested four multicomponent solutions modeling a working medium of production of ternary fertilizers (solution nos. 1 and 3 before evaporation and solution nos. 2 and 4 after evaporation). Three one- and two-component solutions were also studied for comparison. The experimental bases of pitting resistance in the solutions studied are given in the table.

The polarization curves for each solution are shown in Figs. 1a–1g. The following conclusions can be made:

(1) Solutions containing only chloride ions (solution nos. 6 and 7) are rather corrosive. The bases of pitting resistance of 12Cr18Ni10Ti steel in these solutions are very low (Figs. 1a, 1b).

(2) Introduction of nitrate ions into solutions containing chloride ions yields a positive effect. In solution no. 5 the pitting and repassivation potentials

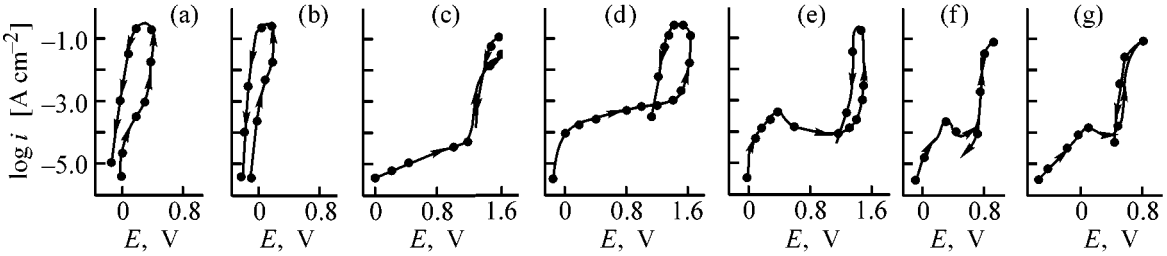

Fig. 1. Direct and inverse polarization curves E–log i of 12Cr18Ni10Ti steel in solution at 90°C. Solution composition (wt %): (a) KCl, 6.6; (b) KCl, 25.4; (c) NH_4NO_3, 8.7; KCl, 6.9; (d) NH_4NO_3, 8.4; $NH_4H_2PO_4$, 5.9; KCl, 5.8; (e) NH_4NO_3, 33.4; $NH_4H_2PO_4$, 23.6; KCl 23.0; (f) KNO_3, 9.7; K_3PO_4, 10.0; KCl, 5.3; KOH, 1.0; (g) KNO_3, 30.3; K_3PO_4, 31.2; KCl, 16.5; KOH, 1.9.

are shifted toward positive values by nearly 1 V (Fig. 1c).

(3) When phosphate and nitrate ions are simultaneously present in chloride solutions, the pitting potentials of 12Cr18Ni10Ti steel are shifted even more toward positive values (soluton nos. 1 and 2), i.e., pitting formation is impeded. At the same time, the extended hysteresis loops on the direct and inverse polarization curves confirm impeded repassivation of the forming pittings (Figs. 1d, 1e), which is undesirable.

(4) Introduction of potassium hydroxide into Cl^--, PO_4^{3-}-, and NO_3^--containing solutions in an amount ensuring conversion of the ammonium to potassium salts, ammonia removal, and maintenance of pH > 9 (solution nos. 3 and 4) results in disappearance of the hysteresis loop (Figs. 1f, 1g). This shows favorable conditions of pitting repassivation and should decrease the local corrosion of 12Cr18Ni10Ti steel in the given solutions.

To confirm results obtained by electrochemical method, ringlike samples with a welded seam made of 12Cr18Ni10Ti steel were placed in flasks with a reflux condenser and subjected to corrosion in solution nos. 1–4 at bp 140–160°C for 400 h. After completing tests, the overall corrosion rate was determined gravimetrically.

Solution no.	1	2	3	4
v, mm year^{-1}	0.001	4.0	0.001	0.001

The corrosion tests showed that, upon evaporation of dilute chloride-containing solutions of ternary fertilizers containing NH_4^+ and Cl^- ions at pH from 3 to 5, the corrosion activity of solutions increased by three orders of magnitude (solution no. 2). Thus, evaporation of dilute chloride-containing solutions of ternary fertilizers can cause considerable corrosion damage of evaporators made of 12Cr18Ni10Ti steel.

CONCLUSION

With potassium hydroxide added to dilute chloride-containing solutions of the NPK ternary fertilizers in amounts ensuring removal of ammonia and at pH above 9, the corrosion effect of these solutions is decreased considerably, which allows their evaporation to be performed in 12Cr18Ni10Ti steel apparatus.

CATALYSIS

Temperature Hysteresis in CO Oxidation on Copper Oxide Catalyst Applied to a Steel Gauze

A. N. Subbotin, M. P. Vorob'eva, B. S. Gudkov, V. I. Yakerson, and L. M. Kustov

Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Moscow, Russia

Received November 21, 2001

Abstract—The temperature hysteresis during the heterogeneous catalysis was studied by an example of model reaction of CO oxidation on copper oxide catalyst applied to a stainless steel gauze.

Over several years, we have been developing a concept that the local overheating of active centers is the main process responsible for the temperature hysteresis in heterogeneous catalysis [1–3]. Such overheating is due to impeded removal of heat from the active centers in the course of exothermic reactions.

Recently, the methods of preparation were proposed and the properties were studied of new heterogeneous catalysts based on a metal gauze [4, 5]. These catalysts, containing supporting and (or) catalytically active metals immobilized on the surface of stainless steel gauze, have a number of advantages, of which the most important is the high heat-exchange coefficient. This makes such catalysts especially promising for reactions with a large positive heat effect.

Here we attempted to use such gauze catalysts to confirm the hypotheses explaining the temerature hysteresis in terms of the local overheating of active centers. The test was performed by an example of the model reaction of carbon monoxide oxidation on copper-containing catalysts.

EXPERIMENTAL

A stainless steel gauze made of a 50-μm-thick wire was used as metallic support of a catalyst. Prior to depositing oxide layer, the gauze surface was treated electrochemically and then by chemical etching.

Two types of catalyst samples were prepared: (1) a steel gauze to which copper oxide was applied directly (CuO/gauze) and (2) a stainless steel gauze to which aluminum oxide and then copper oxide were applied (CuO/Al_2O_3/gauze).

The CuO/gauze catalyst was prepared by electrochemical deposition of copper from a $CuSO_4$ solution with subsequent oxidation. The deposition current was 500 mA. Two parallel copper plates were cathode. The metallic copper was oxidized by calcination in air (flow rate 3 l h^{-1}) at 550°C for 4 h. After calcination, the CuO/gauze sample contained 140 mg CuO.

The CuO/Al_2O_3/gauze catalyst was supported with a steel gauze preliminarily coated with Al_2O_3. Aluminum oxide was deposited electrophoretically [4]. For this purpose, a gauze cathode was plunged into aluminum hydroxide sol containing 5.5 g l^{-1} AlO(OH). The deposition was performed at direct current and a 30 V voltage for 2 min. After that, the sample was dried at room temperature for 24 h and calcined at 550°C for 2 h. Copper oxide was introduced by impregnation of the support with a $Cu(NO_3)_2$ solution followed by calcination in air flow at 550°C for 2 h. The resulting sample contained 25 mg CuO and 100 mg Al_2O_3.

The copper–aluminum–calcium catalyst containing 20% CuO and 80% Talum, a mixture of calcium mono- and dialuminates [3, 6], and platinum foil were used for comparison.

Carbon monoxide was oxidized with atmospheric oxygen in an automated catalytic installation with forced circulation of the reaction mixture at various CO : O_2 ratios and a total flow rate of 8 l h^{-1}. The reactor temperature was raised and lowered in small steps, and time at which the system was kept at each new temperature was sufficient to attain a constant composition of the reaction mixture (commonly, up to 10 min).

The CO content in the reaction mixture was determined by gas chromatography (column 1.5 m long and 2 mm in diameter, packed with a Porapak Q).

1070-4272/02/7504-0582 $27.00 © 2002 MAIK "Nauka/Interperiodica"

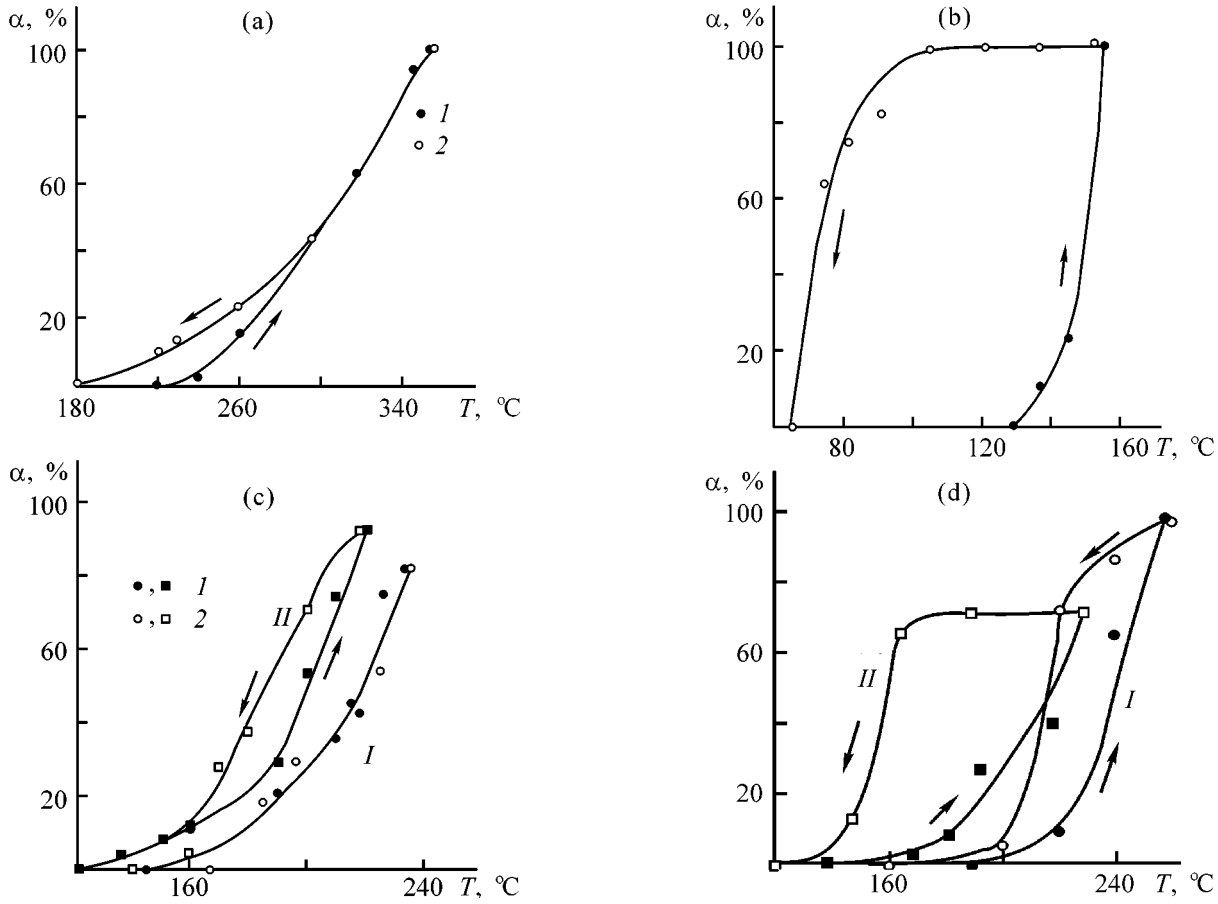

Fig. 1. Degree of CO oxidation α vs. temperature *T* on (a) Pt foil, (b) CuO/Talum, (c, d) CuO/gauze (*I*) and CuO/Al_2O_3/gauze (*II*) catalysts. (*1*) Heating and (*2*) cooling. CO content (%): (a) 7, (b) 14, (c) 11 (*I*) and 10 (*II*), (d) 32 (*I*) and 38 (*II*).

According to the temperature hysteresis concepts, the heat released from the active center of a catalyst in the course of exothermic reaction commonly has no time to dissipate completely. The major dissipation channel is heat transfer through the catalytic mass in the reactor. However, in dispersed solids, to which belongs the majority of catalysts, the conduction of heat via contact is impeded not only by the support but also by the low-active mass of the catalyst itself, which contains rather rarely "interspersed" active centers. As a result, the local temperature of an active center becomes higher than the average temperature measured by a thermocouple in the catalyst bed. Thus, the true reaction temperature under these conditions is higher than its measured value considered as reaction temperature. When the supply of heat from the outside is stopped or limited, i.e., reactor starts cooling, the true temperature of an active center remains higher than the measured temperature. As a result, the descending branch (cooling) on the temperature dependence is shifted to the left with respect to the ascending branch, i.e., an anticlockwise hysteresis loop appears. In light of this concept, the lower the heat conductivity of the catalytic mass under other equal conditions, the more marked the hysteresis. Bulk metals are known to have the highest heat conductivity, and, consequently, they should have the lowest hysteresis effect.[1]

Indeed, during the oxidation of CO on platinum foil, the ascending and descending branches of the temperature dependence diverge only slightly (Fig. 1a). At the same time, for the copper–aluminum–calcium catalyst the hysteresis loop is quite considerable (Fig. 1b).

Evidently, applying catalytically active component to a steel gauze should facilitate removal of heat from the active centers and, consequently, decrease the hysteresis effect. With a heat-insulating layer of aluminum oxide applied between copper oxide and steel gauze, the hysteresis effect should be more considerable.

Figure 1c shows the temperature dependences of the degree of CO conversion on the CuO/gauze and

[1] This concept is developed in more detail in [1, 2].

CuO/Al_2O_3/gauze samples at the close compositions of the reaction mixture. As seen, on the first of them the hysteresis is completely absent, whereas on the second one, a hysteresis (through insignificant) is observed.

Markedly different dependences were also obtained on the same samples at other composition of the reaction mixture, namely, at CO excess (Fig. 1d). It was shown previously [7] that the growth of the CO content extends the hysteresis loop. In line with this, the hysteresis loops are, as a whole, broader in Fig. 1d than in Fig. 1c. At the same time, even in the latter case, a heat-isolating film of aluminum oxide between copper oxide and steel gauze increases the hysteresis effect.

Thus, the results obtained confirm once again that the local overheating of active centers by excess heat released in an exothermic reaction is the main cause of temperature hysteresis in heterogeneous catalysis. These results also show that steel gauze catalytic systems ensure efficient heat release from the reaction zone, and, consequently, create the more favorable conditions of the process.

CONCLUSIONS

(1) The temperature hysteresis in CO oxidation with atmospheric oxygen on copper oxide applied to a steel gauze is more pronounced in the case when a heat-insulating layer of aluminum oxide is present between copper oxide and the gauze. This confirms the concept that the local overheating of active centers is the main cause of the temperature hysteresis.

(2) The catalyst applied to a gauze made of steel wire ensures efficient heat removal in an exothermic reaction and creates more favorable process conditions.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Effect of Acetophenone on Liquid-Phase Dehydration of Dimethylphenylmethanol

E. M. Mamedov, M. A. Gagarin, and Kh. E. Kharlampidi

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 25, 2001

Abstract—The acid-catalyzed liquid-phase dehydration of dimethylphenylmethanol to α-methylstyrene was considered. The scheme and mathematical model of liquid-phase dehydration of dimethylphenylmethanol were proposed, and the effect of acetophenone on the reaction kinetic parameters was studied.

Combined production of phenol and acetone by the cumene method is a widely used process of chemical technology [1]. It yields, along with the target products, many by-products, including dimethylphenylmethanol (DMPM). DMPM is formed through nonselective consumption of cumene hydroperoxide in the stages of cumene oxidation and acid decomposition of hydroperoxide into phenol and acetone. The presence of DMPM in the reaction mixture leads to formation of products impairing the quality of commercial phenol.

As noted in [2–7], DMPM can be dehydrated to obtain α-methylstyrene (α-MS), which is the initial monomer for production of various polymeric materials.

At present, α-MS is prepared in Russia mainly by high-temperature catalytic dehydrogenation of cumene [8]. This process is very power-consuming. Therefore, development and promotion of a process for α-MS production from DMPM, which finds no commercial application yet, is of practical interest.

Dehydration of DMPM to α-MS can be performed in both gas and liquid phases. We consider here the liquid-phase process as the most cost-efficient.

EXPERIMENTAL

DMPM obtained by base decomposition of cumene hydroperoxide was used as a raw material [1]. The sample contained (wt %) DMPM 91.7, acetophenone (ACP) 7.6, α-MS 0.53, cumene 0.28, and cumene hydroperoxide 0.50. A 0.5 M solution of sulfuric acid in acetic acid was taken as catalyst. Kinetic studies were performed in a temperature-controlled glass cell equipped with a magnetic stirrer. During the reaction, an inert gas (nitrogen) was bubbled through the reaction mixture. The reaction course was monitored chromatographically by the concentrations of the initial substances and reaction products [9].

Initially cumene was taken as a reaction medium, since it was the initial substance in DMPM synthesis, which eliminates the stage of additional purification of alcohol.

It is commonly believed [10, 11] that the acid-catalyzed dehydration of alcohols in the liquid phase proceeds via formation of carbocation by the scheme

$$\mathrm{ROH} + \mathrm{H^+} \rightleftarrows \mathrm{ROH_2} \rightleftarrows \mathrm{R^+} + \mathrm{H_2O} \rightleftarrows \text{Olefin} + \mathrm{H_2O} + \mathrm{H^+}, \quad (1)$$

where R is a hydrocarbon radical.

It was found experimentally that DMPM dehydration in cumene decelerates in the course of time (Fig. 1), which is probably due to inhibition of the catalyst by water formed, rather than to attainment of a chemical equilibrium. Special experiments showed that α-MS is not hydrated under these conditions. Since water exhibits higher proton affinity than the other reaction components, its accumulation in the system can cause resolvation of protons with water and, as a result, a decrease in the catalyst activity.

In experiments with various initial DMPM concentrations (Fig. 1), we found that the DMPM dehydration is first-order with respect to the substrate and that the reaction selectivity with respect to α-MS is 100%. The use of special procedures [12] and analysis of the

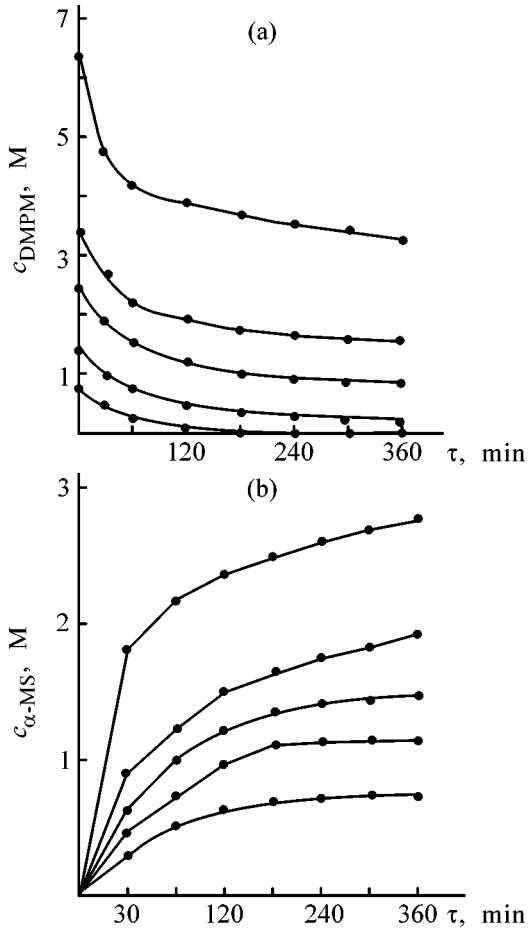

Fig. 1. Kinetic curves of (a) DMPM dehydration and (b) α-MS accumulation in cumene at various initial DMPM concentrations. $c_{H_2SO_4} = 5 \times 10^{-3}$ M, 80°C. (c_{DMPM}) DMPM concentration, ($c_{\alpha\text{-MS}}$) α-MS concentration, and (τ) time.

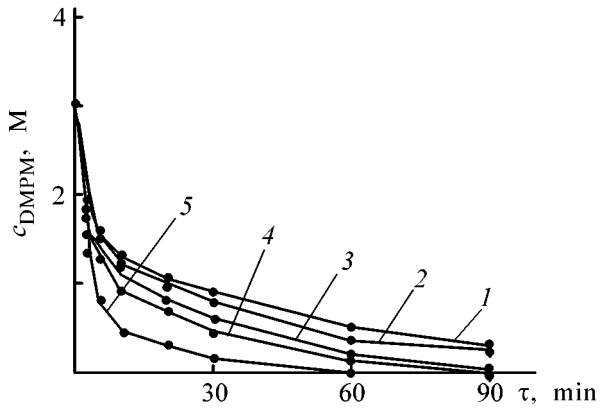

Fig. 2. Effect of the ACP concentration on the kinetics of DMPM dehydration in cumene. $c^0_{DMPM} = 3$, $c_{H_2SO_4} = 5 \times 10^{-3}$ M, 110°C; the same for Figs. 3, 4. (c_{DMPM}) DMPM concentration and (τ) time; the same for Fig. 5. ACP concentration (M): (*1*) 0.28, (*2*) 0.57, (*3*) 1.50, (*4*) 2.10, and (*5*) 5.0.

kinetic data allowed us to suggest a scheme of DMPM conversion, which takes into consideration the stage of catalyst inhibition:

$$\text{DMPM} + \text{cat}_a \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [X] \xrightarrow{k_2} \alpha\text{-MC} + H_2O + \text{cat}_a,$$
$$\text{cat}_a \xrightarrow{k_i} \text{cat}_i, \qquad (2)$$

where cat_a and cat_i are the active and inactive forms of the catalyst; [X] is the intermediate; k_1 and k_{-1} are constants of [X] formation and decomposition, respectively; k_2 is the rate constant of decomposition of [X] with the formation of reaction products; and k_i is the rate constant of catalyst inhibition.

When conversion of [X] into the reaction products is the limiting stage, the concentration of the active form of the catalyst is described by the equation

$$c^a_{cat} = c^0_{cat} \exp(-k_1\tau), \qquad (3)$$

where c^a_{cat} is the concentration of the active form of the catalyst, c^0_{cat} is the initial concentration of the catalyst, and τ is the reaction time.

Thus, the DMPM concentration c_{DMPM} changes in time by the equation

$$-\frac{dc_{DMPM}}{d\tau} = k_{app} c_{DMPM} \exp(-k_i\tau), \qquad (4)$$

where k_{app} is the apparent rate constant defined by

$$k_{app} = k_2 \frac{k_1}{k_{-1}} c^0_{kat}. \qquad (5)$$

Integration of Eq. (4) gives a kinetic equation for DMPM in the integral form, which adequately describes all the experimental data:

$$c_{DMPM} = c^0_{DMPM} \exp\left\{\frac{k_{app}}{k_i}[\exp(-k_i\tau) - 1]\right\}, \qquad (6)$$

where c^0_{DMPM} is the initial DMPM concentration.

Since ACP always accompanies DMPM in phenol and acetone production, it was interesting to study the effect of ACP on DMPM dehydration. ACP, as a more polar solvent than cumene, must undoubtedly affect the process.

To reveal this effect, we performed experiments at 110°C, varied initial ACP concentration, and equal other conditions. It was found that ACP is not consumed; its concentration determined chromatographically remained unchanged. The kinetics of the DMPM dehydration in cumene with various ACP additives is shown in Fig. 2, and the constants calculated by

Eq. (6) and the initial reaction rates v_0 are listed in the table. The initial reaction rates were determined by differentiation of the kinetic curves. The selectivity of DMPM dehydration under these conditions was also 100%.

As seen, the initial reaction rate and the degree of DMPM conversion grow with increasing ACP concentration in the system, which is probably due to a change in the solvent properties, namely, in its dielectric constant.

The dielectric constant of a mixture of substances can be determined from the equation [13]

$$\log \varepsilon = n_1 \log \varepsilon_1 + n_2 \log \varepsilon_2 + \ldots + n_i \log \varepsilon_i, \quad (7)$$

where ε_i is the dielectric constant of ith component and n_i is the mole fraction of ith component of the mixture.

Using Eq. (7), we calculated ε of a mixture of cumene and ACP and correlated the results with the reaction rate. Figure 3 shows the dependence of the apparent dehydration rate constant on ACP concentration, and Fig. 4, the dependence of $\log k_{app}$ on the Kirkwood parameter (KP), which characterizes the solvent polarity [13] and is defined by

$$KP = (\varepsilon - 1)/(2\varepsilon + 1). \quad (8)$$

As seen (Fig. 3), the reaction rate grows with increasing solvent polarity.

In accordance with the classic Arrhenius theory of reaction kinetics, a certain energy barrier must be overcome before conversion of the initial substances into the reaction products. The solvent can change the activation Gibbs energy due to different degrees of solvation of the initial reactants and the activated complex [13]. The degree of solvation is determined by the electric charge of the reacting species: it grows with increasing charge. Reactions in which the activated complex has higher charge density (is more polar) than the initial molecule are accelerated in more polar solvents.

A similar trend is observed in dehydration of DMPM at its various initial concentrations in ACP (Fig. 5): the reaction is accelerated with increasing solvent polarity (Fig. 6). However, the dependence of the apparent rate constant on KP is nonlinear, which suggests the effects of the specific and nonspecific solvation. The rate constants of DMPM dehydration in ACP calculated by Eq. (6) and the initial reaction rates are listed in the table.

* Acetophenone as solvent.

Thus, we can assume that, under conditions of DMPM dehydration, the activated complex is more polar than the initial DMPM molecule. This is confirmed by quantum-chemical calculations of the DMPM molecule and transition complex (protonated DMPM), which were performed using the MORAC program. Calculations showed that dipole moments of

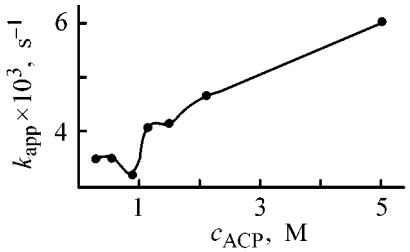

Fig. 3. Apparent rate constant of DMPM dehydration k_{app} in cumene vs. ACP concentration.

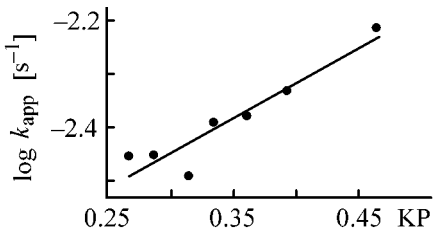

Fig. 4. Effective rate constant of DMPM dehydration k_{app} in cumene with various ACP content vs. Kirkwood parameter KP.

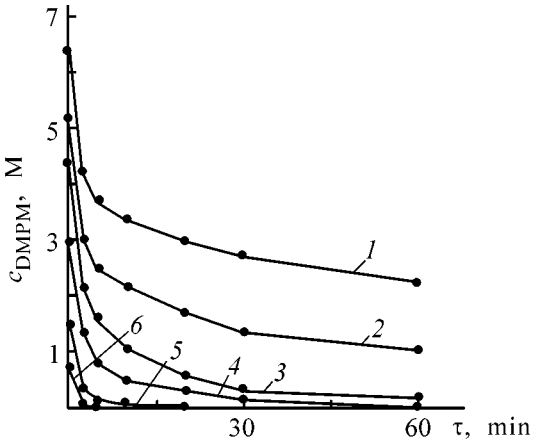

Fig. 5. Kinetic curves of DMPM dehydration in ACP. $c_{H_2SO_4} = 5 \times 10^{-3}$ M, 110°C; the same for Fig 6. Initial concentration of DMPM (M): (*1*) 6.38, (*2*) 5.14, (*3*) 4.32, (*4*) 2.96, (*5*) 1.47, and (*6*) 0.71.

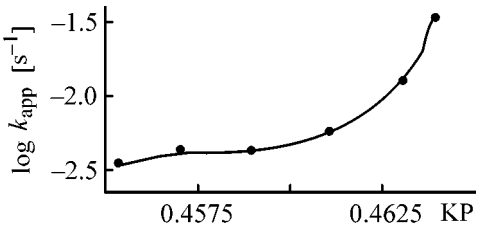

Fig. 6. Apparent rate constant of DMPM dehydration k_{app} in ACP vs. Kirkwood parameter KP.

DMPM and protonated DMPM are 1.549 and 1.915 D, respectively. This fact, combined with the above results, accounts for the acceleration of DMPM dehydration in the presence of acetophenone as a more polar compound.

CONCLUSIONS

(1) The kinetics of dimethylphenylmethanol dehydration in cumene and in acetophenone was studied; it was shown that acetophenone accelerates dehydration.

(2) The rate of dimethylphenylmethanol dehydration in acetophenone is higher than that in cumene under the same conditions.

(3) Dehydration of dimethylphenylmethanol in both cumene and acetophenone is characterized by 100% selectivity; its conversion reaches 87% in cumene and 99% in acetophenone at substrate concentration of 3 M and 110°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Electronic Excitation of Perfluoroolefins

K. K. Kalnin'sh

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received December 24, 2001

Abstract—The electronic structure of the known intermediates of perfluoroolefins was analyzed from the standpoint of thermal electronic excitations. The calculated (*ab initio* DZ) energies of the perpendicular triplet state T_1 of the perfluorolefins are compared with the experimental enthalpies of formation of the intermediates. A new mechanism of cyclodimerization of tetrafluoroethylene is proposed, including its thermal excitation into the lowest triplet state as the limiting stage.

Tetrafluoroethylene (TFE) and its fluorinated analogs are used as initial monomers in preparing fluorinated polymers and resins which find extensive industrial and agricultural application. Of great importance for understanding of the mechanism of polymerization and various chemical transformations of monomers is elucidation of the nature of elementary chemical processes and the structure of intermediates species. Buravtsev *et al.* [1–3] studied systematically TFE C_2F_4, hexafluoropropylene C_3F_6, perfluoro-1-butene 1-C_4F_8, perfluoro-2-butene 2-C_4F_8, and a number of other fluorinated derivatives. They revealed extremely interesting properties of these compounds, exceeding ethylene and its derivatives in thermal stability (at 700–1500 K). Buravtsev and Kolbanovskii heat-treated perfluoroethylenes to "prepyrolysis" temperatures in the gas phase in a free-plunger adiabatic compression setup and reported existence of previously unknown intermediates. It was found that, kinetically, the forward and backward reactions of formation of the intermediates are first-order reactions, which suggests the monomolecular character of the reactions [6]. Therefore, the chemical formulas of the intermediates are identical to those of the initial compounds; they were designated as $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$, and *iso*-$C_4F_8^*$.

A kinetic spectroscopic study revealed two absorption bands of the intermediates in the UV and visible regions, whose positions (nm) are as follows: 236.5 and 500 for $C_2F_4^*$, 240 and 477.5 for $C_3F_6^*$, and 242.5 and 460 for 1-$C_4F_8^*$. These positions differ from those for the initial compounds C_2F_4 (188 nm) and C_3F_6 (185 nm). Studies at different temperatures showed that the new bands are actually those of true intermediates, rather than "hot bands" in the spectra of perfluoroolefins. Special experiments on generating the same intermediates from different compounds showed that the intermediates directly participate in formation of new chemical compounds. For example, the TFE intermediate $C_2F_4^*$ degrades into two difluorocarbenes (DFCs) $:CF_2$ which add to $C_2F_4^*$ to give hexafluoropropylene:

$$C_2F_4 \rightleftarrows C_2F_4^* \rightleftarrows :CF_2 + :CF_2, \quad (1)$$

$$C_2F_4^* + :CF_2 \rightleftarrows C_3F_6^* \rightleftarrows C_3F_6. \quad (2)$$

Elucidation of the nature of these remarkable species, prefluoroolefin intermediates, is of much scientific interest. Now, there is no doubt that they reflect certain common properties of reactive species and, in the case of fluoroolefins, directly participate in chemical transformations of molecules.

Buravtsev and Kolbanovskii characterize the nature of these species as follows [13]: "The $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, and 2-$C_4F_8^*$ intermediates formed in the gas phase upon heating the corresponding perfluoroolefins are the previously unknown, lowest excited singlet states of these perfluoroolefins, since formation of the triplet states of perfluoroolefins in the gas-phase thermal monomolecular reactions is spin-forbidden." In the same work, Buravtsev and Kolbanovskii state further that "the structures of 1,2-biradicaloids $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$, and *iso*-$C_4F_8^*$, revealed in light absorption studies, remain to be proved both experimentally and theoretically." Clearly, the scheme proposed by these authors (see above) does not fully disclose the properties of the intermediates.

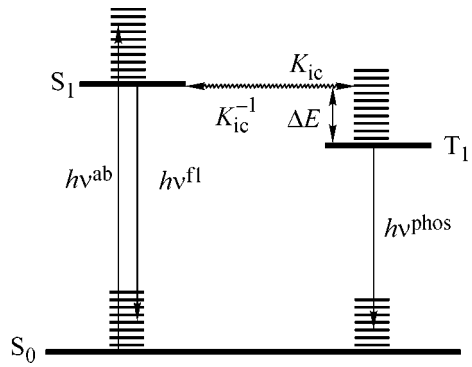

Fig. 1. Energy scheme of thermally activated delayed fluorescence.

In this work, we explain the unique experimental data reported by Buravtsev and Kolbanovskii from another standpoint based on the concept of thermal electronic excitation in chemical reactions as a unique physicochemical process [14]. The assumed triplet nature of the intermediates is supported by the results of nonempirical quantum-chemical calculations. In [15–17], we demonstrated that the triplet excited molecules and complexes are involved in polymerization/depolymerization reactions.

The *ab initio* quantum-chemical calculations were carried out with PC GAMESS routine, version 5.4, in the 6-31G* basis. Also, *ab initio* calculations in the DZ basis were carried out by the HyperChem routine, issue 6.0. The same routine was utilized for optimization of the molecular geometry by the AM1 method, whose results served as the initial approximation for the *ab initio* calculations. The singlet excited states were optimized by AM1 semiempirical methods, using WinMOPAC-2.0 routine. The triplet state energies were calculated in the spin-unrestricted Hartree–Fock approximation, as the differences of the total energies (*ab initio*) or heats of formation (semiempirical methods) of the molecules in the triplet and singlet configurations.

The species with unpaired electrons were additionally characterized by the spin population S_p, which is essentially the difference of the charge densities of alpha and beta electrons. The electronic absorption spectra of the initial olefin molecules and their electronically excited species were calculated by the ZINDO/S semiempirical method (HyperChem-6.0 routine).

Thermal population of the triplet states. In [14], we developed a concept stating that the elementary processes involved in cleavage and formation of a chemical bond are underlain by electronic (thermal-, electric-, or mechanical-) excitation as a fundamental physicochemical process. Therefore, elucidation of the nature of thermally activated intermediates of TFE and its derivatives is clearly related to the problem of thermal electronic excitation of molecules and molecular complexes, which is essentially the population of electronic states.

By contrast to the population of electronic states (forward process), the degradation of electronic energy (reverse process) can be studied in detail. For example, Hunter *et al.* [18] studied degradation of the electronic energy of the triplet state of benzene, 40 000 cm^{-1}, by examining the optoacoustic effect. They showed that, after the excitation event takes place, the electronic energy is transferred to more than ten neighboring molecules, thereby exciting stretching vibrations of the C–H bonds with a frequency of about 3000 cm^{-1}. This is followed by vibrational relaxation (V–V) at a rate of 5×10^{-9} s atm. The vibrational and translational energy exchange (V–T process) proceeds for the lowest-frequency vibrations of benzene, 404 cm^{-1}, at a tenfold lower rate.

Importantly, the exchange efficiency depends on the energy separating the vibrational states [19]. For nonradiative transitions from excited S and T levels, the transition rate is inversely proportional to the energy difference between the $v = 0$ levels of the states involved [20, 21]. This is accounted for by the fact that the rate of a nonradiative electronic transition is determined by the vibrational overlap integral, which is the smaller, the greater the separation between the initial and final states. The same law must be valid for the rates of transitions to higher energy levels.

The restriciton following from the spin exclusion of transitions between the states with different multiplicities (S and T), which is almost strictly obeyed in the case of photoexcitation, is lifted to a significant extent in the case of thermally activated transitions. This follows from high degradation rates of triplet energy [20]. The fact that thermal S–T transitions are not forbidden is clearly demonstrated by the so-called thermally activated delayed fluorescence (Fig. 1). No fluorescence is observed at low temperatures, since under these conditions only the level of the triplet with $v = 0$ is populated. Thermal activation by ΔE, followed by reverse intercombination $S_1 \leftarrow\sim\sim T_1$, yields excited singlets deactivated by fluorescence quantum emission. The fluorescence-to-phosphorescence intensity ratio is described by the exponential dependence

$$\frac{I_{fl}}{I_{phos}} = \exp\left(\frac{E_S - E_T}{kT}\right), \quad (3)$$

which is suitable for estimating the singlet–triplet splitting. At the same time, the E_S–E_T separation is equal to the difference between the fluorescence and phosphorescence frequencies. A comparison of these parameters for a number of dyes with small singlet–triplet splitting revealed close agreement between the activation energy and the single–triplet splitting derived from spectroscopic data. For example, for Acridine Orange $E_S - E_T$ = 31.4 kJ mol^{-1} and E_a = 29.7 kJ mol^{-1} [22].

Turning back to TFE and its analogs, the above data suggest the following. Contrary to the conclusion made by Buravtsev and Kolbanovskii in [13], the spin exclusion does not act in reality in the case of the $T_1 \leftarrow\!\sim\!\sim S_0$ transition, and the rate of transition between the S_0 and T_1 states is the higher, the smaller the energy separation $E(T_1)$–$E(S_0)$. Upon heating to 700–900 K, TFE molecules in the gas phase undergo electronic transition to the excited triplet state, which is deactivated nonradiatively, $S_0 \leftarrow\!\sim\!\sim T_1$. The fact that the lifetime of the experimentally detected TFE* intermediates and analogs makes milliseconds proves once again their triplet nature. The lifetime of singlet excited states S_1 is significantly shorter, namely, under 10^{-9} s.

The energy of triplet states $E(T_1)$ is always lower than that of singlet states $E(S_1)$ [20], and this is a general conclusion. The $E(S_1)$–$E(T_1)$ energy difference, which is termed the singlet–triplet splitting, is large for π–π^* states (up to 292.6 kJ mol^{-1}) but small for n–π^* and charge-transfer states (20.9–41.8 kJ mol^{-1}). For ethylene C_2H_4, the triplet state energy $E(T_1)$ was estimated at 341.2 kJ mol^{-1} [20] (341.9 kJ mol^{-1} according to *ab initio* 6-31G** calculations for the $T_1 \leftarrow S_0$ vertical transition), and the singlet–triplet splitting, at 289.2 kJ mol^{-1} [20] (242.0 kJ mol^{-1} as calculated by the AM1 semiempirical method).

Triplet nature of the TFE intermediates. In the case of TFE, the T_1 triplet energy is also much lower than the S_1 singlet energy (see the calculated data below). Therefore, the singlet nature of the intermediates of TFE $C_2F_4^*$ and its analogs, suggested in [13], is inconsistent with the known relations between the energies of singlet and triplet levels. Noteworthy, Buravtsev *et al.* [8–11] established the biradical nature of the intermediates from the experimental chemical equilibria. This important conclusion disclosing the high chemical activity of the intermediates is consistent with the triplet hypothesis, but contradicts the concept of the singlet nature of the intermediates. Indeed, excited singlets S_1, having two outer electrons with antiparallel spins, do not exhibit properties of biradicals, unlike triplets having essentially biradical nature responsible for their paramagnetism and high reactivity.

Let us turn to the quantum-chemical calculations for the intermediates, which were inexplicitly criticized by Buravstev and Kolbanovskii in [13]. In the opinion of these authors, their own data presented in that work (in particular, the calculated results for the transition state TS) do not account for the structural features of the intermediates. Buravstev and Kolbanovskii [13] take a traditional approach to the chemical reaction mechanism, describing the reactive states of the molecules by the so-called transition states TS. The point is, however, that the TS calculations in the traditional version do not describe the chemical process adequately. A fundamentally different approach developed in [14] is underlain by the concept stating that the reaction states of the molecules have the meaning of electronic states of molecular systems, which can be studied experimentally. These states are determined as electronically excited relaxed (equilibrium) states of the molecules or their complexes, which have low energies (<1 eV) and, therefore, can be thermally populated.

This makes of special interest the absorption spectra of intermediates of perfluoroolefins, recorded by Buravtsev and Kolbanovskii, as this is a rare, maybe even unprecedented, case of directly observed thermally activated reaction states of molecules at high temperatures (700–1000 K) in the gas phase. It should be noted that most of organic molecules cannot be thermally excited into electronic states because of degradation, which typically begins long before the required temperature is attained. For example, according to [13], the lowest electronic state of TFE has an energy of 75.2 ± 8.4 kJ mol^{-1} (vs. 86.8 kJ mol^{-1} from *ab initio* calculations) and this level can be thermally populated. At the same time, for ethylene C_2H_4 the T_1 energy is almost twice that for TFE, namely, 169.5 kJ mol^{-1} (*ab initio* calculation). In the latter case, the Boltzmann factor $\exp(-\Delta E/RT)$ at 700 K is negligible (10^{-13}), which is responsible for the extremely low population of the level and hence for the very low process rate.

The views concerning the electronic excitation as a necessary stage of a chemical process [14] suggest that the reactive species (intermediate, in terms of [13]) preceding formation/rupture of a chemical bond is a biradical. As applied to the [2 + 2] cyclodimerization reaction of TFE

$$C_2F_4 + C_2F_4 \overset{kT}{\rightleftarrows} C_2F_4^* + C_2F_4 \rightleftarrows C^{\bullet}F_2 + C^{\bullet}F_2\cdots CF_2{=}CF_4 \overset{kT}{\rightleftarrows} C^{\bullet}F_2{-}(C^{\bullet}F_2\cdots C^{\bullet}F_2){-}C^{\bullet}F_2 \rightleftarrows C^{\bullet}F_2{-}CF_2{-}CF_2{-}C^{\bullet}F_2 \overset{kT}{\rightleftarrows} \boxed{F}, \quad (4)$$

this means that the formation of stable cyclobutane $\boxed{F}$ is preceded by a number of radical stages, each involving thermal electronic excitation, and CF_2CF_2 does not directly add to CF_2CF_2:

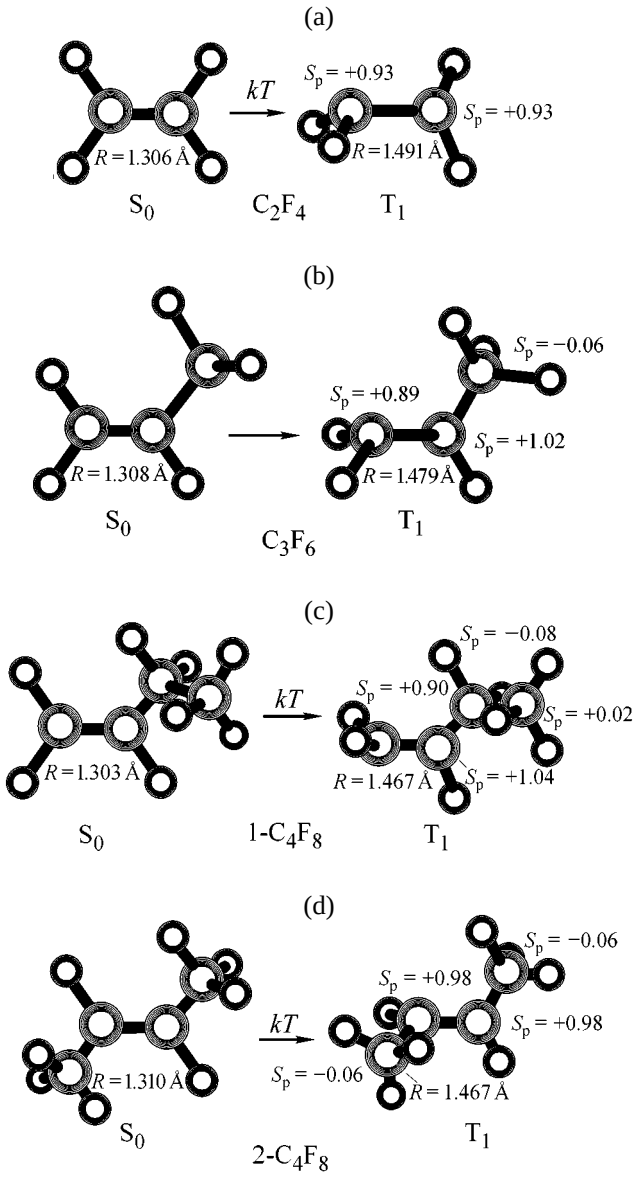

Fig. 2. Optimized (*ab initio* DZ) steric structure of (a) C_2F_4, (b) C_3F_6, (c) 1-C_4F_8, and (d) 2-C_4F_8 in the ground singlet S_0 and excited T_1 states. Indicated are the C=C bond lengths and spin populations at carbon atoms of the double bond.

$$C_2F_4 + C_2F_4 \rightleftarrows \boxed{F}. \quad (5)$$

This excludes, as incomplete, one-step reaction of the type (5), where radical stages are hidden and are not manifested experimentally, e.g, because of their high rate and small lifetime of radical species. In this connection, it should be noted that the radical mechanism of [2 + 2] cyclodimerization of C_2F_4 was confirmed experimentally in [8, 12].

Structure of the olefin molecules in electronically excited state. The triplet, so-called "phantom" states of olefins, e.g., stilbene [23, 24], are known to have a perpendicular configuration. *Cis–trans* isomerization (rotation by 180° about the C=C bond) proceeds specifically via this state. The triplet states of ethylene and other olefins have biradical character, be the configuration perpendicular (equilibrium state) or planar (vertical transition). The radical centers are located at the carbon atoms involved in the double $C^{\bullet}$–$C^{\bullet}$ bond. The decrease in the C=C bond order (degradation of the double bond) under triplet excitation has electronic origin and is not directly related to transition of the molecule into perpendicular configuration. For example, the C–C bond order in ethylene decreases from p = 2.0 to p = 1.0 as a result of vertical transition $T_1 \leftarrow S_0$ which leaves unchanged the initial planar structure.

The molecules of perfluoroolefins C_2F_4 and C_3F_6 (Figs. 2a, 2b) and 1-C_4F_8 and 2-C_4F_8 (Figs. 2c, 2d) in the ground singlet state have planar structures, except in the case of the 1-C_4F_8 molecule in which the CF_3 group lies outside the plane of the central C–C moiety (Figs. 2c, 2d). In the triplet state T_1, these molecules undergo rotation about the C=C bond and take a close-to-perpendicular configuration (Figs. 2a–2d). For fluoroolefins, and especially for TFE, the F–C–C angle at the $C^{\bullet}$ radical centers markedly decreases from 123°–125° for S_0 to 113°–114° for T_1. At the same time, the H–C–C angle for olefins decreases only slightly as a result of transition to the triplet state, namely, from 121.8° for S_0 to 121.2° for T_1. In the optimized singlet excited state, the molecules of olefins and their fluorinated analogs also have nonplanar configuration, but, unlike the case of triplets, the singlet state S_1 is characterized by strictly perpendicular location of the bonds [dihedral angles H–C–C–H (F–C–C–F) are equal to 90°].

Despite the similar steric structures of the olefin molecules in the triplet and singlet excited states, the electronic structures of these molecules differ substantially. Figures 2a–2d show that in the triplet state

the maximal positive spin population S_p is close to unity and is concentrated at the carbon atoms of the double C=C bond, which in the T_1 state degrades to ordinary bond. Also, the spin density distribution S_p is weakly dependent on the type of substituent at the double bond (H, F, or C). This means that olefin molecules in the triplet state are biradicals with all the ensuing consequences, both spectral and chemical. The triplets of the olefins must have characteristic ESR spectra, and they must behave chemically as radical (biradical) species, e.g., participate in dimerization or addition reactions [Eq. (4)] yielding biradical species.

Absorption spectra of olefins. The singlet state S_1 cannot be a biradical by definition and, therefore, must not exhibit paramegnetism typical of triplets. Also, the absorption spectra of the singlets S_1 and triplets T_1 would be expected to differ, though this is not confirmed by the available published data. For the initial olefins, the calculated $S_1 \leftarrow S_0$ spectra reasonably agree with the experimental data (Table 1). In the visible and UV regions of the spectrum, we observe two triplet–triplet transitions allowed by the selection rules, each region containing one transition. The lowest in energy $T_2 \leftarrow T_1$ transition, corresponding to excitation of an unpaired electron, is observed in the visible region, and the $T_3 \leftarrow T_1$ transition observed in the UV region is due to electron excitation from the second double-occupied molecular orbital.

Calculation of the absorption spectra of excited molecules, such as intermediates of perfluoroolefins, is a sophisticated task. Nonempirical calculation yields extremely unsatisfactory results, and semiempirical calculations also present certain difficulties. Table 1 lists the energies calculated by the ZINDO/S method tested previously in solving such problems. It is seen that, for the two experimentally observed transitions, namely, $T_2 \leftarrow T_1$ in the visible and $T_3 \leftarrow T_1$ in the UV region, the experimental and calculated (in our case, evaluated) data agree reasonably.

Energies of triplet and singlet excited states. The triplet hypothesis was most adequately substantiated by calculations of the energies of triplet equilibrium (optimized) states of perfluoorolefins. Specifically these electronic states, which are the lowest in energy, are populated in thermal excitation. The *ab initio* calculation yields the difference of the total energies of the molecules in the triplet T_1 and singlet S_0 configurations, which is defined as the triplet state energy and should be compared with the experimental enthalpies of the intermediates. Buravtsev and Kolbanovskii reported in [13] the same experimental

value of the enthalpy of the formation reaction, ΔH, for all the four intermediates considered, $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$ and 2-$C_4F_8^*$, namely, 75.2 ± 8.4 kJ mol^{-1} (18.0 kcal mol^{-1}).

The energy of the triplet states of TFE calculated *ab initio* in the DZ basis agrees reasonably with the experimental enthalpy of formation of $C_2F_4^*$ (Table 2). At the same time, the extensively used 6-31G* basis somewhat overestimates, and the semiempirical AM1 method underestimates, the triplet energy $E(T_1)$–$E(S_0)$. As to the DZ basis, it also satisfactorily describes other molecules with unfilled shells. For example, the inconsistency between the experimental value of the enthaply of C_2F_4 decomposition into two carbenes $:CF_2$, 290.8 ± 5 kJ mol^{-1} [26] and the calculated value of 235 kJ mol^{-1} [27] mentioned in [13], is eliminated in the case of the *ab initio* DZ calculation yielding $\Delta H = 283.5$ kJ mol^{-1} .

The remaining three perfluorolefins from Table 2 are characterized by higher triplet energies exceeding that for TFE by 20.9–33.4 kJ mol^{-1}, this difference being preserved for all the calculation methods. Common reasoning suggests a certain difference $E(T_1)$–$E(S_0)$ for the fluoroolefins considered, though the experiment yields identical enthalpies of formation for the intermediates, namely, 75.2 kJ mol^{-1} [13]. This conclusion is supported by the regular shift of the band maxima in the pulse absorption spectra of the intermediates [13] upon introducing substituents into the ethylene molecule, namely, a red shift of the short-wavelength band and a blue shift of the long-wave band in the vis-

ible region. It should be noted that Buravtsev and Kolbanovskii also report other enthalpies of formation of the intermediates, e.g., $\Delta H = 71 \pm 4$ kJ mol^{-1} (17 kcal mol^{-1}) for 1-$C_4F_8^*$, and 2-$C_4F_8^*$ in [4] and 92 ± 3 kJ mol^{-1} (22 kcal mol^{-1}) for $C_2F_4^*$ in [8]. In this study, we used the data from the latest work [13], which are, evidently, the most reliable.

The triplet energies for perfluoroolefins exceed those for olefins by approximately a factor of 1.5 (Table 2), which suggests the stabilizing role of the unshared electron pair of the fluorine atoms. Specifically this important fact is responsible for the lowering of the triplet levels toward thermally achievable energies (<1 eV), and favors observation of thermally activated transitional spectra. As far as we know, such experiments are very troublesome in the case of H forms of the olefins . The incorporated fluorine atoms also stabilize other species, e.g., 1,4-biradical participating in [2 + 2] cyclodimerization [Eq. (4)]. In the opinion of Buravtsov and Kolbanovskii [13], this stabilization (by 104.5 kJ mol^{-1}) [28] (our *ab initio* DZ calculations yield 148.8 kJ mol^{-1}) accounts for the more intensive [2 + 2] cyclodimerization of C_2F_4, compared to C_2H_4. In reality, the 1,4-biradical is only an intermediate species with low energy (Figs. 3a, 3b), and the potential barrier of the reaction, which governs the reaction rate, is determined by the triplet state of the olefins.

As already mentioned, the singlet configuration of the fluoroolefin intermediates, discussed in [13], is inconsistent with the experimental evidence of the biradical character of the intermediates. A more serious objection to the singlet hypothesis is that the energies of the singlet excited states are high and exceed severalfold the experimental enthalpies of formation of the intermediates (Table 2). These results were obtained by AM1 semiempirical calculations which describe satisfactorily the singlet ground S_0 and excited S_1 states. Table 2 lists the optimized, equilibrium energies $E(S_1)$–$E(S_0)$. As to vertical, optical transitions, their energies are significantly greater, and the corresponding absorption bands lie, as already mentioned, in the vacuum UV region (<200 nm).

Table 2 also lists the calculated singlet–triplet splittings $E(T_1)$–$E(S_1)$ which take for small molecules, such as ethylene, the maximal values of up to 300 kJ mol^{-1} [20]. These splittings are, on the average, identical (ca. 240 kJ mol^{-1}) for olefins and their fluorinated derivatives, though the latter are characterized by a somewhat lower energy of the singlet S_1 state. The above-cited data suggest that the singlet S_1 excited levels of fluoroolefins and, moreover, of their hydrogencontaining analogs are located much higher (by ≥3 eV) than their corresponding triplet levels and are inaccessible for thermal population under the actual conditions.

Mechanism of [2 + 2] cyclodimerization of ethylene and perfluoroethylene. Let us consider the mechanism of TFE cyclodimerization in the light of our concepts reported in [14] and the new data from [1, 8, 13]. The radical pathway of this reaction naturally stems from the general statement that mono- or bimolecular thermal reactions proceed via relaxed electronically excited states of the molecules and their complexes, which typically have triplet and, hence, radical (biradical) character [14]. Direct experimental verification of this mechanism, with the [2 + 2] cyclo-

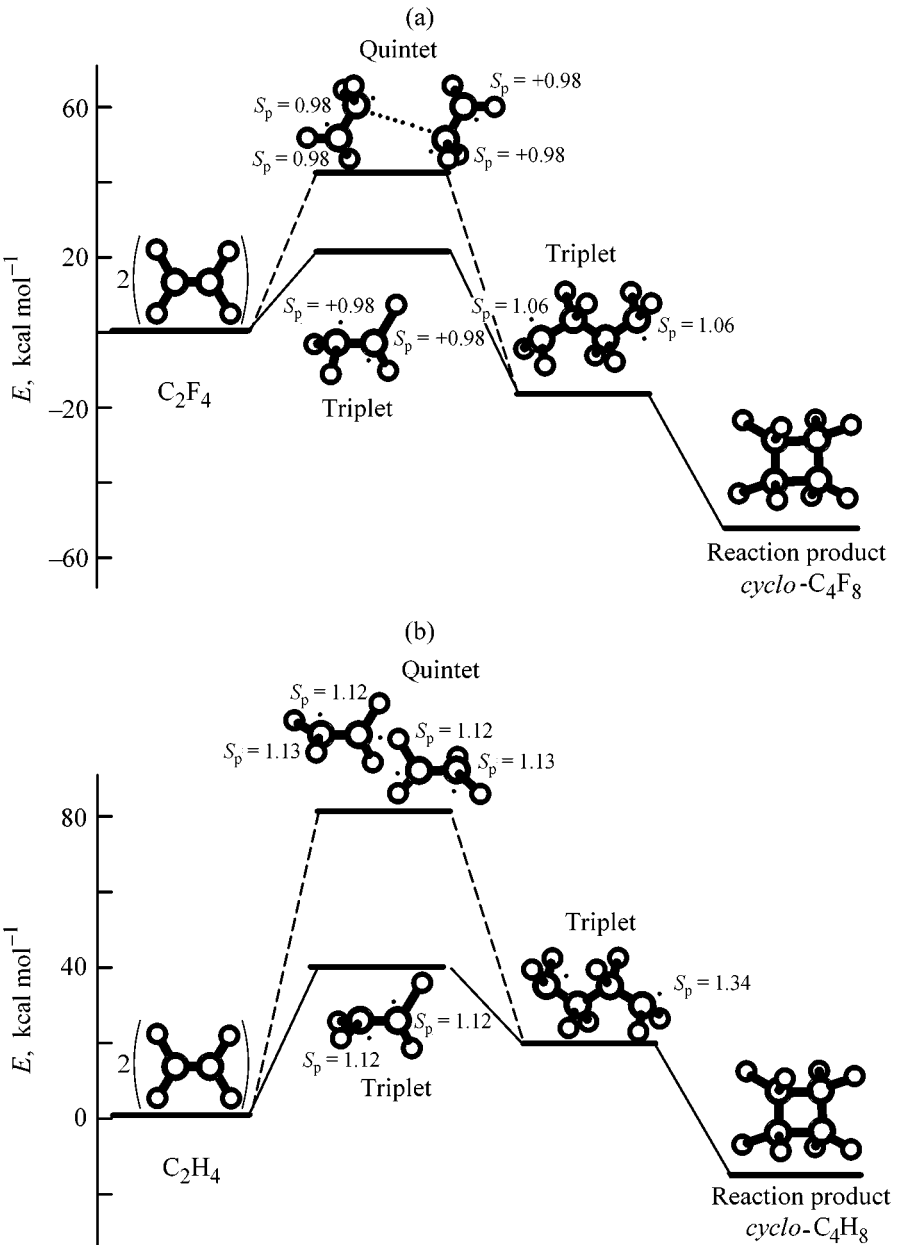

Fig. 3. Energy diagrams of the cyclodimerization reaction for (a) C_2F_4 and (b) C_2H_4. (E) Energy.

dimerization reaction of TFE as an example [8, 13], is of much importance for understanding of the nature of this and many other reactions. The hypothetical ionic mechanism [8] also has an essentially radical nature, as such reactions necessarily involve electronic transfer generating radical (radical ion) species.

Figures 3a and 3b present the energy diagrams for the dimerization reactions of TFE and ethylene, based on the results of *ab initio* DZ calculations. It is assumed that the potential barrier of the reaction is determined either by a quintet (a complex of two molecules in the triplet state) or a triplet state of the olefins. In the latter case, it should be presumed that reaction (4) proceeds via collision of two excited TFE molecules. This collision yields the intermediate 1,4-biradical [Eq. (4)], and this process, evidently, does not require additional thermal activation. Then, taking the activation energy of the forward aggregate reaction (5) $E_a(5)$ [stages from Eq. (4) and Fig. 3a] equal to the triplet energy of TFE, 86.8. kJ mol^{-1} (Table 2) and the heat of forward reaction (5) ΔH = 221.0 kJ mole^{-1} (from *ab initio* DZ calculations; cf. experimental value of 222 kJ mol^{-1} [29]), the activation energy for reverse reaction (5) will be $E_a(-5)$ =

86.8 + 221.0 = 307.8 kJ mol^{-1}. The experimental activation energy for decomposition of octafluorocyclobutane

$$2C_2F_4 \leftarrow \textit{cyclo}\text{-}C_4F_8 \quad (6)$$

is 331 ± 5 kJ mol^{-1} [1], which somewhat exceeds the calculated value of 307.8 kJ mol^{-1}. However, the same work [1] contains data reported by other authors, which suggest that E_a^{exp} (6) varies within 311–316 kJ mol^{-1}.

The alternative reaction pathway via the quintet state yields a less satisfactory agreement between the calculated, $E_a(6)$ = 394.6 kJ mol^{-1}, and the experimental [1], $E_a^{exp}(6)$ = 331 kJ mol^{-1}, values. Also, this pathway assumes generation of the triplet ^{3}TFE from the TFE molecule in the ground state:

$$\underset{\text{Triplet}}{C^{\bullet}F_2\text{–}C^{\bullet}F_2} + CF_2\text{–}CF_2 \rightleftarrows \underset{\text{Quintet}}{C^{\bullet}F_2\text{–}C^{\bullet}F_2\cdots C^{\bullet}F_2\text{–}C^{\bullet}F_2}. \quad (7)$$

However, in the arising quintet state (E = 397.5 kJ mol^{-1}), at least in the framework of the *ab initio* basis sets we used, interaction between its two constituent triplet molecules is weak (e.g., only 0.04 kJ mol^{-1} in the case of C_2H_4). This makes more probable the pathway of reaction between the two triplet TFE molecules to give a 1,4-biradical

$$\underset{\text{Triplet}}{C^{\bullet}F_2\text{–}C^{\bullet}F_2} + \underset{\text{Triplet}}{C^{\bullet}F_2\text{–}C^{\bullet}F_2} \rightleftarrows \underset{\text{Triplet}}{(C^{\bullet}F_2\text{–}CF_2\cdots CF_2\text{–}C^{\bullet}F)}$$

$$\rightleftarrows \underset{\text{1,4-Biradical (triplet)}}{C^{\bullet}F_2\text{–}CF_2\text{–}CF_2\text{–}C^{\bullet}F_2} \quad (8)$$

and *cyclo*-C_4F_8 as the end product.

It is assumed that the reaction follows pathway (8) (Figs. 3a, 3b): two triplet molecules come within a distance of approximately 3 Å from each other, which is followed by intercombination $S_0 \leftarrow\!\sim\!\sim T_1$ and disappearance of one of the triplets, and the resulting $^3(C^{\bullet}F_2\text{–}CF_2\cdots CF_2\text{–}C^{\bullet}F)$ complex is converted into a radical species $^3(C^{\bullet}F_2\text{–}CF_2\text{–}CF_2\text{–}C^{\bullet}F)$ in the triplet configuration, which was termed 1,4-biradicaloid in [8, 13]. *trans*-1,4-Biradical has a symmetric structure with terminal radical centers accommodating the spin population S_p = 1.34, and the $C^{\bullet}F_2\text{–}CF_2$ and $CF_2\text{–}CF_2$ bond lengths are 1.52 and 1.53 Å, respectively. This 1,4-biradical is easily isomerized into *cis* structure which is stabilized, via the second intercombination stage $S_0 \leftarrow\!\sim\!\sim T_1$ toward the ground singlet state S_0, as the reaction product, cyclobutane. The C–C bond length in the symmetric (D_{4h}) molecule of cyclo-$C_4F(H)_8$ is 1.55 Å.

The absorption spectrum of 1,4-biradical C_4F_8 (230 nm) was for the first time recorded directly in the millisecond range in [12]. The lifetime of the hydrogen analog C_4H_8 is significantly shorter and, depending on the pumping energy, amounts to 300–800 fs [29]. In the case of interest, the 1,4-biradical C_4H_8 has, however, the *cis* configuration favoring cyclization and, thus, decreasing the lifetime of the species. It can be assumed that the 1,4-biradical C_4F_8 (230 nm) [12] in the triplet electronic state takes the *trans* configuration.

CONCLUSIONS

(1) The thermally activated intermediates of perfluoroolefins described in the literature are essentially the initial olefins in the triplet electronically excited state. The calculated (*ab initio* DZ) triplet energies of perfluotoolefins reasonably agree with the experimental enthalpies of formation of intermediates. The calculated triplet–triplet absorption spectra reasonably agree with the transitional absorption spectra of the intermediates.

(2) A mechanism of cyclodimerization of tetrafluoroethylene is proposed, which involves thermal excitation into the triplet state, collision of two triplet molecules, their transformation (after $S_0 \leftarrow\!\sim\!\sim T_1$ intercombination) into the triplet 1,4-biradical, and formation of *cyclo*-C_4F_8 from *cis*-1,4-biradical after the second intercombination along the pathway toward the ground state S_0.

Mechanism of Hexafluoropropylene Formation in Gas-Phase Pyrolysis of Tetrafluoroethylene

N. N. Buravtsev and Yu. A. Kolbanovskii

Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Received September 6, 2001

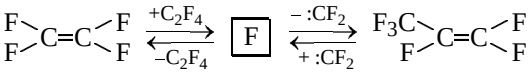
Abstract—The consecutive formation of short-lived intermediates during tetrafluoroethylene conversion into hexafluoropropylene by gas-phase pyrolysis under conditions of pulsed adiabatic compression was studied by kinetic spectroscopy. The process mechanism was determined in detail. The ways for improving the pyrolysis procedure were considered.

Development of processes for preparing hexafluoropropylene C_3F_6 is and urgent problem since this compound is starting reagent in production of fluorinated rubbers. The only process for C_3F_6 production is pyrolysis of tetrafluoroethylene C_2F_4. Since C_2F_4 is relatively expensive, special attention is focused on its consumption coefficients and on improvement of the process selectivity. The main problems are to decrease the yield of fluorocoke and perfluorobutenes C_4F_8, one of which, perfluoroisobutylene *i*-C_4F_8, is highly toxic [1].

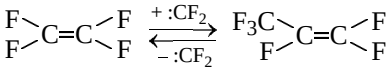
In this work, the mechanism of formation of C_3F_6 and the by-products in C_2F_4 pyrolysis was studied in detail with the aim to improve the technology of C_3F_6 production.

Previous concepts of the mechanism of pyrolytic synthesis of C_3F_6 were only based on studies of the stable reaction products [2–23]. Also, formation of difluorocarbene $:CF_2$ in thermolysis was detected by UV spectroscopy [24–31]. The absorption of other intermediates was not studied. Based on the results of these works, the mechanism of C_3F_6 formation can be represented as two processes:

Process 1 [6, 11, 23]

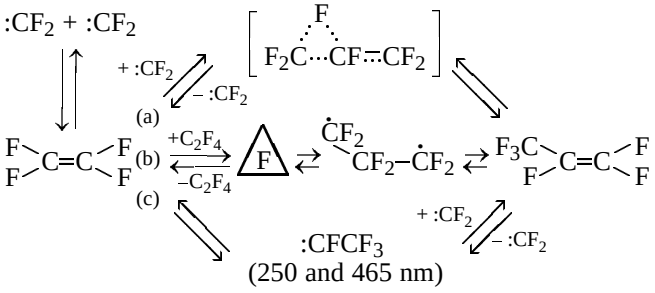


Process 2 [9, 12–14, 21–24, 26]



Scheme 1.

Our previous kinetic data on pyrolysis of octafluorocyclobutane cyclo-C_4F_8 [18] did not confirm the occurrence of the first process. The second process, reaction of $:CF_2$ with C_2F_4, can proceed by three possible mechanisms (a)–(c) [32]:



Scheme 2.

Pathway (b) was rejected on the basis of a kinetic study of pyrolysis of perfluoromethylcyclopropane CF_3-cyclo-C_3F_5, which selectively decomposed into C_2F_4 and C_3F_6 in 1 : 2 ratio [33]. This ratio and the absence of C_4F_8 in the reaction products indicate that the 1,3-biradical formed via opening of the three-membered CF_3-cyclo-C_3F_5 ring does not isomerize and is converted into C_3F_6 and $:CF_2$. Our previous study of thermolysis of CF_3-cyclo-C_3F_5 by kinetic spectroscopy [34, 35] showed that the formation of the 1,3-biradical precedes formation of $:CF_2$. In accordance with the principle of macroscopic reversibility, the reverse process, cycloaddition of $:CF_2$ to C_3F_6, is also a biradical reaction (see Scheme 3).

This indicates that cycloaddition of $:CF_2$ to C_2F_4 can also occur in two steps. However, according to Skell's hypothesis [36], reactions of singlet carbenes

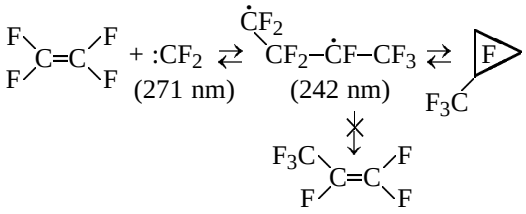

Scheme 3.

with olefins are one-step, as follows from stereoselective *syn* addition of the carbens [37]. The stereoselectivity of this reaction, whose two-step mechanism was confirmed experimentally, is due to the fact that the cyclization of singlet 1,3-biradical is faster than its isomerization by rotation around the C–C bond.

As follows from Scheme 2, the only way to determine the mechanism of C_3F_6 formation [(a) or (b)] is to study spectroscopically the kinetics of transformations of the short-lived intermediates of reaction 2. This study was the aim of the present work.

Homogeneous heating of the gaseous reaction mixture was performed by adiabatic compression [38]. The stable pyrolysis products were analyzed and identified by GLC, GC–MS, and IR spectroscopy. The reaction kinetics of short-lived intermediates was studied by millisecond kinetic spectroscopy in the UV–Vis region [39]. Similar intermediates were generated from different compounds. The kinetics of the examined reactions, including elementary steps involving the detected intermediates, was simulated mathematically [40]. The enthalpies of reversible reactions initial reagent ⇄ primary intermediate were determined from the kinetic spectroscopy data obtained after attainment of the equilibria [41, 42].

First of all, we found whether pathway (c), involving formation of $:CFCF_3$, is actually followed. The electronic spectrum of this radical contains the characteristic band at 465 nm [43]. This band was not observed in the absorption spectra of intermediates of C_2F_4 pyrolysis (Fig. 1). This is possible in two cases: (1) if $:CFCF_3$ is not formed indeed or (2) its concentration is lower than the sensitivity limit of the spectroscopic equipment.

To check the second possibility, we used the results of a study of $C_2F_5SiF_3$ pyrolysis [39]. The formation of $:CFCF_3$ in the course of pyrolysis under adiabatic compression was reliably indicated by the absorption at 465 nm. Up to the complete conversion of $C_2F_5SiF_3$, the final reaction products are SiF_4 and *cis*-2-C_4F_8, the product of steroselective recombination of $:CFCF_3$ radical (hear and hereinafter, the location of the double bond is indicated by the locant).

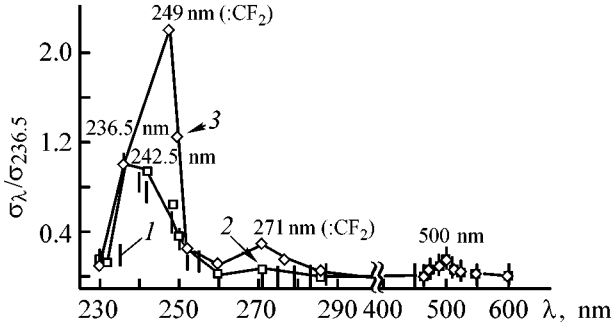

Fig. 1. Absorption spectra of the intermediates of flash pyrolysis of (*1*) 5 vol % C_2F_4 in Xe (890 K), (*2*) 10 vol % C_2F_4 in Ar (1000 K), and (*3*) 5 vol % C_2F_4 in Ar (1170 K). ($\sigma_\lambda/\sigma_{236.5}$) Ratio of molar extinction coefficients; (λ) wavelength.

At higher temperature in a pulse, *cis-trans* isomerization of 2-C_4F_8 was observed after complete conversion of $C_2F_5SiF_3$.

Thus, the direct experiments at temperatures of industrial pyrolysis allowed us to rule out pathway (c) of C_3F_6 synthesis via formation of $:CFCF_3$. Hence, the only possible pathway of C_3F_6 formation is insertion of $:CF_2$ into the C–F bond. However, the detailed mechanism of the synthesis remains unknown.

Previously [34] we detected for the first time the absorption of unknown primary intermediates formed on heating perfluoroolefins to "prepyrolysis" temperatures. Experiments with different initial concentrations of perfluoroolefins showed the first order of the direct and reverse reactions of formation of these intermediates, i.e., these reactions are monomolecular [44]. Thus, the composition of the primary intermediates is identical to that of perfluoroolefins. Hereinafter, these intermediates are denoted by $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$, and *iso*-$C_4F_8^*$ (here and hereinafter, the asterisk indicates an excited state).

The UV absorption spectra of these intermediates contain the bands with $\lambda_{max}^{(1)}$ 236.5 ($C_2F_4^*$), 240 ($C_3F_6^*$ and 2-$C_4F_8^*$), and 242.5 nm (1-$C_4F_8^*$) [44]. These bands differ from the characteristic UV bands of C_2F_4 (λ_{max} = 188 nm) and C_3F_6 (λ_{max} = 185 nm) [29]. The $:CF_2$ spectrum contains bands in the range 236.5–242.5 nm [45]. However, the absorption of $C_2F_4^*$, $C_3F_6^*$, and 1-$C_4F_8^*$ was observed at temperatures lower than that of $:CF_2$ generation.

In this work, we studied the spectral properties of $C_2F_4^*$, $C_3F_6^*$, and 1-$C_4F_8^*$ having absorption bands in the visible region at $\lambda_{max}^{(2)}$ of 500, 477.5, and 460 nm, respectively (Fig. 2). A specific feature of the electronic absorption spectra of these intermediates is

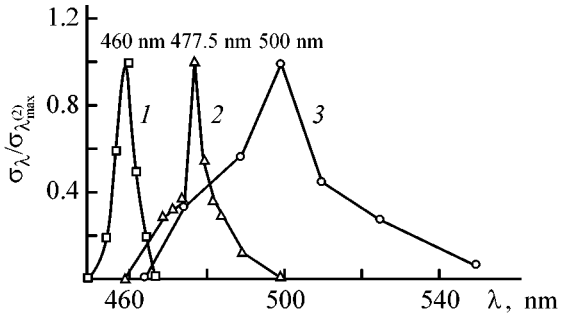

Fig. 2. Visible absorption bands of primary intermediates of pyrolysis of (*1*) 1.2 vol % 1-C_4F_8 (1010 K), (*2*) 1 vol % C_3F_8 (1160 K), and (*3*) 5 vol % C_2F_4 (890 K) in argon (stable pyrolysis products are not detected chromatographically). ($\sigma_\lambda/\sigma_{\lambda^{(2)}_{max}}$) Ratio of molar extinction coefficients and (λ) wavelength.

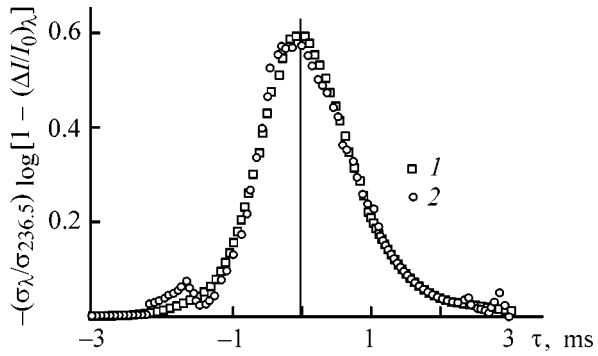

Fig. 3. Absorption of $C_2F_4^*$ intermediate formed in flash heating of 5 vol % C_2F_4 + Xe mixture to T_{max} = 890 K [temperature at the maximal compression (τ = 0 ms)], normalized to the maximal value, vs. time τ. $\sigma_\lambda/\sigma_{236.5}$ is the ratio of molar extinction coefficients, $(\Delta I)_\lambda = (I_0 - I)_\lambda$ the difference in absorption at λ (nm) before and after passage through the reaction mixture, and $(\Delta I/I_0)_\lambda$ the relative absorption (%). λ (nm): (*1*) 236.5 and (*2*) 500.

the presence of two bands, one in the UV and the other in the visible region. The fact that the absorption at $\lambda^{(1)}_{max}$ = 236.5 and $\lambda^{(2)}_{max}$ = 500 nm, normalized to the maximal absorption, varies with time during C_2F_4 heating similarly (Fig. 3) allows these bands to be assigned to the same singlet intermediate $C_2F_4^*$. The absence of long-wave shifts of these bands at higher temperatures (Fig. 1) indicates that they are due to true intermediates and are not "hot bands" [46] in the perfluoroolefin spectra.

The low-energy singlet intermediates $C_2F_4^*$, $C_3F_6^*$, and 1-$C_4F_8^*$, and 2-$C_4F_8^*$ formed by monomolecular reactions of the respective perfluoroolefins at elevated temperatures have been unknown previously.

The enthalpies of formation of $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, and 2-$C_4F_8^*$ are similar and equal to ΔH_r^0 = 75.2 ± 8.4 kJ mol^{-1} [36, 41, 42, 47, 48]. All these intermediates contain the C=C double bond with no less than two fluoride subsituents. The absorption of $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, and 2-$C_4F_8^*$ in the UV–Vis region is due to electronic rearrangement of these fragments.

We failed to determine the structure of these intermediates by millisecond IR spectroscopy. Matrix isolation is complicated by their fast isomerization into the initial perfluoroolefins. The only way to gain insight into the structure of these intermediates was quantum-chemical calculation. The results of these calculations are shown in Fig. 4. The structure of $C_2F_4^*$ is not described by any of the structures calculated in [49–54], with the activation energy of formation of :$CFCF_3$ being higher than that of :CF_2, However, it should be noted that the *ab initio* calculations of the energy of molecules with unpaired electrons do not always agree with experimental data. For example, the calculated enthalpy of decomposition of C_2F_4 into two :CF_2 species is 235 kJ mol^{-1}, whereas the experimental value is 290.8 ± 5 kJ mol^{-1} [27].

Clearly, the π bond in $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$ and *iso*-$C_4F_8^*$ has a decreased order but is not fully ruptured since the enthapy of equilibrium perfluoroolefin $\rightleftarrows$ intermediate (75.2 + 8.4 kJ mol^{-1}) is appreciably lower than the energy of rupture of the π bond (197.3–211.5 kJ mol^{-1} [48]). Thus, $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$, and *iso*-$C_4F_8^*$ must, to a certain extent, resemble biradicals. In accordance with the IUPAC classification [55], they can be termed 1,2-biradicaloids. Previously, we showed [47, 56–58] that these species do exhibit biradical properties.

Formation of 1,2-biradicaloid $C_2F_4^*$ does not contradict the two-step reversible decomposition of C_2F_4 into two carbenes :CF_2 [56, 57].

$$C_2F_4 \underset{-1}{\overset{1}{\rightleftarrows}} C_2F_4^* \underset{-2}{\overset{2}{\rightleftarrows}} :CF_2 + :CF_2$$

Scheme 4.

Ab initio calculations of [2 + 2]-cyclodimerization processes [59] showed that the biradical mechanism, not forbidden by the Woodward–Hoffmann theory [60], is more energetically favorable than the concerted mechanism. The energy of the 1,4-biradical calculated by various *ab initio* procedures [61] is lower by 104.5 kJ mol^{-1} than that of its hydrocarbon analog. That is why, in tetrafluoroethylene pyrolysis, the energy contribution of biradical [2 + 2] cyclodimerization is appreciable, unlike its contribution to thermal conversion of C_2H_4 [62].

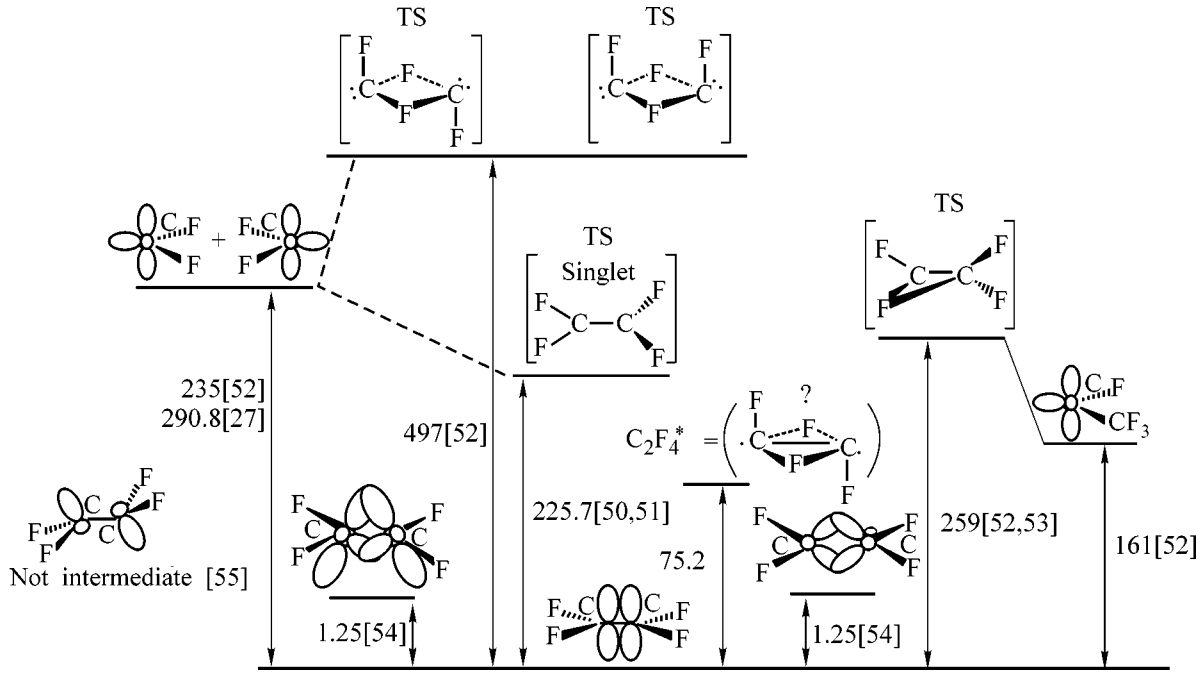

Fig. 4. *Ab initio* relative energies (kJ mol^{-1}) of $C_2F_4^*$ and species formed in the C_2F_4–TS (transition state) system.

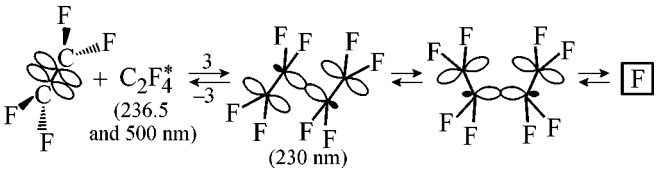
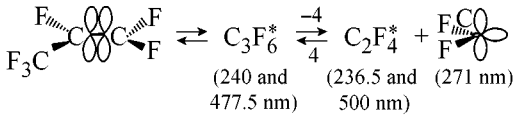
The suggested mechnasim of [2 + 2] cyclodimerization of tetrafluoroethylene is presented in Scheme 5. Reaction (3) is addition of 1,2-biradicaloid to the double bond of $C_2F_4^*$:



Scheme 5.

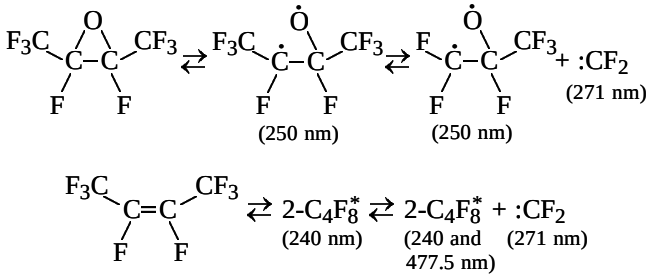
Thus, involvement of $C_2F_4^*$ in biradical [2 + 2] cyclodimerization of C_2F_4, which was proved by direct experiments, confirms biradical properties of this intermediate and indicates that a 1,4-biradical is formed by reaction of C_2F_4 with previously unknown singlet 1,2-biradicaloid $C_2F_4^*$.

The biradical nature of $C_2F_4^*$ was also confirmed by the results of a study of C_3F_6 pyrolysis [37] proceeding via reversible (4,4)-extrusion of $:CF_2$ from the CF_3 group of the C_3F_6 molecule:



Scheme 6.

It should be noted that, at temperatures of industrial pyrolysis, C_3F_6 is formed by reaction (4), whereas the equilibrium addition of $:CF_2$ to the double bond of C_2F_4 (Scheme 3) at these temperatures is shifted to the initial compounds. Hence, the perfluorocyclopropane formation makes no contribution to the C_3F_6 synthesis. The formation of $C_3F_6^*$ and $C_2F_4^*$ 1,2-biradicaloids and the $:CF_2$ extrusion from the CF_3 groups of the biradicals were indirectly confirmed by a study of the thermolysis of compounds containing no CF_2 groups: strained epoxy compound 2-C_4F_8O [52] and 2-C_4F_8 [58]. Generally, $:CF_2$ is extruded from the CF_3 groups at radical centers of primary intermediates. Only after the appearance of a 1,3-biradical or 1,2-biradicaloid 2-$C_4F_8^*$, $:CF_2$ is extruded from the CF_3 group at the radical center:



Scheme 7.

The reverse reaction is insertion of $:CF_2$ into the C–F bond at the radical center of 1,3-biradicals or

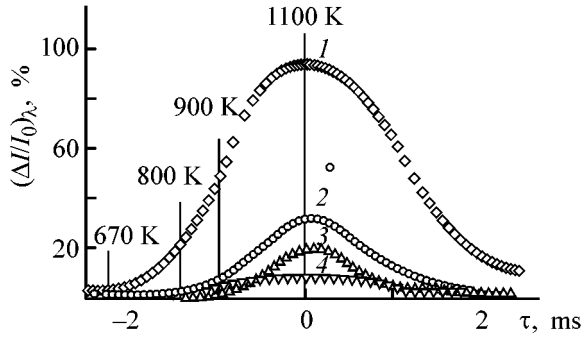


Fig. 5. Absorption of intermediates of flash pyrolysis of C_2F_4 (5 vol % in Ar) vs. time τ. $(\Delta I/I_0)_\lambda$ Relative absorption (%); the same for Fig. 6. λ (nm): (*1*) 236.5 ($C_2F_4^*$), (*2*) 230 (1,4-perfluorotetramethylene), (*3*) 271 ($:CF_2$), and (*4*) 477 ($C_3F_6^*$).

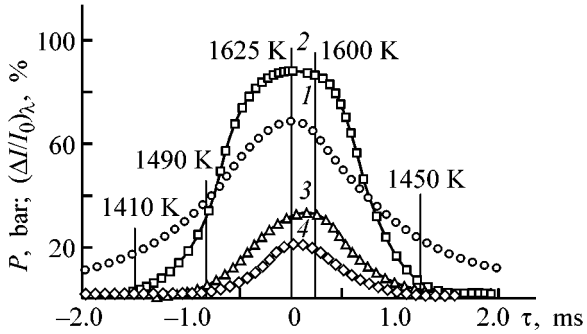

Fig. 6. (*1*) Vapor pressure *P* and (*2*–*4*) light absorption of intermediates of flash pyrolysis of C_3F_6 (1 vol % in Ar) vs. time τ. λ (nm): (*2*) 240 ($C_3F_8^* + C_2F_4^*$), (*3*) 500 ($C_2F_4^*$), and (*4*) 271 ($:CF_2$).

1,2-biradicaloids. In accordance with the above scheme and the principle of microscopic reversibility, the formation mechanism of 2-C_4F_8 is similar to that of C_3F_6 and involves insertion of $:CF_2$ into the C–F bond at the radical center of the primary carbon atom of 1,2-biradicaloid $C_3F_6^*$. Clearly, $:CF_2$ insertion into the C–F bond at the radical center of the secondary carbon atom of 1,2-biradicaloid $C_3F_6^*$ must yield *iso*-C_4F_8. The exception is synthesis of 1-C_4F_8, probably occurring via $:CF_2$ insertion into either a C–F bond of the CF_3 group or a weakened C–C bond at the radical center on the secondary carbon atom of 1,2-biradicaloid $C_3F_6^*$. However, these mechanisms were not confirmed experimentally. It should be noted that $:CF_2$ insertion into the C–C bond has not been reported yet.

Thus, detailed mechanism of formation of C_3F_6 and perfluoroolefins C_4F_8 in the course of gas-phase pyrolysis of C_2F_4 can be described by Scheme 8. This scheme is fully consistent with the sequence of formation of stable products in pyrolysis of C_2F_4 [18, 21], cyclo-C_4F_8 [18], C_3F_6 [21], and C_4F_8 [21]. The migration of double bond in normal perfluorobutenes described in [21], is also included in this scheme [33]:

$$C_2F_4 \underset{-1}{\overset{1}{\rightleftarrows}} C_2F_4^* \underset{-2}{\overset{2}{\rightleftarrows}} :CF_2 + :CF_2$$

(236.5 and 500 nm) (271 nm)

$$C_2F_4^* + C_2F_4 \underset{-3}{\overset{3}{\rightleftarrows}} F_2\dot{C}-CF_2-CF_2-\dot{C}F_2 \rightleftarrows \boxed{F}$$

(230 nm)

$$C_2F_4^* + :CF_2 \underset{-4}{\overset{4}{\rightleftarrows}} C_3F_6^* \rightleftarrows C_3F_6$$

(240 and 477.5 nm)

$$C_3F_6^* + :CF_2 \underset{-5}{\overset{5}{\rightleftarrows}} 1\text{-}C_4F_8^* \rightleftarrows 1\text{-}C_4F_8$$

$$C_3F_6^* + :CF_2 \underset{-6}{\overset{6}{\rightleftarrows}} 2\text{-}C_4F_8^* \rightleftarrows 2\text{-}C_4F_8$$

$$C_3F_6^* + :CF_2 \underset{-7}{\overset{7}{\rightleftarrows}} \textit{iso}\text{-}C_4F_8^* \rightleftarrows \textit{iso}\text{-}C_4F_8$$

$$\textit{cis}\text{-}2\text{-}C_4F_8 \underset{-8}{\overset{8}{\rightleftarrows}} \textit{trans}\text{-}2\text{-}C_4F_8$$

Scheme 8.

Experimental detection of the intermediates included in Scheme 8 does not prove their actual participation in the C_3F_6 formation. To prove the involvement of these intermediate in C_3F_6 synthesis, we generated similar intermediates from different compounds, i.e., used the method similar to independent organic synthesis.

The use of this method is based on the principle of microscopic reversibility, valid for completely homogeneous reversible thermal processes in the gas phase. In accordance with this principle, the same intermediates and stable compounds formed in the forward and reverse reactions must appear in the course of time in forward and reverse sequences.

The first intermediate of C_2F_4 pyrolysis (Fig. 5), $C_2F_4^*$ (236.5 and 500 nm), is formed at 670 K. Then 1.4-perfluorotetramethylene (230 nm) appears at 800 K. On further heating to 90 K, $:CF_2$ (271 nm) and $C_3F_6^*$ (240 and 477.5 nm) are formed virtually simultaneously. The sequence of formation of these intermediates in C_3F_6 pyrolysis (the reverse reaction) is reverse (Fig. 6). As seen from Fig. 6, the first intermediate, $C_3F_6^*$ (240 and 477.5 nm), is formed at 1410 K, and only at 1490 K simultaneous formation of $C_2F_4^*$ (236.5 and 500 nm) and $:CF_2$ (271 nm) is observed.

This indicates decomposition of $C_3F_6^*$ into these two intermediates. 1,4-Perfluorotetramethylene is not formed under conditions of C_3F_6 pyrolysis owing to the high temperature of the process (>1490 K). Since monomolecular degradation of 1,4-perfluorotetramethylene is appreciably faster than the bimolecular reaction of its formation, the concentration of this intermediate is lower than the detection limit. The fact that the maximal absorption at 271 ($:CF_2$) and 500 nm ($C_2F_4^*$) is observed at different times suggests the occurrence of an additional (along with $C_3F_6^*$ decomposition) pathway of $C_2F_4^*$ formation by recombination of $:CF_2$ [reaction (2)].

Thus, the results of direct experiments confirm the proposed Scheme 8. The structure of intermediates (1,2-biradicaloids $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, 2-$C_4F_8^*$, and *iso*-$C_4F_8^*$) detected by light absorption was, however, confirmed neither experimentally nor theoretically.

Based on the results of this work, we propose three ways to improve the procedure of C_3F_6 production by C_2F_4 pyrolysis.

(1) High-temperature pyrolysis of perfluoroolefins by flash bulk heating at cold reactor walls raises the yield of the target product, since C_2F_4 is not consumed under these conditions in side reaction of fluorocoke formation. A reactor constructed on the basis of a standard diesel will not only produce such heating but also convert the reaction heat into mechanical work or electricity [63].

(2) The second direction is based on the fact that perfluorobutenes are formed only after the appearance of C_3F_6 in the reaction mixture. Mathematical modeling of the kinetics of reactions included in Scheme 8 shows that the yields of cyclo-C_4F_8 and C_4F_8 olefins, including highly toxic *iso*-C_4F_8, can be decreased by quenching the products at a rate of 105 deg s^{-1}. The quenching can be performed, e.g., by injection of cyclo-C_4F_8 or cold bottoms formed after C_3F_8 recovery from the pyrolysis products.

(3) Previously [18, 21], we showed that pyrolysis of C_2F_4 at 1100–1280 K and to less than 20% conversion yields only two products, cyclo-C_4F_8 and C_3F_6. Under these conditions, unreacted C_2F_4 can be recycled after separation of the pyrolysis products, thus preventing *iso*-C_4F_8 formation. The accumulated cyclo-C_4F_8 can be selectively converted into C_2F_4 by pyrolysis at 1050–1250 K, which should be performed to no more than 35% conversion [37].

The advisability of using these approaches in thermal production of C_3F_6 can be determined by feasibility studies.

CONCLUSIONS

(1) Synthesis of C_3F_6 by gas-phase pyrolysis of C_2F_4 involves insertion of $:CF_2$ into the C–F bond at the radical center of the 1,2-biradicaloid $C_2F_4^*$.

(2) Formation of C_4F_8 olefins in the course of gas-phase pyrolysis of C_2F_4 involves insertion of $:CF_2$ into the C–F (and probably C–C) bonds at the radical centers of the 1,2-biradicalod $C_3F_6^*$.

(3) The enthalpy of formation of 1,2-biradicaloids $C_2F_4^*$ and $C_3F_6^*$ from the respective perfluoroolefins is 75.2 ± 8.4 kJ mol^{-1}. The absorption spectra of these intermediates contain two bands at 236.5 and 500, and 240 and 477 nm, respectively.

(4) The theoretically predicted stabilizing effect of the F atoms was experimentally confirmed by the millisecond absorption spectra of 1,3- and 1,4-perfluoro biradicals. Indeed, the lifetime of biradical hydrocarbon analogs is shorter by several orders of magnitude.

(5) Three pathways to improve the procedure of C_3F_6 production were proposed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Role of Structural Characteristics of Aromatic Polyimides in Carbonization

A. V. Gribanov, Yu. N. Sazanov, and M. V. Mokeev

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 9, 2002

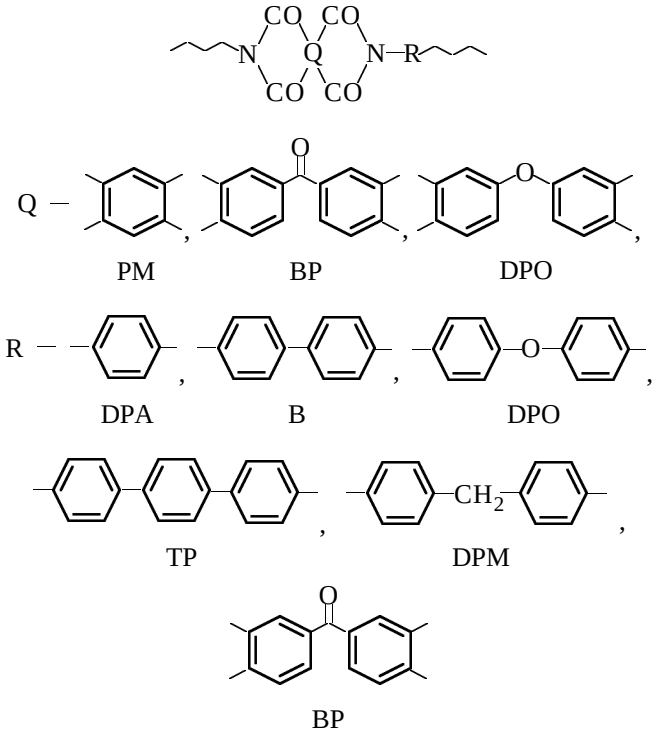
Abstract—The influence of the structural characteristics of polyimides belonging to four standard classification groups was analyzed. The main factors responsible for formation of ordered and/or turbostratic carbon structures in the course of carbonization were studied for the example of film and fibrous materials.

The majority of published data on heat resistance of polyimide materials are related to poly(pyromellitimide diphenyl oxide) (PPM), the first and the most widely used aromatic polyimide [1, 2]. This polyimide is still the most demanded; however, some service characteristics of articles made from it do not meet the modern requirements. In this connection, one of the ways to modify polyimide materials was to vary the chemical structure of the initial components, tetracaboxylic acid dianhydrides and aromatic diamines. By now, active synthetic efforts have resulted in laboratory preparation of several hundreds of polyimides of various structures. For a number of reasons, only a few of these have found real practical use. Published data [3–6] on the heat resistance and mechanical strength of film and fibrous materials based on some polyimides differing in structure from PPM are insufficient to understand the proceses occurring in these compounds at temperatures above 300–400°C. Much less is known about the carbonization process, i.e., conversion to the carbon state, although production of carbon materials by carbonization of polyimide polymers is of prime interest.

Previously [7, 8], we have established some features of high-temperature conversion, i.e., carbonization of PPM polyimide. Here, using the previously developed approach, we make an attempt to elucidate the influence of the chemical structure of aromatic polyimides on their conversion to a carbonized product under similar conditions.

EXPERIMENTAL

Films and fibers produced according to [9] were used as samples of polyimide materials. With respect to their chemical structure, the polyimides studied belong to all the four groups of the standard classification [9]:



where PM is the pyromellitic core, BP is benzophenone, DPO is diphenyl oxide, PPA is *p*-phenylenediamine, B is benzidine, TP is terphenyl, and DPM is diphenylmethane.

In what follows, the first abbreviation will refer to the dianhydride moiety, and the second, to the diamine moiety.

1070-4272/02/7504-0606 $27.00 © 2002 MAIK "Nauka/Interperiodica"

To study the carbonization and the structure of the reaction products, we used thermal gravimetric analysis (TGA) in a vacuum and an inert gas medium in combination with mass spectrometry, thermal volumetric analysis (TVA) of the kinetics of gas release, and complex spectral analysis of the final products and intermediates with the use of high-resolution ^{13}C NMR in solids and X-ray photoelectron spectroscopy (XPES). Some reactions were monitored by DTA. Thermal analysis was carried out using a Du Pont-951 thermal analyzer (TGA), a Mettler thermal balance connected to a Balzer quadrupole mass spectrometer, a Vacuum-Generator X-ray emission spectrometer, a Bruker CXP-100 NMR spectrometer, and a thermal volumetric installation [10].

Up to now, the universally accepted criterion for estimation of the carbonization ability of polymers has been the amount of the coke residue formed in a certain regime of heat treatment. Therefore, when comparing quantitative data on carbonization of polyimides, it is reasonable to consider this characteristic first.

As shown for PPM as an example, carbonization of polyimides begins and proceeds most intensively in the temperature range 500–650°C. In this range, it is of most interest to compare the weight loss and the kinetics of gas release, depending on the structure of the elementary unit of polyimide. The TGA curves of the initial stage of carbonization of polyimides are shown in Fig. 1. It is evident that the most heat-resistant in the temperature range 500–550°C are polyimides of classes A and B, whose structure is rigid because the diamine component contains no "hinged" atoms and groups. For these polyimides (PM–PPA and PM–B) the coke number in the given temperature range is 2 times that of flexible-chain polyimides such as, e.g., BP–PPA and BP–B. This behavior of rigid-chain polyimides corresponds to thermal characteristics of aromatic model compounds of the phenylene series [11]. In the cases when such hinged groups or atoms as –O–, $–CH_2–$, –C(O)–, etc. are incorporated in the polyimide structure, thermal degradation, most likely, starts at these bonds.

Homolytic degradation of benzimide rings with release of carbon oxides begins in the same temperature range.

The curves of simultaneous thermal gravimetric and mass spectrometric analyses of PM–B polyimide (Fig. 2) show a typical pattern of thermal degradation of polyimides. A noticeable weight loss accompanied by release of a number of gaseous products of degradation of benzimide ring (CO, CO_2, H_2O, HCN, H_2, etc.) occurs specifically in the range 500–550°C. The set of these products suggests that the initial phase of carbonization is similar to that considered previously for the example of PPM [8]. However, detailed comparison of these data for various structures of polyimides other than PPM reveals certain qualitative and quantitative distinctions between them in the composition of gaseous carbonization products. For example, for polypyromellitimides in which the diamine fragment consists of phenylene rings (PM–PPA, PM–B, and PM–TP), according to mass-spectrometric data, the products of the initial stage of carbonization consist mainly of carbon oxides, i.e., products of decomposition of benzimide rings. The distinction in the amount and ratio of these products

is caused by different types of structural packing of macromolecules in these polyimides [12]. As regards polyimides with "hinged" bonds in the diamine and dianhydride components, the presence of noticeable amounts of HCN, ammonia, benzonitrile, dicyanobenzene, phenol, and biphenyl in the mass spectra suggests diversity of the initial events in thermal degradation of these polyimides. It should be noted that thermal degradation in a vacuum of polyimides containing methylene, diphenyl oxide, and benzophenone fragments favors secondary cross-linking of solid carbonization residues. This follows from comparison of the amounts of carbonized polyimides formed by heating to 800°C. It is seen from the TGA data that this amount is 80–75% for the DPO–B and DPO–PPA film samples, less by 10% for PM–DPO, PM–B, and PM–PPA, and, on the average, 60–65% for fibrous samples.

As a rule, the main weight loss due to removal of volatile carbonization products is complete by 650°C. Upon further heating, the primary carbonized structure becomes thickened owing to dehydrogenation and removal of residual heteroatoms.

As in the case of PPM, the most interesting data on the influence of chemical structure on the mechanism of conversion of polyimides into carbonizate with ordered and/or disordered structure were obtained using ^{13}C NMR in solids.

A comparison of the high-resolution ^{13}C NMR spectra of rigid-chain PM–PPA and PM–B polymers produced at various temperatures of heat treatment (Fig. 3) showed primarily the high stability of polymer units in this group of polyimides. Up to 600°C, the main signals vary insignificantly. The behavior of the signal at 164 ppm, corresponding to the carbonyl carbon of the imide ring, exhibits a specific feature: even at temperatures higher than 600°C there is a weak signal in this range of spectrum, which suggests the presence of a small amount of carbonyl groups even at these temperatures. On heating at 550°C, a shoulder at 150–155 ppm appears in the spectra. It is well known that this range corresponds to a carbon atom of a benzene ring directly bonded to an oxygen atom. Hence, we can assume a slight increase in the amount of Ph–O–Ph bonds (this is more pronounced in the spectra of PM–PPA than those of PM–B). The appearance of this shoulder is most probably due to formation of new bonds in the polymer through exogenic oxidation. On heating PPM polyimide, the intensity of the signal at 155 ppm decreases out of proportion to the intensity of the carbonyl signal at 164 ppm [13]. However, formation of new Ph–O–Ph bonds could not be detected against the background of the Ph–O–Ph bonds already present in the diamine fragment of PPM. Here, the appearence of oxyphenyl groups in PM–PPA and PM–B was detected for the first time.

Polyimides containing the DPO fragment show different trends in evolution of the NMR spectra upon heating. Even at 500°C the signals become strongly broadened (Fig. 4). The signals corresponding to carbonyl carbons (164 ppm) and quaternary carbons of the imide ring (137 ppm) abruptly decrease in intensity and become significantly broadened. Simultane-

ously, the width of the signal at 130 ppm increases significantly, which suggests rapid growth of a heteroaromatic carbon structure. Since the weight loss at these temperatures is insignificant, these changes in the spectra can be accounted for by interchain cross-linking and rapid formation of a heteroaromatic structure at relatively low temperature. This is also suggested by the coalescence of the signals at 164 and 155 ppm.

These observations are well supplemented by the spectral characteristics of the C, O, and N atomic states of the polymers in carbonization, obtained using XPES. The spectra of intermediates obtained in carbonization of polyimides (heating in a vacuum to 600°C) are shown in Fig. 5. Comparison of the O1*s* spectra shows that, contrary to PPM polyimide, for which the intensity of the signal of the C=O group does not exceed 40–45% of the total intensity of the oxygen signal (in the initial sample, 4 : 1), the similar ratio for the DPO–DPO polyimide is higher, although the initial proportions are lower (2 : 1). This fact suggests that the cleavage of the imide ring in DPO–DPO with increasing temperature is somewhat slower than that in PPM polyimide, and cross-linking through oxygen bridges is less active. Analysis of the oxygen spectra of rigid-chain polymers PM–PPA and PM–B containing no diphenyl oxide oxygen in the chain shows that, with increasing temperature, the C–O–C interchain bonds are formed (the spectral line at 533.6 eV). These conclusisons are confirmed by analysis of the C1*s* lines. It is seen that carbonization is the fastest in this stage for PPM, in good agreement with the curves of weight loss at 600°C. For all the polymers studied in this work, the initial singlet of nitrogen transforms on heating into a multiplet with different binding energies. In PM–B and PM–PPA, the contribution of this spectral line (E = 400.4 eV) in the multiplet is significantly higher than that in PPM and DPO–DPO polyimides. This fact suggests that the content of the residual imide rings in rigid-chain polyimides is significantly higher than that in semicrystalline PPM and flexible-chain DPO–DPO.

Carbonization proper, as a transition from linear to three-dimensional carbon structure, is completed on heating to 800–900°C and is characterized by the formation of a polyaromatic quasi-graphite carbon structure. The ^{13}C NMR spectra of carbon residues of various polyimides were compared with the spectrum of graphite (Fig. 6). A downfield shift of the signal of carbonizates by 5 ppm for PPM and PM–PPA and by 10 ppm for DPO–DPO is attributable to the difference between the resulting carbon structure and the ideal polyaromatic structure of graphite. Comparison of the half-widths of the signals is of greater interest. We believe that the more broadened signal of the DPO–DPO carbonizate suggests the preferable formation of turbostratic irregular structures, while the half-width of the signal of rigid-chain PPA is

close to that of the signal of graphite, which apparently reflects its structural similarity to graphite.

CONCLUSIONS

(1) The model of interchain cross-linking of PPM polyimide is applicable to polyimides of various chemical structures.

(2) Carbonization of rigid-chain polyimides of class A is governed by layered packing of macromolecules, which results in the formation of ordered centers of subsequent graphitization.

(3) Carbonization of flexible-chain polymers of class D is developed through formation of turbostratic structures owing to the significant segmental mobility of macromolecules in these polyimides.

(4) The mechanism of carbonization of polyimides of classes B and C is mainly governed by the parameters of heat treatment.

Abstract—Kinetics of the reaction of resorcinol diglycidyl ether with novolac phenol–formaldehyde resins of various functionalities were studied over a wide temperature range by isothermal calorimetry. The effects of the functionality of oligophenols on curing of epoxy-phenolic composites, structure of the resulting polymer at the chemical, topological, and supramolecular levels, its mechanical and relaxation properties, and the mechanism of its fracture were analyzed.

Success in synthesis of high-performance cross-linked polymers at low production cost depends to a considerable extent on understanding of relationships between the structure of the starting reagents, synthesis conditions, product structure, and product properties. Goal-seeking analysis of these interlinks is known as structural-kinetic approach [1–5]. In these works, the effects of various low-molecular-weight fluids, chemically active tertiary amines [1, 2, 5], and physically active plasticizers [1, 3] on the kinetics and mechanism of curing, relaxation and mechanical characteristics, and fracture of polymers were examined for the examples of epoxy–amine [1–3, 5] and epoxy–phenolic cross-linked polymers [4].

It is known [6–10] that oligophenols obtained by condensation of phenol and formaldehyde, among them novolac phenol–formaldehyde resins (NPFRs) [6], are widely used as cheap hardeners for epoxy resins of various purposes. However, only very limited published data are available concerning the effect of the molecular weight or functionality of NPFRs on the kinetics of their reaction with epoxides and also on the mechanical characteristics of novolac epoxy composites [11]. Therefore, the goal of this work was to analyze the effect of the molecular weight or functionality of NPFRs on the kinetics and mechanism of curing, structural organization at various levels, and properties of epoxy–phenolic cross-linked polymers (EPCLPs) using the structural-kinetic approach.

EXPERIMENTAL

As an epoxy resin we used resorcinol diglycidyl ether purified by high-vacuum distillation. A novolac phenol–formaldehyde resin was synthesized by the procedure described in [12] and used without further purification. The average functionality of the novolac resin was controlled by varying the phenol-to-formaldehyde ratio.

As reference compounds we used the monofunctional phenol studied previously [13, 14] and also SF-010 commercial high-molecular-weight novolac resin [GOST (State Standard) 18694–73]. Phenol and sulfolane (used as a strongly solvating agent) were purified by high-vacuum distillation. The reactivity of the epoxy and phenol groups was characterized by the initial rates, which were determined from differential calorimetric curves obtained on an EK-2 fast-response calorimeter over a wide temperature range [15].

Phenolic rings of oligophenols can be bound to each other via *ortho,ortho*, *ortho,para*, and *para,para*

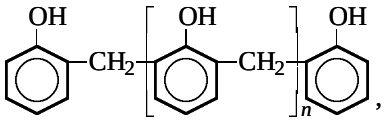
methylene bridges [16]. Below is given typical oligophenol structure



where n = 0–10.

A gel-permeation chromatographic study of NPFRs showed that the oligophenols obtained are characterized by a broad distribution over molecular weights and, therefore, with respect to functionalities (Fig. 1). As seen from the table, with variation of the phenol-to-formaldehyde molar ratio (P_1 : FA) from 10 : 1 to 10 : 7, the mean molecular weight of NPFR $\overline{M}_n$ increases from 232 to 556, and the mean functionality $\overline{f}_n$, determined from $\overline{M}_n$ and the hydroxy group content (see table), from 2.3 to 5.32. In this case, the contents of fractions with n = 0 (P_2) and n = 1 (P_3) and of high-molecular-weight fractions (HMWF) noticeably change, as also does the excess phenol content P_1^e. At the same time, the phenol group content (wt %) in NPFRs remains practically unchanged, regardless of their functionality. From the kinetic standpoint, this must cause the equality of the rates of curing with these resins. However, the calorimetric data obtained over a wide temperature range appeared to be unexpected.

With increasing functionality of NPFRs, the activation energy E_a of the reaction of the diepoxide with oligophenols considerably decreases (Fig. 2a); the

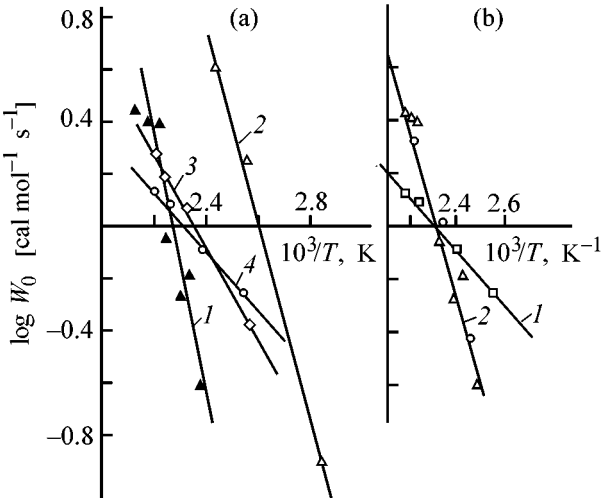

Fig. 2. Arrhenius plots of the initial rates W_0 of curing in the bulk of epoxy–phenolic polymers obtained with (a) NPFRs of various mean functionalities $\overline{f}_n$ and (b) at $\overline{f}_n$ = 5.3 in the presence or absence of monophenol. (T) Temperature; the same for Fig. 3. (a) $\overline{f}_n$: (*1*) 1, (*2*) 2.3, (*3*) 3.5, and (*4*) 5.3. (b) Monophenol concentration (wt %): (*1*) 0 and (*2*) 6.

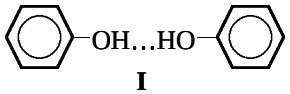
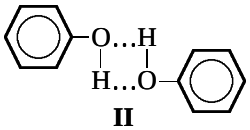
monofunctional phenol demonstrates the highest E_a. Addition of a small amount of phenol (6 wt %, which is a typical concentration of phenol as an impurity in commercial NPFRs) to a mixture containing oligophenol with $\overline{f_n}$ 5.3 also considerably increases E_a (Fig. 2b).

Note that the increasing activation energy of curing is an important factor in molding goods from prepreg-based composite materials [17]. The higher E_a, the lower the reactivity of a binder (the longer the prepreg shelf life) at a given temperature of storage and the higher the reactivity at the temperature of molding. Therefore, optimization of the NPFR functionality allows control of the prepreg performance.

It was demonstrated in studying the kinetics of curing of the same composites in sulfolane that the functionality of NPFRs has practically no effect on E_a. In this case, E_a of all the NPFRs studied becomes equal to that of phenol (Fig. 3), which can be attributed to the clearly pronounced tendency of phenols toward self-association. It is typical of monophenols to form linear (**I**) or cyclic (**II**) associates:



I



II

It is known [13, 18] that, the higher the degree of saturation of hydrogen bonds and the degree of delocalization of the electron density in autocomplexes, the more stable and the less reactive they are. More stable cyclic associates of monophenols, having higher enthalpy of complexation (6–8 kcal mol^{-1}), must increase the activation energy of the reaction of oligophenols with epoxides. That is why the reaction of the diepoxide with monophenol is characterized by the highest E_a.

In oligophenols, formation of cyclic intermolecular associates is hindered by steric factors, and intramolecular association, evidently, dominates in this case. The resulting chains of oligophenols roll up into globules [19]. This trend must become more pronounced with increasing molecular weight of oligophenols. Therefore, the reactivity of phenol groups in oligophenols can increase as a result of formation of less stable associates, but the steric accessibility of these groups to reagents may be lower as compared to monophenols

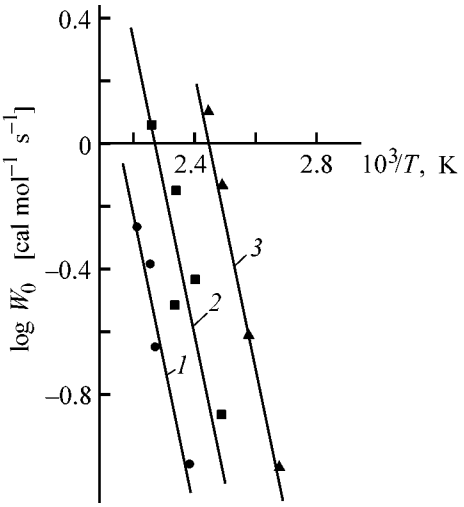


Fig. 3. Arrhenius plots of the initial rates of curing W_0 of epoxy–phenolic composites in sulfolane for NPFRs of various mean functionalities $\overline{f_n}$: (*1*) 1, (*2*) 2.3, and (*3*) 5.3.

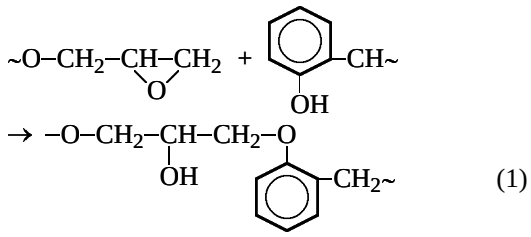
because of the globular structure. As an illustration, with the functionality of NPFR increasing from 2.3 to 5.3, the degree of epoxidation of the oligophenols with epichlorohydrin decreases from 81 to 63%, while in the case of monophenol it is 90–95%.

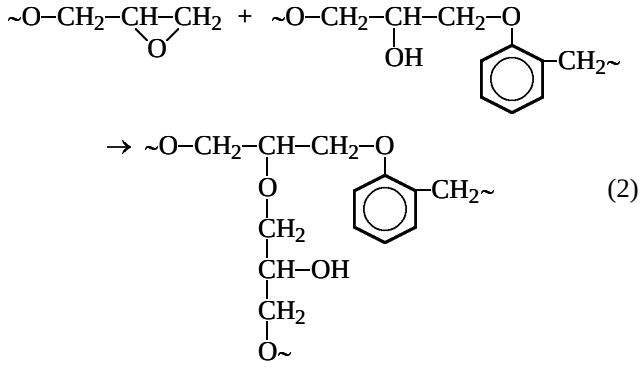
Note that, with the use of polyphenols as curing agents, the topological limit of curing of the final cross-linked polymer (α_∞ = 0.85 [20]) is lower than that of epoxy–amine polymers (α_∞ = 0.95 [21]). This result was attributed in [20] to stronger steric hindrance in epoxy–phenolic systems with respect to interaction of functional groups, with the possible globular structure of the phenolic hardener disregarded. Introduction of sulfolane (highly solvating agent) results in breakdown of the associates of phenol groups and formation of complexes with the solvent, thus saturating all the hydrogen bonds in the reaction system (in this case, open conformations of oligophenols can be formed). All this explains the observed rise in the activation energy. Introduction of a small amount of monophenol to high-functionality oligophenols must also favor formation of more stable H complexes, causing increase in E_a.

It follows from the results obtained that association plays an important part in curing of epoxides with oligophenols. The practical aspects of this effect have been considered elsewhere [22]. At the same time, high degree of association in oligophenols (especially in high-molecular-weight fractions) can reduce α_∞ and create prerequisites for formation of a microheterogeneous cross-linked structure. It was demonstrated in [4] that formation of a cross-linked structure involves two reactions: main reaction (1), in which the epoxy

groups are consumed in the polycondensation (PC) process with participation of the phenol groups of EPCLP, and side reaction (2), in which the epoxy groups react with secondary alcohol groups [products of reaction (1)] by the polymerization (PM) mechanism:

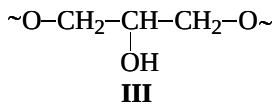


(1)



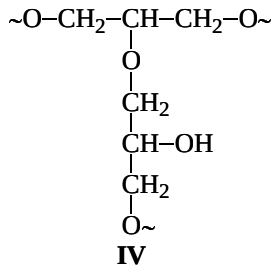
(2)

The typical unit of a cross-linked structure formed in the purely PC process is hydroxy ether fragment **III** of the interjunction chain:



III

whereas ether fragment **IV** is the characteristic unit of a cross-linked structure formed in a side PM reaction:



IV

Note that hydroxy ether fragments **III** of the interjunction chain formed by the PC mechanism may serve as a flexible link decreasing the degree of cooperativity of motion of network junctions as the major kinetic unit of large-scale segmental motion [23]. Furthermore, the secondary alcohol group of fragment **III**, which is the major unit of the H-bonded network structure in EPCLPs [24], controls to a considerable extent the properties of these polymers in the glassy state. In its turn, the ether fragment **IV** is an additional junction in the chemical network formed by the PM mechanism. The appearance of this junction changes the length and nature of the interjunction chain, deteriorating the relaxation and mechanical characteristics of EPCLPs.

It follows from the kinetic results that the functionality of NPFRs has a strong effect on the structure of the resulting cross-linked polymers. The structure and properties of cured EPCLPs were mainly studied at an epoxy to phenol group ratio of 1 : 0.5. This was caused by the fact that the oligophenol content in the epoxy-phenolic composite is a key factor controlling its viscosity as a binder for wet winding. Taking into account that the strength of EPCLPs decreases with increasing epoxy to phenol group ratio [24], the selected ratio was accepted as the optimal from the standpoint of the product performance. Such a selection of this ratio suggests *a priori* a high contribution of the PM process to the formation of the crosslinked structure of EPCLPs. However, this contribution must also depend on the degree of conversion of the phenol groups, i.e., on their steric accessibility, depending, in its turn, on the functionality of the oligophenols.

It should be pointed out that epoxyphenolic composites were cured in the presence of 1% triethanolamine (TEA) as a catalyst, with stepwise rise in the temperature, which allows separation of reactions (1) and (2) in time and provides completeness of PM reaction (2) in the final stages of curing [4]. Chemical analysis for the epoxy groups in cured EPCLPs showed that, regardless of the NPFR functionality, the conversion with respect to the epoxy groups is 94–96%, i.e., it is constant to within the determination error. This result shows that the observed evolution in the structure and properties of EPCLPs is directly governed by the functionality of NPFRs.

The effect of the functionality of oligophenols on the structure of cross-linked epoxy–phenolic polymers is manifested differently at the molecular, topological, and supramolecular levels [25].

This effect is not pronounced at the molecular level at the given initial ratio of the reactive groups and practically constant conversion of the epoxy groups.

Topologically, the structure can be characterized, to a first approximation, by the number of cross-links and also by the sol fraction content. The effective cross-link density was determined (with the front fac-

tor disregarded) from the modulus of elasticity in the hyperelastic state [26]:

$$G_\infty = 3\rho RT/\overline{M} = 3\nu RT,$$

where ν is the effective cross-link density; ρ, the density; $\overline{M}$, the mean molecular weight of the interjunction chain; R, the gas constant; and T, the measurement temperature.

The dependence of the effective cross-link density ν on the mean functionality of NPFR (Fig. 4) passes through a maximum at $\overline{f_n}$ = 3.5–4.0. For the same polymers, we determined the sol fraction content which is commonly used as an integral parameter characterizing the degree of topological faultiness of the cross-linked structure, associated with formation of rings, linear chains, or with the presence of unreacted components [25]. Figure 4 demonstrates that the sol fraction content Z (wt %) as a function of the hardener functionality passes through a minimum at $\overline{f_n}$ approximately corresponding to the maximal ν.

Thus, the dependences of both the parameters characterizing the topology of the cross-linked structure on the hardener functionality show extrema. The variation trends of these parameters are evidently caused by the increasing functionality of network junctions and, as a result, by changing relative contributions of the PC and PM mechanisms to formation of the cross-linked structure in the course of curing. It may be suggested that, at low hardener functionality, the PC process dominant in the initial stages of curing must produce essentially linear chains. Further cross-linking of these chains in the course of gelation proceeds by reaction (2). At medium functionality of the hardener (about 3.5), cross-linking must proceed by the PM mechanism [reaction (1)], at least at the microscopic level (formation of microgels). In this case, the PM mechanism promotes further monolithization, i.e., linking of separate microblocks or cross-linked microaggregates to form a macroscopic block or network.

The expected course of cross-linking at various hardener functionalities is confirmed by experimental data on the evolution of mechanical properties of the composites in curing (Fig. 5). For NPFR of low functionality, the rise in the relative shear modulus G_{rel} in the course of curing is strongly extended in time, although the initial heat liberation rate for this resin is considerably higher.

The decrease in the cross-link density and increase in the sol fraction with NPFR functionality increasing further are probably due to lower steric accessibility of their phenolic hydroxyls as a result of intramolecular self-association to give globular species. It is clear that the increase in steric hindrances must be accompanied by a decrease in the epoxy to phenol group ratio, i.e., the contribution of the secondary reaction (2) involving the alcohol hydroxy groups must increase. Furthermore, partly or totally unreacted high-molecular-weight fractions of polyphenols must accumulate in the resulting polymer composite. They can serve as a polymeric binder making the sol fraction content higher and the cross-link density lower, which is supported by the results of dynamic mechanical tests using the bending resonance vibration method. The relaxation spectra of EPCLPs in the initial stages of curing demonstrate the presence of a high-temperature φ peak, whose intensity decreases with increasing reaction temperature or time, in addition to the basic relaxation peak (α peak). This is particularly typical of commercial high-melting NPFRs, e.g., SF-010, containing high-molecular-weight fractions. In the relaxation spectra of low-melting NPFRs of low functionality these peaks are not found.

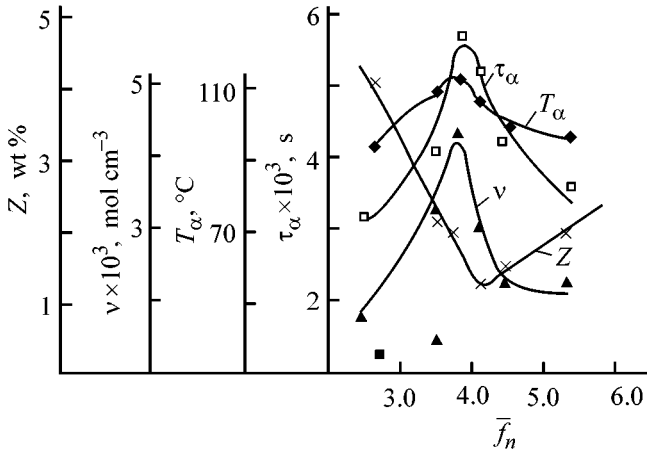


Fig. 4. Sol fraction content Z, cross-link density ν, peak temperature T_α, and relaxation time τ_α of α transition vs. the mean functionality $\overline{f_n}$ of NPFRs.

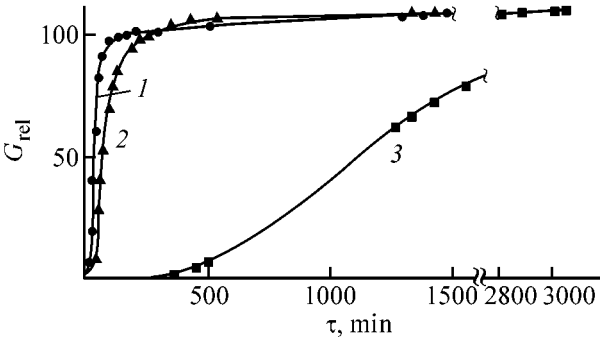

Fig. 5. Relative shear modulus G_{rel} vs. the curing time τ for NPFRs with various mean functionalities $\overline{f_n}$: (*1*) 5.32, (*2*) 3.52, and (*3*) 2.3.

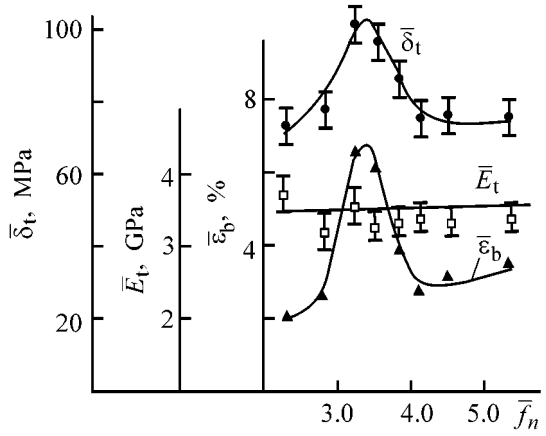

Fig. 7. Tensile strength $\overline{\delta}_t$, Young modulus $\overline{E}_t$, and elongation at break $\overline{\varepsilon}_b$ vs. the mean functionality of NPFR.

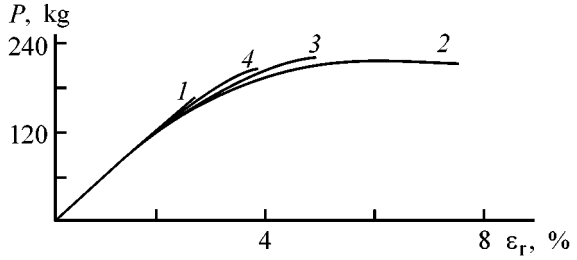

Fig. 8. Stress–strain curves for the strongest EPCLP samples obtained with NPRF of various functionalities. (P) Stress and ($\overline{\varepsilon}_r$) rupturing deformation. $\overline{f_n}$: (*1*) 2.3, (*2*) 3.52, (*3*) 3.82, and (*4*) 5.3.

To conclude, the functionality (or the molecular weight) of NPFRs can influence the mechanism of curing by changing the relative contributions of reactions (1) and (2). As a result, the proportion of the hydroxy ether and ether fragments of the cross-linked structure may change, thus modifying the structure at the topological level.

The supramolecular organization of these polymers was studied by electron microscopy and low-angle X-ray scattering. With increasing hardener functionality, the microroughness of the chip surface of the polymers in the electron micrographs of EPCLPs initially decreases and then starts to increase. In this case, the size of supramolecular species (globules) passes through a minimum near $\overline{f_n} \approx 3.5$ (Fig. 6). The degree of inhomogeneity, estimated from the low-angle X-ray scattering data, also passes through a minimum at approximately the same $\overline{f_n}$. It should be pointed out that the peak values of the parameters characterizing the supramolecular structure fall into the same range of $\overline{f_n}$, suggesting some genetic relation between the two levels of the structural organization of EPCLPs, similarly to the case described in [4].

To examine the structure–properity interrelations, we studied the structural, deformation, and elastic characteristics of EPCLPs obtained with NPFR of various functionalities. With increasing $\overline{f_n}$, the tensile strength $\overline{\delta}_t$ and elongation at break $\overline{\varepsilon}_b$ change in parallel (Fig. 7), and their dependences on $\overline{f_n}$ demonstrate maxima at $\overline{f_n}$ close to 3.5. At the same time, the Young modulus $\overline{E}_t$ is virtually independent of $\overline{f_n}$. The linear section in the stress–strain curves of EPCLP samples obtained with NPRF of low and high functionality (Fig. 8) corresponds to brittle fracture. For the samples with $\overline{f_n}$ ranging from 3.0 to 4.0, the contribution of forced elastic deformation increases noticeably. In the limiting case, at $\overline{f_n} = 3.5$, we can find a distinctly pronounced plateau corresponding to forced rubberlike elasticity.

Changes in the structural and deformation properties with varying NPFR functionality are accompanied by alteration of the fracture mode in the cross-linked polymers. It should be pointed out that, depending on $\overline{f_n}$, the areas of the smooth and rough fracture zones change, which is typical of a transition from brittle to forced elastic fracture [27]. The observed change of the mode of fracture can be attributed to the action of two major factors: (1) variation in the relaxation characteristics of EPCLPs as a result of modification of the cross-linked structure at the topological level and (2) variation in the degree of structural heterogeneity or changing size of supramolecular forms, as directly follows from the well-known Griffits equation for the critical strength, relating the major structural parameters to each other [28]:

$$\sigma_{cr} = \sqrt{\frac{2E\gamma}{\pi l_{cr}}}.$$

Among these parameters are the modulus of elasticity E (elasticity parameter), surface fracture energy γ (dissipation parameter), and defect critical size l_{cr} (structural parameter characterizing local stress).

Since the modulus of elasticity remains virtually unchanged, the strength variation may be due to a change in γ or (and) l_{cr}. It is worth noting that the strength and the major characteristics of the α relaxation process, caused by long-range segmental mobility, pass through a maximum at approximately the same $\overline{f_n}$ of NPFR (Fig. 4). Among the dissipation parameters are the peak (or glass transition) temperature T_α, effective cross-link density ν, and relaxation time τ_α determined from the resonance condition $\omega\tau_\alpha = 1$ in dynamic mechanical tests of EPCLPs by the resonance bending vibration method with dead-ended samples. The results obtained are indicative of extremal increase in the effective size of the kinetic unit of segmental motion. This may suggest [29] that, in the polymeric system studied, the parameters of the α process control the energy dissipated in EPCLP under static stress. The larger the effective size of the kinetic unit of segmental motion, the greater, evidently, the volume of the yielded region at the mouth of a growing crack and the higher the dissipated energy.

At the same time, we can speak about the correlation between the structural characteristics and the dimensions of supramolecular structures. Evidently, in this case, the size of supramolecular structures may be equated, to a first approximation, to the critical defect size in the Griffits equation. Therefore, the larger the supramolecular form, the more pronounced will be the local overstrains at the boundary surface, and the sooner the catastrophic failure of the polymeric material will start.

CONCLUSIONS

(1) The functionality of novolac phenol–formaldehyde resins controls the degree of structural heterogeneity at the topological and, particularly, supramolecular levels, thus causing differences in the structural and deformation characteristics of epoxy–phenolic cross-linked polymers and also in their fracture mode.

(2) Decision on the optimal commercial hardeners should be made taking into account the effect of their functionality on both the processing and performance characteristics of epoxy–phenolic composites.

Received August 2, 2001; in final form, February 2002

Abstract—Structural rearrangements occurring in the course of oxidation of isotropic and oriented samples of isotactic polypropylene were studied. The mechanisms of structural rearrangement in intercrystallite regions of isotropic and oriented samples were examined. The character of relaxation transitions in oriented polypropylene was studied in relation to the structures of the initial fibrils and of interfibrillar and intrafibrillar regions.

The heat resistance of a polymeric material is determined by its capability to preserve structural parameters in the course of thermal oxidative degradation. Elucidation of the features of structural rearrangements that accompany thermal oxidation allows more adequate evaluation of the performance limit of a polymeric material under particular conditions. At the same time, oxidation modifies a polymer, affecting its structural parameters and properties. Modification of a polymer by oxidation can improve its compatibility with other polymers. Therefore, elucidation of regular trends in the effect of oxygen on the polymer structure is of practical importance.

The influence of the polymer structure on its oxidation has been studied extensively, whereas data on the effect of oxidation and thermal degradation on the polymer structure are scarce [1–10]. Changes in the molecular structure of a polymer in the course of oxidation are poorly understood.

The goal of this study was to reveal regular trends in structural changes occurring in isotactic polypropylene (PP) in the course of its thermal oxidation and to examine the influence of the initial structure [isotropic (iPP) or oriented (oPP) sample] on these trends.

EXPERIMENTAL

We used isotactic PP of the Moplen brand with the following characteristics: M_w = (3.3–3.6) × 10^5, M_n = (3.6 – 4.1) × 10^4, intrinsic viscosity η = 1.53 dl g^{-1} (tetralin, 135°C), density d = 0.92 g cm^{-3}, degree of isotacticity 96%. The polymer was studied in the form of films prepared by pressing under nitrogen at 180°C and a pressure of 10 MPa in the quenching mode. Uniaxial orientational extension of films was performed by local heating at 130°C. The relative elongation reached 600–950% (λ = 6.0–9.5). The thickness of isotropic films varied within 40–100 μm, and that of oriented films, within 10–20 μm.

The structure and volume of crystalline regions of the initial and oxidized PP samples was determined by X-ray diffraction (XRD) using Ni-filtered Cu_{K_α} radiation. The degree of crystallinity was evaluated by differential scanning calorimetry (DSC; DSM-2M device) and was also monitored by IR spectroscopy (M-80 spectrometer), using the intensity ratio of the bands at 1220 and 1256 cm^{-1} [11].

The thermal parameters were determined by DSC at a scanning rate of 16 deg min^{-1}; the polymer sample weight was varied from 2 to 20 mg. The calorimeter was calibrated against indium (mp 156.6°C).

The microstructure, or conformational composition, of polymeric chains was determined by IR spectroscopy from the structure-sensitive bending vibration bands of CH_2 and CH_3 groups, and also from the intensity of the bands originating from coupling of the rocking vibrations of these groups with the stretching vibrations of the carbon skeleton (500–1500 cm^{-1}) [11–17].

The structure of oriented samples (degree of crystallinity æ, conformational composition of macromolecules, orientation of macrochains in the crystalline and amorphous regions) was determined by polarization IR spectroscopy. The polarization spectra were recorded with Hitachi polarizers. The optical densities were calculated by the formula $D^0 = (D_{||} + 2D_\perp)/3$, where $D_{||}$ and $D_\perp$ are the optical densities of bands in the spectra measured with the incident bean polarization parallel and perpendicular to the orientation axis, respectively.

Table 1. Structural parameters of unoxidized and oxidized samples of isotropic and oriented PP films

Sample	Degree of extension λ	State	Major period $d \pm 5\%$	Crystallinity index $X \pm 5\%$	Large-angle reflections
iPP	0	Unoxidized	180	64	Rings
	0	Oxidized	185	62	"
oPP	6	Unoxidized	178	60	Strokes
	6	Oxidized	178	60	Points
	9	Unoxidized	187	60	Strokes
	9	Oxidized	187	60	Points

The orientation of macrochains in crystalline and amorphous regions was characterized by the Freser orientation factor f [17], which is related to the IR dichroism value $R = D_{||}/D_{\perp}$ by

$$f = (R - 1)(R_0 + 2)/(R + 2)(R_0 - 1), \qquad (1)$$

where $R_0 = 2\text{cotan}^2\,\alpha$, and α is the transition moment angle (angle between the direction of the transition moment vector of the vibration, **M**, and the electrical vector of the beam, **E**).

This angle ranges from 0° to 55° for *A* bands (manifested in IR spectra with parallel polarization) and from 55° to 90° for *E* bands (manifested in IR spectra with perpendicular polarization). Correspondingly, $0 < R_0 \le \infty$ for *A* bands and $1/\infty \le R_0 < 1$ for *E* bands.

From the polarized spectra, we obtained the IR dichroism values R for each band. To calculate the orientation factors by formula (1), we took the angles α from [17].

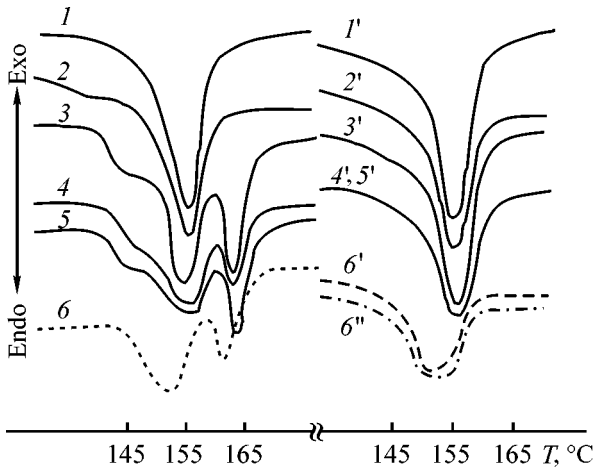

Fig. 1. Endotherms of melting of the initial and oxidized (130°C, P_{O_2} = 20 MPa) PP samples. (*T*) Temperature; the same for Fig. 5. Endotherm of (*1*–*6*) first melting, (*1*'–*6*') second melting after recrystallization, and (*6*") third melting. Oxidation time (min): (*1*, *1*') unoxidized sample, (*2*, *2*') 5, (*3*, *3*') 30, (*4*, *4*') 60, (*5*, *5*') 85, and (*6*, *6*', *6*") 120.

The kinetics of oxygen uptake by PP was studied with a manometric unit [18]. The nonvolatile oxidation products were studied by IR spectroscopy. The content of carbonyl (>C=O) and hydroxy groups was determined from the intensities of bands in the ranges 1700–1800 and 3320–3600 cm^{-1}, respectively; the OH groups in blocks absorbed at 3420, and isolated OH groups, at 3560 cm^{-1}. For the molar extinction coefficients used to calculate the concentrations of the carbonyl and hydroxy groups, we took the values of 220 and 70 kg mol^{-1} cm^{-1} [5].

The accuracy of determination of the structural and kinetic parameters was 10–15%. The conformational composition and composition of the oxidation products were determined simultaneously in the same experiment.

Isotropic PP samples. The endotherms of melting of iPP crystallites (initial and oxidized) are shown in Fig. 1. As seen from Fig. 1, thermal oxidation of the polymer significantly affects the shape of the melting peak of its crystallites; the extent of the observed changes depends on the time and extent of oxidation. In the initial stage, a low-temperature shoulder appears. With increasing oxidation time, it grows in intensity, and one more, high-temperature, peak appears. Thus, the thermogram of oxidized PP contains three peaks, one of which lies more than 10°C lower, and the other, higher than the melting point of crystallites in unoxidized PP. At large extents of oxidation, when carbonyl and hydroxyl-containing products are accumulated in significant amounts, the intensity of the low-temperature peak considerably increases, and the intensity of the high-temperature peak and the temperature of its maximum decrease (Fig. 1). Appearance of new peaks in the endotherms of melting of oxidized PP suggests changes in the modification or size of the crystallites. However, XRD data show that the modification of the PP crystallites remains unchanged (Table 1).

Recrystallization of oxidized PP after melting results in disappearance of both high- and low-temperature peaks (Fig. 1). In the endotherms of second melting of PP a single peak with the melting point close to that of the initial PP is observed, except in the case of the most deeply oxidized samples, instead of three peaks. The single melting peak is preserved after repeated recrystallizations. In the more deeply oxidized samples, recrystallization also results in that the endotherm of melting becomes more similar to that of the initial sample, but there are still two peaks, and the melting point after one and two recrystallizations remains lower than that of the initial polymer. It should be noted that the enthalpies of melting and hence the degrees of crystallinity, æ, increase slightly in the initial stage of PP oxidation. However, with increasing oxidation time, the difference between ΔH of the first and repeated meltings grows. After remelting, ΔH and æ decrease. It is also significant that the endotherms of the first and second meltings give noticeably different dependences of æ on the oxidation time. Namely, in the first case, α first increases and then decreases with increasing oxidation time, whereas in the second case it decreases monotonically (Fig. 2).

The presence of a low-temperature peak and its growth in intensity with simultaneous decrease in the degree of PP crystallinity suggest breakdown of crystalline regions and amorphization of crystallites, induced by thermal oxidative degradation. The appearance of fine PP crystallites in further oxidation stages is confirmed by the preservation of the low-temperature peak in the DSC curve recorded after recrystallization.

Nevertheless, the presence of several peaks in the endotherm of first melting of PP and their disappearance after remelting indicate that changes in the melting point of the crystallites in the oxidized samples are not necessarily associated with changes in the structure and size of the crystallites and may be due to changes in the thermodynamic parameters or to relaxation processes in interlamellar tie chains [19]. The fact that oxidation of PP does not change significantly the crystallization temperature T_{cr} (Fig. 2) suggests, most likely, the occurrence of relaxation processes in interlamellar tie chains, which precede melting of the crystallites or accompany their intrachain cooperative melting. This is also indicated by the appearance of a high-temperature endothermic peak.

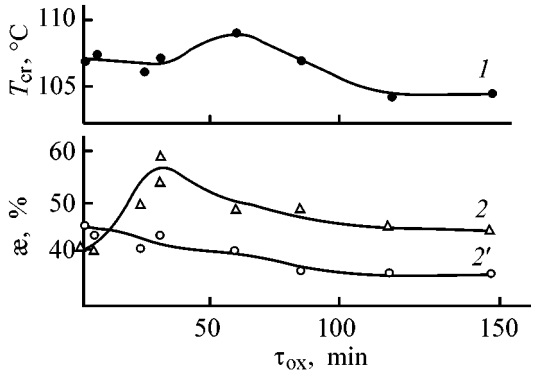

Fig. 2. Variation of the (*1*) crystallization temperature T_{cr} and (*2*, *2*′) degree of crystallinity æ, determined from DSC data, in the course of iPP oxidation. T = 130°C, P_{O_2} = 150 mm Hg; the same for Fig. 4. (τ_{ox}) Oxidation time. Curve *2* was obtained using data on the heat of first melting, and curve *2*′, using data obtained after recrystallization.

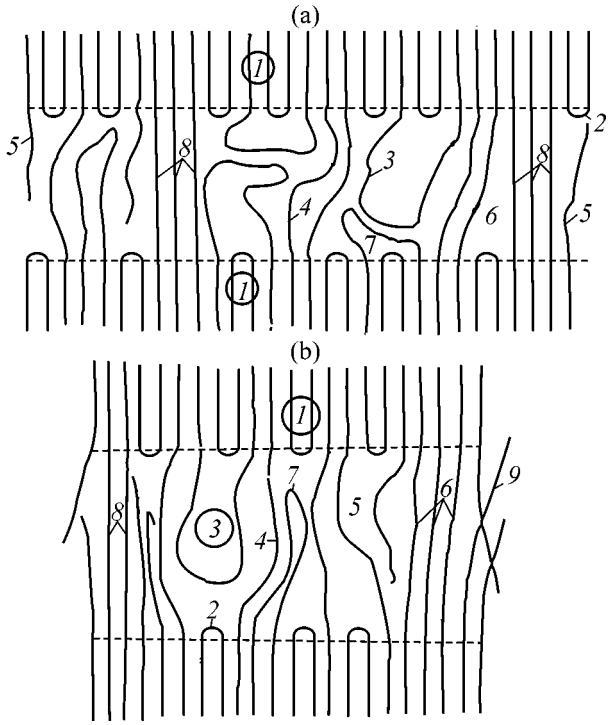

Fig. 3. Interlamellar layer in (a) iPP and (b) oPP: (*1*) crystalline cores of lamellas, (*2*) regular folds with suppressed mobility, (*3*) long irregular loops, (*4*) folded tie chains, (*5*) long terminal chains, (*6*) weakly folded tie chains, (*7*) folds in which the motion is restricted by the crystals, (*8*) fully straightened tie chains with the ends fixed in lamellas, and (*9*) interfibrillar tie chains.

In accordance with the generally accepted scheme [20], interlamellar layers in IPP have a conformational structure (Fig. 3a). Between the crystalline cores of lamellas *1* and regular folds with suppressed mobility *2*, there are macromolecular elements with different conformational mobilities below the melting point T_m: long irregular loops *3*, folded tie chains *4*, and long ends of molecules *5* emerging from the crystals; weakly folded tie chains *6* and folds *7* in which the motions are restricted by the crystals to the greater

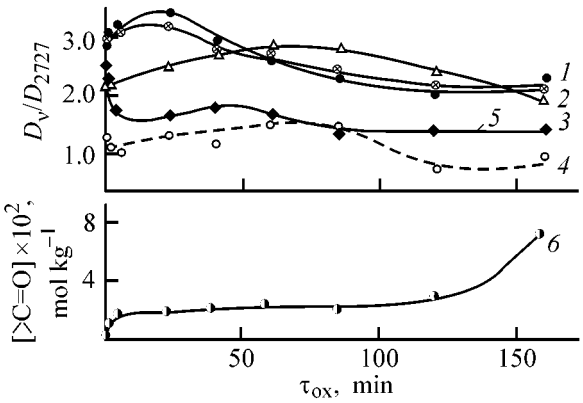

Fig. 4. Variation with oxidation time τ_{ox} of the (*1*–*5*) relative intensities D_ν/D_{2727} of the IR bands and (*6*) the content of carbonyl groups [>C=O], as determined from D_{1720}/D_{2727}. ν, cm^{-1}: (*1*) 840, (*2*) 998, (*3*) 975, (*4*) 810, and (*5*) 1155.

extent, the lower the extent of chain folding ($y = l/h$, where h is the distance between the molecule ends, and l is the length of the molecular contour); and straightened tie chains *8* with ends fixed in lamellas. Apparently, the relaxation processes in these irregular loops and folded tie chains occur at temperatures considerably lower than T_m of the crystallites and cannot affect their melting. The motions in straightened tie chains fixed by the crystals are defrosted as the rotational-isomeric composition of these chains changes by the mechanism of $T \rightarrow G$ transitions [21]. Defrosting will occur with the onset of melting of the smallest lamellas and will determine relaxation at temperatures 10–15°C lower than T_m. The most probable reason for the appearance of the lowtemperature shoulder in the DSC curve of oxidized PP is folding of the least folded interlamellar tie chains formed by thermal oxidation as a result of high-temperature annealing. The rise in intensity of the low-temperature shoulder with increasing time of PP oxidation is probably indicative of an increase in the content of straightened tie chains in the helical *TG* conformation in the intercrystallite regions of oxidized samples.

On the one hand, the high-temperature peak may be due to relaxation processes in maximally straightened chains in interlamellar regions, which can form "strands" similar to those appearing in oriented PP samples [20, 22]. On the other hand, this peak may belong to the high-melting fraction of crystallites, formed owing to the fact that crystallization of straightened tie chains, which prevent crystallite formation, is accelerated in the course of oxidative degradation.

Changes in the structure of macromolecules in the course of oxidation were monitored by IR spectroscopy. The results are shown in Fig. 4. The initial period of the polymer oxidation is characterized by enrichment in straightened, and depletion of folded conformations, i.e., by occurrence of relaxation $G \rightarrow T$ transitions. Upon longer oxidation, the content of straightened chains reaches a maximum and then starts to decrease monotonically. This is indicated by the variation of the band intensities at 975 and 998, and at 840 and 810 cm^{-1}. The content of folded conformers in amorphous regions of PP (a band at 1155 cm^{-1}) in the course of oxidation first decreases sharply, then increases, and, finally, decreases slowly again (Fig. 4). The changes in the relative content of the folded and straightened conformers correspond to $G \rightarrow T$ transitions in the initial stage of oxidation. With the progress of oxidation, in the stage of accumulation of carbonyl-containing oxidation products, the content of straightened conformers decreases, and that of folded conformers grows. As carbonyl compounds are accumulated further, the content of both conformers decreases (Fig. 4).

It should be noted that the bands at 998 and 975 cm^{-1} start to grow in intensity earlier than the bands at 810 and 840 cm^{-1}. The peaks in the curves of the intensities of the latter bands vs. oxidation time are shifted toward longer times. Apparently, all the four bands describe the features of the chain structure in different PP regions. This is confirmed by the IR spectra of the iPP samples treated with boiling concentrated HNO_3. It is known [3] that such a treatment breaks down the chains in the amorphours regions, with the crystallites remaining intact. We found that, after the acid treatment, the intensity of the bands at 998 and 975 cm^{-1}, belonging to regular structures, decreases slightly, and the intensity of the band at 840 cm^{-1} either remains unchanged or increases somewhat, depending on the chosen reference band. Thus, the bands at 975 and 998 cm^{-1} characterize the presence of long helical sections in tie chains, mainly in amorphous intercrystallite regions, whereas the band at 840 cm^{-1} is more sensitive to changes in the chain structure in PP crystallites. Apparently, the different trends in variation of the intensities of these bands (Fig. 4) should not be attributed to different rates of structural rearrangements of chains in lamellas and of interlamellar tie chains, considered separately; more likely, they reflect correlations between these rearrangements.

Apparently, the factors affecting the polymer structure in the course of thermal oxidation are high temperature and oxygen, i.e., annealing and thermal oxidative degradation. Comparison of changes observed in the structure of PP macrochains in the course of

heat treatment in air and in a vacuum at the same temperature shows that, initially, the changes are mainly due to the effect of high temperature (Table 2). At large extents of oxidation, a low-melting crystallite fraction appears as a result of degradation of both interlamellar tie chains and crystallites (probably, of their plane surfaces) in the course of high-temperature oxidation.

A sharp decrease in the extent of folding of tie chains in the iPP samples under consideration, observed after short oxidation, is associated with specific features of the molecular structure of intercrystallite regions of the unoxidized polymer, namely, with the distribution with respect to contour length of chains fixed between lamellas. Such a decrease may be due to the conformational state of macromolecules in which single $G \rightarrow T$ transitions decrease the extent of folding, or to the high content of tie chains in which these transitions occur [22, 24]. Apparently, the same factors determine the rate of variation of the crystallite structure.

Oriented PP samples. An X-ray diffraction study of oPP samples showed that the morphology of PP crystallites does not change after orientational extension. The crystallites in oPP become more oriented (Table 1), which agrees with previous data [5, 20, 22]. The thermograms of melting of the isotropic and oriented samples differ appreciably (Fig. 5). The endotherms of oPP melting consist of two overlapping peaks. As a result of melting and subsequent recrystallization of oPP, the low-temperature shoulder disappears, and T_m of the remaining peak decreases (Fig. 5). A low-temperature shoulder appearing in the

endotherm of the first melting of oPP may be due to melting of linear systems in amorphous regions consisting of intrafibrillar and interfibrillar tie chains (Fig. 3b) in the maximally straightened 3_1 helical conformation characteristic of PP crystallites. In contrast to crystallites, the linear systems show no three-dimensional ordering [19, 20, 22]. The change in the shape of the oPP endothermic peak after recrystallization is probably due to the breakdown of the linear systems. This is also indicated by the shape of the oPP crystallization peak and by its T_{cr}, which is close to T_{cr} of iPP (Fig. 5).

Structural rearreangements in the course of thermal oxidation of oPP samples with different degrees of extension were monitored by XRD, DSC, and IR spectroscopy. The structural parameters of unoxidized and oxidized oPP, determined by XRD, are listed in Table 1. It is seen that, in the course of low-temperature oxidation (below the melting point of the crystallites), the major period and the degree of oPP crystallinity change insignificantly. The orientation of crystallites changes noticeably. According to the IR spectra, oxidation of oPP results in structural changes of polymeric macrochains. The following specific features of the IR spectra of oPP samples should be noted. A decrease in the intensity of bands after treatment of oPP with boiling concentrated HNO_3 shows that both bands of regular structures at 840 and 998 cm^{-1} belong to macrochains in amorphous regions. By the intensities of these bands, it is possible to monitor the variation of the content of straightened conformers in intercrystallite regions of oPP. In some experiments, to determine the content of folded conformers, we used, along with the band at 1155 cm^{-1}, also the bands at 528 and 460 cm^{-1}. We also used the bands at 945, 955, and 962 cm^{-1}, which are the low-frequency shoulders of the band at 975 cm^{-1}. These bands are sensitive to stresses and stress relaxation in intrafibrillar tie chains [25]. Wool [25] showed that the intensities of these bands are a measure of accumulation of local strains in tie chains.

An analysis of the kinetic curves characterizing variation of the intensities of these bands in the IR spectra of oPP samples with different λ in the course of oxidation showed that the physical processes accompanying the oxidation depend on the initial oPP structure and on the oxidation conditions.

Changes in the conformational compositions of chains, occurring in the course of thermal oxidation of oPP with λ = 9 under isometric conditions (l = const) and in the free shrinkage mode, are given in Table 3. As seen from these data, the observed changes depend on the oxidation mode. Oxidation of oPP in the isometric mode initially affects the rotameric composition of the chains: the content of straightened chains increases, that of folded conformers decreases, and local stresses in tie chains increase. The first trend is indicated by the rise in the intensity of the bands at 998 and 840 cm^{-1} and the decrease in the intensity of the band at 1155 cm^{-1}, and the latter trend, by growth of the bands at 945, 955, and 962 cm^{-1}. With the progress of oxidation, relaxation of stresses occurs, and the intensities of the bands at 945, 955, and 962 cm^{-1}

decrease. It should be noted that the decrease in the intensity of these bands coincides in time with the appearance of terminal >C=O groups. This process is not accompanied by noticeable changes in the isomeric composition of the chains. Only upon prolonged oxidation the chains tend to become more regular. However, this is not accompanied by accumulation of large amounts of carbonyl groups.

Oxidation under free shrinkage conditions proceeds differently. Even in the first 20 min of oxidation, the content of the regular conformers decreases drastically, and the content of folded conformers grows, with a simultaneous decrease in the stresses in tie chains (the intensity of the bands at 945, 955, and 962 cm^{-1} decreases). This is accompanied by accumulation of carbonyl-containing oxidation products. After these products are accumulated in oPP in large amounts, the local stresses in tie chains start to build up again, in proportion with [>C=O], both in the isometric oxidation mode and under free shrinkage conditions (Table 3).

Changes in the structure of the chains in the course of thermal oxidation are accompanied by changes in their orientation (Table 3). Oxidation in the isometric mode causes a certain increase in the orientation of tie chains. Oxidation under free shrinkage conditions is initially accompanied by disorientation of macromolecules (the dichroism of the bands at 840 and 998 cm^{-1} decreases), and then, by an increase in the orientation of regular chains. The XRD data indicate that the orientation of crystallites in oxidized oPP samples increases (Table 2).

Changes in the chain structure in the course of oPP oxidation depend on the initial structure of a sample. In the sample with λ = 9.5, characterized by the larger degree of extension and lower degree of folding (or by higher content of tie chains), oxidation under the same conditions in the free shrinkage mode also causes a change in the conformational composition of chains due to $T \rightarrow G$ relaxation transitions (a decrease in the content of straightened chains is accompanied by an increase in the content of folded chains). However, this transition is appreciably delayed. Instead of relaxation of stresses existing in tie chains of an unoxidized sample, stresses build up, and relaxation occurs only after oxidation for more than 50 min. This sample is also characterized by decelerated accumulation of oxidized products as compared with the sample with λ = 9. However, in this sample, too, the onset of accumulation of carbonyl groups corresponds to a decrease in stresses in tie chains and to an increase in the content of folded conformers (the intensity of the bands at 945, 955, and 965 cm^{-1} decreases, and that of the bands at 528 and 1155 cm^{-1} increases).

Experiments on heat treatment of an oPP sample with λ = 9 in an inert atmosphere, with the other conditions being the same as those in oxidation (Table 4), shows that changes in the structural features of the chains (conformational pattern and local stresses) in the initial stage are independent of the annealing conditions. In the isometric mode and under free shrinkage conditions, the orientation of chains in the crystallites (R_{840}) and the content of straightened conformers increase, whereas the content of folded

conformers decreases. Local stresses in tie chains are preserved for a long time even under free shrinkage conditions. The oxidation mode affects the orientation factor of the band at 998 cm^{-1}. In oPP annealed under free shrinkage conditions, the dichroism of this band and, correspondingly, the orientation factor drastically decrease. The orientation factor of the band at 945 cm^{-1} decreases too.

Comparison of changes occurring in the oPP structure upon oxidation and annealing under identical conditions shows that, in oxidation, the initial portion of the curves characterizing structural changes of polymeric chains reflects relaxation conformational transitions and build up of stresses in tie chains due to the effect of high temperature. The relaxation of local stresses in tie chains and the decrease in the content of straightened conformers (increase in the content of folded conformers), occurring with further progress of oxidation, are due to oxidative degradation of tie chains.

The role of oxidation in structural rearrangements is related to the dependence of the relaxation rate on the oxygen concentration. At increased oxygen pressure, the content of regular conformers in the initial stage decreases faster, and the maximally straightened chains become less oriented (the dichroism of the bands at 998 and 840 cm^{-1} decreases). Simultaneously increases the rate of accumulation of nonvolatile oxidation products.

The experimental data listed in Tables 3 and 4 illustrate the correlation between the relaxation and oxidation processes. The acceleration of structural rearrangements promotes oxidation of oPP. As shown previously, the initial rate of accumulation of >C=O groups varies in parallel with the rate of stress relaxation in tie chains. However, the concentration of products in the oriented polymer depends on the rate of chain folding ($T \rightarrow G$ transitions) and increases with decreasing content of straightened conformers; the folded conformers are consumed in oxidation. It should be noted that this dependence is determined by the initial structure of PP and, being pronounced in oriented samples, is not manifested noticeably in iPP. In further oxidation stages, as carbonyl groups are accumulated in appreciable amounts, these groups start to affect the conformational composition of the chains, their orientation, and stresses in tie chains. With increasing [>C=O], the chains become more oriented, and the stresses in tie chains grow. The IR dichroism and the orientation factors of the bands at 998, 975, and 840 cm^{-1}, as well as the intensities of the bands at 945, 955, and 962 cm^{-1}, increase.

A clearly defined correlation between the structure of the chains in various oPP samples, their relaxation characteristics, and kinetic parameters of oxidation follows from Table 5. It is seen that the relaxation processes determine not only the oxidation rate but also the composition of oxidation products. The rates of oxidation and accumulation of volatile products, and also their composition differ significantly for oPP samples that have the same degree of extension but differ in the structure of the chains or in the oxidation modes. In samples differing in the initial chain struc-

ture and oxidation conditions, the relaxation processes are different and occur at different rates. This is manifested in the kinetics of particular oxidation stages, in the contributions of the intermolecular and intramolecular chain transfers, and, as a result, in the ratios of the carbonyl and hydroxy groups and of the block and isolated hydroperoxy groups (Table 5). With respect to these ratios, the oPP samples under consideration can be ranked in the following order: **I** < **II** < **III** < **IV**.

In this order, the contribution of the intermolecular transfer of the oxidation kinetic chain grows, as indicated by an increase in the ratio of the carbonyl and hydroxy groups and in the content of isolated hydroxy groups relative to the total OH content. The first in this order is oPP sample **I** with $\lambda = 6$; in this sample, relaxation of interfibrillar chains is manifested in that the orientation factor of the band at 998 cm^{-1} decreases appreciably, and that of the band at 975 cm^{-1} increases. In sample **II** with $\lambda = 6$, these chains do not relax; sample **III** with $\lambda = 9$ is oxidized in the isometric mode when relaxation of all the chains is hindered; and sample **IV** with $\lambda = 9$ is oxidized under free shrinkage conditions.

In this connection, an important question arises: Relaxation of what chains (interfibrillar or intrafibrillar) exerts a stronger effect on the rate of the polymer oxidation? To answer this question, we annealed an oPP sample with $\lambda = 9$ at 130°C in an inert atmosphere under free shrinkage conditions. In the process, the dichroism (orientation factor) of the band at 998 cm^{-1} decreased. After annealing, the sample was divided in two portions, one of which was subjected to oxidation under free shrinkage conditions, and the other, in the isometric mode. If accumulation of solid oxidation products were mainly determined by the relaxation rate of interfibrillar tie chains, then the oxidation mode would have no effect on the rate of product accumulation. However, the oxidation in the isometric mode was actually considerably slower than that under free shrinkage conditions. In the isometric mode, high concentrations of oxidation products were not attained, in contrast to oxidation under free shrinkage conditions, which yielded significant amounts of oxidation products in a considerably shorter time.

Comparison of changes in the conformational composition of chains, which occur in these samples in the course of their oxidation, demonstrated, above all, the different changes in the local stresses in tie chains. In the IR spectrum of PP oxidized under free shrinkage conditions, in contrast to the spectrum of a similar sample oxidized in the isometric mode, the intensities of the bands at 945, 955, and 962 cm^{-1}, and also at 998 and 840 cm^{-1} rapidly decrease, as also does the dichroism of the band at 840 cm^{-1}. Taking into account the fact that the relaxation of tie chains in interfibrillar amorphous regions of both samples occurred before the onset of oxidation, we can state that the changes in the conformational pattern and in the local stresses, occurring in the course of oxidation, are associated with the relaxation processes in tie chains of intrafibrillar amorphous interlayers.

Oxidation of a similar sample after shrinkage of not only interfibrillar but also intrafibrillar chains (at 155°C, when the mobility of interlamellar chains is defrosted owing to partial fusion of crystallites) is considerably faster than oxidation after shrinkage of interfibrillar chains only.

CONCLUSIONS

(1) Structural rearrangements in the course of oxidation of an isotropic sample involve changes in the structure of both crystallites (annealing of crystallites) and intercrystallite regions (conformational transitions). The main mechanisms of structural rearrangements occurring in oriented polypropylene in the course of its oxidation are relaxation conformational transitions and relaxation of stresses in tie chains.

(2) The relaxation properties and the oxidation rate are interrelated. The oxidation rate of an oriented polymer is determined by its molecular structure and hence by the character and rate of relaxation processes that accompany oxidation. The relaxation processes, in turn, affect the oxidation kinetics.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Grafting of Glycidyl Methacrylate to Polypropylene in an Extruder, Initiated with Organic Peroxides

S. S. Pesetskii and O. A. Makarenko

Belyi Institute of Mechanics of Metal–Polymer Systems, State Scientific Institution, National Academy of Sciences of Belarus, Gomel, Belarus

Received January 8, 2002

Abstract—The efficiency of grafting of glycidyl methacrylate to polypropylene and the degree of degradation of macromolecules, evaluated from the melt flow index, were studied in relation to the structure of the peroxide initiator.

Reactive extrusion is widely used for production of a wide set of polymeric products [1]. In this process, the starting polymers are usually polyolefins, which is largely due to their availability, low cost, and wide use in engineering, and also to the possibility of controlling the physicochemical properties of the resulting materials by chemical modification. In particular, reactive extrusion is used for chemical modification of olefin polymers and copolymers and their blends by grafting polar monomers to their macromolecules with the aim to enhance adhesion or to prepare polymer–polymer systems [1, 2].

Chemical reactions in a polymer melt in an extruder occur, as a rule, by the radical mechanism [1–3]. Most often, these reactions are initiated with organic peroxides. Examples of such reactions are graftings to polypropylene (PP) of acrylic acid and its derivatives [4, 5], maleic anhydride [6–9], glycidyl methacrylate (GMA) [10–14], and oxazoline [15–20].

Under conditions of fast processes characteristic of reactive extrusion, the course of grafting and concomitant transformations are largely influenced not only by the chemical activity of a peroxide initiator, but also by its solubility in the main components of the reaction mixture: a polymer and a monomer [21, 22]. The influence of the mutual solubility of the components is particularly strong at poor mixing efficiency, which is characteristic of, e.g., single-screw mixer–extruders [21].

The influence of the peroxide structure on the kinetics of monomer grafting to PP was considered in [23]. All the peroxides used in [23] had asymmetric structure and simultaneously were monomers containing a carboxy group. Therefore, decomposition of the peroxides was accompanied by their grafting to the macromolecules. It was found that peroxides generating methyl radicals in decomposition afford higher efficiency of grafting than peroxy acids generating ethyl radicals.

In this work, we considered the specific features of GMA grafting to PP in the presence of peroxide initiators that exhibit increased affinity for the polymer. Previously [21], we showed for the example of grafting of methylenebutanedioic acid to polyethylene that such peroxides ensure the highest yield of the grafted products. With peroxides exhibiting increased affinity for the monomer, the grafting efficiency was lower.

EXPERIMENTAL

In our study, we used PP of Kaplen brand [Moscow Oil Refinery, 01030 grade, TU (Technical Specifications) 2211-015-00203521–95, density 0.905 g cm^{-3}, melting point (determined by differential scanning calorimetry) 169°C] and organic monoperoxides (*tert*-butyl peroxide, TBP; dicumyl peroxide, DCP, Orgsintez Joint-Stock Company, Russia) and diperoxides {2,5-dimethyl-2,5-di(*tert*-butylperoxy)hexane (L-101), 2,5-dimethyl-2,5-di(*tert*-butylperoxy)-3-hexene (L-130), both ELF Atochem, France; di(*tert*-butylperoxyisopropyl)benzene (Perk-14, P-14), Aldrich; 2,2-di(*tert*-butylperoxy)-5,5,6-trimethylbicyclo[2.2.1]heptane (D-1); and 2,2-di(3-methyl-1-butyn-3-ylperoxy)-3,5,6-trimethylbicyclo[2.2.1]heptane (D-2) [24]}.

The structures and properties of these peroxides are given in Table 1. The solubility parameters δ of the

L-130		15.0	10.2
P-14		16.4	9.0

peroxides were calculated, as in [21], by the method of group contributions [25, 26].

The parameters δ were calculated for 25°C (298 K). Naturally, these parameters are temperature-dependent. However, the paramaters δ of polymers and low-molecular-weight compounds vary with temperature similarly [27]:

$$\ln \delta_T = \ln \delta_{298} - \beta k(T - 298),$$

where δ_T and δ_{298} are the δ values at a temperature T and at 298 K, respectively; k the coefficient approximately equal to unity for polyolefins and 1.25 for peroxides and GMA; and β the linear coefficient of thermal expansion.

Therefore, characterization of the solubility of peroxides and GMA in PP by the solubility parameters determined for 25°C is fairly adequate. The calculated solubility parameters of PP and GMA at 25°C are 16.1 and 29.8 $(J\ cm^{-3})^{0.5}$, respectively.

As in [21], graftings were performed in a single-screw extruder (screw diameter 36 mm, L/D = 20) under the following conditions: screw rotation rate 27 rpm (shear rate about 30 s^{-1}); temperatures in zones I and II–IV 175 and 190°C, respectively.

The grafting was characterized by the grafting efficiency defined as the ratio of the grafted monomer to its total introduced amount. As in [21], the grafting efficiency α (wt %) was determined with film samples (40–60 μm thick) by IR absorption spectroscopy, using the formula

$$\alpha = \frac{D_\tau}{D_0} \times 100,$$

where D_0 and D_τ are, respectively, the optical density of the GMA carbonyl absorption band (1735 cm^{-1})

** Characteristics of vaporization and partial decomposition of TBP.

in the initial PP sample and that in the PP sample after grafting and extraction of the residual unchanged monomer with acetone at 40°C [28]. In calculations, we used as internal reference the band at 465 cm^{-1} characterizing the skeleton vibrations of PP macromolecules. The viscosity of the polymer melt was evaluated by the melt flow index (MFI), which was determined at 210°C and a load of 2.16 kg with an IIRT-AM device (Ekodatchik Private Company, Tula, Russia). Thermal decomposition of peroxides was studied with a Q-1500 derivatograph (MOM, Hungary) at a heating rate of 5 deg min^{-1} and sample weight of 100 mg. The results are given in Table 2.

The structure of functionalized PP was examined by differential scanning calorimetry with a DSM-3A microcalorimeter (Institute of Biological Instrument Making, Russian Academy of Sciences) at a sample weight of 4 mg and heating rate of 16 deg min^{-1}. The changes in the sample crystallinity were characterized by the crystallinity index, which was defined as the ratio of the crystallization peak area of the functionalized PP to that of the initial polymer. Measurements were performed with samples heated in a calorimetric cell to 190°C and kept at this temperature for 1 min.

Table 1 shows that all the chosen peroxides exhibit increased thermodynamic affinity for the polymer. Peroxides D-1, D-2, and P-14, whose solubility parameters are the closest to that of PP, must be the most soluble in PP. The solubility parameter of L-101 is also close to that of PP, which suggests good solubility of this peroxide in the polymer melt {according to [29], in the absence of strong specific interactions between solvent and solute molecules, the solvent and solute are thermodynamically compatible when their solubility parameters differ by no more than 2 $(J\ cm^{-3})^{0.5}$}. Thus, none of the peroxides is compatible with GMA.

The results of thermal analysis (Table 2) show that the chosen peroxides significantly differ in thermal stability. It should be noted that the data obtained for the solid peroxides (CDP, D-1, D-2, P-14) are more reliable: For these compounds, the temperatures of the onset and maximal rate of decomposition, determined from the DTG and DTA curves, are in good agreement. For liquid peroxides L-101 and L-130, the DTA peaks are slightly shifted to higher temperatures relative to the DTG peaks, which may be due to evaporation of the compounds. With TBP, which is highly volatile, thermal analysis does not give reliable information on decomposition. Dicumyl peroxide is the most thermally stable, and *gem*-diperoxides D-1 and especially D-2, as expected, are the least thermally stable. D-1 actively decomposes in the range 95–125°C with a maximum at 117°C (DTG data), and D-2, at 85 to 110°C with a maximum at 104°C.

Evaluation of the half-lives of peroxides in a moving PP melt subjected to shear stresses (calculated shear rate 30 s^{-1}) appeared to be impossible. However, since the temperature in the reaction zone of the extruder was as high as 190°C, and the residence time of the melt in this zone was 1.25 min, the decomposition of peroxides must be complete (cf. half-lives of the peroxides in benzene, Table 2; the half-lives must not change significantly in going from benzene to the polyolefin melt).

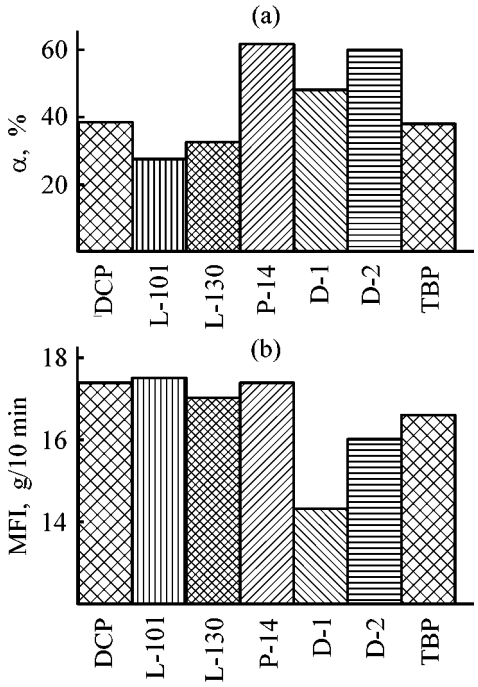

Fig. 1. Influence of peroxides on (a) efficiency of GMA grafting α and (b) melt flow index MFI of the PP-*graft*-GMA melt. Concentration, wt %: peroxides 0.2 and GMA 1.0.

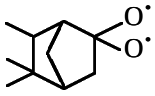
Figure 1 shows how the grafting efficiency and MFI are influenced by the structure of a peroxide. It should be noted that, here and hereinafter, experiments were performed under the same temperature conditions in the extruder. According to [22], peroxide-initiated GMA grafting is not significantly affected by temperature variation in the range 170–200°C. It is known that grafting of monomers to PP is usually accompanied by competing degradation of macromolecules. Therefore, the main problem in preparation of a functionalized polymer is to ensure the highest yield of the grafted product with the molecular weight preserved. The melt flow index directly characterizes the molecular weights of the initial and grafted (PP-*graft*-GMA) polypropylene and is very sensitive to β-cleavage of the PP chain [30].

It is known that the structure of the peroxide affects significantly the characteristics of the resulting graft copolymer. It should be noted that the highest grafting efficiencies α were obtained with P-14, D-1, and D-2, which are the most soluble in PP. With D-1 and D-2, the degree of degradation of PP-*graft*-GMA was the lowest, as judged from the lowest MFI. A somewhat lower α (and, correspondingly, higher MFI) was obtained with TBP.

The peroxides D-1, D-2, and TBP are the least thermally stable among the peroxides tested in this work; their active decomposition (onset of the exothermic peak in the DTA curve, Table 2) starts at 96, 86, and 30°C. In our procedure, the temperature in the reactant loading zone of the extruder is 175°C. In this zone, the peroxides and GMA dissolve in the PP melt, and the peroxides decompose to radicals. Because the affinity of D-1, D-2, and TBP for the polymer is higher than that for GMA, and GMA is less soluble in PP than the peroxides, the radicals, apparently, mostly attack PP macromolecules. The resulting macroradicals then react with GMA to give PP-*graft*-GMA and are involved in β-cleavage resulting in degradation of the polymer. Since the grafting efficiency is relatively low even with the least thermally stable peroxide initiator, TBP, we can assume that the arising macroradicals have a fairly long half-life (the total residence time of the reaction mixture in the extruder was 1.5 min). This result confirms the previously found possibility [21] of using peroxides with low thermal stability to initiate grafting of unsaturated monomers to polyolefin macromolecules by reactive extrusion.

tert-Butyl peroxide, being highly volatile, is partially evaporated in the extruder loading zone. Therefore, its actual concentration in the reaction zone at the beginning of grafting will be lower than that of the other peroxides. However, in decomposition of TBP, the yield of active radicals $^{\bullet}CH_3$ and $^{\bullet}OC(CH_3)_3$ is higher, compared to the other peroxides [31]. Therefore, the concentration of macroradicals will be high even in the extruder loading zone. Because GMA is relatively poorly soluble in PP, effective molecular contact of the active macroradicals with the monomer is not attained in this zone, and a significant part of macroradicals are deactivated by the β-cleavage pathway. Therefore, PP-*graft*-GMA prepared in the presence of TBP initiator apparently, has lower α and higher MFI as compared to D-1 and D-2 initiators (Fig. 1).

The different initiating activities of the *gem*-diperoxide D-2 and its saturated analog D-1 may be due to the following. Decomposition of D-1 generates a weakly active biradical



A

and two $^{\bullet}OC(CH_3)_3$ radicals whose fragmentation gives active methyl radicals $^{\bullet}CH_3$ [21, 31]. Decomposition of D-2 generates biradical **A** and two $^{\bullet}OC(CH_3)_2C{\equiv}CH$ radicals, which are less active than $^{\bullet}CH_3$ [31]. Despite the higher content of available oxygen in D-1 as compared to D-2 and formation of

more active radicals in its decomposition, the α values are higher with D-2 and the extent of macromolecule degradation is greater (Figs. 1a, 1b). This means that the chemical activity of the peroxide is not the decisive factor affecting the yield of the graft copolymer and grafted products. D-2 is better soluble in PP melt than D-1. Therefore, D-2 initiates the grafting and macromolecule degradation more efficiently than D-1. On the whole, the molecular weight of PP-*graft*-GMA decreases with D-1 and D-2 to a lesser extent than with the other peroxide initiators. This fact may be due to a reaction of tertiary PP macroradicals with biradical A, yielding inactive products.

The most active initiator of both grafting and degradation is P-14 (Figs. 1a, 1b). As compared to the other peroxides, it is better soluble in PP and more thermally stable (Table 2). The temperature interval of P-14 decomposition is the optimal for GMA grafting. The maximal amount of free radicals will be generated at the moment when PP is melted completely and the monomer is well dispersed in the melt. Hence, the solubility in the polymer and the thermal stability of a peroxide initiator are the major factors governing the GMA grafting and macromolecule degradation.

The decreased α in initiation with peroxides L-101 and L-130, which are structurally similar to P-14 (Fig. 1a), is apparently due to their lower solubility in PP. Therefore, the concentrations of the forming macroradicals are insufficient to initiate grafting, and these macroradicals are mainly consumed in β-cleavage reactions (Fig. 1b).

The yield of PP-*graft*-GMA with DCP initiator is approximately the same as that with L-101, although the content of available oxygen in DCP and the affinity of DCP for PP are lower (Table 1). Probably, these factors are compensated for by favorable features of thermal behavior of DCP. The temperature range of its decomposition, as in the case of P-14, is the optimal for grafting under our experimental conditions.

As the concentration of the peroxide initiator is increased, both α and MFI grow, with the degree of PP degradation increasing to a greater extent [30]. Under our experimental conditions (Fig. 2), the increase in the DCP concentration from 0.1 to 0.3 wt % did not cause significant changes in MFI, and α even decreased somewhat. As compared to [30], the concentration of GMA was considerably lower under our experimental conditions (1 wt % against 6–10), and the concentration of the initiator was also lower and varied within narrower limits. Figure 2 shows that initiation of grafting is the most efficient at a

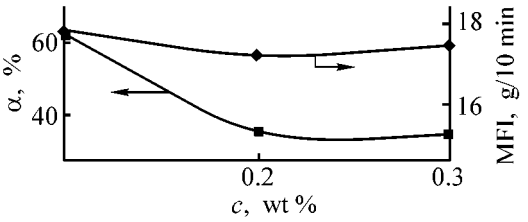


Fig. 2. Influence of DCP concentration *c* on the efficiency of GMA grafting to PP α and on the melt flow index of PP-*graft*-GMA. GMA concentration 1.0 wt %.

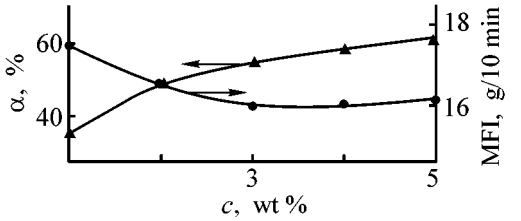

Fig. 3. Influence of GMA concentration *c* on the efficiency of its grafting to PP α and on the melt flow index of PP-*graft*-GMA. DCP concentration 0.3 wt %.

DCP concentration of 0.1 wt %. Hence, increased concentrations of the initiator are not appropriate in grafting of relatively small amounts of GMA to PP. Excess free radicals generated by decomposition of the peroxide are, probably, spent for oligomerization of ungrafted GMA occurring concurrently with GMA grafting and PP degradation [30].

With increasing GMA concentration in the reaction mixture, the grafting efficiency increased, as expected [30], and the degree of macromolecule degradation decreased (Fig. 3). However, the extent to which the monomer suppressed the degradation of macromolecules was appreciably lower than, e.g., with D-1 initiator (Figs. 1b, 3). Therefore, to obtain an optimal

5.0	0.3	165.8	117.5	48.3	0.93

ratio between grafting and chain cleavage, it is preferable to choose appropriate peroxide and take it in appropriate concentration, rather than to vary the concentration of the monomer.

Grafting of methylenebutanedioic acid to LDPE does not affect significantly the crystallinity of the polymer [32, 33]. Only at relatively high concentrations of the peroxide initiator, when functionalized polyethylene transforms into a highly viscous, partially cross-linked product, crystallization decelerates somewhat, and, according to DSC, the crystallinity decreases by 8–12%.

In contrast to polyethylene, PP undergoes degradation in the course of peroxide-initiated grafting of monomers. Taking into account the higher rate of PP crystallization and its dependence on the viscosity of the polymer melt [34], we expect that the structural changes in this polymer after grafting will be more significant. Indeed, as seen from Table 3, functionalized PP prepared by grafting of GMA exhibits higher crystallinity than the initial polymer. Only PP-*graft*-GMA prepared in the presence of 5 wt % GMA and 0.3 wt % DCP has lower crystallinity (I_{cr} = 0.93). In all the cases, grafting leads to a decrease in the melting point and an increase in the crystallization point of the polymer. The extent of variation of both parameters depends on the composition insignificantly: The difference $\Delta T = T_m - T_{cr}$, equal to 59°C for PP, varies within 46–50°C for PP-*graft*-GMA. Hence, even at the lowest peroxide concentration (0.1 wt %), the viscosity of the melt and the molecular weight of the polymer change to such an extent that the crystallization is appreciably accelerated.

The dependences of I_{cr} on the peroxide concentration pass through a maximum, or through a maximum and a minimum (Table 3). These changes are due to variations of the melt viscosity, grafting efficiency, and, probably, degree of the monomer oligomerization [10–14, 30]. The lower I_{cr} of PP-*graft*-GMA prepared in the presence of 5 wt % GMA and 0.3 wt % DCP is probably due to oligomerization of the monomer. Like other high-molecular-weight additives, oligo(glycidyl methacrylate) can prevent crystallization, affecting the mobility of macromolecules.

CONCLUSIONS

(1) To ensure high yield of the grafted product, it is appropriate to use peroxides that exhibit high thermodynamic affinity for polypropylene and decompose in the temperature range matching the temperature of reactive extrusion. These conditions are met to the greatest extent by di(*tert*-butylperoxyisopropyl)benzene.

(2) To attain the desired balance between the grafting efficiency and the degree of degradation of macromolecules, it is preferable to properly choose the peroxide and its concentration, rather than to vary the monomer concentration.

(3) Grafting of glycidyl methacrylate can be initiated with peroxides that decompose at temperatures considerably lower than the temperature in the main reaction zone of the extruder.

(4) Irrespective of the type of the peroxide, grafting of glycidyl methacrylate is accompanied by β-cleavage of macromolecules, which raises the melt flow index; this increase is significant even at a minimal peroxide concentration (0.1 wt %).

(5) Degradation of polypropylene macromolecules in the course of functionalization accelerates its crystallization from the melt (crystallization occurs at temperatures 5–8.5°C higher than the crystallization point of the initial polypropylene; the crystallinity increases by 20–60%). At high concentration of glycidyl methacrylate (5 wt %), the crystallinity of functionalized polypropylene is lower than the initial value, which is probably due to oligomerization of the monomer.

ACKNOWLEDGMENTS

The authors are grateful to A.P. Yuvchenko for placing samples of D-1 and D-2 peroxides at their disposal.

Abstract—The thermal stability and mechanical strength of composites based on ED-20 epoxy oligomer cured with isomethyltetrahydrophthalic and methylendic anhydrides was studied as influenced by the nature and properties of finely dispersed inorganic fillers, such as carbon black, aluminum oxide, and silica nanoparticles.

Modern industry requires development of new polymeric materials with specific properties, especially with enhanced strength, hardness, and heat resistance. Owing to high mechanical and adhesion characteristics and strong resistance to various solvents and aggressive solutions, composite polymeric materials based on epoxy resins are widely used in industry. These epoxy resins are cured in a wide temperature range without liberation of volatile compounds. The main disadvantage of epoxy binders is their low softening point; the strength of polymers drastically decreases on heating to temperatures close their glass-transition point.

The properties of epoxy polymers can be easily controlled both by selection of the epoxy oligomer–curing agent system and by addition of fillers [1–3]. Almost all natural and artificial materials with suitable properties, including polymers, can be used as fillers for polymeric composites. A combination of a polymer with filler allows preparation of materials with desired processability and performance. Usually, primary attention is given to the effect of fillers on the mechanical strength of polymers, but fillers also decrease the fluidity and thermal and chemical volume shrinkage, increase moldability and dimensional stability, decrease inflammability, and improve friction or antifriction, electrical, thermal, and other properties.

To find an optimal combination of the polymer and filler, it is necessary to take into account not only their nature, shape, size, and distribution of nanoparticles, but also their interaction at the interface. The chemical composition is the main characteristic of fillers, and in most cases it determines the possibility of their use. The reactivity of fillers, being the surface property directly related to the chemical composition, is of particular importance [4].

By now, various properties of filled epoxy polymer have been studied (Table 1), but primary attention was focused on coarse fillers with particle size larger than 1 μm, and at relatively high degree of polymer filling (>10 wt %).

The effect of "small addition" [10], namely, improvement of physical and mechanical properties of polymer at small and very small degrees of filling is rather promising. It was found that, upon addition of a filler, the glass-transition point of a polymer T_g may increase, and a greater increase is observed at small degrees of filling (Table 1). Very often, with increasing degree of filling the rise in T_g terminates even at very low concentrations, and it remains almost constant up to fairly high concentrations of the solid additive. The effect of "small addition" is pronounced only in the case of filling of a polymer with solid particles smaller than 1 μm in diameter (d), which follows from the data on the length of tie chains binding various supramolecular structures. The nanoparticles are accumulated in boundary sections, and thus even insignificant amounts of a solid additive can affect the flexibility of tie chains and hence the physical

and mechanical properties of the polymer. The stability of the polymer properties upon further increase in the filler content is due to the fact that additional amounts of the filler cannot penetrate into boundary regions (owing to their complete filling), and thus their effect on the already ordered structures is insignificant.

The aim of this work was to improve the thermal and mechanical properties of epoxy materials, with the low viscosity of the resin and curing agent in the uncured state preserved, because this composite is used as binder in production of glass-fiber-reinforced plastics by the winding procedure. Special attention was focused on nanosize fillers that enhance the heat resistance and strength of polymer at low degrees of filling [2, 3].

EXPERIMENTAL

In our work, we used formulations based on ED-20 epoxy–4,4'-isopropylidenediphenol oligomer, cured with isomethyltetrahydrophthalic (MTHPA) and methylendic (MEA) anhydrides and filled with K-354 carbon black (specific surface area S_{sp} = 137 $m^2 g^{-1}$, effective particle size 10–30 nm), alumina (S_{sp} = 50–70 $m^2 g^{-1}$, effective particle size 20–30 nm), and silica (S_{sp} = 40–60 $m^2 g^{-1}$, effective particle size 20–30 nm). The nanopowders of alumina and silica were prepared by an original procedure [11].

Various fillers (1–10 wt % degree of filling) were added to an epoxy binder containing (wt. parts): 100 ED-20, 80 MTHPA or MEA, 5 EDOS plasticizer, and 1.5 activator 2,4,6-tris(dimethylaminomethyl)phenol. The components were mixed at 70–90°C; filler particles were first homogenized in a low-viscosity hardener and then mixed with a resin and other components. The formulation was cured at 160°C for 3 h.

The thermal stability of the resulting composites was studied by differential thermogravimetry in the 293–1050 K range at a heating rate of 10 deg min^{-1}; the temperature was measured with an accuracy of

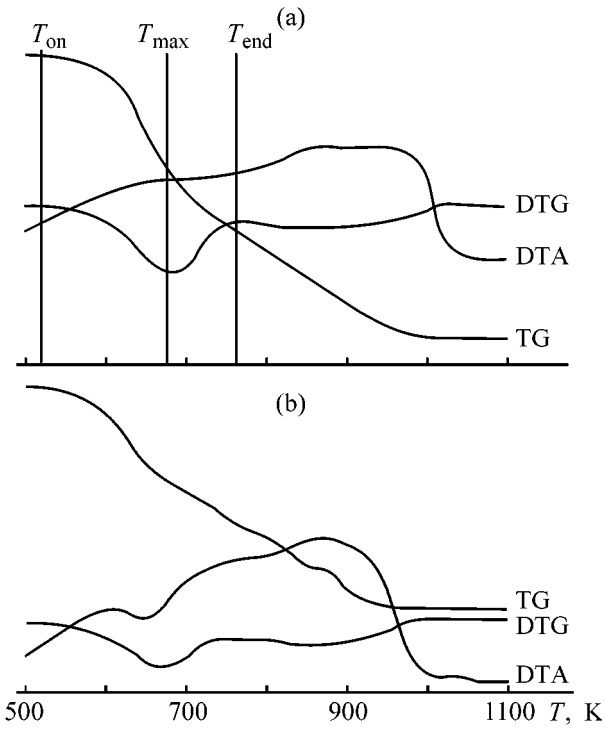

Fig. 1. Thermogravimetric curves of cured epoxy binder containing (a) no filler and (b) Al_2O_3 nanoparticles (2.5 wt %).

±0.5 deg. The samples were prepared by mechanical grinding of the cured formulations. The experimental data on the weight loss $m = f(T)$ (TG), rate of weight loss $dm/dT = f(T)$ (DTG), and thermal effects (DTA) are shown in Figs. 1a and 1b. Using these results, we calculated the reduced decomposition temperatures and evaluated the thermal stability of various materials (Table 2).

* MEA-cured polymer.

The reduced decomposition temperature T_{dec}, as a criterion of thermal stability, was calculated by the following equation:

$$T_{dec} = (1 - \alpha_{end})(T_{end} - T_{on}) + T_{on},$$

where T_{on} and T_{end} are the temperatures of the onset and end of the rapid decomposition interval corresponding to the peak in the DTG curve, and α_{end} is the weight loss at T_{end}.

More adequately, the thermal stability of a material can be evaluated by considering the TG and DTG curves in combination.

As seen from Table 2, composites cured with MEA are more thermally stable than those cured with MTHPA (the onset temperature of rapid decomposition and the reduced temperature of decomposition increase by 98 and 51°C, respectively). Fillers significantly enhance the thermal stability of the epoxy compositions. Addition of carbon (1 wt %) raises T_{dec} by 16–35°C, whereas with carbon content increasing to 5 wt %, the thermal stability of the composite slightly decreases. This is probably due to the ability of the active surface of carbon to adsorb the functional groups of the curing agent, which must participate in the oligomer hardening. As a result, defective regions appear in the cured polymer, and, thus, the thermal stability of the material decreases with increasing carbon filler content.

The tensile strength was measured on an FPZ-10 tensile-testing machine (velocity of the mobile clamp 10 mm min^{-1}) using 200 × 10 × 3 mm plate samples. The results of tests performed at various temperatures are listed in Table 3.

As seen from Table 3, the formulations cured with MTHPA have higher strength than those cured with MEA. The formulations containing 2 wt % carbon have the highest strength (at 23°C). With increasing degree of filling, the mechanical strength of this polymer becomes lower than the strength of the unfilled material by 23–32%, which is probably due to the increase in the content of defective regions as a result of adsorption of the functional groups of the hardener on the carbon surface. At 115°C, the highest strength (10 times the strength of the unfilled polymer) is typical of composites containing mixed fillers (SiO_2 + Al_2O_3 or C + Al_2O_3) or pure alumina. The observed strengthening of the structure upon addition of alumina or silica is attributable to the active surface of these oxides. The surface of alumina and silica contains hydroxy groups, which can form hydrogen bonds with the polymer molecules. As

* MEA-cured polymer.

compared with silica, the alumina surface is more active in chemical reactions with electron-donor molecules of the polymer. Along with hydroxy groups, the alumina surface can also contain other active centers, e.g., Lewis acid centers formed by coordination-unsaturated aluminum atoms. Hence, in the case of alumina, the coordination interaction between the Lewis centers and polymer molecules occurs simultaneously with the formation of hydrogen bonds. As a result, the epoxy composites filled with oxides exhibit enhanced strength at elevated temperature.

CONCLUSIONS

(1) Composites based on ED-20 epoxy resin cured with isomethyltetrahydrophthalic (MTHPA) and methylendic (MEA) anhydrides and filled with nanoparticles of carbon black, alumina, and silica were prepared. The thermal stability and mechanical strength of these materials was studied.

(2) Addition of fillers to epoxy polymer enhances its thermal stability and mechanical strength at elevated temperature.

(3) The composites containing filler (2 wt % carbon or 1 wt % silica) exhibit the highest strength at 23°C. At elevated temperatures all the fillers enhance the strength properties of the polymers, and the highest strength is observed for the materials filled with alumina, silica, and mixed fillers. Strengthening of the polymer structure upon addition of oxide fillers is due to the presence on their surface of hydroxy groups, which can form hydrogen bonds with the polymer molecules, and in the case of alumina, additional coordination bonds can arise from the interaction of the surface Lewis acid centers (coordination-unsaturated aluminum atoms) and polymer.

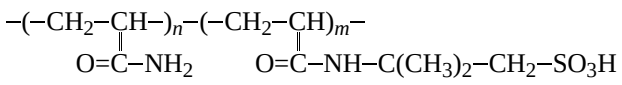
Abstract—The kinetics of radical copolymerization of acrylamide with lithium, sodium, and potassium 2-acrylamido-2-methylpropanesulfonates in concentrated aqueous solutions in the presence of potassium persulfate as initiating agent at pH 9 and 50°C was studied by dilatometry.

Owing to high hydrophilicity and high resistance to salts, hydrolysis, and heat, and also high thickening, flocculating, and structuring power, copolymers of acrylamide (AA) with salts of 2-acrylamido-2-methylpropanesulfonic acid (H-AMS)



are widely used in drilling, petroleum production, and water treatment [1, 2]. This fact, and also the observed features of radical copolymerization of the ionic monomers [3–5], which are unusual from the viewpoint of classical theory, call for development of new procedures for direct synthesis of AA copolymers with H-AMS salts with various service properties. One of the factors strongly affecting the radical copolymerization of salts of unsaturated acids in ionizing media is the kind of cation. Previously, we have studied the effect of cations on polymerization of H-AMS salts with single- [6] and double-charged [7] cations in aqueous solutions, and also on the flocculation [8] and thermal properties of the resulting polymers [9]. In this work, we studied the kinetics of radical copolymerization of acrylamide with lithium, sodium, and potassium 2-acrylamido-2-methylpropanesulfonates in aqueous solutions and the molecular properties of the resulting copolymers, as influenced by the kind of cation.

EXPERIMENTAL

In our work, we used acrylamide purchased from Mitsubishi Chem. Ind. Ltd. (Japan) (mp 84.5°C), H-AMS purchased from Lubrizol Corp. (United Kingdom) (mp 185°C), distilled water, and other chemically pure grade reagents. Lithium, sodium, and potassium 2-acrylamido-2-methylpropanesulfonates were prepared by potentiometric titration of aqueous H-AMS solutions with aqueous solution of LiOH, NaOH, and KOH to pH 9; the resulting salts were used as aqueous solutions.

The procedures of copolymerization, dilatometric measurements, copolymer isolation, and tests were presented previously in [10]. The shift of the meniscus of the reaction mixture in a dilatometer capillary in the course of kinetic measurements was monitored with a KM-8 cathetometer; the dilatometers were temperature-controlled with an E3E thermostat (Germany) with an accuracy of ±0.05°C.

The solution acidity was measured with a pH-121 pH-millivoltmeter with an ESL-63-07 working glass electrode and an EVL 1M-3 silver chloride reference electrode.

The molecular weight of copolymers M was determined from the intrinsic viscosity [η], because [η] ~ M according to the Mark–Kuhn–Houwink equation. The intrinsic viscosity [η] of copolymer solutions was measured in a 0.5 M NaCl solution at 25°C, using a VPZh-3 viscometer (d_c = 0.43 mm). The content of ionic groups in the copolymer was determined from the content of sulfur [11].

Copolymerization of AA (M_1) with Li-, Na-, and K-AMS salts (M_2) was carried out in concentrated aqueous solutions ([M_1] + [M_2] = 10–30 wt %) at

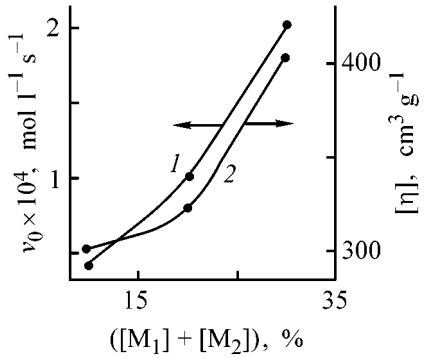

Fig. 1. (*1*) Initial rate of copolymerization of AA with Na-AMS v_0 and (*2*) intrinsic viscosity of copolymers [η] vs. concentration of the initial monomer mixture ([M$_1$] + [M$_2$]). Initial molar ratio [M$_1$] : [M$_2$] = 1 : 1.

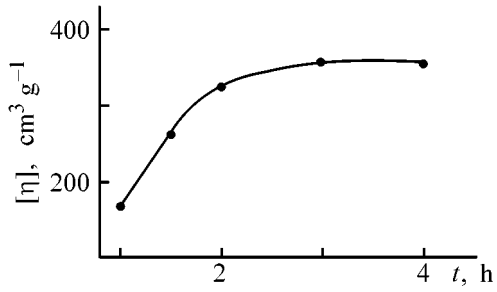

Fig. 2. Intrinsic viscosity of AA and Na-AMS copolymers [η] vs. copolymerization time. ([M$_1$] + [M$_2$]) = 15%, initial molar ratio [M$_1$] : [M$_2$] = 7 : 3, [PP] = 5.86×10^{-3} M.

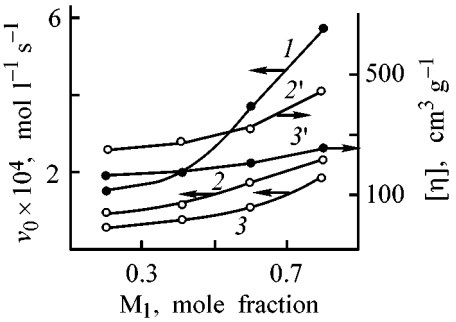

Fig. 3. (*1–3*) Initial rate of copolymerization v_0 of AA with H-AMS salts and (*2*', *3*') intrinsic viscosity of copolymers [η] vs. AA content in the initial monomer mixture M$_1$. ([M$_1$] + [M$_2$]) = 15 wt%. (*1*) Li-AMS, (*2*, *2*') Na-AMS, and (*3*, *3*') K-AMS.

pH 9 and 50°C in the presence of potassium persulfate (PP) as initiating agent. Constant pH 9 was maintained in the reaction mixture (1) to provide constant rate of initiation at solution ionic strength varying [12] as a result of changes in the concentration of the ionic monomers and of increasing conversion in the course of copolymerization, (2) to hinder hydrolysis of H-AMS salts [13], and (3) to prevent imidization of amide groups in concentrated aqueous solutions [14]. Variation of the ionic strength of solutions at changing concentration of the ionic monomer does not affect the reactivity of AA and of the corresponding propagating radical, because the rate of AA polymerization in aqueous solutions is independent of salt additions [15]. Copolymerization was carried out under homogeneous conditions, and no spontaneous polymerization was observed in the absence of the initiating agent.

First, we studied copolymerization of AA and Na-AMS as influenced by the concentration of the initial monomer mixture, which was varied within the range ([M$_1$] + [M$_2$]) = 10–30%; the initial molar ratio [M$_1$] : [M$_2$] was 1 : 1, other experimental conditions being equal. In all cases, the initial portions of the kinetic curves were linear, and, using them, we determined the initial copolymerization rates v_0 at low conversions (<3%). The kinetic curves of copolymerization, obtained by the dilatometric procedure (in a time τ = 2 h), are shown in Fig. 1. As seen, v_0 and [η] of copolymers grow with increasing ([M$_1$] + [M$_2$]) concentration in the reaction mixture, which agrees with the general pattern of radical copolymerization.

The variation of [η] in the course of copolymerization of AA and Na-AMS is illustrated in Fig. 2. The intrinsic viscosities of copolymers grow with increasing reaction time and become nearly constant at τ = 2 h; thus, in our further tests [η] was determined after a 2-h reaction.

The effect of the alkali metal cation in the H-AMS salts on their copolymerization with AA was studied at various initial molar ratios [M$_1$] : [M$_2$], ([M$_1$] + [M$_2$]) = 15%, other experimental conditions being the same. The dependences of v_0 and [η] of copolymers on the content of AA in the initial reaction mixture M$_1$ are shown in Fig. 3. In all the AA-Me-AMS systems, v_0 and [η] grow with increasing M$_1$, which suggests higher reactivity of AA in copolymerization as compared with H-AMS salts. A comparison of the experimental data at fixed [M$_1$] : [M$_2$] > 4 : 6 (Fig. 2) showed that both v_0 and [η] increase in the following order: $K^+ < Na^+ < Li^+$.

The dependences of the current composition of copolymers (conversion <3%) on the content of AA in the course of AA copolymerization with Li-, Na-, and K-AMS are shown in Fig. 4. These dependences correspond in all the systems studied to the following relative activities of the monomers: $r_1 = k_{11}/k_{12} > 1$ (for AA) and $r_2 = k_{22}/k_{21} < 1$ (for H-AMS salts),

which confirms the higher reactivity of AA in copolymerization, compared with H-AMS alkali metal salts. As seen from Fig. 4, enrichment of copolymers in AA units is observed in a wide concentration range in all the systems studied. Moreover, at fixed M_1, the content of the ionic units in copolymers increases in the order $K^+ < Na^+ < Li^+$ (Fig. 4, passing from curve *1* to curve *3*).

To explain the observed trends, let us consider the ionization equilibrium of the ionic groups of the H-AMS salts and their units in growing macroradicals in aqueous salt solutions:

$$\underset{\text{I}}{A^-X^+} \rightleftarrows \underset{\text{II}}{A^- \| X^+} \rightleftarrows \underset{\text{III}}{A^- + X^+}, \qquad (1)$$

where A^- is the anion of the monomer or macroradical; X^+ is the cation; and I, II, and III are contact ion pairs, ion pairs separated with a solvent, and free ions, respectively.

As known, the sulfonate groups in the H-AMS salts and in the units of these salts in copolymers are completely ionized in aqueous solutions. With increasing ionic strength and degree of binding of alkali metal cations with polysulfonate anions, the ionization equilibrium (1) is shifted to the left; as a result, the relative content of various ionic species with different reactivities change, and the intra- and intermolecular electrostatic interactions in the reaction system decrease. This, in turn, affects the polymerization constants and relative activities of the monomers in copolymerization, r_1 and r_2, which are actually the apparent characteristics of the process; therefore, we did not determine them.

It is known [16] that the degree of alkali metal cation binding in solutions of AA copolymers with H-AMS salts increases in the order $K^+ < Na^+ < Li^+$. In this order, the electrostatic repulsion of similarly charged monomers (H-AMS salts) and macroradicals with the terminal ionic groups decreases, which makes k_{22} and v_0 larger (Fig. 3) and causes the observed enrichment of the copolymer with ionic groups (Fig. 4) in the order $K^+ < Na^+ < Li^+$.

Contrary to the above data on copolymerization of AA and H-AMS alkali metal salts, in homopolymerization of H-AMS salts in aqueous solutions [6], v_0 varied with the cation nature in the opposite direction, namely, v_0 decreased in the order $K^+ > Na^+ > Li^+$. This can be accounted for by similar order of changes in binding of the alkali metal cations with H-AMS salt homopolymers [16]. A similar difference in the

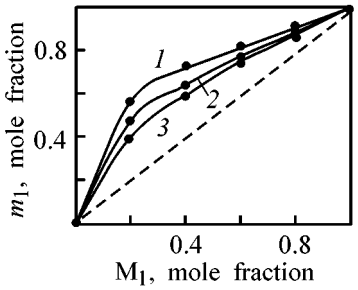

Fig. 4. Content of AA units m_1 in AA copolymer with (*1*) K-AMS, (*2*) Na-AMS, and (*3*) Li-AMS as influenced by the mole fraction of AA in the initial monomer mixture M_1. ($[M_1] + [M_2]$) = 15%; conversion <3%.

trends observed in copolymerization of H-AMS salts with *N*-vinylpyrrolidone and in homopolymerization of H-AMS salts in aqueous solutions was found in [17, 18]; for copolymerization of methyl methacrylate with lithium, sodium, and potassium methacrylates and homopolymerization of alkali metal methacrylates in methanol solutions, such a difference was observed in [19].

Thus, the kinetic parameters of copolymerization of AA with H-AMS salts of single-charged cations and the properties of the resulting copolymers can be controlled by varying the type of cation in the ionic monomer.

CONCLUSIONS

(1) The v_0 and [η] values grow with increasing concentration of the monomer mixture (acrylamide + alkali metal 2-acrylamido-2-methylpropanesulfonate) and content of acrylamide in the reaction system; v_0 increases in the order $K^+ < Na^+ < Li^+$, and [η], on passing from K^+ to Na^+ and with increasing conversion.

(2) The content of the ionic groups in the copolymers increases in the order $K^+ < Na^{2+} < Li^+$; as a result, copolymers enriched in nonionic acrylamide units are formed in all the systems studied.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Rheological Properties of Aqueous *H*-Carboxymethyl Cellulose Solutions with Various Additives

A. M. Bochek, L. D. Yusupova, N. M. Zabivalova, and G. A. Petropavlovskii

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 1, 2001

Abstract—Rheological properties of moderately concentrated aqueous solutions of carboxymethyl cellulose in the H form with various additives were studied.

It is known that carboxymethyl cellulose sodium salt (NaCMC) is readily soluble in water at a degree of substitution (DS) above 0.4. Aqueous solutions of NaCMC are used in food, cosmetic, fragrance, and textile industries, in petroleum production, and also in manufacture of detergents [1]. Heavy metal (Ag, Pb, Zr, Cu) salts precipitate NaCMC from solutions [2]. Introduction of Cr(III) into an NaCMC solution may result in the formation of a gel, in which syneresis proceeds in the couse of time [3]. With increasing Cr(III) concentration, the solution viscosity grows and cross-linking occurs.

The viscosity and structural organization of CMC solutions depend on the degree of its neutralization [1, 4, 5]. On passing from the Na to H form (HCMC), the solution viscosity increases and cross-linking occurs. Dry HCMC is insoluble in water, and its aqueous solutions can be prepared by passing NaCMC solutions through strongly acidic cation-exchange resins [1]. When an HCMS solution free from granules of a cation-exchange resin is allowed to stand at 5–10°C, gelation starts, caused by accumulation of weakly dissociated carboxy groups in the polymer macromolecules [1, 4]. The resulting HCMS gel is stable in time. We observed no syneresis or polymer degradation even after keeping an HCMC solution for a year at 5–10°C in an oxygen-free atmosphere [4]. Thus, a gel obtained from aqueous HCMC is a three-dimensional (3D) cross-linked system formed through intra- and intermolecular hydrogen bonding between the carboxy and hydroxy groups of HCMC and water molecules.

Addition of heavy metal salts to HCMC solutions initiates chemical cross-linking through carboxy groups of the polymer. It was of considerable scientific and practical interest to study the effect of various additives (heavy metal salts and weak bases and acids) on the rheological properties of aqueous HCMC solutions and also to elucidate the mechanisms of action of these additives on gelation.

Therefore, we studied in this work the features of gelation in aqueous HCMC solutions with various additives.

EXPERIMENTAL

As a starting material we used commercial NaCMC (degree of substitution DS 0.46; degree of polymerization DP_η 460). The degree of polymerization was determined viscometrically using an NaCMC solution in 6% NaOH. We used in calculations the relationship $[\eta] = 7.3 \times 10^{-3} M^{0.93}$ [1]. The degree of substitution in NaCMC was estimated from the sodium content by Eq. (1).

$$DS_{Na} = \frac{162n}{2300 - 80n}, \quad (1)$$

where n is the Na content in the polymer (wt %).

The sodium content in CMC was determined by conductometric titration with 0.1 N HCl. The degree of substitution of HCMC by carboxy groups DS_{COOH} was estimated by Eq. (2).

$$DS_{COOH} = \frac{162m}{4500 - 58m}, \quad (2)$$

where m is the carboxy group content (wt %).

The carboxy group content was determined by conductometric titration with 0.1 N NaOH. The DS_{Na} and DS_{COOH} were coincident in the CMC samples studied.

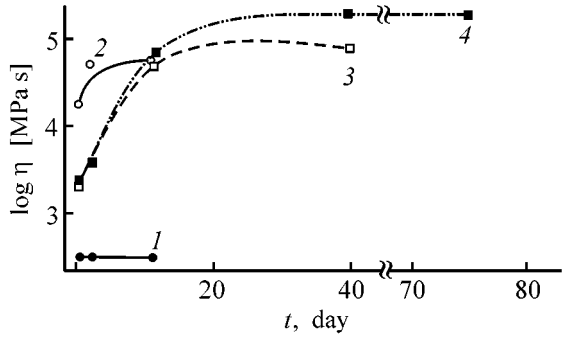

Fig. 2. Viscosity η of 3% aqueous solutions of (*1*) HCMC and (*2–4*) HCMC with various additives: (*2*) $CuCl_2$, (*3*) urea, and (*4*) boric acid vs. time *t*. Additive concentration 0.5 mol/mol COOH; log τ = 2.7.

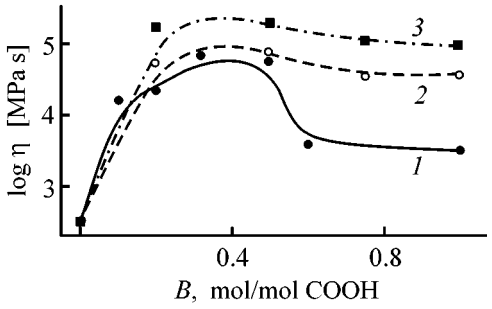

Fig. 3. Viscosity η of 3% aqueous HCMC solutions (log τ = 2.7) vs. additive concentration *B* (mol/mol COOH): (*1*) $CuCl_2$, (*2*) urea, and (*3*) boric acid. Time elapsed after solution preparation (days): (*1*) 3, (*2*) 11, and (*3*) 40.

Commercial NaCMC may contain low-molecular-weight impurities, particularly, chlorides used in cellulose carboxymethylation [1]. To remove foreign compounds, the sample was pretreated in a Soxhlet apparatus with hot 70% aqueous isopropanol for 4 h to negative reaction for chloride ($AgNO_3$) and then vacuum-dried at 50°C for 12 h. The DS_{Na}, DS_{COOH}, and DP_η were determined for thus treated samples.

The initial 3% aqueous NaCMC solution was prepared by dissolution in distilled water at room temperature with stirring for 5 h. Then the solution was filtered under pressure through a three-layer fabric (coarse calico) filter and then centrifuged for 1 h at 5000 rpm.

To convert NaCMC into the H form, we used commercial KU-2 sulfonic cation-exchange resin. A fixed amount of the resin was added to an NaCMC solution, and a mixture was stirred vigorously. In a 3% NaCMC solution the total conversion into the H form took 5 h. The resulting solution showed pH 3.0 (degree of neutralization α = 0). It preserved its fluidity for 24 h at 5–10°C, and then gelation started.

As additives to HCMC we used 20% aqueous solutions of $CuCl_2$ and urea and 2% boric acid.

The rheological properties of HCMC with various additives were studied with a Rheotest 2.1 rotation vis- cometer (cylinder–cylinder working unit) under a shear stress of 3–600 Pa. Solutions of HCMC appeared to be more cross-linked as compared to the initial NaCMC solution [4].

Figure 1 shows the flow curves of HCMC solutions containing various additives in amount of 0.5 mol/mol COOH. The curves were measured 1 h after the solution preparation. Introduction of any of the additives used induces cross-linking of the HCMC solution, considerably increasing its viscosity. The observed strong dependence of the viscosity on the shear stress is typical of thermoreversible physical gels [6] and chemically cross-linked systems [7]. After introduction of an additive with stirring, the solution viscosity increases, approaching saturation (Fig. 2). The time required for reaching the limiting viscosity is different for systems with different additives. This parameter is the highest in the case of boric acid and the lowest in the system with $CuCl_2$. Therefore, the effect of the additive content on the rheological properties of the solutions was studied after reaching the limiting viscosity, i.e., the systems with $CuCl_2$, urea, and boric acid were allowed to stand for 3, 11, and 40 days, respectively, prior to measurement.

It follows from Fig. 3 that the trend of viscosity variation with the additive concentration depends on particular additive, i.e., the additives differently interact with the polymer macromolecules.

Upon addition of $CuCl_2$ the viscosity increases up to a salt concentration of 0.5 mol/mol COOH, then decreases, and, finally, becomes constant. It is known that salts of copper, lead, and other heavy metals precipitate NaCMC from aqueous solutions [2]. At

a $CuCl_2$ concentration of up to 0.5 mol/mol COOH we did not observe noticeable turbidity. It may be suggested that the initial increase in the viscosity is due to cross-linking of the polyelectrolyte macromolecules by reaction (3):

$$\begin{aligned} &2\text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{O}-\text{H} + \text{CuCl}_2 \\ &\rightarrow \text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{O}-\text{Cu}-\text{O}-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{CH}_2-\text{O}-\text{Cell} \\ &+ 2\text{HCl}. \end{aligned} \quad (3)$$

To confirm the possibility of reaction (3), we determined the copper concentration in the systems just after addition of $CuCl_2$ in amount of 0.5 and 1.0 mol/mol COOH and 3 days after. Copper was determined [8] in the solution after removal of the precipitated polymer. The copper concentration in the solution decreased by 16.0 and 12.0%, respectively, against the initial value. Therefore, only partial chemical cross-linking by reaction (3) occurs, which is due to the fact that $CuCl_2$ is added to an acid solution, and the equilibrium is shifted to the left. Nevertheless, even partial cross-linking noticeably increases the solution viscosity.

The decrease in the solution viscosity at an additive concentration above 0.5 mol/mol COOH is accompanied by the appearance of a noticeable turbidity, which is an indication of phase separation occurring in the system as a result of either polymer precipitation in the presence of copper or syneresis of the chemically cross-linked network.

In the systems HCMC–urea and HCMC–boric acid, the viscosity reaches a maximum at an additive concentration of 0.5 mol/mol COOH and then slightly decreases.

Urea is a weak base [9]. In an acidic HCMC solution (pH 3.0) it occurs in the undissociated form, and the following reactions can take place:

$$\begin{aligned} &\text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{O}-\text{H} + \text{NH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{NH}_2 \\ &\rightarrow \text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\overset{-}{\text{O}}\text{H}_3\overset{+}{\text{N}}-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{NH}_2, \end{aligned} \quad (4)$$

$$\begin{aligned} &2\text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{O}-\text{H} + \text{NH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{NH}_2 \\ &\rightarrow \text{Cell}-\text{O}-\text{CH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\overset{-}{\text{O}}\text{H}_3\overset{+}{\text{N}}-\overset{\overset{\text{O}}{\|}}{\text{C}}-\overset{+}{\text{N}}\text{H}_3\overset{-}{\text{O}}-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{CH}_2-\text{O}-\text{Cell}, \end{aligned} \quad (5)$$

$$\text{---NH}_2-\overset{\overset{\text{O}}{\|}}{\text{C}}-\text{NH}_2\text{---}. \quad (6)$$

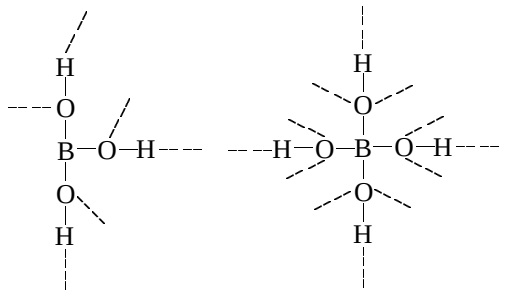
The formation of an amine salt of CMC in the reaction of HCMC with ethylenediamine (EDA) was reported in [10]. Similar reaction (4) can also proceed with urea. After formation of a film from a solution of HCMC with urea, cross-linking of the macrochains by reaction (5) may occur, as in the case of EDA [10]. Formation of H bonds between urea molecules and carboxy and hydroxy groups of the polymer (6) may also occur. It should be suggested for the system under consideration that the formation of a salt (4) and hydrogen bonding (6) are dominating processes. The formation of an H-bonded network is a slower process as compared to the chemical reaction occurring in the system with $CuCl_2$. As a result, the limiting viscosity is reached in a longer time in the systems with urea and boric acid. Reaction (5) could not be realized in this work, since it requires heating of the films formed in the system at a temperature above 100°C [10].

With the urea concentration increasing above 0.5 mol/mol COOH the viscosity decreases slightly, which can be due to the presence of free urea capable of forming additional H bonding, thus stabilizing the system and decelerating the syneresis. Among other factors is dilution of the solution, i.e., decrease in the polymer concentration. Generally, formation of additional H bonds makes the solution more viscous, and a decrease in the polymer concentration, less viscous. We observed no syneresis in the system with urea even after its being kept for more than 40 days, which suggests that this system is a mixture of the amine salt of CMC, stabilized through H bonds, with water molecules also involved in H bonding.

Introduction of boric acid into HCMC solutions increases the solution viscosity up to the additive concentration of 0.4–0.5 mol/mol COOH. With the additive concentration increasing further the viscosity decreases slightly. In this case, the polyacid (HCMC having $K \approx 5.0 \times 10^{-5}$ [1] is close to acetic acid in strength) reacts with even weaker boric acid ($K_1 = 6.0 \times 10^{-10}$, $K_2 = 5 \times 10^{-13}$, and $K_3 = 4 \times 10^{-14}$ [11]). In aqueous solutions, boric acid occurs as a weakly dissociated hydroxide, $B(OH)_3$. It was suggested also that boric acid can form a donor–acceptor bond with one water molecule, giving rise to one more boron hydroxide species [11]:

$$H_2OB(OH)_3 \rightleftarrows H^+ + [B(OH)_4]^-.$$

The occurrence of weakly dissociated boron hydroxide species $B(OH)_3$ and $[B(OH)_4]^-$ in HCMC solutions suggests that the increase in the HCMC solution viscosity and its cross-linking are caused by formation of a 3D H-bonded network, in which the indicated boron hydroxide species serve as network points, i.e., H bonds are formed between the OH groups of boron hydroxide and COOH and OH groups of the polymer. One of the possible models for H bonding is presented below.



It should be pointed out that introduction of aqueous boric acid in a solution of the stronger acid, HCMC, shifts the equilibrium of $[B(OH)_4]^-$ formation to the left. Therefore, involvement of this form of boron hydroxide in H bonding is hardly probable. Hydrogen bonding can involve both protons and oxygen atoms of ionic boron species. The process is kinetically controlled, and the limiting viscosity is reached in 40 days. The resulting gel is quite stable, and no syneresis is observed. As in the case with urea, no considerable decrease in the viscosity was observed with the boric acid concentration increasing above 0.5 mol/mol COOH. This can be interpreted as follows. Occurrence of free boric acid in the system increases the density of H bonds, which must increase the solution viscosity. The observed insignificant decrease in the viscosity is probably due to dilution of the polymer solution as a result of addition of a dilute boric acid solution (2 wt %).

Finally, introduction of $CuCl_2$ in HCMC solutions initiates gelation by the mechanism of chemical cross-linking at the carboxy groups with Cu^{2+} ions. In the course of time, the gel undergoes syneresis. In the system with urea, the gelation mechanism includes formation of CMC amine salt and a 3D H-bonded network. In the case of boric acid, gelation proceeds through H bonding. Gels formed in the systems with urea (weak base) and boric acid (weak acid) are stable in time (no syneresis). Therefore, an increased viscosity of HCMC solutions and cross-linking of HCMC-based systems can be achieved by various methods, which expands the potentialities of their practical use as thickeners. Weak bases and acids can be used to obtain stable HCMC-based gels, depending on a field of application.

CONCLUSIONS

(1) Rheological characteristics of moderately concentrated solutions of H-carboxymethyl cellulose can be modified with additives of various natures.

(2) Introduction of $CuCl_2$ into HCMC solutions initiates formation of a chemically cross-linked gel, which undergoes syneresis.

(3) Introduction of weak base or acid into HCMC solutions increases the viscosity as a result of formation of a 3D H-bonded network with participation of water molecules.

(4) Aqueous HCMC solutions modified with various additives can be used to prepare stable gels.

Abstract—The genetic relationship of quinoline and isoquinoline compounds present in semicoking tars of Kimovsk lignites (near-Moscow fields) with the initial vegetable material is discussed. Transformation pathways of the native compounds in the course of lignite formation are suggested.

Recently there has been a considerable progress in detailed studies of biological markers bearing information about the initial biomaterial, primary sedimentation, and hence about further diagenesis and catagenesis. Such studies formed a new direction in geoorganic chemistry. Alkaloids form one of the most important groups of lignite biomarkers. Structural studies of individual nitrogen-containing heterocycles isolated from lignites give insight into their genesis. Extensive data have been obtained [1] on the composition of various extracts and tars formed in low-temperature semicoking of lignite from the Kimovsk open pit, near-Moscow fields.

It was found that the major organic bases of semicoking tars (SCTs) are nitrogen-containing heterocycles boiling below 300°C (wt % of fraction): pyridine (1.2), C_1-alkylpyridines (2.1), C_2-alkylpyridines (5.8), C_3-alkylpyridines (6.5) >C_4-alkylpyridines (8.9), alkylquinolines (5.0), alkylisoquinolines (10.4), hydrogenated quinolines (10.2), polycyclic aromatic compounds (5.5), indoles (5.6), alkylindoles (5.4), C_3-alkylindoles (5.0), >C_4-alkylindoles (1.2), carbazoles (3.9), and hydrogenated benzopyrroles (12.3).

The share of quinoline and isoquinoline derivatives in nitrogen-containing compounds is fairly high; therefore, it seemed of interest to study the genesis of these structures in the organic matter of lignites (OML). A detailed study of organic bases from lignite SCT by IR, UV, ^{1}H NMR, and ^{13}C NMR spectroscopy, cryoscopy, preparative thin-layer chromatography, GC–MS, and elemental and quantitative functional analyses allowed identification of compounds **I**–**XXVII** characterizing structural fragments of OML and elucidation of the features of nitrogen distribution (see scheme 1).

Scheme 1.

In this connection, it was necessary to pay attention to biomarkers that give insight into the relationship between the nitrogen-containing lignite fragments and the biological material. Structures **I**–**XXVII** in OML should be associated with vegetable alkaloids, because so strong enrichment of the initial organic matter with oxygen-containing and alkyl groups by other pathways of biogeochemical degradation seems improbable. Alkaloids occur most widely in Angiospermae, especially in *Papaveraceae*, *Ranunculaceae*, *Leguminosae*, *Rubiaceae*, *Solanaceae*, and some other families. In algae, fungi, mosses, ferns, and Gymnospermae, alkaloids occur relatively seldom; therefore, as noted in numerous papers [2], the content of heterocyclic nitrogen in sapropelic caustobioliths is relatively low. The fact that alkaloids are distributed among botanic families nonuniformly gives reason to consider them as fairly selective biological markers. It should be noted that the group of quinoline and especially isoquinoline alkaloids is characterized by the largest number of representatives and diversity of their structures. This is confirmed by a large content of quinolines and isoquinolines in SCT [1].

To reveal a genetic relationship between this group of nitrogen-containing compounds and natural alkaloids, we performed their structural classification based on the structure of the heterocycle. Structures **I**–**XVII**, **XIX**, and **XX** were classed with the quinoline series; structures **XVIII**, **XXV**, and **XXVI**, with the isoquinoline series; **XXI**–**XXIII**, with the quinazoline series; and structure **XXVII** belongs to belong to the group of natural alkaloids of the quinolizidine series.

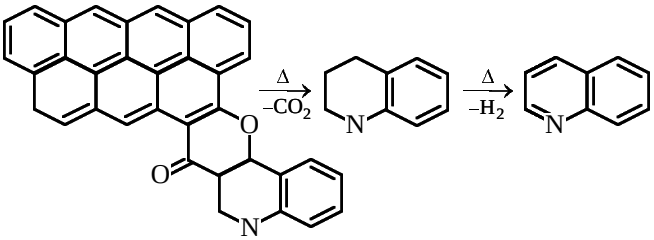
Distribution of various groups of alkaloids in the biological material

Plant family	Quinolines	Isoquinolines	Quinazolines	Quinolizines
Rutaceae	+	+	++	
Rubiaceae	++	+		+
Papaveraceae		++		
Ranunculaceae		+		+
Acantaceae		+	+	
Leguminosae		+		++
Chenopodiaceae		+		+
Berberidaceae		+		+
Solanaceae		+		+
Menispermaceae		+		+
Fungi producing alkaloid precursors in OML		+	+	+

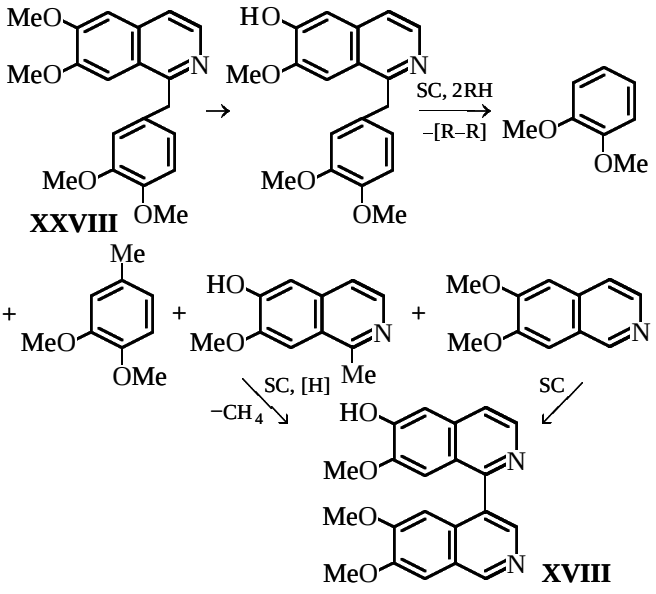
A comparison of the molecules isolated from OML with various natural compounds allowed the former compounds to be classed with biomarkers of the second kind, in which the thermodynamically stable molecular core is preserved, but substituents have underwent changes in the course of biogeochemical transformation of the organic matter of the initial vegetable material, or in the course of semicoking (SC). The structures of the organic bases allow fairly accurate identification of families, genera, and even species of plants from which lignite was formed (see table).

A large number of quinolines and isoquinolines are produced by the *Rutaceae*, *Rubiaceae*, *Leguminosae*, and *Solanaceae* families. Alkaloids of the quinoline series occur in almost all the families, but in *Papaveraceae* their content is the highest. The theory of the biological conservatism of plants gives grounds to state that evolutionary precursors of these plant families were involved in the primary sedimentations. Also, a very important part in the stage of peat genesis was played by fungi which produced various aliphatic amines and polypeptides. Under the action of microbial enzymes, these compounds transformed into various nitrogen-containing heterocycles, including those of the classes under consideration.

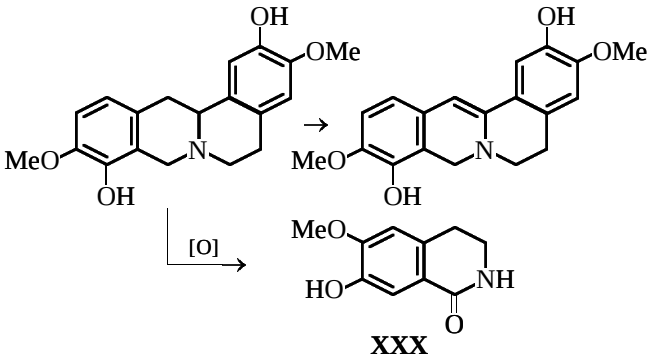
The preservation of the quinoline and isoquinoline cores in OML is due to their fairly high thermodynamic stability. It has been noted that these structures are linked to the peripheral part of the coal macromolecular network; however, owing to increased stability, they are also involved in formation of the polymeric core of a caustobiolith macromolecule. That is why data on recovery of nitrogen-containing heterocycles by nondestructive methods (e.g., extraction) are scarce [1]. A large number of such structures, detected in SCT, were released in the course of thermal degradation of the polymeric matrix. For example, the following mechanism can be suggested for formation of quinoline in pyrolysis of coal:



Quinolines formed in thermal degradation of caustobioliths and occurring in the nature contain, as a rule, a reduced (di- or tetrahydro) heteroring. This fact gives grounds to state that, in chemical transformations occurring in the course of semicoking or of biosynthesis in the initial vegetable material, isoquinolines are formed by decarboxylation of aromatic amino acids, many of which have been identified in aqueous extracts of coals. One of the major producers of isoquinolines in the modern flora is the *Papaveraceae* family. Representatives of this family contain such alkaloids as, e.g., morphine, codeine, papaverine, etc. One of possible pathways of biochemical transformations of native compounds is as follows:



Papaverine **XXVIII** undergoes enzymatic demethoxylation. In the course of semicoking, one phenyl radical undergoes radical elimination, and two isoquinoline fragments are coupled to form product **XVIII** identified in SCT. In the course of biogeochemical and subsequent thermochemical transformations, such a structure can be yielded by degradation of polymethylene bridges in such compounds as salsoline (*Solanaceae*) and laudanine (*Papaveraceae*). It has been found previously [3] that the organic matter of some lignites contains isoquinoline lactams (isoquinolones), which are presumably formed by amination in aqueous solutions of the corresponding isocoumarins. Substituted isoquinolones were also isolated from SCTs of lignites from the near-Moscow fields. The involvement of plants producing alkaloids in the primary sedimentation suggests that isocoumarin lactams could also be formed by oxidative degradation of the corresponding substituted isoquinolines. For example, skulerine **XXIX**, which belongs to the subclass of diisoquinolines occurring mainly in the *Papaveraceae*, *Menispermaceae*, and *Berberidaceae* families in both hydrogenated and dehydrogenated forms, gives hydrogenated isoquinolone **XXX**:



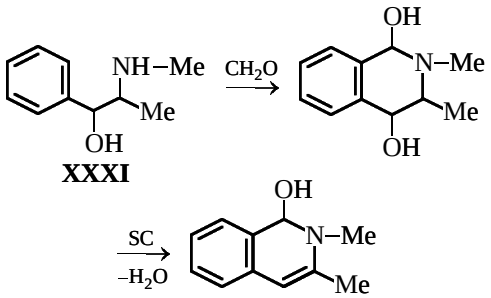
XXX

Hydrogenated rings in nitrogen-containing alkaloids can act as hydrogen donors in various coal treatment processes. Correspondingly, the higher the content of hydrogenated isoquinolines in OML, the more facile is the destructive thermal hydrogenation of this caustobiolith.

A more detailed comparative analysis of the chemical structures identified in SCT showed that the nitrogen-containing organic bases in OML do not always correspond to the natural isoquinoline and quinoline alkaloids; hence, biogeochemical transformation does not always account for the formation of particular structures in the organic matter of a caustobiolith.

It is widely believed that alkaloids are formed from amino acids under the action of microbial enzymes in the stage of peat genesis. Changes in the composition of the organic matter initially buried in sediments and the degree of decomposition of the organic matter supplied to the sediments will depend on the extent and nature of microbial activity [2]. Microbial oxidation can cease in any stage, and the selective effect of microorganisms can result in concentration of biologically more stable organic residues and of nitrogen-containing heterocyclic systems. Enzymes are either accumulated in the organic matter, increasing its weight, or favor transformation of organic substances into water-soluble or colloidal forms. Thus, isoquinolines of OML can be formed *in vitro* from the corresponding amino acids containing a phenylethylamine residue under the action of various microbial enzymes. It is believed that an important part is played in the process by formaldehyde (the primary product of CO_2 assimilation), which acts as a methylating and ring-closing agent, as shown for isoquinolines. Furthermore, in the course of lignite formation, isoquinolines can also be formed from acyclic alkaloids. This group of alkaloids consists of aliphatic amines formed in the course of life activity of fungi (degradation of polypeptide fungal toxins) in the peat genesis stage.

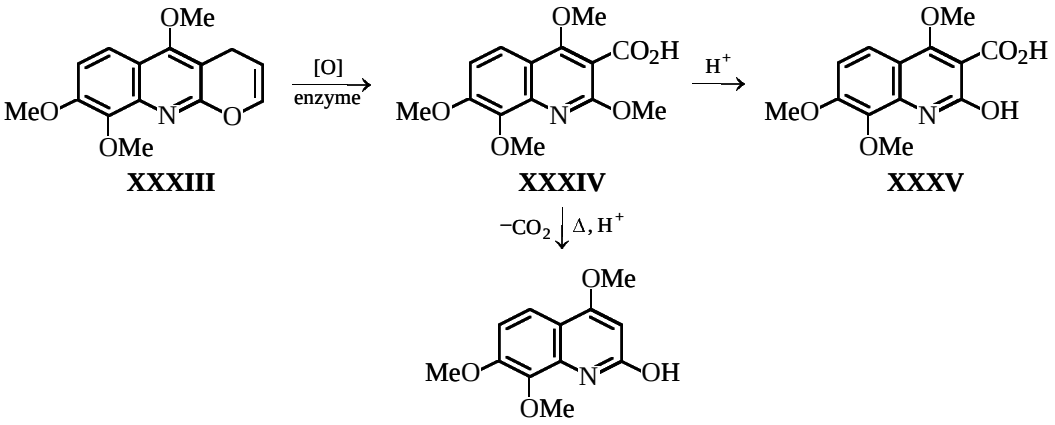
Gymnospermae can also be involved in OML formation. Below we show as example the scheme of formation of isoquinoline **XXXII** from ephedrine **XXXI**, suggesting participation of coniferous plants in primary sedimentation. As far as modern coniferous plants are concerned, ephedrine was isolated from plants of the *Ephedra* (*Gnetaceae* family) genus and from *Taxus laceata* (*Taxaceae*). The reaction occurs *in vitro* and is effected by enzymes:



XXXI

XXXII

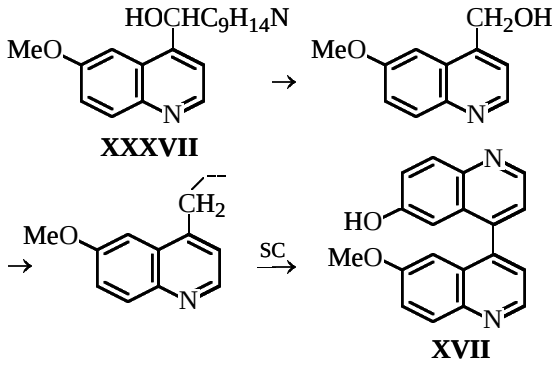
It is important that, as compared to isoquinolines, quinoline alkaloids are considerably less abundant in the flora and occur in a very narrow group of families. For example, two structurally related alkaloids, skimmianine and dictamnine, have been isolated from two closely related *Rutaceae* plants, namely, *Skimmia japonica* and *Dictamnus albus* [4]. Below is given the scheme of biogeochemical transformations of skimmianine **XXXIII** under conditions of lignite formation:



XXXIII **XXXIV** **XXXV** **XXXVI**

The reaction occurs via skimmianic acid **XXXIV** and yields two substituted isoquinoline structures **XXXV** and **XXXVI**, identified in lignite SCT.

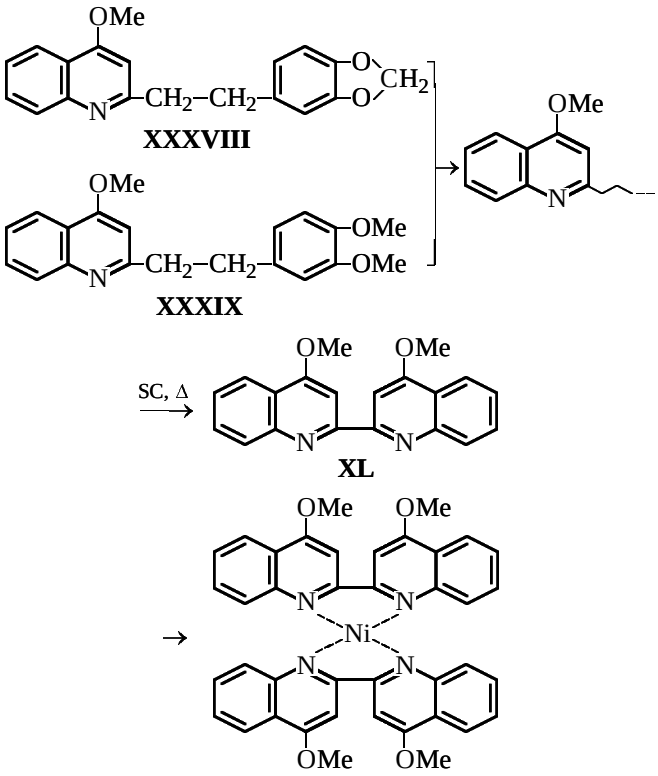
It is interesting that more than half of natural compounds containing a quinoline core belong to the group of quinine alkaloids, which is inherent in certain species, namely, *Cinchona* and *Remija* (*Rubiaceae* family). Presumably, the evolutionary precursors of these species, producing a large number of quinine alkaloids (quinoline group), such as cinchonine, quinine, quinidine, hydrocinchonine, hydroquinine, hydroquinidine, homoquinine, quinallene, aricine, cusconine, paricine, etc., could be the suppliers of aromatic and hydroaromatic substituted isoquinolines to OML. Below is given the scheme of possible biogeochemical transformations of quinine **XXXVII**:



XXXVII **XVII**

The first stage of microbiological degradation of quinine is accompanied by elimination of the quinuclidine core. After that, the structure becomes incorporated via the methylol substituent in the periphery of the lignite macromolecular network. In the course of SC, the quinoline fragments may undergo radical coupling to give structure **XVII** identified in SCT of near-Moscow lignites.

Of particular interest is formation of substituted 2,2'-biquinoline **XL**. Firstly, this structure was presumably formed from the natural quinolines cusparine **XXXVIII** and galipine **XXXIX**, which are produced in the modern flora by *Calipea cusparia*:



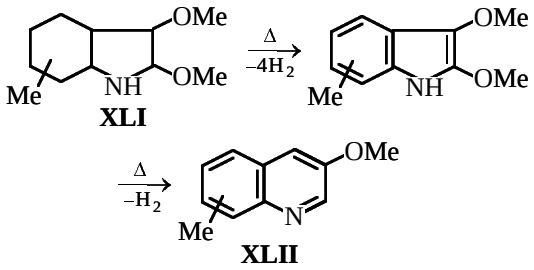
XXXVIII **XXXIX** **XL**

After structures **XXXVIII** and **XXXIX** become incorporated in the lignite matrix via alkyl radicals in 2-position, the 2,2'-biquinoline structure is formed by free-radical thermochemical degradation. Under the conditions of degradation of the polymeric molecule, two molecules of such a dimer react with the mineral matter of coal to form chelates with various metals.

For example, a similar nickel complex **XII** was identified in SCT. Presumably, nickel and other elements pass into such chelates from metal porphyrins, which results in metal migration in the course of thermochemical reactions.

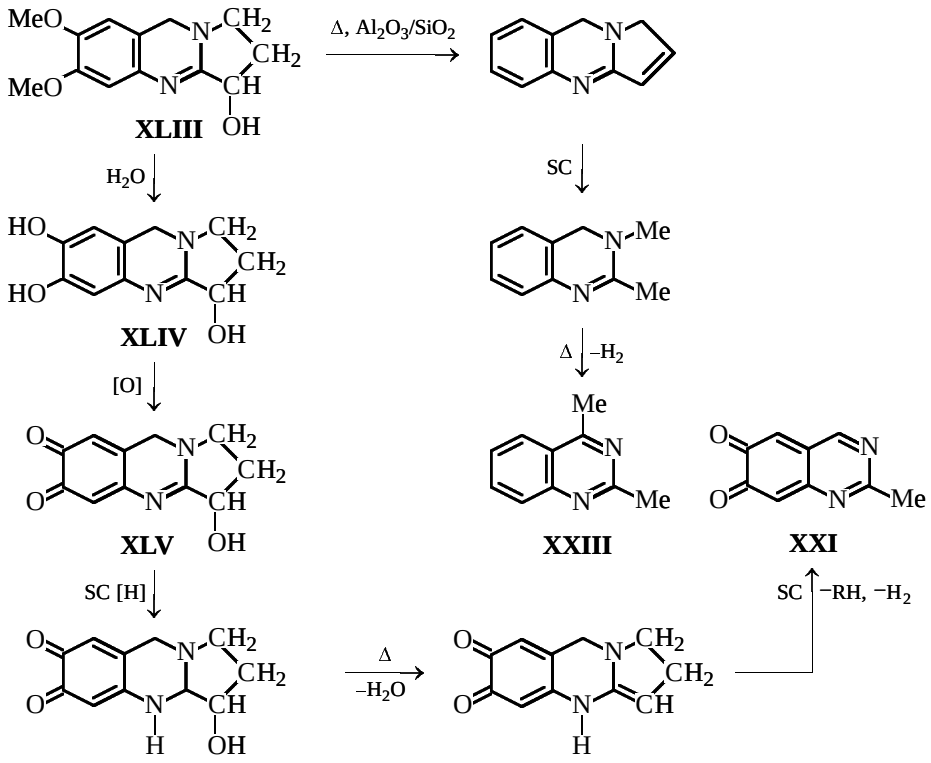
Secondly, some authors note that 2,2'-biquinoline is formed in 15% yield by heating of quinoline with nickel on alumina at 325°C. Thus, the quinoline dimer is synthesized either from molecules that have been already eliminated from the matrix or from biogeochemically transformed quinoline alkaloids conserved in lignite pores.

Detailed analysis also reveals inconsistency between the relatively small number of natural quinoline alkaloids and fairly large number and diversity of nitrogen-containing organic bases incorporating the quinoline core. This fact is attributable to the formation of quinolines, similarly to isoquinolines, from amino acid residues in the biochemical stage *in vitro* of lignite formation under the action of enzymes. Also, as noted in [5], pyrolysis of lignite SCT is accompanied by ring extension: The content of nitrogen atoms incorporated in six-membered aromatic heterocycles increases, whereas the content of five-membered rings decreases. Hence, one of the pathways of thermochemical transformations of nitrogen is the formation of six-membered heterocycles in general, and of quinoline cores in particular. For five-membered heterocyclic systems, ring extension under conditions of thermal degradation of lignites is quite possible. The scheme of thermochemical transformation of indoles **XLI** into quinolines **XLII** is shown below:



Compounds structurally similar to **XLII** were identified in lignite SCT in a fairly large amount. Thus, a significant part of quinolines could be formed from indole compounds in the course of semicoking. Furthermore, these reactions are promoted by carbonyl compounds whose content in primary tars is fairly high, because the caustobiolith under consideration has a low degree of metamorphism and high degree of oxidation (with oxygen mainly occurring in keto and quinoid groups). Taking into account the degree of metamorphism of caustobiolith, we find that the

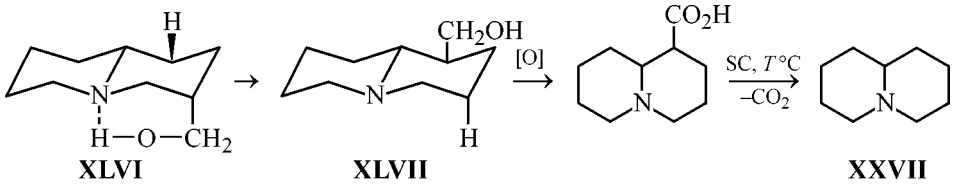
Scheme 2.



yield of indoles from coals is considerably higher than that from lignites, i.e., indoles exhibit increased thermodynamic stability. Comparison of the compositions of SCTs from coals and lignites shows that the content of quinolines in coals is higher than that in lignites, which confirms the assumption that quinolines are formed from substituted indoles. This assumption is also supported by the fact that indole alkaloids prevail in modern flora, and isoquinolines are present in a considerably smaller amount, being produced by a fairly narrow group of plants. It is significant that indoles are produced in large amounts by fungi; therefore, we can make an important conclusion that substituted quinolines originate from the activity of fungi that produce indole compounds undergoing subsequent thermochemical transformations.

Structures **XXI**–**XXIII** in OML are attributable to participation of plants producing a relatively small group of quinazoline alkaloids in the primary sedimentation. These compounds are produced by *Acanthaceae* and *Rutaceae* plants; also, they are microbial metabolites. For example, peganine (vasicine) **XLIII** was isolated from two species, *Peganum harmala* and *Adhatoda vasica*. The process can occur by two different pathways yielding structures **XXI** and **XXIII**. The pathway of formation of *o*-quinoid compound **XXI** is of particular interest. Vasinine, most probably, undergoes enzymatic hydroxylation in the *o*-position in the stage of peat genesis to form structure **XLIV**, which is oxidized by atmospheric oxygen under aerobic conditions with the participation of bacteria, yielding quinone **XLV**. It was noted previously that the introduction of hydroxy groups into an aromatic substrate is effected by bacteria of the genera *Pseudomonas* and *Nocardia*, and also by *Aspergillus niger* fungus (see scheme 2).

Quinolizine compounds **IV**, **VII**, and **VIII** are still more specific alkaloids than quinazolines. The involvement of the biological material producing compounds of this class is responsible for the presence in the organic matter of near-Moscow lignites of substances with structure similar to **XXVII**. The quinolizine core usually occurs in alkaloids in the fully reduced quinolizidine form, e.g., in *Leguminosae* family and in lupines, in particular. When heated in aromatic hydrocarbons, lupinine **XLVI** isomerizes in the course of enzymatic processes into epilupinine **XLVII**:



XLVI **XLVII** **XXVII**

This fact suggests that the primary alcoholic group in lupinine occurs in the less sterically favorable axial position owing to hydrogen bonding. The hydrogenated quinolizidine rings are hydrogen donors in thermal transformations of OML; therefore, the presence of structures similar to **XXVII** in the organic matter positively affects various processes of coal treatment.

CONCLUSIONS

(1) A genetic relationship was revealed between quinolines and isoquinolines detected among organic bases of semicoking tars of near-Moscow lignites, on the one hand, and vegetable alkaloids and fungal metabolites, on the other.

(2) Pathways of possible biogeochemical transformations of the initial nitrogen-containing compounds in the course of lignite formation and semicoking were suggested.

Synthesis of $Ce_4MnO_x \cdot nH_2O$ Layers on Silica Gel Surface by Ionic Layer Deposition

V. P. Tolstoi

St. Petersburg State University, St. Petersburg, Russia

Received November 29, 1999, in final form, July 2000

Abstract—The possibility of synthesizing $Ce_4MnO_x \cdot nH_2O$ nanolayers on silica gel surface by ionic layer deposition was examined. The layers synthesized were studied by X-ray photoelectron spectroscopy, UV-Vis diffuse reflection spectroscopy, and powder X-ray diffraction.

According to [1–3], nanolayers of metal oxides and hydroxides can be synthesized on solid surfaces by ionic layer deposition in two ways. In the first case, a layer of adsorbed cations is oxidized to higher oxidation states to form compounds significantly less soluble at pH values in use (scheme I). In the second, cations are converted to more difficulty soluble peroxide compounds (scheme II). For example, nanolayers of hydrated CeO_{2+x} have been synthesized previously [1] by oxidation of an adsorbed layer of Ce^{3+} ions to Ce^{4+}.

The aim of this study was to synthesize nanolayers of hydrated double cerium manganese oxide by ionic layer deposition according to scheme I. These oxides are widely used as solid electrolytes with oxygen conductivity, adsorbents, catalysts, etc.

EXPERIMENTAL

As reagents in the synthesis, we used $CeCl_3$ and $KMnO_4$ aqueous solutions with KOH added to pH 9–10. The Ce(III) → Ce(IV) oxidation in a layer of an adsorbed hydroxide was assumed to be effected by MnO_4^- ions, which also form upon reduction a poorly soluble compound incorporated in the layer. The working concentration of the reagents was selected on the basis of the data [3] on MnO_2 nanolayer synthesis by ionic layer deposition. Merck 60 silica gel with specific surface area of 360 $m^2\ g^{-1}$, average pore size of 12 nm, and granulometric composition of 0.2–0.63 mm was used as a support. To carry out the synthesis, a 0.5-g weighed sample of silica gel was placed in a beaker containing 200 ml of a $CeCl_3$ solution. The solution with silica gel was kept for 30 min with intermittent stirring and, after the sedimentation of silica gel particles, the excess amount of the solution was decanted. Then silica gel was washed four times by decanting with distilled water, the contact time being in each case 5 min. Then 200 ml of $KMnO_4$ (KOH) solution was poured in the beaker and the mixture was kept for 30 min with intermittent stirring. After sedimentation of silica gel particles, the excess amount of the solution was removed. Then the silica gel sample was decanted with distilled water four times.

One treatment sequence of this kind constituted a single cycle of ionic layer deposition resulting in the formation of a nanolayer of synthesized compound on the silica gel surface. Subsequent layers were synthesized by multiple repetition of elementary ionic layer deposition cycles.

The layers synthesized were studied by diffuse reflection (DR) spectroscopy in the UV and visible spectral regions, X-ray photoelectron spectroscopy (XPS), and powder X-ray diffraction. Diffuse reflection spectra were recorded on a Perkin–Elmer Lambda-9 spectrophotometer (scan rate 50 nm min^{-1}, slit program 2 nm). X-ray photoelectron (XP) spectra were obtained on a Perkin–Elmer 5400 spectrometer, using Mg_{K_α} line as exciting radiation. The quantitative content of each element of the layer was determined with an accuracy no worse than 10%. The X-ray diffraction patterns of silica gel samples with layers synthesized were obtained on a DRON-3.0 diffractometer (Cu_{K_α} radiation).

As follows from the diffuse reflection spectrum (Fig. 1), a strong absorption band in the range of 300–

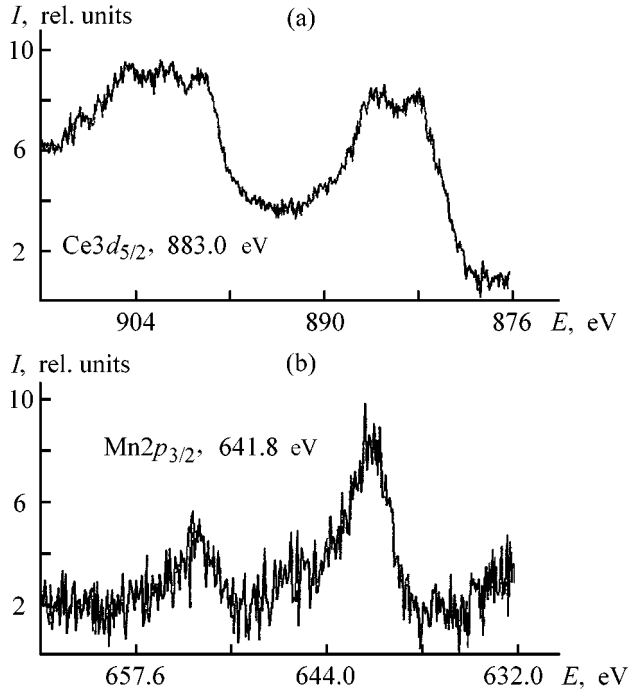

Fig. 2. XPS spectrum of a $Ce_4MnO_x \cdot nH_2O$ layer synthesized by 10 ionic layer deposition cycles on silica gel surface. (*I*) Intensity and (*E*) bond energy. Range: (a) Ce and (b) Mn.

400 nm appears after the first ionic layer deposition cycle. Subsequent cycles result in an increase in its intensity approximately in proportion to the number of ionic layer deposition cycles, and a weaker band appears in the range 450–600 nm. Unfortunately, it was impossible to construct quantitative dependences of the optical density (absorption) on the number of ionic layer deposition cycles, because adequate quantitative models for diffuse reflection spectra are presently available only for the concentrations of substances under study that are much less than those corresponding to one monolayer thickness. However, the spectra obtained, taken together with ellipsometric data for Mn-containing layers [3], suggest that the thickness of the layers synthesized grows stepwise with increasing number of ionic layer deposition cycles.

As for the composition of the layer synthesized, comparison of its spectrum with that of an MnO_2 layer (Fig. 1, spectrum *5*) synthesized by ionic layer deposition [3] shows that it contains no manganese(IV) ions which are characterized by a broad absorption band in the range 400–800 nm.

A more detailed information on the composition of the layer synthesized was obtained from an XP spectrum (Fig. 2). Indeed, manganese is characterized by a peak at 641.8 eV, corresponding to $2p_{3/2}$ electrons of Mn(III) [4]. Cerium has a peak at 883.0 eV, which is difficult to assign owing to the lack of reference data on Ce(IV) compounds. However, the data of [4] allow us to state that this peak does not refer to Ce(III). At the same time, the ratio of the intensities of Ce and Mn bands is, with regard to the experimental error, 4 : 1, which indirectly confirms the presence of cerium in oxidation state +4, because the transition $Mn(VII) \rightarrow Mn(III)$ requiring four electrons is clearly identified in the layer of adsorbed ions on the surface upon synthesis. If the Ce/Mn ratio is four, these four electrons can be provided by a one-electron reaction $Ce(III) \rightarrow Ce(IV)$ and the above-mentioned peak corresponds to Ce in oxidation state +4.

Thus, the surface reactions can be described by the following schemes. Treatment of silica gel with a $CeCl_3$ solution and removal of the excess amount of the solution with water lead to replacement of chlorine ions by hydroxide in the layer of adsorbed cerium ions to form a hydrate–hydroxide cerium complex $\equiv Si–OH \cdot Ce(OH)_3$ or a $\equiv Si–OCe(OH)_2$ complex. This scheme is confirmed by the absence of chlorine bands in the XP spectrum. Further, cerium(III) reacts with a $KMnO_4$ solution to give cerium(IV) and manganese(III), and a new poorly soluble compound is formed. Cerium(IV) and manganese(III) hydroxides and oxides are known to be difficulty soluble at pH corresponding to this synthesis, and, thus, an equilibrium in solutions is shifted toward their formation on the surface in the form of a layer. The only problem in this scheme is the mechanism of transition of four electrons from cerium(III) to the permanganate ion, because the probability of simultaneous transition of four electrons is extremely low. However, a step-by-step transition can be assumed: an intermediate

adsorbed complex of MnO_4^- is first formed with one adsorbed cerium(III) ion, then with two cerium(III) ions, etc. A hydrate–hydroxide complex of Mn(III) bound with four hydrate–hydroxide complexes of Ce(IV) located at vertices of a tetrahedron or a square is likely to be formed in the last stage of such a reaction. The formation of such a complex is quite probable from the steric viewpoint. If ionic layer deposition is repeated many times, a layer of proportionally greater thickness is formed on the surface. According to the XRD data, a layer of this kind, synthesized by ten ionic layer deposition cycles, is X-ray amorphous. Apparently, such a layer contains water molecules and hydroxide ions in addition to Ce and Mn ions. Consequently its formula can be written as $Ce_4MnO_x \cdot nH_2O$. Unfortunately, we are presently unable to determine the amounts of oxygen atoms and water molecules in a layer, owing to its small thickness.

CONCLUSION

Successive and multiple treatments of silica gel surface with $CeCl_3$ and $KMnO_4$ (KOH) solutions, carried out by ionic layer deposition, results in the formation of a $Ce_4MnO_x \cdot nH_2O$ surface layer. The thickness of this layer is determined by the number of ionic layer deposition cycles.

Abstract—Separation of a mixture of naphthalene derivatives by reversed-phase high-performance liquid chromatography with UV detection was studied. Chromatographic characteristics were calculated for nine compounds, including naphthalene.

Naphthalene and its derivatives are intermediates in the synthesis of organic dyes, medicines, and surfactants; they also serve as auxiliary agents in the industry of polymeric materials. Many of these compounds are toxic, and some of them are carcinogenic [1]. This necessitates permanent monitoring of these compounds in production zones and the environment.

Certain naphthalenes can be determined by spectrophotometric, chemiluminescent, and chromatographic methods [2–9]. Among these methods, high-performance liquid chromatography (HPLC) seems the most promising, as it affords analysis of multicomponent mixtures of various naphthalene derivatives.

This work is aimed at studying the conditions of separation of a mixture of nine derivatives of naphthalene, having different functional groups, in methanol and water by reversed-phase HPLC with UV detection.

EXPERIMENTAL

We carried out chromatographic studies at room temperature on a Milikhrom-1 chromatograph with UV detector and a steel column (64 × 2 mm) packed with Separon C18 sorbent. The column efficiency was 2100 TP for naphthalene. The measurements were made on the optical density scale 1.6 – 0.4 at λ = 280 nm. This wavelength allowed detection of all the components under study. We injected methanolic (1 μl) and aqueous (10 μl) solutions of the components. As mobile phase served methanol and a water–methanol mixture in a micropump chamber; the methanol concentration in water was 50, 60, 80, and 100 vol %. The eluent flow rate was 100 μl min^{-1}, and each run took 15–25 min.

The optimal conditions of separation were elucidated with an artificial mixture of straight substances prepared by mixing 1 mg ml^{-1} methanolic solutions of the components. To this end, we used nine compounds of naphthalene series: naphthalene, α-naphthol, β-naphthol, α-naphthylamine, 1,5-dihydroxynaphthalene, 1,7-dihydroxynaphthalene, 1,5-dinitronaphthalene, 2-nitroso-1-naphthol, and disodium 1,5-naphthalenedisulfonate.

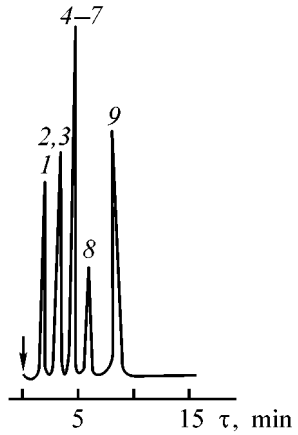

Fig. 1. Chromatogram of a mixture of naphthalene derivatives. Eluent methanol, wavelength 280 nm, flow rate 200 μl min^{-1}. (τ) Time. The *figures at peaks* correspond to the compound nos. in the table; the same for Fig. 2.

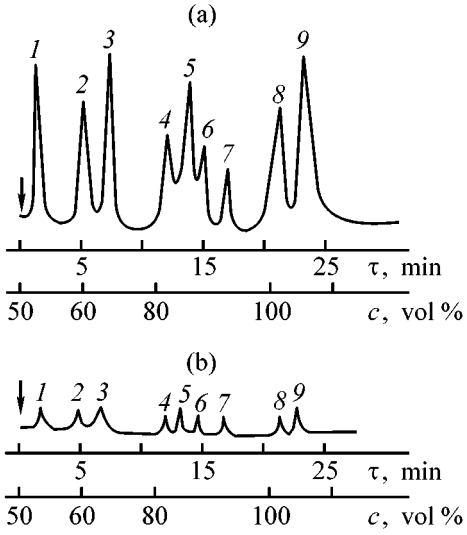

Fig. 2. Chromatograms of (a) naphthalene derivatives in methanolic solution and (b) water with added naphthalene derivatives. Eluent aqueous solution of methanol, wavelength 280 nm, eluent flow rate 100 μg min^{-1}. (τ) Time, and (*c*) methanol concentration in water, vol %.

Our study showed that exhaustive separation of the mixture components cannot be achieved with methanol (100%) as eluent (Fig. 1). Hence, we used as mobile phase for mixture separation methanol–water mixtures containing 50, 60, 80, and 100 vol % methanol (Fig. 2a). The peaks were identified by the retention time of individual compounds; for compounds with close retention times we used the method of additives. Based on our data on separation of methanolic solutions, we calculated the following chromatographic characteristics of the compounds under study: reduced capacity coefficients k', selectivity with respect to adjacent component pairs α, and their resolution R_s [11] (see table).

Parameters of chromatographic separation of naphthalene derivatives*

Compound no.	Compound	τ, min	$k' \pm 0.11$	$\alpha \pm 0.07$	$R_s \pm 0.21$
1	Disodium 1,5-naphthalene-disulfonate	1.33	0.25	16.33	1.96
2	1,5-Dihydroxy-naphthalene	5.47	4.16	1.46	1.02
3	1,7-Dihydroxy-naphthalene	7.50	6.07	1.87	2.08
4	2-Nitroso-1-naphthol	13.12	11.38	1.08	0.75
5	α-Naphthylamine	14.06	12.26	1.12	0.67
6	β-Naphthol	15.62	13.74	1.14	0.84
7	α-Naphthol	17.66	15.66	1.34	2.39
8	1,5-Dinitro-naphthalene	23.34	21.02	1.07	1.63
9	Naphthalene	24.91	22.50	–	–

* τ_m = 1.06 min is the dead time of the column.

To elucidate the chromatographic behavior of a mixture of the compounds studied in water, we also prepared an artificial mixture. The concentration of each component in the mixture was 0.4 μg ml^{-1}; for disodium 1,5-naphthalenedisulfonate and naphthalene it was 0.1 μg ml^{-1}. The sensitivity of the instrument was increased to a maximum, so that the noise level did not prevent detection of the signal to be measured. The chromatogram of this mixture is shown in Fig. 2b. As seen, it is feasible to determine certain naphthalene derivatives in water in concentrations of 0.1–0.4 μg ml$^{-1.}$ The root-mean-square deviation is no greater than 12%.

CONCLUSIONS

(1) The chromatographic characteristics, namely, reduced capacity coefficients, selectivity with respect to adjacent component pairs, and their resolution, were determined by reversed-phase high-performance chromatography for nine compounds of the naphthalene series, including unsubstituteed naphthalene.

(2) Conditions of chromatographic separation of these compounds in aqueous medium were chosen, and the detection limit of individual components was estimated at 0.4 μg ml^{-1}; for disodium 1,5-naphthalenesulfonate and naphthalene this concentration is 0.1 μg ml^{-1}.

Abstract—The electrochemical dissolution of molybdenum and tungsten in a 0.5 M solution of sodium sulfate at various temperatures was studied. The conditions of the efficient recovery of molybdenum from the binary metal system Mo–W were determined.

In modern lamp manufacturing, molybdenum core is removed from incandescent bodies by chemical dissolution of molybdenum from the binary metal system Mo–W. The tungsten loss during molybdenum dissolution should not exceed 5% [1]. The etching solution contains 56% nitric acid and 78% sulfuric acid at a volume ratio of 1 : 3 [1]. The chemical dissolution is environmentally hazardous process yielding strongly acidic solutions containing approximately (wt %) 1.6–3 Mo(VI), 18 H_2SO_4, 8 HNO_3, SO_2, and nitrogen oxides. The Mo(VI) concentration in washing solutions attains 8 mg l^{-1} against maximum permissible concentration of 0.0012 mg l^{-1}. This level cannot be ensured by purification of wastewater.

In [2], we proposed to use the anodic dissolution of molybdenum instead of chemical dissolution. The dissolution of molybdenum in salt solutions is intense [3, 4]. At the same time, the rate of the anodic dissolution of tungsten is considerably lower.

In this work, we studied the conditions of the preferable dissolution of molybdenum from the binary metal system Mo–W in sulfate solutions. For this purpose, the anodic dissolution of molybdenum and tungsten in a 0.5 M solution of sodium sulfate was studied at various temperatures.

EXPERIMENTAL

The specific features of the anodic dissolution of molybdenum and tungsten were studied by voltammetric method using a YASE–2 temperature-controlled glassy three-electrode cell with separated electrode spaces. The working electrodes were prepared from molybdenum wire. Platinum auxiliary electrode and silver chloride reference electrode were used (all potentials are given relative to this electrode).

The electrochemical study was performed in the potentiodynamic mode with a PI-50-1 potentiostat and a PR-8 programmer. The curves were recorded with ENDIM, Kh-306, and Kh-307/1 two-coordinate recorders.

The temperature in the electrochemical cells and electrolyzers was maintained at a prescribed value with liquid and air laboratory thermostats.

Measurements were performed in a 0.5 M solution of Na_2SO_4. Chemically pure reagents and distilled were used. Prior to the experiment, the electrodes were trimmed with a no. 0 abrasive paper and washed in the electrolyte to be tested.

The steady-state potential of molybdenum in a 0.5 M Na_2SO_4 solution was 0.121 V. When the potential was changed from the steady-state potential to +1.5 V with a scanning rate from 10 to 100 mV s^{-1}, the maximum of the anodic current was observed on the corresponding voltammograms, depending on potential scan rate V_{sc} (Fig. 1a). With growing V_{sc}, the current peak potential shifts to the anodic region, and the peak current increases. At the polarization varied in the opposite direction, no current maximum

1070-4272/02/7504-0662 $27.00 © 2002 MAIK "Nauka/Interperiodica"

was observed. The shape of the obtained voltammograms suggests occurrence of processes limiting molybdenum dissolution [3, 5]. Among possible processes are formation of sparingly soluble compounds on the electrode surface (passivation) or impeded removal of the reaction products (diffusion) into the solution [5].

With the temperature increased to 60°C at a constant scan rate V_{sc}, the peak current increases and the peak potential is shifted (by 0.15–0.2 V) toward negative potentials. The currents corresponding to the inverse branches of the voltammograms also increase with temperature.

The voltammograms on tungsten have two current peaks at all scanning rates V_{sc} (Fig. 1b). This shows that at least two stages control the process. The current peaks were also observed on the inverse branches of the voltammograms. With the temperature raised to 60°C at a constant scanning rate, the peak currents grow by an order of magnitude and the peak potentials are shifted toward negative potentials.

The comparison of the peak currents for anodic dissolution of Mo and W showed that the rate of the anodic dissolution of molybdenum considerably exceeds that of tungsten. In the case of molybdenum, the dissolution is limited by liquid diffusion, and in the case of tungsten, by formation of passivating oxide film on the electrode (solid diffusion). The results of the study are in agreement with the data of [6, 7].

Using the data obtained, we calculated the efficiency coefficients of the anodic dissolution of molybdenum at various potentials and temperatures by the formula

$$K_{ef} = i_{Mo}/i_W,$$

where i_{Mo} and i_W are the densities of the anodic dissolution currents of Mo and W, respectively, at the same potential.

The results obtained are plotted in Fig. 2. As seen, with increasing temperature the efficiency coefficient of the anodic dissolution of Mo decreases. It is the most promising to recover molybdenum from the binary metal system Mo–W at 20°C and at potentials within 0.7–0.9 V.

The results of the study were tested on incandescent bodies anodically polarized under the steady-state conditions. It was shown that the surface of the tungsten helices obtained meets the regulations.

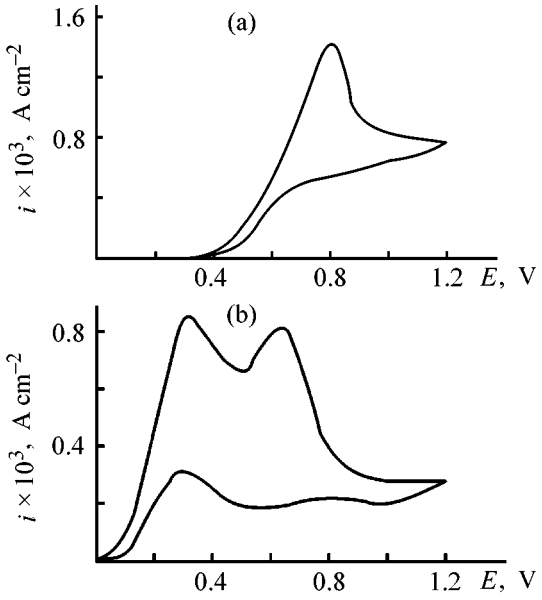

Fig. 1. Volt–ampere curves on (a) molybdenum and (b) tungsten in a 0.5 M Na_2SO_4 solution. Potential scanning rate 10 mV s^{-1}, temperature 20°C. (i) Anodic current density and (E) potential.

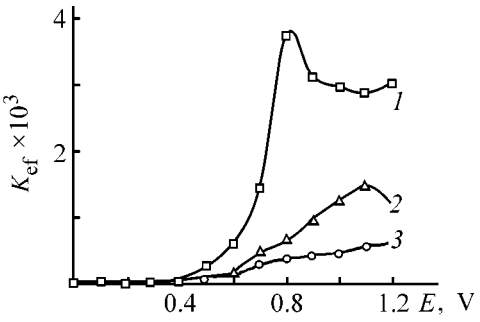

Fig. 2. The efficiency coefficient K_{ef} of the anodic dissolution of molybdenum vs. potential E. Temperature (°C): (*1*) 20, (*2*) 40, and (*3*) 60.

CONCLUSIONS

(1) The study of the effect of temperature on the rate of the anodic dissolution of molybdenum and tungsten in a 0.5 M Na_2SO_4 solution showed that for tungsten the dissolution rate depends on temperature to a considerably greater extent than for molybdenum.

(2) The efficiency coefficient of the anodic dissolution of molybdenum as a function of potential was determined at various temperatures. The efficiency of molybdenum dissolution is the highest (K_{ef} = 4000) at 20°C and a potential of 0.8 V.

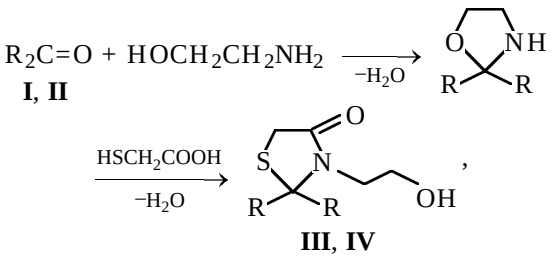
Abstract—A one-pot procedure was developed for synthesis of *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones in 64–68% yield by reactions of monoethanolamine with carbonyl compounds and mercaptoacetic acid. The synthesized compounds were characterized by IR and ^{1}H NMR spectra, and their anticorrosive properties were studied.

Nitrogen-containing alcohols and some sulfur-containing organic compounds are known to exhibit anticorrosive properties [1–3]. In this work, we prepared, with the aim to reveal anticorrosive properties of other amino alcohol derivatives, a series of substituted *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones and studied them as inhibitors of carbon dioxide and hydrogen sulfide corrosion of steel. One of routes to *N*-(2-hyroxyethyl)-1,3-thiazolidin-4-ones is reaction of oxazolidinies with mercaptoacetic acid [4]. Oxazolidines are, in turn, prepared by condensation of carbonyl compounds with 1,2-amino alcohols [5–7]:



I, **II** **III**, **IV**

where R = H (**I**, **III**): R + R = $(CH_2)_5$ (**II**, **IV**).

With this synthesis scheme, the yield of *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones **III** and **IV** is 62–63% [4]. The initial oxazolidines were prepared from monoethanolamine and the corresponding carbonyl compounds in 90–94% yield [6, 7].

In this study, we examined the possibility of combining in one-pot synthesis the stages of preparation of oxazolidines and their subsequent transformation into *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones.

When developing the synthesis procedure, we took into account the conditions under which the separate stages were performed in [4, 6, 7]. We used benzene as solvent. Condensation of monoethanolamine with carbonyl compounds **I** and **II** was performed by refluxing an equimolar mixture of the reactants, with azeotropic distillation of water. After the release of water was complete, a stoichiometric amount of mercaptoacetic acid was added, and the mixture was refluxed until the release of the next portion of water was complete.

The yield of *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones **III** and **IV** under these conditions was 70 and 68%, respectively. The yield of thiazolidinones is the highest at the equimolar ratio of monoethanolamine and carbonyl compounds. With 10% molar excess of the carbonyl compound, the yield decreased by 6–10%, and with 10% molar excess of monoethanolamine, it decreased by 20–25%.

To evaluate the inhibiting power of **III** and **IV**, we studied their effect on steel corrosion under conditions simulating steel corrosion in petroleum production [8].

The anticorrosive activity was evaluated gravimetrically with St. 3 steel samples of size 2 × 20 × 6 mm, according to GOST (State Standard) 9.505–86, in a 1% NaCl solution saturated with CO_2 in the presence of hydrogen sulfide. Tests were performed at 20, 40, and 60°C for 3 h. At a 10^{-3} M concentration of **III** or **IV** and varied temperature, we obtained the following protective effect *Z* (%): **III**, 95.9 (20°C), 80.5 (40°C), and 45.5 (60°C); **IV**, 96.3 (20°C), 83.3 (40°C), and

1070-4272/02/7504-0665 $27.00 © 2002 MAIK "Nauka/Interperiodica"

62.7 (60°C). Thus, search for new corrosion inhibitors among thiazolidinone alcohols shows much promise.

EXPERIMENTAL

In syntheses, we used commercial paraform (99.3% purity), cyclohexanone, monoethanolamine, and mercaptoacetic acid, which were purified by distillation to the main substance content of no less than 99.8%.

N-(2-Hydroxyethyl)-1,3-thiazolidin-4-one III. A mixture of 30.5 g (0.5 mol) of monoethanolamine, 15.1 g (0.5 mol) of paraform, and 100 ml of benzene was refluxed with a Dean–Stark trap until the release of water was complete. Then, 46.1 g (0.5 mol) of mercaptoacetic acid was added, and the mixture was refluxed until the release of water was complete. The mixture was cooled and distilled to give 47.9 g (65%) of **II**; bp 176–178°C at 3 mm Hg; mp 63–64°C. IR spectrum (thin film, ν, cm^{-1}): 1630 (C=O), 3300 (OH). ^{1}H NMR spectrum ($CDCl_3$, 90 MHz), δ, ppm: 3.49 t (2H, NCH_2), 3.56 d (2H, SCH_2CO, ^4J 1.4 Hz), 3.76 t (2H, OCH_2), 4.0 s (1H, OH), 4.54 d (2H, SCH_2N, ^4J 1.4 Hz).

Found, (%): C 40.97, H 6.03, N 9.28, S 21.63.

Calculated, (%): C 40.80, H 6.16, N 9.52, S 21.78.

N-(2-Hydroxyethyl)-1-thia-4-azaspiro[4.5]decan-3-one IV was prepared similarly from 30.5 g (0.5 mol) of monoethanolamine, 49.1 g (0.5 mol) of cyclohexanone, and 46.1 g (0.5 mol) of mercaptoacetic acid. Yield 73.5 g (68%); bp 200–203°C at 2 mm Hg; mp 86–87°C. IR spectrum (thin film, ν, cm^{-1}): 1630 (C=O), 3420 (OH). ^{1}H NMR spectrum ($CDCl_3$, 90 MHz), δ, ppm: 1.08–1.79 m [10H, $(CH_2)_5$], 3.44 t (2H, NCH_2), 3.50 s (2H, SCH_2CO), 3.74 t (2H, OCH_2), 4.08 s (1H, OH).

Found, (%): C 55.63, H 7.88, N 6.55, S 14.99.

$C_{10}H_{17}NO_2S$.

Calculated, (%): C 55.78, H 7.96, N 6.51, S 14.89.

CONCLUSIONS

(1) Conditions were found for one-pot synthesis of *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones from monoethanolamine, carbonyl compounds, and mercaptoacetic acid. The product yield is higher than that in the two-stage synthesis with intermediate isolation of oxazolidines.

(2) The protective effect of *N*-(2-hydroxyethyl)-1,3-thiazolidin-4-ones against carbon dioxide and hydrogen sulfide corrosion of steel reaches 96%.

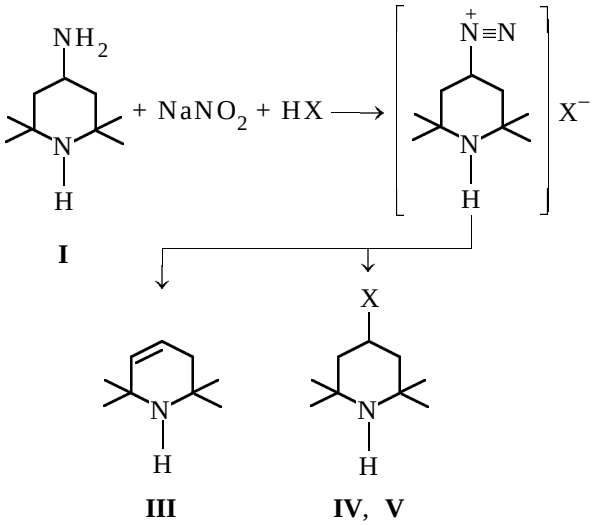
South-Russian State Technical University (Novocherkassk Polytechnic Institute), Novocherkassk, Rostov oblast, Russia

Received October 29, 2001; in final form, January 2002

Abstract—Diazotization of 4-amino-2,2,6,6-tetramethylpiperidine in acetic or sulfuric acid affords 2,2,6,6-tetramethyl-1,2,3,6-tetrahydropyridine in high yield. Under the same conditions, the corresponding nitroxyl radical transforms into 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl.

Recently, there has been much interest in synthesis of 2,2,6,6-tetramethylpiperidine derivatives, which are widely used for stabilization of polymers and monomers against light and heat [1, 2]. In this work, we studied the synthesis of nitroxyl radicals and sterically hindered amines by diazotization of 4-amino-2,2,6,6-tetramethylpiperidine **I** and 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl **II**. Compound **I** is commercially available and is used for production of polymer photostabilizers.

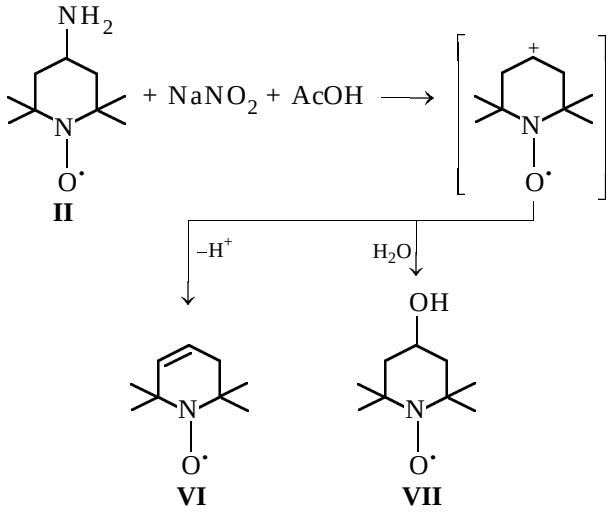
Diazotization of **I** in the presence of HCl or HBr gave 1,2,5,6-tetrahydro-2,2,6,6-tetramethylpyridine **III** in 80% yield. Under these conditions, 4-chloro-2,2,6,6-tetramethylpiperidine **IV** or 4-bromo-2,2,6,6-tetramethylpiperidine **V** is formed in 10–15% yield, along with **III**.



where X = Cl (**IV**), Br (**V**).

The best result was obtained when diazotization was performed in the presence of acetic or sulfuric acid (yield of **III** 90%). This is due to the fact that the acetate and sulfate ions are less nucleophilic than the chloride and bromide ions. Thus, the proposed reaction can be used for preparing **III**. Oxidation of **III**–**V** with hydrogen peroxide in the presence of Na_2WO_4 yields the corresponding nitroxyl radicals [3].

Of particular interest is diazotization of 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl **II**:



This reaction cannot be performed in the presence of mineral acids, as the radical center decays under these conditions [4]. However, the reaction can be performed in the presence of 30% acetic acid, which leaves the radical center intact. The nitroxyl group strongly affects the reaction course. The yield of **VI** is as low as 10% (cf. **III**), and the major product (80% yield) is 4-hydroxy-2,2,6,6-tetramethylpiperi-

1070-4272/02/7504-0667 $27.00 © 2002 MAIK "Nauka/Interperiodica"

dine-2-oxyl **VII** (cf. **IV** and **V**). Probably, the reaction pathway depends on the basicity of the initial substances. With **I**, elimination of N_2 and HX is the prevailing process.

When diazotization of **I** is performed in glacial acetic acid, the only reaction product is 4-acetylamino-2,2,6,6-tetramethylpiperidine **VIII**. Compound **II** is also acylated with glacial acetic acid at room temperature; the yield of 4-acetylamino-2,2,6,6-tetramethylpiperidine-1-oxyl **IX** is 95%. According to [5], 2,2,6,6-tetramethylpiperidine derivatives are only acylated with acetic anhydride.

EXPERIMENTAL

2,2,6,6-Tetramethyl-1,2,5,6-tetrahydropyridine III and 4-chloro-2,2,6,6-tetramethylpiperidine IV. To a solution of 7.8 g (0.05 mol) of amine **I** in 10 ml of water, 9 ml of HCl (ρ = 1.19 g ml^{-1}) was added. Then, a solution of 5.2 g (0.075 mol) of $NaNO_2$ in 10 ml of water was added dropwise with stirring. In the course of the reaction, the pH was maintained within 3–5 by adding aqueous HCl (1 : 1). After the reaction was complete, the mixture was alkalized first with K_2CO_3 and then with KOH to pH 10–12, after which it was extracted with benzene (3 × 10 ml). The benzene extracts were combined, the solvent was evaporated, and the residue was distilled under atmospheric pressure. Yield of **III** 5.5 g (80%), bp 143–145°C (cf. bp 145–146°C [3]). The residue was recrystallized from methanol. Yield of colorless crystalline compound **IV** 0.9 g (10%), mp 37–38°C; the compound was identified using a mixing test with an authentic sample [6].

When the reaction was performed in HBr, the yield of **III** was 80%, and that of 4-bromo derivative **V**, 10%; mp 43–45°C (from methanol; cf. mp 44–45°C [6]).

2,2,6,6-Tetramethyl-1,2,5,6-tetrahydropyridine-1-oxyl VI and 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl VII. To a solution of 8.5 g (0.05 mol) of **II** in 40 ml of distilled water, 20 ml of glacial acetic acid was added, the mixture was cooled to 5°C, and a solution of 6.4 g (0.075 mol) of $NaNO_2$ in 20 ml of water was gradually added. The resulting mixture was stirred for 2 h, alkalized with a KOH solution to pH 10–11, and extracted with benzene (3 × 50 ml). The benzene extracts were combined, the solvent was removed, and the residue was treated with hexane (50 ml). Compound **VI** passed into hexane, and compound **VII** remained in the residue. After removal of the solvent, 0.9 g (12%) of **VI** was obtained; mp 34–35°C (cf. mp 33°C [3]). The insoluble product **VII** was purified by column chromatography (l = 50 cm, r = 1.5 cm, sorbent Al_2O_3, Brockmann grade II, eluent CH_2Cl_2). Yield of **VII** 6.8 g (80%). The mixing test with an authentic sample gives no depression of the melting point [3].

4-Acetylamino-2,2,6,6-tetramethylpiperidine-1-oxyl IX. To 30 ml of glacial acetic acid, we added with stirring 2.6 g (0.015 mol) of radical **II**. The stirring was continued for 1 h, after which the mixture was alkalized with a KOH solution to pH 10–11 and extracted with methylene chloride (3 × 30 ml). The organic extracts were combined and dried over Na_2SO_4; the solvent was removed. The remaining red-orange crystalline compound **IX** (3.3 g, 95%) was recrystallized from water; mp 145–146°C. The compound was identified by a mixing test with an authentic sample and by comparison of the IR spectra [3].

CONCLUSIONS

(1) Diazotization of 4-amino-2,2,6,6-tetramethylpiperidine in HCl, HBr, H_2SO_4, and dilute AcOH affords 2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridine in 80–90% yield.

(2) Diazotization of 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl in 30% AcOH gives 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl in 80% yield.

(3) In glacial AcOH, 4-amino-2,2,6,6-tetramethylpiperidine and the corresponding radical are converted virtually completely to the corresponding *N*-acetyl derivatives.

Oxidation of Tetrahydrofuran and 1,4-Butanediol with Nitric Acid

N. V. Svetlakov, V. G. Nikitin, and A. O. Orekhova

Kazan State Technological University, Kazan, Tatarstan, Russia

Received August 13, 2001; in final form, January 2002

Abstract—Preparation of succinic acid by oxidation of tetrahydrofuran and 1,4-butanediol with nitric acid was studied.

One of practically important aliphatic dicarboxylic acids is succinic acid (SA). Owing to its unique biological properties, this acid is widely used in medicine and agriculture [1, 2].

Succinic acid is prepared in industry [3] by reduction of maleic and fumaric acids. The production process is being constantly improved [4, 5]. A promising procedure for preparing SA is oxidation of butadiene rubber with ozone [6]. Oxidation of tetrahydrofuran (THF) with nitric acid [7] is also of practical interest. However, this procedure is poorly studied.

Tetrahydrofuran was oxidized with nitric acid of various concentrations (97–30%) at a temperature lower than 25°C. THF vigorously reacts with concentrated HNO_3 (80–97%) with liberation of nitrogen oxides and heat. Already 30–40 min after mixing of the reactants, crystalline SA starts to precipitate. The oxidation is complete in 3–4 h after mixing the reactants. The SA yield is 80–85%. An additional amount of SA is precipitated after prolonged storage of the filtrate. The total yield exceeds 90%.

Oxidation of THF with 40–60% nitric acid is less exothermic. The liberation of nitrogen oxides, whose composition was not studied, is less vigorous. Oxidation of THF with 30% HNO_3 continues for several days. The SA yield was 40–45%, which is due to losses with spent nitric acid.

Nitric acid with a concentration higher than 70% contains nitronium cation, which is a strong electrophile [8]. We suggested that, in concentrated HNO_3, nitronium cation must cleave the C–O bond of THF to form 1,4-butanediol dinitrate (BDN). To confirm this assumption, we performed the reaction of THF with fuming nitric acid at temperatures lower than 0°C. After reaction completion, the reaction mixture was diluted with water and extracted with chloroform. As determined by elemental and spectral analysis, the isolated liquid product was BND.

1,4-Butanediol dinitrate thus obtained is converted into SA by treatment with nitric acid at 25–30°C.

These results suggest that SA can also be prepared by oxidation of 1,4-butanediol (BD) with nitric acid. 1,4-Butanediol was oxidized with 30–97% HNO_3 at 25–30°C. At nitric acid concentration higher than 80%, vigorous liberation of heat and nitrogen oxides was observed. In 3–4 h, precipitation of crystalline SA from the reaction mixture and liberation of nitrogen oxides were complete.

The yield of SA prepared by oxidation with 80% HNO_3 is as high as 90%. When 60–40% nitric acid is used, the SA yield decreases to 40–60%. This is due to dissolution of SA in spent HNO_3. The SA loss can be decreased if the spent nitric acid is recycled by mixing with concentrated HNO_3.

Since alcohols are *O*-nitrated readily and fast [9], BDN is apparently the intermediate of BD oxidation with concentrated nitric acid.

It is known than BDN can be prepared by esterification of BD with a mixture of sulfuric and nitric acid at temperatures below 0°C. At higher temperatures BDN is unstable [10]. BDN was oxidized to SA by the above procedure. The SA yield was 85%. Nitrogen oxides evolved in BD oxidation probably affect the oxidation. For example, N_2O_4, NO, and

1070-4272/02/7504-0669 $27.00 © 2002 MAIK "Nauka/Interperiodica"

N_2O_3 readily react with alcohols to form nitrous acid esters [11], which are subsequently converted into the carboxylic acid.

Preparation of SA by oxidation of BD has the following advantages over THF oxidation: reaction occurs under milder conditions, the reaction temperature can be easily controlled, the SA yield is sufficiently high, and BD is appreciably cheaper than THF.

EXPERIMENTAL

The IR spectra of SA (Nujol mull) and BDN (thin film between KBr discs) were recorded on a UR-20 spectrometer. The 1H NMR spectra of the reaction products were recorded at room temperature in acetone-d_6 on a Tesla-497 spectrometer operating at 100 MHz. HMDS was used as internal reference. THF and BD were of pure grade. Nitric acid solutions were prepared by dilution of 97% nitric acid (technical grade) with distilled water to the required concentration.

THF oxidation. To 80% nitric acid (56.7 g of 100% HNO_3, 0.9 mol), THF (10.18 g, 0.15 mol) was added with stirring at a temperature below 25°C. Crystalline SA started to precipitate 30–40 min after mixing the reactants. When heat evolution and liberation of nitrogen oxides terminated, the reaction was considered complete. Then the mixture was allowed to stand for 3–4 h and after that cooled to 0°C. SA was filtered off on a glass frit under reduced pressure produced by a water-jet pump and dried. Yield 14.8 g (89%). Melting point of the product recrystallized from water was 185°C [2]. ^{1}H NMR (δ, ppm): 2.5 s (4H, CH_2), 7.0 br. s (2H, 2OH). IR (ν, cm^{-1}): 1700 (C=O), 2500–3000 (COOH).

Preparation and oxidation of BDN. To 97% HNO_3 (57.7 g, 0.9 mol) THF (10.18 g, 0.15 mol), was added with stirring at a temperature from –10 to 0°C. Then the reaction mixture was allowed to stand for 15 mim and poured into a water–ice mixture. The resulting solution was extracted with three 50-ml portions of chloroform, and the extract was dried over Na_2SO_4. The solvent was removed, and BDN was purified by distillation. Yield 9.7 (38%); bp 103–104°C (4 mm Hg); n_D^{20} = 1.4450 {bp 104–105°C (4 mm Hg); n_D^{20} = 1.4470 [9]}. IR (ν, cm^{-1}): 870, 1280, 1650 (ONO_2). ^{1}HNMR (δ, ppm): 2.4 s (4H, CH_2), 4.2 s (4H, OCH_2).

Found, %: C 26.16, H 4.14, N 15.16.
$C_4H_8O_6N_2$.
Calculated, %: C 26.66, H 4.44, N 15.15.

BDN was oxidized as described. The reaction mixture was allowed to stand at 20°C for 14 h after mixing the reactants. Yield of SA 84%.

BD oxidation. To 80% nitric acid (56.7 g of 100% HNO_3, 0.9 mol) stirred at 25–30°C, BD (13.5 g, 0.15 mol) was added at the rate at which liberation of nitrogen oxides was not vigorous. When 35–40 min passed after the beginning of BD addition, SA started to precipitate. The reaction completion was judged from cessation of heat evolution and change of the color of the reaction mixture from brown to yellow. The reaction mixture was allowed to stand at 20°C for additional 2–3 h. SA was filtered off and dried. Yield 16 g (90%), mp 185°C (from water).

The NMR and IR spectra of SA prepared by this procedure were identical to those of SA prepared from THF.

BD oxidation with nitric acid solutions of other concentrations was performed similarly. The reaction completion was judged from cessation of heat evolution and end of liberation of nitrogen oxides, and from SA precipitation.

Preparation of BDN from BD and BDN oxidation. To a mixture of 94% H_2SO_4 (36.8 g, 0.38 mol) with 97% HNO_3 (30.2 g, 0.47 mol), BD (8 g, 0.08 mol) was added at a temperature below 10°C. The reaction mixture was allowed to stand at this temperature for 30 min and then poured into cold water. The resulting solution was extracted with two 50-ml portions of chloroform. The extract was washed with water and dried over Na_2SO_4. The solvent was removed, and BDN was purified by distillation. The properties of the product were in agreement with published data [10].

Oxidation of BDN to SA with 80% HNO_3 was performed similarly. Yield 85–90%.

BRIEF COMMUNICATIONS

Solid-Phase Synthesis of Triethylammonium Salt of 4-Oxothiazolidine-2-thione

E. B. Aronova and A. I. Ginak

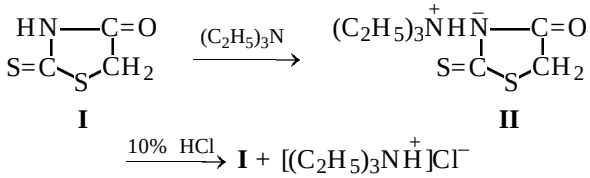
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received December 23, 2001; in final form, January 2002

Abstract—A procedure was developed for solid-phase synthesis of triethylammonium salt of 4-oxothiazolidine-2-thione.

3-R-Substituted 4-oxothiazolidinethiones are natural biologically active substances. They are plant growth stimulants [1] and metabolites of amino acid synthesis in cells [2]; their synthetic analogs exhibit a wide spectrum of biological activity, from herbicides [3] to antitumor agents [4]; also, these compounds are used as complexones for noble metals. The main synthetic route to these compounds involves nucleophilic substitution in polar solvents in the presence of bases. In the process, the main reaction of electrophile addition to the sulfur or nitrogen atom of the heterocycle is accompanied by base hydrolysis of the initial and final products with ring cleavage. This side reaction significantly decreases the yield of the target products and complicates their purification. It is known [5] that the nucleophilic substitution is preceded by the formation of salts of the substrate with a base, and in some cases, these intermediate salts are isolated to prevent hydrolysis. However, synthesis of these salts is also labor-consuming and requires proper choice of solvents for neutralization and crystallization.

To eliminate these drawbacks, we attempted to prepare alkylammonium salt of 4-oxothiazolidine-2-thione by solid-phase synthesis. Crystalline 4-oxothiazolidine-2-thione **I** was treated with triethylamine vapor at 50–120°C in a tubular reactor with false bottom. The reaction gives no by-products, and the desired 4-oxothiazolidine-2-thione triethylammonium salt **II** is formed in 98% yield.



The resulting product contains no impurities and does not require additional purification. Its composition was confirmed by elemental analysis, and the structure, by a mixing test with an authentic sample.

Received December 19, 2001

Abstract—Copolymerization of vinyl chloride with 1-vinylpyrazole was studied. The copolymerization constants were determined. The chemical structure of the copolymers was studied by NMR and IR spectroscopy.

In [1–3], we studied copolymerization of *N*-vinyl-4,5,6,7-tetrahydroindole, 2-methyl-5-vinylpyridine, and 1-vinyl-1,2,4-triazole with vinyl chloride (VC) and showed that copolymers are formed at any initial ratio of the monomers and that copolymerization is accompanied by dehydrochlorination of the resulting macromolecules. Therefore, revealing the effect of the structure of the azole ring on the degree of dehydrochlorination in the course of copolymerization and on the composition and properties of the resulting copolymers remains a topical problem.

In this work, we studied radical copolymerization of 1-vinylpyrazole (1-VPR) with VC.

The reaction yielded powders soluble in DMF, DMSO, *N*-methyl-2-pyrrolidone, and benzene. The IR spectra of the VPR–VC copolymers contain absorption bands at 1400–1525 cm^{-1}, corresponding to vibrations of the pyrazole ring; the bands at 1650 and 960 cm^{-1}, characteristic of the residual double bond, are lacking.

As seen from Table 1, copolymers are formed at any ratio of the monomers within the examined range and are always enriched in VPR units.

As the VPR content in the initial mixture is increased, the copolymer yield and intrinsic viscosity grow. In contrast to copolymerization of VC with *N*-vinyl-4,5,6,7-tetrahydroindole, 1-vinyl-1,2,4-triazole, and 2-methyl-5-vinylpyridine, copolymerization of VC with VPR is not accompanied by elimination of HCl, which is confirmed by the absence of signals from –CH=CH– groups in the ^{13}C NMR spectrum. For the system VPR–VC, we determined at low conversions the copolymerization constants: $r_{VPR} = 0.79$, $r_{VC} = 0.015$. From these quantities, we calculated the parameters of the molecular structure of the copolymers (Table 2).

An increase in the VPR content in the initial mixture makes formation of the alternating copolymers less probable. In contrast to polyvinyl chloride, the VPR–VC copolymers prepared in this work are soluble in a wide range of organic solvents; they can be processed under milder conditions as compared to VC and vinylidene chloride homopolymers.

It is known [4] that polyvinyl chloride and polyvinylidene chloride can form only dilute (≤5%) solutions in mixtures of acetone, butyl acetate, and cyclo-

hexanol. The limited solubility of the copolymers precludes use of their solutions for varnishing. We found that VPR–VC copolymers can form solutions with concentration as high as 50%, which meets the modern requirements to varnishes.

Thus, VPR–VC copolymers exhibit a number of interesting properties, different from those of the VC homopolymer, and can find new applications.

EXPERIMENTAL

Copolymerization of monomers was performed in sealed ampules at 60°C in the presence of azobis(isobutyronitrile) under argon. The reaction mixture was dissolved in DMF, and the copolymer was precipitated with acetone. After reprecipitation into acetone, the copolymers were vacuum-dried to constant weight. The intrinsic viscosity was determined in DMF at 20°C by the dilution procedure. The relative activity constants were calculated by the Fineman–Ross and Kelen–Tudos methods, using a program developed by G.I. Deryagina and the Mortimer–Tidwell experimental design method. In the calculations, we used experimental data for low (≤10%) conversions. The IR spectra were measured on a Specord 75-IR spectrometer (KBr pellets, mulls in mineral oil). The ^{13}C NMR spectra of copolymer samples were recorded with proton noise decoupling on a Varian VXR-500 spectrometer (working frequency 125.5 MHz) in DMSO-d_6 at a relaxation delay of 2.5 s and 90° pulse. Chromium tris(acetylacetonate) (0.02 M) was used as relaxant.

CONCLUSIONS

(1) Radical copolymerization of 1-vinylpyrazole with vinyl chloride is not accompanied by dehydrochlorination; 1-vinylpyrazole is more reactive.

(2) Incorporation of 1-vinylpyrazole units in the copolymer increases its solubiity in organic solvents.

Abstract—Synthesis and properties of solder creams based on polyester resin modified with rosin and diethyldibenzylammonium bromide were studied. The feasibility of using diethyldibenzylammonium bromide as soldering flux in low-temperature solder creams was analyzed.

The modern trend in the development of electronics is the increase in the number of components per unit volume, which is achieved by wide use of microassemblies and functional microelectronic devices. Electronic devices are produced to a significant extent by hybrid integrated methods. In this case, the passive section of the hybrid microchips (HMCs) can be produced by both thick- and thin-film procedures. The working hours of the manual hybrid-circuit packaging comprised nearly 50% of the total working hours of the HMC production, and a decrease in the manual operation is a topical problem.

At present, the component leads are connected to thick-film pads of the chips by various methods: adhesion connection, welding, and soldering. Soldering with low-temperature creams is the most widely used and effective method [1].

The organic fraction of the solder cream contains three main components: flux, binder, and solvent [2]. These components provide the required consistence of the solder cream, low melting temperature, and high adhesion to the surface being soldered.

The flux in the solder cream is analogous to the common fluxes; it removes oxide films from the surface of metals being soldered and solder, protects the contact surfaces from oxidation during soldering, and decreases the surface tension of molten solder at the metal–solder flux interface. Thus, the flux must meet the following requirements: necessary activity in the given temperature range, low corrosion activity and toxicity, stability upon prolonged storage, and easy elimination after soldering.

This paper continues our study aimed at the development of low-temperature noncorrosive solder creams [3, 4].

EXPERIMENTAL

We used diethyldibenzylammonium bromide (DEDBAB) flux. The solder cream was prepared as follows: DEDBAB (2 g) was added to the polyester resin (15 g) modified with rosin synthesized as described in [3]. The components were thoroughly mixed.

The parameters of the thermal-oxidative decomposition of the resulting mechanical mixture of polyester resin, DEDBAB, and flux were studied by dynamic thermogravimetry [5]. For more correct determination of the temperature of the onset of sample decomposition, we recorded TG, DTG, and DTA curves. The thermogravimetric curves were registered on an MOM Q-1000 device (Hungary) in the programmed-heating mode. The sample (0.03 g) was heated in a platinum crucible in air at a heating rate of 10 deg min^{-1}. The scales of the balance, DTA galvanometer, and DTG galvanometer were 50 mg, 1/3 and 1/10, respectively.

The thermal stability of the polyester resin with added DEDBAB was determined from the temperature of the onset of sample decomposition [T_{dec}^{DTA} is the temperature at which the exothermic effect (related to oxidation) appears in the DTA curve, and T_{dec}^{DTG} is the temperature at which the DTG curve starts to deviate from the horizontal] [6]. The results are listed in the table.

1070-4272/02/7504-0675 $27.00 © 2002 MAIK "Nauka/Interperiodica"

Thermal stability of the samples, calculated from dynamic thermogravimetry data

Sample	T_{dec}^{DTG}	T_{dec}^{DTA}	T_{dec}^{av*}
	°C		
Polyester resin	540	460	500
Polyester resin + DEDBAB	500	460	480

* $T_{dec}^{av} = (T_{dec}^{DTG} + T_{dec}^{DTA})/2$.

As seen from the table, for the polyester resin mixed with DEDBAB, the average decomposition temperature (T_{dec}^{av}) is lower as compared to straight polyester resin, which is probably due to an increase in the chemical activity and specific surface area of the mixture [5].

Our analysis of the TG and DTA curves recorded for DEDBAB flux shows that the sample decomposes in the 160–220°C range, which suggests that DEDBAB can be used in solder creams with melting point lower than 230°C.

To study the properties of the solder cream based on the polyester resin containing DEDDBAB, the mixture was placed on chip pads (obtained by the thick-film procedure using silver-containing and silver–palladium conducting formulations) and thin-film copper guides coated with tin or gold. The solder creams were prepared using the POSK 50-18 and POIn 52 solders; the tinning temperature was 180 ± 10 and 150 ± 10°C, respectively. The fusing mode of the solder cream must provide aggregation of the solder particles and wetting of the contact surfaces. Usually, the fusing temperature is 30–50°C higher than the melting point of the straight solder, and in this case fusing and wetting proceed in 10–30 s [7].

The quality of tinning was studied using an MBS-9 microscope (8–16× magnification). The surface area of untinned sections of the contact pads was determined using a measuring microscope. The wetting coefficient K_w (%) was calculated from the following equation:

$$K_w = \frac{S_1 + S_2 + \ldots + S_n}{S_0},$$

where S_1, S_2, …, S_n are the areas of the untinned sections of the contact pad (mm^2), and S_0 is the total area of the contact pad (mm^2).

In the case of the solder cream based on polyester resin and DEDBAB flux, the quality of tinning was fairly high [according to GOST (State Standard) V 20.39.304–76], because the untinned area was less than 20% of the total surface area being tinned.

The adhesion of the solder cream layer to a contact pad after fusion was determined by the anchor-film method on an MP-05 tensile-testing machine.

The tests were performed as follows. Four brass rods with heads about 2 mm in diameter were soldered to four (2×2 mm) contact pads of a test-chip, using the solder cream. Then the soldered junctions were tested on a tensile-testing machine. The post-fusion adhesion of the solder cream to a contact pad was determined from the breakout force.

The post-fusion adhesion of the solder cream to contact pads prepared by the thick- and thin-film procedures was no less than 50 and 25 kg cm^{-2}, respectively. In most cases, the strength of the soldered junction was higher than the adhesion of the contact pad to the support.

CONCLUSIONS

(1) The composition and preparation procedure of low-temperature solder creams based on polyester resin binder and diethyldibenzylammonium bromide flux were developed.

(2) By thermal stability, tinning quality, and adhesion strength, the mixtures obtained meet the requirements to solder creams.

Abstract—Binary radical polymerization of vinyl chloride with 1-(vinyloxyalkoxy)-2,3-epoxypropanes in acetone and dimethyl sulfoxide was studied. The copolymerization constants and the microstructural parameters of the resulting copolymers were calculated.

Vinyl ethers are widely used in syntheses of organic chemicals, polymers, and copolymers exhibiting valuable properties [1–4], and also in production of modified polyvinyl chloride materials [5, 6]. We have shown [7] that copolymers of vinyl chloride (VC) with *n*-butyl vinyl ether surpass polyvinyl chloride in heat resistance and solubility in organic solvents. One of the major drawbacks of copolymers of VC with vinyl ethers is their lower, compared to the homopolymers, softening point. Therefore, it is appropriate to introduce into vinyl ethers functional groups (e.g., epoxy groups) capable of forming three-dimensional macromolecular networks and thus increasing the softening point of the material [8].

In this work, we studied radical copolymerization of VC with 1-(vinyloxyalkoxy)-2,3-epoxypropanes (VEPs)

$$CH_2{=}CH{-}O{-}R{-}CH_2{-}\underset{\diagdown\,O\,\diagup}{CH}{-}CH_2,$$

where R = CH_2–CH_2–O [1-(2-vinyloxyethoxy)-2,3-epoxypropane, VEP_1], (CH_2–CH_2–O)$_2$ {1-[2-(2-vinyloxyethoxy)ethoxy]-2,3-epoxypropane, VEP_2}, and (CH_2–CH_2–O)$_3$ (1-{2-[2-(2-vinyloxyethoxy)ethoxy]-ethoxy}-2,3-epoxypropane, VEP_3).

Copolymerization in the VC–VEP systems yielded copolymers in the form of yellow or light gray powders (at the VEP content in the initial monomer mixture ≤30%) or yellow oily substances (at the VEP content in the initial monomer mixture >30%).

The IR spectra of the copolymers show no absorption in the range 1620–1650 cm^{-1}, characteristic of the vinyl group. The presence of oxirane rings is confirmed by the bands at 765, 820, 915, 960, 1230, and 3060 cm^{-1}. The ^{13}C NMR spectra of the copolymers contain broadened signals suggesting the presence of units of both monomers, δ, ppm: 43.9 (–CH_2O–), 44.9–47.4 (>CH_2), 51.04 (–CHO–), 58.59–56.6 (>CHCl), and 68.2–72.7 (–CH_2–CH_2–O–). The signals assignable to the =CH_2 (86.7 ppm) and =CH–O– (152.7 ppm) groups are absent.

Experimental data on copolymerization in the systems VC–VEP are listed in the table. The content of VEP in the copolymers increases in parallel with its content in the initial monomer mixture. In the entire range of the initial mixture compositions, the copolymers are enriched in the VC units relative to the monomer mixture, which indicates that VEPs are less reactive than VC. This is also indicated by the copolymerization constants *r* (see table). With increasing solvent polarity [in going from acetone to dimethyl sulfoxide (DMSO)], the reactivity of the monomers relative to the like radical decreases, as indicated by decreased copolymerization constants. Such a solvent effect on the monomer reactivity may be due to the volume effects [9].

The microstructural parameters of the copolymers, calculated from the copolymerization constants (see table), show that the macromolecules are built of long blocks of VC units (L_1) separated by single VEP units (L_2). When the VEP content in the initial mixture is increased, or when the copolymerization is performed in DMSO, the length of VC blocks in the copolymers decreases.

The viscosity of the copolymers decreases with an increasing content of VEP units (Fig. 1). The relative viscosities in the VC–VEP_1 system are lower than those in the VC–VEP_2 and VC–VEP_3 systems.

* (*L*) Mean block length; $L_2 = 1$.

In all the systems studied, the copolymer yield grows with increasing VEP content in the initial monomer mixture (see table). This effect becomes more pronounced in going from VEP_1 to VEP_2 and then to VEP_3 and is manifested irrespective of the solvent polarity. The product yield increases because of the involvement of larger amounts of VC (Fig. 2).

EXPERIMENTAL

Copolymerization was performed at 70°C in glass ampules under argon, in the presence of 1.0 wt % AIBN initiator. Copolymers were purified by double reprecipitation with methanol from acetone, after which they were dried in a vacuum oven to constant weight.

The composition of the copolymers was determined by elemental analysis (chlorine content) and ^{13}C NMR spectroscopy. The ^{13}C NMR spectra of copolymer samples were recorded with proton noise decoupling on a Varian VXR-500 spectrometer (working frequency 125.5 MHz) in DMSO-d_6 and acetone-d_6 at a relaxation delay of 2.5 s and 90° pulse. Chromium tris(acetylacetonate) (0.02 M) was used as relaxant.

The IR spectra were recorded on a Specord IR-75 spectrometer from thin films and KBr pellets.

The relative viscosity of copolymers was determined with an Ubbelohde viscometer at 25°C. Copolymers were taken as 1 wt % solutions in cyclohexanone. The relative viscosity was recalculated to the intrinsic viscosity according to [10].

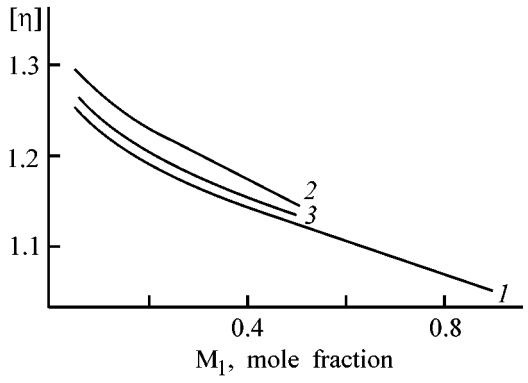

Fig. 1. Intrinsic viscosity [η] of VC–VEP copolymers prepared in acetone vs. mole fraction M_1 of VEP in the initial monomer mixture: (*1*) VEP_1, (*2*) VEP_2, and (*3*) VEP_3.

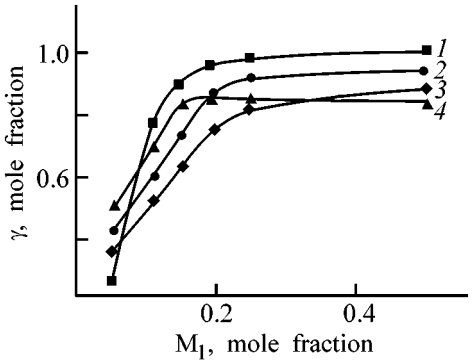

Fig. 2. VC conversion γ vs. mole fraction M_1 of VEP in the initial monomer mixture. Systems: (*1, 2*) VC–VEP_2 and (*3, 4*) VC–VEP_3; solvent: (*1, 3*) acetone and (*2, 4*) DMSO.

The copolymerization constants were determined by the least-squares method, using the Mortimer–Tidwell method of experimental design. In calculations, we used data obtained at monomer conversions ≤10%. The error of determining the constants was 3%.

CONCLUSIONS

(1) In radical copolymerization of vinyl chloride with 1-(vinyloxyalkoxy)-2,3-epoxypropanes, the latter compounds are less reactive than vinyl chloride.

(2) With increasing content of 1-(vinyloxyalkoxy)-2,3-epoxypropanes in the reaction mixture, the intrinsic viscosity of the product decreases, but the copolymer yield grows.

BRIEF COMMUNICATIONS

Reaction of Dextran Polyaldehyde with Aminohydroxypyrimidines

E. V. Tishchenko, A. A. Iozep, and B. A. Ivin

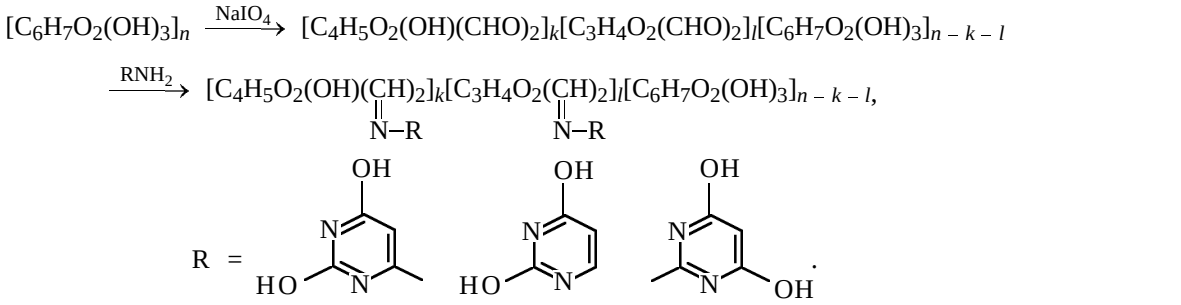
St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received December 6, 2001

Abstract—Reaction of dextran polyaldehyde with aminohydroxypyrimidines is proposed as a procedure for modifying polysaccharides with low-molecular-weight compounds. The influence exerted by the reaction temperature and time and by solution pH on the number of incorporated heterocyclic fragments was examined.

Many heterocyclic structures are fragments of molecules that are responsible for functioning of living bodies. Heterocyclic compounds are widely used in syntheses of biologically active substances and, in particular, such drugs as fluorouracil, methotrexate, and idoxurin. Unfortunately, all these drugs exhibit side effects and toxicity; they are rapidly eliminated from the body. At the same time, it is known that modification of drugs with polysaccharides is a way to decrease their toxicity, prolong their effect, and provide the required lipophilic–hydrophilic balance. Therefore, the goal of this study was to develop a procedure for binding 5- and 6-aminouracils and 2-amino-4,6-dihydroxypyrimidine with dextran polyaldehyde (DPA).

Chemical modification of DPA was performed by the scheme



Dextran was oxidized with sodium metaperiodate in 0.1 N formate buffer solution (pH 4) in the course of 48 h at 6–8°C [1]. The oxidant consumption was monitored spectrophotometrically (λ 222.5 nm), and the amount of the released formic acid was determined by titration. To isolate the target product, the reaction mixture was dialyzed to remove low-molecular-weight substances and concentrated in a vacuum (20–25 mm Hg) at 50°C; DPA was precipitated with ethanol, filtered off, washed with alcohol and ether, and dried for 2–3 h in a vacuum (20–25 mm Hg) at 60°C.

The compounds synthesized were characterized by the degree of substitution C_{sa} (number of aldehyde groups per monosaccharide unit of the polymer); the content of aldehyde groups was determined by the oxime and hydroxamic methods [2, 3]. In this work, we used DPA with C_{sa} = 0.86.

Reactions of DPA with heterocyclic amines were performed at 20–80°C for 0.5–48 h at a molar ratio of the heterocyclic compound and DPA aldehyde groups of 3 : 1 and pH 4–10.2. The reaction was heterogeneous, since the major fraction of the amine occurred in the solid phase and dissolved with the progress of the reaction with DPA. After reaction completion, excess undissolved substances were filtered off, and the reaction product was precipitated with ethanol, filtered off, washed with ethanol and ether, and dried for 2–3 h in a vacuum (20–25 mm Hg) at 60°C. The absence of low-molecular-weight compounds in the products was checked by thin-layer chromatography.

1070-4272/02/7504-0680 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The products are white, light yellow, or light brown amorphous powders insoluble in water, alcohol, ether, and most of other organic solvents, but soluble in aqueous alkalis.

The IR spectra of the products contain strong absorption bands at 1630 and 1720 cm^{-1}, which can be assigned to C=N and C=O stretching vibrations of the heterocyclic fragment incorporated in the polysaccharide aldehyde molecule.

The UV spectra of solutions of the reaction products in 0.02 N NaOH contain absorption bands that are absent in the spectrum of the polyaldehyde but are similar to the bands observed in the spectra of the initial heterocycles (see table).

Heterocyclic polyaldehyde compounds were characterized by the degree of substitution C_s (number of heterocyclic fragments per monosaccharide unit), which was calculated from the results of elemental analysis; the reactivity of DPA and aminopyrimidines was judged from the degree of conversion of aldehyde groups C_{ca} (%), which was calculated by the formula

$$C_{ca} = (C_s / C_{sa}) \times 100.$$

The conditions for incorporation of aminohydroxypyrimidines in the polyaldehyde molecule were determined from data on the influence exerted by the reaction temperature and time and by solution pH on the degree of substitution in reaction products of DPA and 6-aminouracil (Figs. 1a, 1b).

As expected, the number of heterocyclic fragments in the reaction products of DPA and 6-aminouracil grows from 0.01 to 0.58 mol mol^{-1} as the temperature is raised from 20 to 80°C. However, the temperature dependence of the degree of substitution reflects not only the increase in the reactivity, but also, probably, the fact that the solubility of 6-aminouracil in water and, hence, its concentration in solution grow with temperature (Fig. 1a).

With the solution pH increasing from 4 to 10.2, the degree of conversion of DPA aldehyde groups in the reaction with 6-aminouracil grows virtually linearly from 1.4 to 63.6%. This trend is apparently related to ionization of 6-aminouracil, formation of soluble anionic species, and increase in its concentration in the solution.

At 20°C, the conversion is low even at long reaction times (Fig. 1b); the curve of conversion vs. time flattens out, with the limit of 21.1% reached in 45 h. At 50°C, the content of heterocyclic fragments in the polysaccharide aldehyde increases considerably more rapidly: the conversion reaches 65% in 24 h.

Positions of bands in the electronic absorption spectra of aminohydroxypyrimidines and heterocyclic polyaldehyde derivatives (HC–DPA) (2×10^{-4} M solutions of substances in 0.02 N NaOH)

Amine	λ_{max}, nm	
	free amine	HC–DPA
5-Aminouracil	216, 288	216, 290
6-Aminouracil	216, 264	216, 268
2-Amino-4,6-dihydroxypyrimidine	208, 258	210, 262

As shown previously [4], with amine taken in the reaction with DPA in an amount exceeding 3 mol per mole of aldehyde groups, the degree of substitution does not increase further. Furthermore, large excess of 6-aminouracil is not appropriate because of its low solubility in water.

The results obtained allowed us to choose the best conditions for the reaction of DPA with 6-aminouracil: 80°C, 2 h, pH 10, and molar ratio of the amine to aldehyde groups 3 : 1. However, even under these conditions, the degree of conversion of the aldehyde groups does not exceed 87%, which may be due to side reactions of the polyaldehyde in alkaline solutions, which make smaller the amount of aldehyde groups capable of reacting with the heterocyclic compound. When DPA was kept under these conditions in the absence of 6-aminouracil, the content of aldehyde groups in DPA decreased approximately by half.

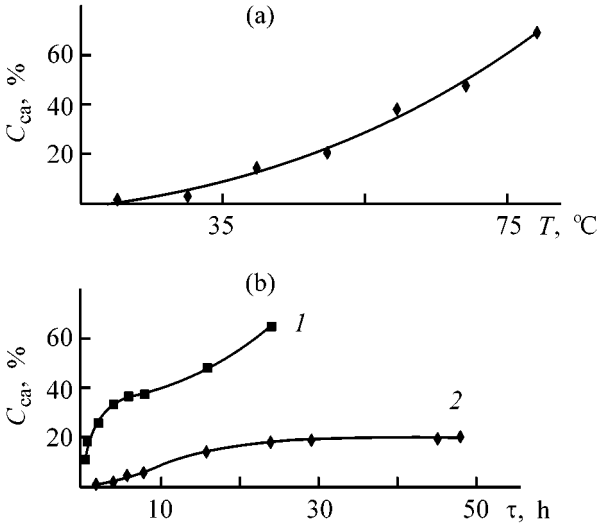


Fig. 1. Degree of conversion C_{ca} in reaction of 6-aminouracil with DPA vs. (a) temperature T and (b) time τ at (*1*) 50 and (*2*) 18–20°C.

Experiments on modification of DPA under these conditions with 5-aminouracil, 2-amino-4,6-dihydroxypyrimidine, 6-methyluracil, and uracil showed that 5-aminouracil is appreciably more reactive than 6-aminouracil (C_{ca} = 92%), 2-amino-4,6-dihydroxypyrimidine is less reactive (C_{ca} = 23%), and 6-methyluracil and uracil do not react with DPA at all under these conditions. This fact suggests that, under these conditions, aminouracils react with DPA via the amino group.

CONCLUSION

Dextran polyaldehyde can be modifed with aminohydroxypyrimidines. Its reactions with 5- and 6-aminouracils (80°C, 2 h, molar ratio of amine to aldehyde groups 3 : 1, pH 10) allow binding of up to 0.79 mol of the heterocyclic compound per monosaccharide fragment.

Vladimir Vladimirovich Skorchelletti (To the Centenary of His Birthday)

Vladimir Vladimirovich Skorchelletti, a scientist and lecturer, made a major contribution to investigations of corrosion and corrosion protection of metals and to improvement of teaching of theoretical electrochemistry and fundamentals of metal corrosion. For many years he was a member of the Editorial Board of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry).

V.V. Skorchelletti was born on May 17, 1902, in Odessa but lived in St. Petersburg from childhood. His father was a shipbuilding engineer and technical director of Baltiiskii plant, and his mother, an opera soloist at Mariinsky Theater. Having completed his secondary education in 1920, Vladimir Vladimirovich entered the mining faculty of the Mining Institute. At those years, such known scientists as N.S. Kurnakov, N.I. Stepanov, N.P. Aseev, and K.F. Beloglazov were among professors of this oldest institution of higher education. Skorchelletti's labor activities started after he graduated from the institute in 1925 and were originally associated (untill 1929) with Nevsky machine-building plant and department of shipbuilding in Leningrad. From February to December 1927, he was on a business trip to Germany where he familiarized himself with the technology of shaped steel casting at quite a number of plants.

In June 1929, Skorchelletti was invited to work at the Central Institute of Metals, established in Leningrad by that time, where he studied corrosion and chemical resistance of alloys. In 1932, he organized and headed a laboratory of metal corrosion, one of the first of this kind in the country. Skorchelletti's close scientific cooperation with A.I. Shultin (1898–1978), also a graduate of the Mining Institute (1926), proved to be rather fruitful.

Skorchelletti and Shultin's papers on chemical stability of cast iron alloyed with tin and copper, and also with antimony and copper, were published in a special collection *Voprosy khimicheskoi stoikosti splavov* (Problems of Chemical Stability of Alloys, Moscow, Leningrad: Gosmashmetizdat, 1933). The same papers discussed the stability of various kinds of alloyed cast iron used for fabrication of sulfuric acid pumps and the chemical stability of steel alloyed

with tin and copper and of steel with high content of aluminum. Already these first studies combined the high scientific level with the solution of specific applied problems.

Further development of Skorchelletti and Shultin's investigations in the field of corrosion and metal protection was reflected in their joint monograph *Khimicheskoe razrushenie metallov* (Chemical Degradation of Metals, Moscow–Leningrad: Metallurgizdat, 1934). The authors subjected to thorough critical analysis the theory of local elements, widely accepted at that time, and formulated a modern approach to corrosion as a redox reaction, whose possibility of occurrence is determined by thermodynamic properties of the system. The electrochemical mechanism of corrosion assumes that oxidation and reduction are described by characteristic relationships between potential and current, with the current expressing the rate of corrosion. The corrosion kinetics is governed by the kinetics of metal oxidation and oxidant reduction.

1070-4272/02/7504-0683 $27.00 © 2002 MAIK "Nauka/Interperiodica"

These concepts were further developed in Shultin's works and were entirely shared and supported by Skorchelletti.

The same monograph paid, for the first time, much attention to theoretical analysis and experimental verification of the law established in 1919 by G. Tammann (1861–1938), according to which the corrosion resistance of metallic solid solutions changes stepwise at compositions which are multiples of 1/8 of the least active component. Critically assessing all objections to Tammann's theory, Skorchelletti points to conditions under which the "*n*/8 law" is obeyed and mentions that Tammann's theory explains in a simple and logical way all the phenomena observed in corrosion of binary solid solutions. Also, the chemical stability of two-phase alloys is discussed.

Skorchelletti and Shultin were the first to systematize the material on chemical stability of iron alloys on the basis of the available published data and numerous investigations of their own [*Khimicheskaya stoikost' splavov na zheleznoi osnove: Spravochnaya kniga* (Chemical Stability of Iron-based Alloys: Reference Book, Moscow–Leningrad: GONTI, 1938)]. This publication had no analogues in the world literature and required vast authors' work on assessment of the chemical stability of alloys in wide variety of media, including acids, their mixtures, and alkali and salt solutions.

A large paper concerned with measurements of capacitance, transient resistance, and potentials, carried out to study the passive state of metals, was published by Skorchelletti in *Proceedings of the Second Conference on Metal Corrosion* (Moscow, 1940). Rather fine investigation techniques were employed to obtain interesting new data on properties of passivating layers.

As early as 1932, Skorchelletti began teaching at the Polytechnic Institute, and, since 1936, when the Institute of Metals was reorganized, all his scientific activities were associated with Leningrad Polytechnic Institute, where he delivered courses of general chemistry and metal corrosion, and, later, physical chemistry and theoretical chemistry. From 1941 to 1943, he was with the front-line forces.

In 1959, Skorchelletti published his fundamental work *Teoreticheskaya elektrokhimiya* (Theoretical Electrochemistry), highly appreciated by specialists and widely used as a textbook on electrochemistry. The book was twice republished in the subsequent years. Of particular interest were its chapters concerned with electrochemical kinetics and occurrence of spontaneous processes. One more book, *Teoreticheskie osnovy korrozii metallov* (Theory of Metal Corrosion, Leningrad: Khimiya, 1973), was published by Vladimir Vladimirovich in 1973.

His postwar scientific activities were associated with the most important problems of corrosion and metal protection. By means of original experiments, he studied the conditions necessary for the appearance on the metal surface of a layer of adsorbed water, which can serve as electrolyte, and demonstrated the electrochemical nature of atmospheric corrosion. Together with A.M. Borshchevskii and L.P. Baturova he continued to pay much attention to investigation of passivity of metals and alloys and conditions under which an oxidized state of the surface is formed in various media. Skorchelletti' s works put forward a new approach to corrosion cracking. He established the important role played in this process by electrocapillary phenomena changing the surface strength of a metal. The influence of various factors on the corrosion cracking of brass in ammonia solution was studied in detail (together with V.A. Zaitsev). A large number of corrosion studies was performed under Vladimir Vladimirovich's supervision by industrial request.

Skorchelletti was among those who organized publication of the first country's journal devoted to metal protection *Korroziya i bor'ba s nei* (Corrosion and Corrosion Protection) (1935–1941) and repeatedly published his works in this journal.

Before 1918, Vladimir Vladimirovich studied at May Gymnasium, one of the best men's gymnasiums in St. Petersburg, which gave to Russia dozens of outstanding persons of science, culture, and art during the period of its existence (1857–1918). Skorchelletti was a broadly educated person, fluently spoke foreign languages, and was an excellent draftsman.

For his pedagogical and scientific activities he was decorated with a number of State awards.

Vladimir Vladimirovich died of a serious disease on November 7, 1984, at the age of 82. All those who knew him, his colleagues and pupils, will preserve thankful memory of this true scientist, excellent lecturer, and exclusively modest man of principle. He devoted fifty years of his life to corrosion protection of metals—experimented, dug up parts of truth, generalized new facts, and taught the youth.

========== BOOK REVIEWS ==========

Naboichenko, S.S., *Metallurg Nikolai Baraboshkin* (Metallurgist Nikolai Baraboshkin), Yekaterinburg: Ural'sk. Univ., 2001, 584 pp.

The book is devoted to 120th anniversary of Prof. N.N. Baraboshkin's birthday, a prominent specialist in chemistry of platinum-group metals, pedagogue, and one of organizers of higher metallurgical education in the Urals.

Nikolai Nikolaevich Baraboshkin was born on October 24 (November 6, new style), 1884, in St. Petersburg; his parents originated from peasants of Moscow guberniya. After graduating from a nonclassical secondary school ("real'noe uchilishche") in 1899, he entered one of the oldest higher education institution of Russia, Empress Catherine II Mining Institute in St. Petersburg (founded in 1773). The time of his education was prolonged substantially, since Nikolai Nikolaevich participated in numerous expeditions of various purposes and also carried out scientific investigations on his own. Among N.N. Baraboshkin's teachers were such known professors as N.A. Iossa, D.P. Konovalov, I.F. Shreder, N.S. Kurnakov, and N.P. Aseev. Having graduated from the institute in the beginning of 1915, N.N. Baraboshkin went to Yekaterinburg and commenced organization of the first Russia's plant for platinum refining. By that time he had already shown himself as one of the most talented representatives of the chemical school founded by Academician Kurnakov. N.N. Baraboshkin and N.I. Podkopaev's works on analysis of platinum ore and products of its processing were widely known. N.N. Baraboshkin was the first to analyze, with exhaustive completeness, Ural placer platinum and, in particular, determined the content of ruthenium in the soluble part of platinum black sands.

The book reconstructs, on the basis of a great number of archival documents, the history of construction of the refining plant in Yekaterinburg. The plant brought, into service in 1916, produced nearly 267 tons of platinum till the beginning of 1921, despite some interruptions of operation in 1917–1918. Later, methods for obtaining other platinum-group metals: palladium (1922), iridium (1923), rhodium (1925), osmium (1927), and ruthenium (1930), were developed under N.N. Baraboshkin's supervision.

Naboichenko pays much attention to Baraboshkin's involvement in organiztion of higher education in Yekaterinburg. In October 1914, a decision was made to found the Mining Institute, and it was opened in October 1917. Already beginning in 1915, Nikolai Nikolaevich took active part in composing the curricula of the institute and providing equipment for its laboratories; he became a lecturer, and taught the assay techniques, in 1917; professor in 1919, and the dean of the Metallurgical Faculty in 1920. After opening of the Ural State University in 1921, Baraboshkin became professor of the Chair of Metallurgy of Nonferrous Metals. Later, he established the Chair of the Metallurgy of gold, platinum and less common metals and chair of the theory of metallurgical processes at the Ural Polytechnic Institute. Baraboshkin's merits in organization of training, in the Urals, of metallurgy engineers of every description are quite remarkable.

N.N. Baraboshkin actively promoted the foundation of the specialized Research Institute of Nonferrous Metals in Yekaterinburg in 1930 and was its scientific supervisor. A large number of academic and applied studies were carried out with his direct participation. Of importance for the industry of the Ural region were investigations in the field of metallurgy of nickel, copper, selenium, and arsenic.

Nikolai Nikolaevich Baraboshkin died on June 15, 1935.

The appendix to the book includes a list of Baraboshkin's works, a list of publications about the scientist, and notes his followers. Baraboshkin's son, Aleksei Nikolaevich Baraboshkin (1925–1995), academician of the Russian Academy of Sciences, had headed, over several years, the Institute of

1070-4272/02/7504-0685 $27.00 © 2002 MAIK "Nauka/Interperiodica"

High-Temperature Electrochemistry, Ural Scientific Center, Russian Academy of Sciences, in Yekaterinburg.

The author of this, undoubtedly useful book is a corresponding member of the Russian Academy of Sciences, rector of the Ural State Technical University (Ural Polytechnic Institute). He pays much attention to the history of metallurgy in the Urals. The book contains a large number of previously unpublished documents, materials from archives, recollections of persons who knew Baraboshkin, an outstanding scientist and citizen, at different times. All those who are interested in the history of science and technology, in general, and history of the modern industry of nonferrous and noble metals in Russia, in particular, will read this book with keen interest and gratitude to its author.

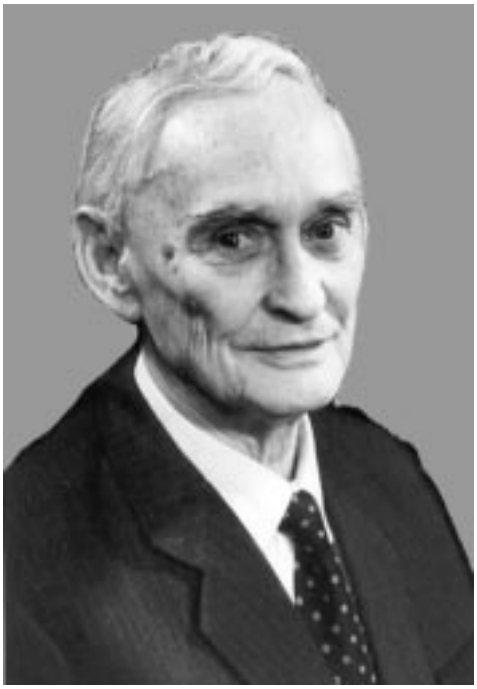
Valentin Borisovich Aleskovskii (on the 90th Anniversary of His Birthday)

On June 3, 2002, Valentin Borisovich Aleskovskii, doctor of chemical sciences, corresponding member of the Russian Academy of Sciences, honored scientist and technologist of the Russian Federation, and professor of the Chemical Faculty of St. Petersburg State University, was 90.

Valentin Borisovich graduated from the Leningrad Technological Institute (LTI) in 1937 and then worked at the same institute. In 1941–1945, he served at the fronts of World War II, and then again returned to LTI. He defended his doctoral dissertation in 1952, was rector of the Leningrad Technological Institute in 1965–1975, and headed the Leningrad State University (LGU) in 1975–1985.

Aleskovskii is an outstanding scientist in the field of solid state chemistry and technology of inorganic materials and the author of more than 450 publications, including 12 monographs and textbooks, and more than 150 inventions. Aleskovskii's investigations are mainly concerned with the nature and chemical transformations of solids, including those of highly organized substances. He created a new direction in the solid state chemistry: chemistry of highly organized substances.

The part played by Aleskovskii in the foundation and development of solid state chemistry in our country is tremendous. He organized the first chairs of chemistry of solids (LTI, 1967) and solid state chemistry (LGU, 1978). Aleskovskii is a talented teacher who has trained a group of specialists in physical chemistry of solids, who are working in our country and abroad, and created a productive scientific school "Chemistry of Highly Organized Substances." More than 25 doctors and 100 candidates of sciences are among his disciples.



For his scientific and pedagogic activities and participation in the defense of the Motherland, Aleskovskii has been decorated with a large number of State awards and honorary titles.

We heartily congratulate Valentin Borisovich on his glorious jubilee and wish him sound health and creative longevity.

A Way To Develop an Environmentally Safe Technology

V. B. Aleskovskii

Abstract—It is known that the fastest way to develop environmentally safe technologies is to model natural processes. This can be done using processes of chemical assembling and self-assembling, which are, similarly to biosynthesis, processes of production and materialization of information. The previously unknown chemical-informational laws controlling these processes are considered. The notion of information is represented as a property of substance to adapt to the existence conditions via structuring under external actions.

The world community, concerned with the progressing deterioration of the environment, adopted in 1992 the "Strategy of Stable Development." However, its implementation and, in particular, taking nature-protecting measures, which require enormous expenditure, fail, nevertheless, to produce noticeable results: the technological impact on the nature builds up. An adequate survival strategy of coevolution of humans and the environment was proposed by N. Moiseev [1]. From this strategy follows that it is high time to create a technology whose processes would be harmoniously incorporated in the ecosystem of the planet. Fortunately, this is possible.

In the middle of the XX century, the influx of new knowledge virtually washed away the classical scientific picture of the world. According to Prigogine [2, p. 13], the world cannot already be regarded as a kind of museum where every bit of information is preserved. The world consists of processes destroying and generating the information and structure. These processes occur in open physical systems under joint action on the substance of flows of energy and information under conditions of strong departure from thermodynamic equilibrium. Our planet is an oasis in which "the interplay of nonlinear dynamic processes in systems of this kind very frequently leads to self-organization..." [3, p. 450]. In the course of evolution, an ideal process of substance organization, biosynthesis, was formed. The substance is structured in this process at minimum energy consumption. A major part of the substance is incorporated into the most complicated supramolecular structures, living bodies, and a minor part, into such structures as H_2O and CO_2. As is known, this is a complex process in which matrix synthesis (transcription of the genetic information) is conjugated with molecular self-assembling (translation of this information) [4].

However, some outdated scientific concepts are still alive. One of these is the concept of "nonstoichiometry," adopted in the early XX century. According to this concept, a solid substance cannot have constant stoichiometric composition because of its not being defect-free [4]. This concept could be shaken neither by the known existence of biopolymers, nor by the discovery among biosynthesis products of solid substances with constant composition (oxalates, carbonates, and phosphates, e.g., hydroxyapatites), nor even by the fact that synthesis of individual polyatomic chemical substances has been carried out and numerous researchers have successfully mastered its techniques, e.g., the method of molecular layer deposition (for a review of early works, see [5, 6]).[1]

Technologists disoriented by this concept are unaware of the fact that they have at their disposal pure, individual solid substances, together with the widely occurring substances of variable composition, which are to be freed from "impurities," i.e., unnecessary components of the corresponding solid solutions. This circumstance hinders the development of technology, and especially that of "high technology."

Individual polyatomic chemical substances (those same substances which are assumed to be nonexistent according to the above-mentioned outdated concepts) were synthesized in the early 1960s. Polymers were obtained abroad [7], and solid compounds of constant composition, in the former Soviet Union [5, 6]. About 20 years later, it was found [8] that the absence of individual polyatomic chemical substances among the surrounding substances is due to the fact that they cannot adapt to existence conditions and should be synthesized by special methods based on the same principles as biosynthesis.

(1) Molecular layer deposition and chemical assembling. In developing a catalyst for decomposition of hydrogen peroxide with a low water content

[1] Among these researchers was T. Suntola, responsible for the fact that the method of molecular layer deposition is not quite correctly termed atomic layering epitaxy (ALE).

1070-4272/02/7505-0688$27.00 © 2002 MAIK "Nauka/Interperiodica"

(1952), various functional groups (FG) were grafted to the silica skeleton of a silica gel by means of irreversible chemisorption. In this process, with the chemisorption occurring via chemical condensation, the skeleton of a sorbent (silica gel, in particular) is overbuilt with new structural units, e.g., the following:

$$\equiv Si–OH + ClSi(CH_3)_3 \rightarrow \equiv Si–O–Si\equiv(CH_3)_3 + HCl. \quad (1)$$

For process (1) to be complete, chemisorption was carried out far from equilibrium during a time sufficient for the entire surface of the sorbent to be covered with a monolayer of structural units.

A study of this process allowed understanding of the fact that "destruction in one or another way of organic groups of methylsilylated silica gel and hydration of silicon liberated in the process may presumably lead to hydrated silica with completed skeleton... And, repeating chemisorption and hydrolysis procedures, one can build up monolayer by monolayer the mass of silica" [9, p. 28].[2] Experience suggests (for a review of early works, see [10]) that deposition of monolayers of appropriate structural units on the surface of a solid in this way can produce not only silica, but also various other solids of constant composition. The deposition onto a surface of a number of identical monolayers, or a single monolayer, was termed molecular layer deposition, and synthesis of monolayers with varied composition, alternating in a prescribed sequence, was named chemical assembling [10, 11].

Molecular layer deposition (MLD) is a process of synthesis of simple substances and not-too-complex compounds and, in particular, binary compounds. This method is used, e.g., for obtaining silicon dioxide by synthesizing one its monolayer after another on the surface of pores in silica gel. For this purpose, air-dry silica gel is treated at 180°C for approximately 1 h in a flow of thoroughly purified nitrogen saturated with water vapor. As a result, the silica gel surface is completely covered with a monolayer of silanol functional groups, which gives polysilicic acid (PSA) $[SiO_2]_aOH_2$, a solid compound of constant composition, where a is the number of moles. The PSA surface is treated at the same temperature in a flow of nitrogen, bringing $SiCl_4$ vapor and carrying away hydrogen chloride, by-product of $SiCl_4$ condensation with hydrated silica gel. When this reaction is complete, which is indicated by ceased liberation of HCl, the PSA surface is completely covered with a monolayer of (≡SiCl), which gives polysilicic acid chloride, $[SiO_2]_aO_2SiCl_2$. Hydrolysis of this chloride by the same method as that used for hydration of silica gel yields a monolayer of (≡Si–OH) whose addition to the PSA skeleton transforms this solid acid into its homologue, $[SiO_2]_{a+1}OH_2$. Performing molecular layer deposition of, alternately, (≡SiCl) and (≡Si–OH) monolayers again and again, one can synthesize a silicon dioxide layer of desired thickness with hydrated surface, which is one of higher homologues of polysilicic acid, $[SiO_2]_{a+n}OH_2$, where n is the number of moles equal to the number of MLD cycles. An MLD cycle consists of a pair of solid-state or, more precisely, supramolecular chemical reactions: condensation of completely hydrated silica gel, $[SiO_2]_aOH_2$, with silicon tetrachloride [reaction (2)] and condensation of the product formed in reaction (2) with water molecules [reaction (3)]:

$$[SiO_2]_aOH_2 + SiCl_4 \rightarrow [SiO_2]_aOSiCl_2 + 2HCl, \quad (2)$$

$$[SiO_2]_aOSiCl_2 + H_2O \rightarrow [SiO_2]_aOSi(OH)_2 + 2HCl. \quad (3)$$

The MLD technique has been used to obtain quite a number of simple solid substances and solid compounds of constant composition, and also their isomers, including polymorphic modifications.

Nanostructures reproducible with atomic precision, including $(SiO_2)_m/Si_n$ nanostructures differing in the number n of silica monolayers, have been synthesized for the first time [10]. Such a structure is a single crystal of silicon on whose faces is deposited, by the MLD method, a silicon–oxygen layer of a precisely known thickness (10 nm). The thickness of the layer synthesized was determined ellipsometrically. Measurements of the thickness of the silicon dioxide layer synthesized in 10, 20, 30, 40, 50, and 60 cycles (2) + (3) demonstrated that synthesis of the given layers proceeds with quite satisfactory reproducibility. For example, it was found by measuring the layer thickness in five sets of samples obtained after 50 MLD cycles that its deviation from the average value (equal to 4.25 nm) is ±0.1 nm. As expected, the thickness of layers in the set of samples linearly depends on the number of MLD cycles.

Chemical assembling (CA) is done by alternating in a prescribed sequence cycles of molecular deposition of monolayers of different compositions. This gives solid compounds with both periodic and nonperiodic regular structure. Synthesis by CA is carried out following a program that sets the number and alternation sequence of different cycles, their duration,

[2] This casual mention in [9] was actually the first published report on chemical assembling.

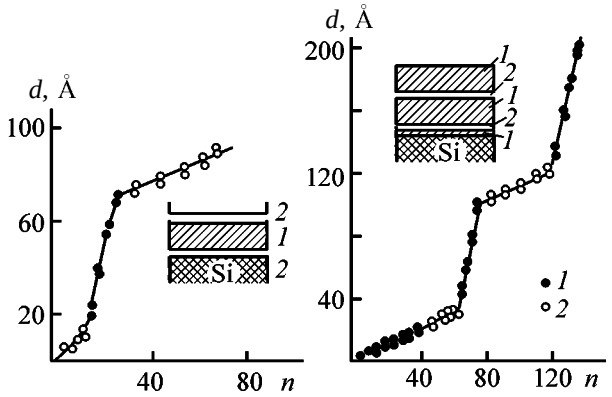

Fig. 1. Thickness d of synthesized layer vs. number n of MLD cycles. Layers: (*1*) TiO_2 and (*2*) SiO_2.

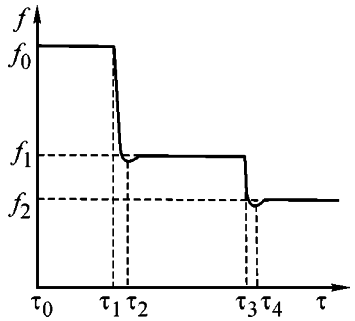

Fig. 2. Variation of the oscillation frequency f of a quartz resonator with time τ during an MLD cycle.

and thermodynamic and physicochemical conditions of synthesis. This technique has been employed to synthesize quite a number of individual solid chemical substances. For example, phosphorus and titanium chlorides and water were used to obtain all the 14 different nanostructures that can be constructed from four phosphorus–oxygen (P) and titanium–oxygen (T) monolayers: TTTP, TPTT, TTPP, etc. Their study demonstrated that the composition and properties, e.g., solubility and catalytic activity, of products composed of the same number of the same structural units T and P, but alternating in different order, are not identical. The products whose outer layer consisted of P structural units exhibited virtually zero catalytic activity in hydrolysis of CCl_4, whereas structures with outer layer composed of T units were exceedingly active. Measurements of the contact potentials of nanostructures of the given type, grown on a silica or titania substrate, revealed that the contact potential decreases as the number of layers constituting this substrate increases to 6–8 monolayers for silica and 4 monolayers for titanium oxide, and then remains constant.

Synthesis of individual complex supramolecular chemical substances is conducted by the program specifying the starting compounds, reactions, procedures, synthesis mode, and, in the first place, the sequence of MLD cycles. The formation in the course of chemical assembling of a multilayer structure of total thickness d is described by the equation

$$d_n = d_1n_1 + d_2n_2 + \ldots + d_in_i, \qquad (4)$$

where d_n is the nanostructure thickness, d_i is the thickness of a monolayer in ith layer, n_i is the number of MLD cycles necessary for ith layer to be formed, and d_in_i is the thickness of ith monolayer belonging to the given nanostructure.

The thicknesses d_1, d_2, …, d_i of monolayers composed of different structural units (silica and titania) are unequal, and, therefore, the slope angles of portions of the $d = f(n)$ curve with the n axis (α_1, α_2, …, α_i), given by the dependence $\tan\alpha = d/n$, are not equal either.

As expected, the plot of the dependence $d = f(n)$ (Fig. 1) is a broken curve with slopes of its separate linear portions and thicknesses of the corresponding layers of different compositions exactly equal to the values predicted theoretically and, at the same time, known from crystal chemistry. The coincidence of slopes for TiO_2 and SiO_2 layers, observed in the initial portion, indicates that the structure of the first monolayers coincides with the structure of the silica matrix.

Chemical assembling is rather slow, for obvious reason, under atmospheric pressure, and much faster under conditions of dynamic vacuum. "Dynamic synthesis" of chalcogenide nanostructures (including superlattices) composed of monolayers of cadmium and zinc sulfides and selenides is performed as follows [11, 12]. Ultrapure dimethyl- or diethylzinc and dimethylcadmium are taken. Substrates are prepared from mica, indium antimonide or arsenide, fused silica, or single-crystal silicon. Silicon wafers are treated first plasmochemically and then with hydrogen fluoride vapor. Arsenide or antimonide wafers are cleaned with 3% solution of bromine in methanol and then washed with ethanol. The synthesis is carried out at 290–300 K, pressure of 500 Pa, exposure of 5–10 s, and cycle duration of chemical assembling equal to 2 min.

The synthesis is commenced with substrate saturation with hydrogen sulfide and continued as follows: evacuation to 10^{-2} Pa, initial instant of time τ_0 (Fig. 2); admission of an organometallic compound of zinc or cadmium at a pressure of 500 Pa, initial instant of time τ_1; evacuation of gaseous reaction prod-

ucts and excess amounts of reactants to 10^{-2} Pa, initial instant of time τ_2; admission of hydrogen sulfide at 500 Pa, 5–10 s, initial instant of time τ_3; and evacuation to a pressure of 10^{-2} Pa, initial instant of time τ_4.

The thickness of the layers being synthesized is determined in the course of synthesis ellipsometrically and, simultaneously, found from the mass gain measured using a quartz resonator. This method is used to construct precision superlattices. Their parameters (thickness D; number of periods k; number of monolayers of different compositions, n and m; and monolayer thicknesses d_1 and d_2) are specified by the program

$$D = k(nd_1 + md_2). \quad (5)$$

St. Petersburg scientific school has synthesized by the method of chemical assembling films of diamond, silicon, silicon dioxide, and complicated supramolecular solid compounds of constant composition, e.g., various polypyrosilicic acid derivatives, of the type of iron(III) oxychloride pyrosilicate $[SiO_2]_{a-1}[OSi\cdot(OFeCl_2)_2]_{1-n}(OSiO)_n$, and many others [11, 12].

Smirnov [13] considered the chemistry of nanostructures. Malygin [14] laid foundations of the technology of chemical assembling of materials, and Alekhin [15] developed chemical and process principles of nanostructure synthesis.

(2) Principles of chemical treatment. The main specific feature of synthesis by chemical assembling is that it is programmed: reactions alternate in a prescribed sequence and occur in an open system during a time necessary for their full completion [11, 16]. As also in the case of catalysis, a solid reactant plays here an exceedingly important part of a stationary phase. A flow of reactants along the surface of a solid makes this solid-state process irreversible, with the surface serving as a matrix for assembling of the target product on it and, simultaneously, as a quantum and electron exchanger, thermostat, and heat exchanger discharging into the environment the energy released in the process. As already mentioned, the synthesis program specifies the starting substances and reactants and sets thermodynamic and other conditions under which reactions and procedures are carried out.

(3) Chemical self-assembling and assembling of polyatomic units. J.M. Lehn and D.J. Cram, followers of Pedersen's scientific school, developed a method for synthesizing highly organized individual chemical substances, which is based on intermolecular

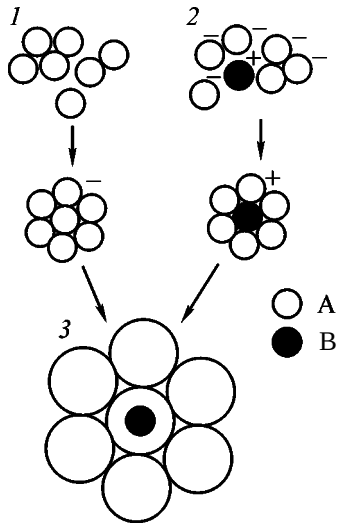

Fig. 3. Scheme of liquid-phase synthesis of quaternary supramolecular structures (*3*) from sols of structured globules (*1*) A and (*2*) B.

interaction of complementary molecules and macromolecules, method of autoensembling, and that of molecular self-assembling, similar to the homonymous biosynthesis process. The mutual complementarity of properties, structures, and forms, ensuring the "recognition" and linkage of complementary structural units in the very first collision in thermal motion, is specified by the information contained in them.

This method was applied in [17] to obtain polymolecular ensembles as models of electronic, photonic, and ionic devices. A number of chemical models of natural prototypes, from ion-conducting channels to artificial cells, have been created.

The method of "unit assembling," which combines chemical assembling and molecular self-assembling, has been proposed for synthesizing particularly complex structures. Nanoglobules of, e.g., Aerosil doped, if necessary, with one or another substance (compound of nickel, iron, etc.) are coated by the method of chemical assembling in a prescribed sequence with doped layers of thickness ranging from one to tens of nanometers, composed of monolayers of different compositions. This gives structured nanoglobules in the form of various nanostructures. These nanounits are used to obtain, e.g., by the sol–structure method, similar to the known sol–gel method, ultracomplex and, in particular, quantum structures (Fig. 3).

Linkage of polyatomic units with one another by the method of "chemical welding" [12] gives various precision nanodevices.

(4) Structural organization of substance. As is known, the substance is an hierarchical multilevel dynamic system of interacting structural units composed of lower-rank structural units, in their turn constituted by even lower-rank structural units consisting of subunits, etc., to particles of incredibly small size (on the order of 10^{-33} cm). All substances consist of atoms and are at one of the following three structural levels: molecular, supramolecular (prebiotic), or biological. In contrast to substances of the first and third kinds, which are chemically individual substances, supramolecular substances occur only as solid solutions.

It was shown in [8] that formation of an individual chemical substance is rather unlikely, and that of individual polyatomic substances (polymers and solids of constant composition), even exceedingly unlikely.

Low-molecular-weight, i.e., low-atomic compound AB is obtained in the individual state when reactants A and B are taken in a certain excess and their residual amounts are removed from the reaction sphere and the equilibrium is thereby shifted to the right, toward AB formation. However, if the reaction product is a polyatomic high- or supramolecular substance, then an inseparable mixture of all innumerable compounds composed of A and B and also their isomers and homologues, rather than a single compound, is formed in the equilibrium process. In this case, the structural units contained in a supramolecule (solid) being synthesized should be dosed and linked in certain order. The point is that a multitude of N compounds, rather than a single compound, can be formed in chemical synthesis from n atoms of m elements. In the process, the probability of formation of one of these compounds, namely, an individual chemical species of interest for us, depends on the number N, given by the rules of combinatorial analysis:

$$N \cong m^n. \tag{6}$$

The number N is small for low-atomic, low-molecular-weight compounds, and exceedingly great for polyatomic (high- and supramolecular) compounds. For example, for hydrocarbon $C_{34}H_{66}$, comprising 100 atoms, $N \approx 2^{100} \approx 10^{30}$. Thus, the number of possible synthesis products depends both on the number of atoms of the elements constituting the target product and on the number of these elements, i.e., on the extent to which this individual substance is polyatomic. As follows from S. Shchukarev's observations [18], each supramolecular compound is a member of a vast family including all innumerable compounds of those same elements which constitute the given individual chemical substance, together with isomers and homologues of all these compounds. With the exception of comparatively scanty low-molecular-weight analogs and homologues, all of them have identical properties, being, therefore, formed simultaneously as mixture of compounds in the form of a solid solution. The probability of formation in the course of chemical synthesis of a mixture of all the possible N products is unity:

$$P = N/N = 1. \tag{7}$$

The probability of formation of one of these in individual state is given by

$$P_i = 1/N. \tag{8}$$

Only simple substances are formed with probability equal to unity, since, in this case too, $N = 1$ and

$$P = 1/N = 1/1 = 1. \tag{9}$$

Thus, the probability P_i of formation of an individual chemical substance is the lower, the larger the number N of chemical compounds that can be formed from the given number of atoms of the given elements. And, since this number is incredibly enormous for individual polyatomic substances, the probability of formation of individual high- and supramolecular substances approaches zero; the probability of formation of a mixture of isomorphic compounds is unity. That is why only low-molecular individual compounds are produced in chemical synthesis, with the corresponding mixtures, imaginary compounds of variable composition, formed instead of individual high- and supramolecular compounds. At the same time, not only polyatomic chemical compounds, but also much more complex biological products, whose appearance is seemingly utterly incredible, are continuously formed in cells of any organism. The secret of biosynthesis is known: information is produced in its course. But what the problem at hand has to do with information?

According to Shannon's theory, the quantity of information contained in a text depends on the probability of its formation from the symbols constituting this text. This theory formed a foundation of informatics, which studies the laws and methods of accumulation, processing, and transmission of information. This information is drawn from the knowledge acquired by studying the nature. However, information can also be obtained directly in structuring processes. It is important that this opens up a possibility of

shifting the focus of acquisition of new knowledge to structuring processes, with any amount of information extracted directly in synthesis processes. This was made clear by an analysis of data obtained in studying the mechanism of biosynthesis, and also by a certain development of the theory.

(5) Complementary theorem. Prigogine established (1947) that, under external conditions hindering the attainment of equilibrium by a system, the steady state of the system corresponds to the minimum production of entropy. Under the action of a sufficiently high-power flux of energy, the substance of the nonequilibrium system acquires a dissipative structure, which is dynamic and disintegrates when these conditions disappear for gases and liquids, and stationary, preserved when an external action is terminated, for solids.

According to Prigogine [2], the dissipative structure appearing when a system attains the steady state is a random structure, one of the innumerable multitude of structures whose formation is possible with the same probability at the bifurcation point. At present, in view of the theory of structural organization, it is seen that this is not the case.

As is known, the quantities of information and entropy are related by

$$I + S = \text{const.} \quad (10)$$

Relation (10) is a universal law according to which the corresponding amount I of information is produced simultaneously with entropy S, with a decrease in entropy necessarily entailing an increase in the quantity of information. Since $S = 0$ and $I = 1$ in full order, const = 1. Thus,

$$I + S = 1. \quad (11)$$

At $S_{\min}$

$$I_{\max} = 1 - S_{\min}. \quad (12)$$

When the entropy produced in the given process falls to a minimum and the quantity of information produced reaches a maximum, a structure is formed. In this case, the entropy is conveyed to the medium and the information is imparted to the substance, forming its structure.

The production of entropy in this process is a result of decoherentization of the energy flux acting upon the substance. Another result is the saturation of substance with information brought from the outside by this flux. Hence follows that the structure appearing in the given process at the bifurcation point is not accidental, as it follows from the theory of self-organization, but is programmed by the information brought by the flux generating the given structure. If this is the case, then the major factor in the formation of dissipative structures is information, and not entropy (indicated as a key parameter by Prigogine's thermodynamic theorem).

(6) What is information? By information is understood the quantity of information contained in any object of interest for us: text, solid (supramolecule), etc. There exists a mathematically exact definition of information, but here "we deal with just the numerical expression of the volume of information, irrespective of its conceptual content" [3, p. 431]. The meaning of the notion of information is revealed by the theorem presented above. It follows from this theorem that information is a property of substance to adapt to the existence conditions.

The information and structure both appear and disintegrate together. Thus, the structure and information are a single whole. A decrease in entropy production to a minimum in the course of structuring indicates that, when the system passes to a steady state, the degradation of energy acting upon the system decreases, i.e., the "energy conductivity" of the system increases as a result of dissipative structuring. This means that, being structured and saturated with information, the substance belonging to the given system accommodates itself to the changing conditions. In other words, the ability to interact with the medium, to condense, to undergo polymorphic transitions, and to evolve in general, is imparted to the inert matter by the information contained in it.

All the existing things, from the universe to each newly discovered "elementary" particle (quantum of radiation), have structure and, consequently, contain information. The structure is the "flesh" of the substance, and information is its "soul," i.e., something programming in a literal sense the existence of the substance. True, information differs, as heaven from earth, from Aristotle's entelechy enveloped in dense mystical fog. It suffices to say that, as also the substance itself, information can well be described scientifically. It is discrete and diverse, similarly to the substance itself.

Phase transformations of a substance result from its saturation with different portions of information. The structure and properties of a substance change stepwise at certain critical amounts of information. For example, a laminar flow becomes turbulent at a certain Reynolds number, acquiring a more complex

vortex structure, which contains an increased amount of information, and new properties, e.g., the property to centrifuge suspensions.

The property of a substance structured under external action and saturated with information to adapt to the existence conditions and give birth to alike is inherent in all kinds of substance, including radiation, but is manifested only in interaction of appropriate carrier and detector of information. Formation of dissipative structures is no exception. Production of entropy in this process is a result of decoherentization of the energy flux acting upon the substance and saturation of the substance with information brought from the outside. Hence follows that the structure appearing in the given process at the bifurcation point is not accidental, as follows from the theory of self-organization, but is programmed by the information brought by the flux generating the given structure. Generally speaking, information generates information, and structure gives birth to structure. For example, it is known that the information produced in the course of biosynthesis is generated by genetic information.

Matter quanta of increasing mass, structural units of substance of increasing rank, are elementary particles, atoms, molecules, supramolecules, cells, and living bodies. The last kind of structural units appeared after structures (cells) gained the capacity to reproduce, and the history of living, biological individuals began. However, in order to exist, individual polyatomic chemical species must possess a much greater amount of information than low-atomic species. The latter, even if these are compounds of the same elements, e.g., H_2O and H_2O_2, do not loose completely their individuality when mixed with one another because of their having distinctly different properties. They can be separated without using chemical methods. Polyatomic chemical species are a different matter. Each of them is a member of an unimaginably vast family of compounds consisting of atoms of the same elements bound in different ratios (having different compositions) and also their innumerable isomers and homologues. By virtue of the law of degeneracy of large quantities, these species have nearly, or exactly the same properties and are, therefore, formed as families, in closest mixture with one another. These are the solid solutions which are recognized as "nonstoichiometric compounds" surrounding us. The probability of formation of any individual polyatomic compound tends to zero. To raise it to unity, it is necessary to produce a sufficiently large quantity of information in the course of synthesis. We could not conjecture this before making closer acquaintance with biosynthesis and becoming aware of the fact that chemical assembling and self-ensembling, artificial processes for synthesis of individual polyatomic chemical substances, are, similarly to the corresponding biological prototypes, processes for production and materialization of information.

(7) Way to create an environmentally acceptable technology. Synthesis of individual polyatomic chemical substances is becoming a matter of routine. Maybe it is high time to go further: start to create processes for synthesis of living substance? And this substance must not necessarily be organic, since the main indications of life are individuality of substance and its ability to reproduce, preserved over generations. Consequently, it is necessary to synthesize individual superpolyatomic chemical substances saturated with a sufficiently large amount of information, equal to [19]

$$I = \log_2 N, \tag{13}$$

where N is very large quantity whose order can be readily found by formula (6).

However, there is one more, no less important, but more topical, vitally important task. Here, we are dealing with the development—instead of the existing, actually destructive technology, using only rich raw materials, deadening the soil, water, and atmosphere with wastes and discharges—of a new chemical-informational technology whose processes would be harmoniously included in the ecosystem of the planet.

As predicted by Frenkel [20], the creation of such a technology will apparently be based on imitation of living systems and be implementation of principles of molecular cybernetics. As far back as the 1970s, he demonstrated that synthesis processes are described by a hyperbolic dependence of the amount T of work expended in them on the quantity I of information produced in these processes, i.e., IT = const. It is owing to this dependence that biosynthesis, a process in which, in principle, unlimited quantities of information are generated, occurs under exceedingly mild conditions with extremely high efficiency.

A limited amount of genetic information introduced by DNA chains in biosynthesis is transcribed, translated, and multiplied, being imparted in the course of self-assembling of protein molecules to the substance of biological tissues at a minimum expenditure of energy. It may be assumed in this connection that the technology based on the biosynthesis principles will be low-temperature liquid-phase programmable technology with completely utilizable wastes.

It is apparent that, even if the entire mankind occupied itself with invention, it would not develop anything more perfect and, at the same time, simpler than that created by nature. Therefore, it would be necessary to make it a rule to create anything new and complex following the natural samples, using processes of production and materialization of information and programming them with appropriate genetic information transferred, when necessary, by the chemical assembling method (replication) from one or another natural carrier to artificial matrices.

The solution of these problems is ensured by the development of the information theory [21–23] and chemistry of highly organized substances [24], and by investigations of the physicochemical aspect of the theory of information and chemical informatics.

Thus, a way to develop processes harmoniously incorporated in the ecosystem of the planet has been outlined.

ACKNOWLEDGMENTS

The author is deeply grateful to his dear colleagues, members of the scientific school of the chemistry of highly organized substances, for fruitful collaboration. The study was supported by the Russian Foundation for Basic Research (project no. 00-15-97356).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Transformations of Hydrated Titanium Dioxide with a Globular Structure of Aggregates

A. V. Tolchev, V. Yu. Pervushin, and D. G. Kleshchev

Chelyabinsk State Pedagogical University, Chelyabinsk, Russia

Received December 13, 2001

Abstract—The phase and chemical transformations in hydrated titanium dioxide with a globular structure of aggregates, prepared by thermal hydrolysis of aqueous solution of oxotitanium(IV) sulfate and calcined in air at 200–1100°C, were studied. The effect of modifying additives (potassium, zinc, magnesium, and phosphorus compounds) and seed crystals of rutile-like structure on the kinetics and temperature of the polymorphous transition of anatase into rutile, morphology of crystals, and particle size of the resulting product was studied.

In a sulfate method of synthesis of titanium dioxide pigment of anatase and rutile modifications, hydrated titanium dioxide (HTD), which was obtained by thermal hydrolysis of titanium(IV) sulfate solutions, is calcined at ~900°C in air [1, 2]. HTD samples prepared in open reactors at atmospheric pressure by standard procedure have the empirical composition $TiO_2 \cdot xSO_3 \cdot nH_2O$, with x and n depend on the hydrolysis conditions, and are finely crystalline powders (crystal size 10–20 nm [2]) tending to the form dense irregular polydispersed aggregates. The thermal treatment of HTD results in the dehydration, desulfation, and the anatase $\rightarrow$ rutile phase transition [2–5]. The latter two processes are accompanied by coalescence and sintering of TiO_2 crystals [6–8]. To control the phase composition and particle size of TiO_2 in HTD, the modifying additives and seed crystals (SCs) of rutile-like structure are added before calcination. Potassium, silicon, and phosphorus compounds increase the temperature of the anatase $\rightarrow$ rutile transition, whereas zinc, magnesium, and iron compounds, as well as seed crystals, act oppositely [2]. Owing to the HTD dispersity, titanium dioxide obtained by the traditional procedure is characterized by a broad size distribution of globules. This results in the deterioration of its pigment properties.

HTD obtained by thermal hydrolysis of titanium(IV) sulfate solutions at 130–170°C is a nearly monodisperse powder with a globular structure of aggregates. Its calcination should result in the formation of anatase and rutile crystals of the same shape and size.

In this work, we studied the effect of seed crystals and modifying additives on the phase transitions and chemical transformations of such HTD and on the particle size of the resulting titanium dioxide.

EXPERIMENTAL

Hydrated titanium dioxide with a globular structure of aggregates (Fig. 1) and an average globule size $D \sim 250$ nm was obtained by thermal hydrolysis of 1.25 mol g^{-1} aqueous solution of chemically pure grade oxotitanium(IV) sulfate at 130°C for 1 h. To separate the mother liquor and remove free sulfuric acid, the deposit was filtered under pressure and washed with distilled water until the absence of sulfate ions in the filtrate.

Water-soluble compounds of potassium, phosphorus, magnesium, and zinc, which are widely used

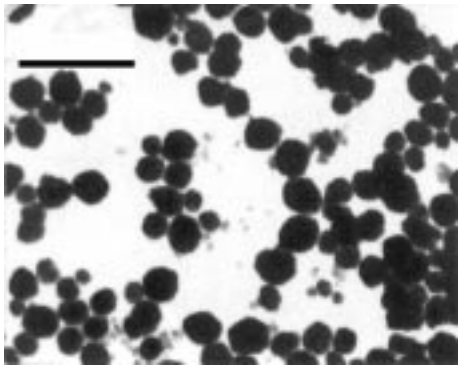

Fig. 1. Photomicrograph of the HTD sample with globular structure of aggregates, obtained by thermal hydrolysis of oxotitanium(IV) sulfate solution at 130°C. Magnification 10000. The bar corresponds to 10 μm.

* Anatase and rutile samples were obtained by calcining HTD for 2 and 4 h at temperatures 25°C lower and higher than T_1; (m) stands for the anatase globules of mosaic structure.

** Weight percentage with respect to TiO_2 in HTD, in terms of the corresponding oxide.

for synthesizing titanium dioxide pigment of anatase and rutile modifications, were modifying additives [2]. To attain the uniform distribution throughout the sample bulk, the modifying additives in the form of aqueous solutions of KOH, H_3PO_4, $MgCl_2$, and $ZnCl_2$ (all chemically pure grade) were added to concentrated HTD suspensions with vigorous stirring. In some tests, rutile crystals, obtained by the method described in [2], were introduced into HTD suspension as a seed. The composition of the modifying additives in the HTD samples is given in the table.

The HTD samples obtained were dried at 100°C to constant mass, ground, and subjected to isothermal calcination at 200–1100°C for 0.5–5 h in air.

The phase composition and particle size of the samples were determined by X-ray phase analysis (DRON–3 diffractometer, filtered CuK_α radiation) and transmission electron microscopy (UEMV-100K electron microscope), and their chemical composition, by volumetric chemical analysis and thermogravimetry [MOM derivatograph (Hungary)]. The unit cell parameters a and c of HTD and anatase were determined from the (116) and (220) reflections with polycrystalline MgO reference (chemically pure grade). The average size of the crystals D was estimated by the Selyakov–Scherrer formula [9]. In this case, it was taken into account that, according to the approximation results [(200) and (400) reflections of HTD and (004) and (008) reflections of anatase] and the data of [3], small crystals produce the main contribution to the physical broadening β of the reflections. The degree of the phase transition of anatase into rutile was determined by standard procedure of quantitative X-ray phase analysis [10]. The determination accuracy was ±1.5 wt % at a 0.95 confidence level.

According to chemical analysis, the initial HTD sample has the composition $TiO_2 \cdot 0.035SO_3 \cdot 0.61H_2O$. The DTA curves have two broad endothermic peaks due to HTD dehydration (at 150–500°C) and desulfation (at 600–900°C).

The X-ray phase analysis showed that the initial HTD has an anatase-like structure with increased, however, unit cell parameters a and c (a = 0.31812 ± 0.0007 and c = 0.9530 ± 0.0005 nm). The average size of the HTD crystals is 16 nm. The comparison of the sizes of aggregates and crystals showed that each globule contains about 4000 randomly oriented primary HTD crystals.

In the temperature range of dehydration, the unit cell parameters of the samples monotonically decrease to the values typical of anatase [11], with the reflection half-width remaining virtually constant: a = 0.3785 ± 0.0007 and c = 0.9514 ± 0.0005 nm. The desulfation is accompanied by a sharp narrowing of all the anatase reflections, which shows that the average size of the crystals increases (16 nm at 500°C and 90 nm at 900°C). The diffraction patterns of the samples thermally treated at 900°C and above contain, along with anatase reflections, also rutile reflections.

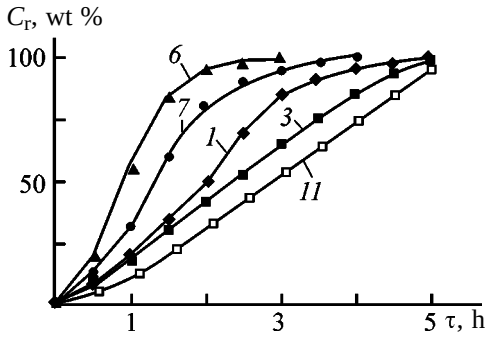

Fig. 2. Rutile content C_r in titanium dioxide vs. time of isothermal calcination τ of the HTD samples. Calcination temperature (°C): (*1*) 925, (*3*) 1025, (*6, 7*) 825 and (*11*) 975. Curve nos. are sample nos. in the table.

The rutile content monotonically increases with calcination time (Fig. 2).

No significant changes in the globule shape and size upon HTD dehydration and desulfation were revealed by electron microscopy. In the anatase sample obtained at 600°C, the globules have a mosaic structure, which confirms formation of 15-nm pores or cavities in the course of dehydration. With calcination temperature increased above 900°C, the number of defects in the globules is decreased and their average size is increased to approximately 75 nm. Upon the phase transition of anatase into rutile, the size of the titanium dioxide globules sharply increases. The photomicrographs of the rutile sample obtained at 975°C revealed the single crystals of about 0.2 μm size with the morphology close to that of the initial HTD globules. The bulk of the sample consists of irregular aggregates of up to 1.5 μm size, formed by sintering of several spherical globules.

The thermal transformations in the modified samples at $T_1 \leq 750$°C are similar to those in the initial HTD. At higher calcination temperatures, the modifiers affected the anatase coalescence and (or) the polymorphous transition of anatase into rutile, as well as the particle size of titanium dioxide (see table).

The effect produced on the HTD transformations by each individual modifier is as follows: (a) magnesium and zinc compounds, as well as seed crystals, decrease by ~100°C the temperature T_1 of the anatase → rutile transition. At the same time, they facilitate sintering of rutile crystals into dense aggregates; (b) phosphoric acid retards anatase coalescence, increases by ~100°C the temperature T_1, and promotes formation of large aggregates of anatase and rutile; (c) potassium hydroxide does not noticeably affect the size of titanium dioxide aggregates and increases by ~50°C the temperature of the rutile formation. When several modifiers producing opposite effects on the anatase → rutile transition are added into HTD simultaneously, the modifier whose individual influence is greater produces the greater effect. Note that potassium hydroxide and phosphoric acid, jointly introduced into HTD, intensify mass exchange in titanium dioxide. This is manifested in "healing" of defects in the surface layer of anatase globules, which maintain initial form and size, and also in the formation of nearly isometric rutile crystals.

Comparison of the experimental results and published data [2, 3] shows that HTD formed by thermal hydrolysis from titanium(IV) sulfate solutions has an approximately 3 times smaller water content and has the 100–150°C higher transition temperature than the samples synthesized at atmospheric pressure.

When discussing the localization of water molecules and sulfate ions in HTD and the processes occurring upon their thermal desorption, it should be noted that variations of the unit cell parameters *a* and *c* upon dehydration agree, on the whole, with the data of [3] and show that the water (or at least its part) can enter the HTD crystal. In the course of dehydration, cavities and channels appearing at the crystal boundaries owing to H_2O diffusion within the HTD globules form their pore structure, which is observed on the photomicrographs of the dehydrated samples.

It may be assumed that, according to Belov's data [12], sulfate ions are located on the surface of the initial HTD crystals and form chemical bonds stabilizing the surface layer of crystals. In the course of breakdown of sulfate ions and removal of SO_3, two types of active centers are formed on the surface of anatase crystals: Ti(III) ions and unsaturated O^{2-} radicals [13]. As a result, the surface layer becomes unstable, which facilitates the mass exchange of crystal-forming complexes between anatase single crystals (coalescence). Since at relatively low temperatures (600–900°C) the mass exchange occurs via surface diffusion [14], the coalescence can be localized within a single globule. This fact can explain why HTD globules and anatase crystals acquire a similar shape.

Unlike topochemical solid-state reactions of dehydration and desulfation [14], the phase transitions in finely dispersed systems can proceed by the dissolution–deposition mechanism [15] involving formation of nuclei of the equilibrium phase (rutile), dissolution of crystals of metastable phase (anatase), and transfer of crystal-forming complexes to rutile nuclei and their incorporation into them. Since the probability of nucleus formation is proportional to the equilibrium concentration of the crystal-forming complexes c_{cfc},

which, in its turn, varies regularly with temperature, the nucleation is the limiting stage at relatively low calcination temperatures. This can explain the decreased temperature of the anatase → rutile phase transition in the HTD samples with added seed crystals of a rutile-like structure and in those with added magnesium and zinc compounds. The latter interact with TiO_2 with formation of titanates, which, having rutile-like crystal structure, act as seed crystals [2].

The anatase → rutile transition is exothermic. The calculations performed in [6] on samples consisting of anatase crystals, which are in contact between each other, showed that the phase transition, while starts, results in an approximately 140°C overheating of the anatase crystals in the boundary layer, which intensifies the polymorphous transition within a single polycrystalline globule. Therefore, under the conditions of hindered diffusion, the configuration of the rutile crystals being formed is largely determined by the initial HTD structure, including contacts between neighboring globules, and the resulting rutile crystals have no regular morphology.

The experimental data on the effect of H_3PO_4 and $KOH + H_3PO_4$ additives on the thermal transformations of HTD and the dispersion composition of titanium dioxide can be unambiguously judged in the framework of the given model. For example, in the samples modified with phosphoric acid, phosphate ions can replace sulfate ions with the formation of stronger chemical bonds with Ti(IV) ions [2]. This decreases c_{cfc}, and, as a consequence, hinders the anatase coalescence and increases the temperature of the anatase → rutile transition. Moreover, compared to SO_4^{2-} ions, PO_4^{3-} ions can form a larger number of bonds, including those with atoms of the surface layer of neighboring globules. As a result, the size of the anatase and rutile aggregates increases. The joint introduction into HTD of potassium hydroxide and phosphoric acid yields potassium phosphates. In this case, the enhanced mass exchange in the titanium dioxide samples may be due to the formation of fusible eutectics, leading to the increase in the surface diffusion coefficient of the crystal-forming titanium(IV) complexes.

CONCLUSIONS

(1) The temperature ranges of dehydration, desulfation, and the anatase → rutile phase transition, occurring in calcination in air of hydrated tianium dioxide with globular structure of aggregates, obtained by thermal hydrolysis of oxotitanium(IV) sulfate solution at 130°C, were refined.

(2) The effect of modifying additives of potassium, magnesium, zinc, and phosphorus compounds, as well as seed crystals of rutile-like structure, on the thermal transformations of hydrated titanium dioxide and its particle size were studied.

Received May 7, 2001; in final form, February 28, 2002

Abstract—Oxidation of Sn(II), hydrolysis, and colloid formation in storage of acidic and alkaline $SnCl_2$ solutions were studied as influenced by various ligands. The correlation between these processes was analyzed, and the composition of the colloids and precipitates was determined.

Tin-containing solutions, among them $SnCl_2$ aqueous solutions, are used for plating with tin and its compounds. In these solutions, Sn(II) can be reduced to metal by various procedures: addition of appropriate water-soluble reductants, use of a reducing metal support, and disproportionation. These procedures allow production of protective-decorative wear-resistant and solderable coatings. The combined reduction of tin and other metals is also widely used [1–9]. Films based on SnO_2 can be prepared by a sol–gel process based on hydrolysis of tin-containing compounds. These films are used in production of selective gas sensors and liquid-crystalline indicators [10–13]. The hydrolysis of $SnCl_2$ is used also for activation of dielectric surface, with the aim of subsequent metal coating, by predeposition of discontinuous films based on tin hydroxo complexes [1–3, 14–21]. The Sn(II) compounds are oxidized with atmospheric oxygen. It was found that UV irradiation of discontinuous films, promoting their oxidation with atmospheric oxygen, results in loss of their reducing power. This effect is used for selective activation of separate sites of the support surface [14–18].

As a rule, films based on pure metallic tin and its alloys, and also tin-containing oxo and hydroxo compounds are deposited from acidic (pH 1–3) or alkaline (pH 9–12) $SnCl_2$ solutions containing tin complex ions. In these solutions, a set of complexes are formed [1–5, 19–24]. These complexes are slowly hydrolyzed to give polycondensed and polymerized species which, even at thorough adjustment of pH, are converted to colloid particles capable of coagulation and sedimentation. Depending on the rate and features of these processes, they can play either positive or negative role in both the coating with metallic tin and its alloys and predeposition of discontinuous films. Colloid particles must have definite composition, size, and concentration to obtain tin-containing films with definite characteristics. For example, if in preparation of tin hydroxide films, along with sorption of colloid particles of nanometer size, coarser particles with a size of a few tens of nanometers are also sorbed, the coating adhesion deteriorates and looser films are formed. In subsequent palladium deposition on such loose films by reduction of Pd(II) in solution, the palladium particles are distributed nonuniformly over the film surface. All these drawbacks are also typical of metallic films deposited from solutions containing nonuniform palladium particles as catalyst [1, 9, 16, 19–21]. It was found [4–6] that, in cathodic electroplating, the sorption of nanometer tin-containing colloid particles favorably changes the overvoltage and improves the film microstructure [4–6]. In sorption of coarse colloid particles formed in hydrolysis of Sn(II) on the cathode surface, loose films are formed. Under these conditions, the tin deposition is suppressed because of passivation of the growing film surface. To eliminate Sn(II) hydrolysis, various procedures were developed including not only pH adjustment, but also introduction into the coating solutions of appropriate ligands (chloride, citrate, tartrate, diphosphate, fluoride, and fluoroborate anions) [14, 22, 23] and colloid stabilizers (gelatin, polyethylenepolyamine, phenol, etc.) [5, 24].

At present, in production of tin-containing films and coatings with prescribed characteristics by their deposition from $SnCl_2$ solutions, the optimal conditions and procedures are chosen empirically. In this connection, it is important to study the effect of colloid formation, coagulation, and sedimentation on the composition of the coating solutions in their storage. These factors are poorly understood. Data on the

1070-4272/02/7505-0700$27.00 © 2002 MAIK "Nauka/Interperiodica"

composition of colloid particles and also on the effect of the storage time on the composition, size, and concentration of the colloid particles are lacking. Data on colloid formation in alkaline tin-containing coating solutions also are extremely scarce. It is known that Sn(II) is fairly rapidly oxidized with atmospheric oxygen [14, 16, 19–21, 25–27]. In the majority part of published works, the kinetics of Sn(II) oxidation was studied in hydrogen chloride solutions, and different kinetic equations were reported [19–21, 26, 27]. These equations do not take into account the fact that, simultaniously with Sn(II) oxidation, the hydrolysis of the oxidized species proceeds, which is followed by colloid formation and sorption of hydrolyzed tin-containing species on the solid surface [1, 2]. Neglect of these factors can be responsible for the discrepancy between the above-noted kinetic equations. To date, only sparse data were reported on the correlation between Sn(II) oxidation and hydrolysis, relationships of colloid formation in storage of $SnCl_2$ solutions, and factors influencing the coagulation and sedimentation of colloid particles.

Therefore, we performed a combined study of Sn(II) oxidation, hydrolysis, colloid formation, coagulation, and sedimentation in storage of both acidic and alkaline $SnCl_2$ aqueous solutions in the presence of various ligands. The correlation between these processes was studied as influenced by the composition of solutions.

EXPERIMENTAL

The compositions of $SnCl_2$ aqueous solutions used in our experiments are listed in Table 1. These solutions were placed in approximately spherical 1-l flasks, to ensure the minimal ratio of the glass surface to solution volume, and stored in the dark at $20 \pm 2°C$. The solutions were kept without stirring under conditions of free diffusion of oxygen. The oxygen concentration in the solutions was constant ($\sim 1.3 \times 10^{-3}$ M) owing to its easy transfer from air. Under these conditions, the equilibrium between the solutions and atmospheric oxygen was reached within 20 min which is considerably less than the time required for formation of detectable amounts of oxidized tin species (several hours or days). The Sn(II) concentration in solutions was determined by titration with iodine under a CO_2 atmosphere at HCl concentration of 1.5 M. This procedure ensures the tin(II) determination in amounts as small as 0.0025 M [28]. In the separate experiments, we found that this analytical procedure allows determination of Sn(II) occurring in the form not only of truly soluble species but also of colloid particles soluble in 1.5 M HCl. In determination of the total amount of Sn(II) and Sn(IV), Sn(IV) was preliminarily reduced with aluminum cuttings in a CO_2 atmosphere [29]. The relative error of Sn(II) determination does no exceed 5%. The reproducibility of the analytical results was no less than 90%. To estimate the sorption loss of tin on a glass surface, the total concentration of Sn(II, IV) was determined before and after the contact of the tin-containing solution with a glass plate for a prescribed time.

Table 1. Composition of tested solutions

Solution no.	$SnCl_2$	Medium
	c, M	
1	0.11	HCl, 0.11
2	0.11	HCl, 0.06
3	0.11	HCl, 0.11 + KCl, 1.60
4	0.11	HCl, 0.66
5	0.11	HCl, 0.66 + KCl, 1.60
6	0.22	NaOH, 1.40 + EDTA, 0.01
7	0.22	NaOH, 1.50 + $NH_3 \cdot H_2O$, 0.4
8	0.22	NaOH, 2.50
9	0.22	NaOH, 1.00 + $KNaC_4H_4O_6$, 0.28

Electron-microscopic and electron diffraction studies were carried out on an EM-125 transmission electron microscope. The specimens for electron-microscopic study of solid particles formed in the $SnCl_2$ solutions were prepared by placing a drop of the colloid solution or suspension on a collodion film. The powder electron diffraction patterns of the same samples were obtained with the electron microscope in the microdiffraction mode. The phase composition of the solid was determined from no less than four diffraction maxima at the accuracy of determination of the interplanar spacings no less than 0.01–0.02 Å. The diffractometer was equipped with a Powder Diffraction File software based on the ICPDC-89 data bank.

We found that, with increasing storage time, the Sn(II) content in $SnCl_2$ aqueous solutions gradually decreases. We believe that the main process causing the depletion of Sn(II) solution are as follows: Sn(II) oxidation, hydrolysis of tin-containing compounds, formation of tin-containing sols, coagulation, and sorption of the coagulated species on the surface of the flask walls. In storage of acidic Sn(II) solutions, the Sn(II) content rapidly decreases in the first 5–10 days, after which the tin loss becomes slower. With increasing HCl concentration, Sn(II) loss from solution decreases. The effect of the HCl concentration on the Sn(II) loss is demonstrated in Table 1. These data

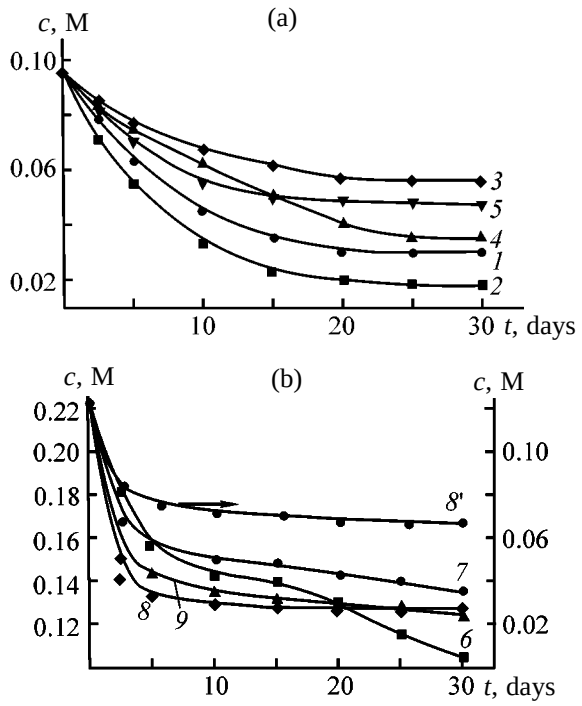

Fig. 1. Sn(II) concentration c in $SnCl_2$ solutions as a function of the storage time t. Solution: (a) acidic and (b) alkaline; the same for Fig. 2. The solution numbers (Table 1) are indicated at the corresponding curves; (*8'*) alkaline solution no. 8 with $SnCl_2$ concentration of 0.11 M.

show that, in solution no. 1, about 50% of Sn(II) was lost in the course of 10-day storage. In passing to solution no. 2 with the lowest HCl concentration, the tin loss increased to 60%. At the same time, at the maximal HCl concentration of 0.66 M (solution no. 4), only about 30% of Sn(II) was lost. We found that addition of excess KCl to $SnCl_2$ solutions decreases the Sn(II) loss to the same extent as the addition of excess HCl (solution nos. 3 and 5, Table 1). In the presence of a 15-fold excess of chloride anions introduced as KCl (solution nos. 3 and 5), the oxidation of Sn(II) in the late stage of storage (after 15–30 days) was noticeably slower than in solutions with a 6-fold excess of chloride anions introduced as HCl only. In storage of acidic $SnCl_2$ solutions containing predominantly Sn(II) aqua and hydroxychloride complexes (solution nos. 1 and 2), the average rate of the Sn(II) loss within the first five days was approximately 8×10^{-3} mol l^{-1} day^{-1}. In storage of solutions with prevalence of tin chloride complexes (solution nos. 3–5), the rate of Sn(II) loss decreased by a factor of 2.

In storage of $SnCl_2$ alkaline (solution nos. 6–9, Fig. 1b) and acidic (solution nos. 1–5, Fig. 1a) solutions, the shape of the kinetic curves and the rate of Sn(II) loss are similar. In the main part of our experiments, we used alkaline $SnCl_2$ solutions with the Sn(II) concentration twice that in the acidic solutions. The similar alkaline solutions are applied, as a rule, in production of tin films by Sn(II) dispropotionation and electroplating. Figure 1b shows that, in passing from acidic to alkaline solutions, the fast stage of Sn(II) loss is shortened by a factor of two and the loss is faster. The increase in Sn(II) loss in alkaline solutions correlates with the higher $SnCl_2$ concentration in them. The minimal Sn(II) loss occurred in storage of $SnCl_2$ solutions containing $NH_3 \cdot H_2O$ as an additive (solution no. 7). The stabilization of $SnCl_2$ alkaline solutions on addition of tartrate and ethylenediaminetetraacetate anions was insignificant. The fastest Sn(II) loss occurred in storage of $SnCl_2$ solutions within the first 10 days. The enhanced stability of Sn(II) to oxidation in acidic $SnCl_2$ solutions is caused by complexation of Sn(II) with chloride anions on addition of a 6–15 fold excess of this ligand. In alkaline solutions oxidation of Sn(II) can be eliminated by addition of a 6–7-fold excess of NaOH along with the two-fold excess of $NH_3 \cdot H_2O$.

As seen from Fig. 1, in storage of acidic $SnCl_2$ solutions for 10–15 days, the Sn(II) loss is decelerated by a factor of 8–10. For alkaline solutions, the same deceleration is observed after 3–5-day storage. Within these periods, the oxygen concentration in $SnCl_2$ solutions does not change noticeably and the Sn(II) content in them remains sufficiently high (no less than 20–70% of the initial $SnCl_2$ concentration). Therefore, most likely, the nearly complete cessation of the Sn(II) loss after 10–15 day storage is caused by the fact that by this time the most reactive complexes have been already oxidized, and only species that are the most stable to oxidation and hydrolysis remain in the solution. The exception are solution nos. 4, 6, and 7 in which transformations of tin-containing compounds continue at a low rate. The total amount of Sn(II) + Sn(IV) sorbed on flask walls is about 0.005–0.008 mol m^{-2}, which is substantially smaller than the tin loss in storage of $SnCl_2$ solutions.

In storage of $SnCl_2$ solutions, a small precipitate is gradually formed. In acidic $SnCl_2$ solutions, this precipitate usually becomes visible within 30–45 days after preparation of fresh solution. In the solution no. 2 with the minimal content of chloride anions, the visible precipitation is observed within a shorter time (12 days). The weight fraction of this initially formed precipitate is no more than 8 wt % of the total $SnCl_2$ amount in the fresh solution. In further storage, the weight of the precipitate slightly increases. In alkaline

solutions, the precipitate is formed within the first day after preparation of the fresh solution, and its amount varies from 4 to 9 wt % of the initial $SnCl_2$ content. After storage for 10 days, the weight fraction of this precipitate increases to 7–15 wt % . The precipitate formation is the fastest in solution no. 6. In further storage, the precipitation sharply decelerates. The slowest precipitation was observed in solution no. 7.

Our results show that precipitation of tin-containing compounds cannot be responsible for Sn(II) depletion in storage of acidic $SnCl_2$ solutions for 12–30 days. The Sn(II) loss found by us in storage of $SnCl_2$ alkaline solutions exceeds the expected Sn(II) depletion due to precipitation by a factor of 2–5. These facts suggest the existence of additional factors along with the sorption and precipitation, responsible for decrease in the Sn(II) concentration. To elucidate these additional factors, we determined the total concentration of Sn(II) + Sn(IV) in the solutions as influenced by the storage time. The kinetic curves (Fig. 2) show that, in storage of both the acidic and alkaline solutions, the total content of analytically determinable tin-containing compounds decreases. This fact only partly can be attributed to precipitation of tin compounds, which is particularly typical of alkaline solutions. Most likely, the "loss" of tin is caused by the fact that a certain tin fraction occurs as an analytically undeterminable colloid insoluble in 1.5 M HCl.

The data on the Sn(II) and Sn(II) + Sn(IV) loss are listed in Table 2. These data show that, after storage, more than a half of the initial Sn(II) cannot be determined in solutions even after reduction of Sn(IV). In most cases, the total Sn(II) and Sn(IV) loss ranges from 50 to 70%. In solution no. 5 with prevalence of chloride complexes, the fraction of undeterminable tin-containing species is considerably lower. In solution nos. 6 and 7, within the storage time tin almost completely transforms into undeterminable species.

The difference between the initial and current tin amounts shows that, in storage of both acidic and alkaline $SnCl_2$ solutions, colloid species insoluble in 1.5 M HCl are formed. The tin amount contained in these colloids cannot be determined by titration with iodine.

In storage of $SnCl_2$ solutions, Sn(II) oxidation correlates with colloid formation. Oxidation of Sn(II)

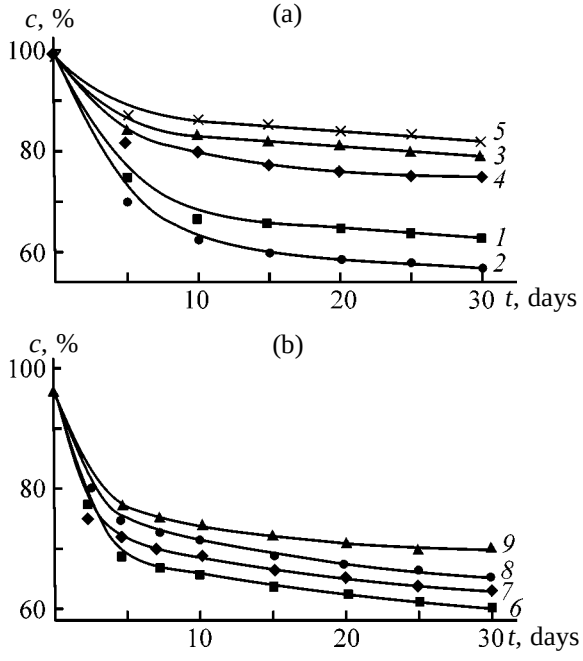

Fig. 2. Total relative Sn(II) + Sn(IV) concentration c in $SnCl_2$ solution as a function of the storage time t. The solution numbers (Table 1) are indicated at the corresponding curves.

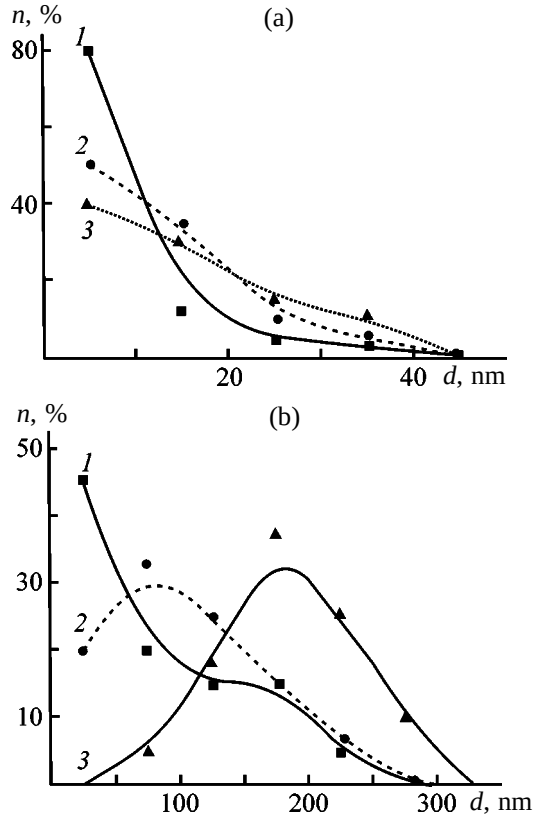

Fig. 3. Size distribution of colloid particles in (a) solution no. 1 and (b) solution no. 2 (Table 1). (*n*) Fraction of particles with a given size, and (*d*) particle size. Storage time (days): (a) (*1*) 0, (*2*) 15, and (*3*) 25; (b) (*1*) 1, (*2*) 7, and (*3*) 15.

promotes the colloid formation, and colloid particles are enriched in Sn(IV). The Sn(II) : Sn(IV) molar ratio is approximately 1 : 3 both in the precipitates formed spontaneously and in those obtained by coagulation of the colloid particles with a strong electrolyte. Such a pattern is observed with both the acidic and alkaline $SnCl_2$ solutions, irrespective of the storage time. The electron-microscopic study showed that about 80% of colloid particles formed in the freshly prepared acidic $SnCl_2$ solutions have a size in the range 5–20 μm (Fig. 3a). The amount of coarser (40–60 nm) particles is no more than 1-2% of the total number of the colloid particles in the freshly prepared acidic solutions and increases to 8–10% during 30-day storage. At the similar storage time, the colloid formation is considerably slower in solutions containing excess H^+ and Cl^- ions than in those containing aqua and hydroxo complexes. Thus, excess H^+ and Cl^- ions suppress the colloid formation and coagulation of colloid particles. In storage of alkaline $SnCl_2$ solutions, the colloid particles also are coarsened and their size exceeds that of colloids formed in acidic solutions by an order of magnitude (Fig. 3b). For example, the main fraction (about 50%) of colloid particles formed in freshly prepared alkaline solutions have a size in the range 20–50 nm. Upon storage of these solutions for 15 days, the size of the particles increases to 15–150 nm. After 30-day storage, aggregates with a size of 150–300 nm are formed, and their fraction is no less than 70%. The coarsening of the colloid particles in storage of solutions is accompanied by a decrease in the content of fine colloids. The electron diffraction phase analysis showed that the precipitates isolated from acidic $SnCl_2$ solutions include the phases of Sn(II, IV) hydroxychlorides and other oxo and hydroxo complexes: SnO_2, $Sn_4(OH)_6Cl_2$, Sn_3O_4, $Sn_{21}Cl_{16}(OH)_{14}O_6$, and $Sn_3O_2(OH)_2$. The precipitates isolated from alkaline solutions include, along with the phases of hydroxo complexes $Sn_3O_2(OH)_2$ and $Na_2[Sn(OH)_6]$, also the phase of metallic tin (β-Sn).

Our results show that Sn(II) is lost by simultaneously occurring Sn(II) oxidation to Sn(IV) and hydrolysis. With increasing Sn(IV) concentration, the hydrolysis rate increases. The hydrolysis products polymerize to form colloid particles including Sn(II) hydroxychloride and hydroxo complexes and also stannic acids capable of converting into SnO_2 and Sn_3O_4. More than a half (with respect to mole fraction) of the tin-containing oxidized and hydrolyzed species are insoluble in 1.5 M HCl and cannot be determined by titration with iodine. Due to gradual coagulation and sedimentation of colloids, the precipitates are formed whose chemical composition is similar to that of the colloid particles. The size of the colloid particles ranges from units to tens of nanometers. The colloid particles formed in acidic solutions are finer than those formed in alkaline solutions. The colloid solutions concerned are sufficiently stable, and therefore their existence should be taken into account in electrodeposition of multicomponent films based on metallic tin and its dioxide.

CONCLUSIONS

(1) In storage of both acidic and alkaline $SnCl_2$ solutions containing different ligands, the Sn(II) concentration decreases by 10–70% within 5–10 days, and then the Sn(II) loss decelerates.

(2) The decrease in Sn(II) concentration is caused by Sn(II) oxidation, hydrolysis, and formation of colloid particles containing Sn(II) and Sn(IV) in the 1 : 3 ratio. In acidic solutions, the colloids are formed including poorly crystalline SnO_2, Sn_3O_4, $Sn_4(OH)_6Cl_2$, $Sn_{21}O_{16}(OH)_{14}O_6$, and $Sn_3O_2(OH)_2$. In

alkaline solutions, the colloids consist of poorly crystalline $Sn_3O_2(OH)_2$, $Na_2[Sn(OH)_6]$, and β-tin.

(3) In storage for 5 days, about 50–70% of the initial Sn(II) is converted to colloid particles. The colloid solutions are fairly stable to coagulation and sedimentation. The tin contained in the colloid particles cannot be determined titrimetrically, which should be taken into account in analysis of tin-plating solutions.

(4) The oxidation of Sn(II) and simultaneous hydrolysis of tin-containing compounds can be controlled by complexation with chloride and hydroxide anions at their 5–10-fold excess.

Abstract—Coprecipitation of 3*d*-element impurities from solutions of calcium nitrate with hydrated aluminum oxide (collector) was studied using radioactive tracers. The structure of the collector was studied by ^{1}H NMR and IR spectroscopy.

In chemical industry, calcium nitrate is a key compound for preparing practically important calcium products (carbonate, fluoride, phosphate, chromate, oxalate, etc.) [1, 2].

Recently, ultrapure calcium compounds (carbonate, phosphate, and fluoride) have found application in manufacturing optical fibers, optical glasses, single crystals, luminophores, etc. Therefore, it is urgent to develop a method for thorough purification of calcium nitrate, which is the most accessible raw material.

The prospects of using the known methods for purification of calcium nitrate were considered in detail [3]. Two purification methods were studied experimentally: crystallization from aqueous solutions and coprecipitation of impurities with inorganic collectors. The efficiency of using calcium hydroxide, calcium carbonate, and hydrated oxides of aluminum and zirconium as inorganic collectors was checked with radioactive tracers, and hydrated oxides of aluminum and zirconium showed much promise in this respect [3].

Despite a great deal of works concerning coprecipitation of impurities with collectors, use of this process in purification of inorganic substances is largely limited by complexity and insufficient understanding of the occurring processes [4–7].

Collectors show promise in technology of ultrapure substances, as they provide highly efficient simultaneous removal of a great number of impurities to virtually zero residual concentration in the solution. The isomorphism and isodimorphism, though complicating crystallization of the majority of salts from aqueous solutions [8], in the given case play the positive role, facilitating coprecipitation of impurities.

In this work, we studied the purification of aqueous solutions of calcium nitrate using an inorganic collector, hydrated aluminum oxide (HAO).

EXPERIMENTAL

Since at present the efficiency of coprecipitation of impurities with inorganic collectors cannot be calculated theoretically, the conditions of purification of calcium nitrate solutions with HAO were studied experimentally.

As collector for purification of aqueous solutions of calcium nitrate, we chose HAO of the composition $Al_2O_3 \cdot nH_2O$, precipitated in a purified solution by addition of calculated amounts of aluminum nitrate $Al(NO_3)_3 \cdot 9H_2O$ [ultrapure 17–3 grade, TU (Technical Specifications) 6-09-3657–74)] and aqueous ammonia [chemically pure grade, GOST (State Standard) 3760–64].

Aluminum(III) is readily hydrolyzed in aqueous solutions: the precipitation starts at pH 4 and is complete at pH 7.5–8.2 [9]. At pH 4–7, the precipitate is amorphous and contains aquahydroxo complexes of various compositions, whereas at pH 8–11 it contains crystalline particles [10].

Solutions of calcium nitrate were prepared from analytically pure grade $Ca(NO_3)_2 \cdot 4H_2O$ (GOST 4142–77). Its concentration was 20 wt %, as at higher concentrations the solution becomes too viscous, which hinders sedimentation and separation of the collector, whereas at lower concentration the process becomes less efficient because of large volumes of water to be evaporated.

The study was performed using ^{59}Fe, ^{60}Co, ^{54}Mn,

^{63}Ni, ^{51}Cr, and ^{64}Cu radioactive tracers. The γ-radiation was measured with a BDIS 3-05 device equipped with a thallium-activated NaI detector and a PS-2 scaler. The accuracy of the radioactive measurements was 2–3 rel %.

The β-radiation (^{63}Ni) was measured with scintillating granules [11]. The measurement accuracy was ±10 rel. %. The purification coefficient K_p was calculated as the ratio of the specific activities of the initial and purified calcium nitrate solutions [8].

To a 20% calcium nitrate solution (50 ml), we added calculated volumes of tracer solutions. The mixture was stirred, and the radioactivity was measured. After that, we added the calculated amount of a 20% solution of aluminum nitrate and then, gradually with stirring, 25% aqueous ammonia to pH 7.5–8 (pH-262 pH meter). After that, the mixture was stirred for 0.5 h. The precipitated collector was separated on a TsLN-2 centrifuge, and the purified solution was taken for the radioactivity measurement. The solution pH was maintained at 7.5–8.0 in all the tests, unless otherwise stated. The impurity elements were added in concentrations excluding formation of individual phases of the corresponding metal hydroxides. The collector weight was constant in all the experiments, except those on choosing the precipitation conditions.

In experiments on choosing the collector weight, the content of iron(III) and copper(II) impurities in a solution before and after purification was determined by the extraction-photometric procedure: iron(III), in the form of dibenzoylmethanate and copper, in the form of diethyldithiocarbamate (detection limit 5×10^{-6} and 4×10^{-6} wt %, respectively) [12].

The ^1H NMR spectra were recorded on a W 2112 NMR spectrometer (Varian, the United States) at –193°C and room temperature.

The IR spectra were recorded on a Specord 75-IR spectrophotometer in the 400–4000 cm^{-1} range (KBr pellets). The error in determining the band maximum frequencies did not exceed 3–4 cm^{-1}.

We studied how the collector weight, the time of contact of a solution with a collector, solution pH, the concentration of microimpurities, and the oxidant affect the process efficiency and then chose the conditions of purification of calcium nitrate solutions with HAO.

The kinetics of coprecipitation of impurities from a 20% solution of calcium nitrate with HAO was studied with ^{59}Fe and ^{64}Cu tracers. The iron(III) and copper(II) concentrations were 1×10^{-4} and 5×10^{-5} wt %, respectively, solution pH was 7.5–8.0, and the amount of $Al(NO_3)_3 \cdot 9H_2O$ added was 2 g per 100 g of $Ca(NO_3)_2$. Iron(III) and copper(II) impurities were chosen as typical double- and triple-charged ions differently interacting in the systems $M(NO_3)_n$–$Al(NO_3)_3$–$NH_3 \cdot H_2O$–H_2O (M is Fe or Cu) at 25°C, constant aluminum(III) concentration, and pH 7 and 9 [13, 14].

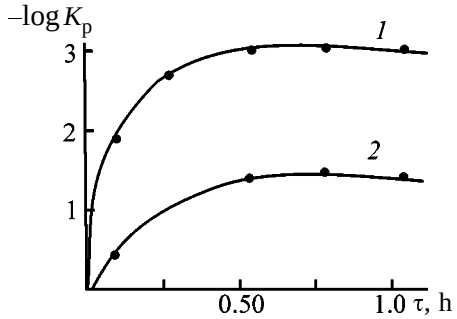

Fig. 1. K_p of a 20% solution of calcium nitrate on HAO vs. τ. (*1*) Fe(III) and (*2*) Cu(II).

Our results (Fig. 1) show that the equilibrium is virtually attained within 30 min. Increasing the process time did not considerably increase the purification coefficient. Therefore, the time of contact of a collector with a solution was 30 min in all subsequent tests.

The study of the $M(NO_3)_n$–$Al(NO_3)_3$–$NH_3 \cdot H_2O$–H_2O systems [M is Cu(II), Mn(II), Ni(II), Fe(III), or Cr(III)] at 25°C in a wide range of component concentrations by the method of isomolar series at a constant concentration of aluminum nitrate and pH 7–10 [13–17] showed that, in the range of low concentrations, the distribution of 3*d*-element impurities is uniform. The minimal collector weight ensuring thorough purification of a calcium nitrate solution was determined from the results on the coprecipitation of iron(III) and copper(II) impurities with HAO. The contact time was 30 min, the iron(III) and copper(II) concentrations were 2×10^{-4} and 7×10^{-5} wt %, respectively, solution pH was 7.5–8.0, and the concentration of the calcium nitrate solution was 20 wt %.

Our results (Table 1) show that the addition of a small amount of the collector-forming compound (0.73–1.11 g) results in virtually complete coprecipitation of iron(III); the copper(II) impurity is captured to a slightly lesser extent. Therefore, 2.0 g of $Al(NO_3)_3 \cdot 9H_2O$ should be added per 100 g of $Ca(NO_3)_2$.

In the course of the aluminum nitrate hydrolysis, a series of its hydroxo complexes, from $Al(OH)_2^+$, $Al_2(OH)_2^{4+}$, $Al_3(OH)_4^{5+}$, $Al_7O_2(OH)_{14}^{3+}$ to the limiting composition $[Al_{13}(OH)_{32 \pm 2}]^{7+}$, are formed in solution

Table 1. Content of impurities in 20 wt % $Ca(NO_3)_2$ solution depending on the weight of the collector-forming compound

$m_{Al(NO_3)_3 \cdot 9H_2O}$, g/100 g $Ca(NO_3)_2$	Fe(III)	Cu(II)
	wt %	
0.73	1×10^{-5}	1×10^{-5}
1.11	5×10^{-6}	7×10^{-6}
2.00	$<5 \times 10^{-6}$	4×10^{-6}
4.40	$\leq 5 \times 10^{-6}$	$\leq 4 \times 10^{-6}$
11.10	$<5 \times 10^{-6}$	$\leq 4 \times 10^{-6}$

[9, 18, 19]. The aluminum aquahydroxo and aquaoxohydroxo complexes, via hydrogen bonds and van der Waals forces, form three-dimensional cluster structures, which act as nuclei of the dispersed phase of the collector. The NMR spectra showed that, in the sol particles being formed, the aluminum ion has tetrahedral and octahedral ligand surrounding, indicating the presence of $[Al_{13}(OH)_{32 \pm 2}]^{7+}$, $Al_2(OH)_2^{4+}$, and $Al(H_2O)_6^{3+}$ complexes [20].

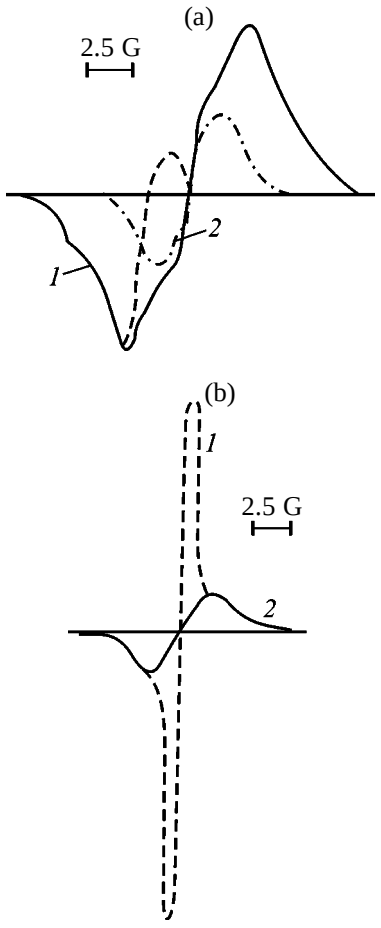

Fig. 2. ^1H NMR spectrum of HAO at (a) –193 and (b) 20°C. (*1*) H_2O and (*2*) OH groups.

We used ^1H NMR and IR spectroscopy to ascertain the role of OH groups and H_2O molecules on the HAO surface in the course of the coprecipitation and the nature of the forming solid phases.

The ^1H NMR spectrum (the first derivative of the absorption line) of the HAO sample that was precipitated at pH 6–8 and has the composition $Al_2O_3 \cdot 6H_2O$ (Fig. 2a), taken at –193°C, is the sum of a doublet from water molecules (δ_H = 12–13 G) and a singlet belonging to OH groups (δ_H = 5–6 G). The share of OH protons in the total amount of the absorbing species (xOH + $2y$$H_2O$) is small and can be determined by graphic integration of the corresponding lines. Water is weakly bound on the HAO surface and at 20°C is mobile on the NMR time scale (rotation, translation) (Fig. 2b). Therefore, at –193°C the doublet due to the rigid lattice of water molecules transforms into a strong narrow singlet (Fig. 2b) superimposing on the OH line, whose parameters are virtually the same at –193 and 20°C. Comparatively high mobility of the water molecules at room temperature is explained by the HAO structure and by hydrogen bonding of H_2O molecules [21]. Our results show that the HAO collector, when precipitated at room temperature, contains OH groups and water molecules coordinated via H bonds.

The IR spectrum of HAO contains structureless absorption bands in the ranges 3000–3600 (H_2O and OH stretching vibrations) and 1400–1600 cm^{-1} (OH^-, H_2O, NH_4^+ bending, and NO_3^- stretching vibrations), and a broad absorption band in the range 400–500 cm^{-1}. In the 3000–3600 cm^{-1} range, the absorption band with a 500 cm^{-1} half-width has no single maxima and is commonly assigned to the stretching vibrations of water molecules hydrogen-bonded with hydroxide ions or each other. The 1400–1600 cm^{-1} range cannot be assigned unambiguously, since it corresponds to bending vibrations of OH groups, water molecules, and NH_4^+ ions and to NO_3^- stretching vibrations [22, 23]. A weak band at 1050 cm^{-1} may be assigned to bending vibrations of Al–O–H bonds. A broad band in the range 400–500 cm^{-1} shows that Al–O oxygen atoms form bonds with other groups, probably with H_2O [22]. The IR spectrum of HAO does not contain narrow bands at 3025, 3290 (boehmite), 3533, 3454 (bayerite), and 3518, 3616 cm^{-1} (hydrargillite), characteristic of OH stretching vibrations. This shows that, in HAO, isolated OH groups are absent and all OH groups form hydrogen bonds with H_2O molecules.

Thus, the ^{1}H NMR and IR study of HAO revealed a large mobility of H_2O molecules and OH groups and showed the possibility of formation of bridging bonds (hydrogen, ol, or oxo bonds) with metal cations.

The speciation of impurities in a solution being purified is largely determined by its pH [8, 9, 24]. The study was performed using radioactive tracers. The concentration of the iron(III), chromium(III), copper(II), manganese(II), and cobalt(II) impurities was 2×10^{-4}–2×10^{-5} wt %, time of contact with a collector, 30 min, and the weight of the collector-forming compound, 2.0 g $Al(NO_3)_3 \cdot 9H_2O$ per 100 g $Ca(NO_3)_2$. The coprecipitation of the iron(III), chromium(III), manganese(II), and cobalt(II) impurities is maximal at pH 8.0–8.5, and that of copper(II), at pH 6.0–6.5 (Fig. 3a). The distribution factor of iron(III) and chromium(III) impurities is virtually pH-independent ($K_p \geq 1000$). Comparison of the data on the Fe(III) behavior (Fig. 3a, Table 1) shows that K_p does not depend on pH and HAO weight. This means that it is uniformly distributed throughout the AHO volume and exists in the nonsorbable forms [6]. The K_p value for copper(II) decreases from 280 to 21 as pH is increased from 6.0 to 9.0. This results from the fact that stable and well soluble complexes $[Cu(NH_3)_4]^{2+}$ are formed in a solution at higher ammonia concentrations [8]. The IR, ^{1}H NMR, and ESR spectra showed that, at low concentrations, virtually all Cu(II) ions coprecipitate with HAO in the form of copper hydroxide. This is due to the replacement of protons of hydroxy groups and to complex formation [13, 25]. The coprecipitation of Mn(II) is a complex process: at pH increased in the range 6.2–8.2, K_p increases, and then it decreases owing to the amphoteric properties of HAO. The ESR spectra show that, at low concentrations and pH 7.0–8.5, Mn(II) is uniformly distributed throughout the HAO precipitate and exists in the form of $[Mn(H_2O)_6]^{2+}$. According to the X-ray phase analysis data, at pH above 9.0, manganese hydroxide is formed and is partially oxidized [15]; the precipitation of $Mn(OH)_2$ is complete at pH ~10.4 [8]. The coprecipitation of cobalt(II) with HAO increases at higher pH values, which is consistent with the data [26, 27] on its state in aqueous solutions.

The effect of H_2O_2 oxidant on the behavior of Cu(II), Mn(II), Co(II), and Cr(III) impurities in coprecipitation from a solution of calcium nitrate was studied using radioactive tracers. After introducing the tracer, the content was treated with an H_2O_2 solution [5 ml of 30% solution per 100 g $Ca(NO_3)_2$] and stirred for 1 h at 60–70°C. Our results show that addition of H_2O_2 facilitates copper(II), manganese(II), and cobalt(II) precipitation (Table 2). Under these conditions, copper forms a peroxide complex [28, 29] detected by ESR (paramagnetic complex with $g_{||}$ = 2.28±0.005, $A_{||}$ = 173.5±5 Oe) [30], whose coprecipitation with HAO increases K_p.

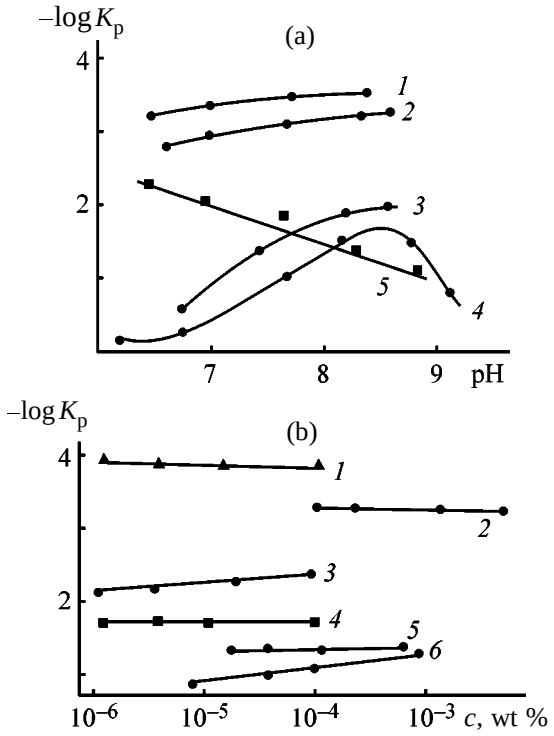

Fig. 3. K_p of a 20% calcium nitrate solution on HAO as a function of (a) pH and (b) impurity concentration c. (*1*) Cr(III), (*2*) Fe(III), (*3*) Co(II), (*4*) Mn(II), (*5*) Cu(II), and (*6*) Ni(II).

The published data on the formation of Mn(II) peroxo complexes are controversial [31, 32]. In HAO precipitates containing manganese(II), obtained at pH 8 in a solution with added H_2O_2, only two known paramagnetic complexes have been revealed by ESR spectroscopy [15]. This means that, under these condi-

Table 2. Effect of H_2O_2 on the purification coefficient of $Ca(NO_3)_2$ solutions with respect to copper(II), manganese(II), cobalt(II), and chromium(III) impurities on HAO

Impurity, wt %	pH	K_p	
		without H_2O_2	with H_2O_2
^{64}Cu, 1×10^{-4}	8.1	34±1	119±3
^{54}Mn, 5×10^{-5}	8.2	35±1	78±2
^{60}Co, 1×10^{-5}	8.2	61±2	187±5
^{51}Cr, 5×10^{-5}	8.1	3000±50	200±6

tions, manganese(II) peroxo complexes are not formed [32] and no marked oxidation of manganese(II) occurs. The observed purification effect (Table 2) may be assigned to some modification of the HAO surface by the formation of peroxide bridging bonds.

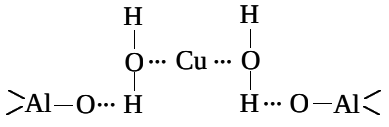
The fact that the purification of calcium nitrate solutions by coprecipitation of cobalt(III) impurity with HAO becomes more efficient on adding H_2O_2 can be explained by $Co(OH)_2$ oxidation to $Co(OH)_3$ [33], whose solubility product is considerably lower [$SP_{Co(OH)_2} = 1.6 \times 10^{-18}$, $SP_{Co(OH)_3} = 1 \times 10^{-45}$] [8]).

The purification factor with respect to chromium(III) decreases upon adding H_2O_2 (Table 2). This is due to its partial oxidation to chromium(VI), which does not coprecipitate with HAO [34, 35]. The observed purification effect (Table 2) can be explained by the fact that a part of Cr(III), along with oxidation to Cr(VI), forms chromium(V) peroxo complexes, which coprecipitate with HAO [36].

In a series of experiments, the concentration of microimpurities in the initial calcium nitrate solution was varied from 10^{-3} to 10^{-6} wt %. The study was performed using radioactive tracers by the procedure described above. The results show that the microimpurity concentration does not affect the purification coefficient in this range (Fig. 3b).

Considering the data on coprecipitation of impurities from aqueous calcium nitrate solutions with HAO in combination with the results of studying the processes occurring in the system by modern analytical methods [isomolar series; physicochemical analysis with constant concentration of aluminum(III) and varied concentration of 3*d*-element impurity; X-ray phase analysis; ^{1}H NMR, IR, and ESR spectroscopy] [13–17, 25, 30], we can conclude that the impurities are captured owing to the formation of bridging bonds with a collector. At pH 6–10, the main 3*d*-element species in nitrate solutions are hydrated cations and hydroxo complexes. Owing to complexation and replacement of protons of OH groups in polymeric chains, the distribution of impurities throughout HAO is uniform in the range of the microconcentrations (10^{-4}–10^{-5} wt %), which is in satisfactory agreement with the data of [4, 5].

The appearance of bridging bonds results in the formation of a complex compound whose structural fragment in the case of Cu(II) has the form



Taking into account the well developed HAO surface, the first stage of coprecipitation is adsorption of hydrated Cu(II) ion. The process mechanism can be presented by the following scheme (fragment) [4, 5, 34]:

$$Al^{3+} \rightleftarrows AlOH^{2+} + Cu(H_2O)_6^{2+} \rightleftarrows AlOCu(H_2O)_5^{+}$$
$$\rightleftarrows AlOCuOH(H_2O)_4^{2+} \rightleftarrows \ldots \rightleftarrows AlOCu(OH)_x^{(5-x)+}$$

As the concentration of 3*d* elements on HAO increases, their distribution becomes nonuniform owing to the formation of large aggregates of the corresponding hydroxides. This results in the ordering of the HAO structure and facilitates formation of chemical compounds (aluminates) for Cu(II), Mn(II), and Ni(II) impurities, and solid solutions for Fe(III) and Cr(III) impurities [37].

CONCLUSIONS

(1) The parameters of the efficient purification of calcium nitrate solutions were found.

(2) The ^{1}H NMR and IR spectra of hydrated aluminum oxide confirmed the large mobility of H_2O molecules and OH groups and showed the possibility of formation of bridging bonds with 3*d*-element ions. The mechanism of coprecipitation was proposed.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Complexation of Calcium Ions with Dicarboxylic Acids in Aqueous Solutions

G. V. Mitrofanova

Mining Institute, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received July 11, 2001; in final form, December 2001

Abstract—Complexation of calcium ion with malonic, succinic, glutaric, and adipic acids at 25°C and ionic strength I = 0.3 (KCl) was studied by pH-potentiometric titration.

Monocarboxylic acids obtained from vegetable raw material are the traditional collecting agents in apatite flotation from apatite–nepheline ores. However, permanent increase in the cost of these reagents and their short supply make urgent the search for new collecting agents obtained from inexpensive raw materials. It is known that introduction of a second functional group into a collecting agent molecule changes its flotation properties. Among the bifunctional compounds capable to be collectors, dicarboxylic acids are of interest as the basis of new synthetic reagents capable to substitute collectors of vegetable origin in apatite flotation [1].

In dressing of apatite-containing ores under conditions of circulating water supply, the liquid phase of the flotation pulp contains substantial amounts of calcium (up to 30 mg l^{-1}), which decreases the activity of reagents and increases their consumption. Therefore, it is important to study complexation of dicarboxylic acids with calcium ions.

The reference data on stability constants of calcium complexes with these acids [2–4] either are inconsistent (i.e., for succinic acid) or refer to formation of only one complex. The known stability constants of calcium complexes with malonic, succinic, glutaric, and adipic acids, recalculated by Davies equation to zero ionic strength, are listed in Table 1.

In this work, complexation of calcium ion with malonic, succinic, glutaric, and adipic acids was studied, and the stability constants of the compounds formed were determined.

EXPERIMENTAL

Complexation was studied by pH-potentiometric titration at 25°C and ionic strength of 0.3 (KCl). Preliminarily we determined under the same conditions the protonation constants of the corresponding acid dianions B_i, required to calculate the complexation constants [5].

The pH of solutions was measured with glass and Ag/AgCl electrodes on an I120.1 ionometer with an error of 0.01 pH unit.

Preliminary studies with 5×10^{-3}–5×10^{-2} solutions at $Ca^{2+} : H_2L = 1 : 1$ [5] showed the absence of calcium complexes in the solution [the formation function $\bar{n} = (c_L - L_f)/c_M$ calculated from the experimental data was negative]. Therefore, we took more concentrated solutions of acids (0.10–0.15 M) and added calcium nitrate (0.1 M, I = 0.3). The concentration ratio $Ca^{2+} : H_2L$ was 1 : 5 and 1 : 3.

The dicarboxylic acids were recrystallized three times from ethanol and dried at reduced pressure. The acid concentration in the solution was set gravimetrically and refined by pH-potentiometric titration. Chemically pure grade calcium nitrate and potassium chloride were used. The calcium concentration was determined by complexometric titration. The KOH

Acid	$\log \beta^0_{CaL}$	References
Malonic H_2Mal	2.50, 2.16,	[2]
	2.75, (1.25)*	[3]
Succinic H_2Suc	2.00	[4]
	2.40, 1.90	[2]
	2.10 (0.99)	[3]
Glutaric H_2Gl	1.76	[2]
Adipic H_2Ad	2.19	[4]

* In parentheses is $\log \beta^0_{CaHL^+}$.

1070-4272/02/7505-0712$27.00 © 2002 MAIK "Nauka/Interperiodica"

concentration in the solution prepared by dilution of the saturated KOH solution [5] was refined by potentiometric titration. All solutions were prepared with freshly boiled distilled water.

Solutions of the acid H_2L, calcium nitrate, and potassium chloride were placed into a temperature-controlled cell, and pH was measured after addition of 0.1-ml portions of 0.3 M KOH. The equilibrium was considered to be attained when pH of the solution remained constant for 2–3 min. A glass electrode was calibrated by buffer solutions before each series of measurements. The calibration curve was plotted by the least-squares method and then was used for refining the pH values of the solutions studied. After the titration procedure, the ionometer was checked by a buffer with pH 4.01. When the buffer pH measured with the ionometer differed from the above value by more than 0.02 pH unit, the result was discarded.

The protonation constants B_1 and B_2 of malonic, succinic, glutaric, and adipic acid anions were determined by titration at 25°C and ionic strength $I = 0.3$ (KCl). The experimental data were treated by the least-squares method with the approximation confidence no less than 0.99. For each acid, 6–8 independent determinations were obtained. The protonation constants of the anions of the dicarboxylic acids studied are listed in Table 2. The $\log B_1$ error was determined as probable deviation of the arithmetic mean at a confidence probability of 0.95.

The equilibria of acid dissociation (1) and (2) and of Ca^{2+} complexation with products of H_2L acid dissociation (3)–(5) were taken into consideration:

$$H^+ + HL^- \rightleftarrows H_2L, \quad (1)$$

$$H^+ + L^{2-} \rightleftarrows HL^-, \quad (2)$$

$$Ca^{2+} + HL^- \rightleftarrows CaHL^+, \quad (3)$$

$$Ca^{2+} + L^{2-} \rightleftarrows CaL, \quad (4)$$

$$Ca^{2+} + 2L^{2-} \rightleftarrows CaL_2^{2-}. \quad (5)$$

Since alkali and alkaline-earth metals form no hydroxide complexes at pH < 6, the Ca^{2+} hydrolysis was not taken in account.

To calculate the equilibrium concentrations of species, we used the mass action law and equations of the material balance:

$$c_L = [H_2L] + [HL^-] + [L^{2-}] + [CaL] + [CaHL^+] + [CaL_2^{2-}],$$

$$c_H = 2[H_2L] + [HL^-] + [H^+] + [CaHL^+],$$

Table 2. Protonation constants of dicarboxylic acid anions. $I = 0.3$, $T = 25$°C

Acid	$\log B_1$	$\log B_2$
Malonic	5.20 ± 0.01	7.85 ± 0.02
Succinic	5.22 ± 0.02	9.23 ± 0.02
Glutaric	4.99 ± 0.08	9.18 ± 0.04
Adipic	5.03 ± 0.04	9.31 ± 0.04

$$c_M = [Ca^{2+}] + [CaL] + [CaHL^+] + [CaL_2^{2-}],$$

$$B_1 = \frac{[HL]}{[L^{2-}][H^+]}, \qquad B_2 = \frac{[H_2L]}{[L^{2-}][H^+]^2},$$

$$\beta_{CaL} = \frac{[CaL]}{[Ca^{2+}][L^{2-}]}, \qquad \beta_{CaHL^+} = \frac{[CaHL^+]}{[Ca^{2+}][HL^-]},$$

$$\beta_{CaL_2^{2-}} = \frac{[CaL_2^{2-}]}{[Ca^{2+}][L^{2-}]^2},$$

where c_L, c_H, and c_M are the total concentrations of the ligand, H^+, and metal ion, respectively; B_1 and B_2 are the protonation constants of dicarboxylic acid anion; and β_{CaL}, β_{CaHL^+}, and $\beta_{CaL_2^{2-}}$ are the stability constants of the corresponding calcium species.

The formation function $\bar{n}$ is

$$\bar{n} = \frac{[H^+][L^{2-}]\beta_{CaHL^+}B_1 + \beta_{CaL}[L^{2-}] + 2\beta_{CaL_2^{2-}}[L^{2-}]^2}{1 + [H^+][L^{2-}]\beta_{CaHL^+}B_1 + \beta_{CaL}[L^{2-}] + 2\beta_{CaL_2^{2-}}[L^{2-}]^2}.$$

After transform, it becomes

$$\bar{n} + (\bar{n} - 1)[H^+][L^{2-}]\beta_{CaHL^+}B_1 + (\bar{n} - 1)[L^{2-}]\beta_{CaL} + (\bar{n} - 2)[L^{2-}]^2\beta_{CaL_2^{2-}} = 0.$$

The experimental data were treated by the least-squares method assuming (to a first approximation) $\beta_{CaHL^+} = 0$. The complex formation constants obtained under these conditions were used for refining the calculation. The finally obtained constants β_{CaL}, β_{CaHL^+}, and $\beta_{CaL_2^{2-}}$ for calcium complexes with malonic, succinic, glutaric, and adipic acids at $I = 0.3$ (KCl) and 25°C were recalculated to zero ionic strength by Davies equation.

The complexation constants obtained independently by approximation of the experimental data to the $y = a + bx + cz$ form with a confidence probability of 0.95 and a confidence interval not exceeding a factor of 2 are listed in Table 3.

Table 3. Stability constants of calcium complexes with dicarboxylic acids

Acid	$\log\beta^0_{CaL}$	$\log\beta^0_{CaHL^+}$	$\log\beta^0_{CaL_2^{2-}}$
Malonic	2.47 ± 0.05	0.08 ± 0.01	3.73 ± 0.1
	2.48 ± 0.05*	–	3.77 ± 0.08*
Succinic	2.08 ± 0.02	0.86 ± 0.05	3.41 ± 0.06
Glutaric	1.75 ± 0.07	0.92 ± 0.07	2.72 ± 0.09
Adipic	1.78 ± 0.05	0.82 ± 0.08	3.25 ± 0.08

* Without taking into consideration formation of protonated complex.

Calculations showed that, for malonic acid, formation of the $CaHL^+$ complex can be neglected. The stability constants obtained with and without regard to formation of $CaHL^+$ are virtually the same.

For malonic and succinic acids, the logarithms of stability constants $\log\beta^0_{CaMal}$ and $\log\beta^0_{CaSuc}$ are close to those obtained in [2, 3], respectively. For glutaric acid, $\log\beta^0_{CaGl}$ is virtually the same as in [2]. For the 1 : 1 complex with adipic acid, we obtained $\log\beta^0_{CaAd}$ = 1.78, which substantially differs from the value of 2.19 reported in [4] and can be thought to be more reliable because of taking into account formation of the protonated complex.

It follows from Table 3 that the stability of 1 : 1 complexes decreases in the order malonic > succinic > glutaric ~ adipic acid. Two carboxy groups in the acid molecule allow formation of chelates with metal ions. In accordance with the Tschugaeff rule, complexes with five- and six-membered rings are the most stable. Among the acids considered, only malonic acid can form a six-membered ring with calcium ion, which agrees with the maximal value of the stability constant. Bukolov *et al*. [7] proposed probable structures for metal ion complexes with succinic and glutaric acids, in which weakly stable seven- and eight-membered rings are formed. Close stability constants for calcium complexes with glutaric and adipic acids ($\log\beta^0_{CaGl} \sim \log\beta^0_{CaAd}$) obtained by us suggest that glutaric acid forms long-chain complexes similar to complexes with adipic acid [7]. The same trend toward decrease in the stability of the complex with increasing distance between the carboxy groups is also observed for 1 : 2 complexes. The stability constants of protonated complexes are approximately the same for succininc, glutaric, and adipic acids; for malonic acid, $\log\beta^0_{CaHMal^+}$ is very small, i.e., this complex is not present in solution in noticeable amounts.

CONCLUSIONS

(1) The stability constants of 1 : 1 and 1 : 2 calcium complexes with malonic, succinic, glutaric, and adipic acids were determined by potentiometric titration.

(2) The stability constants decrease with the increasing number of carbon atoms between carboxy groups of the dicarboxylic acid molecule.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Analysis of Electrical Properties of Thin Film Samples in the Course of Phase Transformations of Cadmium Sulfide and Telluride Solid Solutions

A. P. Belyaev, V. P. Rubets, I. P. Kalinkin, and M. Yu. Nuzhdin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 3, 2000; in final form, September 2001

Abstract—Phase transformations in layers of cadmium sulfide and telluride solid solutions, synthesized under nonequilibrium conditions, are studied. Thermally activated decomposition of a single-phase CdS_xTe_{1-x} solution containing an α_1 phase (x_1 = 0.4–0.6) into two phases, α_2 (x_2 = 0.1–0.2) and α_3 (x_3 = 0.78–0.99), is chosen as a model process. Electron diffraction patterns and temperature dependences of photoconductivity and conductivity, measured both in the course of phase transformations and after them, are presented. The results of electrical studies are compared with structural data.

Solid solutions based on compounds of Group II and VI elements (II–VI compounds) show promise as materials for microelectronics owing to their widely varying properties. These materials are used in developing photoelectric converters, detectors of ionizing radiation, and sensors of gaseous chemical compounds. Among the factors hindering their wider use are phase transformations occurring in solid solutions in the course of time. In this connection, an attempt is made here to trace the course of transformations in a typical system, CdS–CdTe [1]. There has been virtually no reports on experimental studies of this kind. This is presumably due to the limited sensitivity and complexity of continuous monitoring by means of structural analytical methods widely used to study the phase composition of substance.

It is known that the electrical properties of a substance are the most sensitive to its structural state. The prospects for use of electrical properties to analyze materials were mentioned already by Kurnakov [2]. However, studies concerned with application of electrical measurements to analysis of phase transformations are still virtually lacking. Here we attempt to use current transport measurements as a tool in analysis of thermally activated phase transformations in CdS_xTe_{1-x} solid solutions.

EXPERIMENTAL

Samples obtained in a vacuum (residual pressure 10^{-3} Pa) by the thermal shield method under strongly nonequilibrium conditions were studied [3, 4]. A mechanical mixture of CdS and CdTe powders taken in 40 : 60 (at. %) ratio was subjected to thermal evaporation. Small sheets of mica (muscovite) served as substrates for condensation. The nonequilibrium conditions were chosen because of the necessity to obtain samples prone to phase transformations.

The thus prepared samples were CdS_xTe_{1-x} films with polycrystalline structure, composed of 0.1–0.2-μm crystals of the cubic modification and definite chemical composition. The composition of the solid solution was constant within a sample. Samples with $0.4 < x < 0.6$ were studied. The uniformity of the solid solution throughout the sample volume and its specific composition were found by electron diffraction. All structural and morphological studies were carried out with EMR-100 electron diffractometer and PEM-100 electron microscope. The electron diffraction patterns were identified using the ASTM file.

The sample thickness was varied in the range 0.30–0.50 μm. Within a sample, the layer thickness was constant and invariable in the course of experiments. The thickness was measured on an MII-4 microinterferometer with accuracy of ±0.03 μm.

All the techniques employed to measure electrical and photoelectric characteristics [5] were chosen with account of the fact that solid solution layers are semiconducting film materials [6]. Electrical measurements were carried out in a vacuum (residual pressure 10^{-3} Pa), in which samples were kept for several days.

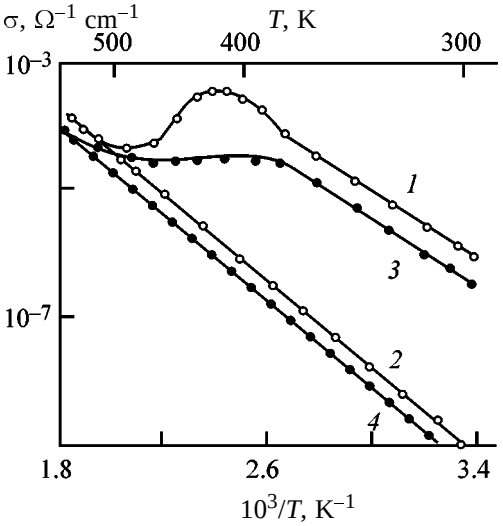

Fig. 2. (*1, 3*) Variation of electrical conductivity σ in the course of phase transformations in cadmium sulfide–telluride layers (x = 0.5) under heating at a rate v_T and (*2, 4*) temperature dependences of the conductivity of these layers after phase transformations. (*T*) Temperature. Heating rate v_T (K s^{-1}): (*1, 2*) 0.05 and (*3, 4*) 0.2.

The measurements were done in the current mode with the use of a V7-30 electrometer and electrostatic shields at electric field strength of 100 V cm^{-1}. The electrical conductivity of the films was measured in the dark and under illumination (photoconductivity). For this purpose, silver contacts were deposited onto $0.4 \times 0.4 \times h$-cm samples, where $2h$ is the layer thickness. The choice of the material of contacts is governed by the necessity for obtaining contacts with properties having no effect on the electrical conductivity to be measured. The contact properties were judged from the initial portions of current–voltage characteristics. No nonlinearities or asymmetry of electrical properties were revealed.

The contacts spaced by 0.4 cm were deposited by thermal evaporation of silver.

The effect of surface charge transport on the electrical properties and the contribution of the ionic charge transport were studied by measuring band and transient characteristics. No asymmetry of electrical properties acquired under the action of electric field was revealed.

Integral photoelectric characteristics of the samples were studied under irradiation with light of a 90-W incandescent lamp with tungsten filament (rated filament temperature 2270 K). Spectral characteristics were measured on a DMR-4 monochromator. In doing so, a signal induced by a single light quantum was taken as analytical signal. The radiation intensity was measured with a nonselective radiation detector, radiation thermocouple.

The sample temperature was maintained constant in measurements with an accuracy of ± 0.1 K or varied at a constant rate of 0.05–0.20 K s^{-1}. Heating at higher rate was done with a beam of electrons having energy of several thousand electronvolts, directed onto a copper substrate holder.

The possible influence of the probing electric field on phase transformations was monitored by comparing the properties of samples that underwent phase transformations under the action of electric field with those of samples not subjected to electric field.

The effect of temperature on the properties of the contacts was monitored by comparing the electrical properties of samples with contacts deposited before annealing with those of samples having contacts deposited after the heat treatment.

The measurement results were processed by methods of mathematical statistics. The relative measurement error did not exceed several percent. The main experimental results are presented in Figs. 1–5.

Figure 1 shows typical electron diffraction patterns of freshly prepared and annealed films of the solid solution. Curve *1* points to the presence in the freshly prepared film of only a single phase, α_1, corresponding to a composition with x_1 = 0.5. Curve *2*, measured

with annealed samples, indicates the appearance in the bulk of the sample of two phases, α_2 and α_3, of the solid solution CdS_xTe_{1-x}, with compositions x_2 = 0.15 and x_3 = 0.85. The phase segregation of annealed samples was also revealed by analysis of an optical transmission spectrum [7].

The method of sample annealing and the rate of heating in annealing had no effect on electron diffraction patterns. Electron microscopic studies revealed no differences, either. The size of crystallites constituting the film remained unchanged: on the order of several tenths of a micrometer.

The difference in annealing methods affected the electrical and photoelectric properties of the objects of study. Figure 2 shows typical differences in the temperature dependences of electrical conductivity, associated with the annealing rate. Curves *1, 2* and *3, 4* were obtained in annealing with heating rates of, respectively, 0.05 and 0.2 K s^{-1}. Curves *1* and *3* characterize the electrical conductivity of freshly prepared samples. These curves differ in the presence, or absence, of a region with increased rate of conductivity change. At a heating rate of 0.05 K s^{-1} the conductivity increases at a temperature of about 360 K and then rapidly decreases; further, the temperature dependence of conductivity is linear in the coordinates $\ln\sigma$–$10^3/T$ (with activation energy of 0.72 eV). At heating rate of 0.2 K s^{-1} there is no region with increased rate of conductivity change (curve *3*). Irrespective of the annealing rate, the linear temperature dependence is preserved further, in subsequent heating and cooling runs (curves *2* and *4*), over the entire temperature range.

The same linear temperature dependence with the same activation energy was reproduced for each particular sample after its being brought in contact with the atmosphere.

Keeping samples in a vacuum at the highest annealing temperature for 5–6 h had no effect on their conductivity at this temperature. As a result of annealing (in any mode), the dark electrical conductivity of the samples decreased manyfold (by three orders of magnitude, Figs. 1 and 2).

Samples with similar properties could be obtained from freshly prepared samples by shock heating with electron beam.

A photoconductivity study revealed the influence of the heating rate on the electrical and optical properties of the samples: the lower the heating rate, the higher the photoconductivity to dark conductivity ratio. For example, for a part of a sample annealed

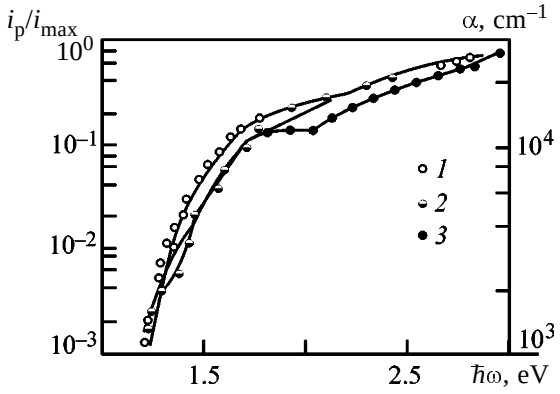

Fig. 3. (*1, 3*) Spectral dependences of the photocurrent and (*2*) absorption edge of cadmium sulfide–telluride layers. (i_p/i_{max}) Relative photocurrent, (α) absorption coefficient, and ($\hbar\omega$) quantum energy. Sample: (*1, 2*) annealed and (*3*) freshly prepared.

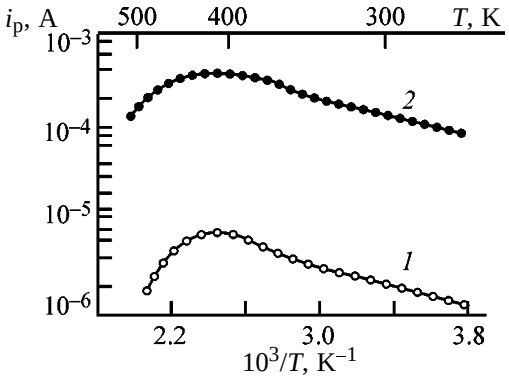

Fig. 4. Photocurrent in cadmium sulfide–telluride samples (x = 0.5) annealed at heating rates of (*1*) 0.2 and (*2*) 0.5 K s^{-1} vs. temperature T. (i_p) Photocurrent.

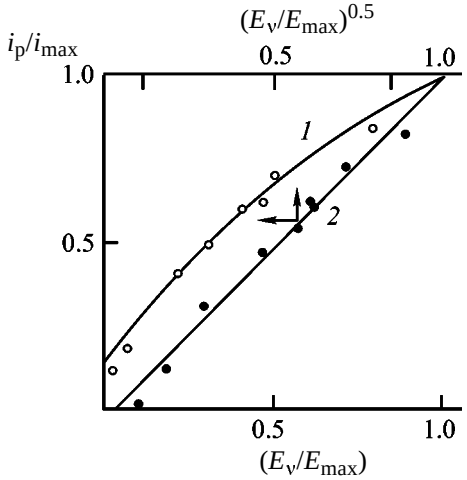

Fig. 5. Current–light characteristics of a cadmium sulfide–telluride sample (x = 0.5) annealed at a rate of 0.05 K s^{-1}. (i_p/i_{max}) Relative photocurrent and (E_v/E_{max}) relative sample illuminance. Characteristic: (*1*) total and (*2*) high-illuminance portion.

at a heating rate of 0.05 K s^{-1} (Fig. 2, curves *1* and *2*) this ratio was ~10^3 at room temperature, whereas the part of the same sample heated by the shock method exhibited virtually zero photosensitivity. Freshly prepared samples increased their photoconductivity 2–3-fold under the action of light.

Comparison of the photoconductivity spectra of the samples (Fig. 3) shows that annealing has virtually no effect on the shape of the spectra.

Figure 4 presents the temperature dependences of photocurrent in samples annealed at different rates. The run of these dependences is nearly independent of the sample heating rate. Figure 5 shows current–light characteristics of cadmium sulfide–telluride.

To conclude, it should be noted that structural studies revealed no differences in the phase composition and microstructure of layers subjected to thermal treatment at different heating rates. Only photoelectric measurements demonstrated their significant distinctions.

Let us now discuss the experimental results obtained. As seen from the electron diffraction patterns (Fig. 1, curve *1*), a freshly prepared sample is formed of a single-phase CdS_xTe_{1-x} solid solution of strictly defined composition with $x_1 = 0.5$. However, according to the equilibrium phase diagram [8], the composition $0.4 < x < 0.6$ corresponds to the region of limited mutual solubility, in which the stability of a single-phase solid solution must be lost entirely. The contradiction between the experiment and theory is eliminated if the elastic stress appearing in samples that have been formed under nonequilibrium conditions is taken into account [4, 9]. Such a stress in a II–VI solid solution favors formation of samples with increased Gibbs energy [7], a single-phase $CdS_{0.5}Te_{0.5}$ solid solution in the given case. Heating of such systems must lead to overcoming of the activation barrier keeping them in a state with increased energy and, consequently, to a phase transformation, and, in the case under study, to decomposition of the single-phase solid solution into several phases.

The results obtained are fully consistent with the aforesaid. Figure 1 shows that the electron diffraction method reveals in the sample only a single phase ($CdS_{0.5}Te_{0.5}$ solid solution) before, and two phases ($CdS_{0.15}Te_{0.85}$ and $CdS_{0.85}Te_{0.15}$ solid solutions), after annealing. In this case, the phase composition falls into the regions of mutual solubility in the equilibrium phase diagram [8].

Thus, it can be stated that we have analyzed a phase transformation of the system from a metastable state (single-phase solid solution) into the equilibrium state (mixture of two solid solutions).

Transition of the system from the metastable into the equilibrium state is only possible via a fluctuation, i.e. through nucleation and growth of new phase nuclei. This process occurs in the course of time. Naturally, the conditions existing during this period of time must affect both the kinetics of phase transformation and the properties of the phases formed. Therefore, samples subjected to annealing at different heating rates acquire different electrical and photoelectric properties. The electrical and photoelectric studies reveal differences undetectable by the electron diffraction technique.

Let us analyze the phase transformation of a solid solution with account of the dynamics of its electrical and photoelectric properties. Condensed layers of a solid solution belong to disordered systems [3]. Charge transport at high temperature in such systems occurs at the so-called mobility edge E_μ, which corresponds to the energy of carriers at which they can be involved in current transport. This process is described by the following expression [6], which qualitatively satisfies the experimental data obtained in the present study (Fig. 2):

$$\sigma = \sigma_0 \exp[-(E_\mu - E_F)/kT], \quad (1)$$

where σ_0 is a pre-exponential factor (Ω^{-1} cm^{-1}), E_μ is the mobility edge (eV), E_F is the Fermi level (eV), k is the Boltzmann constant (eV K^{-1}), and T is temperature (K).

The occurrence of current transport at the mobility edge is also evidenced by results of calculations. A kind of a conduction test is representation of conductivity in the form $\sigma = C\exp(-E/kT)$ with subsequent calculation of the parameter C [6]. For the samples studied, the factor C is on the order of 10^3 Ω^{-1} cm^{-1} both before and after annealing, in good agreement with the data of [6] and the σ_0 value in expression (1). Thus, it may be considered proven that current transport occurs at the mobility edge both in the course of the phase transformation and after it.

A significant change in conductivity in current transport at the mobility edge is only possible via a change in the Fermi level position. This may occur for two reasons: because of a change in the band gap and through a change in the density of states in the gap. No experimental evidence in favor of the first factor has been found. The photoconductivity spectrum remained virtually unchanged after the phase transformation (Fig. 3, curves *1* and *3*). By contrast, the results of photoelectric studies support the second

assumption. In the first place, it should be noted that the photoconductivity spectrum has no falloff at high energies (Fig. 3). Consequently, the recombination rates at the surface and in the bulk are rather close and a high density of states exists in the gap. The high density of states favors monomolecular recombination, which is reflected in the linear run of the current–light characteristic of the systems studied (departure from linearity at high excitation intensities is due to the influence of nonequilibrium carriers on the random field [10]).

The monomolecular photocurrent i_p (A cm^{-1}) can be described by the following expression [6]:

$$i_p = e E_e \mu_D \nu \tau, \quad (2)$$

where e is the elementary charge (C), E_e is the electric field strength (V cm^{-1}), μ_D is the carrier mobility (cm^2 V^{-1} s^{-1}), ν is the generation intensity of nonequilibrium carriers (s^{-1} cm^{-1}), and τ is the lifetime of nonequilibrium carriers (s).

The μ_D value is, as a rule, weakly dependent on states in the band gap. It is considered an intrinsic property of the material. This parameter is commonly responsible for the temperature dependence of the photocurrent. Figure 4 is in agreement with the aforesaid. The run of the temperature dependences of the photocurrent is independent of the annealing mode and, consequently, of the photosensitivity of the samples.

By contrast, the lifetime τ is rather sensitive to the density of states at the Fermi level and weakly depends on temperature [6]. Consequently, the difference in the photoelectric properties of the samples studied is due just to the difference in the density of states at the Fermi level. An additional argument in favor of this conclusion is the absence of IR quenching of photoconductivity, which is known to be characteristic of materials with sensitizing centers.

Thus, it may be stated that the photosensitive properties acquired by samples of a cadmium sulfide–telluride solid solution in the course of their phase transformations are due to a change in the density of states at the Fermi level. The density of states in the band gap, in its turn, determines the Fermi level position, and the Fermi level, as shown above, governs the conductivity of a disordered system. Therefore, it seems natural to relate changes in conductivity in the course of annealing to changes in the density of states. Consequently, curves *1* and *3* in Fig. 2, reflecting changes in the conductivity of a cadmium sulfide–telluride solid solution in the course of phase transformations, simultaneously describe changes in the Fermi level position and in the density of states in the course of thermally activated decomposition of a single-phase solid solution CdS_xTe_{1-x}. However, the relatively long response time of the recording equipment tells upon the results obtained at high heating rates, and, therefore, there is no region with increased rate of change in conductivity in curve *3* (Fig. 2).

CONCLUSIONS

(1) Changes in electrical conductivity, observed in the course of thermally activated decomposition of the solid solution, reflect the occurring changes in the density of states in the system and those in the Fermi level position.

(2) The thermally activated decomposition of the solid solution is accompanied by a steplike change in the position of the Fermi level in the system and its subsequent monotonic relaxation to a new equilibrium value.

(3) The process of thermally activated decomposition of the solid solution is accompanied by a short-term increase in the density of states in the system.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of $[Au(CN)_2]^-$ Ions from Cyanide Solutions with Activated Carbon Fiber

Abstract—Sorption of $[Au(CN)_2]^-$ ions from cyanide aqueous solutions with activated carbon fiber was studied, and the effect of the gas phase composition and additives (phenol, hydroquinone, ethanol, Na_2SO_3, $Na_2S_2O_3$) on sorption was considered. The results are compared with data on interaction of C_{60} with $[Au(CN)_2]^-$.

Sorption of Au(I) from cyanide aqueous solutions with carbon sorbents is believed to be the most promising hydrometallurgical process of gold recovery. In spite of its long history, which began in 1894 [1], the mechanism of $[Au(CN)_2]^-$ adsorption is still the matter of discussion. We can formulate the following viewpoints.

(1) The $[Au(CN)_2]^-$ ion is sorbed by activated carbon owing to donor–acceptor interaction between the delocalized carbon π system and the vacant Au(I) *d* orbital [2].

(2) The main mechanism of sorption is the ion exchange, i.e., substitution of anions, e.g., chloride ions, in the carbon matrix by the $[Au(CN)_2]^-$ ion [3].

(3) During sorption, Au(I) in $[Au(CN)_2]^-$ is completely [to Au(0)] or partially reduced. In the latter case, the degree of Au oxidation in the carbon matrix n varies within the $0 < n < 1$ range [4, 5].

(4) The $[Au(CN)_2]^-$ sorption is accompanied by formation of the polymeric insoluble compound $[Au(CN)]_\infty$ in the sorbent phase [6].

(5) The Au(I) sorption with activated carbon involves sorption of ion pairs $M[Au(CN)_2]_n$ ($M = Na^+$, $n = 1$; Ca^{2+}, $n = 2$, etc.) in the sorbent pores [7–9].

In practice, sorption of $[Au(CN)_2]^-$ with activated carbon proceeds in air, i.e., from the solution saturated with oxygen and nitrogen. It is known [10] that the gas phase composition affects sorption of ions with activated carbon. For instance, sorption of cations increases in a hydrogen atmosphere, and the carbon capacity for anions, in an oxygen atmosphere. Frumkin [11] considered the activated carbon–water–oxygen system as an oxygen electrode. On the carbon surface, the following reactions proceed:

$$O_2 + H_2O + 4e \rightarrow 4OH^-, \quad (1)$$

$$O_2 + H_2O + 2e \rightarrow OH^- + HO_2^-. \quad (2)$$

Reaction (1) corresponds to occurrence of hydroxide anions in the electrical double layer (but not in the solution bulk). Both reactions accompany sorption of $[Au(CN)_2]^-$ ion and can affect it.

Up to now, almost all studies of Au(I) sorption from cyanide solutions were performed with granulated activated carbon. Fibrous structure of the sorbent allows increase in the sorption rate due to decrease in the external and internal diffusion resistance to mass transfer, as compared to granulated sorbents. In addition, fibrous carbon sorbents can exist as various textiles including nonwoven materials, which allows more convenient design of the sorption process.

Thus, fibrous activated carbon is a promising sorbent of gold. It should be noted that the chemical composition of the surface layers of fibrous carbon sorbents is similar to the composition of the surface layers of granulated activated carbon.

This work is the first paper devoted to study of the mechanism of $[Au(CN)_2]^-$ sorption from alkaline cyanide solutions on activated carbon fibers (ACFs) and presents data on effect of the gas phase composition on the $[Au(CN)_2]^-$ sorption and electrochemical transformations of the sorbent surface due to metal sorption. In addition, sorption properties of ACF and complexation of C_{60} with $[Au(CN)_2]^-$ were compared.

Air	9.0	0.77	N.d.**	N.d.
Argon	9.0	0.76	0.0	0.0

* (V_{O_2}) Volume of oxygen sorbed.

** (N.d.) Not determined.

EXPERIMENTAL

ACF was prepared by carbonization of hydrated cellulose fiber in a nitrogen atmosphere at 1500°C [12]. The carbon content in the product amounted to 90%. Carbonized fiber was activated with water vapor at 800°C, which ensures its high porosity and increased sorption activity. The ACF specific surface area measured by the low-temperature nitrogen adsorption (SORTY 1750 Carlo Erba Strumentazione, Italy) was 1300 $m^2 g^{-1}$.

The content and halfwidth of meso- and micropores were determined from the benzene vapor sorption isotherm. The elemental analysis of ACF was performed on a CHN-3 analyzer.

The elemental composition of ACF (wt %) was as follows: C 97.5, H 1.7, and N 0; pore structure characteristics ($cm^3 g^{-1}$): mesopores 0.11 and micropores 0.36; micropore halfwidth 0.73 nm.

$Na[Au(CN)_2]$ was prepared by the method described in [13]. In volumetric experiments, the solution volume was 20 ml, and the fiber sample weight, 0.2 g. In experiments on sorption with various additives, the gold concentration was 0.45 mM, solution volume, 250 ml, and fiber sample weight, 0.25 g.

The content of sorbed gold(I) was determined as the difference between its initial and residual concentrations on a SpectrAA 110 Varian device (Australia).

To determine the effect of the gas phase composition on $[Au(CN)_2]^-$ sorption with ACF, we used a volumetric device described in [14]. Experiments were performed in air, oxygen, and argon (Table 1).

To study the sorption in argon, the solution and ACF were separately deoxygenated by passing argon for 1 h. In all the experiments, the time of contact of ACF with the solution in the volumetric device was 40 min.

It follows from Table 1 that the rate of $[Au(CN)_2]^-$ sorption with ACF in the oxygen atmosphere is substantially lower than in air and argon, and the process is accompanied by increased (by a factor of 3–5) sorption of oxygen (as compared to sorption from solution containing no $[Au(CN)_2]^-$).

Such a character of $[Au(CN)_2]^-$ sorption at increased oxygen content suggests that the processes of Au(I) and oxygen sorption with carbon fiber are interrelated.

According to Frumkin's concept [10], sorption of oxygen with ACF is an electrochemical process accompanied by one- or two-electron oxygen reduction. In the case of one-electron reduction, highly reactive species, e.g., O_2^- radical ion or $OH^\bullet$ radical, can be formed as intermediates. These species can react both with the sorbent surface and with $[Au(CN)_2]^-$. As a result, the rate of Au(I) sorption can decrease and the rate of oxygen uptake can increase. Thus, the reactions of $[Au(CN)_2]^-$ sorption may be radical.

To confirm this assumption, we studied $[Au(CN)_2]^-$ sorption with ACF in the presence of various additives: hydroquinone, phenol, ethanol, sodium sulfite, and sodium thiosulfate. The first two compounds are known as effective oxidation inhibitors [15] scavenging $RO^\bullet$ and $RO_2^\bullet$ radicals. Both these compounds are well sorbed with activated carbons and can be used for suppressing Au(I) sorption at cyanidation of gold ores containing impurities of carbonaceous materials [16].

Ethanol is also an effective radical scavenger and can be used for "cold" (nonautoclave) desorption of Au(I) from activated carbon. Sodium sulfite is an effective reagent for deoxygenation of aqueous solu-

Table 2. Kinetics of Au(I) sorption from aqueous solutions in the presence of various additives

Additive, 0.1 M	Au(I) content, mmol g^{-1}, in ACF at indicated τ, min				
	60	120	180	1200	1440
–	0.193	0.197	0.198	0.217	0.217
Hydroquinone	0.000	0.000	0.000	0.000	0.000
Phenol	0.000	0.000	0.000	0.000	0.000
Na_2SO_3	0.204	0.211	0.217	0.224	0.224
$Na_2S_2O_3$	0.223	0.240	0.244	0.253	0.253

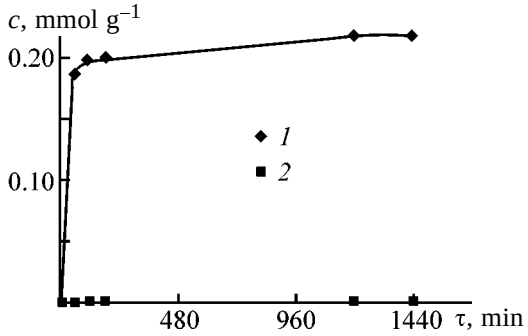
* (τ) Time of contact with gold-containing solution.

tions. Its reduction under the action of solvated electron or H• and R• radicals is unlikely, but sulfite is fairly efficient as inhibitor of radical oxidation. Finally, $Na_2S_2O_3$ does not noticeably decrease the oxygen concentration in water and is substantially less efficient as radical scavenger; however the $[Au(S_2O_3)_2]^{3-}$ ion, in contrast to the cyanide complex, is not sorbed with activated carbon. The results are listed in Table 2.

As seen, phenol and hydroquinone completely inhibit the $[Au(CN)_2]^-$ sorption, while sodium sulfite and thiosulfate increase the sorption rate.

With ethanol (20 vol %) introduced into 0.02 mM $[Au(CN)_2]^-$ solution, the Au(I) content in the ACF phase amounts to 0.004 mmol g^{-1} (constant at the contact time varied within 1–24 h), while without ethanol the Au(I) content under the same conditions is about 0.02 mmol g^{-1}.

To determine how Au(I) cyanide complexes interact with the carbon surface, we studied certain electrochemical properties of ACF before and after sorption. The electrophoretic mobility of the finely divided fractions of fiber (after grinding of ACF to the size no more than 1×10^{-4} M) was measured on a microelectrophoretic device [17], and their migration to electrode with the opposite charge sign was observed.



Kinetics of Au(I) sorption from aqueous solutions with various carbon materials. (*c*) Au(I) content in ACF; (τ) time. Sorbent: (*1*) ACF and (*2*) C_{60}.

It was found that the initial ACF has the ξ potential of 7.2 mV and positive sign of the surface charge. After $[Au(CN)_2]^-$ sorption, the ξ potential becomes 22.4 mV, and the sign of the surface charge becomes negative. Previously, Adams *et al*. [8] observed the change of the sorbent surface charge sign after $[Au(CN)_2]^-$ sorption on granulated activated carbon. The change of surface charge shows that the Au(I) species sorbed on the ACF surface are negatively charged.

We believe that $[Au(CN)_2]^-$ chemisorption cannot be explained by formation of donor–acceptor bond between Au(I) and the π system of the carbon surface. Two facts support this assumption.

First, the concentration of the free CN^- ion in the solution during sorption exceeds by an order of magnitude the $[Au(CN)_2]^-$ concentration. The CN^- ion forms strong π bonds with the gold atom and is characterized by a strong *trans* effect. As a result, the π bond between the $[Au(CN)_2]^-$ ion and graphite [in the case of formation of the Au(I) complex, with the gold coordination number greater than 2] should be labile, and hence, the η^n coordination π bond between the ACF surface and Au(I) atom should be unstable and dissociate under the action of excess of CN^- ions. However, desorption of $[Au(CN)_2]^-$ from the ACF surface occurs under rigid conditions [18] and takes long time. Thus, formation of bonds between the $[Au(CN)_2]^-$ ion and π system of graphite is hardly probable.

Second, we found that under the same conditions fullerene C_{60} does not react with $[Au(CN)_2]^-$ ions (see figure). It should be noted that the η^5-ligand properties of fullerene and its derivatives are well known [19].

We assume that the difference in behavior of ACF and C_{60} with respect to the $[Au(CN)_2]^-$ ion may be due to the fact that fullerene C_{60} contains no impuri-

ties, in contrast to ACF whose surface contains atoms of various elements chemically bound with carbon (mainly hydrogen and oxygen atoms). The ACF surface is very defective owing to different orientation of graphenes [20], while the C_{60} surface is practically defect-free. In addition, it was shown that C_{60} derivatives are scavengers of radicals (i.e., O_2^-) [21], while the ACF surface, on the contrary, generates them. This is confirmed by formation of H_2O_2 in the activated carbon–O_2–H_2O system [10].

CONCLUSIONS

(1) The rate of $[Au(CN)_2]^-$ sorption from aqueous cyanide solutions decreases with increasing oxygen content in the solution.

(2) In the presence of effective radical scavengers (hydroquinone, phenol, ethanol), the rate of $[Au(CN)_2]^-$ sorption on activated carbon fiber sharply decreases.

(3) Microelectrophoretic data show that sorption of $[Au(CN)_2]^-$ ion on activated carbon fiber is accompanied by changing sign of the sorbent surface charge. This shows that the chemisorbed Au(I) species are negatively charged.

(4) Under the same conditions, fullerene C_{60} does not interact with $[Au(CN)_2]^-$ in aqueous solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Uranium(VI) Sorption on Polysilsesquioxanes with Various Organic Functional Groups

Abstract—Sorption of UO_2^{2+} on polysilsesquioxanes with thiourea dioxide, acetamide, phthalimide, and malonamide functional groups was studied.

Proceeding with systematic study of ion-exchange and complexing properties of polysilsesquioxanes with organic functional groups [1–3], we studied in this work sorption of uranyl cations on the following sorbents: poly[*N*,*N*'-bis(3-silsesquioxanylpropyl)thiourea dioxide] $\{[O_{1.5}Si(CH_2)_2NH]_2C(SO_2)\}_n$ (**I**) [4], poly[*N*-(3-silsesquioxanylpropyl)acetamide] $[O_{1.5}Si\cdot(CH_2)_3NHC(O)CH_3]_n$ (**II**) [5], poly[*N*,*N*'-bis(3-silsesquioxanylpropyl)phthalamide] $\{[O_{1.5}Si(CH_2)_3\cdot NHCO]_2C_6H_4\}_n$ (**III**) [6], and poly[*N*,*N*-'bis(3-silsesquioxanylpropyl)malonamide] $\{[O_{1.5}Si(CH_2)_3\cdot NHCO]_2CH_2\}_n$ (**IV**).

Extraction [7] and sortion [8–11] recovery and analysis of uranium(VI) have been extensively studied. However, data on the use of organosilicon polymers, in particular, polyorganosiloxanes, are scarce. Since uranyl cations form stable complexes with O,N-containing ligands [7], we examined polymers **I**–**IV** as uranyl sorbents. Kinetic study of UO_2^{2+} sorption on polymers **I**–**IV** showed that in all cases the sorption equilibrium was attained within 30 min, with the major portion being sorbed within the first 5–10 min (Fig. 1a).

The degree of U(VI) recovery increases with increasing pH of the solution (Fig. 1b), which is likely due to stronger sorption of hydrolyzed UO_2^{2+} species. At pH > 2.5, UO_2OH^+ [12] is formed, and at pH 5 $UO_2(OH)_2$ starts to precipitate from 1.1×10^{-4} M UO_2^{2+} solution.

To simulate uranium(VI) sorption from highly saline waters, we studied UO_2^{2+} sorption as influenced by the NaCl concentration in the solution. Appreciable decrease in the UO_2^{2+} recovery at the NaCl concentration higher than 1.0 M may be due to both ionic

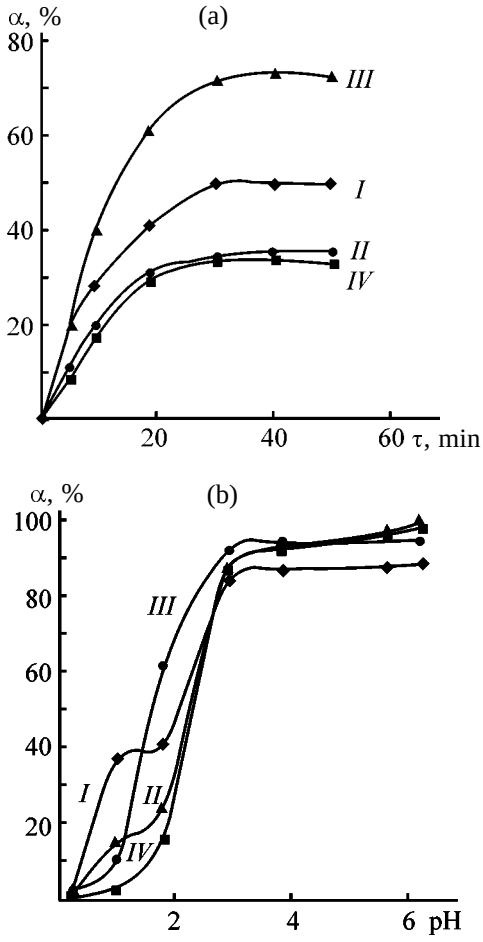

Fig. 1. Degree of uranium(VI) recovery α with polymers **I**–**IV** as a function of (a) phase contact duration τ and (b) pH. Eluent volume 20 ml; U(VI) weight 600 μg; sorbent weight 20 mg; pH 2, T = 20°C. Roman figures *I*–*IV* at the curves are polymer nos. **I**–**IV**.

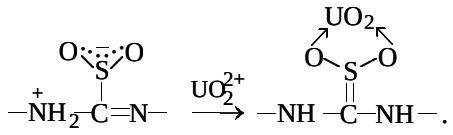
strength effect and competing complexation with Cl^- in the solution.

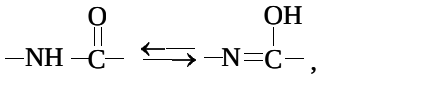
We studied the degree of uranium recovery as influenced by the UO_2^{2+} concentration in the solution. The static sorption capacities (SSC) of polymers **I**–**IV** and distribution coefficients of uranium *D* between solution and these polymers (Table 1) were determined from the sorption isotherms. High distribution coefficients make polymers **I**–**IV** promising for recovery of uranium(VI) traces from solution. Polymers **I**–**IV** are more effective uranium(VI) sorbents than many of organic chelating sorbents such as Polyarsenazo-*n* (SSC 70 mg g^{-1}) [9], resin with amidoxime functional groups (SSC 36–60 mg g^{-1}) [10], and organosilicon analogs, e.g., PSTM-3 sorbent (SSC 15 mg g^{-1}) [11].

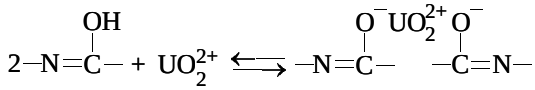
The results of UO_2^{2+} desorption from polymers **I**–**IV** are presented in Table 2. Uranium(VI) is almost completely desorbed from these sorbents with 5% sodium carbonate or 6 M HCl.

To determine the sorption mechanism, we studied the IR spectra of polymer **I** before and after saturation with UO_2^{2+}. Disappearance of the ν(S=O) bands at 1100 cm^{-1} and weakening of the ν(C=N) band at 1695 cm^{-1} in the spectrum of polymer **I** saturated with uranium(VI) suggest that UO_2^{2+} and UO_2OH^+ are coordinated with thiourea dioxide groups in the zwitter-ionic form [4]:



With **II**–**IV**, uranium(VI) is probably sorbed on deprotonated (imidate) acetamide fragments of the polymers by the ion-exchange mechanism:





In this case, formation of uranyl chelates is also possible.

To estimate the interfering effect of other cations on the U(VI) recovery from multicomponent solutions, we studied sorption of Cu(II), Zn(II), Cd(II), Co(II), and Ni(II) on polymers **I, II**, and **IV** in a wide pH range. The static exchange capacities of **I, II**, and **IV** for these cations and the distribution coefficients of the cations between the solution and sorbent, determined under the best conditions of U(VI) sorption, are presented in Table 3. As seen from Table 3, polymers **II** and **IV** are more effective sorbents of these metals than polymer **I**. The sorption capacity of polymers **I, II**, and **IV** for Cu(II) is the highest.

Table 1. Static sorption capacity of the polymers and uranium(VI) distribution coefficient *D* at pH 3

Sorbent	SSC, mg g^{-1}	$D \times 10^{-3}$, $cm^3\ g^{-1}$
I	120	7.3
II	80	1.6
III	110	7.0
IV	127	7.8

Table 2. Uranium(VI) desorption under static conditions. Eluent volume 20 ml, U(VI) content in the sorbent 600 μg

Desorbent (5%)	Degree of desorption, %			
	I	**II**	**III**	**IV**
Sodium carbonate	99	100	100	100
Tartaric acid	74	68	46	76
Hydrochloric acid*	100	100	97	100
Citric acid	38	70	30	35

* 6 M

In all cases, Cd(II), Zn(II), and Cu(II) at U(VI) : metal ion = 1 : 1 and Ni(II) and Co(II) at U(VI) : metal ion = 1 : 10 do not interfere with the uranium(VI) recovery. U(VI) can be quantitatively recovered from solutions with prevailing total content of the examined metals. For example, the uranium recovery with polymer **I** [*n* = 4, *p* = 0.95, 0.2 g] from a solution (200 ml) containing Cu(II), Cd(II), Zn(II) (0.5 mg l^{-1}), Co(II), Ni(II) (5 mg l^{-1}), and NaCl (6×10^4 mg l^{-1}) is as follows:

Introduced U(VI), mg l^{-1}	Recovered U(VI), mg l^{-1}
0.05	0.045 ± 0.007
0.10	0.09 ± 0.02
0.50	0.51 ± 0.07
0.90	0.87 ± 0.03
2.00	1.96 ± 0.04

EXPERIMENTAL

Polymers **I**–**IV** are pale yellow powders insoluble in water and organic solvents and stable up to 200°C.

Table 3. Static sorption capacity of polymers **I**, **II**, and **IV** and distribution coefficients of Cd(II), Zn(II), Cu(II), Ni(II), and Co(II) at pH 3

Ion	**I**		**II**		**IV**	
	SSC, mg g^{-1}	D, cm^3 g^{-1}	SSC, mg g^{-1}	D, cm^3 g^{-1}	SSC, mg g^{-1}	D, cm^3 g^{-1}
Cd(II)	15	170	24	780	35	840
Zn(II)	12	170	28	410	36	580
Cu(II)	36	245	80	700	88	860
Ni(II)	6	110	8	120	9	380
Co(II)	10	140	14	250	15	308

Sorption properties of polymers **I**–**IV** were studied at room temperature under static conditions. A weighed portion of the polymer was mixed with a solution with definite pH and metal ion concentration.

A standard 1 mg ml^{-1} U(VI) solution was prepared from $UO_2(NO_3)_2 \cdot 6H_2O$ of chemically pure grade. The uranium(VI) content in solutions was determined spectrophotometrically with arsenazo III [13]. The absorption was measured on a Specol 10 spectrophotometer.

The concentrations of Cu(II), Zn(II), Cd(II), Co(II), and Ni(II) in the solution were determined by atomic absorption spectroscopy [14].

SORPTION AND ION-EXCHANGE PROCESSES

Tetraphenylporphyrin Sensors with High Cross Sensitivity for "Electronic-Tongue" Analyzers

A. V. Legin, S. M. Makarychev-Mikhailov, O. E. Goryacheva, A. M. Rudnitskaya, and Yu. G. Vlasov

Abstract—Tertaphenylporphyrin-based film sensors were prepared with anionic and cationic lipophilic ionic additives introduced into polyvinyl chloride membranes plasticized with various solvents. The data obtained with these sensors were used to calculate the parameters of the cross sensitivity of the sensors. A multisensor system of the "electronic tongue" type was developed on the basis of the sensors studied.

Chemical sensors and sensor systems form a rapidly developing class of analytical instruments with a wide variety of fields and objects of application. Porphyrins and their derivatives play increasingly important part in chemical analysis [1], with chemical sensors constituting one of the most important fields of application of porphyrins and metal porphyrins. Highly selective electrodes for determining chloride [2, 3], nitrite [4, 5], thiocyanate [6], salicylate [7], and other anions have been developed on their base. In view of the specific interaction between metal porphyrins and anions, the selectivity of sensors of this kind markedly differs from the selectivity of sensors based on classical anion exchangers, quaternary ammonium salts characterized by the so-called Hofmeister selectivity series [8].

At present, active research is also being conducted in the field of cation-sensitive sensors, in particular, nickel(II)-sensitive devices [9, 10], on the basis of porphyrins and related compounds, but the selectivity of sensors of this kind is poor. Nevertheless, such sensor materials may be of much interest.

Using a multisensor system of the "electronic tongue" type, including sensors that are weakly selective but exhibit high cross sensitivity (CS) to various solution components [11, 12], one can analyze multicomponent media with complex composition. The response of sensors belonging to the system contains information about many components of the complex solution; the multidimensional analytical signal generated in such a system is commonly processed using modern methods of mathematical statistics, e.g., image recognition and multidimensional calibration. The use of multisensor systems enables quantitative determination of many ions and other components whose activity or concentration cannot be determined by the conventional potentiometric techniques. The "electronic tongue" enables multicomponent quantitative analysis, with several substances determined in a complex liquid medium simultaneously. In addition, multisensor systems can be used to perform integrated qualitative analysis (identification, recognition, classification) of various liquid media.

In terms of the "electronic tongue" concept, specific requirements are imposed upon the sensors, the main of which is high cross sensitivity understood as the sensitivity of a sensor material to, simultaneously, several or many solution components, which are not necessarily ionic, and high reproducibility of characteristics of the system in operation in complex media. Previously, parameters for evaluation of the cross sensitivity and possible ways of search for new sensor materials have been proposed [13].

Tetraphenylporphyrin is rather promising membrane-active component (MAC) owing to its ability to form complexes with numerous cations [14]. Although some selective sensors on the basis of tetraphenylporphyrin have already been reported [9], the appearance of a new approach to evaluation of the sensor sensitivity requires a reconsideration of the views about the possibilities of many known MACs. For example, not-too-highly selective sensors exhibiting reproducible cross sensitivity can be successfully used to create multisensor systems. Polymer film cation-sensitive sensors based on MAC of varied nature have been studied previously [15].

o-NPOE	–	–	–	65.5	65.1	67	–	–	–
TOP	–	–	–	–	–	–	65.5	65.1	67
PVC	33	33	33	33	33	33	33	33	33

The aim of this work was to analyze the sensitivity characteristics of film sensors with tetraphenylporphyrin-based polyvinyl chloride membranes plasticized with solvents of varied nature, with anionic and cationic lipophilic ionic additives introduced into these membranes. The selectivity coefficients of the sensors were determined and the effect of the pH value on the sensor response was studied. The CS parameters of the sensors were calculated. The possibility of using sensors in a multisensor system of the "electronic tongue" type was analyzed.

EXPERIMENTAL

The following reagents were used in the study: *meso*-tetraphenylporphyrin (TPP), potassium tetra(*p*-chlorophenyl)borate (PTPB), tetradecylammonium chloride (TDACl), di(2-ethylhexyl) sebacate (DOS), *o*-nitrophenyl octyl ether (*o*-NPOE), tri(2-ethylhexyl) phosphate (TOP), high-molecular-weight polyvinyl chloride (PVC), and tris(hydroxymethyl)aminomethane (TRIS) of Selectophore® or "analytical reagent" grade, purchased from Fluka (Switzerland), and tetrahydrofuran manufactured by Akros Organics (Belgium) and distilled from potassium hydroxide prior to use. All the salts, acids, and bases (Ekros, St. Petersburg) were of chemically pure or analytically pure grade. Double-distilled water was used in all the experiments.

Sensor membranes were prepared using a standard procedure. Weighed portions of membrane components were placed in THF and the mixture was stirred with a magnetic rabble till complete dissolution. The resulting cocktail was poured into a weighing bottle with flat bottom and allowed to stay to complete THF evaporation (~48 h). Discs 6 mm in diameter were cut from the membrane obtained and glued onto the edge of plastic electrode cases. Prior to measurements, the sensors were soaked in a 0.01 M sodium chloride solution. The electrode case was filled with the same solution; Ag/AgCl was the internal reference electrode. Three sensors with membranes of each composition were used in all measurements, with each measurement replicated at least thrice. The compositions of the membranes studied (including blank membranes, i.e., those containing no membrane-active components) are presented in Table 1.

The emf measurements were carried out in the following electrochemical cell:

$$\mathrm{Ag}\left|\begin{matrix}\mathrm{AgCl}\downarrow,\\ \mathrm{KCl_{sat}}\end{matrix}\right|\begin{matrix}\text{Solution}\\ \text{studied}\end{matrix}\Big|\text{Membrane}\Big|\begin{matrix}\text{0.01 M. NaCl,}\\ \mathrm{AgCl}\downarrow\end{matrix}\Big|\mathrm{Ag}. \quad \text{(I)}$$

As reference electrode served EVL1M3 electrode (Gomel). The pH values were measured with a glass hydrogen electrode of the ESL-43-07 type, calibrated against standard buffer solutions. Sensor signals were recorded with a 30-channel electronic voltmeter with high input resistance, connected to a computer. The accuracy of emf measurements was 0.1 mV. All measurements were carried out at room temperature ($20 \pm 2°C$).

The selectivity coefficients were determined by the methods of biionic potentials (BIP) and mixed solutions, recommended by IUPAC [16]. In the BIP method, 0.1 M solutions of metal chlorides or nitrates was used. In the method of mixed solutions, the background concentration of interfering ions was 10^{-4} M. The effect of the pH value on the electrode response was studied in a solution containing 0.01 M TRIS and 0.5 M sodium chloride (pH 10.5), to which sulfuric acid was added dropwise.

When developing an analyzer of the "electronic tongue" type for experiments on recognition of specific objects,[1] a multisensor system comprising sensors

[1] Three samples of 100% apple juice from different manufacturers (samples I–III) were studied, together with a sample of an apple drink containing 12% juice (sample IV).

with each of the compositions studied was developed. The sensor signals were recorded 5 min after sample stirring. Between measurements, the sensors were washed several times with double-distilled water for 2–3 min. Measurements were repeated 3–4 times for each sample, with the order in which the samples were measured changed to reduce systematic errors associated with the action of samples on the sensor materials. The resulting data of high dimensionality were mainly processed by the principal component analysis. The results were processed using license software Unscrambler 6.11 (CAMO ASA, Norway, 1998).

The slopes of the calibration plots of the emf of the electrochemical cell (I) against the activity of a wide variety of cations in pure nitrate or chloride solutions are presented in Table 2. Most of sensors exhibited noticeable sensitivity to nearly all of the cations studied. Previously, it has also been shown that TPP-based sensors show a nearly Nernst function with respect to nickel(II).

Table 2 shows that, on the whole, sensors containing PTPB exhibit higher slopes. Nevertheless, the slopes are frequently smaller than the theoretical values. This can be accounted for by the fact that sensors preliminarily soaked in sodium chloride solution, rather than in a solution of the potential-determining ion, were used in all measurements. The super-Nernst slope of the sensor function in the case of copper(II) and lead(II) ions can be accounted for by variation of the solution pH with the ion concentration due to hydrolysis of salts or by the possible contribution of nonexchange sorption.

In addition to the sensors listed in Table 1, TPP-based sensors, also containing an anion-exchanger (TDACl), were fabricated. Electrodes of this kind exhibited a partial anionic function (with slopes less than 40 mV/pA). The anionic function of the membranes with anion exchanger indicates that TPP in the membrane is rather a neutral carrier [17]. These membranes were of no interest for the present study.

To reveal the effect of pH on the sensor response, the *E*–pH dependence was studied (Fig. 1). Membranes with TOP as plasticizer are insensitive to pH in the range studied. This refers both to modified (Table 1, compositions 7 and 8) and to blank (composition 9) membranes. Membranes plasticized with DOS and containing TPP exhibit weak pH sensitivity at pH < 4, and membranes without cation exchanger, also at pH > 8. The blank membranes based on DOS show virtually zero pH function. Membranes plasticized with *o*-NPOE exhibit a pH function with

slopes of 30–35 mV/pH in the neutral and acid regions. The slope is smaller in membranes containing PTPB. The pH sensitivity of DOS-based sensors in the acid region can be accounted for by the tendency toward porphyrin protonation [18], and the pH sensitivity of sensor membranes plasticized with *o*-NPOE is probably largely due to the influence exerted by the solvent-plasticizer itself.

The selectivity coefficients of the sensors, determined using the BIP method, are presented in Fig. 2. The selectivity coefficients with respect to singly charged ions, found for sensor membranes plasticized with DOS and *o*-NPOE, are in agreement with the lipophilic series for these cations, and this agreement is more pronounced for membranes containing a cation exchanger (PTPB). Membranes plasticized with DOS show no noticeable selectivity with respect to

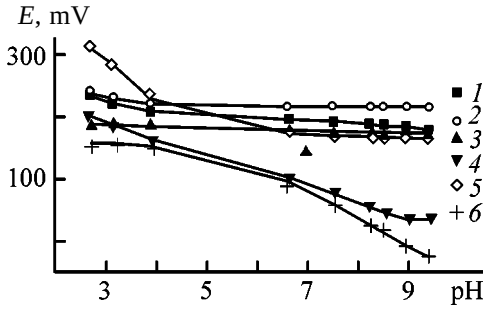

Fig. 1. Sensor response *E* vs. pH. Supporting electrolyte 0.5 M NaCl and 0.01 M TRIS. (*1*–*6*) Membrane compositions (Table 1).

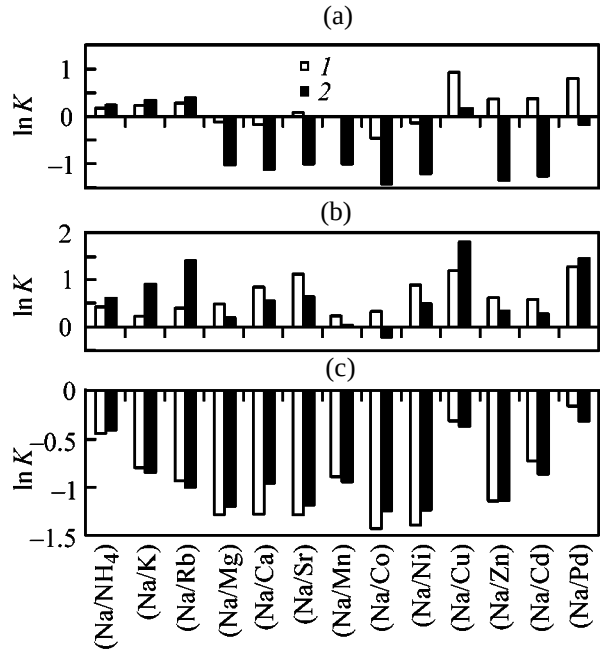

Fig. 2. Selectivity coefficients K(Na/X) measured by the BIP method. Sensor membrane: (*1*) TPP-based and (*2*) TPP- and PTPB-based. Plasticizer: (a) DOS, (b) *o*-NPOE, and (c) TOP.

cations of alkaline-earth metals. The logarithms of their selectivity coefficients are close to zero, whereas for membranes with an ion additive they are nearly unity. Sensors based on *o*-NPOE exhibit selectivity that increases with cation lipophilicity, with the selectivity of membranes with cation exchanger being, on the whole, lower. The results obtained are in agreement with the known data on the effect of solvent-plasticizer on the membrane properties: the more polar solvent, *o*-NPOE, shows better ability to solvate double-charged anions. The low selectivity of the sensors with respect to ions of alkali and alkaline-earth metals can be accounted for by the ability of these metals to form only labile, coordination-unsaturated complexes with porphyrin, mainly of the ionic type [19]. Another situation is observed in the case of transition metal ions. The ability of porphyrin to form stable over-plane complexes, in which the pyrrolenine nitrogen atoms are coordinated with a metal ion and pyrrole protons remain in their original positions, has been confirmed experimentally; however, published data on formation constants of such complexes with a wide variety of transition metals in various solvents are unfortunately lacking. Nevertheless, the data of [20] show that the formation constants of copper(II) complexes exceed by two orders of magnitude those for zinc(II). These data are in qualitative agreement with the experimental selectivity coefficients of the sensors with respect to ions of these metals. The selectivity coefficient series for membranes plasticized with DOS and *o*-NPOE are similar, but in sensors based on *o*-NPOE the selectivity with respect to transition metal ions is more pronounced. The highest selectivity is observed for copper(II) and lead(II) ions.

Sensors with membranes plasticized with TOP are characterized by negative logarithms of the selectivity coefficients with respect to all the ions.

The selectivity coefficients measured by the method of mixed solutions are in good agreement with the data obtained by the BIP technique (Fig. 3).

The slopes of the calibration plots, obtained for the sensors in solutions of varied nature, were used to calculate the cross sensitivity parameters (Table 3): average cationic slope

$$S_{av} = n^{-1} \sum_i S_i, \quad (1)$$

nonselectivity factor

$$f = S_{av}/s^2, \quad (2)$$

and reproducibility factor

$$K_{av} = n^{-1} \sum_i (S_i/s_i^2), \quad (3)$$

where S_i is the slope of the electrode function of

Table 3. Parameters of cross sensitivity of sensors

Membrane	S_{av}, mV/pX	F	K
1	28(11)*	0.22	2.7
2	34(13)	0.19	4.1
4	18(10)	0.19	1.4
5	27(13)	0.17	2.2
7	35(13)	0.21	7.6
8	39(10)	0.39	13.4

* rms deviation of S is given in parentheses.

a sensor in a solution of *i*th ion, *n* is the number of ions, *s* is the rms deviation of the average cationic slope, and s_i is the rms deviation of S_i.

The cross sensitivity parameters of TPP-based sensors were calculated using the slopes of the electrode function in solutions of 15 cations and their standard deviations. The data obtained are listed in Table 3.

The average slopes of the electrode function (cationic slope of the sensors) S_{av} is within the range 18–39 mV/pX. This parameter is the most important, and the higher its value, the better the cross sensitivity of a sensor. The rms deviation of the average slope *S* is commonly used to calculate the nonselectivity factor. The nonselectivity factor, characterizing the uniformity of distribution of the sensor sensitivity to various cations, takes values in the range from 0.17 to 0.39, and the higher this factor, the more uniform the selectivity of a membrane material with respect to various ions. Finally, the reproducibility factor characterizes the reproducibility of the electrode function of sensors. This factor is commonly calculated using the rms deviation of the cationic slopes of sensors, found on the basis of three calibrations against solutions of individual ions. The reproducibility factor is within the range 1.4–13.4. Correspondingly, the higher this value, the better the reproducibility of the sensor signal. The calculated cross sensitivity parameters show a rather high cross sensitivity for all of the sensors studied. The best cross sensitivity is observed for sensor nos. 7 and 8 with membranes plasticized with TOP, and also membranes based on DOS and *o*-NPOE, containing an ionic additive.

The results of tests of a multisensor system with TPP-based sensors in recognition of specific objects are presented in Fig. 4.

The system reliably distinguishes apple juices of various manufacturers and differentiates all 100% juices from an apple drink. Thus, the system can be used in practice for monitoring the quality and identifying apple juices.

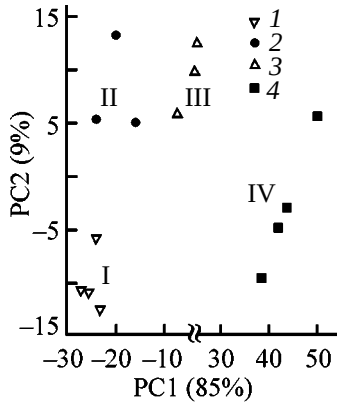

Fig. 4. (*1–4*) Recognition of samples I–IV. The result of principal component analysis is presented in the form of a plot of scores; PC1 and PC2 are the first and second principal components, respectively; percentages in parentheses are the explained variances for a given principal component.

CONCLUSION

Tetraphenylporphyrin-based polyvinyl chloride sensor materials plasticized with solvents of varied nature and containing cationic lipophilic additives were developed and studied. It was established that the properties of sensor materials containing tri-(2-ethylhexyl) phosphate are mainly determined by the solvent-plasticizer itself. A pronounced contribution to the properties of sensors based on di(2-ethylhexyl) sebacate and *o*-nitrophenyl octyl ether comes from the lipophilic additive and *meso*-tetraphenylporphyrin. The selectivity of the sensors was measured by the methods of biionic potentials and mixed solutions and their high cross sensitivity to cations of alkali, alkaline-earth, and transition metals. A multisensor system of the "electronic tongue" type was developed on the basis of sensors with *meso*-tetraphelylporphyrin and was successfully used to recognize various drinks.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrode Reactions on Synthetic Diamond and Cubic Boron Nitride in Ionic Melts[1]

I. A. Novoselova and A. I. Gab

Received November 13, 2001

Abstract—The behavior and corrosion resistance of synthetic diamond and cubic boron nitride in chloride, chloride–oxide, and oxide salt melts at 750–900°C were studied by potentiometric and voltammetric methods.

Considerable recent attention of electrochemists has been focused on diamond as a new electrode material whose behavior in aggresive media is characterized by unique chemical, physical, and electrochemical features [1, 2]. All the studies were carried out in aqueous and organic electrolytes, mainly with film diamond and diamond-like electrodes doped and modified with various dopants (B, N, Pt). No such researches were made in molten media because of difficulties in designing a diamond electrode suitable for the operation in salt melts at high temperatures. Furthermore, diamond materials were used as inert electrodes for the implementation of processes that are difficult to realize on usual electrodes such as platinum or glassy carbon (for example, electrolytic reduction of nitrate ions to ammonia [3]).

This work is concerned with deposition of high-melting metals on grains of dielectrics. Plating of grains of superhard materials by high-melting metals is one of the most radical ways for improving the performance of abrasive tools [4]. This problem was first solved for diamond [5]. To explain the appearance of the electrode function of dielectric diamonds in salt melts, the concept of surface conductivity arising from redox reactions on the diamond–ionic melt interfaces was offered [6, 7]. Having extended the range of supports, we were able to metal-plate cubic boron nitride, which is the closest structural analog of diamond. In was also shown [8] that these two dielectrics exhibit a similar electrochemical behavior in salt melts. This work summarizes earlier data and new experimental data on the electrochemical behavior of diamond and cubic boron nitride (c-BN).

[1] Reported at the X Kola Seminar "Electrochemistry of Rare Metals," Apatity, December 4–7, 2000.

EXPERIMENTAL

In this work we used dielectric powders of single crystals of AS15 and ASS diamonds (grain size 650/500, 315/250, and 160/125 μm) and of KR cubic boron nitride c-BN (grain size 200/160 and 160/125 μm), and also compact c-BN pelletized in disks of diameter 6.45 mm and thickness 0.66 mm.[2]

Synthetic diamonds were synthesized from the system Ni–Mn–C under static conditions and purified to remove the residual melt-solvent by acid methods (boiling with $K_2Cr_2O_7$–H_2SO_4). Cubic boron nitride of KR grade was obtained from hexagonal boron nitride at high pressures and temperatures in the field of thermodynamic stability of the cubic modification using magnesium as a process stimulant. To isolate the cubic modification of boron nitride from the synthesis products, we treated them with dilute solutions of hydrochloric acid and with a mixture of molten potassium and sodium hydroxides. The content of the cubic modification in thus isolated c-BN crystals was 99% [9].

Pelletized compact c-BN was obtained by solid-phase polymorphic transition of hexagonal graphite-like form of boron nitride at high pressures (about 8.5 GPa) and temperatures (1573–2273 K).

The impurity content of the samples under study is given in Table 1.

We determined the dc resistivity of natural diamond and compact c-BN at 1023 K with an R5083 bridge. The resulting values are given below:

Material	Natural diamond	AS15 (500/400)	c-BN
ρ, Ω m	7.2×10^8	2.7×10^6 [10]	4.7×10^2

[2] The samples were prepared in the Institute of Superhard Materials, National Academy of Science of Ukraine.

The resistivities of diamond and cubic boron nitride at the experimental temperatures allow them to be classed with dielectric materials.

Potentiometric and voltammetric mesurements were carried out in a three-electrode electrochemical cell with a PI-50-1.1 potentiostat and a PR-8 programmer. Voltammograms were recorded on an LKD 4-003 device at scanning rates from 0.02 to 0.2 V s^{-1}. The electrode potentials were recorded on Shch68003 and F4800 high-resistance voltmeters. The experiments were carried out in an electric furnace at 973–1173 K. The working electrode in a three-electrode cell was a platinum-grid container filled with a dielectric powder and immersed in a melt with the aid of a platinum wire. This electrode was called a combined platinum–dielectric electrode (CPDE), as it contains two phases: platinum as a conductive phase and diamond or c-BN powder as a dielectric phase. Further studies have shown that both phases participate in electrochemical processes.

We used a lead electrode Pb | NaCl–KCl–$PbCl_2$ in chloride and chloride–oxide melts as a reference electrode [11]. A platinum or glassy carbon crucible served as a container for a melt and simultaneously as an anode.

The graphite electrode was a rod of diameter 5 mm made from spectrally pure graphite. Its upper part, which extended from a melt, was covered with a porcelain tube. A platinum wire served as a current lead. A pellet of cubic boron nitride was immersed in a melt with the aid of a platinum wire.

The chemicals in use were of chemically pure and analytically pure grades. Before and after each experiment, we controlled the weight and appearance of powders and made their X-ray phase analysis using a DRON 3.0 X-ray diffractometer.

To deposit coatings, we used nickel grids and current leads to a dielectric material powder and tungsten or molybdenum rods of diameter 10 mm, which served as anodes. Metal-plated grains were separated from the remaining electrolyte by decanting after 30-min boiling in distilled water.

The thermogravimetric studies were carried out on a Q-1500D derivatograph, and atomic absorption analysis, on a PYE UNICAM SP 9 atomic absorption spectrophotometer. The X-ray emission spectra were taken on an RSM-500 X-ray ultrawave spectrometer with oil-free evacuation. The ESR spectra were recorded on an SE/X 2547 (Radiopan corporation) radiospectrometer of 3-cm range at room temperature.[3]

To estimate the chemical resistance of the diamond and c-BN, we have carried out thermodynamic analysis of possible reactions of these substances with oxygen-containing compounds of Group IV–VI elements [12]. On this basis, we constructed series of such compounds in the order of increasing oxidizing power toward the dielectrics under study (at 1000 K). For diamond, such a series is as follows: Na_2CO_3, Na_2O, Na_2WO_4, Na_2MoO_4, $Na_2W_2O_7$, CO_2, WO_3, Na_2SO_4, Na_2CrO_4, $Na_2Mo_2O_7$, MoO_3, SO_3, and CrO_3.

[3] The X-ray emission spectra were taken in the Institute of Materials Science Problems, National Academy of Sciences of Ukraine. The ESR spectra were taken in the Institute of Superhard Materials, National Academy of Sciences of Ukraine.

$8BN + 2Na_2Mo_2O_7 = 4NaBO_2 + 2Mo_2N + 3N_2 + 2B_2O_3$	–454.59	–501.58	–549.11	–589.48

Table 3. Results of corrosion tests of AS-15 (315/250) diamonds in Na_2WO_4 melts at 1173 K

Addition to melt, 20 mol %	Δm, %	$V \times 10^{-1}$, g m^{-2} h^{-1}	Δm, %	$V \times 10^{-1}$, g m^{-2} h^{-1}	Δm, %	$V \times 10^{-1}$, g m^{-2} h^{-1}
	at indicated test duration, h					
	1.0		2.0		5.0	
–	1.39	7.24	2.22	5.92	5.23	5.51
WO_3	1.49	7.84	2.33	6.14	4.78	4.13
MoO_3	2.47	13.01	3.62	9.53	9.75	10.27

The series for cubic boron nitride is $Na_2W_2O_7$, Na_2WO_4, CO_2, Na_2CO_3, WO_3, Na_2MoO_4, Na_2SO_4, $Na_2Mo_2O_7$, MoO_3, Na_2CrO_4, SO_3, and CrO_3.

It is evident that the "mildest" oxidizing agents for diamond and c-BN are tungstate, ditungstate, sodium carbonate, and carbon dioxide, i.e., on the one hand, redox processes in melts containing these compounds can occur on the surface of the dielectric materials under study, and, on the other hand, the corrosion of these latter should not be very strong.

It is necessary to note that, according to our thermodynamic analysis, the nitrides Mo_2N and W_2N of high-melting metals can be formed in the reactions of c-BN with Na_2MO_4, $Na_2M_2O_7$, and MO_3 (M = Mo, W) along with the high-melting metals and their dioxides (Table 2). However, our thermogravimeric study of the behavior of cubic boron nitride in the system Na_2WO_4–WO_3 has not revealed changes in the weight and phase composition of c-BN, and by the data of the atomic absorption analysis this melt contains no boron. Therefore, the occurrence of the reactions listed in Table 2, despite their high negative Gibbs energies, was not proved experimentally.

We studied corrosion of diamond and c-BN in halide, halide–oxide, and oxide melts during long-run tests. Changes in the weight and phase composition of the powders under study in the system NaCl–KCl (1 : 1) were detected neither in air nor in argon atmosphere. Addition of sodium tungstate (or molybdate) in amounts of up to 50 mol % into this melt results in minor weight losses Δm (up to 1% in 2 h). The bubbling of CO_2 through the NaCl–KCl melt (1 : 1) does not change the appearance and weight of the dielectric powders either.

Weight losses Δm of both diamond and c-BN were detected in melts of sodium tungstate and oxide mixtures based on it (Table 3). No changes in the phase compositions of the powders under study were found in the corrosion tests.

It follows from Table 3 that the weight loss of diamonds increases with addition of 20% of WO_3 or MoO_3 into an Na_2WO_4 melt. The corrosion rate V decreases as the time of keeping the sample in the melts increases.

Chemical reactions occurring in the melts under study can be described by the following equations:

$$Na_2WO_4 + 3C \rightarrow W + 3CO + Na_2O,$$

$$\Delta G = 176.22 \text{ kJ};$$

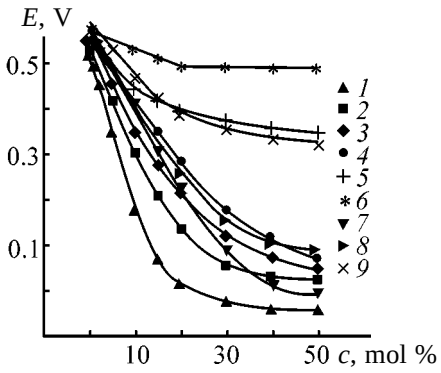

Fig. 1. Potential E as a function of concentration c of (*1, 2, 6–9*) Na_2WO_4 and (*3–5*) Na_2MoO_4, as measured in an NaCl–KCl (1 : 1) melt on various electrodes. Electrode: (*1–3*) combined diamond AS15 (160/125), (*2–4*) combined diamond AS15 (315/250), (*5, 6*) platinum, (*7*) combined c-BN KR (250/200), (*8*) combined c-BN KR (160/125), and (*9*) compact c-BN.

$$2Na_2W_2O_7 + 3C \rightarrow 2W + 3CO_2 + 2Na_2WO_4,$$

$$\Delta G = -84.66 \text{ kJ};$$

$$2Na_2Mo_2O_7 + 3C \rightarrow 2Mo + 3CO_2 + 2Na_2MoO_4,$$

$$\Delta G = -263.73 \text{ kJ}.$$

A high-melting metal formed on the surface of diamonds apparently dissolves in oxide melts.

Using X-ray emission spectroscopy and electron spin resonance (ESR), we have studied how the treatment of diamonds in various melts [equimolar mixture NaCl–KCl, equimolar mixture NaCl–KCl–CO_2 (pressure 10 atm), Na_2WO_4, and Na_2WO_4–xWO_3 (MoO_3)] at 1023 K affects the surface texture of the diamonds. The ESR experiments have not revealed any conductive (metallic) films on the surface of diamonds after their 3-h keeping in the above melts in the absence of current. We have shown by X-ray emission spectroscopy that the treatment with melts results in a rupture of bond between the surface carbon atoms and atoms of other elements adsorbed on the diamond surface during synthesis and subsequent removal of the residual melt-solvents from the diamonds. In this case, recombination of C–C bonds, reconstruction of the diamond surface, and filling of the surface carbon atoms with electrons can take place. Ihm *et al*. [13], using the self-consistent pseudopotential method, calculated the electronic structure of (111) diamonds and drew on this basis a rather interesting conclusion: an ideal surface of diamonds should have a metallic conductivity.

Thus, our thermodynamic analysis and experimental data on the chemical behavior of diamonds in oxide melts qualitatively give the same results and demonstrate that the redox reactions on the interface give rise to an electrochemical equilibrium and to the appearance of an intrinsic electrolytic potential.

The potentiometric study of the behavior of combined diamond and c-BN electrodes in chloride–oxide systems was carried out by measuring emfs of the following circuits:

$$\text{Pt, dielectric} \mid \text{NaCl–KCl (1 : 1)} \parallel \text{NaCl–KCl (1 : 1)–2.5 mol \% } PbCl_2 \mid \text{Pb}, \quad (1)$$

$$\text{Pt, dielectric} \mid \text{NaCl–KCl (1 : 1)–}x\text{Na}_2\text{WO}_4(\text{Na}_2\text{MoO}_4) \parallel \text{NaCl–KCl (1 : 1)–2.5 mol \% } PbCl_2 \mid \text{Pb}, \quad (2)$$

$$\text{Pt, dielectric} \mid \text{NaCl–KCl (1 : 1)–}CO_2\text{ (bubling)} \parallel \text{NaCl–KCl (1 : 1)–2.5 mol \% } PbCl_2 \mid \text{Pb}, \quad (3)$$

where dielectric is diamond or c-BN.

We found that the potential of combined diamond and c-BN electrodes in a pure chloride melt NaCl–KCl (1 : 1) coincides with the potential of platinum. Addition of Na_2WO_4 (or Na_2MoO_4) into the melt results in the displacement of potentials of the combined electrodes to the negative region (Fig. 1). The compact c-BN electrode behaves similarly to the combined c-BN electrode. In this case, the following relation was observed: the finer the grains of a dielectric material, the greater the deviations of its potential from the platinum potential. The potentials of all the combined electrodes under study became more negative than the potentials of platinum, which served as a metal container.

Bubbling CO_2 through an NaCl–KCl (1 : 1) melt also results in displacement of potentials of graphite, platinum, and combined platinum–dielectric electrodes to the negative region, the potential of a combined diamond electrode approaching the potential of the graphite electrode [7]. When the gas feeding is terminated, the initial potentials of all the electrodes are restored.

The potentials of combined platinum–diamond electrodes (CPDE) in oxide melts appreciably differ from the potential of platinum. They are sensitive to the variations of acid–base properties of melts. When acid components (WO_3 and MoO_3) are added, the potential of a combined dielectric electrode is shifted to the positive region, and basic additions (Na_2CO_3)

Table 4. Effect of MoO_3 concentration on steady-state potentials E of electrodes in an Na_2WO_4 melt at 1173 K

* Potentials are given relative to the reference electrode Na_2WO_4–0.2 mol % $WO_3 \mid O_2$, Pt.

shift it to the negative region of potentials [6]. The results of our potentiometric study of the behavior of combined platinum–diamond, graphite, and metallic (Pt and Mo) electrodes in an oxide melt at varied concentration of molybdenum oxide are given in Table 4.

Table 4 shows that the CPDE potential in pure melt of sodium tungstate is more negative that the potential of the platinum electrode approximately by 400 mV, and this difference increases to 600 mV when molybdenum oxide is added. At the same time, the CPDE potential is more positive by 200 mV than the potential of the graphite electrode in a tungstate melt, but these potentials become almost equal as molybdenum oxide is added. The potential of the molybdenum electrode in all experiments was more negative than the CPDE potential.

We can assume that the potential-determining processes on graphite and combined platinum–diamond electrodes are similar and can be described by the following electrode reaction:

$$C + O^{2-} \rightleftarrows C \mid O_{ads} + 2e.$$

We can write the following expression for the potential of this electrode:

$$E = E^0 + \frac{RT}{2F}\ln\frac{[C \mid O_{ads}]}{[O^{2-}]} = E^0_* + \frac{2.3RT}{2F}pO^{2-},$$

where $E^0_* = E^0 + \frac{RT}{2F}\ln[C \mid O_{ads}]$.

Correspondingly, the equation of the electrode reaction and the potential of the combined c-BN electrode can be presented as [6]

$$BN + 2O^{2-} \rightleftarrows BO_2^- + 1/2N_2 + 3e,$$

$$E = E^0 + \frac{RT}{3F}\ln\frac{[BO_2^-][N_2]^{1/2}}{[BN][O^{2-}]}.$$

In this work we have studied the CPDE behavior at 750°C by voltammetry in the following systems:

$$NaCl–KCl\,(1:1)–0.5\ M\ Na_2WO_4–0.05–0.15\ M\ NaPO_3, \quad (4)$$

$$NaCl–KCl\,(1:1)–0.5\ M\ Na_2MoO_4–0.05–0.20\ M\ NaPO_3. \quad (5)$$

These systems were developed for the electrolytic deposition of tungsten, molybdenum, and their carbides on metallic electrodes [14].

The cyclic I–E curves obtained on a platinum electrode and CPDE are given in Fig. 2. The presence of current maxima in the curves is characteristic of the processes with a mixed kinetics when the rates of the charge transfer and mass transfer of ions are comparable. This is confirmed by the dependence of the peak potentials on the potential scanning rate. It follows from Table 5 that diamond powder AS15 (315/250) behaves as an electroconductive constituent of an electrode: the cathode current peak $I_{p(c)}$ increases as compared to the platinum electrode, and its

potentials are strongly stretched along the potential axis. More positive peak potentials of anode current $E_{p(a)}$ as compared to the platinum electrode, seem to result from a chemical reaction between a generated high-melting metal and diamond. Therefore, the product formed in the cathode cycle on CPDE (a carbide phase) is more difficult to dissolve than a high-melting metal formed on platinum. Apparent charge-transfer coefficients αn_α for the cathode process, calculated by the equation for irreversible charge transfer [15], are given in Table 5.

$$E_{p/2(c)} - E_{p(c)} = 1.857\ RT/\alpha n_\alpha F.$$

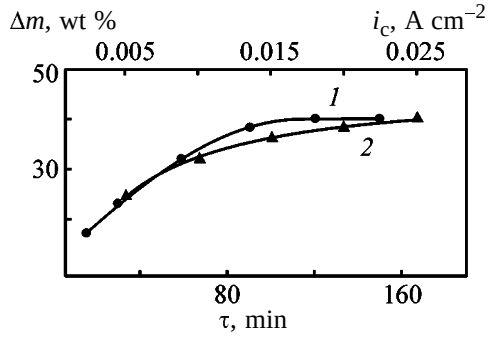

Fig. 3. Degree of c-BN plating Δm with molybdenum carbide as a function of (*1*) electrolysis duration τ and (*2*) cathode current density i_c measured in the melt NaCl–LiF (3 : 1)–1.3 mol % Na_2MoO_4–1 mol % Na_2CO_3 at 1173 K.

The degree of irreversibility of the electrode process on a diamond electrode is much greater.

Knowing the specific surface area of diamond powders in use, we determined the fraction of the surface participating in the electrode process. We found that this fraction increases with increasing $NaPO_3$ concentration from 0 to 18.10% for system (4) and from 3.30 to 13.00% for system (5).

The voltammetric study of the CPDE behavior in systems (4) and (5) allowed us to determine the optimal conditions for the electrodeposition of carbides of high-melting metals (W_2C, Mo_2C) on diamond. Electrolyte composition (mol %): NaCl 45.00–47.30, KCl 45.00–47.30, Na_2MoO_4 (or Na_2WO_4) 5.00–8.00, and $NaPO_3$ 0.40–2.00. Current density i_c = (7–10) × 10^{-3} A cm^{-2}, temperature 750–800°C. The optimal electrolysis duration, as follows from Table 6, is 60 min.

Continuous solid coatings of molybdenum carbide on cubic boron nitride were obtained from the system NaCl–LiF (1 : 1)–1.3 mol % Na_2MoO_4–1 mol % Na_2CO_3.

When this system is used for plating c-BN with molybdenum carbide, the degree of plating depends on the cathode current density and the electrolysis time (Fig. 3). At T = 1173 K, τ = 90 min, and i_c = 0.02 A cm^{-2}, we obtained a solid Mo_2C coating on c-BN with the thickness h 4.80 μm.

Continuous and well adhering to the support coatings of high-melting metals (Mo, W) were obtained on c-BN from the following systems: NaCl–LiF (1 : 1)–2.5 mol % Na_2MoO_4 at T = 1173 K, i_c = 0.02 A cm^{-2}, τ = 45 min, Δm = 14.6 wt %, h = 1.02 μm; Na_2WO_4–1 mol % WO_3 at T = 1173 K, i_c = 0.20–0.30 A cm^{-2}, τ = 90 min, Δm = 220 wt %, h = 7.80 μm.

The optimal systems and conditions for the deposition of coatings of high-melting metals and their carbides on diamond and c-BN are given in Table 7.

Table 7. Optimal conditions for the deposition of coatings of high-melting metals and their carbides with thickness *h* on dielectric materials

	Mo	NaCl–LiF (3 : 1)–2.5 mol % Na_2MoO_4	1173	0.020	45	1.02
	W	Na_2WO_4–1 mol % WO_3	1123	0.220	90	7.80

CONCLUSIONS

(1) Potentials of combined dielectric electrodes (diamond and c-BN) in pure chloride melts coincide with the potential of platinum. In this case, no weight and phase changes take place in the dielectrics.

(2) When weak oxidizing agents (Na_2WO_4, Na_2MoO_4, and CO_2) are added to a chloride melt, minor weight losses (up to 1 wt %) of diamond and c-BN are observed. The potential of a combined platinum-dielectric electrode becomes more negative than the potential of platinum, the deviations of the potentials depending on the grain size. Electroplated coatings of tungsten and molybdenum carbides up to 0.50 μm thick can be obtained from halide–oxide electrolytes.

(3) Both diamond and c-BN have their interinsic potentials in purely oxide melts based on sodium tungstate. These potentials are more negative than the potential of platinum. The potential of a combined platinum–dielectric electrode depends on acid–base properties of a melt. The corrosion of the dielectrics is determined by the concentration of acid additions and corresponds to the series of oxidizing powers constructed on the basis of the thermodynamic analysis.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Thermodynamics of Lithium Intercalates in Carbonized Fabric

L. N. Ol'shanskaya and E. N. Astaf'eva

Technological Institute, Saratov State Technical University, Engels, Saratov oblast, Russia

Received August 31, 2001; in final form, January 2002

Abstract—The method of quasi-equilibrium galvanostatic curves was applied to study the thermodynamics of lithium deintercalation from the system Li_xC_6 (solid phase)/Li^+ (solution) in the interval 293–323 K and the thermodynamic characteristics (ΔG, ΔS, ΔH) of lithium intercalation compounds in a carbonized fabric in relation to the degree of intercalation x.

The basic challenge in fabrication of rechargeable lithium power cells (LPCs) is creating high-energy-capacity reversible negative electrodes on the basis of lithium. The processes of charging–discharge of LPC electrodes, involving conversion of some chemical compounds into others, entail changes in thermodynamic functions: Gibbs energy ΔG, entropy ΔS, and enthalpy ΔH. Knowledge of these parameters may be of key importance not only for predicting electrochemical processes occurring in the system, but also for improving the LPC operation [1–4].

Compounds produced by lithium intercalation into carbon-containing materials (CCMs): coke, carbonized fabrics, fibers, pyrocarbon, etc., are widely used today as the active substance of negative electrodes for lithium-ion batteries [5–22]. The mechanism and kinetics of intercalation/deintercalation of lithium in the CCM structure have been the subject of numerous studies [5–21]. However, insufficient attention has been given to the thermodynamics of lithium intercalates in CCMs.

In this work we analyze the thermodynamic functions of lithium deintercalation from the Li_xC_6 compound formed in the structure of a carbonized fabric (CF) of the ELUR brand in a 1 M solution of $LiClO_4$ in a 1 : 1 (v : v) mixture of propylene carbonate and dimethoxyethane, PC + DME.

EXPERIMENTAL

The carbonized fabric ELUR is a fabric 50 cm wide and ~68 μm thick. Curved bent fibrils predominate in the CF structure. Voids with pore size of 10–50, 50–200 nm and more have nearly cylindrical shape and are oriented along the fibers. In the directions normal to the fiber axis, there are pores whose average diameter is approximately 1.6 nm. The cross-sectional structure of the fabric fibers shows no radial component, being preferably lamellar. It can withstand the disintegrating action of lithium being intercalated into the fabric and an increase in the interlayer spacing. Carbonized fabric has disordered structure.

Working electrodes were prepared from CF as follows: a layer of inert binder (F-42 L fluoroplastic, 10 wt %) dissolved in acetone was deposited onto a separator made of nonwoven polypropylene, and a fabric was manually rolled over it. After that, the electrodes were dried at 80°C in an oven to remove acetone. The thickness of the solid active layer after rolling and drying did not exceed 50–55 μm. Finished electrodes, having the form of spatulas with the working surface area of 1 cm^2, were fixed in a metallic holder. With account taken of the sufficient conductivity of the starting carbon materials and its increase upon formation of intercalation compounds with graphite [20, 22, 23], no additional metallic current leads were used.

Li_xC_6 electrodes were formed in the FC structure by the method of cathodic intercalation [9, 10] in the fifth cycle in a 1 M solution of $LiClO_4$ in 1 : 1 PC + DME [with water content not exceeding $(5–7) \times 10^{-3}$%] at a cathodic polarization potential E_c = –3.1 V relative to a nonaqueous silver chloride reference electrode (NSCRE) in the working solution. The intercalation time was 2 h, and the temperature range studied, 293–323 K (with a step of 5 K). Electrochemical measurements were carried out in a hermetically sealed three-electrode cell with cathode and anode spaces separated by glass frits. As counterelectrodes served 3 cm^2 plates of A 99.99 aluminum; as reference electrode was used NSCRE in the working electrolyte solution. To eliminate the diffusion poten-

1070-4272/02/7505-0740$27.00 © 2002 MAIK "Nauka/Interperiodica"

tial, LiCl crystals were introduced into the working solution of $LiClO_4$ [9, 24]. The silver chloride reference electrode is reversible and stable in the solvents used in the study [24]. The stability of the electrode potential was constantly monitored. If the solution turned yellow (in approximately 6 months), the electrodes were prepared anew. The NSCRE potentials measured relative to the standard aqueous silver chloride and lithium reference electrodes at different temperatures are presented in the table. Temperature measurements were done in a UTU-4 ultrathermostat, with temperature maintained constant to within ±0.1°C. The cell and the reference electrode were thermostated in a hermetically sealed dry vessel equipped with additional thermometers for visual inspection of the temperature of the electrolytes (at the working and reference electrodes). In each set of experiments, 3–5 parallel runs were done, and the results were processed by the least-squares method [25–27].

Figure 1 presents the equilibrium galvanostatic discharge curves E_{eq}–x of lithium deintercalation, measured at discharge current of 0.075 mA cm^{-2} (~5 mA g^{-1}). The difference between the curves obtained in the cathodic and anodic runs did not exceed 3–5 mV, which allowed them to be considered rather close to equilibrium [21, 28]. The process of lithium intercalation/deintercalation in the system studied, Li/Li^+(solution)/Li_xC_6, is described by the equation

$$Li_xC_6 + mLi^+ + me^- + \square_{vacancy} \rightleftarrows Li_{x+m}C_6. \quad (1)$$

No side reactions proceed in the system under study, and the lithium intercalation/deintercalation is accompanied by redistribution of the electron density in the forming phases Li_xC_6 and $Li_{x+m}C_6$. Owing to the small radius of the Li^+ ion (r_{Li^+} = 0.068 nm) [29] as compared to the interlayer spacings and voids in CF (~0.350–1.6 nm), the processes occur reversibly and at high rate.

Three regions of potential variation with x can be distinguished in the E_{eq}–x curves obtained ($x = Q_{eq}/Q^*$, where Q^* = 339 mA h g^{-1} is the theoretical specific capacity of Li_xC_6 at x = 1). In portion *I*, the reaction product is a compound of the composition $Li_{0.3 \le x \le 0.5}C_6$. This region is characterized by a decrease in potential, and a simultaneous decrease in x, with increasing temperature. This points to acceleration of lithium deintercalation from the structure of the active material with increasing temperature. In portion *II*, a steeper decrease in potential is observed until $x \approx 0.23$ is reached. In the vicinity of this x value, the electrode potential is independent of temperature. Further, deintercalation of lithium from the structure of carbonized fabric (portion *III*) is accompanied by a more stable and less steep run of E_{eq} at elevated temperatures, whereas at 293–308 K the potential decreases in the course of discharge. Such a behavior of the E_{eq}–x curves may be due to processes occurring in the solid phase of the active substance and to structural transformations in the lithium–graphite electrode, which are affected, as shown by the experimental data obtained, by temperature. Information about processes occurring in discharge can be obtained by analysis of how thermodynamic characteristics vary with the degree of intercalation x and the equilibrium potential established in the system Li_xC_6 (solid phase)/Li^+ (solution) in different stages of the anodic process

in the temperature range 293–323 K:

$$\Delta G(x,T)_{eq} = -EF, \quad \Delta S(x,T)_{eq} = F(dE/dT)_{eq},$$

$$\Delta H = \Delta G + T\Delta S, \qquad (2)$$

where $F = 964585$ C mol^{-1} is the Faraday number.

To determine the temperature coefficient $(dE/dT)_{eq}$, the dependences E_{eq}–x (Fig. 1) were replotted in the coordinates E_{eq}–T for different x (Fig. 2). The results show that the temperature coefficient $(dE/dT)_{eq}$ is positive in the interval $0.5 > x > 0.23$, approximately equal to zero at $x \approx 0.23$, and negative at $x < 0.23$. The sign of the temperature coefficient determines the relationship between ΔG and ΔH [1, 2]. This allows evaluation of the heat effect and nature of the reaction (Peltier heat, exo- or endothermic process) and calculation of the entropy [1–4].

The dependences E_{eq}–T, ΔG–x, ΔS–x, and ΔH–x, obtained in this study and presented in Figs. 1–4, can be interpreted as follows. At positive temperature coefficient $(dE/dT)_{eq} > 0$ in the interval $0.23 < x \le 0.50$, ΔS is positive (Fig. 3). In this case, $T\Delta S > 0$, i.e., the work done by the electric current exceeds the heat effect of the corresponding process (1). This leads to energy deficiency in the system (endothermic reaction). The lithium deintercalation process is accompanied by energy expenditure and experiences certain hindrance associated, in all probability, with structural transformations in the electrode material [5, 13, 14, 21, 28] (lattice expansion, phase transformations).

A rise in ΔH, giving way to a plateau, is observed in the ΔH–x plot (Fig. 4) in the initial stage of lithium deintercalation at $0.23 \le x \le 0.50$. Analysis of changes in the entropy of the system in the coordinates ΔS–x (Fig. 3) also shows that lithium deintercalation is accompanied in the initial stage by an increase in ΔS, which may be due to structural ordering of the compound Li_xC_6 at these x values. The subsequent lithium deintercalation results in that $(dE/dT)_{eq} \approx 0$ at $x \approx 0.23$ and the potential E_{eq} is temperature-independent. The work is done in the system at the expense of enthalpy, without heat exchange, and lithium deintercalation proceeds without hindrance: the ΔS and ΔH values decrease (Figs. 3, 4).

At $x < 0.23$, $T\Delta S < 0$ $(dE/dT < 0)$ and the process is exothermic. According to the laws of thermodynamics, the work done by electric current in this case is lower than the heat effect of the reaction [1–4]. An excess amount of energy appears in the system: in all probability, the parameters of the compound Li_xC_6 change (recombination of excess energy is possible).

On the basis of the data of [3, 4, 21, 30, 31] and the analogy between processes occurring in intercalate formation from substances with lamellar, channel-like, or tunnel structure, some suggestions can be made about the mechanisms of the processes and the structural changes in the Li_xC_6 electrode. In the initial stage of deintercalation $(0.50 > x \ge 0.23)$, the structure of the compound Li_xC_6 changes significantly. Lithium ions leaving the lattice are, in all probability, surrounded in this case by lithium bound both to intercalated lithium ions and to carbon particles (the so-called short-range-order lithium occupying vacant

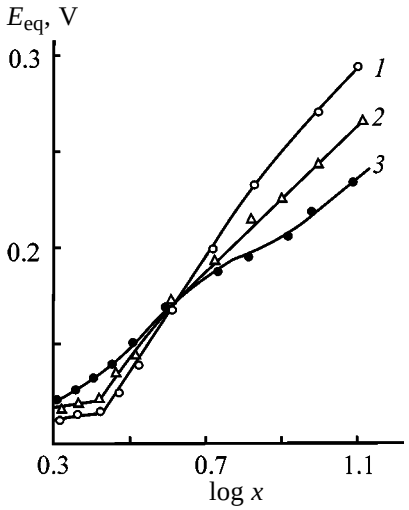

Fig. 5. E_{eq}–log x dependence for Li_xC_6 electrode in 1 M solution of $LiClO_4$ in PC + DME (1 : 1). Temperature (K): (*1*) 298, (*2*) 308, and (*3*) 323.

adjoining sites [12, 13, 17]). This must enhance deformation interactions between lithium species and lead to a change in the lattice parameters of Li_xC_6, which affects the thermodynamic properties of the system: ΔH and ΔS grow with decreasing x. At $x \approx 0.23$, lithium is surrounded in the structure by free vacancies. In this case, the thermodynamic characteristics are stabilized and lithium deintercalation is accompanied by a decrease in ΔH and ΔS. The subsequent decrease in ΔH and ΔS of the system at $x < 0.23$ can be accounted for by lattice recombination in the carbonized fabric.

The occurrence of structural transformations in the Li_xC_6 compound is confirmed by the E_{eq}–log x dependence obtained at different temperatures, in which three (at 293, 298, 303, and 308 K) to four (at 313 and 323 K) straight-line portions characteristic of the case of structural changes in the carbon material in the course of lithium deintercalation (or intercalation) can be distinguished [21, 32].

CONCLUSION

The choice of the interval of degrees of intercalation $0.5 > x > 0.1$ for measuring quasi-equilibrium curves can be accounted for as follows. At very small x values ($x < 0.08$), the intercalation/deintercalation process (1) is already not the only potential-determining process (corrosion and chemical processes may occur in parallel). At the same time, at large x and potentials close to the lithium electrode potential, parasitic processes (impurity reduction in electrolyte etc.) are accelerated. As a result, the current efficiency becomes less than unity, and the experimental curve cannot longer be considered as close to equilibrium.

CATALYSIS

Synthesis of Cement-Containing Nickel–Copper Catalytic Systems Using Formic Acid Aqueous Solutions

Received September 25, 2001; in final form, February 2002

Abstract—Regular trends in the formation of phase composition, structure, and mechanical strength of nickel–copper catalysts used for treatment of process and off-gases were considered in relation to the concentration (5.0–60.0 wt %) of formic acid aqueous solutions used in their preparation. The optimal conditions of the preparation process were determined.

In modern industrial installations, oxygen is removed from process gases with platinum and palladium catalysts, the use of which is limited by high cost and short supply of these metals. A series of NKO-type cement-containing nickel–copper catalysts were developed[1] [1] for a wide range of catalytic processes, in which PK and APK catalysts with platinum and palladium active components are the most active. As opposed to these catalysts, the use of NKO-type catalysts requires their preliminary reduction by a hydrogen-containing gas at 350–450°C. In some cases it is difficult to provide such temperatures in the existing installations.

The goal of this work was to develop a mechanically strong and highly active nickel–copper catalyst, which can be activated in an inert medium at low temperatures (180–280°C).

There are various procedures for the preparation of nickel–copper catalytic systems. These procedures mainly consist in deposition of an active component on a support by impregnation, coprecipitation, or fusion of catalyst components and mixing active components with the support.

Published data on the use of salts of carboxylic acids and of carboxylic acids themselves as liquid reagents in catalyst production suggest the possibility of obtaining supports and also high-performance catalysts that are activated at low temperatures (150–250°C) in a stream of inert gases.

There are three main directions of using carboxylic acids in catalyst production: for preparing high-performance catalyst supports [2–6], for synthesizing catalytic systems [7–14], and for regenerating dead catalysts [15–18].

[1] Developed at the Novomoskovsk Institute of Nitrogen Industry.

EXPERIMENTAL

As the raw material we used substances applied in the synthesis of cement-containing nickel-copper catalytic systems: nickel(II) (NSC) and copper(II) (CSC) subcarbonates, and technical-grade calcium aluminate (talum), which is a mixture of calcium monoaluminate ($CaO \cdot Al_2O_3$, CA) and dialuminate ($CaO \cdot 2Al_2O_3$, CA_2). Samples were synthesized by mixing the initial components in the presence of formic acid aqueous solution, the concentration of which was varied within 5.0–60.0 wt %. The mixing (liquid : solid ratio from 1 : 1 to 1.5 : 1) was carried out at 60–80°C. The catalyst mass with 15–20% moisture content was dried at 100°C, crushed, and pressed at 650 MPa into cylindrical pellets 6.0 mm in diameter and 5.0 mm high.

The X-ray phase analysis (XPA) of the samples was carried out on a DRON-2 diffractometer with CuK_α radiation, and the thermogravimetric analysis, on a Q-1500 D derivatograph. The stages of phase formation in inert media were studied in the linear heating mode on a thermochromatographic installation. The specific surface area was measured on a Tsvet-211 device by thermal desorption of argon. The mechanical strength was determined by crushing granules with application of load on their faces. The catalytic activity in oxygen hydrogenation was studied under atmospheric pressure on a laboratory flow-through installation with a four-channel reactor. The input gas mixture contained 2.0 vol % O_2, 6.0 vol % H_2, and remainder argon. The tests of the catalytic activity were carried out at the space velocity of

6000 h^{-1}. The degree of oxygen conversion was taken as a measure of the catalytic activity.

The characteristic decomposition temperature of the initial NSC $NiCO_3 \cdot 2Ni(OH)_2 \cdot 4H_2O$ is 320°C. The specific surface area of NiO obtained by NSC calcination does not exceed 40 $m^2 g^{-1}$. The compound $CuCO_3 \cdot Cu(OH)_2$ (CSC) decomposes at T_{max} = 280°C to CuO, which has disordered crystal lattice and specific surface area of no more than 10–20 $m^2 g^{-1}$.

According to the XPA data, treatment of the initial NSC with formic acid gives nickel formate $Ni(HCOO)_2 \cdot 2H_2O$, and treatment of CSC, anhydrous copper formate $Cu(HCOO)_2$.

Figure 1 shows the rates of the weight loss by samples of NSC, CSC, and their mixture (50 wt % NSC–50 wt % CSC) treated with 40% aqueous solution of formic acid under conditions similar to the conditions of the synthesis. Nickel formate decomposes in two stages (Fig. 1, curve *2*). The first stage (230°C) corresponds to the loss of water of crystallization, and the second (290°C), to exhaustive decomposition of nickel formate, which passes at a high rate, as shown by the intensity of the second peak. The further heating of the sample in the oxidizing atmosphere results in oxidation of the formed nickel (370°C). Copper formate (Fig. 1, curve *1*) decomposes in one stage (180°C). The resulting metallic copper is oxidized first to Cu_2O (220°C) and then to CuO (355°C).

It is known [19] that salts of carboxylic acids and, in particular, nickel and copper formates decompose in oxidant-free media to give metals. The decomposition of these salts is exothermic and occurs with a high rate at relatively low temperatures.

The decomposition temperature of formates can be considerably lowered [20] by adding a formate with a lower decomposition temperature. The decomposition of a mixture of Ni(II) and Cu(II) formates (Fig. 1, curve *3*) is characterized by two intensive exothermic peaks. The exothermic effect at T_{max} = 180°C is due to decomposition of $Cu(HCOO)_2$ and dehydration of $Ni(HCOO)_2 \cdot 2H_2O$, and that at T_{max} = 215°C, to decomposition of $Ni(HCOO)_2$. Thus, the presence of copper formate in a sample decreases the decomposition temperature of nickel formate from 290 to 215°C. At the same time, it cannot be ruled out that a double Cu(II) and Ni(II) salt such as $CuNi(HCOO)_2 \cdot 2H_2O$ can form under the experimental conditions of processing the NSC and CSC mixture [21]. This salt can also decompose in two stages.

To understand phase formation processes occurring in the course of the synthesis of cement-containing nickel–copper catalytic systems, we studied samples obtained by treatment of active aluminum oxide, $CaCO_3$, and calcium aluminate with a 40% aqueous solution of formic acid. The DTG curves of these samples are shown in Fig. 1. The experimental data indicate that treatment of aluminum oxide and $CaCO_3$ with HCOOH yields anhydrous aluminum and calcium formates (Fig. 1, curves *4*, *5*). In the case of treated talum (curve *6*), the peak at 300°C corresponding to the decomposition of aluminum formate prevails. Furthermore, two exothermic peaks were recorded at 350 and 420°C, which are characteristic of the calcium formate decomposition. The endothermic peak at 790°C corresponds to the decomposition of $CaCO_3$ formed by calcium formate thermolysis. The effect of heat treatment on the specific surface area of talum S_{sp} ($m^2 g^{-1}$) treated by aqueous solution of formic acid is given below.

This dependence passes through a maximum (140 $m^2 g^{-1}$) at 280°C. When preparing cement-containing nickel–copper catalytic systems (25 wt % NiO–10 wt % CuO– 65 wt % talum), we found that, at

T, °C	S_{sp}, $m^2\ g^{-1}$
150	5.0
200	10.0
220	25.0
250	70.0
280	140.0
300	135.0
350	80.0
400	45.0

room temperature, the reaction of a mixture of the initial components (NSC + CSC + talum) with an aqueous solution of formic acid occurs at a relatively low rate, which reaches a maximum at 70–75°C. This temperature is optimal for the reaction of the mixture of components and also of each component separately with an aqueous solution of formic acid. For comparison, we prepared a catalyst sample (no. 1) using distilled water. The experimental data obtained by derivatography (Fig. 2) and by X-ray phase analysis allowed us to subdivide the samples under study in three groups depending on the concentration (%) of formic acid aqueous solution used in the stage of mixing: no. 1, H_2O, no. 2, 5.0, and no. 3, 10.0 (first group); no. 4, 15.0, no. 5, 20.0, no. 6, 25.0, and no. 7, 30.0 (second group); and no. 8, 40.0, no. 9, 50.0, and no. 10, 60.0 (third group).

The study of thermal transformations of the samples (Fig. 3) allowed us to establish the sign of thermal effects, determine a mode of heat treatment, and, using also the XPA data, identify phases formed in the course of the preparation. Thermal transformations of all the samples under study involve weight loss, its value increasing as the concentration of HCOOH is increased. The XPA data show that sample no. 2 is almost identical to sample no. 1. The phase composition of these samples includes NSC and CSC, mixed nickel and copper subaluminate, CuO, $CaO \cdot Al_2O_3$, $CaO \cdot 2Al_2O_3$, and a minor amount of nickel, copper, aluminum, and calcium formates (for sample no. 2). The increase in the HCOOH concentration to 10% (sample no. 3) results in increased conversion of the initial components. Sample no. 5 prepared by treatment with 20% HCOOH solution considerably differs in the phase composition from the previous samples. In its phase composition, two types of nickel and copper subaluminates dominate: (1) standard Ni(II) and Cu(II) subaluminates (SA-I) having basic interplanar spacings d = 7.6 and d = 3.8 Å, respectively; (2) Ni(II) and Cu(II) subaluminates differing from standard subaluminates by the fact that their structure contains an additional anion $(HCOO)^-$ (SA-II). They are characterized by the basic interplanar spacings d = 11 and d = 5.5 Å, respectively.

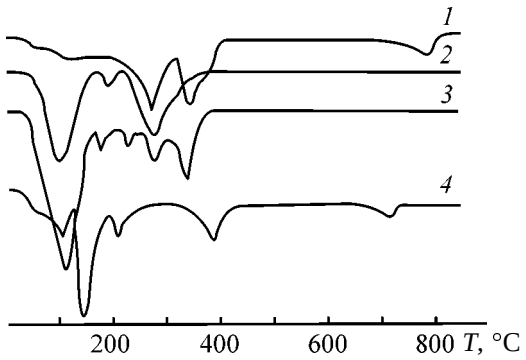

Fig. 2. DTG curves of catalyst samples prepared using aqueous solutions of formic acid. HCOOH concentration (%): (*1*) 0, (*2*) 5, (*3*) 20, and (*4*) 30.

Metal subaluminates can contain various anions replacing their OH^- groups [22], e.g., CO_3^{2-}, NO_3^-, etc. The formula of SA-I in the general form can be written as $MAl_2(OH)_8$ (M = Ni, Cu, Zn, Mg, etc.), and the formula of SA-II, as $MAl_2(OH)_{8-x}(HCOO)_x$, i.e., as a metal subaluminate formate.

A number of well pronounced effects due to the decomposition of SA-II-type compounds and also of Ni(II) and Cu(II) formates were detected in the range 120–280°C for sample no. 5 (Fig. 2, curve *3*).

The further increase in the acid concentration to 30% (Fig. 2, curve *4*) results in preferential formation of compounds such as SA-II, i.e., of Ni(II) and Cu(II) subaluminoformates. Furthermore, in this sample the amount of the formed Ni(II), Cu(II), Al(III), and Ca(II) formates increased, and a certain amount of NSC, CA, CA_2, CuO, and $CaCO_3$ was present.

The phase composition of sample no. 8 contains mainly Ni(II), Cu(II), Al(III), and Ca(II) formates; only small amounts of Ni(II) and Cu(II) subaluminate formates were detected. The use of a 50% aqueous solution of the acid (sample no. 9) promotes the formation of Ni(II), Cu(II), Al(III), and Ca(II) formates. The further increase in the acid concentration to 60% does not affect the phase composition. The phase of $CaCO_3$, which is a product of the exchange reaction of NSC and CSC with talum in the mixing stage, was detected in all the samples. The heat treatment of the samples increases the content of this phase. An additional amount of $CaCO_3$ is formed as a result of the decomposition of Ca(II) formate.

One of the main stages in formation of an active catalytic structure is the catalyst activation, and such characteristics as catalytic activity, mechanical strength, and service life depend on the conditions of this stage.

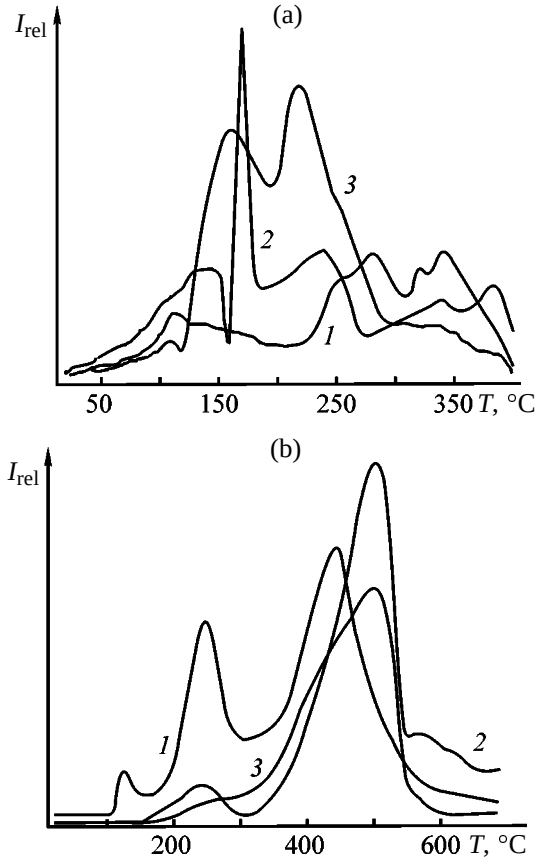

Fig. 3. Thermochromatograms of catalyst samples prepared using aqueous solutions of formic acid and activated in (a) helium and (b) hydrogen. (I_{rel}) Relative intensity and (T) temperature. Concentration of HCOOH (%): (*1*) 5, (*2*) 30, (*3*) 40.

We studied reduction of the samples on a thermochemical installation allowing temperature-programmed reduction in various gas media and temperature modes. The curves of temperature-programmed reduction at linear heating rate of 5 deg min^{-1}, obtained in helium and hydrogen streams, respectively, are shown in Figs. 3a and 3b. These data show that the thermolysis of samples in a helium stream is in fact the stage of their activation. This process, which occurs in the range 125–400°C, is multistage. We can subdivide the samples under study into three groups with respect to the nature of activation. Sample nos. 2 and 3 comprise the first group, for which the main activation process takes place in the range 200–400°C with a rather small intensity. The second group (sample nos. 4 and 5) is characterized by occurrence of the activation in three stages (130–170, 200–300, and 300–400°C). In the third group, the activation is more intense and involves two stages (170–190°C and 215–225°C), corresponding to the decomposition of nickel and copper formates in an inert gas stream. The temperature-programmed reduction data well correlate with the data of the X-ray phase and thermal analyses.

After activation, samples were cooled in a helium stream to room temperature and then heated in a hydrogen stream in a linear heating mode (Fig. 3b). For comparison, we studied simultaneously sample no. 1 prepared with distilled water. At temperatures below 300°C, no effects corresponding to the reduction of active components were detected, which suggests that the catalysts were completely activated in the inert gas stream. For all the sample under study, the curves of temperature-programmed reduction in hydrogen contain a single strong peak in the range 350–550°C, which corresponds to the low-temperature catalytic decomposition of calcium carbonate [23]. The shift of T_{max} of decomposition of this phase, as compared to this effect in sample no. 1, results from the presence of dispersed nickel and copper with a highly developed surface in all the samples except for sample no. 1.

The specific surface area, mechanical strength, and catalytic activity of samples reduced with hydrogen are given in the table. We chose the activation temperatures taking into account the data of the thermogravimetric, X-ray, and thermochromatographic analyses.

Products of the talum hydration and of its reaction with nickel and copper subcarbonates, and partially products of the decomposition of nickel and copper formates make the major contribution to the surface area development in sample no. 2, whereas in sample nos. 4–10 these are products of the decomposition of nickel and copper subaluminoformates (SA-II) and subaluminates formates (SA-I). In these samples the specific surface area, which was measured by argon thermal desorption on a Tsvet-211 instrument, is the total active surface area of nickel and copper. The fact that this surface area mainly corresponds to the active components is confirmed by the data on the surface area of talum treated with a 40% aqueous solution of formic acid and calcined in an inert medium at 240°C. The S_{sp} of this sample does not exceed 10–15 $m^2 g^{-1}$.

When developing new catalysts and improving available catalysts, a special attention is given to their strength properties principally determining their service life. The greatest decrease (30–50%) in the mechanical strength takes place during activation of catalysts. This is due to phase transformations causing changes in their crystalline and porous structures. Our experimental data on the mechanical strength of both starting samples and samples activated in an argon stream at 180°C are given in the table.

Specific surface area S_{sp} of samples, their mechanical strength P, and degree of oxygen conversion α at various activation temperatures T_a in argon stream

The catalytic activity in oxygen hydrogenation was determined at a space velocity of 6500 h^{-1}. The working gas mixture contained 2.0 vol % O_2, 6.0 vol % N_2, and the remainder Ar. The catalytic activity of the samples was judged from the degree of oxygen conversion (see table). Prior to the experiments, the samples were activated at 150, 160, and 180°C for 1 h in an argon stream at W = 6500 h^{-1}. It is seen that, as the concentration of formic acid increases, the catalytic activity (after activation at 150 and 160°C) monotonically increases and reaches a maximum for sample nos. 8–10. The increase in the activation temperature to 180°C sharply increases the catalytic activity, and sample no. 4 ensures almost 100% oxygen conversion. Under these activation conditions, however, sample no. 1 still exhibits zero catalytic activity.

We also tested the catalytic properties of sample nos. 4–7, activated under similar conditions, in the course of carbon monoxide hydrogenation. The experiments were carried out at a pressure of 3.0 MPa, space velocity of 30 000 h^{-1}, and carbon monoxide concentration at the reactor inlet of 0.6–0.75 vol %. We evaluated the catalytic activity in this process by the temperature of the 10 ppm CO breakthrough and found that sample nos. 6 and 7 have the maximal activity (220 and 215°C, respectively). These data indicate high catalytic performance of the system under study. Based on the experimental data, we chose for practical applications a catalyst with the composition 10 wt % CuO–25 wt % NiO–65 wt % talum prepared using 20% aqueous solution of formic acid in the stage of mixing.

We have studied in detail variation of the phase composition of this sample on its heating in air and argon flows, using a GPVT-1500 high-temperature X-ray camera. The phase composition of the initial catalyst sample includes Ni(II) subcarbonate, Ni(II) and Cu(II) subaluminates, mixed Ni(II) and Cu(II) subaluminoformate, Ni(II), Cu(II), Al(III), and Ca(II) formates, and also CuO, CA, and CA_2 phases. The heating to 100°C results in the decomposition of mixed Ni(II) and Cu(II) subaluminoformate to mixed Ni(II) and Cu(II) subaluminate. This phase transformation results in a considerable increase in the intensity of reflections of mixed Ni(II) and Cu(II) subaluminate in the X-ray pattern. The heating to 175°C promotes partial decomposition of formates. At the same temperature, Ni(II) and Cu(II) subaluminates start to decompose with the removal of interlayer water, as indicated by the shift of the SA-I lines to larger angles (d = 7.2 Å). The heating to 200°C induces further SA-I decomposition with the shift of the interplanar spacing to d = 6.9 Å. The decomposition of Ni(II), Cu(II), and Al(III) formates is complete at 250°C and yields nickel and copper, which are converted to NiO and CuO in this oxidizing medium. The thermolysis of aluminum formate yields γ-Al_2O_3. The X-ray pattern contains only reflections of Ca(II) formate. The decomposition of SA-I also continues, its interplanar spacing decreases in this case to d = 6.7 Å. At 300°C, calcium(II) formate starts to decompose to give $CaCO_3$, whereas the decomposition of SA-I approaches completion. Its interplanar spacing d becomes equal to 6.2 Å. The intensity of diffraction reflections of this phase in the X-ray pattern considerably decreases. The further temperature increase by 50°C results in complete decomposition of calcium

formate, as indicated by an increase in the intensity of $CaCO_3$ reflections. Mixed Ni(II) and Cu(II) subaluminate also completely decomposes. Nickel subcarbonate starts to decompose intensively to form finely dispersed nickel oxide. At 400°C, its decomposition is complete. The phase composition of the catalyst after thermolysis at this temperature includes the following compounds: NiO, CuO, $CaO \cdot 2Al_2O_3$, $CaO \cdot Al_2O_3$, and $CaCO_3$. The phase composition remains unchanged on cooling to ambient temperature.

The evolution of the phase composition of this sample on heating in an argon stream is almost identical, except for the fact that the dispersed Ni and Cu phases originating from the decomposition of Ni(II) and Cu(II) formates are not oxidized.

The studies of phase composition and phase transformations occurring on heating in both air and inert gas streams, of the activation stage, and also of changes in the specific surface area and mechanical strength allow us to make a substantiated choice of the scheme of the catalyst preparation. According to this scheme, the catalyst should be prepared as follows. The initial components (NSC, CSC, and talum) are mixed in the presence of 15–20% aqueous HCOOH in mixers equipped with heaters. The mixing occurs most intensively at 70–75°C. The catalyst mass with 15–20% moisture content is dried at 100–110°C in rack dryers, then crushed, mixed with graphite, and molded either as cylindrical pellets or as rings with external diameter of 10–15 mm and height not greater than 10 mm. The prepared catalyst is loaded in a reactor and activated in a stream of an inert or working gas at 180–280°C.

The experimental batch of the catalyst[2] in amount of 300 kg was tested in deoxygenation of electrolytic hydrogen.[3] The catalyst was activated in a working gas stream (hydrogen + 0.5 vol % O_2) at 180°C, which is lower by 100–120°C than the activation temperature of NKO-2-3 catalyst used in this process. The time of attaining the working conditions was reduced by 12–15 h. The residual oxygen content in the purified hydrogen did not exceed 0.002–0.005 vol % [24].

CONCLUSIONS

(1) The evolution of the phase composition of cement-containing nickel–copper catalysts synthesized using aqueous formic acid involves the formation of both mixed nickel copper subaluminate and mixed nickel copper subaluminoformate, and also of nickel, copper, aluminum, and calcium formates. The quantitative ratio of these phases depends on the concentration of the aqueous solution of formic acid used.

(2) The mutual influence of metal formates on their decomposition temperature was established.

(3) The optimal concentration of formic acid aqueous solution was chosen, which allowed preparation of mechanically strong and highly active catalysts.

(4) The scheme of catalyst production taking into account basic parameters of the preparation process was offered.

CATALYSIS

Influence of Modification of Pentasils with Alkaline-Earth Metals on Their Acid and Catalytic Properties in Conjugate Conversion of Methanol and Propane–Butane Fraction

Abstract—Acid and catalytic properties of Pentasils in conjugate conversion of methanol and propane–butane fraction, as influenced by their modification with Ca, Sr, Ba, and Mg, were studied.

It is known [1–4] that zeolite-containing catalysts based on high-silica zeolites (HSZ) of the ZSM type are effective catalysts of a number of petrochemical and oil-refining processes. The aim of this work was to study the catalytic activity of Pentasils in conjugate conversion of methanol and propane–butane fraction (PBF) into lower olefins as influenced by modification of Pentasils with alkaline earth metal (AEM) cations and to correlate the catalytic activity with the surface acidity of the samples.

EXPERIMENTAL

High-silica zeolites of Pentasil type with silicate ratio of 30 were prepared by the hydrothermal procedure from alkaline aluminosilica gels in the presence of a structure-forming organic cation [5]. Modification was performed by impregnation of the HSZ in the H form with Mg, Ca, Sr, and Ba salts. The content of these metals recalculated to their oxides was 2 wt %. Identification and determination of the degree of crystallinity of the HSZs were performed by IR spectroscopy and X-ray diffraction analysis (Mo anode, Ni filter). All the samples belong to the ZSM-5 zeolite type with 90–95% degree of crystallinity.

The initial compounds for the conjugate process were commercial methanol produced by Tomsk Petrochemical Plant Joint-Stock Company and PBF (1.7 wt % ethane, 61.4 wt % propane, 32.4 wt % butane, and 4.5 wt % isobutane) produced by Surgut Gas Processing Plant. Conjugate conversion of methanol and PBF was performed on a laboratory flow unit. The initial methanol–PBF mixture (4 : 1 weight ratio) was fed into a quartz reactor with a fixed catalytic bed. The reaction products were analyzed on an LKhM-80 chromatograph with a thermal conductivity detector. The catalytic activity of zeolites was estimated by the yield of C_2–C_4 alkenes based on the feed. The coking of the catalyst was studied by differential thermal analysis (DTA) with an MOM derivatograph (Hungary). The acid properties of the zeolites were studied by temperature-programmed desorption (TPD) of ammonia at a heating rate of 10 deg min^{-1} [6].

As seen from Table 1, the ethylene and propylene yields on H-HSZ increases from 3.6 to 14.8 and from 4.5 to 14.2% with increasing temperature from 500 to 650°C, respectively. The temperature dependences of the ethylene and propylene yield on modified Pentasils pass through extrema. With all the tested catalysts the content of C_2–C_4 alkenes in the gas phase is maximal at 600°C. Modification of the initial H-HSZ with Mg^{2+} and Ca^{2+} increases the yield of C_2–C_4 alkenes and decreases the arene yield. Modification with Sr^{2+} and Ba^{2+} decreases the yield of the target products and increases the yield of C_2–C_4 alkanes and coking of the catalyst surface (Table 2). The fact that the content of C_2–C_4 alkanes in the reaction products formed on Ba-HSZ is higher and the yield of aromatic hydrocarbons is lower than those on H-HSZ indicate deactivation of the catalysts by coking.

The maiximal yield of C_2–C_4 alkenes (56%) was obtained on Mg-HSZ. The yield of ethylene and propylene on Ca-HSZ was lower (51.2%).

The DTA curves of zeolite-containing catalysts clogged with coke under similar conditions of conjugate conversion of methanol and PBF show pro-

nounced exoeffects with maxima in the range 460–660°C, which are due to coke burning-out. The most friable low-temperature coke is formed on Ca-HSZ. The T_{max} of coke burning-out from this sample is shifted by 30°C to lower temperatures as compared to the other samples (Table 2). The temperatures of the onset and completion of coke burning-out on this catalyst are also lower. The densest high-temperature coke is formed on Sr-HSZ.

This difference in the catalytic properties of the HSZs can be due to a change in their acidity after modification with alkaline-earth metals. The study of the acid properties of the zeolite-containing catalysts by ammonia TPD showed that the acidity of H-HSZ substantially changes after impregnation with AEMs (see figure). With Mg^{2+}, Sr^{2+}, and Ba^{2+}, the number of low-temperature centers increases and that of high-temperature centers decreases (Table 3). The total acidity of these samples decreases after modification.

Introduction of Ca^{2+} into H-HSZ increases the total amount of the acid centers from 1215 to 1294 μmol g^{-1} owing to a sharp increase in the number of low-temperature Lewis centers. The increase in the selectivity of cojugate conversion of methanol and PBF into C_2–C_4 olefins and the decrease in coke formation on the catalysts after modification with calcium ions are probably due to an increase in the number of strong Brønsted acid centers in the sample. The maximal decrease in the concentration of strong Brønsted acid centers was observed after modification with magnesium cations (from 535 μmol g^{-1} in the initial H-HSZ to 336 μmol g^{-1} in Mg-HSZ). This

Table 2. Amount of coke deposits on zeolite-containing catalysts in conjugate conversion of methanol and PBF

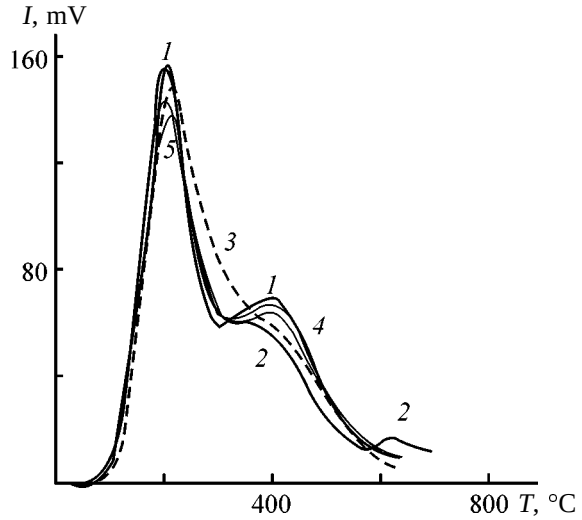
Catalysts	Temperature of coke burning-out from the catalyst, °C			Coke formation, mg/100 mg zeolite
	T_{onset}	T_{max} of peak	T_{fin}	
H-HSZ	490	580	640	10.7
Mg-HSZ	500	580	640	11.8
Ca-HSZ	470	550	620	7.0
Sr-HSZ	500	580	660	11.7
Ba-HSZ	460	580	640	13.8

Table 3. Acid properties of zeolite-containing catalysts determined by ammonia TPD

Catalyst	T_{max} of peak, °C		Number of acid centers, μmol g^{-1}		
	form I	form II	form I	form II	total
H-HSZ	208	411	683	532	1215
Mg-HSZ	206	362	753	336	1089
Ca-HSZ	213	425	808	486	1294
Sr-HSZ	208	406	722	466	1188
Ba-HSZ	215	403	703	430	1133

change in the nature of the acid centers is manifested in the shift of the desorption peaks I and II in the DTA curves of modified catalysts as compared to those of the initial H-HSZ (Table 3).

Thus, the acidity of H-HSZ and hence the catalytic activity and selectivity of the catalyst can be controlled by modification of the zeolite with AEMs. The selectivity of conjugate conversion of methanol and propane–butane fraction into C_2–C_4 olefins increases in the following order: Ba < Sr < Ca < Mg.



Curves of ammonia desorption from (*1*) H-HSZ, (*2*) Mg-HSZ, (*3*) Ca-HSZ, (*4*) Sr-HSZ, and (*5*) Ba-HSZ at 100°C. (*I*) Intensity and (*T*) temperature.

CONCLUSIONS

(1) Introduction of Mg, Ca, Sr, and Ba into Pentasil increases the strength and concentration of weak Lewis acid centers of the catalyst and substantially decreases the concentration of strong Brønsted acid centers, which increases the yield of C_2–C_4 olefins in conjugate conversion of methanol and propane–butane fraction.

(2) The selectivity of conjugate conversion of methanol and propane–butane fraction into C_2–C_4 olefins increases in the following order: Ba < Sr < Ca < Mg.

PRODUCTION AND USE OF NEW MATERIALS

Industrial Synthesis of Ultradisperse Detonation Diamonds and Some Fields of Their Use

G. Post, V. Yu. Dolmatov, V. A. Marchukov, V. G. Sushchev, M. V. Veretennikova, and A. E. Sal'ko

Abstract—The cluster nature of detonation-synthesized ultradisperse diamonds (UDD) is considered. The industrial cycle employed for obtaining ultradisperse diamonds is described, with different variations of this process and the basic principles of design of the necessary equipment noted. Priority product areas and advantages of use of ultradisperse diamonds in metal–diamond electrochemical coatings and polymer–diamond composites are discussed in detail.

Detonation-synthesized ultradisperse diamonds (UDD, or nanodiamonds) are a promising component for development and creation of composite materials and coatings of a new generation [1–4].

Ultradisperse diamonds were discovered in the Soviet Union in the early 1960s in the carbon black formed in detonation of explosive mixtures of a certain composition. It was found that, in view of the ultrasmall particle size (smaller by three orders of magnitude than the size of dynamically synthesized diamond) and specific conditions of formation, UDD exhibit quite a number of unique properties uncharacteristic of diamond and, in particular, the high and peculiarly manifested chemical activity.

The aim of this study was to generalize and systematize data on UDD properties, variations of UDD preparation techniques, optimal technology of chemical purification of nanodiamonds, and advantages of UDD application in the most important fields related to surface treatment: electroplating and polymer chemistry.

Nanodiamonds are characterized by average particle size of 4–6 nm [5, 6], cubic crystal lattice with lattice constant $a = 0.3562 \pm 0.0003$ nm, density of 3.05–3.25 g cm^{-3} [7], and microstresses of about 10 GPa [7]. The specific surface area of UDD is 250–450 m^2 g^{-1}, pore volume 0.3–1.1 cm^3 g^{-1}, and average pore diameter 8–10 nm [8, 9]; the density of proton-donor groups is 0.34–2.52 μg-equiv m^{-2} [10]. The quantitative elemental composition of UDD is as follows (wt %): carbon 80–90, hydrogen 1–2, nitrogen 1–3, and oxygen 8–15 [7, 11]. The onset temperatures of UDD oxidation in air is 430–450°C, and that of graphitization in an inert medium, 1100°C.

A UDD particle is composed, being a cluster formation, of a relatively dense and ordered crystal-like core and loose, chemically labile periphery. The diamond core is the bearer of the basic "diamond" properties of UDD, namely, the thermal and chemical stability, heat and temperature conductivity, low electrical conductivity, X-ray diffraction pattern, quasi-abrasivity, and quasi-hardness. The peripheral structures of the cluster are responsible for such substance characteristics as sign and amount of surface charge on UDD particles; absorption, adsorption, and chemisorption; chemical composition of surface functional groups; and colloid stability of UDD particles in liquid and other media. In UDD clusters, both the core and the stabilizing shell are mainly composed of carbon atoms. In this case, a continuous transition is possible from the diamond lattice to nondiamond periphery via a system of skeleton, polyhedral, and polycyclic structures and networks. The cluster boundary is stabilized by products of interaction of peripheral carbon atoms with the substance of the surrounding medium: gaseous detonation products, air, oxidizing mixtures in chemical purification, and modifying reagents. The peripheral structures play a decisive part in aggregation of diamond clusters and their interaction with the host substances of composite materials and coatings.

The structure of the outer peripheral shell of a

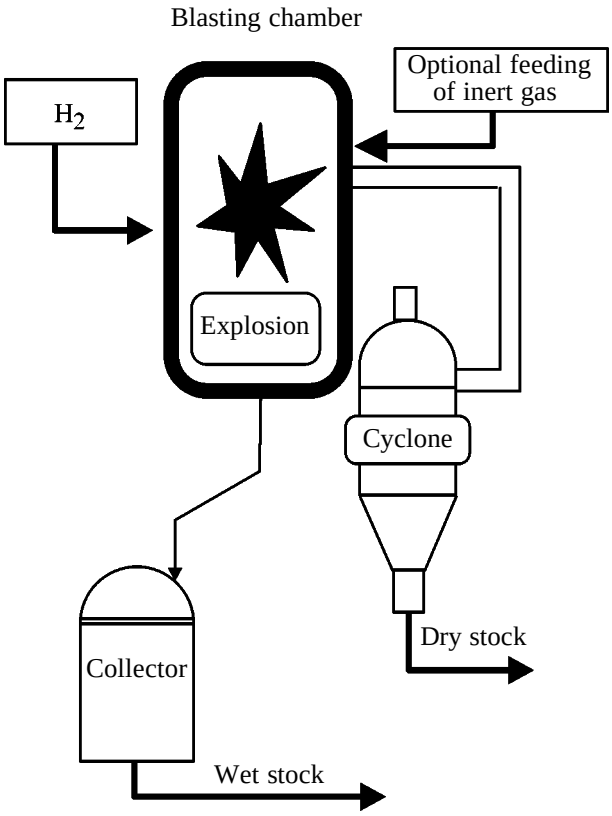

Fig. 1. Scheme of detonation synthesis of UDD.

diamond cluster was analyzed by various methods, including thermal desorption. The composition of desorption products is complex and diverse. In addition to hydrocarbons, they contain oxygen- and nitrogen-containing compounds formed in oxidation of the carbon surface. Benzene and C_7–C_{10} homologues are widely represented, being exceeded in abundance only by alkanes C_{10}, among which *n*-decane predominates.

The major bridged alicyclic compounds are camphene and terpene $C_{10}H_{16}$. Such a composition of the desorption products points to low probability of finding diamond structures proper at the phase boundary. These structures are also stabilized in a UDD cluster by various transition structures.

So dissimilar and diverse fragments are integrated in a single particle and, further, in an ensemble of particles by the rule of fractals via discontinuous filling of a random volume with a mass of substance [12]. In our opinion, the fact that the experimental values of the fractal dimensionality of UDD (2.1–2.3) do not correspond to any particular type of aggregation (cluster–cluster, cluster–particle) [13] can be rationalized just with account of the structural nonuniformity of the primary cluster, ambiguous interaction of clusters with one another and with separate carbon-containing molecules, and also in view of the strongly nonequilibrium conditions of UDD formation.

UDD synthesis based on detonation conversion of high-power blend explosives with subsequent chemical treatment of condensed explosion products has been studied in sufficient detail, both theoretically and in practical regard [5, 6, 14–16]. These studies served as a basis for the development of several pilot installations,[1] which successfully demonstrated the possibility of commercial manufacture of the new product in amounts of tens to hundreds of kilograms of UDD per year.

The production at Tekhnolog Special Engineering Design Office includes detonation synthesis (Fig. 1), chemical purification and washing of UDD to remove acid, conditioning of the product, and modification of diamonds (Fig. 2). The production infrastructure also includes systems for catching and utilization of acid vapor and gases, treatment and recycling of nitric acid, and water treatment.

Detonation synthesis is carried out in special blasting chambers with volume, as a rule, in the range 1–20 m^3. The chambers are made of low- and high-alloy steels. The optimal chambers are those made of low-alloy steel (e.g., boiler steel), clad from the inside with corrosion- and impact-resistant alloys. The chambers are equipped with gas-transport lines and a system for removal and catching of condensed detonation products.

The blasted charge (cast of pressed) is, as a rule, a mixture of TNT and hexogen in approximately 50 : 50 ratio. The charge mass ranges from 0.5 to 2.0 kg. The blasting can be done in three variants: (1) in the medium of detonation products or in inert gases (nitrogen, carbon dioxide) with a yield of condensed explosion products (diamond stock, DS) of 3 to 8 wt % and UDD content in DS of 30–45%, (2) in water with DS yield of 6–12% and UDD content of DS equal to 50–63%, and (3) with charge in an ice shell with DS yield of 8 to 16 wt % and UDD content in DS of 60–75%.

In the case of blasting in a gas medium, the temperature mode of the apparatus ensures separation of water vapor from the carbon condensate. Such a DS is characterized by finely dispersed state, high specific surface area, and its own hydrophilic–hydrophobic balance of surface active centers. The level of noncarbon DS contamination is largely determined, at any

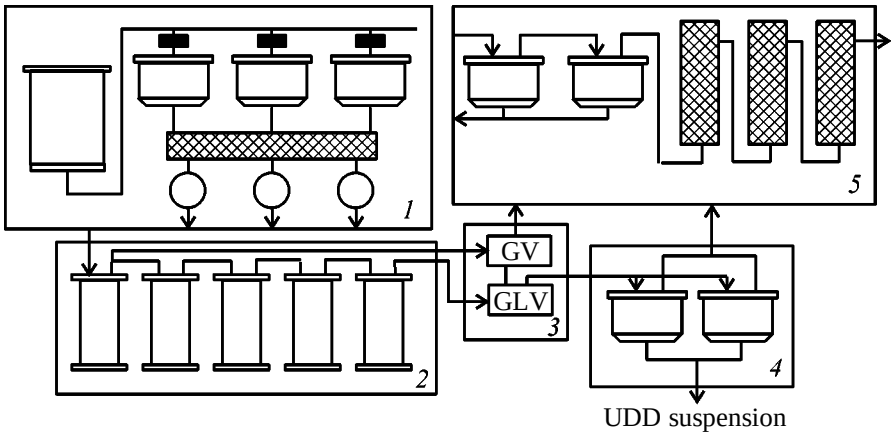

Fig. 2. Chemical purification of UDD. (*1*) Preparation, activation, and batching of suspension; (*2*) barothermal oxidation; (*3*) unit for high pressure relief (GV, gas valve; GLV, gas–liquid valve); (*4*) receiver of UDD suspension; and (*5*) system for environment protection.

kind of blasting, by the material of walls of the blasting chamber and by the chamber volume relative to the charge.

These properties directly affect the applicability of DS as a structuring and modifying agent in synthesis of composites and coatings based on organic matrices (polymers, lubricants, cutting fluids, etc.).

The diamond stock produced in "dry" blasting (in gas medium) has the following composition (wt %): UDD 30–45 and total carbon 88–92; at ash content (mainly metal oxides) of 2–5% and moisture content of 8–14%.

Blasting a charge in water or ice not only makes higher the yield of DS and UDD in terms of the starting explosives, but also markedly changes the hydrophilic–hydrophobic balance of the surface active centers. Nevertheless, a DS of this kind can be used for the same purposes as "dry" DS, naturally, after appropriate treatment. The composition of a "water" blasting DS[2] is as follows (wt %): UDD 50–63 and total carbon 88–95, at ash content of 1.5–3.0%. The "ice" blasting DS[3] contains (wt %) UDD up to 75 and total carbon 88–95, at ash content of 1–2%.

The UDD proper is obtained by barothermal oxidation of DS with aqueous nitric acid (Fig. 2) [17–20]. In this process, DS is thoroughly mixed with the acid and fed into the reaction zone by high-pressure batcher pumps. The acid suspension passes through a cascade of electrically heated titanium reactors and is heated in steps to 280–300°C, thermostated, and then cooled and supplied into the high-pressure relief unit. The relief is done with a complex heterophase mixture: liquid saturated with gases and containing up to 3% diamond particles. Compressed air is fed into the suspension receiver for blowing to remove nitrogen oxides. Clarified UDD suspension in spent nitric acid is directed at regular intervals to the washing unit. The purification is performed continuously in automated mode with UDD output capacity of up to 1 kg (5000 carat) an hour (up to 5 tons a year).

The advantages of using nitric acid as oxidizing agent is that it exerts combined effect on all impurities in DS: nondiamond carbon and particles of metals and oxides, most of carbides [19]. Under high-temperature conditions, the reactivity of nitric acid is much enhanced. As a result, the target reactions occur at high rate, which favors organization of a high-output-capacity process.

Nondiamond carbon in DS is nonuniform in structure and chemical activity [21], and, therefore, the process can be conditionally divided into three stages: preliminary oxidation (10–20% of nondiamond carbon); oxidative breakdown of nondiamond carbon (65–80% of its amount); and additional oxidation of the most stable nondiamond structures, with prescribed oxidation level of diamond particles achieved (5–15% of nondiamond carbon).

The final stage is thermostating of the suspension at a temperature ensuring complete breakdown of nondiamond structures into gases and formation on the diamond particle surface of a stable and uniform coating of oxygen-containing functional groups.

Carrying out this complex multistage process in

[2] Manufactured by Tekhnolog Special Engineering and Design Office.

[3] Manufactured by Russian Research Institute of Technical Physics, Russian Federal Nuclear Center.

a continuous mode required a solution of diverse design and process problems. As experience shows, it is advisable to use controlled heat supply into a rather extended zone. As regards the UDD quality, this means that the degree of decomposition of the nondiamond carbon and the oxidation of the diamond surface will be constant and reproducible.

The second advantage of the purification method employed is that the oxidation products are mainly gaseous compounds. Consequently, the main reaction products are not accumulated in spent acid, which facilitates its recycling.

The technical solutions were based on detailed kinetic studies of the process. The specific design of high-pressure reactors assumes the presence of an air-cooled damping gas volume over flows of the liquid reaction mixture. The volume of the forming gases is estimated at 3.5–5 $m^3 h^{-1}$.

Nitric acid and nitrogen oxides can be regenerated in high yield and used in acid recycling. The extent of acid recycling is 75%, which markedly affects the economic and, what is more, environmental characteristics of the process. A severe problem is presented by UDD washing to remove acid and salt solutions. The small particle size, high sorption capacity, and the colloid stability of suspension, which grows in the course of washing, require a serious approach to the problem. Practice has demonstrated the advantage of intensive separation of finely dispersed suspensions and, in particular, tangential filtration on membrane filters and porous partitions [22].

An even more important problem is the necessity for modification of the surface properties of purified UDD, since it is this factor that affects the applicability of UDD in one or another process or composite. Methods for modifying the surface properties of nanodiamonds are diverse. This may be a purely thermal treatment of a suspension, treatment with various chemical reagents in various media with simultaneous action of high or low temperature, various physical methods. All these treatments markedly change the aggregative state of UDD, relative amounts of hydrophilic and hydrophobic groups on the diamond surface, sorption properties, surface charge, etc. Fine details of the processes of synthesis, chemical purification, and modification of UDD may strongly affect both the physicochemical properties and the performance of diamonds in composite materials and coatings.

We developed various methods for modification of the UDD surface, which allow production of that kind of diamonds, which is best suited for a particular field of their application.

The peculiar composition and complex structure of UDD cause a dualism of their properties, manifested in various physicochemical interactions, and the resulting unique influence on processes involving UDD. On the one hand, UDD inherit such characteristic properties of diamond as resistance to corrosive media, uncommon electrical properties, and high microhardness. On the other hand, the well-developed surface and the presence of a shell composed of dissimilar functional groups lead to a pronounced chemical activity, manifested under certain conditions, and even to the ability to reduce ions to free metals, by decomposing at room temperature aqueous solutions of K_2PdCl_4 and $Fe(C_2H_3O_2)_2$.

At present, 3 or 4 plants in Russia retain indisputable priority of "pathfinders" in the field of UDD synthesis and application. A number of plants in industrially developed countries introduce some processes of UDD application (predominantly metal–diamond electrochemical coatings), but there is no published evidence of any advances of their own in this field, with the exception of a Japanese concern Tokyo Daiyamondo Kogu Seisakusho K.K.

In processes aimed at creating new materials with the use of UDD, these latter act, as a rule, as a strong structure-forming agent. A common factor in these processes is the rather low expenditure of nanodiamonds (frequently, fractions of a percent), i.e., the useful effect is achieved not by changing the properties of a product manufactured, but by modification in the presence of UDD of the course of the corresponding process, be it polymerization, formation of lubricant films, or electrochemical deposition of metals. As a result, the structure of the final product may be altered to such an extent that its service characteristics will change fundamentally.

At present, the priority directions of UDD application are electrochemical and chemical metal–diamond coatings, polymer–diamond composites (film coatings, membranes, rubbers, plastics), lubricant oils, medicine (gastroentherological and antitumor preparations, immobilizers, adsorbents, etc.), polishing systems, and diamond ceramics (electronics, cutting tools).

The first to be developed in the early 1980s were chromium–diamond coatings on blade and pressing tools [1, 23]. As a rule, standard chromium plating electrolytes were used, containing a suspension of colloid UDD particles in amounts of 10–30 $g l^{-1}$. The content of UDD in a coating was in the range from 0.3 to 1.5 wt %. A chromium–diamond coating ex-

tends the service life of tools and articles 2–10-fold. Later, a similar study was carried out in Japan [24].

Nickel–diamond coatings are ideal choice for wear protection of machinery. The service life of articles with a coating of this kind is 5–20 times that for articles with purely nickel or other nickel composite coatings [1, 3, 25]. The UDD content of the electrolyte is 2 to 20 g l^{-1}, and the content of diamonds in a nickel film, from tenths of percent to 7–8% (this parameter is affected by a wide variety of factors, including the state of the surface of an article being treated). In electroless nickel plating, the content of UDD in the electrolyte is 15 to 80 g l^{-1}. At the same time, use of UDD of UDD-SPT brand [TU (Technical Specifications) 05 121 441-275–95] allows a decrease in the nanodiamond concentration in the electrolyte to 2 g l^{-1} at the equally high strengthening of the nickel coating by a factor of 4–12.

Introduction of UDD into an acid copper plating electrolyte gave nonporous copper coatings with 1.5 times higher microhardness, 2 times higher coating elasticity, 9–10 times lower wear, and manyfold higher corrosion resistance; the throwing power of an electrolyte with UDD increased by a factor of 3. The process of copper plating with UDD was described in detail in [4].

Approximately half the electroplated coatings in the world are those of zinc. Their main purpose is to protect articles from corrosion, especially under unfavorable conditions (sea water and atmosphere, tropics, industrially contaminated air, etc.). Previous studies have shown that the corrosion resistance of zinc–diamond coatings increased, without additional treatment, by 60–100%; microhardness, by 30%; and throwing power of the electrolyte, by 20–35% [4, 26–28]. Surface phosphatization raises the corrosion resistance by 200–250%, making it close to that of cadmium coatings.

Use of UDD in tin plating markedly decreases the porosity of a coating (by a factor of 3–9), raises its corrosion resistance, and makes the wear resistance 3 times higher [1, 4, 27]. In this case, the soldering ability and electrical properties of the coating remain virtually unchanged.

The wear resistance of silver coatings increases by a factor of 3–10, and the microhardness becomes as high as 180 kg mm^{-2} [1, 4].

The wear resistance of gold coatings increases by a factor of 1.8–5.5 at average UDD content in a coating of 0.1% [1, 28].

The wear resistance of an anodic film of aluminum and its alloys, filled with UDD in the course of electrolysis, increased by a factor of 10–13, the mass (filling) of the coating became 2–3.5 times higher, and corrosion resistance and dielectric properties grew substantially [1, 4, 29]. The coating is virtually pore-free and has good outward appearance.

Kinetic studies in copper, tin, and zinc plating electrolytes demonstrated that UDD do not change the mechanism of the process, their influence being associated with the surface-adsorption interaction of the most energetically active nanodiamond particles with growing metal crystals.

The common features of metal–diamond films are as follows: (1) markedly enhanced adhesion and cohesion, (2) increased microhardness and wear resistance, (3) improved corrosion resistance and lower porosity, (4) much higher antifriction, and (5) high throwing power of electrolyte.

The use of UDD and DS as active fillers of polymer formulations and, in particular, film coatings proved to be very efficient [1, 30–32]. For example, the process that we developed for cold vulcanization and filling with UDD yields coatings with the following characteristics. Fluoroelastomer-based coatings have approximately 50 times lower permeability to hydrocarbons and polar solvents, 2 times higher elastic and strength parameters, and high resistance to thermal aging. Polysiloxane-based coatings have 3 times higher tensile strength (154 against 53 MPa) at also approximately 3 times greater absolute elongation (1970 against 730%), with the set of elastic and strength characteristics improved by a factor of 3–5.

A film-forming material for creating antifriction coatings on metal surfaces was developed on the basis of fluoropolymers and UDD, with a previously unachievable coefficient of dry friction on metal (<0.01) obtained.

Fluoropolymeric films with UDD are interior coatings of fuel tanks, depositories, and any other surfaces, which are resistant to the action of corrosive media.

Polysiloxane films with UDD are anti-icing heat- and radiation-resistant coatings (aerials, hulls of Arctic ship, cases of radio beacons and radio buoys, plane wings and fuselage, etc.).

The developed process of hot curing of industrial polymers with UDD ensured higher wear resistance and better elastostrain, radiation-resistant, antifriction, and protective properties of composites. The content of UDD in the formulations is 0.1 to 2.0 wt %. The new properties of rubbers make them efficient in fric-

tion units, seals (including those in outer circuits of nuclear reactors), and coatings protecting from the action of corrosive media.

Ultradisperse diamonds constitute one of the most interesting objects of study and application. According to specialists' prognoses, it is UDD that are capable of occupying a key position in manufacture of composite materials and coatings of a new generation, with the result that the demand for UDD will form and soar.

CONCLUSIONS

(1) Ultradisperse diamonds have the form of a cluster–cluster system of the fractal type, possessing an uncommon combination of properties.

(2) Three main methods for synthesis of UDD are described: in the gas medium, in water, and in ice.

(3) The optimal version of the UDD purification process is proposed: oxidation of impurities with dilute nitric acid at high temperature and pressure.

(4) Good service characteristics of metal–diamond electroplated coatings and polymer–diamond films are analyzed in detail.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Hydrodynamic Model of Restrained Flare of Atomized Fluid

O. I. Protod'yakonova and S. V. Aniskin

St. Petersburg Technological Institute of Plant Polymers, St. Petersburg, Russia

Received January 16, 2002

Abstract—A flow model of a restrained gas–fluid jet with a cocurrent flow is constructed, taking into account the nonuniformity of gas velocity distribution across the jet and the polydisperse composition of drops.

The chemical and related branches of industry, where a problem is encountered of gas discharge cleaning, widely employ mass-exchange apparatus with atomized fluid jets whose development is restrained by apparatus walls. Among the known examples of such apparatus are Venturi ejector scrubbers and straight-flow spraying apparatus with cylindrical and rectangular cross section. In apparatus of this kind, a gas–fluid jet develops in a surrounding gas flow with certain initial velocity. This gas flow is a cocurrent flow with respect to the gas–fluid jet.

Of much practical interest is evaluation of the ejection effect arising in a spraying apparatus for the following reasons.

The fluid flowing out of the atomizer imparts momentum to the surrounding gas. As a result, the gas velocity increases and a gas jet is formed inside the fluid flare. After this jet comes in contact with the apparatus walls, the nonuniformity of the gas velocity across the apparatus diminishes. The kinetic energy of the gas jet also decreases and, correspondingly, its potential energy grows. Consequently, the pressure in the gas flow increases in the course of gas–fluid jet motion. As a result, the pressure difference between the initial and the following (downstream) parts of the apparatus grows. Thus, the ejection effect arises, resulting in that the gas fed into the apparatus inlet is entrained by the gas–fluid jet and moves in the same direction as this jet, forming a cocurrent flow. If a spraying mass-exchange apparatus of this kind is a part of a hydraulic system along which a gas flow moves, then the existence of the ejection effect described above enables the apparatus to perform in the same system also the function of a fan (the so-called flow booster), which can in some cases lower the energy expenditure for gas transport in the system.

The presently known models of flows of this kind have a number of disadvantages [1, 2]. The most significant of these are the lack of a method for determining the gas jet boundaries, the assumption of uniform distribution of the velocity and pressure of gas across the jet, and the failure to take into account the polydispersity of fluid drops, which is particularly important in calculations of heat- and mass-exchange processes in spraying apparatus. Our earlier models are free of these disadvantages [3, 4]. However, these models are only applicable to describing a jet with motion not restrained by apparatus walls, having no cocurrent flow.

A general scheme illustrating the structure of the gas–fluid flow in a straight-flow spraying apparatus is presented in Fig. 1. The apparatus comprises an atomizer *1* in a cylindrical case *2*. The gas flow processed in the apparatus is fed into it from above at a certain constant rate. The fluid fed into the atomizer under pressure is dispersed into drops moving inside the apparatus by inertia and forming a conical flare. The fluid motion velocity in the apparatus exceeds that of the gas. The gas flow from the near-wall region is drawn into this flare to form a gas jet. This process is responsible for the continuous rise in gas flow rate within the fluid flare, which expands as the fluid jet moves along the apparatus. At a certain distance from the atomizer, the gas flow rate inside the flare becomes equal to that at the apparatus inlet. Further increase in the gas flow rate inside the fluid flare may occur, before the flare comes in contact with the apparatus walls, only via gas circulation in the near-wall region. In this case, the circulation also encompasses that region which lies below the point of contact between the fluid flare and the apparatus walls.

It should, however, be noted that, at a certain combination of operating conditions (such as gas and fluid velocities, flare angle, apparatus diameter, drop size,

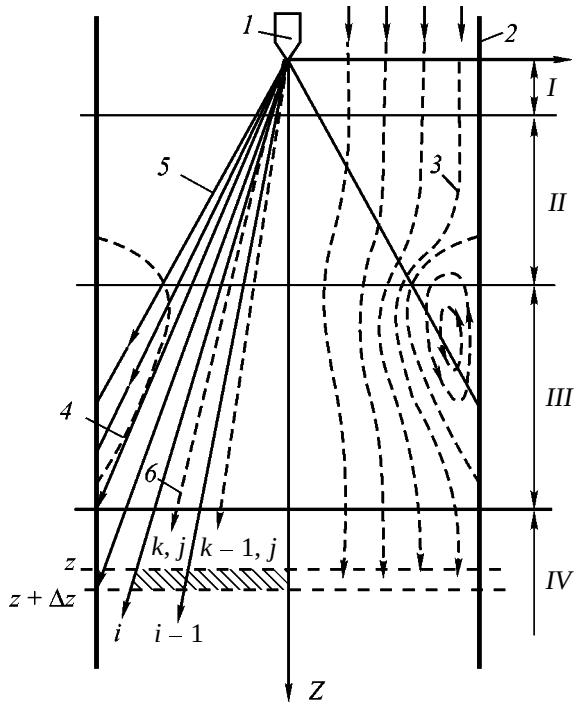

Fig. 1. Schematic of gas–fluid flow in a cylindrical straight-flow spraying apparatus. (*1*) Atomizer, (*2*) apparatus wall, (*3*) lines of gas flow, (*4*) inner boundary of the near-wall gas circulation region, (*5*) line of fluid flow, (*6*) line of flow of a drop jet of *j*th fraction, $j = 1, 2, \ldots, m$ (where m is the number of fraction composed of drops with the maximum size). (*I*) Zone of fluid jet breakdown, (*II*) zone of drop flow of a gas–fluid jet with a cocurrent gas flow, (*III*) zone of gas–fluid jet flow with a near-wall region of gas circulation, and (*IV*) zone of gas–fluid jet flow after the instant of contact between the gas jet and the apparatus wall.

atomizer nozzle diameter, etc.) and also on varying the shape of the spraying apparatus, e.g., with a Venturi tube used instead of a cylinder, there may be no gas circulation in the apparatus. After the fluid flare comes in contact with the apparatus wall, fluid drops settle on the wall to form a downflowing fluid film.

The gas jet inside the fluid flare reaches the apparatus walls after the fluid flare comes in contact with the apparatus walls. Owing to the presence of the above-described gas circulation zone in the near-wall region, the point of contact between the gas jet inside the fluid flare and the apparatus wall may lie below the point of contact between the fluid flare and the apparatus wall. After the gas jet comes in contact with the apparatus wall, the gas velocity profile across the jet is flattened out, with the kinetic energy of the gas jet transformed into its potential energy, characterized by gas pressure.

In accordance with specific features of the gas–fluid jet flow, the jet is conditionally divided, in constructing its mathematical description, into four zones with, to a certain extent, different natures of flow of media. The existence of these zones makes necessary construction of separate mathematical models of flow for each of these zones. The hydrodynamic models of the selected zones of the gas–fluid jet can be used as elements in constructing a general model of a restrained flare of atomized fluid, by combining these elements with the help of appropriate boundary conditions.

Let us consider the first zone of the gas–fluid jet flow (Fig. 1). In this zone, the continuous flow of the fluid outflowing from the atomizer breaks up into drops. Since this flow is swirling because of the atomizer design features, the tangential component of the fluid velocity is transformed into the radial component in the course of flow disintegration into drops. As a consequence, the jet flare angle increases, with the resulting gas–fluid jet having a conical shape.

The distribution of the fluid flow across the flare can be characterized by dimensionless volume density of the liquid phase, β, defined as the fraction of the liquid phase in the space occupied by the gas–fluid mixture. Any cross section of the gas–fluid jet, perpendicular to the Z axis, is characterized by a certain distribution of β over the cross-sectional area. Such a distribution has a certain maximum value $\beta_z^{\max}$.

By analogy with [3], we consider that the first zone of the gas–fluid jet is confined between the lower boundary of the atomizer nozzle, wherefrom the fluid flow runs, and the coordinate $z = L_1$, on reaching which $\beta_z^{\max}$, decreasing in the Z axis direction, takes a value of 0.02. We assume that the relative motion of phases in this zone can be represented as gas filtration through a certain porous medium formed by disintegrating fluid flow and characterized by constant equivalent channel diameter. Then we can use, in describing mathematically the gas–fluid jet flow in this zone, the equations derived in [3].

Let us write an equation describing the momentum change in the flare in a horizontal layer of height dz at a certain arbitrary distance z from the nozzle exit section. The form of this layer, further used to illustrate equations of the mathematical models for the distinguished flare zones, is specified in the bottom part of Fig. 1.

$$\frac{\mathrm{d}}{\mathrm{d}z}\sum_{i=1}^{i}(\rho_g Q_{gi} V_{zi}) - \rho_g V_{z,\,i+1}\sum_{i=1}^{i}\mathrm{d}Q_{gi}/\mathrm{d}z + \sum_{i=1}^{i}(\mathrm{d}w_{zi}/\mathrm{d}z - gG_i/u_{zi}) + \pi\sum_{i=1}^{i}(y_i^2 - y_{i-1}^2)\mathrm{d}P_i/\mathrm{d}z = 0, \qquad (1)$$

where ρ_g is the gas density, kg m^{-3}; Q_g, the volumetric gas flow rate, m^3 s^{-1}; V_z, the gas velocity in the Z axis direction, m s^{-1}; W_z, the flux of the fluid momentum in the direction of the Z axis, N; y and z, the radial and vertical coordinates, respectively, m; P_i, the gas pressure, Pa; i, the fluid jet index; and y_i, the radial coordinate of the intersection of ith line of fluid flow with the cross section (Fig. 1).

It should be noted that, in deriving this equation, the whole volume of the fluid flare is divided in n jets forming a structure of coaxial conical fluid tubes (Fig. 1). In this case, the indices of fluid jets, and also indices of lines of flow delimiting the corresponding fluid jets from the outside, coincide in the adopted indexation system. The equation describes how the flux of momentum changes in an elementary layer of height dz of a gas–fluid jet delimited by ith line of flow (shaded region in Fig. 1).

The equation describing how the momentum varies along the radial coordinate y in an elementary layer of height dz in the gas–fluid jet, which is valid for conditions of a minor variation of the gas flow momentum in this direction, has the form

$$\sum_{i=1}^{i} dW_{yi}/dz + 2\pi \sum_{i=1}^{i} y_i(P_{i+1} - P_i) = 0, \qquad (2)$$

where W_{yi} is the flux of the fluid momentum in the Y axis direction, N.

The equation of gas flow rate conservation in the Z axis direction in a jet layer of height dz, written with account of the fact that part of the gas flow moves into this layer from the outside, has the form

$$\sum_{i=1}^{i} dQ_{yi}/dz + 2\pi y_i v_{y,i+1}, \qquad (3)$$

where v_y is the radial component of the gas flow velocity, m s^{-1}.

Relations closing the set of Eqs. (1), (2), and (3) were considered in detail in [3].

Introducing a function $y_w(z)$ defining the apparatus wall coordinates, we can formulate boundary conditions for these equations with account of the fact that the diameter of the fluid jet outflowing from the jet nozzle is small in comparison of the apparatus diameter. At $z = 0$:

$$G_i = G_{i0};\ u_{zi} = u_{zi0};\ u_{yi} = u_{yi0};$$

$$u_{yi} = u_{yi0};\ y_i = 0;\ v_{z,n+1} = v_0;\ P_i = P_0; \qquad (4)$$

$$\sum_{i=1}^{n} Q_{gi} = 0; \quad Q_{g,n+1} = \pi y_c^2.$$

At $y = 0$:

$$v_{y1} = 0. \qquad (5)$$

At the outer boundary of the jet, i.e., at $y_n < y < y_w$:

$$v_{z,n+1} = Q_{g0} - \pi \sum_{i}^{n} (y_i^2 - y_{i-1}^2) v_{zi}/[\pi(y_w^2 - y_n^2)],$$

$$v_{y,n+1} = (2\pi y)^{-1}(dQ_{g,n+1}/dz), \qquad (6)$$

$$dP_{n+1}/dz = -v_{z,n+1}(dv_{z,n+1}/dz).$$

Let us construct a model of restrained flow of a polydisperse gas–fluid jet for the second zone (Fig. 1). In this zone, the dispersion composition of drops becomes constant, and motion of each drop becomes independent of the motion of other drops. In formulating model equations, we divide the jet flare into m mutually penetrating flares, each composed of drops of the same size. As in constructing the model of a gas–fluid flow for the first zone, we divide the space occupied by each of the above m fluid flares along the radial coordinate by lines of fluid flow into n jets in such a way that the fluid flow rate in each of these jets is constant.

Let us denote the number of a drop fraction by index j, and the number of a fluid jet, by index k. Then the following condition will be satisfied for arbitrary kth fluid jet composed of drops of jth fraction:

$$G_{kj} = \text{const}. \qquad (7)$$

Let us consider a disperse fluid flare composed of drops of one of the fractions $j = 1, 2, \ldots, m$.

We choose a number j corresponding to the fraction composed of maximum-size drops, i.e., $j = m$, and select within the second flow zone an elementary layer of height Δz, delimited along the radial coordinate by lines of fluid flow k and $k - 1$, in the flare in question. This layer will be denoted by a pair of indices k and m, which characterize the number of fluid jet (coinciding with the number of the line of flow) and the number of fraction with drops of maximum size. The layer of the dispersed fluid jet, considered here and denoted by indices k and m, occupies a unit space, denoted by index i to make convenient derivation of further equations of the model. Through this space pass, in motion of a gas–fluid jet, fluid jets

containing drops of all fractions j. As is known, owing to the difference between trajectories of drops of different sizes, the jets composed of drops of one fraction are shifted along the radial coordinate relative to drops of another fraction (Fig. 1). As a result of this shift of jets, they may pass through the selected unit space i entirely, partly, or may not enter this element at all. Thus, k fluid jets and j drop fractions may pass, in principle, through the unit space i. The fraction G of the fluid flow rate of an arbitrary fluid jet kj passing through unit space i can be expressed using the coefficient θ_{ikj}. Then, the expression for the total flow rate of the fluid passing through a unit space i in motion of the gas–fluid jet takes the form

$$G_i = \sum_k^n \sum_j^m \theta_{ikj} G_{kj}. \quad (8)$$

Expressions for W_{zi} and W_{yi} can be obtained similarly, which enables use of Eqs. (1), (2), and (3) for describing the second flow zone. Relations closing these equations were reported in [4].

These relations must be supplemented with boundary conditions taking into account the restrained nature of the gas–fluid flow. At $z = L_1$:

$$G_{kj}^{(2)} = G_{kj0}, \qquad \sum_{j=1}^m \theta_{kj} G_{kj}^{(2)} = G_i,$$

$$u_{zkj}^{(2)} = u_{zi}^{(1)},\ u_{ykj}^{(2)} = u_{yi}^{(1)},\ v_{zi}^{(2)} = v_{yi}^{(1)},\ v_{yi}^{(2)} = v_{yi}^{(1)},$$

$$v_{z,n+1}^{(2)} = v_{z,n+1}^{(1)},\ y_i^{(2)} = y_{kj}^{(2)} = y_i^{(1)},\ P_i^{(2)} = P_i^{(1)}.$$

At $y = 0$ and at $y_n < y < y_w$, the boundary conditions are identical to those for the first zone, (5) and (6).

The next stage of our theoretical study of the flow in a restrained flare of atomized fluid consists in construction of a model for the third flow zone of those selected in Fig. 1.

A distinctive feature of the third flow zone of the gas–fluid jet consists in that the gas flow rate inside this jet becomes higher than the gas flow rate at the apparatus inlet. This is due to an increase in the gas flow velocity in the jet flare, resulting from further rise in the momentum imparted by the fluid phase to the gas flow. This feature, however, does not entail any change in the basic equations used to describe the second flow zone of the gas–fluid jet. Thus, the system of equations for the third flow zone, considered here, must include Eqs. (1), (2), (3), (7), and (8). The distinction of the model for the third zone from that for the second is in the kind of boundary conditions for the equations mentioned. At $z = L_2$:

$$G_{ki}^{(3)} = G_{ki}^{(2)},\ u_{zki}^{(3)} = u_{zkj}^{(3)},\ u_{ykj}^{(3)} = u_{ykj}^{(2)},$$

$$v_{zi}^{(3)} = v_{zi}^{(2)},\ v_{yi}^{(3)} = v_{yi}^{(2)},\ v_{z,n+1}^{(3)} = v_{z,n+1}^{(2)},$$

$$y_{kj}^{(3)} = y_{kj}^{(3)}, \quad P_i^{(3)} = P_i^{(2)}. \quad (10)$$

At $y = 0$, the condition (5) is preserved.

In formulating conditions at the outer boundary of the flare, account should be taken of the following. By virtue of the law of conservation of the flow rate of gas passing through the apparatus, a local excess of gas flow velocity in any jet flow zone over that at the apparatus inlet is only possible when the motion direction of a part of the gas flow changes in the near-wall region to the opposite as a result of formation of the corresponding circulation flows.

It seems natural to assume that this change in flow direction occurs at the outer boundary of the gas–fluid jet flare. Then the boundary condition accounting for this fact can be written in the form

$$v_{z,n+1} = 0. \quad (11)$$

It is known that, in the case of gas flow circulation, the gas pressure in the near-wall region is equalized and it may be considered that at the outer boundary of the flare

$$P = \text{const}. \quad (12)$$

When the fluid flare comes in contact with the apparatus walls, the gas pressure in the gas–fluid jet may increase stepwise by ΔP as a result of abrupt deceleration of the gas flow. In terms of the formalism used, it is believed that, after the gas–fluid jet touches the apparatus walls, its outer boundary successively moves, as the fluid falls onto the wall, inside the flare from line of flow with number $i = n$ (Fig. 1) to that with number $n - 1$, then to line of flow $n - 2$, etc., within the gas circulation zone.

This feature must be taken into account by the boundary conditions for the flow velocity and pressure of gas. For example, depending on the index of the line of flow, i_b, along which the corresponding boundary is established, the conditions (11) and (12) have the following form.

At $i_b = n$:

$$v_{z,n+1} = 0, \qquad P_{n+1} = P_{n+1}^{(2)},$$

At $i_b = n - 1$:

$$v_{z,n} = 0, \quad p_n = P_{n+1}^{(2)} + \Delta P_n, \tag{13}$$

at $i_b = n - 2$:

$$v_{z,n-1} = 0, \quad P_{n-1} = P_{n+1}^{(2)} + \sum_{i=n-1}^{n} \Delta P_n,$$

etc., where $P_{n+1}^{(2)}$ is the gas pressure in the near-wall region at the boundary separating the second and third zones of the gas–fluid jet: ΔP_i is the pressure jump in the near-wall region, which results from deceleration of ith gas jet in its collision with the apparatus wall.

In view of the fact that the gas flow velocity v_z decreases to zero under the conditions (13), the momentum of ith gas jet is completely transformed into gas pressure:

$$\Delta P_i = \frac{\pi_g Q_i v_{zi}}{\pi y_w^2}. \tag{14}$$

and, thus, the flow model of the gas–fluid jet in the third zone is constructed.

Let us now construct a gas–fluid jet flow model for the fourth zone. The specific features of this zone are the following: adhesion of the gas jet to the walls and leveling-out of the gas flow velocity distribution across the apparatus, which is known to be accompanied by an increase in gas pressure. Similarly to the case of the third zone, these features do not entail any need to change the type of the basic equations (1), (2), (3), (7), and (8), used to describe the flow of the gas–fluid jet in the second zone.

Let us formulate the boundary conditions for these equations. For this purpose, we consider a method for determining the coordinate z of a cross section that is the upper boundary of the zone in question. If there is no flow separation from the apparatus walls, i.e., there is no third zone of the gas–fluid jet, then it seems natural to regard as the beginning of the fourth zone the coordinate z at which nth line of fluid flow touches the apparatus wall. In this case, the conditions at this boundary completely coincide with the conditions (10). If, however, there is flow separation from the apparatus walls and there exists the third flow zone in the gas–fluid jet, then the boundary between the third and fourth zones is found from the following considerations. The zone of gas circulation in the near-wall region ends at this boundary and the gas jet adheres to the apparatus walls. This means that the gas flow tube, within which a gas flow moves with flow rate Q_0, again comes in contact with the apparatus walls after flow separation from these walls in the third zone. It is this flow tube that is the boundary of the near-wall circulation zone (Fig. 1).

In terms of the formal concepts used in modeling the flow of the gas–fluid jet under consideration, the boundary between the third and fourth zones is found as follows. A jet cross section passing through the point at which an arbitrary ith line of flow (i_w) touches the wall may be considered, to a first approximation, as the boundary between the third and fourth zones if the line of gas flow, belonging to a flow tube delimiting a gas flow q_{g0}, passes between the lines of fluid flow i_w and $i_{(w-1)}$. Then the following condition is satisfied:

$$\sum_{i=1}^{i_w} Q_{gi} > Q_{g0} > \sum_{i=1}^{i_w - 1} Q_{gi}. \tag{15}$$

The accuracy of finding the position of the sought-for boundary by calculation improves with increasing number n of jets into which the gas–fluid flare is divided in constructing the model.

The conditions at the boundary between the third and fourth zones are as follows.

At $z = L_3$:

$$G_{kj}^{(4)} = G_{kj}^{(3)}, \quad u_{zkj}^{(4)} = u_{zkj}^{(3)}, \quad u_{ykj}^{(4)} = u_{ykj}^{(3)}$$

$$y_i^{(4)} = y_i^{(3)}, \quad y_{kj}^{(4)} = y_{kj}^{(3)}, \quad P_i^{(4)} = P_i^{(3)} + \Delta P_w.$$

where

$$\Delta P_w = \rho[(v_{ziw}^{(3)})^2 - (v_{ziw}^{(4)})^2]. \tag{16}$$

For the boundary region satisfying the condition

$$y \le y_{i-1}: \quad v_{zi}^{(4)} = v_{zi}^{(3)}, \quad v_{yi}^{(4)} = v_{yi}^{(3)}. \tag{17}$$

In the boundary region satisfying the inequality $y_{iw} \le y \le y_{i,w-1}$, the boundary conditions must take into account the stepwise change in gas flow velocity and pressure, resulting from an abrupt change in the nature of the gas flow (in this part of the boundary), consisting in that there occurs a transition from circulation gas motion to motion without circulation at a constant flow rate Q_0, which is established at the instant of gas flow adhesion to the apparatus walls. These boundary conditions have

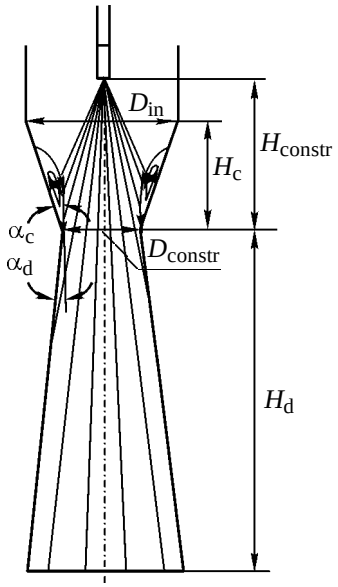

Fig. 2. Basic design parameters of a jet scrubber. (D_{in}) Inlet diameter, (D_{constr}) constriction diameter, (H_{constr}) distance between the atomizer and the constriction section, (H_d) diffuser length, (α_c) confuser angle, (α_d) diffuser angle, and (H_c) confuser length.

the following form:

$$v_{zi\text{w}}^{(4)} = \left[Q_0 - \sum_{i=1}^{i\text{w}-1} Q_i\right]/[\pi(y_{i\text{w}}^2 - y_{i\text{w}-1}^2)]^{-1},$$

$$v_{yi}^{(4)} = -(2\pi y_{i\text{w}-1}^{(3)})^{-1} \sum_{i=1}^{i\text{w}-1} \mathrm{d}Q_i^{(3)}/\mathrm{d}z. \qquad (18)$$

At the apparatus wall, the following condition must be satisfied:

$$v_y = 0. \qquad (19)$$

Thus, the resulting model of the gas–fluid jet for the fourth zones includes Eqs. (1), (2), (3), (7), and (8), and boundary conditions (16)–(19).

The developed hydrodynamic model of the restrained flare of a gas–fluid jet can be verified by comparing the distribution of the statistical pressure $P(z)$ along the flare length, calculated by numerical solution of the model equations by the Runge–Kutta method, with the results of an experimental study of this distribution in a jet scrubber [5]. In [5], a jet scrubber with the case in the form of a Venturi tube was studied.

The design characteristics of a jet scrubber, which appear as constants in the expressions for y_w and are presented in Fig. 2, have the following values: D_{in} = 0.2 m, D_{constr} = 0.126 m, H_c = 0.36 m, H_d = 0.7 m, α_c = 12°, and α_d = 6°. The gas flow velocity at the apparatus inlet was v_{g0} = 3.5 m s^{-1}. The atomizer used in the experiments had the following parameters: nozzle diameter d_n = (3±0.01) mm, flow coefficient μ = (0.9±0.01) mm, flare angle α = 48°, and fluid pressure before the atomizer P_f = 0.6 MPa.

The experimentally obtained [5] values of the spraying density distribution function along the radial coordinate can be approximated by the following formula [6]:

$$I = \frac{a}{1 + bx^n} - \frac{c}{1 + dx^n}, \qquad (20)$$

where I is the relative spraying density, and x is the relative radius.

The I and x values are given by

$$I = J/\bar{J}, \quad x = y/R, \qquad (21)$$

where J, $\bar{J}$ are the spraying density and average spraying density, m s^{-1}, over an area delimited by radius R, through which 95% of the fluid passes.

The constants a, b, c, d, and n, appearing in formula (20), were found by calculation from the condition that this formula ensures the best fit to the experimentally obtained [5] values of the spraying density distribution function: a = 2.93, b = 47.7, c = 2.17, d = 20 158, and n = 15.4. The I value calculated using the above constants makes it possible to determine the fluid flow rate G_i in ith jet, which appears in the boundary conditions (14), using the formula [6]

$$G_i = 1.9\, G_0 \int_{x_{i-1}}^{x_i} I x \mathrm{d}x, \qquad (22)$$

The G_{kj} value, appearing in the boundary conditions (9), (10), and (16), is determined with account of the dispersion composition of the drop flow in the gas–fluid jet.

In the case under study, we can characterize the dispersion composition of the drop flow, using the results obtained in [16], owing to the fact that the impermeability and operation characteristics of the centrifugal-jet atomizer, reported in [5] and [6], are identical, except for the flare angle. However, as is known [1], the effect of this parameter on the dispersion composition of drop flow in the gas–fluid jet is negligible.

Under the hydrodynamic conditions considered here, the dispersion composition of the drop flow can be described by the Rosin–Rammler distribution [6]:

$$S_j = 1 - e^{-(dj/a)^l}, \quad (23)$$

where S_j is the volume fraction of drops with size smaller than d_j, and a and l are distribution constants: $a = 0.34 \times 10^{-3}$ m and $l = 3.1$.

With account of (23), the G_{kj} value is found as follows:

$$G_{kj} = (S_j - S_{j-1})G_i \text{ at } k = i. \quad (24)$$

As additional boundary conditions, necessary for solving numerically the equations of our hydrodynamic model with account of the specific conditions of an experimental study of a restrained flare of atomized fluid in a jet scrubber, we used the following simple relations:

$$P_0 = -38\text{Pa}, \; u_{zi0} = \mu(2\rho_l/\rho)^{1/2}\cos(\alpha_i/2),$$
$$u_{yi0} = u_{zi}\tan(\alpha_i/2), \quad (25)$$

where α_i is the angle of deflection of ith jet from the Z axis.

The distribution function of the statistical pressure $P(z)$ along the gas–fluid jet was plotted in Fig. 3 on the basis of a numerical solution to the equations of our hydrodynamic model of a restrained flare of atomized fluid, with the boundary conditions considered above.

The points in Fig. 3 represent the values of the function $P(z)$, obtained in [5] in an experimental study of a restrained flare of atomized fluid in a jet scrubber. It should be noted that the results obtained in solving numerically the equations of our hydrodynamic model take into account the specific features of all the four flow zones of the gas–fluid jet, which were observed in its experimental study. The rms deviation of the theoretical and experimental $P(z)$ values related to the total pressure drop across the jet scrubber (142 Pa) was 6%.

CONCLUSIONS

(1) A one-dimensional integral hydrodynamic model of a restrained flare of atomized fluid in a jet scrubber is constructed. The model takes into account the real distribution of the spraying density and the dispersion composition of the flow of fluid drops.

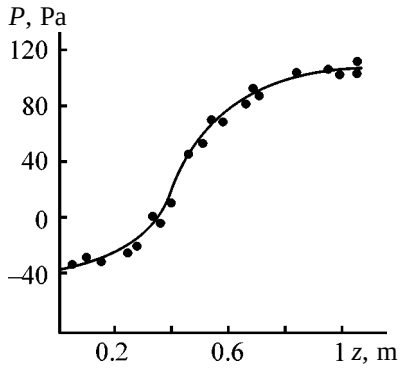

Fig. 2. Distribution of statistical pressure in a jet scrubber. (P) Statistical pressure and (z) distance from the atomizer.

(2) Comparison of the distribution of static pressure in a jet scrubber, obtained by solving numerically the equations of the model of a restrained flare of atomized fluid, with experimental data confirms the validity of the hydrodynamic model constructed in the present study.

Abstract—A highly sensitive and selective procedure was developed for determining specific impurities of isonicotinic acid hydrazide and vanillin in Metazid and Ftivazide preparations by thin-layer chromatography.

One of the principal characteristics of drugs is their purity. In this work, we chose for our studies derivatives of isonicotinic acid hydrazide, Metazid and Ftivazide, which are widely used in medicine as antitubercular drugs.

In accordance with the preparation procedure, Metazid can contain as specific impurities isonicotinic acid hydrazide (INAH) and formaldehyde. The initial compounds for preparing Ftivazide are INAH and vanillin whose content in the product should be monitored. According to the existing regulations [1, 2], the content of these specific impurities in Metazid and Ftivazide should be determined chemically. Isonicotinic acid hydrazide is determined with iodine in the presence of starch, and vanillin, by the reaction with phenolphthalein in the presence of alkali. These procedures are low-selective, because their results can be affected by oxidizing and reducing agents.

The drugs under consideration and the possible impurities contain different functional groups and therefore show different physicochemical properties. In this connection, it seems appropriate to detect them by such a quick, selective, and sensitive method as thin-layer chromatography (TLC) [3].

The goal of this study was development of a procedure for detecting and separating impurities in Metazid and Ftivazide by TLC.

EXPERIMENTAL

The test solutions of Metazid and Ftivazide were prepared by dissolving 5 g of the preparation in 10 ml of 95% ethanol (hereinafter, ethanol). The solutions were subsequently filtered. Standard solutions of INAH and vanillin were prepared by dissolving 0.01 g of the substances in 100 ml of ethanol.

Structural features of Metazid, Ftivazide, and the possible impurities suggest that the best sorbent for their separation is silica gel. It is an acidic sorbent allowing separation of substances that differ in acid–base properties. In our studies we tested several brands of silica gel.

The chromatograms were developed by UV irradiation (λ 254 nm). The detection sensitivity was 0.5 μg.

To choose the best mobile phase (MP), we studied the chromatographic behavior of Metazid, Ftivazide, INAH, and vanillin in a series of solvents. The results are listed in the table. It is seen that the mobility of the compounds increases with increasing solvent polarity. Therefore, we chose as the major components of the mobile phase chloroform and ethanol, which significantly differ in the polarity. The compositions of the solvent systems and the results of chromatographic analysis of Ftivazide and Metazid are given in Figs. 1 and 2.

Our results show that, in chloroform, vanillin is the most mobile, and Ftivazide, Metazid, and INAH show low mobility because of their poor solubility (Figs. 1, 2, MP no. 1). Isonicotiic acid hydrazide in chloroform shows the same chromatographic mobility as Ftivazide and Metazid. In ethanol, all the compounds are more mobile (Figs. 1, 2, MP no. 2). The difference between the retention factors of Ftivazide and INAH increases considerably, but the bands of Ftivazide and vanillin become closer. The bands of INAH and Metazid are separated, but ΔR_f is as small as 0.07.

The subsequent experiments were performed with

Benzene	2.28	0.00	0.01	0.00	0.00

binary mobile phases consisting of chloroform (major solvent) and ethanol. By varying the content of ethanol in MP, we chose a chromatographic system (Fig. 1, MP no. 4) allowing separation of Ftivazide, vanillin, and INAH. However, the Ftivazide band in this case has an irregular shape. To obtain a Ftivazide band with clear and regular boundaries, we added 25% ammonia and glacial acetic acid. Addition of 25% ammonia to MP results in that the Ftivazide band becomes well-bounded, but the bands of the other substances virtually coalesce (Fig. 1, MP nos. 6, 7). Replacement of 25% ammonia by glacial acetic acid allows separation of Ftivazide, vanillin, and INAH (Fig. 1, MP nos. 8–10). However, the mobility of vanillin increases considerably, and its band approaches the front, which is undesirable. To decrease the mobility of vanillin, we added to MP a fourth component, 25% ammonia (Fig. 1, MP nos. 11–13). By varying the amounts of glacial acetic acid and 25% ammonia, we obtained an optimal MP for monitoring the purity of Ftivazide (Fig. 1, MP no. 11): chloroform–ethanol–glacial acetic acid–25% ammonia, 9 : 1 : 1 : 0.5.

The results of chromatographic study of Metazid and INAH show that the MP with glacial acetic acid ensures good separation of the substances (Fig. 2, MP nos. 8–10). However, higher values of R_f, especially for Metazid, are desirable. This was attained by increasing the content of ethanol in MP (Fig. 2, MP nos. 15–17). Our experiments showed that the best MP for monitoring the Metazid purity is chloro-

Mobile phase no.: 1, chloroform (Cl); 2, ethanol (Et); 3–5, Cl–Et (9 : 0.5, 9 : 1, 9 : 2, respectively); 6 and 7, Cl–Et–25% ammonia (Am) (9 :1: 0.25 and 9 : 1 : 0.5, respectively); 8–10, Cl–Et–glacial acetic acid (AA) (9 : 1 : 0.25, 9 : 1 : 0.5, 9 : 1 : 1, respectively); and 11–13, Cl–Et–AA–Am (9 : 1 : 1 : 0.5, 9 : 1 : 0.5 : 1, 9 : 1 : 0.25 : 1, respectively).

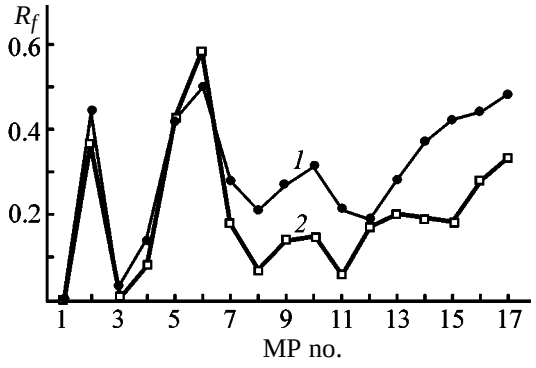

Fig. 2. R_f of (*1*) INAH and (*2*) Metazid as a function of the MP composition. Mobile phase no.: 1, Cl; 2, Et; 3–5, Cl–Et (9 : 0.5, 9 : 1, 9 : 2, respectively); 6 and 7, Cl–Et–Am (9 : 1 : 0.25, 9 : 1 : 0.5, respectively); 8–10, Cl–Et–AA (9 : 1 : 0.25, 9 : 1 : 0.5, 9 : 1 : 1, respectively); 11–13, Cl–Et–AA–Am (9 : 1 : 1 : 0.5, 9 : 1 : 0.5 : 1, 9 : 1 : 0.25 : 1, respectively; and 14–17, Cl–Et–AA (9 : 2 : 0.5, 9 : 2 : 1, 9 : 3 : 1, 9 : 4 : 1.5, respectively).

form–ethanol–glacial acetic acid (9 : 4 : 1.5, Fig. 2, MP no. 17).

The procedure for determining the Ftivazide purity was as follows. A 0.5-g portion of Ftivazide sample was shaken with 10 ml of ethanol for 5 ml and filtered. The resulting solution (0.02 ml; 1 mg) was applied to the start line of a Silufol UV-254, Armsorb UV-254, or other suitable plate (7.5 × 15 cm). In the vicinity, 0.01 ml of 0.01% solution of a reference INAH sample in ethanol and 0.02 ml of a 0.01% solution of a reference vanillin sample in ethanol were applied. The plate with the samples was dried in air for 5 min and then placed in a chamber containing a chloroform–ethanol–glacial acetic acid–25% ammonia solvent mixture (9 : 1 : 1 : 0.5) and chromatographed in the ascending mode. After the solvent front passed 3/4 of the plate length, it was taken out of the chamber, dried in air for 10 min, and examined under UV light (λ 254 nm). The spots of INAH and vanillin in the chromatogram of the test sample should not exceed in size and color intensity the spots of the corresponding reference samples (content no higher than 0.1 and 0.2%, respectively).

By this procedure, we analyzed ten commercial batches of Ftivazide. In all the samples we detected INAH and vanillin impurities, but their content did not exceed the prescribed limits (0.1 and 0.2%, respectively). The retention factors were as follows: Ftivazide, 0.32–0.35; INAH, 0.21–0.23; and vanillin, 0.79–0.81. The sizes and color intensities of the impurity spots did not exceed those of the references.

The purity of Metazid was determined similarly. Along with the test sample, 0.01 mol of a 0.01% solution of INAH reference sample in ethanol was applied to the start line. The plate with the applied samples was dried in air for 5 min and then placed in a chamber containing the chloroform–ethanol–glacial acetic acid solvent mixture (9 : 4 : 1.5) and chromatographed in the ascending mode. The resulting chromatogram was worked up as described above. The spot of the INAH impurity should not exceed in the size and color intensity the spot of the INAH reference (≤0.1%).

By this procedure, we analyzed ten commercial batches of Metazid. In all the samples, INAH impurity was detected, but its content did not exceed 0.1%. The retention factors were as follows: Metazid, 0.33–0.35 and INAH, 0.48–0.50. The sizes and color intensities of the impurity spots did not exceed those of the reference.

The developed procedures for monitoring the purity of Ftivazide and Metazid by thin-layer chromatography were approbated in the Quality Control Department, Usol'e-Sibirskoe Chemical and Pharmaceutical Combine, Joint-Stock Company. These procedures were included into the projects of the pharmacopoeia items of the enterprise for these drugs.

CONCLUSION

(1) Chromatographic behavior of Ftivazide, Metazid, and their possible impurities in various mobile phases was studied; the feasibility was demonstrated for their chromatographic separation at properly chosen composition of the mobile phase.

(2) Quick and selective procedures for checking the purity of Ftivazide and Metazid were developed, using TLC under the experimentally determined optimal conditions.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A Study of Trichloroethylene Hydrofluorination Using a Kinetic Model[1]

A. V. Dmitriev, I. G. Trukshin, and P. Yu. Smykalov

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

Received January 17, 2002

Abstract—The kinetic features of catalytic hydrofluorination of trichloroethylene and 2-chloro-1,1,1-trifluoroethane on chromium fluoride/magnesium fluoride catalyst were studied. The effect of pressure and addition of various components of the reaction mixture at the reactor inlet was studied using the developed model.

The procedure of production of 1,1,1,2-tetrafluoroethane by gas-phase catalytic hydrofluorination of trichloroethylene is well known in the world practice and is commercially used by various companies. There are many patents related to this procedure of tetrafluoroethane production [1–3] and to the catalyst production [4, 5]. In gas-phase fluorination processes, chromium(III) compounds in the form of fluorides and oxofluorides are mainly used.

At the same time, there are no published data on the kinetics and mechanism of hydrofluorination of trichloroethylene, which are necessary to design the reaction unit.

The goal of this work was to study experimentally this process on the chromium fluoride/magnesium fluoride catalyst and, based on the developed kinetic model, to study the effect of pressure and addition of various components of the reaction mixture (hydrogen chloride, 1,1-difluoroethylene, 1,1,1-trifluoroethane, and pentafluoroethane) at the reactor inlet.

EXPERIMENTAL

The study was carried out on a continuous installation consisting of a nickel reactor with electrical heating, units for dosing the initial reagents, and a system for collection and analysis of the synthesis products. The total capacity of the reactor was 1000 cm^3; the inner diameter was 36 mm. The reactor temperature was monitored by a multizone thermocouple. Hydrogen fluoride and 2-chloro-1,1,1-trifluoroethane were fed into the reactor through nickel capillaries. The flow rate of these reagents was set using the calibrating plot of the flow rate vs. the pressure in the service vessels, which, in turn, was produced by their temperature control. Trichloroethylene was fed into the reactor with a dosing pump. The flows of the initial reagents were mixed and fed into a coil-type evaporator equipped with electrical heating, and then into the reactor. After washing with water, neutralization, and drying, the reaction mixture was collected in a glass condenser cooled with a mixture of dry ice and $CCl_4/CHCl_3$.

The reaction mixture was analyzed on a Tsvet-500M chromatograph equipped with a heat conductivity detector. The 2-m chromatographic column was packed with ASK silica gel impregnated with liquid paraffin (10%).

The products were identified by gas chromatography–mass spectrometry on a Hewlett–Packard device equipped with an Al_2O_3/KCl capillary column (l = 50 m).

To determine the kinetic parameters, the experiments were performed in the reactor with a fluidized bed of the chromium fluoride/magnesium fluoride catalyst.[2]

The initial 2-chloro-1,1,1-trifluoroethane and trichloroethylene were purified by fractional distillation.

When developing the kinetic model, the following assumptions were made: the process is kinetically controlled; the catalyst activity is constant in time;

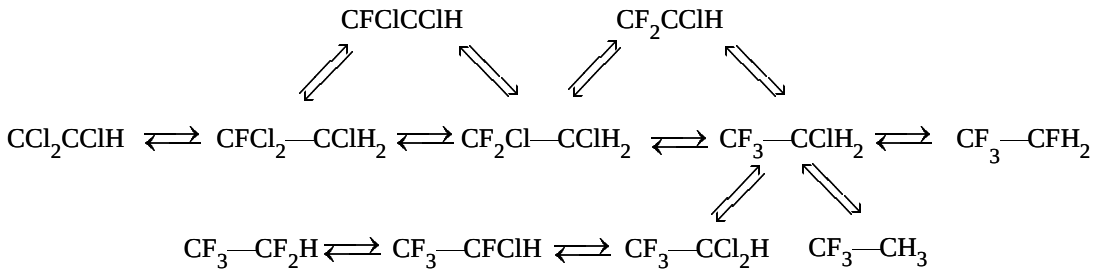
[1] Reported at the Third International Conference "Chemistry, Technology, and Application of Fluorine Compounds," St. Petersburg, June 6–9, 2001.

[2] This catalyst (chromium fluoride applied to magnesium fluoride) is produced by the pilot plant of the Prikladnaya Khimiya Russian Scientific Center and is used in various hydrofluorination processes.

1070-4272/02/7505-0771$27.00 © 2002 MAIK "Nauka/Interperiodica"

the catalyst can operate as a fluorine transfer agent; thermal decomposition of synthesis products is insignificant [6]; in the course of synthesis, products of asymmetric structure are mainly formed; only one fluorine atom in CrF_3 participates in exchange with chlorine atom; and the reaction of CrF_3 with HCl is significantly faster than the reaction of CrF_3 with chlorine-containing organic compounds.

With these assumptions, the process scheme can be presented as a series of successive stages considering the processes related to production of 2-chloro-1,1,1-trifluoroethane from trichloroethylene and subsequent fluorination to 1,1,1,2-tetrafluoroethane:



$$CF_3–CClH_2 + =Cr–F \rightleftarrows CF_3–CFH_2 + =Cr–Cl \quad \{k_1/k_{-1}\}, \quad (1)$$

$$=Cr–Cl + HF \rightleftarrows =Cr–F + HCl \quad \{k_2/k_{-2}\}, \quad (2)$$

$$=Cr–F + 2CF_3–CClH_2 \rightleftarrows [=Cr–F \cdot 2CF_3–CClH_2] \quad \{k_3/k_{-3}\}, \quad (3)$$

$$[=Cr–F \cdot 2CF_3–CClH_2] \rightleftarrows CF_3–CH_3 + CF_3–CCl_2H + =Cr–F \quad \{k_4/k_{-4}\}, \quad (4)$$

$$CF_3–CCl_2H + =Cr–F \rightleftarrows CF_3–CFClH + =Cr–Cl \quad \{k_5/k_{-5}\}, \quad (5)$$

$$CF_3–CFClH + =Cr–F \rightleftarrows CF_3–CF_2H + =Cr–Cl \quad \{k_6/k_{-6}\}, \quad (6)$$

$$CF_3–CClH_2 + =Cr–Cl \rightleftarrows CF_2Cl–CClH_2 + =Cr–F \quad \{k_7/k_{-7}\}, \quad (7)$$

$$CF_2Cl–CClH_2 + =Cr–F \rightleftarrows [=Cr–F \cdot CF_2Cl–CClH_2] \quad \{k_8/k_{-8}\}, \quad (8)$$

$$[=Cr–F \cdot CF_2Cl–CClH_2] \rightleftarrows CF_2=CClH + HCl + =Cr–F \quad \{k_9/k_{-9}\}, \quad (9)$$

$$CF_2=CClH + HF + =Cr–F \rightleftarrows [CF_2=CClH \cdot HF \cdot =Cr–F] \quad \{k_{10}/k_{-10}\}, \quad (10)$$

$$[CF_2=CClH \cdot HF \cdot =Cr–F] \rightleftarrows CF_3–CClH_2 + =Cr–F \quad \{k_{11}/k_{-11}\}, \quad (11)$$

$$CF_2Cl–CClH_2 + =Cr–Cl \rightleftarrows CFCl_2–CClH_2 + =Cr–F \quad \{k_{12}/k_{-12}\}, \quad (12)$$

$$CFCl_2–CClH_2 + =Cr–Cl \rightleftarrows CCl_3–CClH_2 + =Cr–F \quad \{k_{13}/k_{-13}\}, \quad (13)$$

$$CCl_3–CClH_2 + =Cr–F \rightleftarrows [CCl_3–CClH_2 \cdot =Cr–F] \quad \{k_{14}/k_{-14}\}, \quad (14)$$

$$[CCl_3–CClH_2 \cdot =Cr–F] \rightleftarrows CCl_2=CClH + HCl + =Cr–F \quad \{k_{15}/k_{-15}\}, \quad (15)$$

$$CCl_2=CClH + HF + =Cr–F \rightleftarrows [CCl_2=CClH \cdot HF \cdot =Cr–F] \quad \{k_{16}/k_{-16}\}, \quad (16)$$

$$[CCl_2=CClH \cdot HF \cdot =Cr–F] \rightleftarrows CFCl_2–CClH_2 + =Cr–F \quad \{k_{17}/k_{-17}\}, \quad (17)$$

$$CFCl_2–CClH_2 + =Cr–F \rightleftarrows [CFCl_2–CClH_2 \cdot =Cr–F] \quad \{k_{18}/k_{-18}\}, \quad (18)$$

$$[CFCl_2–CClH_2 \cdot =Cr–F] \rightleftarrows CFCl=CClH + HCl + =Cr–F \quad \{k_{19}/k_{-19}\}, \quad (19)$$

$$CFCl=CClH + HF + =Cr–F \rightleftarrows [CFCl=CClH \cdot HF \cdot =Cr–F] \quad \{k_{20}/k_{-20}\}, \quad (20)$$

$$[CFCl=CClH \cdot HF \cdot =Cr–F] \rightleftarrows CF_2Cl–CClH_2 + =Cr–F \quad \{k_{21}/k_{-21}\}. \quad (21)$$

Based on the developed scheme of this catalytic process, using the methods of pathways for com-

plicated reactions [7], we derived a kinetic model considering the stages of formation of 2-chloro-1,1,1-trifluoroethane and 1,1,1,2-tetrafluoroethane. In so doing, each reaction was considered as a multistage process [8]. The developed model describes variation of the concentrations of HF, HCl, CF_3–$CClH_2$, CF_3–CFH_2, CF_3–CH_3, CF_3–CCl_2H, CF_3–CFClH, CF_3–CF_2H, CF_2Cl–$CClH_2$, C_2HCl_3, CF_2=CClH, $CFCl_2$–$CClH_2$, and CFCl=CClH:

$$\frac{dc_1}{d\tau} = k'_{-7}c_8 - k_7c_1c_{11} - k'_1c_1 + k_{-1}c_3c_{11} + k'_{10}c_2c_{10} - k_{50}c_1 - 2k_3c_1^2 + 2k_nc_1^2 + 2k_tc_4c_{11},$$

$$\frac{dc_3}{d\tau} = k'_1c_1 - k_{-1}c_3c_{11},$$

$$\frac{dc_4}{d\tau} = k'_3c_1^2 - k_nc_1^2 - k_tc_4c_{11},$$

$$\frac{dc_5}{d\tau} = k'_3c_1^2 - k_nc_1^2 - k_tc_4c_{11} - k'_5c_5 + k_{-5}c_6c_{11},$$

$$\frac{dc_6}{d\tau} = k'_5c_5 - k_{-5}c_6c_{11} - k'_6c_6 + k_{-6}c_7c_{11},$$

$$\frac{dc_7}{d\tau} = k'_6c_6 - k_{-6}c_7c_{11},$$

$$\frac{dc_8}{d\tau} = k_{-12}c_2c_{12} - k_{12}c_8c_{11} - k'_{-7}c_8 + k_7c_1c_{11} - 0.5k'_8c_8 + 0.5k'_{-9}c_{10}c_{11} + k'_{20}c_2c_{13},$$

$$\frac{dc_9}{d\tau} = -k'_{16}c_2c_9 + k_\Sigma c_8c_{11} + k_\sigma c_9c_{11},$$

$$\frac{dc_{10}}{d\tau} = 0.5k'_8c_8 - 0.5k'_{-9}c_{10}c_{11} - k'_{10}c_2c_{10} + k_{50}c_1,$$

$$\frac{dc_{12}}{d\tau} = k'_{16}c_2c_9 - k_{-12}c_2c_{12} + k_{12}c_8c_{11} - 0.5k'_{18}c_{12} + 0.5k'_{-19}c_{11}c_{13},$$

$$\frac{dc_{13}}{d\tau} = 0.5k'_{18}c_{12} - 0.5k'_{-19}c_{11}c_{13} - k'_{20}c_2c_{13},$$

$$c_2 = c_2^0 - 3(c_1 - c_1^0) - 4(c_3 - c_3^0) - 3(c_4 - c_4^0) - 3(c_5 - c_5^0) - 4(c_6 - c_6^0) - 5(c_7 - c_7^0) - 2(c_8 - c_8^0) - 2(c_{10} - c_{10}^0) - (c_{12} - c_{12}^0) - (c_{13} - c_{13}^0),$$

Table 1. Rate constants and activation energies of the process stages

k'_{16}	33.8	29.9			

$$c_{11} = c_{11}^0 + (c_1^0 - c_1) + 2(c_5^0 - c_5) + (c_6^0 - c_6) + 2(c_8^0 - c_8) + 3(c_9^0 - c_9) + (c_{10}^0 - c_{10}) + 3(c_{12}^0 - c_{12}) + 2(c_{13}^0 - c_{13}),$$

where c_1 is the concentration of CF_3–$CClH_2$ (Freon 133a), c_2 is that of HF, c_3 is that of CF_3–CFH_2 (Freon 134a), c_4 is that of CF_3–CH_3 (Freon 143a), c_5 is that of CF_3–CCl_2H (Freon 123a), c_6 is that of CF_3–CFClH (Freon 124a), c_7 is that of CF_3–CF_2H (Freon 125), c_8 is that of CF_2Cl–$CClH_2$ (Freon 132a), c_9 is that of C_2HCl_3 (trichloroethylene), c_{10} is that of CF_2=CClH (1,1-difluorochloroethylene), c_{11} is that of HCl, c_{12} is that of $CFCl_2$–$CClH_2$ (Freon 131), c_{13} is that of CFCl=CClH (1-fluoro-1,2-dichloroethylene); and k_i are the kinetic constants:

$$k_\Sigma = 2\frac{k'_{14}k_{13}k_{12}}{k'_{-13}k_{-14}},\ k_\sigma = \frac{k_{-14}k'_{14}k'_{-15}}{k_{-15}k'_{-13}},\ k_n = \frac{k_{-3}k'_3}{k_{-3} + k_4},$$

$$k_t = \frac{k_{-3}k'_{-4}}{k_{-3} + k_4},\ k_{50} = \frac{k_{-1}k'_{10}}{k'_{10} + k_{11}},$$

$$k'_i = k_i[\text{=Cr–F}];\ [\text{=Cr–F}] \approx \text{const}.$$

The constants were determined by regression analysis. The functional to be minimized was the weighted sum of squared deviations of the experimental and calculated concentrations. As a procedure of numerical integration, we used the LSODA method designated for solving rigid systems of differential equations [9]. The functional was minimized by the Gauss–Newton method.

The kinetic constants obtained are listed in Table 1. The developed kinetic model is adequate in the

* Molar ratio HF : CF_3–$CClH_2$ = 4 : 1, 380°C
** Molar ratio HF : C_2HCl_3 = 3.4 : 1, 200°C.

following intervals of the process parameters: temperature 175–420°C; molar ratio of reactants HF : $C_2H_2ClF_3$ = (2–18) : 1 and HF : C_2HCl_3 = (3.4–13.6) : 1.

Using this kinetic model, we studied the influence of the process parameters on the main reaction stages. The influence of pressure was studied under the following conditions: molar ratio of reactants HF : C_2HCl_3 = 3.4 : 1, 200°C (first stage); HF : Freon 133a = 4 : 1, 380°C (second stage); and contact time τ = 10 s. The course of the process was analyzed at a pressure of 1, 3, 6, and 10 atm. The results of evaluation (Figs. 1, 2) show the following.

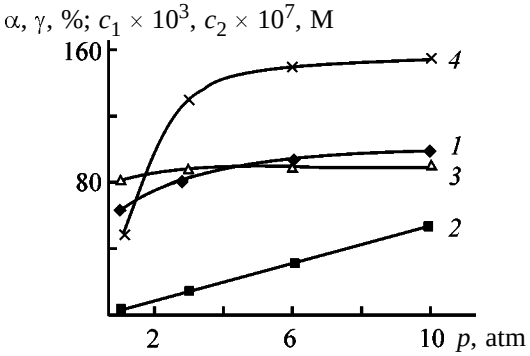

Fig. 1. Hydrofluorination of trichloroethylene: (*1*) conversion of trichloroethylene α, (*2*) concentration of 2-chloro-1,1,1-trifluoroethane $c_1 \times 10^3$, (*3*) selectivity with respect to 2-chloro-1,1,1-trifluoroethane γ, and (*4*) concentration of 1,1,1,2-tetrafluoroethane $c_2 \times 10^7$; (*p*) pressure.

(1) In the stage of trichloroethylene hydrofluorination with hydrogen fluoride to Freon 133a, conversion of trichloroethylene increases (to 95–97%) with increasing pressure to 6 atm, the selectivity with respect to Freon 133a increases up to a pressure of 3 atm and then becomes practically constant (approximately 90%); the concentration of Freon 134a increases up to a pressure of approximately 6 atm and then increases insignificantly, but the yield of by-products increases. Thus, increase of the pressure above 6 atm is not appropriate.

(2) In the stage of hydrofluorination of Freon 133a

7	–	CF_3–$CClH_2$ ~ 100	CF_3–$CClH_2$ 82.39, CF_3–CFH_2 16.93, CF_2=CClH 0.15, others 1.13
8	Mixture of CF_3–CFH_2 and CF_2 = CClH	CF_3–$CClH_2$ 71.45, CF_3–CFH_2 25.41, CF_2 = CClH 1.56, others 1.58	CF_3–$CClH_2$ 56.66, CF_3–CFH_2 41.12, CF_2=CClH 0.10, others 2.12

* Reactor with fixed catalyst bed, V = 0.25 l (run nos. 1–3) and with fluidized catalyst bed, V = 0.4 l (run nos. 4–8); molar ratio HF : CF_3–$CClH_2$ = 8.3 : 1 (run nos. 1–3), 10 : 1 (run nos. 4–6), 19.6 : 1 (run nos. 7 and 8); temperature 400 (run nos. 1–3), 420 (run nos. 4–6), and 380°C (run nos. 7 and 8); residence time 4.8 (run nos. 1–3), 6.1 (run nos. 4–6), and 4.3 s (run nos. 7 and 8; with addition of a mixture of CF_3–CFH_2 and CF_2=CClH, 3 s).

with hydrogen fluoride, an increase in the pressure results in decreased conversion of Freon 133a; in this case, the conversion is decreased to the greatest extent in the pressure range from 1 to 3 atm (from 22.3 to 15.8%). At a higher pressure, the conversion becomes practically constant (14.6–14.9%). Thus, elevated pressure has a detrimental effect on this stage.

Calculated data on the effect of adding various components of the reaction mixture at the reactor inlet are listed in Table 2.

Our results show that addition of 2-chloro-1,1-difluoroethylene decreases the degree of its formation in the course of synthesis, i.e., in the process a mixture of Freon 134a and 2-chloro-1,1-difluoroethylene can be supplied to the reactor inlet for subsequent recovery. In a similar manner, addition of Freons 125 and 143a into the initial mixture decreases the degree of their formation in the course of synthesis. However, the presence of hydrogen chloride in the initial mixture in the stage of formation of Freon 134a from Freon 133a decreases the yield of Freon 134a. The results of the experiments confirmed the validity of evaluation of the influence of the process parameters (Table 3).

CONCLUSIONS

(1) Study of the process of 1,1,1,2-tetrafluoroethane production using the developed kinetic model describing the process in the temperature range 175–420°C at a molar ratio of reagents HF : $C_2H_2ClF_3$ = (2–18) : 1, HF : C_2HCl_3 = (3.4–13.6) : 1 showed that an increase in pressure to 6 atm has a positive effect on the conversion and selectivity in hydrofluorination

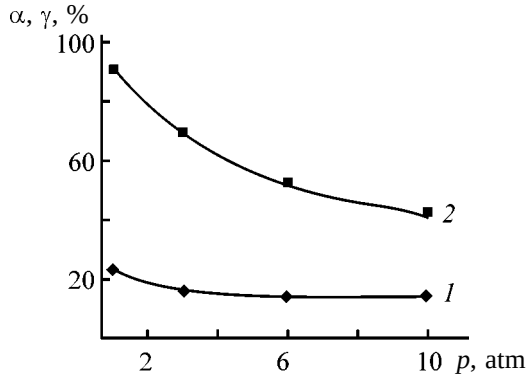

Fig. 2. Hydrofluorination of 2-chloro-1,1,1-trifluoroethane: (*1*) conversion of 2-chloro-1,1,1-trifluoroethane α and (*2*) selectivity with respect to 1,1,1,2-tetrafluoroethane γ; (*p*) pressure.

of trichloroethylene. However, in hydrofluorinaton of 2-chloro-1,1,1-trifluoroethane, an increase in pressure to 3 atm adversely affects the process.

(2) A partial return of by-products (pentafluoroethane, 1,1,1-trifluoroethane, and 2-chloro-1,1-difluoroethylene) to synthesis decreases their formation in the synthesis.

(3) Owing to reversibility of 2-chloro-1,1,1-trifluoroethane hydrofluorination, the presence of hydrogen chloride in the initial reaction mixture adversely affects the process of 1,1,1,2-tetrafluoroethane production. Removal of hydrogen chloride from the reaction area is favorable for increasing the yield of the target product.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymeric Materials Derived from Vanillic Acid

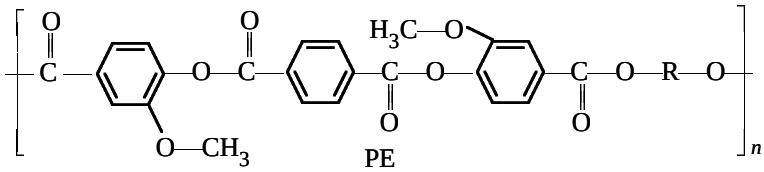
Received January 23, 2002

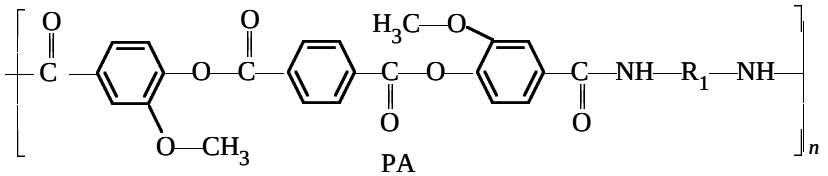
Abstract—Film and fibrous materials derived from vanillic acid, one of promising products from processing of industrial lignin, were prepared and characterized. Thermochemical reactions of degradation and carbonization of films and fibers of vanillic acid polyesters and polyamides were considered, and the main relationships of thermal transformations of the materials were revealed.

Industrial lignin is one of major intermediates in chemical processing of wood. Subsequent processing of lignin yields such important products as vanillin, vanillic acid (VA), phenol and its derivatives, pyrocatechol, etc. [1, 2]. From the viewpoint of polymer chemistry, VA (3-methoxy-4-hydroxybenzoic acid) is of the most interest among these products. On the one hand, the presence of a side methoxy group increases the solubility and fusibility of polyamides (PAs) and polyesters (PEs), which simplifies production of materials therefrom. On the other hand, a new possibility is opened up for synthesis of PEs with mesogenic groups in the backbone chain, by analogy with synthesis of PEs from *p*-hydroxybenzoic acid [3, 4]. As for polyamides derived from VA, they show promise as heat-resistant binders exhibiting enhanced adhesion in production of prepregs from technical fabrics.

In our study, we used the following polyesters and polyamides derived from VA:



PE



PA

where R = $-(CH_2)_6-$ (PE-1), $-(CH_2)_{10}-$ (PE-2),  (PE-3),  (PE-4),

 (PA-1),  (PA-2),  (PA-3),

 (60%) +  (40%) (PA-4).

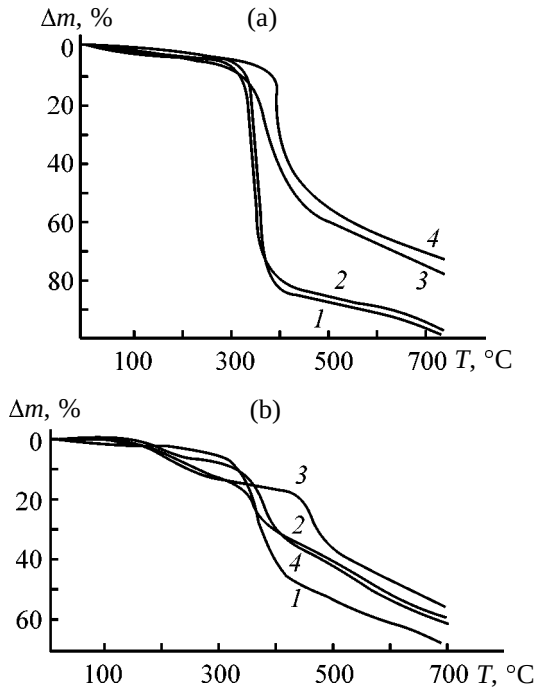

Fig. 2. TG curves for (a) polyesters and (b) polyamides derived from VA. (Δ*m*) Weight loss and (*T*) temperature.

The polymers were prepared as described in [3]. Polymer films were cast from solutions in *N*-methylpyrrolidone on glass supports and dried to constant weight at 115–120°C. The films were 30–50 μm thick. Fibers were formed on a PIFV-01 installation by a wet procedure, using a 1/0.4 die and an ethylene glycol–ethanol (1 : 1 by volume) precipitation bath.

The films and fibers were tested on an Instron-1145 tensile-testing machine. The following parameters were determined: tensile strength σ_t, enlogation at break ε_b, and modulus of elasticity *E*. Thermal analysis (TGA and DTA) was performed with an MOM derivatograph (Hungary), model C, heating rate 10 deg min^{-1}, sample weight 50 mg.

All the polymers prepared are soluble in aprotic polar solvents. Solutions for forming films and fibers were mainly prepared in *N*-methylpyrrolidone; the solubility in dimethylformamide and dimethylacetamide was also estimated qualitatively. The forming solutions had the instrinsic viscosity at 25°C ranging from 3.0 to 3.5 dl g^{-1}.

Data on fusion and softening of samples were obtained by thermal analysis, primarily DTA. Figures 1a ad 1b show the DTA curves of VA polyesters and polyamides; the endothermic effects observed with some samples are due to melting. It can be readily seen that the quantitative characteristics of these effects (peak temperatures and areas) depend on the chemical structure of radicals R and R_1. For example, PE with long aliphatic units in the chain (PE-1, PE-2) show noticeable ordering: Mesomorphic structures are observed, responsible for the endothermic minima at 127 and 190°C. As the aliphatic units are replaced by aromatic groups, especially by those with a pendant phenyl substituent (PE-4), the structural ordering of the macromolecule is broken. The inflections of the DTA curves of PE-3 and PE-4 samples at 235 and 204°C indicate their softening (Fig. 1a, curves *3*, *4*). As for the other thermal characteristics of these samples, asymmetric phenyl substituents in PE-4 render the structure fully amorphous, whereas in the PE-3 sample the *m*-phenylene moiety allows preservation of certain ordering. This is indicated by an endothermic effect (DTA curve with a maximum at 347°C) and by appreciable heat absorption with a maximum at 393°C, accompaied by only insignificant weight loss (Fig. 2a, curve *3*), which allows this effect to be assigned to the polymer melting. As the temperature is increased further, the melt undergoes thermal degradation with release of large amounts of volatiles, mainly carbon oxides according to mass spectrometry.

A different pattern was observed on heating PE-4

in the range 403–445°C corresponding to the onset of the thermal degradation of the polymer. In this case, no endothermic effects of melting are observed, and the DTA curve shows exothermic effects of thermal oxidative degradation with maxima at 431–442°C.

The thermal behavior of VA polyamides appreciably differs from that of VA polyesters. As far as the morphology is concerned, the DTA curves suggest that only PA-1 shows certain ordering, whereas the other PAs have an amorphous structure; this result is consistent with the previous X-ray diffraction and DSC data [5]. Also, as shown by TG curves, in almost all the PA samples the onset of thermal degradation with release of volatiles is observed at approximately 170°C. According to mass spectrometry, initially the polymer–solvent solvation complexes, characterized by relatively high energy in the case of PA [6], are broken down. When the temperature reaches 290–300°C, thermal degradation of the PA backbone starts, with the release of pyrolysis products reaching a maximum at 330–430°C. Calculated data and results of the analysis of the gaseous thermal degradation products, performed for PA-1, show that the thermal degradation of PA is a superposition of cleavage of the ester and amide bonds, with the predominant release of carbon oxides:

Product	O	N	CO	CO_2	H_2O	NH_3	$(CH_3)_2CO$
Content, %	26.0*	5.0	35.3	31.8	22.7	6.1	16.6
of initial structure	–	–	20.2	28.3	6.5	3.0	8.4

* Numerator: content of O, N, and volatiles after complete degradation of PA-1; denominator: actual release of volatiles in the stage of intense degradation (330–430°C).

Thus, examination of the initial stage of thermal transformations of the polymers shows that the fusibility and solubility of PEs are associated with formation of oriented structures, and the solubility and softening of PAs are associated with formation of stable solvation complexes with the solvent.

The TG curves of polyesters (Fig. 2a) show that the PEs containing aliphatic units in the polymer chain are less heat-resistant than PEs containing aromatic grops. This difference is especially noticeable for the degradation rates in the range 335–460°C. By the end of this interval, aliphatic PEs volatilize to approximately 80%, whereas their aromatic analogs at the same temperature lose no more than 25% of their weight. On further heating, PE-3 and PE-4 transform into carbonization products, with the yield of the coke residue of 30–40%. It should be noted that the mesogenic oriented structure allows PEs to withstand dynamic heating to 335°C without noticeable weight loss. For PEs with pendant aromatic substituents in the chain, in which the mobility is restricted by the steric factor, the temperature of the thermal degradation onset increases to 405°C.

Deformation-strength characteristics of films and fibers from PEs and PAs

Polymer bas	σ_t, MPa	ε_b, %	*E*, GPa
Film:			
PE-2*	283	234.0	2.18
PE-3*	68	67.0	1.58
PA-1	125	17.4	3.43
PA-2	159	15.6	4.07
PA-3	136	20.8	2.69
PA-4	225	18.5	5.94
PA-4 fiber	525	14.1	17.8

* Calculated for the initial cross section area of the sample.

For PAs, the pattern of thermal degradation is complicated by decomposition of solvation complexes, stable to 170–180°C. The rate of their degradation, the temperature interval of the solvent release, and the weight of the volatiles evolved in the process depend on the chemical structure of R_1. Active thermal degradation occurs at 310–500°C; the width of this interval for each particular sample is about 70–100°C. The temperature range of degradation depends on the structure of R_1, because its structure governs the intermolecular interaction of PA chains and the mechanism of cross-linking competing with thermal degradation. For example, PA-3 exhibits a plateau of thermal stability in the range 325–440°C, which is due to cross-linking following cleavage of methylene bridges, as noted in [7]. For PA-4, the heat resistance is enhanced by pyrimidine rings introduced into the polymer chain. As for carbonization, all the PAs show a noticeable tendency to cross-linking (coke residue about 40–50%), which makes them promising as heat-resistant binders.

The deformation-strength characteristics of PEs and PAs (see table) show that, with respect to the strength and elasticity, these materials well compete with aromatic compounds of the same class, described in [8].

It should be noted that the mechanical characteristics of PA samples are appreciably improved on introducing rigid 2,5-bis(aminophenyl)pyrimidine fragments into the polymer chain (PA-4); in the course of fiber forming, these fragments exert a cross-linking effect on the system and allow preparation of fibers

with high strength and elasticity without additional thermal and plasticizing stretchings.

CONCLUSIONS

(1) A series of new aliphatic and aromatic polyesters with mesogenic groups in the polymer chain were prepared; from these substances, soluble and fusible materials in the form of films and fibers were prepared by a simple process.

(2) Aromatic polyamides derived from vanillic acid exhibit enhanced heat resistance and are capable of forming fibers and films characterized by a high coke residue in thermal carbonization.

Abstract—Radical polymerization of methyl methacrylate in the presence of 1,3-diphenyl-1-hydroxytriazene and nitrosobenzene as sources of stable nitroxyl radicals was studied.

Recently there has been a considerable progress in a new field of radical polymerization, pseudoliving polymerization. Several approaches were suggested to perform such processes, in particular, introduction into a polymerizing system of stable radicals, e.g., nitroxyl [2,2,6,6-tetramethyl-1-piperidinyloxyl (TEMPO) and its analogs] or carbon-centered, or of iniferters combining the functions of initiators and chain-terminating agents. The most widely used iniferters are alkoxyamines, alkylthiocarbamates, phenylazotriphenylmethane, hexaphenylethane, etc. [1–5]. These compounds effectively control the chain propagation only at temperatures above 100°C and are used exclusively in polymerization of styrene or its analogs, or in copolymerization of styrene with other monomers.

In previous studies, to control the chain propagation under conditions of radical initiation, it was suggested to use spin traps: *C*-phenyl-*N*-*tert*-butylnitrone (PBN) [6–9] and 2-methyl-2-nitrosopropane (MNP) [10], and also a binary iniferter, 1-*tert*-butyl-3-phenyl-1-hydroxytriazene (BPT) + oxidant [11, 12]. These chain-terminating agents allow controllable synthesis of polymers based on (meth)acrylates and even vinyl chloride to high conversions in the range 50–70°C, i.e., at temperatures close to those used in commercial syntheses of the polymers; this is a significant advantage over the previously known chain-terminating agents (phenylazotriphenylmethane, TEMPO, etc.).

In this work, to perform low-temperature controllable radical polymerization of methyl methacrylate (MMA), we suggested to use nitrosobenzene (NB) and 1,3-diphenyl-1-hydroxytriazene (DPT). Using the results obtained and published data [5, 10, 11], we analyzed how the structure of the organic radical in the nitroxyl spin adduct affects the kinetic parameters of MMA polymerization and the molecular-weight characteristics of the polymer.

EXPERIMENTAL

DPT [13] and NB [14] were prepared by published procedures. Dicetyl peroxydicarbonate (DPC) used as initiator, and also the monomers and solvents were purified by common procedures. The physicochemical constants of the chemicals used agreed with the reference data. The polymerization kinetics was monitored gravimetrically, dilatometrically [15], and thermographically [16]. The molecular weight M of the polymer was determined viscometrically [17] and by gel permeation chromatography (GPC) with a Waters device (the United States) equipped with five Styrogel columns (pore diameter 10^5, 3×10^4, 10^4, 10^3, and 250 Å) and an R-403 (Waters) differential refractometer as detector. The eluent was tetrahydrofuran (THF). Calibration was performed with close-cut polystyrene references [18].

The kinetic study of MMA polymerization showed that, in the presence of 0.05–0.15 mol % DPT and 0.1 ml % DPC (widely used radical polymerization initiator), the gel effect regularly decreases with increasing DPT concentration and appears at higher conversions (Fig. 1a). These data are in good agreement with the previously published data on synthesis of polymethyl methacrylate (PMMA) in the presence of BPT [11] and are, on the whole, typical of polymerization under conditions of living chains and reversible inhibition.

Additional information on the mechanism of the polymer chain propagation can be derived from the molecular-weight characteristics of the polymers synthesized. As seen from Fig. 2, a pronounced increase of M of the polymer at the instant of the gel effect for PMMA (curve *1*) synthesized in the presence of DPC initiator is not manifested when DPT is added to the

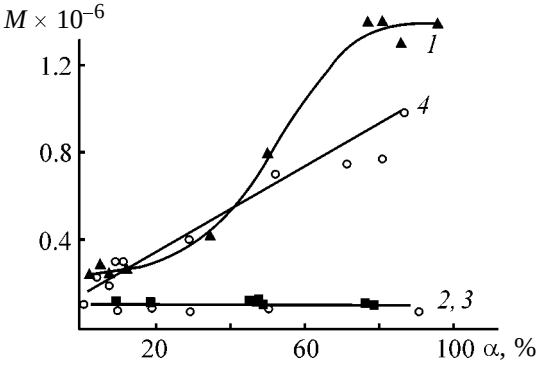

Fig. 2. Effect of DPT and NB on the pattern of variation of the (*1*, *2*, *4*) viscosity-average and (*3*) number-average molecular weight M of PMMA with conversion α. Initiator 0.1 mol % DPC, 323 K; the same for Fig. 3. (*1*) No additives; additive, mol %: (*2*, *3*) DPT, 0.2 and (*4*) NB, 0.06.

reaction mixture (curve *2*). Furthermore, the polydispersity coefficients calculated from the GPC data are 1.4–1.5 at high conversions and are considerably lower than those of the polymer prepared without DPT (see table).

Our results, in total with published data [11, 12, 19], suggest that, in this case, similar to polymerization of acrylic monomers in the presence of BPT, oxidation of DPT with peroxide [reaction (1)] or its reaction with alkoxy radicals [reaction (2)] generates NB, which subsequently reacts with the propagating polymer radical to form stable nitroxyl radical [reaction (3)] terminating the polymer chain [reaction (4)]:

$$\mathrm{Ph{-}N{=}N{-}\underset{\displaystyle OH}{\underset{|}{N}}{-}Ph} \xrightarrow{(O)} \mathrm{Ph^{\bullet} + N_2 + Ph{-}N{=}O}, \qquad (1)$$

$$\mathrm{Ph{-}N{=}N{-}\underset{\displaystyle OH}{\underset{|}{N}}{-}Ph + RO^{\bullet} \rightarrow ROH + Ph{-}N{=}N{-}N{-}Ph}, \qquad (2)$$

$$\mathrm{\downarrow O^{\bullet}}$$

$$\mathrm{Ph^{\bullet} + N_2 + Ph{-}N{=}O}$$

$$\mathrm{\sim Ph^{\bullet} + Ph{-}N{=}O \rightarrow \sim Ph{-}\underset{\displaystyle O^{\bullet}[X^{\bullet}]}{\underset{|}{N}}{-}Ph}, \qquad (3)$$

$$\mathrm{\sim P_n^{\bullet} + {}^{\bullet}X \underset{k_d}{\overset{k_t}{\rightleftarrows}} \sim P_n{-}X}, \qquad (4)$$

(k_p above the propagation arrow)

where $\sim P_n$ is the propagating radical.

To confirm the suggested mechanism, we have studied radical polymerization of MMA in the presence of NB additions. In accordance with the suggested scheme [Eqs. (1)–(3)] and previous data [11], the nitroso compound generated in the course of polymerization should be responsible for formation of stable nitroxyl radicals and subsequent synthesis of the polymer in the controllable mode.

We found that addition of NB in amounts comparable with that of the initiator decreases the gel effect and shifts it to higher conversions (Fig. 1b). Correspondingly, the unimodal curves of molecular-weight distribution (MWD) of PMMA samples are regularly shifted toward higher M (Fig. 3), and the molecular weight of the polymer linearly grows with conversion (Fig. 2), which is one of the most important evidences of the polymerization in the living chain mode.

It should be noted that, in contrast to NB, when the polymerization of MMA is performed in the presence of DPT, M of the polymer does not noticeably increase with conversion (Fig. 2). This may be due to

Molecular-weight characteristics of PMMA (initiator 0.1 mol % DPC, 323 K)

Conversion	$M_n \times 10^{-4}$	$M_w \times 10^{-4}$	$M_\eta \times 10^{-4}$	M_w/M_n
No additive

1,3-Diphenyl-1-hydroxytriazene added				
10	7	13	12	1.8
19	8	12	11	1.5
30	7	12	11	1.5
51	9	14	11	1.7
80	8	12	11	1.5

participation of DPT in chain transfer reactions involving both the phenyl moieties and the labile hydrogen atom of the hydroxy group. Furthermore, relatively low values of M of PMMA synthesized in the presence of DPT may also be due to relatively fast exhaustion of the initiator (DPC) at the beginning of the polymerization, since DPC participates simultaneously in thermal initiation of the polymerization and in the reaction with DPT [reaction (1)]. As a result, no "dead" high-molecular-weight polymer, yielded by a common radical polymerization and contributing to the overall molecular weight of the polymer, is formed. This assumption is indirectly confirmed by relatively low polydispersity coefficients, remaining virtually constant throughout the polymerization (see table).

Comparison of our results with published data on polymerization of MMA in the presence of BPT [11, 12] shows that, despite a good correlation between the results obtained with two different hydroxytriazenes (DPT and BPT), the latter compound is more promising as chain-terminating agent. This may be due to the presence in BPT [and hence in the nitroxyl spin adduct formed from BPT, reactions (1)–(3)] of bulky *tert*-butyl radical. Published data show [19, 20] that the structure of the organic radical at the nitroxyl moiety largely affects the rate constants of the forward (K_t) and reverse (k_d) reactions (4) and also the bond energy in the adduct [~P_n–X]. In particular, nitroxyl radicals with a bulky *tert*-butyl group are more effective as chain-terminating agents in radical polymerization than TEMPO and nitroxyl spin adducts containing an aromatic ring.

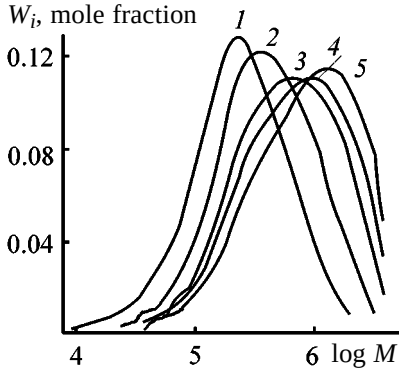

Fig. 3. Molecular-weight distribution of PMMA: (W_1) mole fraction and (M) molecular weight. NB concentration 0.06 mol %. The high-molecular-weight wing of the MWD is not shown because of limited sensitivity of the gel chromatograph in this range of M. Conversion, %: (*1*) 8, (*2*) 30, (*3*) 52, (*4*) 72, and (*5*) 89.

At the same time, an interesting feature of MMA polymerization in the presence of DPT should be noted. DPT actually allows synthesis of PMMA with a constant, independent of conversion molecular weight, which can be important in production of low-molecular-weight castable organic glass.

CONCLUSION

1,3-Diphenyl-1-hydroxytriazene and nitrosobenzene show promise as agents controlling the lifetime of a polymeric chain under energetically favorable conditions. These agents can be used for developing simple and efficient processes for production of low-molecular-weight polymethyl methacrylate in a controlled mode.

Abstract—The kinetic parameters of radical copolymerization of butyl methacrylate and zinc-containing monomer were studied as influenced by the structure and concentration of various emulsifiers such as oxyalkylated alcohols and alkylphenols. Some physicochemical properties of the resulting copolymers were determined.

It is known [1] that the features of radical polymerization in the presence of nonionic emulsifiers differ from those typical for the process performed in the presence of ionic compounds. Based on the constancy of the polymerization rate up to high conversion, cubic dependence of the particle number on the emulsifier concentration, and independence of the particle size from conversion, it was proposed that in this case polymerization proceeds not through the formation of micelles yielding the latex particles, as in the case of ionic emulsifiers, but in the surface layers of the monomer droplets [2].

Study of how the structure and concentration of various emulsifiers (such as oxyethylated alcohols, alkylphenols, and propylene oxide) affect the kinetics of emulsion polymerization and properties of the resulting polymers revealed the following trends in emulsion polymerization in the presence of nonionic emulsifiers.

(1) The increase in the emulsifier concentration relative to the monomer causes certain decrease in the particle size, which is accompanied by increase in the number of the particles and their total surface area; as a result, the polymerization rate and molecular weight of the product increase [3, 4].

(2) The increase in the degree of oxyethylation in a series of various emulsifiers increases the surface activity of the emulsifier [5, 6] owing to the increase in the surface area occupied by a single surfactant molecule in the adsorption layer on the particle surface (with addition of one $–CH_2–CH_2–O–$ group the surface area S increases by 0.055 nm^2). With increasing surface activity, the stability of the initial monomer emulsion and of the resulting latex increases; simultaneously, the particle size decreases and the process rate correspondingly increases.

The above assumptions are based on the data on the emulsion polymerization of styrene in the presence of oil-soluble initiators such as azobis(isobutyronitrile) (AIBN) and benzoyl peroxide (BP) [3–6]. It was supposed that polymerization proceeds in the particle bulk, although the initiator degradation can proceed in the surface layers of the latex particles [6]. Also, in the case of styrene the coordination and chemical interaction between the monomer and emulsifier molecules is virtually absent.

Previously [7], in our study of copolymerization of zinc-containing monomers with acrylates, we suggested that emulsion copolymerization of zinc methacrylate acetate (MAcZn) with alkyl methacrylates in the presence of a water–soluble redox system and a nonionic emulsifier based on oxyethylated alkylphenols proceeds in the adsorption layer on the particle surface. Due to almost total insolubility of MAcZn in methacrylate monomers, polymerization in the particle bulk is impossible. At the same time, the interaction of the zinc-containing monomer with oxyethylated emulsifiers cannot be ruled out [8].

In this work we studied the effect of the nature and concentration of oxyethylated emulsifiers on the kinetics of emulsion polymerization of butyl methacrylate (BMA) with MAcZn and the properties of the resulting products.

EXPERIMENTAL

Zinc methacrylate acetate was prepared by reaction of zinc oxide and a mixture of acetic and methacrylic acids in water at equimolar component ratio [9]. Then zinc dimethacrylate precipitate insoluble in water was filtered off. The content of zinc diacetate was determined from the NMR spectra.

The emulsion copolymerization of MAcZn and BMA was performed in the presence of the ammonium persulfate–sodium dithionite–iron(II) sulfate redox system and nonionic emulsifiers DS-10 [monoalkyl ethers of polyethylene glycol and primary fatty alcohols of the general formula $C_nH_{2n+1}O(C_2H_4O)_mH$, where n = 10–18, m = 8–10] and OP-7 and OP-10 [monoalkylphenyl ethers of polyethylene glycol of the general formula $C_nH_{2n+1}C_6H_4O(C_2H_4O)_mH$, where n = 8–10, m = 6–7 (OP-7) and m = 10–12 (OP-10)]. The monomer : water weight ratio was 1 : 6.

The polymerization rate was monitored by the amount of unchanged monomers in the samples taken from the reaction mixture in the course of polymerization. The polymer was precipitated with isopropanol. The content of BMA was determined on a Tsvet-100 chromatograph equipped with a flame-ionization detector (2 m column length, PEG-6000 sorbent, helium carrier gas, flow rate 35 ml min^{-1}, 120°C). The content of unchanged zinc methacrylate acetate was determined spectrophotometrically [10] after washing out the residual monomer from preliminarily dried samples with subsequent analysis for the content of Zn^{2+} ions in the washing waters.

The effective radius R of the latex particles was determined by turbidimetry [11].

The number of particles in 100 g of latex was calculated from the equation

$$N = m/m_1,$$

where $m = 15A$ is the weight of the polymer (g) per 100 g latex, A is the conversion, $m_1 = 4/3\pi R^3/\rho$ is the weight of a single latex particle (g), R is the effective radius of the latex particles (m), and ρ is the polymer density (g m^{-3}).

The total surface area of the latex particles S (m^2) was calculated from the equation

$$S = NS_1,$$

where $S_1 = 4\pi R^2$ is the surface of a single latex particle (m^2).

The molecular weight of the chain between the cross-links was determined by the Flory–Rehner method [12]. The content of the gel fraction in the polymer was measured by extraction in butyl acetate [13].

The NMR spectra were registered on a Bruker DPX-200 spectrometer with working frequencies of 200 (^{1}H), 12.5 (^{67}Zn), and 44.4 MHz (^{113}Cd) using ampules 10 mm in diameter. A weighed portion of zinc or cadmium methacrylate acetate was dissolved in D_2O (2 ml) or a mixture of D_2O and H_2O (1 : 10). Emulsifiers were added into this solution before the NMR measurements. The molar ratio of the emulsifier and zinc or cadmium salt was determined by ^{1}H NMR spectroscopy.

Study of the radical copolymerization of BMA and MAcZn in the presence of oxyethylated alkylphenols with various degrees of oxyethylation (OP-4, OP-7, and OP-10) showed that the emulsion polymerization occurs only with OP-7 and OP-10 emulsifiers.

The BMA–MAcZn copolymerization in the presence of OP-4 emulsifier is extremely slow, conversion in 24 h does not exceed 3%. The emulsion of the initial monomers is unstable and rapidly segregates, and the size of the initial emulsion and final latex is greater than 170 nm. Realization of the emulsion mechanism starting from certain degree of the emulsifier oxyethylation was observed previously, e.g. in homopolymerization of styrene [5]. This is probably due to the small surface activity of emulsifiers with small degrees of oxyethylation, which is insufficient to provide required stability and dispersion of the emulsion and thus realization of the mechanism of emulsion polymerization.

It was found that the increase in the concentration of OP-7 and OP-10 emulsifiers decreases the particle size and thus makes the system more disperse (see table). As seen by the example of OP-10, with increasing emulsifier content the process rate increases (Fig. 1), which is largely determined by the degree of emulsion dispersion [4]. In this case, the compliance of the dependences derived by Medvedev *et al*. for radical polymerization with participation of nonionic emulsifiers in the surface layer of the latex particles [$V \approx S$ (Fig. 2), $N \approx c_e^3$ (Fig. 3), and $V \approx N^{1/5}$ (Fig. 4), where V is the polymerization rate (% conversion/min), S is the total surface area of the latex particles (m^2), N is the number of particles, c_e is the emulsifier concentration (wt % with respect to monomer)] indicates that copolymerization of BMA and MAcZn proceeds in the adsorption layers on the latex particle surface.

* N_c is the effective density of the polymer cross-linking, R is the effective radius of the latex particles, M_c is the molecular weight of the chain between the cross-links, G is the content of the insoluble gel fraction in the polymer, and α is the conversion in 24 h.

At the same time, comparison of the size of the latex particles stabilized with various emulsifiers (see table) showed that, the larger the size of the emulsifier molecule and the higher the degree of its oxyethylation, the smaller the size of the latex particles. The different performance of oxyethylated alcohol DS-10 and OP-10 with the same degree of oxyethylation (n = 10) is probably due to different area of the phase boundary stabilized with a single surfactant molecule [5, 6, 14].

The emulsifier structure, in particular, the degree of its oxyethylation affects the polymer properties, especially the degree of its cross-linking. It was proposed previously [15] that the cross-linking in the zinc-

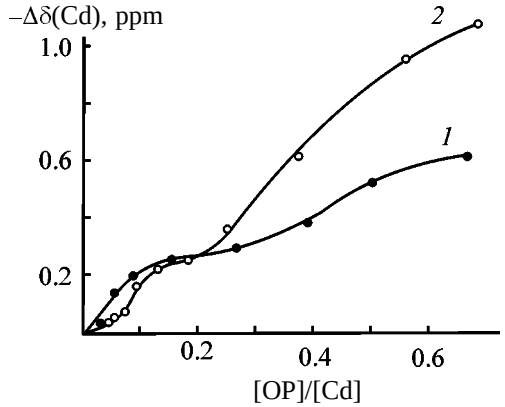

Fig. 5. Chemical shift $-\Delta\delta$(Cd) as a function of the [OP]/[Cd] molar ratio. Emulsifier: (*1*) OP-7 and (*2*) OP-10.

containing polymers is due to complexation of zinc ions with the functional groups of the polymer. Owing to the reaction of the zinc-containing monomer with an emulsifier in the adsorption layer on the particle surface, the polymer cross-linking depends on the emulsifier structure. The larger the size of the emulsifier molecule and the higher the degree of its oxyethylation, the lower the efficiency of the polymer cross-linking N_c, which is probably due to the steric hindrance.

It should be noted that the effective density of the polymer cross-linking depends only on the emulsifier structure, but is independent of its concentration (see table). As shown by the example of OP-10 emulsifier, the increase in the emulsifier concentration increases the content of the cross-linked fraction in the polymer (G). These features of the behavior of the zinc-containing monomer are probably due to the reaction of MAcZn with the emulsifier in the adsorption layer on the particle surface.

The ^{67}Zn NMR signals are broadened owing to the quadrupole moment of the ^{67}Zn nucleus; the width of the zinc methacrylate acetate signal in D_2O exceeds 1200 Hz. With increasing emulsifier concentration, the signal becomes still broader and finally disappears. The quadrupole broadening depends on the symmetry of distribution of the electrical charges around the nucleus. This symmetry is probably decreased owing to the substitution of the water molecules in the zinc environment by the ether fragments of the emulsifier molecule.

Since observation of the chemical shift of ^{67}Zn is rather difficult, in our study we used the monomer containing the closest analog of zinc, cadmium methacrylate acetate. As seen from Fig. 5, with increasing content of emulsifier the chemical shift of the ^{113}Cd signal [$\Delta\delta$(Cd)] increases. The chemical shift observed in presence of OP-10 emulsifier is greater than that with OP-7 emulsifier. This agrees with weaker interaction of OP-7 emulsifier with cadmium methacrylate acetate. In the case of zinc methacrylate acetate, the weaker interaction with OP-7 emulsifier corresponds to higher density of cross-linking of the polymer prepared in the presence of OP-7 emulsifier.

CONCLUSIONS

(1) Realization of the emulsion mechanism of copolymerization of zinc methacrylate acetate with butyl methacrylate depends both on the type of the nonionic emulsifier (oxyethylated alcohol and alkylphenols) and the degree of oxyethylation. Copolymerization of zinc methacrylate acetate with butyl methacrylate proceeds in the adsorption layers on the surface of the latex particles.

(2) The emulsifier structure, in particular, the degree of its oxyethylation affects such physicochemical properties of the polymer as effective density of cross-linking and content of the cross-linked gel fraction. The effective density of cross-linking is independent of the emulsifier concentration.

(3) The interaction of zinc methacrylate acetate with oxyethylated emulsifiers such as oxyethylated alcohols and alkylphenols was confirmed by NMR spectra. The efficiency of this interaction depends on the degree of the emulsifier oxyethylation.

Abstract—Effect of anionic polysaccharide, sodium alginate, on the rheological characteristics of gelatin gels is studied. It follows from the rheological curves that low-temperature gelatin gels with sodium alginate can be classified with elastoviscoplastic systems. Multicomponent gels obtained with the two gel-forming agents demonstrate synergism of the rheological characteristics.

Thanks to their specific gel-forming, emulsifying, and stabilizing characteristics, systems protein–polysaccharide–water are widely used in pharmacy, microbiology, medicine, and other branches. Hydrogels based on gelatin and anionic polysaccharides find wide applications in the food industry, being of interest in view of developing new synthetic food substances [1, 2].

Gels of gelatin are two-phase lyophilic disperse systems. Thermoreversible structurization in gelatin gels occurs on cooling below 35°C through renaturation of collagen-like spirals followed by separation of a new phase (aggregates of gelatin macromolecules) and formation of a three-dimensional gel structure [3, 4]. Contacts between the aggregates can be realized through H bonding and also through hydrophobic and Coulombic interactions. A model for the structural network in gelatin gel can be thought as a combination of elastic (triple collagen-like spirals serving as network junctions) and viscous chain units (disordered polypeptide fragments). These units form an infinite cluster characterized by a set of rheological parameters typical of a solid [5]. Mechanical properties of gelatin gels are thoroughly studied in [3, 6–11] using rheological methods.

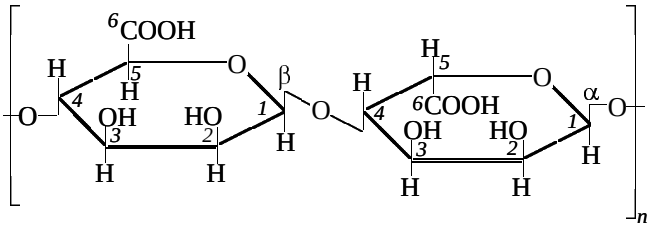
Complexation of proteins with anionic polysaccharides, including that of gelatin with sodium alginate (NaAlg), is examined in [1, 12, 13]. The resulting complexes are considered as gelforming agents of a new type, on the basis of which food gels with various properties can be obtained [14–16]. Rheological properties of such gels are insufficiently studied yet.

Therefore, the goal of this work is to study rheological characteristics of multicomponent gels of gelatin with sodium alginate. Particularly, we studied the effect of the anionic polysaccharide concentration on the rheological behavior of gelatin gels. Sodium alginate was added in low concentrations at which the polysaccharide itself does not act as a structuring agent, but has a positive synergistic effect on the gel-forming properties of the mixed systems.

EXPERIMENTAL

In the work we used food-grade gelatin 250. Isoelectric point pI 4.9; moisture content 10.4 wt % (20°C); and ash content (20°C) 0.87. The molecular-weight distribution determined by HPLC is given in Fig. 1a. The weight-average molecular weight M_w was found to be 109 000.

Also we used food-grade sodium alginate (produced by the Arkhangelsk Algal Pilot Plant). This polysaccharide is a sodium salt of alginic acid, whose molecules consist of the residues of β-*D*-mannuronic and α-*L*-guluronic acids:



β-*D*-mannuronic acid residue

α-*L*-guluronic acid residue

The molecular-weight distribution of NaAlg, determined by HPLC, is given in Fig. 1b; M_w = 366 000, moisture content 12.6 wt % (20°C), ash content 17.1 wt %, and content of fraction insoluble in boiling water 0.3 wt %.

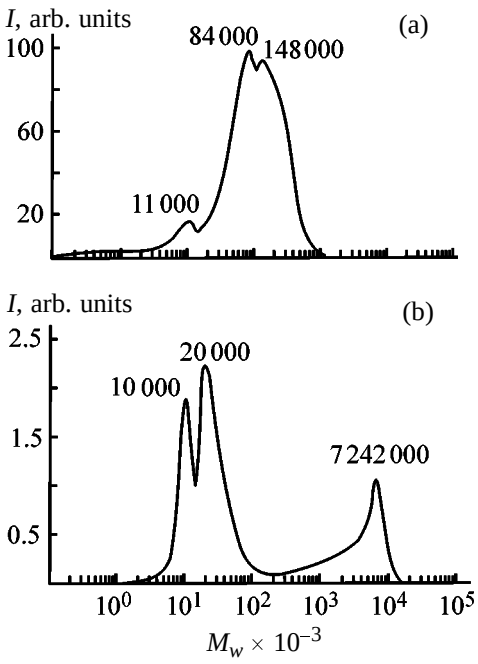

Fig. 1. Molecular-weight distribution determined by HPLC: (a) gelatin and (b) sodium alginate. (*I*) Peak intensity and (M_w) weight-average molecular weight.

In this work we studied low-concentration gels (c_g = 1%, c_{NaAlg} = 0.0001–0.15%) at 16°C and pH 5.3–6.0. It should be pointed out that NaAlg does not form gels under these conditions. It is typical for this polysaccharide to form ionotropic rather than thermotropic gels [17].

Turbidimetric results obtained at pH 5.8–6.0 (pH > p*I*) showed that gelatin interacts with NaAlg with formation of finely dispersed insoluble complexes. The effective size of the resulting particles in the bulk was determined at 40°C by the light scattering variance method (turbidity spectrum) [18]. The effective radius *R* of the particles increases with time from 50–100 to 590–920 nm, depending on the NaAlg concentration in the system (see table). The occurrence of an induction period as well as the observed variation in the particle size in time suggest that complexation proceeds by the nucleation mechanism. The system, representing a suspension of particles of insoluble complexes, remained stable over the observation period (6 days), i.e., no macroscopic phase separation was observed.

Variation of the effective radius of particles *R* with time *t* in aqueous gelatin–sodium alginate systems at c_g = 1.0% and various sodium alginate concentrations (T = 40°C, pH 5.8–6.0)

Formation of the complexes from the likely (negatively) charged macromolecules of gelatin and anionic polysaccharide (pH > p*I*) can proceed through hydrophobic interaction, hydrogen bonding, and also salt-like interaction between positively charged amino acid (lysine and arginine) residues of gelatin and negatively charged groups of the polysaccharide. Formation of similar complexes of proteins with polysaccharides was examined in [1]. The observed aggregative stability of the system is probably due to the fact that the resulting complexes are likely charged, which prevents aggregation and macroscopic phase separation. At pH < p*I*, gelatin reacts with NaAlg with formation of neutral complexes, resulting in separation of the system into two phases accompanied by coacervation [19].

Rheological characteristics of low-concentration mixed gelatin–NaAlg gels was measured at 16±0.1°C with shear stress using a Polimer RPE-1M.2 rotary concentric-cylinder viscometer (radius of outer cylinder 20.0 mm, outer to inner cylinder radius ratio R_o/R_i = 1.03). The effective viscosity was determined over the shear rate range $\dot{\gamma}$ = 0.7–708.8 s^{-1}. The shear stress was estimated by Eq. (1):

$$\tau = \eta\dot{\gamma}, \quad (1)$$

where τ is the shear stress (Pa) and η is the effective viscosity (Pa s).

The Reynolds number was found to be no more that 254.6, confirming the laminar type of motion in the investigated systems in measuring the effective viscosity.

It is known that rheological characteristics of gelatin-based gels change with time as a result of structurization processes occurring in the gels below the gelation temperature [3]. Gelation in gelatin-based systems was demonstrated to be a kinetically controlled process, which, once starting, continues prac-

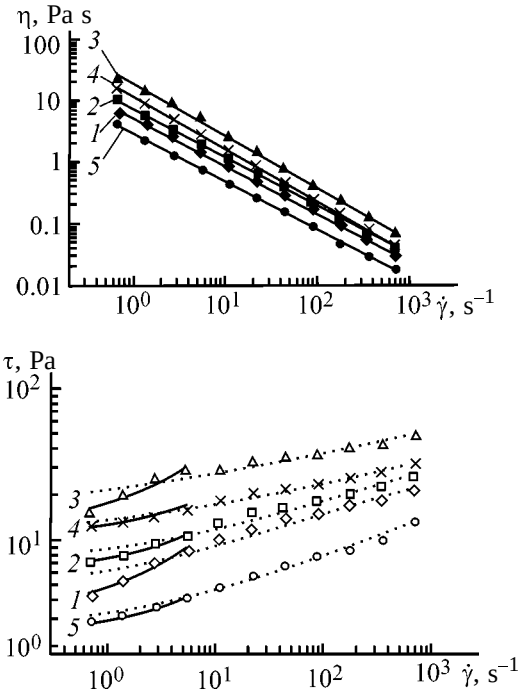

Fig. 2. Flow curves of multicomponent gels of gelatin with sodium alginate. c_g = 1.0%, 16°C, pH 5.2–5.6, and time of gel formation 4 h; the same for Fig. 3. (η) Effective viscosity, (τ) shear stress, and ($\dot{\gamma}$) shear rate. c_{NaAlg} (%): (*1*) 0, (*2*) 7.0×10^{-4}, (*3*) 1.3×10^{-3}, (*4*) 1.8×10^{-3}, and (*5*) 1.4×10^{-2}. Dashed and solid lines in the τ–$\dot{\gamma}$ plot refer to the Herschell–Bulkley and Casson's models, respectively.

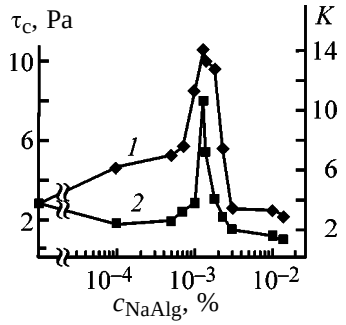

Fig. 3. Rheological characteristics of gelatin gels with sodium alginate: (*1*) yield point τ_c and (*2*) consistency index *K*. (c_{NaAlg}) Sodium alginate concentration.

tically endlessly [20], making rheological study difficult. Nevertheless, it appeared possible to determine the time of gel formation after which the mechanical characteristics increased only slightly. The strength of the gelatin–NaAlg gels studied is practically saturated in 4–5 h at 16°C.

As an example, Fig. 2 shows the flow curves of gelatin–NaAlg gels, measured 4 h after the gelation started. The effective viscosity is a function of the shear rate, the shape of this function being dependent on the component ratio in the system. For the case of simple shear in the nonlinear viscoelastic range, the shear stress fits the Herschell–Bulkley model [21, 22]:

$$\tau = \tau_c + K\dot{\gamma}^n, \quad (2)$$

where τ_c is the yield stress (Pa), *K* is the consistency index, and *n* is the flow index (0.20–0.35 for the systems studied).

There is an initial section of the elastic state in the flow curves, where the shear stress is below the yield stress: $\tau < \tau_c$. In this region, elastic deformations are totally reversible, and the system can be described by the modulus of elasticity. At the same time, it follows from the results obtained in [23] that gelatin gels with a viscosity of 10^8–10^{11} Pa s demonstrate long-time steady afterflow linearly depending on the concentration, suggesting the lack of the equilibrium modulus of elasticity in physical gelatin gels.

The rheological behavior of the gels studied at low shear rates (0.7–5.5 s^{-1}) can be described with a sufficient accuracy by the Casson's model [21, 22]:

$$\tau^{1/2} = \tau_c^{1/2} + (\eta_p\dot{\gamma})^{1/2}, \quad (3)$$

where η_p is the plastic viscosity (Pa s).

For the gels studied, the plastic viscosity varies within the range from 0.06 to 0.95 Pa s.

As seen from Fig. 2, both models reproduce quite adequately the rheological behavior of the gels. The yield stress values, characterizing the strength of the gels, estimated using the Herschell–Bulkley and Casson's models, differ from each other by no more than 6%. Therefore, analysis of the rheological curves (Fig. 2) allows classification of low-concentration gelatin–NaAlg gels with elastoviscoplastic systems.

As an example, Fig. 3 shows the dependences of the yield stress τ_c (curve *1*) and consistency index *K* (curve *2*) on the NaAlg concentration. It is seen that the rheological characteristics of the gels are controlled by the component ratio. The curves show distinctly pronounced maxima, i.e., combination of gelatin and NaAlg provides a synergistic effect. The peak values of the rheological characteristics are observed at $c_{NaAlg} = 1.3 \times 10^{-3}$%, at which complexes with the maximal effective radius of particles are formed (see table). Similar results were obtained also for other rheological parameters such as the flow index *n*

and plastic density η_p. With increasing NaAlg concentration ($c_{NaAlg} > 1.8 \times 10^{-3}$%) the rheological characteristics abruptly decrease, and at $c_{NaAlg} > 3.0 \times 10^{-3}$% they become lower than those of gelatin gels containing no NaAlg.

The rheological methods are sensitive to evolution of the microscopic structure of the gels [4]. The maximal strength of the gelatin–NaAlg gels (Fig. 3) corresponds, evidently, to the maximal number of salt-like bonds formed between the components at pH > p*I*. In this case, the effective particle size is the maximal (see table). It was demonstrated in [24] that the degree of spiralization of the gelatin macromolecules in mixed gels decreases and the thermal stability of triple-stranded collagen-like spirals increases with increasing relative NaAlg concentration, as for association of gelatin with low-molecular-weight surfactants [25]. Stabilization of the three-dimensional structure of gelatin–NaAlg gels, as compared to straight gelatin gels, was attributed in [24] to transformation of the initial salt-like bonds with formation of an electrostatically bonded network. This is most clearly pronounced at pH below the isoelectric point of gelatin and with long aging of the gel (for more than 15 h) [6]. Evidently, high content of NaAlg in the system (in our case $c_{NaAlg} > 3.0 \times 10^{-3}$%) suppresses to a considerable extent the interactions, primarily electrostatic, between the likely charged macromolecules of gelatin and the polysaccharide. As a result, gelatin gels filled with sodium alginate are formed [15].

CONCLUSION

Rheological behavior of gelatin gels with the anionic polysaccharide, sodium alginate, is studied for various gel compositions at pH above the isoelectric point of gelatin. Rheological parameters (yield point, consistency index, and plastic viscosity) of multicomponent gels measured under shear stress conditions are characterized by a distinctly pronounced composition dependence, reaching the maximal values at a fixed component ratio [$(1.3–5.4) \times 10^{-3}$ g NaAlg per gram gelatin). Low-concentration gels (c_g 1%, c_{NaAlg} 0.0001–0.15%) represent elastoviscoplastic systems.

Combination of two gel-forming agents, gelatin and sodium alginate, provides synergism in the rheological properties of the resulting multicomponent gels.

Received July 9, 2001

Abstract—Transformations of polymers containing C_{60} fullerene: poly-*N*-vinylpyrrolidone with the complex and covalent-graft structure, polyphenylene oxide with the complex structure, and polyethylene glycol and polystyrene with beam structure, were studied by differential scanning microcalorimetry. The observed effects were assigned to the change in nanofragmentary topology on heating.

Fullerenes and fullerene-containing compounds, including polymers, are of scientific and practical interest. Fullerene molecules are characterized by nanometric ordering owing to the presence of developed π-electron system in their molecules. A domain structure ordered at a distance of up to 60 nm is formed in solutions of C_{60}-containing polymers with starlike and complex structures [1, 2]. Okamura *et al.* [3] showed that ordering of the polymer in solutions appreciably depends on the solvent: the domain structure is formed in aromatic solvents and is absent in nonaromatic solvents. Hence, the solid-state properties of fullerene-containing polymers can depend on their structural transformations in solution.

In this work we studied the influence of the type of C_{60}–polymer interaction on calorimetric properties of fullerene-containing polymers [poly-*N*-vinylpyrrolidone (PVP), polyphenylene oxide (PPO), polyethylene glycol (PEG), and polystyrene (PS)] with complex, graft, and starlike structures.

EXPERIMENTAL

Thermograms of the polymers were recorded on a DSM-2M scanning microcalorimeter in the temperature range 30–400°C with the scanning rate of 16 deg min^{-1} (8 deg min^{-1} for graft PVP). Several successive scans were made. To determine the content of volatile products (residual solvents or thermolysis products), the capsules were weighed after the measurements. The threshold sensitivity of the calorimeter was 0.04 mW.

In Table 1, we summarize the main preparation procedures of the polymers, data on the structure and content of C_{60} in the polymer, and the parameters of molecular structure of the polymers with different nature of C_{60} bonding: complex in PVP 1 (C-C_{60}), PVP 2 (C-C_{60}), and PPO (C-C_{60}); covalent graft in PVP 3 (gr-C_{60}); covalent in hexagonal star PS_6-C_{60}; and covalent cross-linked in trigonal star PEG_3-C_{60}.

Table 1. Main properties of the examined polymers

Sample no.*	Polymer	C_{60}, %	Molecular properties**
1	PVP 1 (C-C_{60}) [4]	1	MW = 10^4
2	PVP 2 (C-C_{60}) [4]	1	MW = 10^3, MWD = 1.5
3	PVP 3 (gr-C_{60})	3	Partially cross-linked with irregular network
4	Precursor of PVP 1 (C-C_{60}) PVP 1 (C-C_{60})	0	MW = 70×10^3, broad MWD
5	PPO (C-C_{60})	1	MWD = 1.5
6	Initial PPO	0	MW = $(55–100) \times 10^3$
7	PS_6-C_{60} [5]	2	MWD = 1.03
8	Initial PS	0	MWD = 1.05–1.1
9	PEG_3-C_{60}	0.5	MW = 10^3, partially cross-linked

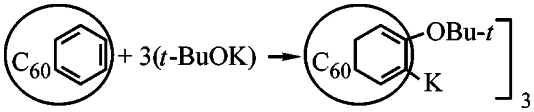
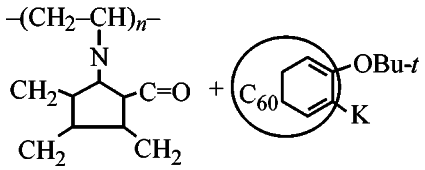
Sample nos. 1 and 2 were prepared by mixing 1% solutions of C_{60} in toluene and PVP in chloroform. The resulting solution was evaporated to dryness. The dry residue containing 1% C_{60} and 99% PVP was dissolved in distilled water, and unchanged C_{60} was filtered off. Powdered C_{60}–PVP complex was obtained by lyophilic drying of the filtrate. Complexes of polymer nos. 1 and 2 with C_{60} were prepared from commercial PVP with MW = 70×10^3 and from the polymer with a lower polydispersity (MW = 1×10^3), respectively.

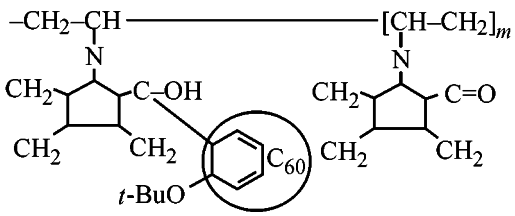
Graft polymer no. 3 was prepared by activation of C_{60} with *t*-BuOK [4]. The first step involves addition of three *t*-BuOK molecules to C_{60}:



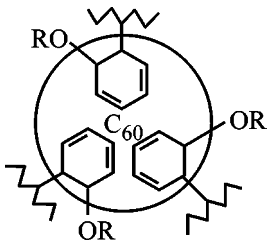
The second step is reaction of the C_{60}-C group with the carbonyl groups of pyrrolidone rings



to form both (a) linear and (b) partially cross-linked polymer containing C_{60}.



(a)



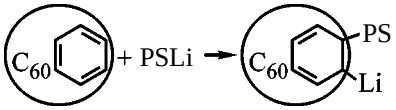
(b)

(R) OBu-*t*, (⩙⩙) PVP chain.

PEG_3–C_{60} was prepared by reaction of C_{60} with polyethylene glycol dialkoxide, which, in turns, was obtained by reaction of polyethylene glycol with metallic potassium in toluene. In this case, two terminal OK groups of polyethylene glycol dialkoxide react with C_{60} to form cross-linked polymer.

(*T*) Temperature; the same for Fig. 2. Intense liberation of volatile products is indicated with an arrow. Figures to the right of the curves corresponds to sample nos. in Table 1.

Polymer no. 7 was prepared by reaction of C_{60} with polystyryl lithium chains [5]:



The thermograms of the fullerene-containing and initial polymers are shown in Figs. 1a (first scan) and 1b (second scan). The total thermal effect $\Sigma\Delta H$, the peak temperatures T_{max} of these effects in the first and second scans, and the weight loss of capsules after scanning Δm are summarized in Table 2.

The endothermic peaks have a peculiar shape of a hole but not the shape of step or sharp maxima typical for vitrification or melting, respectively. Such peaks are typical for vitrification with liberation of volatile products. Similar results were obtained when studying soprtion of water by PVP [6].

Figure 1 and Table 2 show that introduction of C_{60} into PVP polymers strongly affects their calorimetric

properties. The peaks of polymer nos. 1 and 3 are broader than that of the initial polymer no. 4.

The thermal effect of graft polymer no. 3, registered in the first and second scans, is broader by 130–140°C than that of the initial polymer. It should be noted that no intense evolution of gaseous products was observed on heating of this sample to 290°C, whereas, on the first heating of the initial polymer no. 4, gaseous products evolved at 140°C.

This cannot be due to the presence of large amounts of impurities in the polymer, since the weight loss Δm of the initial polymer is smaller than that of the fullerene-containing polymers. Hence, PVP polymer with grafted C_{60} undergoes thermolysis at higher temperatures. It should also be noted that the endothermic effect manifested in the first scan as a single peak is resolved into two peaks in the second scan. Thus, introduction of C_{60}, on the one hand, enhances the thermal stability of the polymer and, on the other hand, results in the formation of energetically different fragmentary structures during the first heating.

Formation of energetically different structures during the first heating of graft PVP is confirmed by three scans of the thermogram (Fig. 2). Comparison of the first and third scans (scanning rate 16 deg min^{-1}) with the second scan (scanning rate 8 deg min^{-1}) shows temperature redistribution of the endoeffect. In the second slower scan, a three-step thermal effect appears after the single peak. In the third scan, the three-step peak is also observed; at temperatures below 300°C the peaks are noticeably shifted, but above 300°C the thermogram does not appreciably differ from that obtained in the second scan. Since in this case no intense liberation of volatile thermolysis products is observed up to 400°C, these peaks can be assigned to transformations of the structural topology of the sample.

Introduction of fullerene into PVP [sample PVP 2 (C-C_{60})] does not appreciably improve the thermal properties of the polymer. $\Sigma\Delta H$ and ΔT_{endo} of the

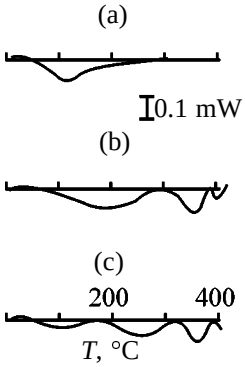

Fig. 2. (a) First, (b) second, and (c) third scans of the PVP 3 (gr-C_{60}) thermograms Thermal effect power 0.1 mW. Scanning rate (deg min^{-1}): (a, c) 16 and (b) 8.

modified polymer, measured in the first scan, are only slightly higher than those of the initial polymer. The onset temperatures of intense evolution of volatile thermolysis products are the same. In the second scan, the total thermal effects are the same, and the temperature of intense evolution of volatile thermolysis products of the modified polymer is lower.

In the first scan, the thermal properties of polymer no. 1 with the complex structure are substantially better than those of the initial polymer: $\Sigma\Delta H$ is higher by 100 kJ kg^{-1} and ΔT_{endo} is higher by 40°C. In addition, no intense thermolysis was observed up to 200°C (thermolysis of the initial polymer starts at 140°C). Hence, formation of a complex structure in PVP 1 (C-C_{60}) increases the thermal stability of the polymer. However, in the second scan the onset temperature of intense liberation of volatile products of PVP 1 (C-C_{60}) and the initial polymer are the same, with $\Sigma\Delta H$ of PVP 1 (C-C_{60}) being slightly lower. This indicates degradation of the complex after the first heating.

Thus, the thermal properties of fullerene-containing polymer nos. 1 and 2 substantially differ. The thermal properties of PVP 2 (C-C_{60}) prepared from the polymer with the lower molecular weight are virtually similar to those of the initial PVP. These results reflect the influence of the structural genesis, in particular, molecular properties of the initial polymer, on the thermal behavior of the modified polymers.

The first scan of the thermogram of PPO (C-C_{60}) complex shows both endo- and exoeffects. $\Sigma\Delta H$ and ΔT of the endoeffect are virtually identical to those of the initial polymer, whereas in the case of the exoeffect these parameters increased by a factor of 2 and by 30°C, respectively. No effects stronger than the determination error were observed in the second scan, which indicates the absence of energetic transformations with thermal effects in both the complex and the initial PPO polymer. Hence, after the first heating PPO is transformed into a thermodynamically stable state. Introduction of C_{60} affects the exothermic but not the endothermic peak and increases the degree of the polymer cross-linking, which is confirmed by $\Sigma\Delta H$ of the first and the second scan and by the fact that the resulting polymer becomes insoluble.

The thermogram of trigonal-star PEG (first scan) contains a broad endothermic peak (ΔT = 170°C). In the second scan, it is broadened to 400°C to form a doublet which, as in the case of PVP 3 (gr-C_{60}), is induced by the first heating.

The endoeffect in the thermograms of fullerene-containing styrene is broader by 100°C than that of the initial PS. The fact that this effect lasts to intense evolution of volatile products indicates higher thermal stability of the modified polymer.

The published data on structural transformations of C_{60}-containing polymers, determined by other methods, agree with our results and their interpretation. The study of free PEG and graft PEG (C-C_{60}) by mass-spectrometric thermal analysis showed an increase in the thermal stability of graft PEG whose pyrolysis temperature increased to 400°C [7]. Quantum chemical calculation of the bonding between C_{60} and PVP and PEG confirmed that formation of grafted and complex structures is thermodynamically favorable [8]. The results of [7, 8] and our calorimetic study show that the thermal stability of graft PVP and graft PEG increases to 400°C. These data agree with the data on the onset temperature of thermolysis of the starlike polymer determined by MTA [9], on the use of C_{60} as inhibitor of thermal oxidative degradation and antioxidant [10, 11], and on the vitrification temperature of PS determined by DSC [12].

The most important result of this work is revealing two- and three-step endoeffects on heating of graft PVP and trigonal-star PEG. These peaks are due to a complex topology of the molecular structure with nanofragmentary separation of these polymers, which changes on heating. The nanodomain structure of the fullerene-containing polymer is formed in solution [1, 2] and is retained in the solid state [13]. Since the size of domains and their bonding energy differ, the nanofragment structure substantially changes on heating, which affects the calorimetric properties.

Thus, DSC performed in a wide temperature range and under different operating conditions gives an insight into high-temperature transformations of fullerene-containing polymers. The mechanism of these transformations can be determined by comparison of DSC and MTA data.

CONCLUSION

The graft structure of C_{60}-containing poly-*N*-vinylpyrrolidone polymers is the most stable. Formation of the complex structure in fullerene-containing polymers strongly depends on the molecular properties of the initial polymer. Multistep enodeffects observed in a wide temperature range in the thermograms of poly-*N*-vinylpyrrolidone with covalent graft structure and in polyphenylene oxide with the complex structure suggest fragmentary structure of these polymers, with its topology changing on heating.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Gradient Semiinterpenetrating Polymer Networks Based on Polyurethane and Polyvinylpyrrolidone

L. V. Karabanova, T. I. Novikova, L. M. Sergeeva, and E. D. Lutsyk

Institute of Chemistry of Macromolecular Compounds, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received March 11, 2001; in final form, April 2002

Abstract—Common and gradient semiinterpenetrating polymer networks based on polyurethane and polyvinylpyrrolidone were prepared. The physicomechanical and IR spectroscopic parameters of these networks were determined and compared.

Among diverse polymeric composites suggested in the recent years, composites with a gradient of properties are of particular interest. Among such materials are gradient interpenetrating polymer networks (IPNs); their preparation and properties are described in [1–8].

With the progress of new technologies (aerospace, computer, biotechnologies), a demand arose for materials with highly specialized functions. To meet these demands, functional gradient materials were developed. Their properties (hardness, conductivity, dielectric constants, etc.) continuously change across the thickness of the material.

Typical functional gradient materials are characterized by continuous changes in the composition, microstructure, and properties from one surface to another, which gives rise to multifunctional characteristics.

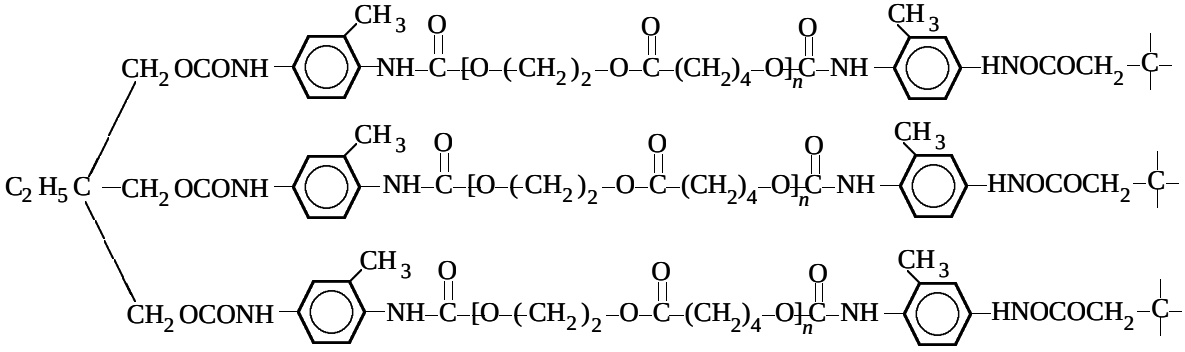
Gradient interpenetrating polymer networks as representatives of gradient functional materials can be considered as stack of layers of polymer blends with the composition and properties gradually changing from the surface to the center of the sample.

In this connection, it seemed interesting to study and compare the properties of common and gradient semi-IPNs similar in the chemical nature.

EXPERIMENTAL

Semi-IPNs and gradient semi-IPNs were prepared on the basis of three-dimensional polyurethane (PU) and linear polyvinylpyrrolidone (PVP).

The polyurethane network was prepared in two stages. First, we prepared an adduct of trimethylolpropane with toluene diisocyanate by reaction of 1 g-equiv of trimethylolpropane with 1.5 g-equiv of toluene diisocyanate at 338 K. The reaction was performed until the theoretically calculated content of isocyanate was attained. Then, three-dimensional polyurethane was prepared by reaction of polyethylene glycol adipate (molecular weight M = 2000) with the adduct of trimethylolpropane with toluene diisocyanate (equivalent ratio 1 : 2) at 353 K under nitrogen:



1070-4272/02/7505-0800$27.00 © 2002 MAIK "Nauka/Interperiodica"

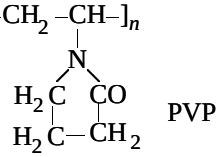
The unchanged components were removed from the polyurethane network by extraction with ethyl acetate in a Soxhlet apparatus.

Semi-IPNs and gradient semi-IPNs were prepared by successive polymerization. The polyurethane network was allowed to swell in a monomer (*N*-vinylpyrrolidone) containing a photopolymerization initiator.

To obtain semi-IPN, the polyurethane after swelling in the monomer was kept in a hermetically sealed vessel to attain equilibrium distribution of the components, after which photopolymerization was performed.

Gradient semi-IPNs were formed by swelling of the polyurethane network in the reaction mixture for a definite time estimated from the preliminarily obtained data on the swelling kinetics. Then, without attaining the equilibrium distribution of the components, photopolymerization of *N*-vinylpyrrolidone was performed.

As a result, we obtained a series of semi-IPNs with different content of the components and a block of gradient semi-IPN 6 mm thick with an overall PVP content of 24.1%.



PVP

The systems obtained were studied by IR spectroscopy and by sorption of solvent vapors [10]. The physicomechanical tests were performed on an Instron machine by standard procedures. Thin chips at different distances from the surface of the gradient semi-IPN were obtained with a microtome.

The depth distribution of polymers in gradient systems is usually studied by layer-by-layer elemental analysis [11–13]. However, the qualitative elemental composition of PU and PVP is similar, and layer-by-layer elemental analysis in this case is of little use. Therefore, to study the depth distribution of PVP (overall content 24.1%) in a block of gradient semi-IPN, we choose IR spectroscopy.

The IR spectra of the initial PU, PVP, and semi-IPNs of several concentrations were measured on a Specord M80 spectrophotometer in the range 4000–300 cm^{-1}, using KBr technique (3 mg sample per 600 mg KBr).

Examination of the IR spectra of PU, PVP, and semi-IPNs with definite component ratios showed that the absorption bands of PU at 1740 cm^{-1} and of PVP at 1678 cm^{-1} are the best suited for quantitative determinations.

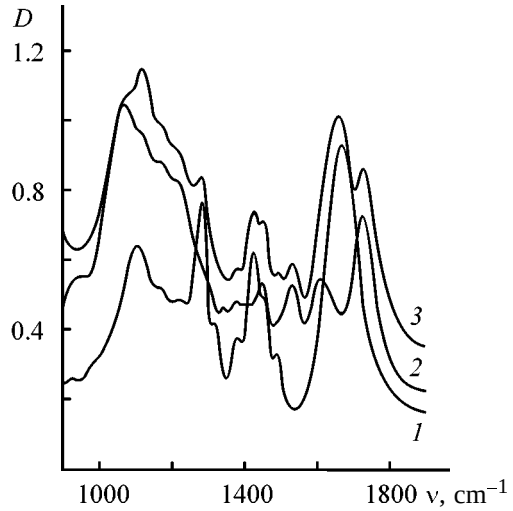


Fig. 1. IR spectra of (*1*) PVP, (*2*) PU, and (*3*) semi-IPN containing 57.3% PVP. (*D*) Optical density and (ν) wave number; the same for Fig. 2.

The IR spectra of PVP, PU, and semi-IPN with a PVP content of 57.3% are shown in Fig. 1. It is seen that, in the spectrum of the semi-IPN, the bands at 1740 (PU) and 1678 cm^{-1} (PVP) partially overlap.

The separation of particular absorption bands, determination of their spectroscopic characteristics, and calculation of the peak areas and intensities were performed using the Band Separation software adapted to the Specord M80 spectrophotometer [14]. The error in calculating the peak areas and intensities was 3–5%.

To perform an IR study of the gradient semi-IPN sample (overal PVP content 24.1%), we made thin chips at different distances from the sample surface. The chips were pulverized and pelletized with KBr.

Figure 2 shows the spectra of gradient semi-IPN specimens taken at different distances from the sample surface. The overall spectrum was mathematically resolved into components in the range 1960–1600 cm^{-1}.

Components a_1–a_5 correspond to vibrations of the C=O bonds in PVP, and components a_6–a_8, to vibrations of the C=O bonds in PU.

In the spectra of the surface layers of the gradient semi-IPN block (Fig. 2a), the major band is that at 1655 cm^{-1}, characterizing vibrations of the C=O bonds in PVP. In the layers located at a depth of about 1.5 mm from the sample surface (Fig. 2b), the carbonyl band of PVP decreases in intensity, and that of PU (1740 cm^{-1}) grows.

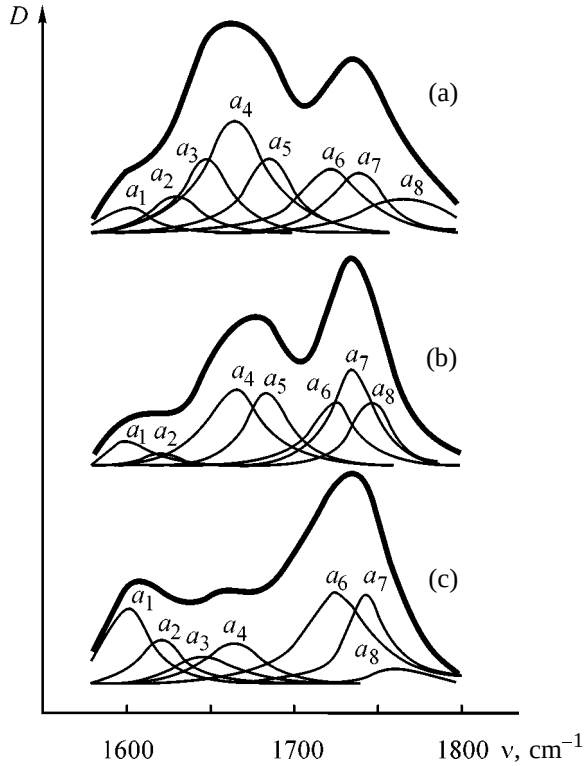

Fig. 2. IR spectra of the (a) first (surface) layer of gradient semi-IPN, (b) second layer of gradient semi-IPN, and (c) core of the gradient semi-IPN block, with mathematical resolution into components in the range 1800–1600 cm^{-1}.

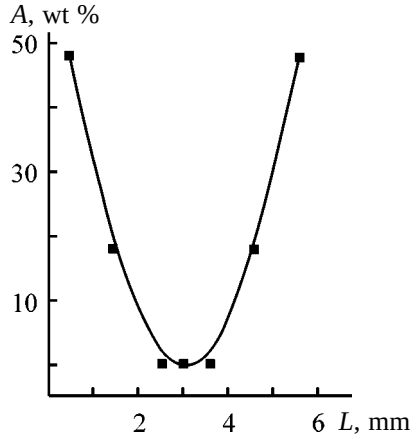

Fig. 3. Concentration depth profile of PVP in the sample of gradient semi-IPN: (*A*) PVP concentration and (*L*) depth.

In the layer located in the center of the gradient block of semi-IPN (Fig. 2c), the PVP vibration band is virtually absent. This fact shows that PVP is concentrated in the surface layers of the gradient block and that its content decreases in going to the sample core.

Based on the results of the IR study of semi-IPN samples, we constructed a calibration plot for the intensity ratio of the C=O vibration bands in PU and PVP. The calibration plot does not pass through the origin, because a number of components a_i in the spectra of PU and PVP overlap. This fact was taken into account when calculating the gradient of the PVP distribution in gradient semi-IPNs.

The quantitative calculation of the PVP content from the IR data for various layers of the gradient semi-IPN allowed construction of the concentration depth profile of PVP in a 6 mm thick sample of gradient semi-IPN (Fig. 3). It is seen that the PVP concentration in the sample varies by a parabolic law. In the surface layers of the sample, the PVP concentration is as high as 48.1%; at a depth of 1.5 mm, it is 17.5%; and at a depth of 2.5 mm it is close to zero. The fourth layer (sample core) contains PU only.

In curing of a gradient system, the conditions of transition from the range of compatibility to the two-phase state are different across the sample, because the ratio of the first network to the monomer, from which the polymer creating the concentration gradient is formed in the course of curing, changes from the surface to the depth of the sample.

In the course of curing, owing to kinetic factors, the components are not completely separated into two phases; instead, nonequilibrium structures with different levels of microphase segregation are "frozen." It was interesting to study how the thermodynamic compatibility of the components changes with the depth. For this purpose, we studied the sorption of vapors of low-molecular-weight compounds with samples of the initial polymers and with layers of the gradient block and performed calculations of the thermodynamic parameters.

Figure 4 shows the isotherms of benzene vapor sorption at 298 K by samples of PU and PVP and by layers of the gradient block of semi-IPN. With PU, the sorption isotherm (curve *1*) has a shape typical of sorption by polymers in the hyperelastic state. With PVP (Fig. 4, curve *2*), at $P/P_0 < 0.45$, the sorption is low, which is due to close packing of macromolecules in the glassy state [15]; in the range of the relative vapor pressures of the solvent $P/P_0 > 0.45$, the polymer undergoes devitrification, which is followed by a sharp increase in the benzene vapor sorption.

Layers of the gradient semi-IPN demonstrated a complex sorption behavior (Fig. 4, curves *3*–*5*). For the surface layer of the gradient block (48.1% PVP), in the range of relative vapor pressures 0–0.4, the isotherm is similar to that of pure PVP, but the sharp increase in the vapor sorption after devitrification is

Physicomechanical properties of semi-IPNs of definite compositions and of layers of gradient semi-IPN based on PU and PVP

Sample	Elongation at break, %	Breaking stress	Young's modulus	Adsorption energy at break, N mm^{-1}
		MPa		
PU	215.3	4.5	4.9	6.4
Semi-IPN, PVP, %:				
7.1	123.4	9.60	17.4	6.3
13.3	82.5	13.5	49.3	5.8
22.5	70.4	15.9	130.6	7.2
30.4	76.9	25.8	411.9	13.7
41.0	68.6	26.4	473.2	14.3
57.3	57.1	28.9	691.4	13.6
Gradient semi-IPN, layer:				
first	65.3	27.1	485.4	13.2
second	80.6	14.8	103.2	7.1
third	176.3	6.2	9.3	6.7
fourth	211.5	4.7	5.1	6.4
Semi-IPN, 24.2% PVP	73.2	19.2	196.4	8.9
Gradient semi-IPN, 24.1% PVP	70.1	25.1	390.2	12.6

not observed. As the PVP content in the layers of the gradient block decreases (curves *4*, *5*), the isotherms acquire the shape characteristic of PU (curve *1*).

The fact that blends formed at different depths differ in the component ratio and structure is also confirmed by physicomechanical tests (see table).

As seen from the table, for semi-IPNs, with increasing PVP content, the elongation at break decreases, and the breaking stress and the adsorption energy at break regularly increase. The Young's modulus increases with increasing PVP content: In going from PU to the semi-IPN with the highest (57.3%) PVP content, the Young's modulus increases by more than two orders of magnitude.

For chips of the gradient block, the trends are as follows (see table). The parameters of the fourth layer (core) are close to those of PU. The physicomechanical characteristics of the surface (first) layer are close to those of the semi-IPN with 41.0% PVP. The parameters of the third and fourth layers are consistent with the low content of PVP in these layers, as determined by IR spectroscopy.

Comparison of the physicomechanical parameters of the semi-IPN and gradient semi-IPN (at equal overall PVP content, see table) shows that the gradient semi-IPN exhibits a higher failure energy. The growth of the Young's modulus is especially pronounced: For the gradient semi-IPN it is higher by a factor of approximately 2. These data show that creation of a gradient structure in a polymeric material allows its mechanical properties to be substantially improved. A number of hypotheses were advanced in [1] to account for this phenomenon. According to one of them, gradient IPNs are considered as a set of an infinite number of layers whose compositions and Young's moduli gradually change. Under strain, all

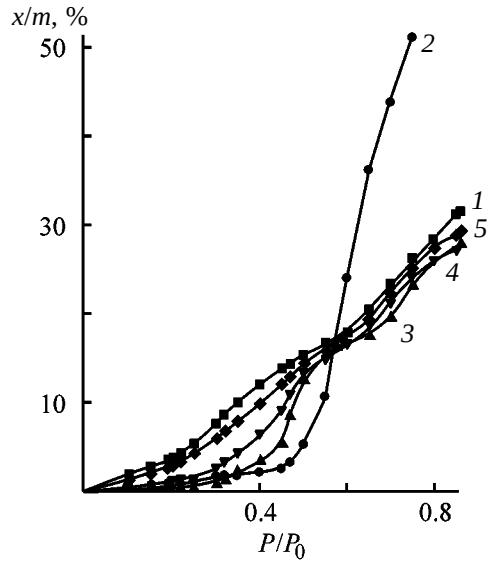

Fig. 4. Isotherms of benzene vapor sorption at 298 K by (*1*) PU, (*2*) PVP, and (*3*–*5*) layers of the gradient semi-IPN with the overall PVP content of 24.1%. (*x*/*m*) Sorption and (P/P_0) relative vapor pressure. The layers are numbered in the direction from the surface (*3*) to the core (*5*).

the layers are stretched to an equal extent, and the stress in each layer corresponds to its modulus. Such a stress distribution favors plastic deformation rather than brittle failure and increases the failure energy.

CONCLUSIONS

(1) Gradient semiinterpenetrating polymer networks can be considered as sets of layers of incompatible polymer blends, differing in the composition and extent of heterogeneity.

(2) An IR study showed that the concentration depth profile of polyvinylpyrrolidone in a gradient semiinterpenetrating polymer network is parabolic. The concentration of polyvinylpyrrolidone changes from 48.1% in the surface layer to 0 in the sample core.

(3) The physicomechanical properties of gradient semiinterpenetrating polymer networks vary along the concentration gradient. At different depths from the surface layers with different morphologies and physicomechanical parameters are formed.

Abstract—The effect of a blowing agent, cellulose diacetate, on the structural nonuniformity and physicomechanical properties of polyimide films was studied by thermogravimetric analysis and scanning electron microscopy. Changes in the gas permeability of the films in the course of thermal degradation of the blowing agent were estimated. The feasibility was demonstrated of using these films for fabrication of composite membranes.

Membrane processes are widely used in various branches of industry for separation and purification of liquids and gases. Polymer membranes used as filters are characterized by a wide range of pore size: from 0.001 to 1 μm. Such membranes are produced by various procedures, including addition to the initial forming solutions of polymeric blowing agents, followed by their removal in the course of precipitation or heating. The latter procedure is used, in particular, for production of microporous membranes based on aromatic polyimides (PIs) [1]. In this case, thermal cyclization of PI prepolymer, polyamido acid (PAA), is combined with removal from the film of residual solvent and blowing agent. In this case, blowing agents with a high boiling point are chosen, such as phenanthrene, α-chloronaphthalene, etc. The microporous membranes prepared by this procedure are of interest primarily for filtration of corrosive liquid or gaseous media at high temperatures, thanks to unique properties of aromatic PIs [2–4]. Also, membranes based on PIs can be used as supports in forming diffusion composite membranes. An advantage of such chemically resistant supports is that forming of the diffusion layer from a solution of another (chemically different) polymer can be performed using any solvents.

The goal of this work was to prepare microporous polyimide films from blens of PAA with a polymeric blowing agent, cellulose diacetate (CDA). We have studied the features of thermal degradation of CDA in the course of thermal cyclization of PAA and the influence of this additive on the physicomechanical properties, structural characteristics, and gas permeability of porous polyimide films.

EXPERIMENTAL

As the initial material we used 20% solution of poly-4,4'-oxydiphenylenepyromellitamido acid (PAA–PM) (Plastik Research and Production Association, Moscow), to which a 10% solution of CDA in DMF was added. The degree of polymerization of CDA was 570, and the degree of substitution, 2.37.

The compatibility of PAA-PM and CDA solutions was studied photocolorimetrically with a KFK-2 device at 20°C and λ = 670 nm. On mixing of dilute (2%) solutions of PAA-PM and CDA in any proportions, the optical density of solutions did not increase, whch indicates that the solutions are compatible. However, addition of even small amounts of a more concentrated (10%) CDA solution to a concentrated (20%) PAA-PM solution caused phase separation, detected visually (turbidization) and photocolorimetrically. An emulsion of CDA in PAA-PM solutions was formed.

Unfortunately, the full compatibility of dilute solutions of PAA and CDA is of little practical use, because drying of solutions in the course of film preparation is accompanied by a continuous growth of the concentration and inevitably leads to the phase separation. Therefore, in the subsequent experiments we used a 20% solution of PAA-PM and a 10% solution of DA in DMF. It should be noted that the occurrence of phase segregation requires thorough choice of the

conditions for preparing the initial solutions of the polymer blends.

Solutions of PAA-PM and CDA were mixed with an ultrasonic disperser and mechanically, with a glass stirrer. In the former case, the solutions strongly warmed up, and even short sonication resulted in a sharp decrease in the viscosity, indicating unacceptable decrease in the molecular weight of PAA-PM. The PI films prepared by this method exhibit poor mechanical characteristics: even at low (<5%) CDA concentrations in a PAA-PM–CDA blend, the resulting PI films were brittle and unsuitable for use. Therefore, in the subsequent experiments we used a stirrer.

PAA-PM–CDA films were prepared by casting of solutions onto glass supports with a laboratory die, followed by drying at 80°C. Thermal cyclization of PAA in films, accompanied by thermal degradation of CDA and removal of the degradation products from the films, was performed under conditions of step heating (50°C steps, keeping at each temperature for 0.5 h). Initially, cyclization was performed in a vacuum. Cyclized films differ from common PI films by considerably enhanced adhesion to glass; therefore, cyclization was performed with a free film of dried PAA after its separation from the support. An additional advantage of cyclization under such conditions is easier removal of CDA thermal degradation products from the film.

To optimize the conditions for film preparation, it was necessary to determine the best conditions for the heat treatment, and primarily the final temperature. To complete the cyclization of PAA, the temperature should not be lower than 300°C. At the same time, on heating the films above 400°C PI starts to degrade [2]. Within this interval, it was necessary to find a temperature ensuring sufficient extent of CDA degradation and complete removal of the degradation products from the film.

To find conditions for CDA degradation, films prepared from PAA-PM–CDA blends and heated for cyclization at 300°C (lower boundary of the temperature range of interest), and also films of pure CDA and PM were studied by thermogravimetric analysis (TGA).

The weight loss curves obtained with PM and CDA are shown in Fig. 1. The CDA film was cast from a solution in DMF with subsequent vacuum drying at 150°C to constant weight (16 h). The PM film was prepared under the same conditions as films from the PM–CDA blend (cyclization at 300°C). Active decomposition of CDA with release of volatiles starts at 250–280°C (Fig. 1, curve *2*). The process sharply accelerates on heating to 300°C, above the glass transition point T_g. By the moment of reaching the temperature of 380°C, more than 80% of CDA passes into the gas phase. After that, the release of volatiles continues with a lower intensity and is accelerated again at 450°C. At 500°C, the sample fully decomposes, and the degradation products pass to the gas phase. The weight loss of the PM film becomes noticeable only above 450°C.

In PI films prepared from PAA-PM–CDA blends, intense weight loss is observed at temperatures from 300 to 360–380°C (Fig. 2). The lower temperature boundary of the weight loss depends on the thermal history of the sample. Since the weight of pure PM films does not change noticeably in this temperature range, this process can be attributed with confidence to removal of volatile products of CDA thermal degradation. It is seen that, after heating at 300°C, a significant amount of CDA remains in the films (Table 1); the degradation products of the residual CDA are actively removed on heating to 360–380°C.

Figures 1 and 2 show that efficient removal of volatile products of CDA degradation is ensured by heating the films to 380°C. However, mechanical tests of the films (Table 2) show that introduction of CDA into PAA-PM results in considerably decreased elongation at break ε_b of the polyimide film. The same effect is observed when the heat treatment of the films is completed at higher temperatures. The practically acceptable value of ε_b of the films should be no less than 5–6%. When the heating is completed at 300°C, ε_b reaches this minimal value at 30% content of CDA in PAA-PM. The TGA data show that the amount of CDA remaining in the films at 300°C is significant. When the heat treatment is completed at higher temperatures, the elongation at break decreases to an unacceptable level.

To optimize the heat treatment conditions, we performed an experiment on isothermal heating in a self-generated atmosphere of films whose cyclization was completed at 300°C (initial CDA content in PAA film 30%). Additional heating was performed in the course of thermogravimetric tests. At 300°C, the heating was stopped, and the film was kept at this temperature to constant weight. The results are shown in Figs. 2 and 3. It is seen that such conditions ensure the maximum possible removal of products of DCA thermal oxidative degradation. However, the total weight loss due to removal of CDA degradation products from the film is somewhat lower than the content of CDA in the initial films. This may be due to several factors: the presence of ash in film pores after CDA carbonization, the presence of residual CDA in closed or blind pores, and partial removal of CDA degradation products from the films already in the stage of thermal cyclization performed by heating to 300°C.

Our results show that, to efficiently remove CDA from PM films, heat treatment in air (i.e., thermal oxidative degradation of CDA), rather than heating in a vacuum, is preferable. Therefore, in the subsequent experiments we chose a procedure involving cyclization of PAA in air followed by isothermal heating of the film in air at the final temperature of cyclization. Under such conditions, we attained efficient removal of CDA from the film without its heating above 300°C. In the process, the elongation at break remained sufficiently high.

The mechanical and thermomechanical tests of the films were performed with a UTS 10 universal installation (UTS Testsysteme, Germany). In the course of tensile tests at room temperature, we determined the modulus of elasticity E, tensile strength σ_t, induced hyperelasticity limit σ_h, and elongation at break ε_b.

** Sample nos. 1–4: cyclization at 300°C; sample no. 5: cyclization at 400°C; sample no. 6: cyclization at 300°C followed by heating in air at 300°C for 2 h.

In the course of heating at a rate of 5 deg min^{-1}, we determined the glass transition point T_g.

Our results (Table 2) demonstrate high level of the strength characteristics of the films. Although, as

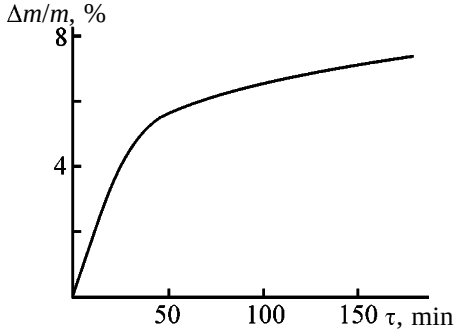

Fig. 3. Weight loss $\Delta m/m$ of a PM film, prepared from PAA with addition of 30% CDA by heating in a vacuum to 300°C, in the course of subsequent isothermal heating in air at 300°C (Fig. 2, curve *5*). (τ) Heating time.

noted above, increased content of CDA in the initial blend results in noticeable decrease in the elongation at break and hence in the strength of the polyimide film, in all cases the σ_t values remain acceptable for practice.

The results of the tests (Table 2) show that addition of CDA to PAA affects the structure of the PI formed by cyclization: plasticization effects are observed. Indeed, as the initial concentration of CDA in PAA is increased, the modulus of elasticity, induced hyperelasticity limit, and glass transition point of the polyimide films monotonically decrease.

To confirm this conclusion, PM films prepared from PAA-PM with addition of 30% CDA and heated in the course of imidization to 300°C in a vacuum were additionally heated in air for 2 h at 300°C. It was shown that such a heating allows more complete removal of CDA degradation products from the film. After the repeated heat treatment, the modulus of elasticity and the glass transition point of the film increase (Tale 2, sample no. 6).

As the concentration of CDA in PAA is increased, the heat resistance of PI films noticeably decreases (Table 1). For example, as the CDA concentration is increased from 0 to 30%, the temperature T_5, corresponding to 5% weight loss of the film in the course of TGA, decreases by 45°C. Since at these temperatures the film contains neither residual CDA nor gaseous products of its degradation, we can suggest that the presence of CDA or initial products of its degradation affects the PI structure at the cyclization stage. At the same time, in all cases the heat resistance of the films remains sufficiently high.

We have estimated the pore concentration in the films from comparison of their density with that of the pure PM film. This was necessary, in particular, for correct calculation of the film strength parameters (E, σ_h, σ_t) from the results of mechanical tests. We found that the volume concentration of pores in the materials was insignificant. For example, the density of PM films prepared from pure PAA was ρ = 1.403 g cm^{-3}, whereas the density of PI films prepared from the blend of PAA with 30% CDA was 1.385 g cm^{-3}.

The morphology of the films prepared from PAA-PM–CDA blends was studied by scanning electron microscopy with an Akashi MSM-V device (Japan). Prior to microscopic examination, the sample surface was coated with a 20-nm gold layer by thermal vacuum sputtering (VEF device, Akashi, Japan). The electron micrographs of both surfaces and transverse chips of the films were obtained, and the pore size and pore distribution across the thickness of the films prepared under different conditions were determined.

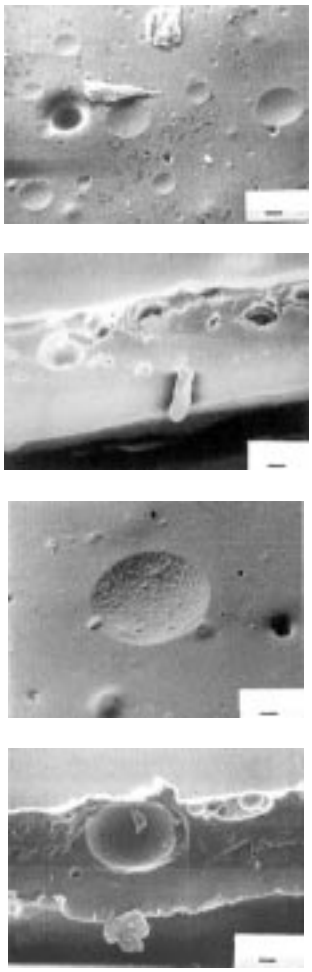

Fig. 4. Electron micrographs of polyimide films prepared from PAA-PM–CDA blends (CDA content 30%) and heated to (a, b) 300 and (c,d) 400°C. (a, c) Free surface and (b, d) transverse chip. The bars correspond to 10 μm.

The electron micrographs of the upper (free) and lower (contacting the support in the course of casting) surfaces of the films heated to 300°C show that the structure of the films is highly nonuniform. The upper surface has a rough relief (Fig. 4a), with open pores 2–10 μm in diameter and spherical pits of 10–40 μm size, probably originating from degradation of coarse CDA particles. A large amount of open pores is also observed on the lower surface of the film; these pores were probably produced by release of volatiles from the film (1–3-μm pores) and degradation of coarse aggregated CDA particles (larger, 10–30-μm, pores).

On the transverse chip (Fig. 4b), we see close pores 2–20 μm in diameter, concentrated mainly in

** In air.

the sample layers adjacent to the free surface, which suggests partial segregation of the PAA-PM–DCA blend. The presence of very large pores of 50–60 μm size is indicative of inefficient dispersion of CDA in the blend.

After heating to 400°C, the general morphology of the film surface does not change (Fig. 4c), but the pores undergo contraction. In the section view (Fig. 4d), we see close pores, which are distributed across the sample thickness more uniformly than in the previous case. On the inner surface of coarse pores, there are residues of carbonized degradation products of coarse CDA particles. Apparently, the differences in the morphology of the chips are due to nonuniform distribution of CDA throughout the bulk of the initial film, rather than to changed conditions of the heat treatment.

To assess the possibility of using these materials as membranes, we determined their gas permeability. For the PI films prepared from blends with different initial content of CDA and heat-treated at different temperatures, we determined the permeability coefficients *P* for oxygen and nitrogen by a chromatographic procedure with a PGD-1 device at a pressure differential of 1 atm. The data obtained (Table 3) are compared with the permeabilities of the nonporous PM film [5] and of the porous film obtained from PAA-PM with phenanthrene as blowing agent [1] (sample nos. 7 and 8, respectively).

Table 3 shows that, for the films prepared from blends containing up to 15% CDA and heated in a vacuum to 300°C, the gas permeability is comparable to that of a pure PM film. As the CDA concentration is increased to 30%, with the same treatment conditions, *P* increases by 1–2 orders of magnitude, and the gas selectivity is lost, which is probably caused by an increase in the free volume due to thermal degradation of CDA. This trend is manifested still more strongly in samples from which CDA was removed to a maximal extent (heating to 400°C, prolonged isothermal heating at 300°C in air, sample nos. 4–6). The permeability of such samples increases by more than three orders of magnitude, the selectivity is also lost, but the films exhibit barrier properties with respect to water and ethanol at pressures of up to 4 atm.

Along with the characteristics of the films prepared by us, we also present in Table 3 the published data on the gas permeabillity of microporous PI films (sample no. 8) prepared as described in [1]. These films show a considerably higher (by two orders of magnitude) gas permeability than the films prepared by us. This fact, in combination with the morphological features of the films considered above and with their barrier properties with respect to liquids, allows certain conclusions about the causes of the observed effects.

Increase in the gas permeability by 3–4 orders of magnitude as a result of CDA removal from the film is mainly due to formation of large amounts of close (blind) pores observed on the transverse chip. At the same time, the lack of gas selectivity suggests formation of through channels; however, their amount per unit surface area is apparently low.

Thus, the films prepared are hardly suitable as filtering materials. At the same time, fairly high gas permeability in combination with high levels of chemical stability, mechanical strength, and heat resistance makes these films promising as supports for compo-

site diffusion (gas separation or pervaporation) membranes. It seems feasible to apply to the surface of such supports diffusion coating layers of various polymers, including those similar to PAA, with subsequent thermal cyclization.

CONCLUSIONS

(1) Mixing of solutions of cellulose diacetate and poly-4,4'-oxydiphenylenepyromellitamido acid, followed by degradation of cellulose diacetate in the course of thermal cyclization of the polyamido acid, allows preparation of porous polyimide films.

(2) Additions of cellulose diacetate to the initial solution of poly-4,4'-oxydiphenylenepyromellitamido acid affect the heat resistance and physicomechanical properties of the cyclized polyimide films.

(3) The procedure for preparing the initial solutions of poly-4,4'-oxydiphenylenepyromellitamido acid and cellulose diacetate and the imidization conditions strongly affect the shape and size of pores and their distribution in the polymer matrix.

(4) The gas permeability for nitrogen and oxygen of the polyimide films prepared from blends of poly-4,4'-oxydiphenylenepyromellitamido acid and cellulose diacetate was studied. These microporous films are suitable as strong, heat-resistant, and chemically stable supports for multilayer composite diffusion membranes.

Received December 4, 2001

Abstract—A formulation based on quinone dioxime and a mixture of sterically hindered phenols *tert*-butylpyrocatechol–2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (Agidol-2) was suggested for inhibiting terpolymerization of styrene.

Styrene, like many other monomers, extremely readily polymerizes on heating; therefore, its industrial distillation should be performed in the presence of inhibitors. At Russian styrene-producing plants, the most widely used and reliable inhibitor of styrene thermal polymerization is *p*-quinone dioxime (QD) [1, 2]. a typical scavenger of alkyl radicals. It is used in combination with various synergistic additives [3]. In other countries, there has been a trend toward using various soluble inhibiting systems based on more effective compounds, in particular, on inhibitors of the latest generation, nitroxyl radicals [4]. Many of the modern inhibiting systems are not commercially produced in Russia, and therefore research groups at the enterprises make efforts to improve commercially used QD-containing formulations, with the aim to enhance their performance and decrease the consumption of the main inhibitor. Such drawbacks of QD as poor solubility in aromatic hydrocarbons and high cost are a common knowledge.

The goal of this study was to extend the range of inhibiting formulations, to decrease the QD consumption, and to enhance the efficiency of inhibiting thermal polymerization of styrene in the course of its distillation from process solutions.

The performance of the inhibiting formulations was evaluated under laboratory conditions using pure freshly distilled styrene; experiments were performed without passing an inert gas. The temperature in all the experiments was maintained at 119 ± 1.5°C. The heating time after adding an inhibitor or inhibiting formulation was 7 h. The polymer yield was determined by taking samples at 1-h intervals and distilling off the unchanged monomer on a boiling water bath at reduced pressure (20 mm Hg). The experimental results are listed in the table.

One of the possible ways to improve the performance of inhibiting formulations is the use of QD in combination with various coinhibitors, most often phenolic compounds, exhibiting a synergistic effect [3]. Some of such formulations were suggested previously, e.g., QD + sterically hindered phenols (SHPs) [5, 6] (run no. 5), QD + methoxylated phenols [7, 8] (run no. 6), and QD + fraction of dihydric phenols from coke-chemical production (pyrocatechol fraction, PCF) [9, 10] (run nos. 7, 8). With these formulations, the efficiency of inhibiting thermal polymerization of styrene was considerably enhanced, but the consumption of QD was not appreciably reduced. The highest inhibiting efficiency was observed at a QD consumption of 0.017–0.011 wt % relative to styrene. Better results, with a decrease in consumption of the main inhibitor, were attained by using as a coinhibitor *N*,*N*-dimethyl-3,5-di-*tert*-butyl-4-hydroxybenzylamine (Mannich base, MB). For example, with the formulation QD + MB + SHP [2], the QD consumption was as low as 0.002–0.003 wt % relative to styrene, although the optimal level in commercial production of styrene is somewhat higher: 0.0046–0.006 wt % (run no. 11). Nevertheless, even such consumptions are lower by a factor of 3–4 than those of the previously used formulations. Run no. 10 shows that straight QD, when taken in such amounts, does not ensure the required inhibiting effect.

One of the possible ways to decrease the QD consumption is increasing the content of coinhibitors in the system. Actually, as the consumption of QD as an individual inhibitor is decreased, the inhibition effi-

* (PNF) *p*-Nitrophenol, (TBPC) *tert*-butylpyrocatechol, (PSBP) *p-sec*-butylphenol, (PCF) pyrocatechol fraction, (MB) Mannich base, and (A-2) Agidol-2.

ciency increases; when QD is used without coinhibitors, it should be taken in increased amounts to attain the required effect (see table, run nos. 1, 3, 6). The QD consumption can be decreased by using PNP as coinhibitor and by choosing appropriate dosage mode (simultaneously with the main inhibitor or in portions at definite time intervals; run nos. 2, 4, 5).

Experiments showed that the inhibition efficiency can be enhanced by replacing less active coinhibitors by more active agents. An example is replacement of PNP, a relatively low-effective component of the QD + PNP formulation [1], by a synergistic mixture of mono- and dihydric SHPs, namely, TBPC and Ionol (weight percentage of QD, TBPC, and Ionol relative to styrene 0.017, 0.005, and 0.001, respectively [5]).

With another inhibiting system consisting of QD, MB, and PCF ([11] (run no. 12), the polymer yield was considerably reduced as compared to the similar system containing PNP instead of PCF [2] (run no. 11); the percentages of QD, MB, and PNP or PCF were varied within 0.0023–0.0046, 0.012–0.023, and 0.006–0.023, respectively. When the QD consumption is reduced to so great extent, it is very important to ensure stable inhibiting effect. However, the performance of the QD + MB + PNP system drastically decreases even at a slightly reduced content of the main inhibitor, and the inhibiting effect is observed only during a relatively short time.

Therefore, we suggested an inhibiting formulation allowing the consumption of QD to be reduced further. This formulation exhibits stable performance and effectively suppresses styrene polymerization. It includes QD as the main inhibitor and a mixture of 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (Agidol-2) with TBPC as a coinhibiting and antioxidant component. With this system, the QD consumption could be decreased to 0.001 wt % and even lower value. As compared to the formulation QD + MB + PNP, the consumption of phenols (0.038 wt %) differed insignificantly from that of MB + PNP (0.035 wt %), and

the QD consumption was somewhat lower (0.004 against 0.0046 wt %).

In the new formulation (run no. 13), as compared to QD + MB + PCF (run no. 12), we replaced MB and PCF by a mixture of Agidol-2 (a monohydric bisphenol) and TBPC (QD + A-2 + TBPC). It is noted in the literature [12] that replacement of mononuclear phenolic compounds in inhibiting systems by binuclear compounds (e.g., diphenylolpropane) enhances the inhibiting power of the formulations. Data obtained in run no. 13 show that such a replacement, indeed, somewhat improves the results (the yield of the polymer in 7 h decreased from 0.85 to 0.77%). When the total concentration of the inhibitors is reduced, with their ratio and the QD concentration remaining the same, the results get worse (run no. 14). Increase in the amount of Agidol-2 (run no. 15), with the amount of QD being the same, drastically weakens the inhibiting power of the formulation.

As seen from the table, replacement of a mixture of MB and PCF (run no. 12) by the above-mentioned SHP mixture (run nos. 16, 17) enhances the inhibiting effect and allows the consumption of QD to be reduced to 0.00144–0.00099 wt % relative to the monomer, whereas with the QD + MB + PCF system the QD consumption can be reduced only to 0.004 wt % at a relatively high consumption of the sum of the inhibitors (0.035 wt %). Experiments showed that decrease in the consumption of the main inhibitor requires certain compensation, i.e., increase in the consumption of the coinhibitors loaded simultaneously with QD. The reduce the consumption of QD, the larger amount of coinhibitors should be added. The best results are obtained when 30–40% of the coinhibitor mixture is added simultaneously with QD, and the remaining amount, after 2 h. Our experiments also showed that the optimal ratio of TBPC to A-2 is 1.5 : 1, i.e., the consumption of the dihydric phenol in such formulations should be higher than that of the monohydric phenol; the total consumption of the phenols is 0.025–0.038 wt %. It is seen that the best result can be attained at a lower consumption of the main inhibitor (run nos. 13, 16, 17).

Thus, our experiments showed that further decrease in the QD consumption in inhibiting formulations preventing thermal polymerization of styrene in the course of its distillation is quite feasible and can be attained both by using more effective coinhibitors and by varying the relative amounts of the inhibitor and coinhibitors at their initial simultaneous loading.

CONCLUSION

In inhibiting thermal polymerization of styrene, the consumption of the main inhibitor (quinone dioxime) can be considerably reduced, without decreasing the inhibition efficiency, by using quinone dioxime in combination with two sterically hindered phenols: *tert*-butylpyrocatechol and 2,2'-methylenebis(6-*tert*-butyl-4-methylphenol) (Agidol-2). The optimal ratio of the phenols in the mixture and the optimal amount of coinhibitors added simultaneously with quinone dioxime were determined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polymers Based on Epoxy Resins and Functional Derivatives of Polychlorobiphenyls

N. Yu. Ostanina, L. D. Dul'tseva, A. L. Suvorov, and O. N. Chupakhin

Institute of Organic Synthesis, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received November 13, 2001; in final form, January 2002

Abstract—A new way to utilize polychlorobiphenyls was suggested: transformation of Sovol base hydrolysis products into glycidyl ethers and titanates. The resulting products were tested as components of epoxy compounds which are subsequently cured to obtain three-dimensional polymer networks.

The problem of rendering harmless polychlorobiphenyls (PCBs), which were widely used in various branches of industry, is extremely urgent, because these compounds are stable ecotoxicants. One of the ways to solve this problem is chemical processing (utilization) of PCBs by their functional substitution followed by transformation into useful nontoxic products [1, 2]. In particular, it seems promising to prepare cross-linked polymers from which the diffusion of the components into the environment will be *a fortiori* low.

In this work, we examined the possibility of using glycidyl ethers and titanates prepared from the products of base hydrolysis of Sovol [3, 4] as components of epoxy compounds. Glycidyl ether resins are prepared by treatment with epichlorohydrin of products of Sovol base hydrolysis in ethylene glycol (SEG) or diethylene glycol (SDEG). Titanates SEG-Ti and SDEG-Ti are prepared by interchange of tetrabutoxytitanium with the ethers produced by Sovol hydrolysis. The compositions of these compounds correspond to the formulas

$$C_{12}H_{4.09}Cl_{4.74}(OH)_{0.46}(OCH_2CH_2OH)_{0.07}(OCH_2\underset{\backslash\ /}{CH}{-}CH_2)_{0.64}\quad \text{SEG}$$
$$O$$

$$C_{12}H_{4.69}Cl_{3.61}(OH)_{0.79}(OCH_2CH_2OCH_2CH_2OH)_{0.64}(OCH_2\underset{\backslash\ /}{CH}{-}CH_2)\quad \text{SDEG}$$
$$O$$

$$Ti[(O)_{0.8}C_{12}H_{5.4}Cl_{3.62}(OCH_2CH_2O)_{0.184}]_{3.24}(OC_4H_9)_{0.76}\quad \text{SEG-Ti}$$

$$Ti[(O)_{1.06}C_{12}H_{4.69}Cl_{3.61}(OCH_2CH_2OCH_2CH_2OH)_{0.64}]_{2.86}(OC_4H_9)_{1.14}\cdot$$
$$4.4(OH)_{1.06}C_{12}H_{4.69}Cl_{3.61}(OCH_2CH_2OCH_2CH_2OH)_{0.64}\quad \text{SDEG-Ti}$$

SEG and SDEG were used as active diluents of epoxy copounds with common curing agents such as hexamethylenediamine (HMDA) or isomethyltetrahydrophthalic anhydride (*i*-MTHPA). These ethers were added in amounts of 15–46 wt % into the compounds with HMDA and 30 or 40 wt % into the compounds with *i*-MTHPA.

The titanates SEG-Ti and SDEG-Ti were used themselves as curing agents for epoxy resins. The molar ratio of the resins and titanates was varied from 2 to 32. SEG-Ti is incompatible with the epoxy resin; therefore, it was preliminarily dissolved in Laprol L-503 (a polyether based on propylene oxide).

As epoxy component we took ED-20 commercial resin. The diluent in the reference compound was dibutyl phthalate (DBP). As catalysts we used the complex of BF_3 with *p*-toluidine (UP-605/5) and oligoethylene glycol phthalate titanate (EGPT) [5].

The compound formulations and the properties of

* (τ_{sh}) Shear strength of steel adhesive joint, (c_δ) gel fraction content, (Δm) weight loss at 250°C (DTA), and (y) specific impact resilience.

the resulting polymers are listed in the table. It is seen that, for the compounds containing, along with the common curing agents, also SEG and SDEG, the gel point T_{gel} is below 70°C for the compound with HMDA and 130–150°C for the compound with *i*-MTHPA. In the case of the systems with *i*-MTHPA, such samples can be obtained only at the ether content not exceeding 30 wt %. At a higher ether content, addition of catalysts is required.

Figure 1 shows the thermomechanical curves (TMCs) of a series of polymers cured with HMDA (curves *1*) and *i*-MTHPA (curves *4–7*) in the presence of SEG as diluent. Curve *1*, lacking the hyperelasticity plateau, refers to the polymer cured with HMDA containing almost 50% SEG. This polymer is characterized by thin cross-linking and poor mechanical strength; the sample is fully deformed even at 100°C. At the SEG content decreased to 30%, highly cross-linked and mechanicaly strong polymers are formed (curves *2*, *3*). Polymers with better properties are formed when the maximal heating temperature is much higher than T_{gel} (curve *2*).

The physicomechanical and thermal properties of the polymers and the content of the gel fraction in the samples cured with HMDA under various conditions are listed in the table. It is seen that the glass transition point T_g varies within 45–62°C, the gel fraction content reaches 74%, and the shear strength of steel adhesive joint is 8.4–9.6 MPa. Although such adhesion strength is lower than that attained in the steel–steel couple with commercially available epoxy compounds, it is sufficiently high for practical use.

Since the working life of the compounds under consideration is short (up to several hours), they are suitable as adhesives to be prepared immediately before use.

The TMCs of the samples cured with *i*-MTHPA (curves *4–7*) indicate formation of highly cross-linked mechanically strong polymers. With EGPT, the glass

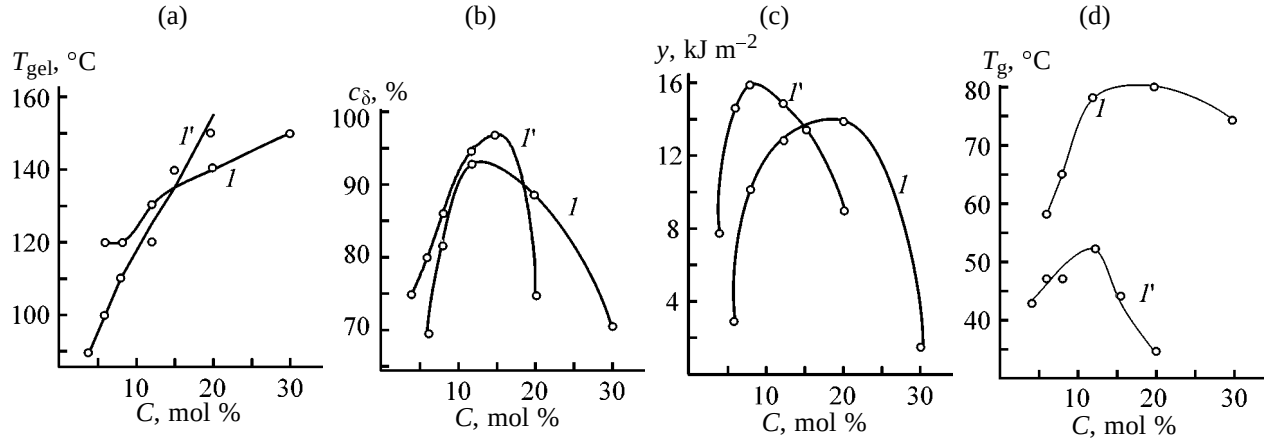

Fig. 2. (a) Gel points of compounds T_{gel} and (b) gel fraction content c_δ, (c) specific impact resilience y, and (d) glass transition point T_g of polymers as functions of the curing agent content c for the compounds containing (*1*) SDEG-Ti and (*1*') SDEG-Ti + L-503.

transition point is higher (curve *4*, *5*), and with UP-605/5, the hyperelasticity plateau is more extended (curves *6*, *7*).

The glass transition points of sample nos. 3 and 4, determined from the TMCs and listed in the table, vary from 36 to 78°C depending on the amount and nature of the catalyst. The τ_{sh} values for these samples are close, irrespective of the composition and curing temperature, and are considerably lower than those for the HMDA-cured systems. The cross-linking in this case is 95% complete. The weight loss in most cases does not exceed 10%. For one of the polymers, we determined the specific impact resilience y, which proved to be sufficiently high: 9.6 kJ m^{-2}.

Thus, the compounds cured with *i*-MTHPA demonstrate a high level of thermal and physicomechanical properties. The polymers prepared in the presence of EGPT are more cross-linked and have higher softening point and higher heat resistance. In contrast to compounds with amines (see table, compound no. 1), the working life of these compounds reaches several days. They can be used as adhesives and are promising as casting compounds.

Figure 2 shows the concentration dependence of the properties of the initial compounds and polymers for the samples in which the titanates themselves are used as curing agents. Figure 2a shows that the gel point of the titanate-containing compounds decreases as the titanate content is increased. The working life of these compounds reaches several months and considerably exceeds the working lives of the above-considered compounds containing SEG or SDEG along with traditional curing agents. The plots of y, T_g, and gel fraction content vs. composition of the initial compound (Figs. 2b–2d) pass through maxima. The highest level of these parameters is attained for the compounds containing 8–25 (for SDEG-Ti) or 8–15 (for SEG-Ti) mol of the resin per mole of the curing agent. Thus, for the polymers cured with SEG-Ti, the optimal properties are attained in a narrower composition range shifted toward higher content of the curing agent. The maximal values of the parameters of the polymers cured with SEG-Ti and SDEG-Ti (see table, compound nos. 5, 6) are fairly high, approximately equal, and close to the parameter values for the previously studied polymers based on epoxy resin and EGPT (compound no. 7), successfully used as adhesives, binders, and casting compounds [6]. The observed differences in the properties of the polymers cured with SEG-Ti and SDEG-Ti, in particular, lower T_g values in the maximum for the polymers based on SEG-Ti (Fig. 2), are due to different chemical nature of the systems.

Thus, we have shown that glycidyl and titanate derivatives of PCBs can be used for preparing epoxy polymers. The resulting products are insoluble, three-dimensionally cross-linked glassy polymers exhibiting hyperelasticity in the range 40–250°C. A wide range of concentrations prividing a high level of physicomechanical and thermal properties of the polymers makes it possible to choose a formulation ensuring the required characteristics of the product. The fairly high level of heat resistance and mechanical properties makes these compounds suitable for practical applications, which opens up a new opportunity to utilize PCBs.

EXPERIMENTAL

Compounds containing HMDA and SDEG-Ti were prepared by mixing the components on heating (50–

70°C), and those containing *i*-MTHPA and SEG-Ti were prepared at room temperature. The ready compounds, except those containing HMDA, were heated in a vacuum (55–80°C) until the foaming ceased. The compounds were cured under conditions with the maximal temperature T_{max} of 70 or 180°C.

The temperature of gelation onset T_{gel} was determined visually as the temperature at which stepwise heating of the compound (10°C steps, 1 h at each temperature) yields an elastic product.

The thermomechanical studies were performed at a constant load of 8 kg cm^{-2}. The thermomechanical curves were plotted as temperature dependences of the deformation ε (%). The glass transition points T_g were determined from TMCs.

The gel fraction content was determined by exhaustive extaction of polymer samples with acetone in a Soxhlet apparatus.

The specific impact resilience was determined with an MK-0.5 pendulum impactor.

The DTA curves were obtained on an OD-102 derivatograph in air in the dynamic mode at a heating rate of 5 deg min^{-1}.

The shear strength of steel–adhesive–steel joints τ_{sh} was determined with a ZDM 5/91 machine.

CONCLUSIONS

(1) Glycidyl ethers and titanates prepared from products of base hydrolysis of Sovol were used for preparing epoxy polymers.

(2) The temperatures of gelation onset, the conditions and extent of curing of the compounds, and the main physicomechanical and thermal characteristics of the polymers were determined in a wide range of the component ratios.

(3) Regular trends were revealed in variation of the polymer properties depending on the qualitative and quantitative compositions of the compounds. The best attained properties are close to those of the known epoxy polymers, which makes the new compounds and polymers suitable for practical use.

ACKNOWLEDMENTS

The study was financially supported by the Russian Foundation for Basic Research (project no. 01-03-96447).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Transfer of Metal Compounds at Contact Oxidation of Polyethylene on Copper

D. G. Lin and E. V. Vorob'eva

Skorina State University, Gomel, Belarus

Received December 25, 2001

Abstract—Transfer of metal into the polymer bulk during contact oxidation of polyethylene films on a copper support was studied. The metal distribution in the sol and gel fractions of the polymer was determined.

Oxidation of polyethylene at contact with catalytically active metals (including copper) is accompanied by dissolution of the support and transfer of the metal into the polymer bulk [1–3]. This phenomenon, first detected in [4], was confirmed by various methods: visual registration of disappearance of the fine metal layer under the polymer film [4]; measurements of the electrical conductivity of this layer [5]; microscopic study of the disappearance of metal particles in the polymer during its oxidation [6]; IR and ESR spectroscopy of polymer films separated from the metal supports after oxidation [7, 8]; and determination of the metal traces in the ash residue of the polymer sample [9].

The IR spectra of polymeric films containing transferred metal contain absorption bands at 1500–1600 cm^{-1} typical for the ionized carboxy group in metal salts (metal carboxylates). In a polymer, metal carboxylate can occur as both anhydrous salt and hydrate [8]. The experimental results suggest the carboxylate mechanism of transfer of active metals into the oxidizing polymers. Copper carboxylate is detected at fairly large distance, hundreds of micrometers, from the adhesion contact boundary. The mechanism of the metal transfer during contact oxidation of polyethylene is still poorly studied. Two schemes of the metal transfer are assumed [8]: diffusion of low-molecular-weight metal carboxylates or "relay" diffusion of metal ions with participation of the carboxy groups. At present, unambiguous data on what transfer mechanism prevails are lacking. Moreover, data based on the direct measurements of the content of metal transferred into the polymer and its distribution between the gel and sol fractions are lacking; the effect of the oxidative cross-linking of macromolecules on the metal transfer is also poorly understood. In this work, we studied the above problems by the example of polyethylene–copper adhesion composite.

EXPERIMENTAL

We used unstabilized high-density polyethylene prepared at low pressure on complex organometallic catalysts [GOST (State Standard) 16338–85, 20306-005 brand). The 100-μm-thick films were prepared from the polymer powder. The films were then oxidized in the molten state on preliminarily cleaned copper (M1 brand) and aluminum (A99 brand) foils. After oxidation, these films were separated from the supports and used in our tests.

We determined the degrees of oxidation and oxidative cross-linking of the polymer and the content of transferred copper.

The degree of polyethylene oxidation was characterized by the extinction coefficient [the ratio of the optical density to the film thickness (cm)] of the absorption band at 1720 cm^{-1} in the IR spectra of the polymer films.

The degree of oxidative cross-linking of macromolecules was determined as the content of the gel fraction in the sample (%), which was recovered from the polymer after boiling in *o*-xylene for 2 h.

The content of copper in the polymer was determined by polarography [9] using solutions prepared from the ash residue of the polymer. The sample was ashed by a two-stage thermal treatment [10], and the resulting ash residue was dissolved in a supporting electrolyte. The resulting solution was studied on a PU-1 device equipped with a mercury dropping electrode; the copper content was determined using calibration curves. In the quantitative analysis, we

1070-4272/02/7505-0818$27.00 © 2002 MAIK "Nauka/Interperiodica"

used both polymer films separated from the supports and the gel fraction recovered from the samples. The difference between the metal contents in the film and gel fraction allows determination of the copper content in the sol fraction (soluble fraction of the sample).

Data on the accumulation of carbonyl groups and copper in the polyethylene films and on the progress of oxidative cross-linking are given in Fig. 1. Metal becomes detectable in the polymer simultaneously with carbonyl groups (Fig. 1, curves *1* and *3*), whereas traces of the insoluble phase appears 1 h later (Fig. 1, curve *2*). All the dependences are plotted as ascending curves with saturation (stabilization), though the pronounced stabilization section is typical only for the kinetic curve of accumulation of the carbonyl groups (Fig. 1, curve *1*). However, stabilization of the content of the carbonyl groups is probably an apparent process. From our viewpoint, in the course of oxidation the dynamic equilibrium is attained between the carbonyl groups in acidic oxidation products (absorption band at 1720 cm^{-1}) and in low-molecular-weight fatty acids participating in the reactions yielding copper-containing compounds (products of the contact reactions). During oxidation on the support, the polyethylene film accumulates significant amounts of copper: up to several tenths of percent.

As seen, in the initial stage of oxidative cross-linking the kinetic curves of metal accumulation in the gel fraction and in the film as a whole approximately coincide (Fig. 1, middle sections of curves *3* and *4*). Hence, in this oxidation stage the copper content in the soluble polymer fraction is also similar. At prolonged oxidation, copper accumulates more actively in the gel fraction (Fig. 1, curves *3* and *4* diverge from each other). For example, after oxidation for 10.5 h, the content of copper in the cross-linked fraction reaches 0.52%, with the film as a whole containing 0.45% Cu and the minor sol fraction, only 0.18% Cu. The increased copper concentration in the gel fraction is probably due to the fact that, with increasing density and branching of the oxidative cross-links, the greater number of low-molecular-weight copper-containing compounds are encapsulated in the polymer network and cannot be recovered by boiling in *o*-xylene. As a result, only copper compounds with a linear structure and a small molecular weight are recovered from the sample. In this stage of oxidation, the content of metal in the films changes only slightly, because the polymer cross-linking hinders the metal transfer (Fig. 1, curve *3*).

Thus, the metal transfer into the polymer bulk almost ceases on passing of the polyethylene film into

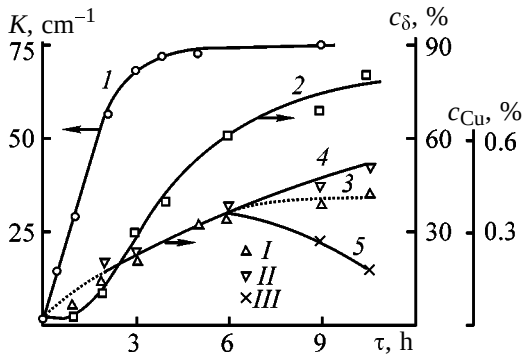

Fig. 1. (*1*) Extinction coefficient K of the absorption band at 1720 cm^{-1}, (*2*) content of the gel fraction c_δ, and (*3*–*5*) content of copper c_{Cu} in polyethylene films as functions of the time τ of their oxidation at 150°C on copper supports. Variation of the metal concentration in the (*I*) film, (*II*) gel fraction, and (*III*) sol fraction.

the inhibited state, and formation of the cross-linked structure causes redistribution of the metal between the sol and gel fractions of the polymer. At denser cross-linking of polyethylene, the copper content in the gel fraction is significantly greater than that in the sol fraction.

To elucidate the mechanism of the copper transfer (diffusion of low-molecular-weight metal carboxylates or "relay" transfer of copper ions with participation of carbonyl groups) at contact oxidation of polyethylene, we performed the following experiment. A series of 100-μm polyethylene films was oxidized on a copper support at 150°C for 10.5 h. Then, they were separated from the support, and the samples for measurements were prepared as follows. Two films of equal thickness of unoxidized (film I) and oxidized (film II) polyethylene were put in contact (as a two-layer stack) and then were melted on an inactive support (aluminum foil). In the sample, film II was in contact with a support, whereas film I was placed on the top, i.e., it formed the outer layer of the stack. The scheme of the sample is shown in Fig. 2. The resulting stack was placed in an oven and heated in air at 150°C; then the sample was cooled and films I and II were separated from each other. The changes in the content of copper, gel fraction, and carbonyl groups in the films during their heat treatment are illustrated by Figs. 2 and 3.

The redistribution of copper between films I and II is shown in Fig. 2; the total content of metal in the sample is 100%. As seen, at contact thermal treatment copper passes from film II into film I, and nearly 30% of copper occurring in film II transfers into film I during 8-h heat treatment.

The kinetics of various processes occurring in

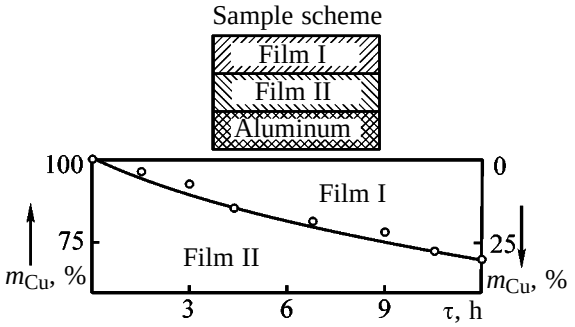

Fig. 2. Redistribution of copper m_{Cu} during heat treatment at 150°C of a stack consisting of a film oxidized on a copper support (film II) and an unoxidized film (film I). (τ) Time.

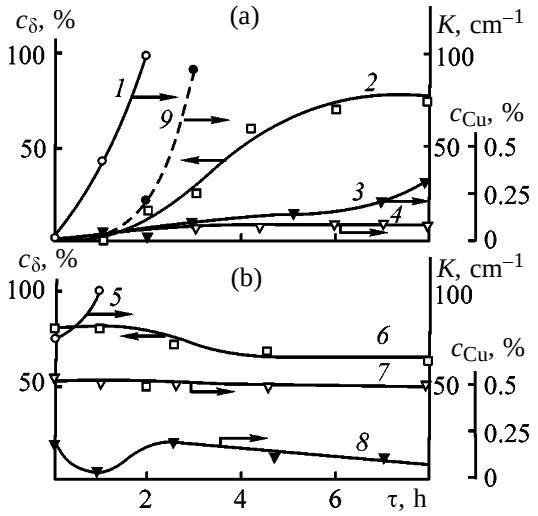

Fig. 3. (*1, 5*) Extinction coefficient K of the absorption band at 1720 cm^{-1}, (*2, 6*) content of the gel fraction c_δ, and content of copper c_{Cu} in the (*4, 7*) gel and (*3, 8*) sol fractions of polyethylene films (a) I and (b) II as influenced by the time τ (h) of oxidation of their stack at 150°C. (*9*) Variation of the extinction coefficient during oxidation of polyethylene film on the aluminum support.

films I and II are shown in Fig. 3. In the initial stage of the thermal treatment ($\tau \leq 1$ h), copper disappears from the soluble fraction of film II almost completely, its content becomes as low as 6% of the total copper content in the sample (Fig. 2; Fig. 3, curve *8*), whereas the content of the gel fraction in film II remains constant (Fig. 3, curve 6). Simultaneously, the same amount of copper appears in film I (Fig. 2). These data suggest that the copper transfer from the bottom film proceeds by the diffusion of low-molecular-weight metal-containing compounds in the sol fraction of film II. As for metal occurring in the gel fraction of film II, it is retained in the film during its thermal treatment.

Copper compounds passing into film I catalyze the oxidative transformations of the polymer, which is confirmed by the higher rate of accumulation of carbonyl groups in film I as compared with the film oxidized on the inert support (Fig. 3, curves *1* and *9*).

In the course of the thermal treatment of film II, intensive accumulation of oxidation products is resumed (Fig. 3, curve *5*). In our opinion, this is probably due to the transfer of the low-molecular-weight oxidation products from intensively oxidized film I and further oxidation of film II, owing to a decrease in the concentration of copper-containing compounds in the film. As known [1], inhibition of polyethylene oxidation at contact with a copper support is due to the accumulation of the critical content of copper, and the residual content of copper in film II (decreased as a result of the metal transfer into film I) does not provide inhibition of the oxidative degradation of the polyethylene film.

At further thermal treatment of the sample ($\tau \geq 1$ h), the oxidative cross-links in film II partially degrade (Fig. 3, curve *6*), which increases the content of the sol fraction; simultaneously occurs further accumulation of copper in film I. It should be noted that the concentration of copper in the gel fraction of film II remains constant (Fig. 3, curve *7*). This suggests that, with decreasing content of the gel fraction in film II, copper still passes into film I by the mechanism of diffusion of low-molecular-weight copper-containing compounds. After a decrease in the initial stage of the process, the copper content in the sol fraction of film II passes a weakly defined maximum (Fig. 3, curve *8*). This maximum is probably due to competition of two processes: increase in the content of the sol fraction in film II (with the corresponding increase in the metal content) and transfer of copper-containing compounds into film I (with the corresponding decrease in the metal content in the sol fraction of film II).

Copper passing into film I is distributed between the sol and gel fractions nonuniformly. In the cross-linked fraction of the polymer, the content of metal in the course of thermal treatment remains almost unchanged, being as low as 0.08% (Fig. 3, curve *4*). This fact suggests that the cross-linked structure is formed in the most rapidly oxidized areas of the polymer (small metal content), i.e., the cross-links appear predominantly in the course of oxidation. In the sol fraction of film I, the content of copper monotonically increases during its heat treatment, and after 8-h heating the metal content reaches 0.3% (Fig. 3, curve *3*). Thus, copper compounds obviously cannot

pass into the gel fraction of the film and are accumulated in its soluble fraction.

CONCLUSION

Our tests showed that the diffusion of low-molecular-weight copper carboxylates, which are the products of contact reactions, is the most probable mechanism of the metal transfer at contact oxidation of polyethylene on a copper support.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electrochemical Preparation of Chitin Materials

E. E. Kuprina, K. G. Timofeeva, and S. V. Vodolazhskaya

State Research and Design Institute for Fishing Fleet (GYPRORYBFLOT), St. Petersburg, Russia

Received September 21, 2001; in final form, January 2002

Abstract—Electrochemical processes for preparation of various chitin materials are examined. Physicochemical and biochemical properties of the products are studied, particularly the effect of deproteinization and degreasing of chitin materials on their sorption and other characteristics.

Materials based on the natural polysaccharide chitin are of steadily growing interest in view of their use as sorbents for environmental remediation (treatment of industrial wastewaters, potable water, and soils) and also for medical purposes. The reason is that natural sorbents are generally nontoxic and biologically active. Along with anion-exchange capacity, among useful properties of chitin is its cation-complexing ability.

However, the existing methods for manufacture of chitin materials, based on deproteinization, demineralization, and decolorization of raw material (shells of crustaceans, fungi, and insects) using alkalis, acids, oxidants, or enzymatic agents are cost-inefficient and not environmentally safe. Furthermore, the use of chemically corrosive reagents often deteriorates the quality of chitin and associated products (proteins, lipids) as a result of chemical or oxidative degradation [1]. The necessity in performing repeated deproteinization and demineralization with intermediate washings to neutral reaction makes the process multistage, also considerably increasing the product cost.

In some application areas (water and soil treatment to remove heavy and transition metals and radionuclides), such intermediate products of chitin manufacture as chitin–glucan, chitin–protein, and chitin–mineral complexes are competitive [2, 3]. In addition to low cost, among the advantages of, for example, chitin–mineral complexes, chisites, is high sorption capacity for heavy and transition metals (up to 2–3 mg-equiv g^{-1}), which is higher by an order of magnitude as compared to straight chitin.

In mid-1990s, an electrochemical process for preparation of chitin materials was developed as an alternative to the traditional methods [4].

It is known that electrochemical methods are fairly efficient in processing biological raw materials, as providing a direct effect of the electromagnetic field on a substrate (without intermediate transformation of the energy) [5]. By virtue of heterogeneity of the electrical properties, a shell-containing raw material is readily polarized, charged, and yielded to the strength of the electromagnetic field. As a result, all the mass-transfer processes accelerate, the cell structure transforms, and the penetrability of membranes and cells increases as well as the extraction rate.

The essence of the electrochemical method for chitin manufacture is that a shell-containing raw material as an aqueous salt emulsion is processed in a specially designed electrolyzer. In this case, deproteinization, demineralization, and decolorization proceed under the effect of the electromagnetic field. The OH^- and H^+ ions, produced as a result of electrolysis of water, and a number of low-molecular-weight products control pH and the redox potential [6]. The process demonstrates such advantages as environmental safety and the possibility of realizing deproteinization, demineralization, and decolorization in one stage at very low alkali and acid concentrations (0.05–0.1%) without intermediate washings to neutral reaction of the medium.

However, while deproteinization proceeds quite rapidly at low solid to liquid phase ratio (1 : 6), completion of demineralization requires 12–24 h at a considerably higher solid to liquid phase ratio, thus reducing the efficiency and profitability of the electrochemical process. Furthermore, owing to low reagent concentrations in the process, the resulting chitin is characterized by increased (by 6–10%) content of lipids, which, as known, shield the reaction centers of chitin, deteriorating its performance [7].

Therefore, the goal of this work was to develop a profitable electrochemical process for production of chitin with improved sorption characteristics.

1070-4272/02/7505-0822$27.00 © 2002 MAIK "Nauka/Interperiodica"

EXPERIMENTAL

As a raw material for preparation of chitin materials, we used the freshwater crustacean *Gammarus pulex* in the dispersed frozen or dry form. Chitin-based materials were prepared by two different methods involving deproteinization only, or deproteinization and demineralization. A raw material in the form of an aqueous salt emulsion (particle size $d \le 5 \times 10^{-3}$ m) at a fixed solid to liquid phase ratio was processed in an electrolyzer at a current density of 300–500 A m^{-2} for 30–40 min. Deproteinization was performed at pH ≥ 12.4. Then the system was heated to 60°C and allowed to stand at this temperature for 45 min. Demineralization was carried out at pH ≤ 2.0. Then the system was allowed to stand for 12–18 h at room temperature. In other experiments, deproteinization was performed off the electrolyzer by treating the raw material with a catholyte representing an electrochemically activated solution at pH > 12.0, prepared in the cathode cell of the electrolyzer. The anode material was platinized titanium, and the cathode material, stainless steel. A membrane was prepared from a sulfonic cation-exchange material. The products prepared by this method were supplied with names ended with el, for example, chitinel and chisitel.

For comparison, we prepared a sample of chisite by deproteinization of the dispersed raw material with 4% NaOH (solid to liquid phase ratio 1 : 10) at 65°C for 2.5 h [8].

Total nitrogen and mineral residue after calcinations were determined according to GOST (State Standard) 7636–85.

To determine the water-retaining capacity (WRC), a sample was held in distilled water for 20 h, filtered through a fabric, and centrifuged at 4000 rpm for 10 min. The WRC was estimated as

$$\mathrm{WRC} = [(m_1 - m_0)/m_0] \times 100\%,$$

where m_0 and m_1 are the sample weights after drying to constant weight at 105°C and after centrifugation, respectively.

Infrared spectra were registered on a Perkin–Elmer 16 PC FTIR spectrometer using KBr technique. Samples (2 mg) were vacuum-dried at 80°C for 12 h and mixed with KBr (100 mg). Then disks (0.5 mm thick) were pressed and vacuum-dried at 110°C for 24 h. The infrared spectra were processed using PeakFit software pack for Windows.

Sorption characteristics of chitin materials were studied in the static mode using an original technique. In one series of experiments we used solutions containing Cu^{2+} in a low concentration (up to 0.7 mM), which is typical of potable water, and in another series, solutions containing up to 30.0 mM, simulating industrial wastewater. The static sorption capacity SC was estimated from the sorption isotherms:

$$\mathrm{SC} = (c_0 - c_{eq})\Gamma,$$

where c_0 and c_{eq} are the initial and equilibrium metal concentrations (mM) and Γ is the liquid to solid phase ratio.

In the experiments with low copper concentration, a weighed portion of a sorbent (0.25 g) was poured over with 50 ml of a 0.5 to 0.7 mM copper solution (solid to liquid phase ratio 1 : 200). One day after, the residual equilibrium copper concentration in the solution was determined. The copper concentration in the initial and equilibrium solutions was determined as follows. A 50-ml sample of the solution was acidified with 2–3 drops of dilute (1 : 1) HCl. The sample was then placed into a separating funnel, and 12.5 ml of 0.3 g l^{-1} lead diethyldithiocarbamate in carbon tetrachloride was added. The funnel was vigorously shaken for 2 min, and the phases were separated. The organic phase was analyzed for copper spectrophotometrically at a wavelength of 440 nm.

In the experiments with high copper concentration, the sorption isotherm was obtained at constant copper concentration (29.3 mM) and variable weight of a sorbent sample (0.2–1.0 g in 50 ml of the solution). In these experiments, the copper concentration was determined on a KFK2 photoelectric colorimeter at a wavelength of 750 nm.

The degree of deacetylation of chitin-based materials was determined by potentiometric titration of a suspension of the sample in 0.1 N NaOH with 0.1 N HCl in the presence of a supporting electrolyte. The amount of NH_2 groups was estimated by the standard method [9].

The lipid concentration was determined by extraction using the Folch method. The fractional composition and percentage of individual lipids were determined by TLC on KSK silica gel using the solvent system hexane–diethyl ether–acetic acid (70 : 30 : 2). The fractional compositions of phospholipids was studied by TLC. The phospholipid content was determined colorimetrically [10]. The fatty acid composition of phospholipids was studied by GLC (with pre-

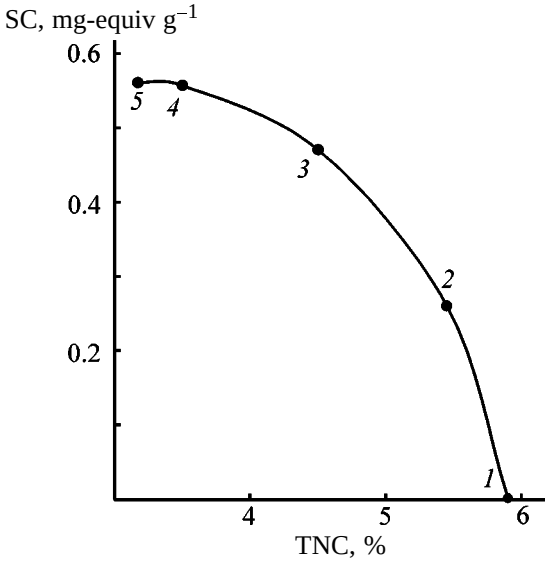

Fig. 1. Static sorption capacity (SC) for copper of chitin-based materials as a function of the degree of deproteinization expressed via the total nitrogen content TNC. The numbers at the points correspond to the sample numbers (see text).

liminary methylation of samples) on a Perkin–Elmer chromatograph [10].

It is known that, in the shell, proteins are in immediate vicinity of chitin fragments. This organic matrix is surrounded by the mineral phase (complex calcide mosaic) [11]. Therefore, removal of the protein component provides access to functional groups of chitin.

We studied the effect of the degree of deproteinization of the shell on its sorption characteristics. For this purpose, samples of chitin materials were prepared using various methods for deproteinization of dispersed *Gammarus*: treatment with water (sample no. 1); treatment for 6 h with the alkaline catholyte solution remaining after deproteinization of the previous portion of the raw material (sample no. 2); double treatment with the alkaline catholyte solution (sample no. 3); as for sample no. 2, but with aftertreatment in the cathode cell of the electrolyzer (sample no. 4); and double treatment in the cathode cell of the electrolyzer with intermediate heat treatment between the stages (sample no. 5).

The sorption capacity for copper of the resulting samples as a function of the degree of deproteinization is shown in Fig. 1.

The results show that the degree of deproteinization has a considerable effect on the sorption capacity (SC of sample nos. 4, 5 is higher by a factor of 1000 than that of the initial raw material). The maximal SC (0.28 mmol g^{-1}) is realized at high degree of deproteinization (TNC = 3.5%).

To provide the desired high degree of deproteinization, we developed a process for preparing highly deproteinized chitin materials, chisitels (see scheme below).

In addition to the basic stage of electrochemical deproteinization II in the cathode cell of the electrolyzer, the process flowsheet includes preliminary deproteinization I (pretreatment of the raw material in the catholyte solution representing a waste from the deproteinization II). This operation allows the required degree of deproteinization to be attained at reduced by half energy and reagent consumption and the pollution of the electrolyzer elements with protein-lipid components to be decreased. The previous electrochemical process included double treatment of the raw material in an electrolyzer [4].

It is known that chitin-containing materials demonstrate high affinity for lipids, causing the need in their degreasing. Lipids shield the reaction centers of polar functional groups in chitin substances, thus deteriorating their reactivity, sorption capacity for metal ions, and also organoleptic characteristics [7].

There is only limited information on the methods for degreasing of chitin-containing materials. This is probably due to the fact that, in preparation of chitosans, which are mostly used in sorption processes, from chitins in concentrated alkaline solutions, lipids are practically totally decomposed and removed. We demonstrated that in the proposed electrochemical process the lipid content in the resulting chisitel is twice that in the product obtained by the alkaline method. The reason is that in our process deproteinization proceeds under mild conditions ([OH$^-$] <0.1%).

Organic solvents commonly used for degreasing (alcohols, ethers, etc.) provided a desired effect only with multiple and long-time extraction at elevated temperature. Furthermore, organic solvents are toxic and fire hazardous.

To understand the fate of chitin–lipid complexes in electrochemical preparation of chitin from crustaceans and to select a method and conditions for degreasing of chisitel, we made a characterization of lipids of raw materials [*Gammarus*, chisitel I (see process flowsheet), and chisite].

It follows from Tables 1 and 2 that lipids of *Gammarus* consist essentially of neutral lipids and free fatty acids (FFAs). Increased FFA content, as known, is a result of high activity of lipolytic enzymes. The major fraction of fatty acids (64.1%) is represented by

Process flowsheet for preparation of chisitel.

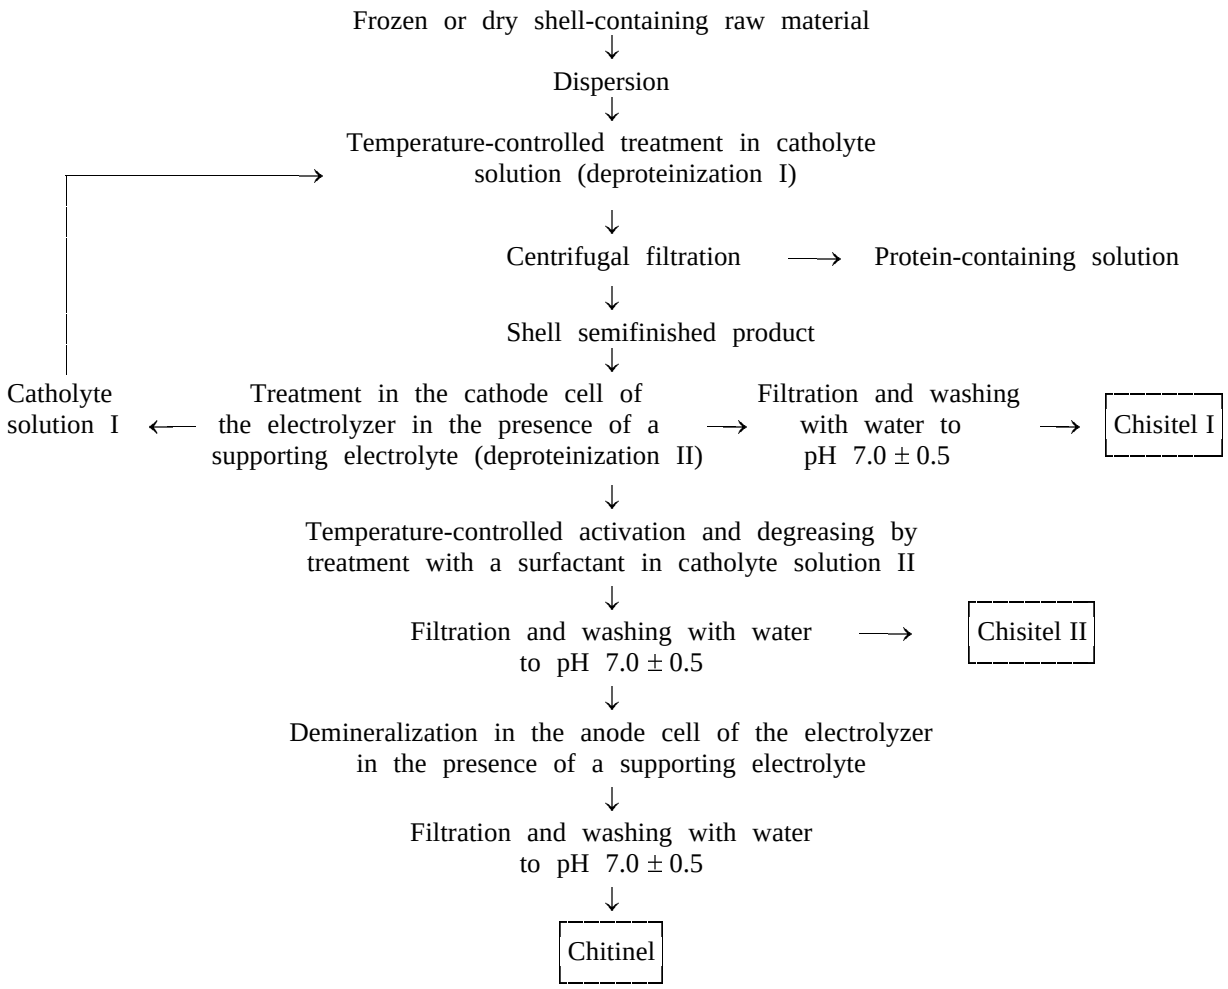

Table 1. Fractional composition of lipids

Fraction	Content, mg %			
	Gammarus	chisite*	chisitel I	chisitel II
Phospholipids, among them:	263.00	343.06	315.40	27.60
phosphatidylserine	11.18	–	–	–

phosphatidylcholine	81.77	–	–	–
phosphatidylethanolamine	72.48	–	–	–
diphosphatidylglycerol	13.89	–	–	–
phosphatidylinositol	30.53	–	–	–
Mono-, diglycerides	323.85	451.96	590.53	61.60
Triglycerides	1020.94	694.30	885.30	130.00
Free fatty acids	1136.21	1230.67	1954.67	180.80
Cholesterol, cholesteryl esters	46	–	–	–

* Obtained by alkaline treatment.

Table 2. Fatty-acid composition of lipids

Fatty acids	Content, % of the total fatty acids		
	Gammarus	chisite	chisitel I
Saturated	35.9	1.1	0.9
Monounsaturated	38.0	8.8	7.7
Polyunsaturated	26.1	90.1	91.4

unsaturated, primarily monounsaturated acids. It was demonstrated that the fractional composition of lipids of *Gammarus* is similar to that of small sea crustaceans [12], i.e., a degreasing process suitable for *Gammarus* can be then expanded to other kinds of raw material.

It is also known that, in the traditional deproteinization with NaOH, the relative contents of neutral lipids and FFAs decrease to a more considerable extent as compared to the electrochemical process. This is due to the fact that hydrolysis of neutral lipids and saponification of free fatty acids in the cathode cell occurs to a considerably lesser extent, as a result of lower OH^- concentration and temperature [13].

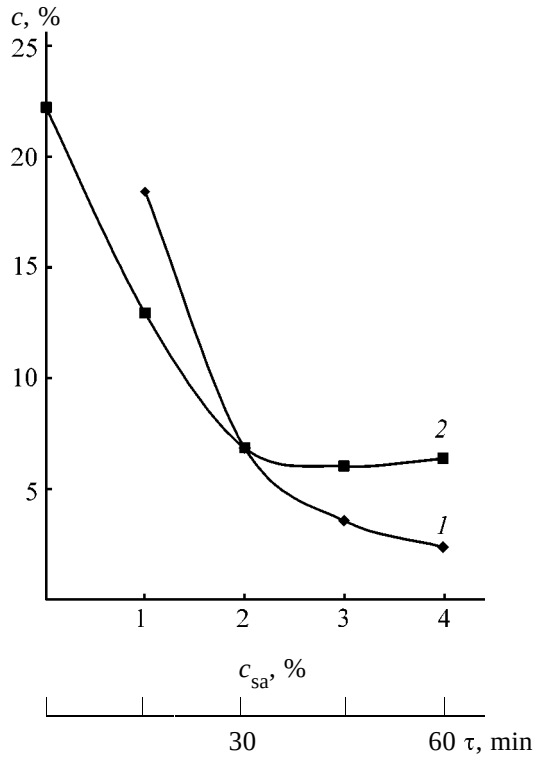

Fig. 2. Lipid content c in chisitel as a function of (*1*) surfactant concentration c_{sa} and (*2*) treatment time τ. Temperature 82°C; τ = 30 min (*1*); and c_{sa} = 2% (*2*).

Analysis of the fatty-acid composition of lipids showed (Table 2) that, in both alkaline and electrochemical deproteinization, the most active process is hydrolysis of saturated and monounsaturated lipids. As a result, their relative content in chitin–mineral complexes significantly decreases.

It is known that base hydrolysis of liquid and solid fats with formation of water-soluble products does not control the efficiency of degreasing action of a reagent. The key factor is the capacity to decrease the surface tension at the water–fat interface [13]. Therefore, we proposed to use anionic surfactants [7] for degreasing chitin materials obtained by the electrochemical method. The function of surfactants is to decrease the surface tension and to increase the wettability of the shell. Also they favor dispersion of solid lipids and emulsification of liquid lipids, preventing their secondary deposition onto the chitin surface.

We optimized the degreasing parameters (surfactant concentration, solid to liquid phase ratio, temperature, and treatment time) (Fig. 2) and demonstrated that it is advisable to perform degreasing simultaneously with the stage deproteinization II (this simplifies the process flowsheet, increasing the profitability).

The use of surfactants instead of conventional organic solvents eliminates fire hazard, decreases the process cost, and provides decrease in the lipid content in chisitel from 17–23 to 1–3%.

Physicochemical and biochemical characteristics of the shell-containing raw material, chisite, chisitels, and chitinel are summarized in Table 3. The results show that all the chisitels differ from chitinel by higher ash content, which is due to the lack of the demineralization stage. The total nitrogen content, characterizing the degree of deproteinization, is higher in chisitel obtained electrochemically than in that obtained by treatment with NaOH by 1.2% on the average.

Degreasing allowed increase in the specific surface area of chisitel from 2.0 to 11.0 $m^2 g^{-1}$.

Sorption isotherms show that, among the chitin materials studied, chisitel II is the most efficient sorbent for copper (Fig. 3).

As compared to chitinel, chisitels demonstrate better sorption of copper even at low copper concentration (<0.5 mM), while conventional ion-exchange resins are practically inoperative at such a low concentration; in this case the degree of recovery approaches 80–90%. This suggests high binding energy and sorp-

Table 3. Physicochemical and biochemical characteristics of chitin-containing materials

Parameter	*Gammarus*	Chisite	Chisitel I	Chisitel II	Chitinel
Total nitrogen, %	8.9	4.8	3.5	3.5	6.1
Ash content, %	17.5	27.0	28.1	27.8	0.8

Lipids, % of dry weight	10–12	12–14	20–23	1–3	30–36

tion by the complexation mechanism, which is typical of chitin materials.

The static sorption capacity of chisitel II (3.2 mmol g^{-1}) is higher by an order of magnitude than that of chitinel (Fig. 3), approaching SC of chitosans [2], which cannot be explained by only the presence of mineral salts of the carbonate–phosphate type.

It is well known [14] that carbonates and phosphates of such metals as Ca, Mg, and others are capable of sorbing metal ions by the mechanism of heterogeneous exchange at the phase boundary. For this to be realized, their specific surface area should be at least 100–200 $m^2 g^{-1}$. In the chitin materials studied in this work, this parameter is only 1.8 and 11.0 $m^2 g^{-1}$ for chitinel and chisitel, respectively. The degree of deacetylation, also influencing the sorption characteristics, is practically the same in these materials, being 0.2–0.3. Therefore, one may suggest that sorption processes in chitin–mineral complexes occur by virtue of metal complexation to acetamide groups, as demonstrated by infrared spectroscopic data. Indeed, a 10-cm^{-1} high-frequency shift of the absorption band due to bending vibrations of amides I (C=O…H–N) at 1656 cm^{-1}, caused by intermolecular interaction, was observed in the IR spectra of chisitel containing adsorbed Cu^{2+} ions, suggesting that the bond energy increases by virtue of metal complexation. An additional evidence in favor of such specific interaction is provided by the fact that the intensity of the amide I band in the spectrum of chisitel containing adsorbed Cu^{2+} ions increases by 40%, while that of amide II (C–O…H–N) at 1565 cm^{-1}, caused by intramolecular interaction, decreases. In the absorption spectra of chisitels, the intensities of these bonds are practically the same.

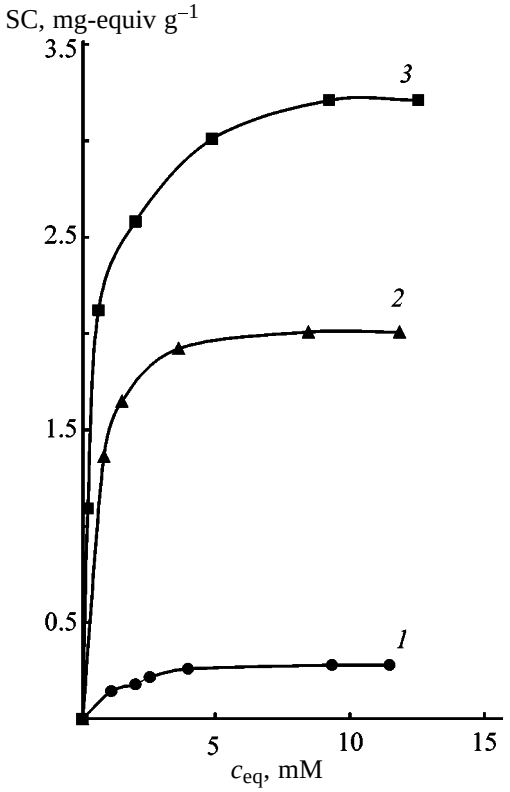

Fig. 3. Copper sorption isotherms: (*1*) chitinel, (*2*) chisitel I, and (*3*) chisitel II. (SC) Static exchange capacity and (c_{eq}) $Cu(NO_3)_2$ concentration in the equilibrium solution.

CONCLUSIONS

(1) An electrochemical process is developed for preparation of the chitin–mineral complex, chisitel, with a high sorption capacity for Cu^{2+}.

(2) A method for degreasing of chitin-containing materials is proposed, based on the use of an anionic surfactant.

(3) The sorption capacity of chisitels increases and the water-retaining capacity decreases with increasing degrees of deproteinization and degreasing.

Received June 21, 2001; in final form, January 2002

Abstract—Quantitative and qualitative changes in humic acids of meadow soddy soils, occurring under the action of various fertilizer systems, were studied by ^{13}C and ^{31}P NMR.

NMR spectroscopy is an extremely promising method of studying the structure of soil organic substance whose main components are humic acids (HAs). Since the late 1970s, various soils were extensively studied by ^{13}C and ^{1}H NMR [1]. In 1980, ^{31}P NMR was first used for studying alkaline soils extracts [2]. Only this method allowed identification of various forms of phosphorus addition to HA macromolecule and estimation of quantitative relationships between these species. Therefore, this method is widely used for studying various types of soils and soil fractions [3–5]. Data on transformations of soil organic components under the action of cultivation are limited [6].

Here we report on the quantitative and qualitative changes proceeding in HAs of meadow soddy soils under the action of various fertilizer systems, as studied by ^{13}C and ^{31}P NMR.

EXPERIMENTAL

We studied the HAs of soils subjected to the action of fertilizers under the stationary field conditions.[1] Peat–manure compost (C) was used as an organic fertilizer. A mixture of granulated ammonium nitrate NH_4NO_3, granulated double superphosphate $Ca(H_2PO_4)_2$, and potassium chloride KCl were used as mineral fertilizers. The amount and composition of the added fertilizers are listed in Table 1. Humic acids were recovered by the standard procedure [7].

The total phosphorus content was determined spectrophotometrically with the vanadium–molybdenum reagent after combustion of the samples in a flask filled with oxygen.

To obtain NMR spectra, 50 mg of an HA sample was dissolved in 0.5 ml of a 0.5 M NaOH solution in D_2O and placed into an ampule of 5 mm outer

Table 1. Amount and composition of the added fertilizers

Sample no.	Note	Amount of added fertilizers, kg ha^{-1}
1	Control (no fertilizers)	–
2	1NPK	N60P90K90*
3	1C	100×10^3 C
4	2C	200×10^3 C
5	1NPK + 2C	N60P90K90 + 200×10^3 C
6	3NPK + 1C	N180P270K270 + 100×10^3 C
7	3NPK + 2C	N180P270K270 + 200×10^3 C

* (NPK) Active elements of a mineral fertilizer (nitrogen, phosphorus, and potassium); the number to the right of the corresponding element corresponds to the amount of this element in kilograms added per hectare of the soil, evaluated from the formulas of components of the mixed fertilizer.

[1] The experiments were carried out at the Novoaleksandrovskoe pilot station (Sakhalin Island) since 1990. The soil of the pilot parcel was meadow soddy, medium-loamy, and old arable. At the pilot plots, feed crop rotation was maintained for 8 years. The fertilizers were added three times at 1-year intervals and then, after three years (in 1994). In all runs, the soil samples were withdrawn from a depth of 0–20 cm.

diameter. The ^{13}C and ^{31}P NMR spectra were recorded on a Bruker DRX-500 spectrometer at 125.76 and 202.46 MHz, respectively. To exclude the nuclear Overhauser effect, the ^{13}C NMR spectra were recorded with proton decoupling in the INVGATE mode, and the ^{31}P NMR spectra, in the single resonance mode.

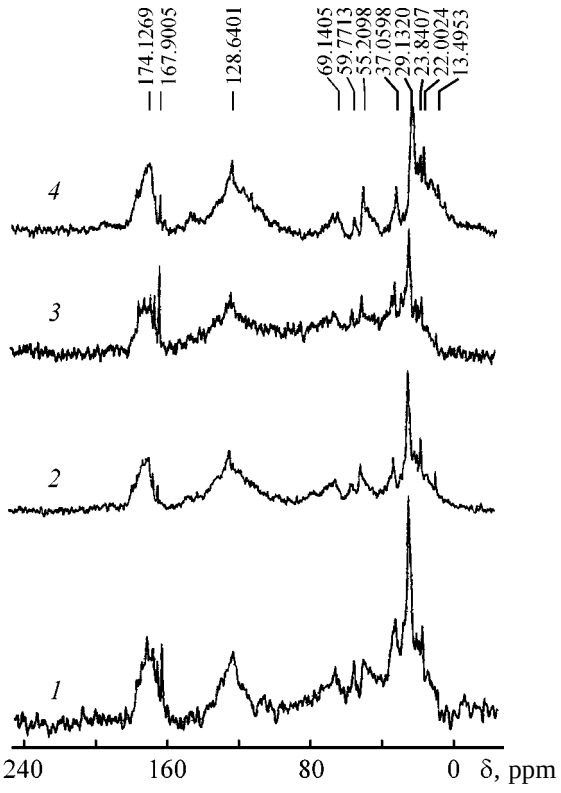

Fig. 1. ^{13}C NMR spectra of the HA samples: (δ) chemical shift; the same for Fig. 4. Figures at curves are sample nos. in Table 1; the same for Fig. 4.

Tetramethylsilane (TMS) and 85% H_3PO_4 were used as external references. The spectra were recorded at pulse delay of 1 s.

Typical ^{13}C NMR spectra of the studied HAs are shown in Fig. 1. They allow distinction and quantitative evaluation of the relative content of the following fragments of HA macromolecule: alkyl (aliphatic) carbon (0–65 ppm); carbon in carbohydrates, alcohols, and acetals, designated as polysaccharide carbon (65–90 ppm); aromatic carbon (90–160 ppm); and carboxylic carbon (160–200 ppm). These are the commonly adopted intervals in which ^{13}C NMR spectra of HAs are integrated, though the limits of these intervals can differ by 5–10 ppm [8]. The relative content of individual carbon-containing functional groups in HAs was estimated by integration of the signals in the above intervals. The results are given in Table 2. The relative standard deviation of the results of tenfold manual integration did not exceed 3%.

Humic acids recovered from control soils are characterized by a low fraction of aromatic carbon (25.6%). The remaining carbon is distributed in macromolecules among aliphatic groups, polysaccharides, and carboxyls in the 44.4 : 6.4 : 23.6 ratio.

All the fertilizers taken in the indicated amounts decrease the amount of carboxy groups in HAs (Fig. 2): organic, by 6.7–5.1% and mineral, by more than 10%. The shapes of the ^{13}C NMR spectra of carboxylic carbon (160–200 ppm), namely, significant decrease in the number of narrow signals at 170 ppm, suggest that addition of mineral fertilizers affects so-called "peripheral" acids weakly bonded to aromatic compounds. These acids, entering into the reaction with additional cations of fertilizers, are hydrolyzed. The remaining carboxy groups are bonded to the

bulky aromatic "core" of HA and are manifested in the spectrum as a broadened structureless peak (Fig. 1). Organic fertilizers do not affect the fraction of weakly bonded acids (narrow lines in the spectrum of sample no. 3, as well as in the spectrum of control sample); however, an increase in the amount of weakly bonded acids results in increased fraction of acids bonded to the core.

All the fertilizers taken in the indicated amounts increase the relative amount of aromatic carbon in HAs (90–160 ppm). This increase is maximal for sample no. 5 (close to 11%) and minimal for sample no. 3 (approximately 5%). The characteristics of sample nos. 2 and 5 are practically the same. This suggests that mineral fertilizers exert a decisive effect on the HA structure, and the effect of compost against this background is insignificant. A minor difference between sample nos. 2 and 5 is observed only for aliphatic and polysaccharide carbon. The maximal amount of the added organomineral fertilizers (sample nos. 6 and 7) gives the maximal increase in the relative content of aromatic carbon.

The use of mineral or organic fertilizers does not appreciably affect the relative content of aliphatic carbon, except the case when triple doses of mineral fertilizers were used. In this case, the amount of aliphatic carbon somewhat decreased. This combination of changes in the relative content of aromatic and aliphatic carbon in HAs suggests the decisive role of high concentrations of salts entering into composition of mineral fertilizers in hydrolysis of aromatic and aliphatic fragments of HA.

The use of mineral fertilizers (sample no. 2) results in the maximal increase in the polysaccharide carbon fraction (by a factor of almost 2 in comparison with the control sample): addition of the organic fertilizer (sample no. 5) somewhat moderates this effect. Addition of organic fertilizers somewhat increases the fraction of polysaccharides (sample no. 3), but an increase in the amount of organic fertilizers (sample no. 4) brings the amount of polysaccharides to the minimum. The use of organomineral fertilizers (sample nos. 6, 7) somewhat decreases, in comparison with the control sample, the fraction of carbon atoms surrounded by oxygen atoms.

Even with the use of large amounts of fertilizers, the ratio of aromatic and aliphatic carbon in the HAs studied differs essentially from that in HAs of chernozem, the richest soil in which the relative fractions of aromatic and aliphatic carbon are 53.4 and 13.3%, respectively [9].

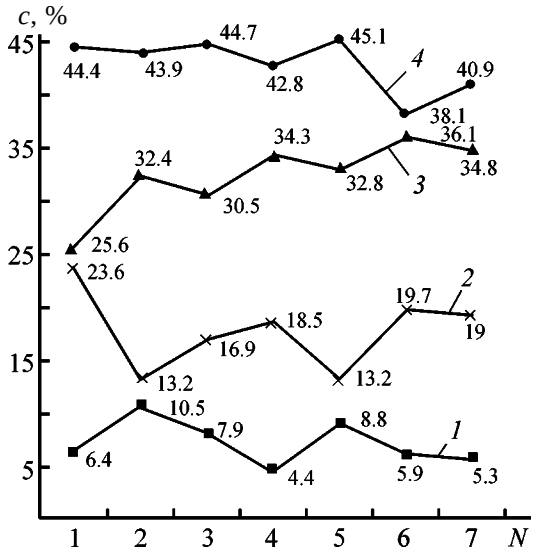

Fig. 2. Relationship between various carbon-containing functional groups in the samples of HAs studied: (*c*) content of functional groups in HA and (*N*) sample no. in Table 1. Carbon: (*1*) polysaccharide, (*2*) carboxy, (*3*) aromatic, and (*4*) aliphatic.

In the course of soil formation, phosphorus entering into the composition of mineral phosphates of soil-forming rocks is incorporated into the soil organic substance and is accumulated in the soil, being the important reserve of phosphorus supply to plants. Incorporation of inorganic phosphorus of fertilizers into soil organic substance proceeds indirectly through involvement of phosphorus in biological processes in the soil. The results of numerous studies suggest that the use of organic and inorganic fertilizers increases the content of organic phosphorus P_{org} in various soils. However, the phosphorus content can decrease during soil cultivation, which is caused either by increased activity of phosphatase and intensity of mineralization of organophosphorus compounds, or by chemical transformations of the initial organophosphorus compounds increasing their solubility and migration activity. On the whole, the resources of organic phosphorus in the soil are more stable in comparison with inorganic phosphates [6].

According to elemental analysis, humic acids recovered from the control soils are characterized by low content of phosphorus, 0.60%. According to ^{31}P NMR, monophosphate esters (77.8%), mineral orthophosphate (9.95%), and diphosphate esters (12.25%) constitute the major fraction of phosphorus compounds (Fig. 3).

Elemental analysis shows (Table 3) that addition of 1NPK, 2C, and 1NPK + 2C significantly (by a factor

6	0.66	0.09	13.60	0.51	77.30	0.06	9.1
7	0.60	0.04	6.70	0.47	78.62	0.09	14.67

* Data of elemental analysis.

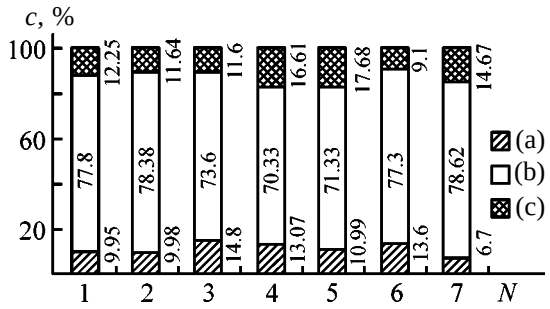

Fig. 3. Ratio between phosphorus-containing species in the HA samples: (*c*) content of various phosphorus-containing species in HA and (*N*) sample no. in Table 1. (a) Mineral orthophosphate, (b) monophosphate esters, and (c) diphosphate esters.

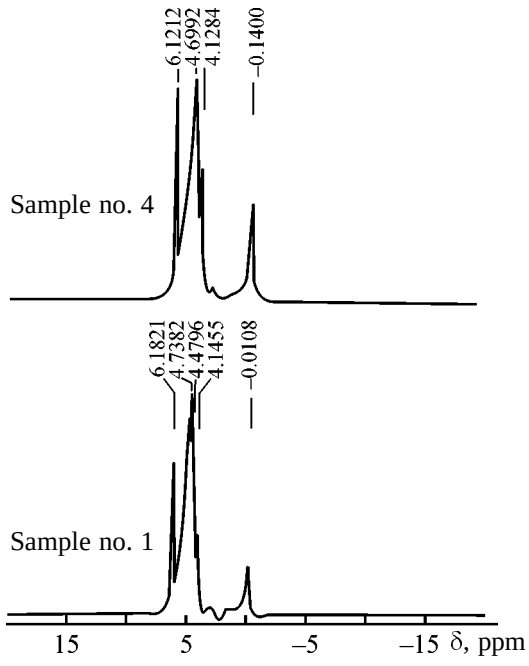

Fig. 4. ^{31}P NMR spectra of HA samples.

of 2–3) increases the phosphorus content in HAs. The use of 1C increases the phosphorus content in HA insignificantly. The maximal amounts of organomineral fertilizers (in sample nos. 6 and 7) do not exert an appreciable effect; the phosphorus content in these samples is comparable with that in the control sample. It can be assumed that large amounts of mineral fertilizers suppress the microbiological activity in the soil and prevent phosphorus incorporation into the HA macromolecule.

Typical ^{31}P NMR spectra of HAs are shown in Fig. 4. The identified signals correspond to the following phosphorus-containing compounds [6]: narrow signal at 6.2–5.8 ppm suggests the presence of mineral orthophosphate ion; in the range of chemical shifts from 5.8 to 3.5 ppm, phosphate monoesters are identified (inositol phosphates, saccharophosphates, and mononucleotides); and a signal in the range from 0.5 to –0.5 ppm corresponds to phosphate diester bond in phospholipids and nucleic acids.

The relative content of individual phosphorus compounds in HAs was estimated by integration of the intensity of the signals in the above intervals. The relative standard deviation of the results of tenfold manual integration did not exceed 1%.

According to data obtained, monophosphate esters (70–80%), mineral orthophosphate (10–15%), and diphosphate esters (10–15%) constitute the major portion of phosphorus compounds in HAs (Fig. 3).

Addition of mineral fertilizers does not change the ratio of phosphorus-containing species in HAs (though its absolute value increases by a factor of 3), and addition of organic fertilizers decreases the fraction of monophosphates owing to increase in the fractions of mineral orthophosphate (sample no. 3) and diphosphates (sample no. 4). Addition of organic fertilizers to 1NPK also decreases the fraction of

monophosphates owing to increase in the amount of diphosphates. The use of maximal amounts of mineral fertilizers in combination with a small amount of compost (sample no. 6) does not alter the amount of monoesters, but decreases the relative content of diesters owing to increase of the amount of mineral orthophosphate. Addition of a larger amount of organic fertilizers (sample no. 7) somewhat increases the fraction of monoesters; in this case, the fraction of monoesters noticeably increases and the amount of mineral orthophosphate reaches the maximum in the series in hand.

CONCLUSIONS

(1) The use of organic fertilizers decreases the amount of carboxy groups in humic acids of the soils by 6.7–5.1%, and the use of mineral fertilizers, by more than 10%; the relative amount of aromatic carbon increases by 5–11%. With addition of mineral fertilizers, the fraction of polysaccharide carbon reaches a maximum. With most of fertilizer systems, the relative content of aliphatic carbon does not noticeably change, though the triple dose of mineral fertilizers decreases its fraction by 3–6%.

(2) Even with addition of large amounts of fertilizers, the ratio of aromatic and aliphatic carbon in the humic acids appreciably differs from that in the chernozem humic acids.

(3) Addition of mineral fertilizers does not affect the ratio of phosphorus-containing species in humic acids, though the absolute value of phosphorus content increases by a factor of 3; addition of organic fertilizers increases the microbiological activity of the soil and decreases the fraction of stable monoesters.

CHEMISTRY OF FOSSIL FUEL

Development and Optimization of the Procedure of Gas-Chromatographic Elemental Analysis of High-Carbon Solid Fossil Fuels

Abstract—A procedure was developed for gas-chromatographic elemental analysis of coals. The conditions of exhaustive oxidation of weighed microportions of the coals were optimized. The procedure of calculating the results of analysis was modified with the aim to improve its reproducibility.

The elemental composition of the organic matter (OM) of solid caustobioliths is one of their most important characteristics governing their properties such as, e.g., the capability for destructive hydrogenation, coking, plastic state formation, etc. One of the best and promptest automated methods of elemental analysis (EA) is gas chromatography. It is equal, or sometimes superior, in precision and reproducibility to the classic EA. However, EA of solid fossil fuels has so far followed old classic procedures [1, 2]. The use of modern micromethods, in particular, gas chromatography has been extremely limited.

This is due, above all, to the lack of reliable methods of exhaustive oxidation of weighed microportions of fossil fuel under conditions of pyrolysis. Most of catalyzing oxidants used as additives to ensure exhaustive combustion and obtain a gas mixture to be further analyzed chromatographically prove to be inefficient in the case of fossil fuels. The organic matter of the latter is typically a highly condensed, high-carbon, high-molecular-weight matrix. The presence of a mineral fraction, sometimes very substantial, ever more complicates exhaustive oxidation of the fuel under the conditions of analysis.

With efficient micromethods of EA, the analytical procedure is significantly simplified and accelerated and can be carried out on a commercial scale with the precision remaining equal to that of classic methods. This makes urgent development and optimization of micromethods of gas-chromatographic EA of fossil fuels and, in particular, search for efficient catalyzing oxidants able of exhaustive oxidation of weighed microportions of fuel under EA conditions.

Published data suggest that modern elemental microanalysis utilizes effective oxidants such as silver permanganate $AgMnO_4$ and its thermal degradation product (Körbl catalyst SPTDP), as well as Co_3O_4, MnO_2, WO_3, and Cr_2O_3 [3–5]. Among these, the first-named four reagents act primarily as oxygen donors. It should be noted that SPTDP also acts as a catalyst and a reagent partially absorbing halogens and sulfur. The function of WO_3 is, essentially, that of binding the interfering elements into thermally stable salts [4, 5]. Fadeeva and Moryakina [6] studied such catalysts as NiO, V_2O_5, MnO_2, PbO_2, Cr_2O_3, WO_3, and their mixtures and showed that some of these compounds (NiO, V_2O_5, Cr_2O_3, WO_3) catalyze surface burning, and others (MnO_2, PbO_2) are oxygen donors. The highest performance was exhibited by MnO_2, NiO, and PbO_2; V_2O_5 performs somewhat worse, and WO_3 proved to be the least effective. Individual oxides were found to strongly corrode the combustion tube, while their mixtures proved to be less aggressive. Fadeeva and Moryakina [6] developed a very effective oxidizing catalyst with the following composition, %: MnO_2 64, Cr_2O_3 13, PbO_2 13, and SiO_2 10.

Thus, numerous and diverse inorganic compounds and their mixtures were suggested as oxidative additions to the specimen to be burnt. However, these do not include silver compounds such as, e.g., Ag_2O_2 or $Ag_2Cr_2O_7$, which are promising as active oxidants for

1070-4272/02/7505-0834$27.00 © 2002 MAIK "Nauka/Interperiodica"

gas-chromatographic EA. As to Ag_2O_2, it is an effective oxygen donor superior in the oxygen content to $AgMnO_4$. The silver metal yielded by its degradation is an effective catalyst of surface oxidation. This made reasonable testing the suitability of these oxidants for gas-chromatographic EA.

Conventional calculational methods, such as, e.g., those described in [4] utilizing response factors for the elements to be analyzed, do not accurately account for the errors associated with the oxidant proper. These methods yield an averaged value of the "zero peak" of the oxidant which is to be subtracted in the appropriate formulas from the peak value for the substance to be analyzed or the reference. This necessitates modification of the formulas for calculating the response factors and the weight fractions of the elements analyzed to accurately account for the errors associated with the oxidants utilized.

The aim of this work was to modify the gas-chromatographic EA procedure as applied to analysis of coals so as to improve its precision and reproducibility.

Our study was concerned with coal from the Sangarskaya mine, Yakutsk coal field.

The analyses were carried out on an Carlo Erba-1100 gas-chromatographic analyzer.

The procedure proposed by the manufacturer is intended for EA of individual organic compounds or their mixtures; it exhibited fairly high precision and reproducibility. We attempted application of this procedure to EA of fossil fuels and certain products thereof such as lignites and coals, shales, sapropel, peat, humic acids, and various extracts thereof. The results of analysis proved to be very distorted, namely, the content of all the elements determined, especially carbon, was considerably (by ~40–50%) underestimated, and also the reproducibility of analysis was considerably deteriorated, i.e., the content of C, H, and N elements proved to be appreciably scattered around the average values. We attempted to explain this phenomenon by the presumed unsuitability of the V_2O_5 oxidant, proposed by Carlo Erba, for exhaustive oxidative pyrolysis of the analyzed fossil fuels (and some of their products) under the actual conditions. These fuels are typically highly condensed, high-molecular-weight, and high-carbon compounds (coals) or have a significant mineral constituent which strongly complicates analysis (lignites, sapropels, and extracts thereof).

The unsuitability of V_2O_5, suggested by the manufacturer as oxidant for analyzing fossil fuels and products thereof, necessitates selection of oxidants able of efficiently oxidizing the above-mentioned compounds during the analytical cycle.

Using the procedure from [7], we prepared certain amount of individual $AgMnO_4$. We tested this compound as a substitute to V_2O_5 in EA of fossil fuels and products thereof and found that $AgMnO_4$ is significantly superior to V_2O_5: Unlike the latter, $AgMnO_4$ exhaustively oxidizes the OM even in substances with a very high mineral component, e.g., in sapropels.

Exhaustive oxidation of the OM from fossil fuels with $AgMnO_4$ was confirmed by model experiments on analysis of artificial 9-nitroanthracene–TiO_2 mixtures of the known elemental composition. The results of analysis proved to be highly accurate and reproducible even for TiO_2 content in the mixture of up to 90 wt %.

However, our studies revealed some major drawbacks of $AgMnO_4$. This compound is prepared by the exchange reaction between $AgNO_3$ and $KMnO_4$ and necessarily comprises water incorporated into the crystal lattice. This water cannot be fully eliminated even by heating in a vacuum because of thermal instability of $AgMnO_4$ which begins to decompose above 100°C. Certain amount of NO_3^- anions is also incorporated into the resuting $AgMnO_4$ crystals, which generates unavoidable, though minor, zero peaks of nitrogen associated with the oxidant proper.

Unlike V_2O_5, which withstands heating to 400°C without decomposition, $AgMnO_4$ cannot be freed by calcination from trace amounts of organic substances, contributing to the zero peaks of C, H, and N, either. But the strongest effect is exerted by the coprecipitated water responsible for major zero peaks of hydrogen. In view of the fact that the standard procedure prescribes taking oxidant in approximately the same amount as the substance being analyzed, rather than weighing, the zero peaks of C, H, and N, when in small amounts in the oxidant (which is easily attainable for V_2O_5 by calcining at 400°C), will be low and not strongly dependent on the oxidant mass fluctuations. Therefore, these latter will not significantly contribute to the error and only insignificantly affect the reproducibility of analysis.

With $AgMnO_4$ as oxidant, major amounts of C, H, and N (especially H) in the oxidant will be responsible for major fluctuations of the zero peak values owing to the oxidant mass fluctuations. This necessitated modification of the analytical and calculational procedures to accurately account in analysis of every

sample for the contribution from zero peaks due to the oxidant. Also, it proved to be necessary to change the mode of charging the combustion reactor with the oxidant, as with CuO wire in the high-temperature zone of the reactor the latter is rapidly fused with reduced copper metal, plugging the tube.

The nitrogen content of fossil fuels is typically low and seldom exceeds 2–3%, while the carbon content often proves to be very high (60–80%). This makes desirable selecting among individual organic compounds the appropriate reference with the elemental composition approximately identical to that of fossil fuels. Also, of much interest is testing silver compounds other than $AgMnO_4$, as well as PbO_2, as potential oxidants for EA.

We suggested the following modifications to the analytical procedure:

(1) To replace cyclohexanone 2,4-dinitrophenylhydrazone by 9-nitroanthracene, whose elemental composition is closer to that of coals, namely (%): C 75.34, H 4.04, N 6.28, and O 14.34.

(2) To change the mode of charging the combustion reactor by placing in succession the beds of the CuO wire (10 cm), Cr_2O_3 (9 cm), and quartz crumble (1 cm). Cr_2O_3 efficiently catalyzes exhaustive burning in excess oxygen of the products formed from inexhaustive burning of the samples analyzed such as, e.g., CO. This does not deteriorate the burning conditions and the reactor does not get plugged with fused copper wire.

(3) To modify the sample weighing procedure and the calculational procedure so as to accurately account in each analytical run for the errors introduced by the C, H, and N from the oxidant proper. After weighing the sample in an aluminum container and adding the oxidant, the filled container is weighed once again. This yields the precise mass of the oxidant added to the sample in each run. The resulting value of the oxidant mass m_{ox} is then substituted into the modified calculational formulas. For "blank" analytical runs, the container with the oxidant taken separately is also weighed so as to determine m_{ox}. Next, the specific value of the zero peak of the oxidant is calculated by the formula

$$y^0_{e(sp)} = y^0_e/m_{ox},$$

where y^0_e is the zero signal for a given element in the blank run (area or height of C, H, and N chromatographic peaks for the oxidant sample), m_{ox} is the mass of the oxidant sample, and $y^0_{e(sp)}$ is the specific zero signal in a single run for a given element.

From the results of several blank runs, it is possible to calculate the average value of the specific zero peak

$$\bar{y}^0_{e(sp)} = n^{-1}\sum_{i=1}^{n} y^0_{e(sp)}.$$

The resulting $y^0_{e(sp)}$ value is to be substituted into the modified calculational formulas:

$$K_e = \frac{\omega^e_{ref} m_{ref}}{y^e_{ref} - m_{ox}\bar{y}^0_{e(sp)}},$$

$$\bar{K}_e = n^{-1}\sum_{i=1}^{n} K_{ei},$$

$$\omega^e_{sam} = \frac{\bar{K}_e(y^e_{sam} - m_{ox}\bar{y}^0_{e(sp)})}{m_{sam}},$$

where K_e is the response factor for the corresponding element; ω^e_{ref} is the mass fraction of the element analyzed in the reference; m_{ref} is the mass of the reference with the known elemental composition; m_{sam} is the mass of the sample with unknown elemental composition; m_{ox} is the mass of the oxidant added; y^0_{ref} is the value of the analytical signal (chromatographic peak area or height) of the given element for the given reference; y^e_{sam} is the analytical signal of the element for the given sample of unknown elemental composition; $\bar{K}_e$ is the averaged response factor of the given element as calculated for at least two (better, three–four) values of K_e; $y^0_{e(sp)}$ is the value of the specific zero signal of the given element for a single blank run with individual oxidant; $\bar{y}^0_{e(sp)}$ is the averaged value of the specific zero signal of the given element; and n is the number of analytical runs for the reference or of the blank runs for the oxidant.

These modifications allow precisely accounting for the errors in each run due to the presence of C, H, and N in the oxidant, which significantly improves the reproducibility of analysis.

(4) To wrap with metal wire the containers charged with samples and oxidants before placing them in automated sample dosing unit. This prevents the oxidants from spilling out of the container during the weighed sample discharge, which improves the reproducibility of analysis as well. Also, the specimens do not jam at the combustion reactor inlet.

(5) To replace V_2O_5 by other oxidants, namely, $AgMnO_4$, Ag_2O_2, $Ag_2Cr_2O_7$, and PbO_2, in studies on

optimizing the combustion regime. The three first-named oxidants were prepared by the procedures described in [7, 8], and the latter was taken as-received (analytically pure).

The oxidants prepared, as well as PbO_2 and V_2O_5, were tested with the aim to elucidate their suitability and efficiency in burning coal samples during chromatographic EA. To this end, the samples were placed into the dosing unit in the following order: reference (9-nitroanthracene), oxidant (pure), three coal specimens, reference, oxidant, three coal specimens, reference, oxidant, four coal specimens, reference, oxidant, and reference.

The analyses were carried out in the dynamic mode, in an oxygen-enriched medium, at the rate of helium flow through the C, H, and N channels of 30 ml min^{-1} and that through the reference channel, of 20 ml min^{-1}. The analyzed coal samples with oxidant in the sealed aluminum containers were burnt in a tube of a stainless-steel reactor charged in the above-described manner. The combustion temperature was 1050°C. The combustion products of coal and final oxidation products of gas came then to a U-shaped reactor charged with copper metal heated to 650°C, where excess O_2 and SO_2 were absorbed and nitrogen oxides were reduced. Next, the analyzed gas mixture containing He, N_2, CO_2, and water vapor (at 120°C) came into a 4-m chromatographic column packed with Al_2O_3-supported Chromosorb-102, where the gas mixture was separated. Katharometer served as detector. The content of C, H, and N was calculated from the heights of their chromatographic peaks. The containers, first empty and then filled with a coal sample or reference, were weighed on a Cahn electromagnetic balance. The weights of the coal and reference specimen were about 0.5 mg. After adding the oxidant to the specimen, the container was weighed on a VLA-200M analytical balance to determine the mass of the oxidant added. After weighing, the containers were wrapped before placing them in the corresponding cells of the ring-shaped dosing unit for samples, and the system was hermetically sealed and blown through with a helium stream. The samples were supplied manually. Each analytical run took 12–15 min.

For $AgMnO_4$, we carried out two analytical series. In the first series, we analyzed coal by the old, unmodified, procedure utilizing unwrapped containers and unmodified weighing system and calculational procedure not accounting precisely for errors due to the oxidant. In the second series, we analyzed ten coal specimens by the modified procedure described above. Other oxidants were tested by the modified procedure only. Based on the results of analyses, we calculated the following parameters: the content of the elements analyzed ω_e; the arithmetic means of the content of the elements analyzed $\bar{\omega}_e$; standard deviations in a single run for each element S_e; estimated standard deviations of the content of each element S_e^2; confidence intervals $\bar{\omega}_e \pm t_{p,f}(S_e/10^{1/2})$, where $t_{p,f}$ is the Student's t-distribution coefficient; $t_{0.95;9} = 2.26$ for the confidence probability $p = 0.95$ and the significance level $f = 9$.

$AgMnO_4$, Ag_2O_2, and PbO_2 proved to be the most effective oxidants for coal analysis. Under pyrolysis conditions, they decompose presumably according to the following equations:

$$3AgMnO_4 = 3Ag + Mn_3O_4 + 4O_2,$$

$$Ag_2O_2 = 2Ag + O_2,$$

$$2PbO_2 = 2PbO + O_2.$$

The released oxygen is spent for sample burning and oxidation of aluminum containers. All the three oxidants gave reproducible results, the $\bar{\omega}_e$ values falling within the following confidence intervals as calculated using the Student's coefficients:

$AgMnO_4$:

$$\bar{\omega}_C = 70.73 \pm 3.36 \times 10^{-2} \approx 70.73 \pm 0.03,$$

$$\bar{\omega}_H = 5.15 \pm 1.50 \times 10^{-2} \approx 5.15 \pm 0.02,$$

$$\bar{\omega}_N = 0.99 \pm 8.57 \times 10^{-3} \approx 0.99 \pm 0.01;$$

Ag_2O_2:

$$\bar{\omega}_C = 70.72 \pm 7.86 \times 10^{-2} \approx 70.72 \pm 0.08,$$

$$\bar{\omega}_H = 5.16 \pm 1.20 \times 10^{-2} \approx 5.16 \pm 0.01,$$

$$\bar{\omega}_N = 0.98 \pm 7.86 \times 10^{-3} \approx 0.98 \pm 0.01;$$

PbO_2:

$$\bar{\omega}_C = 70.74 \pm 2.07 \times 10^{-2} \approx 70.74 \pm 0.02,$$

$$\bar{\omega}_H = 5.16 \pm 1.5 \times 10^{-2} \approx 5.16 \pm 0.02,$$

$$\bar{\omega}_N = 0.99 \pm 1.2 \times 10^{-2} \approx 0.99 \pm 0.01.$$

The reproducibility (agreement between the estimated standard deviation of the average and the confidence interval limits for all the elements analyzed)

was the best for $AgMnO_4$ and PbO_2. A somewhat worse reproducibility for carbon (by a factor of ~5.4 lower than that of $AgMnO_4$) was achieved for Ag_2O_2. This is probably due to a greater (by a factor of ~50) value of the zero peak for carbon $\bar{y}^0_{C(sp)}$ in the case of Ag_2O_2 compared to $AgMnO_4$. This is presumably due to the presence of Ag_2CO_3 impurity in the Ag_2O_2 prepared.

Under the actual conditions, silver dichromate decomposes by the scheme

$$Ag_2Cr_2O_7 = 2Ag + Cr_2O_3 + 2O_2.$$

The decomposition of this oxidant yields free oxygen, silver metal, and chromium(III) oxide. The latter, similar to silver metal, efficiently catalyzes surface oxidation. Our experimental data showed, however, that with $Ag_2Cr_2O_7$ the sample combustion is fairly calm and almost flameless, with its rate and intensity being lower compared to the three first-named oxidants for which an instantaneous bright flash is observed. This lower degradation rate is, probably, responsible for incomplete oxidation of carbon in the sample and for underestimated C content as calculated from the analytical data.

Within the confidence interval for $Ag_2Cr_2O_7$ we obtained the following results: $\bar{\omega}_C = 60.61 \pm 2.36$, $\bar{\omega}_H = 5.15 \pm 0.025$, and $\bar{\omega}_N = 0.98 \pm 0.01$.

Thus, for $Ag_2Cr_2O_7$, compared to $AgMnO_4$, Ag_2O_2, and PbO_2, there is a systematic, by ~10%, underestimation of the carbon content. The reproducibility, as estimated from the random deviation of the mean, is also worse by a factor of approximately 5×10^3. At the same time, both the calculated values and the corresponding random deviations and confidence intervals for H and N are fairly consistent with those for $AgMnO_4$, PbO_2, and Ag_2O_2. Thus, $Ag_2Cr_2O_7$ is unsuitable for analyzing carbon in coals, though suitable for analyzing nitrogen and hydrogen.

It should be noted that, with PbO_2 as oxidant, the EA of coals, though providing exhaustive burning and good reproducibility, is accompanied, unfortunately, by prominent oxidative corrosion of combustion tubes. This is due presumably to the high temperature evolving in oxidation of aluminum containers by the aluminothermic reaction

$$3PbO_2 + 4Al = 3Pb + 2Al_2O_3.$$

Major amount of heat evolving in this reaction and the oxygen-enriched atmosphere are responsible for fast burn-out of the tubular combustion reactor. This sets certain limits on application of individual PbO_2. At the same time, with $AgMnO_4$ and Ag_2O_2 aluminum containers do not undergo intensive oxidation, whereas the specimen burns efficiently. This fact justifies the use of individual $AgMnO_4$ and Ag_2O_2.

The worst oxidant among those tested is V_2O_5, which degrades under the actual conditions by the equation

$$2V_2O_5 = 4VO_2 + O_2.$$

Thermal degradation of this oxidant is significantly slower compared to the others. The input of the specimens (even individual organic compounds) is not accompanied by a flash. Slow degradation is evidently responsible for inexhaustive oxidation of the organic constituent of difficultly combustible fossil fuels. The confidence intervals are as follows: $\bar{\omega}_C = 29.03 \pm 5.00$, $\bar{\omega}_H = 4.36 \pm 0.89$, and $\bar{\omega}_N = 0.35 \pm 0.02$.

Thus, with V_2O_5, compared to $AgMnO_4$, there is a systematic underestimation of the content of the elements analyzed, namely, by factors of approximately 2.4, 1.2, and 2.8 for C, H, and N, respectively. Also, for the same elements, the reproducibility of analysis decreased by factors of approximately 2.2×10^4, 3.5×10^3, and 4, respectively. This makes V_2O_5 virtually unsuitable for coal analysis.

The results of a comparative study of the old and new, improved, analytical procedures also gave very interesting results. The old procedure for EA, namely, not accounting precisely for the error due to oxidant but utilizing $AgMnO_4$ as oxidant, exhibits virtually the same precision which is worse, however, compared to the improved procedure, namely, by factors of approximately 3.0, 6.6, and 12.8 for C, H, and N, respectively. The corresponding confidence intervals are as follows: $\bar{\omega}_C = 70.73 \pm 5.79 \times 10^{-2} \approx 70.73 \pm 0.06$, $\bar{\omega}_H = 5.16 \pm 3.86 \times 10^{-2} \approx 5.16 \pm 0.04$, and $\bar{\omega}_N = 0.98 \pm 3.07 \times 10^{-2} \approx 0.98 \pm 0.03$.

Thus, the reproducibility of the improved gas-chromatographic EA procedure is higher by a factor of 7.5 on the average.

CONCLUSIONS

(1) The procedure of gas-chromatographic elemental analysis of solid fossil fuels was improved, which substantially increased the reproducibility of analysis.

(2) The suitability of Ag_2O_2 and $Ag_2Cr_2O_7$ as oxidants in gas-chromatographic elemental analysis was proved for the first time.

(3) The best oxidants for elemental analysis of coals are $AgMnO_4$, Ag_2O_2, and PbO_2. To improve the reproducibility of carbon determination, Ag_2O_2 should be freed from Ag_2CO_3 impurity.

(4) The use of PbO_2 in elemental analysis is limited by its strong oxidative-corrosion action on the combustion tube material.

(5) V_2O_5 proves to be unsuitable for elemental analysis of coals; the use of $Ag_2Cr_2O_7$ for gas-chromatographic elemental analysis of coals is restricted to analysis of nitrogen and hydrogen.

CHEMISTRY OF FOSSIL FUEL

Trace Contaminants in Tars and Bitumens from West-Siberian and Yarega Crude Oils

O. Yu. Begak, A. M. Syroezhko, and V. V. Fedorov

Mendeleev Research Institute of Metrology, Federal State Unitary Enterprise, St. Petersburg, Russia
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 28, 2002

Abstract—The trace contaminant levels were determined for ten tar samples and six bitumen samples available from Kirishi, Yaroslavl, and Ukhta refineries, as well as from Neste (Finland).

High quality of road bitumens[1] is of decisive importance for lengthening the lifetime of asphalt concrete pavement [1]. In recent years the quality of tar[2] used as raw material for bitumen preparation was stabilized. Also, bitumen production (Kirishi refinery) widely utilizes bitumen compounding with tars and vacuum gas oils, which significantly improves the performance characteristics of commercial road bitumens. BDUS 70/100 and BDUS 100/130 (produced by the KINEF Limited Liability Company) bitumens substantially exceed in quality BND 40/60, BND 60/90, and BND 90/130 bitumens that were previously produced by this enterprise. However, the possibilities for improving the bitumen quality at the enterprise are not exhausted.

As known, bitumens with close group and chemical compositions obtained from the same raw material often differ in the thermal stability (penetration P_{25} and ductility $D_{h.t.}$ sharply decrease after heat treatment). The above parameters strongly depend on the amount and composition of the impurity metals and nonmetals both in the initial tars and commercial products. This study was devoted to elucidation of this dependence in the case of raw materials available from the above-listed refineries.

EXPERIMENTAL

Ten samples of BDUS 70/100 and BDUS 60/90 bitumens and tars from bitumen installations at the KINEF Limited Liability Company and bitumen samples from Yaroslavl refinery were taken on May 17–24, 2001. Bitumens from the Ukhta refinery and Neste were prepared in September 1999 and were stored for two years in closed reservoirs under laboratory conditions, at room temperatures.

All the tar and bitumen samples (Tables 1, 2) were studied by a common scheme: (a) determination of the acid numbers, ANs, mg KOH g^{-1}; (b) determination of the content of trace contaminants by mass spectrometry with ionization in inductively coupled plasma (ICP-MS) on a CG Plasma Quad Turbo Plus (England) instrument: Weighed portions (75–100 mg) of tars and bitumens were degraded by a 1 : 2 mixture of concentrated boiling nitric and hydrochloric acids for 3 h on a sand bath, and the trace contaminants were transferred to the aqueous phase, which was followed by multielement analysis of the resulting solutions; (c) deasphalting of tars and bitumens by cold or hot precipitation (in a Soxhlet apparatus); (d) separation of the recovered malthenes into polar and nonpolar components using dimethylformamide (DMF); (e) exhaustive deasphalting of polar and nonpolar components of tars and their corresponding bitumens; (f) chromatographic separation of polar and nonpolar components of tars and bitumens into group components and IR, ^{1}H NMR, and ^{13}C NMR studies; and (g) elemental analysis and X-ray diffraction study of the initial tars and bitumens, malthenes, asphaltenes, and polar and nonpolar components.

The entire complex of investigations was aimed at revealing the most significant differences in quality standard and substandard bitumens and tars.

We found (Table 1) that, on storage for 6 months under laboratory conditions, tars get harder, and their penetration significantly decreases, for example, ap-

[1] The major suppliers of oxidized road bitumens in Northwest Russia are Kirishi, Yaroslavl, and Ukhta refineries. The two first-named enterprises are engaged in processing of the commercial mixture of West-Siberian crude oils, and Ukhta refinery, in processing of high-resin heavy Yarega crude oil. Also, bitumens are supplied by Nafta, Finland.

[2] The KINEF Limited Liability Company has undertaken major reconstruction of the vacuum block of the AVT-6 installation.

* The acid numbers of PCs and NPCs of bitumen nos. 4 and 6, measured in November 2001, are 19.6 and 12.4, and 14.7 and 10.7 mg KOH g^{-1}, respectively.
** BDUS sample nos. 1–12 were prepared at Kirishi refinery.

proximately twofold for tar nos. 5 and 9, which were studied in detail by a complex of physicochemical methods.

It should be noted that the acid numbers of bitumen nos. 13 and 14 (Table 2) are fairly large (30.9–52 mg KOH g^{-1}). As carboxy groups intensively interact with the active centers of mineral fillers, the content of these groups governs the durability of the asphalt concrete pavement. Evidently, bitumen nos. 13 and 14 (Ukhta refinery) will ensure a greater durability of the pavement than bitumen nos. 1–12 (KINEF Limited Liability Company).

Interestingly, the acid numbers of bitumen no. 15 (Table 2) are close to those of the similar bitumen

Table 3. Content of trace contaminants in tars from KINEF Limited Liability Company

no. 8 from Kirishi refinery. However, in thermal stability (resistance to aging), bitumens from Kirishi refinery are exceeded by those from Yaroslavl refinery.

It is seen that bitumen nos. 1–12 have fairly good initial parameters (ring-and-ball softening point, P_{25}, D_{25}) and fully satisfy the requirements set on BND bitumens. Interestingly, acid numbers of the bitumens of virtually the same brand (BDUS 70/100) differ significantly (range from 3.8 to 31.2). The acid numbers of the analogous bitumens from Neste and from Ukhta and Yarislavl refineries vary more widely. For example, bitumen from Neste has the acid number of 15.1 mg KOH g^{-1}, that from Ukhta refinery, 52 (ring-and-ball softening point 45°C) and 30.9 (ring-and-ball softening point 49°C), and that from Yaroslavl refinery, 15.6 mg KOH g^{-1} (ring-and-ball softening point 47°C) (Table 2). It should be noted that the adhesion properties of the bitumens studied are determined not only by the nature but also by the content of polar groups (including carboxylic).

Tables 3 and 4 present the results of analysis of the tar and bitumen specimens studied.

It should be noted that the total error of the ICP-MS method is no greater than 20%. As seen from Table 3, the tars differ significantly in the content or elements such as Mg, Na, Al, P, Ti, Ca, Fe, Mn, V, Ni, Sr, Zr, I, Ba, Bi, and Pb.

The tars chosen for detailed studies by a complex of physicochemical methods (samples with P_{25} = 305 and 390 mm × 0.1) were characterized by increased iron content and fairly high content of vanadium, nickel, sodium, calcium, and copper. Tar sample with P_{25} = 390 mm × 0.1 had a high iodine content.

* Bitumen sample: nos. 1 and 2 from KINEF Limited Liability Company; nos. 3 and 4, from Ukhta refinery; no. 5, from Neste, and no. 6, from Yaroslavl refinery.

** The figures in parentheses are the ring-and-ball softening points, °C.

The total content of trace contaminants in tar sample no. 5 was 1265, and in tar sample no. 9, 1253 ppm.

The dominating elements for bitumens selected among those prepared from tars with P_{25} = 305 and 390 mm × 0.1 are Mg, Na, Fe, Cu, Ni, and V, and for bitumen no. 2 (Table 4), I. The vanadium and nickel contents in these samples are comparable (0.77–0.94 ppm).

The fact that the content of trace contaminants in bitumens tends to decrease relative to the corresponding tars is, evidently, explained by their dilution with vacuum distillates in the compounding stage.

It should be noted that these impurity elements can exert a catalyzing action on oxidation of tars into bitumens and on their structure at the molecular and supramolecular levels. The reason is that heavy metals (in particular, vanadium and nickel) occur in resin–asphaltene substances as metal–porphyrin complexes and are linked by coordination bonds to nitrogen atoms in these complexes.

Tables 3 and 4 show that there exists certain correlation between the contents of microelements in tars (sample nos. 5 and 9) and in their corresponding bitumens (sample nos. 1 and 2, Table 4). Nevertheless, all the bitumens studied differ in the content of each of the 25 elements analyzed.

Similar to tars, impurity Na, Mg, Ca, Ba, Fe, Cu, V, Ni, and I dominate in the bitumens studied.

It should be noted that the total content of trace

contaminants in tars exceeds that in their corresponding bitumens. Evidently, oxidation with atmospheric oxygen is responsible for dissolution in the resulting distillate products and water (distillate) of a substantial amount of alkali netals, in particular, sodium. A portion of the alkaline-earth elements, evidently, is hydrolyzed. At the Kirishi refinery, the characteristics of commercial bitumens (P_{25}, D_{25}) are adjusted by adding the starting tars and vacuum gas oils. As the content of trace contaminants in tars videly varies with the batch, this fact can explain the experimental data obtained.

The initial tars (sample nos. 5 and 9), which will be further studied in detail, are distinguished (see below) by a fairly high content of trace contaminants Na, Ca, Fe, V, and Ni (Table 3). The studied samples differ in the content of Mg, Ca, Al, Bi, Pb, Mo, and Fe by factors of 10, 1.57, 2, 5.12, 2.43, 8.3, 9.3, and 1.72, respectively. In tars we quantitatively identified (Table 3) 3*d* elements (Ni, V, Co, Cu, Mn, Fe, Cr), which catalyze the homolytic degradation of hydroperoxides forming from oxidation of tars into bitumens, as well as Group VI elements (W, Mo), which catalyze heterolytic degradation of these hydroperoxides. Such *s* elements as Mg, Ca, Sr, and Ba also form complexes with oxygen-containing compounds of the initial tars and bitumens. However, their catalytic effect is substantially weaker compared to 3*d* elements [2].

The dominating trace contaminants in tar no. 5 are Na, Mg, Ca, Ba, Al, W, Fe, Cu, V, and Ni, and in tar no. 9, Na, Ca, Ba, Al, Bi, Pb, Fe, Cu, V, Ni, I, and Sn. Tar nos. 1–10 differ fairly substantially in the content of trace contaminants. Table 3 does not contain data for tars with identical content of trace elements, that is, each initial tar and bitumen has its individual content of trace elements. Each tar is characterized by the maximal content of specific element (one of several). However, the set of the dominating microelements is fairly constant for virtually all tars. The main trace contaminants are the following elements (including organometallic compounds): Na, Mg, Ca, Ba, Al, Fe, Cu, V, and Ni.

Evidently, the total amount of about 1 g kg^{-1} tar is sufficient for trace contaminants to act as a catalyst in the oxidation stage. The effect of this catalyst is manifested in each tar in a specific way, that is, tar oxidation into bitumen and its cross-linking are affected by this factor. Eventually, this affects the consumer properties (above all, thermal stability) of the resulting bitumens.

The above data are insufficient for making a conclusion as to what trace contaminants (when all of them occur in comparable amounts) are desirable in tar and what are not. Undoubtedly, 3*d* elements (Fe, Cu, V, and Ni) exert the strongest influence on oxidation and probably cross-linking of bitumens. This influence is much stronger than that of *s* elements (Na, Mg, Ca, Ba).

Notably, unlike Kirishi refinery, bitumens available from Ukhta and Yaroslavl refineries, as well as from Neste, do not contain tin and tungsten. The total contents of trace contaminants, both metals and nonmetals, in the bitumens studied (Table 4) are comparable. Heavy oil residues (tars and bitumens) are characterized by the occurrence of porphyrin complexes of vanadium and nickel [3]. The content of these elements in the bitumens proved to differ substantially. Moreover, the vanadium-to-nickel ratios differ as well (Table 4).

Thus, each of the tars and bitumens studied (Tables 3, 4) has its specific content of trace contaminants, both metals and nonmetals, which undoubtedly affects the commercial characteristics of bitumens both during their production and under operation as road pavements.

CONCLUSIONS

(1) Tars available from Kirishi refinery, when stored for 6 months under laboratory conditions in closed reservoirs, get harder, as indicated by approximately twofold increase in their conventional viscosity and decrease in penetration.

(2) Tars available from Kirishi refinery differ substantially in the content of active carboxy groups (3.87–17.86 mg KOH g^{-1}). BDUS 70/100 bitumens prepared from the above-mentioned tars are characterized by a fairly widely varying content of active carboxy groups (3.8–31.2 mg KOH g^{-1}). Bitumens available from the Ukhta refinery have the maximal content of carboxy groups.

(3) Tars available from Kirishi refinery differ significantly in the amount of Mg, Na, Al, P, Ti, Ca, Fe, Mn, V, Ni, Sr, Zr, Ba, Bi, and Pb. Similar to tars, the trace contaminants contained in the maximal amounts in the bitumens studied are Na, Mg, Ca, Ba, Al, Fe, Cu, V, Ni, and I.

(4) The tars and bitumens studied contain up to 25 trace contaminants, both metals and nonmetals, whose total content varies within 443–1265 ppm.

(5) The total content of trace contaminants in

bitumens available from Kirishi refinery is lower than in tars owing to dilution of the commercial product by vacuum gas oil.

Kinetics of Cadmium Sulfide Precipitation from Aqueous Thiourea Solutions

A. A. Uritskaya, G. A. Kitaev, and N. S. Belova

Ural State Technical University, Yekaterinburg, Russia

Received December 26, 2000; in final form, August 2001

Abstract—Kinetics of cadmium sulfide precipitation with thiourea from solutions of cadmium(II) ammine complexes under conditions of spontaneous nucleation of the solid phase in the bulk of solution was studied.

Cadmium sulfide is widely used in semiconductor devices [1]. One of the methods for obtaining cadmium sulfide as precipitates and thin films on the surface of dielectrics is its chemical precipitation with thiourea from alkaline solutions of cadmium complexes [2]. The properties of semiconducting materials based on CdS essentially depend on their preparation procedure.

In this work we studied the kinetics of chemical precipitation of cadmium sulfide. When thiourea is added to an alkaline solution of a complex cadmium salt, the transparent solution becomes turbid owing to formation of the CdS solid phase by the reaction

$$[Cd(NH_3)_n]^{2+} + (NH_2)_2CS + 2OH^- = CdS + nNH_3 + H_2NCN + 2H_2O. \quad (1)$$

The surface of the solid phase forming under conditions of homogeneous nucleation continuously changes owing to an increase in the size of CdS particles during the process.

The kinetics of this heterogeneous process was monitored by sampling from a reactor. The cadmium(II) concentration in samples was determined with Dithizone [3]. The experiments were carried out at 298, 308, and 318 K. Working solutions were prepared in volumetric flasks by combining appropriate volumes of the starting solutions in the following sequence: 1 M solution of cadmium sulfate, 25% aqueous ammonia, 0.5 M solution of thiourea, 1 M solution of alkali, and distilled water.

Typical kinetic curves are S-shaped, which is characteristic of heterogeneous autocatalytic processes. Since cadmium sulfide is formed by the reaction of two compounds, a complex cadmium salt and thiourea, we described the reaction rate by the equation

$$\omega = d(c_{0,A} - c_A)/dt = K_{exp}(c_{0,A} - c_A)^{2/3} c_A c_B, \quad (2)$$

where $c_{0,A}$ and c_A are the concentrations of the complex cadmium salt (M) at $t = 0$ and $t > 0$, respectively; $c_{0,B}$ and c_B are the concentrations of thiourea (M) at $t = 0$ and $t > 0$; $(c_{0,A} - c_A) = (c_{0,B} - c_B) = x$ is the amount of cadmium sulfide (M) formed in time t from the beginning of the reaction; $(c_{0,A} - c_A)^{2/3} = x^{2/3}$ is a quantity proportional to the surface area of CdS particles formed in a homogeneous solution.

The number of particles is assumed to remain constant, and their weight and size increase in the course of the process [4].

Equation (2) is integrated by reducing it to the tabular integral [5]. After introducing the dimensionless parameters $a = c_A/c_{0,A}$ and $b = c_{0,B}/c_{0,A}$, the equation takes the form

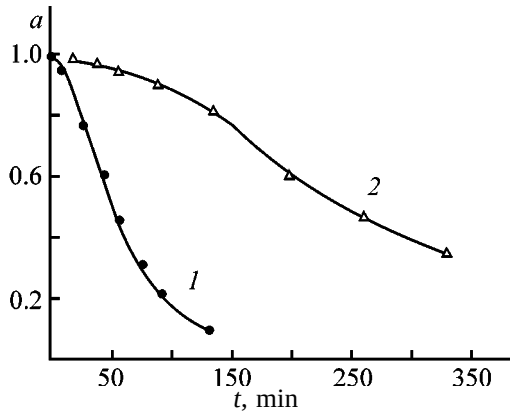

Fig. 1. Kinetic curves at 308 K: (*a*) $c_A/c_{0,A}$ and (*t*) time. pOH and c_{NH_3} (M): (*1*) 1.4 and 1; (*2*) 1.8 and 1.25; the same for Fig. 2.

1070-4272/02/7505-0846$27.00 © 2002 MAIK "Nauka/Interperiodica"

$$Z(a,t) = 0.5\ln\frac{[1-(1-a)^{2/3}]^3}{2} - \frac{1}{2b^{2/3}}\ln\frac{[b^{1/3}-(1-a)^{1/3}]^3}{b-(1-a)}$$
$$- 3^{1/2}\arctan\frac{2(1-a)^{1/3}+1}{3^{1/2}} + \frac{3^{1/2}}{b^{2/3}}\arctan\frac{2(1-a)^{1/3}+b^{1/3}}{b^{1/3}3^{1/2}}$$
$$- \frac{3^{1/2}(1-b^{2/3})}{b^{2/3}}\arctan 3^{-1/2} = c_{0,A}^{5/3}(1-b)K_{exp}t. \quad (3)$$

Equation (3) is linear in the coordinates $-Z(a, t)$–t (Fig. 2) with the slope $K_{op} = c_{0,A}^{5/3}(1 - b)K_{exp}$. From Eq. (3), we calculated the experimental rate constant of the reaction K_{exp}. This constant depends on temperature and carries information on the influence of all the substances involved in the process.

The results of treating the experimental data by Eq. (3) (MathCAD 2000 Professional package) are given in Fig. 2. The obtained data allow us to determine the reaction order n_i with respect to each reagent from the experimental rate constants of the reaction at various initial concentrations of the ligand and thiourea and various pH. We calculated the kinetic orders with respect to the components by the equation

$$\ln K_{exp} = \ln K_i + n_i \ln c_i. \quad (4)$$

The graphic solution of Eq. (4) is given in Fig. 3.

The kinetic studies showed that the rate of cadmium sulfide formation is proportional to the product of the concentrations of the reaction mixture components, raised to the following powers:

Reactant	n_i
$[Cd(NH_3)_n]^{2+}$	1.0
OH^-	1.0
$(NH_2)_2CS$	1.0
NH_3	–3.0

The experimental constants obtained by processing the kinetic curves by Eq. (3) at 289, 308, and 318 K allowed us to determine the activation energy of the process by Arrhenius equation (Fig. 4).

The activation energy of the process is 77 843 J mol^{-1}. The pre-exponential factor of the Arrhenius equation was calculated from the true rate constant K_0 of reaction (1) related to unit concentrations of the reaction mixture components (with regard to the reaction order with respect to the reactants):

$$K_0 = \frac{K_{exp}c_{NH_3}^3}{c_{OH}} = 1.27 \times 10^{17}. \quad (5)$$

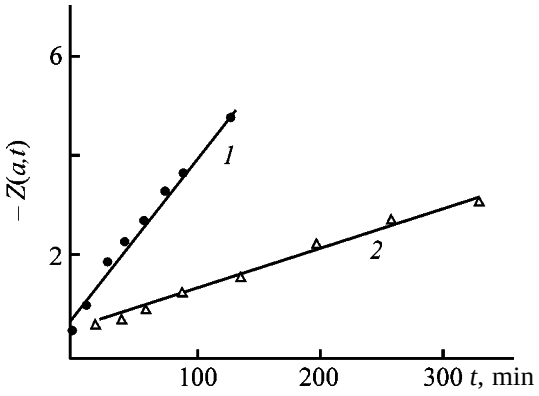

Fig. 2. Plot of $Z(a,t)$ vs. time t at 308 K.

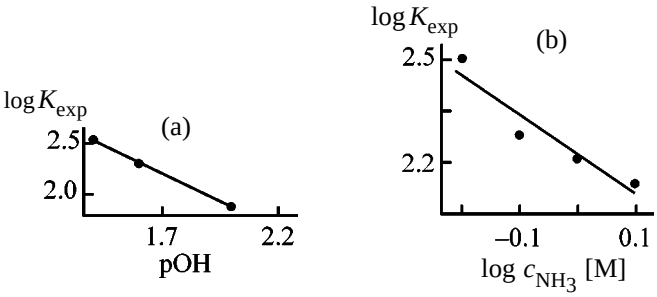

Fig. 3. Graphic determination of the reaction order with respect to the concentrations of (a) OH^- ions and (b) ammonia c_{NH_3}.

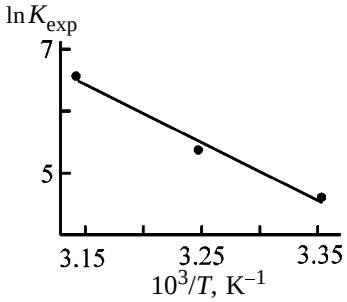

Fig. 4. Determination of the activation energy by Arrhenius equation. (T) Temperature.

From the experimental data on cadmium sulfide precipitation with thiourea from ammonia solutions, we obtained a kinetic equation allowing evaluation of conditions that provide the required reaction rate; the rate, in turn, governs the morphology of the precipitate or film of cadmium sulfide:

$$dx/dt = 1.27 \times 10^{17}\exp(-77\,844/8.134T)x^{2/3}c_{NH_3}^{-3}c_{OH^-}$$
$$\times (c_{0,A} - x)(c_{0,B} - x). \quad (6)$$

Effect of KBr Additions on NiS Anodic Dissolution in Sulfate Electrolytes

M. I. Natorkhin

St. Petersburg State Technical University, St. Petersburg, Russia

Received October 21, 1999; in final form, July 2001

Abstract—Electrochemical behavior of nickel sulfide (NiS) in 0.5 M solutions of Na_2SO_4 and $CuSO_4$ at pH 2.0–2.2 and T = 90°C was studied. A possibility was shown for depassivation and efficient dissolution of nickel sulfides upon addition of KBr to the electrolyte.

Oxidative dissolution of sulfides of non-ferrous metals is a promising hydrometallurgical process [1–3]. As found previously [4, 5], autoclave leaching by H_2SO_4 solution results in active dissolution of nickel sulfides with H_2S evolution. However, utilization of the forming H_2S is a serious problem, and therefore efforts are made to develop alternative procedures for leaching of nickel concentrates.

In this study we examined the effect of bromide ions on the anodic dissolution of nickel sulfide in acidic sulfate solutions.

According to [6], autoclave leaching of lower nickel sulfides (Ni_3S_2 and Ni_7S_6) results in stepwise formation of sulfides with increasing sulfur content, up to NiS. Therefore, for our study we chose β-NiS with 50% nickel content obtained by a direct synthesis from cathodic nickel (N0 grade) and sulfur (analytically pure grade) [7]. The working electrode was made by soldering a piece of nickel sulfide to a copper holder. The back side of the electrode was insulated with nitrolacquer. The working surface of the electrode (surface area 1 cm^2) was smoothed out with a flint-paper no. 0 and washed with alcohol and distilled water. Electrolytes was prepared using Na_2SO_4 and $CuSO_4 \cdot 5H_2O$ (both analytically pure grade). Solution pH 2.0–2.2 was adjusted with a solution of H_2SO_4 (ultrapure grade). Potassium bromide was of chemically pure grade.

The study was carried out by cyclic voltammetry (CVA) on a PI-50-1.1 potentiostat and a PDP4-002 recorder in a YaES-1 standard electrochemical cell at 90 ± 0.5°C (Fig. 1). The temperature was controlled with a UTU-2/77 thermostat. We used the following three-electrode scheme: nickel sulfide sample as a working electrode, platinum auxiliary electrode, and saturated silver chloride reference electrode (the potentials are referenced to standard hydrogen electrode).

To carry out the experiments, we filled the cell with 50 ml of 0.5 M solutions of $CuSO_4$ or Na_2SO_4 with a KBr addition. The nickel(II) content in the anolyte was determined by the known photometric procedures [8, 9].

The anodic dissolution of nickel sulfide in $CuSO_4$ solution is accompanied by electrode passivation

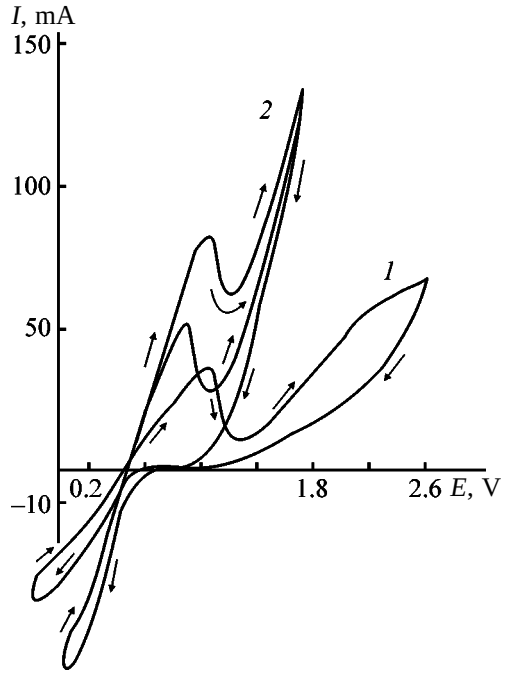

Fig. 1. Cyclic voltammograms of NiS (50%) in solutions of (*1*) 0.5 M $CuSO_4$ and (*2*) 0.5 M $CuSO_4$ + 100 g l^{-1} KBr at pH 2.1. Temperature 90 ± 0.5°C, scanning rate 100 mV s^{-1}; the same for Fig. 3. (*I*) Anode current and (*E*) potential; the same for Fig. 3.

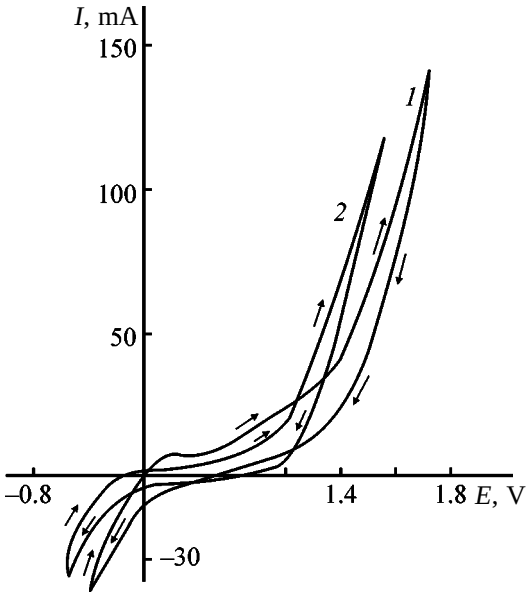

Fig. 3. Cyclic voltammograms of NiS (50%) in solutions of (*1*) 0.5 M Na_2SO_4 and (*2*) 0.5 M Na_2SO_4 + 40 g l^{-1} KBr at pH 2.0.

owing to the formation of a dense black-blue Cu_2S film at the potential of +1170 mV. Sodium chloride is known as a depolarizer of this process [10, 11]. Chlorides are inconvenient for industrial use because, first, chloride depolarization becomes apparent at a relatively high concentration of chloride ions [11], and, second, chloride ions prevent subsequent nickel electroextraction. Bromide ions forms stronger complexes with Cu(I) than chloride ions: $\log\beta_{Cu(I)}$ is 5.92 for Br^{-1} and 5.35 for Cl^{-1} [12]. We performed the experiments with KBr additions (Fig. 2). The effect of these additions becomes appreciable at a KBr concentration of 40 g l^{-1}. In the process, a blue solution of copper sulfate changes its color for green owing to the formation of Cu(I) complex compounds, nickel sulfide is actively dissolved, and a thin yellow deposit of elemental sulfur and foxy drops of bromine are formed on the electrode surface.

The electrochemical behavior of nickel sulfide changes in the absence of copper(II) ions. The CVA curves for nickel sulfide (50%) in 0.5 M Na_2SO_4 solution and in the same electrolyte with addition of 40 g l^{-1} of KBr are shown in Fig. 3. A small anode maximum corresponding to the NiS dissolution and to its conversion to a passive state is observed in the direct branch of the potential scanning curve. Up to potentials of +970 (curve *2*) and 1370 mV (curve *1*), the sulfide dissolves only slightly. Starting from the potential of +970 mV, bromide ions are oxidized to evolve elemental bromine on the electrode surface:

$$2Br^- - 2e = Br_2^0,\ E^0 = +1065\ \text{mV (SHE)}.$$

Elemental bromine is precipitated as fine drops on the surface of the working electrode over the yellow layer of elemental sulfur. We failed to detect free bromine by the reaction of eosin formation [13] in the cell volume, probably owing to the fact that bromine is poorly soluble in water at 90°C [14] and reacts with water:

$$3Br_2 + 3H_2O = 5HBr + HBrO_3.$$

In addition, drops of free bromine do not stay too long on the surface and penetrate into the bulk of the electrode, giving rise to pitting corrosion and promoting additional dissolution of nickel sulfide.

We calculated the partial currents of nickel(III) passing into the solution (Fig. 4) by the Faraday law using the nickel(II) concentration found in the anolyte after dissolution of the working electrode for 15 min at a prescribed potential. The curves of these currents vs. voltage resemble to some extent the CVA curves. The equivalent nickel(II) current (i.e., the current required for the dissolution of the nickel amount found in the cell volume by the photometric technique) appeared to be significantly higher than the integral current measured with a potentiostat. This may be due to secondary dissolution of nickel sulfide in elemental bromine deposited on the electrode surface.

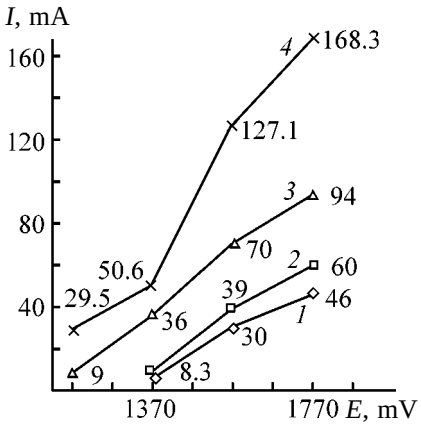

Fig. 4. Partial nickel(II) currents for NiS (50%) dissolution in solutions of (*1*) and (*2*) Na_2SO_4 and (*3*) and (*4*) 0.5 M Na_2SO_4 + 40 g l^{-1} KBr at 90°C. Current: (*1, 3*) NiS and (*2, 4*) partial.

CONCLUSIONS

(1) An addition of KBr to a solution of copper sulfate results in the depolarization of the anodic dissolution of NiS. The addition becomes effective at the KBr concentration of 40 g l^{-1}.

(2) Anodic dissolution of nickel sulfide in the presence of bromide ions results in deposition of elemental bromine on the sulfide surface, which causes pitting corrosion and secondary oxidation of nickel sulfide with elemental bromine. The pitting corrosion leads to rapid breakdown of NiS.

BRIEF COMMUNICATIONS

Procedure for Estimating Nickel Plating Rates

E. Binkauskene

Institute of Chemistry, Vilnius, Lithuania

Received March 22, 2000

Abstract—A method was developed for quick determination of nickel plating rates in sulfate and chloride nickel plating solutions using the Hull cell.

One of topical directions of upgrading nickel plating processes is the development of electrolytes ensuring sufficient intensity of the electrodeposition at reduced concentrations of precursor salts. This is important, on the one hand, for decreasing the amount of toxic nickel(II) salts in electroplating sewage and, on the other hand, for reducing the nickel plating cost (saving of anodes and nickel salts). No reequipment is necessary in this case. However, up to now there are no sufficiently simple and reliable methods for reproducible quantitative estimation of the rate of nickel plating from the electrolytes used in electroplating. The method applied for the total assessment of electrolytes using the Hull cell [1] is unsuitable. The method of rotating disk electrode [2] requires a certain hydrodynamic regime to be maintained during the experiments and therefore is too complicated for industrial use and is not commonly accessible.

The aim of this study was to develop a quick procedure for estimating the rate of nickel plating from nickel solutions in a Hull cell using data furnished by the method of rotating disk electrode. This quick method was tested using five model systems of dilute nickel solutions as example.

EXPERIMENTAL

We used $NiSO_4 \cdot 7H_2O$, $NiCl_2 \cdot 6H_2O$, and H_3BO_3 of chemically pure grade and Na_2SO_4 and $MgSO_4 \cdot 7H_2O$ of analytically pure grade. A sulfate nickel plating solution contained (g l^{-1}) $NiSO_4$ 140, $NiCl_2$ 30, and H_3BO_3 30; in certain cases, we added saccharin (1.5, to reduce the inner tension in electroplated coatings [3]) and sodium or magnesium salts (to increase the electrical conductivity and throwing power of the electrolytes). A chloride nickel plating solution with the same nickel content was also used. A rotating titanium disk electrode built in a fluoroplastic case with a visible surface area of 2 cm^2 served as working electrode. We carried out polarization measurements in a temperature-controlled H-shaped cell with the electrode spaces separated by a diaphragm from Schott glass no. 4. The electrolysis was performed in the galvanostatic mode. We measured the potentials vs. saturated silver chloride electrode. The electrolyte temperature was 30°C, the electrode rotation rate, 950 rpm, and pH, 4.0. From the data obtained, we constructed partial polarization curves of the metal deposition. The current efficiency with respect to nickel was determined by weighing the coatings separated from the titanium support.

The method used for the general assessment of electrolytes in a Hull cell [1] was modified. First, a nickel layer was deposited on the cathode in the electrolyte under study for 5 min at a current of 0.5 A, and then the current was increased in 0.05 A steps, with keeping at every step for 30 s. We stopped increasing current when it attained the critical value I_{cr} at which hydrogen bubbles began to evolve on the nearest edge of the cathode to give a narrow strip of blackening (scorching). We did not stir the solution in the Hull cell, since the bubbling with compressed air gives no way for detecting the onset of hydrogen evolution on the cathode edge. A copper plate of 0.5 dm^2 area served as cathode. The experiments were carried out at 50°C.

The cathodic partial polarization curves obtained on a rotating disk electrode in the course of nickel plating are shown in Fig. 1. It is seen that the introduction of sodium sulfate (curve *2*) into the Watts electrolyte (curve *1*) results in an approximately 75 mA decrease in the current at which low-grade coatings start to form. This corresponds to a decrease in the current density j_c and in the rate of electrodeposition by 3.5 A dm^{-2} and 0.75 μm min^{-1}, respectively. Addition of magnesium sulfate and saccharin

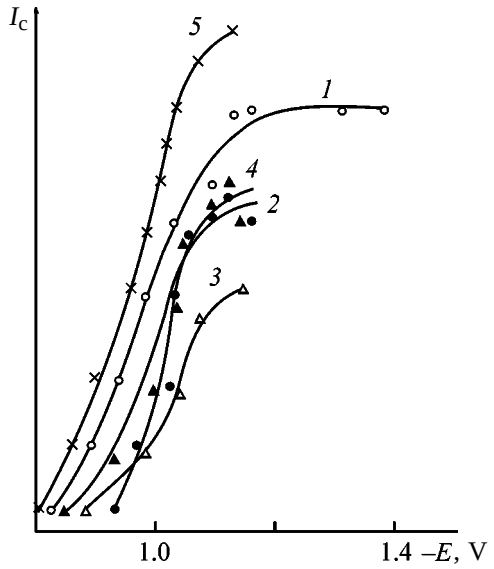

Fig. 1. Partial current I_c of nickel plating as a function of potential E, as measured with a rotating disk electrode in various nickel plating solutions. Temperature 30°C, pH 4.0, n = 950 rpm. Electrolyte composition, g l^{-1}: (*1*) $NiSO_4$, 140; $NiCl_2$, 30; H_3BO_3, 30; (*2*) the same as for *1* + Na_2SO_4, 70; (*3*) the same as for *2* + $MgSO_4$, 20 + saccharin, 1.5; (*4*) the same as for *1* + saccharin, 1.5; and (*5*) $NiCl_2$, 148; Na_2SO_4, 70, H_3BO_3, 30.

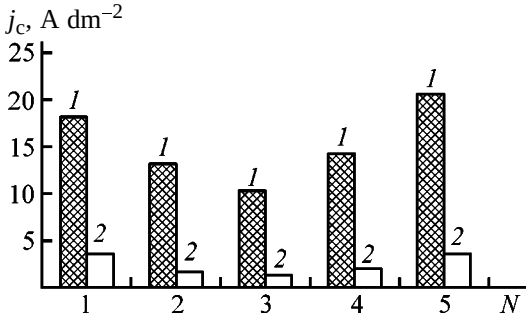

Fig. 2. Limiting current density j_c as a function of the composition of nickel solution for (*1*) rotating disk electrode and (*2*) Hull cell. (*N*) Electrolyte number (as in Fig. 1).

(curve *3*) strengthens the negative effect. In the chloride nickel plating solution (curve *5*), as compared to the sulfate electrolyte (curve *2*), the current at which low-grade coatings start to form is approximately 150 mA higher, which corresponds to an increase in the electrodeposition rate by 1.50 μm min^{-1}.

In spite of the fact that the character of the liquid flow in the vicinity of a rotating disk electrode is rather far from the real nickel plating conditions, the method is flawless from the viewpoint of the stability of the hydrodynamic conditions [2], which eventually allows the mass transfer to be described quantitatively. Hence, the rates of nickel plating determined for five model compositions of electrolytes allow optimization of the deposition rate measurements using the Hull cell.

The cell is connected to an electric circuit with a fixed current of 2 or 1 A, depending on the presence or absence of stirring and heating of the cell, with its size being standard [1] and the size of the cathode being 50 × 100 mm. Usually the nearest edge of the cathode is not scorched under these conditions. Scorching is observed only at a deficiency of nickel salts or at a substantial excess of luster-producing agents or strong foreign inhibitors. To estimate the electrodeposition rate in a solution without stirring, it is necessary to determine experimentally the minimal values of I_{cr} in the cell circuit at which the evolution of hydrogen bubbles on the nearest edge of the cathode, accompanied by scorching, becomes visible. If this condition is met, j_c on the cathode of the Hull cell must correspond to j_c in the polarization curve, which should not exceed the limiting current density j_c observed in the corresponding nickel plating solution.

The limiting values of j_c determined on a rotating disk electrode and in a Hull cell under identical conditions are correlated in Fig. 2. In spite of the fact that the actual values differ from each other by almost an order of magnitude, their dependences on the composition of electrolytes obtained by both methods are in good agreement. Consequently, the advanced procedure using the Hull cell can be used for predicting the nickel plating rates.

Mutual Transformations of Isomers in *N*-Methyl-5-vinyltetrazole Copolymers

G. T. Sukhanov and O. A. Ivashkevich

Altai Federal Research and Production Center, Biisk, Altai krai, Russia

Received December 18, 2000

Abstract—Mutual transformations of N^1 and N^2 isomeric derivatives of 5-vinyltetrazole polymers in the absence of a solvent were studied.

Polymeric materials based on vinyltetrazoles exhibit a combination of unique properties, in particular, high heat resistance (T = 230–380°C) at a high energy capacity (Q_{comb} up to 2800 kcal kg^{-1}, ρ = 1.32–1.5 g cm^{-3}) and a high nitrogen content (up to 65%) [1], high sorption capacity for environmentally hazardous ions of heavy and transition metals [2], and physiological activity of some derivatives [3, 4].

Mutual transformations of 1,5 and 2,5 isomers of disubstituted low-molecular-weight tetrazole derivatives in solution are described in [5, 6]. Since the physicochemical properties of tetrazoles are largely dependent on the position of substituent at the nitrogen atom of the heteroring, it is important to study possible mutual transformations of isomeric derivatives of *N*-substituted 5-vinyltetrazole polymers.

When studying transformations occurring in a copolymer of 1-methyl-5-vinyltetrazole (1-MVT) and 2-methyl-5-vinyltetrazole (2-MVT) on storage and heating in the absence of a solvent, we detected mutual transformation of the 1-MVT and 2-MVT isomeric units. At 20–25°C, the relative content of the 2-MVT units slowly grows. An equilibrium is attained at the ratio 1-MVT : 2-MVT = 1 : 3. Prolonged heating at 80°C, on the contrary, results in a slow increase in the 1-MVT fraction (by 1% in 25–30 h).

By analogy with the chemistry of tetrazole monomers [5, 6], mutual transformations of N^1 and N^2 isomers are facilitated by alkylating agents or by formation of the corresponding tetrazolium salts. Therefore, it can be suggested that, under polymerization conditions, *N*-methyl-5-vinyltetrazole units undergo partial quaternization.

An ^{1}H NMR study of the products (PVT-M, M-PVT, see below) formed in heterophase methylation of poly-5-vinyltetrazole (PVT) with dimethyl sulfate showed that the spectrum of the M-PVT copolymer, along with the signals of the monomethylated products (methyl groups of 1-MVT, 3.6 ppm, and 2-MVT units, 4.2 ppm) [7], contains a weak signal at 4.6 ppm, which can be assigned [8] to the products of "second" exhaustive methylation with formation of *N*,*N*'-dimethyl-5-vinyltetrazolium methyl sulfate (TS) fragments.

The samples of poly-1-methyl-5-vinyltetrazole (PMVT-1), poly-2-methyl-5-vinyltetrazole (PMVT-2), PVT-M, and M-PVT prepared under conditions excluding formation of TS showed no evidence of mutual transformation of the isomers under similar conditions. Apparently, mutual transformation of 1-MVT and 2-MVT units occurs via TS.

EXPERIMENTAL

Polymers and copolymers of 1-MVT and 2-MVT were prepared by two pathways: a sequence of polymer-analogous transformations [1] polyacrylonitrile → PVT → 1-MVT–2-MVT copolymer (M-PVT) and radical copolymerization of freshly distilled 1-MVT and 2-MVT (PVT-M) in the bulk in the presence of azobis(isobutyronitrile) (0.5 mol %) at 65°C or homopolymerization of 1-MVT (PMVT-1) or 2-MVT (PMVT-2), followed by reprecipitation of the resulting polymers from dimethylformamide solution into methanol. The conditions of PVT synthesis are given in [9].

Changes in the isomeric composition of the polymers were monitored by IR spectroscopy (Perkin–Elmer spectrometer, model 684) using KBr technique (4 mg polymer per 600 mg KBr), namely, by changes in the intensities of the bands at 1100 (characteristic of stretching–bending vibrations of the ring in PMVT-

1070-4272/02/7505-0854$27.00 © 2002 MAIK "Nauka/Interperiodica"

1) and 734 cm^{-1} (characteristic of out-of-plane bending vibrations of the ring in PMVT-2) [8].

The ^1H NMR spectra were recorded on an INM PS-100 spectrometer (~3% solutions of polymers in DMSO-d_6, 353 K).

The degree of methylation of PVT was determined by titration of dimethylformamide solutions of the polymers, from the sum of the residual N–H groups of the acid and alkali metal ions.

To a solution of 0.1 mol of PVT and 0.06 mol (6.34 g) of sodium carbonate in 75 ml of water at 35–40°C, we added 110 ml of methylene chloride and then, dropwise over a period of 60 min, 0.12 mol (15.12 g) of dimethyl sulfate. The mixture was allowed to stand for 30 min, after which methylene chloride was distilled off, the mother liquor was decanted, and the polymer was reprecipitated two times from aqueous acetone into isopropyl alcohol. Yield 9.9 g (90%), degree of alkylation 99.9%. IR spectrum, ν, cm^{-1}: 734 (δ_{ring}), 1041, 1100 (ν, δ_{ring}); 1494, 1525 (C=N). ^1H NMR spectrum, δ, ppm: 3.6 (3H, N^1–CH_3), 4.2 (3H, N^2–CH_3), 4.6 (3H, N^4–CH_3). Content, wt %: 1-MVT 44.4 and 2-MVT 54.6.

CONCLUSION

In copolymers of *N*-methyl-5-vinyltetrazoles containing an impurity of *N*,*N*'-dimethyl-5-vinyltetrazolium salt units, in the absence of a solvent, the 1-methyl-5-vinyltetrazole and 2-methyl-5-vinyltetrazole units undergo mutual transformations. At 20±5°C, the content of the second component grows, and an equilibrium is attained at a component ratio of 1 : 3. Heating of such a copolymer at 80°C causes a reverse process: increase in the fraction of 1-methyl-5-vinyltetrazole units (by 1% in 30 h).

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

70th Anniversary of the Foundation of Russia's Aluminum Industry

Among nonferrous metals, aluminum holds the first place in the production volume. The prospects for this metal are favorable: the demand for aluminum will grow steadily. The annual rise in aluminum consumption is 2.5–3.0% [1, 2].

In 1998, for the first time in its history, the Russian aluminum industry produced more than 3 million tons and in 1999, 3146.2 thousand tons of aluminum. Russia is second in the world in production of primary aluminum only to the United States and first in export amounting to 90% of the metal produced. The share of aluminum in the total export of nonferrous metals by Russia is 46% [3].

According to the available estimates, the production of primary aluminum in Russia will grow within the next few years owing to intensification of the already existing plants and possible construction of new ones. It is expected that the metal production will be 3.7 and 4.2 million tons in, respectively, 2005 and 2010. In the course of the recovery of the national economy, the annual rise in the aluminum consumption within the country, according to different estimates, will be in the range from 50 to 200 thousand tons. This communication briefly outlines the history of setting up the aluminum production in Russia.

Metallic aluminum was first obtained in 1825 by H.Ch. Oersted (1777–1851), a Danish physicist, by reacting aluminum chloride with potassium amalgam. Later, in 1827, F. Wöhler (1800–1884), a German physicist, replaced potassium amalgam in this process with metallic potassium. The further development of methods for producing aluminum is associated with French scientists L. Le Chatelier (1815–1873) [father of H. Le Chatelier (1850–1936), a famous physical chemist] and H. Sainte-Claire Deville (1818–1881). In 1855, L. Le Chatelier developed a method for producing alumina from bauxites, based on heating of powdered bauxites and soda in a reverberating furnace, subsequent separation of sodium aluminate from iron oxide, and treatment of the resulting solution with carbon dioxide. In 1854, Sainte-Claire Deville proposed to reduce the double salt $AlCl_3 \cdot NaCl$ with metallic sodium. In 1856, this method was applied to obtain 25 kg of aluminum. The double salt was, in turn, obtained by heating a mixture of Al_2O_3, NaCl, and carbon in a flow of chlorine, and metallic sodium, by reduction of Na_2CO_3 with carbon at high temperature.

Nikolai Nikolaevich Beketov.

N.N. Beketov (1827–1911), professor of Kharkov University and Academician of the Russian Academy of Sciences since 1886, continued in Russia the studies on mutual displacement of metals, commenced by him in France, and found that aluminum can be obtained by the reaction of cryolite with magnesium (1865). Aluminum was produced during a certain period (1886–1890) at a plant in Germany.

In 1885–1888, a small plant producing aluminum by Sainte-Claire Deville's method existed near Moscow, but the cost of the metal was too high. Aluminum, its properties and alloys, and production process were the subject of several books published in Russia [4, 5].

1070-4272/02/7505-0856$27.00 © 2002 MAIK "Nauka/Interperiodica"

During the period when the chemical method was used (from 1854 till 1890), i.e., for more than thirty years, only about 200 tons of aluminum was produced by all plants.

On April 23, 1886, Paul Heroult (1863–1914) in France, and independently on July 9 of the same year, Charles Hall (1863–1914) in the United States, claimed patents for a method for obtaining aluminum by electrolysis of alumina dissolved in molten cryolite. These dates signify the birth of the modern aluminum production and, simultaneously, the beginning of wide use of aluminum in engineering.

The commercial production of aluminum by electrolysis was commenced in France in 1889. The presence of large high-quality bauxite deposits (with SiO_2 content <3%) and rich hydroelectric resources favored the successful development of aluminum industry in this country. The development of the industrial technology was much promoted by C. Bayer (1847–1904), an Austrian chemist-technologist, who, when working at Russian chemical plants, proposed a rather perfect way to produce alumina from bauxites. This method was used already in the first French plants. To the centennial anniversary of Bayer's method, Habashi devoted a paper published in 1988 [6].

By 1912, aluminum was commercially produced already in nine Western countries, with about 60 thousand tons of the metal smelted annually; however, the theory of electrolysis of alumina–cryolite melts was not developed, and physicochemical properties of the electrolyte were known poorly.

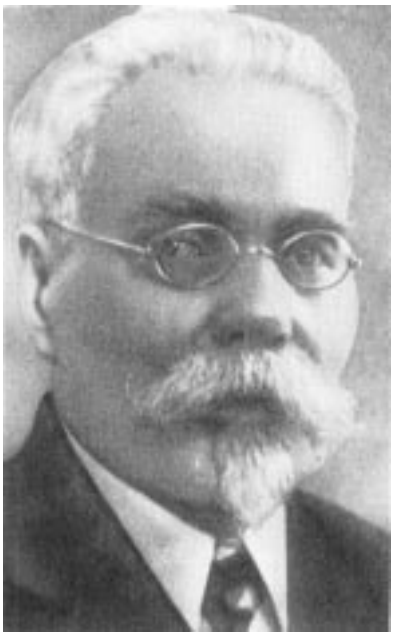
In Russia, the electrolytic production of aluminum was initially studied in St. Petersburg at two higher school institutions: Institute of Electrical Engineering and Polytechnic Institute. Both the institutes started, already in the beginning of the XX century, training of specialists in applied electrochemistry. Professors A.A. Krakau (1855–1909) and N.A. Pushin (1875–1947) at the Institute of Electrical Engineering and V.A. Kistyakovskii (1865–1952, academician of the Academy of Sciences of the USSR since 1929) and P.P. Fedot'ev (1864–1934, corresponding member of the Academy of Sciences of the USSR since 1933) took active part in this process.

In 1909–1914, Pushin and co-workers actively studied electrolytic production of aluminum [7]. In particular, they studied equilibria in binary fluoride systems, including those in the system $NaF–AlF_3$. The absence at that time of any reliable evidence concerning bauxite deposits in Russia forced Pushin to obtain alumina from a Ural mineral soimonite (corundum) containing in anhydrous form (wt %) Al_2O_3 63, SiO_2 13, Fe_2O_3 18, CaO 3, and MgO 1. Alumina was produced in amount of 7 kg, but the content of SiO_2 could not be made less than 1%.

Pavel Pavlovich Fedot'ev.

Electrolysis of fluoride melts with dissolved alumina at 800–900°C was used to obtain for the first time 0.4 kg of aluminum entirely from domestic raw materials. The researchers aimed to obtain aluminum, even if not very pure, but yet produced "...from exclusively Russian materials, i.e., those of Russian origin" [7].

Thorough investigations were also performed in 1910–1912 by P.P. Fedot'ev and V.P. Il'inskii (1885–1964). They studied the binary system $NaF–AlF_3$, solubility of Al_2O_3 in cryolite, interaction of aluminum with cryolite–alumina melts, decomposition potential of electrolyte in an aluminum bath, formation of aluminum carbide in the bath, and specific features of the anodic process [8, 9]. The authors proposed the optimal composition of the electrolyte and studied all the basic phenomena accompanying electrolysis. Experiments were performed in a laboratory electrolyzer at a current of 200 A. This study laid foundation of in-depth research into the electrolytic production of aluminum and exerted profound influence on the subsequent experimental studies.



Aleksandr Yakovlevich Yakovkin.

In 1915, Prof. A.N. Kuznetsov (1877–1946) and E.I. Zhukovskii (1892–1965), staff members of the Mining Institute in Petrograd, proposed a method for producing alumina from various kinds of low-grade raw materials, which consisted in smelting in an ore-thermal furnace of aluminosilicates mixed with barium carbonate, carbon, and iron shavings [10]. This smelting yielded a slag containing barium aluminate and ferrosilicon. To isolate pure aluminum hydroxide, the slag was subjected to hydrothermal treatment.

In 1916, a bauxite deposit was discovered near Tikhvin (now in Leningrad oblast). In view of the situation in the country at that time, a geological survey of the deposit was started only in 1920 by a group of geologists headed by professor S.F. Malyavkin (1876–1937). By 1923, it was found that, in the nearest future, the Tikhvin deposit of bauxites can meet the demands of the USSR for aluminum; the low cost of bauxite mining was also noted.

However, these bauxites had a high SiO_2 content (up to 18%) and required development of a new technology for their processing. A search for the most efficient flowsheet for processing of Tikhvin bauxites was commenced at scientific institutions in Leningrad. Such well-known scientists as A.A. Yakovkin (1860–1936), N.P. Aseev (1871–1952), and G.G. Urazov (1884–1957, academician of the Academy of Sciences of the USSR since 1946) took part in these studies. In all stages, much attention was given to the problem of aluminum production from domestic raw materials by such outstanding Russian chemists as academicians V.N. Ipat'ev (1867–1952), V.I. Vernadsky (1863–1945), and N.S. Kurnakov (1860–1941). In the years of World War I, lieutenant-general Ipat'ev headed the Chemical Committee, an institution created to ensure rapid development of the Russian chemical industry and provide the front-line forces with means of chemical protection. In 1915–1916, the scientist did a tremendous work on creating the military-chemical industry in Russia. In 1918–1926, Ipat'ev held high positions in the Soviet State machinery, was a member of the Presidium of the All-Russia Council of National Economy and chairman of the Central Chemical Directorate. In 1919, he headed a special State Committee of Aluminum.

The necessity for obtaining aluminum from domestic ores was stated by Vernadsky and Kurnakov as far back as March 1915 at a meeting of the Department of Physical and Mathematical Sciences of the Academy of Sciences. Vernadsky wrote in 1916 that aluminum has bright future, both in the form of alloys and as pure metal. He mentioned that this is one of most abundant elements of the earth's crust. In 1916, a Directorate for Construction of Aluminum Plants was formed, headed by A.P. Kurdyumov (1857–1926), but no practical results followed under the conditions of that time.

In March 1919, Kurnakov made large efforts to coordinate studies of bauxites, carried out at different institutions. In 1922, Kurnakov and Urazov made a joint report at the III Mendeleev Congress, "Thermal Analysis of Clays and Bauxites," in which they underlined the vital importance of the bauxite rocks found near Tikhvin for creation of the Russian aluminum industry [11]. Urazov, one of Kurnakov's disciples, commenced extensive studies of the chemical and physicochemical properties of domestic bauxites already in 1920. The method of thermal analysis was for the first time applied to determine the mineralogical composition of the rocks.

In 1925 (March 30–April 6), the First All-Union Symposium on nonferrous metals was held. One of the most topical problems discussed at the Symposium was associated with setting up aluminum production in the Soviet Union. This problem was discussed in a report by Kurnakov and co-workers "On Use of Tikhvin Bauxites To Obtain Aluminum" [12]. At the same Symposium, Malyavkin delivered a report on advances in exploration and the expected resources of bauxites in the Tikhvin region [13].

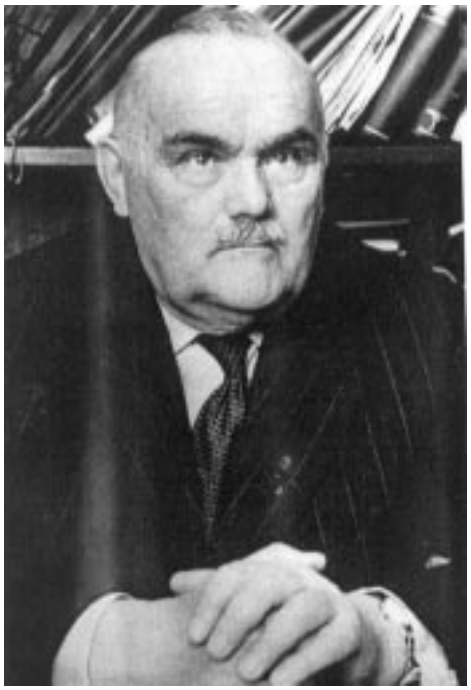
Much attention was given to studies of various

techniques for dressing of Tikhvin bauxites by K.F. Beloglazov (1887–1951), a professor of the Mining Institute.

A key contribution to the development of a technology for processing of high-silica bauxites was made by Prof. Yakovkin, who performed his studies at the Russian Institute of Applied Chemistry. The process was based on sintering of bauxites with soda and lime, which was proposed by G. Muller as far back as 1880 (German Patent 12947 of April 13, 1880). In large-scale laboratory experiments, Yakovkin optimized the composition of the starting stock for the Tikhvin bauxites and developed, together with I.S. Lileev (1882–1966), a method for fractional precipitation of aluminum hydroxide from an aluminate solution (USSR Patent 3985 of November 30, 1927). Later, a desiliconization procedure was introduced to eliminate the fractional precipitation and obtain high-quality alumina. Yakovkin wrote [14]: "The researchers did not aim to develop a certainly original production technique. The task was more moderate: to find the simplest method applicable to our bauxites."

The Second All-Union Symposium on Nonferrous Metals (March 27–April 5, 1927) also paid much attention to processing of domestic bauxites. In an extensive report, Urazov (together with Ya.E. Vil'nyanskii and Yu.V. Morachevskii) considered in detail theoretical foundations of the lime–sodium method for producing alumina from natural aluminosilicates [15]. Lileev reported the results of studies concerned with alumina production from Tikhvin bauxites by sintering.

A pilot production of aluminum from entirely domestic raw materials was organized at Krasnyi Vyborzhets plant in Leningrad under the supervision of P.P. Fedot'ev with participation of his son N.P. Fedot'ev (1897–1969) and Yu.V. Baimakov (1894–1980), chief metallurgist of the plant. Alumina was obtained at the Pilot Plant of the Institute of Applied Chemistry from Tikhvin bauxites by the Muller–Yakovkin–Lileev method. Cryolite and carbon materials used in the process were produced in Russia. The current in the electrolyzers was 2000–2200 A. The first batch of aluminum (8 kg) was produced on March 27, 1929. In the same year, the construction of the Pilot aluminum plant in Leningrad was commenced, which was finished in May 1930. Its aim was to develop a commercial process of aluminum production and to test under industrial conditions various electrolyzer designs for aluminum plants of the country. Baimakov was the chief engineer of the plant; two electrolyzers were designed by N.P. Fedot'ev.



Yurii Vladimirovich Baimakov.

The world production of aluminum grew swiftly in the beginning of the XX century: it increased 30-fold during the period from 1900 to 1927 [16] to become 219.7 thousand tons in 1927, 243.2 thousand tons in 1928, and 264.4 thousand tons in 1929. The actual output capacity of aluminum plants all over the world was as high as 325 thousand tons already in 1925 [17].

On September 14, 1929, the Soviet Government finally defined the scale and schedule of construction of first aluminum plants. A decision was made to construct a plant with annual aluminum output capacity of 5 thousand tons on the basis of Volkhov hydroelectric power station, whose first units were put in operation on December 19, 1926, and a plant producing 15 thousand tons of aluminum annually on the basis of Dnieper hydroelectric power station (Dneproges) whose construction was started in May 1932.

After the Government decision, the production process to be used at these plants was discussed at a special meeting in Moscow. Kurnakov explicitly supported use of the Muller–Yakovkin–Lileev method for the Volkhov aluminum combine and the Kuznetsov–Zhukovskii method for the Dnieper aluminum combine. The latter technique, being more power-consuming, required less expensive electric power that could only be provided by Dneproges. Both the combines were to use Tikhvin bauxites as raw material.

The construction on the Volkhov riverbank was commenced in June 1930. Baimakov, later a professor of the Polytechnic Institute in Leningrad (from 1934 to 1974), was appointed its chief engineer. The construction was fast and the plant was put into operation in the first half of 1932. On May 14, 1932, the first batch of aluminum was obtained (in the initial stage, imported raw materials were used: French alumina and anodes, and cryolite from Greenland). This day is commonly considered the birthday of the domestic aluminum industry. By the end of 1933, the combine reached its designed output capacity [18].

In 1930, the construction of the Dnieper Aluminum Combine was commenced near the hydroelectric power station. Zhukovskii, later a professor of the North-Caucasian Mining and Smelting Institute (from 1938 till 1965), was the chief engineer of the project. The first set of electrolyzers was put in operation in June 1933, and the alumina production, in April 1934. At those years, the Dnieper plant was one of the largest in Europe.

At present, 11 aluminum plants are in operation in Russia, which include such giants as Bratsk and Krasnoyarsk plants having no analogs in the output capacity in the world. The annual output of aluminum by each of these plants exceeded 800 thousand tons (in 1998, 844 and 802 thousand tons at the Bratsk and Krasnoyarsk combines, respectively).

At the same time, the established Russia's resources of the main aluminum raw material, high-quality bauxites processable by the simplest and most economical Bayer method, are scanty. According to the available estimates, after the disintegration of the Soviet Union, about 50% of Russian aluminum is produced from imported raw materials. At the same time, the share of raw materials in the production cost of aluminum is rather high. The complicated economical and environmental problems associated with the operation of aluminum plants in Russia and new kinds of market relationships in the domestic aluminum industry were analyzed in detail in [19].

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Properties of Thermally Expandable Residual Graphite Hydrosulfite Obtained in the System HNO_3–H_2SO_4

Received January 15, 2002

Abstract—Synthesis of bloating residual graphite hydrosulfide with the use of an oxidizing system, fuming nitric acid–concentrated sulfuric acid, was studied at ultralow expenditure of reagents and their separate introduction into the reaction mass. Important parameters of the process were revealed and their effect on the properties of the target product was determined. Ways to diminish to the maximum possible extent the adverse influence of by-products formed in the stage of graphite oxidation on the properties of the target product were found.

Nitric acid, one of the cheapest and most accessible oxidants, is widely used in synthesis of thermally expandable residual graphite hydrosulfites (RGH) [1–6]. Previously, an approach to RGH synthesis at "ultralow" expenditure of components of the intercalation solution has been developed for the example of graphite oxidation in the system chromic anhydride–sulfuric acid [7, 8]. In the present study, the same approach is applied to graphite oxidation in the system fuming nitric acid–concentrated sulfuric acid.

Formation of intercalation compounds of graphite in the system graphite–HNO_3–H_2SO_4 can be described by the following reactions [7]:

$$C_n + Ox \rightarrow C_n^+ + Red, \quad (1)$$

$$C_n^+ + A^- + HA \rightarrow C_n^+A^- \cdot HA. \quad (2)$$

Nitric acid oxidizes the graphite matrix, and sulfuric acid supplies intercalating species (HSO_4^-) and solvating ligands for them. The final product is graphite hydrosulfite.

To control the process of RGH synthesis with the use of the system HNO_3–H_2SO_4 and to vary purposefully the properties of the products obtained, a knowledge is necessary of the nature of active species directly involved in reactions (1) and (2), by-products and their influence on the process of graphite oxidation and on the structure and properties of the graphite intercalation compounds obtained.

Fuming nitric acid, its mixtures with concentrated sulfuric acid, and also mixtures of sulfuric and aqueous nitric acids have been long, and successfully, used in various industrial chemical processes for oxidation and nitration of alkanes, alkenes, arenes, and many other classes of organic compounds. These systems are used to obtain explosives and serve as a medium for carrying out inorganic reactions [9]. The data accumulated for these reactions can be used to describe processes occurring in RGH synthesis with nitric acid oxidizing the graphite matrix.

It is known that fuming nitric acid self-ionizes

$$2HNO_3 \rightleftarrows NO_2^+ + NO_3^- + H_2O, \quad (3)$$

with the content of ionization products depending on temperature. In most cases, the ability of fuming HNO_3 to oxidize and to nitrate is due to the presence of nitronium cations NO_2^+ in the acid.

Formation of graphite nitrate in the system graphite–fuming nitric acid is described by the following scheme [10]

$$\left.\begin{aligned} 2HNO_3 &\rightleftarrows NO_2^+ + NO_3^- + H_2O, \\ C_n + NO_2^+ &\rightarrow C_n^+ + NO_2\uparrow, \\ NO_3^- + mHNO_3 &\rightarrow NO_3^- \cdot mHNO_3, \\ C_n^+ + NO_3^- \cdot mHNO_3 &\rightarrow C_n^+ \cdot NO_3^- \cdot mHNO_3. \end{aligned}\right\} \quad (4)$$

1070-4272/02/7506-0861 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The forming nitrogen dioxide is partly removed into the gas phase and partly reacts in the liquid phase by the scheme [11]

$$\left.\begin{aligned} 2NO_2 + H_2O &\rightarrow HNO_2 + HNO_3, \\ 3HNO_2 &\rightarrow HNO_3 + 2NO + H_2O. \end{aligned}\right\} \quad (5)$$

Introduction of water into fuming nitric acid suppresses the self-ionization reaction (3): the content of nitronium cations NO_2^+ and, consequently, the oxidizing ability of HNO_3 decrease. At water content of 5–8 wt %, NO_2^+ species are no longer formed in nitric acid. It is noteworthy that treatment of graphite with dilute aqueous solutions of nitric acid does not yield intercalation compounds of graphite, and use of fuming nitric acid gives graphite nitrite only in the second stage.

In H_2SO_4–HNO_3 mixture, nitric acid is ionized to give nitronium cation by the scheme

$$HNO_3 + H_2SO_4 \rightleftarrows NO_2^+ + HSO_4^- + H_2O. \quad (6)$$

A similar reaction proceeds in mixtures of HNO_3 with other strong acids, e.g., $HClO_4$, H_2SeO_4, HF, or HBr. Use of H_2SO_4–HNO_3 mixtures makes it possible to achieve a higher concentration of nitronium cations in the reaction mass, compared with that in fuming HNO_3. In addition, NO_2^+ cations in the system HNO_3–H_2SO_4 completely disappear at much higher content of water, compared with the case of nitric acid.

The equilibrium constant of reaction (6) is 30 – 42 [9]. This means that, at a sufficient excess of nitric acid and low content of water, nitric acid is nearly completely ionized to give a nitronium cation. With increasing content of water and nitric acid, the degree of conversion of the acid into the nitronium cation becomes lower. As a result, the concentration of undissociated nitric acid and nitrate anions in the system decreases. Below are given degrees α of conversion of anhydrous nitric acid into the nitronium cation in HNO_3–H_2SO_4 mixtures of varied composition [9]:

H_2SO_4 : HNO_3, wt % : wt %	α	H_2SO_4 : HNO_3, wt % : wt %	α
95 : 5	1.0	40 : 60	0.167
90 : 10	1.0	20 : 80	0.098
85 : 15	0.8	10 : 90	0.059
80 : 20	0.625	0 : 100	0.01
60 : 40	0.288		

Analysis of the results of oxidation and nitration of various organic compounds in the system H_2SO_4–HNO_3 shows that nitrogen oxides formed in the reaction mass decelerate the main reactions, lower the concentration of sulfuric acid, react with the starting substrates, and, in some cases, complicate the process control [9].

The main primary by-product is nitrogen dioxide. It can react by reactions (5) or disproportionate to form nitrosonium cation and nitrate anion:

$$2NO_2 \rightleftarrows NO^+ + NO_3^-. \quad (7)$$

Nitrosonium cations further react with bisulfate anions to give nitrosylsulfuric acid:

$$NO^+ + HSO_4^- \rightarrow NOHSO_4. \quad (8)$$

Thus, $NOHSO_4$, H_2O, and NO_3^- species are accumulated in the reaction mass in the course of nitration and oxidation in the system HNO_3–H_2SO_4 (as nitric acid is spent), the concentration of sulfuric acid decreases, and, consequently, the main process becomes slower.

It is known that nitrosylsulfuric acid forms stable complexes with aromatic hydrocarbons (Battge complexes), e.g., $(C_6H_6)_n \cdot (NOHSO_4)_{n1} \cdot (H_2SO_4)_{n2}$ and $(C_6H_5CH_3) \cdot 2(NOHSO_4) \cdot 3(H_2SO_4)$ [6]. Complexes of this kind are decomposed by introduction into the reaction mass of an excess amount of nitric acid at 40–50°C. The most stable complexes with $NOHSO_4$ are formed by benzene, whereas homologues of benzene form less stable complexes.

Nitrosylsulfuric acid is stable in solutions of sulfuric acid with concentration exceeding 75 wt %. Lowering the H_2SO_4 concentration to 70 wt % leads to fast decomposition of $NOHSO_4$:

$$2NOHSO_4 + H_2O \rightarrow 2H_2SO_4 + N_2O_3. \quad (9)$$

It has also been proposed to decompose nitrosylsulfuric acid by its oxidation with oxygen, persulfates, and chromic anhydride [9]. For example, in the case of oxidation with oxygen, the reaction is described by the equation

$$2NOHSO_4 + O_2 + 2H_2O \rightarrow 2H_2SO_4 + 2HNO_3. \quad (10)$$

Let us consider in terms of the above concepts data on the influence exerted by the process conditions on the characteristics of RGH synthesized in the system fuming nitric acid–concentrated sulfuric acid.

RGH was synthesized using natural scaly graphite of the GT-1 brand from Zaval'evskoe deposit, concentrated sulfuric acid of chemically pure grade (d =

Bloating coefficient of RGH in relation to the duration of treatment of graphite with sulfuric (τ_1) and nitric (τ_2) acids

* Acid expenditure, cm^3/100 g: H_2SO_4 24, HNO_3 6 (variant 1); H_2SO_4 40, HNO_3 8 (variant 2).

1.836 g cm^{-3}, 95.8 wt %) and fuming nitric acid (d = 1.518 g cm^{-3}).

RGH samples were obtained using the scheme of successive introduction of components of the intercalation solution into the reaction mass. In what follows, the acid expenditures are given in cubic centimeters per 100 g of starting graphite.

A glass reactor was charged with 25 g of graphite and stirring was switched on. At the instant when the stirring started, the first component of the intercalation solution (fuming nitric acid or concentrated sulfuric acid) was fed into the reactor and the reaction mass was stirred for a time τ_1. Then the second component of the intercalation solution was introduced into the reactor and stirring was continued for a time τ_2. The parameters τ_1 and τ_2, and also expenditures of the components of the intercalation solution and order of their introduction, were varied.

Upon completion of the acid treatment of graphite, the oxidized graphite was washed with water on a filter to washing water pH 5–6 and dried at 100–110°C to constant weight. For all of the RGH samples obtained, the product yield in terms of the starting graphite, mass loss in bloating, and bloating coefficient K_v ($cm^3\ g^{-1}$) at 900°C were determined. The data on the yield of the product were used to calculate the content m_i of intercalate in it.

The bloating coefficient was found in the shock-heating mode as follows. A 150-cm^3 stainless steel cuvette was placed in a muffle furnace heated to 900°C. A weighed portion of the product (m = 0.2–0.3 g) was introduced into the heated cuvette in the furnace and kept there for 60 s. Bloated graphite was carefully transferred into a glass graduate and the volume V (cm^3) occupied by the graphite was measured. The bloating coefficient was found using the relation $K_v = V/m$ as arithmetic mean of three parallel measurements. The admissible discrepancy between the K_v values found in parallel runs is 5%.

Graphite was treated with acids in two variants. In variant 1, graphite was treated with sulfuric acid (40 cm^3/100 g, τ_1 = 10 min) and then with fuming nitric acid (8 cm^3/100 g, τ_2 = 10 min). In variant 2, first fuming nitric acid (8 cm^3/100 g, τ_1 = 10 min) and then sulfuric acid (40 cm^3/100 g, τ_2 = 10 min) were added to graphite. In synthesis by variant 1, the evolution of nitrogen oxide, observed visually after nitric acid was introduced, terminated 3–4 min after the beginning of HNO_3 introduction into the reactor. In variant 2, evolution of nitrogen oxide was observed upon introduction of any of the acids into the reactor. The K_v values for RGH samples obtained in two variants of acid introduction into the reactor are given below:

Variant of synthesis	Order of introduction of acids	K_v, $cm^3\ g^{-1}$
1	H_2SO_4, HNO_3	110
2	HNO_3, H_2SO_4	125

It follows from the data presented that the coefficient of RGH bloating is virtually independent of the order in which the acids are introduced into the reactor.

The influence exerted by the duration of treatment of graphite with sulfuric and nitric acids was studied for both variants of acid introduction into the reactor. The data obtained for varied parameters τ_1 and τ_2 are presented in the table for variants 1 and 2.

The data in the table indicate that, for both variants of acid introduction, the decisive influence on the parameter K_v is exerted by the duration of reaction mass treatment with the second component of the intercalation solution—τ_2. The optimal duration of treatment of graphite with each component of this solution is 5–10 min. Unexpectedly, it was found that raising the parameter τ_2 leads to a dramatic decrease in K_v of the final product. Raising the reaction time in the second stage from 5–10 to 60 min results in a decrease in the bloating coefficient of the final product by a factor of 2.5–3 for both variants of synthesis.

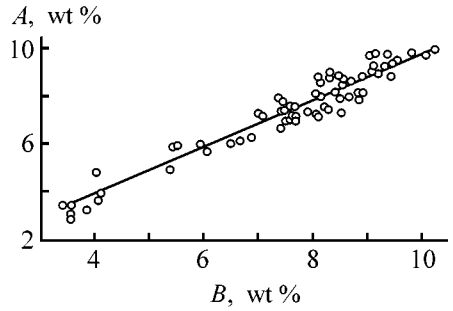

Fig. 1. Mass loss A of RGH in bloating at 900°C vs. intercalant content B in the samples. $y = 0.99x$, $R^2 = 0.93$.

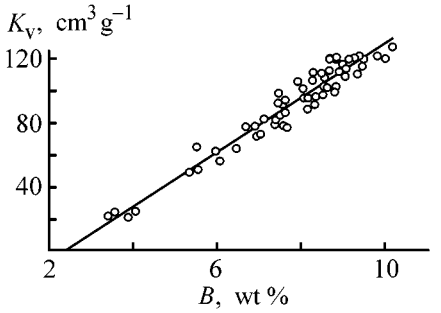

Fig. 2. Bloating coefficient K_v of RGH at 900°C vs. intercalant content B in the samples. $y = 16.91x - 39.46$, $R^2 = 0.96$.

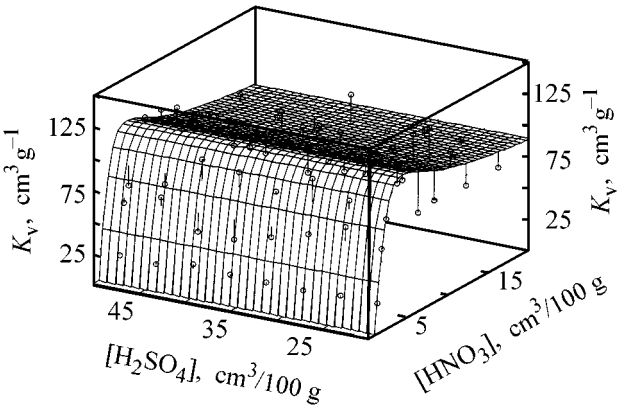

Fig. 3. Bloating coefficient K_v of RGH at 900°C vs. expenditures of sulfuric and nitric acids used in the synthesis stage.

The RGH properties were studied in relation to the expenditure of the components of the intercalating solution under standard conditions for the case of an acid treatment of graphite by variant 1, i.e., first with sulfuric, and then with nitric acids. The expenditure of sulfuric acid was varied within the range 20–48 cm^3/100 g with a step of 4 cm^3/100 g, and that of nitric acid, in the range 1–16 cm^3/100 g with a step of about 2 cm^3/100 g. In this case, the duration of treatment of graphite in each stage was $\tau_1 = \tau_2 = 10$ min.

It was found that the loss of mass in bloating of RGH samples depends linearly on the intercalant content in the samples (Fig. 1). The slope of the straight line obtained is close to unity, which indicates a virtually complete removal of the intercalating agent from the RGH matrix in bloating. Figure 2 presents the dependence of the bloating coefficient of RGH samples at 900°C on the content of intercalant in these samples. The linear run of the dependence may indicate an invariable chemical nature of the intercalant over the entire range of its content in the samples studied.

It also follows from the data in Fig. 2 that, for RGH samples, there exists a threshold content of the intercalating agent, approximately equal to 2.3 wt %, below which no bloating must be observed at 900°C. The dependence of the bloating coefficient of RGH samples at 900°C on the expenditure of acids in synthesizing these samples is represented in Fig. 3 as a three-dimensional diagram. This dependence has the form of a plateau with a precipice at nitric acid expenditures of about 3 cm^3/100 g.

Unexpectedly, it was found that the whole set of experimental data is described, with a correlation coefficient of 0.93, by a single-parameter equation taking into account only the dependence of K_v on the expenditure of fuming nitric acid, [HNO_3]:

$$K_v = 59.55 + 128.67/[HNO_3]^{0.5} - 449.6\exp(-[HNO_3]). \quad (11)$$

In this case, the expenditure of sulfuric acid in the range studied has, to a first approximation, no effect on the bloating coefficient of the final product. These data indicate that even an expenditure of sulfuric acid of 20 cm^3/100 g ensures an acidity of the medium that is sufficient for the intercalation process to occur. This amount of sulfuric acid is also sufficient for ensuring the required amount of hydrosulfate anions to be intercalated into graphite.

At small expenditures of fuming nitric acid, raising the amount of acid introduced from 0 to ~3 cm^3/100 g leads to a steep rise in the bloating coefficient of the product. With the expenditure of nitric acid raised further, this parameter decreases gradually to a certain extent. The dramatic increase in the parameter K_v at small expenditures is presumably due to a rise in the degree of oxidation of the graphite matrix, caused by an increase in the content of the oxidizing agent—nitronium cations, in the reaction mass. Further increase in the expenditure of fuming nitric acid makes the acidity of the reaction mass lower, which leads to a decrease in the concentration of nitronium cat-

ions. This, in turn, lowers the degree of oxidation of the graphite matrix and, as a result, leads to a decrease in the bloating coefficient of the final product.

A dramatic decrease in the bloating coefficient of the final product was observed on making longer the reaction duration in the second stage of synthesis (parameter τ_2). This can be accounted for as follows. In both variants of synthesis, a mixture of fuming nitric acid and concentrated sulfuric acid is formed in the reaction mass in the second stage. Immediately after the introduction of the second reagent there begins intensive oxidation of graphite, which is complete in 5–10 min. Simultaneously with the onset of graphite oxidation, nitrogen oxides appear in the reaction mass and nitrosylsulfuric acid starts to accumulate in the system. This acid forms stable complexes (of the type of Battge complexes [9]) with the matrix of the graphite intercalation compound and, being a reducing agent, presumably promotes the deintercalation process which leads to a decrease in the bloating coefficient of the final product. Theoretical analysis of reactions whose occurrence is possible in the system studied made it possible to account for the experimentally observed dependences of the bloating coefficient of the final product on process parameters.

CONCLUSION

The data obtained in studying the influence exerted by synthesis conditions on the properties of final products in the system graphite–fuming nitric acid–concentrated sulfuric acid indicate that products with practically acceptable characteristics can be synthesized at exceedingly low, compared with those in the conventional methods, expenditures of sulfuric and nitric acids. To obtain a high-quality product, it is necessary to strictly observe the process parameters and especially the duration of treatment of the reaction mass with the second reagent.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Complexation and Intramolecular Redox Decomposition of Cerium(IV) Hydroxo Complexes with Oxycarboxylic Acids

O. O. Voskresenskaya and N. A. Skorik

Received January 15, 2001; in final form, March 2003

Abstract—Spectrophotometry, pH-metry, and kinetic method were applied to study the complexation and redox decomposition of cerium hydroxo complexes formed in the systems Ce^{4+}–SO_4^{2-}–H_mL, where H_mL (m = 2, 3, 4) are, respectively lactic, malic, and tartaric acids.

A study of thermodynamic and kinetic characteristics of complexation and redox decomposition of complexes formed in the first stage of oxidation by cerium(IV) of polar organic compounds is of theoretical and practical interest. It is rather important in connection with the problem of stabilization of unstable oxidation states of metals [1–4] and use of these systems as a source of radicals in radical polymerization [5, 6], and also in view of their other applications—analytical [7], in a theoretical study of the electron transfer rates in intermediate complexes [8], and in separation of a mixture of rare-earth elements [1–3].

For example, separation of a mixture of rare-earth elements is based on the ability of cerium to form compounds in which it is in oxidation state +4. This leads to a pronounced difference between the properties of cerium compounds and those with rare-earth elements in oxidation state +3 and improves the efficiency of methods for separation of rare-earth elements. However, the problem of cerium stabilization in this "anomalous" oxidation state, especially in complexation with oxyacids, has been studied insufficiently.

Previously, the influence exerted by the stability constants of complexes, reducing ability of ligands, their denticity, and other factors on the rate of the redox interaction in systems containing cerium(IV) and organic ligands (carboxyl-containing complexons, oxycarboxylic acids, etc.) [3]. It has been established that there is a correlation between the rate of the redox interaction in the systems and the instability constant of cerium(IV) complexes. No simple relationship could be revealed between the stability of the complexes and the rate and apparent activation energy of the redox interaction in cerium(IV) complexation with oxyacids [3]. It has been shown that intramolecular redox interaction cannot be completely eliminated in systems of this kind, with only its partial suppression possible [3, 4].

As characteristics of the redox interaction were employed the conditional rate of the redox process, its apparent activation energy, and reducing power of an organic ligand [3]. Such a direct characteristic of the kinetic activity of the complexes as rate constant of their intracomplex redox decomposition was not determined in the previous studies mentioned here. It is also evident that such a property of an organic ligand as its reducing capacity may play an important part in the case of a bimolecular (free-radical), but not intermediate, mechanism occurring in oxidation of oxy acids by cerium(IV) [9]. A study of the problem of stabilization in the given context is inseparable from a study of the mechanism and kinetics of the redox process occurring in the systems.

The kinetics of oxidation of oxycarboxylic acids by cerium(IV) was studied in [5, 9–13]. In [10–12], a mechanism of the redox process was postulated, in which an intermediate complex is formed and the decomposition of this complex is the rate-determining stage of the process. However, it has been noticed that kinetic data are insufficient for confirming the formation of such an intermediate complex [11]. A synergistic effect of the carboxylic and hydroxy groups of α oxyacids, and also intermediate and free-radical mechanisms of oxidation of organic ligand by ceri-

1070-4272/02/7506-0866 $27.00 © 2002 MAIK "Nauka/Interperiodica"

um(IV) for, respectively, oxy acids and succinic dicarboxylic acids have been noted [9]. A bridge mechanism of electron transfer in such an intermediate has been suggested and necessity for revealing the states in which the metal and ligand are present in this complex has been indicated [13].

It is noteworthy that the complexation pre-equilibrium in the redox process has not been studied specially, being either postulated or studied using methods yielding only effective complexation constants related to a fixed pH value and indeterminate form of the ligand and metal in the complex. At the same time, the kinetic dependences themselves were interpreted on the basis of assumptions about the composition, structure, and reactivity of the complexes and characterized by effective rate constants. Data on the rate constants of intramolecular decomposition of cerium(IV) complexes with organic ligands are unavailable in the literature. Of interest in this regard are generalized methods for investigation of complexation, proposed in this study, and their application to analysis of the kinetics and thermodynamics of the initial stages of the processes mentioned, the mechanism of these processes, and the reactivity of intermediate complexes involved.

A comparative evaluation of the effective formation constants of intermediate cerium(IV) complexes with lactic α oxyacid and other hydroxyl-containing compounds in a perchlorate medium was made in [5]. The composition and stability of complexes have been studied in a nitrate medium for the malate complex $[Ce(NO_3)_zMalt]^{2-z}$ [3, 14] and binuclear tartrate complex of cerium(IV) $[Ce_2(NO_3)_zTart]^{6-z}$ [3, 15]. Other researchers [3, 14, 15] could not study the complexation in a sulfate medium in the systems we investigated.

In the present study, the methods commonly used to investigate complexation and generalized to the case of kinetically active complexes were applied to determine in a sulfate medium the composition, stability constants β_1, rate constants k_2, and activation energy of intramolecular redox decomposition of lactate, malate, and tartrate hydroxo complexes of cerium(IV) $[CeOH\ H_{m-x}L]^{3-x}$ (m = 2, 3, 4) formed in the first stage of oxidation by cerium(IV) of the above-mentioned organic ligands:

$$CeOH^{3+} + H_{m-x}L^{x-} \overset{\beta_1}{\rightleftarrows} [CeOHH_{m-x}L]^{3-x} \xrightarrow{k_2} Ce^{3+} + \cdot LH_{m=1-x}^{x-} + H_2O, \quad (1)$$

$$\beta_1 = k_1/k_{-1}, \quad k_1 >> k_{-1} >> k_2.$$

was studied, and the law governing its rate was established.

The composition of intermediate complexes formed in the systems Ce^{4+}–SO_4^{2-}–H_mL at the instant of mixing of the reaction mixture components was studied by the methods of isomolar series (Fig. 1) and molar ratios (Fig. 2). The results obtained indicate that 1 : 1 complexes are predominant in all the systems in the pH range studied. The formation of complexes with 1 : 1 composition in the systems studied was additionally confirmed by using kinetic analogues of the above methods [Figs. 1c and 1e; Fig. 2, curve *2*; Eq. (16)], which are particularly appropriate in the cases of low yield or low light absorption by the complexes.

The data on the composition of the complexes, obtained in the present study, is in agreement with the assumption that an intermediate cerium tartrate complex of composition 1 : 1 is formed in oxidation of tartaric acid by cerium(IV) [10, 12] and also with the conclusions of [5] that the 1 : 1 composition of intermediate organocerium complexes is independent of the denticity of the organic ligand and can be regarded as their proof. The composition of the malate complex of cerium(IV) in a sulfate medium coincides with that in a nitrate medium, established in [3. 14].

The form in which a coordinated ligand is present in the complexes and their stability constants were determined using the *D*–pH method [16]. As the dominant form of cerium(IV) in the pH range studied was taken the monohydroxo form $CeOH^{3+}$ [17].

* $\log \beta_1 = 18.45 \pm 0.34$, $\log k_2 = \bar{3}.42 \pm 0.03$ (18.0°C).

ion $CeOH^{3+}$ displaces 2, 3, or 4 protons from the ligand molecule in complexation with, respectively, lactic, malic, and tartaric acids. In this case, similarly to that of interaction of oxyacids with the cations Sc^{3+}, Ga^{3+}, In^{3+}, and Th^{4+} [18], protons of the oxy groups of oxyacids are displaced because of the high coordination numbers of rare-earth elements and the effective negative charge on electron-donor oxygen atoms.

Consequently, the complexation pre-equilibrium in oxidation of the acids under consideration by cerium(IV) can be represented as

$$CeOH^{3+} + L^{x-} \overset{\beta_1}{\rightleftarrows} [(CeOH)L]^{3-x} \qquad (5)$$

or, which is equivalent in terms of the theory of ionic equilibria,

$$CeOH^{3+} + L^{x-} \overset{\beta_1}{\rightleftarrows} [(CeO)HL]^{3-x}, \qquad (6)$$

where $x = 2$, 3, and 4 for, respectively, H_2Lact, H_3Malt, and H_4Tart.

It is noteworthy that, in a sulfate medium, the formula $[CeOHL]^{3-x}$ should be only regarded as an abbreviated designation of all the possible substances with variable number of ions of the ionic background $\Sigma_y\Sigma_z[(NH_4)_yCeOHL(SO_4)_z]^{3-x+y-z}$, where y and z can be estimated by the inequalities $y \geq 0$, $0 \leq z \leq 3$ [19].

For the complexation equilibrium (5), the equilibrium constant β_1:

$$\beta_1 = \frac{[CeOHL]}{[CeOH][L]} \qquad (7)$$

(charges are omitted) was calculated from the data of the series D^0–pH and the ascending portion of the saturation curve by the formula

$$\beta_1 = \frac{c^0_K}{(c_M - c^0_K)(c_L - c^0_K)} f = \beta_{1eff} f, \qquad (8)$$

$$f = 1 + \sum_{i=1}^{m} B_i [H]^i$$

for each point of the dependence

$$\log \beta_1 = \log \beta_{1eff} + \log f \qquad (9)$$

with the subsequent averaging of the $\log \beta_1$ values obtained (Tables 1–4).

The agreement between the results obtained by different methods (D–pH, molar ratios) in determining the stability constants for, e.g., the malate complex of cerium(IV) ($\log \beta_1 = 18.39$, $\log \beta_1 = 18.45$, Tables 2

and 4) indicates that the basic equilibria in solution are taken into account correctly. The $\log \beta_1$ value for the complex $[CeOHL]^{3-x}$ (x = 2, 3, 4), found in a sulfate medium by averaging data of two to four series for each of the systems, grows in order $H_2Lact < H_3Malt < H_4Tart$ with increasing ligand denticity from $\log \beta_1 = 14.97 \pm 0.18$ for H_2Lact to $\log \beta_1 = 27.83 \pm 0.23$ for H_4Tart.

The kinetics and mechanism of the redox process observed in the system was studied by analyzing the dependence of its initial rate $-\dot{D}^0$ on the equilibrium concentration of hydrogen ions at the initial concentration of the organic ligand in terms of the generalizations of the D^0–pH and D^0–c_L/c_M methods to the case $\dot{D}^0 \neq 0$ (see below), which can be named the D^0, $\dot{D}^0$–pH and D^0, $\dot{D}^0$–c_L/c_M methods, respectively.

The rate constants of the redox decomposition of $[CeOHL]^{3-x}$ complexes were calculated from the data of series D^0–pH, D^0–c_L/c_M (supplemented with the dependences $\dot{D}^0$–pH, $\dot{D}^0$–c_L/c_M) with the use of the equilibrium concentrations of the complex, calculated from the series D^0–pH, D^0–c_L/c_M (Tables 1–4):

$$c_K^0 = \begin{cases} \dfrac{D^0 - D_M}{D_\infty^0 - D_M} c_M, & c_M < c_L; \\ \dfrac{D^0 - D_M}{D_\infty^0 - D_M} c_L, & c_L < c_M, \end{cases} \quad (10)$$

where c_M and c_L are the initial concentrations of the metal ion and ligand, D_M the optical density of the metal ion solution, and D_∞^0 the light absorption by the reaction mixture at the instant of time $\tau = 0$, corresponding to a yield of the complex equal to unity.

The analysis of nonlinear dependences $\dot{D}^0$–pH (Fig. 4) and $\dot{D}^0$–c_L/c_M (Fig. 2) within the series D^0, $\dot{D}^0$–pH, D^0, $\dot{D}^0$–c_L/c_M was supplemented with analysis of linear dependences $\dot{D}^0$–c_K^0 (Fig. 5):

$$-\dot{D}^0 = A + k_{app} c_K^0, \quad (11)$$

allowing, in particular, graphical evaluation of the rate constants of the intramolecular redox decomposition.

An analytical calculation of the logarithm of the apparent rate constant of intramolecular redox decomposition was carried out for each point of the dependence

$$\log k_{app} = \log \dot{D}^0 - \log c_K^0 \quad (12)$$

with the subsequent averaging of the $\log k_{app}$ values obtained.

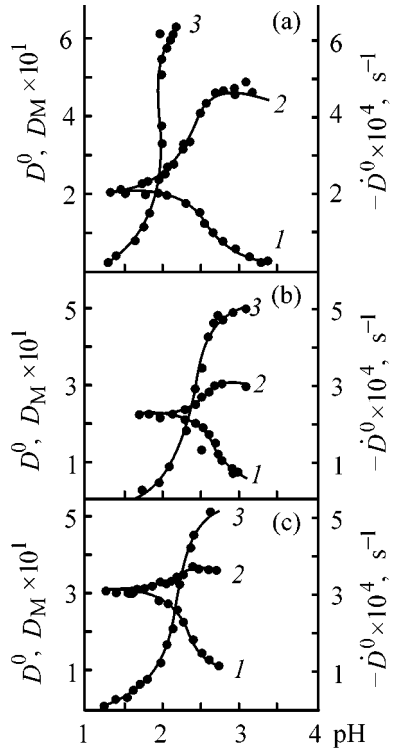

Fig. 4. (*1*) D^0–pH, (*2*) D_M–pH, and (*3*) $-\dot{D}^0$–pH diagrams. System: (a) Ce^{4+}–SO_4^{2-}–H_4Tart ($c_M = c_L = 2.14 \times 10^{-3}$ M, I = 2, T = 28.0°C, λ = 400 nm), (b) Ce^{4+}–SO_4^{2-}–H_3Malt ($c_M = 2.14 \times 10^{-3}$, $c_L = 2.00 \times 10^{-3}$ M; I = 2; T = 17.7°C; λ = 400 nm), (c) Ce^{4+}–SO_4^{2-}–H_2Lact ($c_M = 6.0 \times 10^{-3}$, $c_L = 3.0 \times 10^{-2}$ M; I = 2; T = 18.0°C; λ = 400 nm).

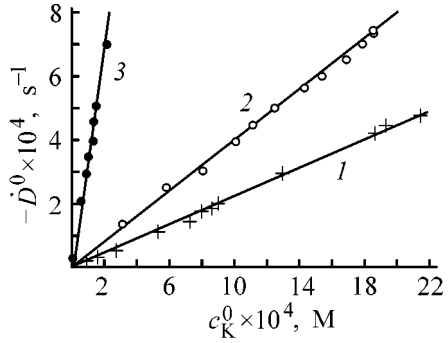

Fig. 5. $-\dot{D}^0$–c_K^0 diagrams. System: (*1*) Ce^{4+}–SO_4^{2-}–H_2Lact ($c_M = 6.0 \times 10^{-3}$, $c_L = 3.0 \times 10^{-2}$ M; I = 2; T = 18.0°C; λ = 400 nm); (*2*) Ce^{4+}–SO_4^{2-}–H_3Malt ($c_M = 1.88 \times 10^{-3}$, $c_L = 3.00 \times 10^{-3}$–$2.11 \times 10^{-2}$ M; pH 2.70; I = 2; T = 18.0°C; λ = 400 nm); (*3*) Ce^{4+}–SO_4^{2-}–H_4Tart ($c_M = c_L = 2.14 \times 10^{-3}$ M; I = 2, T = 28.0°C, λ = 400 nm).

Since the apparent rate constants of redox decomposition of the complexes, k_{app} ($l\ mol^{-1}\ s^{-1}$) depend on their extinction coefficients:

$$k_{app} = \varepsilon_K l / k_2 \quad (13)$$

(l is the thickness of the absorbing layer of the solution), logarithms of the true rate constants k_2 (s^{-1}) of the intramolecular redox decomposition were also calculated (Tables 1–4):

$$\log k_2 = \log k_{app} - \log \varepsilon_K l. \quad (14)$$

The calculated k_2 values were used to evaluate, in accordance with the formula

$$E = 2.303R \frac{\log k_{2\,T_2} - \log k_{2\,T_1}}{\Delta T} T_1 T_2 \quad (15)$$

[R = 8.314 J K^{-1} mol^{-1} is the gas constant, T the absolute temperature (K); $\Delta T = T_2 - T_1$, $T_2 > T_1$], the activation energy of redox decomposition of the complexes (Table 2).

The fact that the dependence $\dot{D}^0 = f(c_K^0)$ remains linear in the concentration ranges under study (Fig. 5) and the constancy of the calculated $\log k_{app}$ value within the series D^0, $\dot{D}^0$–pH, D^0, $\dot{D}^0$–c_L/c_M (Tables 1–4) indicate that a single kinetically active complex is predominant in the systems; and the equality to zero of its free term A (Fig. 5) points to the absence of any contribution from the bimolecular pathway to the process within the concentration ranges studied. Thus, we have an intermediate mechanism of oxidation of the organic ligand by cerium(IV).

In this case the initial rate of the redox process, found using generalized methods of isomolar series and molar ratios, depends on the yield of the complex

$$-\dot{D}^0 = k_{app} c_K^0 = \begin{cases} k_{app}\alpha_K^0 c_M, & c_M < c_L; \\ k_{app}\alpha_K^0 c_L, & c_L < c_M; \end{cases} \quad (16)$$

[$\alpha_K^0 = (D^0 - D_M)/(D_\infty^0 - D_M)$ is the yield of the complex at instant of time $\tau = 0$] and reaches a maximum simultaneously with its maximum yield—at the stoichiometric ratio of the components. In the case in question, this indicates that an intermediate complex of composition 1 : 1 is formed in the system (Figs. 1c and 1e; Fig. 2, curve *2*).

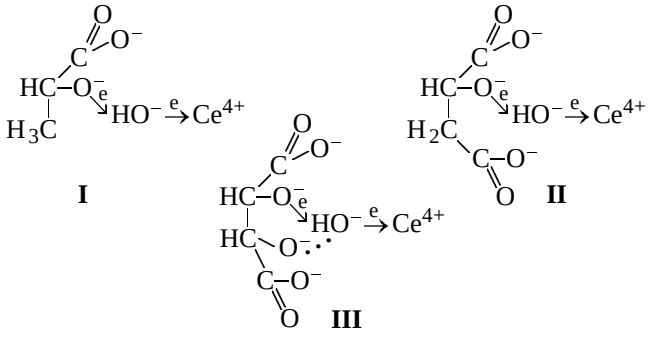
The logarithm of the apparent rate constant of redox decomposition of the complexes, $\log k_{app}$ (12), grows in the order lactic < malic < tartaric acid from $\bar{1}.39 \pm 0.06$ to 0.11 ± 0.04 (18°C). However, the logarithms of true rate constants, $\log k_2$, calculated using expression (14), are constant and equal to $\bar{3}.40 \pm 0.05$ for all the complexes (18°C). The activation energy of intramolecular decomposition also takes a constant, within experimental error, value $E = 132.71 \pm 1.40$ kJ mol^{-1} for H_2Lact, H_3Malt, and H_4Tart.

The rate constants and activation energy of intramolecular redox decomposition, obtained in the present study, are in agreement with the corresponding rate constants and activation energy ($\log k_2 = \bar{3}.36 \pm 0.06$, recalculated to 18°C) and activation energy ($E = 131.8 \pm 1.2$ kJ mol^{-1}) for cerium tartrate $[(CeOH)_2Tart]^{2+}$ [20] and quinate complexes of cerium(IV) $CeOHL]^+$ [21].

The rise in the rate pseudoconstants, observed in going from H_2Lact to H_3Malt [12] and from H_2Malt to H_4Tart [3, 19], is, thus, only apparent and reflects the increase in the extinction coefficients of the complexes in the series in question. Not only the composition of the intermediate complex [5], but also its reactivity are found to be independent, in the given series, of the denticity of the organic ligand. The rise in the stability of the complexes $[CeOHL]^{3-x}$ (x = 2, 3, 4) with increasing ligand denticity is not accompanied by stabilization of cerium(IV) in this series of oxyacids.

The independence of the true rate constants k_2 and the activation energy E of intramolecular redox decomposition from the denticity of oxyacids can be accounted for (as is done in [20]) by the common (single-electron) mechanism of electron transfer via one and the same bridge group in the complexes $[CeOHL]^{3-x}$ (x = 2–4). According to the assumption made in [13], this group is the oxo group of the ceryl ion, which can form a hydrogen bond with the alcohol hydroxyl of tartaric acid. In terms of the theory of ionic equilibria this is equivalent to the formation of a hydrogen bond between a deprotonated alcohol hydroxyl of anions of oxyacids and the hydroxy group of monohydroxo ion of cerium(IV) [Eqs. (5) and (6)].

Thus, the following structure of the intermediate complexes formed in oxidation by cerium(IV) of the ligand series under consideration—H_2Lact (**I**), H_3Malt (**II**), and H_4Tart (**III**), can be suggested:



The equation for the initial rate of the redox process occurring in the systems can be represented, with account of expressions (3), (7), and (12), as

$$-\frac{dc_M}{dt} = k_2R_1[CeOH^{3+}][H_mL][H^+]^{-x}$$

$$= k_2\beta_1[CeOH^{3+}][H_{m-x}L^{x-}] \quad (x = m = 2, 3, 4). \quad (17)$$

This equation establishes the type of the functional dependence of the rate on the equilibrium concentration of hydrogen ions in solution and indicates that oxyacids are involved in the redox process not as molecules, contrary to the previous assumption, but as L^{x-} anions, where $x = 2, 3, 4$.

To conclude, it should be mentioned that the redox reactions analyzed in the present study can be, apparently, regarded as indicator reactions [22] for the corresponding complexation pre-equilibria and used not only to solve the inverse problem of determining the rate constants of intramolecular redox decomposition, but also to tackle with the direct problem of finding the equilibrium concentrations of the complexes (and, as a consequence, of their stability constants) by kinetic methods.

EXPERIMENTAL

Twice recrystallized lactic H_2Lact, malic H_3Malt, and tartaric H_4Tart acids, oxycarboxylic acid of chemically pure grade, and cerium(IV) sulfate $Ce(SO_4)_2 \cdot 4H_2O$ of analytically pure grade were used in the study. The required ionic strength of solution, $I = 2$, was created with ammonium sulfate of analytically pure grade. The initial solutions wee prepared from precisely weighed portions. The concentration of organic acid solutions was refined by pH-metric titration with a NaOH solution containing no CO_3^{2-} ions. The content of cerium (IV) in the salt and a freshly prepared solution were determined by back titration with Mohr's salt in the presence of ferroin [23] before and after an experiment.

The optical density of the solutions was recorded with a Specord UV VIS recording spectrophotometer and a KF-5 photoelectrocolorimeter with MEA-4 recording unit, mainly at a wavelength of 400 nm. As the time of reaction onset was taken the instant at which the mixing vessel, in which the starting components were placed, was turned upside-down. The initial optical density of the reaction mixture of the metal and the ligand D^0 was found by linear extrapolation of the kinetic curves plotted in semilogarithmic coordinates to the instant of time $\tau = 0$. The solutions were thermostated using a Wobser thermostat.

The pH value was measured in a mixture of components, after the recording of the optical density ($\tau \approx 1$ min and also $\tau \approx 10$ min), and in cerium(IV) sulfate solutions with a pH-673 precision pH meter.

The step constant of protonation of the carboxy group in the lactic acid anion was also determined at an ionic strength $I = 2$

$$æ_2 = \frac{[H_2L]}{[HL][H]}. \quad (18)$$

The value $\log æ_2 = 3.72 \pm 0.02$, obtained for H_2Lact, is in agreement with $\log æ_2 = 3.69$ ($I = 2$) [7]. The logarithms of step constants of protonation of carboxy groups in the malic acid anion ($\log æ_1 = 3.22$, $\log æ_2 = 4.71$) were taken from [24], and those for the tartaric acid anion ($\log æ_1 = 2.95$, $\log æ_2 = 4.11$), from [25].

Since, according to the dissociation constants of oxy groups, oxyacids are weak acids, the following value of the logarithm of the dissociation constant of the oxy group was used in calculations for all oxyacids: $\log B_1 = 14.6$ (obtained by averaging the data of [16, 25]; in [25], the value of $\log B_1$ was determined by mathematical modeling). The logarithms of the total protonation constants $B_i = [H_iL] / [L][H]^i$, $i > 1$, were taken to be as follows: $\log B_2 = 18.31$ for H_2Lact; $\log B_2 = 19.31$, $\log B_3 = 22.53$ for H_3Malt; and $\log B_2 = 25.90$, $\log B_3 = 30.01$, and $\log B_4 = 32.96$ for H_4Tart.

CONCLUSIONS

(1) A generalization of the methods used to study complexation (D–pH method and methods of molar ratios and isomolar series) to the case on nonzero rate of redox decomposition of complexes was proposed.

(2) The above methods were used to determine the composition, stability constants, true rate constants, and activation energies of intramolecular redox decomposition of hydroxo complexes of cerium(IV) with a number of organic ligands; the law governing the rate of the redox process occurring in the systems and its intermediate mechanism was established.

(3) The absence of stabilization of cerium(IV), with the stability of its complexes increasing in the series of the α oxycarboxylic acids considered, and the independence of the reactivity of these complexes from the denticity of an organic ligand were demonstrated.

(4) The independence of the rate constants and activation energy of redox decomposition of complexes from the denticity of oxyacids was interpreted in

terms of the bridge mechanism of redox decomposition as transfer of an electron via one and the same bridge group in the complexes $[CeOHL]^{3-m}$ (m = 2, 3, 4).

(5) A conclusion was made that the redox reactions considered in the present study can be used as indicator reactions in investigating the corresponding complexation equilibria by kinetic methods.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Composition of a Solid Phase Isolated on Heating Acid Solutions of Titanium(IV) Sulfate

L. G. Gerasimova, R. F. Okhrimenko, and N. M. Zhdanova

Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received: March 11, 2001; in final form, December 2001

Abstract—The mechanism of solid phase formation in hydrolysis of titanium(IV) sulfate solutions was studied at elevated temperature (boiling).

Thermal treatment of acid solutions of titanium(IV) sulfate, with precipitation of hydroxides, is used to manufacture titanium dioxide of pigment and nonpigment brands, each of which must meet the certain requirements to the dispersity, impurity content, solubility of particles in organic and aqueous media, etc. [1, 2]. The conditions of thermal treatment of the solutions affect the composition of the forming solid phase and, consequently, the above properties of the final technological product. In spite of numerous studies in this field, data on the structure of titanium(IV) hydroxide are controversial. Some researchers classed it with acids, namely, metatitanic acid $H_2TiO_3 \cdot nH_2O$ [1], and others, with the hydrated oxides $TiO_2 \cdot nH_2O$ or hydroxides of the type $TiO(OH)_2 \cdot nH_2O$ [3, 4]. Apparently, both standpoints have right to exist, since the structure and composition of titanium hydroxide depend on the preparation conditions. It is known, in particular, that the solid phase separated in the first stage of heating (thermal hydrolysis) of an acid sol ution of titanium(IV) sul- fate contains two OH groups bound to a single titanium(IV) atom. Prolonged heating of such systems results in splitting of hydroxide groups and transformation of metatitanic acid into hydrated titanium dioxide. In addition, the solid phase contains sulfate groups bound to titanium(IV). The relative content of the components and the character of bonding between them depend on the composition of the initial solution (c_{TiO_2}, $c_{H_2SO_4}$, impurity components) and the conditions of its thermal treatment (time and temperature) [1].

In this communication, we present the results obtained in a study of the solid phase separated from acid solutions of titanium(IV) sulfate upon thermal hydrolysis under comparable conditions. Such data, being of theoretical and practical importance, are lacking from the literature.

We used in the study acid solutions of titanium(IV) sulfate, prepared from the salts $TiOSO_4 \cdot H_2O$ [oxotitanium(IV) sulfate monohydrate] and $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ (ammonium monooxodisulfate titanate mohohydrate). The titanium(IV) concentration in solutions was 1.5 M in terms of TiO_2; the content of free sulfuric acid in $TiOSO_4 \cdot H_2O$ solutions was varied from 0.25 to 0.5 M, and that in $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ solutions, from 0.1 to 0.5 M at a 0.15–0.75 M content of free ammonium sulfate.

The experimental procedure was as follows. A solution to be studied was placed in a heat-resistant three-necked flask equipped with a stirrer, reflux condenser, and a thermometer, heated to the boiling point (103°C), and boiled for 3 h. The phase composition of the precipitate formed in the solution under heating was analyzed by X-ray phase analysis, and the content of OH groups bound to titanium(IV) in the precipitate was found by the known procedure [5]. For this purpose, a sample of the suspension was filtered in a vacuum on a dense glass filter, the precipitate was washed with water, its weighed portion (0.2 g) was placed in water (15 ml), to which ammonium solution was added to pH 8.25. Then 50–70 ml of a potassium fluoride solution (250 g l^{-1} KF) and several drops of phenolphthalein were added and the mixture was titrated with 0.1N HCl solution, first, every 2 min (during the first 30 min), then, every 30 min (during the first 3 h), and, finally, every 24 h.

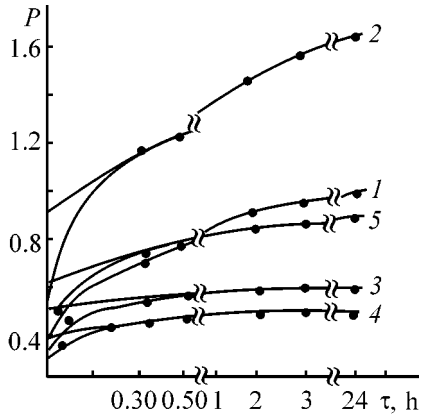

Fig. 1. Variation of the composition of the precipitates obtained from titanium(IV) sulfate solutions heated to the boiling point. c_{Ti} = 1.5 M in terms of TiO_2. (*P*) Amount of OH groups per Ti(IV) and τ time. Solution composition (M): (*1*) 0.25 H_2SO_{4f} and 0.25 $(NH_4)_2SO_{4f}$; (*2*) 0.5 H_2SO_{4f} and 0.15 $(NH_4)_2SO_{4f}$; (*3*) 0.1 H_2SO_{4f} and 0.75$(NH_4)_2SO_{4f}$; (*4*) 0.25 H_2SO_{4f}; and (*5*) 0.5 H_2SO_{4f}; the same for Fig. 2.

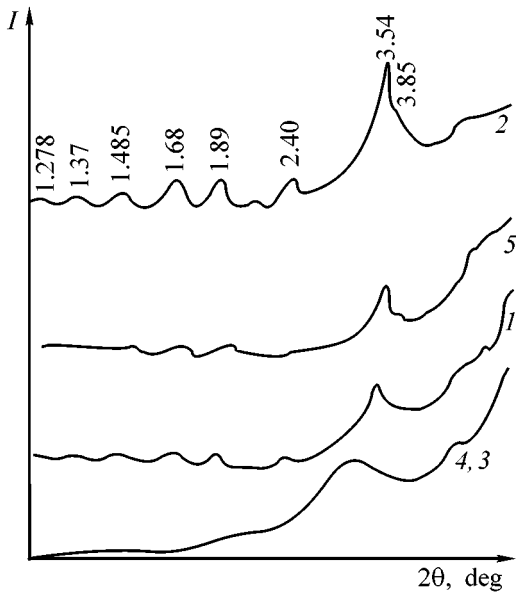

Fig. 2. X-ray diffraction patterns of precipitates obtained from acid solutions of titanium(IV) sulfate. (*I*) Intensity and (2θ) Bragg angle.

In reaction with potassium fluoride, two successive processes occur: fast replacement by fluoride ions of free (terminal) OH groups bound to titanium(IV) and slow rupture of bridging bonds [6, 7]. The replacement of OH groups by fluoride ions is intensive during about 15 min. Then the process decelerates somewhat, and, after 25–30 min, its rate decreases markedly. The amount of active (terminal) OH groups bound to titanium(IV) was found graphically from the intersection with the ordinate axis of the tangent to the flat portion of the curve corresponding to the 0–30 min interval.

The number of the bridging oxo bonds, $Ti^{(IV)}$–O–$Ti^{(IV)}$, was determined from the results of precipitate titration with HCl solution 24 h after the introduction of KF into a suspension. For this purpose, the number of active OH groups was subtracted from the value obtained from the intersection of the ordinate axis with the tangent to the *P*-vs.-τ curve for $\tau \geq 24$ h (Fig. 1).

The correlation between the composition of the acid titanium(IV) sulfate solution, heated to the boiling point (103°C), and the amount of active and inactive OH groups in the precipitates forming under the given conditions is presented in Fig. 1. With increasing acidity, the number of active OH groups in $TiOSO_4 \cdot H_2O$ solutions grow 1.5-fold, with the number of inactive groups increasing by an order of magnitude (curves *4*, *5*). For $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ solutions with similar basicity, the character of the correlation between the solution composition and the number of active and inactive OH groups in the precipitates is the same, with the quantitative parameters being, however, markedly higher (curves *1*, *2*). In the solid phase precipitated from a $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ solution with the lowest concentration of H_2SO_{4f} and high concentration of $(NH_4)_2SO_{4f}$, inactive OH groups are virtually absent (curve *3*).

The table presents the compositions of the solid phases precipitated from acid sulfate solutions boiled for 2 and 3 h. Analysis of the data suggests that the effect of solution acidity on the precipitate composition is, in this case, weaker than that in the initial period of heating. The precipitates 3 and 4 contain virtually no inactive OH groups. This points to a different mechanism of solid phase formation in thermal hydrolysis.

The X-ray diffraction patterns of the precipitates obtained from acid titanium(IV) solutions boiled for 3 h (Fig. 2) were taken on a DRON–2 diffractometer (Cu_{K_α} radiation, graphite monochromator, 2 deg min^{-1} counter velocity). The reflection intensities show that sample 2 is decrystallized to a larger extent than the other samples. The crystalline impurity phase is titanium dioxide of anatase modification, formed via particle growth involving Ti–O–Ti– polymeric chains, with their subsequent further incorporation into micelles, i.e., by the crystal-chemical mechanism [8]. The content of the crystalline phase in precipitates 1 and 5 decreases; precipitates 3 and 4 are completely X-ray-amorphous. Such precipitates are formed by

Variation of the c_{OH}/c_{Ti} ratio P in the precipitates

τ, h	OH group	P in a sample*				
		1	2	3	4	5
2	Active	0.38	0.32	0.33	0.34	0.38
	Inactive	0.20	0.24	0.07	0.05	0.11
3	Active	0.32	0.28	0.32	0.27	0.28
	Inactive	0.13	0.13	0.05	0.02	0.10

* Suspension was sampled after indicated boiling time τ; the sample number is the same as the number of the solution composition in Fig. 1.

the colloid-chemical mechanism, with particles growing via cross-linking of hydroxo complexes by OH groups to form colloid particles with loose structure. The colloid-chemical mechanism of precipitate formation is initiated both by the low solution acidity and by the presence of ammonium sulfate in solution [9].

A comparison of the precipitates obtained from $(NH_4)_2TiO(SO_4)_2 \cdot H_2O$ and $TiOSO_4 \cdot H_2O$ solutions heated under similar conditions demonstrated that, in the absence of ammonium sulfate, the solid phase is largely formed by the colloid–chemical mechanism.

CONCLUSION

A study of the thermal hydrolysis of acid solutions of titanium(IV) sulfate with the formation of a hydroxide precipitate demonstrated that, depending on the solution acidity and on the content of ammonium sulfate in solution, two mechanisms, crystal-chemical and colloid-chemical, are responsible for the solid phase formation, and this fast determines the structure of the resulting precipitate.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Porous Ceramic Based on Aluminomagnesium Spinel

Abstract—Powdered precursors of an aluminomagnesium spinel were synthesized by joint crystallization of magnesium and aluminum salts from solutions. The sequence of stages of the $MgAl_2O_4$ formation was studied in relation to the nature of initial reagents and temperature of heat treatment. Optimal modes of sintering of the aluminomagnesium spinel for obtaining ceramic materials with porosity greater than 50% were determined.

Presently, procedures for manufacturing construction and functional ceramics are being intensively developed in order to create a new generation of materials for modern technology. The topicality of the problem is due to unique properties of ceramic materials consisting of crystallites with size of about 10–100 nm. Much attention is given to preparation and use of porous materials based on various ceramic formulations, including ceramics with aluminomagnesium spinel as a component.

The $MgAl_2O_4$ spinel has thermodynamically stable structure, resistance to corrosive media, low heat-conductivity, and high dielectric characteristics, and, therefore, materials on its base are of great practical interest for electrochemical engineering.

The aim of this study was to obtain a high-permeable porous matrix of an aluminomagnesium spinel for creating galvanic cells with salt bridges made of fluorides of alkali and alkaline-earth metals, which could find wide use in monitoring the activity of oxygen ions in oxide melts in industrial glass manufacture, black and non-ferrous metallurgy, and cement production [1].

Various methods of $MgAl_2O_4$ synthesis have been described in the literature [2–8]. From the technological standpoint, the simplest way to obtain this material is solid-phase synthesis from magnesium and aluminum oxides. However, this procedure involves high temperatures synthesis and sintering of ceramics (1600–1800°C), which makes it impossible to achieve the required open porosity (>50%) and homogeneous distribution of pores in ceramic compacts. It was shown in [9] that a ceramic based on aluminomagnesium spinels with stable porous structure can be obtained by sintering at rather low temperatures (<1400°C) nanosize precursor powders thermally activated at a temperature below 860°C.

To obtain precursor powders with sintering activity, we chose the method of joint crystallization from a mixture of solutions of magnesium nitrate $Mg(NO_3)_2 \cdot 6H_2O$ (analytically pure grade) and various aluminum compounds, with the subsequent decomposition and heat treatment of the crystals obtained. Aluminum nitrate $Al(NO_3)_3 \cdot 9H_2O$ (chemically pure grade), aluminum isopropylate $Al[(CH_3)_2CHO]_3$, and aluminum hydroxide (boehmite) AlO(OH) were used as Al_2O_3 sources.

The starting reagents, taken in the following stoichiometric ratios:

I, $Mg(NO_3)_2 \cdot 6H_2O + 2Al(NO_3)_3 \cdot 9H_2O$,

II, $Mg(NO_3)_2 \cdot 6H_2O + Al(NO_3)_3 \cdot 9H_2O + Al[(CH_3)_2CHO]_3$,

III, $Mg(NO_3)_2 \cdot 6H_2O + 2Al[(CH_3)_2CHO]_3$,

IV, $Mg(NO_3)_2 \cdot 6H_2O + 2AlO(OH)$,

were dissolved in water acidified to pH 4 with nitric acid. The salt solutions were thoroughly stirred and evaporated on a water bath in the course of 3 h, after which the remainder was calcined in a muffle furnace at 250°C (2 h).

The thus synthesized powders I–IV were studied by differential thermal analysis (DTA, Netzsch dif-

1070-4272/02/7506-0878 $27.00 © 2002 MAIK "Nauka/Interperiodica"

fractometer) and X-ray phase analysis (XPA, D-500/HS Siemens diffractometer). Thermal effects corresponding to the instant of $MgAl_2O_4$ formation were not recorded by the DTA method in any of the cases. Comparison of DTA and XPA data for the powders obtained with the relevant published data on dehydration and decomposition of the starting compounds (200–500°C) [10] shows that the temperature ranges of these processes and those of spinel crystallization of amorphous precipitates overlap. According to the XPA data, the initial stage of formation of compounds with spinel structure is already observed at 300°C, and all main spinel peaks are recorded in the X-ray patterns of samples I–IV annealed at 400°C (see, e.g., Fig. 1). The characteristic redistribution of peak intensities and the narrowing of peaks in the X-ray patterns of samples I–IV at above 400°C (Fig. 2) indicate the occurrence of crystallization, ending at about 900°C in the formation of a normal $MgAl_2O_4$ phase (lattice parameter a = 0.806–0.808 nm, ratio of peak intensities I_{400}/I_{311} = 0.57–0.62). Such a two-stage scheme of $MgAl_2O_4$ formation and crystallization from amorphous precipitates has been proposed earlier by Bratton [11]. According to this scheme, a number of solid solutions based on spinel phases $MgAl_2O_4$, γ-Al_2O_3, and MgO* are formed in the amorphous oxide matrix in the intermediate stage (350–400°C). In the second stage (above 400°C), solid-phase reactions between these solid solutions result in the crystallization of the normal $MgAl_2O_4$ phase. The acceleration of the crystallization of aluminomagnesium spinel above 800°C is related, in the first place, to increasing rate of magnesium oxide diffusion at this temperature.

The heat treatment mode, as well as individual properties of the reagents and, in particular, specific features of structural transformations of starting aluminum compounds in thermal decomposition affect the course of the $MgAl_2O_4$ crystallization. According to the XPA data (Fig. 2), α-Al_2O_3 can be formed in amounts of no more than 5%, in addition to the main spinel phase, under conditions of fast heating in calcination of systems I–III in the range 900–1200°C. At the same time, with boehmite used [system IV], the α-Al_2O_3 phase is not detected. It is known that the γ-Al_2O_3 formation in thermal decomposition of boehmite is completed earlier (<500°C) than in the case of nine-water aluminum nitrate (>650°C), and the subsequent transformation of spinel phases to corundum occurs in the case of boehmite at a temperature considerably higher (about 1100°C) than that for the salt (820°C) [12]. It is probable that, in fast heating of amorphous precipitates I–III to 900–

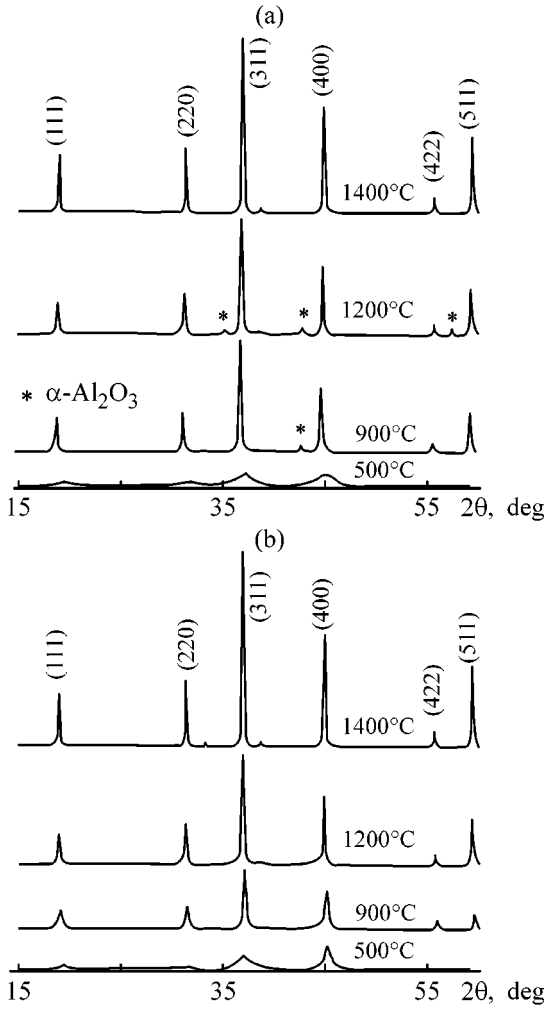

Fig. 2. Effect of the nature of starting aluminum compounds on the $MgAl_2O_4$ formation in the range 500–1400°C. System: (a) I and (b) IV.

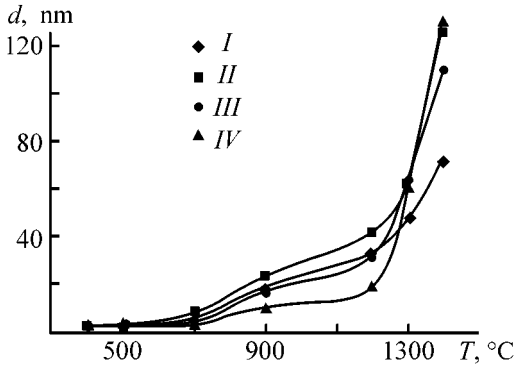

Fig. 3. Change in average size of spinel crystallites, *d*, in the range 400–1400°C. (*T*) Temperature. (*I–IV*) Systems I–IV, respectively.

1200°C, the intermediate γ-Al_2O_3 phase has no time to react completely with MgO and its unreacted part is converted to α-Al_2O_3. The peaks of α-Al_2O_3 are absent from the X-ray patterns of powders I–III calcined above 1200°C, in good agreement with the considerable increase in the solubility of aluminum oxide in $MgAl_2O_4$ at above 1100°C [13].

We determined the average size of primary spinel crystallites formed in precursor powders I–IV heat-treated at 400–1400°C from the Fourier transform of the 311 peak, corrected for the instrumental broadening. In is seen from Fig. 3 that, in the nucleation stage, the size of primary particles of the spinel phase (3–5 nm) is virtually independent of the nature of the starting reagents. In the crystallization stage (400–900°C), the growth rate of crystallites is slow owing to the low diffusion coefficients of the oxides. The crystallite growth becomes essential above 1200°C.

We thermally activated the resulting nanosize precursor powders I–IV of aluminomagnesium spinel at 400°C for 2 h. Compacts pressed from the activated powders I–IV were used to study the effects of sintering temperature and cellulating agents on the formation of porous structure of ceramic materials. The samples were sintered in a silit furnace in air at 1100–1400°C. The total porosity of the samples was calculated from the apparent density of the sintered compacts. The open porosity was determined by hydrostatic weighing. The size distribution of pores was characterized using mercury porosimetry. The main aim of this stage of the study was to obtain sintered ceramic compacts with open porosity greater than 50%.

The initial calcination was carried out at 1400°C (2 h). The porosity of the sintered samples was 30–33%. Calcination at higher temperatures is in expedient, as it leads to gradual "slamming" of a part of pores, formation of closed porosity, and compaction of the sample [4]. The lower temperature boundary of compact sintering was 1100°C. At this temperature, sintered samples were obtained only from powder IV. The above-described formation of α-Al_2O_3 on the surface of spinel crystallites is one of possible reasons for the loosening of samples I–III at 1100°C. A similar effect was noted earlier in [14].

Well-sintered samples of activated powders I–IV were synthesized with the calcination temperature raised to 1150–1300°C. However, the porosity of the material increased by no more than 5% as compared with the samples sintered at 1400°C (see table). A comparison of the total porosity of the samples with their open porosity determined by hydrostatic weighing demonstrated that the closed porosity of the samples did not exceed 3%.

The method proposed did not reveal any advantages of using the expensive aluminum isopropylate as an additive to aluminum nitrate [system II] or as the only source of aluminum [system III]. The main characteristics of porous ceramics (phase and granulometric composition, porosity parameters, shrinkage, and mechanical strength) found for systems I–III coincide within the experimental error. The data in the table show that use of boehmite in synthesis of precursor powders results in a 4–8% decrease in the porosity of the sintered compacts. At the same time, the strength of the ceramics synthesized from powder IV was the highest.

Influence exerted by calcination temperature and by cellulating agent (C) on the shrinkage $\Delta L/L$ and total porosity P_{tot} of ceramic materials prepared from $MgAl_2O_4$

Calcination mode	Parameter	Sample			
		I	II	III	IV
		%			
1150°C, 4 h	$\Delta L/L$	15	15	18	23
	P_{tot}	36	38	36	31
	$\Delta L/L^*$	9	14	16	13
	P^*_{tot}	65	53	53	55
1300°C, 2 h	$\Delta L/L$	16	15	18	23
	P_{tot}	34	38	36	30
	$\Delta L/L^{**}$	17	16	19	21
	P^{**}_{tot}	59	60	60	53

* 20% C added to the blend.

** 30% C and 5% NH_4F added to the blend.

Thus, we failed to obtain sintered ceramics with porosity greater than 50% by simply varying the temperature mode and selecting Al_2O_3 sources.

It is known that one of methods used for creating porous structures is introduction of burning-out additives into a powder to be sintered. In this study, we used highly dispersed activated carbon introduced into the stock before pressing compact samples.

Well-sintered materials with required strength and porosity were obtained by introducing 20% activated carbon (calcination mode 1150°C, 4 h). To sinter samples with higher content of activated carbon (30%), we introduced a sintering component NH_4F (5%) into the stock and raised the calcination temperature to 1300°C (2 h) (see table). The closed porosity of the samples was less than 3%. It is seen from the table that the introduction of carbon into precursor powders allowed us to raise the porosity of samples by more than 25% and to exceed in all cases the required open porosity of 50%. It was also found that the technological procedures applied in the study (use of various initial aluminum compounds in synthesis of precursor powders, variation of the amount of the burning-out additive, variation of the sintering mode, and introduction of a sintering additive) make it possible to control the pore size distribution in a wide range. As an illustration, Fig. 4 presents data obtained by mercury porosimetry for the porous structures of three $MgAl_2O_4$ ceramics. It can be seen that macropores with radius from 0.5 to 3 μm dominate in all the samples. These macropores are formed in the spinel matrix through burning-out of carbon and migration of the combustion products. Raising the sintering temperature to 1300°C and introducing an NH_4F additive makes the pore size distribution narrower and leads to elimination of pores with radius less than 1 μm. Irrespective of the nature of an initial powder-precursor I–IV, the ceramics synthesized under these conditions had similar porous structures (Fig. 4c). At the same time, Figs. 4a and 4b demonstrate a direct dependence of the porous structure of the materials sintered at 1150°C on the nature of a precursor powder used. For example, with powder I (1150°C, 4 h, 20% C), a ceramic with bimodal pore size distribution and a considerable (up to 40%) fraction of pores with radius less than 100 nm was obtained. The average radius of such pores is about 15 nm. This value well agrees with the average size of spinel phase crystallites, which is about 30 nm at 1150°C, as seen from Fig. 3. This coincidence suggests that the porosity is of intercrystallite nature. A possible reason for the additional loosening of the spinel matrix of materials obtained from precursors I–III, compared with the samples obtained from a boehmite-based powder, was discussed above in considering the data on sintering of ceramics at 1100°C without carbon additives.

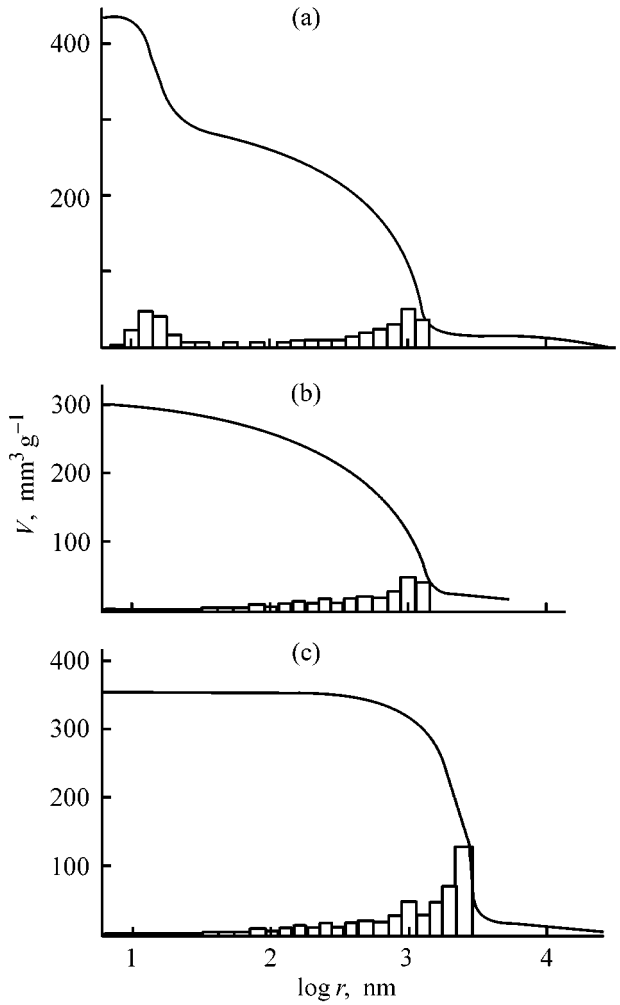

Fig. 4. Pore size distribution in samples of $MgAl_2O_4$ ceramics obtained under various conditions. (V) Volume of pores and (r) pore radius. (a) System I, 1150°C, 4 h, 20% C; (b) system IV, 1150°C, 4 h, 20% C; and (c) system I, 1300°C, 2 h, 30% C, 5% NH_4F.

CONCLUSIONS

(1) Nanosize sintering-active precursor powders of aluminomagnesium spinel were synthesized. Ceramic materials with open porosity exceeding 50% were obtained by introducing a burning-out carbon additive into the stock. The effect of phase transformations and dispersity of spinel powders on the specific features of sintering of the ceramics was determined.

(2) The possibility of controlling the porous structure of spinel materials by varying the source of alu-

minum oxide in synthesis of precursor powders, by changing the sintering modes of ceramics, and by introducing burning-out and sintering additives into the stock was demonstrated.

ACKNOWLEDGMENTS

This study was supported financially by Presidium of the Russian Academy of Sciences according to the results of expertise of the sixth competition between scientific projects presented by young scientists of the Russian Academy of Sciences in the field of fundamental and applied research. Project "Development of a Method for Monitoring P_O Oxide Melts," headed by V.G. Konakov.

Abstract—The hydraulic activity of portland cement in a solution of polysulfide CaS_n was studied. The characteristics of this activity are determined by the alkalinity of the liquid phase and by chemical transformations of the reagent. Generalizations are made, concerning the choise of parameters of joint conversion of the cement and polysulfide at lowered pH values, which ensure direct hardening.

The parameters of hydration hardening of portland cement largely depend on mineral salt additives differently affecting the hardening process. Water-soluble salts of calcium, whose efficiency is accounted for by the action of the Ca^{2+} cation on hardening, are frequently used in practice. This cation exerts positive influence on hardening when introduced in compounds with a wide variety of anions, which is indicated by the list of known additives: gypsum of various kinds, anhydrite, and calcium chloride, formate, nitrate, nitrite, and thiosulfate.

Among the water-soluble potassium salts, ISO preparation, obtained by dissolution of sulfur in calcium hydroxide, has gained wide recognition [1–3]. The interest in this preparation is due, on the one hand, to the ability of ISO to enhance the activity of portland cement, shown in the patent literature, and, on the other, to its low cost and plentiful availability. However, testing the preparation on portland cements manufactured by domestic plants demonstrated that, depending on experimental conditions (mineralogical and chemical composition of cements, thermomoist treatment mode, and amount of additive in tempered paste), its effect on the hardening characteristics may vary, being not always positive. In particular, in the case of a certain excess of dissolved sulfur in the liquid phase, the final parameters of hardening, determined at the age of 28 days, are impaired by the unrecoverable loss of strength by the samples in the course of hardening, which is to some extent characteristic of portland cements as a whole.

The aim of this study was to analyze the mechanism of activation of minerals in portland cement subjected to hydration in a polysulfide solution and to substantiate the choice of a proper scheme for hydration hardening of a modified mixture in dependence on the mineralogical and chemical composition of portland cement.

EXPERIMENTAL

Comparative evaluation of the action of ISO on the binding properties of the portland cement paste of standard thickness was done by studying its effect on the hardening characteristics of cubic samples under normal temperature and humidity conditions (room temperature, air humidity of no less than 90%). The samples were prepared from clinker paste into which gypsum and ISO were introduced in varied ratio in the tempering stage. Clinker[1] ground to 11% residue on sieve no. 008 was used in the experiments. The chemical composition of the clinker (wt %) was as follows: SiO_2 20.73, Al_2O_3 6.86, Fe_2O_3 4.63, CaO 65.46, MgO 1.38, and SO_3 0.45. The additive was prepared in the form of a liquid preparation, originally containing calcium polysulfide and thiosulfate in equimolar ratio, by dissolution of powdered sulfur in a heated lime suspension. The amount of the additive in the samples was controlled by the mass of dissolved sulfur, varied by changing its concentration in the tempering solution. The pH value and the con-

centration of hydration products in the liquid phase were found by the known methods [4] by analyzing samples of solutions squeezed out of the cement paste.

The chemical activity of a preparation can be judged from its ability to decelerate the hardening of a clinker paste or, conversely, to accelerate this process through joint action with calcium sulfate contained in portland cement. According to the results of experiments (see table), in which a portland cement containing 7.5% gypsum dihydrate served as standard, even minor amounts of the preparation (in terms of dissolved sulfur) inhibit cementation of the clinker paste. At the same time, joint addition of ISO and gypsum converts the portland cement paste into a fast-cementing mass hardening at increased rate. However, the experimental data presented here are characterized by wide scatter relative to the standard final strength parameters. These parameters may deviate from the standard values both toward improvement, indicating the potentially high strength reserve of the modified system, and toward deterioration of the results obtained.

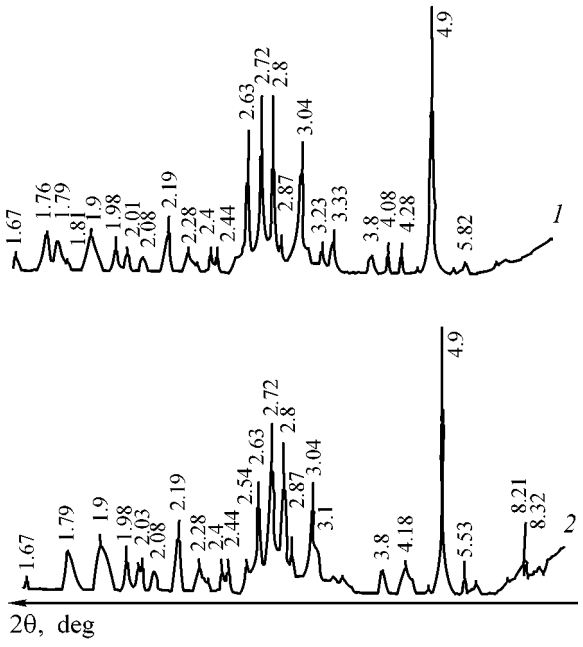

Fig. 1. X-ray diffraction patterns of cement stones. (2θ) Bragg angle. (*1*) Portland cement–water and (*2*) portland cement–ISO (c_S = 180 g l^{-1})

According to experimental data, the improvement of the binding properties of the modified portland cement, which became possible under conditions of a stable hardening rate, is due to changes in the mineralogical and chemical composition of the new formations. For example, the shortening of the paste cementation time correlates with the predominance in the hydroaluminate phase of a new complex salt, $Ca_8Al_4O_{12}SO_4S_2O_3 \cdot 24H_2O$, identified by the presence in the X-ray diffraction pattern (Fig. 1) of diffraction peaks with $d \times 10^8$ = 832 and 418 m. In accordance with the commonly adopted, in cement practice, way of composition presentation, the stoichiometric formula can be represented as $3CaO \cdot Al_2O_3 \cdot CaS_2O_3 \cdot xH_2O \cdot 3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot (24 - x)H_2O$, composed of, respectively, the thiosulfate and sulfate forms of hydrosulfoaluminate. The absence of mono- and trisulfate forms of hydrosulfoaluminate, typical of portland ce-

ments hydrated in water, as a separate phase in the hydroaluminate structures obtained after different times of hardening indicates that substitution of the sulfate ion by the thiosulfate group is possible in this compound.

Significant changes occur in the hydrosilicate phase. This is demonstrated by X-ray diffraction patterns indicating the presence of tobermorite-like hydrosilicates and more compositionally and structurally complex hydrosilicates $2CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 8H_2O$ with $d \times 10^8$ 821, 553 m and $Ca_2Fe_5^{2+}[Si_8O_{22}][OH]_2$ with $d \times 10^8$ 254, 203 m, which can condense into stronger microconglomerate structures under the action of intergrain cohesion forces.

Additional data on changes in the structure and phase composition of portland cements hydrated in a polysulfide solution are furnished by IR spectra (Fig. 2) obtained on a JFS-66 Fourier spectrometer in the range 400–4000 cm^{-1}. These data mainly refer to the range corresponding to vibrations of the silica fragment. For example, in going from the starting cement to that hydrated in water, the frequency of stretching vibrations is shifted from 924 to 974 cm^{-1}, which indicates the strengthening of the S–O bond because of the disappearance of the originally isolated silica tetrahedra and their polymerization into a silica network. Remarkably, in going from spectrum *2* to spectrum *3*, the stretching vibration frequency shifts further, to 997 cm^{-1}. The increase in the degree of tetrahedron polarization in the modified mixture is probably favored by strong amorphization of hydrosilicate particles, whose exceedingly high dispersity is responsible for their colloid properties.

Changes also occur in the range corresponding to vibrations of the sulfate ion. Instead of the structurally broadened band of stretching vibrations of the S–O bond (1115 and 1151 cm^{-1}) in the starting cement, a broad band appears in the case of cement hydrated in water or CaS_n solution. The bands in the range of deformation vibrations are also broadened as a result of formation of complex salts similar to calcium hydrosulfoaluminate. The sulfate group in the structure of these salts is in a more strongly chemically bound state. At the same time, it should be noted that the intensity of the broadened band of stretching vibrations markedly grows in passing from spectrum *2* to spectrum *3*. This is due, as mentioned above, to the possible partial or total (depending on the concentration of dissolved sulfur) substitution of the sulfo group in the hydrosulfoaluminate.

The observed changes in the structure and composition of new formations, and the resulting improvement of the hardening parameters, are related to the ability of CaS_n polysulfide, as a weakly hydrolyzable salt, to stabilize the solvent pH at a lower level (Fig. 3), compared with the conventional aqueous portland cement suspensions, and also to chemical transformations of the salt. It has been established [4] that the polysulfide contained in the liquid phase of the cement paste is subject to transformation by the scheme

$$2HS_n^- + 2(n-1)OH^- + (n+1)O_2 \rightarrow nS_2O_3^{2-} + H_2O, \quad (1)$$

$$S_n^{2-} + 6Fe^{3+} + 6OH^- = S_2O_3^{2-} + 6Fe^{2+} + (n-2)S^0 + 3H_2O, \quad (2)$$

$$(n+2)S^0 + 6OH^- = S_n^{2-} + S_2O_3^{2-} + 3H_2O, \quad (3)$$

according to which it serves as a source generating the thio salt, which is an element of the hardening structure. At the same time, the inhibition of hydration, observed experimentally upon excessive lowering of the pH value and weakly catalytic action of hydrosulfoaluminates, is caused by complications in the protolytic reaction involving the basic mineral—

alite, since it is associated with low pH as a reflection of the equilibrium $Ca(OH)_2$ concentration in a solution of the weakly hydrolyzable CaS_n. The high supersaturation of the solution with respect to the equilibrium concentration of calcium hydroxide and the redistribution in the system between $CaOH^+$ and hydroxide proper in favor of the latter make the hydrolytic stage a surface reaction, which is controlled from the very beginning by solvent diffusion through a hydroxide film. Such a concept of the passivation mechanism is consistent with the rather high activity of the protonation event itself. This high activity is due to the increased mobility of the H^+ ion (compared with Ca^{2+}), which, in addition, can be transferred by the so-called go-ahead scheme via hydrogen bonds in the structured film of water. Consequently, the introduction of this ion into the crystal lattice and the very event of protonation weakly depend on the mode of interphase transitions.

The aforesaid suggests as a primary version accounting for the decrease in the hydraulic activity of the mineral $3CaO \cdot SiO_2$ in a CaS_n solution the passivation of the surface first by the crystallizing $Ca(OH)_2$ and then, additionally, by the barrier created by Ca^{2+} ions.

The property of the modified system to combine simultaneously an increased energy of interaction between protolysis products and solvent with enhanced resistance to the solvent flow toward the particle surface can account for the seemingly contradictory phenomena of increased dissolving ability of water and the simultaneously reduced hydraulic activity of silicates. This general property of portland cement binders objectively restricts the possibility of obtaining, under normal conditions at lowered alkalinity of the liquid phase, low-basic hydrosilicate dispersions forming stable structures. The kinetics of such processes strongly depends on the energy parameters of interphase transformations and, as a rule, reaches technologically acceptable values under hydrothermal conditions of autoclave hardening. In the case of a portland cement system modified with polysulfide, this problem, i.e., elimination of the diffusion resistance and activation of silicate minerals, is solved by combining mineral hydration with a chemical transformation of the polysulfide into a thiosulfate structurally bound in the hydrosulfoaluminate. In such a variant of hydration conversion of cement, the disturbance of the dynamic equilibrium in the system $Ca(OH)_{2\,solid} \rightarrow Ca(OH)_{2\,dissolved}$, which initiates hydration, is ensured by the involvement of the dissolved hydroxide in the reaction of ionization of polysulfide sulfur with zero degree of oxidation. The increase in the hydraulic activity of silicates, in its turn, facilitates the attainment of the saturation concentration with respect to silica and mass nucleation of crystal hydrates in the bulk of the liquid phase and makes closer the rates of formation of the basic structures. As a result, the acceleration of the hardening process becomes noticeable, and the process itself, more stable and productive.

Such an interpretation of the mechanism of inhibition of cement hydration in a polysulfide solution can be considered sufficiently substantiated also in the case when there exists an induction period, occurring in common portland cement systems in the initial stage of the process, soon after the spontaneously beginning hydration. The problem of its nature remains to be discussed. Of the known versions, those deserve attention, which give insight into the hydrolytic nature of the hydration conversion of silicate minerals and, in particular, relate the inhibition to incongruent decomposition of $3CaO \cdot SiO_2$ and passivation of the particle surface by crystallizing calcium hydroxide, in one case [5], and to formation by Ca^{2+} ions sorbed from the solution of a barrier limiting the mass exchange, in the other [6]. In the case of ISO, both these phenomena occur as a result of surface reactions in which strong covalent bonds are protonated and the calcium ion is hydrated. However, in both these cases, the hindered stage is represented functionally as induction of the crystallization energy of hydrates, with the limiting supersaturation of the liquid phase reached and critical mass of nuclei of calcium hydroxide formed, after which there occurs its mass crystallization initiating the protolytic reaction.

Noteworthy are two concepts interpreting the driving force of the hydration conversion of portland cement. According to one of these [7, 8], the end of the induction period and continued hydration are enabled by the osmotic pressure formed as a result of the increasing difference between the concentration of calcium hydroxide in solution in the zone of contact under the semipermeable hydrate shell and that in the intergrain space. According to the other [9], the flow of solvent toward the surface is due to a build-up of the difference of electric potentials at the phase boundary with increasing excess of the Ca^{2+} ion sorbed on the surface. It is noteworthy that both these phenomena are physical in nature and, from the standpoint of the mechanism of reaction inhibition described in this communication, are due to accumulation on the surface being hydrated of protolysis products weakly diffusing into solution. Their importance presumably varies between different stages of portland cement hardening. In any case, it is the

accumulation of energy in the system and transformation of this energy into acceleration of hydration that ensure the achievement of a sufficiently high strength of the cement stone in a technologically acceptable interval of time.

CONCLUSIONS

(1) The binding properties of portland cement in a CaS_n solution are determined, on the one hand, by the lowered concentration of $Ca(OH)_2$ in the liquid phase, compared with the conventional suspensions, and, on the other, by ionization of zero-charge polysulfide sulfur and liberation of a thio salt serving as an element of the hardening structure.

(2) The improvement of the hardening parameters of a portland cement mixture in the presence of a polysulfide in the liquid phase is due to a change in the phase composition and structure of both the hydrosulfoaluminate dispersion determining the time of paste cementation and the hydrosilicate suspension responsible for the final parameters of the process.

(3) In the presence of an excess amount of CaS_n in the binder mixture, the inhibition of cement hydration is due to deceleration of the protolytic reaction of the basic mineral ($3CaO \cdot SiO_2$) with the solvent, caused by surface passivation first by the crystallizing $Ca(OH)_2$ and then by the ionic barrier appearing as the diffusion resistance builds-up in the hydration shell.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Saturated Vapor Pressure Over Melts of the Binary System $NaNO_2$–KNO_3

V. I. Glazov, G. P. Dukhanin, and V. A. Losev

Volgograd State Technical University, Volgograd, Russia

Received January 22, 2002

Abstract—The partial pressures of sodium nitrite and potassium nitrate over melts of the binary system $NaNO_2$–KNO_3 were measured at 798, 823, and 848 K. Negative deviations of the vapor pressure from Raoult's law, which decrease with increasing temperature, are established. Coefficients *A* and *B* of the Clausius–Clapeyron equation, partial molar heats of vaporization, activity and activity coefficient are calculated as functions of composition for potassium nitrate.

Molten nitrites and nitrates of alkali metals, and systems based on them, are used as high-temperature heat carriers in vulcanization of extruded rubber articles, in thermal treatment of metals, and in preparing heat-resistant lubricants [1]. For this reason, a study of physicochemical properties of nitrite–nitrate molten salt systems is of both theoretical and practical importance.

In the present study, we measured the saturated vapor pressure *P* over melts of varied composition of the binary system $NaNO_2$–KNO_3 and the partial pressures of the components at 798, 823, and 848 K. The experimental procedure and the method used for determining the saturated vapor pressure of individual molten salts were described in [2]. Mass-spectrometric data [3, 4] for vapors of alkali nitrite and nitrate revealed monomer molecules coexisting with salt melts in the vapor phase. This enabled calculation of the saturated vapor pressure over pure components and their mixtures [5–7].

The results of measurements of the saturated vapor pressure over sodium nitrite and potassium nitrate melts of various compositions at 798 and 848 K are presented in Fig. 1. As seen, the concentration dependence of the saturated vapor pressure in the $NaNO_2$–KNO_3 system shows negative deviations from Raoult's law, which decrease with increasing temperature. Under isothermal conditions, the saturated vapor pressure over the binary melts decreases monotonically with increasing content of potassium nitrate in a mixture. In the regions with component content of less than 5 mol %, the saturated vapor pressure as a function of composition is adequately described by Raoult's law. At equimolar content of the components the extent of negative deviations increases.

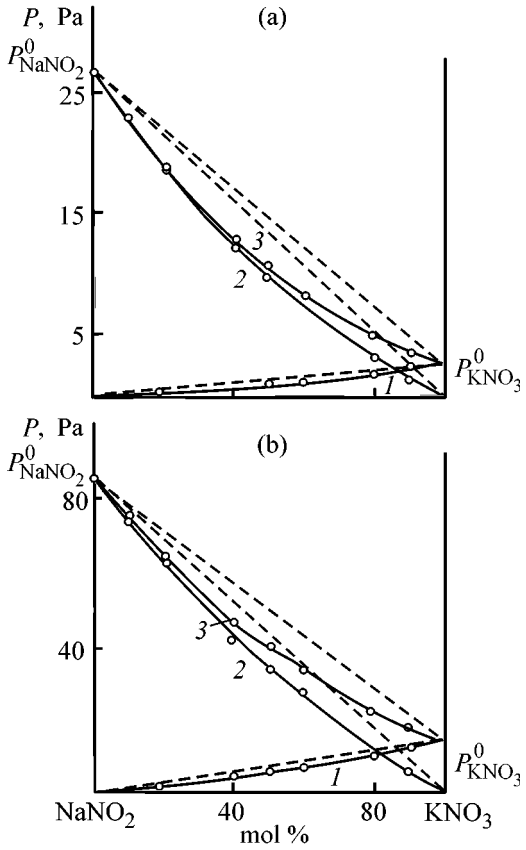

Fig. 1. Vapor pressure *P* over melts of the system $NaNO_2$–KNO_3 (mol %) at (a) 798 and (b) 848 K. $P^0_{NaNO_2}$ and $P^0_{KNO_3}$ are saturated vapor pressures over pure components. (*1*, *2*) Partial pressure of KNO_3 and $NaNO_2$, respectively, and (*3*) total pressure.

90	2.023	5.093	12.165	10.66	13.66	204.13
100	2.483	6.140	14.38	10.33	13.34	197.69

The system $NaNO_2$–KNO_3 is characterized by a simple fusion diagram of eutectic type [8]. The nature of the concentration dependences of the saturated vapor pressure curves for the $NaNO_2$–KNO_3 system is determined by the predominance of interaction between the unlike species upon replacement of a part of Na(I) cations with K(I) cations in the monomer molecules.

Because the saturated vapor pressures of sodium nitrite and potassium nitrate differ widely, the total saturated vapor pressure over the system is determined by the $NaNO_2$ partial pressure.

The temperature dependence of the potassium nitrate vapor pressure over melts of various compositions is adequately described by the Clausius–Clapeyron equation $\log P_{KNO_3} = B - A/T$. The coefficients of the equation are given in Table 1. Figure 2 shows the $\log P_{KNO_3} = f(1/T)$ plot for potassium nitrate at its varied content in the melt.

The partial molar heats of vaporization of potassium nitrate from the melts of the corresponding compositions were calculated from the slope of the straight lines in Fig. 2:

$$\Delta H_{vap}^{KNO_3} = 2.34RA,$$

where R is the gas constant (8.314 J mol^{-1} K^{-1}).

With decreasing content of potassium nitrate in the system, the heat of vaporization increases, i.e., the strength of interaction between the unlike species grows. The experimental data and results of their processing are presented in Table 1. The coefficient of linear correlation of $\log P$ as a function of $1/T$ varies from 0.81 (at low content of KNO_3) to 1.

The experimentally determined values of the saturated vapor pressure over the pure components, P_i^0 (where i is KNO_3 and $NaNO_2$), and their partial pressures P_i in the system were used to calculate the activities $a_i = P_i/P_i^0$ and the activity coefficients $\gamma_i = a_i/N_i$ for potassium nitrate in the $NaNO_2$–KNO_3 binary system [N_i is the KNO_3 content of the melt (mol %)] [9]. The results of calculation are presented in Table 2.

As seen, the activity of potassium nitrate exhibits negative deviations ideality, and, therefore, the calculated activity coefficients are less than unity.

In the system $NaNO_2$–KNO_3 the extent of departure from ideality is smaller than that in the previously studied system $NaNO_2$–KNO_3 [7]. This may be accounted for by weakening interaction between

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Partial Saturated Vapor Pressure of Sodium Nitrite Over the System $NaNO_2$–KNO_3

V. I. Glazov, G. P. Dukhanin, and V. A. Losev

Volgograd State Technical University, Volgograd, Russia

Received March 4, 2002

Abstract—The partial pressure of sodium nitrite in the system $NaNO_2$–KNO_3 was measured at 798, 823, and 848 K. The dependence of the logarithm of the $NaNO_2$ pressure on inverse temperature is presented. Coefficients *A* and *B* of the Clausius–Clapeyron equation and the partial molar heats of vaporization are calculated. The activity and activity coefficient of sodium nitrite are determined. The dependences of activity and activity coefficient of sodium nitrite and potassium nitrate are presented as functions of composition of the $NaNO_2$–KNO_3 system. The consistency of the activity coefficients is verified using the Redlich–Kister integral.

Proceeding with investigations of the physicochemical and thermodynamic properties of molten nitrite–nitrate systems [1–3], we studied the partial pressure of saturated vapor of sodium nitrite over the system $NaNO_2$–KNO_3.

The method used to prepare salts and the experimental installation have been described previously [1]. The saturated vapor pressure of sodium nitrite over the melts of the $NaNO_2$–KNO_3 system of varied composition was measured at 798, 823, and 848 K.

Table 1. Vapor pressure P_{NaNO_2}, coefficients *A* and *B* of the Clausius–Clapeyron equation, and partial molar heats of vaporization $\Delta H_{vap}^{NaNO_2}$ of sodium nitrite in the $NaNO_2$–KNO_3 system

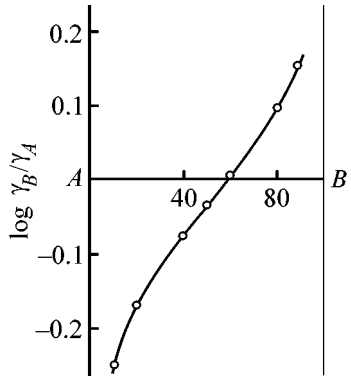

Fig. 3. Verification of the consistency of the activity coefficients for the $NaNO_2$–KNO_3 system, using the Redlich–Kister integral at T = 848 K. (*A*) $NaNO_2$ and (*B*) KNO_3.

The temperature dependence of sodium nitrite vapor pressure is well described by the Clausius–Clapeyron equation $\log P = B - A/T$. The results of measurements of the sodium nitrite vapor pressure over the system, the calculated coefficients of the Clausius–Clapeyron equation, and the partial molar heats of vaporization of $NaNO_2$ are presented in Table 1.

Figure 1 shows the logarithm of the sodium nitrite pressure over the melts of various compositions as a function of inverse temperature. The linear correlation coefficient of $\log P$ as a function of $1/T$ varies from 0.81 (at low sodium nitrite content) to 1.

As shown previously [3], the concentration behavior of the partial pressure curves for sodium nitrite and potassium nitrate exhibits negative deviations from Raoult's law. Under isothermal conditions, the sodium nitrite vapor pressure increases steadily with decreasing content of the second component.

With decreasing content of sodium nitrite in the system, the heat of its vaporization increases, i.e., the interaction between the unlike species becomes stronger.

The experimental values of the saturated vapor pressure P_i^0 over pure components (KNO_3, $NaNO_2$) were used to calculate the activities a_i and activity coefficients γ_i of sodium nitrite in the $NaNO_2$–KNO_3 system. The results of calculations are given in Table 2. The activity and activity coefficient of potassium nitrate in the system studied have been reported previously [3].

Figure 2 shows the activity and activity coefficient of sodium nitrite and potassium nitrate as functions of the composition of the system at 798 and 848 K. As seen, the activities of sodium nitrite and potassium nitrate exhibit negative deviations from ideality. For this reason, the calculated activity coefficients are smaller than unity.

The isotherms of activity of potassium nitrate show large negative deviations. This is due to an increase in the cationic radius. The negative deviations indicate a certain extent of complexation in the system and the predominance of interaction between the unlike cations (Na–K). With increasing temperature, the negative deviations become less pronounced.

The independently obtained activity coefficients of the components of the $NaNO_2$–KNO_3 system must correspond to the Gibbs–Duhem equation. The thermodynamic consistency of the data on the activity

coefficients was verified using the Redlich–Kister integral [4]:

$$\int_{N_B=0}^{N_B=1} \log \gamma_B/\gamma_A \mathrm{d}N_B = 0.$$

The verification results are plotted in Fig. 3. It can be seen that the activity coefficients of the components of the $NaNO_3$–KNO_3 system are in satisfactory agreement with the Gibbs–Duhem equation.

SORPTION AND ION-EXCHANGE PROCESSES

Interaction of Co(II), Ni(II), and Cu(II) with Quartz Surface in Aqueous Solutions at Varied pH

K. P. Tikhomolova and I. N. Urakova

St. Petersburg State University, St. Petersburg, Russia

Received November 30, 2001

Abstract—Sorption/desorption of Co(II), Ni(II), and Cu(II) on quartz was studied in aqueous solutions at pH 3.0, 5.0, and 7.3 [for Co(II) and Ni(II)] and 3.0 and 5.0 [for Cu(II)].

Specific adsorption in disperse systems containing aqueous solutions of various metal salts has been a subject of a great number of experimental and theoretical works. However, some points related to the adsorption mechanism are not understood yet.

The classical theory of electrical double layer (Gouy's theory) formally treats the resultant action of two forces, electrostatic (Coulombic) and diffusion, without taking into account the adsorbate (metal cation in our case) nature. In other words, this theory considers nonspecific adsorption. However, in many cases the classical theory cannot reproduce experimental results adequately. In these cases, the necessity arises to involve specific interactions into consideration, depending on the metal nature and speciation in the solution bulk. Many questions of specific adsorption have been studied insufficiently. To solve these questions, new approaches have been developed [1–19]. A series of works have been based on the concept of the determining role of complexation [7, 9–19], with the term complex is used in different senses. The chemical (coordination) concept of specific adsorption from aqueous solutions on oxides is also related to this research [16].

In this work, we studied adsorption of double-charged cations of 3*d* metals [Co ($3d^7$), Ni ($3d^8$), and Cu ($3d^9$)]. In the experiments we used quartz (SiO_2) from the Kyshtym deposit (99.8% α-quartz). The sample preparation procedure was as follows. Quartz was ground into a powder in a steel ball mill, washed first with dilute sulfuric acid to negative reaction for iron and then with distilled water to neutral reaction, sieved to obtain a desired fraction, dried at about 110°C, and, finally, poured over with distilled water. In the adsorption–desorption experiments, we employed the fraction with equivalent particle diameter d_e of 40–70 μm. The specific surface area S_{sp} of this fraction was determined from adsorption of nitrogen (BET) and Methylene Blue to be 0.20–0.21 $m^2\ g^{-1}$.

Adsorption of the metals on dispersed quartz was monitored by the M(II) concentration in the solution bulk, c_M. Hereinafter quartz after adsorption is called modified. Also, we determined the amount of adsorbed M(II) per unit area of the adsorbent surface Γ (mol m^{-2}). The M(II) concentration in the solution was determined spectrophotometrically on a Specol-10 instrument: Co(II) with Nitroso R salt (λ = 520 nm), Ni(II) with PAN (λ = 540 nm), and Cu(II) with Xylenol Orange (λ = 580 nm). The Γ was estimated from the change in the metal concentration in the aqueous phase. The error of spectrophotometric determinations was within 0.5–3.0%.

The working solutions were prepared from M(II) nitrates. The characteristics of these solutions are as follows: M(II) concentration 10^{-4} M; pH 3.0, 5.0, and 7.3 [only for Co(II) and Ni(II)]; and ionic strength 10^{-3} M. The ionic strength and the desired pH were adjusted by adding KNO_3, KOH, or HNO_3. In addition to the working solutions, we used reference solutions with the same pH values and ionic strengths, but containing no M(II).

The solution pH values were chosen was made in view of the following considerations. Firstly, the initial necessary condition was that the adsorbate solution should be a true solution, i.e., a solution containing only species of molecular dimensions. The systems with Co(II) and Ni(II) meet this requirement at all the three pH values, and in the case of Cu(II), hydroxide particles are formed at pH 7.3. Note that, accord-

1070-4272/02/7506-0894 $27.00 © 2002 MAIK "Nauka/Interperiodica"

ing to the speciation diagrams given in [18] and constructed using potentiometric titration data,[1] Co(II) and Ni(II) occur as aqua ions at the indicated three pH values, and Cu(II), practically totally as aqua ions at pH 3.0 and 5.0. Secondly, in the case of Cu(II), pH 5.0 is only slightly lower than pH 5.8 of dimerization with the formation of $[Cu_2(OH)_2]^{2+}$, and pH 7.3 is lower than the pH of formation of Co(II) and Ni(II) hydroxides (7.8 and 8.5, respectively). Finally, pH strongly affects the amounts of negatively charged $[\equiv SiO]^-$ and neutral active sites $[SiOH]^0$ on the quartz surface. As stated previously [16, 17], these surface groups can serve as ligands, i.e., they can participate in the formation of surface complexes with an adsorbed cation as acceptor; $[\equiv SiO]^-$ being a more reactive ligand than $[SiOH]^0$.

Taking into account the very high sensitivity of the surface properties to even extremely slight variations in the chemical composition of the surface, and to make comparative analysis of results obtained for various metals, all the experiments were carried out with the same quartz sample.

To estimate the degree of dissociation of the quartz surface sites at various pH values, we used the known method of continuous potentiometric titration [20]. Before starting titration of the quartz dispersion, the sample was dried a little on a paper filter, and then a weighed portion was taken and equilibrated with a solution at pH 3. The ionic strength of both the solution and the dispersions was 10^{-3} M (KNO_3). In the course of titration, pH varied from 3 to 10. The amount of OH^- ions consumed in the course of titration is equal to the amount of the $[\equiv SiO]^-$ groups formed on the surface. The potentiometric titration data are presented in Fig. 1.

Before starting the adsorption–desorption experiment, a quartz sample was poured over with the supporting electrolyte solution at a fixed pH. The solution was refreshed at regular intervals over a period of 1–2 days. If no specific interaction occurs in the dispersion at a given pH, this time is enough for the formation of an electrical double layer. Then the solution was decanted, the solid phase was washed with a fresh portion of the supporting electrolyte, and the adsorption experiment started at once.

Adsorption was studied by the static method, and desorption, by the static and electroosmotic displacement methods differing in the effect on the adsorption layer (stronger in the second case [21]). In all cases, we used in the desorption stage M(II)-free solutions (supporting electrolyte solutions). Publications devoted to the potentialities of the electroosmotic technique for this purpose are extremely scarce [19, 21, 22]. The main concern of these works is mostly soil compaction or consolidation grouting [23].

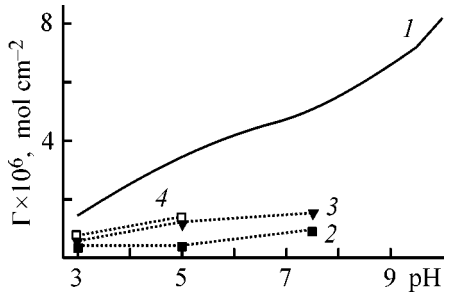

Fig. 1. Specific adsorption Γ vs. pH: (*1*) OH^-, (*2*) Co(II), (*3*) Ni(II), and (*4*) Cu(II).

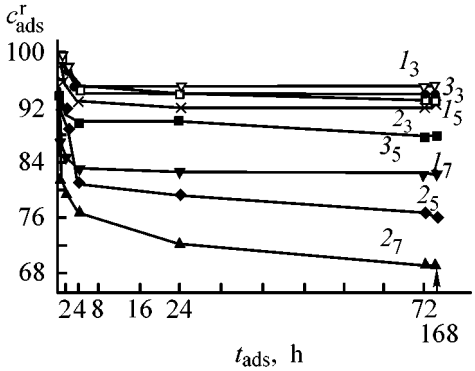

Fig. 2. M(II) concentration in the liquid phase, c^r_{ads} (in percent relative to the metal concentration in the initial working solution c_0) as a function of the adsorption time t_{ads}. Adsorbed ion: (*1*) Co(II), (*2*) Ni(II), and (*3*) Cu(II). The subscripts denote pH of the initial working solution.

In all the adsorption experiments, we used dispersions containing 2 g of a quartz powder and 20 ml of fresh working solution. Weighing bottles were hermetically sealed. After a fixed time t_{ads} varied from 1 to 7 days, the weighing bottle was opened, and the solution was removed by decantation and analyzed for pH and M(II). The solid phase (modified quartz) was then used in the desorption experiment.

In static desorption, modified quartz was placed in a weighing bottle, poured over with 20 ml of supporting electrolyte at the same pH as in the adsorption stage, and sealed. Then we used the same procedure as in the adsorption experiments.

In electroosmotic desorption experiments, the electric field was applied to a diaphragm formed from modified quartz (dc field strength 10 V cm^{-1}).

[1] Since the metal and supporting electrolyte concentrations in [18] differ from those in this study, to refine M(II) speciation, we performed potentiometric titration.

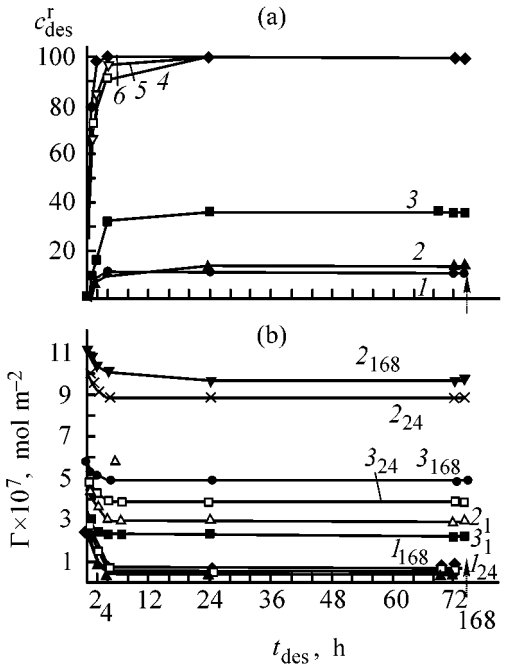

Fig. 3. (a) Ni(II) concentration in the liquid phase at pH 5.0 in the course of the desorption experiment, c^r_{des} (in percent relative to the concentration in the working solution after the adsorption stage) and (b) the specific adsorption of Co(II), Ni(II), and Cu(II) Γ (mol cm^{-2}) at pH 5.0 vs. the desorption time t_{des}. (a) (*1*–*3*) Static desorption and (*4*–*6*) electroosmotic displacement. t_{ads}: (*1*, *4*) 7 days, (*2*, *5*) 1 day, and (*3*, *6*) 1 h. Adsorbed ion: (*1*) Co(II), (*2*) Ni(II), and (*3*) Cu(II); the same for Fig. 4. The subscripts denote the adsorption time in the adsorption stage, expressed in hours.

The amount of desorbed metal was estimated from the M(II) concentration in the filtrate and the filtrate volume.

Variation of the M(II) concentration in the aqueous phase, c^r_{ads} (in percent relative to the metal concentration in the initial working solution c_0) in the course of the adsorption experiment is shown in Fig. 2.

Adsorption of all the three ions grows with increasing solution pH. The c^r_{ads} and adsorption rate are different for different ions. At any pH, the adsorption rate decreases in the order Ni(II) > Cu(II) > Co(II).

For all the three ions, c^r_{ads} approaches saturation at a sufficiently long adsorption time. The time of equilibrium attainment, t^{eq}_{ads}, is found to exceed 1 h and to be much longer than that in ion-exchange processes, when counterions are fixed in the surface layer only by the Coulombic forces.

The time of equilibrium attainment decreases in the order Ni(II) > Cu(II) > Co(II). For Ni(II) t^{eq}_{ads} = 1–3 days, becoming longer with increasing pH; and for Co(II) and Cu(II), t^{eq}_{ads} = 2–4 and 4 h at both pH values.

The relationship between t^{eq}_{ads} and the firmness of metal fixation in the adsorption layer was studied in the static and electroosmotic experiments with varied t_{ads}. As a parameter characterizing the desorption efficiency we used c^r_{des} written as

$$c^r_{des} = (c_{des}V_{des}) \times 100/(c_{ads}V_{ads}),$$

where c_{des} is the current M(II) concentration in the course of desorption; V_{ads} and V_{des} are the volumes of the liquid phase in the course of adsorption and desorption, respectively; and c_{ads} is the M(II) concentration in the working solution after adsorption.

According to the static desorption data, t_{ads} strongly influences the desorption efficiency. With increasing t_{ads}, the firmness of M(II) fixation on the quartz surface grows; the more so with increasing pH. Figure 3a shows the time dependences of c^r_{des}, obtained for Ni(II) in both the static and electroosmotic desorption experiments (t_{ads} 1 h, 1 and 7 days; pH 5.0). It is clearly seen from the electroosmotic desorption data that, with increasing t_{ads}, the same c^r_{des} is attained in a longer time.

Figure 3b shows the desorption curves obtained for Co(II), Ni(II), and Cu(II) by the static method at pH 5.0 (t_{ads} 1 h, 1 and 7 days). The results show that the effect of t_{ads} on $\Gamma_{des} = \Gamma_{ads} - (c_{des}V_{des}/S_{sp})$, where $[\Gamma_{ads} = (c_0 - c_{ads})V_{ads}/mS_{sp}$ and m is the adsorbent weight], is considerably lower for Co(II) than for Ni(II). Note that this effect is quite clearly pronounced in the case of dispersions consisting of a Cu(II) solution at pH 5.0 and modified quartz (t_{ads} 1 h, 1 and 7 days).

It has been demonstrated by several authors that, after an adsorbate enters the surface reaction zone, surface processes can be extended in time relative to the time of the equilibrium attainment, determined using the parameter c_{ads}. In particular, this refers to the phenomenon of specific adsorption [21]. Our data on static desorption provide an additional evidence in favor of this view (Figs. 2, 3b).

Figure 4 shows how the amount of adsorbed M(II) varies with time in sorption and in static and electroosmotic desorption experiments (all the desorption experiments were performed with quartz modified for 7 days).

First, the results show that, at any experimental pH, the limiting amount of adsorbed M(II) increases in the order Co(II) < Cu(II) < Ni(II) (Fig. 4a).

Let us now analyze the most significant features of desorption (Figs. 4b, 4c). Under any experimental conditions studied, the highest desorption efficiency is observed for Co(II). In static desorption, the residual amount of Co(II) adsorbed on the quartz surface was estimated to be about 5, 20, and 45% at pH 3.0, 5.0, and 7.3, respectively. Since the electroosmotic displacement involves a more severe treatment, the fact of rapid total desorption of the metal ions is quite natural [19, 21, 22]. Therefore, our results show that the bonds formed by Co(II) with the surface sites of quartz are the weakest among the metals studied.

As for Ni(II), Fig. 4b shows that static desorption of Ni(II) is rapid, but inefficient process [residual amount of adsorbed Ni(II) is 80, 85, and 87% at pH 3.0, 5.0, and 7.3, respectively]. Only electroosmotic displacement provides total desorption of Ni(II), but it requires longer time than that for Co(II), suggesting firmer fixation of Ni(II). Therefore, Ni(II) forms fairly strong bonds with the active sites of quartz at any pH studied.

The parameters of static desorption of Cu(II) at pH 5.0 virtually coincide with those of Ni(II), and at pH 3.0, they take an intermediate position between Co(II) and Ni(II).

Similarly to the other metals investigated, Cu(II) is totally desorbed by the electroosmotic method, regardless of pH.

In addition to the potentiometric titration data, Fig. 1 also shows the pH dependences of the amounts of all the adsorbed cations. It is clear that the positive charge due to adsorption of M(II) at the quartz–solution interface ($\Sigma|e_M^+|$) is twice the product $\Gamma_M N_A$. Recalculation of Γ (mol m^{-2}) given in Fig. 1 to the corresponding amount of the positive charge in EDL and its comparison with the amount of the negative charges localized on the surface groups $[\equiv SiO]^-$ ($\Sigma|e^-| = \Gamma_{SiO} N_A$) show that $\Sigma|e^-| > \Sigma|e_M^+|$ in all cases.

In this connection, let us estimate the significance of the $[\equiv SiO]^-$ and $[\equiv SiOH]^0$ surface centers as centers determining the electric field of the surface layer and also as ligands of the surface complexes. Taking into account the inequality given above, it may be suggested that the $[\equiv SiO]^-$ sites contribute significantly to the specific adsorption through an essentially Coulombic interaction M(II)–$[\equiv SiO]^-$. The role of the Coulombic forces, as the longest-range forces, is restricted to attraction of the M(II) ions to the zone of action of short-range forces responsible for specific adsorption.

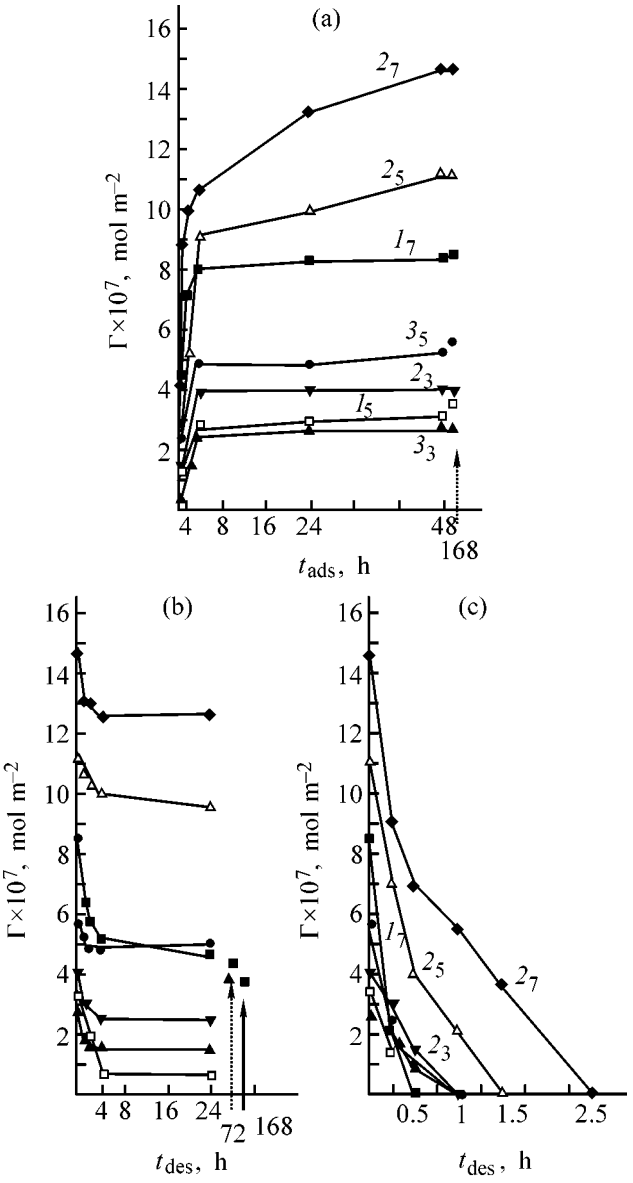

Fig. 4. Amount of M(II) adsorbed on the unit surface area of quartz, Γ, vs. (a) adsorption time t_{ads} and (b, c) desorption time t_{des} at t_{ads} = 168 h. Desorption method: (b) static and (c) electroosmotic. Subscripts denote pH of the initial working solution.

Evidently, the M(II) aqua cations are bound to primarily $[\equiv SiO]^-$ groups on the quartz surface. At the same time, the interaction of M(II) with $[\equiv SiOH]^0$ cannot be ruled out. Also, the forces retaining the adsorbate at the $[\equiv SiO]^-$ active site cannot be restricted to the Coulombic interactions only. The following facts additionally count in favor of the specific adsorption of M(II) on the active site of the quartz surface. In solutions with pH 3.0 and 5.0, in which the initial Ni(II) and Cu(II) concentrations were lower by a factor of 10 than the total concentration of all

other cations, the electrical neutrality of EDL is provided by considerably higher amounts of the Ni(II) and Cu(II) ions, compared to the amounts corresponding to their adsorption as indifferent ions. Indeed, it follows from the recalculated data of Fig. 1 that in the systems containing Ni(II) and, to a lower but also remarkable extent, in Cu(II)-containing systems, the ratio $\Sigma|e_M^+|/\Sigma|e^-|$ is considerably above 0.1–0.2. Moreover, in the case of Ni(II), this ratio only slightly differs from 0.85 at pH 3.0 and 0.8 at pH 5.0; the corresponding values for Cu(II) are 0.5 and 0.6.

At present, the coordination chemistry in aqueous solution is extensively studied. There is a great body of data on the effect of the nature of metals and ligands on the strength and structure of coordination bonds M–L. To our knowledge, such data on surface complexes are lacking in the literature.

At the same time, the force field at the interface is very asymmetrical. Its strength drops from a high value to zero over molecular ranges [19]. Therefore, we analyzed the correlation of the experimental data obtained with coordination model of adsorption, by analogy with consideration of the effect of metal ions and ligands on the formation of the bulk and surface complexes. Of course, this is not the literal meaning. We only point out the known general trends in the effect of the nature of M(II) and L on the properties of the surface complexes formed.

The observed relatively weak fixation of Co(II) on the quartz surface can be attributed to the well-known fact that the coordination numbers 4 and 6, corresponding to the tetrahedral and octahedral surroundings of Co(II), respectively, are the most typical of this cation. Complexes of Co(II) with monodentate ligands, having an oxygen atom as a donor center, are mostly labile [24–26].

The desorption results obtained by the static method suggest that, in the case of Ni(II), donor–acceptor bonds must be relatively strong. For d^8 complexes of Ni(II), both coordination numbers 4 (tetrahedral or square-planar structure) and 6 (octahedron) are typical. According to the crystal field theory, ligand substitution in d^8 complexes by the S_N1 or S_N2 mechanism is slow [27]. Most likely, Ni(II) complexes formed on the α-quartz surface have square-planar or octahedral configuration.

In the systems with Cu(II), like in those with Ni(II), the lack of noticeable desorption in the static mode suggests the formation of relatively strong donor–acceptor bonds between Cu(II) as a central atom and the oxygen atom of the surface ligand $[\equiv SiO]^-$. Note also that, for d^9 complexes of Cu(II), the most typical structures of the inner coordination sphere are square-planar and octahedral.

CONCLUSIONS

(1) The adsorption efficiency of Co(II), Ni(II), and Cu(II) on quartz increases in the order Co(II) < Cu(II) < Ni(II), growing with pH. The time of attainment of the adsorption equilibrium varies in the same order, ranging from 2 h to 3 days.

(2) Desorption of M(II) from quartz depends on a desorption procedure used. In the static desorption, the desorption efficiency of Co(II) is higher than that of Ni(II) at all the experimental pH values and than that of Cu(II) at pH 5.0. At pH 3.0 the static desorption of Cu(II) is lower than that of Co(II), but higher than that of Ni(II). In electroosmotic replacement, all the cations are totally desorbed quite rapidly (in at least 2.5 h).

(3) In both static and electroosmotic desorption modes, the desorption efficiency depends on the adsorption time. In static desorption, the metal cations adsorbed in 1 h are desorbed more efficiently that at an adsorption time of 1 and 7 days. In electroosmotic displacement mode, the same equilibrium c_{des}^r is attained in longer time with increasing t_{ads}.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Iridium(IV) from Hydrochloric Acid Solution with Bis(piperidinoethylthioethyl)-1-phenyl-1-ethanone

Abstract—A bidentate organic compound containing nitrogen and sulfur donor atoms was tested as a reagent for extraction of iridium(IV) from aqueous solutions. The composition of the extractable Ir(IV) complex was determined by ^{1}H NMR, UV, and IR spectroscopy and elemental analysis.

Because of the kinetic inertness of Ir(IV) halide complexes, iridium is weakly extracted from aqueous hydrochloric acid solutions with organic sulfides. It is known that extraction of kinetically inert complexes of iridium(III) and ruthenium(III) is accelerated when using reagents containing simultaneously sulfur and nitrogen atoms [1].

In this work, we studied the extraction of iridium(IV) from hydrochloric acid solutions with bis(piperidinoethylthioethyl)-1-phenyl-1-ethanone (L) $C_6H_5COCH[CH_2SCH_2CH_2N(C_5H_{10})_2]$ synthesized by the procedure reported in [2].

The purity of L was monitored by elemental analysis, thin-layer chromatography, and ^{13}C and ^{1}H NMR spectroscopy. This reagent is a viscous light yellow liquid with specific odor.

It is known that iridium(IV) is an oxidant. It was reported in [3] that, in extraction of iridium(IV) with octylaniline, iridium(IV) is reduced to iridium(III).

We found that, on keeping iridium(IV) solutions in water or 2–3 M HCl or on their stirring with a pure diluent (*m*-xylene, chloroform) for 90 min, the iridium(IV) concentration does not change.

In our experiments, we used iridium(IV) salt K_2IrCl_6 of pure grade and iridium(III) salt K_3IrCl_6 synthesized by the procedure reported in [4]. The working solutions were prepared by dilution of a stock solution with 3 M HCl.

The total iridium(IV) content in solutions was determined spectrophotometrically [5]. Extraction was carried out in temperature-controlled cells at organic to aqueous phase ratio of 1 : 1 at 20 ± 0.5°C. The phases were stirred with a magnetic stirrer.

The electronic spectra (ES) were recorded in quartz cells on a Specord M-40 spectrophotometer. The ^{1}H NMR spectra of the organic extracts diluted with deuterochloroform were registered on a Bruker AM-300 spectrometer (300 MHz). The electrical conductivity of the organic extracts was measured in acetone solutions on a Radelkis OK-102/1 conductometer (Hungary). The IR spectra of the extractant, extracts, and extracted complexes were recorded on a Specord M-80 spectrophotometer in the range 4000–200 cm^{-1} using KRS-5 disks for the range 4000–400 cm^{-1} and polyethylene disks for 400–200 cm^{-1}.

Our previous testing showed that, in extraction of iridium(IV) from 2–3 M HCl, the equilibrium distribution was attained within a contact time not exceeding 10 min. All the subsequent experiments were performed at this contact time.

It is known that, in hydrochloric acid medium, both aminoketo sulfides and amino sulfides are converted to the corresponding salts due to protonation of the amine nitrogen atom [1]. Therefore, iridium(IV) can be recovered from 2–3 M hydrochloric acid solutions with the reagent L in the form of ionic associates by the mechanism of interphase anion exchange:

$$[IrCl_6]^{2-} + C_6H_5COCH\{CH_2SCH_2CH_2\ddot{N}H(C_5H_{10})_2\}_2 \cdot 2H\ddot{C}l \rightarrow C_6H_5COCH\begin{matrix}\diagup\ CH_2SCH_2CH_2\ddot{N}H^+(C_5H_{10})_2 \\ \\ \diagdown\ CH_2SCH_2CH_2\ddot{N}H^+(C_5H_{10})_2\end{matrix} [IrCl_6]^{2-} + 2Cl^-$$

* At saturation of the organic phase with iridium(IV) ions on the contact with iridium(IV) solution in 3 M HCl.

** At saturation of the organic phase with iridium(IV) ions on the contact with iridium(IV) solution in 2 M HCl.

The set of absorption bands in the ESs of both the aqueous solution and organic phases after their 10-min contact shows that iridium is present in the form of the octahedral anion $[IrCl_6]^{2-}$ (Table 1, Fig. 1) [6, 7]. In spite of the fact that iridium(IV) is a strong oxidant, no Ir(III) appeared in the aqueous phase after extraction. Owing to resistance of the extractant to oxidation, the extraction does not affect the electronic spectra of iridium in the aqueous solution.

Measurements of the electrical conductivity of an extract diluted with acetone showed that the extraction complex is an electrolyte of the 2 : 1 type (λ = 190 Ω^{-1} m^2 mol^{-1}).

The IR spectrum of a complex of L with HCl, formed in iridium(IV) extraction from hydrochloric acid solution, contains a band at 2550 cm^{-1}, belonging to NH stretching vibrations in the $\equiv NH^+$ cation. The formation of this cation also shows that Ir(IV) is extracted in the form of a tertiary ammonium salt containing iridium in the form of $[IrCl_6]^{2-}$ anionic complex. The band of $\equiv NH^+$ stretching vibrations in the range 2700–2250 cm^{-1} is typical of tertiary ammonium salts [9].

To choose the optimal conditions for extraction of iridium(IV) with ketoamine sulfide we studied how the extraction of Ir(IV) depends on the HCl concentration in the aqueous phase. Figure 2 shows that, with

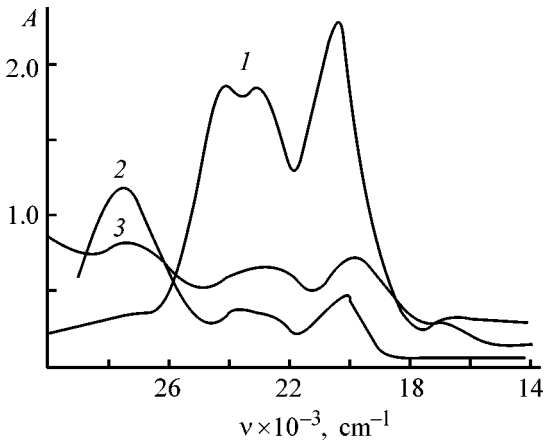

Fig. 1. Electronic spectra of iridium(IV) extracts: (*A*) optical density [8] and (ν) wave number. HCl concentration in the aqueous phase (M): (*1*, *2*) 3 and (*3*) 2. Contact time (min): (*1*) 10 and (*2*) 30.

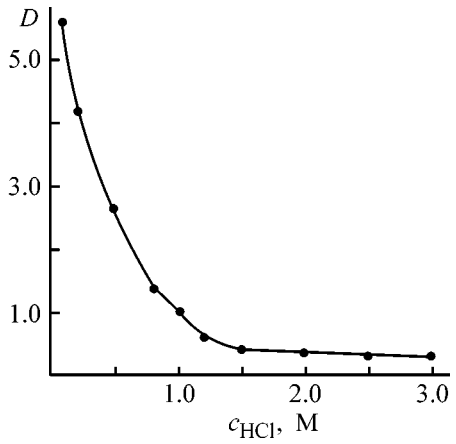

Fig. 2. Distribution factor of iridium(IV) $D = (c_{Ir(IV)})_{org}/(c_{Ir(IV)})_{aq}$ vs. HCl concentration in the aqueous phase. Concentration (M): Ir(IV) 0.0005 and (L) 0.005.

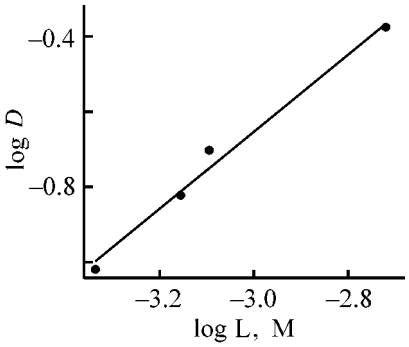

Fig. 3. Distribution factor of iridium(IV) vs. concentration of the free reagent at c_{HCl} 2 M.

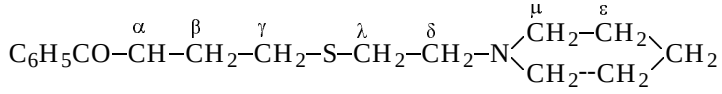
increasing HCl concentration, the distribution coefficient of iridium(IV) D decreases. This suggests that the initial solution contains a large amount of readily extractable iridium(IV) chloride complexes which are converted to poorly extractable species with increasing HCl concentration.

The extraction of iridium(IV) from 2 M HCl was studied in more detail. To determine the composition of the iridium(IV) complex extracted with L from 2 M HCl, we studied how the proton concentration at a constant ionic strength [NaCl + HCl] = 2 M affects the iridium(IV) distribution factor. Our results show that the slope of the dependence $\log D = f(c_{H^+})$ is close to 2, i.e., iridium(IV) is extracted in the form of a negatively charged iridium(IV) anionic complex $[IrCl_6]^{2-}$.

The number of extractant molecules incorporated into the iridium-containing extractable complex was evaluated by the dilution method. Figure 3 shows that the extractable complex contains one molecule of L.

The chemical shifts of proton signals in the ^1H NMR spectra of free reagent L and of the extracts obtained by contacting L with both straight aqueous HCl (2 and 3 M) and iridium(IV) solution in HCl (2 and 3 M) for 10 and 30 min, respectively, are listed in Table 1. Comparison of the ^1H NMR spectra shows that the additional chemical shift on protonation is the strongest for protons of the mehylene groups at the nitrogen atom, while the chemical shifts of protons at the sulfur atom are minor. In extraction of iridium(IV) from 2 and 3 M HCl, the appearing signals at 11.34 and 11.60 ppm are due to protonation of the nitrogen atom of L (Table 2).

Table 2. Chemical shifts of protons in the ^1H NMR spectra of pure reagent L and its complexes with HCl and iridium(IV) in deuterochloroform



Sample	Proton chemical shift in ^1H NMR spectra δ (ppm) and additional chemical shift Δδ, ppm

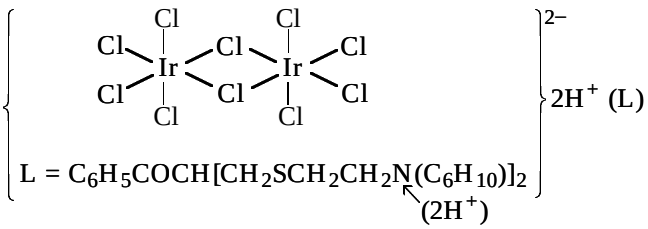
II from 2 M HCl	35.8	4.7	3.5	7.9	22.0	23.9	35.6	4.6	3.7	8.0	23.0	23.5	108–110

* This compound is a red-brown powder.

Under the conditions of saturation of the organic phase ($c_{Ir(IV)}$ = 0.005 and c_L = 0.05; contact time 30 min) binuclear complexes are obtained (Table 3, Fig. 1).



The electronic spectra of extracts saturated with iridium(IV) contain bands at 28000 and 23000 cm^{-1}, which, according to [6], indicate a polynuclear structure of the extractable complexes. Figure 1 shows that, in the UV spectra of complex **I** obtained by extraction of iridium(IV) from 3 M HCl, the absorption band at 28000 cm^{-1} is stronger compared to complex **II** obtained by extraction from 2 M HCl. This result agrees with published data [6, 7], which show that the fraction of extractable polynuclear Ir(IV) complexes increases with increasing acid concentration in aqueous phase.

An elemental analysis of these complexes showed that their composition corresponds to a dimeric structure with Ir : Cl : L = 2 : 10 : 1.

Measurements of the electrical conductivity of the extracts diluted with acetone suggested that the extracted complex is a 2 : 1 type electrolyte (λ = 190 $\Omega\,m^2\,mol^{-1}$).

We found that prolongation of the phase contact to 30 min does not affect the ^1H NMR spectra substantially (Table 2). This fact confirms our assumption that, in extraction of iridium(IV) from concentrated (>2 M) HCl solutions, the sulfur atoms of the reagent molecule do not enter to a significant extent the inner coordination sphere of iridium(IV). Iridium(IV) is extracted as ionic associates.

The long-wave length IR spectra of complexes **I** and **II** are given in Fig. 4. The similarity of these spectra shows that, at HCl concentrations in the aqueous phase higher than 2 M, iridium(IV) is recovered in the form of ionic associates containing bridging cloride ions. In the IR spectra, a broad strong band at 316 cm^{-1} is due to the stretching vibrations ν_μ(Ir–Cl) of terminal bonds [10, 11]; and the strong absorption band at 274 cm^{-1} is due to vibrations of the bridging chloride anions in the extractable complexes.

CONCLUSIONS

(1) A bidentate reagent containing electron-donor sulfur and nitrogen atoms was tested in extraction of iridium(IV) from aqueous (2 and 3 M) HCl.

(2) The composition of iridium(IV) complexes extracted from aqueous HCl was studied by ^1H NMR, UV, and IR spectroscopy and elemental analysis. Depending on the phase contact time, either mononuclear or binuclear iridium(IV) chloro complexes are extracted in the form of ionic associates with the reagent.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Deposition of Cobalt(III) Oxide in the Presence of Nickel(II) and Chromium(III) Ions

V. M. Nagirnyi, R. D. Apostolova, A. S. Baskevich, P. M. Litvin, and E. M. Shembel'

Received August, 23, 2001; in final form, January 2002

Abstract—Preparation conditions and nature of anodic processes in electrolytic deposition of cobalt(III) oxide in the presence of nickel(II) and chromium(III) ions from mixed aqueous solutions of their sulfates were studied. The deposits obtained are of interest for creating effective cathode materials for lithium batteries.

Cobalt(III) oxides in compounds with lithium are effective cathode materials for lithium batteries. Among their advantages mention should be made of high energy capacity and satisfactory stability in cycling [1–3]. According to the results of numerous studies [4–6], these characteristics of cobalt(III) oxide are much improved when complex oxide systems of the types Ni_xCo_{1-x}, $Cr_yCo_{1-y}O_2$, etc., are used. The possibility of obtaining and the preferable parameters of electrolysis in anodic deposition of cobalt(III) oxide from an aqueous solution of its sulfate have been established previously [7]. It has been shown that quantitative amounts of deposits, which are binary oxide systems, are formed on the anode in electrolysis of manganese(II) and cobalt(II) sulfate solutions mixed in a certain ratio [8]. The phase composition of the systems can be controlled to a certain extent by choosing the solution composition and process parameters.

It seemed appropriate to study the nature of anodic processes in electrolytic deposition of cobalt(III) oxide from aqueous sulfate solutions in the presence of nickel(II) and chromium(III) ions in order to determine whether its electrolytic alloying with oxide compounds of these metals is possible. No relevant evidence could be found in the literature.

As objects of study served sulfate solutions of the metals at varied ratio of their concentrations. The concentration of cobalt(II) sulfate in an additive-free solution was 0.09 M, and the total concentration, 0.12–0.13 M for the Co–Ni system and 0.09–0.1 M for the system Co–Cr at salt concentration ratios of 1 : 1–1 : 5 and 1 : 1–5 : 1, respectively, (the figures in the first and second positions refer to, respectively, the base and alloying component). The solutions were prepared from pure and analytically pure reagents and distilled water. The electrolysis was carried out in a 200-ml glass cell. The materials under study were deposited in the form of compact coatings onto smooth $1 \times 1 \times 0.03$-cm smooth plate anodes made of 12Kh18N9T steel (on both sides) at $S_a : S_c$ ratio of 1 : 5. Dispersed deposits with mass of 0.1–0.15 g for X-ray structural analysis were obtained on a smooth plate of VT-1 technical-grade titanium. Smooth plates of the same material served as cathodes. All experiments were done at a temperature of 85°C and pH 2.5–3.0, with these values of the parameters chosen on the basis of preliminary experiments. The deposition rate V_d (mg cm^{-2} h^{-1}) was determined from the anode mass gain after electrolysis per unit area per unit time. A copper coulometer was connected to the circuit to measure the current efficiency by the anodic product. The current efficiency was calculated on the assumption that the entire useful current was expended for formation of cobalt oxide Co_2O_3 [electrochemical equivalent 3.08 g (A h)$^{-1}$]. Polarization curves were measured in a three-chamber cell on an anode made of 12Kh18N9T steel (∇ 7–8, S_a = 1 cm^2, $S_a : S_c$ = 1 : 5) at the above-mentioned electrolysis parameters in the range I_a = 0.5–60 mA cm^{-2}. The potentials were measured relative to silver chloride reference electrode (φ = +0.255 V) with a V7-16A digital instrument. The phase composition of the deposits was determined qualitatively and, approximately, quantitatively using X-ray structural data obtained on a DRON-2 diffractometer, compared with reference data by means of a calibration plot [9]. The microstructure and surface morphology of the deposits were studied on thin-film coatings (2.5–3.5 μm) with a digital nanoscope (Nano Scope IIIa, Digital Instruments).

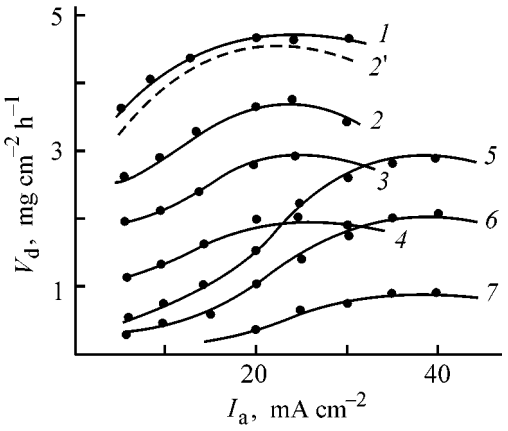

Fig. 1. Deposition rate V_d of electrolytic oxide materials vs. anode current density I_a in electrolysis of (*1*) cobalt(II) sulfate solution, and also in the presence of nickel(II) and chromium(III) sulfate (c_{tot} 0.12–0.13 and 0.09–0.1 M, respectively). Temperature 85°C, pH 2.5–3.0. Co : Ni: (*2*) 1 : 1, (*2'*) 1 : 1 (at double excess of total concentration), (*3*) 1 : 3, and (*4*) 1 : 5; Co : Cr: (*5*) 5 : 1, (*6*) 3 : 1, and (*7*) 1 : 1.

Figure 1 presents the dependences of the deposition rate V_d on the anode current density I_a for deposition of cobalt(III) oxide from a sulfate solution without additives and in the presence of nickel(II) and chromium(III) ions at different ratios of the component concentrations (henceforth Co : M), with all other conditions being the same. A common feature of all the dependences is that V_d gradually increases with I_a to a certain limiting value and then tends to decrease slowly. The extremal points of the dependences are shifted to higher I_a values in the interval 15–25 mA cm^{-2} with increasing relative content of the alloying component in solution. In the same order decrease the V_d values—from 4.7 mg cm^{-2} h^{-1} for cobalt(III) oxide to 1.9 mg cm^{-2} h^{-1} for the system Co–Ni at Co : M = 1 : 5. In the presence of chromium(III), the extrema of the V_d–I_a dependences lie at higher current densities (35–40 mA cm^{-2}), with their numerical values not exceeding 3.0 mg cm^{-2} h^{-1} even upon a fivefold decrease in the relative content of the alloying component in solution (Co : M = 5 : 1). At the same ratio Co : M = 1 : 1, the corresponding value for the system Co–Ni is 5 times that for the system Co–Cr.

Such a significant difference in character between the processes under consideration is due to their specific nature, governed by the kinetic and energy characteristics of the reactions occurring simultaneously at the anode. Only cobalt(III) oxide is deposited quantitatively under real conditions from aqueous solutions of cobalt salts in anodic oxidation of Co(II) in accordance with the reaction equation

$$2Co^{2+} + 3H_2O - 2e \rightarrow Co_2O_3 + 6H^+,\ E^0 = 1.83\ V\ [10]. \quad (1)$$

Under standard conditions, nickel does not form stable oxide compounds with oxidation level exceeding 2; nevertheless, it is thermodynamically possible that a nickel oxide Ni_2O_3 is formed by the reaction

$$2Ni^{2+} + 3H_2O - 2e \rightarrow Ni_2O_3 + 6H^+,\ E^0 = 1.75\ V\ [10]. \quad (2)$$

However, this reaction is impossible in an aqueous solution because of its complete suppression by oxygen being liberated and oxidation of the surface layers of the anode base. In contrast to the case of nickel(II), the transition $Cr^{3+} \rightarrow Cr^{6+}$ occurs under standard conditions via anodic oxidation of the corresponding salt from solution by the reaction

$$2Cr^{3+} + 7H_2O - 6e \rightarrow Cr_2O_7^{2-} + 14H^+,\ E^0 = 1.33\ V\ [10]. \quad (3)$$

Kinetically, formation of molecular oxide compounds of chromium (Cr_2O_3, CrO_3), with the simultaneous deposition of a compact coating on the anode surface, is complicated by the multiple-stage nature of such a process and the suppressing influence of the competing reaction of oxygen liberation. Quantitative deposition of nickel and chromium oxides under the conditions studied is enabled by codeposition on the anode in the form of an alloying phase in the binary oxide system when reactions (2) and (3) are combined with reaction (1). This is presumably favored by a decrease in energy expenditure in the overall anodic process, which may result from the simultaneously occurring reactions of interphase and interion interactions of the forming and reacting substances.

The effect of alloying components in the form of nickel(II) and chromium(III) salts in cobalt(II) sulfate solutions is manifested in a significant decrease in the rate of formation of the anode deposit, nearly independently of the total concentration of salts in solution for the Co–M systems under study. Even in the case of a twofold excess of the total concentration of the salts in a solution with Co : Ni = 1 : 1 with respect to the optimal concentration of cobalt(II) sulfite in an additive-free solution, the dependence V_d–I_a for the binary oxide Co–Ni runs below the corresponding dependence for cobalt(III) oxide (Fig. 1, curves *1* and *2'*). The decrease in the rate of the overall process, observed on raising the relative content of the alloy-

ing component in the system Co–Ni should be presumably attributed to an increase in the unproductive contribution of reaction (2) toward anodic polarization and to deceleration of cobalt(II) oxidation [reaction (3)]. Possibly, this mechanism occurs with higher probability in the presence of chromium(III) ions because of the less positive standard potential of reaction (1), compared with that for reaction (3). This results in that chromium(III) oxidation by reaction (1) at the anode may be faster than reaction (3), which leads to the corresponding deceleration of the process of cobalt(II) oxidation and to the formation of an anodic deposit. In the end, this causes an increase in the share of oxygen, liberated as a by-product, in the overall anodic process. This is clearly seen when analyzing the dependences of the current efficiency by anodic deposits on the current density for different Co : M ratios in solution (Table 1). In the system Co–Ni, the current efficiency (CE) is inversely proportional to the current density and concentration of the alloying component in solution, with the maximum CE in the I_a range studied not exceeding 20 wt % for cobalt(II) sulfate solution. This may indicate a key role of the concomitant reaction of oxygen liberation in the kinetics of the anodic processes under study. These phenomena are even more pronounced in the system Co–Cr, in which the yield of the anodic product is only noticeable at $I_a \geq 20$ mA cm^{-2} and remains nearly unchanged with increasing I_a. A probable reason for the independence of CE from the current density is a rise in the oxygen overvoltage with increasing amount of the oxide phase of chromium in the anodic deposit. With decreasing relative concentration of chromium(III) ions in solution, the CE increases; however, even at Co : Cr = 5 : 1 the CE values fluctuates within 2.3–2.5 wt %, which is apparently due to the increasing rate of oxygen liberation under the given conditions.

The presence of alloying oxide phases of nickel(II) and chromium(III) in the anodic deposits studied is confirmed by the results of X-ray diffraction analysis, which indicate that anodic materials deposited in electrolysis of cobalt(II) sulfate solutions in the presence

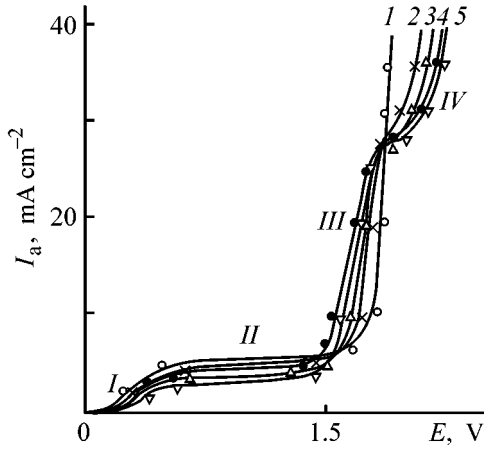

Fig. 4. I_a–E dependences for anodic processes of deposition of (*1*) cobalt(III) oxide from a sulfate solution and (*2*–*5*) oxide systems from solutions with varied Co : M concentration ratio. Temperature 85°C, pH 2.5. Co : Cr: (*2*) 5 : 1 and (*4*) 1 : 1; Co : Ni: (*3*) 1 : 1 and (*5*) 1 : 5.

of nickel(II) and chromium(III) ions are complex multiphase systems composed, under standard conditions, of thermodynamically stable oxide compounds: Co_2O_3, Co_3O_4, NiO, Ni_2O_3, Cr_2O_3, and CrO_3, and also some single-phase compounds of the type $M_xCo_{1-x}O_2$, where M = Ni, Co (Fig. 2). According to approximate estimate, the content of the alloying phase (wt %) in the deposits under study (Table 2) depends on the concentration of the corresponding component in solution and on the current density; however, even in the limiting cases, this content does not exceed 2.5 and 5 wt % for, respectively, the Co–Cr and Co–Ni systems.

The codeposition of the alloying phase markedly affects the kinetics of formation of the anodic deposit and formation of its structure. Comparison of the surface microreliefs and microstructures of the deposits under study (Fig. 3) indicates that their structure changes fundamentally with electrolysis conditions. Cobalt oxide (Fig. 3a) is mainly composed of rather coarse chaotically oriented crystalline grains of globular type. In the presence of nickel(II) and chromium(III) ions, the anodic deposits become finely crystalline, with a certain tendency toward formation of spheroidal blocks preserved in the first case (Fig. 3b) and a more uniform and ordered finely grained structure formed in the second (Fig. 3c). This is more clearly manifested after thermal treatment of deposits at 300°C, after which the binary oxides obtained show a pronounced crystalline structure, more ordered in the case of the Co–Cr binary system with a characteristic layer-by-layer growth of separate crystalline grains. The formation of structures of this kind is possibly due to interaction of the codeposited phases at the molecular level, accompanied by suppression of the growth of "base" cobalt(III) oxide crystals by the molecules of the alloying component.

The above dependences and relations, determined by the nature of the anodic processes under study, are in satisfactory agreement with the voltammetric characteristics measured at different Co : M concentration ratios and constant temperature and pH (Fig. 4). The I_a–E dependences presented can be divided into four regions (*I*–*IV*) defined by the nature of the processes under study at different polarizing currents. The portions of the curves in region *I* apparently reflect the oxygen liberation process, which follows from the coincidence of their position with the potential range of its liberation under the given conditions [10]. The shift of these portions to higher potentials corresponds to the increase in the concentration of the alloying components in solutions in the sequence Co–(Co–Cr)–(Co–Ni), which points to the important part played by the alloying components in the kinetics of the anodic process. In the given case, this is manifested in that the oxygen overvoltage grows in the same order, which is, possibly, a con-

sequence of the influence exerted by the total concentration background in region *I* with predominant effect of cobalt(II) and nickel(II) ions. This is partly indicated by the fact that the portion of the curve (in region *I*) (Fig. 4, curve *4*) for a solution with Co : Cr = 1 : 1 lies at more positive potentials than a similar portion (Fig. 4, curve *2*) for a solution with 5 times lower concentration of the chromium salt (Co : Cr = 5 : 1) and by a more pronounced shift of the potential in the presence of nickel(II) ions at the same Co : M concentration ratio.

The transition plateaus in region *II* are arranged in order of decreasing polarizing current in accordance with the increasing relative concentration of the alloying component in solution, which is in agreement with their above-mentioned influence on the polarization of the electrode process. The appearance and position of the curve portions in region *III* are mainly determined by the relative rates of cobalt(III) oxide deposition and oxygen liberation, with account of the influence exerted by concurrent reaction in which nickel(II) and chromium(III) ions are oxidized. Apparently, the stronger the influence exerted by these latter, the stronger the hindrance to the reaction of cobalt(II) oxidation, the larger the increase in the rate of oxygen liberation, and, consequently, the more pronounced the decrease in the polarization of the overall anodic process. This corresponds to the shift of the ascending portions of the curves in region *III* toward less positive potentials with increasing relative concentration of the second component in solution (Fig. 4). Simultaneously with an increase in the polarizing current, the concentrations of ions of the metals being codeposited and of the products of their oxidation in the near-electrode become higher, with the resulting limitation of the deposition rate of cobalt oxide. This, in the end, gives rise to conditions favorable for formation at the anode of alloying oxide phases simultaneously with that of cobalt(III) oxide. In this case, the anodic polarization is markedly enhanced, which, correspondingly, causes the subsequent inflection of the curves and their transition to the ascending portions of region *IV*. These latter characterize the process of joint formation of cobalt(III) oxide and associated alloying phases, with a simultaneous increase in the oxygen discharge overvoltage on a substrate with changing nature. The shift of the curve portions in region *IV* to positive potentials becomes more pronounced in accordance with the increasing relative concentration of ions of the alloying components in solution. For example, at the same concentration ratio Co : M = 1 : 1 in solution the process of binary oxide formation in the system Co–Ni (Fig. 4, curve *3*) is less polarized than that in the system Co–Cr (Fig. 4, curve *4*). Possibly, this is a consequence of both the more pronounced decrease in the rate of the overall process in the presence of chromium(III) ions and to increased oxygen evolution on the substrate formed in the given system. At the same time, a fivefold increase in the concentration of nickel(II) ions in solution (Co : Ni = 1 : 5) causes a shift of the corresponding portion of the curve (Fig. 4, curve *5*) to potentials with respect to the similar portion for a solution with Co : Cr = 1 : 1 (Fig. 4, curve *4*).

Thus, analysis of the I_a–E dependences for anodic deposition of cobalt(III) oxide in the presence of nickel(II) and chromium(III) ions under different electrolysis conditions supplements to a certain extent the data on the nature of the processes under study and allows refinement of the working parameters of electrolytic deposition of mixed oxide systems Co–Ni and Co–Cr from sulfate solutions.

CONCLUSIONS

(1) A study of the deposition conditions and the nature of the occurring anodic processes revealed that complex binary oxide systems Co–Ni and Co–Cr are formed at the anode in electrolytic deposition of cobalt(III) oxide in the presence of nickel(II) and chromium(III) ions.

(2) The most favorable conditions for quantitative formation at the anode of these oxide materials with prescribed characteristics are achieved at 80–85°C and pH 2.5–3.0 at salt concentration ratios in solution of, respectively, 1 : 1–1 : 5 and 5 : 1–1 : 1 and anode current densities of 10–25 and 25–35 mA cm^{-2} for the systems Co–Ni and Co–Cr.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Preparation of Anodized Aluminum for Electrodeposition of Metals (Co–Cu System) into Pores of Oxide

A. Timinskas, A. Cheshunene, M. Kurtinaitene, and V. Skominas

Institute of Chemistry, Vilnius, Lithuania

Received June 14, 2001; in final form, November 2001

Abstract—Conditions under which anodized aluminum is treated first in a dilute solution of phosphoric acid and then in a fluoroborate immersion solution in order to deposit a multilayer system of cobalt and copper in the pores in the oxide were studied.

One of promising newest directions in the electrochemistry of metals is deposition of various metals, including multilayer functional systems, from a single solution into pores of specially pretreated membranes [1–3].

The method of deposition of coatings with varied composition from a single solution is commonly used when it is necessary to obtain multilayer coatings with layers having different properties. Use of a single solution in deposition of such coatings markedly simplifies the technology employed. Nevertheless, this technique has a number of limitations and is rather complicated. First of all, it is necessary to use electroplating solutions with two or more kinds of discharging metal ions, and the deposition potentials of metals forming separate layers must differ to a sufficient extent. Electrodeposition of such multilayer functional systems into pores of specially pretreated membranes has been studied insufficiently, and, therefore, some problems concerning the mechanism of deposition processes are incompletely understood. One of such problems is, e.g., diffusion of discharging ions within narrow pores in membranes.

An attempt was made in the present study to use for metal electrodeposition a membrane of anodic aluminum oxide (ADOM brand), obtained in a solution of certain composition. This composition was chosen in such a way that anodizing could be done at voltages sufficiently high for obtaining pores with large diameter. These conditions were satisfied by a 0.045 M (0.4%) solution of oxalic acid at a voltage of 90 V. The anodizing was carried out for 80 min, and then the voltage was lowered stepwise by 10 V every 5 min. The anodizing process was terminated on reaching a voltage of 0.1 V.

Since the membrane thus obtained could not be separated from the aluminum base and the barrier layer formed at pore bottom had high ohmic resistance hindering the electrodeposition of metals, this barrier layer was to be removed. During the process of stepwise voltage lowering, the barrier layer thickness decreases somewhat; however, its complete removal is impossible [4]. It is proposed to use for this purpose a two-stage chemical treatment of anodized aluminum. The first stage involves treatment with a 0.08 M solution of phosphoric acid, and the second, with a fluoroborate immersion solution of composition (M): $Ni(BF_4)_2$ 0.87, $Zn(BF_4)_2$ 0.17, and NH_4BF_4 0.38; pH 4. This solution is commonly used to prepare the surface of aluminum and its alloys for electroplating [5, 6]. The process of barrier layer removal was monitored by changes in the potential of anodized aluminum in relation to duration of treatment in the immersion solution (Fig. 1). The barrier layer was considered removed when the potential of anodized aluminum reached a value of about –0.8 V, corresponding to a steady-state potential in treatment of air-oxidized aluminum with the immersion solution (the potentials are given relative to standard hydrogen electrode).

As it can be seen from Fig. 1, curve *1*, the potential shifts toward negative values on submerging anodized aluminum in the immersion solution. The change in potential is rather fast initially, but slows down in the course of time, with the potential of –0.8 V attained in 16–17 min. It is known that treatment

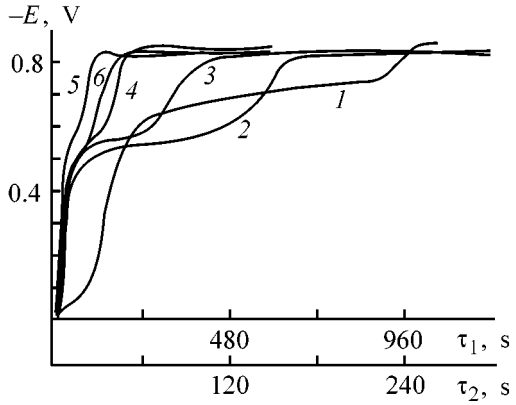

Fig. 1. Potential E of anodized aluminum vs. time of its exposure, (*1*) τ_1 and (*2–6*) τ_2, to immersion solution at different durations of the first stage of treatment. Time of treatment (h): (*1*) 0, (*2*) 0.5, (*3*) 1, (*4*) 2, (*5*) 3, and (*6*) 5.

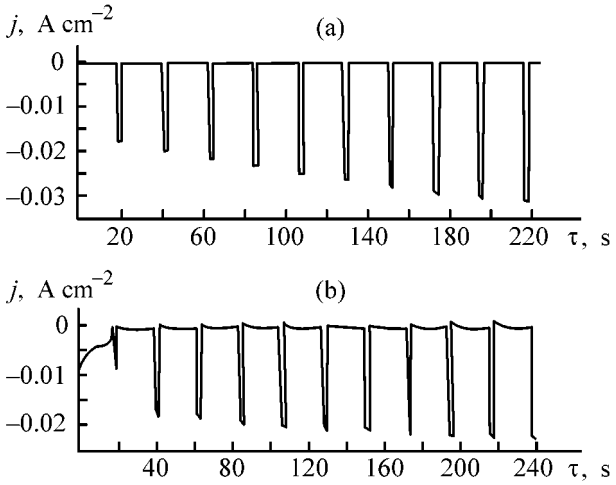

Fig. 2. Current density *j* of pulsed deposition of the Co–Cu system vs. time τ, measured on anodized aluminum in different pretreatment modes. Pulse duration (s): Cu 20, Co 2. Potential amplitude (V): Cu –0.2, Co –0.9. Treatment duration: first stage: (a) 0.5 and (b) 5 h; second stage: (a, b) 10 min.

of anodized aluminum in a phosphoric acid solution leads to widening of pores in aluminum oxide [7]. Therefore, prior to being treated in the immersion solution, anodized aluminum was additionally treated with a phosphoric acid solution. As shown by the experiments (Fig. 1, curves *2–5*), the additional treatment makes the changes in potential faster. For example, after treatment for 0.5 h in a phosphoric acid solution, the shift of potential toward negative values in the immersion solution is accelerated by approximately a factor of 5–6, with the potential reaching the value of –0.8 V in 3 min (Fig. 1, curve *2*). On raising the duration of aluminum treatment in phosphoric acid solution further, the potential of –0.8 V is reached in the immersion solution even faster (Fig. 1, curves *3–6*). However, treatment for more than 2 h does not affect significantly the rate of change in potential (Fig. 1, curves *4* and *5*). Thus, successive two-stage treatment of anodized aluminum in a phosphoric acid solution and immersion solution is a rather efficient way to activate pores in anodic aluminum oxide. This treatment leads to an increase in pore diameter and dissolution of the barrier layer formed at pore bottom.

A multilayer system Co–Cu was deposited into the pores of aluminum prepared by the method described. This was done using a solution of composition (M): $CoSO_4$ 0.5, $CuSO_4$ 0.01, and H_3BO_3 0.65. The electrodeposition was carried out by alternating two potentiostatic pulses. Copper was deposited during the first of these (0 to –0.4 V), and cobalt with minor amount of copper during the second (–0.7 to –0.9 V). The potentials chosen are commonly used in deposition of the given metals onto metal electrodes. The duration of separate pulses was selected depending on the required thickness of metal layer to be deposited. Since copper deposition occurs in the potential range employed at the limiting current, the copper layer thickness was only controlled by varying the deposition duration. The cobalt layer thickness could be controlled by varying the deposition duration or the potential. The results obtained in pulsed deposition demonstrate that the current of cobalt electrodeposition grows with increasing number of cycles on anodized aluminum not subjected to treatment in a phosphoric acid solution or treated in this solution for a relatively short period of time (Fig. 2a). This phenomenon virtually disappears with increasing time of exposure of anodized aluminum (for no less than 2 h) in a phosphoric acid solution. Typical variation of currents in separate pulses with the time of metal deposition is shown in Fig. 2b.

The electrodeposition of the Co–Cu system into pores of aluminum oxide differs from the deposition onto a copper electrode in that the deposition current on anodized aluminum is approximately 20% of the deposition current observed in deposition of these metals on a copper cathode under the identical conditions. Apparently, this is due to the fact that pores into which the metals are deposited occupy only a part of the entire surface area of anodized aluminum.

The area occupied by pores on the surface of anodized aluminum was evaluated. This was done using electron micrographs of the surface of anodized aluminum (Fig. 3a). Calculations show that, after the first stage of treatment of anodized aluminum for 3–5 h, the pore diameter is, on the average, 60 nm and

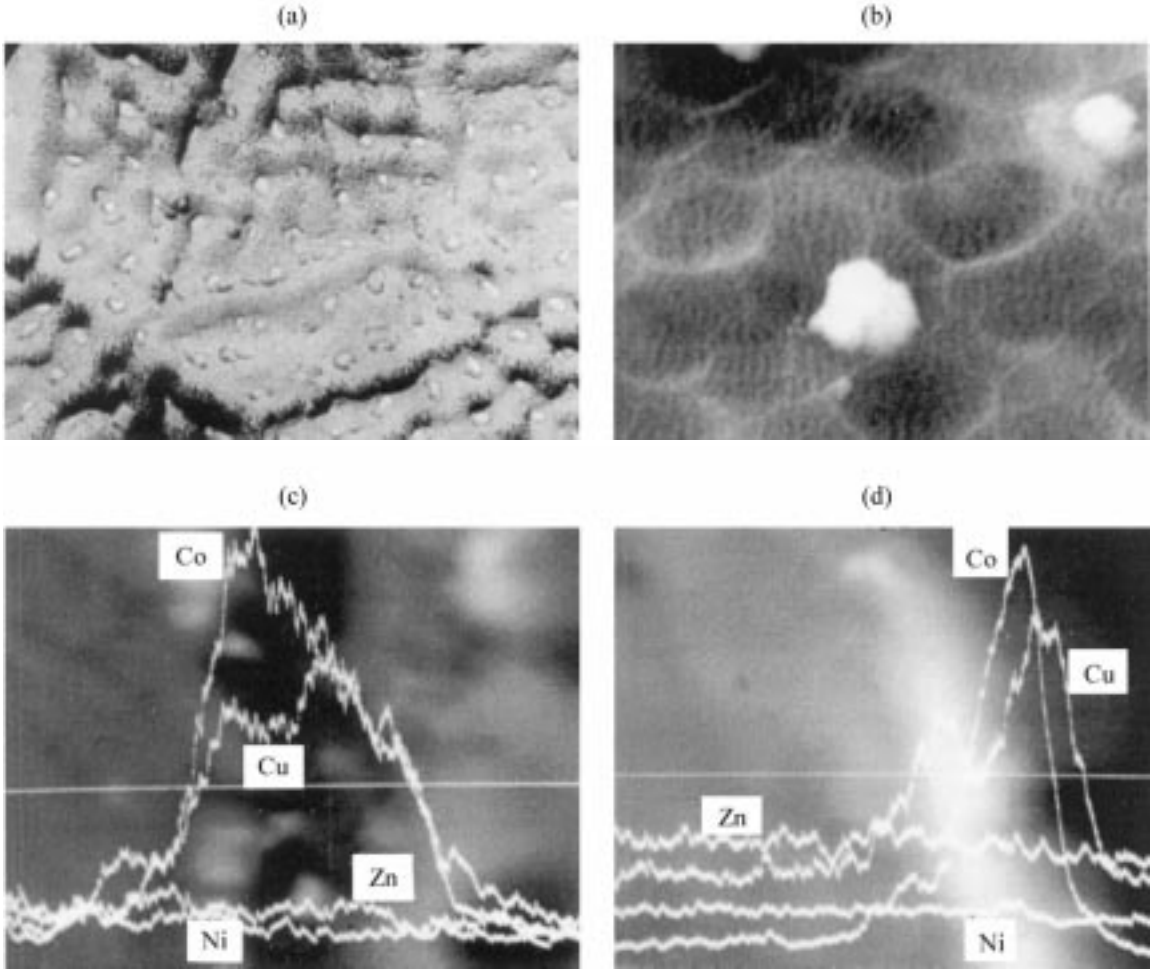

Fig. 3. Electron micrographs of the surface of anodized aluminum (a) before and (b) after deposition of the Co–Cu system and (c, d) shapes of signal from a cross-section of aluminum oxide containing the Co–Cu system, obtained in different pretreatment modes. Magnification: (a) 45000, (b) 10000, and (c, d) 5000. Treatment time: first stage (h): (a) 5, (b, c) 3, and (d) 0.5; second stage (min): (b, c) 10.

pores occupy 10–15% of the entire surface area. Comparison of the pore areas with the relative deposition currents on anodized aluminum and copper cathode shows that the current density in pores is 1.5–2.0 times that on the copper cathode. Possibly, this is associated with specific features of diffusion of the metal ions into a large number of small pores constituting a kind of a microelectrode system [8]. Under these conditions, the contribution of radial diffusion to the total diffusion flux commonly grows, resulting in a higher current density.

SEM studies demonstrated that, after the oxide pores are filled in a more prolonged deposition of the multilayer Co–Cu system, metals being deposited extend over the surface. This process is also accelerated by the higher deposition rate in separate places of the surface of anodized aluminum (Fig. 3b). It may be assumed that this is favored by defects of anodic oxide, formed in anodizing and subsequent treatment of aluminum.

The metals were determined in pores of anodic aluminum oxide by microprobe analysis. For this purpose, sections of anodized aluminum subjected to two-stage treatment with subsequent electrodeposition of the Co–Cu system were fabricated. As shown by the data obtained (Figs. 3c and 3d), Co and Cu are found in the oxide bulk, irrespective of the duration of treatment in a phosphoric acid solution. These metals are present in the bottom layer of the oxide.

The data obtained indicate that the two-stage treatment of anodized aluminum favor metal electrodeposition into the oxide pores at potentials close to those of electrodeposition of the same metals onto metal electrodes. This enables deposition of various metal systems possessing required functional properties into pores of anodized aluminum.

CONCLUSION

A study of the voltammetric characteristics of deposition and determination of the places of copper and cobalt localization in pores of anodic aluminum oxide demonstrated that two-stage treatment of anodized aluminum in a phosphoric acid solution and then in a fluoroborate immersion solution creates conditions favorable for metal deposition at pore bottom at potentials close to those commonly used in electrodeposition of these metals on metallic electrodes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of $K_2Cr_2O_7$ Addition on Anodic Dissolution of NiS in Acid Sulfate and Ammonia Electrolytes

M. I. Natorkhin

State Technical University, St. Petersburg, Russia

Received October 21, 1999; in final form, July 2001

Abstract—The depassivating effect of $K_2Cr_2O_7$ additions on the electrochemical dissolution of nickel sulfide in 0.5 M solutions of $CuSO_4$ and Na_2SO_4 and in 5.8 M NH_4OH was studied at 90°C.

The interest in studying the autoclave leaching of nonferrous metal sulfides remains rather intense [1, 2]. Electrochemical modeling of autoclave leaching is of considerable importance in these studies [3, 4]. It has been shown earlier [5] that the anodic dissolution of nickel sulfides in acid copper sulfate electrolytes rapidly decelerates in the course of time owing to the formation of a Cu_2S passivating film on the nickel sulfide surface. However, Cu_2S is known to be soluble in $FeCl_3$ and $K_2Cr_2O_7$ solutions, which is often used in analytical practice [6] and in industrial leaching of sulfides [7].

The aim of this study was to make an attempt to eliminate nickel sulfide passivation in $CuSO_4$ solutions by adding $K_2Cr_2O_7$ and to analyze the electrochemical behavior of nickel sulfide in chromium-containing electrolytes.

We choose NiS synthesized by the known procedure [8, 9] as an object of study. A working electrode was fabricated by soldering a nickel sulfide sample to a copper rod 2 mm in diameter in such a way that its working surface area was 1 cm^2. Backsides of NiS and copper rod were insulated with nitro lacquer. The working surface of the electrode was smoothed with no. 0 flint-paper and washed with alcohol and distilled water before experiments. Electrolytes were prepared using Na_2SO_4 (analytically pure), $CuSO_4 \cdot 5H_2O$ (chemically pure), NH_4OH (analytically pure), and H_2SO_4 (special-purity grade). As an additive we used $K_2Cr_2O_7$ (chemically pure).

Electrochemical experiments were carried out by a three-electrode scheme [10] in a YaES-1 electrochemical cell, using a PI-50-1.1 potentiostat and a PDP4-002 recording potentiometer. The cell temperature was maintained at 90 ± 0.5°C with a UTU-2/77 thermostat. Platinum wire was used as a counter electrode and saturated silver chloride electrode as a reference. All potentials are given relative to the standard hydrogen electrode.

Cyclic voltammograms (CVA) of NiS, obtained in a pure 0.5 M $CuSO_4$ (pH 2.1) solution and in a solution with $K_2Cr_2O_7$ additive, are shown in Fig. 1. It is seen that the passivation region corresponding to the forward CVA run (curve *3*) disappears as the

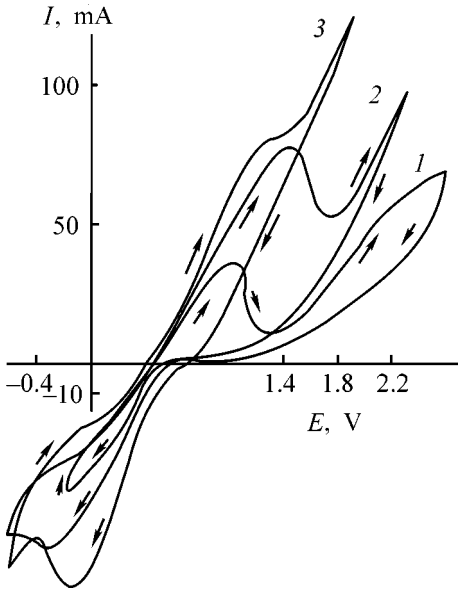

Fig. 1. Cyclic voltammograms obtained on NiS in (*1*) 0.5 M $CuSO_4$ solution (pH 2.1) and (*2*, *3*) the same solution with $K_2Cr_2O_7$ additions. dichromate concentration becomes higher. Making longer the exposure of the working electrode to 0.5 M $CuSO_4$ containing 30 g dm^{-3} of $K_2Cr_2O_7$ under potentials of 0.8–1.0 V results in the formation of a thin gray-black film with small bright specks. The dependence of the current on the duration of exposure under various potentials to a 0.5 M $CuSO_4$ solution containing 3.0 and 30 g dm^{-3} of $K_2Cr_2O_7$ is shown in the table.

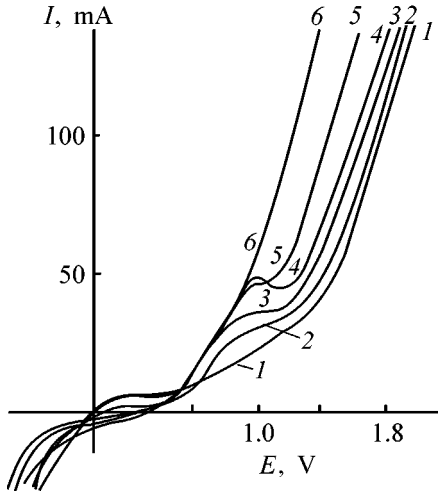

Fig. 2. Voltammetric curves obtained on NiS in (*1*) 0.5 M solution of Na_2SO_4 and (*2*–*6*) in the same solution with $K_2Cr_2O_7$ additive. $K_2Cr_2O_7$ concentration (g dm^{-3}): (*1*) 0, (*2*) 3, (*3*) 6, (*4*) 12, (*5*) 24, and (*6*) 48.

According to the data in the table, addition of $K_2Cr_2O_7$ makes itself evident even at low electrode potentials and $K_2Cr_2O_7$ concentrations. As the $K_2Cr_2O_7$ concentration increases, the dissolution of NiS becomes stable: the current remains almost constant in time.

Forward runs of CVA curves obtained on NiS in a pure 0.5 M Na_2SO_4 solution and in the same solution with $K_2Cr_2O_7$ additive are shown in Fig. 2. No passivation occurs in sulfate solutions containing no copper ions. Addition of $K_2Cr_2O_7$ makes the currents of NiS dissolution higher. However, at a $K_2Cr_2O_7$ concentration of 12 g dm^{-3} (curve *4*), a narrow passivation area appears in the forward CVA run. Its appearance is attributable to a secondary process of sulfur oxidation to sulfate ions, as in the case of anodic dissolution of a Fe–S alloy [11]. At high potassium dichromate concentrations, no sulfur was detected on the electrode surface and within the cell volume, with a slight inflection appearing in the polarization curves.

The stationary currents of NiS dissolution are shown as functions of potential and potassium dichromate concentration in a three-dimensional diagram (Fig. 3). It is necessary to point out that an increase in the $K_2Cr_2O_7$ concentration from 30 to 48 g dm^{-3} results in the appearance of a rather flat "top," and an intermediate "plateau" is observed in the concentration range 18–24 g dm^{-3}. Thus, minor addition of $K_2Cr_2O_7$ results in an increase in the rate of NiS dissolution in the Na_2SO_4 solution, whereas raising the potassium dichromate concentration to more than 30 g dm^{-3} is inexpedient. A slight decrease in the rate of NiS dissolution is observed at potassium dichro-

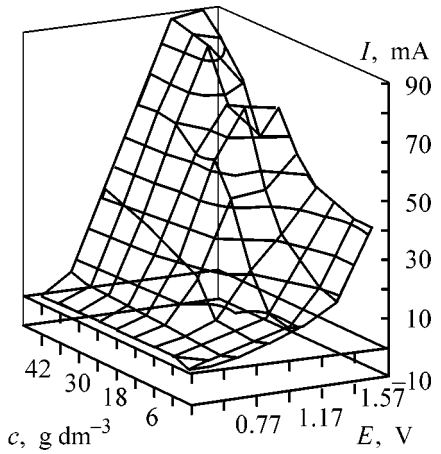

Fig. 3. Stationary NiS dissolution currents I vs. potential E and $K_2Cr_2O_7$ concentration c.

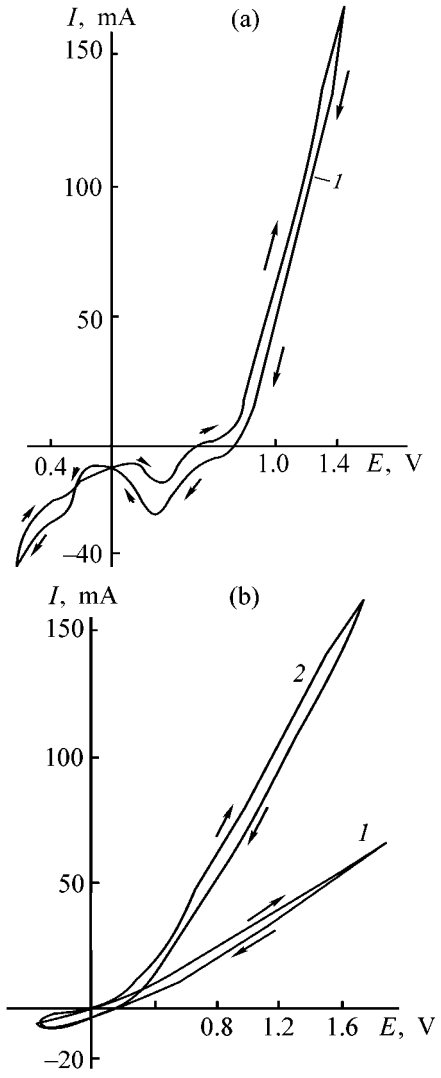

Fig. 4. Cyclic voltammograms obtained on NiS in (a) 0.5 M solution of $K_2Cr_2O_7$ and (b) 5.8 M solution of NH_4OH with $K_2Cr_2O_7$ additions. $K_2Cr_2O_7$ concentration (g dm^{-3}): (*1*) 6 and (*2*) 30.

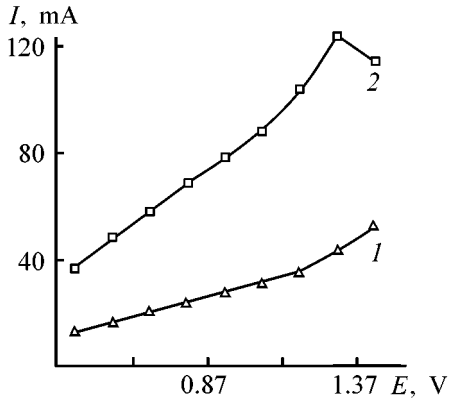

Fig. 5. Stationary currents *I* of NiS dissolution vs. the potential *E* in 5.8 M NH_4OH solution with $K_2Cr_2O_7$ additions. $K_2Cr_2O_7$ concentration (g dm^{-3}): (*1*) 6 and (*2*) 30.

mate concentrations of 42–48 g dm^{-3} at potentials from 1.37 to 1.57 V.

Since a passivation region appears in the sulfate–dichromate systems with increasing $K_2Cr_2O_7$ concentration, it was of interest to study the dissolution of NiS in dichromate solutions containing no sulfate ions. Figure 4 shows, a CVA curve for NiS in pure 0.5 M $K_2Cr_2O_7$. It is seen that no NiS passivation is observed at potentials in the range 1.0–1.4 V, and uniform dissolution occurs. Sulfur is completely oxidized to the sulfate ion in a 0.5 M $K_2Cr_2O_7$ solution.

Nickel sulfide dissolves most completely in ammonia solutions. To prepare the electrolytes, we used 10% (5.8 M) NH_4OH solution because it is sufficiently stable at 90°C [12, 13]. Nickel sulfide is insoluble in pure aqueous ammonia solutions under anodic polarization. Addition of $K_2Cr_2O_7$ makes higher the rate of NiS dissolution (Fig. 4b), no passivation region being observed in the CVA curve within the potential range under study. Raising the $K_2Cr_2O_7$ concentration leads to an increase in the rate of NiS dissolution. The currents of NiS dissolution remain almost unchanged in the course of time. The stationary currents are given for certain potentials in Fig. 5. It can be seen that NiS dissolution is decelerated at high potentials and high $K_2Cr_2O_7$ concentrations. No sulfur is formed, as is the case of 0.5 M $K_2Cr_2O_7$. The electrode surface retains its pure white-yellow color. Raising the ammonia concentration to 13.4 M at 58–60°C leads to solution boiling and cracking of the nickel sulfide surface. This cracking seems to be similar to corrosion cracking of brasses in aqueous ammonia solutions [14].

CONCLUSIONS

(1) Potassium dichromate depassivates the anodic dissolution of NiS in $CuSO_4$, Na_2SO_4, and NH_4OH solutions.

(2) The optimal concentration of potassium dichromate is in the range 6–30 g dm^{-3}. The sulfide sulfur completely oxidizes to SO_4^{2-} in NiS dissolution in solutions containing $K_2Cr_2O_7$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Inversion-Voltammetric Determination of Heavy Metal Ions on Electrodes Modified with Mono- and bis-*N*-Thiophosphoryl Thiourea

Abstract—A method is proposed for determining Ni^{2+}, Co^{2+}, Cu^{2+}, Cd^{2+}, and Pb^{2+} ions by inversion voltammetry on carbon-paste electrodes modified with *N*-diisopropoxythiophosphoryl-*N*'-phenyl thiourea and its derivatives: *N*,*N*'-bis-(diisopropoxythiophosphorylamidothiocarbonyl)-1,5-diamino-3-oxapentane, *N*,*N*'-bis-(diisopropoxythiophosphorylamidothiocarbonyl)-1,8-diamino-3,6-dioxaoctane and *N*,*N*'-bis-(diisopropoxythiophosphorylaminothiocarbonyl)-1,10-diaza-18-crown-6.

A promising approach to improvement of the efficiency of electrochemical methods for determining heavy metal ions uses chemically modified electrodes (ChME) [1]. The electrode surface can be modified by various methods. Immobilization of a modifier into a carbon-paste electrode (CPE) deserves special attention. Compared with other electrodes, the CPE has more developed working surface and shows enhanced adsorption of various organic and inorganic substances. This property is widely used for adsorption concentration, including that of metal ions, in inversion voltammetry (IVA) [1–3]. Combining ChME with a variety of IVA improves the sensitivity and selectivity of analysis. Carbon-paste electrodes modified with O-, N-, and S-containing compounds are commonly used in IVA for determining various metal ions [4]. The high sensitivity of the IVA method for determining metal ions with the use of ChME is ensured by combination of concentration in the form of a surface-bound complex with a modifier and subsequent quantitative electrochemical determination. Recently, macrocyclic compounds capable of forming complexes of the host–guest type have been used as organic reagents and CPE modifiers [5–7].

The expansion of the ChME range via immobilization of new organic reagents is of indubitable interest from the standpoint of development of IVA techniques. The presence in the molecule of an organic compound of several functional groups enabling different complexation mechanisms (chelate and guest–host) may improve the sensitivity of metal ion determination.

The present study is concerned with the possibility of determining a number of metal ions (Ni^{2+}, Co^{2+}, Cu^{2+}, Cd^{2+}, and Pb^{2+}) by inversion voltammetry with electrodes modified with *N*-diisopropoxythiophosphoryl-*N*'-phenyl thiourea, TPhTU, (**I**) and its crown-containing or open-chain analogs: *N*,*N*'-bis(diisopropoxythiophosphorylamidothiocarbonyl)-1,5-diamino-3-oxapentane (**II**), *N*,*N*'-bis(diisopropoxythiophosphorylamidothiocarbonyl)-1,8-diamino-3,6-dioxaoctane (**III**) and *N*,*N*'-bis(diisopropoxythiophosphorylaminothiocarbonyl)-1,10-diaza-18-crown-6 (**IV**):

* (v) Rate of potential sweep.

Purposeful selection of organic reagents as ChME modifiers requires a knowledge of the chemical properties of TPhTM and crown-containing and open-chain *N*-thiophosphoryl thioureas, and also of the electrochemical activity of the ligands themselves and metal complexes on their base.

N-Thiophosphorylated thioureas belong to NH acids since they contain two acceptor groups, thiocarbonyl and thiophosphoryl, at the nitrogen atom. These groups draw the electron density off nitrogen, which markedly raises the mobility of hydrogen atoms. To evaluate the acid–base properties, potentiometric titration was performed in a water–ethanol medium and the dissociation constants were calculated using Gran's method [8]. Crown-containing and open-chain bisthiophosphoryl thioureas are weak dihydric acids with close pK_1 and pK_2 values: pK_1 8.5 and pK_2 9.3 for compound **II** and pK_1 9.2 and pK_2 10.2 for compound **IV**. Comparison of the acid properties of crown-containing and open-chain bisthiophosphoryl thioureas with the acidity of their mono analogue [pK_a 8.1 for compound **I**] shows that the macrocycle and the ethylene oxide fragment exert no significant influence on the acidity of the proton in the NH group.

The compound TPhTM forms with heavy metal ions complexes of composition ML_2 with the formation of a chelate site MS_4 [9]. The bisthiophosphoryl thioureas under consideration contain several functional groups, which leads to formation of complexes with composition M_2L_2. An X-ray structural analysis revealed that two molecules of a bidentate ligand form binuclear complexes with metal atom [10]. Spectral data (IR, ^{31}P and ^{1}H NMR), also indicating the formation of an M_2L_2 complex with two chelate sites MS_4, were presented in [10]. The influence exerted by the structure of ligand molecules on the stability of the corresponding complexes was studied for the example of complexes with cobalt(II). The stability constants of the complexes were determined by redox potentiometric titration in acetone, using a sulfide–disulfide reversible system [11]. The step constants $\log\beta_1$ of cobalt complexation with compounds **I**, **IV**, and **II**, calculated using the Bjerrum method, are, respectively, 5.4, 5.8, and 6.2. The data obtained suggest that the stability of complexes with bisthiophosphoryl thioureas somewhat exceeds that of the mono analogue. Introduction of a macrocyclic fragment into the TPhTM molecule enhances the specificity of the metal–ligand interaction and, correspondingly, raise the stability of the forming complexes. The most stable is the complex with compound **II**. The difference in structure between mono- and bisthiophosphoryl thioureas, and also between their complexes with metals, affects the parameters of their voltammograms.

The compound TPhTM oxidizes on a graphite electrode to form two waves (Table 1). The first wave corresponds to reversible transfer of a single electron. The electrochemical reversibility of the first wave was confirmed using several known diagnostic criteria [wave slope, tan β, (~59 mV) in the classical voltammogram; difference of the potentials of the cathodic and anodic peaks, $\Delta E_{ca} \approx 59$ mV; ratio of cathodic to anodic peak currents in the cyclic voltammograms, I_c/I_a, close to unity]. As done in [12], it may be assumed that the thiocarbonyl group is oxidized in the first stage; at the second wave potentials, products of electron transfer are oxidized further. The voltammograms of crown-containing and open-chain derivatives are identical and largely coincide with that of their mono analogue (Table 1). Apparently, electrooxidation schemes of mono- and bisthiophosphoryl thioureas are the same. The observed insignificant shift of $E_{1/2}$ into the anodic range of potentials can be accounted for by steric factors, and the decrease in current, by an increase in their molecular weight.

Among the *N*-thiophosphoryl thioureas considered here, only TPhTM is reduced on the graphite electrode in acetone at potentials of about –1.4 V (Table 1). As follows from the data of cyclic voltammetry, the electrochemical signal corresponds to reversible single-electron transfer and, in accordance with the results of [12], the electrode process corresponds to reversible reduction of the thiocarbonyl

Table 2. Parameters of voltammograms of oxidation and reduction of Co(II), Ni(II), and Cd(II) complexes with mono and bis-*N*-thiophosphoryl thioureas on a graphite electrode in acetone ($c = 5 \times 10^{-4}$ M)

group. Bisthiophosphoryl thioureas are not reduced in the potential range in question (down to –1.8 V). Probably, the thiocarbonyl group in these compounds is reduced at more negative potentials. The difference in behavior between mono- and bisthiophosphoryl thioureas is due to the presence in the TPhTM molecule of a benzene nucleus whose π-electron-acceptor properties favor transfer of an electron to the ligand molecule and its delocalization. No effect of this kind is observed in the case of bisthioureas.

In electrooxidation of metal complexes, different numbers of waves can be observed, depending on the ligand nature. Table 2 presents parameters of voltammetric characteristics of metal complexes that could be isolated and whose structure could be studied [9, 10]. The results obtained in studying the electrochemical behavior of copper(II) complexes with mono- and bisthiophosphoryl thioureas were reported in [12]. According to cyclic voltammetry, the first wave is reversible and single-electron for Co(II) and

Ni(II) complexes with TPhTM. As a standard of single-electron transfer was used the oxidation current of a nickel complex with diethyl dithiocarbamate [13]. Commonly, Co(II) and Ni(II) complexes with a coordination site MS_4 are oxidized in the first stage to form particles in which metal is in the oxidation state +3. By analogy with the results of [13], it may be assumed that oxidation of Co(II) and Ni(II) complexes with TPhTM also follows the scheme

$$M(II)L_2 - e \rightleftarrows M(III)L_2.$$

Co(II) and Ni(II) complexes with bisthiophosphoryl thioureas, and also with their analogues, are oxidized in the first stage reversibly, with two electrons involved in the electrochemical reaction ($\tan\beta \approx 30$ mV) as a result of the binuclear structure of the complexes. The subsequent waves probably correspond to oxidation of the ligand bound in the complex, since their half-wave potentials are shifted to a more anodic region than the $E_{1/2}$ of the waves corresponding to oxidation of a free ligand. In electrooxidation of Cd(II) complexes with the compounds under consideration, waves are recorded in the range of potentials exceeding 1.0 V, in which the ligands themselves exhibit electrochemical activity. Therefore, by analogy with the electrochemical behavior of complexes with nontransition metals [13], it may be assumed that a coordinated ligand is involved in the reaction of electrochemical oxidation. All the reactions of electrooxidation of metal complexes are diffusion-controlled ($\Delta\log i/\Delta\log v \approx 0.5$).

In reduction of metal complexes with TPhTM, two waves are recorded in the voltammogram. The absence of waves in the anodic portions of the cyclic voltammograms of the complexes of Co(II), Ni(II), and Cd(II), considered here, in the first stage indicates that the reduction is irreversible. The first stage probably corresponds to a change in the metal oxidation state, M(II) $\rightarrow$ M(0), and the second manifests itself in the range of potentials corresponding to reduction of a free ligand and, therefore, is associated with reduction of the thiocarbonyl group. Since bisthiophosphorylated thioureas are electrochemically inactive in the working range of potentials, the electrochemical signals observed in voltammograms of metal complexes with these ligands can be attributed to a change in the oxidation state of the central atom in a complex. Comparison of wave heights for complexes with TPhTM and bisthiophosphoryl thioureas shows (Table 2) a twofold increase in signal intensity for the latter, which may be due to involvement in electron transport of two active centers (two central atoms in the M_2L_2 molecule), in contrast to a single center in the mono analogue. It should be noted that electroreduction of metal complexes with bisthiophosphoryl thioureas is complicated by adsorption, which manifests itself in that a strong adsorption peak is recorded. The rate constant of the electrode process ($\Delta\log i/\Delta\log v \approx 0.8$) points to an adsorption contribution to the limiting current value. In addition, voltammograms of the Cd(II) complex show an overvoltage of reduction of the supporting electrolyte, proceeding in this case at $E \approx -2.5$ V. For Co(II) and Ni(II) complexes, catalytic currents of hydrogen evolution are observed at $E > -1.4$ V, with the electrochemical signals having the form of narrow peaks exceeding in intensity 50–100-fold the level of the single-electron diffusion current and evolution of gas in the form of bubbles observed on the electrode surface.

The results obtained in studying the electrochemistry of complex compounds of Co(II) and Ni(II) with mono and bis-*N*-thiophosphoryl thioureas suggest that anodic voltammetry should be chosen for determining ions of these metals in view of the reversibility of the electron transfer, M(II) $\rightleftarrows$ M(III). In this case, inversion-voltammetric determination of Co^{2+} and Ni^{2+} ions involves concentration of metal ions on the surface of a modified electrode in the form of a complex with modifier under open-circuit conditions. As a supporting electrolyte for the concentration stage was chosen, to prevent formation of insoluble hydroxides, an ammonia buffer solution with pH 9–10. The electrochemical stage includes preliminary electrolysis at a potential of +0.7 V and potential sweep into the cathodic region. An inversion voltammogram shows peaks corresponding to reduction of Ni(III) and Co(III) complexes (Fig. 1a). The processes occurring at the electrode can be represented as (for ML_2):

$$M^{2+} + 2HL_{(ads)} \rightarrow M(II)L_{2(ads)} + 2H^+,$$

$$M(II)L_{2(ads)} - e \rightarrow M(III)L_{2(ads)},$$

$$M(III)L_{2(ads)} + e \rightarrow M(II)L_{2(ads)}.$$

The choice of the electrolysis potential E_e is based on the fact that the cathodic peak grows in intensity on shifting the potential into the anodic region to 0.7 V, and, upon further shift, oxidation of the ligand itself becomes possible, which enhances the chemical noise. The inversion current grows with increasing accumulation time t_a and reaches a limiting value after accumulation for 1 min.

It is undesirable to determine in a similar way Pb^{2+}, Cd^{2+}, and Cu^{2+} ions since they are oxidized at

more positive potentials and their signal may overlap with the signal associated with the oxidation of the ligand or supporting electrolyte.

Anodic voltammetry was chosen to determine Pb^{2+}, Cd^{2+}, and Cu^{2+} ions. The accumulation of these metal ions on a ChME was performed on the background of an acetate buffer solution with pH 4–5. A voltammogram was recorded after preliminary electrolysis at negative potentials. The analytical signal corresponds to oxidation of a metal to oxidation state (0). The metal is not bound in a complex and is adsorbed on the electrode surface after electrolysis of the surface-bound complex [12]. The processes occurring at the electrode can be represented (for ML_2) as:

$$M^{2+} + 2HL_{(ads)} \rightarrow M(II)L_{2(ads)} + 2H^+,$$
$$M(II)L_{2(ads)} + 2e \rightarrow M(0)_{(ads)} + 2L^-_{(ads)},$$
$$M(0)_{(ads)} - 2e \rightarrow M^{2+}.$$

Figure 1b shows an inversion voltammogram obtained in determining Pb^{2+}, Cd^{2+}, and Cu^{2+} on a CPE modified with compound **II**. The voltammogram was recorded in the ac mode under the following conditions: E_e = –1.0 V, time of electrolysis t_e = 20 s, potential sweep from –1.0 to 0.0 V, rate of potential sweep $v = 10^{-1}$ V s^{-1}.

The inversion currents are mainly determined by the stability of the forming complexes with the CPE modifier. It was found that for all the metal ions the compounds can be arranged in order of increasing inversion currents as **I** ≤ **IV** ≤ **II**, **III**. However, the differences between the currents are only slight. For example, the following currents were obtained in determining Ni^{2+} ions (μA): 96 (**I**), 100 (**IV**), and 105 (**II**), (**III**). Since use of bisthiophosphoryl thioureas as modifier does not lead to any significant increase in the inversion current, compared with the mono analogue, it may be concluded that complexes with approximately the same stability are formed, which is confirmed by the $\log \beta_1$ values presented above.

The choice of a supporting electrolyte in the accumulation stage is governed by the acid-base properties of ligands and metal ions. For example, in determining Pb^{2+}, Cd^{2+}, and Cu^{2+} ions, the maximum inversion currents were recorded in the case of accumulation in an acetate buffer solution in which these metals are in the form of aqua complexes, and in determining Co^{2+} and Ni^{2+} ions, in an ammonia buffer solution, in which the metal ions are in the form of soluble ammonia complexes. Changing the nature of the supporting electrolyte in the electrochemical stage

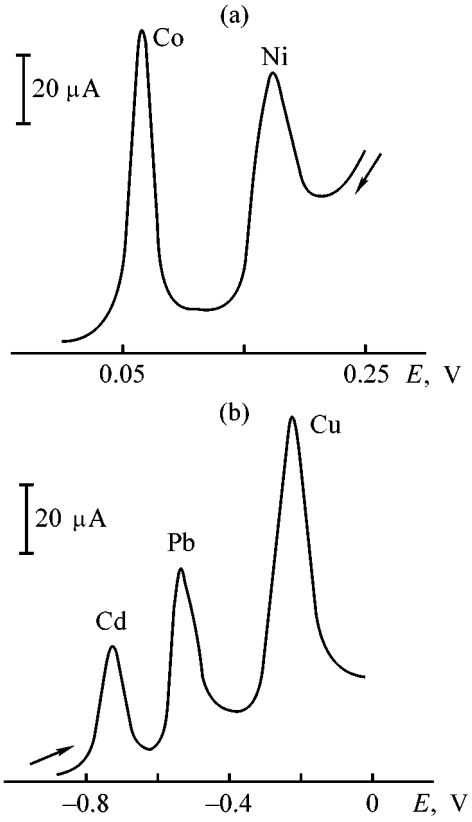

Fig. 1. Inversion voltammograms obtained on ChME with compound **II** on the background of a 0.1 M NaCl solution after stage of accumulation of (a) Co^{2+} and Ni^{2+} and (b) Pb^{2+}, Cd^{2+}, and Cu^{2+} ions. Concentration of metal ions 1×10^{-4} M. (*E*) Potential. Background buffer solution: (a) ammonia, pH 9.0; (b) acetate, pH 4.5.

leads to an increase in the degree of accumulation of any of the metals under consideration in the following order: $CH_3COO^- < ClO_4^- < NO_3^- < Br^- < Cl^-$. This is due to the fact that chloride anions are the best electron carriers among the anions in question.

The ability of compound **IV** to form not only chelate complexes with a coordination site MS_4, but also complexes of the guest–host type with a crown ether fragment manifested itself in inversion-voltammetric determination of Pb^{2+} ions. Changing the nature of a cation in the supporting electrolyte affects the analytical signal recorded. The inversion current obtained on the background of KCl (i = 195 μA) much exceeds that measured with NaCl as supporting electrolyte (i = 112 μA). In view of the competitive complexation, an inverse dependence would be expected, since the stability constants of metal complexes with the crown-compound diaza-18-crown-6 are larger in the case of potassium ions ($\log \beta_{NaL^+}$ = 0.1, $\log \beta_{KL^+}$ = 0.8) [5]. Probably, the effect of the electrolyte on the amplitude of the electrochemical signal

Table 3. Conditions of inversion-voltammetric determination of metal ions on CPE modified with compound **II**

Metal ion	Experimental conditions		E_p, V	c_{min}, M (mg l^{-1})	Maximum permissible concentration, mg l^{-1}
	accumulation stage	electrochemical stage			
Cu(II)	Acetate buffer solution, pH 4.5, t_a=60 s	0.1 M NaCl, E_e = –1.0 V, t_e = 20 s, E = –1.0…0.0 B	–0.15	3×10^{-8} (0.002)	0.1
Pb(II)			–0.56	9×10^{-9} (0.002)	0.1
Cd(II)			–0.75	5×10^{-8} (0.006)	0.01
Ni(II)	Ammonia buffer solution, pH 9.0, t_a = 60 s	0.1 M NaCl, E_e = –1.0 V, t_e = 20 s, E = 0.7–0.0 V	0.15	8×10^{-8} (0.005)	0.1
Co(II)			0.05	9×10^{-8} (0.005)	1.0

is due to the formation of a more stable heteronuclear complex with Pb^{2+} ions and alkali metal cation, by analogy with the data obtained previously for similar complexes with crown ethers [14].

A comparison of the voltammetric characteristics demonstrated that use of bisureas as CPE modifier does not lead to any significant increase in the current, compared with the case of TPhTM; however, bisthiophosphoryl thioureas are more chemically stable than their mono analogue and are electrochemically inert in a wider range of potentials, which depresses the chemical noise level. The best metrological performance ($S_r < 0.07$ in the concentration range studied) was observed with ChME based on compound **II**. A linear dependence of the peak current on the concentration of metal ions was observed in the range 1×10^{-7}–1×10^{-3} M.

Thus, inversion-voltammetric determination of the metal ions considered was done by oxidation or reduction of metal complexes adsorbed on ChME, after preliminary electrolysis. The conditions under which metal ions were determined by IVA are presented in Table 3. The results obtained demonstrate that the techniques proposed extend the range of determinable concentrations and make lower the detection limit c_{min}. The achieved c_{min} values are much lower than the maximum permissible concentrations (MPC).

EXPERIMENTAL

The procedure for determining heavy metal ions by inversion voltammetry includes the stages of concentration of metal ions in the form of a complex compound on the electrode surface and quantitative determination of the surface-bound complex by ac voltammetry. The metal accumulation was done from a solution in the presence of a supporting electrolyte under open-circuit conditions; the time of accumulation was chosen depending on the nature and concentration of a metal. Then the electrode was transferred into an electrochemical cell with another indifferent electrolyte for recording a voltammogram.

Voltammograms were recorded with a PU-1 polarograph, cyclic voltammograms were measured with a PI-50-1.1 potentiostat. A three-electrode cell was used in recording the voltammetric curves. As indicator, reference, and auxiliary electrodes served, respectively, a stationary glassy carbon electrode with apparent surface area of 0.01 cm^2 or modified CPE, saturated calomel electrode, and platinum wire.

The modified CPE was prepared from activated carbon, with Vaseline oil as binder and mono- or bisthiophosphoryl thiourea as modifier, taken in a 60 : 38 : 2 ratio. Chemically modified electrodes were prepared as described in [16]. The electrode surface was refreshed mechanically.

Compounds **I**–**IV** and their complexes with metals were synthesized by procedures described in [9–10]. Working solutions of mono- and bisthiophosphoryl thioureas under study and their complexes were prepared by dissolving their precisely weighed portions in a freshly distilled solvent.

Sets of metal ion solutions were prepared by diluting the initial standard solutions whose precise concentration was determined titrimetrically.

Acetone purified by the known methods [17] was used as solvent in studying the electrochemical properties. As indifferent electrolyte served a 0.1 M solution of $LiClO_4$ of chemically pure grade. Inversion voltammograms were recorded on the background of ammonia and acetate buffer solutions and on the background of NaCl, KCl, KNO_3, and Na_2SO_4 salts with concentration of 0.1–0.5 M.

Potentiometric measurements were carried out with a pH-150 pH meter. The pK values of the ligands were determined in an aqueous-alcoholic solution (80%)

with a glass electrode calibrated in aqueous-alcoholic solutions of HCl with known concentration [18]. The stability constants of metal complexes were found by measuring the potential of a platinum electrode in acetone at varied M : L ratio, using the following galvanic cell:

$$Pt \mid R'_2P(S)NHC(R'')S–SC(R'')HN(S)PR'_2,$$

$$R'_2P(S)NHC(S)R'', \ M^{2+}, \ LiClO_4 \mid KCl, \ AgCl \mid Ag.$$

CONCLUSIONS

(1) An inversion-voltammetric method for determining heavy metal ions (Ni^{2+}, Co^{2+}, Cu^{2+}, Cd^{2+}, and Pb^{2+}) on a carbon-paste electrode modified with mono- or bis-*N*-thiophosphoryl thioureas was developed.

(2) It was shown that conditions under which the electrochemical signal is recorded depend on the nature of metal. In the case of Ni^{2+} and Co^{2+} ions, peaks associated with reduction of complexes of metals in the oxidation state +3, obtained after preliminary electrolysis at E = 0.7 V, were used as analytical signals. In determining Pb^{2+}, Cd^{2+}, and Co^{2+} ions, peaks associated with oxidation of electrodeposited metal (0), obtained after electrolysis at E = –1.0 V of metal complex formed on a chemically modified electrode, were recorded.

(3) A comparison of the voltammetric characteristics demonstrated that use of a bisthiophosphoryl thiourea as modifier of the carbon-paste electrode does not lead to any significant increase in current, compared with the case of *N*- diisopropoxythiophosphoryl-*N*'-phenyl thiourea; however, in contrast to their mono analogue, bisthiophosphoryl thioureas are chemically more stable and electrochemically inert in a wider range of potentials. The best metrological performance was obtained on a chemically modified electrode based on *N*,*N*'-bis-(diisopropoxythiophosphoryl-amidothiocarbonyl)-1,5-diamino-3-oxapentane.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Solid-Contact Polymer Sensors Based on Composite Materials

A. V. Legin, S. M. Makarychev-Mikhailov, D. O. Kirsanov, and Yu. G. Vlasov

St. Petersburg State University, St. Petersburg, Russia

Received February 5, 2002

Abstract—Ammonium and nitrate polymer sensors with solid contact, based on composites formed by a mixture of a membrane cocktail with metallic silver and silver chloride, were developed and studied for the first time.

Beginning with the appearance of an analytical technique employing chemical sensors (electrodes), the researchers' attention has been attracted to improvement of the design of the existing sensors, especially in their practical use. A topical issue in applied problems and industrial analysis is use of entirely solid sensors without liquid filling typical of many polymer sensors. Using an entirely solid contact gives a number of advantages over the conventional liquid contact, e.g., possibility of simple miniaturization of sensors, extended temperature range of their operation, arbitrary spatial position of the electrode in measurements, prolonged shelf life, etc.

The basic requirements to the solid contact for ion-selective electrodes were formulated in [1]: existence of a fast reversible reaction in which the carrier type is changed at the interface between the membrane and the current lead (as a rule, the membrane exhibits ionic conduction, and the current lead, electronic type) absence of side processes at this interface and buffering of the contact zone with respect to the potential-determining ion.

Meeting these requirements must ensure stable and reproducible signal of a solid-contact sensor (electrode) for a long time. Such a solid contact was created and has been successfully functioning for glass and crystalline membranes [2], but in the case of polymer film membranes, attempts to create a reversible solid contact have encountered severe difficulties. The first proposed were the wire electrode with a coating [3] and selectrode [4]. These sensors, however, show a noticeable drift of the standard electrode potential, which is due to charge transfer blocking at the interface between the membrane and the current lead. Of interest among recent advances are solid contacts based on electrically conducting polymers (polythiophene, polypyrrole, polyaniline) [5–7]. Conducting polymers with electron or hole conduction are to ensure a change of the type of carrier in transfer across the interface between the membrane and the solid contact and, as a result, make the standard potential of the sensor stable. By practical application of this idea showed that electrodes fabricated from conducting polymers possess noticeable redox sensitivity and are characterized by drift of the standard potential.

The approach to fabrication of a solid contact, taken in this study, consists in using composites for creating at the internal interface (membrane|contact) a chemically stable gradient layer with mixed ionic and electronic conduction. This could reduce the drift of the standard potential and ensure stable and reproducible sensor signal during a long period of time.

The aim of this study was to develop solid-contact potentiometric sensors based on membranes of plasticized polyvinyl chloride (PVC), which are reversible with respect to ammonium and nitrate ions. These two kinds of sensors were chosen in view of their wide occurrence and multiple fields of application. However, the method proposed for obtaining a solid contact with the use of gradient layers can be used for other kinds of sensors. The present study is concerned with such working characteristics of sensors as sensitivity, long-term stability of the standard potential, selectivity coefficients, and redox sensitivity. The method of electrochemical impedance spectroscopy was applied to determine, for the example of ammonium sensors, the contribution of the solid contact to the total resistance of a membrane.

The properties of solid-contact sensors are compared with those of ion-selective electrodes with internal liquid filling.

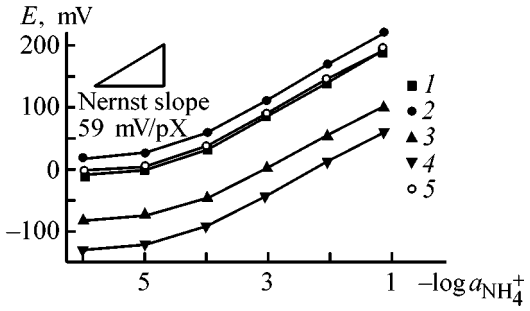

Fig. 1. Calibration plot for ammonium sensors. (*E*) Potential; the same for Fig. 4. (*1*, *2*) TK-1, (*3*, *4*) TK-2, and (*5*) standard electrode with liquid filling.

EXPERIMENTAL

The membranes studied were fabricated from reagents purchased from Fluka (Switzerland). All salts and organic solvents were of chemically pure grade. The solutions were prepared using twice-distilled water.

The composition of PVC-plasticized membranes for the ion-selective electrodes studied is given below:

Membrane	Component, wt %
NO_3^-	Tridodecylmethyl ammonium nitrate, 2 PVC, 33 Diethylhexyl cebacate, 65
NH_4^+	Nonactine, 1 Potassium tetra(*p*-chlorophenyl)borate, 0. PVC, 33 Diethylhexyl cebacate, 65.5

The sensor membranes were prepared by the standard procedure. Weighed portions of membrane components were placed in tetrahydrofuran (THF) and the mixture was stirred with a magnetic stirrer to complete dissolution. The cocktail obtained was poured in a weighing bottle with flat bottom and allowed to stand to complete evaporation of THF (~48 h). Discs 6 mm in diameter were cut out from the membrane obtained. A solid composite contact was deposited onto one side of the disc. The composite was composed either of the membrane material proper, dissolved in cyclohexanone, and metallic silver dispersed in this solution (henceforth TK-1) or of the membrane material with a mixture of Ag and AgCl dispersed in it (henceforth TK-2).

In depositing the composite material onto the membrane surface, a layer with mixed conduction, ionic because of the membrane formulation and electronic as a result of the presence of metallic silver, is formed. A current lead in the form of a copper wire was submerged in the formulation deposited onto the membrane. The assembly was left till complete evaporation of cyclohexanone, and then the membrane was glued into a plastic electrode case. Four sensors were fabricated for each of the two types of solid contacts and two conventional sensors with liquid filling. The numerical values of various electrode characteristics, reported in the present communication, are averaged over sensors of the same kind.

The potentiometric measurements were done with a galvanic cell

$$\mathrm{Cu}\,|\,\mathrm{Ag}\,|\,\underset{\downarrow}{\mathrm{AgCl,\ KCl_{sat}}}\,|\,\text{Solution under study}\,|\,\text{Membrane}\,|\,\text{Composite}\,|\,\mathrm{Cu}$$

The readings were taken with a multichannel electronic digital voltmeter with high input resistance. The stability and reproducibility of the standard potential, and also the sensitivity, were studied by periodically calibrating the sensors in solutions of salts of the potential-determining ion in the concentration range 10^{-6}–10^{-1} M. The selectivity coefficients were determined by the method of biionic potentials in 0.1 M solutions, in conformity with the IUPAC recommendations [8].

The redox sensitivity of the sensors was measured using a series of solutions containing the redox pair $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ in ratios of 100/1, 10/1, 1/1, 1/10, and 1/100, The solutions were prepared on the background of 0.01 M of the potential-determining ion in order to model the real conditions of sensor operation. A platinum electrode was also used to compare the redox response.

The electrochemical impedance of the ammonium membranes was measured with computer-controlled Agilent Technologies instruments. The measurements on the membranes under study were carried out in two symmetric cells. In the first of these (liquid contact), both sides of a membrane were in contact with a 0.01 M ammonium chloride solution, and silver electrodes served as working electrodes. In the second cell, the electric contact between a membrane and the external electric circuit was effected by the composite layers under study, deposited onto both sides of the membrane.

A typical calibration curve is shown for the example of ammonium sensors in Fig. 1. A study of the sensor sensitivity demonstrated that the slope of the electrode function is, on the average, 55.4 ± 0.6 mV/pX for NH_4^+ sensors and 53.6 ± 0.5 mV/pX for NO_3^- sensors, irrespective of the contact type. The results obtained in studying the long-term stability of the sensors are presented in Figs. 2a and 2b in the form of the dependence of the slope on the service life of a sensor. Ammonium sensors exhibited stable performance for 7 months, after which the slope decreased by 6–7 mV (Fig. 2a). Probably, this is due to washing-out and onset of decomposition of the main membrane-active substance, nonactine. The slopes of the electrode functions of nitrate sensors increased somewhat during the first 2–3 weeks and then remained constant within experimental error during the entire time of experiment, for about 8 months (Fig. 2b).

The standard sensor potential varied during this time as follows (Fig. 3). During the first 15–20 days after the sensor fabrication, a drift of E^0 toward more negative values by up to 40–50 mV was observed, which is probably due to permeation of electrolytes through the membrane and occurrence of stabilization processes at the interface between the membrane and the solid contact. Then the potentials leveled off and changed only slightly during more than 5 months. In the subsequent 2 months of experiment, a somewhat wider scatter of E^0 values was observed for ammonium electrodes and a certain tendency toward a decrease in the standard potential for nitrate sensors. Interestingly, the E^0 scatter within a series of three identical electrodes was rather wide, being as large as 80 mV. In the course of time, the standard potentials became closer within a series and the E^0 scatter between different sensors of the same composition was no more than 20 mV. Between calibration measurements, two sensors of each type were stored in a 0.01 M solution of the salt of the potential-determining ion, and two sensors of each type, in air. It was found that storage in air is preferable for ammonium sensors, which ensured higher reproducibility of electrode characteristics in a regular calibration measurement. Apparently, this is due to relatively intensive washing-out of nonactine and ionic additive from a membrane stored in the solution. For nitrate solid-contact sensors, no significant difference in behavior between electrodes stored in air and in solution was observed. This may be due to the higher lipophilicity of the tridodecylmethyl ammonium cation and, consequently, to lower extent of its washing-out from the membrane in solution.

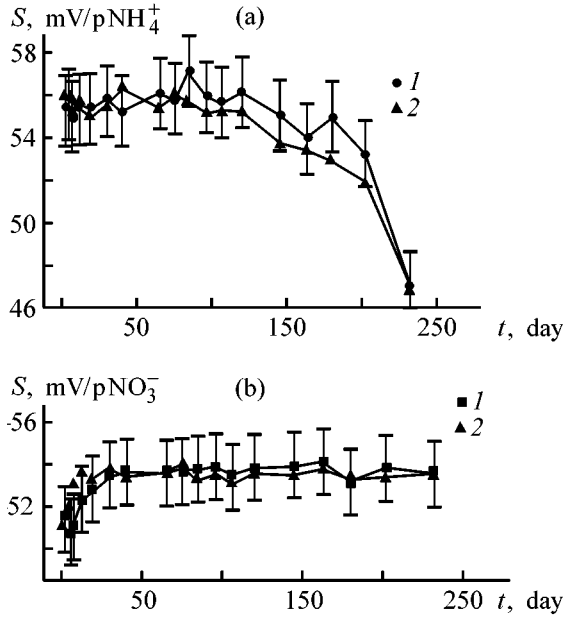

Fig. 2. Long-term stability of the slope S for (a) ammonium and (b) nitrate sensors. (t) Time; the same for Fig. 3. (*1*) TK-1 and (*2*) TK-2.

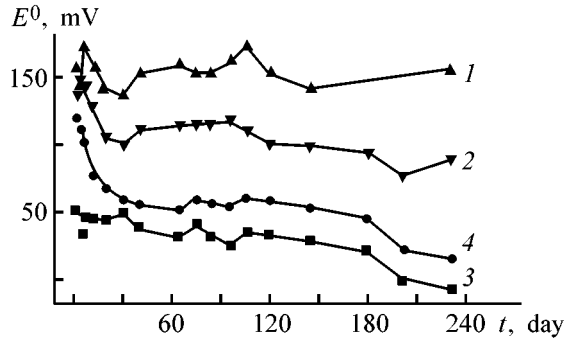

Fig. 3. Long-term stability of the standard potential E^0 of sensors. Sensor: (*1*, *2*) ammonium and (*3*, *4*) nitrate. (*1*, *3*) TK-1 and (*2*, *4*) TK-2.

The selectivity coefficients of sensors, found in this study, are independent of the type of contact, and the characteristics of the solid-contact sensors do not differ from those of the conventional electrodes with liquid filling. For ammonium sensors, $\log K^{pot}_{NO_3X}$ is -2.5 ± 0.1 for sodium ions, -0.83 ± 0.07 for potassium, -3.1 ± 0.2 for calcium, and -2.7 ± 0.2 for magnesium. For nitrate sensors, $\log K^{pot}_{NO_3X}$ is -1.73 ± 0.04 for the chloride ion, -0.55 ± 0.07 for the bromide ion, and -2.3 ± 0.1 for the sulfate ion. The selectivity coefficients of the solid sensors under study toward a number of interfering ions are in good agreement with the available published data, mainly concerning the sensors with liquid filling [9, 10].

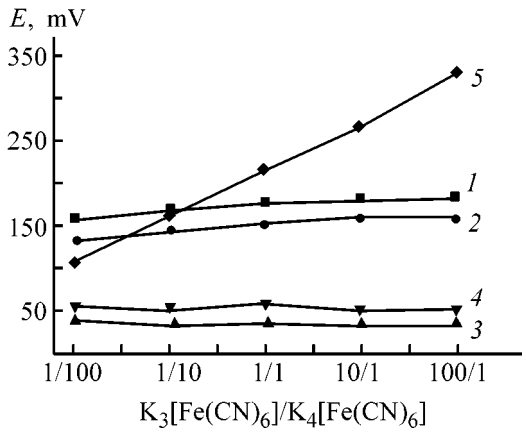

Fig. 4. Redox sensitivity of (*1*, *2*) nitrate sensors with different types of contact and (*3*, *4*) ammonium sensors in $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ solution. (*1*, *3*) TK-1, (*2*, *4*) TK-2, and (*5*) response of a platinum electrode—theoretical function with a slope of 59 mV/pX.

It can be seen from Fig. 4 that the sensors developed show no noticeable redox sensitivity. In this regard they compare favorably with electrodes based on conducting polymers, which expands the field of their possible application. The absence of redox sensitivity is due to the fact the change in the type and parameters of conduction and carriers mainly occurs in the composite gradient layer at the internal interface of the membrane and does not affect the bulk properties of the material and the properties of the outer surface of the membrane.

The conductivity of ammonium membranes with liquid contact and composite solid contacts of different compositions is as follows:

Contact	$-\log \sigma_{298}$
TK-1 (metallic silver dispersed in the membrane cocktail)	6.7 ± 0.1
TK-2 (mixture of silver chloride and metallic silver, dispersed in the membrane cocktail.	6.83 ± 0.05
Liquid contact (0.01 M NH_4Cl solution, Ag/AgCl electrode)	6.80 ± 0.08

The total conductivity indicates that the solid contact does not affect noticeably the electrical resistance of the membrane. The lack of a polarization branch in the impedance locus points to an unhindered transport of charge carriers (electrons) at the interface between the membrane and the solid contact. It may be concluded that the value observed is largely the bulk resistance of the membranes.

With technique employed for depositing a composite layer from an organic solvent, the surface of the sensor membrane itself is to some extent dissolved. This leads to the formation of a gradient layer between the membrane and the current lead. It is within this gradient layer that a gradual transition from mainly ionic conduction in the bulk of the membrane to purely electronic conduction in the metallic current lead occurs. The impedance of the gradient layer does not exceed the bulk resistance of the membrane, and the electron (or hole) conduction induced in this layer is sufficient for stable operation of the composite material and the sensor as a whole. Thus, the use of composite layers enables an efficient change of conduction type near the contact and yields polymer sensors with long service life and stable analytical characteristics.

CONCLUSIONS

(1) Polymer (polyvinyl chloride) chemical sensors (ammonium and nitrate) with solid contact based on composites consisting of a membrane cocktail proper and metallic silver or a mixture of silver and silver chloride, dispersed in the membrane cocktail, have been developed.

(2) The slope of the electrode function is 55.4 ± 0.6 mV/pX NH_4^+ sensors and 53.6 ± 0.5 mV/pX for NO_3^- sensors, irrespective of the type of contact.

(3) The slope remains unchanged for 8 months for nitrate sensors and 6 months for ammonium sensors. The standard potentials change during 15–20 days after sensor membrane preparation by 40–50 mV and then remain stable for more than half a year.

(4) The sensors obtained show no redox sensitivity. The solid contact based on the composites proposed does not increase the electrical resistance of the membranes, with the conductivity remaining at the level $-\log \sigma_{298} = 6.8 \pm 0.1$ for the ammonium sensors. The solid contact technology developed in the study enables easy miniaturization of sensors and can be recommended for use in, e.g., flow-injection analysis.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Conductivity of Contact Corrosion Layer at Interface between Current Lead and Active Paste in Lead Battery

Yu. B. Kamenev, E. I. Ostapenko, K. V. Kozerog, and Yu. V. Skachkov

Research Center, AOZT Elektrotyaga, St. Petersburg, Russia

Received October 4, 2001; in final form, March 2002

Abstract—The conductivity of the contact corrosion layer at the interface between the current lead and the active paste in a lead battery was studied.

The corrosion layer formed on the current lead surface plays an important part in battery operation. For example, it was shown in [1] that corrosive destruction of current leads may limit the service life of batteries to 1500 cycles; sag of the active paste, to 200–300 cycles; and low conductivity of the corrosion layer (CL) at the interface between the current lead and the active paste, to 20–30 cycles. Such a strong influence of the CL characteristics on the working capacity of a battery stems from the fact that, in the end, the entire current generated by the active paste passes through this layer. According to [1], the ratio between the surface area of the active paste and the contact surface area of the electrode is on the order of 10^6. Thus, any, even very small, change in the CL characteristics may produce a substantial effect. The most important characteristic of the CL is its electrical conductivity. It is known [2] that the critical value of the stoichiometric coefficient of the compound PbO_x is approximately 1.5. At lower values, an increase in the oxidation level leads to an insignificant rise in conductivity because of the higher defectiveness of the PbO crystal lattice as a result of its saturation with oxygen. At $x \approx 1.5$, the PbO lattice transforms into the PbO_2 lattice having higher electronic conductivity.

Another important characteristic is the rate of CL reduction ($PbO_2 \rightarrow PbO_x$) in discharge. Apparently, if this rate is high, the CL is rapidly reduced to a low-conducting oxide and the process of active paste discharge is markedly decelerated. If the rate of active paste reduction exceeds that of blocking layer formation, its utilization factor will be higher.

Design of low- or zero-maintenance batteries requires that their positive current leads should be made of alloys with low or zero content of antimony. This is due to the fact that antimony, characterized by relatively low overvoltage of hydrogen evolution, may accumulate at the negative electrode as a result of corrosion of the positive current lead and favor an increase in the gas evolution rate. The latter leads to limited applicability of the batteries in closed compartments not equipped with special ventilation systems and also makes more expensive the maintenance of batteries, involving their frequent filling-up with water.

It was shown in [3] that expenditure for maintenance of stationary batteries over their entire service life (10–15 years) is comparable with their original cost. In the case of sealed batteries, high rate of gas evolution is unacceptable because it leads to irreversible loss of capacity and shorter service life. However, lowering the content of antimony in the alloy impairs their mechanical and casting properties and markedly raises the CL resistance. Consequently, the content of antimony in the alloys can only be lowered in the case of their additional alloying.

The most promising alloying elements are Sn, As, and Ag. Such additives improve the mechanical characteristics of low- and zero-antimony alloys and also favor an increase in the conductivity of CL. The latter occurs for, at least, three reasons. First, these additives affect the structure of oxides in the CL through the formation of compounds of the type $Pb_{1-x}K_xO_2$, where K = Sb, Sn, As, Ag, characterized by increased electronic conductivity [4]. Second, they hinder PbO_2 reduction to poorly conducting PbO_x oxides with

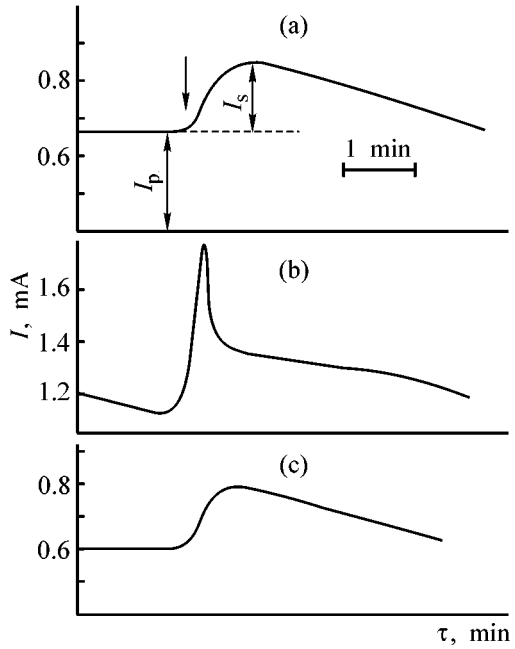

Fig. 1. *I*–τ curves obtained for (a) Pb–Sb–Sn and (b, c) Pb–Sb (5.5%) alloys. Time of keeping at a potential of 700 mV (min): (a, b) 3 and (c) 180.

$x < 1.5$ [4]. Finally, addition of tin or antimony favors formation in the CL of amorphous "gel zones" relieving the internal stresses in the layer, whose appearance is due to bulk changes in the transitions $PbO_2 \leftrightarrow PbO_x \leftrightarrow PbSO_4$. The build-up of stresses may lead to cracking of the CL and to an increase in its resistance because of the decreasing area of the conducting surface [1].

This study is concerned with the effect of tin additives on the conductivity of CLs formed on low- and zero-antimony alloys.

As objects of study served Pb–Sb (1.5–3.0%)–Sn 0.0–3.0% and Pb–Ca (0.07%)–Sn (0.5–1.5)% alloys and, for comparison, the widely used alloy Pb–Sb (5.5%) (named henceforth commercial).

Samples of the alloys under study were cast in the form of discs 20 mm in diameter. To obtain a mirror-smooth surface, ensuring a relatively constant specific surface area, the samples were dressed and compressed between two chromium-plated steel mirrors. After being deformed, the samples were annealed at 180°C. An area in the form of a circle 18 mm in diameter was selected on the mirror-smooth surface of a sample and the rest of the surface was coated with a nitrocellulose lacquer. Thus, all the samples had approximately the same surface area.

The conductivity of the oxide layer formed on the surface of test alloys was evaluated electrochemically. For this purpose, a sample was placed in a three-electrode thermostated cell containing 50 ml of sulfuric acid with density of 1.28 g cm^{-3}. The electrolyte was stirred with an MM2 magnetic stirrer. The electrolyte temperature of 30 ± 0.5°C was maintained with a UT-2 ultrathermostat. A mercury sulfate electrode was used as reference, and lead electrode, as auxiliary electrode. The samples were polarized with a PI-50-1 potentiostat with PR-8 programming unit. The current was recorded with a PDA-1 *X*–*Y* recorder.

An oxide film on the sample surface was formed in the potentiostatic mode in the potential range 1500–700 mV at a sweep rate of 1 mV s^{-1}. Then the electrode was kept for 3 min at the final sweep potential of 700 mV. Such a polarization ensured the formation of oxide films similar to those appearing on alloys of the positive current leads in deep discharge of batteries. After 3 min of potentiostatic polarization, 2 ml of a 0.02 M solution of $FeSO_4$ was introduced into the electrolyte under stirring, with a steplike increase in the anode current observed in the *I*–τ curve.

At a potential of 700 mV, the electrode is in passive state, to which corresponds a constant value of the passivation current I_p. Introduction of iron ions into the solution enables occurrence of the reaction $Fe^{2+} \rightarrow Fe^{3+} + e$ at the electrode. The rate of this reaction depends on the rate of electron transfer through the oxide film, i.e. is governed by the conductivity of this film. Thus, the conductivity of the oxide layer on the current lead surface can be judged from the amplitude of the step in the anode current, I_s, observed upon introduction of $FeSO_4$ into the solution, and the effect of the alloy composition on this conductivity can be studied. To eliminate the influence of the electrode area on the absolute value of the anode current step, the ratio of the currents, I_s/I_p, was used as a measure of the CL conductivity.

Figure 1a shows a typical *I*–τ curve obtained for Pb–Sb (1.5–3.0%)–Sn (1.5–3.0%) alloys. It can be seen that introduction of iron sulfate into the solution under stirring leads to the appearance of an anode current step. For the commercial alloy Pb–Sb (5.5%) the shape of the *I*–τ curve (Fig. 1b) is somewhat different from that for the curves obtained for low-antimony alloys. It can be seen from Fig. 1b that the passivation current does not become constant by the instant of $FeSO_4$ introduction into the solution, and a sharper peak of the anode current is observed after $FeSO_4$ introduction, with its subsequent rapid decrease. The occurrence of the peak in the anode current, which much exceeds the passivation current, indicates that addition of iron sulfate gives rise to an intensive ox-

idation process whose rate decreases abruptly, remaining approximately equal to the Fe(II) → Fe(III) process rate characteristic of ternary alloys.

The shape of the I–τ curve for the commercial alloy can be accounted for by the following mechanism of the occurring processes. It is known that the passivating film formed on lead–antimony alloys with high content of Sb is not so dense as that on lead [5]. Consequently, it would be expected that the passivating film formed upon polarization of the Pb–Sb (5.5%) electrode at the final sweep potential for 3 min has through pores allowing iron(II) ions to reach the alloy surface. In this case, the rate of the Fe(II) → Fe(III) process will be high because the hindrance to electron motion, present when this process occurs on the surface of oxide layers with denser structure, is lacking.

The accumulation of a considerable amount of Fe(III) ions in the CL pores leads to build up of positive charge in the solution, which must be compensated for by a counter flow of HSO_4^- anions. However, it is known that passivating layers formed at a potential of 700 mV have an outer sulfate layer creating a considerable diffusion resistance to motion of sulfate ions. To ensure the electroneutrality of the solution in pores, an electrophoretic flow of electrolyte, directed toward the solution, may appear. Possibly, the most mobile H^+ ions are the first to be removed from the pores. This leads to alkalization of the solution inside the pores and creates conditions for precipitation of a poorly soluble hydroxide $Fe(OH)_3$, which, in its turn, blocks the through pores and displaces the process of oxidation of iron(II) ions to the outer interface between metal oxide and the solution. In view of the limited electronic conductivity of PbO_x, the current decreases abruptly and the I_s value characterizes the conductivity of the given oxide.

The mechanism proposed is supported by the fact that, with the formation time of a passivating film on the Pb–Sb (5.5%) alloy increasing to 180 min, denser oxide layers are formed and no sharp anode current peak is observed in the I–τ curves after introduction of iron sulfate into the solution (Fig. 1c). In this case, the steady-state current is independent of the time of preliminary polarization.

Figure 2 (curve *1*) presents the dependence of the parameter I_s/I_p, characterizing the conductivity of the passivating layer, on the content of antimony in the binary alloy Pb–Sb. It follows from the figure that lowering the content of antimony in the Pb–Sb alloy leads to a pronounced decrease in the conductivity of oxide corrosion layers formed on the surface of these alloys. Such a decrease in the conductivity of

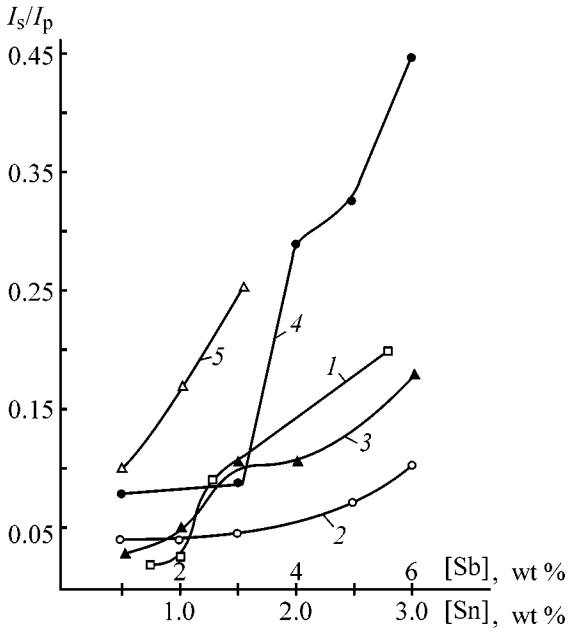

Fig. 2. I_s/I_p parameter vs. the content of (*1*) Sb and (*2–5*) Sn in Pb–Sb alloys. (I_p) Passivation current and (I_s) peak current. Alloy: (*1*) Pb–Sb, (*2*) Pb–Sb (1.5%), (*3*) Pb–Sb (2.0%), (*4*) Pb–Sb (2.5%), and (*5*) Pb–Ca (0.07%).

the contact layer makes necessary additional alloying of low-antimony alloys. Figure 2 (curves *2–4*) shows the dependences of the parameter I_s/I_p on tin content for low-antimony alloys (1.5–2.5% Sb). It can be seen that the dependences are rather complex, which is, in the first place, due to a change in the phase composition of the Pb–Sb alloys upon introduction of tin and to the corresponding change in the composition and structure of passivating films formed in oxidation. However, the principal, and practically important, feature is that addition of tin makes the electronic conductivity of oxide layers higher for all of the low-antimony alloys. For example, for a Pb–Sb (1.5%) alloy, the parameter I_s/I_p grows nearly twofold with the content of tin increasing from 0 to 3%. For the Pb–Sb (2.0%) and Pb–Sb (2.5%), the parameter in question grows approximately 6-fold. It is important to note that the Pb–Sb (2.5%)–Sn (2–3)% alloys have much higher conductivity than the commercial Pb–Sb (5.5%) alloy.

As already mentioned, the effect of tin on the conductivity of the corrosion layer formed on Pb–Sb alloys is due to its influence on the semiconducting properties of oxides. Tin ions are incorporated in the PbO_2 and PbO_x structure to form oxides of the spinel type, $Pb_{1-x}Sn_xO_2$, characterized by higher conductivity.

Moreover, it is known [4] that tin catalyzes the reactions:

$$PbO + (1 - x)O \rightarrow PbO_x,$$

$$PbO_x + (2 - x)O \rightarrow PbO_2,$$

which favors preservation of a high conductivity of oxides on the alloy surface in discharge of the positive active paste.

Figure 2 (curve *5*) shows the dependence of I_s/I_p on the content of tin for antimony-free Pb–Ca (0.07%) alloys. It can be seen that the parameter I_s/I_p grows with the content of tin increasing in the range 0.5–1.5%. At tin content exceeding 1%, the CL conductivity becomes higher than the conductivity of films formed on the commercial Pb–Sb (5.5%) alloy.

CONCLUSION

High CL conductivity can be achieved by introducing tin in amounts less than 2.0–2.5% for alloys containing less than 3% antimony and no less than 1.0% tin for antimony-free Pb–Ca (0.07%) alloys.

Abstract—The relationship between the catalytic activity of various manganese dioxide samples and the electrical characteristics of chemical power cells with cathode materials on their base was studied.

Chemical power cells (CPC) with cathode mass based on manganese dioxide find widest application. About 70–80% of the total amount of power cells manufactured are CPCs with manganese dioxide. This can be attributed to the fact that CPCs of this kind have an almost horizontal discharge curve, are efficient in a wide temperature range, and their cathode material is less expensive as compared with other oxide materials. In addition, manganese dioxide is stable in aqueous and organic electrolytes, i.e., the 1.5–3.0-V electrochemical systems operate on its basis.

CPCs predominantly employ electrolytic γ-manganese dioxide (EMD-2), since it is more active as compared with other modifications [1].

The wide use of this compound in CPCs brings forth the problem of raising its activity, in particular, via directional disordering of the manganese dioxide structure. All other conditions being the same, the most active compounds are those whose structure is characterized by a larger number of defects [2–4], nonstoichiometric compounds among them, e.g., MnO_x ($1.7 < x < 2$) [1].

The aim of this study was to determine how the electrical characteristics of CPCs depend on the catalytic activity of various samples of manganese dioxide. In this connection, we studied various samples of this compound, differing in the preparation procedures, for the electrochemical system manganese dioxide–zinc.

EXPERIMENTAL

We studied the following manganese dioxide samples: synthesized electrochemically: no. 1, from fluorine-containing electrolytes (EMD_u) [5]; no. 2, from sulfate electrolyte (EMD-2), Georgia, OST (All-Union Standard) 6-22-34–76; and chemically: no. 3 (CMD_p) at Pridneprovskii chemical plant, TU (Technical Specifications) 14312708, 174–94; and no.4 (CMD) of special-purity grade.

Chemical analysis was carried out by the known procedures. The total manganese was determined in the samples by redox titration with $KMnO_4$. The percentage of Mn^{4+} was estimated using oxalic acid. The content of manganese(II) was determined by the procedure given in [6]. The difference between the total manganese and the content of manganese (IV) [after correction for content of manganese(II)] corresponded to the experimental content of manganese(III) ions [7]. The data on the content of manganese ions were given in terms of MnO_2, Mn_2O_3, and MnO; the x value was calculated for all the samples from the content of differently charged manganese ions in a sample under study [8]:

$$x = \frac{2 + 1.5R}{1 + R}, \quad R = \frac{[Mn^{3+}]_s^1}{[Mn^{3+}]_s^1}.$$

We carried out electrochemical studies in 9 N aqueous solutions of analytically pure KOH at 18–20°C. Pellets of diameter 4 mm served as working electrodes.

The weighed portions for preparing cathode samples were chosen in such a way that the sample thickness was almost the same (0.55 ± 0.02 mm). The electric contact with the pellets was effected by pressing

a pellet with a constant force to a current lead made of 1Kh18N10T stainless steel. The case of this device was made of fluoroplastic.

Polarization measurements were carried out in a standard cell with a platinum auxiliary electrode of area 4 cm^2. The electrode potential was measured relative to a mercury oxide reference electrode in the same solution. The studies were performed on a PI-50-1 potentiostat with an LKD-4-003 XY self-recorder. Each measurement was done with a new pellet. The reproducibility of the experiments was not worse than 15–20 mV. The content of hydroxide groups was determined by thermogravimetry on an MOM derivatograph (Hungary) with an Al_2O_3 reference and heating in air within the range 20–600°C. To estimate the catalytic activity, we used the model reaction of hydrogen peroxide decomposition [9], readily occurring in aqueous medium at room temperature. We studied the hydrogen peroxide decomposition by gasometry. The volume of released oxygen was recalculated to the normal conditions. A weighed portion of a manganese dioxide sample under study was 10 mg, the concentration of hydrogen peroxide (4.92 M) was determined by titration with 0.1 N solution of potassium permanganate. The catalytic activity of the samples was evaluated by the reaction rate constant determined graphically in accordance with the equation

$$W = kc^n,$$

where W is the reaction rate, k is the rate constant, and n is the reaction order.

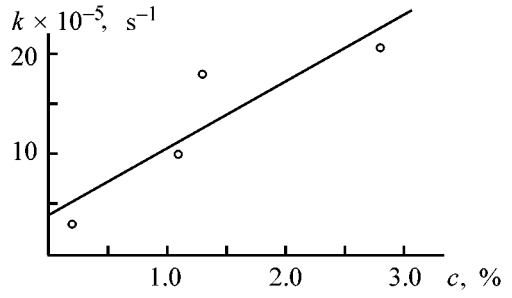

Fig. 1. Catalytic activity k in the model reaction of hydrogen peroxide decomposition vs. concentration c of hydroxy groups on the surface.

We determined the electrical characteristics on model CPCs of 1142 type. The cathode mass consisted of manganese dioxide (85%), an electrically conducting component (10%), and a binder (5%). We prepared the model CPCs by the standard procedure. The discharge characteristics were recorded at external loads of 5.6, 1.0, and 0.3 kΩ.

The data on the composition of the samples and their catalytic activity are given in Table 1. The reaction of hydrogen peroxide decomposition is first-order for all the samples under study. The highest catalytic activity is observed for the manganese dioxide sample obtained electrochemically from a fluorine-containing electrolyte, and the lowest, for the β-modification of manganese dioxide with stoichiometric composition (sample no. 4).

It is known that the catalytic activity is largely determined by the concentration of atomic defects (charge carriers) and their mobility [1]. This accounts for the observed relationship between the catalytic activity and the concentration of surface hydroxy groups, which fix defects of the Mn^{n+}/Mn^{n+1} type. In this case, differently charged Mn^{3+} and Mn^{4+} ions are present in the lattice at the same crystallographic positions [4, 6] (Fig. 1).

It should be noted that the total number of OH groups in the samples of electrochemically synthesized manganese dioxide, especially in sample no. 1 (5–7%), is much greater than that in sample no. 2 (2–3%). The catalytic activity of sample no. 1 is also higher. A correlation is observed between the catalytic

and electrochemical activities. We estimated the electrochemical activity by the current of manganese dioxide electrolytic reduction in the alkali medium at certain potentials (Table 2). The first portion of the *I–E* plot characterizes the electrolytic reduction of manganese dioxide on the electrode surface. Indeed, the rate of the process is in this case proportional to the catalytic activity of manganese dioxide (Fig. 2).

Sample nos. 1 and 3 are the most active. In order of increasing catalytic and electrochemical activity the samples under study can be arranged as follows: nos. 1, 3 > no. 2 > no. 4.

These data are in agreement with the electrochemical characteristics of real chemical power cells. Noteworthy is the possibility of achieving high current densities (5 mA cm^{-2}) in CPCs with cathode material based on manganese dioxide no. 1. The chemical power cell can operate under severe conditions, i.e., at a smoll external ohmic load resistance, which virtually does not occur with other samples and is impossible with sample no. 4.

It follows from these data that an increase in the number of defects in the crystal lattice of manganese dioxide makes higher the catalytic and electrochemical activity, which allows the rate of the electrochemical process to be raised essentially.

Sample no. 3, produced by Pridneprovskii chemical plant, is rather close to sample no. 1 in its characteristics. Since the chemical method of manganese dioxide synthesis is substantially less expensive than the electrochemical method, and the plant can produce manganese dioxide in any quantities (it works on the basis of the largest Nikopol deposit of MnO_2), we should pay attention to this sample. By modifying this product to a certain extent, we obtained a cathode material which is highly competitive with the best samples of manganese dioxide, including foreign analogs. After modification, its capacity exceeds that reported in the advertising brochures of the leading companies, being 105 mA h for the same cell type (for comparison, the capacity of LR 43 cells manufactured by Toshiba is 80 mA h, as also that of Varta cells).

The discharge characteristics of model Zn–MnO_2 cells are presented in Fig. 3. The curves for sample nos. 2 and 3 are measured after modification. Sample no.1 shows the maximal height of the discharge plateau and the longest discharge time because of its defective structure. The chemical modification as a method for disordering the structure further allowed, in accordance with the concept mentioned above, improvement of the characteristics of CPCs with cathodes made of samples nos. 2 and 3 by 15–20%.

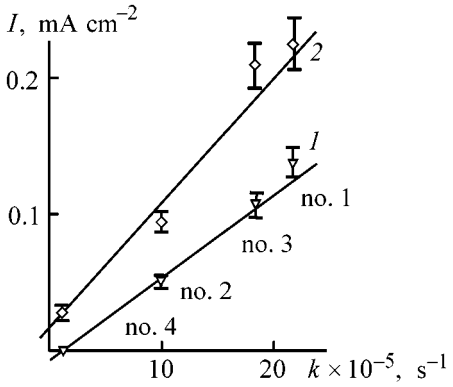

Fig. 2. Current *I* in the initial stage of electrolytic reduction vs. the catalytic activity *k* of manganese dioxide samples under study at $V = 20$ mV s^{-1}. Potential (mV): (*1*) +50 and (*2*) –50.

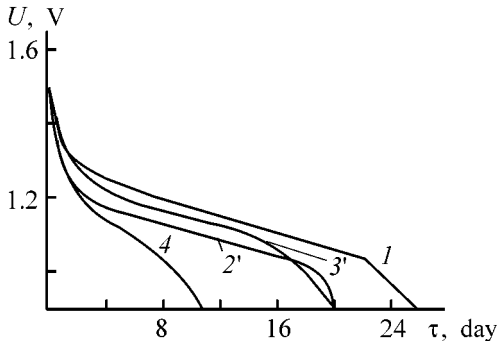

Fig. 3. Discharge characteristics of MnO_2–Zn cells at a load of 5.6 k for the manganese dioxide samples under study. (*U*) Voltage and (τ) time. Curves *1* and *4* correspond to, respectively, sample nos. 1 and 4; and *2'* and *3'*, to modified sample nos. 2 and 3.

CONCLUSIONS

(1) The catalytic activity of manganese dioxide can be used to characterize it as a starting material.

(2) A satisfactory correlation is observed between the catalytic and electrochemical activities of the cathode materials for chemical power cells.

(3) The expediency of using modified chemical manganese dioxide in chemical power cells based on the Zn–MnO_2 system is demonstrated.

Received December 19, 2001

Abstract—Studies of the electrolyte redistribution in a sealed nickel–cadmium battery with combined electrode design, fabricated using the separation fabric recommended for replacing the previously used and presently laid off perchlorovinyl fabric, were carried out.

A specific feature of the design of sealed nickel–cadmium batteries widely used in various fields of technology is the strict limitation on the amount of electrolyte and the use of a fabric woven from alkali-resistant polymer fibers as separator material. These design features ensure relatively free transport of oxygen evolved in charging at the surface of the cadmium electrode, with its subsequent ionization. In this connection, a number of requirements are imposed on the separator material, which ensure, together with good gas permeability, a uniform distribution of the electrolyte throughout the battery. Unfortunately, alkali-resistant polymer fibers that can be used to fabricate the separator are, as a rule, highly hydrophobic. One of the best separator materials is that based on perchlorovinyl fibers, which show good performance in batteries for various purposes. However, the termination, for environment protection reasons, of the industrial manufacture of perchlorovinyl fibers required that a new separator material with characteristics close to those of the perchlorovinyl fabric should be created. As a result of a series of experimental-technological studies [1], a polypropylene-based separator materials has been developed, whose characteristics are the closest to those of the previously manufactured separator based on perchlorovinyl fibers (Table 1), although the material developed is inferior in its hydrophilicity to the perchlorovinyl material.

This communication presents the results obtained in studying the electrolyte redistribution in batteries with separator made of polypropylene separator fabric of the 5254–96 brand [TU (Technical Specification) 8378-476-36545028–99) in the course of their prolonged operation.

EXPERIMENTAL

The investigation was performed on NKGK-90SA sealed nickel–cadmium batteries having, in addition to the working electrodes, also an auxiliary gas-diffusion oxygen electrode made of activated carbon and connected to the cadmium electrode. All the batteries were equipped with pressure sensors limiting the battery charging on an increase of the internal oxygen pressure to 1.5 atm.

The content of electrolyte in the separator was evaluated by measuring the content of alkali at four

* Originally, 380 g of electrolyte containing 102 g of alkali in terms of KOH was poured in the battery; mass of dry carbon 16 g.
** N is the number of cycles.

levels of the separator material along its height. Simultaneously, the content of alkali in the separator edge projecting beyond the electrode plates, in the spacer of separator fabric separating the plate unit from carbon, and in the carbon itself was monitored.

Balance calculations of the content of electrolyte in terms of potassium hydroxide were carried out using data obtained in analyzing the separator material. The analysis was made by the classical titrimetry, which allows simultaneous determination of the total alkali content and degree of carbonization [2].

The content of lithium hydroxide, which is also introduced into the electrolyte, was found by a conductometric method specially developed for this purpose [3].

Table 2 and Fig. 1 present data that allow complete characterization of battery parameters in different stages of operation.

To electrical parameters of the battery belong: discharge capacity C (A h) of the battery to a voltage of 1.0 V after its charging under control of pressure sensor; open-circuit voltage of a battery discharged to 1.0 V; and the ohmic component R of the internal resistance of 50%-charged battery.

As follows from the data obtained, intensive electrolyte redistribution between the separated plate unit and dry carbon occurs in the first cycles. In further operation, the electrolyte gradually flows down into the carbon, with, however, the relative redistribution of alkali over the height of the separator material remaining virtually unchanged, which indicates a constant electrolyte composition as regards the total alkali (in terms of KOH) (Fig. 2).

The process of carbonization is interrupted in those parts of the separator, which are not in contact with the electrodes by 25th cycle (Fig. 3). The content of carbonates in the separator material lying higher than the plate unit is markedly higher. The rise in carbonization of the electrolyte on the spacer terminates in further cycling, and the carbonization even decreases at the separator edge. In the main parts of the separator, which are in contact with the working electrodes, the increase in the degree of carbonization of the carbon and the separator occur in parallel. Simultaneously with the drainage of the electrolyte into carbon, accumulation of lithium compounds is ob-

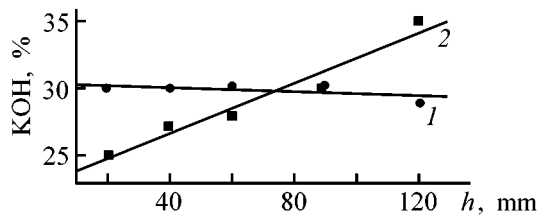

Fig. 2. Electrolyte distribution along the separator height h with respect to the total mass at different times of cycling. (KOH) Content of KOH relative to its total content. Number of cycles: (*1*) 25 and (*2*) 250.

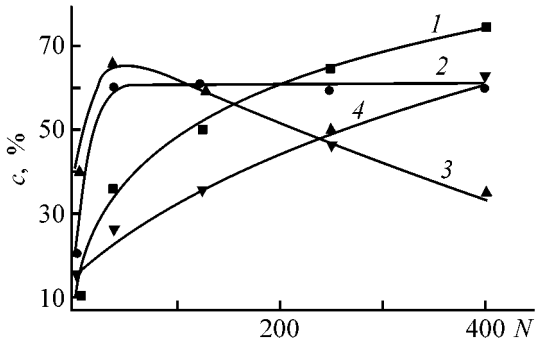

Fig. 3. Degree of electrolyte carbonization in different parts of a battery subjected to prolonged cycling. (*c*) Content of carbonates and (*N*) number of cycles. (*1*) Separator, (*2*) edging, (*3*) spacer, and (*4*) carbon.

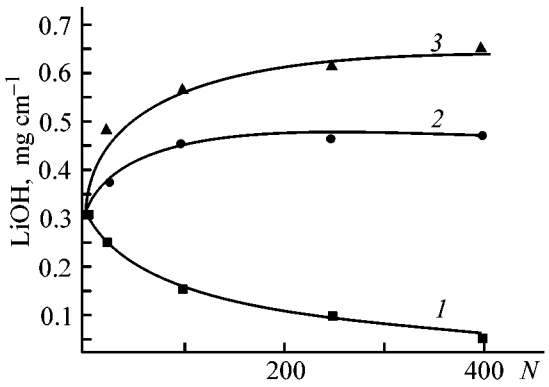

Fig. 4. LiOH content in different layers of the separator in prolonged cycling of a battery. (*N*) Number of cycles. (*1*) Top, (*2*) mid part, and (*3*) bottom.

served in the lower parts of the separator (Fig. 4). The mass and composition of the electrolyte in carbon, determined to within 5%, suggest that lithium compounds accumulate in the auxiliary electrode. Compared with LiOH content in the electrolyte filling the battery in its fabrication (~10% in terms of alkali), the content of LiOH in carbon increases dramatically.

The accumulation of lithium compounds in the bottom part of the separator and in the carbon is due to low solubility of lithium carbonate, which falls with increasing temperature. It is known that warming-up of a battery, associated with the intensive operation of the carbon electrode, is observed just in the bottom part of a battery.

The investigation performed indicates that prolonged operation of a sealed nickel–cadmium battery under terrestrial conditions leads to drainage, under the action of the gravity force, of the electrolyte in the separator and accumulation of the alkali in the carbon. Special additional studies of batteries exhibiting a dramatic decrease in capacity demonstrated that the critical mass of electrolyte in the separator, at which the internal resistance increases, is lower by approximately a factor of 10 than the initial value. For example, a test sample with 2 times smaller amount of electrolyte, which lost half the initial capacity by 130th cycle, had an internal resistance 10 times higher that the common value [73×10^{-4} Ω against $(6.5–7.5) \times 10^{-4}$]. Visual inspection demonstrated that the separator is virtually dry. At its edges, a large amount of salts (carbonates) is accumulated. An analysis revealed that the total content of alkali in the separator is, in terms of KOH, 2.6 g instead of 25 g (standard value for an efficiently operating battery; Table 2).

Under zero-gravity conditions, phenomena of this kind cannot be so pronounced. Presumably, this is the reason why the battery that operated at the Mir space station for five years retained both its initial electrical parameters and its chemical composition [4].

CONCLUSIONS

(1) Balance calculations of the electrolyte distribution in an NKGK sealed battery fabricated using a new separator material—woven polypropylene, were carried out.

(2) It was shown that the electrolyte mass is preserved (to within 5%), being only redistributed among the separator and carbon. Li^+ ions accumulate in carbon and lower parts of the separator in the form of a poorly soluble carbonate. The maximum extent of carbonization is observed at those parts of the separator, which are not in contact with the working plates.

(3) The electrolyte concentration (total alkali in terms of KOH) is not changed noticeably in prolonged operation of a battery.

CATALYSIS

Liquid-Phase Heterogeneous Oxidation of Hydroxypivalaldehyde with Oxygen in Alkaline Aqueous Solution in the Presence of Supported Palladium Catalyst

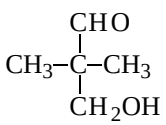
S. V. Zhizhkun, S. S. Chernaya, and S. R. Trusov

Riga Technical University, Riga, Latvia

Received July 10, 2001; in final form, February 2002

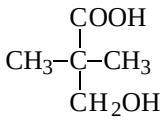
Abstract—The kinetics of a model reaction of hydroxypivalaldehyde oxidation with molecular oxygen in alkaline aqueous solution in the presence of 4% Pd/Al_2O_3 was studied with the aim of searching for promising heterogeneous catalysts for *D*-glucose oxidation.

Previously [1–3] we have shown that *D*-glucose can be rapidly and selectively oxidized with molecular oxygen in the presence of sodium nitrite in strongly acidic aqueous solutions. *D*-Gluconic or *D*-glucaric acid is formed, depending on the conditions of catalytic oxidation. Although the oxidation in the presence of sodium nitrite is highly selective, a search for catalysts allowing this process to be performed on the industrial scale is a topical problem. Oxidation of organic compounds on supported heterogeneous catalysts is widely used in practice. The use of these catalysts appreciably increases the oxidation selectivity [4]. It is known [5] that *D*-glucose derivatives can be oxidized to *D*-glucuronic acid in weakly alkaline solutions in the presence of a heterogeneous catalyst, 1.8% Pd/C. However, this process is slow and complex, especially in the stage of isolation of the oxidation products. There are no reports on heterogeneous catalytic oxidation of *D*-glucose to *D*-gluconic and *D*-glucaric acids. Our previous results [1–3, 6] and published data [5, 7] show that the kinetics of catalytic oxidation of *D*-glucose with oxygen is complex. However, the features of chemical transformations of reaction centers in these reactions can be revealed using similar model substrates. To simulate *D*-glucose oxidation, we studied in this work the oxidation of hydroxypivalaldehyde (HPA), which, as *D*-glucose, contains terminal hydroxy and aldehyde groups:

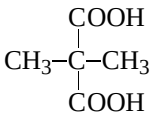


HPA

The presence of hydroxy and aldehyde groups in an HPA molecule suggests that its oxidation is similar to that of *D*-glucose. The absence of "internal" hydroxy groups (which are present in *D*-glucose) in HPA has no effect on the reactivity of the terminal groups being oxidized and does not complicate the kinetic study of the catalytic oxidation. The study of HPA oxidation was also stimulated by the fact that its oxidation products, hydroxypivalic acid (HPAc) and dimethylmalonic acid (DMMA)



HPAc



DMMA

are precursors of plasticizers of a new generation. For HPA oxidation we used the conventional industrial heterogeneous supported catalyst, 4% Pd/Al_2O_3. No data on the kinetics of HPA oxidation with oxygen in the presence of heterogeneous palladium catalysts have been reported. However, palladium catalysts are successfully used in oxidation of various alcohols and aldehydes [8–10].

EXPERIMENTAL

Kinetic experiments on liquid-phase catalytic oxidation of HPA were performed in a temperature-controlled gasometric unit in a closed volume under conditions providing kinetic control of the reaction. The oxidation was performed in alkaline aqueous solutions in a glass reactor magnetically stirred at 3000 rpm. The volume of the liquid phase of the system being

1070-4272/02/7506-0942 $27.00 © 2002 MAIK "Nauka/Interperiodica"

oxidized was 3 ml. The process was initiated by adding NaOH. The oxidation rate was monitored by the rates of oxygen uptake and accumulation of the oxidation products. The oxidation products were analyzed by GLC on a Tsvet-500 chromatograph equipped with a 5-m steel column, 2.2 mm i.d., packed with 5% OV-17 on Chromaton N-AW-DMCS. The column was heated to 60–150°C at a rate of 10 deg min^{-1}; the vaporizer temperature was 200°C. Nitrogen was the carrier gas.

Since these are no published data on use of 4% Pd/Al_2O_3 supported catalysts in HPA oxidation with molecular oxygen, we optimized the oxidation conditions by the Box-Wilson procedure [11]. We found that the most important parameters affecting the HPA oxidation were the amount of catalyst, temperature, and NaOH concentration. The experimental results were fitted by the equation

$$Y = 13.590 + 0.848X_1 + 1.768X_2 + 2.025X_3, \quad (1)$$

where Y is the volume (ml) of oxygen taken up within 30 min; X_1 is the catalyst concentration (wt %), $X_1 = \omega_{cat} \times 100\%$, where $\omega_{cat} = m_1/m_2$ is the content of heterogeneous catalyst (wt %), m_1 is the weight of 4% Pd/Al_2O_3 (g), and m_2 is the weight of the system being oxidized (g); X_2 is the NaOH concentration (M); and X_3 is temperature (K).

A kinetic study of the catalytic oxidation of HPA was performed under conditions optimized by experimental design. The concentrations of HPA and NaOH were varied from 0.2 to 1.2 and 0 to 1.2 M, respectively; T = 293–323 K; P_{O_2} = 0.21–1 atm; $\omega_{cat} = (0.1–1.8) \times 10^{-2}$ wt %. The total pressure in the system was maintained constant (1 atm).

As determined by both gas volumetric analysis and GLC, the HPA oxidation occurs in two consecutive steps. The first step is formation of hydroxypivalic acid by the reaction

$$2C(CH_3)_2(CH_2OH)(CHO) + O_2 \xrightarrow[NaOH]{4\%\ Pd/Al_2O_3} 2C(CH_3)_2(CH_2OH)(CHOH). \quad (I)$$

Hydroxypivalic acid is oxidized further to dimethylmalonic acid

$$C(CH_3)_2(COOH)(CH_2OH) + O_2 \xrightarrow[NaOH]{4\%\ Pd/Al_2O_3} C(CH_3)_2(COOH)_2 + H_2O. \quad (II)$$

This step obviously involves formation of dimethylmalonic acid monoaldehyde. However, this reaction is too fast for the aldehyde to be detected in the oxidation products.

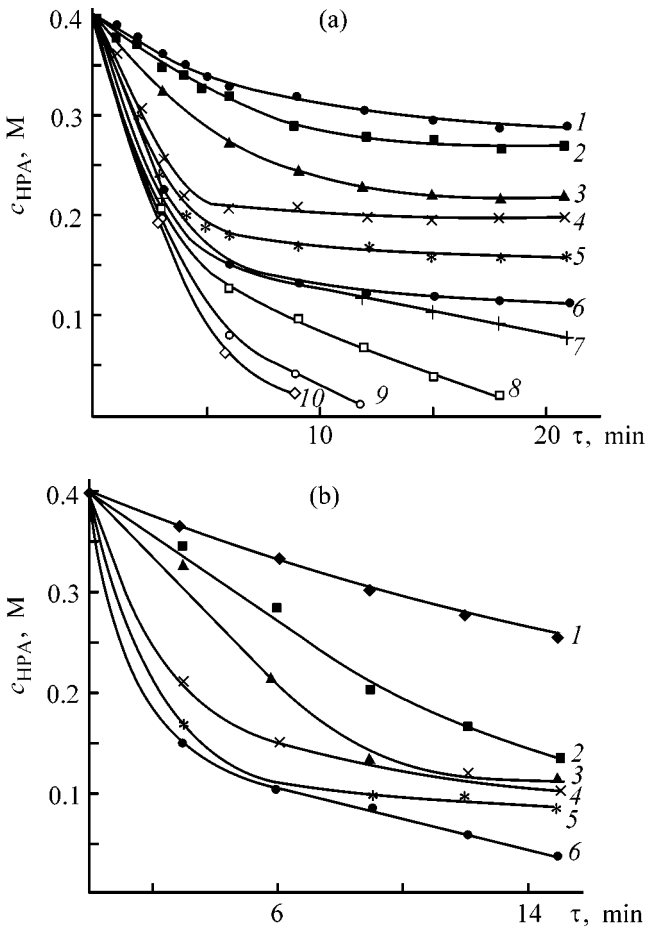


Fig. 1. Kinetic curves of HPA oxidation with oxygen: (a) at weight fraction of the catalyst $\omega_{cat} \times 10^2$: (*1*) 0.1, (*2*) 0.2, (*3*) 0.4, (*4*) 0.6, (*5*) 0.7, (*6*) 0.8, (*7*) 1.0, (*8*) 1.2, (*9*) 1.5, and (*10*) 1.8, T = 313 K; (b) (*1*) at 293, (*2*) 303, (*3*) 308, (*4*) 313, (*5*) 318, and (*6*) 323 K, $\omega_{cat} = 1 \times 10^{-2}$. Initial HPA and NaOH concentration 0.4 and 0.7 M, respectively, p_{O_2} = 1 atm.

In this work, we studied in detail the kinetics of the first step of HPA oxidation [reaction (I)]. All results of gas-volumetric measurements were recalculated in accordance with the stoichiometry of reaction (I) to the current HPA concentration c_{HPA} (M).

A mathematical treatment of the kinetic data showed that the reaction is first-order with respect to HPA in the whole range of HPA concentrations, i.e., at ω_{cat} = const

$$W = k_1 c_{HPA}, \quad (2)$$

$$k_1 = k_2 p_{O_2}, \quad (3)$$

where W is the rate of HPA oxidation (mol l^{-1} s^{-1}), and k_1 and k_2 are the rate constants of oxidation (s^{-1}).

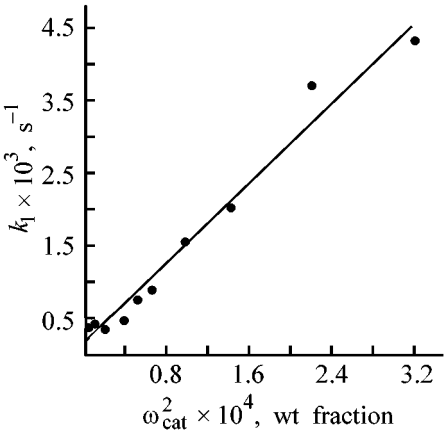

Fig. 2. Rate constant k_1 vs. the initial content of the catalyst, ω_{cat}. T = 313 K and p_{O_2} = 1 atm.

Figures 1a and 1b show how the rate of catalytic oxidation of HPA with oxygen depends on the catalyst content and temperature, respectively. We found that, under the above conditions, HPA oxidation starts at NaOH concentration of 0.3 M and higher. The results of a treatment of the kinetic data on HPA oxidation with oxygen in the presence of 4% Pd/Al_2O_3 are presented in the table.

These data show that at $c_{NaOH} \geq 0.3$ M and p_{O_2} = 1 atm.

$$\frac{\partial k_1}{\partial c_{NaOH}} = 0; \quad \frac{\partial k_1}{\partial \omega_{cat}}, \frac{\partial k_1}{\partial T} > 0. \tag{4}$$

The dependence of the oxidation rate on the catalyst content is shown in Fig. 2. The results presented in Fig. 2 and the table can be described by the equation

$$k = a + b\omega_{cat}^2, \tag{5}$$

where a and b are constants equal to 0.17×10^{-3} and 1.35×10^{-3} s^{-1}, respectively.

As seen from Eq. (5), the reaction is second-order with respect to the content of 4% Pd/Al_2O_3 supported heterogeneous catalysts.

A mathematical treatment of the temperature dependence of the rate constant of catalytic oxidation at $\omega_{cat} = 1 \times 10^2$, c_{NaOH} = 0.7 M, and p_{O_2} = 1 atm gave the following Arrhenius equation:

$$k_1 = 1.2 \times 10^8 \exp(-66\,510/RT), \tag{6}$$

with activation energy of the process equal to 66 510 J mol^{-1}.

On the basis of the above relationships, the kinetic equation for W (mol l^{-1} s^{-1}) of HPA oxidation to hydroxypivalic acid in the presence of 4% Pd/Al_2O_3 in alkaline aqueous solution ($c_{NaOH} \geq 0.3$ M) can be described by the equation

$$W = kc_{HPA}p_{O_2}\omega_{cat}^2. \tag{7}$$

It is known [12] that liquid-phase oxidation of hydrocarbons with molecular oxygen in the presence of heterogeneous supported catalysts may involve the step of oxygen activation by the reaction

$$S...S + O_2 \longrightarrow [S–S...O_2^{\delta-}], \tag{III}$$

where S is a catalyst.

Since water is a polar electron-donor solvent, it favors charge transfer to an electron-acceptor oxygen molecule when both are sorbed on the catalyst surface [13]:

$$H_2O \overset{\delta^+}{—} S \overset{\delta^-}{—} O_2.$$

As a result, molecular oxygen is intensively activated, with generation of radicals by a heterogeneous reaction, which do not escape into the liquid phase. As a results, nonchain intraspheric or purely heterogeneous selective catalytic oxidation occurs. Clearly, the mechanism of HPA oxidation with molecular oxygen in the presence of 4% Pd/Al_2O_3 is similar, which

is confirmed by the experimental dependence (7). The features of HPA oxidation with oxygen in the presence of 4% Pd/Al_2O_3 suggest that the kinetics of *D*-glucose oxidation under similar conditions will be similar. The process will also occur in two steps. In the first step, formation of *D*-gluconic acid is possible, which will be further oxidized to *D*-glucaric acid.

CONCLUSIONS

(1) A kinetic study of liquid-phase oxidation of hydroxypivalaldehyde with molecular oxygen in the presence of a heterogeneous catalyst, 4% Pd/Al_2O_3, showed that the oxidation occurs in two steps. Hydroxypivalic acid formed in the first step is oxidized to dimethylmalonic acid in the second step.

(2) A kinetic equation of hydroxypivalaldehyde oxidation to hydroxypivalic acid was derived. The activation energy of this process was determined.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Plasmochemical Neutralization of Ozone-Destroying Chladones and Fluorine- and Chlorine-containing Wastes[1]

Yu. P. Malkov, A. A. Davidyan, Yu. E. Filippov, and M. A. Rotinyan

Prikladnaya Khimiya Russian Scientific Center, St. Petersburg, Russia

Received January 17, 2002

Abstract—A plasmochemical technique for neutralizing ozone-destroying chladones and fluorine- and chlorine-containing wastes is considered. Experimental results obtained on applying this technique to neutralization of some halogen-containing substances are presented, together with the information gained on using the technological scheme of the process in designing and constructing an industrial installation for neutralizing wastes of a plant manufacturing polytetrafluoroethylene.

The intensive development at the end of the XX century of the chemistry and technology of production of fluorine-containing compounds, associated with creation of new materials for various branches of industry, led to their wide introduction into the modern technology. Unfortunately, many of these materials, manufactured on large scale, proved to be ecologically unsafe. No less dangerous are industrial wastes formed in manufacture of virtually all halogen-containing products. Of these halogen-containing compounds, special mention should be made of ozone-destroying chladones. They are highly chemically stable and, when finding way to the environment, can reach the stratosphere to be decomposed there by UV radiation, to liberate atomic chlorine destroying the ozone layer.

The Vienna Convention for the Protection of the Ozone Layer and the Montreal Protocol on Substances that deplete the Ozone Layer envisage not only termination of the manufacture of the above-mentioned fluorine- and chlorine-containing substances, but also their obligatory elimination. Thus, the problem of neutralizing ozone-destroying substances of any kind acquires international importance, and creation of a reliable and efficient technology for performing this elimination becomes a top priority ecological task.

The complexity of solving the problem at hand consists in that incorrect use of thermal techniques for this purpose may give rise to extremely hazardous secondary compounds, such as dioxins, difluoro- and chlorophosgenes, octofluoroisobutylene, benzopyrene, etc. The most dangerous of these are dioxins formed in high temperature processes involving carbon and any chlorine compounds. For example, intensive formation of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin occurs at temperatures in the range from 750 to 900°C, and its effective decomposition onsets only at 1200–1400°C [1–5]. In the same temperature range, the content of phosgene starts to decrease steeply. At a temperature of 1350°C its concentration decreases to the maximum permissible value for the working zone air [6].

The data presented indicate that effective and safe neutralization of organohalogen compounds should be carried out at temperatures of no less than 1400°C. Such conditions are very difficult to create with the use of the conventional thermal techniques with furnace units operating on gas fuel. The most promising is the plasmochemical technique employing plasma generators—plasmatrons, for pyrolysis. Electric arc plasma generators have gained wide acceptance. The choice of these generators is due to the fact that they possess the following important properties: high concentration of energy in a small volume, possibility of achieving very high temperatures of the plasma-forming gas (5000°C and more), convenient control of the temperature mode in a wide range of temperatures, high electrical and thermal efficiency, use as plasma-forming media of any technologically necessary gases (oxidizing, reducing, inert), and simplicity of the process automation because of the fast response of the electric arc.

[1] Report at the 3rd International Conference "Chemistry, Technology, and Use of Fluorine-containing Compounds," St. Petersburg, June 6–9, 2001.

(PG) pressure gages, (T) thermocouples, and (TO) throttling orifices.

Our analysis demonstrated that all the plasmochemical techniques the authors are aware of, created both in Russia and abroad, have some disadvantages hindering their use under industrial conditions. For this reason, a search for a plasmochemical technique for processing of halogen-containing substances, which would be applicable in industrial installations, has been conducted at the Prikladnaya khimiya Russian Scientific Center for several years. As a result of extensive experimental studies, a method has been developed [7], which, in our opinion, best satisfies the requirements to ecologically safe and efficient neutralization.

The essence of this technique is that halogen-containing wastes, both liquid and gaseous, are subjected to pyrolysis in a plasma jet and to oxidation on supplying into the installation of air or steam in amounts required for complete oxidation of carbon contained in the waste to CO_2. In the process, halogens react in the high-temperature zone of the reactor with hydrogen contained in the wastes or in the steam.

The heating of halogen-containing substances and their pyrolysis and oxidation in the plasmochemical technique proposed can be conditionally divided into two stages. The first, preliminary stage proceeds outside the reactor at temperatures close to those of thermal decomposition of the substances being neutralized, but not exceeding these temperatures. In this stage, liquid substances are heated to make lower their viscosity, atomized, evaporated, and the resulting vapors and gaseous components are again heated.

The aim of the first stage is to prepare the wastes being neutralized for the second, main stage of pyrolysis and oxidation in the reactor at the minimum possible residence time of the reaction products in the high-temperature zone. Performing the process in two stages enables a substantial decrease in the dimensions of the reactor, in which corrosion-active components are at very high temperatures, significant reduction of the loss of heat from the hightemperature zone, and pronounced lowering of reactor fabrication costs because of the small reactor dimensions.

To develop this technique, we created a pilot installation with a plasmochemical unit comprising an EDP-109/200 industrial plasmatron, small-size reactor, and a unit for quenching and neutralization of pyrol-

Parameters of plasmochemical neutralization of halogen-containing compounds

ysis products. The output capacity of the unit satisfied the industrial requirements, which enabled, together with a search for optimal conditions of neutralization of halogen-containing compounds, simultaneous improvement of the unit design to increase its reliability and service life.

The figure presents a technological scheme of the pilot plasmochemical installation. Its main units include: (*1*) cylinder with chladone or other substance to be neutralized; (*2*) water evaporator supplying steam into the reactor; (*3*) and (*4*) electric heaters of, respectively, steam and chladone; (*5*) plasmatron; (*6*) reactor with (*7*) quenching and neutralization unit; (*8*) vessel for aqueous solution of alkali; (*9*) vessel receiver for spent alkaline solution; (*10*) heat exchanger; (*11, 12*) cyclones–drop separators for separating residual amounts of the liquid phase from gaseous products discharged into the environment; (*13*) devices for sampling the gas phase for analysis; (*14*) nutsch filter; and (*15*) pressure filter; the last two used to separate salts precipitated in the spent alkaline solution. The installation was used to test neutralization modes of various halogen-containing substances, both gaseous and liquid. As an example, the table presents parameters of neutralization processes for four different compounds.

The specific energy expenditures for neutralization of these compounds, given in the table, are significantly different. This is accounted for by the different thermal stabilities of these compounds, and also by their different contents of halogens and carbon, which make necessary supply into the reactor of sufficient amounts of steam or air to bind halogens into hydrogen halides, and carbon, into gaseous oxides CO_2 and CO.

As seen from the table, the highest energy expenditure is observed for neutralization of a mixture of chladones 13 and 14 with air and for pentachlorobiphenyl. In the first case, a large amount of chladon 14 (tetrafluorometane), the most stable organofluoric compound, was contained in the mixture being neutralized. The high energy expenditure for pentachlorobiphenyl neutralization is due not only to its high thermal stability, but also to the large content of chlorine (~54%) and carbon (~44%) in this compound and its high viscosity (14000 cSt at 20°C) and boiling point (390°C).

The efficiency of the plasmochemical technique for neutralization of halogen-containing compounds was tested not only on the pilot installation. The scheme of this technological process and also the results of experimental studies were used in designing an industrial installation for processing wastes of a plant for polytetrafluoroethylene production.[2] Its construction costs were much lower than those for creation of a similar installation with furnace units operating on gaseous fuel. This industrial installation is used to neutralize gaseous and liquid industrial wastes containing up to 12 different ozone-destroying chladones and other fluorine- and chlorine-containing organic substances.

[2] The installation comprising three plasmochemical units designed at the Prikladnaya khimiya Russian Scientific Center was constructed in China and has been in operation since 1998.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Specific Features of Ion-Exchange Zinc(II) Extraction from Washing Water of Zinc Plating

S. V. Plokhov, I. G. Matasova, V. A. Utkin, and V. Yu. Vodzinskii

Abstract—Specific features of ion-exchange purification of washing water formed in zinc plating in an alkaline medium are considered. The parameters of extraction of zinc ions and regeneration of ion-exchange resins are optimized.

A two-stage technological scheme based on combination of filtration, sorption, ion exchange, and electrolysis, followed by recovery of metal ions, has been proposed for purification of washing water after acidic or neutral zinc plating [1–4]. Filtration is used to remove mechanical impurities, suspensions, and oil; sorption on activated carbon serves to remove organic surfactants. Zinc ions are extracted from solutions by ion exchange onto a cationite. Eluates obtained in regeneration of ion-exchange resins are subjected to electrolysis to recover metallic zinc. Such a wastewater treatment reduces irreversible zinc loss and water consumption, and thereby improves the economical industrial indexes by decreasing pollution taxes and recycling the metal. The use of this method to purify washing water from alkaline (zincate) zinc plating has a number of specific features.

The goal of this study was to analyze ion-exchange purification of washing water from zinc plating and to optimize the technological parameters of metal ion recovery.

As objects of study served model solutions and real washing water (pH 12–13) from metal plating in an electrolyte of composition [5] (g l^{-1}): zinc oxide 10–17, sodium hydroxide 90–120, brightening compounds NBTz-O 4–6 and NBTz-K 4–6. Model solutions contained (g l^{-1}): Zn(II) as ZnO 0.05–3.0, NaOH 0.5–35.0. In addition, real washing water contained the brightening compounds NBTz-O and NBTz-K (0.1–0.2 g l^{-1} each) and metal impurity ions (g l^{-1}): iron(III) up to 0.01; tin(IV), lead(II), copper(II), and chromium(IV) up to 0.005 each. Removal of these ions from washing water is not considered here. Zinc extraction by ion exchange was studied on a laboratory installation with a glass column (i.d. 0.018 m, ratio between inner diameter and height of swollen ion-exchange resin bed 1 : 9). Weights of ion-exchange resins (KU-1 cationite and AV-17-8 anionite) were 25.49 and 27.30 g, respectively. The concentration of zinc(II) ions in solutions was determined spectrophotometrically [6] and by atomic-absorption method [7, 8] on SF-26 and Saturn SF-115 spectrophotometers, respectively. The analytical error was not greater than ±2%.

Metal ions are present in electrolytes of alkaline zinc plating in the anionic form [9]. Accumulation of Zn(II) in washing water results in that not only soluble anions $[Zn(OH)_n]^{-(n-2)}$ with n = 3, 4 are formed, but also white flocculent precipitate $Zn(OH)_2$ (Table 1), which leads to great loss of zinc on filters

Table 1. Amount of Zn(II) in precipitate in relation to the accumulation time of Zn(II) and its concentration in washing water

and in pipe-lines if the above-mentioned technological scheme is used.

Moreover, it was found that ion-exchange extraction of Zn(II) (after filtration of washing water and sorption of surfactants) is insufficiently effective. The efficiency of ion exchange was estimated by the dynamic exchange capacity (DEC) and capacity to breakthrough (CB). By DEC was understood the maximum weight of Zn(II), that can be adsorbed by 1 kg of a swollen ion-exchange resin in a given mode of water treatment till the ion-exchanger inlet and outlet concentrations become equal to each other. The capacity to breakthrough is the maximum weight of Zn(II) that can be adsorbed by 1 kg of a swollen ion-exchange resin in a given mode of water treatment until zinc(II) ions appear at the outlet of the ion-exchange column. The DEC and CB of AB-17-8 anionite for $c_{Zn(II)}$ = 0.35 g l^{-1} at water flow rates (through the inner section of the column) from 0.1 to 6.0 m^3 m^{-2} h^{-1} are 5.0–14.5 and 0.8–8.7 g kg^{-1} of resin, respectively. The values obtained are not sufficiently high owing to the loss of zinc for precipitation.

To reduce the loss of zinc for precipitation and to improve the characteristics of ion exchange, washing water was treated before purification with 1.8 M sulfuric acid (1 : 5), which led to dissolution of the zinc hydroxide precipitate and destroyed complex zinc ions to give transparent solutions containing zinc ions. The amount of acid necessary for such a treatment was found by pH-metric titration of solutions modeling the washing water.

The curves of pH-metric titration of zincate solutions show several characteristic portions (Fig. 1). Portion 0A corresponds to neutralization of free sodium hydroxide. Portion AD characterizes an equilibrium between solution and precipitate, with portions AB (to pH 10.8) and CD (8.3–5.6) corresponding to incomplete formation and dissolution of the precipitate, respectively. Almost complete formation [Zn(II) concentration in solution less than 5×10^{-4} g l^{-1}] is achieved at pH 10.8–8.3. In this case, zinc is present in the precipitate not only as hydroxide, but also as a basic salt of the type $ZnSO_4 \cdot Zn(OH)_2$ [9]. Portion DF is the most interesting for the subsequent zinc recovery from washing water by ion exchange. Complete dissolution of the precipitate can be, in principle, achieved in portion DE (pH 5.6–2.0), but this process is very slow. Portion EF, where precipitate dissolves fast, is more convenient for practical purposes. In this region, the solution has high buffer capacity, and, therefore, it is advisable to treat washing water with acid until pH 1.9–1.8 is reached, with complete dissolution achieved in 0.5 h.

After treatment with sulfuric acid, washing water coming to ion-exchange purification (pH 1.8–1.9) contains Zn(II) in cationic form, so that cationite can be used for its recovery. In this study, we used KU-1 cationite in the H^+ form for technological and economical reasons. A study of various types of cationites de-

monstrated that, although the DEC of many of these cationites is somewhat higher, KU-1 is more than twice less expensive.

According to the present knowledge [10, 11], ion exchange involves a fast chemical stage and slower stages of ion diffusion within phases. Consequently, the DEC and CB values must be affected by the concentration of zinc ions in washing water and by its flow rate. The slower the flow rate (Fig. 2a), the higher the CB value (probably owing to prolonged contact of water with the resin). The greatest increase in the CB value is observed when the rate is changed from 1.0 to 0.5 $m^3 m^{-2} h^{-1}$. Within other flow rate ranges, the change in CB is not so significant. Thus, the water flow rate of no greater than 0.5 $m^3 m^{-2} h^{-1}$ can be assumed optimal.

The DEC and CB values are affected to a greater extent by the Zn(II) concentration in washing water (Fig. 2b). The characteristics of ion exchange are impaired when the Zn concentration becomes higher, which is obviously due to insufficient time of water contact with the resin. The greater $c_{Zn(II)}$, the more pronounced this effect. With the concentration increasing to 0.75 g l^{-1}, the DEC and CB decrease only slightly, so that $c_{Zn(II)}$ should be not greater than 0.75 g l^{-1} to achieve sufficiently high characteristics of ion exchange.

The regeneration of an ion-exchange resin is affected by the concentration of a regenerating solution (sulfuric acid) and its flow rate. The effect of acid concentration on ionite regeneration was studied under static conditions. A cationite saturated with zinc ions was washed with water and dried to constant weight. Ionite samples of the same weight (4 g) were placed in H_2SO_4 solutions of various concentrations. The efficiency of regeneration was estimated by amount of Zn(II) passing into the liquid phase (Table 2).

According to the data presented, the fastest regeneration is observed at H_2SO_4 concentration of 100 g l^{-1}. This concentration can be assumed optimal, and just this concentration was used in studying the influence exerted by the flow rate of the regenerating solution on the efficiency of zinc extraction from the cationite by the dynamic method.

In the range 0.1–0.5 $m^3 m^{-2} h^{-1}$, the flow rate of the regenerating solution passed through a cationite affects the rate of zinc extraction from the cationite only slightly. At higher flow rates the efficiency of regeneration decreases dramatically. For this reason, we recommend an H_2SO_4 solution flow rate of 0.5 $m^3 m^{-2} h^{-1}$, at which the degree of zinc recovery is 90 %.

Table 2. Amount of Zn(II) recovered from cationite in relation to regeneration duration and sulfuric acid concentration

$c_{H_2SO_4}$, g l^{-1}	Amount of Zn(II) (g) recovered in indicated time, h			
	1	3	8	24
200	0.048	0.062	0.071	0.088
150	0.034	0.062	0.087	0.090
100	0.036	0.064	0.090	0.096
50	0.034	0.064	0.072	0.077
25	0.020	0.038	0.051	0.069

Analyzing the dependence of Zn(II) extraction on the volume of regenerating solution passed (Fig. 3), we can determine the reasonable degree of regeneration. We recommend that Zn(II) should be recovered to 80% degree of extraction, because only a quarter of a solution volume required for complete regeneration is consumed in this case. Such regeneration conditions impair somewhat the DEC and CB, which should be taken into account in apparatus design.

One and the same volume of H_2SO_4 solution can be used for regeneration twice, with the Zn(II) concentration in the eluates being 5.0 g l^{-1}. According to the technological scheme, the solutions obtained are subjected to electrolysis, with the result that zinc is deposited onto the cathode as a foil (current density 3–10 A dm^{-2}, 18–25°C, aluminum cathodes, lead

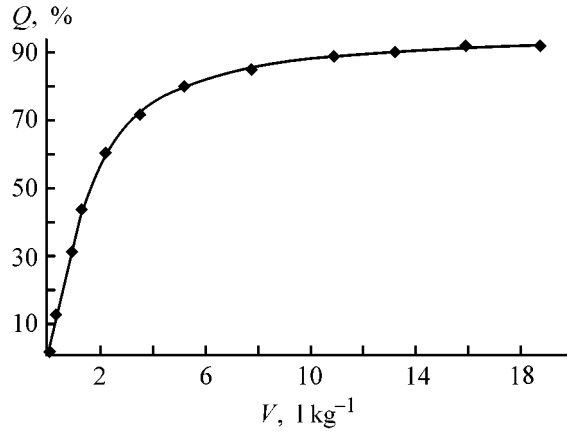

Fig. 3. Degree of extraction of zinc ions, *Q*, in cationite regeneration vs. volume *V* of regenerating solution passed. H_2SO_4 concentration 100 g l^{-1}, solution flow rate 0.5 m h^{-1}.

anodes, no stirring) [12] and can be recycled as anode material in zinc plating, and the H_2SO_4 solution can be used again for regeneration of ion-exchange resins.

CONCLUSIONS

(1) It is established that washing water from zinc plating in alkaline media, treated with 1.8 M solution of sulfuric acid to pH 1.8–1.9, can be purified by cation exchange followed by metal recovery by a technological scheme similar to that proposed for waste water from neutral or acidic zinc plating. The consumption of the H_2SO_4 solution is 20 to 70 ml per liter of washing water.

(2) The optimal parameters of cation-exchange zinc extraction from preliminarily neutralized zincate washing water are as follows: concentration of metal ions in water ≤ 0.75 g l^{-1}, flow rate of water through a cationite ≤ 0.5 m^3 m^{-2} h^{-1}, ionite regeneration with H_2SO_4 solution (100 g l^{-1}) at a flow rate of this solution of 0.5 m^3 m^{-2} h^{-1} to 80 % degree of recovery, Zn(II) concentration in eluates 5 g l^{-1}.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Biological Properties of Antimony(III) Fluoride Complexes[1]

E. V. Kovaleva, L. A. Zemnukhova, V. M. Nikitin, M. D. Koryakova, and N. V. Speshneva

Institute of Chemistry, Far-East Division, Russian Academy of Sciences, Vladivostok, Russia

Received January 17, 2002

Abstract—Result of a study of how antimony trifluoride and fluoride complexes MSb_2F_7 (M = K, Rb, Cs, Tl, NH_4), $MSbF_4$ (M = Na, K, Rb, Cs, NH_4), and M_2SbF_5 (M = Na, K, Rb, Cs, Tl, NH_4) affect the growth of associations of marine bacteria and vital activity of marine alga *Ulva Fenestrata* are presented. The possible ways of using Sb(III) fluoride compounds are discussed.

Complex antimony(III) fluorides attract interest owing to the revealed high mobility of fluoride ions in the crystal lattice of a number of compounds and their suitability as solid electrolytes, piezoelectrics, and ferroelectrics. The preparation and physicochemical properties of antimony(III) fluoride complexes were reviewed in detail in [1, 2]. The information on the part played by antimony(III) in biochemical processes is scarce; biological properties of fluoride complexes are virtually unknown. There are data on the inhibiting effect of some antimony(III) fluoride complexes, when in concentrations of 10^{-5}–10^{-6} M, on the growth of tumor cells of Ehrlich carcinoma and on *Strongylocentrotus intermedius* urchin embryos [3].

The aim of this work was to study the influence exerted by antimony(III) fluoride complexes of the composition MSb_2F_7, $MSbF_4$, and M_2SbF_5 (M = Na, K, Rb, Cs, NH_4, Tl), as well as by their synthetic precursors, namely, alkali metal and ammonium fluorides and antimony oxide and trifluoride, on two test-objects, marine bacteriocenosis and marine algae *Ulva fenestrata*, belonging to the benthos community of the Sea of Japan.

EXPERIMENTAL

The fluoride complexes of antimony(III) MSb_2F_7, $MSbF_4$, and M_2SbF_5 (M = Na, K, Rb, Cs, NH_4, Tl) were synthesized by the procedures described in [2, 4–6] from aqueous solutions of chemically pure grade antimony(III) fluoride, alkali metal fluorides, and thallium carbonate (all water-soluble).

The bactericidal activity of the compounds synthesized was studied by the method of diffusion of a substance being tested into agar containing the test-object [7]. The experiments were conducted as follows. Petri dishes were filled with agarized medium, ribopeptone agar. The solidified agarized plates were uniformly seeded with a bacterial suspension extracted from seawater. Next, the prepared surface was covered with small hollow glass cylinders (0.8 cm in diameter and 1.0 cm high) into which solid substances to be tested (10^{-3} mol) were introduced. For germination of the marine bacteriocenosis, the Petri dishes were kept at a constant temperature of 28°C for 48 h. After the experiments, we measured the sizes of the bacterial growth suppression areas and bacterial growth areas. The toxicity of the substances was judged from the radius of the no-growth area (NGA, cm).

The effect of the compounds on green alga *U. fenestrata* was monitored by variation of the oxygen concentration in the medium (indicating the effect of the substance on the most important metabolic processes in plants: photosynthesis and respiration [8]). The experiments were carried out in 1-l aquariums filled up to the top with seawater. A 5 g portion of thallomes of freshly collected alga was placed in each aquarium, whereupon 0.01 g of the test substance was introduced (this particular weighed portion was selected in preliminary experiments), except for the reference reservoir. Some of the aquariums were kept for 24 h at room temperature (22–24°C) under natural illumination conditions so as to elucidate how the substances studied

[1] Reported at the Third International Conference "Chemistry, Technology, and Application of Fluorine Compounds," St. Petersburg, July 6–9, 2001.

affect photosynthesis. The remaining aquariums (prepared in a similar way) were kept for 1 day in the dark so as to elucidate how the tested compounds affect the alga respiration. After the experiments, we determined the amount of oxygen dissolved in the water from the aquariums by Winkler's method [9].

The mechanism by which fluoride ions influence the vital activity of various organisms is well understood [10–13]. Fluoride ions rank among microelements with fairly high physiological activity, namely, inhibiting enzymatic processes. The biological effect of these compounds is determined by the stability of the bonds and the possibility of their hydrolysis, rather than by the amount of fluorine contained in the molecule. The inhibiting effect of simple fluorides on the vital activity of microorganisms varies with their composition. For example, the toxic effect of NaF is typically lower than that of other fluorides [11], and NH_4F is a widely spread bactericide [10]. At the same time, fluorine ranks among elements indispensable to normal functioning of organisms, and, when in small concentrations, can stimulate biological processes.

Antimony(III) compounds exceed in toxicity antimony(V) compounds and are classed with the so-called thiol poisons [14, 15]. They react selectively with thiol groups belonging to various macromolecules of biological organisms, above all, enzymatic and other albuminous moieties, as well as to certain amino acids. It was found that SbF_3 forms with glycine four types or complexes, where glycine is either coordinated to antimony atom via the oxygen atom from deprotonated carboxy group or forms strong hydrogen bonds between the fluoride complex ions of antimony(III) [16]. As far as we know, the effect of antimony(III) fluoride complexes on biological objects remains, however, to be elucidated.

Our data on how antimony(III) fluoride complexes, fluorides of alkali metals, ammonium, and thallium, and antimony(III) oxide affect the growth of marine alga associations are presented in Table 1. Tables 2 and 3 present analogous data concerning photosynthesis and respiration of marine alga *U. fenestrata*.

Let us consider how the fluoride compounds affect the marine bacteriocenosis (Table 1). The strength of the bactericidal effect of antimony(III) fluoride and oxide and simple fluorides MF (M = Na, K, Rb, NH_4) on associations of marine bacteria, expressed in the NGA size, varies from 0.4 to 1.5 cm. These substances can be arranged in order of decreasing toxicity as $NH_4F > SbF_3 > NaF > KF \cdot 2H_2O$, $RbF > Sb_2O_3$.

Table 1. Bactericidal effect of substances (10^{-3} mol) on the vital activity of marine bacteriocenosis*

Sb_2O_3	9.06	10.25	11.3
$CsSb_2F_7$	6.05	6.49	6.8

The highest toxicity of NH_4F is probably due, above all, to the ability of the cation to easily form hydrogen bonds with other (in this case, organic) compounds or their moieties, so that the fluoride ion is involved into enzymatic processes occurring in bacteria. Antimony trifluoride exceeds antimony(III)

oxide in the inhibiting effect on the vital activity of marine bacteria and is close in its NGA size to NH_4F. Antimony(III) oxide exhibits the lowest toxicity with respect to marine bacteriocenosis throughout the group of the substances studied by us. The lack of toxic effect of Sb_2O_3 on *Pimephales promelas* embryo and larval growth was revealed in [17]. Thus, all the synthetic precursors of antimony(III) complexes, namely, MF (M = Na, K, Rb, NH_4), SbF_3, and Sb_2O_3, inhibit marine bacteriocenosis; the degree of their toxicity, expressed in the NGA size, varies within 0.1–1.5 cm.

In the group of antimony(III) fluoride complexes, the biocidal activity toward associations of marine bacteria is exhibited by MSb_2F_7 (M = K, Rb, Cs, NH_4, Tl), $MSbF_4$ (M = Na, Rb, Cs, NH_4), and M_2SbF_5 (M = K, Tl) (Table 1). The NGA sizes of these compounds vary within 0.2–1.0 cm. As to $KSbF_4$ and M_2SbF_5 (M = Na, Rb, Cs, NH_4), they, by contrast, stimulate bacteria growth.

Table 1 shows that the toxicity of heptafluorodiantimonate(III) ions toward marine bacteria decreases in order KSb_2F_7, $NH_4Sb_2F_7$ > $RbSb_2F_7$ > $CsSb_2F_7$ > $TlSb_2F_7$ and, evidently, depends on the structure of the complexes [2, 6, 18]. The MSb_2F_7 structures are composed of the M^+ cations and dimeric complex anions $[Sb_2F_7]^-$. Compounds with Rb^+ and NH_4^+ cations are isostructural. The structure of the $[Sb_2F_7]^-$ anion depends on the cation nature. For example, the structure of KSb_2F_7 consists of polymeric chains formed by alternating octahedra $Sb(1)F_5E$ (E is unshared electron pair of Sb^{3+}) and trigonal bipyramids $Sb(2)F_4E$ linked by asymmetric fluoride bridges. In the case of $CsSb_2F_7$, the symmetric bridging fluoride ion links two SbF_3 molecules, thus forming dimeric $Sb_2F_7^{2-}$ groups combined into layers connected by Cs^+. The structural motif for $RbSb_2F_7$ is intermediate between those for analogous compounds with M = K and Cs. The coordination polyhedra for Sb(III) are trigonal bipyramids $Sb(1)F_4E$ and $Sb(2)F_4E$, integrated into layers separated by rubidium cations. The most complex structure is exhibited by $TlSb_2F_7$, whose unit cell contains six nonequivalent positions of Sb(III) forming two polyhedron types: SbF_5E octahedra and SbF_4E trigonal bipyramids integrated into a hexanuclear $[Sb_6F_{21}]^{3-}$ ring.

Complex tetrafluoroantimonates(III) are not isostructural [2, 18], but $MSbF_4$ (M = Na, Rb, Cs, NH_4) compounds have a common, polymeric, structure of the anions, unlike $KSbF_4$, where the anion has a tetrameric structure $[Sb_4F_{16}]^{4-}$. The structural dissimilarity is responsible for the difference in the biocidal properties of these substances (Table 1): $MSbF_4$ (M = Na, Rb, Cs, NH_4) inhiibit the bacterial growth similarly (unlike MSb_2F_7), with the NGA size varying within 0.6–0.8 cm. By contrast, $KSbF_4$ stimulates bacterial growth.

Complexes from the series M_2SbF_5 (M = Na, K, Rb, Cs, NH_4, Tl) are composed of isolated SbF_5^{2-} anions and metal cations, and all of them, except Na_2SbF_5, are isostructural [2, 18]. The antimony polyhedron is a square pyramid completed to an octahedron by the E pair, SbF_5E. A weak inhibiting effect on the growth of marine bacteria is only exhibited by two pentafluoroantimonates(III) with K^+ and Tl^+ cations, for which the respective NGA sizes are 0.3 and 0.4 cm (Table 1). The remaining compounds from the M_2SbF_5 series (M = Na, Rb, Cs, NH_4) intensify the growth of marine bacteria. The different biological activities exerted by isostructural pentafluoroantimonates(III) are, probably, due both to the nature of the cation and to certain, previously revealed, specific features of the electronic and crystal structures of these complexes [2]. For example, pentafluoroantimonates(III) of potassium and thallium differ at room temperature from the other M_2SbF_5 compounds

in anomalous behavior of a number of $^{121, 123}$Sb NQR parameters (signal intensity, asymmetry parameter of the electric field gradient); K_2SbF_5, in addition, exhibits a number of phase transitions involving changes in the structure and heat capacity.

Let us consider how the substances tested affect the photosynthesis in *U. fenestrata* alga (Table 2). This process is stimulated by four antimony(III) fluoride complexes: MSb_2F_7 and M_2SbF_5 (M = K, Rb). The greatest activating effect is exhibited by KSb_2F_7; and the remaining three compounds exert insignificant ($RbSb_2F_7$, the weakest) effect on the bio test.

Compounds MSb_2F_7 (M = Cs, Tl), $MSbF_4$ (M = Na, K, Rb, Cs). M_2SbF_5 (M = Na, Cs, Tl), MF (M = K, Rb, Cs), SbF_3, and Sb_2O_3 exhibit algicidity by inhibiting photosynthesis and decreasing the content of dissolved oxygen in water relative to the reference runs. Our experiment on determining the amount of dissolved oxygen in seawater shows (Table 2) that, among simple substances, the strongest algicidal effect is exerted by cesium fluoride, and the weakest, by Sb_2O_3. The algicidal power of the fluoride complexes of Sb(III) on photosynthesis of *U. fenestrata* alga depends on the composition of a complex and can increase or, by contrast, decrease relative to the initial simple compounds used for their synthesis. For example, the powers of all the three antimony(III) fluorocomplexes with Cs^+ cation are weaker as compared with CsF. In accordance with the toxicity relative to simple compounds, these complexes form the series (Table 1): CsF > $CsSbF_4$ > SbF_3 > Cs_2SbF_5 > $CsSb_2F_7$.

At the same time, photosynthesis of the alga is more strongly suppressed by $RbSbF_4$ than by RbF.

The respiratiom of *U. fenestrata* alga also depends on the composition of a substance present in the aquarium (Table 3). A toxic effect, manifested in suppression of the respiration function of plants, is only exhibited by two Sb(III) fluoride complexes, namely, M_2SbF_5 (M = Na, Cs). These same compounds suppress photosynthesis as well (Table 2). The compound with the Na^+ cation is more toxic in the light, and that with the Cs^+ cation, in the dark. According to Table 3, the remaining substances, both simple and complex, which suppress oxygen release during photosynthesis (Table 2), proved to stimulate alga respiration. The dark sensitivities of the alga to the substances tested are different. In the simple compound group, plant respiration is the least affected by antimony(III) oxide, and in the fluoride complex group, by $RbSb_2F_7$.

CONCLUSIONS

(1) The effect of alkali metal and ammonium fluorides, as well as that of antimony(III) fluoride, oxide, and fluoride complexes, on the vital activity of marine bacteriocenosis and marine green alga *U. fenestrata* was assessed.

(2) SbF_3 and compounds of composition $MSbF_4$ and MSb_2F_7 (except for M = K) and M_2SbF_5 (M = K, Tl) exhibit strong bactericidal effect; $KSbF_4$ and M_2SbF_5 (M = Na, Rb, Cs, NH_4), by contrast, stimulate bacteria growth.

(3) Most of solutions of Sb(III) fluoride compounds, when in concentration of 0.01 g l^{-1}, inhibit photosynthesis in algae and activate their respiration.

(4) Biological properties of the compounds studied are, evidently, due both to the properties of the ions [fluoride ions, antimony(III) ions, and cations] consituting the molecule and to the properties of the compounds themselves (composition, crystal lattice structure, electronic structure features). The compounds acting as inhibitors are promising for development of antifouling pastes and paints.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Fluorination of Organic Compounds with Cobalt Trifluoride and Elemental Fluorine in the Presence of Cobalt Trifluoride[1]

D. D. Moldavskii, G. G. Furin, L. V. Shkul'tetskaya, and B. Ya. Eifman

Received January 17, 2002

Abstract—Fluorination of organic compounds with cobalt trifluoride and elemental fluorine in the presence of cobalt trifluoride was studied. Fluorination with elemental fluorine proceeds under external-kinetic control at a constant rate. Examples of fluorination with elemental fluorine of certain fluorinated olefins and polyfluorinated paraffins in the presence of CoF_3 are presented.

Cobalt trifluoride is a common fluorinating agent for synthesis (including commercial production) of perfluorinated organic compounds (paraffins, ethers, etc.) form hydrocarbon and unsaturated analogue [1, 2]. In the reaction, cobalt trifluoride is reduced to difluoride:

$$CoF_3 + C_nH_{2n+2} \rightarrow CoF_2 + C_nF_{2n+2} + HF.$$

Fluorination with cobalt trifluoride is characterized by low yield (30–40%) of target products, limited productivity because of the low content of available fluorine (16.30 wt %; the actual consumption is lower by a factor of 1.2–3), and noticeable amount of residual hydrogen-containing and unsaturated compounds (up to 1 wt %), instead of 1×10^{-3}–5×10^{-4} wt % required in medicine, electronics, and other branches of industry. Therefore, other synthesis methods should be searched for. One of them is catalytic fluorination of fluorine-containing organic compounds with elemental fluorine. Higher fluorides of metals with variable oxidation state, including nickel, copper, and cobalt fluorides [3–5], are usually used as such catalysts. In this work, we studied fluorination of monohydroperfluorotripropylamine $C_3F_6HN(C_3F_7)_2$ (**I**) and monohydroperfluorotributylamine $C_4F_8HN(C_4F_9)_2$ (**II**) with cobalt trifluoride and with elemental fluorine in the presence of cobalt trifluoride. Compounds **I** and **II** are the main process impurities in electrochemical synthesis of perfluorotripropylamine $(C_3F_7)_3N$ and perfluorotributylamine $(C_4F_9)_3N$, respectively. Their content in crude products reaches 30 wt %.

Fluorination was performed in a reactor packed with CoF_3. In the first case, a mixture of vapors of a compound to be fluorinated and fluorine was supplied, and in the second case, nitrogen was introduced instead of fluorine at the same flow rate. The figure shows the kinetics of fluorination of monohydroperfluorotributylamime (**II**).

Curve *2* describing the rate of fluorination with CoF_3 is characteristic for reactions whose initial stage proceeds on the surface of a solid reactant (CoF_3 in this case) under external-kinetic control. Since CoF_3 is consumed in the surface layer, the reaction becomes diffusion-controlled, which accounts for the observed decrease in the reaction rate [6]. It should be noted that the initial section of curve *2* is rather difficult for analysis, and the majority of papers on CoF_3 fluorination kinetics contain only data for the diffusion region, in which the decrease in the reaction rate is neglected and the rate is considered to be constant [6, 7]. Studies of fluorination of fluorinated methanes [7] and hexafluoropropane [8] have shown that the fluorination reaction is first-order.

Fluorination with elemental fluorine in the presence of CoF_3 (curve *1*) proceeds under external-kinetic control since the CoF_3 concentration in the surface

* (*A*) Residual content of hydrogen-containing and unsaturated compounds.

layer is constant owing to timely or even advance supply of fluorine:

$$RH + CoF_3 \rightarrow RF + HF + CoF_2,$$
$$CoF_2 + F_2 \rightarrow CoF_3.$$

This is illustrated by the data on fluorination of CoF_2 and compound **II** at various temperatures presented in Table 1.

It follows from the kinetics of fluorination of **I** that this reaction is second-order. The activation energy amounts to 37.5 kJ mol^{-1}. The equation of the reaction rate is as follows:

$$\log V = \log \text{const} - 4.56E/RT.$$

It should be noted that the catalytic fluorination is characterized by high yield of the target products and their insignificant degradation.

Data on catalytic fluorination of certain hydrogen-containing and unsaturated compounds are listed in Table 2.

The results make evident the difference between fluorination with CoF_3 and that with fluorine in the presence of CoF_3 as a catalyst.

In the first case, the fluorination rate is low and decreases with time; the process is limited by the content of available fluorine, which prevents its being performed in the continuous mode. The residual content of hydrogen-containing or unsaturated compounds in the resulting products is substantial ($> 1 \times 10^{-3}$ wt %), which requires additional purification. In the second case, the fluorination rate is fairly high and constant; the process has no time limitation, which allows it to be performed in the continuous mode; the residual content of hydrogen-containing compounds is less than 1×10^{-3} wt %.[2]

EXPERIMENTAL

The UV spectra were recorded on a UF-26 spectrophotometer; the fluoride ion was determined with an ET-1 fluoride-selective electrode. In chromatographic analysis, a heat-conductivity detector was used; carrier gas helium, solid phase Silokhrom, liquid phase 20% α,α,α-tri(β-cyanoethyl)acetophenone, 2 m × 3 mm

[2] The catalytic fluorination process was implemented at the pilot plant of the "Prikladnaya Khimiya" Russian Scientific Center.

column. The GC-MS analysis was performed on a Hewlett-Packard device comprising an HP-5890 gas chromatograph, an HP5972 mass-selective detector, and a Vectra 5/100 working station with software for data processing and Wiley138.L and NBS75K.L database.

Chromatographic separation was performed on a 30 m HP-5MS capillary column in the programmed-heating mode. Chromatograms were recorded by the total ion current within the 35–700 mass range. The impurities were identified by comparing the mass spectra of separated mixture components with those from the Wiley138.L and NBS75K.L databases and by calculation.

The kinetics of fluorination of **I** was studied in a vertical reactor made from a nickel tube (inner diameter 36 mm). The reactor was packed with CoF_3 with bed height of 300 mm. A thermocouple pocket was arranged along the reactor axis. The temperature variation throughout the bed did not exceed 3°C. From a batcher, a mixture of **I** (25 wt %) with $(C_3F_7)_3N$ (75 wt %) and fluorine were supplied at definite and constant rates into a mixer-evaporator, which was a 500-mm nickel tube 36 mm in diameter, equipped with a controllable heater. The fluorine excess did not exceed 20% relative to the stoichiometry. From the evaporator, the reaction mixture passed through a catalyst bed (with particle size of 0.035–0.05 mm) and condensed in a trap cooled with liquid nitrogen. After process completion, the trap was warmed to room temperature and weighed, and the reaction products were analyzed by GLC. Low-boiling products containing fluorine and HF were neutralized in a column with lime and analyzed by GLC. The experiments were performed at 150, 180, 220, and 250°C.

The fluorination rate constants and activation energy [9] were calculated from the concentration-vs.-time plots for 150, 180, 220, and 250°C.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of 2-Hydroxy-1-Naphthaldehyde under Conditions of Heterogeneous Catalysis

G. V. Kalechits, A. G. Osinovskii, Yu. V. Matveenko, and V. K. Ol'khovik

Institute of Chemistry of New Materials, Belarussian National Academy of Sciences, Minsk, Belarus

Received February 7, 2002

Abstract—A procedure was developed for synthesis of 2-hydroxy-1-naphthaldehyde by Reimer–Tiemann fluorination of 2-naphthol under conditions of heterogeneous catalysis.

Aromatic *o*-hydroxy aldehydes readily enter cyclizations and are therefore important synthetic precursors of carbocyclic and heterocyclic compounds. For example, 2-hydroxy-1-naphthaldehyde **I** is widely used for preparing various luminophores, optical whiteners [1, 2], analytical reagents [3], and drugs.

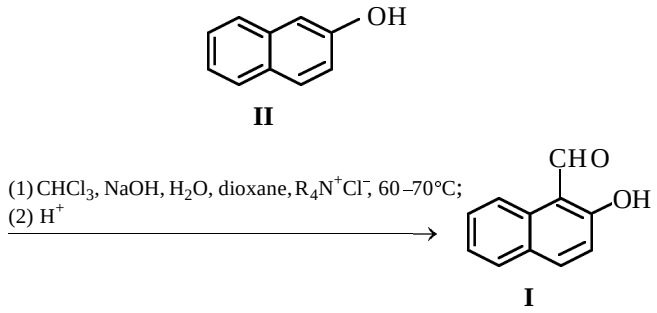
In synthesis and study of various benzocoumarin derivatives, a need arose for relatively large amounts of **I**. Published procedures for preparing **I** [4–7], despite high yields (up to 80%), are complicated by use of expensive and deficient reagents, which are often toxic.

The most acceptable route to **I**, free of the above drawbacks, is formylation of 2-naphthol **II** by the Reimer–Tiemann reaction; however, in the classical version of this procedure, the yields are as low as 38–48% [8], and isolation of a high-purity product is difficult, which makes this procedure unsuitable for large-scale syntheses.

To raise the yield and obtain high-purity product, we examined the possibility of formylation of **II** with chloroform in alkaline solution under conditions of heterogeneous catalysis [9]. Although the Reimer–Tiemann reaction usually does not require catalysts, it was shown in [10] that the use of tertiary ammonium salts for preparing salicylaldehyde from phenol increases the yield of the target product by more than a factor of 2.

Along with the low cost and availability of the starting compounds (naphthol **II**, chloroform, alkali), an advantage of the heterogeneous-catalytic synthesis in alkaline solution is the formylation at the *o*-position and the minimum extent of condensation of the forming aldehyde **I** with the initial naphthol **II**. The possibility of such a condensation in acid solutions with the formation of dibenzoxanthene derivatives and oligomeric substances contaminating the target product was noted in [11].

Aldehyde **I** was prepared by the scheme



It is well known that the reactive species in the Reimer–Tiemann reaciton is dichlorocarbene :CCl_2. The mechanism of dichlorocarbene generation under conditions of heterogeneous catalysis is also understood in detail [12]. The reaction scheme can be described as follows. At the phase boundary, chloroform is deprotonated to give trichloromethylide anion:

$$HCCl_{3(org.\ phase)} + Na^+_{(aq.\ phase)} + OH^-_{(aq.\ phase)} \rightleftarrows CCl^-_{3(interface)} + Na^+_{(interface)} + H_2O. \quad (1)$$

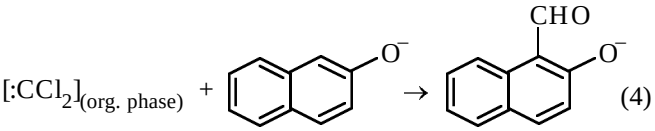
This is followed by exchange with the quaternary ammonium salt (2) and generation of carbene (3) (the reaction is reversible):

$$CCl^-_{3(interface)} + [R_4N^+X^-]_{(org.\ phase)} \rightleftarrows [R_4N^+CCl^-_3]_{(org.\ phase)} + X^-_{(aq.\ phase)}, \quad (2)$$

$$[R_4N^+CCl^-_3]_{(org.\ phase)} \rightleftarrows [R_4N^+Cl^-]_{(org.\ phase)} + [CCl_2]_{(org.\ phase)}. \quad (3)$$

1070-4272/02/7506-0962 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The carbene formed irreversibly reacts with the substrate:



(4)

The reaction was performed in a two-phase aqueous-organic system. The organic phase was 1,4-dioxane or a mixture of 1,4-dioxane with a branched alcohol in a ratio varying from 10 : 1 to 30 : 1. Branched alcohols were added to raise the solubility of sodium naphtholate in the organic phase. As catalysts we tested quaternary ammonium salts: tetrabutylammonium (TBAC), benzyltriethylammonium (TEBAC), and benzyltrimethylammonium (TMBAC) chlorides (0.1–0.4 mol %). Dichlorocarbene was generated from excess chloroform and 40% aqueous NaOH. The reaction was performed at 60–70°C.

The experimental results (see table) show that the Reimer–Tiemann formylation of naphthol **II** under conditions of heterogeneous catalysis gives the target product in a yield 1.5–2 times higher than that in the classical version of this reaction.

The best results were obtained with tetrabutylammonium chloride as phase-transfer catalyst; however, as seen from the table, with the yields the other catalysts are only slightly lower.

It should be noted that this procedure is very easy. Most of the impurities are removed in the stage of isolation of the hydroxy aldehyde sodium salt, so that the target product can be obtained 98% pure without vacuum distillation.

* In all runs, the second component is dioxane (150 ml).
** At 68–72°C.

EXPERIMENTAL

The ^1H NMR spectra were recorded on a Tesla BS-587A spectrometer (100 MHz, internal reference TMS). The IR spectra were taken on a Specord M-80 spectrometer in the range 400–4000 cm^{-1}, using KBr pellets. The melting points were determined on a Boetius stage.

2-Hydroxy-1-naphthaldehyde I. A flask equipped with stirrer, thermometer, reflux condenser, and dropping funnel was charged with 144.2 g (1 mol) of naphthol **II** and 400 ml of 40% NaOH. The mixture was stirred for 0.5 h to obtain a homogeneous solution. Then the mixture was cooled to 65–70°C, and 1.15 g (0.004 mol) of a quaternary ammonium salt and 130 ml of a 30 : 1 mixture of 1,4-dioxane with a branched alcohol were added. This was followed by addition of chloroform (155.2 g, 1.3 mol) at a rate ensuring reaction temperature within 70°C. After adding the whole amount of chloroform, the mixture was stirred at 65–70°C for an additional 1 h and cooled to 20°C; 2-hydroxy-1-naphthaldehyde sodium salt was filtered off. The resulting crystalline product was washed successively with 1% NaOH and a 20 : 1 mixture of dioxane with 1% aqueous NaOH. The wet residue was transferred into a flask and stirred for 1 h with 300 ml of 10–15% aqueous HCl. The precipitate of aldehyde **I** was filtered off, washed with water to neutral reaction and negative reaction for chloride ions, and dried in a desiccator over $CaCl_2$. Yield 78%, mp 80–82°C, main substance content 98%.

The physicochemical and spectral characteristics of **I** are in agreement with reference data [8].

CONCLUSIONS

(1) 2-Naphthol is regioselectively formylated under conditions of the heterogeneous-catalytic version of the Reimer–Tiemann reaction to give 2-hydroxy-1-naphthaldehyde.

(2) This procedure allows preparation of a high-purity target product in 75% yield.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Rheological and Electrical Characteristics of Polyvinyl Alcohol Composites with Phosphoric Acid

T. G. Lazareva, O. V. Yakovleva, and E. V. Shinkareva

Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received October 17, 2001; in final form, February 2002

Abstract—Rheological and electrical properties of fluid PVA-based composites with phosphoric acid are studied. Formation of ordered liquid-crystal structures in the PVA matrix with addition of phosphoric acid to the system is assumed, with the structural ordering dependent on the polymer to acid ratio and solution temperature.

Composites of polyvinyl alcohol (PVA) with inorganic and poly acids (silicotungstic, phosphoric, polyacrylic, polymethacrylic) can find wide application for preparation of membranes, various coatings, paper sizing formulations, etc. Addition of polyacids or inorganic acids to PVA solutions produces hydrogen-bonded complexes [1]. The rheological and electrical properties of PVA composites with water-soluble cellulose ethers (carboxymethyl cellulose, methyl cellulose) and silicotungstic acid have been studied previously [2–4]. The rheological characteristics of the composites as influenced by the temperature, shear stress and rate, and composition suggested the possibility of formation of anisotropic liquid-crystal (LC) structures. Proceeding with these studies, we examined in this work the rheological and electrical properties of PVA-based composites with phosphoric acid H_3PO_4.

EXPERIMENTAL

The test samples were prepared by adding fixed amounts of 90% phosphoric acid to a 10% aqueous polyvinyl alcohol (PVA 16/1) solution at room temperature to obtain composites containing 15, 25, and 40 wt % H_3PO_4. The mixtures were stirred for 30 min on an LR10 laboratory stirrer. The viscosity η was measured on a Rheotest-2 rotary viscometer over the shear rate range from 3 to 1312 s^{-1} at a temperature of 20–80°C. The electrical conductivity æ and dielectric loss tangent tan δ were determined on an E7-15 instrument at a frequency of 1 kHz.

Figure 1 shows the viscosity η as a function of the shear rate $\dot{\gamma}$ for a series of the composites at various temperatures. Raising the temperature to 70°C and higher results in a more pronounced effect of the shear rate for the composites containing from 15 to 25 wt %

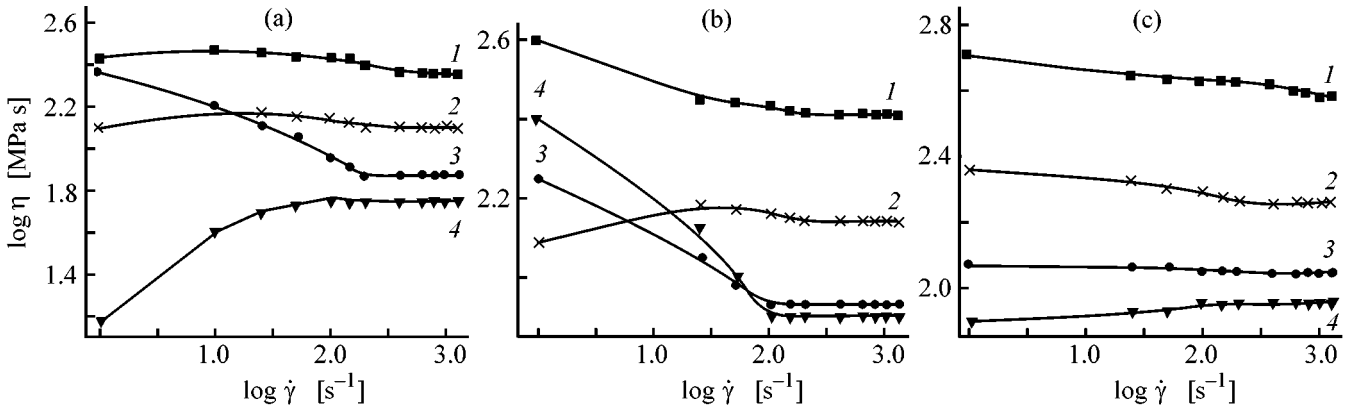

Fig. 1. Dynamic viscosity η vs. the shear rate $\dot{\gamma}$ for PVA-based composites with varied H_3PO_4 content. H_3PO_4 content (wt %): (a) 15, (b) 25, and (c) 40. Temperature (°C): (*1*) 30, (*2*) 50, (*3*) 70, and (*4*) 80.

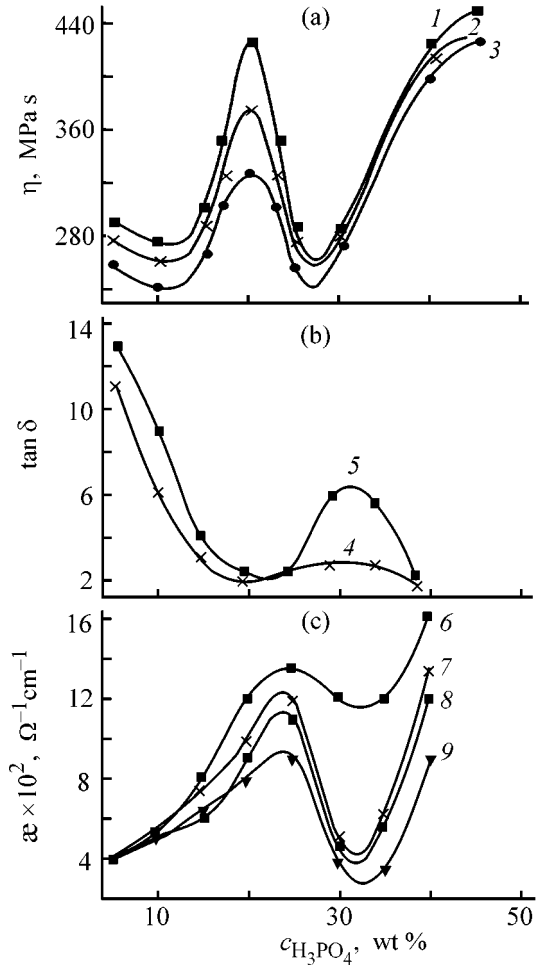

Fig. 2. (a) Dynamic viscosity η at 30°C, (b) dielectric loss tangent tan δ, and (c) conductivity æ vs. the phosphoric acid concentration $c_{H_3PO_4}$. Shear rate $\dot{\gamma}$ (s^{-1}): (*1*) 27, (*2*) 81, and (*3*) 243. Temperature (°C): (*4*, *6*) 30, (*5*, *7*) 60, (*8*) 70, and (*9*) 80.

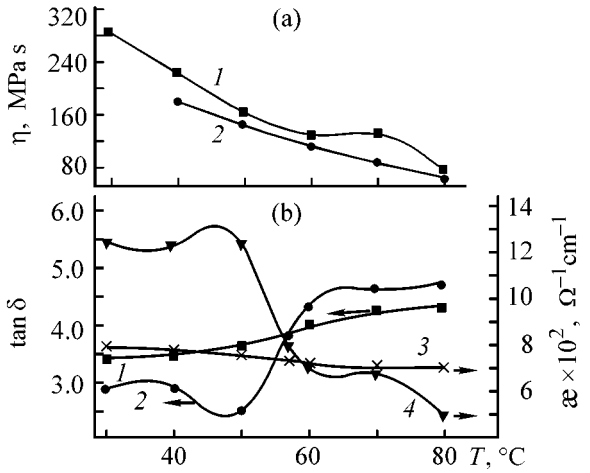

Fig. 3. (a) Dynamic viscosity η at a shear rate of 81 s^{-1} and (b) dielectric loss tangent tan δ and conductivity æ vs. temperature *T*. Phosphoric acid concentration (wt %): (a) (*1*) 30 and (*2*) 15 and (b) (*1*, *3*) 15 and (*2*, *4*) 30.

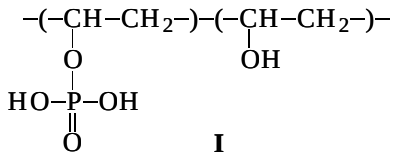
H_3PO_4. Depending on temperature, the viscosity may increase or decrease with increasing shear rate. This can be attributed to weakening intermolecular interactions and growing molecular flexibility of large aggregates of macromolecules in the polymer matrix with increasing temperature and also to aggregation of macromolecules in the mechanical field [5]. With the phosphoric acid content increasing to 40 wt %, the effect of the shear rate on the viscosity becomes less pronounced (Fig. 1c).

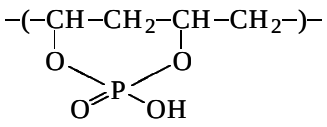
Figure 2 shows the dependences of the viscosity η, dielectric loss tangent tan δ, and conductivity æ on the phosphoric acid concentration in the composites based on 10% aqueous PVA. The composition dependence of the viscosity (Fig. 2a) passes through a maximum at $c_{H_3PO_4}$ = 20 wt % at 30°C. With the shear rate increasing from 27 to 243 s^{-1}, the effect becomes less pronounced. An anomalous behavior of the viscosity is also observed in the composition dependences of tan δ and æ (Figs. 2b, 2c). Comparison of Figs. 2a and 2b shows that the maximum in the concentration dependence of η at $c_{H_3PO_4}$ = 20 wt % corresponds to the minimum in the concentration dependence of tan δ, and vice versa, the maximal tan δ corresponds to the minimal η at an acid content of about 30 wt %. Conversely, the concentration dependences of the viscosity and conductivity are nearly parallel (Figs. 2a, 2c).

The temperature dependences of the viscosity, tan δ, and æ for the composites containing 15 and 30 wt % H_3PO_4 are given in Fig. 3. At low shear rate we observed an anomalous behavior of the viscosity within the temperature range 60–80°C for the composite containing 30 wt % H_3PO_4. With increasing temperature, tan δ grows and æ decreases; the effect being more pronounced for the composite containing 30 wt % H_3PO_4. Taking into account data from [6], demonstrating anomalous viscosity-vs.-temperature curves for the systems with LC structures, one may suggest that the temperature affects the degree of ordering in the PVA–H_3PO_4 system. If so, the effect must be dependent on the molar ratio of the components, at which the LC state occurs and an increase in the flexibility of separate fragments of the polymer chain is observed.

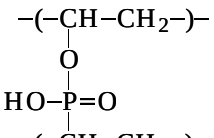
Products differing in structure are formed in the reaction of PVA with phosphoric acid derivatives [4]:



I

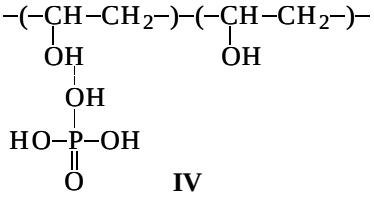


II

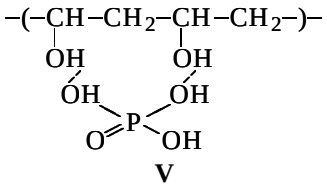


III

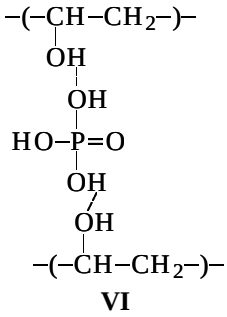
Also, it is not improbable that hydrogen-bonded structures **IV**–**VI** can be formed.



IV



V



VI

The structure of such complexes resembles to a certain extent that of comb-shaped polymers, in which, as known, LC state can be formed. The occurrence of side chains is responsible for anomalous rheological, electrical, and some other properties.

It is known that transition to the LC state can be studied by rheometry [7]. Viscosity discontinuity in the temperature or concentration curves allows quite reliable determination of phase transition points, particularly for the transition from the isotropic to the anisotropic state. Also, transition points can be determined on applying external fields (mechanical, electrical, or magnetic).

Our experimental data show that, the nature of flow changes in the PVA–H_3PO_4 system in the mechanical field is characteristic of both the plastic (Fig. 1a, curve *3*; Fig. 1b, curves *3*, *4*) and dilatant types of behavior (Fig. 1a, curve *4*), depending on the phosphoric acid concentration, temperature (plastic behavior becomes more pronounced with increasing temperature), and shear rate, which is due to structural reorganization.

It is known that anomalous viscous behavior of LC polymers is manifested in the appearance of a maximum in the concentration dependence of the viscosity [8]. Particularly, it was demonstrated in [9] that, with increasing concentration, the decline in the viscosity is followed by an increase in the anisotropic range. With increasing shear rate, this effect becomes less pronounced. Similar results were observed for the PVA–H_3PO_4 system with variable component ratio. According to the concept proposed in [8], the decrease in the viscosity anisotropy with increasing shear rate is associated with the orientation of the isotropic solution in the mechanical field. The observed anomalous viscosity curves and the decrease in the viscosity discontinuity with increasing shear rate are caused by superposition of two factors: inherent LC state, as dependent on the system composition, and the effect of the mechanical field. Data of Fig. 2 give evidence in favor of the formation of an ordered LC phase having lower segmental flexibility.

In lyotropic or thermotropic LC polymers, reaching a certain concentration or temperature changes the bonding nature, which is reflected in the composition–property relationships [10]. In this case, a step-by-step transition from a semidilute to a concentrated isotropic solution occurs, accompanied by the formation of inclusions of an LC phase, followed by reaching their percolation threshold. Then, at a certain concentration, interpenetrating phases, and, finally, a continuous LC phase are formed with the presence of an emulsion of isotropic droplets in the LC matrix. Firther, gel-like or rigid inclusions are formed in the LC phase, which is followed by gelation. The observed anomalous behavior of the viscosity and electrical characteristics, as dependent on the phosphoric acid concentration and the solution temperature, suggest some complex transitions in both the molecular and supramolecular structures in the system.

To conclude, the observed similarity of the viscous behavior of LC polymers and that of PVC-based composites with phosphoric acid suggests that an isotropic–anisotropic transition may also occur in hydrogen-bonded structures in the polymer–acid systems.

CONCLUSIONS

(1) Polyvinyl alcohol composites with phosphoric acid demonstrate a discontinuity in the viscosity curves and also an anomalous behavior of such electrical characteristics as the electrical loss tangent and conductivity.

(2) Formation of ordered liquid-crystal structures in the PVA–phosphoric acid system is assumed, with the structural order being dependent on the PVA–acid molar ratio and temperature.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Reactivity of Phenol-Formaldehyde Microspheres toward PCl_3, $VOCl_3$, and CrO_2Cl_2 Vapors

S. A. Trifonov, V. A. Lapikov, and A. A. Malygin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 30, 2001

Abstract—The products of reactions between $POCl_3$, $VOCl_3$, and CrO_2Cl_2 vapors and phenol-formaldehyde microspheres were studied by chemical analysis and spectroscopy.

Studies of chemical reactions occurring on solid surfaces are of both theoretical and applied interest in, e.g., assessing the reactivity of solid matrices [1, 2]. At the same time, chemical modification, e.g., by molecular layering (ML), which allows selective chemical reactions to be carried out on a solid matrix surface, is utilized for controlling the functional characteristics (adsorption, catalytic, thermal-oxidative, electrophysical, etc.) of substances and materials [3–5]. The foresaid is also true of solid polymer matrices, for which the chemical structure of the surface (elemental chemical composition and occurrence on the surface of various moieties or functional groups) also affects both their performance characteristics and the rate of reactions with other materials [6, 7]. The ML technique shows high performance in controlling the thermal-oxidative properties of phenol-formaldehyde, epoxy, polyamide, and polyvinyl chloride polymers [8, 9]. In this context, studies of the chemical transformations accompanying the gas-phase modification of solid polymer matrix with volatile low-molecular-weight agents will allow not only understanding of the reactions between the element oxide additions introduced and the polymer surface, but also elucidation of their influence on the physicochemical properties of a material.

EXPERIMENTAL

We carried out chemical analysis and spectroscopic [by IR and X-ray photoelectron spectroscopy (XPS)] studies of phenol-formaldehyde microspheres (PFMs) of the BV-01 brand [TU (Technical Specification) 6-05-221-258–77] modified with phosphorus(III) chloride and vanadium(V) and chromium(VI) oxychlorides. The element oxide groups were introduced in a flow-through reactor charged with a weighed portion of PFM (2 g) at room temperature in a dried carrier gas (nitrogen) stream. The extent of the chemical reaction between PCl_3, $VOCl_3$, and CrO_2Cl_2 and the reactive groups of the polymer material was estimated from the concentration of the elements in the modified specimens [10, 11]. Upon completion of the reaction between low-molecular-weight volatile chlorides and PFMs the latter were treated with a flow of dried carrier gas until unchanged initial compounds and formed gaseous products were completely removed from the reaction chamber. The choice of specific modifiers was governed by the fact that phosphorus, vanadium, and chromium compounds in various combinations are used for controlling the thermal-oxidative properties of polymer materials. Also, it was of interest to assess the reactivity of PFMs toward agents exhibiting various redox characteristics (PCl_3 is reductant, and $VOCl_3$ and CrO_2Cl_2 are oxidants).

The XPS[1] studies were carried out on a Perkin–Elmer PH-5000-400 instrument with Mg_{K_α} (1253 eV) exciting radiation. The residual pressure in the chamber of the spectrometer with a semispherical analyzer (energy resolution 0.1 eV) was 10^{-9} torr. The inaccuracy of quantitative analysis was about 10%. The spectrum was calibrated based on the binding energy of C1*s* carbon electrons, 285 eV. The polymer samples were pressed into indium pellets.

The IR spectra[2] of the initial and modified samples were recorded on an FSM-1201 IR Fourier spectrom-

[1] X-ray photoelectron spectra were recorded at the Mekhanobr-Analit Joint-Stock Company (St. Petersburg).

[2] IR spectra were recorded at the Monitoring Scientific and Production Association (St. Petersburg).

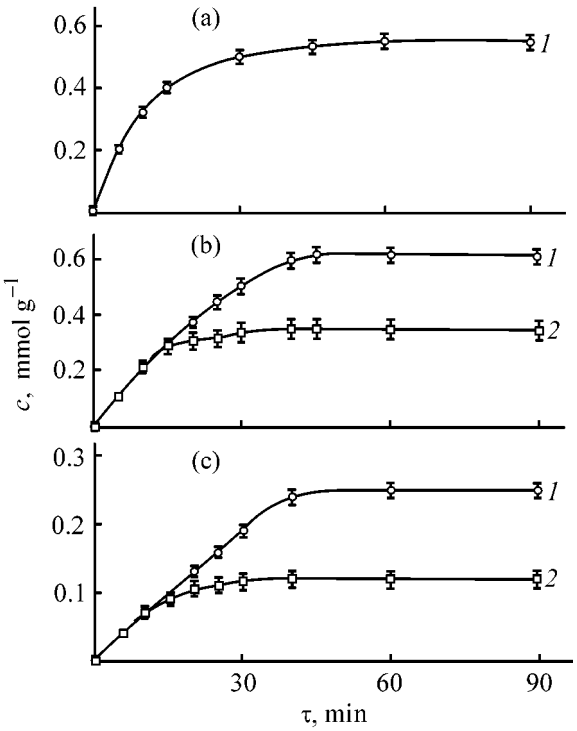

Fig. 1. Variation of the content of elements, *c*, in PFMs with the time of treatment τ with (a) phosphorus trichloride, (b) vanadium(V) oxychloride, and (c) chromium(VI) oxychloride vapors. (*1*) Total concentration of elements in the modified samples and (*2*) V(V) and Cr(VI) concentration.

eter (500–4000 cm^{-1} range, resolution 1 cm^{-1}, self-compensating interferometer). The samples were mixed and pressed with KBr.

To choose the optimal modification modes for the polymer material, we studied how its characteristics vary with the time of treating PFM samples with PCl_3, $VOCl_3$, and CrO_2Cl_2 vapor. Gas-phase treatment of the microspheres was carried out under conditions described in [12], namely, at room temperature, in a flow of air dried to the dew point (–50…–55°C) after the polymer was predried for 60 min.

Figures 1a–1c show how the content of the elements in the microspheres varies with the time of their treatment with the modifier vapor. It is seen that, under the conditions chosen, the total concentration of the elements in the samples attains a constant value within 45–60 min. However, the concentrations of the modifiers in the solid phase after their reaction with the reactive groups of the polymer matrix differ to a certain extent, depending on the chemical nature of the reactant. The maximal amounts of the elements, mmol g^{-1}, in the polymer are as follows: phosphorus(III) 0.56 (Fig. 1a), vanadium (V^{5+}, V^{4+}, and V^{3+}) 0.62 (Fig. 1b, curve *1*), and chromium (Cr^{6+}, Cr^{3+}) 0.25 (Fig. 1c, curve *1*).

We have shown previously [12] that, in reactions with phosphorus(III) chloride, the phosphorus-containing groups are grafted primarily at the phenol hydroxy groups of the microspheres. The appearance of a minor amount of phosphorus in the oxidation state +5 (5–10% of the total amount of the element) in the modified samples may be due to oxidation of PCl_3 in the gas phase to $POCl_3$ and its subsequent chemisorption on the polymer.

Chemical analysis showed that, when PFMs are treated with vanadium(V) oxychloride and chromium(VI) oxychloride vapor, the concentration of the elements in the modified samples in the highest oxidation state [V(+5), Cr(+6)] ceases to change after 15–20 min of synthesis (Figs. 1b and 1c, curves *2*). Since $VOCl_3$ and CrO_2Cl_2 are oxidants, the increase in the content of the modifiers by 50% of the total concentration of the additives may be due to appearance among the reaction products of modifying elements in a lower oxidation state [Cr(+3), V(+3, +4)]. This is probably due to grafting of vanadium- and chromium-containing moieties via redox reactions with the reactive groups of the polymer material.

Thus, in the initial stage of modification of the microspheres with $VOCl_3$ and CrO_2Cl_2 vapors, the element-containing moieties can be grafted by exchange reactions with the phenolic OH groups without changing the oxidation states of the elements, as evidenced by the presence of vanadium(V) and chromium(VI) in the samples (Figs. 1b, 1c, curves *1*). However, it should also be taken into account that phenol-formaldehyde polymers tend to oxidize even during preparation and storage in air [13]. The benzene ring in phenols is easily oxidized. In reactions with oxidants, the orienting action of the hydroxy group is responsible for activation of the carbon atom in the *para* position, which enters into the reaction yielding *p*-benzoquinone and its transformation products [14]. Evidently, treatment of the polymer with a vapor of a modifier with pronounced oxidizing power for a certain time causes structural rearrangement of the polymer surface, thus decreasing the chemical activity and accessibility of the phenol hydroxy groups of the matrix. This, evidently, involves redox reactions between $VOCl_3$ and CrO_2Cl_2, on the one hand, and the reactive centers (e.g., benzene rings, methylene groups), on the other, yielding carbonyl groups. The difference in the concentrations of the modifiers in the vanadium- and chromium-containing microspheres (0.62 vs. 0.25 mmol g^{-1}) may be due to the

difference in oxidizing power between vanadium(V) and chromium(VI). Treatment of PFMs with vapor of CrO_2Cl_2, which is a powerful oxidizing agent for organic compounds [15], causes more substantial changes in the polymer chain, thus decreasing the accessibility of the phenol hydroxy groups to the reactant.

Figure 2 presents an IR Fourier transmission spectrum of the initial microspheres. It contains absorption bands characteristic of phenol-formaldehyde polymers, peaked at [16] 760, 820, and 880 cm^{-1} (bending vibrations of the C–H bonds in substituted benzenes); 1200 cm^{-1} (stretching vibrations of the C–O bond); 1355 cm^{-1} (bending vibrations of phenol hydroxyls); 1475 and 1600 cm^{-1} (stretching vibrations of the C=C bond in the benzene ring); 2850, 2920, and 3010 cm^{-1} (stretching vibrations of the C–H bond in aliphatic and aromatic hydrocarbons); and 3400 cm^{-1} (stretching vibrations of the OH groups.

Chemical modification of the microspheres with PCl_3, $VOCl_3$, and CrO_2Cl_2 vapors changes the spectral characteristics of the polymer. The IR spectra of all the samples are characterized either by disappearance (Fig. 3a) or marked decrease in the intensity (Figs. 3b, 3c) of the absorption band at 1355 cm^{-1}, associated with bending vibrations of the hydroxy group of phenol, and by appearance of new bands at 510–560 cm^{-1}, associated with stretching vibrations of the E–Cl bond (Figs. 3a–3c) [16].

The IR spectra vary to a certain extent with the modifying agent. In the IR spectrum of the phosphorus-containing sample, a new band, associated with stretching vibrations of the P–O–Ar bond appears at 1000 cm^{-1}, and bands at 2360 and 2500 cm^{-1} due to stretching vibrations of the P–H and O–H bonds in phosphorus oxy acids (Fig. 3a). The last two absorption bands are, evidently, due to chemisorption of phosphorus oxychloride on the solid polymer [16].

When chromium-containing groups are introduced into the material, an absorption band at 1650 cm^{-1} appears, originating from stretching vibrations of the C=O bond in carbonyl compounds (Fig. 3c) [16]. The IR spectrum of the vanadium-containing microspheres contains an absorption band near 1010 cm^{-1}, associated with stretching vibrations of the V–O bond [16] (Fig. 3b). A higher reactivity of $VOCl_3$, compared with chromium-containing additives, is manifested in the appearance in the spectrum of two absorption bands at 1650 and 1710 cm^{-1} due to vibrations of the C=O bond. The intensity of the absorption band at 820 cm^{-1} for the samples treated with $VOCl_3$ and CrO_2Cl_2 vapors decreases, which is probably due to

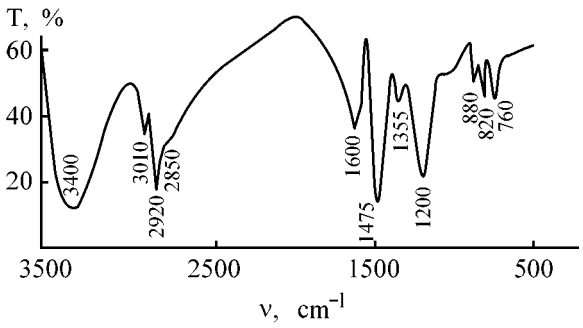

Fig. 2. IR spectrum of the initial PFMs. (T) Transmission and (ν) wave number; the same for Fig. 3.

the change in the substitution pattern in the benzene ring owing to redox reactions between inorganic agents and the polymer matrix [16] (Fig. 3b, 3c).

Figures 4 and 5 show the XPS spectra of the initial and modified PFM samples. The XPS spectrum of the initial microspheres in the C1*s* range contains a band at a binding energy of 285.0 eV, characteristic of the C–H groups, and a band at 286.2 eV. The latter band can be attributed to alcoholic, ester, or ether C–O groups occurring in the chain of the polymeric

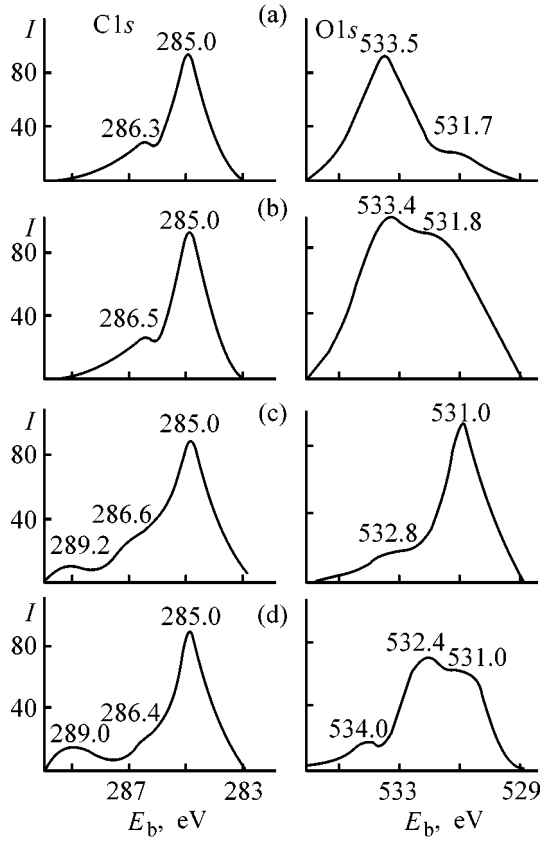

Fig. 4. C1*s* and O1*s* bands in the XPS spectra of (a) initial and (b–d) modified PFMs. (*I*) Relative intensity and (E_b) binding energy; the same for Fig. 5. Modifying agent: (b) PCl_3, (c) $VOCl_3$, and (d) CrO_2Cl_2.

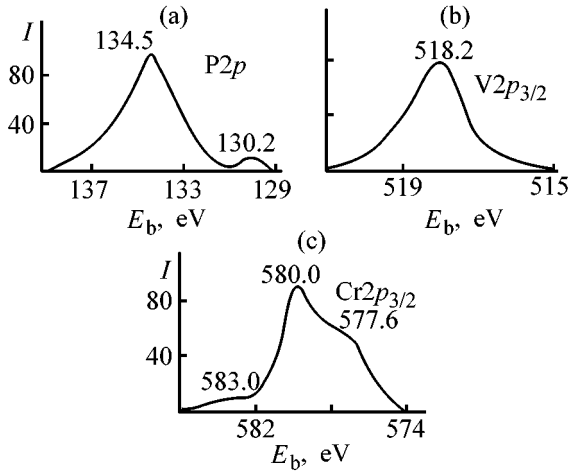

Fig. 5. (a) P2*p*, (b) V2$p_{3/2}$, and (c) Cr2$p_{3/2}$ XPS spectra of the modified PFMs.

material [17]. This is also evidenced by the peaks of the O1*s* electrons with binding energies of 533.5 and 531.7 eV (Fig. 4a).

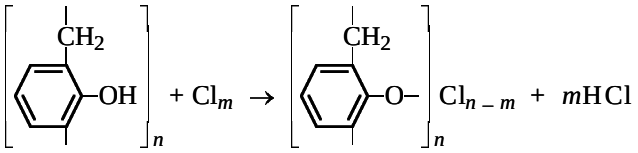
The phosphorus-containing moieties introduced do not affect the binding energy of the C1*s* electrons, which can, evidently, suggest the lack of chemical reactions between the carbon-containing moieties in the polymer chain and phosphorus(III) chloride (Fig. 4a). However, the XPS spectrum of the modified PFMs is characterized by the appearance of lines in the higher-energy region corresponding to the binding energies of P2*p* electrons of 134.5 and 130.2 eV (Fig. 5a). These peaks are, probably, due to formation of phosphorus-oxygen groups linked to aromatic rings [17]. Our data suggest that this chemical reaction can yield not only phenyl phosphorous moieties with the modifying agent in the same oxidation state (130.2 eV) but also moieties of the $(PhO)_3PO$ type yielded by oxidation of phosphorus(III) chloride in the gas phase during modification. This is also evidenced by an increase in the intensity of the band of O1*s* electrons with binding energy of 531.8 eV (Fig. 4b) [18].

Chemical modification of the microspheres with vapor of vanadium and chromium oxychloride (modifying agents with pronounced oxidizing power) is responsible for the appearance in the XPS spectra of carbon of a shoulder with the binding energy of 1*s* electrons equal to 289.2 eV (Fig. 4c, 4d). This band can be accounted for by formation of carboxy groups (>C=O bond) [17] resulting from redox reactions in the polymer matrix with $VOCl_3$ and CrO_2Cl_2. Also, grafting of vanadium-containing moieties to microspheres is responsible for the appearance in the XPS spectra of the modified samples of lines with the binding energy of $2p_{3/2}$ electrons equal to 518.2 eV (Fig. 5b), and for the increase in the intensity of the band of O1*s* electrons with binding energy of 531.0 eV (Fig. 4c). According to published data [18], these changes may be due to formation of vanadium compounds in different oxidation states (V^{3+}, V^{4+}, V^{5+}).

The XPS spectrum of chromium-containing samples of PFMs contains three bands associated with different oxidation states of the element. The appearance of the bands with the binding energy of Cr 2*p* electrons equal to 583.0 eV is due to the presence in the polymer of the modifying agent containing chromium in the oxidation state +6. This probably suggests an exchange reaction between CrO_2Cl_2 and phenol hydroxy groups. The peak with the binding energy of 580.0 eV, as well as the band of O1*s* electrons with the binding energy of 531.0 eV (Fig. 4), may be due to the presence in the polymer of moieties with binding energies intermediate between those of 2*p* electrons of chromium(VI) and chromium(III) [19].

The redox reaction between the modifying agent and the reactive groups of the microshperes, yielding carbonyl bonds, is probably evidenced by the appearance of a band with binding energy of 577.6 eV (Fig. 5c), characteristic of chromium in the oxidation state (+3), and the above-mentioned shoulder in the XPS spectra of carbon with the binding energy of 289.0 eV (Fig. 4d).

Thus, our spectroscopic studies suggest grafting of modifying additives to the solid polymer both by substitution of the hydrogen atoms in phenol hydroxy groups, which probably proceeds according to the scheme



(ECl_m = PCl_3, $VOCl_3$, CrO_2Cl_2), and by redox reactions between the elements introduced [in the case of vanadium(V) and chromium(VI) oxychlorides] and the reactive groups of the material.

CONCLUSION

Chemical analysis and spectroscopic studies point to the occurrence of a chemical reaction between the modifying agents and reactive groups of the polymeric material. For all of the modified samples, the element-containing groups are introduced by exchange reactions with phenol hydroxy groups. When the microspheres are treated with vapor of $VOCl_3$ or CrO_2Cl_2 (modifying agents with pronounced oxidizing powers), the reactive centers of the polymer matrix (e.g., benzene rings and methylene bridges) are partially oxidized, yielding carbonyl moieties.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Oligomerization of Bifunctional Aldehyde in Reactions with Bipolar Ions

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received February 7, 2002

Abstract—Formation of glutaraldehyde oligomers (tri- and pentamers) in reaction of glutaraldehyde with bipolar ions (monoaminoacetic, α-aminoglutaric, and α,ε-diaminocaproic acids and glutatione tripeptide) was studied.

In many methods of protein modification with a bifunctional cross-linking agent, glutaraldehyde (GA), the main attention is paid to carbonyl-amine reactions. These reactions play an important part in various biochemical processes [1]. Therefore, their study in model systems is of interest. In chemical cross-linking of proteins in neutral aqueous solutions, stable Schiff bases are formed by the reaction of protein amino groups with GA functional groups [2, 3]. These bases do not dissociate because of the parallel aldol condensation of GA to give α,β-unsaturated oligomers immobilized on a protein molecule [4].

Previously, we have shown that the GA condensation with glycine involves some parallel reactions [5]. It follows from a comparison of the rate constants that the condensation to give stable aldimine bond (Schiff base) is 20 times faster than the formation of α,β-unsaturated GA oligomers produced by aldol condensation (products were monitored by UV spectroscopy at 267 and 235 nm, respectively) [6]. Hence, we can suggest that a Schiff base is formed initially, being then stabilized by the formation of conjugated double bonds in the course of GA oligomerization (aldol condensation involving the second free aldehyde group of GA).

In this work, the influence exerted by the nature of the bipolar ion on the condensation and, first of all, on the GA oligomerization was studied for the example amino acids and peptides containing, along with carboxy and amino groups (glycine), also sulfhydryl (glutathione), second carboxy (glutathione, glutamic acid), or second amino (lysine) group.

EXPERIMENTAL

Differently charged amino acids: monoaminoacetic (glycine, Glu), α,ε-diaminocaproic (lysine, Lys), α-aminoglutaric (glutamic acid, Glu), and γ- glutamylcysteinylglycine (glutathione, GSH) were studied.

A commercial 25% aqueous solution of GA (Reanal, Hungary) was purified with activated carbon. Its purity was evaluated spectrophotometrically from the ratio of the optical densities of the bands at 235 and 280 nm, D_{235}/D_{280} = 0.4–0.5. Glutaraldehyde exists in aqueous solution at pH 3 as a mixture of the aldehyde proper and its hydrated species. The optical density at λ = 280 nm is due to absorption by the aldehyde group, with molar absorption coefficient ε = 4.2 l mol^{-1} cm^{-1} [7]. The band at λ = 235 nm (ε = 1530 l mol^{-1} cm^{-1}) appears only in the spectra of GA alkaline solutions (pH > 8) and belongs to GA α,β-oligomers with conjugated double bonds (ethylene and carbonyl) formed by aldol condensation [8]

$$\mathrm{CHO{-}(CH_2)_3{-}[CH{=}\overset{\displaystyle HC=O}{\overset{|}{C}}{-}(CH_2)_2]_{\mathit{n}}{-}CHO.}$$

The reactions of GA with bipolar ions were studied in aqueous solutions (pH 6.8–7.2) at 20°C by UV spectroscopy [SF-26 (Russia) and Specord (Germany) spectrophotometers] and pH-metry (Radiometer, Denmark). The reaction products were fractionated by GPC on a 90 × 1.5 cm column packed with Sephadex G-25 (LKB-Pharmacia, Sweden) and eluted with water. The average distribution coefficient K_{av} was deter-

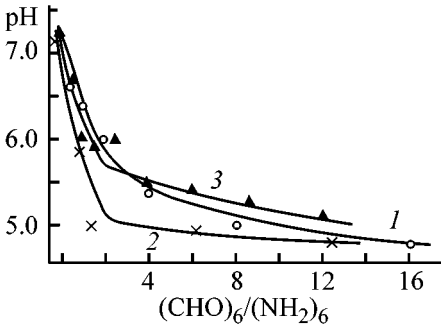

Fig. 3. pH of the reaction mixture vs. the initial molar ratio of functional groups of the components $(CHO)_0/(NH_2)_0$. Reaction time 1 h, 20°C. GA condensation with (*1*) glycine, (*2*) lysine, and (*3*) glutamic acid.

mined by the standard procedure from the corresponding eluate volumes:

$$K_{av} = (V_e - V_0)/(V_0 - V_t),$$

where V_e is the elution volume of the stable GA derivative with bipolar ion, and V_0 and V_t are the elution volumes of dextran-2000 and KI, respectively.

The aldehyde groups were analyzed by reaction with hydroxylamine hydrochloride [9], the amino groups, with 2,4,6-trinitrobenzenesulfonic acid [10], and the sulfhydryl groups, by the Ellman method with 5,5'-dithiobis(2-nitrobenzoic acid) [11]. The degree of conversion of the functional groups (k_{CHO}, k_{NH_2}, k_{SH}) in stable Schiff bases (which do not dissociate under competitive action of hydroxylamine hydrochloride) was estimated as the ratio of the ΔNH_2, ΔCHO, and ΔSH groups that reacted within a definite time interval, to their initial amount $(NH_2)_0$, $(CHO)_0$, and $(SH)_0$, respectively.

The GA condensation with amino acids proceeds in neutral solutions rapidly; with the limiting conversion being attained within 10–15 min [5, 6]. The degree of conversion of amine and aldehyde groups in reaction of GA with glycine, lysine, and glutamic acid (within 1 h) as a function of the initial molar ratio $(CHO)_0/(NH_2)_0$ is shown in Figs. 1a and 1b. The degree of conversion of glycine and lysine functional groups changes with increasing GA concentration similarly and reaches the limiting value of 0.8–0.9 with respect to amino groups. For glutamic acid, k_{NH2} increases only to 0.4 even at excess of GA.

In all cases, the GA aldehyde groups reacted in overequivalent amount as compared with the consumed amino groups of the bipolar ion. (Fig. 2). As the initial molar ratio of GA to glycine or lysine increases, the ratio of the bound aldehyde and amino groups changes similarly, and $\Delta CHO/\Delta NH_2$ varies from 3 to 5. For the GA–glutamic acid system, this ratio varies from 6 to 12, and for the reaction of GA with

the tripeptide, from 1 to 3. It should be noted that at low initial ratios of the components (up to 4–6), $\Delta CHO/\Delta NH_2$ is constant in all cases, but at larger excess of aldehyde groups (up to 16) it increases, and this increase is the greater, the lower the degree of conversion of amino acid amino groups (e.g., for dicarboxylic glutamic acid).

As the acid products are accumulated as a result of formation of stable Schiff bases in the reaction of GA with amino acid, the pH of the reaction mixture decreases (Fig. 3). For all the bipolar ions studied, the dependences of pH on the initial $(CHO)_0/(NH_2)_0$ molar ratio show a bend: sharp initial decrease in pH [to $(CHO)_0/(NH_2)_0 \sim 4$] is followed by a weak variation at high GA concentrations.

Figures 1–3 show two stages of the GA condensation with differently charged amino acids: the first, at low initial molar ratios $(CHO)_0/(NH_2)_0$ [from 0.25 to ~(4–6)], and the second, at larger ratios (>6).

In the first case, the formation of a stable Schiff base is accompanied by oligomerization of GA already linked to amino acid (Fig. 2); in the process, binding of the amino acid reaches a maximum. The observed free aldehyde groups may be the aldehyde groups belonging to the GA oligomer formed. At very small initial ratios (at a large excess of the amino acid), the aldehyde groups are consumed completely (Fig. 1b). At the same time, an overequivalent consumption of the aldehyde groups with respect to amino groups (i.e., GA oligomerization) is observed too. Probably, the reaction products can associate via reaction of free aldehyde groups belonging to the oligomeric fraction of GA.

In the second case, at a large excess of the aldehyde groups, stable Schiff bases are formed by condensation; this process is accompanied by simultaneous GA oligomerization, as in the first case. In all the systems studied, the amount of the overequivalent aldehyde groups consumed increases in comparison with that of the amino groups. For instance, for the GA–glycine and GA–lysine systems (the GA–glutathione system is close to them), the ratio of the consumed groups $\Delta CHO/\Delta NH_2$ increases from 3 (which is characteristic of low initial ratios of the components) to about 5. For the GA–glutamic acid system at low degree of amino group conversion, these changes are substantial: from 6 to 12 and more.

The GA–glycine and GA–glutamic acid systems are compared in Table 1.

As follows from Table 1, with increasing $(CHO)_0/(NH_2)_0$ ratio, the degree of conversion of glycine amino groups in the GA–glycine system (at constant glycine concentration in the solution) increases to 0.84–0.86 due to formation stable Schiff bases, while for the GA–glutamic acid system it reaches only 0.24–0.26 at substantially increased amount of the reacted aldehyde groups.

GA reacts in a specific way with glutathione tripeptide containing, along with amino and two carboxy groups, a sulfhydryl group. Glutaraldehyde can react with both primary amino group and sulfhydryl group. At the initial molar ratio $(CHO)_0/(NH_2 + SH)_0 < 6$ (Fig. 2, curve *4*), a stoichiometric binding of GA and tripeptide functional groups is observed. The positions of CHO groups in the GA molecule and of NH_2 and SH groups in the glutathione molecule are complementary, which suggests that the reaction with GA involves intramolecular cross-linking in the tripeptide molecule, and one molecule of bifunctional GA is consumed per glutathione molecule.The results of GA binding with glutathione at increasing pH of the reaction medium are listed in Table 2.

Table 2. Degree of conversion and ratio of reacted functional groups in the GA–glutathione system [reaction time 20 min; 20°C; $(CHO)_0/(NH_2 + SH)_0$ = 2.5 mol/mol]

It follows from Table 2 that, with increasing pH, the GA condensation with glutathione (molar ratio of the functional groups 2.5) proceeds with growing conversion of the functional groups. In all cases, equivalent binding of functional groups of GA and tripeptide is observed.

Reasing the GA content in the reaction mixture at $(CHO)_0/(NH_2 + SH)_0 > 6$ (Fig. 2, curve *4*) leads to overequivalent binding of aldehyde groups, $\Delta CHO/\Delta(NH_2 + SH) \approx 3$, which corresponds, as in the case of other bipolar ions studied, to formation of GA oligomers, probably, separately with each reactive group of glutathione.

A specific feature of the GA condensation with dicarboxylic glutamic acid is the abnormally high degree of binding of GA aldehyde groups at extremely low conversion of amino groups of glutamic acid (Figs. 1a, 1b). The low degree of conversion of these amino groups may result from insufficient amount of the reactive unprotonated amino groups (nucleophiles), which may be due to suppression of their dissociation because of the existence of two carboxy groups in the molecule of glutamic acid. The consumption of aldehyde groups sharply increases at high GA concentrations in the reaction mixture (Fig. 2) and increasing pH of glutamic acid solution (Table 3).

It follows from Table 3 that the degree of conversion of amino groups in glutamic acid slightly increases with pH increasing within the interval 6–12 because of the increase in the amount of unprotonated (reactive) amino groups. With increasing pH, the GA ability to form α,β-unsaturated oligomers also increases. At an excess of GA in the solution, the ratio of the reacted aldehyde groups to amino groups in the GA–glutamic acid system may reach 20.

To account for the observed specific features of GA condensation with glutamic acid, the reaction products were fractionated on a column with Sephadex G-25 at 10°C. Two experimental procedures were used under the same other conditions. In the first

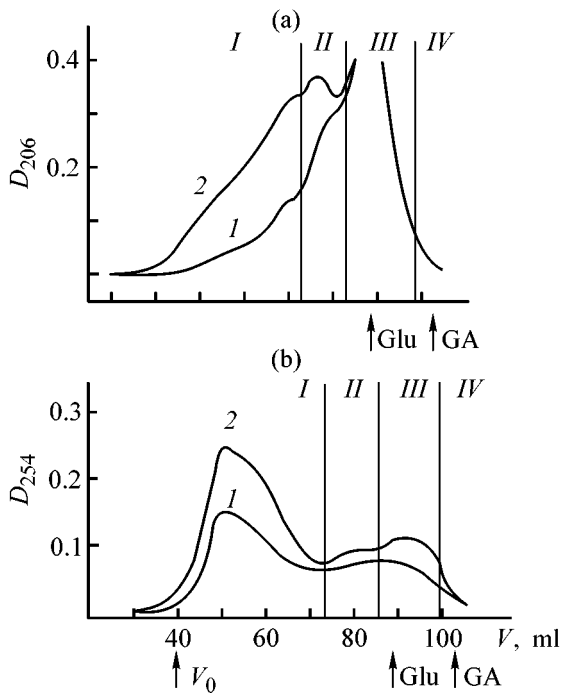

Fig. 4. Gel chromatography on column with Sephadex G-25 of products of GA condensation with glutamic acid (fractions *I–IV*), obtained at 20°C in (*1*) 20 min and (*2*) 2 h. * Results of several experiments.

case, the reaction was stopped by adding sodium borohydride, which reduces both azomethine and carbonyl double bonds. The reaction products were eluted with water and monitored spectrophotometrically at 206 nm (the region of absorption of glutamic acid carboxy groups). Figure 4a shows two chromatograms of products obtained at reaction times of 20 min and 2 h. As seen, the amount of glutamic acid bound in high-molecular-weight products (probably, owing to association of low-molecular-weight components) increases with time.

In the second case, the reaction products were not reduced, and the reaction mixture was introduced into the column directly (Fig. 4b). The fractions obtained were monitored at 254 nm {257–270 nm is the absorption range of aldimine bonds in the stable reaction products [6, 12, 13]; the initial components in the concentrations used do not absorb in this range}. In the four fractions obtained, the amounts of the residual aldehyde and amino groups were determined spectrophotometrically, then the fractions were dried lyophilically, their masses were measured, and the content of nitrogen was found. The amount of strongly bound glutamic acid in the fractions was determined as the difference between the total nitrogen and nitrogen belonging to the free amino groups. The GA amount was determined as the difference between the fraction mass and the amount of amino acid in this fraction, taking into account GA dehydration at the aldol condensation. The yield of products from the column was 90–95%. The results are presented in Table 4.

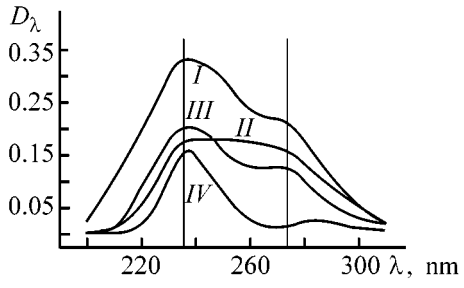

Fig. 5. Differential UV spectra of fractions *I–IV* of products formed in GA condensation with glutamic acid (from Fig. 4b) relative to solution of glutamic acid. (D_λ) Optical density and (λ) wavelength.

Fraction *I*, which amounts to 2–4% of the lyophilically dried reaction mass, is characterized by high optical density at 254 nm. This corresponds to a high content of azomethine bonds in the product. It is known that the separating power of Sephadex G-25 with respect to branched dextrans is limited to the molecular masses of several thousands. In fractions *I* and *II*, no free aldehyde groups were found. These products have molecular mass substantially larger than 1000 and are probably associates of low-molecular-weight products. The active product of the condensation reaction and unchanged glutamic acid are concentrated in fraction *III*. It is interesting that, in fraction *III*, despite a large excess of free glutamic acid, aldehyde groups are detected in substantial amounts and apparently do not react with glutamic acid. We suggest that, in this case, glutamic acid forms with GA common unstable Schiff bases, which are broken down in the reaction with hydroxylamine hydrochloride used to determine free aldehyde groups.

It should be noted that, in the first three fractions of products of the GA condensation with glutamic acid, the ratio of consumed aldehyde groups to amino groups, $\Delta CHO/\Delta NH_2$, is constant, 5–6. This fact suggests that the pentamer with molecular mass of about 600–700 is the main product of GA condensation with glutamic acid.

Fraction *IV* contains free GA and only trace amounts of glutamic acid. The ratio of the optical densities D_{235}/D_{280} in fraction *IV*, which is higher than that in the other fractions, suggests that GA exists in the form of small (probably cyclic) oligomers, since the elution volume of the fraction is close to that of monomeric GA.

The differential UV spectra of four fractions obtained in condensation of GA with glutamic acid are shown in Fig. 5. All the fractions show absorption at 235 nm, characteristic of conjugated double bonds (ethylene and carbonyl) in the products of the GA aldol condensation. Fractions *I–III* show absorption at 260–270 nm, characteristic of aldimine bond in

the stable Schiff bases. Products of fraction *IV* exhibit, along with band 235 nm due to products of aldol condensation of GA, a weak band at 280 nm belonging to the GaA aldehyde group [7].

Thus, in all the GA–bipolar ion systems studied, the composition of reaction products changes with increasing GA concentration. At low ratios of the components $[(CHO)_0/(NH_2)_0 < 4]$, amino acids form with GA products in which GA exists as oligomer (mainly trimer). At $(CHO)_0/(NH_2)_0 > 6$, a higher oligomer (pentamer) is formed. It was noted in [14] that aldol condensation of GA in alkaline media or at its prolonged storage yields GA trimers and pentamers.

The specific feature of the GA reaction with dicarboxylic amino acids is the low degree of conversion of amino groups (up to only 0.4) even in the presence of an excess of GA. Account should be taken of the fact that we monitored only stable Schiff bases containing conjugated double bonds. We can suggest that dicarboxylic glutamic acid prevents intense formation of stable Schiff bases, probably due to sterical factors, but can form usual unstable Schiff bases, which are readily hydrolyzed into the initial components. At the same time, glutamic acid can initiate formation of stable oligomers of GA itself, present in the reaction mixture in excess, while in straight GA solutions no oligomerization proceeds under similar conditions.

The results obtained can be applied to GA polycondensation with proteins: for instance, they confirm that, for intermolecular cross-linking of proteins with excess carboxy groups (with isoelectric points in the acid region), a greater amount of the cross-linking agent and longer condensation time (compared with proteins whose isoelectric points lie in neutral and alkaline regions) are required.

CONCLUSIONS

(1) A study of the condensation of glutaraldehyde with differently charged bipolar ions (glycine, lysine, glutamic acid) at a molar ratio of the functional groups of the initial components varied from 0.25 to 16.0 revealed overequivalent binding of aldehyde groups with amino groups. The reaction products contain amino acid bound with the glutaraldehyde trimer at $(CHO)_0/(NH_2)_0 < 4$ and with the glutaraldehyde pentamer at $(CHO)_0/(NH_2)_0 > 6$. These oligomers are not formed in neutral and weakly acid solutions of glutaraldehyde, containing no bipolar ions.

(2) The highest degree of conversion in the glutaraldehyde-glutamic acid system is 0.4 (cf. 0.8–0.9 for glycine and lysine). Correspondingly, the overequivalent ratio of the reacted aldehyde groups changes from 5–6 to 12 with increasing molar ratio of the initial components. In the presence of glutamic acid, excess glutaraldehyde can form oligomers in weakly acidic solutions, in contrast to straight glutaraldehyde solutions under the same conditions.

(3) Condensation of glutaraldehyde with glutathione may involve intramolecular cross-linking at complementary mutual orientation of the functional groups, when the stoichiometric ratio of the total amount of amino and sulfhydryl groups to the reacted aldehyde groups is attained. At excess of glutaraldehyde $[(CHO)_0/(NH_2)_0 > 6$ mol/mol], the aldehyde groups are consumed in overequivalent amounts to form glutaraldehyde oligomers (trimers) bound with each functional group of the tripeptide separately.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Dibenzyl-*o*-carborane on Radiation Aging of Polymethyl Methacrylate

Abstract—Radiation aging of polymethyl methacrylate produced in the presence of dibenzyl-*o*-carborane was studied. The influence of dibenzyl-*o*-carborane addition on the thermomechanical properties of the resulting polymer was analyzed.

High-energy radiation significantly affects the physicochemical characteristics of polymer materials. The composition, structure, electrical conductivity, creep rate, and tensile strength of a polymer are changed, which results in deterioration of its performance. To decrease or prevent these consequences, stabilizing additives incorporated into the polymer chain or present as mechanical impurities are added. Various classes of organic compounds show protective properties. For example, polymethyl methacrylate (PMMA) is stabilized with compounds containing bivalent sulfur [1] and aromatic hydrocarbons [2]. Owing to a vacant *d* orbital of sulfur and the π-electron system of the benzene ring, aromatic and organosulfur compounds act as "energy sponges" absorbing and dissipating in the form of heat or fluorenscence the energy absorbed by the polymer. Aromatic compounds effect intermolecular energy transfer without any significant variations. Sulfur-containing compounds undergo cleavage across the S–S (or C–S) bond to form the corresponding stable thiyl radicals which deactivate active polymer radicals initiating degradation (or cross-linking) of macromolecules.

Organosulfur and aromatic compounds also exert inhibiting effect on thermal degradation of irradiated polymer, initiated by "defects" arising in the macromelecule (tertiary carbon atoms and unsaturation) under the action of high-energy radiation [3, 4].

Radiation-induced chemical processes in polymers are also affected by boron-containing compounds, among which carboranes are of particular interest. Carboranes are boron compounds with cage structure necessarily incorporating one or more carbon atoms. Owing to delocalization of valent electrons, boranes exhibit properties typical of aromatic systems, such as high thermal stability and low reactivity toward various agents [5]. Their ability to absorb energy is used in synthesis of radiation-resistant polymers to raise the strength of adjacent bonds in the macrochain [5, 6]. For example, addition of carboranes to polyethylene as a comonomer in copolymer of ethylene and isopropylene carborane supresses cross-linkings of macromolecules under the action of gamma radiation [7].

It was of interest to examine the influence of carboranes on the radiation resistance of polymethyl methacrylate for the example of dibenzyl-*o*-carborane (DBOC).

EXPERIMENTAL

Dibenzyl-*o*-carborane was synthesized by the procedure described in [8]; mp 151–152°C; compound with limited solubility in methyl methacrylate (MMA) and polymethyl methacrylate (PMMA); the solubility of DBOC in MMA is approximately 15%, and the compatibility of DBOC with PMMA is preserved at concentrations not exceeding 10 wt %.

The characteristics of PMMA were studied on block samples produced by polymerization of MMA in the bulk at 40°C until complete conversion of the monomer in the presence of 0.05 wt % initiating agent (dicyclohexyl peroxydicarbonate, CPC) and up to 10 wt % DBOC.

The polymerization kinetics was studied by dilatometry at 40 ± 0.2°C. To remove the stabilizing

1070-4272/02/7506-0980 $27.00 © 2002 MAIK "Nauka/Interperiodica"

agent, MMA was treated with 10% aqueous sodium carbonate, washed with water to neutral reaction, dried over calcined $CaCl_2$, and distilled in a vacuum. The purity of the monomer was checked by chromatography. CPC was recrystallized from methanol and dried in a vacuum at room temperature to constant weight; decomposition temperature 35–40°C.

The thermal oxidative stability of polymers was estimated thermogravimetrically on an MOM derivatograph (Hungary) in air. The weighed portion of polymer chips was 100 mg, and the heating rate, 5 deg min^{-1}.

Thermomechanical tests were carried out on an installation with programmed heating by the method of permanent loading of the samples. The load was 0.13 MPa, and the heating rate, 0.04 deg s^{-1}. The glass transition point T_g and flow point T_f were determined from intersections of tangents to the initial sections of inflections in the thermomechanical curves.

The radiation resistance of PMMA was estimated from variation of T_g, T_f, and decomposition point T_d after gamma irradiation of discs 4 mm high on an Issledovatel' installation equipped with a ^{60}Co source. The irradiation dose was varied from 0 to 8.0 Mrad. The irradiation dose rate was 0.7 Mrad h^{-1}.

The chain transfer constants K_z/K_p in polymerization were determined according to the procedure described in [9].

It is well known that, under the action of ionizing radiation, PMMA degrades with random cleavage of the chain: T_f of the irradiated samples abruptly decreases even at small irradiation doses (Fig. 1, curve *1*), since it varies in direct proportion to the molecular weight of the polymer.

Carborane inhibits the PMMA degradation proceeding under the action of gamma radiation, which is manifested in a less pronounced decrease in T_f of the polymer prepared in the presence of DBOC, compared with the polymer prepared in the absence of carborane (Fig. 1, curves *1* and *2*). It seems likely that the polymer is protected owing to the ability of carboranes to absorb and dissipate the incident radiation energy. It is evident that the polymer is also protected by aromatic fragments of DBOC, dissipating the absorbed radiation energy before chemical transformations proceed in the polymer matrix. In addition, there is a possibility of deactivation of free radicals appearing under the action of high-energy radiation by carborane or products of its radiation-induced transformations.

Polymethyl methacrylate produced in the presence of DBOC is a homopolymer of methyl methacrylate

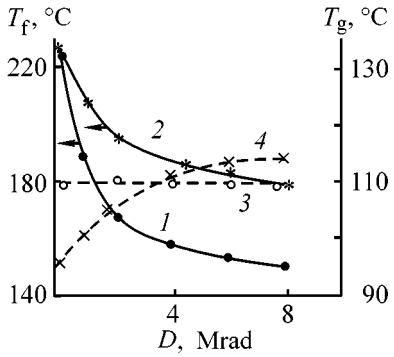

Fig. 1. (*1*, *2*) Flow point T_f and (*3*, *4*) glass transition point T_g of PMMA (*1*, *3*) without additives and (*2*, *4*) with addition of 10 wt % DBOC vs. the irradiation dose *D*.

containing carborane in the form of mechanical impurities. DBOC, having high thermal and chemical stability, does not react with the growing macroradical in polymerization of MMA: the rates of polymerization of monomer both in the presence and in the absence of this compound are the same. Hence, DBOC does not inhibit radical polymerization. In addition, it does not participate in chain transfer: in the presence of DBOC, the molecular weight of the resulting polymer does not change, and the relative inhibition constant K_z/K_p is zero. The macroradical adds neither to aromatic ring owing to abstraction of H atom from the benzene ring nor to the carborane core. It is evident that the reaction conditions are not sufficiently rigorous to form bonds between the carbon atoms of vinyl groups and boron atoms of carboranyl groups. Structures with such bonds were found, along with polyvinyl structures, e.g., in radiation polymerization of 1-vinyl-*o*-carborane [10].

The carborane group is characterized by a large dipole moment (4.5 D for *o*-carborane) and presence of delocalized electrons [11]. These groups can enhance the intermolecular interaction. For example, under isothermal heating in a vacuum and in the presence of oxygen the ester bond in polyarylates containing *o*- and *m*-carborane is cleaved even at 225–325°C. In parallel, the amount of B–H bonds decreases and the B–O–B bonds appear in the carborane fragments, which results in the formation of cross-linked structures [12]. In the presence of oxygen, these structures are formed by the reaction of carborane fragments with oxygen, and in a vacuum, by the reaction with oxygen-containing groups of macromolecules.

Under gamma irradiation of PMMA containing DBOC, carborane or products of its radiation transformations can react with oxygen-containing groups of PMMA (ester groups $-COOCH_3$). In the IR spectra,

there are no changes in the intensities of the absorption bands at 2580–2600 and 1740–1720 cm^{-1}, corresponding to the B–H modes of the carborane core [12] and carbonyl group in the ester fragment; in addition, the absorption band at 1420 cm^{-1} characteristic of the B–O–B bond is absent. However, this does not preclude the possibility of cross-linking of macromolecules via these bonds. The concentration of carborane fragments in the polymer does not exceed 4.4 wt %, and only part of these fragments, not detectable by IR spectroscopy, enter into the reaction.

The observed increase in T_g of the samples containing DBOC after irradiation (Fig. 1, curve *4*) can be accounted for by the appearance of cross-linking, resulting in decreased segmental mobility of macromolecules. Another reason for an increase in T_g of the polymer can be formation of di-, tri-, and tetramers from DBOC under gamma irradiation. For example, these oligomers with the C–C bond are formed in gamma radiolysis of *o*-carborane and 1-phenyl-*o*-carborane [13]. An increase in the molecular weight of the plasticizer, resulting in increased viscosity of the system, must also result in a higher T_g of the sample, in contrast to PMMA without an additive, whose T_g does not noticeably change with increasing irradiation dose and is 110°C (Fig. 1, curve *3*).

Dibenzyl-*o*-carborane in irradiated and nonirradiated PMMA affects the flexibility of macromolecules only slightly and acts as a plasticizer. In the unirradiated polymer, T_g decreases from 110 to 95°C with the content of DBOC increasing from 0 to 10 wt %. In PMMA subjected to gamma irradiation, the plasticizing effect of DBOC is retained up to irradiation dose of 3.5 Mrad: curve *3* lies below curve *4* (Fig. 1).

The thermomechanical curves presented in Fig. 2 are characteristic of linear polymers. Irradiated and unirradiated samples of PMMA containing DBOC are characterized by the presence of glassy, hyperelastic, and plastic states. However, when passing from unirradiated to irradiated samples, the level of hyperelastic deformation decreases somewhat, which suggests the formation of cross-links. The decrease in T_f of the polymer at increasing or constant T_g, occurring under the action of gamma irradiation, results in narrowing of the temperature range of hyperelasticity. The decrease in the $T_f - T_g$ difference for the polymer with addition of DBOC (Fig. 3, curve *2*) is less pronounced than that for the straight polymer (Fig. 3, curve *1*).

Dibenzyl-*o*-carborane not only exhibits radiation-protective effect in radiation aging but also inhibits thermal degradaton of this polymer preliminarily subjected to gamma irradiation. It is well known that at high temperature PMMA degrades by the depolymerization mechanism, in which the primary free radicals are generated by cleavage of "weak bonds" of macromolecule (terminal double bonds, bonds between two tertiary carbon atoms). DBOC does not react with the growing macroradical in polymerization of MMA and does not affect the number of weak bonds in the polymer; therefore, it does not affect the thermal stability of PMMA. The temperatures of the degradation onset and intense degradation do not vary with the concentration of carborane increasing from 0 to 10 wt % and are 250–255 and 290–300°C, respectively. The DTA and DTG curves are characterized by the same shape for PMMA with addition of DBOC and straight PMMA. In the DTA and DTG curves, there are no exothermic peaks caused by oxidation processes and there is an endothermic effect suggesting predominance of thermal degradation of irradiated and unirradiated samples.

The irradiated samples of straight PMMA and PMMA containing DBOC degrade in different ways. The T_d values of the polymer with additives exceed

the corresponding characteristics of the straight polymer at irradiation doses of up to 8 Mrad (Fig. 4). Under the action of radiation, the C–C and C–H bonds are cleaved to form, along with low-molecular-weight products, macroradicals able to participate in further reactions, e.g., initiation of thermal degradation of PMMA. Therefore, irradiation decreases its thermal stability, especially at temperatures above 250°C, which is clearly seen when comparing curves *1* and *3* in Fig. 5. The retention of higher decomposition temperatures of polymers with addition of DBOC as compared with the straight polymer is apparently caused by lower concentration of macroradicals owing to the protection of PMMA against radiation aging in the presence of this compound.

The increase in T_d of DBOC-containing PMMA upon gamma irradiation (Fig. 4, curve *2*) can be accounted for by assuming that oxygen-containing groups of macroradicals react with carborane fragments of the additive to form B–O–B bonds, which results in strengthening of the neighboring C–C bonds in the polymer macrochain. The reaction of DBOC with two macromolecules must result in formation of cross (bridging) chemical bonds, yielding a polymer of three-dimensional network structure. Owing to the "cage effect," free radicals arising in the network polymer under the action of gamma radiation recombine, having no time to leave the cage.

The stabilizing effect of DBOC additive on the thermal aging of irradiated PMMA is manifested both in the initial stages of weight loss and in the range of intensive degradation of the polymer. It should be noted that the thermal stability of irradiated samples increases in the same range of irradiation doses in which their softening point increases (up to 3–4 Mrad). Further irradiation does not alter the thermal stability and thermomechanical properties of the irradiated polymer: the dependences of T_d and T_g on irradiation dose flatten out (Fig. 1, curve *4*; Fig. 4, curve *2*).

Thus, PMAA containing DBOC and subjected to gamma irradiation is characterized by higher thermal stability and softening point than the straight polymer.

CONCLUSIONS

(1) Dibenzyl-*o*-carborane exhibits radiation-protective properties in radiation aging of polymethyl methacrylate. It inhibits thermal degradation of irradiated polymer.

(2) Gamma irradiation of polymethyl methacrylate containing dibenzyl-*o*-carborane raises the thermal stability and softening point of the polymer, apparently owing to the reaction of oxygen-containing groups of macromolecules with carborane fragments of the additive occurring in the polymer matrix in the form of mechanical impurity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Synthesis and Isolation Conditions on Properties of Dextran Polyaldehyde

E. V. Novikova, E. V. Tishchenko, A. A. Iozep, and B. V. Passet

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received November 22, 2001; in final form, February 2002

Abstract—The content of aldehyde groups in dextran polyaldehyde was studied in relation to the pH of the reaction mixture in dextran oxidation and isolation of polyaldehyde.

There are indications in the literature that dextran polyaldehyde (DPA) samples prepared by oxidation of dextran with sodium metaperiodate at 18–20°C for 1 day and then isolated at pH in the range from 3.2 to 8.0 differ in spectral characteristics [1–3]. It was suggested that this is due to keto–enol tautomerism of DPA. In acid solutions, approximately half of aldehyde groups are in the free state and hydrated form. The other half is involved in intermolecular hemiacetal bonds. With increasing pH, the intermolecular networks are broken, and hydrated aldehyde groups form mainly hemiacetal rings with aldehyde groups of the oxidized unit.

Since DPA is used for constructing polymeric drugs, it is of prime importance to ensure the reproducibility of its initial properties. Therefore, the goal of this study was to elucidate the influence exerted by conditions of DPA synthesis and isolation and by the pH of the DPA solution on its characteristics.

To find how the pH of the reaction medium in oxidation of α-glycol groups of the polysaccharide affects the properties of the polyaldehyde, the reaction of dextran with sodium periodate (0.75 or 1 mol of $NaIO_4$ per monosaccharide unit) was performed in aqueous solutions with pH from 1.9 to 5.6 at 6–8°C for 4 h until the oxidant consumption ceased (monitored spectrophotometrically at 222.5 nm [4]). The required acidity was adjusted with 0.1 formate buffer solution, or by adding solutions of HCl and NaOH; pH was monitored with an I-160 laboratory pH meter. The products were isolated as described in [5], analyzed by the oxime [6] and hydroxamic [7] methods, and characterized by the degree of substitution, C_{sa} (number of aldehyde groups per monosaccharide unit). The number of 2,4-oxidized monosaccharide fragments in the polyaldehyde (moles per mole of DPA monomeric unit) was determined from the amount of formic acid formed in oxidation of dextran, which, in turn, was determined by titration with 0.1 N NaOH. The number of 2,3- and 2,4-oxidized fragments, x, was calculated by the formula

$$x = a - 2b,$$

where a is the number of moles of consumed $NaIO_4$, and b is the number of moles of released formic acid per mole of dextran monosaccharide units.

Viscometric studies, performed with a VPZh-2 viscometer (glass capillary diameter 0.56 mm) in water at 21°C showed that the intrinsic viscosity of DPA samples prepared by oxidation of dextran at different pH is approximately the same (0.92 ± 0.04 l mol^{-1}) and equal to that of the initial dextran (0.95 l mol^{-1}). This fact suggests that, under the reaction conditions, cross-linking is improbable, or its extent is equal in DPA samples prepared at different pH. As expected, the solubility of DPA samples decreases as compared to the initial polysaccharide. For example, whereas dextran dissolves at room temperature, DPA dissolves only upon heating.

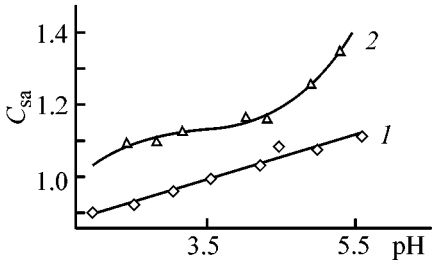

Fig. 1. Degree of substitution, C_{sa}, of DPA, calculated from the results of periodate oxidation, vs. pH of dextran solution (*1*) in formate buffer solution and (*2*) in water (before oxidation).

3.5	0.75	0.25	0.25	–	1.00
4.2	0.75	0.23	0.29	1.0	1.04
4.5	0.75	0.21	0.33	0.95	1.08
5.0	0.74	0.20	0.34	1.11	1.08
5.6	0.75	0.19	0.37	0.96	1.12

* (1) Determined by the oxime method and (2) from $NaIO_4$ consumption; the same for Table 2.

Table 2. Characteristics of DPA samples prepared by oxidation of dextran in water

Solution pH		$NaIO_4$ consumption, mol mol^{-1}	Number of oxidized fragments		C_{sa}	
initial	final		2,4-	2,3-	1	2
2.4	1.8	0.90	0.36	0.18	0.87	1.09
2.8	2.1	0.90	0.35	0.20	0.87	1.10
3.2	2.3	0.90	0.34	0.23	0.87	1.13
3.6	2.3	0.90	0.33	0.24	0.91	1.14
4.0	2.4	0.92	0.33	0.25	0.89	1.17
4.3	2.4	0.91	0.33	0.26	0.88	1.17
4.9	2.5	0.93	0.30	0.33	0.93	1.26
5.3	2.8	0.92	0.24	0.43	0.84	1.35

We found (Tables 1, 2) that, in oxidation of dextran in a buffer solution and in water, the amount of the consumed oxidant is approximately constant (~0.75 and 0.92 ± 0.02 mol per mole of monosaccharide units, respectively) irrespective of pH. The total number of aldehyde groups in DPA samples, calculated from the results of periodate oxidation, increases in both cases by 24% as the pH is raised from 1.9–2.4 to 5.6–5.3 (Fig. 1). However, C_{sa} is a virtually linear function of pH in the formate buffer solution, whereas in oxidation of dextran in water the acidity exerts a stronger effect on the total degree of substitution at pH > 5. At lower pH, the mean C_{sa} of DPA samples is 0.89 ± 0.04 (from elemental analysis) and 1.15 ± 0.07 (from results of periodate oxidation).

In periodate oxidation, the yield of formic acid and hence the number of 2,4-oxidized monosaccharide fragments in DPA decrease with increasing pH of the initial dextran solutions. Here, as in the case of the overall degree of substitution, the number of 2,3- and 2,4-oxidized DPA fragments depends linearly on the pH at which dextran was oxidized in buffer solution and in a more complex fashion in aqueous solutions (Figs. 2a, 2b).

With increasing pH of the reaction mixture in periodate oxidation, the ratio of the 2,4- and 2,3-oxidized fragments changes. Correspondingly, the structure of the polymer chain changes, so that, even at close or the same content of aldehyde groups capable of reacting with a nucleophile, the structure of DPA samples may be essentially different. For example, DPA samples prepared in the buffer solution at pH 1.9 and 5.6 contain, respectively, 15 and 37% 2,3-oxidized fragments; the content of glucopyranose fragments in the samples prepared by dextran oxidation in water at the initial pH 2.5 is approximately 1.5 times that in the samples oxidized at pH 5.3, at approximately equal (0.84–0.87) degree of substitution C_{sa} determined by the oxime method.

In oxidation of dextran in water, the pH of the reaction mixture steadily decreases (due to formation of formic acid), and by the end of the reaction it is lower than the initial value by 0.6–2.6. The final pH in oxidation of dextran solution is the same (2.3–2.4) at different pH values (from 3.2 to 4.3) of the initial dextran solutions. Correspondingly, the composition

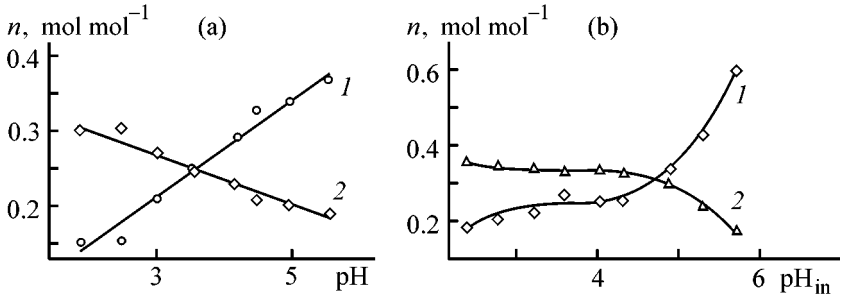

Fig. 2. Number *n* of (*1*) 2,3- and (*2*) 2,4-oxidized monosaccharide units in DPA vs. (a) pH of the buffer solution used in dextran oxidation and (b) initial pH of dextran solution in water in oxidation with sodium periodate.

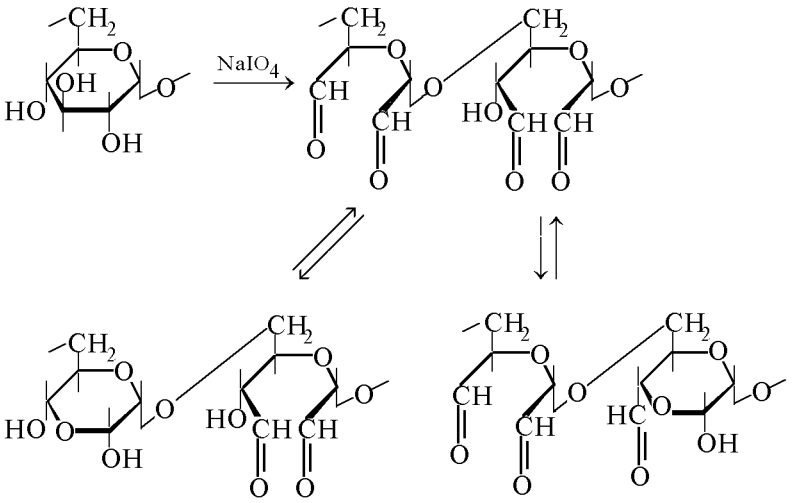
of the DPA samples obtained under these conditions are also close: 33–34% 2,4-oxidized fragments, 26–23% 2,3-oxidized fragments, and 41–43% monosaccharide fragments.

We also found that, for DPA samples prepared by oxidation in water, C_{sa} determined by the oxime method is always lower than it whould be expected on the assumption that the oxidant is fully consumed for α-glycol oxidation. The difference between the C_{sa} values determined by the oxime method and from the periodate consumption is larger for the samples obtained by dextran oxidation at higher pH. This fact confirms the assumptions made by us and other authors [1–3] that 2,3- and 2,4-oxidized fragments can form stable lactol rings, which are not opened in reactions of polyaldehydes with hydroxylamine:



To verify the assumption that not only 2,3-, but also 2,4-oxidized units of the polyaldehyde can form cyclic lactols, we performed oxidation of dextran with excess sodium periodate at pH 2.64 and 5°C until the oxidant uptake ceased. An analysis by the oxime method of the samples containing exclusively 2,4-oxidized fragments showed that the content of aldehyde groups capable of reacting with nucleophiles is only half that expected from the periodate consumption. This may be due to formation of inter- and intramolecular lactols, and also to steric factors.

The influence exerted by conditions of DPA isolation from solution on its characteristics was examined with a sample prepared by oxidation of 10 g of dextran with sodium metaperiodate (0.5 mol of $NaIO_4$ per mole of monosaccharide units) in 1 l of formate buffer solution at pH 4. The mixture obtained by oxidation was dialyzed against water for 2 days, and the resulting solution was concentrated in a vacuum (residual pressure 20–25 mm Hg) at 50°C to 100 ml and divided in five portions; the pH of each portion was adjusted in the range from 2.8 to 5.6, and it was kept for 10 min. To the resulting DPA solutions, ten volumes of ethanol were added, and the products were isolated as described above. The degree of substitution was determined using the hydroxamic reaction.

As expected, the resulting samples had different contents of free aldehyde groups. The highest C_{sa} values were observed in the samples precipitated at pH 3.6–4.0. With pH decreasing to 2.8 or increasing to 5.6, C_{sa} decreased by 8–10% (Fig. 3).

Modification of polysaccharides with amines, phenols, and other compounds is often performed at pH > 7. To determine how C_{sa} of DPA varies in alkaline solutions in the absence of nucleophiles, the

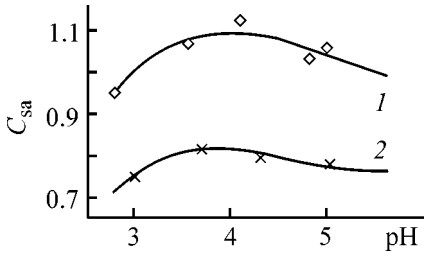


Fig. 3. C_{sa} of DPA samples, determined by the hydroxamic method, vs. pH of their solutions in the stage of precipitation with ethanol. Temperature of oxidation, °C: (*1*) 20, (*2*) 5.

polyaldehyde (C_{sa} = 0.65) was kept for 2 h in 0.02 N NaOH at 15–20°C. At definite intervals, samples were taken, and the amount of aldehyde groups in DPA was determined by the hydroxamic method.

We found that, under these conditions, C_{sa} of this DPA sample decreased to the following level: 15 min, 0.6; 45 min, 0.4; 60 min, 0.35; and 100 min, 0.32. That is, the content of aldehyde groups in DPA decreased approximately by half in 1.5 h, and this process was irreversible. The initial C_{sa} value was not restored after keeping in an acidic solution (pH 3.5) the DPA sample treated with alkali. Such transformations of DPA may involve not only keto–enol tautomerism but also aldol and crotonic condensations and oxidation.

CONCLUSIONS

(1) The ratio of 2,3- and 2,4-oxidized fragments in dextran polyaldehyde formed by oxidation of dextran with sodium metaperiodate is mainly determined by the pH of the reaction solution.

(2) To prepare samples with reproducible characteristics, oxidation of dextran and isolation of dextran polyaldehyde should be performed in the range pH 3.6–4.3.

Interaction of Water with Cellulose and Cellulose Acetates as Influenced by the Hydrogen Bond System and Hydrophilic–Hydrophobic Balance of the Macromolecules

A. M. Bochek and L. M. Kalyuzhnaya

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 16, 2002.

Abstract—Interaction of cellulose and cellulose acetates of different degrees of substitution with water, ethanol, and chloroform was studied by the sorption technique. The factors determining the solubility in water of cellulose acetates with degrees of substitution varied in a narrow range were studied.

Interest in water-soluble cellulose acetates (CAs) is due to a number of their peculiar properties. Films and fibers of water-soluble CAs, unlike water-soluble cellulose ethers (methyl cellulose, ethyl cellulose, etc.), can be readily saponified to form hydrated cellulose fibers and films insoluble in water [1–3]. Cross-linked CA films can also be prepared. Water-soluble CAs are also used for preparing drugs with prolonged effect and as a binder for tablets; in textile industry, they are used to improve the crease resistance of fabrics [3–5].

There are several methods for preparing CAs [1–3, 6–8]. Water-soluble CAs are prepared only by homogeneous saponification of cellulose triacetate (CTA) [1, 6]. Cellulose acetates with degree of substitution (DS) from 0.4 to 1.0 are water-soluble [2, 3, 6–9]. Cellulose acetates prepared by direct acetylation to the same DS are only partially soluble in water (20–25 wt %) [7]. The mechanism of dissolution of CAs in water and the factors preventing dissolution in water of CAs prepared by direct acetylation have been extensively studied both in Russia and in other countries. The studies performed in Russia mainly concern preparation and properties of water-soluble CAs [1–3].

The distribution of acetate substituents in glucopyranose rings and along the macromoleculesis of CAs prepared by direct acetylation is nonuniform. The reactivity of the OH groups of cellulose in acetylation decreases in the order $C_6 > C_2 > C_3$. Homogeneous saponification of CTA with acetic acid involves two processes: hydrolysis (saponification) of acetate groups and ester interchange of hydroxyl groups until an equilibrium is attained [1]. Hence, water-soluble CA can be regarded as cellulose derivative with uniform distribution of substituents in the macromolecules of the natural polymer. The CA solubility in water depends on the location of substituents at the anhydroglucoside chains. Experiments on tritylation of water-soluble CAs (introduction of triphenylmethyl substituents at the C_6 position) showed that acetate groups are in the C_2 and C_3 positions [2, 3]. The primary OH groups (C_6 position) remain unsubstituted, and the distribution of acetate groups over positions C_2 and C_3 is random.

A study of the solubility in water of CAs prepared by three homogeneous procedures [7] showed that CAs with uniform distribution of the substituents over the C_6, C_2, and C_3 positions of glucose units are water-soluble. The decisive influence on the solubility of CA in water is exerted by relative substitution degree of the secondary OH groups. Aqueous CA solutions show no gelation on heating, unlike solutions of methyl and ethyl cellulose. Kamide *et al.* studied the solubility in water of CAs prepared by two methods. They also noted that the solubility strongly depends on the substitution at the C_2 and C_3 positions of the polymer units. They suggested that, for CA to be soluble in water, the OH groups at the C_3 position must be substituted. The degree of substitution at this position must be higher than the critical value estimated at 0.2 [8]. Introduction of hydrophobic substituents at the C_3 position ruptures the $OH_{(3)}\cdots O'_5$ intramolecular hydrogen bond and increases the mobility of macromolecules.

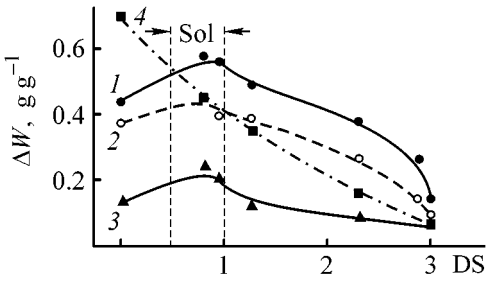

Fig. 1. Water sorption ΔW on cellulose and CA measured at (*1*) 280, (*2*) 293, and (*3*) 310 K and (*4*) calculated by the Van Krevelen procedure, vs. DS. The region of water-soluble CAs is bounded by vertical dashed lines; the same for Figs. 2a and 3.

The influence of the supramolecular structure of CAs on their solubility in water was noted in all the above works. The substituents in water-soluble CAs are uniformly distributed inside the glucopyranose rinds and along the polymeric chains [7–10].

When CA is dissolved in water, H bonds are formed between the solvent molecules and the OH and C=O groups of the acetyl substituents [3]. Introduction of a small number of hydrophobic substituents breaks down the regular structure of cellulose macromolecules and makes the supramolecular structure of the polymer disordered [1]. Hence, the solubility of CA in water depends on both physical (degree of crystallinity and uniformity of substituent distribution) and chemical factors (solvation of hydroxy and acetate groups) [1].

In this work, we studied the solubility of CAs in water as influenced by changes in hydrogen bond network of natural cellulose and in the hydrophilic–hydrophobic balance of its macromolecules. The interaction of cellulose and CA was studied by sorption of solvent vapor at different temperatures.

EXPERIMENTAL

Cellulose acetates with DS of 0.80, 0.95, 1.26, 2.30, 2.88, and 3.00 were prepared by homogeneous saponification of CTA [3]. CA films were prepared by casting CA solutions in water-acetic acid mixture on Teflon plates. To reach complete dissolution of the samples, the solvent composition was varied depending on the DS of the polymer. A film of hydrated cellulose was prepared by saponification of a film of water-soluble CA with DS = 0.80 with a sodium methylate solution [11].

The sorption of saturated solvent vapor on the films at 280–310 K was measured with a McBain spring balance with sensitivity of about 1 mg mm^{-1} (~0.01% error).

To find out how the change in the network of H-bonds of cellulose and in the hydrophilic–hydrophobic balance of the macromoleculs affect the thermodynamic affinity of the polymers for water, we studied the interaction of cellulose and CAs with different DSs with water, ethanol, and chloroform. Ethanol and chloroform can also form hydrogen bonds with the OH groups of the polymer, with ethanol being both donor and acceptor of protons and chloroform being proton donor only [12]. In addition, the hydrophilicity of these compounds varies: ethanol is unlimitedly miscible with water and chloroform is only sparingly soluble in water. The interaction of these solvents with OH groups of cellulose can be estimated from their interaction with water.

Previously, we have found [13] that the energy of H bonds in cellulose is up to 25.0 kJ mol^{-1}. Since the energy of hydrogen bonds in water lies in the range 18.0–21.0 kJ mol^{-1} [14], cellulose is insoluble in water. Cellulose is soluble in tertiary amine *N*-oxides forming H bonds with a polymer with energy higher than 25.0 kJ mol^{-1} [15]. Acetate derivatives of cellulose with DS from 0.4 to 1.0 are water-soluble [3, 7, 8].

Myagkova *et al.* [16, 17] showed that the enthalpy of mixing of CA with water is the factor determining the CA solubility. However, the cellulose structure changes after introduction of a small amount of acetate groups [1, 3], which in turn, affects the network of H bonds in the natural polymer. Introduction of bulky polar substituents into cellulose macromolecules changes fundamentally the polymer properties: network of H bonds, density, molar volume, heat capacity, glass transition point, thermal stability, etc. [18].

Figure 1 shows how the water sorption by cellulose acetate varies with DS at different temperatures. The $\Delta W = f(\mathrm{DS})$ functions pass through a maximum in the DS range corresponding to solubility of CA in water. The presence of the maximum suggests the influence of two processes on the solubility of CA in water. The dependence of water sorption on the DS, calculated by the Van Krevelen procedure [19], is also shown in the figure. It should be noted that the calculated dependence shows no maximum. Only the contribution of various groups to the sorption was taken into account in the calculation, and changes in the degree of crystallinity during swelling and in the system of intermolecular interactions in CA with changing DS were disregarded. As the temperature increases, the water sorption decreases owing

to weakening of CA-water interactions. It should be noted that a maximum in the $\Delta W = f(\mathrm{DS})$ dependence for CA was not always observed [16, 17]. The reason for this phenomenon is considered below.

To evaluate the polymer solubility in a specific solvent, Askadskii *et al*. took into account the surface tension at the solvent–polymer interface and the wettability γ of the polymer surface with the solvent [20, 21]. In this work, we performed similar studies.

The dependence of the solvent sorption at 293 K on the DS and the variation of the surface energy γ of the polymers in going from cellulose to cellulose diacetate (CDA) with DS = 2.40 are shown in Figs. 2a–2c. As seen from Fig. 2a, γ of pure cellulose (curve *2*) is 66.5 mN m^{-1} [22]. The surface energy of commercial CDA is 39–40 mN m^{-1} [23]. The surface tension of water (72.5 mN m^{-1}, curve *3*) is higher than that of cellulose [24]. Introduction of acetate groups into the cellulose macromolecule increases the difference between the surface tension of the polymer and the solvent, i.e., makes the polymer more hydrophobic, decreases the weattability of the polymer with water, and prevents diffusion of solvent molecules in the polymer matrix. As the DS increases further, the difference in γ increases so that CTA virtually does not interact with water. Presumably, the right-hand boundary of the DS range of water-soluble CAs is determined or bounded by the increasing polymer hydrophobicity.

The plots of ethanol and chloroform sorption vs. DS (Fig. 2b and 2c) show that at least two factors affect the solvent–polymer interaction. One of these, the difference in the surface energy of the polymer and the solvent, is manifested to a varied extent.

The $\Delta W = f(\mathrm{DS})$ dependence for ethanol is similar to that for water. However, the ethanol sorption is appreciably lower, which agrees with the data of [16]. The surface energy of CAs with DS > 2.0 approaches that of the solvent; however, cellulose and CA are insoluble in ethanol and swell only slightly. This suggests that the mechanism of interaction of ethanol with CA is similar to that of water, and the energy of ethanol interaction with the functional groups of the polymer is lower.

Cellulose acetate with DS = 3.0 (cellulose triacetate) is soluble in chloroform (Fig. 2c). At DS = 0.8 the sorption passes through a weak minimum. At higher DS the CA-solvent interaction increases. As in the case of ethanol, the surface energies of the polymer and the solvent approach each other, which favors solvent diffusion into the polymer matrix. The fact that CAs with high DS are insoluble in

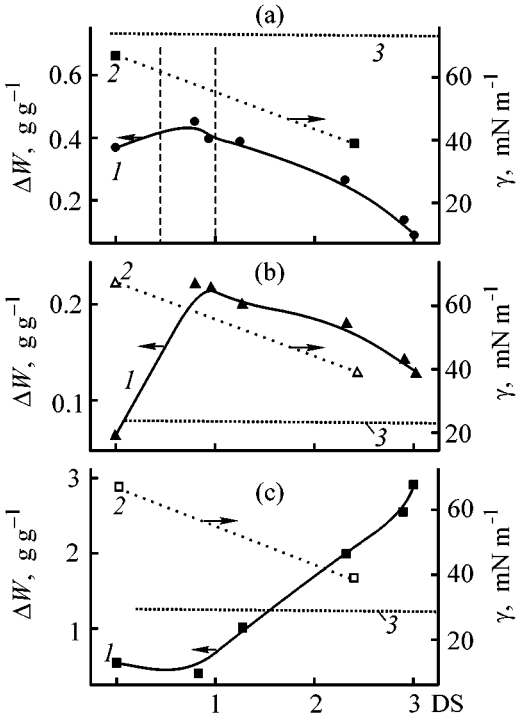

Fig. 2. (*1*) Sorption of (a) water, (b) EtOH, and (c) $CHCl_3$ ΔW at 293 K and (*2*) surface energy of the polymers γ vs. DS; (*3*) the surface energy of liquids.

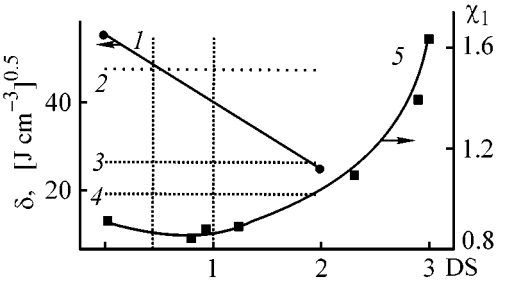

Fig. 3. Solubility parameters δ of (*1*) CA, (*2*) water, (*3*) EtOH, and (*4*) $CHCl_3$, and (*5*) χ_1 interaction parameter vs. DS.

ethanol and chloroform indicates the difference in the specific interaction of these solvents with CA.

Previously, we have shown that the energy contribution of hydrogen bonds and dipole–dipole interactions to the cohesion energy density of CA sharply decreases and the contribution of the dispersion forces grows with increasing DS. The solubility parameter δ and its components for methanol and chloroform are $\delta = 26.5$, $\delta_d = 15.8$, $\delta_p = 8.8$, $\delta_h = 19.4$ and $\delta = 19.0$, $\delta_d = 17.8$, $\delta_p = 3.1$, $\delta_h = 5.7$ $(\mathrm{J\ cm^{-3}})^{0.5}$, respectively [24]. Comparison of the solubility parameters shows that H bond formation makes a major contribution to the cohesion energy density in ethanol, and the contribution of the dispersion interactions is lower.

At the same time, the main contribution in chloroform is due to the dispersion interactions and the energy contribution from H bonding is lower. These different types of interaction cause different mechanisms of interaction of these solvents with CA.

The solubility parameters of water, ethanol, chloroform, and CA and the plot of the parameter of CA–water interaction χ_1 vs. DS are presented in Fig 3. The Flory–Huggins parameter χ_1 was calculated by the equation

$$\ln a_1 = \ln(P_1/P_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \quad (1)$$

where a_1 is the solvent activity and P_1/P_1^0 is the relative vapor pressure of the solvent.

The experiments were performed at the saturated pressure of the solvent: $a_1 = P_1/P_1^0 = 1$, $\ln a_1 = 0$. The volume fraction of the swollen polymer was calculated by the equation

$$\varphi_2 = \frac{1}{1 + \frac{d_2}{d_1}(\Delta W)}, \quad (2)$$

where ΔW is the amount of the solvent sorbed (g g^{-1}), and d_2 and d_1 are the polymer and solvent densities, respectively.

The density was determined by the flotation procedure.

The δ-vs.-DS dependence obtained previously [13] is shown in Fig. 3 (curve *1*). Cellulose acetate is soluble in water when the δ values of the polymer and solvent are close and χ_1 values are minimal. Hence, to make CA water-soluble, the energy contribution of H bonding to the cohesion energy density, which prevails in the initial cellulose, should be decreased. Introduction of a small number of acetate groups appreciably decreases the number of H bonds in cellulose and their energy in the case of uniform distribution of these groups in the macromolecules and glucoside units. As a result, CA becomes water-soluble. Upon further increase in the content of acetate groups, the difference between the surface energies of the polymer and solvent strongly grows (hydrophobization of the polymer), and the polymer becomes insoluble. This is confirmed by the fact that cellulose propionates prepared similarly are hydrophobic and insoluble in water [1].

Superposition of the two trends, the decrease in the contribution of the H bonds to the cohesion energy density of the polymer and the hydrophobization of the macromolecules, affects the thermodynamic affinity of CA for water. Strengthening in the polymer–water interaction up to DS = 1.0 (a decrease in the parameter χ_1 of the polymer–solvent interaction) indicates that rupture of the H bonds in the polymer and a decrease in δ of CA exert a prevailing effect. At higher degrees of substitution the interaction weakens owing to polymer hydrophobization. A decrease in the average energy of H bonds of the OH groups of CA with increasing number of acetate substituents was found in [3].

It should be noted that the degree of crystallinity of CAs with DS ≥ 0.5 sharply decreases [1]. In the order cellulose–water-soluble CA–CTA, the polymer crystallinity may change substantially depending on the conditions of CA saponification and isolation of the products from the solution. The porosity and the specific surface area of CAs depend on the conditions of their precipitation from solution [16]. These factors strongly affect the solvent sorption and can result in disappearance of the maximum in the $\Delta W = f(\mathrm{DS})$ curve at DSs corresponding to the water-soluble polymer. Probably this was the case in [17].

Thus, the solubility of CAs in water is due to a decrease in the energy and, probably, number of H bonds of cellulose (supramolecular level). Introduction of acetate groups makes the macromolecules hydrophobic (molecular level) and insoluble in water. Swelling of water-soluble CAs cannot reach a maximum owing to cellulose crystallization.

CONCLUSION

The factors determining the solubility of cellulose acetates were studied at the molecular and supramolecular levels. At the supramolecular level, the solubility of cellulose acetates in water is due to a decrease in the energy (and probably number) of hydrogen bonds of cellulose. Introduction of acetate groups makes the macromolecules hydrophobic (molecular level) and insoluble in water.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Possibility of Using Organophosphonates in the First Stage of Cellulose Whitening

E. A. Mozyreva, S. A. Kireeva, B. N. Driker, and E. V. Kazuto

Ural State Forestry University, Yekaterinburg, Russia

Received November 5, 2001; in final form, January 2002

Abstract—The influence of organophosphonates on decomposition of equilibrium peracetic acid was studied in the temperature range 50–70°C and pH 4.5–5.0.

One of the promising ways to produce whitened cellulose is to use peroxo compounds, such as peracetic acid and hydrogen peroxide [1]. As a rule, cellulose is whitened in several steps, but the key one is the first stage aimed to complete lignin removal. The efficiency of using formulations based on peroxo compounds is largely governed by the presence of heavy metal ions in the reaction medium and in the material to be treated. Their presence results in catalytic decomposition of these compounds, which deteriorates economical characteristics of delignification and whitening.

It is well known that complexones binding catalyst ions in the reaction mixture into stable complexes enhance the efficiency of peroxo compounds in cellulose whitening [2].

The aim of this work was to study the effect of organophosphonate complexones [3] on the decomposition of equilibrium peracetic acid and on the efficiency of the first stage of whitening of sulfite cellulose.

As object of study served peracetic acid prepared by the procedure described in [4] and containing unreacted acetic acid and hydrogen peroxide. The content of peracetic acid was 15–16%, and that of hydrogen peroxide, 9–10%.

As complexones we used organophosphonates (OPs) with varied number of functional groups and varied length of the hydrocarbon radical: nitrilotrimethylenephosphonic (NTMP), ethylenediaminetetramethylenephosphonic (EDTMP), diethylenetriaminepentamethylenephosphonic (DTPP), methyliminodimethylenephosphonic (MIDP), ethyliminodimethylenephosphonic (EIDMP), butyliminodimethylenephosphonic (BIDMP), and hexyliminodimethylenephosphonic (HIDMP) acids, and also IDMS, inhibitor of deposotition of mineral salts [TU (Technical Specification) 2415-124-166 70872–96], a mixture of organophosphonates in which NTMP and MIDP are the main components:

* Data for M : OP = 1 : 3 are given in parentheses.

The decomposition kinetics of equilibrium peracetic acid was studied in the temperature range 50–70°C with stirring (Re 12 500) for solutions with initial concentration of 0.039 M and pH 4.5–5.0, which corresponds to the conditions of delignification and whitening. Fe^{3+} ions, catalyzing decomposition of peroxo compounds, were added to the reaction mixture in amount of 1 mg l^{-1}, corresponding to their real content in the reaction medium in cellulose whitening.

The content of CH_3COOOH and H_2O_2 in the reaction mixture was determined by the well-known procedure [5]. The experimental data processed according to the equation of second-order reaction [6] are listed in Table 1.

In the presence of Fe^{3+} ions in the temperature range 50–70°C, the decomposition rate of both CH_3COOOH and H_2O_2 increases by a factor of 3–6 at pH 4.5–5.0. It is evident from Table 1 that all the organophosphonates used noticeably decrease the decomposition rate of peroxo compounds. With increasing amount of functional groups in the reactant molecule, the decomposition rate of both CH_3COOOH and H_2O_2 noticeably decreases. In this case, the effect of organophosphonates is enhanced both with increasing temperature and with variation of the molar ratio M : OP. In our opinion, this suggests the occurence of a chemical reaction between organophosphonates and metal ion and increased stability of the resulting complexes.

For all the organophosphonates differing in the length of hydrocarbon radical, the decomposition rate of CH_3COOOH and H_2O_2 noticeably decreases in the temperature range studied. However, the variation of the length of the hydrocarbon radical does not affect significantly the kinetic parameters of decomposition.

With account of the experimental data on the effect of organophosphonate on the decomposition kinetics of peroxo compounds, we prepared the whitening formulations containing equilibrium peracetic acid (PAA) and organophosphonates. It is well known that the quality of the initial cellulose, namely, lignin content (Kapp number), governs the result of whitening. Therefore, we used, as an initial fibrous product for whitening, crude sulfite cellulose (CSC) with various initial whiteness, 62.6 and 59.2%, and Kapp number 18.0 (CSC I) and 26.0 (CSC II), respectively. In the first stage, cellulose was whitened under standard conditions: temperature 70°C, duration 60 min, cellulose concentration 10 wt %, pH 4.5–5.0, and expenditure of whitening formulation 3% in terms of absolutely dry cellulose. Organophosphonates were added in the amount corresponding to the Fe^{3+} content in a material to be treated (0.007–0.01%) at a molar ratio M : OP = 1 : 3. The results are given in Table 2.

Peracetic acid without addition of organophosphonates only slightly affects delignification and whitening of cellulose, which is suggested by the residual amount of CH_3COOOH and H_2O_2 in the mother liquors, Kapp number, and whiteness of the half-finished product. In delignification of the cellulose sample CSC I with solution of equilibrium peracetic acid in the absence of organophosphonates, the Kapp number decreases from 18 to 13. For sample CSC II, this parameter decreases from 26 to 21. Addition of or-

IDMS	17.44	72.90	0.0025	19.00	73.49

ganophosphonates promotes both more complete removal of lignin and increase in the degree of whiteness. The Kapp number decreases to 10–12 for sample CSC I and to 16–19 for sample CSC II. Depending on the length of the hydrocarbon radical of organophosphonate, the degree of whiteness increases from 70.50 to 72.00–76.40%; with organophosphonates differing in the amounts of functional groups, this parameter ranging from 60.08 to 69.00–74.10%.

Most likely, the mechanism of the positive influence exerted by organophosphonates on delignification and whitening consists in the formation of stable coordination compounds with heavy metal ions present in cellulose, which decreases their negative catalytic effect on the decomposition of peroxo compounds. Therefore, peroxo compounds are more completely used in the main process.

The high residual content of H_2O_2 in the equilibrium peracetic acid in mother liquors offers an opportunity for their use in subsequent stages of cellulose whitening.

CONCLUSIONS

(1) Organophosphonates exert stabilizing effect on the components of whitening solutions, CH_3COOOH and H_2O_2. Is is evident that this is caused by the formation of stable coordination compounds of organophosphonates with Fe^{3+} ions.

(2) Composites based on the equilibrium peracetic acid and organophosphonates can be used in the first stage of whitening of sulfite cellulose.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Carbon Fabric Reinforced Composites Based on Modified Epoxy Resins and Prediction of Their Strength Characteristics

Yu. N. Anisimov and S. N. Savin

Mechnikov State University, Odessa, Ukraine

Received March 27, 2000; in final form, July 2001

Abstract—The strength characteristics of composites based on four types of modified epoxy resins and reinforced with carbon fabric were studied as influenced by the filler content. The experimental and theoretical strength parameters of the composites were compared. The correlation between the adhesion strength at the polymeric binder-filler boundary and the impact resilience of the composites was evaluated; a procedure was proposed for predicting the impact resilience of the reinforced composites.

Composite materials based on polymeric binders and reinforced with carbon fibers and fabric have high strength properties and find many applications in aerospace industry and ship building [1, 2]. The nature of polymeric binder and the adhesion properties at the interface between the polymeric matrix and the carbon fabric strongly affect the properties of the reinforced composites, especially in the case of various epoxy binders [1, 3]. The electrical conductivity and strength properties of a series of composites based on modified epoxy resins filled with carbon black and graphite were studied in [3]; the possibility of predicting the strength properties of fiber glass fabric reinforced composites with similar binders was analyzed in [4].

The aim of this work was to study the strength properties of carbon fabric–reinforced composites based on modified epoxy resins and to develop a procedure for calculating their strength properties, taking into account the adhesion characteristics at the interface between the polymeric binder and the carbon fabric boundary.

EXPERIMENTAL

In this work, we used the following polymeric binders: T-10 epoxy-silicone resin [TU (Technical Specifications) 6-02-616–85], UP-637 epoxy-resorcinol resin (TU 6-06-271–86), and ED-20 epoxy-4,4'-isopropylidenediphenol resin [GOST (State Standard) 10587–84], whose characteristics are given in [4, 5]. The filled composites were cured at 20°C using B brand polyethylene polyamine (PEPA) [TU 6-02-596–86] at its content of 14–17 wt % relative to the epoxy resin. The EPU-1 epoxy-polyurethane resin contained 16.5 wt % epoxy groups, and its average relative molecular weight was 1600; all other characteristics of the resin are given in [5]. This resin was cured at 20°C using UP-583 product of condensation of formaldehyde and diethylenetriamine (TU 6-05-341–88) at its content of 14 wt % relative to the epoxy resin.

The composites were reinforced with UTM-8-1 brand carbon satin fabric based on heat-treated polyacrylonitrile fiber (92% carbon content, 0.01–0.05 mm in diameter). The composites were prepared as follows. The binder and the curing agent were deposited on carbon fabric sheets with a putty knife, and the resulting stacks were pressed with a roller. These stacks were cured at 20°C for no less than 24 h. The tensile strength (σ_t) and the ultimate strength at static bending (σ_b) of the resulting composites were studied using the procedures described in [4, 6] according to GOSTs 14236–81 and 9650–81, respectively. In our experiments, we determined the average parameters using at least three samples of each composite. The impact resilience of the composites (a_i) was studied using $60 \times 8 \times 6$ mm rectangular samples with no notches on an MK-05 impact tester with a 40-mm distance between the bearings [6] (GOST 9454–88).

The dependence of the tensile strength of the carbon fabric–reinforced composites based on modified epoxy resins on the filler content (in the range of 0.25–0.60 wt fraction) showed that the highest σ_t is observed for the composites based on ED-20 binder at a filler content of 0.35–0.40 wt fraction (see table).

* (m_1) Filler content; (E_2) modulus of elasticity of the polymeric matrix; (A, B) coefficients in Eqs. (1)–(5); (α) coefficient; (γ_2, γ_{12}) surface tension of the polymeric binder and interphase surface tension, respectively; (A_a) adhesion strength.

With the filler content increasing to 0.5–0.6 wt fraction, σ_t first slightly increases and then decreases. A similar trend is observed for all the other reinforced composites based on epoxy resins, studied here. In a series of composites with the optimal content of the reinforcing filler (0.35 wt fraction), the tensile strength depends on the binder: it increases in passing from T-10 to EPU-1 resin and reaches the highest values with UP-637 binder. In the last case, σ_t significantly exceeds the results obtained with composites based on ED-20 epoxy resin (see table). It should be noted that the dependences of σ_t and σ_b of the reinforced composites on the type of the epoxy binder are similar to those determined previously for unfilled resins and to that of the modulus of elasticity of the polymeric matrix (see table). As seen from the comparison with the strength properties of fiber glass–reinforced composites based on the same binders [4], σ_t of the corresponding carbon fabric–reinforced com posites is 2–2.5 times higher, which agrees with published data for other carbon–reinforced composites [1, 2]. The optimal content of the filler in the carbon fiber–reinforced composites is significantly lower than that for fiber-glass fabric composites (0.6 wt fraction) [4].

A theoretical analysis of the prestressed-deformed state of reinforced composites is commonly made by solving a model problem by the boundary layer procedure [7, 8]. In this case, the reinforced composite is analyzed as a planar layered material, in which sheets of a carbon or fiber-glass fabric are separated by layers of a binder, with boundary layers between them. These boundary layers are regarded as orthotropic materials with zero modulus of elasticity in the tension direction [7]. Using methods of theoretical mechanics to solve the two-dimensional problem of prestressed-deformed degradation of a reinforced composite [8], the tensile strength σ_t and the ultimate bending strength σ_b can be determined by the equations [7]

$$\sigma_t = -E_1\frac{D_{a2}}{D_{a1}}\left(-\frac{P_l}{D_{a1}+D_{a2}} + \varepsilon_{a1} - \varepsilon_{a2}\right)\left(1 - \frac{\mathrm{ch}\alpha X}{\mathrm{ch}X}\right), \quad (1)$$

$$\sigma_b = -\alpha\frac{D_{a1}D_{a2}}{D_{a1}+D_{a2}}\left(-\frac{P_t}{D_{a2}} + \varepsilon_{a1} - \varepsilon_{a2}\right)\frac{\mathrm{sh}\alpha X}{\mathrm{ch}X}, \quad (2)$$

where E_1 is the modulus of elasticity of the carbon fabric reinforcing the material (250 000MPa) [1]; E_2 is the modulus of elasticity of the polymeric matrix (2000 MPa for ED-20 resin [4], data for the other modified epoxy resins are listed in the table); $D_{a1} = E_1F_1$ and $D_{a2} = E_2F_2$ are, respectively, the rigidities of the reinforcing component and the polymeric matrix at tension; F_1 and F_2 are the respective cross section areas; P_l and P_t are the longitudinal and transverse loads on the polymeric composite; ε_{a1} and ε_{a2} are the tensor components of deformation of the car-

bon fabric and polymeric matrix (MPa m^{-2}); α can be calculated from Eq. (3):

$$\alpha = \sqrt[4]{\frac{6E_1E_2}{G_{1,2}(E_1h_1 + E_2h_2)h_2^2}}, \quad (3)$$

$G_{1,2}$ is the shear modulus of the boundary layer in the composite, taken as 30 000 MPa m^{-1} [7].

The quantities h_1 and h_2, varying with the content of the reinforcing filler in the composites, characterize the layer thickness of the carbon fiber and polymeric matrix.

Equations (1)–(3) can be presented in the general form:

$$\sigma_t = A\left(1 - \frac{\mathrm{ch}\alpha X}{\mathrm{ch}X}\right), \quad (4)$$

$$\sigma_b = \alpha B\left(1 - \frac{\mathrm{ch}\alpha X}{\mathrm{ch}X}\right), \quad (5)$$

where A and B are the corresponding coefficients in Eqs. (1) and (2).

The properties of carbon fabric required for calculations were taken from [1, 9]. The calculations were performed on a PC using special software; the content of the reinforcing filler was varied within 0.25–0.60 wt fraction range with a step of 0.05 wt fraction. The dependences of σ_t and σ_b on the type of modified epoxy resin and the content of the reinforcing carbon fabric are given in the table.

As seen, our calculated and experimental data on σ_{st} and σ_b are reasonably consistent, which confirms the reliability of our model calculations of the strength characteristics of the reinforced composites studied. Our calculations confirmed the experimental fact that that the increase in the filler content over 0.35–0.40 wt fraction does not enhance further the tensile strength of the composites (see table). The calculated σ_t and σ_b exceed the experimental values by 15–20%, and such a deviation is quite acceptable in the theoretical mechanics of composites [7, 8]. The highest strength properties were found for the filled composites based on the UP-637 epoxy-resorcinol resin, which also agrees with our calculations (see table).

The impact resilience a_i, which determines the dynamic strength of the composites [1, 4, 7], is the most important performance characteristic of composites. The experimental a_i values for the reinforced composites are significantly smaller than the corresponding data for fiber glass fabric–reinforced composites based on the same binders [4] (see table), which agrees with the known data on the relatively low impact and shear strength of carbon composites [2, 9, 10]. To a first approximation, the ultimate strength at static bending can be compared with a work for the dynamic break and thus the viscosity of components can be calculated from the ratio similar to those determined for fiber-glass–reinforced composites [4, 7]:

$$a_i = 0.2\sigma_b. \quad (6)$$

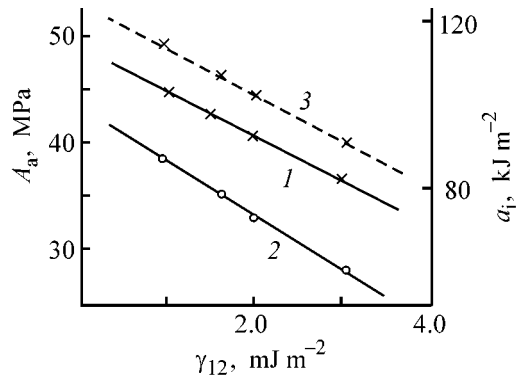
The experimental a_i values significantly exceed the experimental data (see table), which is probably due to structural defects in the real composites as compared with an ideal model used in σ_b calculations. The relative changes in the calculated a_i, as influenced by the type of the polymeric binder, agree with the experimental data (see table), which confirms the possibility of predicting this important characteristic of reinforced composites.

The adhesion strength at the interface between the polymeric binder and the carbon fabric, which is characterized by the work of adhesion A_a, specifically affects the main strength properties of the reinforced composites [4, 9, 11]. In [9], a procedure was proposed for experimental evaluation of the adhesion strength, and A_a values were presented for composites reinforced with fiber glass fabric and carbon fabric, with three of four types of polymeric binders used in this work. With increasing A_a of the reinforced composites studied, their main strength properties increase proportionally (see table), and the highest adhesion strength was observed in the case of UP-637 epoxy-resorcinol binder. At the same time, the degree of filler–binder interaction can be quantitatively evaluated from the dispersion fraction of the interfacial surface tension γ_{12}, using the following equation [4, 11]:

$$\gamma_{12} = \gamma_1 + \gamma_2 - 2(\gamma_1\gamma_2)^{0.5}, \quad (7)$$

where γ_1 and γ_2 are the surface tensions of the filler and polymeric binder, respectively.

As shown previously for composites reinforced with fiber glass fabric, based on modified epoxy resins [5], γ_{12} decreases simultaneously with increasing adhesion strength and impact resilience of composites [4]. Using data on the surface tension of carbon fiber [9] and polymeric matrices [4], we calculated by Eq. (7) the interfacial surface tension γ_{12} of the reinforced composites (see table). The work of adhesion of composites A_a and their impact resilience a_i were correlated to the interfacial surface tension (see figure). The lowest γ_{12} for composites based on epoxy-resorcinol resin corresponds to the highest adhesion and dynamic strength (see table, figure), which agrees with trends found for fiber glass fabric–reinforced



(*1*) Adhesion strength at the polymeric binder–carbon fabric interface between the A_a and (*2*, *3*) impact resilience of composites a_i vs. the interfacial surface tension γ_{12}; 0.35 wt fraction content of the filler in composites. (*1*, *2*) Experimental and (*3*) calculated data.

composites [4]. Using the above dependences (Fig. 2) and the least-squares procedure, we obtained with high reliability the following equations for A_a and a_i:

$$A_a = 49.0 - 4.2\gamma_{12}, \quad (8)$$

$$a_i = 97.2 - 12.1\gamma_{12}. \quad (9)$$

The experimental values of A_a and a_i and those evaluated from Eqs. (8) and (9) are in reasonable agreement (see table, figure). Thus, using a comprehensive approach to the prediction of the strength properties of polymeric composites proposed in [11], which takes into account the strength properties of the polymeric matrix and reinforcing filler [Eqs. (4), (5)] and the adhesion strength and the surface tension at the interface between the polymeric binder and the carbon fiber, we can select the optimal polymeric binders to prepare reinforced composites with improved strength properties.

CONCLUSION

Comparison of experimental and theoretical data on the strength parameters of carbon fabric–reinforced composites based on modified epoxy resins demonstrated the possibility of predicting their properties to prepare reinforced composites with improved strength.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Filling of Castable Polyurethanes with Solid Wastes from Petrochemical Production

T. R. Safiullina, E. A. Sergeeva, V. F. Sopin, and L. A. Zenitova

Kazan State Technological University, Kazan, Tatarstan, Russia

Received December 10, 2001; in final form, February 2002

Abstract—Physicochemical properties of castable polyurethanes based on polyethylene glycol adipate and mixture of 2,4- and 2,6-toluylene diisocyanate (NCO : OH molar ratio 1.6) and filled to 10 wt % with silica gel (waste from petrochemical production) were studied.

Solid wastes, including those from chemical production, are the main sources of lithosphere pollution. Their accumulation in various branches of industry is determined by the existing level of processing of raw materials and by their inexhaustive utilization. Removal (transportation) of the wastes and their storage (design and maintenance of slag-heaps and slurry tanks) are rather expensive [1, 2].

Solid wastes from petrochemical production include rejected and spent gas-purifying filters based, in particular, on silica gel and alumina. Hence, treatment to recycle these compounds is an urgent problem.

It is known that materials of similar composition are used as fillers of various polymeric composites and rubbers [3]. However, these fillers are rather expensive and scarce. Hence, use of wastes containing silicon as alternative fillers of polymeric materials and, in particular, castable polyurethanes (PUs) is a promising way of their safe utilization [4, 5].

EXPERIMENTAL

In this work, we studied castable polyurethanes prepared from polyethylene glycol adipate (PEGA, $M \approx 2000$) and a mixture of 2,4- and 2,6-toluylene diisocyanate (TDI, 80/20) at a PEGA : TDI molar ratio of 1.6 [6]. Preliminarily ground to 10–50 μm spent gas-purifying filters based on silica gel [GOST (State Standard) 3956–76] and pearlite [GOST 10832–91] were used as fillers.

The properties of filled PUs at elevated temperatures were studied by differential scanning calorimetry on a DSC-111 device (Setaram) and thermogravimetric analysis on a TGS-2 automated recording unit (Perkin–Elmer) in the 20–500°C temperature range with heating rate of 5 deg min^{-1}. The effective density of the network ν_e/V was determined from the axial compression measured on a relaxometer according to the Cluff-Glading method [7]. The physicochemical parameters were evaluated according to GOSTs.

As seen from Fig. 1c, the shape of the DSC curves after filling of the polyurethanes with silica gel is retained. The effect of the fillers on the sample properties can be analyzed using the TG curves (Fig. 1a).

At temperatures higher than 244°C, the samples intensively lose weight. At lower temperatures, the polymer loses about 1.0–1.5 wt %, which is probably due to liberation of adsorbed moisture and other volatile products. In the 244–446°C range, the sample

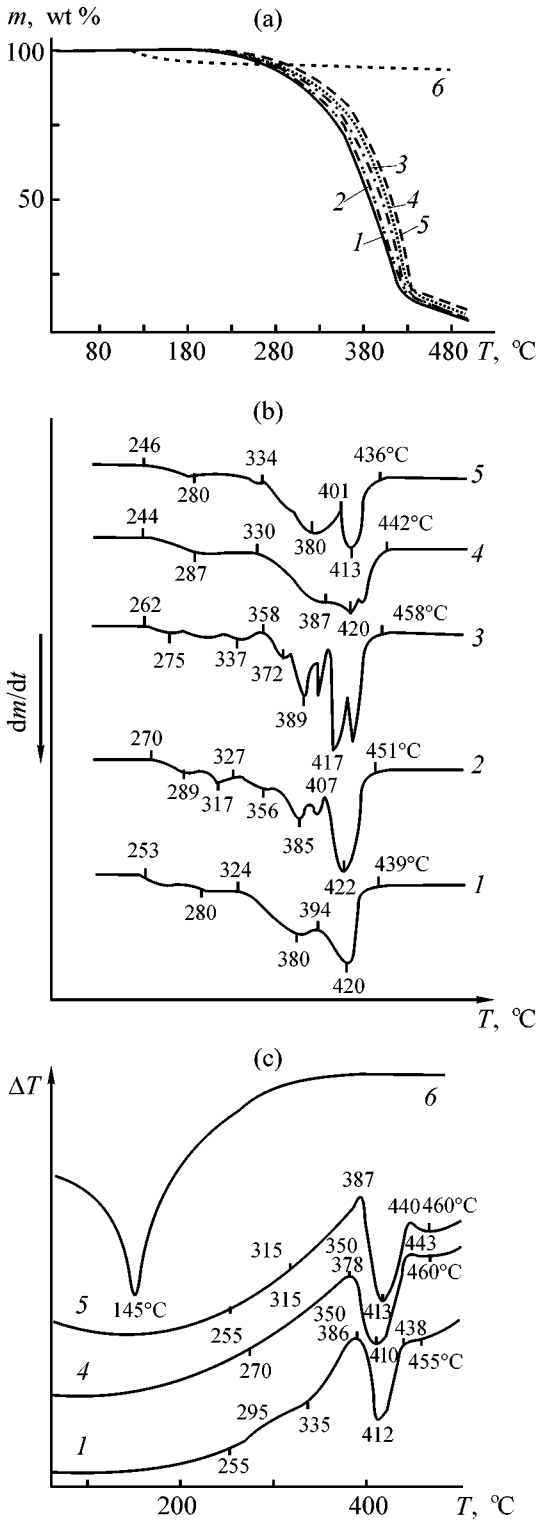

Fig. 1. (a) TG, (b) DTG, and (c) DSC curves of polyurethane filled with silica gel. (*m*) Weight, (d*m*/d*t*) rate of weight loss, and (*T*) temperature; the same for Fig. 2. Silica gel concentration (wt %): (*1*) 0, (*2*) 1, (*3*) 3, (*4*) 5, and (*5*) 10; (*6*) straight silica gel.

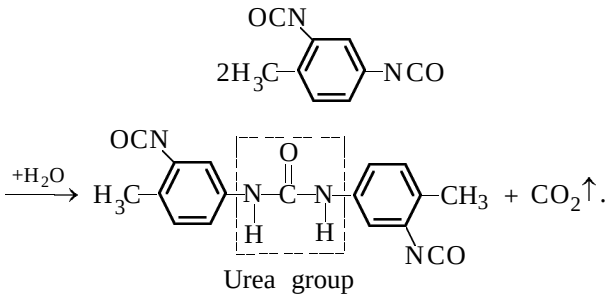
degrades, and at temperatures higher than 446°C the TG curve flattens out. As seen, the greater the PU filling degree, the larger the polymer residue (Table 1).

With increasing degree of filling, the temperature of the onset of intensive weight loss increases, i.e., the thermal stability of the composite is enhanced (Table 1). The shape of the TG curves also changes: the weight loss proceeds in two steps, the first step is less pronounced, whereas the second is more intensive.

As for the DTG curve, with increasing degree of filling, its shape becomes more complex and additional peaks appear (Fig. 1b). Such a course of weight loss and the shape of the DTG curves suggest changes in the mechanism of thermal degradation.

The DTG curves of silica gel indicate the presence of adsorbed water, which is liberated in the 80–130°C range. The endothermic peak in the DSC curve of silica gel at 145°C is also due to water liberation (Fig. 1c, curve *6*). Upon further heating of silica gel to 500°C, the weight losses reaches 13 wt %. Such a run of the DSC curves is probably due to the silica gel structure, which is characterized by highly developed surface of micropores, retaining adsorbed water even at temperatures higher than 100°C. The possibility that it contains the crystallization water which is removed only at temperatures higher than 400°C [8] (Fig. 1a) cannot be ruled out, either.

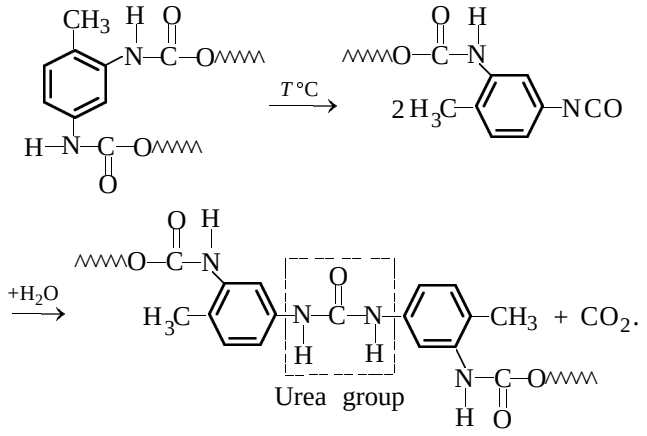
To prepare SKU-OM brand polyurethane, the initial compounds should be dried in a vacuum at elevated temperatures, because moisture deteriorates the quality of the resulting items, reacting with isocyanate to give gaseous products forming gas inclusions:



In our tests, we used preliminarily dried silica gel, but, as seen from Fig. 1a, the content of water in the micropores reaches 5 wt %.

In synthesis and thermal treatment of PU under relatively mild conditions (up to 80 ± 5°C), water contained in micropores and partially crystallization water do not affect noticeably the quality of the polyurethane items. However, water is liberated at ele-

vated temperatures during thermal analysis and reacts with the products of PU thermal degradation. This process is accompanied by breakdown of allophanic, urethane, and other fragments forming the urethane network, and liberated water probably reacts with the isocyanate group formed through bond rupture. Since the reaction of isocyanates with water is significantly faster than the other possible reactions with compounds containing the active hydrogen atom, we assume that the reaction through the isocyanate group is the most probable [9]. As a result, more thermally stable urea groups are formed [10]:



As seen from Fig. 2c, the shape of the DSC curves is almost independent of the degree of polyurethane filling with pearlite.

The effect of the degree of filling on the PU thermal properties can be more clearly seen from the TG and DTG curves (Figs. 2a and 2b).

The shapes of the TG curves of the initial polyurethane and PU filled with pearlite are similar, but in the case of filled composites they lie somewhat higher. With increasing degree of filling, the shape of the DTG curves changes and additional peaks appear (Fig. 2b). The appearance of these peaks suggests that the thermal degradation of the filled PUs becomes more complex and passes several stages as compared with the unfilled polymer. A similar phenomenon was observed in PUs filled with silica gel, and the weaker changes in the case of pearlite filler are probably due to certain differences in the filler structure and smaller degrees of filling as compared with silica gel.

The weight loss of pearlite is illustrated in Fig. 2a (curve *4*). The TG curves show that the content of water in pearlite is significantly lower than that in silica gel.

In the case of pearlite, the dependences of the thermal properties of polyurethanes on the degree of filling (1–3 wt %) are similar to those for silica gel (Figs. 1, 2), because pearlite mainly consists of silica. The only difference is that pearlite has a less developed structure due to the smaller content of micropores. Therefore, the content of adsorbed water in

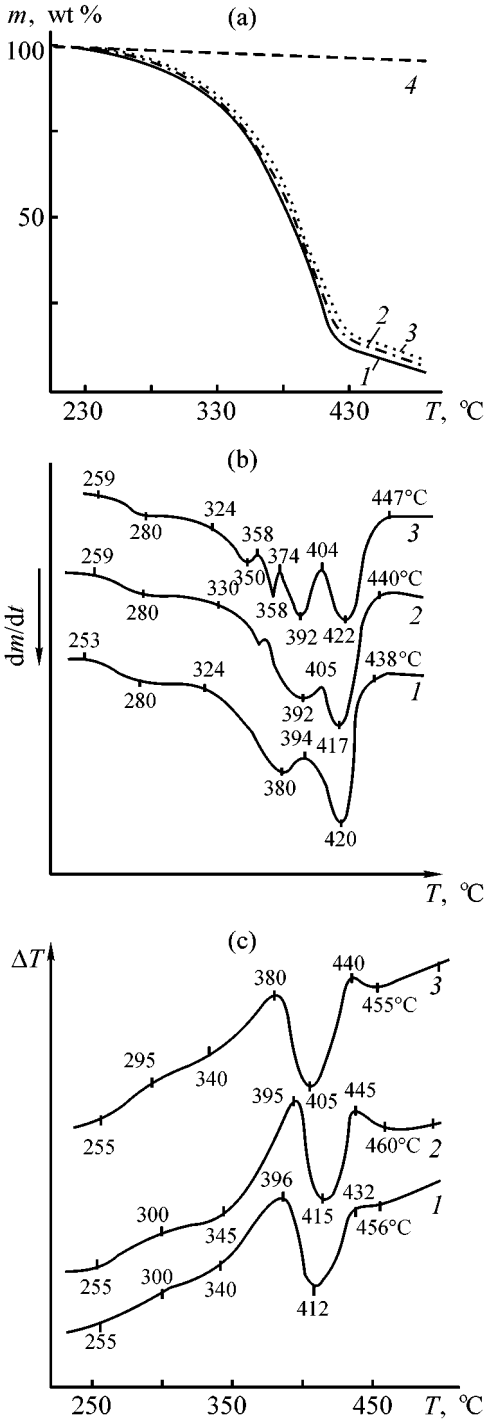


Fig. 2. (a) TG, (b) DTG, and (c) DSC curves of polyurethane filled with pearlite. Pearlite concentration (wt%): (*1*) 0, (*2*) 1, and (*3*) 3; (*4*) pearlite.

Table 2. Effective network density in PU in relation to content of fillers

Filling, wt %	$\nu_e/V \times 10^2$ (mol m^{-3}) at indicated temperature, °C		
	100	120	150
Silica gel			
0	3.828	1.826	0.241
1	5.133	4.508	1.900
3	5.516	5.113	1.706
5	5.603	5.665	1.785
10	6.717	5.627	2.599
Pearlite			
1	5.834	4.643	1.480
3	6.795	4.583	2.039

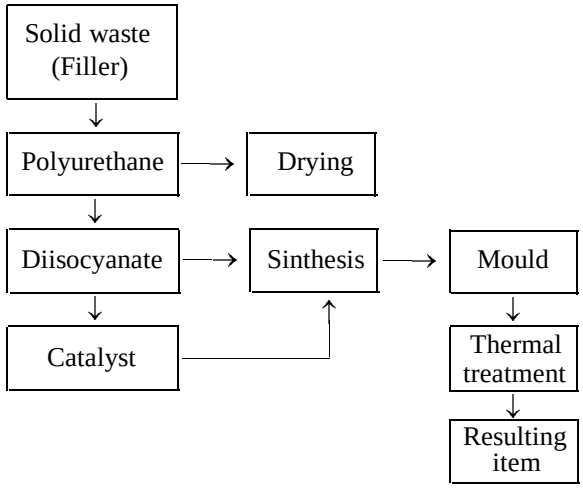
pearlite is smaller than that in silica gel [8] (Table 1). Moreover, pearlite is a light friable material with high bulk density, and its addition in large amounts to the polymer is rather difficult.

As seen from the above data, filling with silica gel enhances the thermal stability of polyurethanes. However, a study of the effective density of the polymer network can give more comprehensive information on the performance of polyurethane items at elevated temperatures (Table 2).

Above 100°C, the physical bonds are predominantly broken and the ν_e/V value is due to the chemical network in the polymer. This network consists of weak allophanic bonds, which break at 100–120°C. Above 120°C, ν_e/V is a function of more thermally stable chemical bonds, such as urethane and triisocyanurate.

As seen from Table 2, with increasing degree of filling, the effective density of the polymer network increases in the entire temperature range studied. At 150°C, unfilled PU completely degrades to form the linear product, whereas filling with silica gel and pearlite significantly enhances the thermal stability of the composites.

We developed a scheme for preparing SKU-OM type castable polyurethane:



The effect of the content of silica gel filler on the physical and mechanical properties of the resulting PU is illustrated in Table 3. With increasing filler content, the hardness of the composites significantly increases, the elasticity slightly decreases, and the strength remains approximately constant. However, raising the filler content to more than 10 wt % promotes aggregation of the filler and its separation into an individual phase, which impairs the strength properties of the composites. Aggregation of silica-containing fillers in the polyurethane matrix is probably due to the presence of silanol groups at their surface, which existed in the initial filler or were

Table 3. Properties of polyurethane composite as influenced by the type of the filler

formed during preparation. These groups are proton donors, and thus such proton acceptors as isocyanates and amines can form strong bonds with the silicate filler surface [11]. Since the rigid aggregates in PU, formed by diisocyanate, form a separate phase [12], the filler chemically bound with such a rigid block also forms a separate phase, i.e., it agglomerates in the polymer bulk.

Thus, using our experimental data, we developed a new environmentally sound and economically profitable procedure for utilization of silica-containing wastes from petrochemical production for preparing SKU-OM castable polyurethane with enhanced thermal stability.

CONCLUSIONS

(1) Utilization of solid silica-containing industrial wastes from petrochemical production as a way to reduce environmental pollution was studied.

(2) Silica- and pearlite-containing wastes can be used as inert cheap fillers providing thermal stabilization of the polymer.

(3) With increasing content of the filler, the effective density of the network in filled polyurethane increases by nearly a factor of two, simultaneously the temperature of the onset of intensive weight loss increases by 25°C.

(4) A procedure was developed for preparing castable polyurethane filled with silica, which decreases the costs of production and allows solution of environmental problems.

Received January 10, 2002

Abstract—Cationic oligomerization of the C_9 fraction of liquid pyrolysis products of petroleum raw materials, catalyzed by aluminum trichloride diphenyl ether complex, was studied, and a procedure was developed for preparation of a petroleum polymeric resin and petroleum polymerizate to be used as film-forming agents in paint-and-varnish materials.

Petroleum polymeric resins (PPRs) are widely used in production of synthetic drying oils, lacquers, and paints, and also as binders in various adhesive, rubber, and other formulations; the fields of their applications are steadily expanding. These products successfully substitute natural and manmade components of various materials, ensuring the same or even better performance of these materials [1].

PPRs are, as a rule, prepared by cationic (catalytic) or radical (thermal or initiated) polymerization of the C_9 fraction recovered from liquid pyrolysis products of hydrocarbons in production of ethylene and propylene from petroleum raw materials. Catalytic synthesis of PPRs has a number of advantages over thermal or initiated polymerization; primarily, it occurs at a higher rate (within 1–2 h) and with quantitative yield of the product, which creates prerequisites for waste-free production of the resins [2]. Furthermore, the yield of the catalytically prepared resin may even exceed 100% based on the monomer, which is due to incorporation of aromatic solvent molecules into the polymeric chain as a result of chain transfer to the solvent [3]. The C_9 fraction is a mixture of monomers (styrene, dicyclopentadiene, indene derivatives, etc.) and nonpolymerizable hydrocarbons; their ratio affects both the polymerization course and the yield and properties of the resins. The composition and properties of the fraction also depend on the raw material and pyrolysis conditions.

In this work, we studied catalytic polymerization of the C_9 fraction of varied origin with the aim to obtain petroleum polymerizate (PP) and PPRs with required physicochemical properties and to use the resulting products as film-forming agents in paint-and-varnish materials.

We have shown previously [4] that donor–acceptor complexes of $AlCl_3$ with dibutyl and diphenyl ethers, ethyl acetate, and urea exhibit high activity in cationic polymerization of the C_9 fraction. For further studies, we chose the complex with diphenyl ether, which can be fairly readily prepared, is highly stable, and is the most suitable for industrial use. The results of oligomerization of fractions **A** (bp 150–175°C, Stavropol'polimer, Budennovsk, Stavropol krai) and **B** (bp 106–180°C, Neftekhim, Nizhni Novgorod) are listed in the table. Fraction **A** is characterized by higher content of dicyclopentadiene and lower content of nonpolymerizable aromatic hydrocarbons, and fraction **B**, by higher content of styrene and low-boiling hydrocarbonds that cannot be converted into resins (toluene, xylenes, ethylbenzene, etc.). Fractions **A** (run nos. 1–8) and **B** (run nos. 9–12) were used both without pretreatment and after preliminary purification, drying, and distillation. Polymerization of crude fraction **A** yields a PPR with low molecular weight and low softening point (run nos. 1–3), which results in a poor quality of the coatings. In this case, the initial C_9 fraction should be subjected to vacuum distillation, since simple distillation does not improve appreciably the properties of PPRs (run nos. 3, 6). To obtain light heat-resistant resins, the fraction should be additionally treated prior to vacuum distillation (run no. 4). In this case, the resulting resins are less colored and have a high softening point. We found that the optimal con-

11*	″	1.0	4 → 60	58	5–10	72–78	595
12**	Crude	1.5	10 → 60	60	5–10	65–70	550

* No maleic anhydride added.

** A pilot batch was produced (1800 kg).

centration of the catalytic complex is 1–1.5 wt % relative to the fraction (run nos. 5–8).

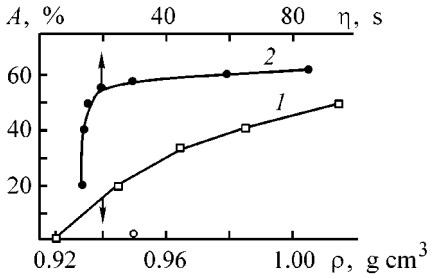
With decreasing amount of the catalyst, both the yield of polymer and its softening point decrease (run no. 5). Taking the catalyst in larger amounts does not further improve the properties of the resins and therefore is not appropriate (run no. 8). Under equal other conditions, fraction **B** is more active in polymerization (run nos. 9, 10) than fraction **A** (run nos. 1, 6). When the reaction is performed without adding maleic anhydride (which enhances the adhesion and thus improves the quality of PPR-based films), the yield and the color on the iodometric scale remain unchanged, but the softening point and molecular weight become lower (run no. 11).

Based on these results, we developed a waste-free catalytic process for production of petroleum polymerizate and PPR. It should be noted that the properties of the PPR from the pilot batch (run no. 12) are in good agreement with the properties of the resins prepared in a lab (run nos. 9, 10).[1] Fraction **B** is preferable for commercial use, as it requires no additional treatment (purification, distillation).

For quickly assessing the quality of the fraction under industrial conditions, we proposed the following procedure: A catalyst solution with 1.5 wt % $AlCl_3$ (relative to the fraction) is added to 100 ml of the fraction, cooled to 10°C. If the temperature of the polymerizing mixture rises to approximately 100°C within 3–5 min, the fraction is suitable for oligomerization. The resin content of the polymerizate can be determined from an experimental correlation between the percentage of the dry residue in the resin solution, its density, and conventional viscosity (outflow time) (see figure).

It should be particularly emphasized that the polymerizates obtained by our procedure have properties similar to those of petroleum polymeric drying oil. For preparing a lacquer, it is the most appropriate to use 60% PPR solutions, readily prepared by diluting or concentrating the polymerizates. The lacquer samples thus prepared exhibit high strength and good water resistance; they quickly dry but show poor elasticity and adhesion. To improve these parameters, we chose appropriate modifiers (dibutyl phthalate and KhT polymer) [5] and developed a formula of

[1] A pilot batch of the polymerizate was produced by the Ozocerite Plant, Joint-Stock Company, Svisloch, Belarus, and subsequently used for manufacturing NP-114 lacquer.



Correlation of the dry residue content *A* at 20°C with (*1*) PPR solution density ρ and (*2*) conventional viscosity η.

an enamel based on oil polymerizates, which is an analog of PF-115 enamel and even surpasses it in hardness and resistance to static action of water.

EXPERIMENTAL

Aluminum chloride diphenyl ether complex was prepared under argon at room temperature in a three-necked flask equipped with a stirrer and a dropping funnel. To a suspension of $AlCl_3$ in toluene, an equimolar amount of a toluene solution of diphenyl ether was added with stirring. For polymerization, we took approximately 1.0 M solutions of the catalyst. The aluminum content was determined by the Wenninen–Ringbom method, and the chlorine content, by the Volhard method.

Oligomerization was performed in a three-necked flask equipped with a stirrer, a dropping funnel, a thermometer, and a cooling water bath. The flask was charged with the C_9 fraction and cooled to 4–8°C, after which the catalyst was added at a rate allowing the reaction temperature to be maintained within 60°C. After the temperature reached a maximum and started to decrease, a definite amount of maleic anhydride was added at 50–55°C. After the temperature decreased to 30°C, the catalyst was deactivated with a solution of ethylene oxide in toluene. The resulting polymerizate was analyzed and directly used for preparing paint-and-varnish formulations. The polymeric oil resin was isolated by distilling off volatile hydrocarbonds at atmospheric pressure and in a vacuum. The composiiton of the fractions was determined by GLC on a Chrom-5 chromatograph equipped with a flame ionization detector; the molecular weight of the resin, cryoscopically in benzene; the softening point, with a Thiele device; and color, using the iodometric scale. The film-forming properties of the polymerizate [TU (Technical Specifications) of Belarus Republic 05568283.017–99] and resins were studied using stationary equipment at the Progress Scientific and Production Enterprise (Minsk).

CONCLUSIONS

(1) The process parameters of oligomerization of C_9 fractions of various compositions were determined, and procedures were developed for synthesis of petroleum polymeric resin or petroleum polymerizate with required physicochemical and technical parameters to be used as film-forming agents in paint-and-varnish materials (drying oils, lacquers, enamels).

(2) The revealed relationships of the oligomerization allowed scaling of the process. Pilot batches of petroleum polymerizate, NP-114 lacquer, and NP-115 enamel (an analog of PF-115 enamel) were produced.

Received October 2, 2001

Abstract—Modification of tar with petroleum polymeric resins yields paving-grade bitumens with enhanced cohesion. With respect to the heat resistance and other parameters, these bitumens meet the requirements of GOST (State Standard) for BND 90/130 paving bitumens.

Rheological and physicochemical characteristics of bitumens are improved by adding various polymers, synthetic rubbers, or rubber crumb [1] in amounts of 1–5%. Blending bitumen with a polymer or a polymer with a solvent requires special equipment ensuring efficient mixing.

Thermopolymeric resins obtained from products of naphtha pyrolysis, having softening points of 80–95°C (Pyroplast, dark resin; Pyroplast-2, light resin), which are produced in compliance with TU (Technical Specifications) 381091–79 and 14689–73, are readily blended with bitumens and petroleum tar on standard apparatus of asphalt-concrete plants. These additives impart to bitumens and tar high heat resistance and plasticity, improve their adhesion to mineral fillers, and enhance the cohesion strength of a pavement [2]. Addition of 1–3% petroleum polymeric resins (PPRs) has been noted to improve such physicomechanical properties of bitumen as ductility, plasticity, elasticity, adhesion strength, and cohesion strength, whereas larger (8–10%) additions of PPRs produced a somewhat weaker effect. At the same time, as noted in [3], such modifiers exert a positive effect mainly on the cohesion of bitumens, decreasing their plasticity (penetration). This study is aimed at refining the effect of these modifiers.

EXPERIMENTAL

The ring-and-ball softening point (°C) was determined according to GOST 9950–83; penetration, according to GOST 11508–78; ductility, according to ASTM D2872–77 standard; and brittle point, according to GOST 11507–78 and by calculation using the Gun formula [4]

$$T_s - T_{br} = 70 - 7PI,$$

where T_s is the softening point (°C), T_{br} is the brittle point (°C), and PI is the penetration index (determined from a nomogram) [4].

The heat resistance of bitumens and modified formulations was determined by a standard procedure. Samples were placed in stainless steel cups (bed height 4 mm, sample weight 60 ± 1 g). The samples were heat-treated at 160°C for 5 h, after which the softening point, penetration P, ductility D, and weight loss Δm (%) were measured.

The adhesion of binder samples to a mineral filler was determined by aqueous cooking with granite and gabbro-diarite (3–5-mm fraction). The filler : bitumen ratio was 15 : 0.6. The cooking was performed for 30 min on a standard grid. The adhesion was evaluated from the weight loss of the material through washout of the binder with boiling water from the filler surface. The specific surface area of the 3–5-mm fraction is close to that of fillers used in Russian plants for production of asphalt concrete.

The water absorption of the binder was determined by the formula

$$W = (W_1/W_2) \times 100\%,$$

** Styrene–indene resin.

where W is the water absorption of the material, %; W_1, the weight of a dry spherical sample of the material (g); and W_2, the weight of the same sample after saturation with water (g).

To prepare a modified bitumen, a metallic crucible placed in an electric oven was charged with a definite portion of tar, the temperature was raised to the required level (110–120°C), and a powdered petroleum polymeric resin (<0.25 mm) was added. The mixture was stirred manually with a metallic stirrer for 10 min. The temperature was chosen taking into account the viscosity of the components (Table 1); it was maintained constant to within ±3°C throughout the stirring time.

Mechanical tests of the samples were performed as follows. The binder was applied as a thin layer onto overlapping steel plates. After 4 days, the force required to break the adhesive joint was determined on a tensile-testing machine. The test was performed with 3–4 samples, and the arithmeric mean was calculated.

To prepare samples of asphalt concrete pavements, a <0.25-mm fraction of mineral fillers (granite, gabbro-diarite, marble) was mixed with bitumen or a bitumen-based formulation taken in amount of 10 wt %. The resulting composites were molded in pellets (15.8 mm in diameter, 8 mm high), which were subjected to a compression test on a press until deformation became detectable.

As the raw material for preparing modified bitumens (binders), we used petroleum tar with ring-and-ball softening point of 38.5°C and petroleum polymeric resins produced in compliance with TU 2451-012-00 149 452–99.

The softening points of the resins were as follows: light thermopolymeric resin P-46, 94°C; P-132, 86°C; styrene–indene resin, 96°C; and Politer, 95°C.

Figure 1 shows how the content of P-46 petroleum polymeric resin affects the softening points of the binary formulations based on petroleum tar and BDUS bitumen. It is seen that, for the formulations based on tar, the softening point grows approximately linearly (except in the initial portion of the curve) with increasing content of P-46, whereas for the formulations based on BDUS 70/100 additions of the same resin affect the softening point insignificantly.

Figure 1b shows that, in the formulations based on tar and bitumen, the penetration decreases with increasing content of P-46, with this trend being more pronounced for the former formulations.

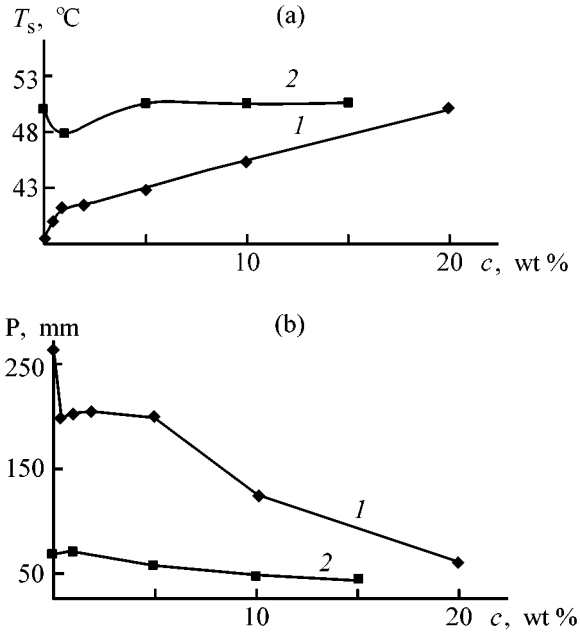

Fig. 1. (a) Softening point T_S and (b) penetration P of formulations vs. the petroleum polymeric (thermopolymeric) resin P-46 *c*: (*1*) tar and (*2*) BDUS 70/100 bitumen.

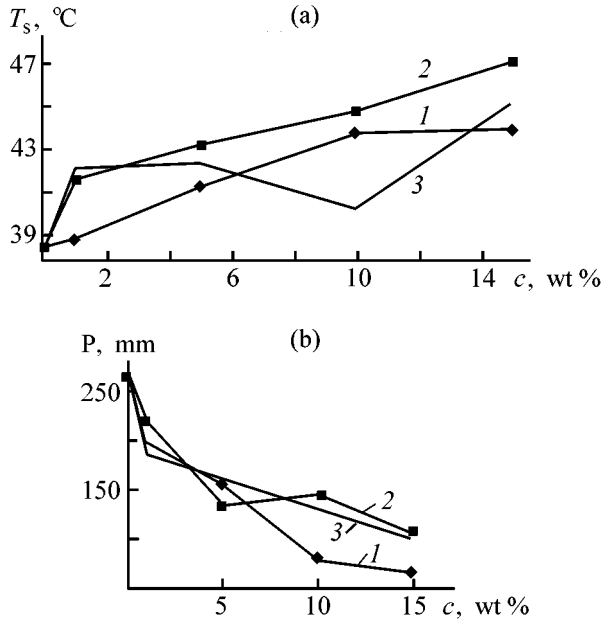

Fig. 2. (a) Softening point T_S and (b) penetration P of formulations based on petroleum tar vs. resin content *c*. Resin: (*1*) Politer, (*2*) P-46, and (*3*) styrene–indene.

Figures 2a and 2b show how the resins added affect, respectively, the softening points and penetrations of the formulations based on tar. The curves in Fig. 2a are similar in shape to those in Fig. 1a, except the curve of the softening point vs. content of the styrene–indene resin. This resin is poorly compatible with tar, and uniform blend cannot be obtained. Figure 2b shows that the penetration of the formulations decreases with increasing content of petroleum polymeric resins.

The requirements to paving bitumens, prescribed by GOST 22245–90, are listed in Table 2.

Among bitumens with satisfactory properties, obtained from tar and thermopolymeric resins, we chose sample nos. 6, 11, 16, 19, 22, and 23 (Table 1), which were tested for compliance with the GOST requirements to paving bitumens. The parameters characterizing the heat resistance of the modified bitumens are listed in Table 3.

Table 3 shows that formulation no. 6 meets all the requirements of GOST to BND paving bitumens. This formulation was subsequently subjected to mechanical tests (strength of a sample with mineral filler) and, together with the other samples, to heat resistance tests.

The parameters of binder-to-filler adhesion are given in Table 2 as mean values of 2–4 measurements. With respect to adhesion to granite, the formulations under consideration (Table 4) are inferior to BDUS 70/100 paving bitumens, but well compete with this bitumen when used with a gabbro-diarite filler. However, the adhesion of these formulations to gabbro-diarite is lower than that of the best samples of Russian bitumens based on high-resin high-viscosity Yarega crude oil. Bitumen sample nos. 6, 9, 14, and 16, meeting the GOST requirements to paving bitumens, were tested for heat resistance, with ductility determined before and after heat treatment (Table 5).

It is seen that the ductility of BDUS 70/100 bitumen (indirectly characterizing the bitumen cohesion) decreases after the heat treatment, whereas that of the formulations based on tar and petroleum polymeric

Table 6. Shear and compression tests of various binder samples

Filler	Sample no. 6	BDUS 70/100	Tar
Compression stress before appearance of detectable deformation, kg cm^{-2}			
Granite	26.9	9.0	1.8
Gabbro-diarite	27	8.4	14.9
Marble	25.4	17.9	4.8
Shear stress, kg cm^{-2}			
–	0.79	1.87	0.42

resins increases, which is important from the practical viewpoint.

The results of mechanical tests of model pavement samples based on formulation no. 6 are listed in Table 6.

Quality bitumens of KINEF Ltd. (mean data for five samples) have the following characteristics: T_s = 43–46°C, P_{25} = 92–97 mm, D_{25} = 147–150 cm, and D_{25} after heat treatment 113–125 cm.

In shear tests, the break of an adhesive joint of metallic plates occurs within the bitumen layer (cohesion break). Since the ductility of sample no. 6 after heating is 80 cm and that of BDUS 70/100 is higher, the trends observed with the shear strength are quite understandable. BND 90/130 bitumen has lower ductility parameters after heating, compared with sample no. 6 (Tables 1, 5). Sample no. 6 in the initial state is characterized by D_{25} = 61.5 cm; for BND 90/130, this value after heat treatment is lower owing to aging (as shown by numerous ductility measurements for laboratory samples and commercial batches of BND bitumens produced from the commercial mixture of West-Siberian crude oils).

From the binders and mineral components, we prepared model pavement samples. The results of compression tests of these samples are listed in Table 6. It is seen that, with all the fillers tested, the model pavement based on formulation no. 6 (90% petroleum tar, softening point 38.5°C, and 10% P-46 petroleum polymeric resin, softening point 94°C) surpasses in compression strength a similar pavement based on BDUS 70/100 commercial bitumen.

CONCLUSION

A paving bitumen formulation, meeting the technical requirements to BND 90/130 paving bitumen, was developed on the basis of tar and light petroleum polymeric resin from thermal polymerization of C_9 naphtha pyrolysis fraction.

Abstract—The structural-group compositions of polar and nonpolar components of malthenes from tars of West-Siberian crude oil and of quality bitumen BDUS 70/100 and substandard bitumen BDUS 60/90 produced from these tars are compared.

According to Pfiffer [1], bitumens are subdivided in three types with respect to their colloidal state: (a) sol, (b) sol–gel, and (c) gel. This classification reflects the viscosity characteristics of bitumens but disregards their chemical composition. It is based on the assumption that the main components of bitumen (paraffins, naphthenes, arenes, resins, asphaltenes) interact via dispersion forces. It has been shown [2] that the primary elements of the disperse structure of bitumens are colloidal (2–10-nm) micelles having the shape of a sphere or a flattened ellipsoid. These micelles are mainly formed by stacking association of planar polyaromatic plates, mainly beloging to asphaltenes and resins, and, to a lesser extent, to mono-, bi-, and polycycloaromatic compounds, with partial overlap of their electron shells.

Kolbanovskaya [3] subdivided bitumens in three types with respect to their disperse structure. Her classification is based on the ratio of asphaltenes, resins, and oils. However, the colloidal stability of bitumens and their physicochemical properties are determined not only by the ratio of oils, resins, and asphaltenes, but also by their specific chemical features.

The experience of using bitumens shows that, if the oil fraction of a bitumen has high content of naphthenoaromatic rings, such a bitumen shows colloidal stability and exhibits high level of physicochemical parameters (penetration P_{25}, ductility D_{25}). If the amount of the oil fraction is low, or it contains mainly paraffinic and naphthenic components, the colloidal stability of the bitumen is lower, and its ductility and strength parameters are worse. The goal of this study was to reveal specific features of structural-group components of tars and bitumens produced from a commercial mixture of West-Siberian crude oils at the Kirishi Oil Refinery.

EXPERIMENTAL

We studied two samples of tars and bitumens prepared by oxidation of these; their characteristics are listed in Table 1.

Table 1. Content of asphaltenes, malthenes, and polar and nonpolar components in tars and bitumens

Product	Yield, wt %, based on tar or bitumen			
	malthenes	asphaltenes	PCs	NPCs
Residue:				
P_{25} = 305 mm × 0.1, conventional viscosity 89 s	89.55	10.45	16.6	83.4
P_{25} = 390 mm × 0.1, conventional viscosity 92 s	88.62	11.38	15.1	84.9

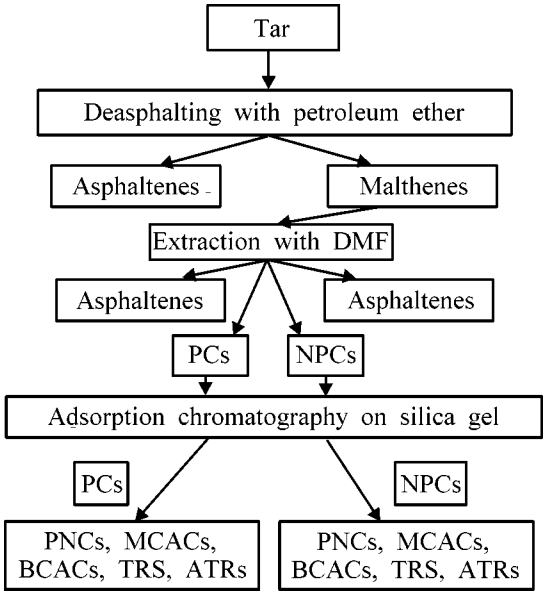
Deasphalting of tars and bitumens was performed by cold and hot Golde procedures [4, 5] in Soxhlet apparatus.

Polar components were recovered from malthenes of tars and bitumens by extraction with dimethylformamide (DMF) (see scheme). Group separation of polar (PC) and nonpolar (NPC) components was performed on silica gel [4]. The boundaries of fractions were determined by characteristic luminescence on a filter paper under UV irradiation. Paraffinic and naphthenic compounds (PNCs) show no specific luminescence. Monocycloaromatic compounds (MCACs) exhibit a blue emission. The emission of bi- (BCACs) and polycycloaromatic (PCACs) compounds is green. Toluene resins (TRs) are yellow-brown under UV light, and alcohol–toluene resins (ATRs) are black. The partitioning scheme of vacuum residue and bitumen is as follows:



The yields of asphaltenes, malthenes, PCs, and NPCs, and also the group composition of the tar and bitumen samples are listed in Table 1. It is seen that the yields of malthenes from tars are close (88.62–89.55%). The differences in the yields of the polar and nonpolar components are also insignificant (~1.5 wt %).

Upon oxidation of these tars to obtain BDUS 70/100 and BDUS 60/90 paving bitumens, the yield of maltenes decreased to 79–80.7%, and the content of asphaltenes increased.

In the initial tars, the asphaltene content is 10.45–11.38%, whereas in the corresponding bitumens, it varies within 19.3–21%. The yield of polar components from bitumens is 4.3–6.3% higher than that from the corresponding tars. The tar characterized by initial penetration of 390 mm × 0.1 and conventional viscosity of 92 s was oxidized to a greater extent (ring-and-ball softening point 48°C) as compared to a tar with initial penetration of 305 mm × 0.1 and conventional viscosity of 89 s. In a bitumen sample with a higher softening point, the content of polar components increased by 1.8%.

Table 2 shows that the content of oils and resins in both polar and nonpolar components of the tars under consideration and corresponding bitumens is noticeably different. In the tar with P_{25} = 305 mm × 0.1, whereas the oils/resins ratio in NPCs is 2.06, whereas in the corresponding fraction of BDUS 70/100 bitumen, it is appreciably lower: 1.73. In polar components of both tars and the corresponding bitumens, the yield of resins is higher, and the above ratio is 1.37 for the tar and 1.25 for bitumen.

The tar with higher penetration (P_{25} = 390 mm × 0.1) is characterized by higher content of oils in both nonpolar and polar components.

The oils/resins ratio in the NPCs of this tar is 2.46, whereas in the tar with P_{25} = 305 mm × 0.1, it is 2.06, and in the PCs of these tars, it is 1.60 and 1.37, respectively.

It should be noted that both samples of tars differ not only in penetration, but also in conventional viscosity, which suggests their essentially different structural types. These differences were also manifested in the stage of oxidation to paving-grade bitumens. From the tar with P_{25} = 305 mm × 0.1, quality bitumen of BDUS 70/100 grade was obtained, whose softening point, penetration, ductility, and also retained penetration and ductility after heat treatment met the requirements. At the same time, from the tar sample with higher conventional viscosity (92 s), larger penetration, and higher oils/resins ratio, it was possible to obtain only harder bitumen BDUS 60/90, exhibiting not only higher softening point (Table 1), but also lower heat resistance. After standard heat treatment (5 h, 160°C), its ductility decreased from more than 150 to 96 cm, and the penetration decreased to 72% of the initial level. For the more heat-resistant quality bitumen BDUS 70/100, the same heat treatment resulted in a decrease in the ductility to 108 cm and in the penetration to 76% of the initial level.

It is interesting that the bitumen BDUS 60/90 obtained from the tar sample with P_{25} = 390 mm and oxidized to a bitumen with higher softening point is characterized by higher oils/resins ratio for both polar

and nonpolar components as compared to BDUS 70/100 quality bitumen.

It is known that the heat resistance of bitumens largely depends on the degree of aromaticity of both the initial tars and the bitumens obtained from them. The heat resistance (possible range of variation of the softening point, penetration, ductility, and brittle point) is affected not only by the extent of oxidation, which is indirectly evaluated by the acid number and oxygen content (elemental analysis), but also by the content of oils, resins, and asphaltenes, and also of aromatic compounds in oils.

It should be noted that not only the total content and ratio of these substances are important, but also their composition (molecular weights; content of polar components, depending on the number of heteroatoms and paramagnetic centers in the system; degree of association of these components; their aromaticity) and the nature of trace impurities (metal complexes). It is noted in the literature that, if polycyclic arenes prevail among aromatic hydrocarbons of oils, the molecules in tars and bitumens are packed into micelles more densely, ensuring higher heat resistance of such bitumens.

Our results show that the ratio of MCACs to BCACs and PCACs is not the only significant factor; the degree of aromaticity of these compounds exerts even stronger influence. It is also clear that, to obtain a heat-resistant bitumen, it is necessary to find the optimal ratio between oils and resins. The excessive amount of oils in the tar with P_{25} = 390 mm × 0.1 results in that their content in the bitumen produced from this tar is also excessive, and the degree of structurization (colloidal stability of the bitumen of type 3, according to Kolbanovskaya's classification) will be lower in this case. As the solvency of malthenes K_s of the oil component increases and the asphaltenes/resins ratio decreases, the colloidal structure of the bitumen becomes less strong:

$$K_s = C_a + 1/3\,C_n,$$

where C_a and C_n are, respectively, the carbon contents in the aromatic and naphthenic structures of malthenes (%).

It seems appropriate to compare quantitatively the group components of the tars and bitumens produced from them. In the quality tar (P_{25} = 305 mm × 0.1), the content of PNCs is 22% in NPC and 10.6% in PC; in the tar with P_{25} = 390 × 0.1 mm, these parameters are similar: 20.1 and 10%, respectively.

For the corresponding bitumens, these parameters are 14.2 and 7.2% for BDUS 70/100 and 15.8 and 7.2% for BDUS 60/90, respectively, i.e., they tend to decrease in going from the tars to bitumens but do not differ significantly between the quality and substandard products.

The content of arenes and resins in the polar components tends to grow in going from the initial tars to bitumens obtained from them. The total content

of MCACs + BCACs and PCACs in NPC and PC of the tar is 45.3–46.9%, and that in the quality bitumen BDUS 70/100, 48.7–49.2%, i.e., oxidation of the tar increases the content of aromatic structures.

In the less heat-resistant bitumen BDUS 60/90, the total content of MCACs + BCACs and PCACs is virtually the same as in the initial tar, ranging from 50.4 to 51.6% for both NPC and PC. It should be noted that the MCACs/BCACs ratio in the heat-resistant bitumen BDUS 70/100 is higher than in BDUS 60/90.

Thus, the most significant differences between the group compositions of the quality (heat-resistant) and substandard bitumens and of the tars are observed in the ratio of resins to sum of arenes in oils. In the quality bitumen BDUS 70/100 and the corresponding tar, this ratio is higher than in the less heat-resistant bitumen BDUS 60/90, in both nonpolar and polar components.

The polar components of tars and the corresponding bitumens are characterized by higher ratio of resins to the sum of arenes than the nonpolar components. Also, in both NPC and PC of the quality bitumen, the ratio of toluene and toluene–alcohol resins and, as already noted, the ratio of MCACs to BCACs and PCACs are higher.

Thus, the heat resistance of bitumen depends not only on the ratio of group components of the tar and bitumen prepared from it, but also on the forming structure (types 1–3). The bitumens under consideration belong to structural type 3 (according to Kolbanovskaya's classification). Probably, the colloidal stability of the forming structures is the highest if the oil fraction contains sufficient amounts of aromatic carbon in MCACs and TRs, with required amount of carbon in cyclic structures. The distribution of heteroatoms is also important.

The optimal structurizing power of asphaltenes and resins should be combined with the optimal ratio of MCACs to BCACs and PCACs to provide formation of the most aggregation-stable (and hence the least temperature-sensitive) structure. Apparently, the penetration and ductility of such a structure would change to the minimal extent in the course of aging, under the action of a mineral filler, or upon heating to simulate the bitumen aging.

Apparently, the major factors determining the aggregative stability of the three-dimensional (3D) coagulation structure of bitumens are the concentration of the dispersed asphaltene phase and its chemical affinity for oils and resins (dispersion medium). Formation of the kinetically stable state of the coagulation structure of bitumens is complete within the first several days after its mechanical or thermal breakdown.

Table 3. Group composition of tars

P_{25}, mm × 0.1	PNCs	Arenes (BCACs + MCACs)	Resins	Asphaltenes
	wt %			
425	10.3	54.2	24.4	11.1
424	9.8	54.6	22.7	12.9
409	11.4	50.9	26.2	11.5
456	11.9	54.9	20.5	12.7
463	11.9	52.4	24.2	11.5
478	7.6	61.7	20.1	10.6
Average: 442.5	10.48	54.78	23.01	11.7

Numerical analysis of small-angle X-ray diffraction patterns shows that the structural state of the disperse system of bitumens is characterized by the presence of microheterogeneities of the first and second order. Interestingly, some authors believe that the size of these microheterogeneities is independent of the component composition and chemical nature of bitumens [6]. This viewpoint seems to be doubtful. In [6], first-order microheterogeneities are interpreted as a primary structural unit with a nucleus of the phase of asphaltene molecules (2–6 nm in diameter), and second-order microheterogeneities, as asphaltene aggregates (about 10 nm in diameter) formed by condensation structurization within a complex structural unit.

The aggregative stability of the 3D coagulation structure of bitumens is determined not only by the concentration of asphaltenes forming the dispersed phase but also by the adsorption factor, namely, the chemical affinity of asphaltenes for the oil and resin components forming the dispersion medium. This affinity is characterized by the lyophobicity index L defined as the difference between the degrees of aromaticity (C_{ar} fraction) of asphaltenes, on the one hand, and oil and resin components, on the other, since specifically the presence of condensed aromatic systems in tars is the necessary condition for their association to form lamellar-block structures. Khryashchev [7] noted that L is independent of the extent of bitumen oxidation but is determined by the chemical composition of the initial tars, amounting to 0.18, 0.28, and 0.31 for bitumens prepared from tars of West-Siberian, Romashkino, and Arlansk crude oils, respectively. Hence, the 3D coagulation structure of

bitumens from Romashkino and Arlansk crude oils will be more stable, and these bitumens will be more heat-resistant than those produced from West-Siberian crude oils. The enthalpy of formation of the 3D coagulation structure of bitumens per unit weight of asphaltenes is independent of the extent of their oxidation and is determined by the nature of the initial tar, amounting to 27, 21, and 9 kJ kg^{-1} for bitumens produced from tars of West Siberian, Romashkino, and Arlansk crude oils, respectively [6].

The lyophobicity index linearly correlates with the rate constant of condensation structurization of the bitumens in hand:

$$K = K_0(L - 0.13),$$

where $K_0 = 8.5 \times 10^{-3}$ year.

Hence follows that disperse petroleum systems with $L < 0.13$ are thermodynamically stable.

For comparison, we present the group composition of a wider set of tar and bitumen samples from KINEF Ltd. (Tables 3, 4).[1] Table 3 shows that the group composition of tars and bitumens is approximately constant. However, in bitumens, compared to the initial tars, the content of arenes (sum MCACs + BCACs and PCACs) tends to decrease, with the content of resins and asphaltenes increasing. The higher heat resistance, as judged from the increase in the softening point (Table 4) and less significant decrease in the penetration and ductility after heat treatment, is observed at the optimal ratio of the sum of MCACs + BCACs, resins, and asphaltenes (sample nos. 1 and 2 in which the ratio of resins to the sum of MCACs + BCACs is 0.65–0.67). Bitumens with $D_{25} < 100$ cm are considered to be substandard after heat treatment for 5 h at 160°C.

It is seen that all the samples (Table 4), except sample no. 4, correspond only to the BND 40/60 hard bitumen grade after heat treatment, i.e., their properties changed to fall beyond the limits prescribed for the initial grade.

Table 4 shows that bitumens prepared from tars of commercial West-Siberian crude oil exhibit poor heat resistance: Their penetration after heat treatment (5 h, 160°C) decreases by 29–43%, the softening point increases by 2–6%, and the ductility decreases appreciably. According to the requirements to BDUS 70/100 bitumens, the ductility retained after heat treatment should be no less than 100 cm. Only sample nos. 1 and 2 meet this requirement. Nevertheless, all the bitumens (Table 4) are in full compliance with the GOST (State Standard) for BND paving bitumens.

CONCLUSIONS

(1) The structural-group compositions of polar and nonpolar components of malthenes from tars of commercial West-Siberian crude oil and from paving bitumens BDUS 70/100 (heat-resistant) and BDUS 60/90 (with low heat resistance), prepared by oxidation of

[1] Samples of tars and bitumens were obtained in May 2000 from AVT-6 and Bitumnaya-2 installations, respectively.

these tars, were compared. The content of the disperse phase, asphaltenes, is approximately equal for the examined samples of tars (10.45–11.38%) and bitumens (19.3–21%). With increasing solvency of malthenes (at constant content of oils) and with decreasing ratio of asphaltenes to resins, the colloidal structure of the bitumen becomes less stable.

(2) Quality bitumen BDUS 70/100 differs from substandard bitumen BDUS 60/90 in the higher content of aromatic structures.

(3) In the quality bitumen BDUS 70/100 and the corresponding tar, the ratio of resins to sum of arenes is higher than in the less heat-resistant bitumen BDUS 60/90, both in the nonpolar and polar components.

(4) The polar components of tars and of the corresponding bitumens are characterized by higher ratio of resins to the sum of arenes, compared to the nonpolar components.

(5) The nonpolar and polar components of the quality bitumen are characterized by higher ratios of toluene to toluene–alcohol resins and of mono- to bi- and polycyclic aromatic compounds.

(6) The colloidal stability of the forming structures is the highest if the oil fraction contains a sufficient amount of aromatic carbon in monocycloaromatic compounds and toluene resins and also a necessary amount of carbon in cyclic naphthenic structures. The decisive factors affecting the aggregative stability of the 3D coagulation structure of bitumens are the concentration of the disperse phase (asphaltenes) and its chemical affinity for oils and resins forming the dispersion medium.

Abstract—Procedures are discussed for production of rubber–bitumen compounds based on spent rubber items. A possibility of using these binders for paving is studied experimentally.

The main problem with road building is the poor quality of bitumens used in asphalt-concrete pavements [1]. One of the ways to improve the quality of the binders is their modification with polymers and rubber crumb from reprocessing of tire industry wastes.[1] Simultaneously, utilization of spent rubber would solve a serious environmental problem. The largest amount of worn rubber is collected in the form of tires and inner tubes [2]. They contain valuable kinds of rubber, such as natural, isoprene, butadiene, butadiene–styrene, etc. Under certain conditions of rubber crumb treatment in bitumen formulations, the valuable properties of rubber components become operative [3]. The resulting rubber–bitumen compounds (RBCs) exhibit elasticity, increased softening point, decreased brittle point, and enhanced strength. These properties allow RBCs to be used both as binders for asphalt concretes and as mastics for pavement repair. Asphalt concrete prepared with RBC exhibits high performance, enhanced wear and heat resistance, and resistance to aging. As a result, the pavement quality grows, and its service life becomes a factor of 1.5–2 longer.

EXPERIMENTAL

When developing RBC, it is necessary first to find conditions for introducing rubber crumb into a bitumen or plasticizer, under which the crumb would act not merely as a filler but also as a modifier improving the bitumen properties. For this purpose, the crumb should be preliminarily devulcanized. It is subjected to thermomechanical treatment in the presence of plasticizers: oil tar, commercial oils, various wastes, and low-viscous and paving bitumens [4]. The process is performed at high temperatures (200–260°C) for 15–20 h with vigorous stirring. Under these conditions, the rubber crumb swells in the oil fraction of a plasticizer, with weakening of the intermolecular bonds. Under severe conditions of thermomechanical treatment in the course of devulcanization, these weakened bonds are broken to leave rubber fragments. Then the resulting concentrate is mixed with a bitumen. Devulcanization can be performed faster (within 1–2 h) by adding appropriate agents [5].

In this study, we examined how the physicomechanical characteristics of RBC are affected by various plasticizers, temperature, plasticizer-to-bitumen ratio, and rubber crumb concentration. We also used rubber crumb of varied origin (tire treads, inner tubes, spent rubber items, reclaim) and size (from 0.5 to 3 mm).[2]

Our initial experiments were aimed at choosing a plasticizer and devulcanization conditions. Rubber crumb was devulcanized at 200–220°C with vigorous stirring. As plasticizers were used BND 90/130 paving bitumen, petroleum tar, and PN-6 oil at various crumb-to-plasticizer ratios (from 1 : 1 to 1 : 4). When

[1] Procedure developed at the Center for Elastomers, Kazan State Technological University.

[2] We used reclaim from Chekhov plant (devulcanizate of tire tread rubbers, mixture of SKI, SKD, and SKS rubbers, 0.5 mm fraction; butadiene–styrene rubber crumb produced by Kvart Joint-Stock Company, 0.5–1 mm fraction; and crumb from Leninogorsk plant (crushed inner tube rubber, 0.5–1.3 mm fraction). Experimental data were obtained with the Leninogorsk rubber crumb, bitumen from Sanbit Joint-Stock Company (Nizhnekamsk), and petroleum tar from Nizhnekamskneftekhim Joint-Stock Company.

1070-4272/02/7506-1020 $27.00 © 2002 MAIK "Nauka/Interperiodica"

using bitumen as plasticizer, it should be borne in mind that prolonged heat treatment of bitumens at so high temperatures results in their rapid aging. With oil, the adhesion of the binder to mineral fillers is considerably worse. The best plasticizer is petroleum tar, which is close to bitumen in composition but contains more oils (in which the rubber crumb swells).

Initially, we added rubber crumb in 10 wt % amount. For the resulting compounds, we determined the main physicomechanical parameters of bitumen: depth of needle penetration (penetration P), ring-and-ball softening point T_p, and Fraas brittle point T_{br}. Also, we determined the parameters characterizing the quality of rubber: relative elongation ΔL, ultimate tensile strength H, and elasticity E.

In devulcanization of rubber crumb, we obtained a concentrate of rubber crumb in petroleum tar; the ratio of the crumb to plasticizers was 1 : 4. With a smaller amount of plasticizer, the fluid compound could not be obtained; with its larger amount, the properties were unsatisfactory. Petroleum tar was mixed with bitumen, since the results obtained with straight tar were also unsatisfactory.

The tar to bitumen ratio in concentrate preparation was varied from 1 : 3 to 3 : 1.

Rubber crumb was swollen in plasticizers for 1 h, after which bitumen was added and the process was continued for another 2 h. Initially, the process was performed at 220°C. The compounds were prepared with continuous vigorous stirring. The physicomechanical quality characteristics of the RBC are given in Table 1.

The adhesion of the samples, determined according to GOST (State Standard) 11 508–74, is similar to that of the control sample (BND 60/90 paving bitumen). As seen from Table 1, with decreasing amount of petroleum tar, the softening point of RBC increases, the relative elongation and elasticity decrease, but the strength grows.

Then we varied the concentration of rubber crumb in a compound. We prepared compounds containing 7 and 15 wt % rubber crumb, at the component ratio in the concentrate rubber crumb : tar : bitumen = 1 : 2 : 2 (220°C). The components were vigorously stirred. The results are listed in Table 2.

Apparently, the parameters characterizing the binder (bitumens) vary regularly: As the penetration (indirect characteristic of viscosity) decreases with increasing rubber crumb content, the softening point grows, as also do the strength parameters. The relative elongation and elasticity pass through a maximum. The optimal content of rubber crumb in a compound is 10 wt %. Then we examined the effect of temperature on the physicomechanical parameters of RBC. We performed additional experiments at lower temperatures: 180 and 150°C. The rubber crumb content in RBC was 10 wt %, and the rubber crumb : tar : bitumen ratio, 1 : 2 : 2. The synthesis was performed for 3 h with vigorous stirring. The results are listed in Table 3.

It is seen that the penetration increases with temperature, whereas the softening point does not change. Hence, at low temperatures, the rubber crumb chiefly behaves as a filler. At higher synthesis temperatures, the relative elongation at break, elasticity, and ultimate strength increase. The best temperature for the

3	220	69	56	445	69	1.03

Table 4. Characteristics of asphalt concrete prepared using RBC

Sample	Bulk weight, g cm^{-3}	Water absorption	Swelling	Ultimate compression strength, kg cm^{-2}				Water resistance coefficient	Bitumen content, wt %
		vol %		R_{20}	R_w	R_{50}	R_0		
RBC	2.39	1.21	0.3	31.2	28.1	14.1	10.6	0.9	5.9
GOST 9128–97		1.5–4.0		22.0		10	≤12	0.85	5–6.5

process is 220°C. Higher temperatures are not appropriate, because specifically at this temperature bitumen is produced in oxidation apparatus and is unloaded from it.

The brittle point of RBC is not given in Tables 2 and 3, because it was about –30°C or higher for almost all the compounds. The adhesion of almost all the RBC samples, measured according to GOST 11508–74, was the same as for sample no. 1.

Thus, for RBCs prepared at the optimal temperature of 220°C, varied ratio of petroleum tar and bitumen, and varied content of rubber crumb, the penetration falls within 48–81, and the softening point, 51 to 64°C. These are the main parameters characterizing the quality and application fields of bitumen. Bitumens with penetration higher than 60 are used as binders for mineral fillers in asphalt concretes. The softening point of BND 60/90 paving bitumens is no less than 47°C, and that of BND 90/130 bitumens, no less than 45°C (GOST 9128–97). The softening point of modified bitumens must be higher. Our results show that the RBCs with penetration higher than 60 (Tables 1, 2, RBC nos. 1, 2) are suitable as binders for asphalt concretes. To assess the quality of an asphalt concrete prepared with a rubber–bitumen binder (RBB), a pilot laboratory batch (2 kg) of the RBC was prepared, which was tested in the Paving Laboratory, Tatneftedor Ltd. (Bugulma).

Table 5. Comparison of rubber–bitumen and polymer–bitumen binders

Sample no.	Sample	P, mm × 0.1	T_p, °C	T, °C	E, %
	RBC:				
1	KSTU	69	56	–30	69
2	MOR	63	47	–28	57
3	PBB (OST 218.010–98)	61–90	≥54	≤–20	80

Table 6. Parameters of mastics for pavement repair

Sample	P, mm × 0.1	T_p, °C	T_{br}, °C	ΔL, %	H, MPa	E, %
KSTU	48	64	–30	350	0.48	53
Tatneftedor Ltd.	60	55	–25	–	–	50
Dormast Private Company	90	100	–35	350	0.13	30

The parameters of the asphalt concrete prepared with RBC are listed in Table 4.

The parameters of our RBB are compared in Table 5 with those of RBB produced by the Moscow Oil Refinery (MOR) and of polymer–bitumen binders (PBBs) prepared with butadiene–styrene thermoelastoplastic [OST (Branch Standard) 218.010–98]. The RBB samples contain 10 wt % rubber crumb.

As seen from Table 5, the parameters of the rubber–bitumen binder developed at the Kazan State Technological University (KSTU) exceed those of the binder from MOR, containing rubber crumb, and well compete with those of the polymer–bitumen binders prepared with thermoelastoplastics.

Thus, the parameters of asphalt concrete prepared using RBC exceed those prescribed by GOST 9128–97 for bitumen-containing asphalt concretes.

Rubber–bitumen compounds with penetration less than 60 and softening point higher than 56°C (Table 1, nos. 3, 4; Table 2, no. 3; Table 3, no. 2) can also be used in road building as pavement-repair mastics and for filling cracks and joints. In Table 6 we compare the parameters of our mastic with those of the mastic developed by Tatneftedor Ltd. and containing SKEPT rubber and of the mastic developed by Dormast Private Company (Naberezhnye Chelny) and containing rubber crumb and DST rubber.

As seen, the rubber–bitumen mastics developed by KSTU and containing wastes from tire industry well compete in quality with mastics developed by road-building institutions and containing SKEPT and DST rubbers and surpass them in strength.

To determine the amount of rubber crumb not incorporated into RBC (under the optimal conditions), we washed the flask with CCl_4 after the synthesis and decanting of the products, because CCl_4 dissolves virtually all the components of petroleum tar and bitumen. Then the solution was filtered. Virtually no rubber crumb was detected on the filter. The same result was obtained in 3–5 replications. Thus, the crumb was almost fully incorporated into the compound.

The degree of devulcanization of rubber crumb in the compound and the percentage of its incorporation into bitumen can be determined by treatment with appropriate solvents. To do this, 1 g of RBC was dissolved in CCl_4, and the solution was filtered. The extent of devulcanization was judged from the presence or absence of rubber crumb on the filter. In this experiment, no rubber crumb was detected on the filter either, suggesting its complete devulcanization with hydrocarbons, plasticizers, and bitumen. Three to five experiments were performed with RBC samples prepared under optimal conditions.

CONCLUSOINS

(1) Among various kinds of plasticizers for rubber crumb, the best is petroleum tar, which is similar in composition to bitumen but contains aromatic and saturated oils promoting swelling of any kind of rubber crumb.

(2) The optimal conditions for rubber crumb compounding with bitumen are as follows: 220°C, rubber crumb to plasticizer ratio 1 : 4, and rubber crumb content in rubber–bitumen compounds from 7 to 12%.

(3) Ways to control the physicomechanical parameters of rubber–bitumen compounds were found. The process developed allows preparation of binders for asphalt concretes used in road building and of mastic for pavement repair.

(4) Rubber crumb from reprocessing of tire industry wastes is a relatively cheap and available modifier improving the bitumen properties. The binders prepared surpass in the parameters the binders produced by the Moscow Oil Refinery and well compete with polymer–bitumen binders produced with styrene–butadiene copolymer (OST 218.010–98) and with mastics produced by Dormast Private Company.

(5) Asphalt concrete prepared using the rubber–bitumen binder developed in this study meets the requirements of GOST 9128–97.

(6) Our results combined with published data, suggest that the service life of pavements made using rubber–bitumen binders will be longer by a factor of 1.5–2.

(7) Utilization of rubber crumb in road building will allow the amount of rubber crumb produced by reclaiming facilities to be considerably increased, which will decrease environmental pollution with spent rubber.

Received November 2, 2001

Abstract—Solubility of lead nitrate in the system H_2O–$Zn(NO_3)_2$–HNO_3 was studied using the simplex-lattice design method. The equations describing the effect of nitric acid and zinc nitrate concentrations on the content of lead nitrate in solution at 25 and 55°C were derived.

In developing hydrometallurgical schemes for reprocessing of lead–zinc ores with the use of nitric acid, data on the mutual solubility of lead and zinc nitrates and on their salting-out with nitric acid are necessary. However, published data on the solubility of $Pb(NO_3)_2$ in nitrate medium are insufficient [1].

In this work, the solubility of lead nitrate in the system HNO_3–$Zn(NO_3)_2$–H_2O was studied.

EXPERIMENTAL

Synthetic lead nitrate obtained by a procedure described in [2], chemically pure zinc nitrate, nitric acid, and distilled water were used as starting reagents.

The equilibration time was established experimentally to be 40–42 h. The experiments runs were performed during 50 h at 25 ± 0.1 and 55 ± 0.1°C. After the experiments were complete, the liquid phase was sampled and the content of lead(II) was determined by atomic absorption spectroscopy and titrimetry [3, 4], and the concentration of nitric acid, by titrimetry [4]. The solid precipitate was filtered off, washed with water and ethanol to remove mother liquor, dried at 80–82°C, and subjected to X-ray phase analysis.

The results obtained were processed by the simplex-lattice method of experiment design [5]. The vertices of the concentration triangle represented the components (in terms of initial concentrations): X_1, distilled water (55.56 M); X_2, $Zn(NO_3)_2$ (1.53 M); and X_3, HNO_3 (3.2 M). As Y functions served the Pb^{2+} concentrations (M) in solution.

The experimental data were used to estimate the coefficients of the polynomials of incomplete third order, having the following form:

$$Y_{25} = 1.500X_1 + 0.338X_2 + 0.275X_3 - 1.068X_1X_2 + 1.014X_2X_3 - 2.006X_1X_3 + 1.500X_1X_2X_3 \quad (25°C),$$

$$Y_{50} = 2.00X_1 + 0.531X_2 + 0.377X_3 - 1.198X_1X_2 + 1.992X_2X_3 - 2.918X_1X_3 + 1.071X_1X_2X_3 \quad (55°C).$$

The root-mean-square error in determining Y was 3%. Verification of the equations with the use of the data obtained in the experiments demonstrated that they adequately describe the experimental data with 97% probability.

The obtained equations were used to plot isoconcentration lines for lead nitrate (see Figs. 1a and 1b).

$Pb(NO_3)_2$–HNO_3–H_2O system. It is known that nitric acid salts-out lead nitrate [2, 6]. The fundamental aspects of this process and the solubility of lead nitrate have been studied previously [6]. The solubility data show that, with increasing nitric acid concentration in the system studied, the solubility of lead nitrate markedly decreases to attain a minimum at the point with the highest concentration of nitric acid.

$Pb(NO_3)_2$–$Zn(NO_3)_2$–H_2O system. To our knowledge, no published data are available on the solubility of lead nitrate in aqueous solutions of zinc nitrate. The data obtained indicate that, in the system studied, the solubility of lead nitrate is considerably higher than that in nitric acid, with the run of the isoconcentration lines following the general pattern. An X-ray phase analysis of the precipitates revealed lead nitrate and no other compounds of lead(II) or zinc.

$Pb(NO_3)_2$–$Zn(NO_3)_2$–HNO_3–H_2O system. A study of the $Pb(NO_3)_2$ solubility in aqueous solutions of zinc nitrate and nitric acid showed that the decrease in

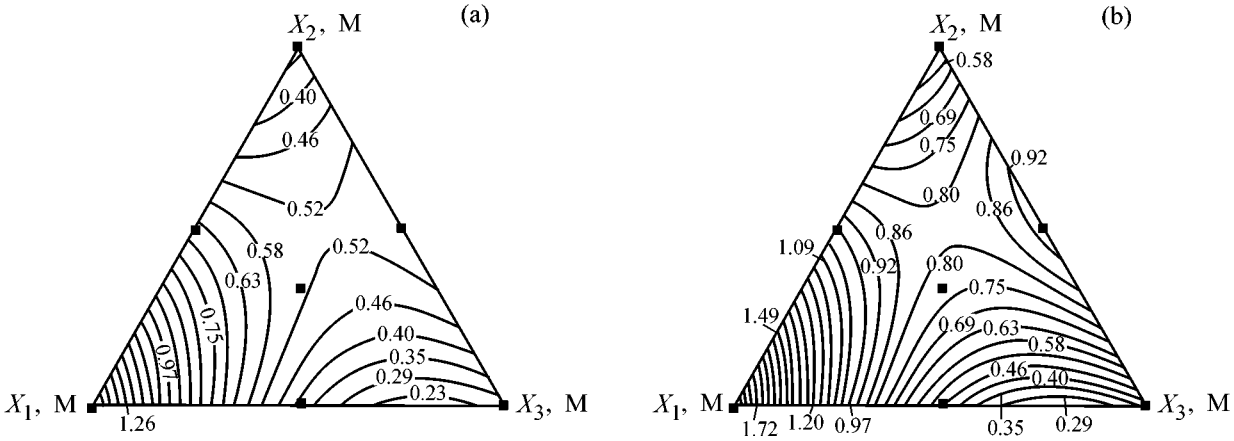

Fig. 1. Isoconcentration lines for $Pb(NO_3)_2$ (M) at (a) 25 and (b) 55°C.

the lead nitrate concentration in solutions becomes more pronounced in solutions with increased nitric acid concentration. The maximum concentration of lead nitrate is observed at the points corresponding to concentrations of 0.81 M $Zn(NO_3)_2$ and 1.50 M HNO_3 at 25°C and at the points with concentrations of 0.83 M $Zn(NO_3)_2$ and 1.47 M HNO_3 at 55°C, with the lead nitrate concentration in solution becoming 0.56 and 0.96 M, respectively. The calculated and experimental solubilities in the given system are presented in the isoconcentration triangles. When zinc nitrate and nitric acid are present in solution simultaneously, the observed behavior is evidently the same as that in the above-presented systems.

A comparison of the lead nitrate solubilities at 25 and 55°C showed that, with increasing temperature, the $Pb(NO_3)_2$ solubility grows and the general tendency is preserved.

It should be noted that an X-ray phase analysis performed for all the points considered revealed only lead nitrate in the precipitate.

CONCLUSIONS

(1) A study of the solubility of lead nitrate in the system H_2O–$Zn(NO_3)_2$–HNO_3 showed that the decrease in the Pb(II) concentration with increasing nitric acid and zinc nitrate concentrations is due to the effect of the NO_3^- ion.

(2) Only a single salt, lead nitrate, precipitates in the system studied.

(3) The regression equations describing the lead nitrate solubility at 25 and 55°C were calculated and used to plot isoconcentration lines.

Abstract—The temperature dependence of conductivity of molybdates in the systems M_2MoO_4–$AMoO_4$–$Zr(MoO_4)_2$ was studied. The starting molybdates and molybdates of 5 : 1 : 3 and 1 : 1 : 1 compositions, formed in the systems, exhibit mixed conduction, turning ionic at high temperatures. The sharp bends in linear portions of the temperature dependence of conductivity coincide with the temperatures of polymorphic transitions in the corresponding molybdates.

Previously, the ternary salt systems K_2MoO_4–$AMoO_4$–$Zr(MoO_4)_2$ have been studied [1–3] and formation of molybdates with three dissimilar cations: potassium, doubly charged metal, and zirconium, was established.

The compounds obtained have general formulas $K_5A_{0.5}Zr_{1.5}(MoO_4)_6$ (5 : 1 : 3)[1] and $KA_{0.5}Zr_{0.5}(MoO_4)_2$ (1 : 1 : 1),[1] where A = Mg, Mn, Ni, Co, Cu, Zn, or Cd.

As shown by investigations, the structures of these complex molybdates have the form of skeletons constituted by ZrO_8 and AO_8 octahedra and MoO_4 tetrahedra connected via oxygen atoms. The structures of these compounds contain large voids, which can accommodate cations of alkali metals and, in particular, potassium [4, 5].

At an appropriate geometrical arrangement of channels and their filling with potassium cations, conditions for fast ionic transport may be fulfilled in skeleton structures and the compounds in question may possess properties of solid electrolytes.

The aim of this study was to analyze the electrical properties of starting molybdates forming the systems M_2MoO_4–$AMoO_4$–$Zr(MoO_4)_2$ and ternary molybdates of compositions 5 : 1 : 3 and 1 : 1 : 1.

[1] Molar ratio of starting molybdates.

The temperature dependences of conductivity σ, dielectric constant ε, and dielectric loss tangent $\tan\delta$ were studied on an experimental setup by the method proposed by Vest and Tallan [6]; the values of σ, ε, and $\tan\delta$ were measured under ac conditions on an E8-4 ac bridge with an R-5025 resistance box serving to extend the range of $\tan\delta$ measurements in the samples. The dc current was measured with an E6-13A teraohmmeter at fixed voltages across a sample (30 and 60 mV).

The electronic transport numbers t_e were found as the ratio of the electronic conductivity σ_e, measured under dc conditions, to the total conductivity $\sigma_e + \sigma_i$, measured under ac conditions at a chosen temperature of experiment (σ_i is the ionic conductivity).

Samples for electrical measurements had the form of pellets 1 mm thick with area of 74–75 mm^2. The pellets were obtained by compaction of powdered preparations, with their subsequent annealing at a temperature equal to 2/3 T_m of the corresponding compound.

As electric contacts served platinum paste fired-in at 500°C on the pellet surface.

Figure 1 presents in the form of Arrhenius plots the temperature dependences of conductivity of a part of molybdates studied, which are the conventional straight lines. The activation energies of conductivity,

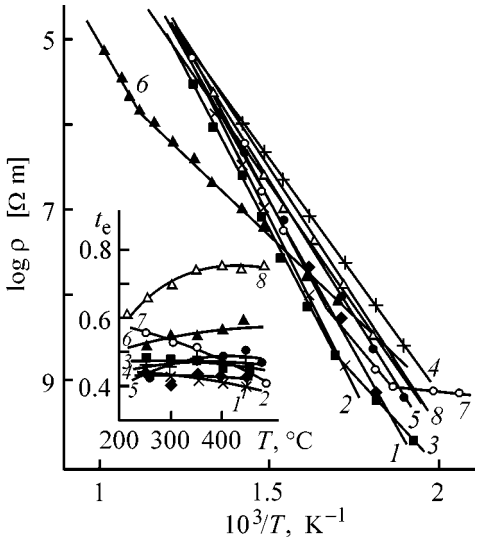

Fig. 1. Electrical resistivity ρ and electronic transport numbers t_e vs. temperature T. Sample: (*1*) $K_5Mn_{0.5}Zr_{1.5}(MoO_4)_6$, (*2*) $K_4MnZr_6(MoO_4)_{15}$, (*3*) $KMn_{0.5}Zr_{0.5}(MoO_4)_2$, (*4*) $K_2Zr(MoO_4)_3$, (*5*) $K_8Zr(MoO_4)_6$, (*6*) $Zr(MoO_4)_2$, (*7*) K_2MoO_4, and (*8*) $MnMoO_4$.

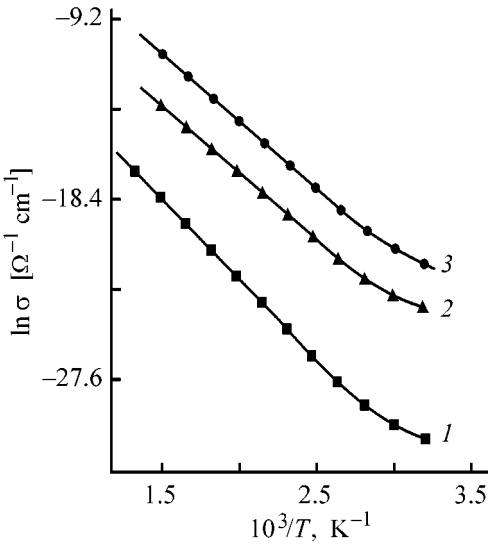

Fig. 2. Electrical conductivity σ of single crystals vs. temperature T. Sample: (*1*) $K_5Mg_{0.5}Zr_{1.5}(MoO_4)_6$, (*2*) $K_5Zn_{0.5}Zr_{1.5}(MoO_4)_6$, and (*3*) $K_5Cd_{0.5}Zr_{1.5}(MoO_4)_6$. E_a (eV): (*1*) 0.806, (*2*) 0.578, and (*3*) 0.591.

E_a, were found from the slopes of these lines for the molybdate samples studied. The experimental values of E_a and σ for the molybdates are presented in the table.

Analysis of the temperature dependences of the electronic transport numbers shows that the ceramic molybdate samples studied exhibit mixed electronic-ionic conduction with predominance of the ionic component at high temperatures of experiment.

Noteworthy are the close values of E_a and comparable values of σ for the ternary molybdates (see table). This circumstance suggests that one and the same ions are charge carriers in these complex oxides of different compositions.

It should be noted that sharp bends are observed in the linear portions of the temperature dependence of conductivity of zirconium and potassium molybdates (Fig. 1, curves *6* and *7*). These bends are not associated with transition from extrinsic to intrinsic conduction. An analysis of the experimental data demonstrated that the positions of the bends on the temperature axis correspond to the temperatures of polymorphic transitions in zirconium and potassium molybdates.

* Single-crystal samples.

It can be seen from Fig. 1 that at high temperature the electronic transport numbers for manganese molybdate show predominance of the electronic conduction over the ionic one. Presumably, this is due to the fact that manganese atoms in this compound are in variable oxidation state, and electron exchange occurs between differently charged atoms in an electric field.

The rise in ionic conductivity on changing A^{2+} at the same singly and quadruply charged (K and Zr) cations in the order Mg $\rightarrow$ Mn $\rightarrow$ Cd (sample nos. 8–10) can be attributed to an increase in the size of voids through which potassium cations move. This confirms the general tendency characteristic of skeleton structures: with increasing size of multiple-charge cations contained in the rigid skeleton, doubly charged cations in the given case, the activation energy and electrical resistance decrease. The decrease in ionic conductivity on passing from potassium compounds to their thallium analogues (sample nos. 8 and 11, 10 and 12) can be attributed to hindered motion of the thallium ion, which is larger than the potassium ion. Since the sizes of zirconium(IV) and molybdate ions remain constant, the free volume of the structure, accessible to singly charged cations, decreases with their increasing radius at invariable doubly charged metal ion (sample nos. 8, 10 and 11, 12), and purely steric hindrance to migration builds up [7].

The low activation energies of conductivity and the sufficiently high ionic conductivity of the ternary molybdates studied class these compounds with solid electrolytes.

A comparison of the conductivities of ceramic and single-crystal samples of the same composition (Fig. 2) revealed higher σ for the ceramic samples. This is presumably due to facilitated migration of conduction ions in an electric field between grains in the ceramic samples.

Abstract—Sorption of ^{137}Cs on NaX zeolite modified with $Cu_2[Fe(CN)_6]$ was studied under dynamic conditions.

After the Chernobyl accident, about 23% of territory of the Belarus Republic was contaminated with radionuclides. The contaminated territories include river basins. Since the natural aquatic systems are zones of the most active migration of radionuclides, a more thorough monitoring of radionuclides, primarily ^{137}Cs, in water is required.

Before determination, radionuclides should be concentrated using any appropriate procedure: vaporization, coprecipitation, or sorption. The most effective is sorption, especially on sorbents highly selective for cesium. For these purpose, we used a sorbent based on NaX zeolite, which was modified with $Cu_2[Fe(CN)_6]$ by a procedure similar to that described in [1]. The optimal conditions for sorption of ^{137}Cs under dynamic conditions were found by us in column experiments.

All sorption experiments were carried out on standard columns 10 mm in diameter and 50 mm high. The volume of a filtering bed was 5 ml at its height of 43–45 mm; the sorbent grain size was 1.5–2.2 mm.

The optimal conditions for sorption of ^{137}Cs were determined in batch experiments by passing the initial model water containing ^{137}Cs (2×10^5 Bq l^{-1}) through a column at different filtration rates. The chemical composition of the initial model water was as follows (mg l^{-1}): suspended matter 17.1 ± 1.7, dry residue 349.5 ± 8.3, sodium 5.8 ± 0.15, potassium 1.0 ± 0.1, ammonium <0.1, calcium 37.6 ± 3.9, magnesium 6.4 ± 0.44, total iron 0.2 ± 0.02; anions: chloride 8.1 ± 0.79, sulfate 4.1 ± 0.02, nitrate 2.2 ± 0.04, hydrocarbonate 164.7 ± 1.24, bromide 0.1 ± 0.01, fluoride 0.13 ± 0.01; and silica 10.77 ± 1.0. The total hardness was 2.47 ± 0.06; the carbonate hardness, 2.46 ± 0.06 mg-equiv l^{-1}; and pH 8.3 ± 0.06. The chemical composition of this model solution meets GOST (State Standard) for potable water.

The filtration rate of the model water through a sorption column was varied from 50 to 150 column volumes per hour. Once a certain number of column volumes of water was passed, a portion of the filtrate was sampled. After completion of the sorption experiment, the activities of the upper and lower parts of the column were measured.

The ^{137} Cs activity was measured on an RUB-01 P4S radiometer equipped with a BDZhB-06P1 detection unit. The relative error of the activity measurement did not exceed $\pm 7\%$.

From the data on ^{137}Cs activity in the initial and filtered water, the decontamination factor K_{dec} from cesium and the degree of cesium sorption S (%) were calculated by the equation:

$$K_{dec} = A_0/A_f, \quad S = \frac{A_0 - A_f}{A_0} \times 100,$$

where A_0 and A_f are the ^{137}Cs activities in the initial and filtered water, respectively. The sorption parameters were calculated as described in [2–5].

Figure 1a shows that the efficiency of sorption recovery of high-activity water from ^{137}Cs, passed through a column packed with NaX zeolite modified with $Cu_2[Fe(CN)_6]$, is sufficiently high at filtration rates ranging from 50 to 150 column volumes per

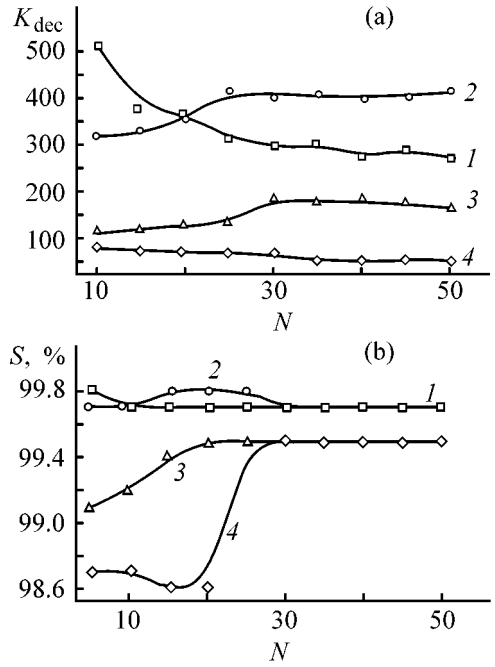

Fig. 1. Cesium decontamination factor K_{dec} and degree of cesium sorption S vs. the number of column volumes of water passed through a column packed with NaX–Cu zeolite at different filtration rates. Filtration rate V (h^{-1}): (*1*) 50, (*2*) 75, (*3*) 100, and (*4*) 150.

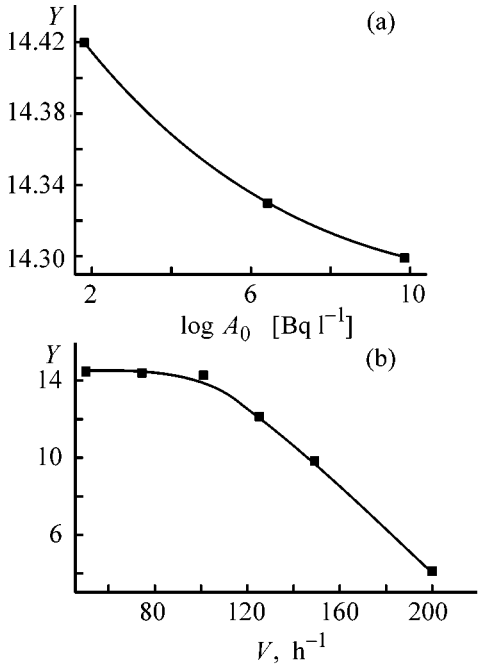

Fig. 2. Ratio of ^{137}Cs activities in the upper and lower parts of the column Y vs. (a) initial water activity A_0, and (b) filtration rate of radioactively contaminated solution V.

hour. Although K_{dec} decreases from 513 to 85, the degree of Cs sorption S remains high: 98.5–99.8% (Fig. 1b). In the first stage of filtration, the decontamination factor either increases or decreases, depending on the filtration rate. In further filtration, the filtering power of the filtering unit is stabilized, and a constant degree of decontamination is attained. Figures 1a and b show that the optimal filtration rate is 75 column volumes per hour. The dependences shown in Figs. 1a and 1b are similar to those reported in [6–13].

Our further experiments on sorption of ^{137}Cs on NaX–Cu zeolite were carried out at the optimal filtration rate of 75 column volumes per hour. In these experiments, the ^{137}Cs content in the initial water ranged from $2\ 10^5$ to 6.2 Bq l^{-1} at the volume of passed water ranging from 50 to 6000 column volumes. Under these conditions, the degree of ^{137}Cs sorption was 96–98%.

We found that, at the optimal filtration rate, the ^{137}Cs level in the initial water does not noticeably affect the ^{137}Cs distribution along a column. Figure 2a shows that, in the range of the ^{137}Cs activity from 2×10^5 to 6.2 Bq, the ratio of the ^{137}Cs activities in the upper and lower parts of the column varies within a very narrow interval, from 14.3 to 14.4.

In filtration of water containing ^{137}Cs in amount of 6.2 Bq l^{-1} at the rate of 200 column volumes per hour, the degree of ^{137}Cs sorption was 95.0–96.0 %.

With the filtration rate increasing from 50 to 200 column volumes per hour, the leading edge of sorption is smeared. As a result, the ratio of ^{137}Cs activities in the upper and lower parts of the column decreases from 14.4 to 4 (Fig. 2b).

CONCLUSION

NaX zeolite modified with $Cu_2[Fe(CN)_6]$ effectively sorbs cesium. The most efficient removal of ^{137}Cs is achieved in filtration of radioactively contaminated drinking water at a rate of 75 column volumes per hour.

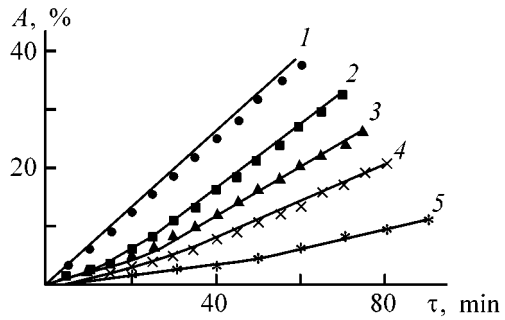
Abstract—A new approach to controlling the molecular weight of polyvinylpyrrolidone in radical polymerization is considered. When the reaction is performed in the presence of a stable nitroxyl radical, 2,2,6,6-tetramethylpiperidyl-1-oxyl, the effect of secondary inhibition is manifested after the end of the induction period. This effect can be used for preparing polymers with prescribed molecular weights.

The molecular weight M of polyvinyllactams, and in particular, polyvinylpyrrolidone (PVP) in radical polymerization can be controlled by weak inhibition and chain-transfer reactions [1]. Previous studies have shown that the post-induction period in polymerization of some vinyl monomers in the presence of stable nitroxyl radicals is characterized by secondary inhibition, which can occur by a catalytic or common mechanism [2, 3]. Here we show that the post-induction inhibiting effect in radical polymerization can be used for preparing PVP of desired molecular weight.

EXPERIMENTAL

The reaction mixture consisting of the monomer, initiator (AIBN), solvent (dioxane), and inhibitor (2,2,6,6-tetramethylpiperidyl-1-oxyl, TEMPO) was placed in glass ampules. The mixture was deaerated by repeated freeze–pump–thaw cycles (residual pressure 0.13 Pa). The synthesis was performed at 60°C. The polymers were reprecipitated into diethyl ether. The polymerization kinetics was studied dilatometrically. The intrinsic viscosity of the polymers was determined in water at 25°C. The experimental data were processed in the Huggins–Kraemer coordinates. For all the samples, the sum of the Huggins and Kraemer constants $K_H + K_K \approx 0.5$. The molecular weights were calculated by the equation $[\eta] = 3.1 \times 10^{-4} M_w^{0.61}$ [1].

The figure shows how the PVP yield varies in the course of synthesis. Immediately after the end of the induction period t_{ind}, a non-steady-state period is observed in which the polymerization rate grows. Then the system reaches a steady state, and VP polymerizes at a constant rate v_p, which is lower than in the absence of TEMPO (see figure, table). The decreased polymerization rate is due, among other things, to partial decomposition of the initiator during the induction period. However, the fact that the product $v_p[I]^{-0.5}$ (where [I] is the AIBN concentration by the end of the induction period) decreases with increasing TEMPO concentration in the initial mixture (see table) shows that the decreased v_p cannot be accounted for solely by the lower initiation rate. Apparently, adducts formed by reaction of active radicals with TEMPO can react with chain propagation radicals, producing weak secondary inhibition after the end of the induction period [5]. This process must affect the molecular weight of PVP. Indeed, despite the fact that the reaction occurs under con-



PVP yield, A, vs. synthesis time τ. [TEMPO] × 10^3, M: (*1*) 0, (*2*) 1.17, (*3*) 2.35, (*4*) 3.52, and (*5*) 4.71. Induction period, min: (*1*) 0, (*2*) 80, (*3*) 140, (*4*) 225, and (*5*) 355.

* The initiator concentration by the end of the induction period was calculated using the decomposition rate constant $K_{dec} = 0.85 \times 10^{-5}$ s^{-1} for AIBN at 60°C [4].

** (φ) Deceleration factor.

ditions of secondary inhibition more slowly than under common conditions, and the molecular weight of the resulting PVP is lower than that of the polymer prepared in the absence of TEMPO. This is seen for the example of PVP samples obtained at high conversions.

CONCLUSION

Polymerization of vinylpyrrolidone in the presence of a stable nitroxyl radical, 2,2,6,6-tetramethylpiperidinyl-1-oxyl, occurs with secondary inhibition in the post-induction period. This reaction controls the molecular weight of the polymer and can be used for controlling the radical polymerization of vinylpyrrolidone.

INFORMATION

X Enikolopov Symposium

X Enikolopov Symposium (March 13, 2002, Moscow) was held at the Enikolopov Institute of Synthetic Polymeric Materials, Russian Academy of Sciences (RAS). Academician Nikolai S. Enikolopov (1924–1993) was one of the most outstanding chemists of the former USSR. The area of his scientific interests covered chemical physics, chemical kinetics, and physics and chemistry of polymers and composite materials. He was a founder and the first director of the Institute of Synthetic Polymeric Materials, RAS. The symposium was organized by RAS (Department of General and Technical Chemistry together with the Scientific Council on Macromolecular Compounds) with active participation of the Enikolopov Institute of Synthetic Polymeric Materials, RAS (Moscow); Semenov Institute of Chemical Physics, RAS (Moscow); Institute for Problems of Chemical Physics, RAS (Chernogolovka, Moscow oblast); and Moscow Physicotechnical Institute (Dolgoprudnyi, Moscow oblast).

The conference participants were 150 scientists from 25 research centers of Russia and other republics of the former Soviet Union.

The symposium program included five plenary lectures delivered by Enikolopov's disciples working in different branches of chemical science.

The first lecture, entitled Quantum-Scale Colloidal Metallic Particles and Structures, was given by V.I. Roldugin (Institute of Physical Chemistry, RAS, Moscow). In this lecture, particular emphasis was placed on methods for preparation of colloid dispersions of nanoparticles, including the methods of chemical and radiation-induced reduction, condensation in a gas flow, methods for preparation of nanoparticles as individual chemical compounds, and also on use of colloid systems for obtaining nanoparticles. Also the lecturer outlined the important contribution of stabilizers physicochemical properties of nanodispersions. Then he considered the features of the electronic structure of metallic nanoparticles, level quantization and statistics, the chemical potential of electrons in small particles, and the effect of the electronic structure on the thermal, magnetic, and optical properties of nanoparticles.

Particular interest was aroused in the audience by data on the contact potential between particles of different sizes, charge transfer in nanostructures, equilibrium distribution of charges in an ensemble of polydisperse particles, and the contribution of this effect to the stability of dispersions. Other aspects of the problem considered in the lecture were the role of colloid processes in the formation of nanostructures, self-organization of nanoparticles into ordered structures, and, finally, physicochemical properties of nanoparticles.

The second lecture, entitled Langmuir's Monolayers in Mesomorphic Polysiloxanes and Their Self-Organizing Collapse, was given by Yu.K. Godovskii (Karpov Physicochemical Institute, Moscow). The lecturer demonstrated that Langmuir's polymeric monolayers may collapse under pressure to form highly ordered polylayers. A self-organized collapse of this type was observed in mesomorphic cyclic-linear polysiloxanes. The lecturer reported the results of the thermodynamic, rheological, and structural studies of monolayers and self-organized polylayers formed at the water–air interface or on a solid surface.

The third lecture, given by S.M. Mezhikovskii (Institute of Chemical Physics, RAS), was devoted to the dynamics of the structure of oligomer blends in the course of establishment of a thermodynamic equilibrium. The lecturer considered the relaxation processes in oligomers and polymer–oligomer blends at various levels of structural hierarchy (molecular, supramolecular, topological, and phase). The author analyzed the experimental results from the standpoint of traditional concepts of anomalous effects. The temperature, concentration, and time dependences of a number of macroscopic characteristics of the systems investigated were interpreted in terms of the aggregate structure of oligomeric fluids. The lecturer also discussed some theoretical models allowing qualitative and, occasionally, quantitative description of the so-called anomalous effects, making it possible to classify them with natural features.

The fourth lecture, given by O.N. Efimov (Institute of Problems of Chemical Physics, RAS), was devoted to conducting polymers and carbon nanostructures.

1070-4272/02/7506-1034 $27.00 © 2002 MAIK "Nauka/Interperiodica"

The author focused on the materials for energy accumulation and transformation, known as synthetic metals. The author overviewed general trends in design of such materials, including composites, and also the prospects for their use in designing energy-converting devices, such as hydrogen and electrochemical energy storage units, electroluminescent diodes, solar cells, sensors, etc.

The last, fifth lecture was devoted to analysis of transition zones in polymer blends (A.E. Chalykh, Institute of Physical Chemistry, RAS). The lecturer formulated a general concept of formation of transition zones and their structure in conjugated phases.

The equilibrium, interdiffusion, and structure of the transition zones were demonstrated to be interrelated. Both in amorphous phase separation and in crystal–crystal and liquid-crystal phase equilibria, gradient structures are formed, corresponding to the phase diagram. The extension of the transition zone depends on the conditions of phase conjugation and the component interaction rate. The phase boundary is one of the elements of the transition zone. In glass transition in solutions, the transition zone is in the nonequilibrium state.

Leading scientists working in the field of polymer physics and chemistry participated in discussions at the symposium. It was demonstrated that Enikolopov's ideas are being successfully developed by his disciples and by the disciples of his disciples.

The next XI Enikolopov Symposium will be held on March 13, 2003 at the Enikolopov Institute of Synthetic Polymeric Materials, RAS.

Shchegolev, V.I. and Lebedev, O.A., *Elecktroliticheskoe poluchenie magniya* (Electrolytic Production of Magnesium), Moscow: Publ. House Ruda i Metally, 2002, 386 pp.

In the 1980s, the magnesium industry of the USSR was one of the most successfully developing segments of nonferrous metallurgy, highly competitive in its scientific and technological level with the similar industries abroad. There were three high-output-capacity titanium-magnesium combines and two magnesium plants in the country. The highest output of magnesium in the USSR in those years was up to 160 thousand tons a year, with 95 thousand tons consumed for titanium production by reduction of titanium tetrachloride with magnesium. The geopolitical changes which occurred in the 1990s resulted in that only two plants out of five remained on the territory of Russia in Perm oblast: titanium-magnesium combine (Berezniki) and magnesium plant (Solikamsk). Their rated output capacities are, respectively, 35 and 20 thousand tons of magnesium a year. The monograph by V.I. Shchegolev and O.A. Lebedev covers a wide range of issues associated with electrolytic manufacture of magnesium from various kinds of raw materials, including information about preprocessing of raw materials, choice of electrolyte, electrolyzer designs, refining of raw magnesium, production of magnesium alloys, and manufacture of high-purity metal. The book comprises an introduction, 15 chapters, a reference list for the entire monograph, and an appendix.

The brief introduction (pp. 3–8) presents evidence of mainly historical nature about magnesium production and creation of the domestic magnesium industry. The Dneprovskii magnesium plant was put into operation on December 23, 1935, and the Solikamsk magnesium plant, on March 10, 1936. The first chapter (pp. 8–17) describes the physicochemical properties of magnesium and its interaction with various reagents. The second chapter (pp. 17–25) summarizes the presently available data on the world production of primary and secondary magnesium and main fields of application of magnesium and its alloys. At present, approximately 80% of magnesium is obtained in the world's technological practice electrolytically, and up to 20% thermally. The largest manufacturer of magnesium in the world is the US. Special attention is given by the authors to the development of magnesium production in China in the recent decade. In 1997, China manufactured 80 thousand tons of magnesium, and the present magnesium production capacity of this country is estimated to be approximately 170 thousand tons. China has, in addition to rather large plants, up to 200 small plants producing magnesium by the thermal method.

The very small third chapter (pp. 27–32) briefly characterizes the main types of magnesium raw materials. The fourth chapter (pp. 32–52) discusses technological schemes for magnesium production by electrolysis, bath feeding with carnallite or magnesium chloride of varied origin, and work by a combined scheme. The fifth chapter (pp. 58–68) is devoted to phisicochemical aspects of the technology of dehydration of chloride-magnesium raw materials. The sixth (pp. 68–98) and seventh (pp. 98–109) chapters describe the apparatus and technology for dehydration of carnallite and crystal hydrates of magnesium chloride. The eighth chapter analyzes in detail various methods for purification of chloride-magnesium raw materials to remove various impurities. The main kind of Russia's raw materials for manufacture of commercial magnesium (Solikamsk magnesium plant) is dehydrated carnallite not subjected to any special treatment. At the same time, preliminary electrolyte purification is necessary for achieving high and stable characteristics on modern diaphragmless electrolyzers.

The ninth chapter (pp. 140–215) discusses the physicochemical properties of salt systems, used in deciding on the electrolyte composition, and formulates main requirements to an industrial electrolyte for ensuring a high current efficiency by magnesium and chlorine, the minimum voltage across the electrolyzer, and lowered sludge formation. The tenth and eleventh chapters (pp. 216–240 and 240–266) describe various designs of electrolyzers with and without diaphragm, analyze their advantages and disadvantages, and advise on how on technological processes are to be carried out, depending on electrolyzer design and type of magnesium-chlorine raw materials (carnallite, magnesium chloride). The twelfth chapter (pp. 267–294) considers possible directions of improvement of the apparatus-technological schemes for electrolytic pro-

1070-4272/02/7506-1036 $27.00 © 2002 MAIK "Nauka/Interperiodica"

duction of magnesium. The authors mention among such directions creation of a flow-line technology of electrolysis and optimization and intensification of operation of a separate electrolyzer. The chapter also considers fundamentally new concepts of the technology and apparatus for electrolytic manufacture of magnesium and the technology for production of granulated magnesium and magnesium powders and discusses some ecological problems and, in particular, those associated with utilization of spent electrolyte.

The thirteenth chapter (pp. 294–316) is devoted to refining and casting of raw magnesium. It analyzes the reasons for the appearance of impurities, requirements imposed by standards on primary magnesium, and methods of its purification. The fourteenth chapter (pp. 316–324) presents evidence on production of magnesium alloys with manganese, zinc, aluminum, zirconium, and other alloying components. The same chapter discusses processing of scrap and waste aluminum alloys. The fifteenth chapter (pp. 324–345) is concerned with manufacture of high-purity magnesium.

The bibliography (pp. 345–357) contains references to 252 publications of mainly domestic authors. The appendix (pp. 358–363) presents evidence concerning the thermodynamic characteristics of various compounds of magnesium and a number of salts used as additives to the electrolyte of the magnesium bath.

The authors of the monograph did an ample amount of work on collecting, systematizing, and analyzing an extensive body of data, furnishing an exhaustive notion of the modern state of magnesium manufacture by electrolysis. The book reflects numerous investigations carried out by staff members of the All-Russia Aluminum-Magnesium Research and Design Institute (St. Petersburg), who made a major contribution to the creation of the domestic magnesium industry.

There is no escape from mentioning that the problem of whether or not it is appropriate to feed baths with dehydrated carnallite, which leads to batch electrolysis, was rather controversial when designing the Solikamsk magnesium plant. A.F. Antipin (1890–1960), one of leading specialists in electrometallurgy of light metals and a corresponding member of the Academy of Sciences of the USSR, believed till the end of his life that this decision was an error. In this connection, an economic assessment of the advisability of this process would be of interest under the present-day market conditions. Unfortunately, the problems of economy and competitiveness of Russian magnesium on the world market are not dealt with in the monograph.

In earlier monographs and textbooks, many important physicochemical laws related to metallurgy of magnesium were illustrated with much more convincing and clear curves than those in the book under discussion. This refers both to processes of carnallite dehydration and to physicochemical properties of the electrolyte and effect of various components on its most important properties. The quality of Figs. 14, 20, 38, 67, and 104 is poor and Fig. 64 is simply erroneous. In our opinion, many apparatus layouts are overladen with unimportant details, which only makes difficult their perception. For unknown reason, names of authors of investigations are mentioned, but no appropriate references are given. The polygraphic design of the book is very well done.

The monograph by V.I. Shchegolev and O.A. Lebedev is of indubitable interest for a wide audience of specialists in manufacture of magnesium and its alloys. The book will be of use for post-graduate students, masters, and undergraduates specialized in metallurgy of light metals or applied electrochemistry.

Stockhausen Eurasia Company, Moscow, Russia

Abstract—General features of degradation of polyacrylamide and its anionic and cationic derivatives under the action of radical degradative agents are considered. The molecular weight of these polymers can be controlled by varying the structure and concentration of the degradative agent and salt additions, the concentration, molecular weight, and composition of the initial (co)polymer, and the process temperature and time.

Polyacrylamide (PAA) and acrylamide (AA) copolymers are widely used in various branches of engineering. Depending on particular purpose, it is appropriate to use PAA and AA copolymers with different characteristics (primarily molecular weight, MW). For example, high-molecular-weight (co)polymers are used as flocculants, thickeners, gel-forming agents, and lubricants, whereas low-molecular-weight (co)polymers are suitable as dispersing agents, coagulants, mud stabilizers, and crude oil thinners [1–4]. However, in the synthesis stage, it is not always feasible to prepare polymers with optimal MW and molecular-weight distribution (MWD); therefore, the MW and MWD of commercially available samples of PAA and AA copolymers are often far from the optimum for a given application. Therefore, it is necessary to develop reliable, simple, and quick procedures for controlling the MW of these polymers. A promising way to solve this problem is controllable degradation [5]. Degradation decreases the MW of polymers and affects their structure and physicochemical characteristics [6], which may deteriorate their performance. However, in some cases degradation can also produce a positive effect. For example, partial degradation of rubbers is used in industry to simplify their processing and application, and degradation of natural polymers allows production of valuable low-molecular weight compounds (e.g., of glucose from starch and of amino acids from proteins; degradation of isoprene rubber yields oligomers suitable as additives to fuels, oils, and paints). Furthermore, controllable degradation can be used to determine the structure and MWD of polymers, to prepare block and graft copolymers, and to study polymer aging and stabilization [5–7]. Some data on degradation of PAA in aqueous solutions are given in a review [8] and a monograph [2].

This review summarizes the data included in [2, 8] and obtained more recently on the degradation kinetics of PAA and its anionic and cationic derivatives in aqueous solutions under the action of radical degradative agents. We also examine the possibility of controlling the MW of the polymers by varying the structure and concentration of the degradative agent and salt additions, the concentration, molecular weight, and composition of the initial (co)polymer, and the process temperature and time.

DEGRADATION AND STABILITY OF POLYACRYLAMIDE AND ITS DERIVATIVES IN AQUEOUS SOLUTIONS

Degradation of PAA and its derivatives in aqueous solutions can occur in the course of synthesis, storage, and use of polymers under the separate or combined action of heat, light, ionizing radiations, mechanical effects, and biological factors.

As noted in [9–16], the viscosity of aqueous solutions of purified technical-grade PAA with $\overline{M}_\eta = 1.5 \times 10^6$ at room temperature in the dark decreased with time; the process occurred without stirring and was intensified by stirring. For example, the viscosity of a 3% aqueous solution of PAA at 25°C decreased by 13.3% in 1 month, and the solution became opalescent; in mixtures of water with 2-propanol, the viscosity did not decrease, and the solution remained transparent [12]. In contrast to high-molecular-weight polymers, the viscosity of solutions of low-molecular-weight PAA did not change in storage [17–19].

The stability of PAA solutions in storage was studied in [20–22]. The observed decrease in the intrinsic viscosity [η] of PAA solutions was attributed

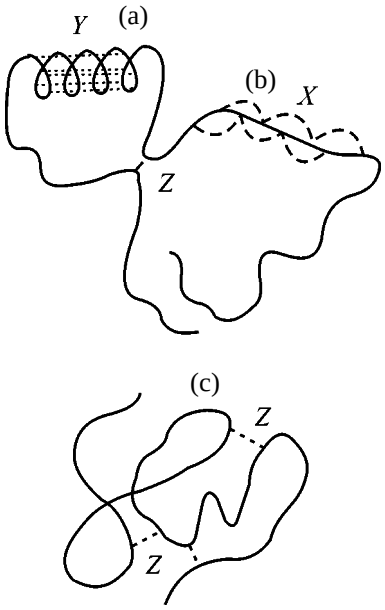

Fig. 1. Conformational transformations of PAA macromolecule in water in storage [22]. State: (a) initial, (b) transition (high viscosity), and (c) final (low viscosity). (*X*, *Y*, *Z*) Various types of H bonds.

to conformational transformations of macromolecules with the redistribution of intramolecular hydrogen bonds (Fig. 1). In the initial PAA solutions, H bonds of different types are formed (*X*, *Y*, *Z*), which accounts for the high viscosity of solutions. In storage, the H bonds of types *X* and *Y* are gradually broken, but the H bonds of type *Z* are preserved, which results in contraction of macromolecular globules and decrease in [η] [22].

The effect of various additions on degradation in storage of a copolymer of AA with sodium acrylate (Na-AA) ($\overline{M}_\eta = 6.5 \times 10^6$, content of Na-AA units 10 mol %) was studied in [23]. It was shown that, after keeping 0.1% solutions of the copolymer at 50°C for 28 days in the presence of Cu^{2+} and Fe^{2+} ions (10^{-3}% relative to the polymer), the reduced viscosity decreased. The intrinsic viscosity [η] of the copolymer also decreases in the presence of some other additives (7×10^{-4} M) in the order thiourea > sodium disulfite > urea > formaldehyde. This is due to degradation of macromolecules under the action of residual amounts of the initiator, potassium peroxosulfate (PP). Addition of reductants induces decomposition of PP and cleavage of backbone chains. Formaldehyde is also a component of redox systems with hydroperoxides [24, 25], and formation of hydroperoxides in storage of copolymer solutions in air is not excluded. An effective agent stabilizing the viscosity in storage of solutions of AA–Na-AA copolymer is KI [23].

After storage in the dark of dry polyacrylglycine cyanamide prepared by radical polymerization in the presence of PP, the viscosity [η] of its solutions decreases [26]. When, in the polymerization stage, PP is taken in smaller amounts, the solutions of high-molecular-weight PAA become more stable in storage, as judged from their viscosity [12].

When exposed to ionizing radiation, high-molecular-weight PAA undergoes degradation in 0.5% solutions and cross-linking in more concentrated solutions; with polymethacrylamide, only degradation was observed [27].

In the presence of bacteria and mold, PAA solutions get turbid with time, and a loose pink precipitate is formed. The microbial activity can result in a 4–5-fold decrease in the MW of PAA [28]. To prevent microbial degradation, bactericides such as Hexachlorophene, Diaphene, pentachlorophenol, etc., are added to polymer solutions [29].

Aqueous solutions of PAA are also unstable to the effect of a hydrodynamic field, deteriorating the polymer properties significant for practice. Stirring of PAA solutions at 4000 and 7000 rpm for 1 h decreases [η], after which it does not change further. According to GPC, the MW decreases from 5×10^6 to $(2.5–3.5) \times 10^6$ [30]. The decrease in [η] under the action of a hydrodynamic field [31] was attributed to a decrease in the size of macromolecular globules and in the flexibility of macromolecules. These factors prevent conformational transformations and orientation of macromolecules in a flow, which decreases the hydrodynamic performance of PAA. As found in [32–34], when solutions of nonhydrolyzed and hydrolyzed PAA are subjected to a shearing hydrodynamic field (at rate gradients of 3×10^3 or 6×10^3 s^{-1} for 30 min), the MW does not change, but the intrinsic viscosity [η], root-mean-square radius of inertia, and second virial coefficient decrease owing to changes in the structural and conformational characteristics of macromolecules [34]. The highest stability was noted for solutions of hydrolyzed PAA at pH 11.5. As shown in [35], at equal shear rate, the flow in dilute solutions of AA–Na-AA copolymers in 1 M NaCl decreases the MW by a factor of 3, and in semidilute solutions this decrease is less pronounced.

Ultrasonic treatment can cause degradation of PAA in aqueous solutions [36, 37]. Mechanical degradation of PAA is enhanced with increasing MW of the polymer and with decreasing solvency of the medium.

Table 1. Variation of molecular characteristics of partially hydrolyzed PAA in the course of thermal degradation in aqueous solutions (pH 7) in the presence of oxygen at 60°C

Characteristic	Time, days							
	0	3	10	34	40	51	75	100
$\overline{M}_w \times 10^{-6}$	3.4	2.2	1.9	1.5	1.2	0.9	0.7	0.5
$\Delta\overline{M}_w/\overline{M}_w$, %	0	35	45	56	64	73	79	83
Content of Na-AA units, mol %	31	31	31	31	34	37	39	41

In a flow through a porous medium, the MW of AA–Na-AA copolymer decreases [38].

The stability of aqueous PAA solutions is largely affected by temperature. A GPC study of the thermal degradation of PAA with $\overline{M}_\eta = 2.9 \times 10^6$ showed that, after keeping the solutions at 50°C for 5 days, the MWD curves change only slightly [39], whereas at 75°C the degradation of PAA with $\overline{M}$ 4.8×10^5 and 2.9×10^6 becomes appreciable.

Oxygen also affects the stability of aqueous PAA solutions. As shown in [40], oxidative degradation of PAA occurs in the presence of dissolved oxygen (~1%), and additions of sodium hydrosulfite and formaldehyde inhibit the polymer oxidation at 120–150°C.

When aqueous solutions of partially hydrolyzed PAA ($\overline{M}_w = 3.4 \times 10^6$, 31 mol % Na-AA units) are kept at 60°C in the presence of atmospheric oxygen, the MW decreases in time (Table 1) [2]. The MW sharply decreases in the first 10 days and more slowly, in the subsequent 10–100 days. The observed decrease in MW cannot be attributed to a change in the degree of hydrolysis of the polymer, since in the first 10 days $\overline{M}_w$ decreased by approximately 65%, whereas the degree of hydrolysis remained unchanged. Apparently, this result is due to the presence in commercial polymer samples of residual initiators, which entered into redox reactions with oxygen and induced degradation of the macromolecules [2]. With purified polymers, oxygen caused no degradation in the temperature range 60–100°C, and $\overline{M}_w$ remained unchanged [42, 42]. The degradation of PAA in aqueous solutions can also be induced by ozone. Ozonolysis of PAA with $\overline{M}_\eta = 3.5 \times 10^5$ in 0.1 and 1% aqueous buffer solutions is slow at pH 2 and faster at pH 10 [43]. With an increase in the oxygen consumption, the number of breaks in macromolecules increases, and $[\eta]$ decreases. The ozonolysis efficiency is determined by the concentrations of dissolved ozone and OH^- ions, temperature, and MW and structure of the polymer [44]. The rate of PAA degradation in aqueous solutions at pH $\leq$ 5.75 is independent of the OH^- concentration and at pH 5.8–8.9 is described by the equation

$$-d\overline{M}_\eta/dt = k_{pAA}[O_3][HO^-]^{0.5}\overline{M}\eta^{1.5},$$

where $k_{pAA} = 1.44 \times 10^{14} \exp(-94 \times 10^4/RT)$.

Thermal degradation of PAA and AA–Na-AA copolymers ($\overline{M}_\eta = 7.6 \times 10^6$) at 150°C is efficiently suppressed by Na_2SO_3 (binding oxygen) and Na_2EDTA (binding metal ions) [45].

The properties of aqueous solutions of PAA and its derivatives can be stabilized by various additives: alkali metal nitrites and iodides, thiocyanates, thiourea, dithionites, benzothiazole, sulfites, pyrosulfites, thiosulfites, mixtures of a guanidine derivative with 50% mercaptobenzothiazole or its salts, glycols, ethers, esters, ketones, etc. [2–8]. As stabilizers in drying of PAA solutions are used cyanamide, guanidine, succinimide, urea, or their mixtures.

The experimental data show that degradation of the polymers can be intensified by active residual impurities, oxygen, and heating. Therefore, to prevent undesirable degradation, the synthesized polymer should be purified to remove residual initiators and impurities by, e.g., reprecipitation or extraction. Residual ionic impurities (initiators, pH-controlling agents, surfactants, modifiers, complexing agents, stabilizers, etc.) can be removed by ion exchange and dialysis. Degradation of macromolecules can also be prevented by excluding access of oxygen to polymer solutions and removing oxygen from them [46]. Also, the polymers should be stored, dissolved, and used at temperatures as low as possible. The effect exerted by the structure of the polymers on the thermal stability of their solutions [47] should also be taken into account.

Despite the above-noted negative effect of degradation on the properties of polymer solutions, in some cases controllable degradation can be used to obtain

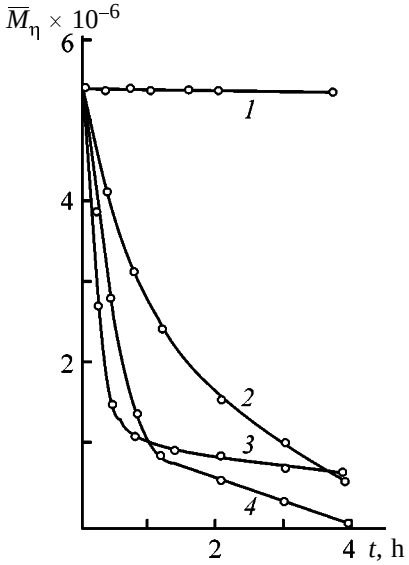

Fig. 2. $\overline{M}_\eta$ as a function of time *t* in degradation of PAA (initial $\overline{M}_\eta = 5.3 \times 10^6$) in the presence of various additives. Additive: (*1*) none, (*2*) ammonium persulfate, (*3*) H_2O_2–$FeSO_4$, and (*4*) PP. [Additive]/[PAA] 5%.

a polymer with the desired molecular weight. Below we discuss the degradation of PAA and its anionic and cationic derivatives in aqueous solutions under the action of radical degradative agents.

DEGRADATION OF POLYACRYLAMIDE AND ITS DERIVATIVES IN AQUEOUS SOLUTIONS IN THE PRESENCE OF RADICAL INITIATORS

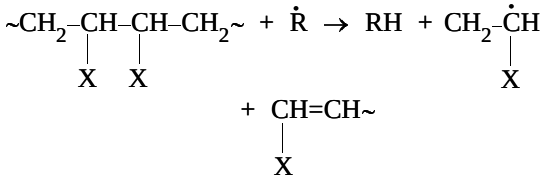
Degradation of polyacrylamide. The main features of degradation of commercial PAA ($\overline{M}_\eta$ 0.95×10^6, 5.3×10^6, and 6.3×10^6) in 0.4% aqueous solutions at 50°C under the action of radical degradative agents were studied in [48, 49]. The kinetic studies were performed viscometrically by the procedure described in [50]. In the course of degradation, [η] of PAA in 0.5 M NaCl at 25°C was determined and $\overline{M}_\eta$ was found by the equation [51]

$$[\eta] = 7.19 \times 10^{-3} \overline{M}_\eta^{0.77}.$$

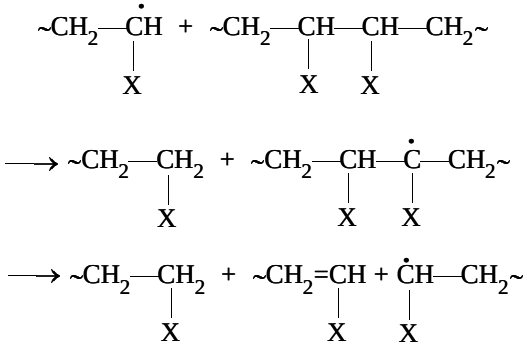
The effect of radical initiators (PP, ammonium peroxosulfate) and the H_2O_2–$FeSO_4$ redox system on variation of $\overline{M}_\eta$ in the course of PAA degradation in aqueous solutions is shown in Fig. 2. It is seen that $\overline{M}_\eta$ does not change in the absence of initiators (curve *1*) and decreases on adding them (curves *2*–*4*). This is due to degradation of the backbone chains under the actions of radicals R$^\bullet$ generated by thermal decomposition of the initiators. The degradation could start from "weak" units of the chain, primarily from the units with abnormal (head-to-head) structure formed by recombination of macroradicals under conditions of PAA preparation. The presence of such abnormal units in PAA macromolecules was confirmed in [52]. The radical R$^\bullet$ abstracts an H atom from the polymer chain, which, at low polymer concentration in solution, results in cleavage of C–C bonds in the backbone [53, 54].

The chain degradation of PAA under the action of radicals R$^\bullet$ can be represented as follows:

Chain initiation:

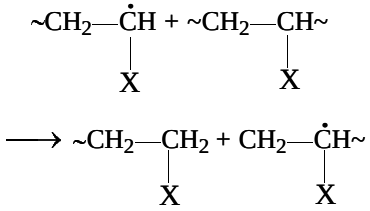


Chain propagation:

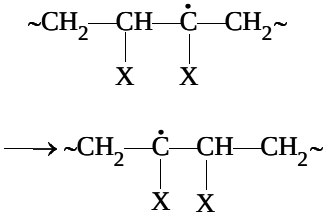


Chain transfer:

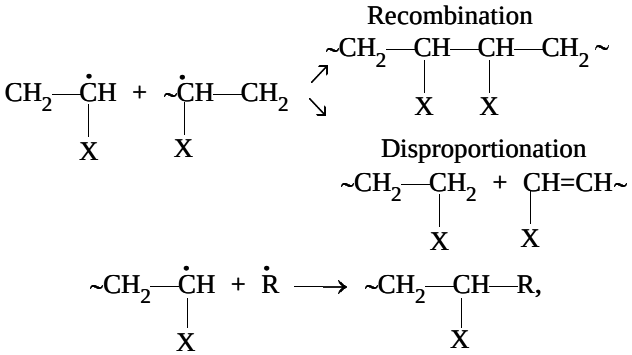
intermolecular



intramolecular



Chain termination:



where X = –$CONH_2$.

For simplicity sake, the fact that PAA degradation can be initiated by different radicals (e.g., sulfate radical ions $SO_4^{\bullet}$ or $OH^{\bullet}$ radicals formed by decomposition of PP in water) is not reflected in the scheme. According to the scheme, degradation of PAA under the action of radical initiators is random.

Figure 2 shows that all the initiators used cause active degradation of PAA chains and allow $\overline{M}_\eta$ of the polymer to be decreased to a widely varied level. For example, after degradation for 4 h under the action of PP, the $\overline{M}_\eta$ of PAA decreases by more than an order of magnitude: from 5.3×10^6 to 0.2×10^6 (Fig. 2, curve *4*).

As the initiator concentration is increased in the range [PP] = 1–7% (relative to PAA), $\overline{M}_\eta$ decreases, because degradation becomes more active (Fig. 3). From data in Fig. 3, we can determine the number of breaks α per macromolecule:

$$\alpha = [(\overline{M}_\eta)_0/(\overline{M}_\eta)_t] - 1,$$

where $(\overline{M}_\eta)_0$ is the initial molecular weight of PAA before degradation, and $(\overline{M}_\eta)_t$ is the PAA molecular weight after degradation for time t.

Variation of α in the course of PAA degradation is shown in Fig. 4; α grows with increasing concentration of the degradative agent and degradation time. However, α does not exceed 0.5 in 4 h, which rules out formation of low-molecular-weight products. The absence of noticeable depolymerization was confirmed by gravimetric analysis. As shown in [55, 56], the initial MWD of the polymer can be quickly and reliably estimated from the data on degradation kinetics. Using this approach, we determined the MWD width for the initial PAA sample from data in Fig. 4:

$$D = \overline{M}_w/\overline{M}_n,$$

where $\overline{M}_w$ and $\overline{M}_n$ are, respectively, the weight-average and number-average molecular weights.

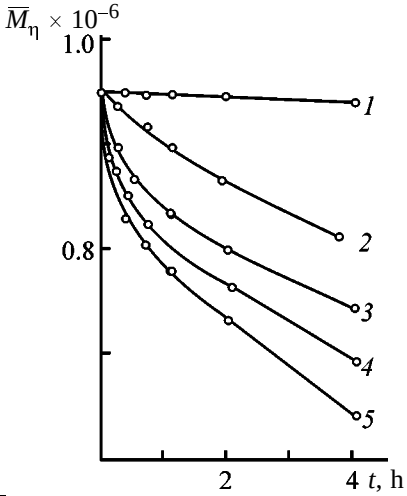


Fig. 3. $\overline{M}_\eta$ as a function of time t in degradation of PAA (initial $\overline{M}_\eta = 0.95 \times 10^6$) in the presence of various concentrations of PP initiator. [PP]/[PAA], %: (*1*) 0, (*2*) 1, (*3*) 3, (*4*) 5, and (*5*) 7.

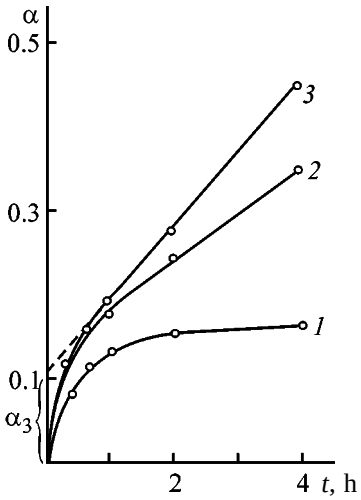

Fig. 4. Number of breaks α per macromolecule as a function of time t in degradation of PAA (initial $\overline{M}_\eta = 0.95 \times 10^6$). [PP]/[PAA], %: (*1*) 1, (*2*) 5, and (*3*) 7.

According to [55, 56], D is determined by

$$D = 2\alpha + 2,$$

where α is the mean length of portions intercepted on the ordinate by the tangents to the curves in Fig. 4. The quantity D found for PAA with $\overline{M}_\eta = 0.95 \times 10^6$ is 2.3, i.e., it somewhat exceeds the most probable value of 2 [5]. In a similar way, we determined D for the PAA sample with $\overline{M}_\eta = 6.3 \times 10^6$; it appeared to be equal to 3.1. Thus, the MWD of the initial PAA sample with $\overline{M}_\eta = 6.3 \times 10^6$ is broader than that of the sample with $\overline{M}_\eta = 0.95 \times 10^6$. The increased polydispersity of PAA with respect to MW was also revealed by light scattering [57, 58] and other methods for estimating MWD [20].

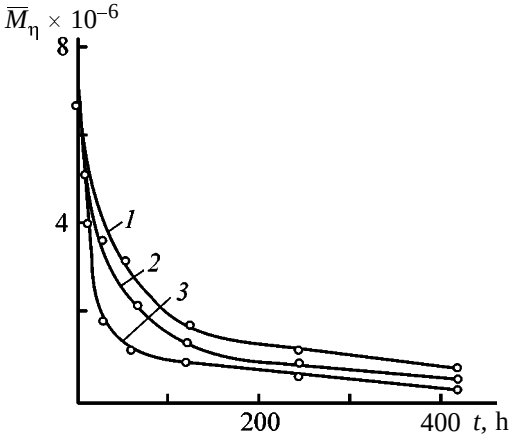

Fig. 5. $\overline{M}_\eta$ of AA–Na-AA copolymers as a function of degradation time *t*. [PP]/[Copolymer] = 1.5%; the same for Fig. 6. Content of Na-AA units, mol %: (*1*) 7, (*2*) 29, and (*3*) 39.

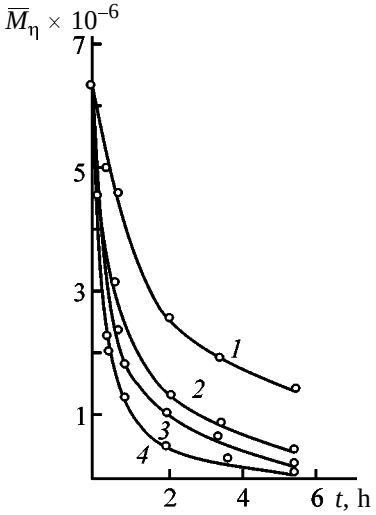

Fig. 6. $\overline{M}_\eta$ of AA–Na-AA copolymers (13 mol % Na-AA units) as a function of degradation time *t* at various NaCl concentrations. [NaCl]/[Copolymer], %: (*1*) 0, (*2*) 1, (*3*) 5, and (*4*) 50.

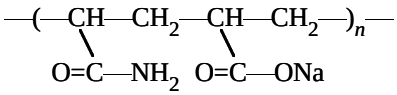
The difference between the molecular characteristics ($\overline{M}_\eta$ and MWD) of the PAA samples is reflected in their degradation rates. Under equal conditions, PAA with $\overline{M}_\eta = 6.3 \times 10^6$ degrades faster than the sample with $\overline{M}_\eta = 0.95 \times 10^6$ [50]. This is due to the presence in longer macromolecules of the larger number of "weak" units as sites of probable chain break; this result is well consistent with the general trends in chain degradation of polymers [6].

One of the factors promoting degradation of polymers is heating. Increasing temperature in the range 40–70°C accelerates degradation of PAA in aqueous solutions under the action of PP [50] owing to faster decomposition of the initiator. As a result, $\overline{M}_\eta$ of PAA appreciably decreases.

Thus, it is feasible to control $\overline{M}_\eta$ of commercial PAA by partial degradation of the polymer in aqueous solutions under the action of radical degradative agents (e.g., PP, ammonium peroxosulfate, H_2O_2–$FeSO_4$). The extent of degradation grows with increasing initiator concentration, $\overline{M}_\eta$ of the initial polymer, and degradation temperature and time.

Degradation of acrylamide–sodium acrylate copolymers. Specific features of degradation of AA–Na-AA copolymers



were studied in aqueous [59] and aqueous-salt [60, 61] solutions. Degradation was performed in 0.1 and 0.4% solutions at 40–70°C in the presence of PP (0.5–5 wt % relative to the copolymer). Copolymers of various compositions were prepared by base hydrolysis of PAA]62]; $\overline{M}_\eta$ was determined by the Mark–Kuhn–Houwink equation $[\eta] = K\overline{M}_\eta^\alpha$, and $[\eta]$ was measured in 0.5 M NaCl at 25°C. The constants K and α varied depending on the content of Na-AA units; their values were taken from [63]. The content of Na-AA units was determined by potentiometric titration [64]; analysis of technical-grade polymer in natural water was performed according to [65].

Variation of $\overline{M}_\eta$ of AA–Na-AA copolymers with degradation time is shown in Fig. 5. The chosen conditions allowed $\overline{M}_\eta$ of all the copolymer samples to be varied in a wide range.

To find how the conformational state of the copolymer macromolecules affects their degradation, the reaction was performed in aqueous-salt solutions [60, 61]. Addition of low-molecular-weight salts alters electrostatic interactions of the ionic group of the copolymer and allows the effective size of macromolecular globules to be varied in a wide range. It was found that the degradation accelerates with increasing NaCl concentration (Fig. 6). The $\overline{M}_\eta$ varied in a range covering 1.5–2 orders of magnitude. Similar results were obtained in the presence of KCl, LiCl, and CH_3COONa. The effect of salts on degradation is associated with variation of the solution ionic strength μ. With increasing μ, the acrylate ions in the macromolecular chain become shielded with Na^+ ions to a greater extent. As a result, according to viscometric data, the reduced viscosity η_{sp}/c of solutions of AA–Na-AA copolymers decreases. The intrinsic viscosity $[\eta]$ and the root-mean-square size of macromolecular globules $\langle r^2\rangle^{1/2}$ vary in parallel, as follows from the Flory equation $[\eta] = \Phi\langle r^2\rangle^{3/2}/\overline{M}$.

A decrease in $\langle r^2 \rangle^{3/2}$ and weakening of electrostatic repulsion between the fixed charges in the chain and the $SO_4^{\bullet}$ radical ions generated by decomposition of PP and initiating degradation resulted in acceleration of the copolymer degradation with increasing μ.

At low concentration of the added salts (1 wt % relative to the copolymer), $\overline{M}_\eta$ of degraded AA–Na-AA copolymer (29 mol % Na-AA units) increased in the order $K^+ < Na^+ < Li^+$ [60]. According to published data for polyacrylic acid [66–69] and copolymers of AA with acrylic acid salts [70], the degree of cation binding with the polyanions decreases in the order $K^+ > Na^+ > Li^+$. Therefore, the electrostatic repulsion between the acrylate ion and the $SO_4^{\bullet}$ radical ions grows in going from K^+ to Li^+, which weakens the degradation of the copolymer. The nature of the salt anion also affects the copolymer degradation. Namely, with NaCl $\overline{M}_\eta$ decreases to a considerably greater extent than with CH_3COONa added in the same concentration [61].

Figure 7 shows how $\overline{M}_\eta$ of AA–Na-AA copolymers degraded for various times depends on the content of Na-AA units. The curves pass through a maximum at 13 mol % Na-AA units. Apparently, in this case an optimal combination of the charge density, flexibility, and $\langle r^2 \rangle^{1/2}$ is attained. Figure 7 also shows that, as the degradation time is made longer, the maximum becomes less pronounced (going from curve *1* to curve *4*). Presumably, the above effect is leveled out by more efficient degradation of long macromolecules.

In [71] we studied degradation of partially hydrolyzed PAA in 0.4% aqueous solutions under the action of PP (5 wt % relative to the polymer) at 50°C. The degradation performed for 4 h resulted in 3.5- and 2.3-fold decreases in $\overline{M}_\eta$ of the polymers with the degree of hydrolysis of 16.2 and 42.0 mol %, respectively.

A combination of PAA hydrolysis and degradation also deserves attention as a way to control $\overline{M}_\eta$ of partially hydrolyzed PAA [62, 72]. The reaction was performed in 2.4% aqueous solutions of PAA with $\overline{M}_\eta = 3 \times 10^6$ in the presence of alkali and PP at 30–70°C. An increase in the PP concentration had no effect on hydrolysis but caused a decrease in $\overline{M}_\eta$ due to degradation of the macromolecules. The influence of the NaOH concentration on the process is illustrated by Fig. 8. In the absence of NaOH, no hydrolysis occurs (curve *1*), and an increase in the NaOH concentration accelerates hydrolysis (curves *2*–*4*). Degradation is also intensified owing to acceleration of PP decomposition (curves *1*'–*3*'). Heating affects

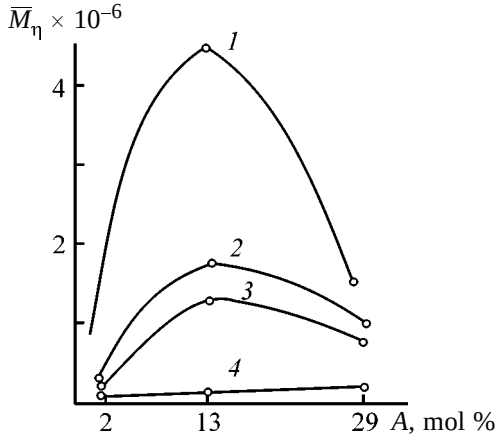


Fig. 7. $\overline{M}_\eta$ of degraded AA–Na-AA copolymers as a function of the content of Na-AA units *A*. [Copolymer] = 0.1%; content of PP and KCl 1.5 wt % relative to copolymer; 50°C. Degradation time, min: (*1*) 20, (*2*) 115, (*3*) 200, and (*4*) 320.

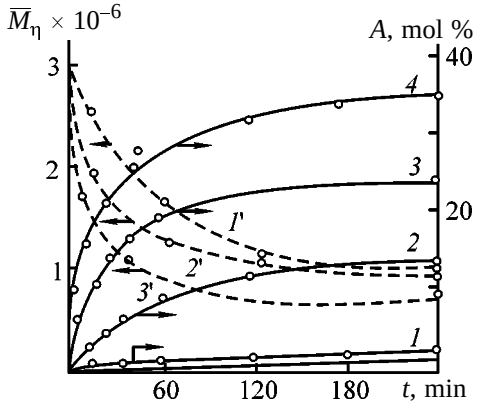

Fig. 8. (*1*–*4*) Content of Na-AA units *A* in AA–Na-AA copolymer and (*1*'–*3*') $\overline{M}_\eta$ as functions of time *t* of hydrolysis of PAA at 60°C in the presence of NaOH. [PAA] = 0.343 base mol l^{-1}; [PP] = 0.033 wt % relative to PAA. [NaOH], M: (*1*, *1*') 0, (*2*) 0.12, (*3*, *2*') 0.44, and (*4*, *3*') 0.73.

the degradation similarly. Thus, it is feasible to prepare partially hydrolyzed PAA with both $\overline{M}_\eta$ and composition being controlled.

A promising and relatively accessible procedure for controlling MW of polymers is ultrasonic degradation (USD) in solution [73, 74]. Myagchenkov and Krikunenko [75] applied ultrasonic treatment to control MW and MWD of partially hydrolyzed PAA in aqueous solutions. They found that USD of partially hydrolyzed PAA ($\overline{M}_\eta = 5.4 \times 10^6$, 18.1 mol % Na-AA units) can decrease MW by more than an order of magnitude, with the average composition and compositional heterogeneity of the samples remaining constant. The molecular characteristics of the degradation products, determined by GPC, are listed in Table 2 [75]. It is seen that $\overline{M}_n$, $\overline{M}_w$, and $\overline{M}_z$ decrease in the course of degradation, both in the absence and in the

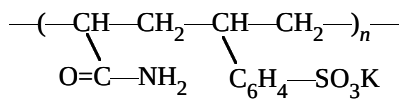
* (*t*) Degradation time; ($\overline{M}_z$) *z*-average MW.

presence of 0.5 M NaCl. According to Table 2, the Schulz parameter of the samples decreases in the course of degradation, approaching the theoretical value $U = 1$, which suggests random degradation [5, 50], The MWD curves and the values of $\overline{M}_n$, $\overline{M}_w$, and $\overline{M}_z$ (for t = const) show that the USD efficiency decreases with increasing μ (adding NaCl). The quantities [η] and $\overline{M}_\eta$ (viscometric data) vary similarly. The lower degree of degradation is due to smaller $\langle r^2 \rangle^{1/2}$, which is confirmed by viscometric analysis of hydrolyzed PAA in aqueous-salt solutions. In contrast to the hydrolyzed polymer, additions of NaCl exert no noticeable effect on $\langle r^2 \rangle^{1/2}$ in solution of nonhydrolyzed PAA; therefore, with this polymer, USD is not noticeably influenced by μ [75].

Degradation of copolymers of acrylamide with potassium *p*-styrenesulfonate. Degradation of copolymers of AA with potassium *p*-styrenesulfonate (K-SSA)



was performed in 0.4% aqueous solutions in the presence of PP in a helium atmosphere at 50°C [76, 77]. The results show that it is feasible to control MW of the copolymers of various compositions within a wide range (covering an order of magnitude), with the chemical composition of the macromolecules being preserved. According to data on degradation of sodium poly-*p*-styrenesulfonate [78], macromolecules of AA–K-SSA copolymer can be randomly cleaved at both acrylamide and styrenesulfonate units. The MW can be decreased by increasing the PP concentration and degradation temperature and time. Figure 9 demonstrates as an example the influence of temperature on degradation of AA–K-SSA copolymers. As the temperature is increased from 30 to 60°C, [η] decreases (with [PP] and *t* being the same), which is apparently due to faster decomposition of the initiator.

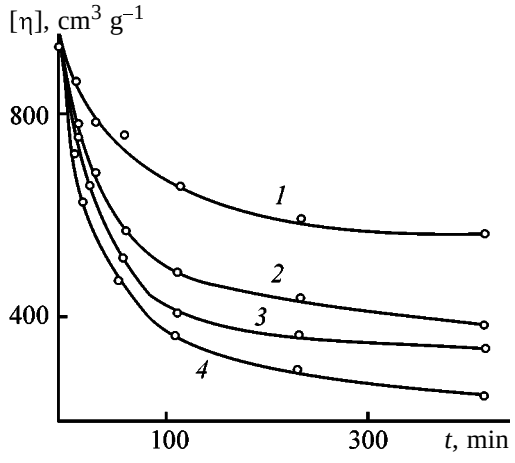


Fig. 9. Plot of [η] vs. time *t* of degradation of AA–K-SSA copolymer (8.4 mol % K-SSA units) at (*1*) 30, (*2*) 40, (*3*) 50, and (*4*) 60°C. [PP] = 1.5 wt % relative to copolymer.

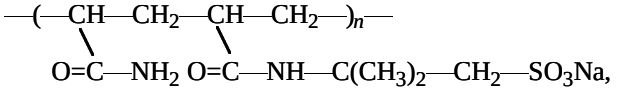
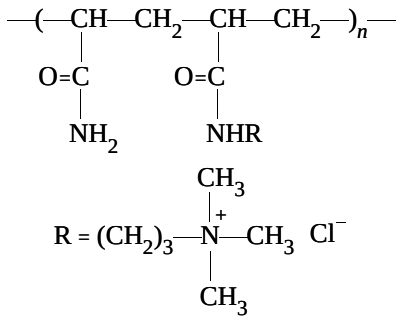
Degradation of copolymers of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate. The degradation of copolymers of AA with the sodium salt of another strong acid, 2-acrylamido-2-methylpropanesulfonic acid (Na-AMS)



was studied in [79]. As shown by viscometry, PP-initiated degradation in 0.4 and 0.5% solutions at 40 and 50°C yields shorter macromolecules as compared to the initial sample. The intrinsic viscosity [η] of AA–Na-AMS copolymers of various compositions can be controlled by varying the PP concentration and the degradation temperature and time.

Degradation of copolymers of acrylamide with (acrylamidopropyl)trimethylammonium chloride. Copolymers of AA with (acrylamidopropyl)trimethylammonium chloride (APTMAC)



with controlled MW were prepared by degradation in 0.1% solutions initiated by hydrogen peroxide and PP (30–50°C), or by persulfate–bisulfite redox system (25°C) [80]. The characteristics of the initial copolymers are listed in Table 3. The performance of these initiators in copolymer degradation is characterized by a significant decrease in [η]. The degradation is promoted by increasing concentration of degradative agents and in going from H_2O_2 to PP, and also by increasing temperature. Sample B, similar in composition to sample C but having higher initial MW (Table 3), degrades to a greater extent, which is consistent with published data [6].

The influence of the concentration of the AA–APTMAC copolymer (33 mol % ionic units) on its degradation is illustrated in Fig. 10. In the tested concentration range, [η] appreciably decreases with increasing degradation time. In more concentrated copolymer solutions, the degradation is less pronounced. This may be due to increased viscosity, which hinders diffusion of the active species.

Figure 11 shows the plots of [η] vs. degradation time for PAA (sample A, curve *1*), AA–APTMAC copolymer (sample B, curve *2*), and AA–Na-AA copolymer (sample D, curve *3*). Experimental data were obtained under identical degradation conditions for the polymers having approximately equal initial intrinsic viscosities [η]; the content of ionic units in the copolymers was also approximately equal (Table 3). Figure 11 shows that the degradation rate decreases in the order PAA > AA–APTMAC copolymer > AA–Na-AA copolymer. The faster degradation of the AA–APTMAC copolymer, compared to AA–Na-AA copolymer, may be due to electrostatic attraction between the $SO_4^{\bullet-}$ radical ions and the cationic units of the AA–APTMAC macromolecule, whereas in the AA–Na-AA macromolecule the $SO_4^{\bullet-}$ radical ions are repelled from the negatively charged ionic units.

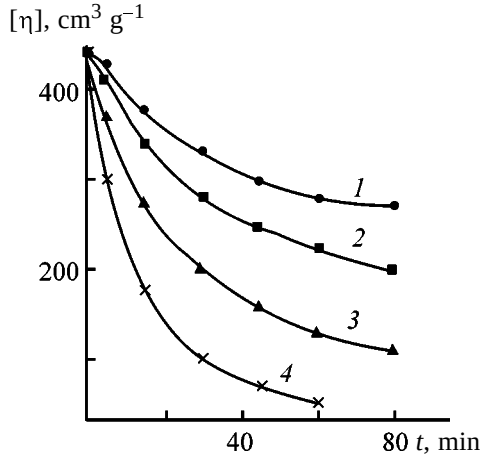


Fig. 10. Plot of [η] vs. degradation time *t* for aqueous solutions of AA–APTMAC copolymer (33 mol % APTMAC units) of various concentrations c_p at 50°C, [PP] = 0.06% (in water). c_p, %: (*1*) 0.5, (*2*) 0.4, (*3*) 0.3, and (*4*) 0.1.

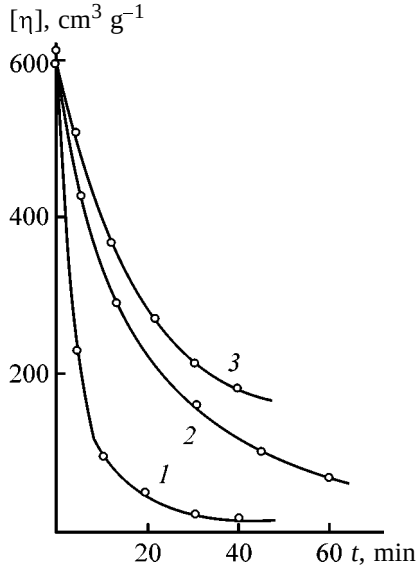

Fig. 11. Plot of [η] vs. degradation time *t* for aqueous solutions of (*1*) PAA, (*2*) AA–APTMAC copolymer, and (*3*) AA–Na-AA copolymer at 50°C. c_p = 0.1 and [PP] = 0.04% (in water).

Table 3. Characteristics of PAA and of AA–APTMAC and AA–Na-AA copolymers

Sample	[η], $cm^3\ g^{-1}$	Content of indicated units, mol %		
		AA	APTMAC	Na-AA
A	600	100	–	–
B	610	73	27	–
C	440	67	33	–
D	600	72	–	28

Thus, by partial degradation in aqueous solutions, it is feasible to control MW of AA–APTMAC copolymers in a wide range covering an order of magnitude.

To conclude, degradation of PAA and its anionic and cationic derivatives in aqueous solutions in the presence of radical degradative agents at 25–60°C is an efficient, reliable, simple, and accessible method for controlling within a wide range (covering two and more orders of magnitude) the MW of commercial (co)polymers. In the process, the chemical composition of the copolymer macromolecules is not altered. The MW of (co)polymers can be adjusted by varying the nature and concentration of the degradative agent and of low-molecular-weight salts added, the concentration, MW, and chemical composition of the initial (co)polymer, and the degradation temperature and time. These data can be used for preparing (co)polymer samples with the required molecular weight under conditions of (co)polymer application in the stage of solution preparation.

The occurrence of degradation should also be taken into account in copolymerization of AA with ionic monomers in water and aqueous-salt solutions in the presence of radical initiators. Degradation is one of the factors complicating copolymerization of ionic monomers [77, 81, 82] and affecting the kinetic and statistical parameters of radical copolymerization.

The degraded polymers and copolymers of various molecular weights show much promise for practice. For example, degraded AA–Na-AA copolymers (MW 7×10^3–5.4×10^4) can be used in medicine as cryoprotectors in conservation of blood components and other biological objects. Samples of AA–Na-AA copolymers with MW $(1.7–6.2) \times 10^4$ positively affect donor erythrocytes: In aqueous solutions of these copolymers, erythrocytes are fully protected from hemolysis and preserve the initial morphological structure.

AA–Na-AA copolymers with MW 0.75×10^3–9×10^4 show high performance as binders and viscosity stabilizers for suspensions of kaolin, calcium carbonate, and other pigments used in paper production [84].

Degraded AA–K-SSA copolymers ($[\eta]$ = 200–700 $cm^3\ g^{-1}$) show high performance as flocculants for kaolin and ocher suspensions [76]. The sedimentation rate of an ocher suspension with these copolymers is by a factor of 2–4.5 higher than with PAA, and for a kaolin suspension it is higher by a factor of 6–7 [77].

Laboratory and commercial tests confirmed the efficiency of using degraded copolymers of AA with dimethylaminoethyl methacrylate hydrochloride [MW $(0.55–6.54) \times 10^5$] as conducting coatings for cellulose triacetate (CTA) and poly(ethylene terephthalate) (PET) films [85]. The electrical conductivity of coatings based on the copolymer exceeds by 7–8 orders of magnitude that of uncoated PET films and by 5–6 orders of magnitude that of uncoated CTA films. The half-time of charge leakage $\tau_{1/2}$ from uncoated PET and CTA films exceeds 120 s, and for the coated films it is less than 1 s. The films not only impart high conductivity to PET and CTA films, but also make their surface lustrous.

Degraded AA–APTMAC copolymers (27 mol % ionic units, $[\eta]$ = 90–200 $cm^3\ g^{-1}$), depending on the copolymer concentration c_p, can act as effective coagulants and stabilizers of kaolin suspensions. For example, with respect to a 0.25% kaolin suspension, the copolymer with $[\eta]$ = 90 $cm^3\ g^{-1}$ behaves as a coagulant at $c_p < 15$ mg l^{-1} and as a stabilizer at $c_p >$ 15 mg l^{-1}. As compared to a mineral coagulant (aluminum sulfate), the organic coagulant (copolymer) ensures a 3.5 times higher coagulating effect at 3–5 times lower concentrations. The efficiency of sedimentation of kaolin suspensions increases when the organic coagulant is used in a combination with a flocculant, AA–Na-AA copolymer ($\overline{M}_\eta = 4.6 \times 10^6$, 11 mol % Na-AA units).

Abstract—Solubility in the systems of CuCl–LiCl–H_2O and CuCl–CsCl–H_2O at 25°C was studied by the method of isothermal removal of oversaturation. The results were examined in terms of the competition between hydration and complex formation processes in water–salt systems.

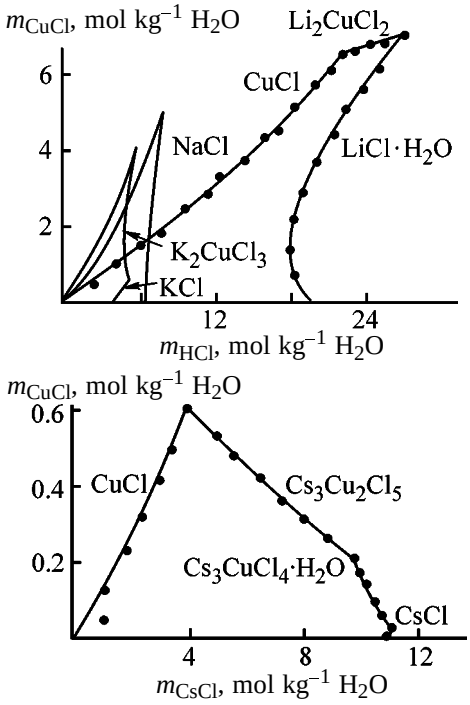
Copper monohalides find growing application in chemistry and chemical technology. They are used as catalysts for a number of reactions, primarily for radical-cation processes involving aromatic compounds (production of phenol and aniline from aryl halides), reactions of diazo compound (Sandmeyer reaction), isomerization of unsaturated compounds, polymerization of alkynes, oxidation of carbon(II) oxide, etc. However, the efficiency of using these compounds is limited by the low solubility of copper monohalides and consequently by difficult homogenization of the reaction mixture. Therefore, it is urgent to search for ways to solubilize copper(I) compounds.

It is known that a second salt component added to a solution often significantly affects the solubility of the starting compound. Examination of the solubility data for systems containing copper monohalides [1] shows that reliable and consistent experimental data on solution–solid phase equilibria are available only for the CuCl–KCl–H_2O system. Therefore, we have studied systematically the solubility in the CuCl–MCl–H_2O system (M is an alkali metal). Data on the solubility in the CuCl–NaCl–H_2O system at 25°C were published previously [2]. Here we report experimental data on the solubility in the CuCl–LiCl–H_2O and CuCl–CsCl–H_2O systems at 25°C.

We used lithium and cesium chlorides (both ultrapure grade) and copper(I) chloride recrystallized from hydrochloric acid. The solubility was determined by the method of isothermal oversaturation removal. Solutions were heated to completely dissolve the solid phases and then were thermostated for two days at 25 ± 0.1°C with continuous stirring. The experiment was performed in darkened vessels to avoid photoinitiated disproportionation of copper(I).

Samples were treated with nitric acid (ultrapure grade), after which the concentration of copper(II) ions was determined by complexometric titration, and that of chloride ions, by mercurimetric titration. The accuracy of the analyses was ±0.5%. The concentration of the alkali metal chloride was calculated as the difference. The compositions of the solid phases were determined by the Schreinemachers method. The results are shown in the figure and table.

It was shown earlier that the solubility in the



Solubility m_{MCl} at 25°C in the systems CuCl–LiCl–H_2O, CuCl–CsCl–H_2O (data of this work), CuCl–NaCl–H_2O [2], and CuCl–KCl–H_2O [1].

$CuCl_2$–MCl–H_2O systems is governed by the competition between hydration and complex formation [3]. As the structure-breaking effect of the cation increases, favoring formation of acido complexes, the transition is observed in the binary electrolytes from the branches of $CuCl_2 \cdot 2H_2O$ and MCl (M^+ = Li^+, and Na^+) salting-out to salting-in. In the case of copper monochloride, the stability constants of acido complexes are higher by several orders of magnitude than those for copper(II) (e.g., β_2 is 1.1×10^6 for $CuCl_2^-$ and 26.2 for $CuCl_2$ [4]). Such a strong acido complex formation results in significant salting-in of copper monochloride on adding alkali metal chlorides (see figure). The factors by which the CuCl solubility in ternary systems m_{max} is higher than in the binary solution m_{bin} are given below for various alkali metal chlorides.

Alkali metal chloride	LiCl	NaCl	KCl	CsCl
m_{max}/m_{bin}	5820	4620	3730	550

Acido complex formation is also responsible for salting-in of alkali metal chlorides on adding copper monochloride. However, the competition of hydration and complex formation in the CuCl–LiCl–H_2O system containing the most strongly hydrated lithium cation results in salting-out–salting-in of $LiCl \cdot H_2O$.

The enhancement of acido complex formation under the action of low-hydrated alkali metal cations, repeatedly discussed in the literature [5], affects the shape of the solubility isotherms of these systems. The intensity of salting-in varies in parallel with the structure-breaking effect of cations: $K^+ > Na^+ > Li^+$, whereas the length of the crystallization branches of the pure components (crystal hydrate in the case of lithium chloride) varies in the opposite direction. However, with cesium the pattern is specific: salting-in in the CuCl–CsCl–H_2O system is weaker than in the CuCl–NaCl–H_2O and CuCl–KCl–H_2O systems (a similar behavior was observed in the $CuCl_2$–CsCl–H_2O system, where salting-in was weaker than in the $CuCl_2$–KCl–H_2O system). This may be due to specific features of the complex formation in the systems containing cesium chloride. It was shown earlier [6] that, owing to the strong association of cesium chloride in binary solutions, Cs^+Cl^- ion pairs can participate along with chloride ions as ligands in the complex formation. Such a process would result in peculiar "hydrophobization" of the forming associates (owing to low-hydrated cesium ions) and, consequently, in their stronger salting-out.

Our results and published data show that, in all the systems except CuCl–NaCl–H_2O, complicated solid compounds are formed. In the CuCl–LiCl–H_2O and CuCl–KCl–H_2O systems, M_2CuCl_3 complex salts are formed. The common formula of these compounds and the absence of water of crystallization in the lithium salt suggest the similar mechanism of their formation, involving complexation of copper(I) with chloride ion. A similar type of salts formed in these systems {in contrast to the corresponding systems containing copper(II) [6]} can be explained by stronger acido complex formation, which dominates in almost the whole concentration range. The weaker complex formation in the system with lithium chloride, as compared to the CuCl–KCl–H_2O system, determines the smaller crystallization area of the complex salt and the shift of its formation area toward higher concentrations.

In the CuCl–CsCl–H_2O system, two complex salts are formed: $Cs_3Cu_2Cl_5$ and $Cs_3CuCl_4 \cdot H_2O$. The different (compared to M_2CuCl_3) compositions of these compounds may be due to different mechanisms of their formation (it is likely that the Cs^+Cl^- associate enters into the inner coordination sphere of the complex-forming cation). As for the absence of complexes

in the CuCl–NaCl–H_2O system, its causes were discussed earlier in detail [2].

Thus, our study of the solubility in the CuCl–MCl–H_2O systems showed that addition of alkali metal chloride results in considerable solubilization of copper monochloride. The dependence of solubility on the nature of the second component, which is similar to that observed earlier in the $CuCl_2$–MCl–H_2O systems, is determined by the prevalence of acido complex formation.

Abstract—The concentration regions of prevalence of various chemical interactions in the $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O system were determined by dilatometry, pH-metry, and electronic spectroscopy of solutions and by X-ray phase and gravimetric analyses of precipitates. The adequacy of the model proposed was confirmed by CPESSP calculations.

Occurrence of equilibria (1) in aqueous ammonia solutions suggests that either ammine complexes or mono- and polynuclear hydroxo complexes, and probably mixed hydroxo ammine complexes can be formed in systems metal ion–ammonia–water:

$$NH_3 + H_2O = NH_3 \cdot H_2O = NH_4^+ + OH^-. \quad (1)$$

The hydrolysis and complex formation can compete. Such reactions, which often take place in heterogeneous systems, result in the precipitation of poorly soluble compounds and, in certain cases, in their subsequent dissolution.

It is often difficult to gain insight into the chemical interactions and state of the components in such complicated systems consisting of both solutions and solids. The subject of this work was the $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O system. The experimental data were obtained dilatometrically. This method allows highly accurate monitoring of changes in the solution volume due to chemical interactions. Also, we used potentiometric titration and electronic absorption spectroscopy of solutions (after thorough filtration to remove precipitates, which, in turn, were studied by chemical and X-ray phase analyses). The data of the dilatometric titration were treated with a simulating CPESSP program.

Hydrolysis and complex formation of copper(II) with ammonia were extensively studied as separate processes. The hydrolysis of copper(II) ions was studied previously in [1] by potentiometric titration with an alkali (NaOH) at a constant ionic strength, and also in [2], with 3.0 M $NaClO_4$ as supporting electrolyte. It was shown that, along with the dominating binuclear complex $Cu_2(OH)_2^{2+}$, the $CuOH^+$ and $Cu_2(OH)^{3+}$ species are formed in solution. Their hydrolysis constants $\log K_h$, equal to -10.93 ± 0.02, -7.4 ± 0.1, and -6.02 ± 0.02, respectively, were determined, and the stability constants $\log\beta$ were calculated in view of $pK_w = 14.09$ found in [3]: 6.69 for $CuOH^+$, 17.25 for $Cu_2(OH)_2^{2+}$, and 8.07 for $Cu_2(OH)^{3+}$. Several authors also detected the trinuclear species $Cu_3(OH)_4^{2+}$. The most probable hydroxo compounds in the solid state are copper hydroxide $Cu(OH)_2$ and also the binuclear complex $Cu_2(OH)_3NO_3$ characteristic of nitrate systems [4].

In solutions of copper ammines, there are only mononuclear complexes $[Cu(NH_3)_n]^{2+}$, n = 1–4 (however, there are also scarce data on the complexes with n 5 and 6). Their step stability constants were determined by many authors [1]. For example, the following values are given in [5]: $\log k_1 = 4.31$, $\log k_2 = 3.67$, $\log k_3 = 3.04$, and $\log k_4 = 2.30$ (thus, $\log\beta_4 = 13.32$ at 18°C in a 2 N solution of ammonium nitrate).

Attempts were made to gain insight into processes occurring under the action of aqueous ammonia solution on the suspension of copper oxide CuO. Gubeli *et al*. [6], when fitting the CuO solubility curve, suggested the presence of a number of species in the system: Cu^{2+}, $Cu(OH)_n^{2-n}$ (n = 2–4), $Cu(NH_3)_n^{2+}$ (n = 2–4), and also $Cu(NH_3)(OH)^+$, $Cu(NH_3)_3(OH)^+$, and $Cu(NH_3)_2(OH)_2$. At the same time, this conclusion seems doubtful, because the well-known existence of binuclear hydroxo complexes was not included in the model.

Comparison of the published data shows that vari-

ous chemical reactions can compete in the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O.

The results of dilatometric and potentiometric titration of copper nitrate solution (with addition of HNO_3 to prevent spontaneous hydrolysis) by an ammonia solution are shown in Fig. 1. The dilatometric curve corresponding to the titration in the system $Cu(NO_3)_2$, (H^+)–NaOH–H_2O, i.e., to the hydrolysis of copper(II) ions without complex formation, is shown in Fig. 2. The dilatometric curves were constructed as the plots of changes in the molar volume ΔV_m ($cm^3\ mol^{-1}$) vs. the number of added moles of a base N per mole of copper ions, N = $[NH_3 \cdot H_2O]/[Cu^{2+}]$ for Fig. 1 and N = $[NaOH]/[Cu^{2+}]$ for Fig. 2.

For more convenient comparison and interpretation, we accepted the starting point of the hydrolysis of Cu^{2+} ions (i.e., point *B*) as the point of zero value of N . Thus, the values $N < 0$ in the beginning of the curve (straight line *AB*) corresponded to the titration region in which the main component [copper(II) ions] yet do not enter into the reaction, and the possible scatter of the starting points *A* in various titration experiments may be due to different amounts of the acid added.

The dilatometric titration curves for such complicated systems as the system under study consist of a number of linear portions, each of which corresponds to various chemical reactions. We have shown earlier [7–9] that the singular points (according to Mendeleev's definition [10]) in the composition–property diagrams correspond to the boundaries of the regions with prevalence of particular types of reactions, depending on *N*. Thus, the change in the solution molar volume ΔV_m for each particular reaction is determined as the slope of the $\Delta V_m = f(N)$ dependence in the dilatometric curve portion under consideration.

A detailed study of the dilatometric titration data for the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O (Fig. 1) in comparison with the data on bulk properties of the system $Cu(NO_3)_2$, (H^+)–NaOH–H_2O (Fig. 2), and also with the data of other methods, allowed us to reveal and interpret the regions of prevalence of the following chemical reactions.

(1) The neutralization of excess nitric acid, which is usually added to the initial solution to prevent the spontaneous hydrolysis of copper(II). The region of the neutralization corresponds to the linear portion *AB* in the dilatometric curves shown in Figs. 1 and 2. A set of facts indicate that specifically neutralization takes place in both systems within boundaries of the *AB* portion. First, point *B* coincides with the calculated equivalence point with respect to the acid. Second, the first equivalence point in the pH-metric curve corresponds to point *B*. Furthermore, after this point, hydroxo compounds start to precipitate.

There is principle difference between the courses of volume changes in neutralization with sodium hydroxide and ammonia aqueous solutions. Reaction (2) involving a strong base and a strong acid (Fig. 2, portion *AB*) is accompanied by an increase in volume

(ΔV_{AB} = 21.06 $cm^3\ mol^{-1}$):

$$NaOH + HNO_3 = H_2O + NaNO_3. \quad (2)$$

The observed positive volume effect agrees well with the published data [9]. The main component of ΔV_{AB} is the partial molar volume of the forming water (V_w = 18.07 $cm^3\ mol^{-1}$ at 25°C). An additional contribution to the volume effect is due to the dehydration of H^+ and OH^- ions and, correspondingly, to their deelectrostriction [11]. Reaction (2) can be written in the ionic form as follows:

$$OH^-_{aq} + H^+_{aq} = H_2O + aq + \Delta V_{AB}, \quad (3)$$

where aq is water in the hydration spheres of ions.

With aqueous ammonia solution (Fig. 1), the pattern of volume changes in the *AB* section is opposite, i.e., the volume of the system decreases. The ΔV_{AB} value for reaction (4) [or (5) in the ionic form] is –4.85 $cm^3\ mol^{-1}$:

$$NH_3 \cdot H_2O + HNO_3 = H_2O + NH_4NO_3, \quad (4)$$

$$NH_{3(aq)} + H^+_{(aq)} = NH^+_{4(aq)}. \quad (5)$$

At first glance, such a difference in the volume effects (as compared to the neutralization with alkali) seems strange, as in both cases water molecules are formed, and dehydration of the acid protons also makes a certain positive contribution. The observed effect is due to specific features of the neutralization with aqueous ammonia (namely, the partial molar volume of the initial ammonia in solution is larger than the partial molar volume of an aquated ammonium ion formed in the reaction [12, 13]).

To confirm additionally the fact that acid is neutralized in the initial stage of the titration (portion *AB*), we titrated a non-acidified solution of copper(II) nitrate with an ammonia solution [the system $Cu(NO_3)_2$–$NH_3 \cdot H_2O$–H_2O]. As expected, the resulting titration curve was similar to the curve under consideration, except for the *AB* portion.

(2) After passing point *B*, a blue precipitate is formed in both systems under consideration, which is accompanied by an increase in volume, suggesting occurrence of a new chemical reaction (Figs. 1 and 2, straight line *BC*) responsible for a sharp change in the molar volume. Point *B* is the starting point for measuring the amount *N* (mol) of a titrant [sodium hydroxide (Fig. 2) or ammonia (Fig. 1)] reacting directly with copper(II). The length of the *BC* section in both cases corresponded to *N* = 1.5 mol. The volume changes describing the *BC* section are ($cm^3\ mol^{-1}$) $\Delta V_{BC}(NaOH)$ = 31.44 and $\Delta V_{BC}(NH_3 \cdot H_2O)$ = 6.04. As found previously for induced hydrolysis of iron(III) ions [8], the hydrolytic polymerization under the action of a strong base is accompanied by an additional positive volume effect, as compared to the first section corresponding to the neutralization of an acid. For the systems under consideration, these additional contributions are as follows ($cm^3\ mol^{-1}$): $\Delta V_{BC}(NaOH)$ – $\Delta V_{AB}(NaOH)$ = 31.44 – 21.06 = 10.38 for NaOH titrant and $\Delta V_{BC}(NH_3 \cdot H_2O)$ – $\Delta V_{AB}(NH_3 \cdot H_2O)$ = 6.04 – (–4.85) = 10.89 for $NH_3 \cdot H_2O$ titrant. This fact allows an important conclusion that, in spite of different nature of the bases in the two titration experiments, the volume effect resulting from the hydrolysis and hydrolytic polymerization remains the same.

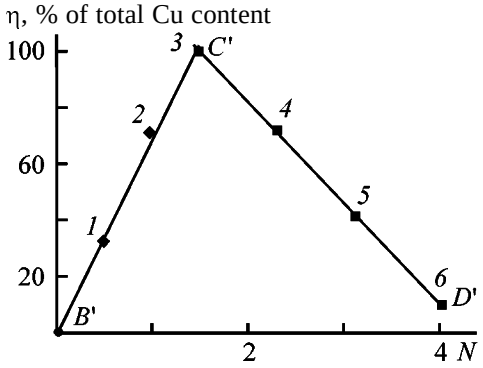

Fig. 3. Plot of the precipitate yield η vs. *N*. *N*: (*1*) 0.5, (*2*) 1.0, (*3*) 1.5, (*4*) 2.3, (*5*) 3.1, and (*6*) 4.0; the same for Fig. 4.

According to X-ray phase analysis, the solid phase is the same in both cases: the known binuclear copper trihydroxonitrate $Cu_2(OH)_3NO_3$. No ammine and mixed hydroxo ammine complexes were detected in the solid phase.

The *B'C'* portion of the plot of the precipitate weight (% of total copper content) vs. *N* in Fig. 3 (in the *B'C'* portion, precipitates were isolated at *N* 0.5, 1.0, and 1.5) is a straight line ascending in parallel to the *BC* portion of the dilatometric curve (Fig. 1). The amount of the precipitate linearly increased, reaching a maximum at *N* = 1.5, i.e., in point *C'*. The electronic absorption spectra (Fig. 4) show that the solutions corresponding to the straight-line portion *BC* of the dilatometric curve contain no Cu(II) ammine complexes (the solutions were prepared by thorough filtration at the same *N* values as the precipitates). The absorption band in the region 600–625 nm, characteristic for copper ammines [14], was absent from the

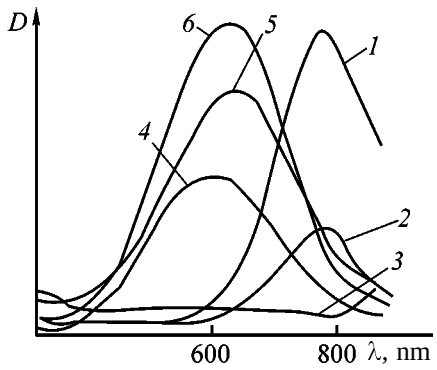

Fig. 4. Electronic absorption spectra of solutions obtained in the system $Cu(NO_3)_2$–$NH_3 \cdot H_2O$–H_2O at various *N* values. (*D*) Optical density and (λ) wavelength.

spectra of solutions corresponding to *N* 0.5, 1.0, and 1.5 (curves *1*, *2*, and *3*, respectively). At the same time, a decrease in the intensity of the absorption band in the region of 800 nm, characteristic for copper(II) aqua complexes [15], was indicative of gradual decrease in the copper amount in the solution. At *N* = 1.5 (singular point *C*), Cu^{2+} ions were almost absent from the solution. Thus, in the range of *N* from 0 up to 1.5 in the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O, the hydrolysis (i.e., interactions also characteristic of the induced hydrolysis under the action of a strong base) prevailed over the formation of ammine complexes.

The following reactions are presumably responsible for the volume changes in the *BC* portions of the dilatometric curves for both systems under consideration:

$$2Cu^{2+} + NO_3^- + 3OH^- = Cu_2(OH)_3NO_3, \quad (6)$$

$$2Cu^{2+} + NO_3^- + 3NH_3 \cdot H_2O = Cu_2(OH)_3NO_3 + 3NH_4^+. \quad (7)$$

Apparently, the hydrolytic transformations described by Eqs. (6) and (7) involve the stages of the formation of copper mono- and polynuclear hydroxo complexes $CuOH^+$, Cu_2OH^{3+}, and $Cu_2(OH)_2^{2+}$, which are precursors of the forming solid phase.

It was shown in [8] that the positive volume effect is due to liberation of water molecules from the hydration shells of the interacting ions upon the hydrolytic polymerization (the molar volume of water in the free state is 18.07 $cm^3\,mol^{-1}$, and in hydration shells of double-charged cations of 3*d* metals it is about 15 [16]). Note that a neutral hydroxo complex was formed from six differently charged species in reaction (6) with liberation of water molecules from the hydration shells of the ions.

The potentiometric titration of the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O (Fig. 1, curve *II*) in the region corresponding to the *BC* portion reveales a slight increase in pH at *N* from 0 to 1.5. The sharp pH increase in the second equivalence point at *N* = 1.5 coincided with singular point *C* in the dilatometric curve. At *N* > 1.5, the pH changed only slightly. Hence, the formation of hydroxo species, with binding of hydroxide ions without noticeable pH change, was complete.

(3) Analysis of the ΔV_{CD}(NaOH) and $\Delta V_{CD}(NH_3 \cdot H_2O)$ values in the *CD* portion (Figs. 1, 2) revealed principal differences in the nature of volume changes and, hence, in chemical reactions in the two systems under consideration (i.e., when sodium hydroxide or aqueous ammonia solution was added). When titrating with sodium hydroxide (Fig. 2), the volume continued to grow up to *N* = 2, with only the value of the volume effect changed [ΔV_{CD}(NaOH) = 13.56 $cm^3\,mol^{-1}$]. The transformations in the system were associated with further hydrolytic reactions whose final solid product was a mixture of copper hydroxide and oxide formed by partial decomposition of $Cu(OH)_2$ (which was also confirmed by X-ray phase analysis). The *CD* portion is located between *N* 1.5 and 2, which apparently corresponds to reaction (8) and parallel partial decomposition (9) of copper hydroxide into copper oxide and water (in the course of the experiment, the precipitate gradually darkens owing to the formation of black copper oxide):

$$Cu_2(OH)_3NO_3 + OH^- = 2Cu(OH)_2 + NO_3^-, \quad (8)$$

$$Cu(OH)_2 = CuO + H_2O. \quad (9)$$

The volume changes are virtually complete in singular point *D* (*N* = 2) owing to the completion of main chemical reactions in the system: after *N* = 2, the titration curve (Fig. 2) flattens out.

At the same time, in titration with aqueous ammonia (Fig. 1), the volume decreased [$\Delta V_{CD}(NH_3 \cdot H_2O)$ = –2.93 $cm^3\,mol^{-1}$], which continued up to *N* = 4.

In the $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O system, the *CD* section gives one more evidence of competition between the chemical reactions. In contrast to the previous example (titration with alkali), the further titration with ammonia results in the dissolution of the copper hydroxo complex and in its conversion to copper(II) ammines:

$$Cu_2(OH)_3NO_3 + 2nNH_3 \cdot H_2O = 2Cu(NH_3)_n^{2+} + 3OH^- + NO_3^- + 2nH_2O. \quad (10)$$

To examine further changes in m_{Cu} (%), we should note that, according to the plot of the precipitate weight (the precipitates were taken at N 2.3, 3.1, and 4.0) vs. N in the range of N from 1.5 to 4.0 in Fig. 3 (straight line $C'D'$), the precipitate amount decreases, and in poing D' it dissolves almost completely (the course of the dilatometric curve is almost repeated). According to the X-ray phase analysis, the composition of the precipitate $Cu_2(OH)_3NO_3$ remains unchanged in the process. No mixed hydroxo ammine complexes were detected. In the electronic spectra (Fig. 4), instead of the completely disappeaing band at 800 nm, an absorption band appears in the range 600–625 nm (spectra of solutions *4*–*6*), which can be assigned, as mentioned above, to copper ammine complexes.

Thus, the nature of the final solid product of hydrolytic transformations of Cu^{2+} ions in $Cu(NO_3)_2$ solutions depends on the titrating base. In the case of NaOH, it is $Cu(OH)_2$, which is converted to CuO with time and in excess of the base, and, in the case of aqueous ammonia, it is $Cu_2(OH)_3NO_3$, which dissolves in excess ammonia to form copper ammines.

Examining Eq. (10), we can characterize the reaction described by the portion *CD* of the dilatometric curve as reverse of the reaction corresponding to the portion *BC*, i.e., as $Cu_2(OH)_3NO_3$ depolymerization and dissolution. On addition of uncharged molecules of hydrated NH_3 to one molecule of the neutral hydroxo complex, six ions are formed at once, which causes a reduction in the volume at the expense of their hydration.

The fact that, in the course of further titration after passing singular point *D*, the molar volume does not change noticeably (straight line *DE*) is due to the completion of the main chemical reactions in the system.

Dark blue $Cu(NH_3)_2(NO_3)_2$ crystals (identified by X-ray phase analysis) were obtained from the solution at $N > 4$.

The interactions revealed in the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O were confirmed by CPESSP model calculations. The initial model included the dissolved complexes $Cu(OH)^+$, $Cu_2(OH)_2^{2+}$, and $Cu(NH_3)_n^{2+}$ (n = 1–4) with the pK values considered above, and also $Cu_2(OH)_3NO_3$ and $Cu(OH)_2$ precipitates. The resulting distribution of hydroxide and ammine complexes is given in Fig. 5. It follows from the calculations that ammine complexes appear in the solution at N = 1.5. Under the experimental conditions, the hydroxo complex species $Cu(OH)^+$, $Cu_2(OH)^{3+}$, $Cu_2(OH)_2^{2+}$, and also the complex $Cu(NH_3)^{2+}$ are present in the system in minor amounts. Our calculations showed that the volume changes in the system are determined first by neutralization of the acid, then by hydrolytic reactions of copper ions with $Cu_2(OH)_3NO_3$ precipitation, and finally by its dissolution in excess ammonia with the formation of ammine complexes. The calculated ΔV values (Fig. 1, solid line) nicely agree with the experiment.

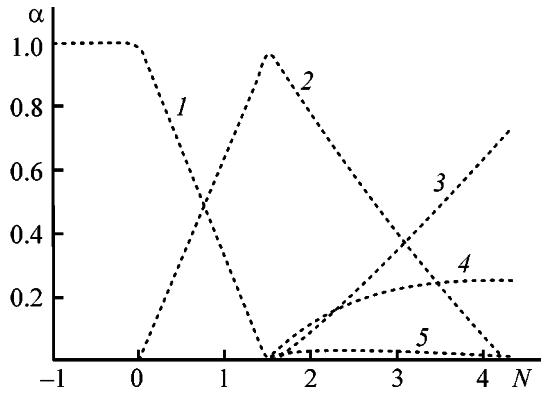

Fig. 5. Distribution of hydroxide and ammine complexes α in the heterogeneous system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O as a function of N: (*1*) Cu^{2+}, (*2*) $Cu_2(OH)_3NO_3$(s), (*3*) $Cu(NH_3)_4^{2+}$, (*4*) $Cu(NH_3)_3^{2+}$, and (*5*) $Cu(NH_3)_2^{2+}$.

EXPERIMENTAL

The dilatometric titration was carried out on a precision installation; its scheme and operation principle were described earlier [17]. The volume changes were detected by the shift of the meniscus of a liquid in a calibrated measuring capillary tube 0.4007 mm in diameter. To ensure the stability of the volume changes, a constant temperature of the system (25.00 ± 0.01°C) was maintained with two UT-2/77 ultrathermostats and an air thermostat, connected in series.

For each point of the dilatometric curves, ΔV_m was calculated from the experimental data by the following procedure. We determined the absolute changes in the volume (cm^3) from the shifts s (cm) of the meniscus of a liquid in a calibrated measuring capillary tube by the formula $\Delta V_{abs} = V_{1\,cm}s$ ($V_{1\,cm}$ is the volume corresponding to 1 cm length of the capillary tube, determined by calibration; for the capillary tube in use, $V_{1\,cm}M$ is 1.261×10^{-3} cm^3). For each point, this quantity were converted to ΔV_m, equal to the ratio of ΔV_{abs} to the number of moles of the component being titrated, namely, Cu^{2+} ions.

The pH-metric titration in the system $Cu(NO_3)_2$–

$NH_3 \cdot H_2O$ was carried out on an EV-74 pH meter with a glass electrode. The electronic absorption spectra of solutions were recorded on a Specord UV-VIS spectrophotometer in the range 400–900 nm.

To obtain quantitative characteristics of changes in the volume corresponding to step complex formation, we performed a mathematical simulation using the CPESSP program [18, 19]. The model for processing dilatometric data is based on an additive scheme, which is given in [20], as applied to volume properties.

The basis included the simple species Cu^{2+}, H^+, OH^-, NH_3, and NO_3^-, and the complex species NH_4^+, $Cu(OH)^+$, Cu_2OH^{3+}, $Cu_2(OH)_2^{2+}$, $Cu(NH_3)_n^{2+}$ (n = 1–4), $Cu_2(OH)_3NO_3$, and $Cu(OH)_2$. The distribution of the complexes as a function of N is given in Fig. 5, and the comparison with the experimental data, in Fig. 1.

CONCLUSION

By comprehensive analysis of the data obtained for the system $Cu(NO_3)_2$, (H^+)–$NH_3 \cdot H_2O$–H_2O by several physicochemical methods, we have determined the ranges of N corresponding to prevalence of various chemical reactions. At $N < 0$, excess acid is neutralized. The volume effects of the neutralization with an alkali and with an ammonia solution differ significantly, which is due to specific chemical features of ammonia. At N from 0 to 1.5, the hydrolytic polymerization occurs, yielding the poorly soluble complex $Cu_2(OH)_3NO_3$ with both bases. At $N > 1.5$, the chemical transformations with the two bases are different: in titration with NaOH, solid binuclear copper trihydroxonitrate is converted to copper hydroxide and oxide, and in titration with $NH_3 \cdot H_2O$, it is converted into soluble copper ammines $Cu(NH_3)_n^{2+}$.

ACKNOWLEDGMENTS

The authors are sincerely grateful to I.I. Kozhina for performing the X-ray phase analyses.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Properties of Binary Solvents Based on Morpholine

V. G. Kozin and A. A. Mukhamadiev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 15, 2001; in final form, December 2001

Abstract—The density and viscosity of the binary solvents monoethanolamine–morpholine and monoethylene glycol–morpholine were determined in the entire concentration range at 20, 30, 40, 50, and 60°C. The concentration dependences of the Gibbs energy, enthalpy, and entropy of activation of viscous flow were calculated for these systems.

Binary solvents morpholine–monoethanolamine (MEA) and morpholine–monoethylene glycol (MEG) exhibit high selectivity and solvency [1] and show much promise for separating complex hydrocarbon mixtures in petrochemical industry.

In this work, we studied the physicochemical properties of the binary extractants morholine–MEA and morholine–MEG (systems **I** and **II**, respectively).

Morpholine has a high solvency with respect to both aromatic and saturated hydrocarbons [2]. As a consequence, it has low selectivity and cannot be used straightly. Evidently, the selectivity of this extractant can be increased by addition of highly associated solvents, such as MEA and MEG, which have high selectivity but low solvency [3].

EXPERIMENTAL

The chemicals were repeatedly purified by vacuum distillation and dried over zeolites to attain the density and refractive index coinciding (within the measurement error) with the published data [4]. The density, viscosity, and molar volume measured at 20, 30, 40, 50, and 60°C in the entire concentration range served as structure-sensitive characteristics of the binary solutions. The density ρ_4^T was determined pycnometrically [GOST (State Standard) 18995.1–73], and the kinematic viscosity ν^T, with VPZh-2 and VPZh-3 capillary viscometers (GOST 33–82), with the subsequent recalculation to the dynamic viscosity η^T. The solution temperature was adjusted to within 0.1°C in a thermostat. Experimental data were processed statistically. The experimental densities and dynamic viscosities of systems **I** and **II** over the entire range of component ratios at the temperatures studied are presented in the table. The data are arranged in groups in the order of increasing morpholine concentration c_m in the binary solution.

The table shows that the density of systems **I** and **II** and the viscosity of system **I** decrease monotonically with increasing morpholine content. The concentration dependence of viscosity for system **II** has a pronounced maximum at 20°C, which is probably due to intense intermolecular interaction between morpholine and MEG. The temperature dependences of the density and viscosity for individual and binary solvents are also monotonic.

Data on the concentration and temperature dependences of the density and viscosity of the solvents are of considerable practical importance. However, to gain a better insight into the character of intermolecular interactions in mixing of extractants, we calculated and constructed the isotherms of the deviation from additivity of the density and volume and the isotherms of the deviation of the viscosity from the known Arrhenius equation assuming no interaction between the solution components [5].

The deviations from additivity of the density and molar volume for the binary systems studied are positive and negative, respectively, and differ in the value (Fig. 1). The solution formation in the MEG-containing system is accompanied by a considerably larger compression, which is probably due to more intense intermolecular interaction in this system. For example, the maximal compression at 40°C is 0.3% for system **I** and 1.7% for system **II**. This assumption is supported by the fact that, for system **I**, the dynamic viscosity has positive deviations from the values calculated by

the Arrhenius equation over the entire range of temperatures and concentrations. At the same time, the deviations for system **II** are nearly zero and at 60°C become negative over the whole range of mixing, reaching 7.9% (not plotted in Fig. 1).

Thus, the results of the physicochemical analysis of system **II** lead to unambiguous conclusions, whereas, with the results of the volume and viscosity measurements for system **I**, the pattern is not so clear. The presence of electron-donor and electron-acceptor groups in MEG, MEA, and morpholine, along with the data presented in the table and Fig. 1, suggest formation in system **II** of intermolecular hydrogen bonds and supramolecular structures. In system **I**, the components of the solutions most likely interact more weakly, and unstable donor–acceptor complexes are probably formed.

An analysis of the thermodynamic characteristics of viscous flow of the mixed solvents furnishes a more detailed information on the solution structure. The experimentally obtained data on viscosity were additionally treated in terms of the theory of activated complex and the Frenkel molecular-kinetic theory [6], which was possible owing to the linearity of the $\ln\eta = f(1/T)$ isotherms in the examined temperature range. We used the well-known Eyring equation

$$\eta = \frac{hN}{V}\exp\frac{\Delta G_\eta^\#}{RT} = \frac{hN}{V}\exp\left(\frac{\Delta H_\eta^\#}{RT} - \frac{\Delta S_\eta^\#}{R}\right),$$

where η is the dynamic viscosity; h, Planck constant; N, Avogadro number; V, molar volume of the solvent; R, gas constant; T, temperature; $\Delta G_\eta^\#$, $\Delta H_\eta^\#$, and $\Delta S_\eta^\#$, the Gibbs energy, enthalpy, and entropy, respectively, of activation of viscous flow (all values in the equation have IS dimensionality).

The experimental dynamic viscosities and the molar volumes calculated by Eq. (1) for each composition were used to calculate $\Delta G_\eta^\#$ in binary systems **I** and **II** at all the temperatures studied. The $\Delta H_\eta^\#$ values were calculated from the slope of the linear plot of $\ln\eta^T$ vs. reciprocal temperature. This two-parameter dependence was considered for each fixed composition of the solution in five points corresponding to experimental temperatures. The linear correlation coefficient was within 0.996–0.999 for all the solutions studied. Figure 2 shows the concentration dependences of the calculated values of $\Delta G_\eta^\#$, $\Delta H_\eta^\#$, and $\Delta S_\eta^\#$ for systems **I** and **II** at 40°C.

With increasing morpholine concentration in the binary solution, $\Delta G_\eta^\#$ decreases, except the range from 0 to 20–25 mol % morpholine in system **II**, in which $\Delta G_\eta^\#$ increases. The character of these dependences is determined by the ratio of the enthalpy and entropy contributions to the Gibbs energy of activation of viscous flow. As seen from Fig. 2, the main contribution to $\Delta G_\eta^\#$ is made by the enthalpy, whereas the entropy contribution is small and decreases with increasing morpholine concentration in the binary sol-

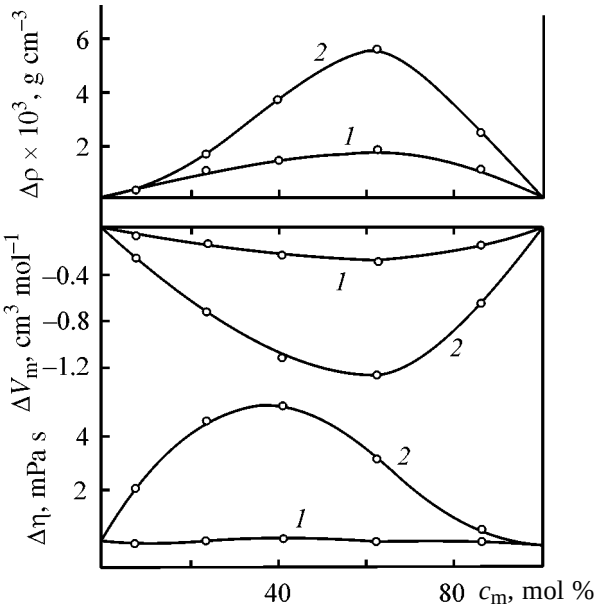

Fig. 1. Deviations of the density $\Delta\rho$ and molar volume ΔV_m from the additivity and of the viscosity $\Delta\eta$ from the Arrhenius equation at 40°C vs. morpholine concentration c_m in binary solutions. Systems: (*1*) MEA–morpholine and (*2*) MEG–morpholine; the same for Fig. 2.

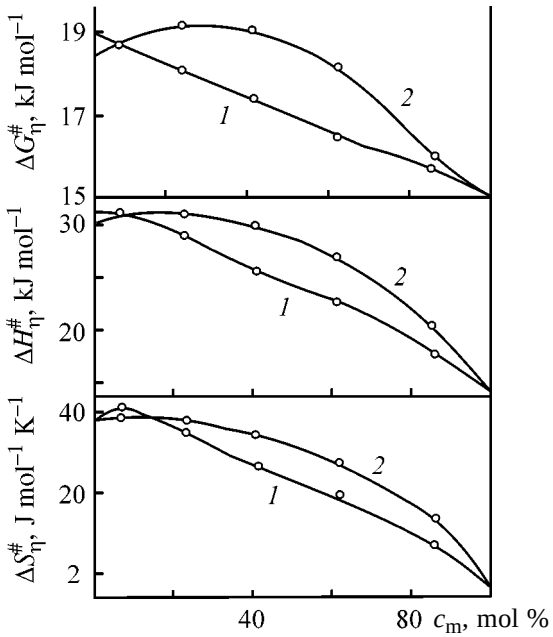

Fig. 2. Gibbs energy $\Delta G_\eta^\#$, enthalpy $\Delta H_\eta^\#$, and entropy $\Delta S_\eta^\#$ of activation of viscous flow for the binary solutions at 40°C vs. morpholine concentration c_m.

vent. The addition of morpholine decreases $\Delta H_\eta^\#$ for both systems. This means that the energy for creation and motion of an activated complex decreases, i.e., the intermolecular interaction in the binary solvents becomes less strong [7]. System **I** is characterized by the lower values of $\Delta H_\eta^\#$, which supports the assumption that interaction in system **II** is stronger (Fig. 2).

The decrease in $\Delta S_\eta^\#$ with addition of morpholine to MEG and MEA shows that the entropy of the initial state increases, i.e., the solution structure becomes less ordered owing to the break of hydrogen bonds between like molecules of MEA and MEG. This fact is apparently responsible for the increase in the solvency of the binary extractants in hand at higher concentrations of morpholine, which is in line with the extraction characteristics of these solvents, studied previously [1]. The disordering effect of morpholine is also confirmed by the negative deviations of the partial derivatives of the thermodynamic functions of viscous flow with respect to morpholine concentration.

CONCLUSIONS

(1) The deviations of the density and molar volume from additivity and the deviations of the viscosity from the values calculated by the Arrhenius equation, in relation to the component ratios, confirm the more intense interaction in the system monoethylene glycol–morpholine.

(2) The addition of morpholine breaks the initial structure of monoethanolamine and monoethylene glycol and increases the solvency of the binary extractants.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Gelation in Extraction Systems with Basic Copper(II) and Neodymium(III) Alkyl Phosphates

E. V. Yurtov and N. M. Murashova

Mendeleev Russian Chemical Engineering University, Moscow, Russia

Received February 13, 2002

Abstract—Gelation in extraction systems containing purified or commercial di(2-ethylhexyl) hydrogen phosphate (HDEHP), copper(II) or neodymium(III) hydroxides, hydrocarbon solvent, and water was studied at different ratios of the metal and extractant. The region was determined in which gelation caused by formation of basic neodymium(III) di(2-ethylhexyl) phosphates occurs in decane. Some characteristics of organogels in the HDEHP (commercial)–$Cu(OH)_2$–organic diluent (decane, hexane or toluene)–H_2O extraction systems were studied.

Structure formation in extraction systems affects their main characteristics, such as the distribution and separation factors and the rates of extraction and phase separation. Formation of disperse structures like gels, liquid crystals, amorphous and crystalline precipitates in the bulk of both aqueous and organic phases or at the interface are the factors which, as a rule, deteriorate the extraction process. One of the consequences of the structure formation is appearance of so-called meduses, i.e., stable emulsions, precipitates, or gels located between partially separated organic and aqueous phases [1]. Accumulation of meduses can deteriorate extraction to so significant extent that the extraction process must be interrupted [2, 3]. To prevent this detrimental effect, the region of formation of the disperse structures and their features promoting meduse formation should be studied.

The most attention is given to the structure formation in extraction of metals with di(2-ethylhexyl) hydrogen phosphate (HDEHP) and tributyl phosphate (TBP), which are widely used for recovery, separation, and purification of various organic and inorganic compounds including nonferrous, rare-earth, and radioactive metals. These meduses contain species typical of detergent solutions, e.g., liquid crystals and associates of polymeric metal hydroxides.

Formation of liquid crystals by lanthanide di(2-ethylhexyl) phosphates in CCl_4 was reported in [4]. Liquid crystals were also found in the HDEHP–NaDEHP–decane–H_2O system at high NaDEHP concentration (>90 wt %) [5].

It was reported [6] that, in organic solutions, metals can form oligomeric neutral and acidic di(2-ethylhexyl) phosphates consisting of several alkyl phosphate units [6]. The degree of polymerization of neutral Y(III) and La(III) di(2-ethylhexyl) phosphates in organic solvents reaches 10^2–10^3 [7]. High polymeric species poorly dissolve in both aqueous and organic phases. Therefore, polymeric metal alkyl phosphates can form gels and precipitates in both aqueous and organic phases. It was found that, in extraction of zirconium(IV) and hafnium(IV) with HDEHP, both gels and gel films are formed in the aqueous phase near the interface [8].

In our preliminary study of structure formation in extraction systems containing HDEHP, copper(II) or neodymium(III), hydrocarbon solvent, and water at different ratio of the metal and extractant, neither liquid crystals nor gels were found in the aqueous phase.

In this work we studied gelation in the organic phase of the HDEHP–$Cu(OH)_2$–decane–H_2O and HDEHP–$Nd(OH)_3$–decane–H_2O systems at different metal to extractant ratios. In the experiments, both purified and commercial HDEHP were used.

EXPERIMENTAL

In our experiments we used two different HDEHP samples: HDEHP containing >98% main substance (Merck) and commercial grade HDEHP containing 66% di(2-ethylhexyl) hydrogen phosphate and 19.5% mono(2-ethylhexyl) dihydrogen phosphate, produced by Khimprom Volgograd Joint-Stock Company.

1070-4272/02/7507-1064$27.00 © 2002 MAIK "Nauka/Interperiodica"

Mono(2-ethylhexyl) dihydrogen phosphate (H_2MEHP) was first separated from commercial HDEHP as a water-soluble sodium salt and then converted to H_2MEHP by treatment with sulfuric acid [9]. The other chemicals [decane, $CuSO_4 \cdot 5H_2O$, $Nd(NO_3)_3 \cdot 6H_2O$, and NaOH] were of pure grade. Double-distilled water was prepared by the standard technique.

Copper(II) and neodymium(III) hydroxides were precipitated from aqueous solutions of the corresponding salts by addition of NaOH to pH >10 for Cu(II) and pH > 12 for Nd(III). The $Cu(OH)_2$ precipitate was rapidly separated from the mother liquor by centrifugation and then was washed with double-distilled water to pH 7. The $Nd(OH)_3$ precipitate was kept under mother liquor for 1 h to complete hydrolysis, separated by centrifugation, and washed with double-distilled water to pH 7. Then the prescribed amounts of water and extractant were added to the precipitates of neodymium or copper hydroxide. To obtain an organogel, this mixture was carefully shaken for 30 s. In the Nd(III)–HDEHP and Cu(II)–H_2MEHP systems, gelation occured within several minutes, and in the Cu(II)–commercial grade HDEHP system, within several hours and became complete after keeping at 20°C for a day. Emulsions in these systems were prepared by stirring the aqueous and organic phases at their volume ratio of 3 : 2 with a stirrer at 3000 rpm for 2 min with copper(II) and 30 s with neodymium.

Before measuring the viscosity and evaluating the stability, the emulsions containing copper(II) or neodymium(III) alkyl phosphates were kept for 1 day and 1.5 h, respectively, to ensure completion of structure formation. The period of half-settling of the emulsion in the organic phase was determined by centrifugation at 90*g*. The emulsion viscosity was measured with a Rheotest-2 rotary viscometer with coaxial cylinders within the shear rate interval of 0.167–16.2 s^{-1} at 20°C. The photographs of emulsions were obtained with an optical microscope equipped with a photographic attachment.

The neutral copper(II) and neodymium(III) salts are hydrolyzed in aqueous solutions to form basic salts. Therefore, in extraction of these metals with HDEHP, their basic alkyl phosphates can be formed as intermediate species. We studied the structure formation in the HDEHP–$Cu(OH)_2$–decane–water and HDEHP–$Nd(OH)_3$–decane–water systems at the ratio of the metal and exractant corresponding to the formation of both neutral and basic alkyl phosphates.

In the organic phase, basic neodymium(III) di(2-ethylhexyl) phosphate is present as precipitate and gel.

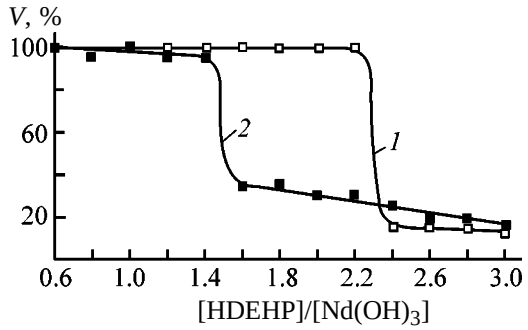

Fig. 1. Apparent precipitate volume *V* (% of the organic phase volume) as a function of the ratio of molar concentrations of HDEHP and neodymium hydroxide. [HDEHP] = 0.3 M; the same for Figs. 3 and 5. HDEHP: (*1*) pure and (*2*) commercial.

The turbid or opalescent gel-like phases do not flow under their gravity. In additional mechanical loading, the structure of these gels is destroyed. Figure 1 shows that, in the HDEHP(pure)–$Nd(OH)_3$–decane–water system at [HDEHP]/[$Nd(OH)_3$] < 2.2, gelation occurs throughout the organic phase. At this ratio of $Nd(OH)_3$ and HDEHP, both mono- and disubstituted basic neodymium(III) di(2-ethylhexyl) phosphates can be formed. With commercial HDEHP contaminated with H_2MEHP, gelation occurs throughout the organic phase at [HDEHP/$Nd(OH)_3$] < 1.4. At higher [HDEHP]/[$Nd(OH)_3$] ratios, either dense precipitate at the water–extract interface or neodymium di(2-ethylhexyl) phosphate solution in decane is formed.

When the concentration of basic neodymium(III) di(2-ethylhexyl) phosphate in organic phase exceeds a certain limit, the gelation in the organic phase starts. At HDEHP concentration > 0.03 M and HDEHP/$Nd(OH)_3$ = 1, the organic phase is completely converted to the gel.

Optical microscopic study of gel-like organic phases containing basic neodymium(III) di(2-ethylhexyl) phosphates failed to reveal any crystal structure. On removal of the solvent from both the gels and precipitate, an amorphous solid is obtained. It is known that neutral lanthanide di(2-ethylhexyl) phosphates form coordination polymers in the organic phase [4, 7]. We believe that basic poorly soluble lanthanide di(2-ethylhexyl) phosphates present in the organic and aqueous phases are also coordination polymers. These polymers build up the three-dimensional network of the organogel.

In the HDEHP (commercial)–$Cu(OH)_2$–decane–water system, gelation occurs within the range of [HDEHP]/[$CuOH)_2$] ratios of 1.0–1.6 (Fig. 2). Under

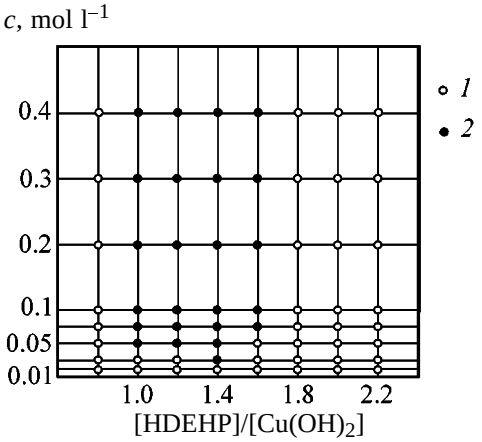

Fig. 2. Gelation in the HDEHP (commercial)–decane–water system at 20°C. (*c*) $Cu(OH)_2$ content. (*1*) No gelation and (*2*) gelation occurs.

these conditions, gelation occurs in the organic phase only, while the aqueous phase is free of the gel. At the ratio of the HDEHP and $Cu(OH)_2$ concentrations outside the gelation region (at excess of HDEHP), the copper alkyl phosphate organic solution is in equilibrium with the aqueous phase. At an HDEHP concentration insufficient for gel formation, a dense crystalline precipitate is formed at the interface.

We found that the gel formation in the systems studied is insensitive to the nature of the nonpolar solvent. Substitution of decane by any other nonpolar solvent results in only minor changes in both the minimal HDEHP concentration and the $[HDEHP]/[CuOH)_2]$ ratio corresponding to the gelation region in the phase diagram. The HDEHP minimal concentration and the ratios of HDEHP and $Cu(OH)_2$ concentrations corresponding to the gelation region in decane, hexane, and toluene are given in the table.

The blue transparent gels initially formed in the HDEHP (commercial)–$Cu(OH)_2$–organic solvent–water system become turbid and whitish on long-term keeping. An optical microscopic study of mature gels showed that their structure is built of fine crystals. On keeping the organogel for several days at 20°C, it becomes turbid owing to increase in the crystal size. The mean size of gel particles in the HDEHP–$Cu(OH)_2$–decane–water system {$[HDEHP]/[Cu(OH)_2]$ = 1.2, [HDEHP] = 0.3 M, T = 20°C} was determined with an optical microscope at 160-fold magnification. These data are given below:

τ, days	1	2	3	4
d, μm	9.4 ± 1.3	18.9 ± 2.5	31.1 ± 4.4	34.9 ± 3.8

On heating above 75°C, the gel is destroyed owing to dissolution of alkyl phosphate crystals. Upon cooling, the structure of the organogel is restored. On mechanical loading, the organogels in the HDEHP (commercial)–$Cu(OH)_2$–decane–water system are irreversibly destroyed.

We found that gelation does not occur in systems containing both commercial HDEHP preliminarily purified as described in [10] and pure HDEHP (Merck) containing more than 98% main substance. In this case, at $[HDEHP]/[Cu(OH)_2] < 1.8$, a dense crystalline substance is precipitated at the interface, which dissolves at $[HDEHP]/[Cu(OH)_2] = 2.0$. These experiments showed that gelation of alkyl phosphates is caused by impurities present in commercial HDEHP.

The main organic impurities present in commercial HDEHP are mono(2-ethylhexyl) dihydrogen phosphate H_2MEHP and 2-ethylhexanol. We found that, on addition of aliphatic alcohols (from butanol to decanol) to pure HDEHP, no gel is formed in the systems concerned. Turbid faintly blue organogels are formed in the H_2MEHP–$Cu(OH)_2$–decane–water systems containing 0.3 M H_2MEHP at $[H_2MEHP]/[Cu(OH)_2] < 2$. Taking into account that H_2MEHP is dibasic acid, both neutral and acidic copper(II) alkyl phosphates can be formed under these conditions. In the region of formation of acidic copper alkyl phosphates, $[H_2MEHP]/[Cu(OH)_2] > 2.0$, two homogeneous liquid phases (aqueous and organic) are formed.

In industrial production of HDEHP, the raw product is washed with NaOH or Na_2CO_3 aqueous solutions to remove H_2MEHP. We found that, after single scrubbing of commercial HDEHP in an organic solvent (0.3 M) with aqueous NaOH, the gelation region is narrowed, and gelation occurs at $[HDEHP]/[Cu(OH)_2]$ 1.6–1.8.

In extraction, a contact between aqueous and organic phases, as a rule, is attained by emulsification of the extraction system at vigorous stirring. We studied

Boundaries of gelation region in the HDEHP (commercial)–$Nd(OH)_3$–organic solvent–water system

Organic solvent	c_{HDEHP}*	[HDEHP]/[Cu(OH)2], mol/mol	
		lower boundary	upper boundary
Decane	0.025	1.0	1.6
Hexane	0.010	1.2	1.8
Toluene	0.050	1.2	2.2

* Minimal HDEHP concentration at which gelation occurred.

the effect of gel formation on the emulsion stability in the HDEHP (commercial)–$Cu(OH)_2$–decane–water and HDEHP (commercial)–$Nd(OH)_3$–decane–water systems. In these systems, emulsions were produced by stirring $Cu(OH)_2$ and $Nd(OH)_3$ precipitates suspended in water with an HDEHP solution in decane. Figure 3 shows how the half-separation time of the emulsion (time of the half-settling of the emulsified organic phase) in the HDEHP–$Nd(OH)_3$–decane–water system depends on the HDEHP/$Nd(OH)_3$ ratio in centrifugation at 90*g*. This figure shows that emulsions are stable only at [HDEHP]/[$Nd(OH)_3$] ratios corresponding to the gelation region. Agitation of the system concerned drastically affects its phase behavior. While no stirring, the gelation occurs in the organic phase only, and in vigorous stirring of the aqueous and organic phases at 3000 rpm, a stable emulsion is formed.

When lanthanide hydroxides suspended in water are stirred with an HDEHP solution in decane, stable emulsions are formed with all the lanthanides. For example, we obtained stable emulsions in the $RE(OH)_3$–HDEHP–decane–water systems (RE = Sm, Dy, Ho, and Yb) at [HDEHP]/[$Ln(OH)_3$] = 1.6 and [HDEHP] = 0.3 M.

In the HDEHP (commercial)–$Cu(OH)_2$–decane–water system, stable emulsions are formed in the range of metal and extractant ratio corresponding to organogel formation. At [HDEHP/[$Cu(OH)_2$] ratios beyond the gelation region (below 1.0 and above 1.6), the emulsions are separated into aqueous and organic phases within 1–2 min.

Figure 4 demonstrates the flow curves of emulsions stabilized with organogels in the HDEHP (commercial)–$Cu(OH)_2$–decane–water and HDEHP (commercial)–$Nd(OH)_3$–decane–water systems. Curves *1* and *2* show that the emulsion viscosity considerably decreases with increasing shear rate. With the subsequently decreasing shear rate (curves *1*' and *2*'), the viscosity of the liquefied emulsions does not return to the initial values, i.e., the initial emulsion structure is not restored. We found that, in mechanically destroyed emulsions, the initial structure is not restored even on keeping for several days. The irreversible breakdown of emulsions under mechanical loading indicates that they are nonthixotropic. Such a behavior correlates with that of organogels of copper(II) and neodymium(III) alkyl phosphates.

The structural features of the emulsions were judged from their viscosity, optical microscopic patterns, and electrolytic conductivity. The miscibility of emulsions with aqueous and organic phases was also

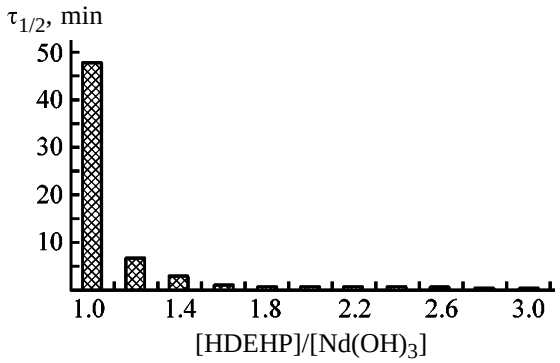

Fig. 3. Time of half-settling of the emulsified organic phase, $\tau_{1/2}$, as a function of the HDEHP and neodymium hydroxide molar ratio in the HDEHP (commercial)–$Nd(OH)_3$–decane–water system.

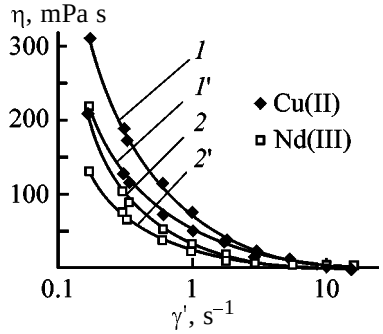

Fig. 4. Effective viscosity η of emulsions stabilized with copper(II) and neodymium(III) organogels as a function of the shear rate γ'. [HDEHP] = 0.3 M, [HDEHP]/[$Nd(OH)_3$] = 1.2 and [HDEHP]/[$Cu(OH)_2$] = 1.2; commercial HDEHP. The viscosity was measured in the course of (*1, 2*) increasing and (*1*', *2*') decreasing the shear rate.

examined. These studies showed that the stability of the emulsion structure is ensured by the organogel network. The photomicrographs of emulsified HDEHP (commercial)–$Cu(OH)_2$–decane–water and HDEHP (commercial)–$Nd(OH)_3$–decane–water mixtures contain light droplets of the liquid phase and darker areas between them. The dark areas correspond to turbid organogels formed by copper(II) mono(2-ethylhexyl) phosphates and basic neodymium(III) di(2-ethylhexyl) phosphates (Figs. 5a, 5b).

Our data on gelation and emulsification in extraction systems containing copper and lanthanide alkyl phosphates allow us to make certain recommendations to prevent the detrimental effect of structure formation. Taking into account that both organogels and stabilized emulsions are irreversibly destroyed under mechanical loading, the mechanical impact can be used for brekdown and removal of meduses.

The removal of H_2MEHP from commercial HDEHP by scrubbing with NaOH aqueous solution

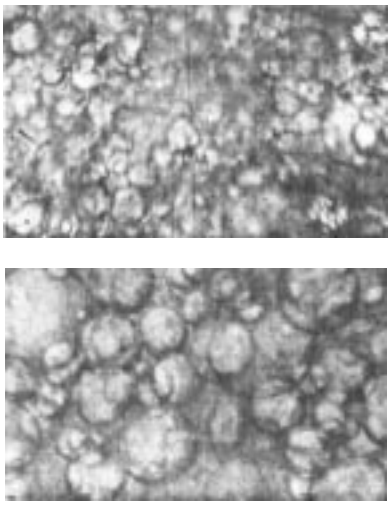

Fig. 5. Photomicrographs of (a) emulsified HDEHP (commercial)–$Cu(OH)_2$–decane–water system with [HDEHP]/[$Cu(OH)_2$] = 1.0 and (b) emulsified HDEHP (commercial)–$Nd(OH)_3$–decane–water system with [HDEHP]/[$Nd(OH)_3$] = 1.0. Scale: 16 mm = 100 μm.

sharply narrows the gelation region in the extraction systems containing copper(II) alkyl phosphates. As a result, purification of the extractant to remove H_2MEHP decreases the probability of meduse formation in the extraction. Under the industrial conditions, the meduse formation is prevented by scrubbing a commercial extractant with Na_2CO_3 aqueous solution. In going from commercial to pure HDEHP, the gelation region of basic neodymium(III) di(2-ethylhexyl) phosphates expands (Fig. 1). Therefore, unlike the cases when, in extraction of metals with commercial HDEHP, gel formation is promoted by organic impurities and, therefore, can be prevented by their removal, in extraction of lanthanides(III) with HDEHP, its purification to remove impurities does not prevent the structure formation.

Our experiments showed that gel formation in the organic phase is caused by basic alkyl phosphates formed at HDEHP deficiency. At sufficiently high acidity suppressing the metal hydrolysis, the meduse formation can be prevented. At low metal concentration and large excess of the extractant, the probability of meduse formation also decreases.

CONCLUSIONS

(1) Conditions of gelation in the basic neodymium di(2-ethylhexyl) phosphate–decane–water system were determined for pure and commercial HDEHP.

(2) The gelation region in the di(2-ethylhexyl) hydrogen phosphate–$Cu(OH)_2$–(decane, hexane or toluene)–water systems was determined at 20°C. A three-dimensional network of organogels is built up by copper(II) mono(2-ethylhexyl) phosphate crystals.

(3) Organogels based on copper(II) mono(2-etylhexyl) phosphate or basic neodymium(III) di(2-ethylhexyl) phosphate promote emulsification in extraction systems.

(4) Different approaches to elimination of the detrimental effect of structure formation in extraction systems containing copper(II) or lanthanide(III) di(2-ethylhexyl) phosphates (e.g., meduse formation) are analyzed.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Lithium from Brine onto Granular $LiCl \cdot 2Al(OH)_3 \cdot mH_2O$ Sorbent under Dynamic Conditions

A. D. Ryabtsev, L. T. Menzheres, and A. V. Ten

Ekostar-Nautekh Private Company, Novosibirsk, Russia

Received January 15, 2001; in final form, December 2001

Abstract—Lithium sorption on, and desorption from sorbent grains of various sizes were studied under dynamic conditions at linear flow velocities in the range 2–34 m h^{-1}.

Many compounds of Group III–VI elements and, in particular, simple hydroxides and difficultly soluble salts of polycharged metals with polybasic salts, such as phosphates of zirconium, titanium, antimony, etc., exhibit selective sorption properties toward lithium ions [1–10]. The most active researchers' interest is attracted by manganese dioxide and composites on its base, whose exchange capacity in alkaline medium is as high as 10 mg-equiv g^{-1}. With decreasing pH, the sorbent capacity decreases to become not higher than 1 mg-equiv g^{-1} in strongly mineralized brines (pH < 7) [7, 8]. Moreover, these sorbents have an expensive matrix, are insufficiently stable, and, in some cases, require that an additional auxiliary sorbent should be present for neutralizing H^+ ions formed in lithium sorption [11, 12].

These disadvantages are not characteristic of a sorbent based on double aluminum lithium hydroxide chloride of the composition $LiCl \cdot 2Al(OH)_3 \cdot mH_2O$ (DALH-Cl), which can selectively recover lithium from highly mineralized chloride brines [5, 6, 13–18]. The sorption properties of this sorbent, which has the layered structure, are based on its capability to release part of LiCl (no more than 40% of the bulk chemical composition) upon treatment with water and recover its initial composition upon treatment with concentrated LiCl solutions or lithium-containing chloride brines, i.e., on its capacity for deintercalation–intercalation of LiCl [19]. A distinctive feature of the sorbent is its unique selectivity, resulting from the fact that only lithium, and no other element, can occupy the site of preliminarily removed lithium in the structure of the compound, which is due to the occurrence of a molecular-sieve effect, as assumed in [19].

It is planned, for the first time in world's practice, to recover lithium from highly mineralized calcium–magnesium chloride brines from the Angara–Lena basin by means of the sorbent in question. For this purpose, we synthesized a large batch of the sorbent and performed its granulation.

Here we report on large-scale laboratory tests of this granular sorbent under dynamic sorption conditions.

EXPERIMENTAL

A DALH-Cl powder was obtained in a mixing apparatus by solid-phase synthesis from a mixture of crystalline LiCl and $Al(OH)_3$, taken in stoichiometric ratio, in the presence of 0.5 mol of water [16]. The powder obtained was activated in a centrifugal apparatus to impart sorption properties to it. The total exchange capacity of the powdered sorbent under static conditions upon 24-h contact with an excess amount of brine was about 7 mg of lithium(I) per 1 g of powder. The powder was granulated using a chlorinated vinyl chloride resin (PVC) of the PSKh-LS brand, soluble in methylene chloride, as a binder [20]. The granulation was carried out in a PSh-45 industrial extruder by extrusion of a paste containing (wt %) DALH-Cl 75.5–75.7, PVC 5.5–6.5, and methylene chloride 18.7–18.9. In terms of dried product, the amount of DALH-Cl in the grains obtained was 92–94%, and that of binder, 6–8%. The exchange capacity of the granular material under static conditions was 5–6 mg g^{-1}.

The dry extrudate of diameter 2 mm was crushed with a rotor; the forming grains were separated on sieves. Grains of the following sizes were chosen as objects of study: $0.63 < l < 1.0$, $1.0 < l < 2.0$, and $l > 2.0$ (mainly 2.5–10), where l is the grain length (mm). The tests were carried out in columns 0.026 m in diameter with the sorbent bed height of 0.49 m.

Table 1. TDEC of sorbent of various fractions and average extent of lithium recovery from brine at varied rates of brine feed into the column

Grain size, mm	Brine feed rate, l h^{-1}									
	0.93		1.20		2.55		5.20		5.80	
	TDEC, mg g^{-1}	α, %	TDEC, mg g^{-1}	α, %	TDEC, mg g^{-1}	α, %	TDEC, mg g^{-1}	α, %	TDEC, mg g^{-1}	α, %
$0.63 < l < 1.0$	–	–	–	–	4.85	33.55	3.99	23.0	–	–
$1.0 < l < 2.0$	3.65	31.3	–	–	2.61	26.0	–	–	2.96	23.0
$l > 2.0$	–	–	1.97	19.1	–	–	–	–	2.00	23.0

The weighed portions of sorbent were 165, 180, and 190 g for, respectively, the fractions $0.63 < l < 1.0$, $1.0 < l < 2.0$, and $l > 2.0$. The experiments were mostly performed on two in-series connected columns with the total sorbent weight of about 400 g and total bed height of approximately 1 m. The column dimensions were chosen so that the geometric similarity to columns of the pilot installation constructed for performing pilot tests was observed.

The investigations were carried out with brine from the Znamenskoe deposit (Irkutsk oblast), with density of 1.34 g cm^{-3} and the following composition (g l^{-1}): $CaCl_2$ 341.0, $MgCl_2$ 126.0, KCl 7.0, NaCl 20.0, and LiCl 2.2–2.5 (total salts ~500 g l^{-1}). The brine was used repeatedly after adjusting its density by evaporation and the lithium content by adding lithium chloride. The brine was fed by a Zalimp typ 315 peristaltic pump from bottom upwards. The desorbing solution temperature was maintained to within ±2°C with a WB-2 water bath.

The content of lithium in solutions and solid phases was determined by flame photometry [21] on an SP-9 atomic-absorption spectrophotometer, and the total hardness (in terms of $CaCl_2$) and the content of Al^{3+} and Cl^-, by volumetric titration [22]. The specific surface area of grains was found by thermal desorption of argon [23], and the pore volume, by mercury porosimetry. The density of the swollen sorbent was determined by a simplified method [24], using the formula

$$\rho = (m_1 - m_2)/(V_2 - V_1),$$

where m_1 is the mass of vessel with water; m_2, mass of vessel with sorbent; V_1, initial volume of water in the vessel; and V_2, the total volume of water and sorbent in the vessel. The swellability of sorbent fractions was determined by the method recommended for use with ion-exchange resins [25].

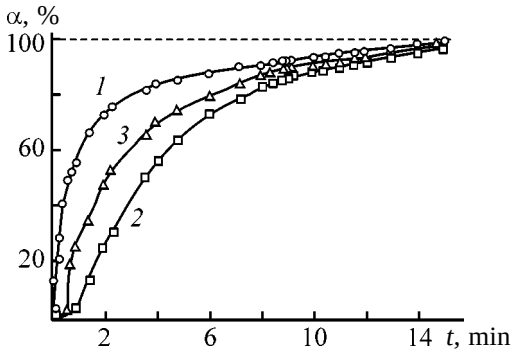

Fig. 1. Extent of lithium(I) recovery, α, from brine vs. sorption duration *t*. Brine feed rate (l h^{-1}): (*1*) 1.2, (*2*) 2.55, and (*3*) 5.2.

Sorption, desorption, and sorbent washing to remove brine were studied with grains of varied size.
