Simultaneous increase in the rotor and disc diameters at their optimal ratio makes it possible to substantially improve the efficiency of suspension separation at small rotor height. Depending on the requirements to the quality of isolation of the dispersed phase from a suspension, the optimal dimensions of the centrifuge rotor can be found.

To separate suspensions containing finely dispersed particles less than 5 μm in size, it is necessary to make larger the geometric dimensions of the centrifuge rotor, specifically, its height, and raise the rate of its rotation, on the basis of the flow rate and concentration of a suspension fed into the centrifuge.

CONCLUSIONS

(1) Centrifugal separation of a low-concentration aqueous suspension of microcrystalline cellulose in the biconical rotor of a centrifuge was simulated numerically on the basis of a mathematical description.

(2) The results of numerical simulation reasonably agree with experimental data.

(3) The mathematical model was used to study the influence exerted by the operation modes of the centrifuge and geometric parameters of its rotor on the efficiency of separation of suspensions containing particles of microcrystalline cellulose 5 to 25 μm in size. The efficiency of suspension separation can be improved by raising the diameter and height of the rotor.

Abstract—The influence of surfactants and temperature on the intensity of interphase mass transfer in back extraction under conditions of forced Marangoni flows was studied.

Spontaneous interphase convection arising at mobile interfaces in fluid–gas and fluid–fluid systems is a powerful tool for intensifying absorption and extraction processes [1, 2]. Several mechanisms of spontaneous interphase convection are known, but the principal one is the c–σ mechanism, or the Marangoni effect [3].

This effect is a consequence of the presence at the phase boundary of places with different concentrations of surfactants and the resulting different surface tensions σ. As a result, there arise surface flows from places with lower surface tension to those with higher σ. Commonly, this process is sporadic and is difficult to control without changing the initial properties of a system. Nevertheless, further intensification of mass transfer across mobile boundaries is largely associated with a search for methods to control the surface convection.

Commonly, studies were concerned with fundamental aspects of mass transfer in systems agitated by the "classical" method in which energy is introduced into the bulk of liquids by stirrers of various types. In this case, only a negligible fraction of energy dissipated by a stirrer reaches the interfacial region in which the main resistance to substance transfer from one phase into another is concentrated.

In [4, 5], another method for energy introduction was proposed. Energy is fed directly into the interfacial region by a flexible band moving across the phase boundary, which can serve not only as a new, rather efficient method for controlling the rate of substance transfer, but also as an effective technique for detection of surface structures and study of the influence exerted by surfactants on the process kinetics.

With the use of the method proposed in [4, 5], a rather interesting type of surface flows, named "tension" flows, was discovered [6]. These flows could have also be named the mechanically induced [7] or forced Marangoni effect. Forced Marangoni flows are readily controllable. They arise upon adsorption of surfactants onto mobile boundaries or upon formation of dynamic dispersed interphase layers [8], across which solid bodies (bands, plates, threads, discs, etc.) move.

It was found that even relatively slow motions of solid bodies may lead to pronounced acceleration of mass transfer. For example, mass transfer could be accelerated by a factor of 30–40 in fluid–fluid systems in the case of formation of dynamic dispersed interphase layers [4, 5]. Despite that this way to control the rate of mass transfer is rather promising, the fundamental aspects of mass transfer under conditions of forced Marangoni flows are poorly understood. For example, there is no evidence concerning the influence exerted by the type and concentration of a surfactant and by temperature on the rate of mass transfer in the case of mechanical perturbation of the phase boundary.

The aim of this study was to determine the effect of surfactants and temperature on the intensity of interphase mass transfer in back extraction under conditions of forced Marangoni flows.

EXPERIMENTAL

We studied the kinetics of nitric acid back extraction from extracts containing solutions of hydrate solvates of tri-*n*-butyl phosphate (TBP) and nitric acid, $TBP(H_2O)_x \cdot HNO_3$, in carbon tetrachloride. Tri-

1070-4272/03/7607-1099$25.00

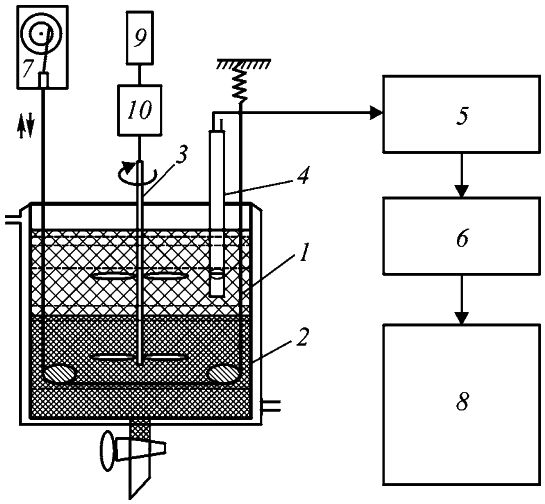

Fig. 1. Schematic of modified Gordon cell: (*1*) band, (*2*) temperature-controlled cell, (*3*) stirrer, (*4*) electrical conductivity pickup, (*5*) conductometer, (*6*) analog-to-digital converter, (*7*) band reciprocating gear, (*8*) computer, (*9*) tachometer, (*10*) dc electric motor.

n-butyl phosphate was preliminarily vacuum-distilled and contained more than 99% main substance. Carbon tetrachloride was of chemically pure grade. The surfactants used: sodium dodecyl sulfate (SDDS, an anionic surfactant) and cetyltrimethylammonium bromide (CTMAB, a cationic surfactant) were of analytically pure grade.

Back extraction of nitric acid from an organic into an aqueous phase is accompanied, as established in [8], by an instantaneous diffusion-controlled reaction (1) and a physical process (2) of phase formation:

$$\mathrm{TBP(H_2O)}_x\cdot\mathrm{HNO_3}_{\mathrm{org}} \rightarrow \mathrm{TBP}_{\mathrm{aq}} + x\mathrm{H_2O} + \mathrm{H^+(H_2O)}_y + \mathrm{NO_3^-}, \quad (1)$$

$$\mathrm{TBP}_{\mathrm{soln}} \rightarrow \mathrm{TBP}_{\mathrm{disp}}. \quad (2)$$

Reaction (1) occurs in aqueous phase layers adjacent to the phase boundary. The reaction ends in the formation of an oil-in-water emulsion from dissolved TBP [8]. This gives reason to suggest that the forced Marangoni effect may strongly affect the kinetics of back extraction, and addition of the surfactants mentioned above must markedly weaken or enhance the effect.

The installation for kinetic studies has been described previously [5]. Its modified design is shown in Fig. 1. The phase boundary is perturbed using a polyethylene band *1* which reciprocates perpendicularly to the phase boundary in the temperature-controlled cell *2* of diameter 50 mm. The fluid at phase cores was agitated with propeller stirrers *3*. The acid concentration in the aqueous (top) phase was determined using an electrical conductivity pickup *4*, conductometer *5*, analog-to-digital converter *6*, and Pentium PC-AT. The band was reciprocated perpendicularly to the phase boundary by a camshaft gear *7*.

The use of the reciprocal motion has certain methodological advantages: here, there is no need to take into account changes in the interface area or complications associated with loss of the bottom phase toward the interface with air, as it would be in the case of a continuous unidirectional motion of an "infinite" band or rotation of discs in the direction perpendicular to the phase boundary.

The kinetics of back extraction of nitric acid was studied under the following conditions: TBP concentration in the organic phase 10 vol %, nitric acid concentration 0.06 M, fixed rate of rotation (1.7 s^{-1}) of propeller stirrers, two fixed frequencies of band motion (0 and 0.8 s^{-1}), band width 2 cm, and fluid temperature in the cell varied in the range 287–308 K.

The experiments were done as follows. A 100 cm^3 portion of a 10% TBP solution in CCl_4 and the same volume of distilled water were placed in cell *2*. The stirrers were switched on, and 1 cm^3 of a solvate (10% $TBP\cdot HNO_3$ in CCl_4, c_{HNO_3} = 0.06 mol dm^{-3}) was introduced into the organic phase under stirring. It was established preliminarily that 8–10 s is necessary for complete agitation of the solvate in the bulk of the organic phase. Therefore, the first 50 s were excluded from consideration, which determined the lower limit of integration in expression (4). Since there existed a one-to-one correspondence between the electrical conductivity of the aqueous solution and the amount of acid transferred from the organic into the aqueous phase (linear relation), calculating the variation of the concentration was rather a simple task.

The experimental data obtained were processed as follows. Kinetic curves $c = f(t)$ are well approximated by the dependence

$$c_t = \sum_{i=l}^{n} a_i t^i + A\ln t \quad (l = -2, -1, 0; n = 0, 1, 2, \ldots), \quad (3)$$

where a_i and A are constants, and c_i is the HNO_3 concentration in the aqueous phase at ith instant of time t.

Differentiation of expression (1) gives

$$dc_t/dt = i\sum_{i=l}^{n} a_i t^{i-1} + A/t. \quad (4)$$

The differential mass-transfer coefficient at instant of time t was calculated using the formula

$$k_t = \frac{dc_t/dt}{(c_{eq} - c_t)(s/v)}, \quad (5)$$

where c_{eq} is the acid concentration in the aqueous phase in equilibrium (since the process is irreversible and the volumes of the organic and aqueous phases are the same and equal to v, c_{eq} is equal to the initial concentration of the acid in the organic phase), and s is the interface area.

Since the mass-transfer coefficients k_i are generally time dependent, the integral, averaged over a period of time equal to 20–200 s, mass-transfer coefficient k was calculated by the formula

$$\bar{k} = \int_{50}^{1000} k_t dt/950, \quad (6)$$

and the factor F_a of mass transfer acceleration (deceleration) upon introduction of a surfactant, by the formula

$$F_a = \bar{k}/k. \quad (7)$$

The coefficients of mass transfer of nitric acid from organic into aqueous phase and errors in determining these coefficients are listed in the table.

It can be seen that relative errors are, on the average, 6% in the case of a perturbed boundary and 11% without perturbation, which well confirms the previous conclusion [3, 4] that random errors in determining the mass-transfer coefficients decrease in the case of agitation of the interfacial layer. The data in the table also confirm the conclusion that the mass-transfer process is strongly (by a factor of 2–3) intensified under agitation of the interfacial layer because of the appearing surface flows [3–6].

Processing a large array of mass-transfer coefficients obtained without perturbation of the phase boundary with a band and in the absence of intentionally introduced surfactants yields the following value of the mass-transfer coefficient averaged over time and over the array itself: $\bar{k} = (0.760 \pm 0.084) \times 10^{-5}$ m s^{-1}. Introduction of 10^{-4} M of a cationic surfactant, CTMAB, into the system leads to a twofold decrease in this value to $\bar{k} = (0.390 \pm 0.043) \times 10^{-5}$ m s^{-1}. Almost the same is the effect of an anionic surfactant, SDDS, added in the same molar amount [$\bar{k} = (0.366 \pm 0.040) \times 10^{-5}$ m s^{-1}]. In other words, the classical case of suppression of the turbulence that comes to the phase boundary from phase cores because of the appearance of Gibbs elasticity of interfacial layers (suppression of capillary waves) is observed in the presence of "strong" surfactants.

Averaged mass-transfer coefficients and errors in determining these coefficients with and without phase boundary perturbation

Without perturbation		With perturbation	
$\bar{k} \times 10^5$, m s^{-1}	Δ, %	$\bar{k} \times 10^5$, m s^{-1}	Δ, %
0.72	9	2.0	9
0.69	13	1.8	2
0.84	6	1.9	3
0.91	15	1.6	10

If the boundary is perturbed not only by propeller stirrers, but also by band movements (f = 0.8 s^{-1}, A = 2 cm), the pattern changes fundamentally (Fig. 2). Introduction of a surfactant into the system under the same conditions leads not to deceleration, but even to a 2–3-fold acceleration of the mass transfer of nitric acid. The mass-transfer coefficients averaged over a period of 950 s are the following: $(1.67 \pm 0.100) \times 10^{-5}$ without surfactant, $(4.04 \pm 0.242) \times 10^{-5}$ in the presence of 10^{-3} M of CTMAB, and $(2.63 \pm 0.159) \times 10^{-5}$ in the presence of the same amount of SDDS. Thus, introduction of CTMAB into the system accelerates back extraction by a factor of approximately 2.8, whereas in the case of SDDS introduction, the acceleration factor is about 1.6, which much exceeds the experimental error.

The table shows that boundary perturbation accelerates the mass transfer even in the absence of special surfactant additives. However, it should be

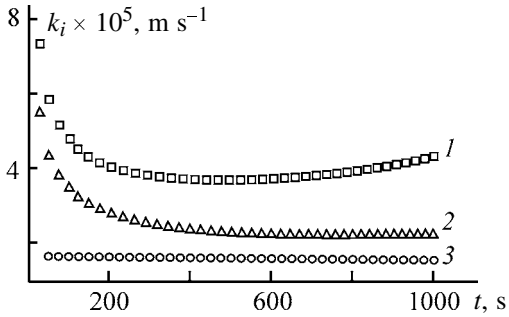

Fig. 2. Effect of surfactants on the differential mass-transfer coefficients k_i of nitric acid in the case of a phase boundary perturbed with a band (f = 0.8 s^{-1}, A = 2 cm). Surfactant concentration 10^{-3} M. (t) Process duration. (*1*) CTMAB, (*2*) SDDS, and (*3*) without surfactant.

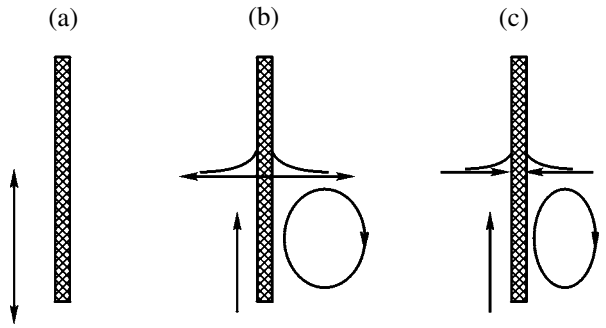

Fig. 3. Schematic of flows in the core and at the surface in band reciprocation.

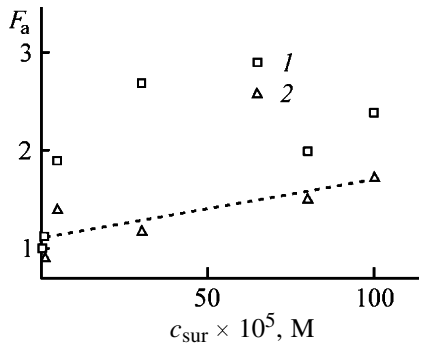

Fig. 4. Effect of surfactant concentration c_{sur} on the mass transfer acceleration factor F_a: (*1*) CTMAB and (*2*) SDDS.

kept in mind that extraction systems actually always contain surfactants. For example, surfactant properties are exhibited in the case in question by the extracting agent (TBP) itself.

The presence of special surfactants gives rise to the already mentioned Marangoni effect, i.e., surface tension flows accelerating the mass transfer, induced by band movements. The effect of a surfactant in the case of a perturbed boundary should be regarded as nonspecific. Characteristic features of these flows were described in [6, 7]. We believe that additional information is necessary for understanding of the pattern observed.

Let us consider only a single part of an infinite band. Here are meant movements induced by such a band in the case of its reciprocal motion. Landau and Lifshits [9] demonstrated that movements of entrained fluid decay fast within the hydrodynamic layer adjacent to the band. In this case, no flows are observed far away from the band (Fig. 3a). If, however, two phases are present with a phase boundary across which a band moves, the theory developed is insufficient for understanding of the arising flows. Experiment shows that two types of flows, which are different not only in nature and intensity, but also in direction (Fig. 3), can arise [5, 7]. These flows cover the entire phase boundary area between the ascending and descending parts of the band and layers adjacent to the phase boundary, in which the main resistance to mass transfer is concentrated. Therefore, even sluggish movements of the band lead to substantial effects. Movements in the bulk of the phases are the most pronounced at places of triple contact (two phases and a solid).

Figure 3b considers the case of a "clean" boundary in the form of a meniscus. Surface flows are of inertial nature: the fluid adhering to the band surface is detached from it when the band is lifted to a certain height and moves by inertia and under the action of gravity forces, spreading at the phase boundary. Thus, there appears a flow directed away from the ascending band.

In Fig. 3c, the surface is contaminated with a surfactant. In view of surfactant adsorption on the band, its motion shifts the entire surface layer of the surfactant. The reason is that there appears a gradient of surfactant concentration and a gradient of interphase tension. The phase boundary and the adjacent fluid layers move toward an ascending band, since its ascending motion is accompanied by simultaneous adsorption of the surfactant onto the band. This leads to a decrease in the surfactant concentration directly at the place where the band traverses the boundary and to an increase in surface tension at this place. This gives rise to a surface flow of molecules toward the band, and just this effect is the forced Marangoni flow.

Forced Marangoni flows can be readily observed visually. Indeed, fine particles of aluminum dust (~1–10 μm) move synchronously with the band along the phase boundary. The amplitude of these movements decreases away from the band, as if the phase boundary possessed both viscosity and mechanical elasticity simultaneously. The velocity of surfactant motion over the surface near the band in almost equal to the velocity of band motion. Moreover, intense vortices appear near the triple contact perimeter even in the case of sluggish motion of the band. Therefore, pronounced intensification of mass transfer occurs upon introduction of soluble surfactants, and even upon deposition of thick insoluble films on the phase boundary, as shown for the case of carbon dioxide absorption by water [6, 7].

One more reason for intensification of mass transfer is settling of microparticles from a dispersed layer onto the moving phase boundary. A mechanism of this kind was considered in [10]. Particles settling

from the dispersed layers onto the phase boundary entrain the substance under study, thus intensifying its transfer. The acceleration upon introduction of a surfactant into a system with perturbed boundary depends on the type of surfactants and their concentration.

Figure 4 shows the dependence of the mass-transfer acceleration factor on the concentration of a surfactant introduced into the system. Even though a wide scatter of experimental data is observed in the case of CTMAB, the tendency toward a rise in the acceleration factor with increasing concentration is clearly pronounced (at least at low surfactant concentrations).

A study of the influence of temperature on the kinetics of HNO_3 back extraction yielded additional information about the mechanism of forced Marangoni flows. The apparent activation energy was 40 kJ mol^{-1} with only propeller stirrers in the absence of surfactants. Perturbation of the phase boundary with a moving band leads to a twofold decrease in the activation energy (E_a = 20 kJ mol^{-1}). If 10^{-4} M of CTMAB is introduced into the system under these conditions, the apparent activation energy becomes negative (E_a = –23 kJ mol^{-1}), i.e., the back extraction rate decreases, rather than grows (as usual), with increasing temperature. A reasonable explanation of this fact is as follows. When the temperature is raised, the surfactant adsorption both at the phase boundary and on the band decreases. Consequently, the conditions of surfactant adhesion to the band and the entrainment of the surface layer by the band must be adversely affected by increasing temperature. This is equivalent to deterioration of the conditions of agitation of the interfacial layer and leads to a decrease in the mass-transfer coefficients with increasing temperature.

CONCLUSIONS

(1) The previous conclusion that introduction of surfactants into a system leads to acceleration, rather than to deceleration (as it commonly occurs), of mass transfer in the case of mechanical perturbation of the phase boundary with solid bodies moving across it is confirmed.

(2) The influence exerted by perturbation of the phase boundary with a solid body on the rate of mass transfer becomes more pronounced with increasing concentration of surfactants.

(3) Raising the temperature may lead, in the presence of surfactants, to deceleration of the mass transfer because of the deteriorating conditions of mixing of interphase layers.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Ultrafiltration of Aqueous Solutions of Bromocresol Purple in the Presence of Dispersed Carbon

S. V. Kozlov

Ochakovo Center of Science and High-Tech, Karpov Research Physicochemical Institute, Moscow, Russia

Received October 22, 2002

Abstract—Ultrafiltration of solutions of Bromocresol Purple on a UFM-50M membrane in the presence of dispersed carbon was studied. The variation of the flow rate through unit surface area of the membrane and of the dye retention factor with time was traced. The influence exerted on the ultrafiltration by dye adsorption on dispersed carbon and by formation of a dynamic membrane was determined. For the initial stage of filtration, the dependence of the retention factor on the dye concentration in solution was found and accounted for.

Ultrafiltration is an effective method for concentrating solutions of synthetic dyes. Ultrafiltration of solutions of this kind has been studied previously [1–3]. The influence exeted by the dye concentration and electrolyte additives on retention of azo dyes on cellulose acetate membranes has been analyzed [1]. In ultrafiltration separation of aqueous and aqueous–salt solutions of Acid Black S, it was found that the retention factor is affected by orientation of anisodiametric dye molecules in a convergent flow at membrane pore mouths [2].

This study is concerned with ultrafiltration of aqueous solutions of Bromocresol Purple in the presence of dispersed carbon. In the absence of the dispersion, the retention of the dye is very low.

EXPERIMENTAL

Bromocresol Purple $C_{21}H_{19}BrNO_5S$ is a water-soluble dye. The concentrations of the dye of analytically pure grade, determined by photometry (λ = 400 nm), were 0.065 to 0.4 g l^{-1}. Dispersed carbon (5 g l^{-1}) was added to a solution 90 min before filtration. This time was sufficient for the adsorption equilibrium of the dye to be established at carbon particles. According to electron microscopy, the average size of carbon dispersion particles was 200 nm. A UFM-50M membrane based on aromatic polyamide with average pore diameter of 30 nm was used in experiments. Different UFM-50M membranes were used in studying the influence exerted by the dye concentration.

Ultrafiltration was carried out on a non-flow-through DKRI-021 installation without agitation, with pressure created by compressed air. The surface area of the membrane was 0.0117 m^2. The ultrafiltration was done at 298 K. The scatter of the experimental data obtained was 6%, and the variance, 0.7%.

In the course of filtration, the dye is adsorbed on the surface and pore walls of the ultrafilter; carbon particles with adsorbed dye are accumulated on the ultrafilter and form a dynamic membrane layer. In the course of time, the thickness of the dynamic membrane layer grows, which leads to a decrease in the flow rate through unit surface area of the membrane. The variation of this parameter is determined by the formula [4]

$$\frac{1}{J_2} = \frac{(R_m\eta)^2}{(\Delta P)^2} + \frac{2ac_s\eta R(1-K)}{\Delta P}t, \qquad (1)$$

where J is the flow rate through unit surface area of the membrane; R_m, hydrodynamic resistance of the ultrafilter; ΔP, pressure difference; η, filtrate viscosity; a, specific resistance of filtration; c_s, substance concentration in solution; R, retention factor; K, fraction of substance transferred from the membrane surface into solution as a result of back diffusion; and t, time.

The hydrodynamic resistance of the membrane was found using the formula

$$R_d = [2ac_sVR(1-K)]A^{-1}, \qquad (2)$$

where V is the filtrate volume, and F is the membrane area.

According to formula (1), the slope of the linear

1070-4272/03/7607-1104$25.00

dependence $1/J^2 - t$ is

$$q = [2ac_s\eta R(1 - K)]\Delta P^{-1}. \quad (3)$$

From formulas (2) and (3) follows that

$$R_d = \frac{V\Delta P}{2A\eta}q. \quad (4)$$

Figure 1 shows dependences of the flow rate through unit surface area of the membrane and of the retention factor on the filtration time at dye concentration of 0.25 g l^{-1} and pressure of 0.05 MPa on a UFM-50M membrane. The retention factor was calculated using the initial concentration of the dye. The flow rate and the retention factor decrease with time. The decrease in the flow rate is accounted for by an increase in the thickness of the dynamic membrane layer composed of carbon particles having adsorbed dye on their surface. The high retention factor of the dye is determined by its adsorption on carbon particles in solution and on the surface of the dynamic membrane and walls of its pores. Without dispersed carbon, the retention factor is 3.8% at dye concentration of 0.25 g l^{-1} and pressure of 0.05 MPa.

Figure 2 shows the time dependence of $1/J^2$. This plot is a straight line which intercepts on the ordinate axis a portion equal to 5.65×10^8 $s^2\,m^{-2}$. At $\eta = 0.894 \times 10^{-3}$ N cm^{-2} and $\Delta P = 5 \times 10^4$ N m^{-2}, formula (1) gives the hydrodynamic resistance of the ultrafilter, $R_m = 1.33 \times 10^{12}$ m^{-1}.

Figure 3 shows the time dependence of the hydrodynamic resistance of the dynamic membrane at dye concentration of 0.25 g l^{-1} and pressure of 0.05 MPa. The quantity q and the volume of the filtrate obtained in a given time were used to determine, using formula (2), the hydrodynamic resistance of the dynamic membrane, which increases linearly with time.

Figure 4 shows the isotherm of dye adsorption on dispersed activated carbon at carbon concentration of 5 g l^{-1}. The initial dye concentrations were in the range from 0.05 to 0.4 g l^{-1}. With increasing equilibrium concentration, the mass of adsorbed dye grows first steeply and then only slightly.

Figure 5 shows the dependence of the retention factor on the initial concentration of the dye in solution at a pressure of 0.05 MPa on the UFM-50M membrane at instant of time t = 60 s (curve *1*). With increasing concentration, the retention of the dye decreases. This is attributed to saturation of the surface of carbon particles with adsorbed dye with its increasing concentration. Previously, a decrease in the retention of azo dyes on cellulose acetate membranes with increasing dye concentration in solution was observed in [1].

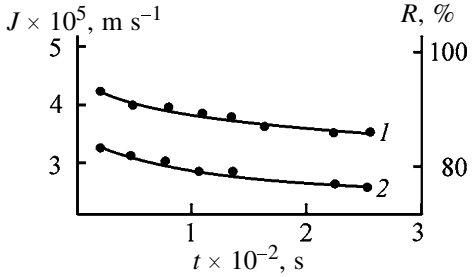

Fig. 1. (*1*) Flow rate through unit surface area of the membrane J and (*2*) dye retention factor R vs. time t on a UFM-50M membrane. Dye concentration 0.25 g l^{-1}, pressure 0.05 MPa; the same for Figs. 2 and 3.

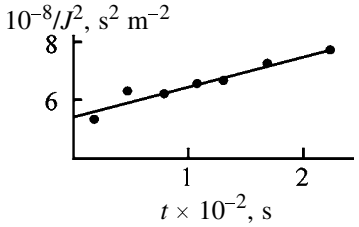

Fig. 2. $1/J^2$ vs. time t on a UFM-50M membrane.

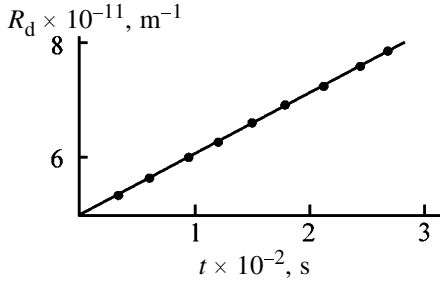

Fig. 3. Hydrodynamic resistance of dynamic membrane, R_d, vs. time t.

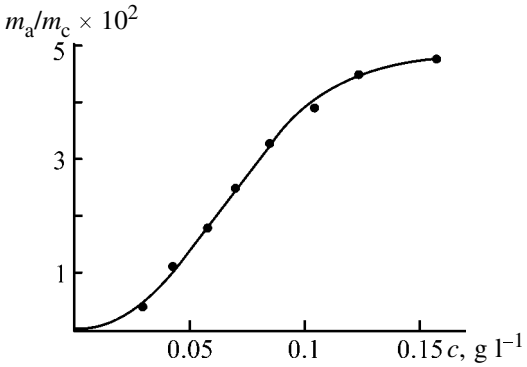

Fig. 4. Adsorbed dye to carbon mass ratio m_a/m_c vs. equilibrium dye concentration c.

Figure 5 also shows the dependence of the retention factor on the dye concentration, which was determined from the adsorption isotherm (curve *2*). Comparison of curves *1* and *2* in Fig. 5 indicates that a

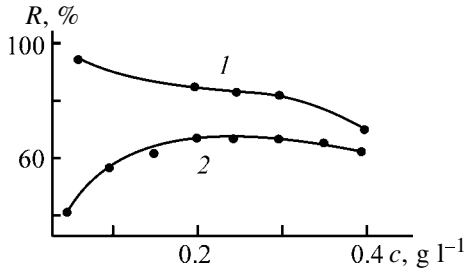

Fig. 5. Dependences of the retention factor R on the dye concentration c, obtained (*1*) in ultrafiltration and (*2*) from adsorption isotherm.

pronounced adsorption of the dye in the dynamic membrane layer occurs in the course of filtration. The enhanced adsorption of the dye on the dynamic membrane, compared with that on the surface of carbon particles, is due to an increase in the adsorption capacity in the narrow pores of the carbon layer because of the additivity of dispersion forces.

CONCLUSIONS

(1) In the presence of dispersed carbon, the retention factor of Bromocresol Purple increases manyfold.

(2) The dye retention factor decreases with increasing dye concentration.

(3) The high retention factor is due to dye adsorption on carbon particles in solution and in filtration through a carbon layer formed on the ultrafilter.

Received April 4, 2003

Abstract—Branched water-soluble *N*-(2-hydroxypropyl)methacrylamide homopolymers containing interchain urethane links were prepared. The hydrodynamic and molecular-weight characteristics of the branched homopolymers and the rate of their hydrolysis under the conditions close to those of a living body (saline, pH 7.0, 37°C) were determined.

Much attention is given today to synthesis and study of biologically active polymers (BAPs) for their use as medicinals. Biologically active polymers, as compared to low-molecular-weight drugs, ensure prolonged effect of a drug and alter its biodistribution, reducing sometimes its toxicity and giving other positive effects. Synthetic BAPs are prepared by radical copolymerization of unsaturated derivatives of existing drugs with hydrophilic copolymers and by binding drugs to a reactive hydrophilic polymeric carrier to form polymer–drug links of various types. The second route to BAPs is the most widely applied, since it allows the use of commercially available drugs; in this case, the major problem is development of a suitable polymeric carrier.

Copolymers of *N*-(2-hydroxypropyl)methacrylamide (HPMA) are widely used as polymeric carriers for drugs and biologically active substances [1–6]. It should be noted that the HPMA homopolymer contains a reactive hydroxy group via which it is possible to link various drugs and biologically active substances. This approach, however, is used relatively seldom [7].

However, since poly-HPMA as a carbon-chain polymer is not biodegradable, its molecular weight M and molecular-weight distribution (MWD) should be strictly limited to ensure easy elimination of BAPs derived from this polymer. With nonfractionated ^{14}C-poly-HPMA as example, it was shown [8] that the radioactivity level originating form this polymer (M = 28000) at single intravenous administration in rabbits decreases by half in 8 h, and in 17 days the circulatory system gets free of the polymer. Accumulation of ^{14}C-poly-HPMA with M = 33000 is temporary: After 6 months, the polymer is detected in none of the eight examined organs. It can be expected that the polymer with $M \geq 100000$ will be retained in the living body for several years, and its deposition can cause diseases. One of the ways to overcome these undesirable side effects is synthesis of high-molecular-weight (M = 70000–100000) branched copolymers containing chemically labile covalent bonds between short backbone chains. These bonds undergo gradual chemical (hydrolysis) or biological cleavage to give low-molecular-weight fragments ($M \leq 40000$) which can be readily eliminated from the living body with kidneys. Preliminary binding of a drug to such chemodegradable polymers will ensure its prolonged effect.

The goal of this study was to prepare and study as drug carriers new branched chemodegradable HPMA homopolymers containing interchain chemically labile urethane links.

N-(2-Hydroxypropyl)methacrylamide is an active monomer. Therefore, the initial linear HPMA homopolymers were prepared by polymerization of HPMA in isopropanol, which is an active transfer agent for the propagating polymeric chain [9] and decreases M of the forming polymer, and in the presence of *p*-nitrophenol (*p*-NP), which is the polymerization inhibitor and chain-terminating agent. The results are listed in Table 1.

It is seen that, under these conditions, we were able to prepare HPMA homopolymers with $\overline{M}_v$ = 7000–30000. The higher was the *p*-nitrophenol content in

the initial monomeric mixture, the lower was *M* of the forming poly-HPMA.

Figure 1 shows the UV spectrum of poly-HPMA **Ib** in DMSO. The absorption band at λ_{max} = 322 nm belongs to the product of the reaction of *p*-nitrophenol with the propagating macroradical under the conditions of HPMA polymerization. As in the case of polymerization of vinyl monomers in the presence of nitrobenzene, this process leads to the chain termination [10]. The lack of absorption at 427 nm proves the absence of free *p*-nitrophenol in the polymers.

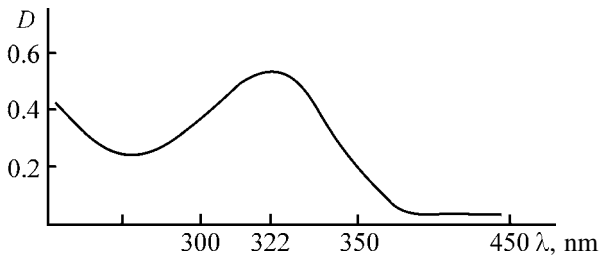

Fig. 1. UV spectrum of poly-HPMA **Ib** in DMSO, *c* = 815 μg ml^{-1}: (*D*) optical density and (λ) wavelength.

The results of the experiment on the synthesis of **If** show that *p*-nitrophenoxyacetic acid, like nitrobenzene and *p*-nitrophenol, can also be used as inhibitor of HPMA polymerization and chain-terminating agent.

It is known [5, 6] that copolymers of HPMA with *p*-nitrophenyl esters of oligopeptide *N*-methacryloyl derivatives and unsaturated phenoxyacetic acids have low *M* and narrow MWD ($\overline{M}_w/\overline{M}_n$ = 1.3–1.8) owing to the fact that the polymerizing system always contains *p*-nitrophenol impurities originating from hydrolysis of activated *p*-nitrophenoxy groups. Therefore, it can be expected that HPMA homopolymers prepared in isopropanol in the presence of *p*-nitrophenol will also have narrow MWD.

Branched HPMA homopolymers were prepared by reaction of linear poly-HPMA with a bifunctional

agent, hexamethylene diisocyanate (HMDIC), in DMF at 130°C in an argon atmosphere, i.e., under the conditions of synthesis of linear polyurethanes [11]. The results of the experiments on the reaction of the initial HPMA homopolymers with HMDIC are given in Table 2. It is seen that [η] and M_{SD} of the branched polymers are by a factor of 1.5–2 higher than those of the initial linear polymers **I**. This result suggests formation of urethane links between the polymeric chains of the initial poly-HPMA in the course of the reaction with HMDIC. The reaction conditions were determined under which the gelation is avoided and water-soluble polymers are obtained. The reaction of linear HPMA homopolymers with HMDIC is characterized by the following trends. An increase in the [HMDIC] : [OH] molar ratio at a constant initial concentration of the polymer results in increased [η] of the reaction product (polymers **IId** and **IIe**). Longer reaction, at equal other conditions, also results in increased [η] of the reaction products (polymers **IIf** and **IIg**). The hydrodynamic characteristics ([η], diffusion and sedimentation coefficients) of branched HPMA homopolymers **IIa**, **IIh**, and **IIj** are given in Table 3.

The presumed scheme of the reaction of linear poly-HPMA with HMDIC to give interchain (structure **A**) and intrachain (structure **B**) urethane links is shown below.

The presence of urethane links in the resulting branched HPMA homopolymer **IIb** was proved by ^{1}H NMR spectroscopy. Figures 2a and 2b show, respectively, the upfield and downfield parts of the spectrum of poly-HPMA **IIb** in dimethylacetamide-d_9. In the range 0.8–2.2 ppm, there are signals of the methylene protons of the backbone, four methylene protons of the cross-linking chain, and two methyl groups (one in the backbone and another in the cross-linking chain). The signal at 3.0–3.3 ppm can be assigned to the $CH_2NHC(O)$ fragment.

The richest information is apparently furnished by the signal at about 4.8 ppm. It can be assigned to the methine proton of the urethane group, –$CH(CH_3)$–OC(O)NH. Comparison of its relative intensity (0.11) with that of the sum of upfield signals (8.63) allows estimation of the content of the –$CH(CH_3)$–OC(O)NH fragments in **IIb** at 8.9 mol %. This value includes both interchain and intrachain urethane links. The content of intrachain links is apparently higher, since the initial homopolymer brought into the reaction with the bifunctional reagent contained a large amount of reactive hydroxy groups. According to [12], the probability of formation of intrachain cross-links is the lower, the smaller the content of reactive groups in the copolymer.

Table 3. Hydrodynamic characteristics of branched HPMA homopolymers

Polymer	[η], dl g^{-1}	$S \times 10^{13}$, Sv	$D \times 10^7$, cm^2 s^{-1}	M_{SD}
IIa	0.11	1.6	6.6	26 000

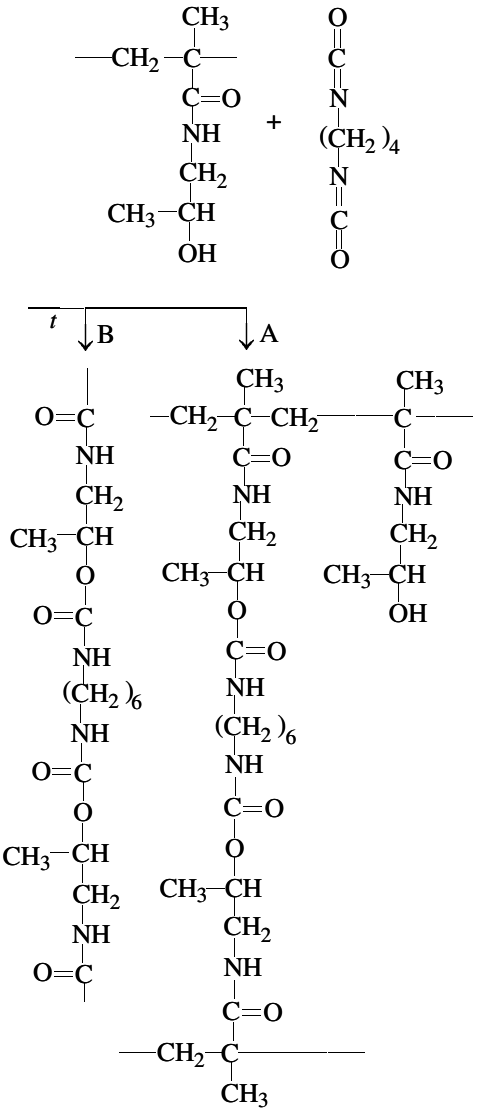
IIj	0.18	3.1	4.8	71 000

The hydrolysis of branched poly-HPMA **IIj** (M_{SD} = 71 000) in saline (pH 7.0) at 37°C was monitored viscometrically. Figure 3 shows that, under these mild conditions, hydrolysis of the interchain urethane links

Scheme



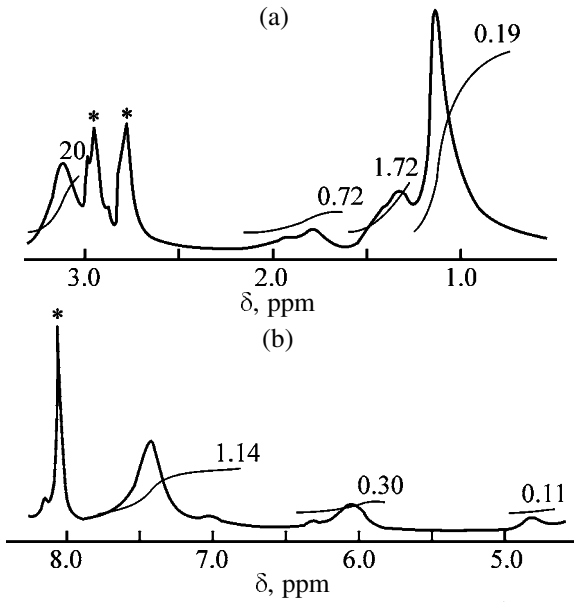


Fig. 2. (a) Upfield and (b) downfield parts of the ^{1}H NMR spectrum of poly-HPMA **IIb** in dimethylacetamide-d_9. The solvent signal is marked with an asterisk. (δ) Chemical shift.

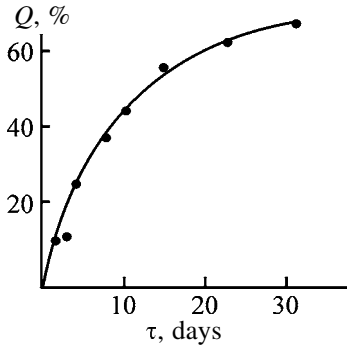

Fig. 3. Hydrolysis of branched poly-HPMA **IIj** (M_{SD} = 71 000) in saline (pH 7.0) at 37°C. (Q) Degree of hydrolysis and (τ) hydrolysis time.

in **IIj** is fairly fast. The degree of hydrolysis Q is 53% in two weeks and 68% in a month. Such a hydrolysis rate can ensure elimination of **IIj** from a living body. On the basis of chemodegradable (**IIj**) and, for comparison, initial (**Ig**) poly-HPMA, we prepared polymeric esters of a β-lactam antibiotic oxacillin.

EXPERIMENTAL

***N*-(2-Hydroxypropyl)methacrylamide** was prepared by acylation of 1-amino-2-propanol with methacrylic anhydride [13]. The elemental analysis of the monomer was consistent; mp 67°C.

AIBN was recrystallized three times from chloroform–methanol (1 : 3) at a temperature no higher than 40°C; mp 103°C.

Hexamethylene diisocyanate was purified by double vacuum distillation. The fraction boiling at 111°C (2 mm Hg) was collected. Found: n_D^{20} = 1.4535, d_4^{20} = 1.0472 g cm^{-3}; published data [14]: bp 127°C (10 mm Hg), n_D^{20} = 1.4530, d_4^{20} = 1.0460 g cm^{-3}. Calculated MR_D = 43.40; found MR_D = 42.65.

***p*-Nitrophenol** (Fisher Biotech. N.Y.) for peptide synthesis was used without additional purification.

Linear low-molecular-weight poly-HPMA Id. A glass ampule was charged with 0.09 g (4.5 wt %) of AIBN. Then a mixture of 2 g of HPMA and 0.1131 g of *p*-nitrophenol (5.5 wt %) was dissolved in 14 ml of 2-propanol in a 50-ml flat-bottomed flask. The resulting solution was added to the ampule through a funnel. The ampule was purged with argon, sealed, and placed in a thermostat maintained at 65 ± 0.5°C. After 24 h, the ampule was cooled and opened; the viscous solution from the ampule was poured dropwise with stirring into 250 ml of dry acetone. The precipitated polymer was collected on a glass frit and vacuum-dried. Yield of poly-HPMA 1.39 g (69.5%), [η] = 0.07 dl g^{-1}, $\overline{M}_v$ = 14 000. The intrinsic viscosity of the polymer was measured in 0.1 M aqueous KCl at 25°C. The viscosity-average molecular weight $\overline{M}_v$ was determined by the Mark–Kuhn–Houwink equation for poly-HPMA [15]. Other poly-HPMA samples were prepared similarly.

Branched poly-HPMA IIg. In a 20-ml conical flask, we dissolved 0.50 g of poly-HPMA ([η] = 0.09 dl g^{-1}, $\overline{M}_v$ = 22 000) in 3.88 ml of DMF, and to the resulting solution we added 42.12 μl of HMDIC, [HMDIC]/[OH] = 0.075 : 1. The reaction mixture was transferred into a glass ampule, which was purged with argon, sealed, and placed in an oil bath heated to 130°C. After 10 h, the ampule was cooled and opened; 0.5 ml of ethanol was added, and the mixture was poured into 200 ml of diethyl ether. The precipitated polymer was filtered off and dried to constant weight. We obtained 0.276 g (55.2%) of a water-soluble product; intrinsic viscosity 0.17 dl g^{-1}.

The ^{1}H NMR spectrum of branched homopolymer **IIb** was recorded on a Bruker AC-200 spectrometer in dimethylacetamide-d_9 (5% solution). The diffusion and sedimentation coefficients and the sedimentation-average molecular weight M_{SD} of branched poly-HPMA samples were determined as described in [16]. The floatability factor (1 – $v\rho_0$) fot poly-HPMA, required for determining M_{SD} by the Svedberg formula, was taken from [17]. Hydrolysis of branched HPMA homopolymer **IIj** was studied as described in [18].

CONCLUSIONS

(1) Low-molecular-weight ($\overline{M}_v$ = 7000–30000) *N*-(2-hydroxypropyl)methacrylamide homopolymers were prepared by radical polymerization in isopropanol in the presence of *p*-nitrophenol.

(2) The reaction of the linear homopolymers prepared with hexamethylene diisocyanate in dimethylformamide at 130°C under argon yielded branched homopolymers, M_{SD} = 53000–71000, containing interchain urethane links. These links are hydrolyzed at a fairly high rate in saline (pH 7.0) at 37°C.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Structure of (Meth)acrylamides on Their Spontaneous Polymerization in Concentrated Aqueous Solutions

Received March 18, 2003

Abstract—A study was made of spontaneous polymerization of (meth)acrylamides of different structures in concentrated aqueous acid solutions, in particular, as influenced by the monomer association.

(Co)polymerization in concentrated aqueous solutions is widely used for preparing polymers from (meth)acrylamides. It was found earlier that, in such solutions, acrylamide [1, 2] and 2-acrylamido-2-methylpropanesulfonic acid (AMPSA) [3] can undergo spontaneous polymerization. Kurlyankina *et al*. [2] demonstrated the radical mechanism of this process, with monomer molecules acting as radical sources. The detailed mechanism is, however, unknown. In this connection, it was of theoretical and practical interest to study the capability of (meth)acrylamides with different structures for spontaneous polymerization in aqueous solutions and to elucidate how the structure of the amide groups affects this process.

The choice of the monomers for the study was determined by their high solubility in water (we studied solutions with concentrations of 50 wt %) and resistance to hydrolysis. Under the experimental conditions (70°C, 3.5 h), the hydrolysis proceeds to no more than 3%.

First, we found that spontaneous polymerization in concentrated aqueous acid solutions is typical not only for acrylamide and AMPSA but also for methacrylamide and a number of N- and N,N-substituted (meth)-acrylamides with alkyl, amine, and carboxy substituents at the amide nitrogen atom. The resulting polymeric products differed in solubility, but in all the kinetic runs the mixtures were homogeneous, at least up to 15–20% conversion.

The process was run both in the presence of oxygen and in a nitrogen atmosphere. There were no peroxy compounds in the initial purified reactants, i.e., initiation of the process was not connected with degradation of the accumulated peroxides. This was emphasized by Kurlyankina *et al*. [2] who studied spontaneous polymerization of acrylamide in an argon atmosphere. The process was suppressed by introducing a sufficient amount of radical polymerization inhibitors.

Figures 1a and 1b illustrate how the structure of (meth)acrylamides affects their spontaneous polymerization in water. Comparative study of the kinetics of homogeneous polymerization of acrylic and methacrylic compounds was difficalt: With methacrylamide, the resulting polymer was insoluble in water, and the process was heterophase even at low conversions; methacrylamides disubstituted at the nitrogen atom (e.g., *N,N*-dimethylmethacrylamide) did not polymerize under the chosen conditions. In the case of monosubstituted amide monomers, we succeeded in comparing the data for *N*-methylacrylamide and *N*-methylmethacrylamide (Fig. 1a, curves *2, 4*). As in polymerization in the presence of initiators [4], the methacrylic monomer is less active than its acrylic analog.

We analyzed how the structure of the amide group affects polymerization of a series of acrylamide derivatives. As seen from the table, the acrylamides studied are characterized by similar initial rates and effective rate constants of polymerization k_{eff}. The calculations of the constants took account of the reaction orders with respect to the monomer, which varied with the amide from 1.8 to 3.6. It should be noted that the orders differed also in a study of spontaneous polymerization of *N,N*-dimethylaminoethyl methacrylates in concentrated aqueous solutions [5].

1070-4272/03/7607-1112$25.00

Influence of the structure of acrylamides CH_2=CHCONR^{1}R^2 on the initial rate v_0 and the effective rate constant k_{eff} of spontaneous polymerization in water* ($[M]_0$ = 50 wt %, 70°C, $[H_2SO_4]_0$ = 0.4 mg-equiv g^{-1})

Monomer no.	NR^1R^2	$-\log v_0$	$-\log k_{eff}$	σ*	$-R_s$
1	NH_2	3.80	3.78	0.870	0.985
2	$NHCH_3$	3.77	3.72	0.870	1.329
3	NHC_2H_5	3.79	3.80	0.870	1.615
4	$NHCH_2COOH$	3.97	3.86	0.696	1.727
5	$NHC(CH_3)_2CH_2SO_3H$	4.20	4.08	0.953	2.337
6	$NH(CH_2)_3N(CH_3)_2$	3.95	4.00	1.055	2.171
7	$NHC(CH_3)_2CH_2CH_2N(C_2H_5)_2$	4.13	4.06	0.985	2.434
8	$N(CH_3)_2$	3.52	3.48	0.835	1.719
9	$N(C_2H_5)_2$	3.86	3.79	0.883	2.199
10		3.75	3.70	0.992	2.070

* σ* and R_s are the induction and steric constants of the NR^1R^2 groups, respectively.
** For monomer no. 5, $[H_2SO_4]_0$ = 0, $[NaOH]_0$ = 1.95; no. 6, $[H_2SO_4]_0$ = 3.52; and no. 7, $[H_2SO_4]_0$ = 2.73 mg-equiv g^{-1}.

The acrylamides studied can be ranked in the following order in accordance with their activities in spontaneous polymerization as characterized by k_{eff} (we show only the amide nitrogen atoms with the substituents):

$N(CH_3)_2$ >  ≅ $NHCH_3$ > NH_2 ≅ $N(C_2H_5)_2$ ≅ NHC_2H_5 > $NHCH_2COOH$ > $NH(CH_2)_3N(CH_3)_2$ > $NHC(CH_3)_2CH_2CH_2N(C_2H_5)_2$ > $NHC(CH_3)_2CH_2SO_3H$. (A)

The structure of acrylamides exerts a much stronger influence on the rate of the previously studied homopolymerization of these compounds in water (at the initial concentration of 1 M) in the presence of an azo initiator [4]. According to their effective rate constants, the acrylamides studied were ranked in the following order:

$NHCH_3$ > $N(CH_3)_2$ > NH_2 >  > NHC_2H_5 > $NH(CH_2)_5COOH$ > $N(C_2H_5)$ >  . (B)

The succession of the amides in series A and B is different. To analyze how the activity of the acrylamides in initiated and spontaneous polymerization is influenced by the structure of the amide groups, we initially used the modified Taft correlation equation

$$\log k_{eff} = \log k_0 + \rho\sigma^* + \delta R_s, \quad (1)$$

where σ* are the induction constants of the NR^1R^2 groups; R_s, steric constants of the same groups; and

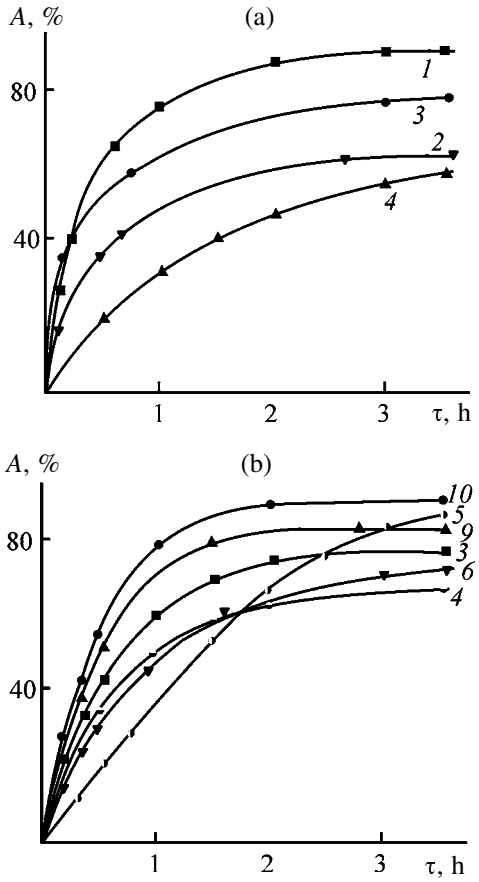

Fig. 1. Degree of conversion A of (a) CH_2=$CR^1CONR^2R^3$ and (b) CH_2=$CHCONR^1R^2$ monomers as a function of the time τ of spontaneous polymerization in water. $[M]_0$ = 50 wt %, 70°C. (a) R^1: (*1–3*) H and (*4*) CH_3; NR^2R^3: (*1*) NH_2, (*2, 4*) $NHCH_3$, and (*3*) $N(CH_3)_2$. (b) Figures at curves correspond to the monomer nos. in the table.

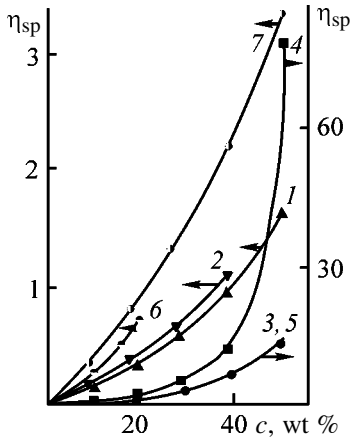

Fig. 2. Specific viscosity η_{sp} of aqueous solutions as a function of the concentration *c* of (meth)acrylamides $CH_2=CR^1CONR^2R^3$ at 25°C. R^1: (*1–5*) H and (*6–7*) CH_3; NR^2R^3: (*1, 6*) NH_2, (*7*) $NHCH_3$, (*2*) $N(CH_3)_2$, (*3*) $NHCH_2CH_2CH_2N(CH_3)_2$, (*4*) $NHCH_2COONa$, and (*5*) $NHC(CH_3)_2CH_2SO_3Na$.

ρ and δ, parameters characterizing the sensitivity of the reaction to the corresponding effects of the amide groups.

In our calculations of the induction and steric constants of the substituents, we took the carbon atom of the carbonyl groups as the reaction center; the σ* parameters were calculated by the procedures from [6, 7] (for nonionic and ionic monomers, respectively); the R_s parameters, by the procedure form [8]; and the bond lengths, using the HyperChem program by the MNDO method.

Using the experimental data from [4] (for initiated polymerization of the series B acrylamides), we obtained an unsatisfactory correlation with Eq. (1) (the correlation coefficient $r = 0.86$). It was shown in [9] that, for many nonradical reactions of (meth)acrylamides in aqueous media, a significant role is played by the hydrogen-bonding capability of the monomers. We introduced into Eq. (1) an additional parameter *n* corresponding to the number of the hydrogen atoms at the amide nitrogen atom and obtained an equation with a good correlation coefficient:

$$\log k_{eff} = 3.100 - 2.009\sigma^* + 1.465R_s - 0.508n, \quad (2)$$

$$r = 0.990, \ s = 0.006.$$

Thus, the rate of initiated polymerization of acrylamides in relatively dilute solutions tends to decrease with increasing *n*, increasing size of the amide groups, and strengthening accepting power of the substituents at the amide nitrogen atom. The first two factors are probably associated with decreases in the molecular mobility and in the accessibility of the reaction centers, respectively, and the third factor, with a decrease in the activity of the radicals due to stronger delocalization of the unpaired electrons and to an additional decrease in the electron density of the C=C bond (which strengthens the electrostatic repulsion of the monomer and propagating radicals having the partial charges of the same sign).

In the case of spontaneous polymerization of acrylamides, such correlation analysis also yielded a poor correlation coefficient with a two-parameter equation of the type (1) ($r = 0.682$) and a good, with the three-parameter equation

$$\log k_{eff} = -2.950 + 0.045\sigma^* + 0.375R_s - 0.286n, \quad (3)$$

$$r = 0.980, \ s = 0.002.$$

Appreciably smaller coefficients at all the three parameters in Eq. (3) compared to Eq. (2) confirmed that, in the monomer series studied, the influence of the structure of the amide on spontaneous polymerization is substantially smoothened compared to polymerization in the presence of initiators. The steric and hydrogen-bonding factors for both processes are unidirectional, and the inductive effect of the amide substituents is not essential for spontaneous polymerization.

Our results suggest the following mechanism of spontaneous polymerization of arcylamides. Egorov and Zubov [10] showed that initiated or spontaneous polymerization of a number of ionic vinyl monomers (salts of vinylpyridines and aminoethyl methacrylates and dimethyldiallylammonium chloride) in concentrated aqueous solutions is affected by their association. This yields precursor structures with the C=C bonds oriented in a favorable for polymerization way.

The association can be verified by a nonlinear plot of the viscosity of solution vs. monomer concentration. Indeed, the viscometric data for (meth)acrylamides of different structures confirmed association at concentrations characteristic for spontaneous polarization (the characteristic plots of viscosity vs. concentration are shown in Fig. 2).

Initiated polymerization of acrylamides was carried out at a moderate concentration of the monomers, which makes association of much smaller importance in this case. This can be responsible for a decrease in the corresponding coefficients in Eq. (3) compared to Eq. (2). For example, increased size of the alkyl substituents at the amide nitrogen atom complicated poly-

merization at moderate concentrations of the monomers, though favors association in concentrated solutions (Fig. 2, curves *3, 5*). Introduction of charged accepting groups into amides has a similar effect (strengthening of the association in such molecules is consistent with aggregation of organic ions in water [11]). Replacement of the hydrogen atoms at the amide nitrogen atom by alkyl groups, on the one hand, decreases the capability of the monomers for association by hydrogen bonding and, on the other, increases the hydrophobicity of the molecules and strengthens their aggregation.

The kinetic curves in Figs. 1a and 1b show that, in the initial stage of the process (series A), the order of the monomer activities significantly differs from the order based on data on conversion in 3.5 h (series C):

$$NH_2 \cong N\langle\rangle O > NHC(CH_3)_2CH_2SO_3H > N(C_2H_5)_2 > N(CH_3)_2 > NHC_2H_5 > NH(CH_2)_3N(CH_3)_2 > NHCH_2COOH > NHCH_3. \quad (C)$$

This may be due to the fact that, upon accumulation of a large quantity of products, the polymerization rate also depends on other factors (excluding those governing the process at low conversions). For example, a nonuniform growth of viscosity of the reaction mixtures affects the mobility of the macroradicals and the chain termination reaction in different ways. In polymerization of ionic monomers, an essential role is played by a change in the ionic strength of solutions due to decrease in the concentration of free ions in the system on changing from the monomer to polymer molecules [12]. Lastly, an important role is played by different solubilities of the products in water: Some systems remain homogeneous during the process and other become heterogeneous. For example, polymers based on disubstituted acrylamides, aminoalkylacrylamides, and AMPSA are well soluble in water, and those based on acrylamides and *N*-methylacrylamides have very limited solubilities.

EXPERIMENTAL

The initial acrylamide, methacrylamide, and AMPSA were recrystallized before use from benzene, 1 : 1 benzene–isopropanol, and acetic acid, respectively. *N*-(1,1-Dimethyl-3-diethylaminopropyl)acrylamide was synthesized by the Ritter reaction [13]; the other monomers were prepared by the Schotten–Baumann reaction [9]. 2-Acrylamidoacetic acid was recrystallized from ethyl acetate, and the other (meth)acrylamides were double-distilled in a vacuum.

The kinetics of polymerization of N- and N,N-substituted (meth)acrylamides in the presence of protic acids were studied in water at 70°C, at the initial concentrations of the reactants of 50 wt %. The polymerization was monitored by determining the concentration of the C=C bonds during the process and by isolating the products formed. The products were isolated by precipitation in acetone or by vacuum distillation of water (followed by separation of the unchanged initial substances by repeated washing with acetone). After purification, the polymers were dried in a vacuum (20°C, 2 mm Hg) to constant weight.

The concentration of the C=C bonds was determined by bromide–bromate titration. The ^{13}C NMR spectra were taken at a frequency of 75 MHz on a Varian Gemini-300 Fourier spectrometer (solvent D_2O, reference DMSO).

Poly-*N,N*-dimethylacrylamide. To 10.0 g (0.101 mol) of *N,N*-dimethylacrylamide in 8.0 ml of water, 1.96 g of 20% aqueous sulfuric acid (0.008 mol) was added. The resulting solution was kept for 4 h at 70°C, whereupon water was vacuum-distilled; the resulting polymer was washed with acetone to remove the unchanged initial monomer and sulfuric acid; the precipitate was filtered off and dried in a vacuum (20°C, 2 mm Hg). Yield 8.2 g (82%). The isolated product contained no double bonds. ^{13}C NMR spectrum, δ, ppm: 175.7–176.1 (–CON), 36.1 (CH_3–), 37.3–37.7 (–CH_2–), 34.4–35.4 (–CH–).

CONCLUSIONS

(1) (Meth)acrylamides with different structures (unsubstituted, N-, and N,N-substituted, nonionic, anionic, and cationic) undergo spontaneous polymerization in concentrated weakly acidic aqueous solutions.

(2) Correlation analysis demonstrated that the amide groups affect spontaneous and azo-initiated polymerization of acrylamides in different ways.

(3) A weak dependence of the spontaneous polymerization rate on the structure of the amide groups is presumably due to association of the monomers. The latter was confirmed by nonlinear concentration dependences of the viscosity of aqueous solutions of (meth)acrylamides.

Received January 17, 2003

Abstract—The influence exerted by the structure of the ammonium group and anion, pH, and surfactant and polymeric additives on hydrolysis of *N*,*N*-dimethylaminoethyl methacrylate and its salts in concentrated aqueous solutions was studied.

N,*N*-Dimethylaminoethyl methacrylate (DMAEM) is the most widely used amine-containing (meth)acrylic monomer; polymers derived from its salts are used for wastewater treatment, in oil extraction, and in paper production [1]. Many industrial processes involve preparation of DMAEM salts in aqueous solution, followed by their (co)polymerization. Therefore, the resistance of DMAEM and its salts to hydrolysis is an important parameter which should be taken into account when choosing conditions for processes involving these monomers.

Hydrolysis of DMAEM and its acrylic analog, *N*,*N*-dimethylaminoethyl acrylate, was studied previously in relatively dilute aqueous solutions [2–4]. It was shown that, at concentrations of 0.5–2.0 M, hydrolysis of amino (meth)acrylates readily occurs at pH > 7 and sharpy accelerates upon quaternization of ammonium groups. Hydrolysis of DMAEM and its salts in more concentrated solutions was not studied, although these monomers are often used as highly concentrated solutions. The goal of this study was to reveal and explain the features of DMAEM hydrolysis in concentrated aqueous solutions.

Hydrolysis of esters can be catalyzed with both bases (the reaction in most cases occurs by the $B_{AC}2$ mechanism) and acids (in most cases, by the $A_{AC}2$ mechanism) [5]. In the absence of added acids or bases, hydrolysis of DMAEM is catalyzed by the amino group present in the molecule. As the DMAEM concentration is increased, the degree of ionization of the amino groups decreases, which should affect the hydrolysis. Furthermore, the hydrolysis yields methacrylic acid:

$$CH_2{=}C(CH_3)COOCH_2CH_2N(CH_3)_2 + H_2O \rightarrow CH_2{=}C(CH_3)COOH + HOCH_2CH_2N(CH_3)_2, \quad (1)$$

which makes lower the solution pH and thus affects the hydrolysis rate also. In base hydrolysis, the catalyst concentration decreases in the course of the reaction, and in acid hydrolysis it grows. Solutions of DMAEM quaternary salts in the absence of added acids or alkalis are neutral and do not undergo noticeable hydrolysis.

When considering the features of DMAEM hydrolysis in concentrated solutions, it should be borne in mind that the free amino ester, in contrast to its tertiary and quaternary ammonium salts, has a substantial range of phase separation in the system with water above 20°C (Fig. 1). Therefore, experiments with free DMAEM were performed at 15–20°C, so as to cover a wider concentration range. As seen from Fig. 2, at this temperature the hydrolysis is fairly slow, and its rate noticeably decreases as the initial concentration of the monomer is made higher. In 90% solutions in 10 days, no hydrolysis was observed at all (at 70%

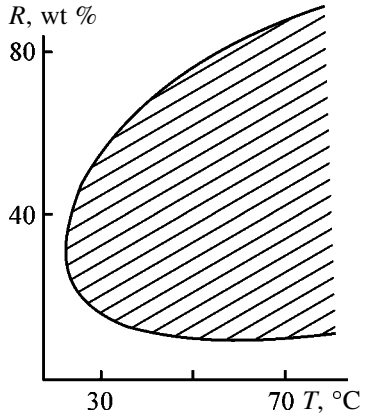

Fig. 1. Solubility diagram of the DMAEM–water system: (*R*) DMAEM content and (*T*) temperature. The phase separation region is cross-hatched.

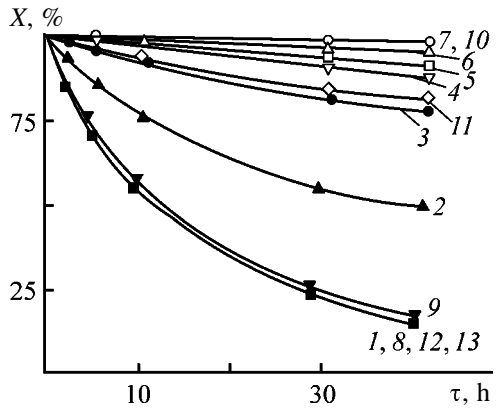

Fig. 2. Degree of DMAEM hydrolysis X as a function of time τ. 20°C. Initial DMAEM concentration, wt %: (*1*, *8*–*13*) 10, (*2*) 20, (*3*) 30, (*4*) 40, (*5*) 50, (*6*) 70, and (*7*) 90. Polymer added (5.0 wt % relative to DMAEM): (*8*) sodium 2-acrylamido-2-methylpropanesulfonate polymer and (*9*) DMAEM · $0.5H_2SO_4$ polymer. Surfactant added, M: (*10*) 5×10^{-5} cetyltrimethylammonium bromide, (*11*) 3×10^{-3} tetrabutylammonium bromide, (*12*) 5.3×10^{-4} Emul'sit 100, and (*13*) 3.13×10^{-4} M Neogen R.

concentration, the degree of hydrolysis in 10 days was 13%).

Hydrolysis of ammonium salts derived from DMAEM (*N*,*N*,*N*-trimethylammonioethyl methacrylate methyl sulfate, DMAEM · DMS; *N*,*N*,*N*-trimethylammonioethyl methacrylate chloride, DMAEM · MC; *N*-benzyl-*N*,*N*-dimethylammonioethyl methacrylate chloride, DMAEM · BC) was fast in alkaline medium (with NaOH added) and stopped on reaching the neutral medium. Therefore, the maximal degree of hydrolysis in these experiments corresponded to the amount of the initially added alkali. In particular, even at a high concentration of DMAEM · MC (70 wt %) at 20°C and NaOH concentration of 2 wt %, the solution became neutral within several minutes.

In acid solutions, the pattern changed. No hydrolysis of tertiary and quaternary salts of DMAEM, both in moderately (30 wt %) and highly (80 wt %) concentrated solutions, was detected at 20°C in several days even at pH 1–2. At 70°C, the hydrolysis became noticeable (Figs. 3, 4). As expected, the hydrolysis accelerated with decreasing initial pH. As in alkaline solutions, the hydrolysis was noticeably slower at higher initial concentrations of the monomer, and quaternary DMAEM salts were more active than the tertiary salts. Also, the consumption of ester groups in the presence of HCl was noticeably faster than in the presence of H_2SO_4 (Fig. 4, curves *7*, *9*). The degree of hydrolysis was also influenced by the structure of the ammonium group (Fig. 4, curves *3*, *4*, *6*). The quaternary salts can be ranked in the following order with respect to activity: DMAEM · MC > DMAEM · BC > DMAEM · DMS. It should be noted that, in DMAEM · DMS, both the carboxylate and sulfate ester groups undergo hydrolysis [reactions (2), (3)], and data are given for the sum of these processes:

$$CH_2=C(CH_3)COOCH_2CH_2\overset{+}{N}(CH_3)_3 + H_2O$$

$$\rightarrow CH_2=C(CH_3)COOH + HOCH_2CH_2\overset{+}{N}(CH_3)_3, \quad (2)$$

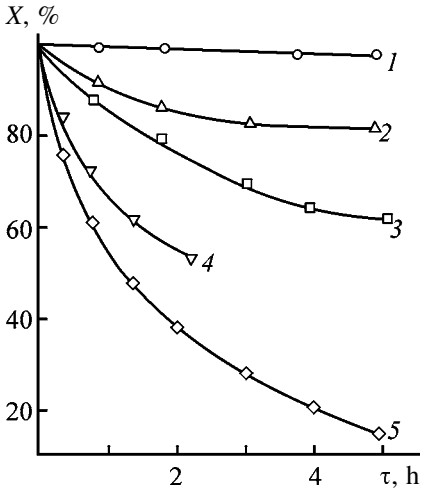

Fig. 3. Degree of hydrolysis X of DMAEM · $0.5H_2SO_4$ (40 wt %) in acid solution as a function of time τ. 70°C; the same for Figs. 4 and 5. H_2SO_4 concentration, wt %: (*1*) 2.5, (*2*) 7.4, and (*3*–*5*) 1.3. Polymer added (5.0 wt % relative to DMAEM): (*4*) sodium 2-acrylamido-2-methylpropanesulfonate polymer and (*5*) DMAEM · $0.5H_2SO_4$ polymer.

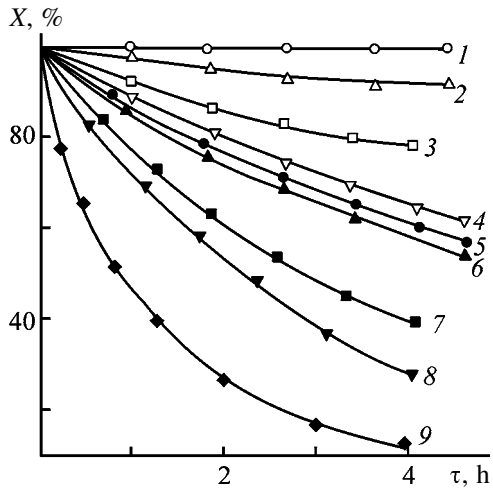

Fig. 4. Degree of hydrolysis X of (*1*, *2*, *5*, *6*–*9*) DMAEM · MX, (*3*) DMAEM · DMS, and (*4*) DMAEM · BC in acid solution as a function of time τ. Monomer concentration, wt %: (*1*, *3*–*6*) 70, (*2*) 85, (*7*, *9*) 40, and (*8*) 20. Acid: (*1*–*6*, *8*, *9*) HCl and (*7*) H_2SO_4. Acid concentration, M: (*1*) 0.01, (*2*, *5*, *8*) 0.4, (*3*, *4*, *6*) 0.5, and (*7*, *9*) 2.5.

$$CH_3SO_4^- + H_2O \rightarrow CH_3OH + HSO_4^-. \quad (3)$$

However, this does not affect the above-given order of activities of monomeric quaternary ammonium salts. For example, in 2.5 h the total degree of hydrolysis of DMAEM·DMS was 8.75% (12.3% of ammonioethyl methacrylate and 5.2% of methyl sulfate groups were hydrolyzed), compared to 27.2% for DMAEM·MC and 23.1% for DMAEM·BC.

It is known [6] that, in concentrated aqueous acidic solutions, DMAEM salts tend to spontaneous radical polymerization. To suppress this process, we added inhibitors. We revealed an interesting feature: When the amount of the inhibitor added was insufficient and spontaneous polymerization started, it accelerated the hydrolysis. Special experiments were made to evaluate the activating effect of polymerization (Fig. 3). It was shown that addition of polymers (cationic, DMAEM·0.5H_2SO_4 polymer; or anionic, sodium 2-acrylamido-2-methylpropanesulfonate polymer) to the solutions of DMAEM salts acidified with H_2SO_4 leads to faster consumption of the monomers (Fig. 3, curves *4*, *5*). It should be noted that the effect of additions of the anionic or cationic polymers on the base hydrolysis of DMAEM was insignificant (Fig. 2, curves *8*, *9*).

Thus, hydrolysis of DMAEM and its salts in highly concentrated aqueous solutions has certain features manifested in specific dependences of the reaction rate on the structure and concentration of the monomer, pH of solution, and additions of polymers. Our results can be explained using concepts of the behavior of monomers associating in aqueous solution.

It was assumed [7] that the influence of the concentration of amino methacrylate salts on features of their radical polymerization in aqueous solutions is due to association of the monomers.

Shibalovich *et al.* [8] measured the surface tension of aqueous solutions of DMAEM and its tertiary salts (monomer concentration ≤10 wt %) and concluded that these compounds exhibit surface activity.

To evaluate the influence exerted by association of DMAEM and its salts on their hydrolysis in concentrated solutions, we measured the concentration dependences of the viscosity (Fig. 6). As certain concentrations of all the DMAEM salts are exceeded, the plots start to strongly deviate from linearity, which is indicative of association. The capability of the monomers for association can be evaluated by the minimal concentration at which the viscosity starts to steeply grow.

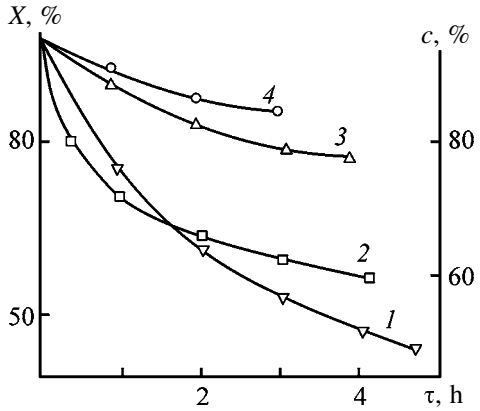

Fig. 5. Degree of (*1*, *2*) hydrolysis *X* and (*3*, *4*) consumption of C=C bonds *c* in DMAEM·0.5H_2SO_4 (40 wt %) in acid solution as a function of time τ. H_2SO_4 concentration, wt %: (*1*, *3*) 11.3 and (*2*, *4*) 8.3.

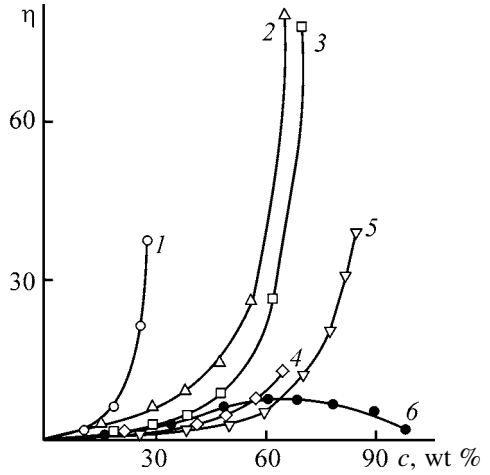

Fig. 6. Specific viscosity η of aqueous solutions of the monomers as a function of concentration *c*. 25°C. Monomer: (*1*) DMAEM·0.5H_2SO_4, (*2*) DMAEM·MC, (*3*) DMAEM·BC, (*4*) DMAEM·HCl, (*5*) DMAEM·DMS, and (*6*) free DMAEM.

Formation of associates should result in the steric shielding of the reaction centers and deceleration of the hydrolysis. Another important factor is the size of the ammonium groups and anions present in the system; apparently, the anions are mainly located on the external surface of the associates, preventing approach of the water molecules to the reaction centers. These factors may be responsible for the difference between the activities of DMAEM salts of different structures.

Polymeric molecules appearing in the system may "loosen" the monomeric associates. This was noted in experiments on addition of poly-2,5-nonene to a solution of a monomeric cationic surfactant [9]. As the molecular "packing" in the associate becomes less dense, the carbonyl carbon atom becomes more ac-

cessible, and hydrolysis should accelerate. This is apparently the case in acid solutions of DMAEM in which the monomer salts are strongly associated. In alkaline solutions, DMAEM is associated to a lesser extent (Fig. 6), and the effect of adding polymers is insignificant.

The presumed role of association of DMAEM and its salts was confirmed by experiments with addition of surfactants (Fig. 2). Cationic surfactants added to 10% DMAEM solutions noticeably decelerated (tetrabutylammonium bromide) or fully suppressed (cetyltrimethylammonium bromide) the hydrolysis. Anionic and nonionic surfactants did not noticeably affect the reaction rate. Thus, cationic micelles appearing in solutions prevent the hydrolysis, which is probably due to the capability of the cationic monomer to be "incorporated" into such micelles. In the case of anionic and nonionic micelles, penetration of the monomer inside the micelles is hindered, and, therefore, these surfactants do not affect the hydrolysis of DMAEM and its salts.

EXPERIMENTAL

Tertiary salts of DMAEM were prepared by addition of equivalent amounts of appropriate acids to aqueous solutions of the monomer. Quaternary salts were prepared in acetone or benzene by alkylation of DMAEM with dimethyl sulfate, methyl chloride, or benzyl chloride.

The hydrolytic stability of the monomers was studied at 15–70°C at a monomer concentration of 10–90 wt %. The spontaneous polymerization was excluded by adding hydroquinone (0.5 wt % relative to the monomer). The progress of hydrolysis was monitored by alkali titration, and the content of C=C bonds was determined by bromide–bromate titration. The specific viscosity of aqueous solutions of the monomers was determined with an Ubbelohde viscometer (d_c 0.56, 0.73, or 0.99 mm depending on the viscosity of the initial solution) at 25°C. When studying the hydrolysis of DMAEM·DMS, the methanol concentration was estimated by gas–liquid chromatography (Tsvet-100 device, flame-ionization detector, 2000 × 3-mm steel column, stationary phase 10% PEGA on Chromaton N-AW, carrier gas nitrogen, flow rate 2×10^{-3} $m^3 h^{-1}$, vaporizer temperature 200°C, column temperature 100°C).

CONCLUSIONS

(1) An increase in the monomer concentration and addition of cationic surfactants result in sharp deceleration of the base hydrolysis of *N*,*N*-dimethylaminoethyl methacrylate.

(2) Acid hydrolysis of *N*,*N*-dimethylaminoethyl methacrylate salts is decelerated with increasing solution concentration and accelerated on adding anionic and cationic polymers; quaternary salts are hydrolyzed more readily than tertiary salts, and their activity decreases in the order *N*,*N*,*N*-trimethylammonioethyl methacrylate chloride > *N*-benzyl-*N*,*N*-dimethylammonioethyl methacrylate chloride > *N*,*N*,*N*-trimethylammonioethyl methacrylate methyl sulfate.

(3) The hydrolysis data and concentration dependences of the viscosity of *N*,*N*-dimethylaminoethyl methacrylate salt solutions suggest that association of the monomers exerts a passivating effect on the hydrolysis.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Reaction Medium on the Kinetics of Copolymerization of *N*-Vinylsuccinimide with Butyl Acrylate

N. A. Lavrov, E. V. Sivtsov, and A. G. Pisarev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received April 4, 2003

Abstract—Radical copolymerization of *N*-vinylsuccinimide with *n*-butyl acrylate in pyridine and the influence of donor characteristics of the solvent on the reaction kinetics were studied. The kinetics of copolymerization in various solvents (dichloroethane, dimethyl sulfoxide, and pyridine) were studied.

It is well known that the reaction medium can significantly affect the kinetics of radical (co)polymerization [1–3] and characteristics of the resulting (co)polymers. The presence in monomer molecules of atomic groups capable to interact with medium components provides conditions for control of the reactivity of monomers and for directed synthesis of polymers. Variation of the relative activity of monomers in copolymerization allows production of copolymers of definite structure, which is of great importance in synthesis of polymers for medical purposes.

Copolymers of *N*-vinylsuccinimide (VSI) with *n*-butyl acrylate (BA) are of interest for production of flexible films for medical and biological purposes [4, 5]. With the aim to obtain soluble VSI–BA copolymers suitable for production of films, the copolymerization is carried out in organic solvents.

It was found [6] that the reactivity of monomers can be affected by using solvents with variable electron-donor power. According to data obtained in studying the kinetics of copolymerization in electron-donor solvent, dimethyl sulfoxide (DMSO), this solvent {Gutmann donor number (DN) 124.7 kJ mol^{-1} [7]} decreases the relative activity of VSI. Variation of the reactivity of VSI is caused by complexation of monomer molecules and solvent, which was confirmed by IR spectroscopy [8] and X-ray diffraction [9].

The results of studying the kinetics of copolymerization of VSI with BA in DMSO [10] suggest the possibility of controlling the relative activity of VSI in copolymerization with acrylic monomers. In view of the fact that the interaction of monomer with the solvent is considerably stronger with VSI than with an acrylic monomer [8, 9], it was suggested that the use of electron-donor solvents will increase the electron density on the double bond of the vinyl group of the VSI molecule, enhance the activity of radicals, and decrease the relative activity of the VSI monomer. To confirm experimentally this suggestion, we studied copolymerization of VSI with BA in pyridine (DN = 138.49 kJ mol^{-1} [7]). Here we report the results of this study.

Monomers and azobis(isobutyronitrile) (AIBN) were prepared by the procedure similar to that described in [10]. We used double-distilled pyridine of analytically pure grade. Copolymerization of monomers was carried out in ampules under argon at 60°C. The total concentration of monomers in pyridine was 0.7, and the concentration of AIBN, 0.0165 M. The reaction kinetics were monitored gravimetrically. After completion of the process, the contents of ampules were poured into distilled water; the precipitated copolymer was filterred off and dried to constant weight at 20°C (660 Pa). The composition of copolymers (Table 1) was determined from IR spectra, namely, from the ratio of the optical density of the band at 1700 cm^{-1}, D_{VSI}, to that of the band at 1735 cm^{-1}, D_{BA}, using the calibrating plot [10].

Copolymerization in pyridine proceeds to high degrees of conversion. The kinetic curves (Fig. 1) show no gel effect characteristic of copolymerization in the bulk. The synthesized copolymers are soluble in organic solvents, which allows production of films from these copolymers by casting from a solution.

Owing to higher reactivity of BA monomer, its concentration in the reaction mixture decreases more rapidly than the VSI concentration (Fig. 2, curves *1, 2*). The curves in Fig. 2 are similar to those describing copolymerization in DMSO [10], but the ratio of

0.25	43.5	19.1
0.50	10.8	8.1
0.75	1.4	1.3

the rates of BA and VSI consumption depends on the nature of the solvent. Table 2 shows that, in pyridine, this ratio is lower in all the cases than that in DMSO; therefore, the copolymers prepared in pyridine should be more uniform in composition than those prepared in DMSO.

The ratio of the rates of BA and VSI consumption in the reaction mixture also depends on the ratio of the monomers: it decreases with increasing mole fraction of VSI in the mixture of the monomers from 0.25 to 0.75, and at the VSI mole fraction of 0.75 the rates of entering of VSI and BA monomers into copolymerization are very close and almost independent of the solvent (Table 2, A = 1.3–1.4). This suggests that, at the molar ratio VSI : BA = 3 : 1, the probability of formation of copolymers with regular alternation of units is the highest.

To estimate the reactivity of VSI and BA monomers as influenced by the solvent, we evaluated the constants of copolymerization of VSI with BA using the modified Ezrielev–Brokhina–Roskin (EBR) [11] and Kelen–Tüdös (KT) methods [12], considering conversion of monomers, and also computer treatment of experimental data [13]. The calculated values were compared with the results obtained in studying co-

polymerization of VSI with BA in DMSO [10] and also with copolymerization constants in an inert solvent, dichloroethane [14], determined using the universal method (UM) [15]. It can be noted that the solvents used differ dramatically in their influence on the relative activity of the monomers (Table 3), probability of formation of diads, and average length of blocks in copolymer chains (Table 4).

Comparison of the copolymerization constants in an inert solvent, dichloroethane, and in an electron-donor solvent, DMSO, shows that the relative activity of VSI in DMSO decreases. This is caused by the interaction of VSI molecules with DMSO molecules via carbonyl groups of VSI and sulfoxide groups of DMSO, resulting in redistribution of the electron density in VSI molecule, increase in the electron density on the double bond, enhancement of the activity of macroradicals with terminal VSI unit, and decrease in the activity of VSI monomer.

The electron-donor power of pyridine is higher than that of DMSO [7]. Therefore, it can be expected that, in copolymerization of VSI with BA in pyridine, the relative activity of VSI should be decreased further. However, the copolymerization constants in pyridine, on the contrary, are closer to each other than those in DMSO. This is caused by steric factors hampering access of bulky pyridine molecule to the electrophilic centers of VSI molecule.

The evaluated copolymerization constants show that the rate constant of the reaction of the macroradical having the BA terminal unit with BA monomer exceeds the rate constant of the reaction of VSI macroradical with VSI monomer in all of the solvents used (Table 3). Evaluation of the relative activities of monomers in the reaction with macroradicals ($1/r$) shows that VSI monomer reacts with the radical having terminal BA unit more rapidly than with the own radical. In this case, the r_2/r_1 values increase in the

series of solvents pyridine < dichloroethane < DMSO, and the $1/r_1$ values increase in the series pyridine < DMSO < dichloroethane, i.e., when the reaction is carried out in pyridine, the rate constants K_{11} and K_{12} become close. Hence, in synthesis of VSI–BA copolymers in pyridine, the probability f_{11} of addition of VSI monomer to the radical with VSI terminal unit to form diads M_1M_1 is higher than that in the reactions in the other solvents (Table 4).

The value of $r_1r_2 < 1$ suggests the possibility of alternation of units in the copolymer, but the effect of cross addition of monomers to macroradicals is insignificant. The tendency for formation of alternating copolymers is pronounced only at VSI mole fraction in a mixture of monomers of 0.70–0.75 (Table 4), which is in good agreement with the conclusion made from Table 2.

The influence of an electron-donor solvent, pyridine, on the cross addition and probability of formation of diads M_1M_2 and M_2M_1 is similar to the influence of another electron-donor solvent, DMSO, on these processes. The probability $f_{12} = f_{21}$ increases in the order DMSO < pyridine < dichloroethane. This confirms validity of the hypothesis that electron-donor solvents (DMSO, pyridine) decrease the relative activ-

* (↓) Increase and (↑) decrease.

ity of VSI in copolymerization with BA as compared to an inert solvent. However, as compared to DMSO, pyridine is favorable for preparing copolymers more uniform in composition.

Taking into account variation of the VSI content in the mixture of monomers with increasing conversion (Table 5), we determined the probability of formation of diads and the average length of blocks in the copolymer chains in various solvents (Table 6). Calculation was carried out by the formulas from [16, 17] using computer software [18].

Tables 5 and 6 show that the high reactivity of BA, responsible for the higher rate of its consumption in the reaction mixture, results in enrichment of the monomer mixture in less active VSI. Therefore, with increasing conversion, the probability of formation of diads M_1M_2 and M_2M_1 increases and the probability of formation of diads containing BA units (M_2M_2) decreases. To estimate the composition uniformity of the copolymers, it is also important to know how the probability of formation of these structures will change with increasing degree of conversion. Table 7 shows that the weaker changes are observed in copolymerization in pyridine: as the degree of conversion of the monomers increases from 0 to 50% (at VSI mole fraction in the monomer mixture of 0.50), the probability of formation of diads M_1M_1 increases by a factor of only 2, that of diads M_1M_2 and M_2M_1, by a factor of 1.2, and that of diads M_2M_2 decreases by a factor of 1.5. When the reaction is carried out in DMSO, these changes are significantly stronger (Table 7).

Therefore, performing the reaction in pyridine allows synthesis of compound whose microstructure depends on conversion of monomers to the least extent, i.e., of copolymers more uniform in composition.

CONCLUSIONS

(1) Experiments on copolymerization of *N*-vinylsuccinimide with *n*-butyl acrylate confirm the influence of the electron-donor power of solvents on the relative activity of monomers and show that electron-donor solvents decrease the relative activity of *N*-vinylsuccinimide.

(2) When the reaction is carried out in pyridine, the relative variations of the probability of diad formation and of the average length of blocks with increasing conversion are the weakest. This allows synthesis of copolymers more uniform in composition, whose microstructure varies less significantly with conversation.

Abstract—The structural parameters of the aggregates of macromolecules of linear flexible-chain poly{*N*,*N*'-bis[4,4'-sulfonylbis(4,4'-phenoxyphenyl)][4,4'-(1,3-phenylenedioxy)bis(phthalimide)} in *N*-methyl-2-pyrrolidone solution and of the clusters of macromolecules on the surface of polyetherimide films formed from the solution were calculated from the capillary-viscometric and electron-microscopic data using the cluster model.

Substantiated choice of the concentration regimes of preparing films and coatings from solutions of polymers is topical for polymer processing technology. Of special interest are aromatic polyetherimides suitable for preparing high-strength and heat-resistant materials [1]. It is known that solution or melts of meltable polyetherimides can be processed directly, yielding thin and ultrathin films and coatings [2]. However, the factors governing the polyetherimide structure in solids at varied concentration c of the polymer in solution are studied inadequately.

As known [3], the structure of the physical network of macromolecules in films and coatings prepared from polymer solutions depends on the macromolecule concentration. The physical network sites are the aggregates or clusters of macromolecules forming in solution [4]. Such clusters have a fractal nature [4] and are characterized by enhanced density of packing of the macromolecules compared to the average density of the polymer. The cluster density and the volume fraction of the polymer occupied by the clusters are governed, in turn, by the parameters of the physical network of intermolecular contacts of the macromolecules [5]. Formation of aggregates of macromolecules in solution and in the course of film formation can be revealed experimentally. By introducing spin markers into a polymer and studying the behavior of the solution in an alternate magnetic field, it is possible to reveal the resonance absorption at low frequencies due to specific convective movements of the macromolecular aggregates. This resonance absorption is lacking in dilute solutions; it appears when a supramolecular structure (aggregates or clusters of macromolecules) arises and persists until complete solvent evaporation [4].

Importantly, during formation of films and coatings from polymer solutions, the mobility of the macromolecular aggregates sharply decreases as the solvent is removed from the system, and the fundamental time of relaxation of the macromolecules and their aggregates increases exponentially in concentrated solutions of polymers with increasing $[\eta]c$ ($[\eta]$ is the intrinsic viscosity) [6]. In this case, the time of the structural relaxation of the clusters, owing to their large size, should substantially exceed the characteristic film formation time [7]. This suggests that the topology of the cluster structure of the polymer films is predetermined by the hydrodynamic parameters of the macromolecular aggregates in solution.

Correlations between the hydrodynamic parameters of the macromolecular aggregates in solutions and the structural parameters of the clusters in a solid can be studied using the fractal cluster model [8]. This model predicts how the cluster density will vary depending on the polymer concentration in solution n [9], which is essential for the substantiated choice of the optimal concentrations for forming polymer films and coatings from solutions.

In terms of the cluster model, formation of a continuous network of intermolecular contacts of macromolecules in solution (an infinite cluster) involves successive formation of finite aggregates (clusters) and cluster–cluster aggregation of macromolecules. The relative density ρ of the sites of the fractal cluster for the Euclidean space with the dimensionality $E = 3$ varies [8] as

1070-4272/03/7607-1127$25.00

$$\rho = sV/\langle V\rangle \sim (\langle V\rangle/V)^{D/3-1}. \quad (1)$$

Here, V is the effective hydrodynamic volume of the macromolecule; $\langle V\rangle$, volume of the aggregate of macromolecules; D, fractal dimension; and s, degree of aggregation.

A transition from finite clusters to infinite cluster or to a continuous fluctuation network of intermolecular contacts of macromolecules near the threshold concentration of the polymer in solution c_{thr} is accompanied by a change in the fractal dimension D of the particles [3, 9].

In [10], we studied the hydrodynamic behavior and aggregation of the macromolecules of amorphous poly{*N*,*N*'-bis[4,4'-sulfonylbis(4,4'-phenoxyphenyl)]-[4,4'-(1,3-phenylenedioxy)bis(phthalimide)} (PEI) in an *N*-methyl-2-pyrrolidone (MP) solution. Interpretation of the viscometric data in terms of the cluster model showed that the density of the macromolecular aggregates in solution decreases with increasing $[\eta]c$. We showed that a transition from a moderately concentrated ($[\eta]c$ = 3–7) to concentrated ($[\eta]c > 7$) PEI solution corresponds to the threshold concentration c_{thr} of 13.5 ± 0.5 g dl^{-1} for linear PEI. At $c >$ 13.5 g dl^{-1} or $[\eta]c > 7$, the degree of aggregation of the macromolecules unlimitedly grows and the concentration of the clusters decreases. This suggests formation of a continuous fluctuation network of intermolecular contacts of the macromolecules in solution [9]. In [10], we also predicted a relatively higher density of the macromolecular clusters in the PEI films obtained at $c < c_{thr}$; the most uniform distribution of the cluster density in the PEI films should be achieved at c_{thr}.

According to the cluster model, the correlation radius ξ of the macromolecular clusters in films should be of the same order of magnitude as the radius $\langle R\rangle$ of the aggregates in solution near c_{thr}; on the scale of the correlation radius ξ, the fractal dimension D and the lattice density ρ_f of the macromolecular clusters in the film should coincide, respectively, with the parameters D and ρ of the aggregates in solution [3, 10, 11].

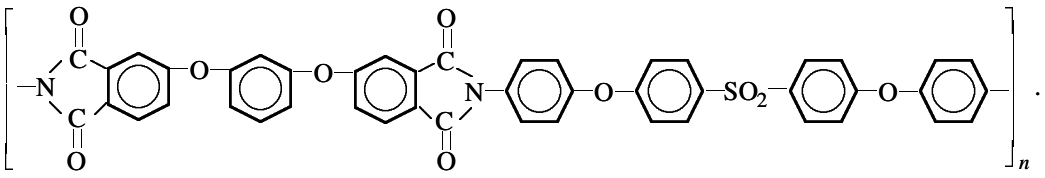
In our previous works [12, 13], we studied the relationships between the structure of the macromolecular clusters in polymer films and the concentrations of polymers in solution during film preparation. Taking the films obtained from solutions of gelatin [12] and epoxy–4,4'-isopropylidenediphenol oligomers [13] as examples, we found that the density of the physical network of macromolecules on the surface of films and coatings depends on the polymer concentration in solution, and the correlation radius ξ of the clusters is close to the hydrodynamic radius $\langle R\rangle$ of the macromolecular aggregates in solution near the threshold concentration c_{thr}.

In this work we continue our previous studies [10] with an electron-microscopic examination of the surface of the PEI films formed from solutions of different concentrations. We applied the cluster model for interpreting the viscometric and electron-microscopic data and calculated the hydrodynamic characteristics of the macromolecular aggregates in solution and the parameters of the cluster structure of the polymer on the film surface.

The aim of this work was to reveal correlations between the hydrodynamic characteristics of the macromolecular aggregates in solution and the parameters of the cluster structure of the film surface at varied polymer concentration.

EXPERIMENTAL

The subject of our study was a sample of amorphous [14] linear flexible-chain aromatic PEI containing in the diamine fragment of the backbone a four-ring 4,4'-sulfonylbis(4,4'-phenoxyphenyl) moiety



PEI was synthesized in two steps by polycondensation of the aromatic diamine and dianhydride in an MP solution, yielding polyamido acid (PAA) in the first stage. The second stage at 120–180°C involved dehydrocyclization of PAA in solution and distillation of the water released in imidization (as a toluene–water azeotrope) [2, 14]. According to the light-scattering and viscometric data [15], the molecular weight of PEI was ca. 5×10^4 Da.

The initial PEI and MP solutions had a concentration of 20.5 g dl^{-1}. The polymer solutions with con-

centrations from 0.1 to 15 g dl^{-1} were prepared by diluting the initial solution.

Films with a thickness of 10–15 μm were prepared from the PEI solutions in MP of the concentrations of 6, 14, 18, and 20.5 g dl^{-1} by casting onto glass substrates followed by vacuum drying at 80°C for 24 h. The degree of imidization of the PEI films was estimated by IR spectroscopy at 93–95% [10].

In the electron-microscopic study of the topological structure of the PEI film surface, we used the technique of gold decoration with bromine preactivation of the surface [14]. The molecular complexes of bromine with electron-donating functional groups of the polymer [16] on the film surface served as active centers for formation of gold particles in decoration [14]. The segments of the surface with enhanced local density of distribution of the decorating particles correspond topologically to the clusters of macromolecules [13, 14]. We proposed this technique in [14] for studying the cluster structure of the surface of PAA and polyimide films.

We studied the PEI film surface formed at the film–air interface. The bromine-activated film surface was subjected to vacuum (0.00133 Pa) sputtering of gold at the flux density of 10^{15}–10^{16} cm^{-2} s^{-1} to an effective layer thickness of 4 Å. The gold particles were separated from the polymer film with a supporting carbon replica and examined on an EMV 100L electron microscope at a ×30 000 magnification.

The topography of distribution of individual gold particles was analyzed using the radial distribution function $g(R)$ obtained by a step-by-step (with a step of $\delta = 3$ nm) scanning of the density ρ_s of distribution of the particles in the micrographs [14]. The scanning area of the micrographs with a ×150 000 magnification during processing on a PC was 2–2.5 μm^2.

The accumulations of the decorating gold particles on the film surface were represented as lattice clusters on the 2D lattice with the intersite distance corresponding to the most probable distance r between the particles and with the coordination number m_s determined using the average number m of the particles in the "coordination" sphere limited by the first minimum of the $g(R)$ function [14].

The average lattice density $\rho_f(R)$ of the clusters on the scale of radius R was calculated by the formula [14] $\rho_f(R) = \rho(R)/\rho'$, where $\rho(R)$ is the average density of distribution of the particles in a circumference with radius R and the center in an arbitrarily chosen particle, and ρ', density of the lattice sites determined by the formulas [17] $\rho' = 0.77/r^2$ for $m_s = 3$ and $\rho' = 1/r^2$ for $m_s = 4$.

The degree of the surface filling with the clusters ρ_f was calculated by the relation [14] $\rho_f = \rho_s/\rho'$ and also as the fraction ω of the surface covered with circumferences with the radius $R = r/2$ and centers in the decorating particles. It should be noted that the parameter ω is a more precise approximation for ρ_f, as it does not require knowledge of the lattice type.

The correlation radius of the clusters ξ was estimated from the position of the inflection point in the $\rho_f(R)$ plot constructed in the logarithmic coordinates [14]. The fractal dimension of the clusters D on the $R \le \xi$ scale was calculated from the slope of this plot using the relation $\rho_f(R) \sim R^{D-2}$ valid for $E = 2$ [8].

The order in the spatial distribution of the clusters was studied using the $g(R)$ function obtained by scanning the distribution density of the decorating particle with a step of $\delta > r$ [14].

The degree of spatial nonuniformity of the cluster density distribution was assessed using the relative fluctuation of the density $\delta\rho = (\Delta\rho^2/\rho)^{1/2}$, which was calculated by the relationship

$$\Delta\rho^2/\rho^2 = 1 + 2\pi\rho_s \int_0^\infty [g(R) - 1)]R\,dR, \qquad (2)$$

where $g(R)$ is the radial distribution function of the cluster density.

The $g(R)$ function was approximated on the $R < \xi$ scale by the power dependence $g(R) \approx R^{D-2}$ valid for fractal clusters [8].

The density ρ of the aggregates and the degree of aggregation s of the macromolecules in solution were calculated using the concentration dependence of the relative viscosity η_{rel} of PEI in MP solution [10] and also the relations from [18]:

$$\rho = (a[\eta]/[\eta]_c)^{a/(a-1)} = (x/\ln\eta_{rel})^{a/(a-1)}, \qquad (3)$$

$$s = (a[\eta]/[\eta]_c)^{a/(1-a)}, \qquad (4)$$

where $[\eta]_c$ is the running intrinsic viscosity [6] calculated from the relationship $[\eta]_c = a[\eta]([\eta]c)^{1-a}$ [18]; a, exponent in the expression $\ln\eta_{rel} = ([\eta]c)^a$, which is equal to $(3 - D)/D$ (D is the fractal dimension of the macromolecule [6]); and $x \equiv [\eta]c$.

For PEI in MP solution, the slope of the three linear portions in the $f(x)$ plot constructed in the $\ln f$–$\ln x$ coordinates (Fig. 1), where $f(x) = [\eta]c/\ln\eta_{rel} =$

* The $\langle R \rangle$ parameters were calculated by the expression $\langle R \rangle = Rw^{-1/D}([\eta]c/\ln \eta_{rel})^{1/(2D-3)}$, where $w = 0.673$ is the packing coefficient, and $R = 20.4$ nm, the macromolecule radius.
** Maximum of the concentration of the aggregates c_s.
*** Threshold concentration c_{thr} of PEI in solution.

$([\eta]c)^{1-a}$, varies in a such way that, in the first portion, $D_1 = 1.60$ ($[\eta]c < 3$), in the second, $D_2 = 1.75$ ($[\eta]c = 3$–7), and in the third, $D_3 = 1.45$ ($[\eta]c > 7$).

To a first approximation, the $\rho([\eta]c)$ plot for PEI in solution can be divided into two portions (Table 1) corresponding to the moderately concentrated and concentrated solutions of the polymer, respectively. A transition from the former ($[\eta]c = 3$–7) to the latter ($[\eta]c > 7$) corresponds to the threshold concentration $c_{thr} = 13.5 \pm 0.5$ g dl^{-1} (Table 1) with $D = 1.75$ in the $6 < c < 13.5$ g dl^{-1} region.

Two stages can be distinguished in the growth of aggregates in the PEI solutions. At $[\eta]c = 3$–7, the degree of aggregation s of the macromolecules tends to slowly increase with increasing concentration c (Table 1), since the probability of formation of the aggregates is primarily determined by pair collisions of the macromolecules. A rapid growth of s at $[\eta]c > 7$ is probably due to the cluster–cluster mechanism of aggregation [9].

The concentration of the aggregates $c_s = c/s$ is at a maximum below the point of transition from finite clusters to infinite cluster at $c < c_{thr}$ [8]. Our data suggest that the plot of the concentration c_s of the macromolecular aggregates vs. the concentration c of PEI in solution passes through a maximum at $c \approx 6$ g dl^{-1} (Table 1). At $c > 13.5$ g dl^{-1} (or $[\eta]c > 7$), the degree of aggregation s increases unlimitedly and c_s decreases, which suggests formation of a continuous network of intermolecular contacts of the macromolecules in solution [9].

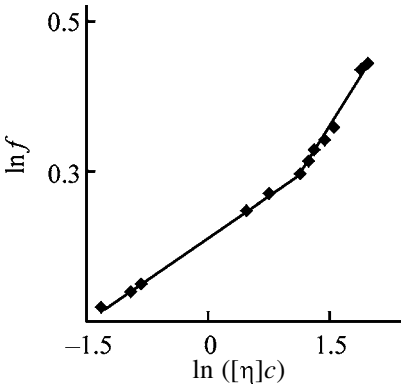

Fig. 1. Plot of $f = [\eta]c/\ln \eta_{rel}$ vs. $[\eta]c$ for PEI in MP solution in the logarithmic coordinates.

Figure 2 presents the electron micrographs of the carbon replicas with gold particles taken from the PEI film surface. The spatial distribution of the decorating particles is nonuniform; the film surface comprises areas characterized by enhanced local density of the particles, which correspond to clusters of macromolecules [14] separated by larger gold particles that are formed by coalescence of the "point" particles [17]. The predominant coalescence of the particles in the space separating the macromolecular clusters is known to be due to intensive chemisorption of bromine in looser areas of the polymer matrix.

The distribution of the cluster density is the most uniform in the case of the film obtained from the PEI solution of the concentration $c = 14$ g dl^{-1} (Fig. 2b). The films obtained from the solutions with $c = 6$ and $c = 20.5$ g dl^{-1} are characterized by major spatial fluctuations of the density (Figs. 2a, 2c).

The computer analysis of the micrographs showed that the decorating gold particles on the surface of the studied PEI films form a continuous spatial network corresponding to the infinite cluster of the PEI macromolecules [14].

Table 2 lists the spatial distribution parameters for the decorating gold particles on the surface of the PEI films. The parameters r and m were derived from analysis [14] of the radial distribution functions $g(R)$ of individual decorating particles on the surface of

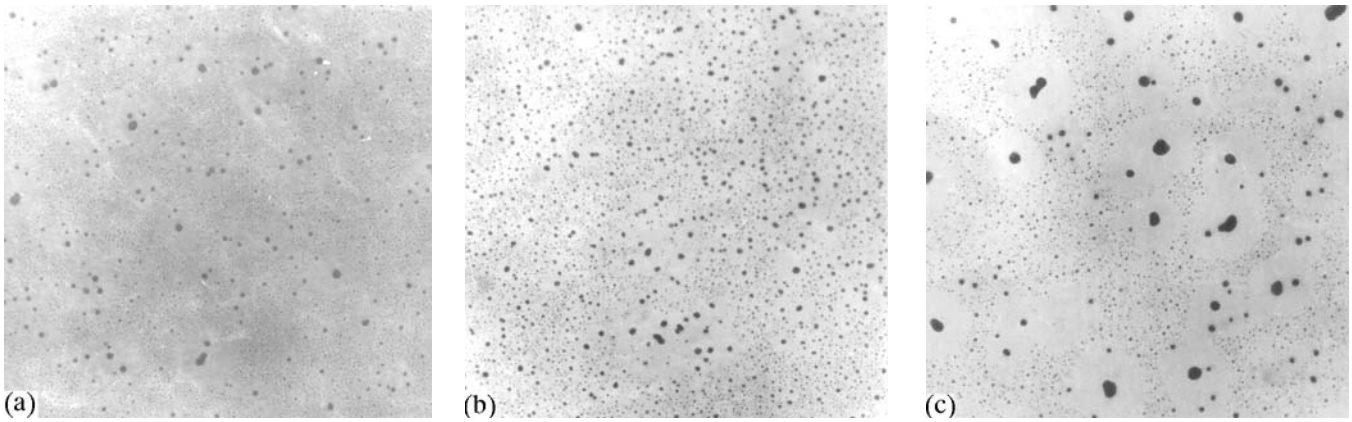

Fig. 2. Electron micrographs of the decorating gold particles on the surface of the PEI films obtained from the MP solution with the concentration c (a) 6, (b) 14, and (c) 20.5 g dl^{-1}. Magnification ×20 000.

the films formed from solutions of different concentrations. Our experimental data suggest that the densest packing of the macromolecular clusters is achieved at the maximal m value corresponding to c = 6 g dl^{-1} (Table 2).

Figure 3 shows the logarithmic plots of the lattice density $\rho_f(R)$ of the clusters of the decorating particles (or PEI macromolecules) vs. the R scale. The parameters ρ_f for the clusters were calculated using a hexagonal lattice with m_s = 3. This choice was correct, as evidenced by good agreement between the degrees of filling of the lattice with gold particles ρ_f and the fraction w of the surface covered by the circumferences representing the particles (Table 2).

For the PEI films formed from the solutions with concentrations c of 14, 18, and 20.5 g dl^{-1}, these plots consist of two linear portions (Fig. 3, curves *2* and *3*). The inflection point in the $\ln \rho_f$ vs. $\ln R$ plots, corresponding to a transition to the portion with a fractal dimension $D \approx 2$, determines the correlation radius ξ of the clusters. The lattice density of the clusters $\rho_f(\xi)$ at $R = \xi$ corresponds to the degree of the surface filling with the clusters ρ_f.

For the PEI film obtained from the solution at c = 6 g dl^{-1}, the plot of $\ln \rho_f$ vs. $\ln R$ consists of three portions (Fig. 3, curve *1*). The first portion ($R \le \xi_1$) corresponds to the fractal dimension of the clusters D = 1.84 ± 0.03, the second ($\xi_1 < R < \xi_2$), to D = 1.7, and $R = \xi_2$ is the point of transition to the portion with $D \approx 2$. Such a run of the $\rho_f(R)$ plot suggests a nonuniform structure of the percolation cluster network. It can be assumed that the skeleton of such a cluster is composed by macromolecular aggregates with the correlation radius $\xi_1 \approx 130$ nm. These aggregates are characterized by a higher local density and D = 1.84 (Table 2).

The lattice density ρ_f of the clusters in the films tends to decrease with increasing concentration c of PEI in solution (Table 2). Importantly, near the threshold concentration c_{thr} the density ρ of the aggregates of the PEI macromolecules in solution as calculated from the viscosity data for E = 2 is virtually identical to the lattice density ρ_f of the clusters on the film surface. Notably, the fractal dimension and the effective size $\langle R \rangle$ of the macromolecular aggregates in solution are close to the parameters D (at $R \le \xi$) and ξ for the cluster in the film (Tables 1, 2).

Figure 4 presents the density distribution functions $g(R)$ for the clusters on the surface of the PEI films. On the $R < \xi$ scale, the $g(R)$ plots obey the power law

Table 2. Parameters of the spatial distribution of the decorating gold particles and the cluster structure of the PEI film surface

c, g dl^{-1}	r, nm	m	$\rho_p(R = \xi) \pm 0.03$	ω	ξ, nm, ±10%	L, nm, ±10%	$D(R \le \xi) \pm 0.03$	$\delta\rho \pm 0.05$

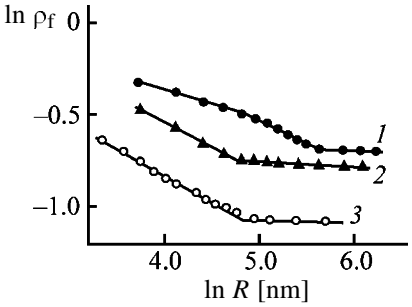

Fig. 3. Logarithmic plot of the lattice density ρ_f of the cluster distribution vs. the scale of radius R on the surface of the PEI films obtained from the MP solutions of the concentration c (*1*) 6, (*2*) 14, and (*3*) 20.5 g dl^{-1}.

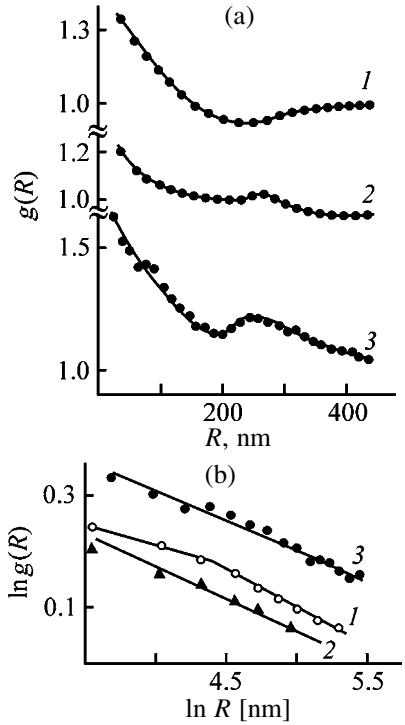

Fig. 4. (a) Density distribution function $g(R)$ for the clusters on the surface of the PEI films obtained from the MP solution of the concentration c of (*1*) 6, (*2*) 14, and (*3*) 20.5 g dl^{-1}, and (b) the same, plotted in logarithmic coordinates. (a) Step of scanning the density of distribution of the decorating gold particles δ = 40 nm; the function values were determined accurately to within 0.02. (*R*) Radius scale, nm.

$g(R) \sim R^{D-2}$ valid for fractal clusters, and in the logarithmic coordinates they are linear (Fig. 4b). These plots suggest that, near the threshold concentration c_{thr} of the polymer in solution, the fluctuations of the spatial distribution of the cluster density in the film are at a minimum. This is also evidenced by the relative fluctuation of the density $\delta\rho$ (Table 2) calculated by formula (2).

In the case of the PEI film obtained from the concentrated solution of the polymer ($c > c_{thr}$), the $g(R)$ function is characterized by a local maximum near $R \approx 250$ nm corresponding to the period L of the spatial alternation of the cluster density or of the network structure of the film surface (Fig. 4a, curve *3*). The parameter L (Table 2) is related to the correlation radius of the clusters ξ as $L \approx 2\xi$ for a hexagonal network (m_s = 3) [14]. Such an order of the topological structure of the film surface may be due to phase segregation in concentrated solutions of polymers, responsible for formation of microdomains differing in the local density of packing of the macromolecules.

CONCLUSIONS

(1) The lattice density ρ of the macromolecular clusters in films tends to decrease with increasing concentration c of the polymer in solution. A spatially uniform network of the percolation cluster characterized by the smallest density fluctuations is formed in the films obtained from solutions near the threshold concentration c_{thr} corresponding to formation of a continuous fluctuation network of intermolecular contacts of macromolecules. Formation of the continuous network of intermolecular contacts in solutions of poly{*N*,*N*'-bis[4,4'-sulfonylbis(4,4'-phenoxyphenyl)]-[4,4'-(1,3-phenylenedioxy)bis(phthalimide} near $[\eta]c$ = 7 is due to unlimited growth of the degree of aggregation s of the macromolecules.

(2) Discrete aggregates of the macromolecules in solutions of poly{*N*,*N*'-bis[4,4'-sulfonylbis(4,4'-phenoxyphenyl)][4,4'-(1,3-phenylenedioxy)bis(phthalimide} at $[\eta]c$ = 3–7 ($c < c_{thr}$) correspond to a nonuniform network of the percolation cluster in the film. The sites of such network are macromolecular aggregates with a relatively higher local density. The network of the percolation cluster in films formed from solutions at $c > c_{thr}$ is characterized by major spatial fluctuations of the density and a decrease in the density due to phase segregation in concentrated polymer solutions.

(3) The established trends in evolution of the cluster structure of the films allow a substantiated choice of the optimal concentrations of the polymer in solution for formation of polymer films and coatings.

Abstract—Chemical and structural transformations in heating of extrusion and porous polyethylene films in air and an inert atmosphere are studied by thermal analysis and differential scanning calorimetry.

In recent years, microporous polymeric films have found wide application for filtration and separation of liquid mixtures and also as separation membranes in chemical power sources. The process for preparation of microporous polyethylene (PE) films by melt extrusion was reported in [1, 2]. The resulting porous films contain through-flow channels, being permeable to fluids and gases. Polyethylene is resistant to organic solvents, acids, and alkalis. Therefore, such films can be used in various media as filters and separators for chemical power sources.

Preparation of porous films involves the extrusion, annealing, and uniaxial extension stages. It is the last stage that provides formation of pores and through channels. The pore structure is stabilized by thermal fixation of samples at elevated temperature, which provides removal of stresses formed in extension of samples in the pore formation stage at room temperature. As a result of the indicated deformation and thermal treatment, porous samples are formed, having an oriented structure and highly developed relief-like surface.

The oriented structure of the films provides good mechanical characteristics, and the relief-like surface, high adhesion to deposited layers and coatings (both polymeric and nonpolymeric), allowing their use as porous supports in composite membrane systems. For example, composite membranes were obtained by polymerization of conducting polymers (polyaniline, polypyrrole) on the surface of porous PE films [3, 4]. Such systems can be used as ion-exchange and gas-separation membranes, and also as gas sensors and active elements in various electrochemical processes.

Wide potentialities of practical use of porous polymeric films initiate the need in comprehensive study of their thermal and deformation behavior. We have performed thermomechanical tests of composite membranes representing polypyrrole layers on a porous PE support [5]. The results showed that, when heated, these systems seem to be mechanically stable at temperatures much above the melting point of PE. To interpret this strange result, it appeared advisable to analyze in detail the behavior of PE supports on heating.

In this work, we studied the chemical and structural transformations occurring in porous PE films on heating in various atmospheres. We used as initial samples extruded PE films which were made porous by appropriate treatment.

EXPERIMENTAL

Extruded PE films were prepared by molding commercial HDPE ($M_w = 1.4 \times 10^5$ and $M_w/M_n = 6–8$). The extruded PE films and porous films obtained from them were studied by thermal analysis with a Netzsch STA 429 differential thermoanalyzer. Samples were heated in air or an inert atmosphere (CO_2) from room temperature to 400°C at a heating rate of 1 and 5 deg min^{-1}.

Structural transformations in cyclic heating were studied by differential scanning calorimetry (DSC) with a DSM-2 microcalorimeter at a heating rate of 16 deg min^{-1}.

Photographs of the samples after heating were obtained with an MPB-2 optical microscope at a magnification of 24.

1070-4272/03/7607-1134$25.00

Thermal behavior of the extruded PE films was studied by heating in the dynamic mode in the static air atmosphere (sample weight about 10 mg, heating rate 1 and 5 deg min^{-1}) (Fig. 1, curves *1* and *2*).

The thermal effects over the temperature range 20–300°C reflect melting of the polymer (endothermic peaks with the maxima at 127.7 and 130.5°C at a heating rate of 1 and 5 deg min^{-1}, respectively). With further heating of the melt from 183.6 and 193.1°C (respectively to the indicated heating rates), structural transformations in the polymer start, accompanied by a considerable exo effect but with no weight loss. Moreover, even some weight gain is observed at the temperature corresponding to the onset of the exo peak. Only in the next stage, on reaching 206.9 or 231.3°C (maxima of the exo peaks at a heating rate of 1 and 5 deg min^{-1}, respectively), the first signs of degradation are observed, accompanied by liberation of volatile products, as demonstrated by the TG data.

Experiments on programmed cooling of the sample from 300 to 70°C revealed the lack of weight loss and a distinctly pronounced exo effect of crystallization with the maximum at 113.9°C (Fig. 1, curve *3*).

The observed small weight gain at the onset temperature of the exothermic process can be attributed to thermal oxidation, which was observed previously in the TG curves [6]. Based on general knowledge [7], a quite substantiated hypothesis was put forward that solid oxidation products are formed via hydroperoxides. However, this phenomenon has not been analyzed in the literature yet. The TG curve obtained at a heating rate of 1 deg min^{-1} (Fig. 2, curve *1*) shows 0.5–0.8% weight gain over the temperature range 180–205°C, which is probably due to surface oxidation of the melt with formation of unstable solid products of thermal oxidation in the initial stage of cross-linking. It was demonstrated in the subsequent experiments that the value of this effect is in proportion to the sample weight and in inverse proportion to the heating rate.

These results suggest that the first section of the exothermic peak in the DSC curve is associated with oxidation and formation of hydroperoxides, whereas the second section, most likely, with subsequent cross-linking, since, as known [8], organic peroxides can initiate this process. This conclusion is also supported by the microscopic data obtained in the course of melting of the PE film. In this case, we observed loss in the melt fluidity above 240°C.

It is quite clear that oxidation and cross-linking are

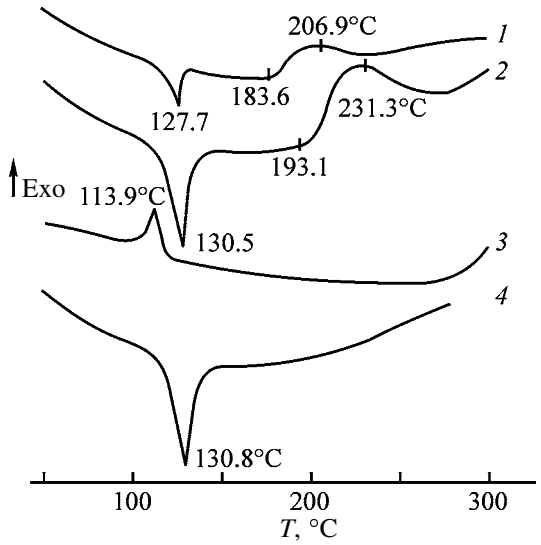

Fig. 1. DSC curves of extruded PE films in (*1–3*) air and (*4*) CO_2. Heating rate (deg min^{-1}): (*1*) 1 and (*2, 4*) 5. (*3*) Cooling at a rate of 5 deg min^{-1}. Netzsch STA 429 thermoanalyzer, sample weight about 10 mg; the same for Figs. 2 and 3. (*T*) Temperature; the same for Figs. 3 and 4.

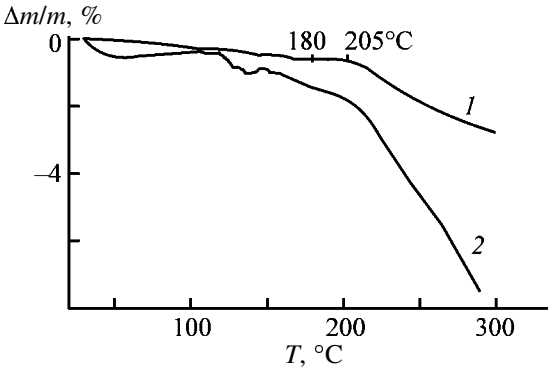

Fig. 2. TG curves in air at a heating rate of 1 deg min^{-1}: (*1*) extruded PE film and (*2*) membrane. ($\Delta m/m$) Weight loss and (*T*) temperature.

irreversible processes. They are completed after the first heating, so that no transformations accompanied by some thermal effects, other than melting and crystallization, are observed in the DSC curves on cooling and repeated heating of the samples.

The sample heated to 300°C and then cooled to room temperature represents a quite regular drop without appreciable signs of surface degradation. Its density is comparable with that of the initial PE granules.

When the experiment was carried out under similar conditions but in the inert CO_2 atmosphere, the endothermic peak caused by melting is identical to that observed in the oxidative atmosphere (Fig. 1, curve *4*). However, in this case, we observed no oxidation and

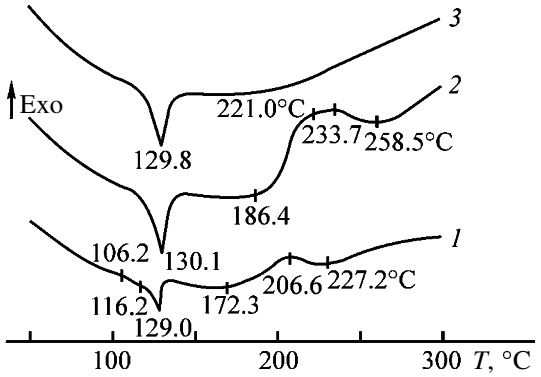

Fig. 3. DSC curves of PE membranes in (*1, 2*) air and (*3*) CO_2. Heating rate (deg min^{-1}): (*1*) 1 and (*2, 3*) 5.

cross-linking effects in the DSC curve over the above-indicated temperature range. Our thought is that this result supports the interpretation offered above for the thermal transformations in the extruded PE samples on heating in air.

On heating of a PE film membrane, we observed the effects similar to those found in studying the extruded films. However, analysis of the results obtained reveals a considerable contribution of the pore structure.

A distinctive feature of the porous samples is the change in their heat capacity at low rates of heating to the melting point. Characteristics knees in the DSC curve of the PE membranes at 101.2, 106.2, and 116.2°C (Fig. 3, curve *1*) can be attributed to changing ordering of particular domains whose relaxation time is comparable with the experimental heating rates. It is known that, above 100°C, the motion of chains in PE crystallites starts, resulting in partial disordering. At a heating rate of 5 deg min^{-1} and higher, these effects are not observed (Fig. 3, curve *2*). It may be suggested that these effects become more pronounced in heating of porous films in which the degree of orientation, size, and structural perfection of crystallites are much higher than in the extruded films, where an ordering loss is not reflected in remarkable thermal effects at temperatures below the melting point.

Figure 2 shows irregular 0.5–1% changes in the sample weight, suggesting thermal oxidation of the sample in the presence of oxygen adsorbed in pores of the membrane. In this case, the amount of adsorbed oxygen is considerably higher as compared to the extruded (nonporous) sample, since the specific surface area of the porous membrane is higher by four orders of magnitude than that of the initial PE film. Correspondingly, the increase in the sample weight caused by oxidation is higher in the membrane too. This is especially pronounced over the temperature range 70–150°C, and, initially, the oxidation is accompanied by increasing weight by virtue of temporary adsorption of primary products of PE oxidation in the membrane pores.

As the melt homogenizes in the course of heating, oxidation is extinguished, and the major changes in the weight are caused by liberation of volatile products of thermal degradation. As for the initial extruded film, in heating of the membrane, the onset of degradation with a remarkable weight loss at 250–300°C is also preceded by PE oxidation and cross-linking starting at 170–180°C. This is supported by the exo effect with the maximum at 206.6 and 221°C at a heating rate of 1 and 5 deg min^{-1}, respectively. It is clearly seen in the curve obtained at a heating rate of 5 deg min^{-1} that the exothermic peak splits into two components with maxima at 221 and 233.7°C.

Structural transformations in PE melt in melting of both films and membranes depend also on the thermal treatment conditions. Figure 4 shows the DSC curves of the extruded film (Fig. 4a) and membrane (Fig. 4b), which were heated in the cycling mode (heating–cooling–reheating). It is clearly seen that no exothermic effects typical of the initial oxidation and cross-linking stages are observed in reheating, and the repeated endo effect of melting is noticeably lower as compared to the initial sample (205 and 175 J g^{-1} in the film and 180 and 150 J g^{-1} in the membrane). Decreasing heat of melting in the second cycle is associated with the orientation loss in the sample in the first heating and also with decrease in its crystallinity, since crystallization conditions in cooling after the first heating differ from those under which the initial samples were obtained, including the lack of orientation. The lack or at least abrupt decrease in the exothermic effects, associated with the oxidation and cross-linking, in the repeated heating cycle suggests that these irreversible processes were practically completed in the first heating cycle.

In heating the membranes in CO_2, we observed no signs of oxidation in the melt as well as no concomitant exothermic effects and weight change (Fig. 2, curve *3*).

The results obtained allow interpretation of the thermodeformation behavior of composite systems based on microporous PE films in which a coating of rigid-chain polypyrrole provides preservation of the sample shape upon heating. In these systems, we

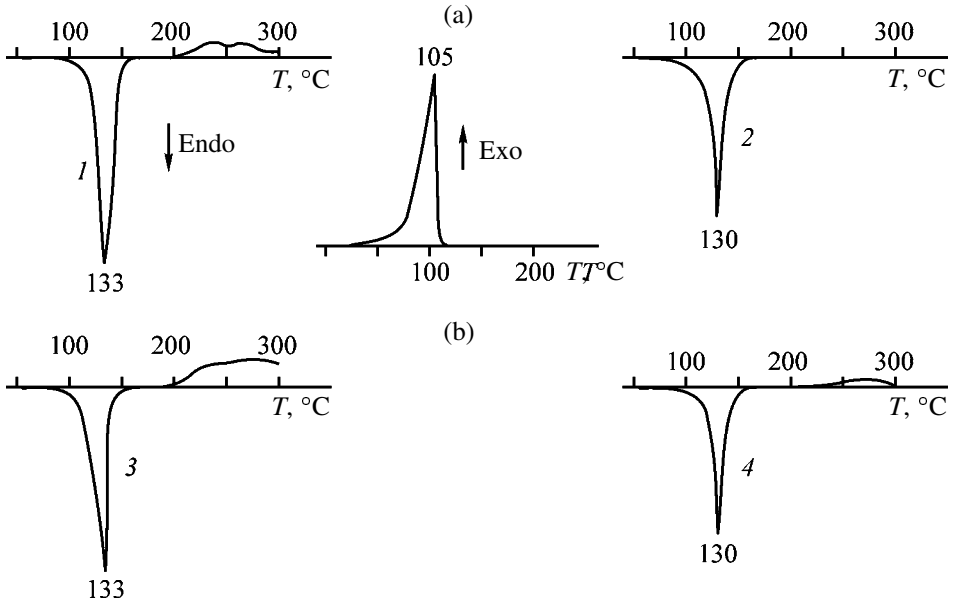

Fig. 4. DSC curves at a heating rate of 16 deg min^{-1} (DSM-2 thermoanalyzer; heating–cooling–heating cycling): (a) extruded PE film and (b) PE membrane. ΔH (J g^{-1}): (*1*) 205, (*2*) 175, (*3*) 180, and (*4*) 150.

observed maintained orientation and good mechanical characteristics of the PE support after heating in air to 200°C [5, 6]. However, irreversible transformations caused by oxidation and cross-linking result in considerable increase in the brittleness after heating to higher temperatures.

In the thermomechanical testing, we monitored evolution of the geometrical size of composite samples in the course of heating under stress in a vacuum (anaerobic conditions). Because of the lack of oxidative degradation in PE melt under these conditions, the systems maintain their dimensions, take a load upon heating, and even preserve their elasticity after heating above 300°C [5].

Above 300°C, degradation and subsequent carbonization proceed similarly in both extruded films and membranes. As demonstrated previously [4, 6] and confirmed in this work, heating above 300°C results in starting degradation with formation of volatile products. Above 400°C, the process becomes avalanche-like, coming to nearly total removal of the polymer chain residues at 500°C and burning out of the 5% solid carbonized residue at 700°C.

The optical micrograph of the PE membrane after heating in air to 400°C demonstrates a strongly carbonized material with an anthracite luster, suggesting high degree of thermal degradation. However, the typical relief-like surface and porous structure of the membrane are still clearly seen.

CONCLUSIONS

(1) Thermal analysis of PE films and porous membranes on their basis in air and inert CO_2 atmosphere showed that their structural characteristics and thermal behavior are controlled by the thermal treatment history.

(2) The surface carbonization effect was observed, controlling some performance characteristics of PE materials.

Abstract—Cross-linking of hydrolyzed Nitron D polyacrylonitrile fiber on exposure to ionizing radiation was studied as influenced by its concentration in the solution, dose rate, and the presence of oxygen in the system. Preparation conditions of polyelectrolyte hydrogel with maximal water absorption by radiochemical cross-linking at the minimal dose were determined.

Polyelectrolyte hydrogels (PEHGs), which can absorb water in amounts hundreds times higher than their weight, are widely used in medicine and in various branches of industry and agriculture [1–3]. Water-soluble acrylamide–sodium acrylate copolymer prepared by radiation cross-linking of base hydrolysis product of polyacrylonitrile fibers can be used as ionic hydrophilic polymer for preparing PEHG [4]. Previously we studied the influence of foreign ions, their concentration, and pH of the solution on synthesis of PEHG by irradiation of the hydrolysis product. The influence of other factors (dose rate, concentration of the hydrolysis product in the solution, and the presence of oxygen) on radiochemical cross-linking of hydrolyzed polyacrylonitrile fiber was not examined.

The aim of this work was to determine the conditions for radiochemical cross-linking of base hydrolysis product of Nitron D polyacrylonitrile fiber to form PEHG with the maximal water absorption at the minimal radiation dose.

EXPERIMENTAL

The main factors affecting radiation cross-linking of polymers in solutions are as follows: the nature of the solvent and polymer (thermodynamic parameters of the solvent as compared to those of the polymer, chemical composition and molecular weight of the polymer, the presence of impurities), solution properties (viscosity, polymer concentration, pH), and irradiation conditions (dose rate, the presence of oxygen in the system) [6]. It is known [7] that water absorption by a polymer depends on its chemical composition, in particular, on the content of ionized groups [7]. When the content of acrylate groups in acrylamide–sodium acrylate copolymer prepared by hydrolysis of polyacrylamide increases, the water absorption by the copolymer and the dose required for its cross-linking increase.

In this work we studied acrylamide–sodium acrylate copolymer with 33 : 67 molar ratio of the units. This is the maximal content of acrylamide units in the copolymer prepared by hydrolysis [8]. Taking our previous results [7] into account, we suggested that this copolymer should be cross-linked at the minimal dose.

The copolymer was prepared by base hydrolysis of Nitron D polyacrylonitrile fiber [9]. The alkali to dry fiber and water to dry fiber ratios in the reaction mixture were 0.55 and 5.5, respectively. The molecular weight of the copolymer was about 10^5 [10]. The reaction mixture was neutralized with acetic acid.

Oxygen was removed by purging solutions with argon. Deoxygenated solutions were irradiated in sealed glass ampules. The polymers were cross-linked by exposure to ^{137}Cs γ-radiation on an LMB-γ-1M unit at the dose rate P = 0.33 Gy s^{-1}. The influence of the dose rate was studied on an RKhM-γ-20 unit with a ^{60}Co source at the dose rates P 0.056 and 0.58 Gy s^{-1}. The absorbed dose was varied from 15 to 120 kGy. The gel fraction content and the water absorption were determined gravimetrically by the procedure in [5]. The results were calculated as average of three measurements.

The dependences of the (a) gel fraction content δ in cross-linked hydrolyzate of Nitron D fiber and

1070-4272/03/7607-1139$25.00

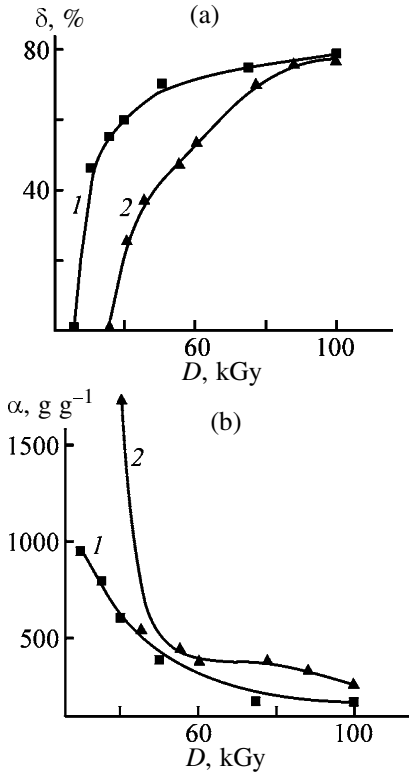

Fig. 1. (a) Gel fraction content δ and (b) water absorption α for Nitron D fiber hydrolyzate cross-linked by irradiation of its 20% aqueous solutions (*1*) in the presence of (*2*) in the absence of atmospheric oxygen as a function of absorbed dose *D*.

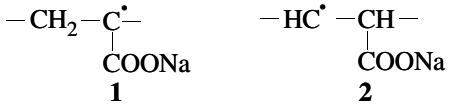
(b) water absorption by this sample on the absorbed dose *D* are shown in Fig. 1. The polymer concentration in these solutions was 20 wt %. As seen from Fig. 1, radiochemical cross-linking of the polymer in a solution in the presence of atmospheric oxygen (Fig. 1a, curve *1*) is more efficient (higher yield of the gel fraction at lower doses) than in a deoxygenated solution of the same concentration (Fig. 1a, curve *2*). The water absorption by 1 g of the polymer cross-linked in the presence of oxygen at a 30 kGy dose is about 1000 g (Fig. 1b, curve *1*), whereas, to reach the same water absorption for the sample prepared in a deoxygenated solution, no less than 40 kGy dose is required (Fig. 1b, curve *2*).

In deoxygenated aqueous solutions, the gel fraction is formed by recombination of macromolecular radicals generated by irradiation of these solutions. The copolymer exposed to radiation contains mainly carboxylate units. In the absence of oxygen, sodium polyacrylate is cross-linked by recombination of macromolecular radicals **1** (α-radicals) and **2** (β-radicals) formed by reaction of water radiolysis products with the polymer [11]:



In the presence of oxygen, α- and β-radicals are converted into peroxy radicals. The rate constant of this reaction (10^8 mol ml^{-1} s^{-1}) is close to that of reaction of sodium polyacrylate with hydroxy radical, the most reactive product of water radiolysis. Liberated peroxy radicals are unstable and transform into carbon-centered radicals by the reaction [10]

More efficient cross-linking of the polymer in the presence of oxygen is likely due to an increase in the current concentration of the carbon-centered macromolecular radicals, since their generation on irradiation of the polymer in a deoxygenated solution is faster than that of α- and β-radicals.

Since the gelation in the presence of oxygen is more efficient than in deoxygenated solutions, the subsequent experiments were performed in the presence of atmospheric oxygen.

Another factor affecting formation and properties of PEHG is the dose rate. The dependence of (a) δ and (b) α on the absorbed dose for a solution of hydrolyzate of polyacrylonitrile fiber cross-linked at various dose rates is shown in Fig. 2. As seen from Fig. 2, the dose rate does not affect the shape of these dependences but changes the minimal absorbed dose causing gelation. When the dose rate increases from 0.056 to 0.58 Gy s^{-1}, the absorbed dose required for formation of the gel fraction increases (28 kGy at P = 0.056 Gy s^{-1} and 38 kGy at P = 0.58 Gy s^{-1}, all other conditions being the same). The samples with the maximal water absorption (750–1100 g of water per gram of cross-linked polymer) were prepared at the absorbed doses close to the doses of gelation onset (Fig. 2b).

As in [11], an increase in the dose of gelation onset with increasing dose rate is due to the fact that bimolecular recombination of macromolecular radicals is accelerated to a lesser extent than side monomolecular chain termination by reaction of the macromolecular radicals with low-molecular-weight radiolysis products. Hence, for the degree of cross-linking at a higher dose rate to be equal to that at a lower dose rate, higher absorbed doses are required. Another

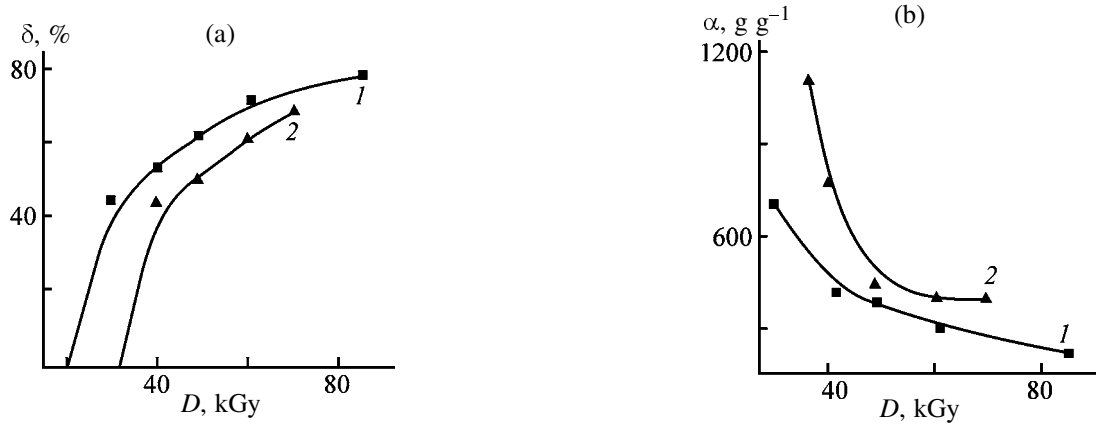


Fig. 2. (a) Gel fraction content δ and (b) water absorption α for Nitron D fiber hydrolyzate cross-linked by irradiation of its 20% aqueous solutions at the dose rate of (*1*) 0.056 and (*2*) 0.58 Gy s^{-1} as a function of the absorbed dose *D*.

factor decreasing the efficiency of radiation cross-linking of the hydrolyzate in a solution at higher dose rates may be degradation of the macromolecule, which is initiated by $OH^{\cdot}$ radicals formed by radiolysis of water.

The depedences of the gel fraction content δ on the dose absorbed by solutions with various concentrations of hydrolyzate of Nitron fiber are shown in Fig. 3. As seen from Fig. 3, the gel fraction is formed on exposure of solutions with 5–30% hydrolyzate content to γ-radiation of the ^{137}Cs source to doses of 18–35 kGy. Solutions with the concentration of 1–2% are not cross-linked up to the dose of 120 kGy. In the whole dose rate range, the gel fraction content and hence the efficiency of radiation cross-linking increase with increasing the hydrolyzate concentration in the solution.

More efficient radiation cross-linking of concentrated aqueous solutions of the copolymer can be due to high probability of recombination of the macromolecular radicals, which, in turn, increases with shortening of the intermolecular distance in more concentrated solutions.

Data on water absorption of PEHG prepared by irradiation of hydrolyzate solutions with different concentrations are presented in the table. As seen from the table, the maximum of water absorption is virtually independent of the hydrolyzate concentrations and is reached at the dose of gelation onset.

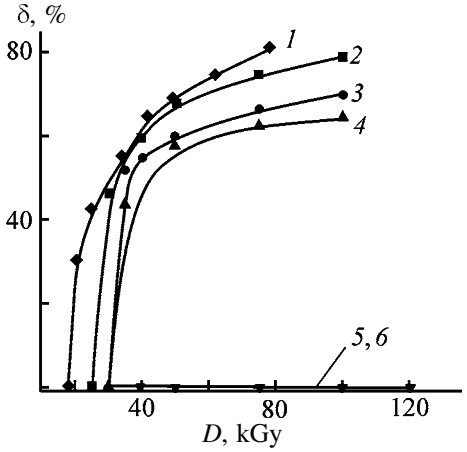

Fig. 3. (a) Gel fraction content δ in Nitron D fiber hydrolyzate cross-linked by irradiation of its (*1*) 30, (*2*) 20, (*3*) 10, (*4*) 5, (*5*) 2, and (*6*) 1% aqueous solutions as a function of the absorbed dose *D*.

CONCLUSIONS

(1) The efficiency of radiation cross-linking in an aqueous solution of acrylamide–sodium acrylate copolymer prepared by base hydrolysis of Nitron D polyacrylonitrile fiber increases in the presence of

Water absorption by Nitron D fiber hydrolyzate cross-linked by irradiation of its aqueous solutions of various concentrations

Abstract—The properties of photographic gelatins in the aqueous phase were studied as influenced by hardeners of various types. The effect of molecular-weight distribution of gelatins, reagent ratios, and temperature on hardening was analyzed.

Gelatin plays various functions in production and operation of light-sensitive materials; in particular, it acts as an active medium in generation of photographic and physicochemical properties of emulsion layers.

In various stages of generation of a photographic material, it is often necessary to change colloidal and chemical properties of gelatin by its chemical modification with hardeners [1]. Therefore, it is urgent to study the effect of various hardeners on the properties of gelatin macromolecules in the bulk [2, 3] and at the phase boundary [4, 5].

In this work we continued our studies of the mechanism of gelatin interaction with hardeners in aqueous medium. We analyzed the relative reactivity of some gelatin fractions with respect to hardeners of various types using high-performance liquid chromatography (HPLC), the molecular mechanism of interaction of gelatin with hardener (high-resolution ^{1}H NMR spectroscopy), the size of gelatin macromolecules chemically modified with hardeners (photon-correlation spectroscopy), and hydrodynamic parameters of macromolecules (capillary viscometry).

Gelatin is a product of thermal, acidic, alkaline, or enzymatic denaturation of collagens. Non-fractionated gelatin is a mixture of α-, β, and γ-chains; two last components are the fragments linked with chemical bonds, double and triple α-chains, or their fragments. These fractions are different in their molecular weight, colloidal, chemical, physicochemical, conformation, and configuration parameters, and reactivity [6].

In [7], the molecular-weight distribution (MWD) of a series of domestic and imported photographic gelatins was studied by gel electrophoresis in polyacrylamide gel and HPLC. Based on these results, a database on the gelatin MWD as influenced by raw materials and treatment procedures was developed.

Using HPLC, we studied the selectivity of interaction of various type of hardeners with separate gelatin fractions as influenced by the contact time, temperature, and reagent concentration. We used a PL gel 10^3 nm Mixed-B column (Hewlett–Packard) with the corresponding precolumn, a PUMP P-500 pump (Pharmacia), and an HP (λ = 630 nm) differential flow refractometer as detector (Hewlett–Packard) [3]. The column was calibrated with respect to water-soluble collagen. The molecular weight M of the gelatin fractions was determined from the following expression:

$$\log M = 3 - 0.057\tau, \quad (1)$$

where τ is the retention time.

In our work we studied polydisperse bone gelatin prepared by alkaline denaturation (sample no. 1) and low-molecular-weight gelatin obtained by acidic treatment of pigskin (sample no. 2); the molecular-weight distribution of the gelatins studied is illustrated in Fig. 1 and Table 1.

In our study we used the hardeners of various types: protected formaldehyde [tetra(hydroxymethyl)-urea (LIKI-1) and *N, N, N, N*-tetra(hydroxymethyl)-

malondiamide (LIKI-19)]; epoxy [triglycidylamine (LIKI-9, TGA) and diglycidyl mono(propylene chlorohydrin) ether of glycerol (DU-652)]; acid chloride [4,6-dichloro-2-hydroxy-1,3,5-triazine (DU-679)]; acryloyl [1,3,5-triacryloylhexahydro-1,3,5-triazine (DU-801)]; and polymeric with hydroxymethyl groups [copolymer of vinylpyrrolidone and *N,N*-di(hydroxymethyl)vinylamine (SPF-1)].

The tests were performed as follows. First, a 2% aqueous solution of gelatins was prepared by the standard procedure; then the hardeners were added [0.01 and 0.001 mol per 100 g of air-dry gelatin (ADG)], and the mixture was heated at 40°C for 1 or 3 h.

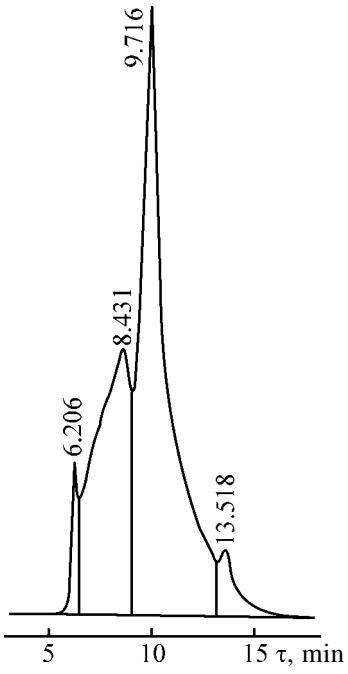

Fig. 1. Chromatogram of bone gelatin prepared by alkaline denaturation (Table 1, sample no. 1). (τ) Retention time (correlates with the molecular weight of the fraction); the same for Fig. 2.

The quantitative changes in the gelatin composition were studied by chromatography. The chromatograms of gelatin (sample no. 1) of alkaline treatment chemically modified with LIKI-19 and TGA hardeners are shown as examples in Fig. 2.

It should be noted that, in all the cases, after hardening the content of gelatin α-fraction decreases, and the greatest consumption of α-fraction is observed in reaction of gelatin with SPF-1 hardener. At the same time, consumption of α-fraction in reaction with LIKI-19 and DU-679 is similar. The trends in the decrease of the content of the α-fraction at hardening with DU-679 and LIKI-9 oxirane compounds are similar. Thus, the trends in variation of the content of the α-fraction clearly depend on the type of the hardener.

In many systems in the course of hardening, a new macromolecular fraction with the molecular weight greater than that of the γ-fraction is formed, and its content in gelatin often increases. The system cross-linking as influenced by the hardener nature, i.e., the total content of the gelatin fractions with molecular weights equal to or greater than that of γ-fraction (%), decreases in the following order: LIKI-19 (45) > SPF-1 (36) > DU-652 = LIKI-9 (30) > DU-679 (22).

Simultaneously with cross-linking, low-molecular-weight fragments of polypeptide chain with molecular weights smaller than that of the α-fraction are formed in all the systems studied. This effect is especially pronounced with DU-679 hardener. The results are summarized in Table 2.

The data on the interaction of hardeners with low-molecular-weight acidic gelatin are shown in Table 3. As seen from the data listed in Tables 2 and 3, hardening depends on the initial fraction composition of gelatins. For low-molecular-weight acidic gelatins, the selectivity of hardeners is more profound, and the most efficient cross-linking agents for the gelatin samples studied are SPF-1, DU-679, and LIKI-19.

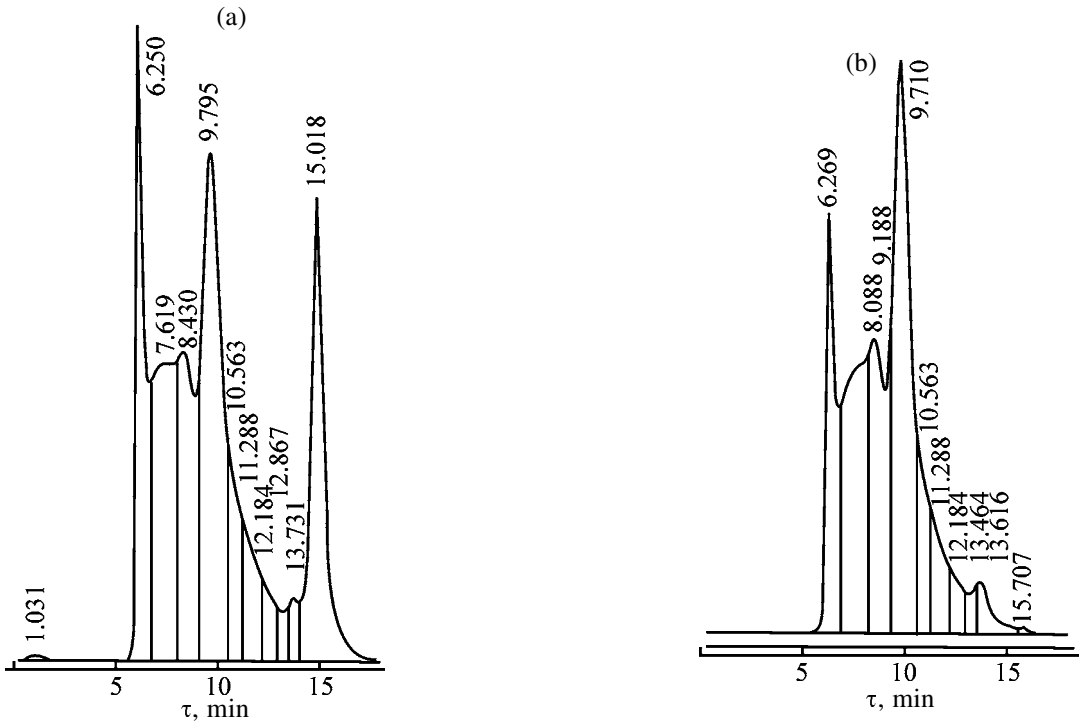

Fig. 2. Chromatograms of bone gelatin (Table 1, sample no. 1) modified with hardeners of various types; contact time with gelatin 3 h, hardener content 0.01 mol per 100 g of ADG, 40°C. Hardener: (a) LIKI-19 and (b) TGA.

DU-801	2.27	16	–	15.5	66.23	–

The temperature also appreciable affects hardening. Gelatin macromolecules in solution can occur in two conformations: globule and collagen-like spiral. At temperatures ≥35°C, gelatin occurs in a globule conformation, and on cooling to temperatures lower than 35°C a collagen-like spiral structure appears.

Hardeners, when added into the gelatin solution, fix the macromolecular conformation typical for the given temperature. Hardening of gelatin at temperatures above 35°C fixes the globule conformation, which remains unchanged at subsequent cooling [8, 9].

To evaluate the temperature dependences of hardening, we studied the interaction of gelatin with hardeners at room temperature by polyacrylamide gel electrophoresis (PAAGE). The fraction composition of gelatin begins to change only on the fifth day after the reagent mixing [3]. The hardening is probably hindered by the partial restoration of the collagen-like spirals and shielding of the reaction centers.

The interaction of various compounds with amino acid groups in the gelatin polypeptide chain can be studied by high-resolution NMR spectroscopy. Interaction of gelatin at 40–45°C in aqueous (D_2O) solution with ionic and nonionic surfactants at wide variation of the component ratio (physical modification) was studied by this method in [10]. Chemical modification of gelatin with LIKI-19 and DU-679 in the globule and spiral conformations was analyzed in [11].

Table 4. Amino acid composition of gelatin

In this work we continued our studies initiated in [10, 11] and, using high-resolution ^1H NMR spectroscopy, analyzed the features of interaction of the LIKI-1 protected formaldehyde hardener with amino acid fragments of the gelatin polypeptide chains at 40°C, when the gelatin macromolecules occur in the globule conformation. The effect of the degree of linking between the gelatin and LIKI-1 hardener was also evaluated.

In these tests, we used the gelatin prepared by alkaline treatment of cattle bones (Kazan Gelatin Plant, Tasma Production Association, Kazan, Tatarstan, Russia). The MWD of the gelatin sample was studied by HPLC (Table 1, sample no. 3).

The 0.3% gelatin solutions in D_2O were prepared by the standard procedure; hardening of the gelatin with LIKI-1 reagent was performed at 60°C for 3 h, the hardener : gelatin ratio was from 10^{-2} to 10^{-4} mol per 100 g of ADG.

The high-resolution ^1H NMR spectra were recorded on a Bruker AC-200 spectrometer (200 MHz) with sodium 2,2-dimethyl-2-silapentane-5-sulfonate [$(CH_3)_3SiCH_2CH_2CH_2SO_3Na$, CSS] as internal reference. The spectra we recorded in a single-pulse mode with suppression of the water signal; sufficiently high signal/noise ratio was obtained after 100–300 scans.

The NMR spectra were analyzed taking into account the chemical composition of the gelatin. The data on the composition of amino acid fragments ω_{am} in gelatin are given in Table 4.

As seen from published ^{1}H NMR data [12], the macromolecules in the globule conformation give high-resolution spectra (Fig. 3, Table 5), which is probably due to the high mobility of the amino acid fragments. In this case, the resonance signals of protons at various carbon atoms (β-C, γ-C, and δ-C) in the side chain are well resolved.

The spectra of unmodified gelatin in D_2O (Table 1, sample no. 3) at 40°C (Fig. 4a) are similar to those recorded previously [11, 12]. The chemical shifts of protons of individual amino acid residues and the intensity of signals well agree with published data. In the general case, the integral intensity is proportional to the number of hydrogen atoms contributing to the ^{1}H NMR signal.

Figure 4b shows the high-resolution ^{1}H NMR spectrum of LIKI-1. The resonance lines are well resolved. The signals (Table 6) were assigned on the basis of their relative intensities.

A high-resolution ^{1}H NMR spectrum of the gelatin solution modified with LIKI-1 hardener is shown in Fig. 4c, and the assignment and integral intensities of the signals are listed in Table 7. The interaction of the components at chemical modification was characterized by changes in the intensities ΔI of the signals in the NMR spectrum of the modified gelatin as compared to the initial gelatin solution in D_2O:

$$\Delta I = I_g - I_m, \quad (2)$$

$$\Delta = (\Delta I / I_g) \times 100, \quad (3)$$

where I_g and I_m are the integral intensities of the signals in the spectrum of unmodified and modified gelatin, respectively, in the region of a given chemical shift and Δ is the ratio characterizing changes in the

integral intensity due to the chemical modification of gelatin (%).

As seen from Table 7, the most pronounced weakening of the signals of all the amino acid fragments studied is observed at the LIKI-1 content of 10^{-4} mol per 100 g of ADG.

At LIKI-1 content of 10^{-3} and 10^{-2} mol per 100 g of ADG, the spectral lines become broader and the resonance signals of all the side gelatin chains become weaker, but this effect is less pronounced. This is probably due to the reaction of LIKI-1 molecules with each other with increasing hardener concentration. As a result, the effect of hardener on the mobility of the gelatin protons is greater at its content of 10^{-4} mol per 100 g of ADG.

The effect of LIKI-1 hardener on the parameters of gelatin macromolecules in the aqueous phase was studied by photon-correlation spectroscopy. The particle size distribution was determined on a Malvern device at 40°C (λ 632.8 nm, scattering angle 90°); the results are listed in Table 8.

The reaction of gelatin with LIKI-1 protected formaldehyde hardener changes the average and most probable radii of the gelatin macromolecules; average R_1 and most probable R_2 radii increase from 11 and 22 to 18 and 32 nm, respectively. We assume that the arising intermolecular covalent bonds hinder compaction of the gelatin macromolecules.

The viscometric data for gelatin macromolecules were published previously in [13–16]; and the hydrodynamic parameters of the gelatin macromolecules modified with hydroxysuccinimide ester of lauric acid and with sodium dodecyl sulfate (SDS) were evaluated in [17].

In this work we determined the limiting viscosity

number, the viscosity increment, and the axial ratio of gelatin macromolecules modified with various hardeners.

The molecular-weight distribution of the gelatin sample (Table 1, sample no. 3) was studied by HPLC. We used aqueous systems containing 0.3% gelatin modified with LIKI-1 in amounts from 10^{-4} to 10^{-1} mol per 100 g of ADG at 60°C and contact time of 3 h. The viscosity of the resulting solutions was measured with a VPZh-4 capillary viscometer placed in a temperature-controlled cell at 40.0±0.1°C. The internal capillary diameter was 0.37 mm, the outflow time of water was 185 s, and the maximal shear rate near the capillary wall was 204 s^{-1} at 40°C. The solutions were thermostated before the test for 40 min. In viscometric experiments, the gelatin concentration was 3×10^{-1}–4×10^{-3} g cm^{-3}, sample volume 5 cm^3, and solution pH 5.6–6.1.

For our modified gelatin systems, the relative viscosity η/η_0 (where η and η_0 are the viscosities of the solution and solvent, respectively), intrinsic viscosity $[\eta]$, viscosity increment ν, and the axial ratio f of gelatin macromolecules in solution were determined. The intrinsic viscosity was determined by extrapolation of the concentration dependence $[\ln(\eta/\eta_0)]/c$ to zero concentration:

$$\lim [\ln(\eta/\eta_0)]/c\Big|_{c\to 0} = \lim [(\eta/\eta_0 - 1)/c]\Big|_{c\to 0} = [\eta]. \quad (4)$$

The intrinsic viscosity $[\eta]$ and viscosity increment ν are expressed through the weight and volume concentrations, and these quantities are related by the following expression:

$$[\eta] = \nu V, \quad (5)$$

where V is the specific partial volume at infinite dilution, i.e., it is the increase in the solution volume on adding a weight unit (1 g) of anhydrous protein to a large volume of solution.

If the protein dissolution proceeds without changes in the solution volume, then the partial specific volume is equal to the reciprocal density of the dry protein [18]. Busol [18] determined the concentration dependence of the density of aqueous gelatin-containing systems. The density of anhydrous gelatin is 1.35 g cm^{-3}, and it decreases with increasing water fraction in the system. In the air-dry state, gelatin contains 10–13% water (ρ 1.32 g cm^{-3}), and the specific partial volume $V = 1/\rho$ was taken as 0.75 $cm^3\ g^{-1}$.

In accordance with the Simha equation,

$$\lim [(\eta/\eta_0 - 1)/\Phi]\Big|_{\Phi\to 0} = \nu, \quad (6)$$

where ν is the viscosity increment, which depends on the axial ratio f of the ellipsoid of revolution; it is equal to 2.5 for spheres and is greater for all the ellipsoids [19].

The intrinsic viscosity $[\eta]$, viscosity increments ν, and axial ratio f for gelatin macromolecules, calculated from these dependences, are listed in Table 9.

As seen from these data, the conformation state of the gelatin macromolecules in dilute solutions at 40°C is the ellipsoid of revolution with the axial ratio of 33 for the given sample. Upon reaction with the hardener, the axial ratio of the gelatin macromolecule increases with increasing degree of modification.

Table 9. Properties of gelatin modified with LIKI-1 protected formaldehyde hardener in aqueous solutions; contact time 3 h, gelatin concentration 0.3%

LIKI-1 content, mol per 100 g of ADG	$[\eta]$	ν	f
0	66	88.1	33
10^{-4}	68	90.6	33.5
10^{-3}	70	93.3	34
10^{-2}	73	97.3	35
10^{-1}	77	102.6	36

Table 10. Characteristics of modified gelatins with various MWD; hardener concentration 10^{-2} mol per 100 g of ADG, 60°C

Sample no.	Hardener	Contact period of gelatin with hardener, h					
		1			3		
		[η]	ν	*f*	[η]	ν	*f*
4	–	51	68	29			
	LIKI-19	68	91	34	72	96	35
	DU-679	61	81	31	62	83	32
5	–	45	60	26			
	LIKI-19	55	73	29	60	80	31
	DU-679	57	76	30	57	76	30
6	–	49	65	28			
	LIKI-19	58	77	30	63	84	32
	DU-679	60	80	31	61	81	31

The dependences of hydrodynamic parameters of modified gelatin on the hardener type and gelatin MWD are of particular importance. For this study, we chose LIKI-19 and DU-679 hardeners and samples of photographic gelatin differing in MWD (Table 1, sample nos. 4–6). The contact time of the gelatin and hardener was 1–3 h at 60°C. The hardener was added into the 0.1% gelatin solutions in amount of 10^{-2} mol per 100 g of ADG. The viscometric measurements were performed at 40°C; the results are given in Table 10.

As seen, in all the cases studied, with increasing contact time the intrinsic viscosity, viscosity increment, and axial ratio of the gelatin macromolecules increase; and this increase is the most pronounced at hardening of the gelatin sample rich in high-molecular-weight fractions (Table 1, sample no. 4). It should be noted that, at hardening of this gelatin sample with LIKI-19 protected formaldehyde hardener, the increase in the hydrodynamic parameters of macromolecules is greater as compared to DU-679 hardener.

The reaction of polydisperse gelatins rich in α-fractions (Table 1, sample nos. 5, 6) with LIKI-19 and DU-679 hardeners also increases the intrinsic viscosity, viscosity increment, and axial ratio of the gelatin macromolecules, but this increase is smaller and depends to a lesser extent on the hardener type.

The contact time of gelatin and hardener also strongly affects the properties of macromolecules. On addition of LIKI-19, the axial ratio of macromolecules increases with time, whereas in the case of DU-679 the properties of macromolecules only slightly change with time.

CONCLUSIONS

(1) Hardening of gelatin as influenced by the molecular-weight distribution, hardener type, temperature, and reagent ratio was studied.

(2) α-Chains of gelatin are the most reactive in hardening.

(3) Based on high-resolution ^{1}H NMR data, the molecular mechanism of reaction between the modifying agent and gelatin was proposed; the decrease in the integral intensity of the resonance signals of the gelatin protons depends on the degree of modification.

(4) The average and most probable radii of macromolecules increase in the course of hardening.

(5) The gelatin macromolecules in dilute solutions at 40°C in the globule conformation state are ellipsoids of revolution (oblate ellipsoid). At chemical modification with hardeners of various types, the axial ratio increases, and the gelatin macromolecule becomes more asymmetrical.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of Styrene-Containing Oligomer Based on Bottoms from Toluene Distillation in Production of Polybutadiene

Abstract—Chemical modification of styrene-containing oligomer with maleic anhydride was studied. The process conditions and content of maleic anhydride were optimized.

The main avenue in processing and utilization of organic and polymeric wastes [1–5] is preparation from them of oligmers by polymerization or degradation. However, low-molecular-weight polymers prepared from petrochemical wastes and by-products, as a rule, do not have the required set of properties, which largely limits their application. Some characteristics of substances obtained from petrochemical wastes and by-products can be improved by modification [6]. An example of such modification can be reaction with maleic anhydride (MA) [7, 8], allowing introduction into oligomers of additional reactive groups and imparting new properties to the products.

The goal of this work was to modify with maleic anhydride the styrene-containing oligomer prepared from bottoms of distillation of recycled solvent, toluene (TDB), in production of polybutadiene, and also to examine the possibility of using the modified oligomer as impregnating material for improving the properties of wood-fiber boards.

Modification experiments were performed with TDB oligomer containing units of styrene (~75%), 4-vinylcyclohexene (VCH), 1,5,9-cyclododecatriene (CDT), and *n*-2,4,6,10-dodecatetraene (NDT). The viscosity-average molecular weight $\overline{M}_v$ of the oligomer was about 1663.

Experiments were performed as follows. A steel ampule was charged with a styrene-containing TDB-based oligmer containing no more than 5 wt % residual low-molecular-weight products (dry residue ≥95 wt %) and with MA. The reaction temperature was 160°C. The MA content was varied from 3 to 7 wt % relative to the oligomer.

The reaction of MA with the oligomer was monitored by intermittent sampling from the ampule, followed by determination of the viscosity-average molecular weight of the product $\overline{M}_v$ and of the acid number (titration with alcoholic alkali to determine the content of anhydride and carboxy groups [9]).

Experimental studies showed that the course of modification of the TDB-based styrene-containing oligomer depends on the MA content in the reaction mixture (Fig. 1a). By computer treatment of the results, we obtained second-order equations describing the influence of the process time and MA content on the viscosity-average molecular weight $\overline{M}_v$ of the modified oligomers:

$$y_1 = 1578 - 34.43x + 0.92x^2, \quad c_{MA} = 3.0 \text{ wt \%};$$

$$y_2 = 1572 - 42.26x + 1.16x^2, \quad c_{MA} = 5.0 \text{ wt \%};$$

$$y_3 = 1634 - 69.38x + 2.06x^2, \quad c_{MA} = 7.0 \text{ wt \%}.$$

All the curves pass through a minimum at the reaction time of 17–19 h. Then the molecular weight of the oligomer starts to grow.

At a low content of MA in the reaction mixture (up to 3.0 wt % relative to the oligomer), in the initial stage of the process the viscosity and hence $\overline{M}_v$ slightly decrease. This trend is particularly pronounced at the reaction time of 17–19 h. Longer (>19 h) reaction results in the growth of the viscosity and hence $\overline{M}_v$.

At the MA content increased to 5–7 wt % relative to the oligomer, the degradation processes in the initial stage become less pronounced (Fig. 1a), as indicated by the less pronounced decrease in the molecular weight of the modified oligomer.

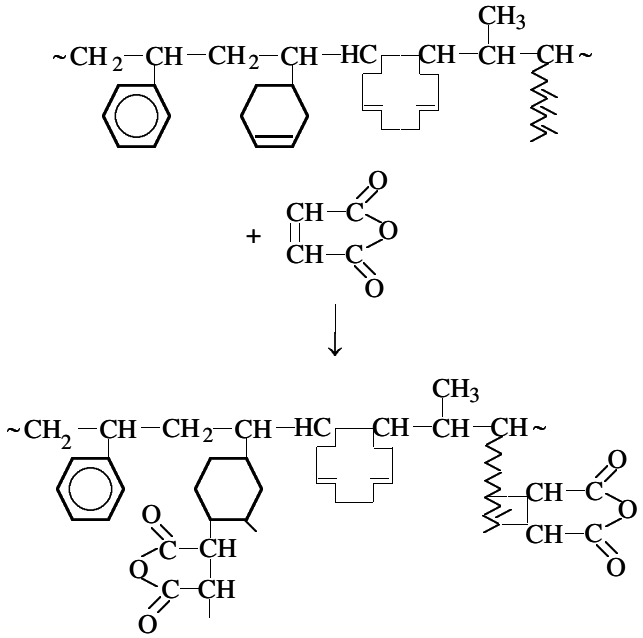
The acid number (Fig. 1b) grows with increasing synthesis time and MA dosage. This suggests predom-

1070-4272/03/7607-1152$25.00

inant occurrence of degradation processes which primarily involve macromolecules with a high molecular weight and also highly unsaturated VCH, CDT, and NDT units. This is also indicated by an increase in the acid number of successively taken samples of the modified oligomer (Fig. 1b). However, increased content of MA causes formation of a precipitate. At an MA content of 3.0 wt %, no precipitate is formed.

The reaction of MA with the TDB-based styrene-containing oligomer can follow several pathways, of which the major pathways are (a) Diels–Alder addition of MA to double bonds [10], decreasing the extent of unsaturation, and (b) copolymerization (or cross-linking) of oligomer molecules with MA, increasing the molecular weight of the resulting product. The relative contributions of these pathways depend on the modification conditions and MA content.

At a low content of MA, the number of the cross-links formed is small, and the modified oligomer remains soluble. At increased MA content, a precipitate forms, which may be due both to formation of insoluble three-dimensional structres and to limited solubility of unchanged MA:



Thus, our results show that the MA content should not exceed 3.0 wt %, since the precipitate formed at a higher MA content causes the loss of the oligomers and gives rise to problems with utilization of this new kind of waste.

The IR spectrum of the MA-modified styrene-containing oligomer based on TDB (Fig. 2) contains characteristic absorption bands of the monosubstituted benzene ring at 700, 760, 1490, and 1600 cm^{-1}. Also,

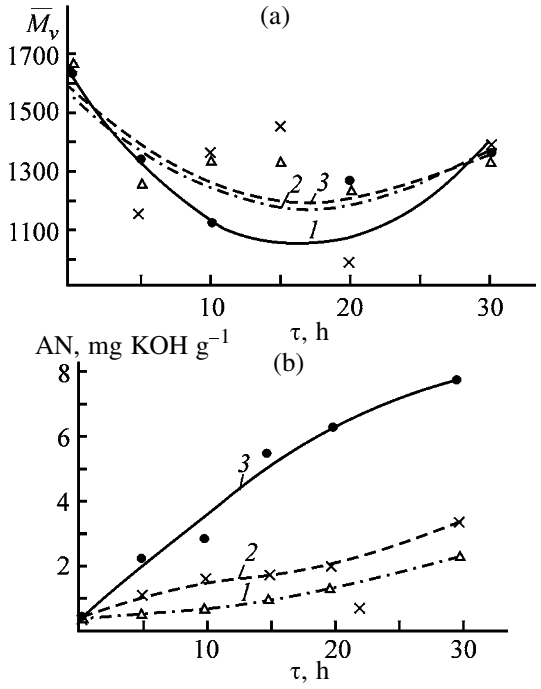


Fig. 1. (a) Viscosity-average molecular weight $\overline{M}_v$ and (b) acid number as functions of the modification time τ. MA concentration, wt %: (*1*) 3.0, (*2*) 5.0, and (*3*) 7.0.

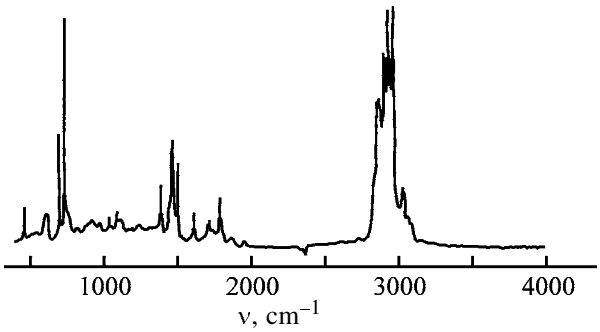

Fig. 2. IR spectrum of modified styrene-containing oligomer based on TDB. (ν) Wave number.

the ν(CO) bands appear at 1710, 1780, and (for the anhydride ring) 1840 cm^{-1}. These bands confirm addition of MA to the oligomer.

Published data suggest that the modified styrene-containing oligomer based on TDB may be promising for protective treatment of wood and wood-fiber boards. For these purposes, it will be possible to utilize substandard oligomers unsuitable for use in paint-and-varnish materials, polymeric formulations, etc. [11, 12].

However, the applicability of styrene-containing low-molecular-weight compounds prepared from petrochemical wastes is limited by the necessity of using an organic solvent, because the products are highly viscous or solid under normal conditions. An

Experimental and calculated parameters of the strength and water resistance of wood-fiber boards

Parameter	Calculation	Experiment	Control*
Ultimate bending strength, MPa	34.3	32.1	15.2
Swelling with respect to thickness in 24 h, %	17.5	17.9	26.0
Water absorption in 24 h, %	20.1	19.5	40.1

* Unmodified wood-fiber boards.

interest in the MA-modified styrene-containing oligomer based on TDB is due the fact that this product remains liquid under normal conditions after distillation of the solvent and other low-boiling components. This allows elimination of solvents from the impregnation process, significant improvement of the environmental characteristics of the process, and its simplification. Thus, the process becomes more promising for commercial implementation.

The process optimization was performed using the 4×4 Latin square experimental plan [13]. As the main factors exerting the major influence on the water resistance and strength of wood-fiber boards, we chose the impregnation temperatre (60, 80, 100, 120°C; factor A), heat treatment temperature (70, 100, 130, 160°C, factor B), and heat treatment time (1, 3, 5, 7 h, factor C). The copolymer content in the wood-fiber boards was evaluated from the weight gain of the sample. After conditioning, the boards were tested according to GOST (State Standard) 19 592–80. The content of the modified oligomer in the wood-fiber boards depended on the process conditions and varied from 12.6 to 19.4 wt %.

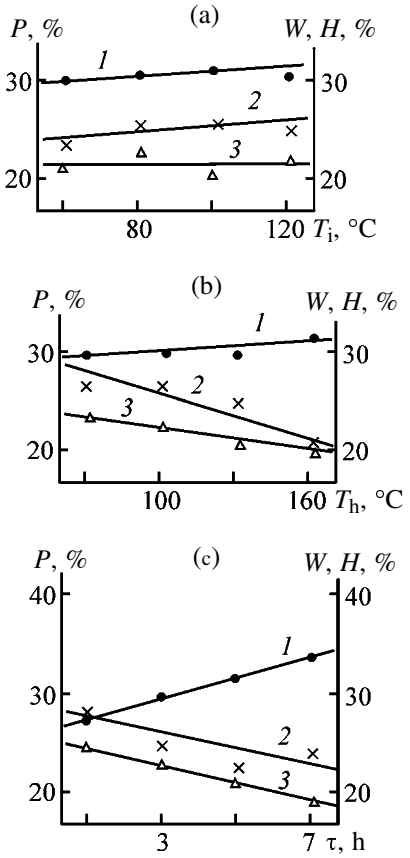

Fig. 3. Properties of modified wood fiber boards as functions of (a) impregnation temperature T_i, (b) heat treatment temperature T_h, and (c) heat treatment time τ. (*P*, *1*) Bending strength, (*W*, *2*) water absorption, and (*H*, *3*) swelling with respect to thickness.

Figure 3 shows the results of testing wood-fiber boards for the strength and water resistance. It is seen that the strongest influence on the properties of the modified wood-fiber boards in exerted by the heat treatment time; the influence of the impregnation and heat treatment temperature is weaker.

The optimal conditions for impregnation of wood-fiber boards with the modified TDB-based oligomer are as follows: impregnation temperature 60°C, heat treatment temperature 160°C, and heat treatment time 7 h. The strength and water resistance of the modified wood-fiber boards, calculated for these conditions, are compared with the experimental values in the table. These values show good agreement.

CONCLUSIONS

(1) A study of chemical modification with maleic anhydride of the styrene-containing oligomer based on the bottoms from toluene distillation showed that the optimal content of maleic anhydride is 3.0 wt %. At a higher content of maleic anhydride, a precipitate is formed.

(2) One of the promising applications of the modified oligomer obtained is treatment of wood-fiber boards.

Abstract—The possibility was examined of processing into a casted item (molding) of the crystallizing thermoplastic polyimide derived from 3,3'-diaminobenzophenone and 3,3',4,4'-benzophenonetetracarboxylic dianhydride and of composites of this polyimide with fullerenes. The tribological characteristics of the moldings were studied.

The demand for structural materials with enhanced properties stimulates active studies of thermoplastic ("fusible") crystallizing polyimides (PIs) [1]. Materials based on these polyimides, in particular, composite materials [2], combine high levels of mechanical properties, heat resistance, and resistance to cracking. The above-noted properties of polyimide materials attract the interest of tribologists whose efforts are aimed at enhancing the antifriction and antiwear characteristics of friction units in machines and mechanisms, in particular, of dry friction units [3].

A promising way to improve the performance of polymeric materials, attracting growing researchers' interest, is modification with fullerenes. For example, it was reported that fullerenes improve the tribological characteristics of polymeric materials in sliding friction [4].

It was shown previously [2] that the crystallizable PI derived from 3,3',4,4'-benzophenonetetracarboxylic dianhydride and 3,3'-diaminobenzophenone (PI BZP–3,3'BZP) can exist in two crystalline modifications: CM-1 with the melting point T_{m1} = 275–290 and CM-2 with T_{m2} = 330–350°C. The structural features of this polyimide are determined by the conditions of its preparation [5]. It was found [5, 6] that formation of amorphous or partially crystalline PI BZP–3,3'BZP is mainly governed by the solvent used in synthesis and imidization of the prepolymer. The partially crystalline PI with the higher melting point T_{m2} is formed under conditions of thermal imidization, whereas chemical imidization in solution in an amide solvent yields the low-melting crystalline modification CM-1. In this case, the viscosity of the polymer melt η (Pa s) at 300–320°C is fairly low ($\log\eta$ = 2.8–3.5), which allows its processing into a matrix of a composite at temperatures close to the glass transition point T_g (245–250°C).

In this work we examined the possibility of processing of various structural modifications of PI BZP–3,3'BZP into a cast item (molding) and studied the mechanical and tribological characteristics of the resulting material. Our goal was also to develop fullerene-containing PI BZP–3,3'BZP composites, prepare moldings from them, and assess the prospects of using fullerene-containing PIs in dry friction couples with steel.

EXPERIMENTAL

Synthesis of 3,3'-diaminobenzophenone and purification of 3,3',4,4'-benzophenonetetracarboxylic dianhydride were described in [5]. The polyamido acid (PAA) was prepared by adding a stoichiometric amount of the dianhydride at 50°C into a solution of the diamine in a solvent suitable for obtaining the

1070-4272/03/7607-1156$25.00

required structural modification according to [5]. The concentration of the PAA solution was 25% (here and hereinafter, wt %), and the synthesis time, 4 h.

Powdered PI samples were prepared by thermal and chemical imidization of PAA. To obtain thermally imidized powdered PI, a 1% solution of PAA was precipitated in benzene, and the precipitate was filtered off and vacuum-dried at 60°C. Imidization was performed by successively heating the PAA powder at 100, 200, 230, and 250°C for 30 min at each temperature. For chemical imidization, the reaction solution of PAA was diluted to 5% concentration with the same solvent as that used for PAA synthesis. Then the imidizing mixture consisting of triethylamine and acetic anhydride (2 and 3 mol, respectively, per mole of elementary units of the polymer) was added. After stirring for 4 h at 50°C, the mixture was cooled to room temperature and allowed to stand for 20 h. The precipitated polymer was filtered off, washed, and dried as described in [5].

To obtain fullerene-containing polymeric samples, we used a mixture of fullerenes C_{60} and C_{70} (weight ratio 78 : 22).[1]

The viscosity of melts obtained from PI powders was determined on a PIRSP rheogoniometer (Russia) with a cone–plate working unit (cone angle 1°, diameter 40 mm) in the constant shear rate mode (10^{-2} s^{-1}) at a preset temperature.

By differential scanning calorimetry (DSC), we determined the glass transition (T_g) and melting (T_m) points (°C) and the enthalpies of melting (ΔH, J g^{-1}) of the PI samples obtained, which were subsequently used for preparing moldings. The measurements were performed with a DSM-2M microcalorimeter at a scanning rate of 10 deg min^{-1}.

The TG curves were taken on a modified (model C) MOM derivatograph (Hungary) in air at a heating rate of 10 deg min^{-1}.

The mechanical characteristics of films were determined in the uniaxial extension mode with samples in the form of 2-mm-wide bands with the working part length of 20 mm. The tests were performed on a UTS 10 universal mechanical testing installation (UTStestsysteme, Germany) at an extension rate of 20 mm min^{-1} (100% of initial length per minute). From the testing results, we determined the modulus of elasticity E (MPa), tensile strength σ_t (MPa), and elongation at break ε_b (rel. %).

[1] The mixture was provided by the Fullerene Technologies Company, Ltd. (St. Petersburg).

The glass transition points of polyimide films were determined thermomechanically on a UMIV-3 installation in the mode of uniaxial extension with a tensile stress of 0.5 MPa under conditions of linear heating at a rate of 5 deg min^{-1}.

Cast samples (moldings) based on PI powders were prepared as follows. Pellets 2–3 mm thick and 20 mm in diameter were pressed from PI powders at room temperature and a pressure of 200 atm. The pressed pellets were heated in a press mold without pressing at 320°C for 1 h. After heating, the mold was removed from the oven and finally pressed for 2–3 min at 150 atm. The mold was then cooled to 60–70°C over a period of 40 min under a pressure of 100–150 atm.

From the pellets thus prepared, we cut $5 \times 2 \times$ 18-mm flat samples for three-point bending tests at a loading rate of 1.3 mm min^{-1} and base length of 15 mm. The bending strength σ_b (MPa), Young's modulus E (MPa), and breaking strain ε_b (rel. %) were determined according to [7].

The tribological parameters and surface characteristics of moldings were studied on a friction installation described in detail in [8]. The face scheme of friction was realized. A rotating steel counterbody (in the form of a ring) was in contact with the flat surface of a polymeric disk 20 mm in diameter and 3 mm thick. The contact pressure was varied within 1.7–6.7 MPa, and the sliding velocity, within 0.047–0.138 m s^{-1}. The following main tribological parameters were determined: coefficient of dry sliding friction f, weight wear Δm (mg), and the dimensionless quantity, linear wear intensity I_w, defined as $I_w = V/(SL)$, where V is the volume (m^3) of the material removed from the contact surface in a definite time (10 min); S, minimal contact surface area (m^2); and L, sliding path (m) equal to 100 m.

In this work we also collected and analyzed polymer particles formed during the test, using a Videolab 2 automated image processing system [9]. With this system and software supplied with it, it is possible to determine the total number of particles in the visual field of the microscope, the area enclosed by the paritcle contour, and perimeter and form factor of each particle. Electron-microscopic examination of the wear particles was performed with a JSM-35 electron microscope (Japan).

By varying the conditions of PI BZP–3,3'BZP synthesis (according to [5]), we obtained powdered PI samples of the same chemical composiiton but different supramolecular structures. We compared the vis-

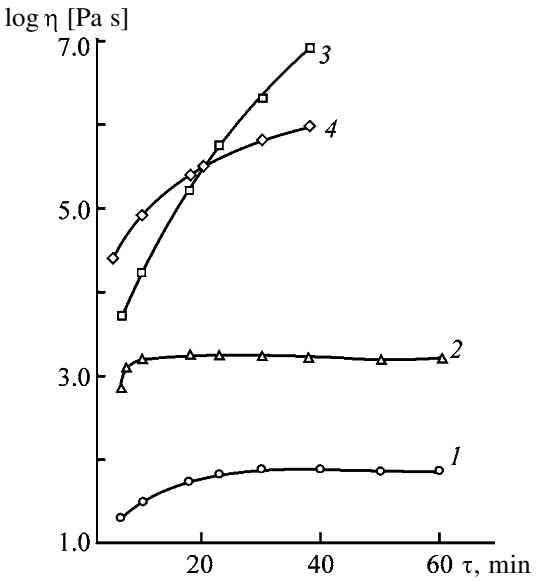

Fig. 1. Viscosity η of the PI BZP–3,3'BZP melt as a function of time τ. Sample: (*1*, *3*) amorphous and (*2*, *4*) partially crystalline. Imidization procedure: (*1*, *2*) chemical and (*3*, *4*) thermal.

cosities of their melts. In these experiments, we used PI samples prepared from PAA with the terminal amino groups protected by treatment with phthalic anhydride. This was done in order to exclude the decrease in the melt flowability caused by an increase in the molecular weight due to condensation of terminal functional groups at temperatures corresponding to the viscous-flow state of the polymer.

The method used allowed us to compare at the same temperature (330°C) the time dependences of the apparent viscosity of the polymer melts for four samples of PI BZP–3,3'-BZP (Fig. 1): amorphous samples prepared by chemical and thermal imidization and partially crystalline samples differing in the melting point. It is seen that the amorphous and partially crystalline samples prepared by chemical imidization have relatively low melt viscosity (Fig. 1, curves *1*, *2*), and the viscosity does not noticeably grow over a period of 60 min, which is particularly important for practice. These data show that such PI BZP–3,3'-BZP samples can be successfully processed into a cast item under conditions of hot pressing. The polymer samples prepared by thermal imidization (Fig. 1, curves *3*, *4*) exhibit a high initial apparent viscosity of the melt, and this parameter rapidly grows with time.

Table 1. Strength characteristics of moldings from PI BZP–3,3'BZP

Sample	σ_b, MPa	*E*, MPa	ε_b, %
Partially crystalline, CM-1:			
no. 1	118	2150	5.5
no. 2	137–160	2540–2960	5.4
Partially crystalline, CM-2	9	820	1.1
Amorphous (chemical imidization)	6	670	0.9

Three of the four structural modifications of PI BZP–3,3'BZP appeared to be suitable for casting at moderate temperatures (300–350°C), substantially lower than the temperatures of the onset of PI thermal degradation (450–500°C). From these three modifications of PI, we prepared samples of moldings and compared their strength characteristics. The results of bending tests for this series of moldings are given in Table 1. We failed to prepare a molding under the chosen conditions (320°C) from the amorphous PI BZP–3,3'BZP sample obtained by thermal imidization of the PAA powder. This is apparently due to the high viscosity (low flowability) of the polymer melt at the process temperature (Fig. 1, curve *3*).

Table 1 shows that the sample prepared from partially crystalline PI of the high-melting crystalline modification CM-2 is brittle and has a very low bending strength. This may be due to the low flowability of the polymer melt at the pressing temperature (320°C), resulting in the nonmonolithic structure of the material. At the same time, our results show that the high melt flowability (Fig. 1, curve *1*) is a necessary but insufficient condition for obtaining cast items of high strength. The molding obtained from the amorphous PI BZP–3,3'BZP sample (the least viscous at the pressing temperature, Fig. 1, curve *1*) also has a poor strength. This is apparently due to the low molecular weight of the sample. According to [5], PI prepared by chemical imidization of PAA in diglyme or *m*-cresol has a lower molecular weight.

The moldings prepared from partially crystalline PI BZP–3,3'BZP of the low-melting crystalline modification CM-1 show high levels of bending strength, modulus of elasticity, and breaking strain (Table 1). Sample no. 2 differs from sample no. 1 (Table 1) in partial protection of terminal amino groups, ensured by adding at the end of PAA synthesis 0.013 mol of phthalic anhydride per mole of PAA elementary unit. Apparently, the increased strength in this case is due to extension of the melt "life" provided by such protection.

It is interesting that the strength characteristics of these moldings are comparable to those of a PI

Table 2. Characteristics of films of fullerene-containing PI BZP–3,3'BZP

BZP–3,3'BZP film prepared by thermal imidization of a PAA film (Table 2, fullerene-free sample). Thus, the bulk cast material obtained from partially crystalline PI BZP–3,3'BZP of the low-melting crystalline modification CM-1 acquires the properties characteristic of a film material obtained by traditional thermal imidization of the PAA film. Thus, proper choice of the structural modification of PI BZP–3,3'BZP and hence of the procedure for preparing the initial press powder allows realization of the intrinsic characteristics of the material.

In view of these results, we chose PI BZP–3,3'BZP of the low-melting crystalline modificatoin CM-1 for further experiments on development of a fullerene-containing polymeric composite. The PI BZP–3,3'BZP chains contain structural fragments (carbonyl groups and terminal amino groups) exhibiting certain affinity for fullerenes [10]. Therefore, we can expect that finely dispersed uniformly distributed fullerene will be bound with the polymeric matrix by complexing interactions.

Fullerene-containing samples of partially crystalline press powder of PI BZP–3,3'BZP (T_{m_1} = 275–290°C) were prepared by introducing a mixture of fullerenes C_{60} and C_{70} into the polymer using several procedures. For more uniform distribution of the fullerene, a solution of the fullerene mixture was mixed with the polymer solution in various stages of PI preparation.

In run no. 1, fullerenes were preliminarily dissolved in dimethylacetamide (DMAA) to a concentration of 0.05 mg ml^{-1}, and the entire subsequent process of preparing partially crystalline PI BZP–3,3'-BZP of the CM-1 modification was performed in this solution as described above. It is known [11] that the solubility of fullerenes in *o*-dichlorobenzene is considerably higher than in DMAA. Therefore, with the aim to introduce larger amounts of fullerenes into the polymer, we used in run nos. 2–4 a 20 mg ml^{-1} solution of the fullerene mixture in *o*-dichlorobenzene.

In run no. 2, we first kept fullerenes and the diamine in a 5 : 1 (by weight) mixture of DMAA and *o*-dichlorobenzene for 1 h at room temperature and then performed synthesis of PAA and imidization as described above. A check experiment showed that synthesis of PAA in such a solvent mixture is not accompanied by a decrease in the molecular weight of the polymer. The reduced viscosity of a 0.5% PAA solution prepared in DMAA and in a 5 : 1 mixture of DMAA with *o*-dichlorobenzene was 0.56 and 0.55 dl g^{-1}, respectively. In run no. 2' (Table 3), the terminal functional groups were partially protected similarly to sample no. 2 from Table 1 (treatment with 0.013 mol of phthalic anhydride per mole of PAA elementary units).

In run no. 3, we added a solution of fullerenes in *o*-dichlorobenzene into a reaction solution (25%) of the synthesized PAA and kept the resulting mixture at room temperature for 2 h. Then, as in the prevoius cases, PAA was imidized with the imidizing mixture after preliminary dilution wiht DMAA to 5% concentration. The weight ratio of DMAA and *o*-dichloro-

benzene in the mixture thus obtained was 40 : 1. In the course of imidization, the polymer lost solubility and precipitated from the reaction mixture in the form of a finely dispersed fullerene-containing powder of PI BZP–3,3'BZP.

In run no. 4, a solution of fullerenes in *o*-dichlorobenzene was added to a polymer solution 3 h after adding the imidizing mixture, i.e., in the course of PAA imidization but before the onset of PI precipitation. With *o*-dichlorobenzene, we introduced into the polymer 0.1% fullerenes (relative to the dry polymer weight), and with DMAA only, 0.015% fullerenes.

The uniform distribution and fixation of fullerenes in the bulk of the polymer can be confirmed by transparency and optical uniformity of films obtained from fullerene-containing PI BZP–3,3'BZP. To obtain such films, we prepared films from fullerene-containing PAAs using the composition of PAA, BZP–3,3'BZP, and fullerenes obtained in run nos. 2 and 3 and performed thermal imidization of these films. For this purpose, before adding the imidizing mixture, we cast films on glass supports from fullerene-containing composition nos. 2 and 3. The films were dried and successively heated for 1 h at 100, 200, and 300°C. As a result, we obtained transparent dark brown optically uniform films from fullerene-containing PI and determined their strength characteristics (Table 2) and T_g. For comparison, we give in Table 2 the characteristics of a fullerene-free PI BZP–3,3'BZP film prepared from PAA that was obtained in run no. 3.

It is known [5] that the PI studied in this work does not itself exhibit good film-forming properties; PAA films break after chemical imidization. Films prepared by thermal imidization of PAA films are fairly brittle (Table 2, sample no. 5). In this connection, noticeable enhancement of the deformation and strength characteristics of fullerene-containing PI BZP–3,3'BZP films is a positive result of our study (Table 2, sample nos. 2 and 3).

The next stage of our study involved preparation of fullerene-containing PI BZP–3,3'BZP press powders by the above-described procedures. We prepared sample nos. 1–4 and compared them to fullerene-free samples of partially crystalline PI BZP–3,3'BZP using differential scanning calorimetry (to determine the glass transition point, melting point, and enthalpy of melting) and thermal gravimetric analysis (to determine the temperatures of the onset of weight loss and of 5 and 10% weight loss: τ_0, τ_5, and τ_{10}, respectively) (Table 3).

Table 3 shows that addition of fullerene to the reaction solution in various stages of PI preparation has no significant effect on structure formation in PI. All the samples of fullerene-containing powdered PI exhibit well-defined softening and melting points in the DSC curves (Table 2) and belong to the low-melting crystalline modification CM-1, i.e., they show promise for casting at 300–350°C. It can be only noted that the enthalpy of melting in some cases decreases, suggesting certain decrease in the degree of crystallinity of the polymer.

Comparison of the heat resistance parameters (Table 3) shows that addition of fullerenes to PI results in a noticeable growth of the thermal degradation temperatures. Presumably, fullerenes acting as radical scavengers inhibit the radical thermal degradation of the polyimide [10].

From the fullerene-containing compositions of partially crystalline PI BZP–3,3'BZP, we prepared moldings as described above and compared their tribological characteristics. The sample prepared from fullerene-containing composition no. 1 was similar in the color (yellow-brown) to the fullerene-free PI BZP–3,3'BZP sample, apparently because of the low fullerene content (0.015%). Moldings prepared from fullerene-containing composition nos. 2–4 were black.

Figure 2a shows the pressure dependences of the sliding friction coefficient f (dimensionless quantity) in the tribocontact with the moldings under consideration. At pressures below 5 MPa, the friction coefficients are virtually constant for all the compositions, ranging from 0.15 to 0.2. At contact pressures above 5 MPa, the friction coefficient does not noticeably increase only with the molding based on the composition from run no. 2; hence, this composition is the most promising for using in friction units at tribocontact pressures of up to 10 MPa. Moldings based on the other compositions show stable operation only at pressures below 5 MPa.

Figure 2b shows the pressure dependences of the weight wear in a tribocontact at a sliding velocity of 0.14 m s^{-1} and sliding path of 100 m. It is seen that the molding sample prepared by the scheme of run no. 2 is the best with respect to the second tribological characteristic, weight wear, also. It is interesting that the weight wear of the fullerene-free moldings and of those with the minimal fullerene content, 0.015% (Fig. 2b, curves *1*, *5*), exceeds the weight wear of the moldings prepared from composition no. 2 by a factor of 15–25.

In separate experiments at low sliding velocities we studied how the linear wear intensity I_w of the

moldings depends on the sliding velocity v (m s^{-1}). We chose the moldings with the minimal (0.015%, sample no. 1), intermediate (0.1%, sample nos. 3 and 4), and maximal (1%, sample no. 3' prepared similarly to sample no. 3 but containing more fullerenes) fullerene content. Figure 3 clearly demonstrates enhancement of the wear resistance of the moldings with increasing fullerene content. It is noteworthy that the wear intensity is a linear function of the sliding velocity for all the moldings and that the moldings containing 0.1–1% fullerenes show an inflection in this dependence at a sliding velocity of 0.12 m s^{-1}.

The mechanism of wear in a friction couple is determined by processes occurring in a surface layer within a depth of several tens of micrometers. Friction of polymers induces structural rearrangements in the surface layers of the contacting materials; the temperature grows, the intermolecular interaction weakens, and, as a result, subsurface cracks and then wear particles are formed. The parameters of wear particles bear information about the surface degradation, changes in the wear mechanism, and, in particular, about the shear strength of a material.

In this work, we studied the physical processes occurring in a surface layer by collecting and analyzing the wear particles formed in the course of friction. The experiments performed at a sliding velocity of 0.14 m s^{-1} and a sliding path of 100 m showed that appreciable changes in the mean particle size occur in the same pressure range, 2.5–5 MPa, for different compositions. The mean area of wear particles is within several hundreds of square micrometers for the moldings based on composition no. 2 and within 10^3 μm^2 in the other cases. Thus, along with the low friction coefficient, moldings based on composition no. 2 also exhibit a high shear strength, which is a very important parameter for applying materials in friction units.

The presence of an inflection point in the curves of the friction coefficient vs. tribocontact pressure (Fig. 2a) can be attributed to changes in the polymer structure occurring as the temperature in the thin contact layer grows owing to an increase in the tribocontact pressure. It is known that friction can cause the temperature in the contacting materials to grow up to the melting point.

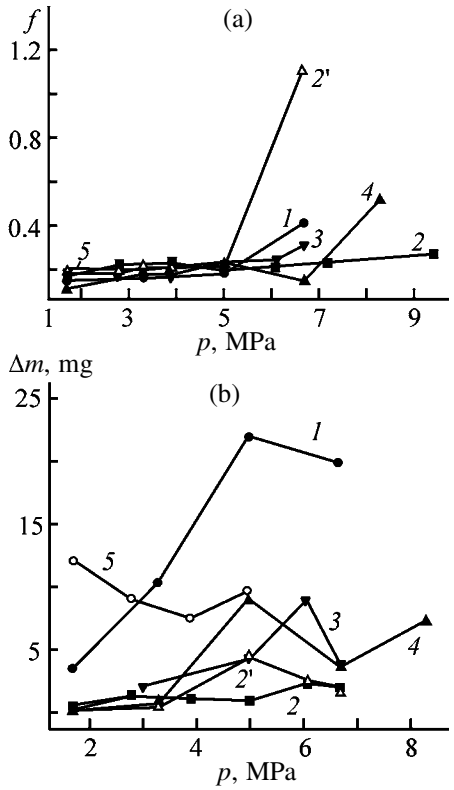

Fig. 2. (a) Sliding friction coefficient f and (b) weight wear Δm as functions of pressure in the tribocontact p with moldings prepared from fullerene-containing compositions. Figures at curves are sample nos. in Tables 2 and 3.

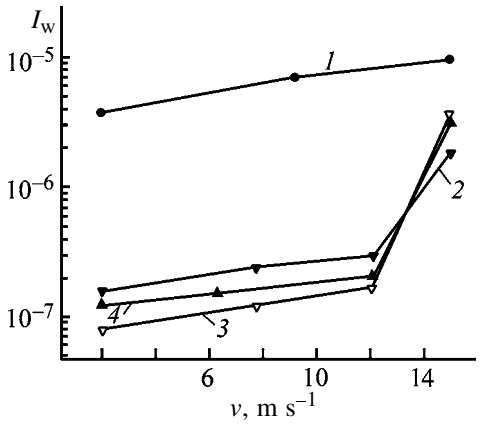

Fig. 3. Linear wear intensity I_w as a function of sliding velocity v for moldings prepared from fullerene-containing compositions that were obtained in run nos. (*1*) 1, (*2*, *3*) 3, and (*4*) 4. Tribocontact pressure 3.9 MPa. (*3*) Sample with the maximal fullerene content.

Structural changes that occur in BZP–3,3'BZP materials with increasing temperature alter the mechanism of the material failure. This is suggested by a number of facts, in particular, by changes in the shape (fractal dimensionality) of wear particles [12] observed before the point at which the properties abruptly change (Fig. 2a). Calculation of the edge of the wear particles (observed with an optical microscope) gives the fractal dimensionality D of 1.13 for low pressures ($p < 5$ MPa) and 1.07 for $p > 5$ MPa. Thus, the wear particles before the inflection point in Fig. 2a seem to have a larger surface area than those after the

(a)

(b)

Fig. 4. Electron micrographs of wear particles formed at (a) low (p < 5 MPa) and (b) high (p > 5 MPa) pressures in the tribocontact. Magnification 6000.

inflection point. Electron microscopic examination shows that actually the wear particles obtained at low pressures (before the inflection point in Fig. 2a) are lumps with a branched surface (Fig. 4a). These particles formed in a contact gap by agglutination of finer particles. At higher pressures (and hence higher temperatures), the particles become coarser, and their surface, smoother (Fig. 4b).

The polymer wear occurs when the stress in the surface layer exceeds its strength. The major wear mechanism is determined by the ratio between the acting stress and strength at a given temperature. If the stress is lower than the yield point, fatigue wear is the most probable. If the stress exceeds the yield point but does not exceed the ultimate strength, plastic ploughing becomes the most probable. In the process, the polymer on the friction surface is pressed out at the edges of friction furrows under the indentor. If the stress exceeds the ultimate strength, abrasive wear prevails, and wear particles are formed immediately, without any incubation period. Electron microscopic examination shows that the critical contact pressure of 5 MPa, apparently, characterizes the transition from wear with plastic flow elements to abrasive wear.

CONCLUSIONS

(1) The polyimide synthesized by chemical imidization from 3,3',4,4'-benzophenonetetracarboxylic dianhydride and 3,3'-diaminobenzophenone can be processed into a cast item at 320–330°C, which allows preparation of moldings with the bending strength of up to 160 MPa, Young's modulus of up to 3000 MPa, and breaking strain of 5–6%. The moldings prepared by a similar procedure from the similar polyimide syntherized by thermal imidization are very brittle and have poor mechanical properties.

(2) In all the cases, the fullerene-containing polyimide studied in this work occurs in a low-melting crystalline modification, which allows its processing into cast items or matrices of composites at 320–330°C.

(3) The optimal procedure for introducing fullerene into the polyimide derived from 3,3',4,4'-benzophenonetetracarboxylic dianhydride and 3,3'-diaminobenzophenone is addition of a solution of fullerene in *o*-dichlorobenzene to a solution of the diamine in dimethylacetamide. The molding prepared from the resulting composition exhibits decreased levels of the friction coefficient, weight wear, and linear wear intensity.

(4) The wear resistance of moldings prepared from the examined polyimides grows with increasing content of fullerenes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Low-Temperature Curing of Poly[*N*-methyl(allyl)-5-vinyltetrazole]

A. M. Belousov, E. A. Paznikov, G. Ya. Petrova, and P. I. Kalmykov

Biisk Technological Institute, Branch of the Polzunov Altai State Technical University, Biisk, Altai krai, Russia

Received December 23, 2003; in final form, May 2003

Abstract—Low-temperature curing of poly[*N*-methyl(allyl)-5-vinyltetrazole) with 1,3-dicyano-2,4,6-triethylbenzene *N*,*N*'-dioxide was studied.

Thermodynamic calculations show that binders based on heterocyclic compounds can be promising components of high-energy-capacity condensed systems thanks to their high enthalpy of formation, increased nitrogen content, chemical compatibility with other components, and low sensitivity to mechanical actions. The most interesting among such compounds are poly(vinyltetrazoles) [1, 2].

In this work we studied low-temperature curing of poly[*N*-methyl(allyl)-5-vinyltetrazole], PMVT-A.

Low-temperature curing was effected by 1,3-dicyano-2,4,6-triethylbenzene *N*,*N*-dioxide (ODTB). In the experiments we used PMVT-A plasticized with various plasticizers (polymer : plasticizer weight ratio 15 : 85). As plasticizers we used a mixed nitrate ester (a mixture of glycerol trinitrate and diethylene glycol dinitrate) (binder 1) and a mixture based on 1-alkyl-3-nitro-1,2,4-triazole (binder 2). The performance of the curing agents was evaluated by changes in the gel fraction content P_g (%) and mean molecular weight of the segment between cross-links M_s.

First we examined the influence of the hardener concentration on the curing of the binders, to determine the optimal hardener concentration.

Curing was performed at 40°C with various ODTB concentrations. The results are shown in Fig. 1. It is seen that, starting from the ODTB concentration of 0.45 wt %, the gel fraction content reaches a stable level of 98–99 wt %. This ODTB concentration can be recommended as optimal.

The next stage of our work was a kinetic study of the binder curing at the optimal ODTB concentration of 0.45 wt %. Curing of binders 1 and 2 was performed at 25, 30, 35, 40, 50, and 60°C. Figure 2 shows that, below 40°C, the kinetic curves have an inflection at the gel fraction content of 85–90 wt %.

Calculation of the apparent activation energies and entropies of curing from the kinetic curves for the temperature range 25–40°C revealed significant differences between the process characteristics before and after the inflection point. The final stage of curing (P_g > 90%) is characterized by the higher activation energy and different activation entropy (see table). With the nitrotriazole plasticizer, the activation energy is lower than with the nitro ester plasticizer. This may

2	15	–52.7	12.5	–55.9

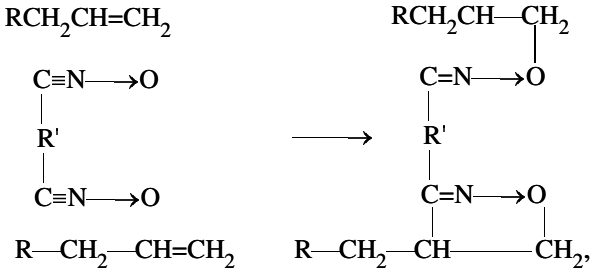
be due to selective complexation processes characteristic of 1,2,4-triazoles [3, 4]. Determination of the mean molecular weight of the segment between cross-links M_s (Fig. 3) shows that M_s decreases with temperature, i.e., the cross-linking is more efficient at elevated temperatures. A minor difference between the M_s values for binders 1 and 2 suggests that a part of the curing agent in the nitrotriazole binder is consumed in side processes, other than formation of the three-dimensional network.

On the whole, our results can be interpreted as follows. First, the stable yield of the gel fraction at the hardener content of 0.45 wt % corresponds to the molar ratio of double bonds to ODTB of 2 : 1. This fact suggests that the curing involves the C=C bonds. This is confirmed by a considerable decrease in the intensity of the IR absorption band corresponding to the double bonds (1638–1648 cm^{-1}). Second, the inflection in the kinetic curves and, correspondingly, different activation energies of the initial and final steps of the low-temperature curing indicate that the reactivities of double bonds are different. Since the transfer of electronic effects in tetrazole compounds largely depends on the substituent position [5], the difference between the reactivities of double bonds can be attributed to the different position in the allyl groups in the tetrazole ring (at N^1 or N^2).

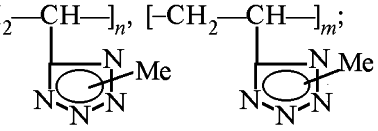
Published data show that units with the N^2-allyl group prevail in PMVT-A [6]. This fact suggests that the cross-linking first involves the N^2-allyl groups, and this process has a lower activation energy. As the N^2-allyl groups are exhausted, further cross-linking involves the N^1-allyl groups. With increasing temperature, the difference between the reactivities of the two kinds of allyl groups levels out, and at 50 and 60°C no inflection can be seen in the kinetic curves.

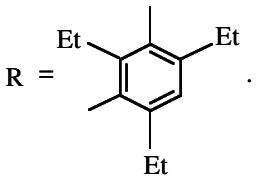
The low activation energies and high negative activation entropies of curing suggest that the [3+2]-cycloaddition of ODTB occurs via highly ordered cyclic transition state [7].

In view of these facts and taking into account data from [7], we suggest the following mechanism of PMVT-A curing with ODTB:



where R = [–CH$_2$—CH—]$_n$, [–CH$_2$—CH—]$_m$;





The content of allylvinyltetrazole fragments n in PMVT-A is 2–4 wt %, and the content of methylvinyltetrazole fragments m, 98–96 wt %.

EXPERIMENTAL

Experiments were performed with commercial PMVT-A samples (Sibreaktiv Joint-Stock Company, Angarsk; batch 9/91). The polymer was ground, sieved through a 100-μm sieve, and dried at 60°C for 2 h. The dried polymer was stored in a desiccator over

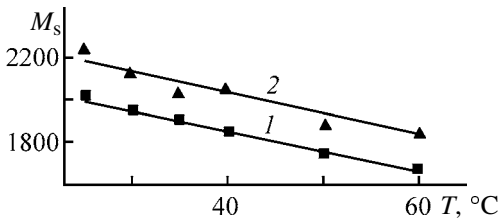


Fig. 3. Mean molecular weight of the segment between cross-links M_s in PMVT-A samples as a function of curing temperature T. Binder: (*1*) 1 and (*2*) 2.

calcined calcium chloride. As curing agent we used commercial ODTB (Tekhnolog Special Designing and Technical Bureau, St. Petersburg), which was dried for a day at 25°C before use. As dispersant we used triacetin (ODTB : triacetin = 1 : 1). The binder was prepared by direct mixing of the polymer with the plasticizer at room temperature, followed by evacuation to constant weight to remove volatiles. Curing was performed in closed aluminum weighing bottles in an oven. By sampling at regular intervals, we determined the time of the onset of curing and the parameters of the vulcanization network. The quantities P_g and M_s were calculated as described in [8]. The correlation coefficient in the calculations was 0.96–0.98.

CONCLUSIONS

(1) Low-temperature curing of poly[*N*-methyl(allyl)-5-vinyltetrazole] with 1,3-dicyano-2,4,6-triethylbenzene *N*,*N*'-dioxide yields the cross-linked polymer with the gel fraction content of 98–99% in a wide temperature range.

(2) The possible mechanism of the reaction of the hardener with the tetrazole polymer, involving addition of nitrile oxide groups to the double bonds of allyl groups to form a three-dimensional structure, was suggested.

Abstract—Synthesis of poly(1,2-dimethyl-5-vinylpyridinium methyl sulfate) and its copolymers with hydrophilic monomers by (co)polymerization initiated with water-soluble peroxides is studied. The flocculating activity of polyelectrolytes is determined in aqueous kaolin suspensions and also in dewatering of an active sludge.

Cationic polyelectrolytes are widely used as flocculants for separating various dispersions [1]. Based on the chemical nature of the cationic center of a macromolecule, two major classes of cationic polyelectrolytes can be distinguished. The first class includes polymers containing ammonium cations. In this case, introduction of cationic groups is realized by using aminoalkyl acrylates and their salts such as (2-acrylamidopropyl)trimethylammonium chloride and dialkyldiallylammonium halides as starting monomers. The second class covers pyridinium polyelectrolytes formed in polymerization of vinylpyridinium salts of various structures. One of the most active among them is poly(1,2-dimethyl-5-vinylpyridinium methyl sulfate) (poly-1,2-DM-5-VPMS) whose primary advantages are high environmental compatibility and efficiency in dispersion separation [2, 3].

In this work we studied synthesis of high-molecular-weight poly-1,2-DM-5-VPMS and its copolymers with hydrophilic monomers having high flocculating activity.

EXPERIMENTAL

Polymerization of 1,2-DM-5-VPMS was carried out in an aqueous solution at 20±0.5°C using the ampule method. A 0.001–0.01 M aqueous solution of an initiator was added to a monomer solution of a fixed concentration. The initial 1,2-DM-5-VPMS was purified by recrystallization from methanol. As initiators we used hydrogen peroxide (HP), *tert*-butyl hydroperoxide $CH_3C(CH_3)_2OOH$ (TBHP), 2-*tert*-butylperoxy-1-ethanol $CH_3C(CH_3)_2OO(CH_2)_2OH$ (TBPE), and 1-*tert*-butylperoxy-2-propanol $CH_3 \cdot C(CH_3)_2OOCH_2CH(OH)CH_3$ (TBPP). TBPE and TBPP were synthesized according to the procedure described in [4]. The organic peroxides were purified by vacuum distillation.

Copolymerization of 1,2-DM-5-VPMS with acrylic (AA) and maleic (MA) acids, acrylonitrile (AN), acrylamide (AAm), *N*-vinylpyrrolidone (VP), and vinyl acetate (VA) was performed in an aqueous solution at 20±0.5°C and various initial comonomer ratios. As an initiator we used TBPP. AAm and MA were purified by recrystallization from acetone, and AN, AA, VP, and VA were distilled prior to polymerization. Physicochemical characteristics of the monomers used were well consistent with the reference data. Copolymerization was carried out to 96–98% conversion. Then the polymerizate was dissolved in methanol and precipitated by diethyl ether. The resulting polymers were additionally purified by reprecipitation from methanolic solutions with diethyl ether and vacuum-dried (p_{res} = 1.5–2.0 mm Hg, T = 20±0.5°C) to constant weight.

The copolymers were analyzed for the carboxy group content by potentiometric titration and for quaternary pyridinium units by titration of the copolymer–polyacrylic acid complex.

The viscosity of dilute polymer solutions was measured with an Ubbelohde viscometer at 30°C in 2 M NaCl or at 25°C in 0.05 M KBr. The intrinsic viscosity was estimated by linear extrapolation of η_{sp}/c and $\ln \eta_{rel}/c$ to zero concentration (η_{sp} and η_{rel} are the specific and relative viscosities, respectively). The viscosity-average molecular weight M_η of the

1070-4272/03/7607-1167$25.00

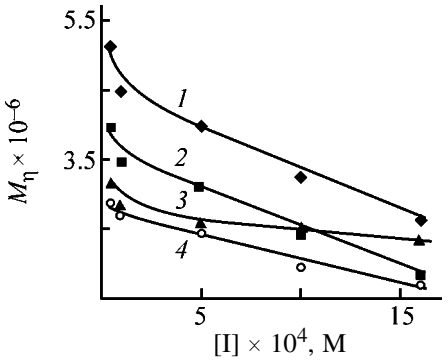

Fig. 1. Molecular weight M_η of poly-1,2-DM-5-VPMS as a function of the initiator concentration [I]: (*1*) TBPP, (*2*) HP, (*3*) TBPE, and (*4*) TBHP. $[M]_0$ = 2.3 M, 20°C.

homopolymer was estimated by Eq. (1) [5]

$$[\eta] = 0.295 \times 10^4 M_\eta^{0.8}, \quad (1)$$

where [η] is the intrinsic viscosity in 0.05 M KBr at 25°C. As a dispersion phase in the flocculation experiments we used kaolin (KSD brand) with a mean particle size of 7 μm. To 0.8% kaolin suspension a flocculant was added in amount of 0–5 mg l^{-1}. The experiments were carried out in 250-ml glass cylinders. After addition of a polyelectrolyte, the suspension was stirred with a rotary stirrer for 2 min (180 rpm) without air access. After an hour, the supernatant was sampled and its optical density A was measured on a KFK-3 instrument at a wavelength of 400 nm against water as a reference. The turbidity of the supernatant τ was estimated by Eq. (2)

$$\tau = 2.3A/l, \quad (2)$$

where l is the path length (cm).

From the experimental data thus obtained we determined the optimal concentrations of the polyelectrolytes c_{opt} providing the minimal turbidity of the supernatant. The clarification factor D_τ was estimated by Eq. (3):

$$D_\tau = \tau_0/\tau - 1, \quad (3)$$

where τ_0 and τ are the supernatant turbidities, respectively, without and with the polyelectrolyte added in a fixed concentration.

In sludge dewatering experiments, we used active sludge from biological treatment plant for sewage water (Volgogradvodokanal Municipal Enterprise). Active sludge (200 ml) was mixed with a 0.1 wt % flocculant suspension. The mixture was agitated by tenfold pouring, filtered after 30-s settling, and the filtrate was analyzed for the residual suspended matter. A filter with the precipitate was additionally dewatered under a 5-kg press. The moisture content in the cake was determined gravimetrically.

The common method for synthesis of soluble polyelectrolytes is radical polymerization of the corresponding monomers in solution or dispersion [6, 7]. In aqueous solutions of monomers, polymerization proceeds mostly at a high rate, and high-molecular-weight polymers are formed. In this case, after completion of the process, the polymerizate can be used directly for preparation of working solutions of polyelectrolytes, eliminating the isolation stage.

Persulfate-initiated polymerization of 1,2-DM-5-VPMS in aqueous solutions became a base for semicommercial production of PPS flocculant [6]. Polymers formed in the process have relatively low molecular weight [$M_\eta = (1.5–1.8) \times 10^6$] and contain some insoluble fractions. Available data on the reactivity of sulfate radical anions and their transformation products [8] and also on the reaction of persulfates with cationic polymers [9] suggest that gelation could be caused by two factors. The first factor is branching and cross-linking of the macromolecules in transfer of a radical center from the sulfate radical anions or hydroxy radicals to the macromolecules. The second possible factor is realization of ionic "pseudo-cross-links" between the macromolecules via the sulfate anions. As a result, the persulfate initiation did not allow synthesis of high-molecular-weight totally soluble polymers.

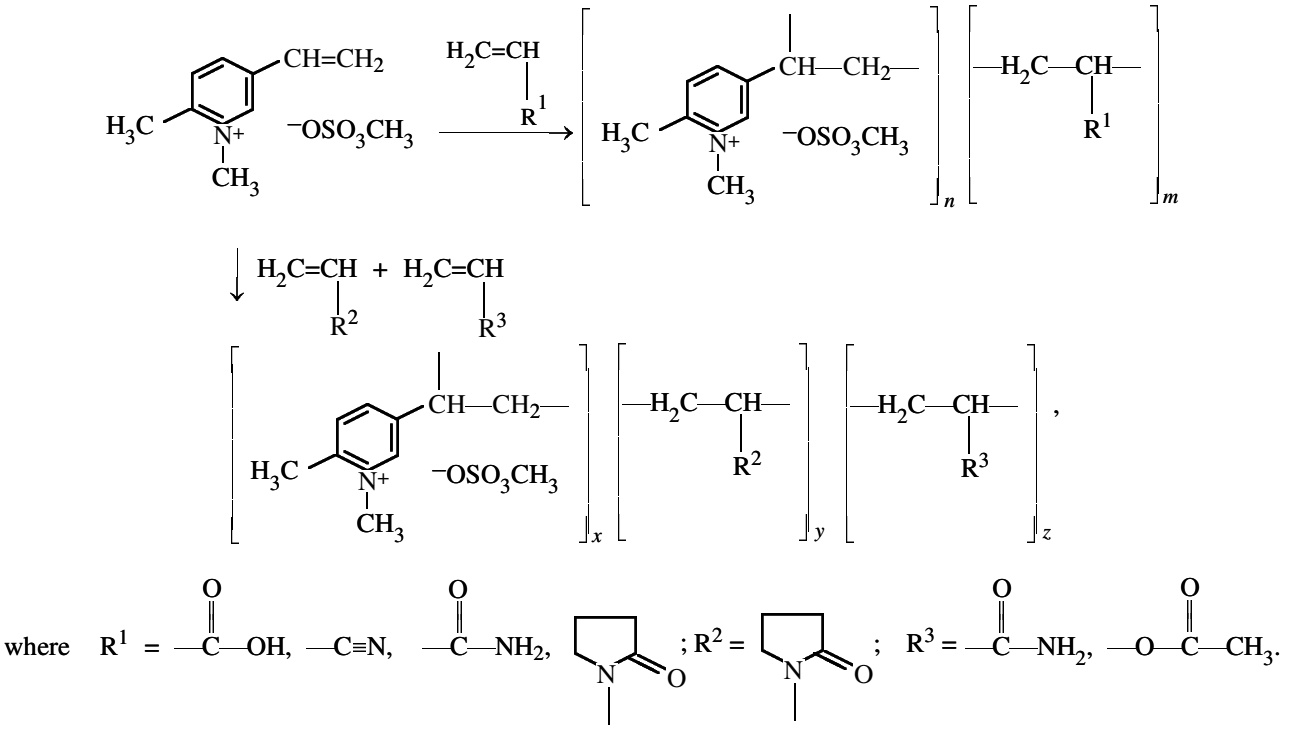
In searching for initiators providing synthesis of a high-molecular-weight readily soluble polymer in a high yield, we tested HP, TBHP, TBPE, and TBPP.

Polymerization of 1,2-DM-5-VPMS with any of the indicated initiators proved to occur even at 20°C, and the polymers formed had a fairly high molecular weight ($M_\eta = 8.0 \times 10^5–5.1 \times 10^6$). The effect of the peroxide structure on M_η is demonstrated in Fig. 1. The highest-molecular-weight poly-1,2-DM-5-VPMS was obtained with TBPP [$M_\eta = (2.96–5.13) \times 10^6$]. Regardless of the initiator structure, increasing its concentration results in decreasing M_η of the polyelectrolyte (Fig. 1).

The effect of the initiator structure can be attributed to differences in the rate of radical generation from peroxides and, correspondingly, in the initiation rate. It is obvious that decomposition of the peroxides in polymerization (T = 20°C) is an activated process. Most likely, the activating factor is the peroxide–monomer interaction with formation of a complex

with considerably decreased peroxide bond strength, as demonstrated for systems peroxide–ammonium salt [10]. It may be suggested that, in this case, the initiation rate is lower with TBPP, providing formation of a higher-molecular-weight polymer.

The differences in the qualitative and quantitative compositions of disperse systems make it necessary to extend the spectrum of flocculating agents. In this connection, it seemed advisable to study copolymerization of 1,2-DM-5-VPMS with other monomers with the purpose of modifying the structural, electrochemical, and adsorption characteristics of the polyelectrolytes, so as to enhance their flocculating activity. Of particular interest was to synthesize polyelectrolytes containing anionic active centers or nonionic elementary units. Therefore, we synthesized copolymers of 1,2-DM-5-VPMS with AA, MA, AN, AAm, VP, and VA:



Copolymerization was carried out in aqueous solutions at 20±0.5°C with TBPP as an initiator. The copolymerization conditions and characteristics of the resulting products are summarized in Table 1. The products obtained with some of the monomers studied were high-molecular-weight copolymers ([η] = 0.5–2.5 dl g^{-1}) soluble in water, methanol, DMSO, and DMF.

Copolymerization of 1,2-DM-5-VPMS with all the monomers studied, except for MA, is characterized by high product yield (96–98%). In some cases (at certain total concentration ΣM_i and ratio f_2/f_1 of comonomers), we observed phase separation in systems with AA and AN, which is probably due to formation of copolymer fractions enriched with the second monomer and insoluble in the reaction mass. Therefore, to realize homogeneous copolymerization of 1,2-DM5-VPMS with AA or AN, it necessary to limit the content of the second monomer in the reaction mixture to 20 mol %.

Note that, in the systems with AN, the intrinsic viscosity of the resulting copolymer is practically independent of its composition, whereas with other monomers, increasing content of the second monomer somewhat decreases [η].

In the system with MA, increasing fraction of the second monomer in the reaction mixture considerably decreases the yield and molecular weight of the copolymer. For example, at an MA concentration of up to 15 mol %, the molecular weight of the resulting copolymer is rather high ([η] = 2.05–1.45 dl g^{-1}), and the product yield is 96–98%. With increasing MA fraction, the viscosity of copolymers decreases to 0.54 dl g^{-1}, and the yield, to 55%, which is caused by

* $F_2 + F_3$.

low polymerization activity of MA. Therefore, to obtain high-molecular-weight copolymer, it necessary to limit the MA content in the reaction mixture to 15 mol %.

As expected, decreasing initiator concentration increases the intrinsic viscosity of the resulting copolymers (Table 2). Simultaneously, the yield decreases, remaining, however, above 90% at an initiator concentration of 10^{-4} M.

Table 2. Influence of the initiator (I) concentration on the yield and intrinsic viscosity of 1,2-DM-5-VPMS copolymers (f_1 = 90 mol %, f_2 = 10 mol %; 20°C)

Comonomer	$[I]_0$, M	Copolymer yield, %	[η], dl g^{-1}

	0.001	98	1.84
	0.01	99	1.61
VP	0.0001	92	2.39
	0.001	99	1.62
	0.01	99	1.26

It appears more technologically advantageous to increase the molecular weight through increasing monomer concentration. Table 3 shows that, for different compositions of the reaction mixture, increase in the total concentration of monomers results in formation of polymers with higher intrinsic viscosity in nearly theoretical yield.

The results of studying the flocculating effect of poly-1,2-DM-5-VPMS in separation of model systems revealed high activity of this polyelectrolyte [2, 3, 11]. However, in the case of the homopolymer, the charge density is independent of its molecular weight, since each elementary unit contains the ionic group. Without question, introduction of nonionic units into the

polymer structure should influence its electrochemical and adsorption characteristics and the flocculating action as well. Therefore, in this work we made a comparative study of the flocculating activity of the copolymers obtained.

The results showed that introduction of some acidic groups into the polyelectrolyte structure decreases the flocculating activity of the copolymers. Copolymers of 1,2-DM-5-VPMS with nonionic monomers such as AAm (samples 1AAm, 2AAm, 3AAm, and 4AAm), VP (samples 1VP, 2VP, and 3VP), VP + AAm or VA [samples 1VP(AAm), 2VP(AAm), 1VP(VA), and 2VP(VA)] seem to be the most promising flocculants.

Figure 2 shows that the dependences of the supernatant turbidity on the polyelectrolyte concentration have extrema. At low flocculant concentration (up to 0.4 mg l^{-1}), the residual turbidity decreases (flocculation branch). With increasing c_f (0.4–2 mg l^{-1}), the range of dispersion destabilization is observed, and with further increasing c_f, the supernatant becomes somewhat more turbid. The latter is commonly interpreted as stabilization of the dispersion through formation of protective layers of the adsorbed polymer. The results show that higher clarification factors are realized when copolymers containing vinylpyrrolidone units are added as flocculants.

The optimal flocculation parameters for kaolin suspension with copolymers of 1,2-DM-5-VPMS with nonionic monomers are given in Table 4. As seen, the flocculating activity of the copolymers depends on their composition. Copolymers containing AAm units are close to poly-1,2-DM-5-VPMS in their flocculation activity and optimal concentration. With increasing AAm content in the copolymer, the flocculating activity decreases, and the optimal concentration increases to 1.2 mg l^{-1}.

The copolymers of 1,2-DM-5-VPMS with VP demonstrate higher flocculating activity than poly-1,2-DM-5-VPMS and the copolymers with AAm. The optimal flocculant concentrations in this case are practically the same, ranging from 0.5 to 1.2 mg l^{-1}. The highest flocculating effect was observed for sample 1VP (D_τ = 174.7).

Simultaneous introduction of VP and VA units in the amounts of 9 and 1 mol %, respectively, results in formation of a copolymer providing a 1.5-fold increase in the clarification factor as compared to the homopolymer. However, in this case, the optimal flocculant concentration increases to 0.8 mg l^{-1}.

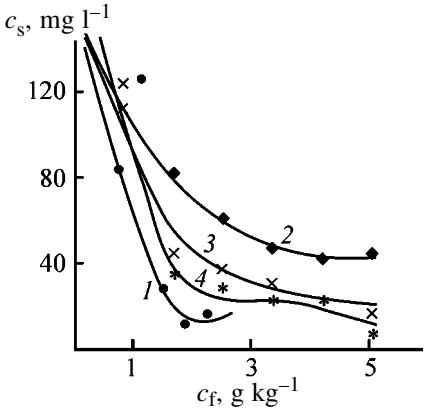

Fig. 3. Effect of the flocculant concentration c_f on the suspended matter concentration in the filtrate c_s: (*1*) poly-1,2-DM-5-VPMS, (*2*) 2AAm, (*3*) 1VP, and (*4*) 1VP(AAm).

mers of 1,2-DM-5-VPMS with VP and AAm showed that the samples containing 9 mol % VP and 1 mol % AAm provide the maximal efficiency of treatment of the kaolin suspension. In their performance these copolymers surpass the homopolymer by a factor of 2.6. In this case, the optimal concentration is 0.8 mg l^{-1}. As for the copolymers described above, with further increasing fraction of the nonionic units in the copolymer structure, the flocculant activity decreases and the optimal concentration increases.

Without question, the sedimentation rate of the kaolin suspension increases in the presence of the copolymers. Determination of the flocculation mechanism requires a thorough study of floccule and precipitate formation as well as the conformation state of copolymers of various compositions with allowance for composition nonuniformity. However, some conclusions can be made from comparison of the results obtained on the flocculating power of copolymers with various hydrophilic monomers.

Table 5. Activity of cationic flocculants in dewatering of excess sludge

Initial sludge moisture content, %	Flocculant	Concentration, g kg^{-1}	Cake moisture content, %	c_s, mg l^{-1}
99.34	KF-91	1.5	87.4	28.0
		1.9	88.6	11.7
		2.3	89.9	16.3
99.7	2AAm	1.7	90.9	81.6
		2.5	91.5	60.6
		3.4	91.9	46.6
99.7	1VP	1.7	88.8	44.3
		2.5	87.5	37.3
		3.4	89.7	30.7
99.7	1VP(AAm)	1.7	91.2	34.9
		2.5	88.0	28.0
		3.4	84.9	22.3

The results show that the flocculating power increases only with VP as a comonomer. It is unlikely that VP units are involved in hydrogen bonding and ion–dipole interactions with sites on the particle surface, because of steric hindrances resulting in shielding of the carbonyl group. Most likely, the increase in the flocculating power is associated with changing the coil conformation in the surface layer of particles and also with increasing probability of association of the coils with participation of the nonionic units, accompanied by formation of bridging bonds through two and more coils.

Based on the results obtained on the flocculating power of copolymers of 1,2-DM-5-VPMS with nonionic monomers, a series of samples were selected for testing in dewatering of excess activated sludge formed in the water treatment plant (Volgogradvodokanal Municipal Enterprise). The processes of water treatment and subsequent dewatering of excess sludge mostly involve the flocculation and filtration stages allowing removal of excess suspended material from the biological treatment zone and also regeneration of activated sludge in aeration tanks [12]. In this case, the residual moisture content of the sediment and the suspended matter content in the filtrate are the parameters characterizing the flocculant performance.

Evaluation of the flocculating efficiency requires data on the effect of the flocculant concentration on the suspended matter concentration in the filtrate c_s. As seen from Fig. 3, the suspended matter concentration abruptly decreases wit increasing flocculant concentration to 2 g kg^{-1}. With further increasing c_f, the range of sludge suspension destabilization is observed. The secondary stabilization range has not been realized under the experimental conditions, since, evidently, it occurs at higher c_f. Thus, the effective flocculant concentration falls into the range 1.5–3 g kg^{-1}. From the dependence of the moisture content of the resulting cake on the reagent concentrations, we can determine the optimal flocculant concentration. The criterion was the minimal moisture content in the cake. The flocculants studied demonstrated high performance in dewatering the sludge and decreasing suspended matter content in the filtrate (Table 5). In the experiments we used activated sludge without preconcentration, i.e., with low suspended matter content (0.3–0.7 wt %), which complicated flocculation with polymers. Nevertheless, the use of the copolymers allowed highly efficient dewatering of the activated sludge.

Table 5 shows that 1VP and 1VP(AAm) samples are more effective flocculants as compared to KF-91 homopolymer, 1VP(AAm) being especially active, having the dewatering effect higher by a factor of 1.3.

CONCLUSIONS

(1) Study of homo- and copolymerization of 1,2-dimethyl-5-vinylpyridinium methyl sulfate initiated by water-soluble peroxides revealed that the polyelectrolytes obtained using 1-*tert*-butylperoxy-2-propanol have the highest molecular weight and solubility in water. Copolymerization initiated with *tert*-butylperoxy-2-propanol allows preparation of high-molecular-weight poly(1,2-dimethyl-5-vinylpyridinium methyl sulfate) [M_η = (2.8–5.1) × 10^5] and its copolymers in nearly theoretical yield at room temperature (~20°C). Decreasing fraction of 1,2-dimethyl-5-vinylpyridinium methyl sulfate in a copolymer results in somewhat decreasing intrinsic viscosity, the effect being more pronounced in copolymers with maleic acid and *N*-vinylpyrrolidone.

(2) Copolymers of 1,2-dimethyl-5-vinylpyridinium methyl sulfate with *N*-vinylpyrrolidone and its terpolymers with *N*-vinylpyrrolidone and acrylamide or vinyl acetate demonstrate higher flocculating performance than the homopolymer. Evidently, this is due to optimal concentration and arrangement of the cationic centers in the polymer chain, and also to direct participation of the nonionic units in floccule formation.

(3) The polymers studied can be recommended as reagents for treatment of industrial reused water and wastewater.

Recovery of Gold from Cyanide Solutions Using Activated Carbon Sorbent Based on Lignite

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received November 21, 2002

Abstract—Recovery of gold cyanide complexes was studied using sorbents prepared from Kansk–Achinsk lignite.

To recover finely ingrained gold, the ore is often leached with a sodium cyanide solution with subsequent preparation of the concentrate or metallic gold. Gold is recovered from solutions and suspensions (in the last 2–3 decades) using predominantly carbon sorbents [1].

Gold is fairly selectively sorbed on carbon sorbents, being concentrated to a level of 1% of the sorbent weight. Concentrates or metallic gold are prepared from the gold-containing solutions obtained after sorbent treatment by various procedures.

Sorption is a decisive step of such procedure, and thus sorbent properties should meet certain requirements. It was found that the specific surface area of sorbents strongly affects the gold sorption [2]. The specific surface area of commercial sorbents prepared from coconut shells reaches 1000 $m^2 g^{-1}$, and their capacity for gold in sorption from solutions with a gold concentration of 1 $mg l^{-1}$ is about 1%.

Sorbents should be abrasion-resistant, and high mechanical strength is important, because in the course of treatment the coarse sorbent (~2 mm particle size) is stirred with finely ground ore (0.07 mm) in a sodium cyanide solution with the content of the solid matter of up to 50%. After prolonged stirring, gold dissolves and passes into the sorbent, and then the gold-containing sorbent is separated from the ground ore using a 0.5-mm gauze. Thus, with a fragile easily grindable material, the loss of gold-containing sorbent with ore will be intolerably high.

All modern procedures employ sorbents prepared from coconut shells, which exhibit acceptable capacity for gold and the required mechanical strength.

Attempts are made to prepared alternative sorbents from liquid products of shale treatment and petroleum residues, technical hydrolytic lignin, furfural, and also from wastes of production of phenol–formaldehyde resins, coal-tar raw materials, petroleum coke, and wood residue with carbonization and ultra-high-frequency activation. However, the mechanical strength of the above sorbents [in accordance with GOST (State Standard) 16-188–70] is insufficient and comprises up to 90%. The demand of the gold-mining industry in Russia is about 1000 t of sorbent per year (data are as of 1990) [2].

At the same time, the use of sorbents prepared from coconut shells in the gold hydrometallurgy has its own disadvantages, because the expenses related to the sorbent loss due to the abrasion at suspension stirring and to its periodical regeneration are nearly 50% of the sorbent cost [1]. Thus, the use of cheap disposable sorbents to recover gold from solutions seems to be advisable.

In this work, we studied the sorption capacity of ABG activated sorbent for gold cyanide complexes. Since the mechanical strength of the ABG sorbent does not allow its use in the pulp process, it was used to recover gold from solutions. Due to low cost, it was planned to ash the gold-containing sorbent with subsequent recovery of gold from the ash residue.

EXPERIMENTAL

The carbon sorbents were tested using industrial solutions from a gold-recovery enterprise with a gold content of 1.32–1.52 $mg l^{-1}$. The following carbon sorbents were used: ABG commercial product (Sorbentugol' Joint-Stock Company, Krasnoyarsk, Russia) prepared from Kansk-Achinsk lignite with the specific surface area of 560–800 $m^2 g^{-1}$ and ash content of 18–25%, commercial coconut coal (Du Pont, the United States) designed for gold recovery from the pulp (nearly 1000 $m^2 g^{-1}$), and GRC-22 commercial coconut coal (Calgon Carbon, the United States)

1070-4272/03/7607-1174$25.00

designed for gold recovery from the pulp (nearly 1000 $m^2 g^{-1}$).

The aim of the work was to study the completeness of gold recovery using the above sorbents.

Gold was recovered using the following procedure. Weighed portions of sorbents (100 mg) were placed into the solutions (100 ml), i.e., 1 g of sorbent per liter of solution (the commercial charge in the pulp is 20 $g l^{-1}$). The mixture was intermittently stirred, and then, after extraction concentration, the residual content of gold in solution was determined using the atomic absorption method, and the sorption ratios were evaluated to compare the sorbent samples. The results are listed in Table 1.

As seen from Table 1, the highest recovery of gold, 99%, is reached with coconut sorbents, and the recovery of gold by ABG sorbents is lower (96%). The lower (by 3%) gold recovery is probably due to the higher ash content and smaller specific surface area of the ABG sorbent, and this disadvantage can be overcome by taking larger amounts of the sorbent, which is acceptable for the production process because of the low cost of the ABG sorbent.

The sorption capacity under the dynamic conditions was determined in a flow of the process solution, and in each case the fresh solution was used. The average content of gold in solution was 1.32 $mg l^{-1}$, and it varied depending on its content in the ore. 1-g portions of sorbents (about 2 mm particle size) in cotton-cloth containers were placed into a column. The solution was supplied from the bottom upwards at a rate of 0.5 $l h^{-1}$; the containers were wetted uniformly. The contact periods of 40 h, 100 h, and 7 days are not related to the rate of the sorbent saturation and can be associated with the diffusion problems in sorption of gold, arising with sorbents placed in containers to simplify analytical control of the gold content. The content of gold in the sorbent was determined by the spectral method; the results are listed in Table 2.

As seen from Table 2, for both coconut and ABG sorbents, the degree of the sorbent saturation with gold is similar. The capacity of the ABG sorbent for gold of 0.5–1.0% relative to the sorbent weight is close to the capacity of the best coconut sorbents, and thus it can be used to develop a process based on the use of the ABG sorbent as disposable material to recover gold from solutions. Taking into account the average ash content of the ABG sorbent of 20%, the calculated content of gold in the ash will reach 5%. Such concentrates are utilized at refining plants; the recovery of gold on the ABG sorbent is competitive with precipitation of gold with a zinc dust, also yielding a 5% concentrate.

Table 1. Equilibrium distribution of gold in sorption on carbon sorbents under the static conditions; initial concentration of gold in solution 1.52 $mg l^{-1}$, solution volume 100 ml, sorbent weighed portion 100 mg

Sorbent	Equilibrium concentration of gold, $mg l^{-1}$	Degree of recovery, %	Ash content, %
ABG	0.06	96	18–25
	0.06	96	18–25
	0.06	96	18–25
Coconut:			
Du Pont	0.02	99	5
GRC-22	0.02	99	5
Calgon Carbon			

Table 2. Capacity of sorbents for gold under the dynamic conditions

Sorbent	Gold content in sorbent, %, at indicated contact time		
	40 h	100 h	7 days
ABG-1	0.1	0.20	0.5
	0.1	0.19	0.5
	0.1	0.20	0.5
	0.2	0.42	1.0
	0.2	0.42	1.0
	0.2	0.42	1.0
Coconut:			
Du Pont	0.2	0.44	1.0
GRC	–	0.44	1.0
Calgon Carbon			

CONCLUSION

The capacity of the ABG sorbent for gold is 0.5–1.0%, which is acceptable for developing a process based on the use of the ABG sorbent as disposable material to recover gold from solutions.

Abstract—The equilibrium swelling of new hydrogels based on sodium acrylate and *N,N*-methylenebisacrylamide modified with 5-vinyltetrazole in water and aqueous solutions of nickel salts in the stage of radical polymerization was studied. The influence of 5-vinyltetrazole concentration in the monomer mixture on the characteristics of the resulting copolymers was studied.

The influence of various modifying copolymers on the characteristics of acrylic hydrogels has been extensively studied in the past ten years, since slight changes in the copolymer composition can result in significant changes in characteristics of the new polymeric materials. Progress in synthesis of tetrazole derivatives gave opportunities for production of new macromolecular compounds, which significantly stimulated an interest in this class of (co)polymers, since introduction of tetrazole-containing monomers into copolymers expanded the application of acrylic hydrogels [1, 2]. For example, copolymers based on salts of acrylic acid (AA) and 2-methyl-5-vinylterazole can be used as a medium for growth of plants at elevated ambient temperature [3].

In this work we studied the behavior of cross-linked copolymers based on salts of acrylic acid, 5-vinyltetrazole (VT), and *N,N*-methylenebisacrylamide (MBAA) in electrolyte solutions and also the kinetics of swelling of the synthesized polymers in distilled water.

EXPERIMENTAL

Hydrogels based on sodium acrylate, VT, and MBAA used as a cross-linking agent were prepared by polymerization in aqueous solution at room temperature; the initiating system was ammonium persulfate (APS)–tetramethylethylenediamine (TMEDA). The degree of neutralization of AA with sodium hydroxide was 0.9. The concentration of acrylate monomers in the reaction mixture was 30, VT, from 10 to 50, and APS, 0.8 wt %. The concentration of cross-linking agent was varied from 0.1 to 0.7 wt % relative to the sum of the monomers. 5-Vinyltetrazole was recrystallized before polymerization.[1] The characteristics and procedures of purification of the other chemicals, and also the copolymerization procedure were described previously [2].

The degree of equilibrium swelling was measured by the standard gravimetric method and evaluated by the equation

$$Q = (m_s - m_d)/m_d,$$

where m_s and m_d are the weights of swollen and dried samples, respectively (g).

In calculations, the results obtained in measurement of swelling of five similar samples were averaged.

The kinetic dependences of the degree of swelling in distilled water with variation of the concentration of the cross-linking agent and VT in the reaction mixture are presented in Figs. 1a and 1b. The experiments were carried out at 50°C. It is seen that, with increasing content of MBAA cross-linking agent, the equilibrium degree of swelling decreases. The results obtained allow preparation of tetrazole–acrylic hydrogels with preset characteristics in a definite time interval, which is significant for specific applications. This problem can be solved, e.g., by properly choosing concentrations of the initial components in the reaction mixture.

Both hydrogen bonds involving tetrazole rings and carboxy groups and hydrophobic interactions between units affect conformation of macromolecules of N–H-

[1] 5-Vinyltetrazole was synthesized at the St. Petersburg State Technological Institute.

1070-4272/03/7607-1176$25.00 © 2003 MAIK "Nauka/Interperiodica"

acidic tetrazole-containing copolymers in solution. As a rule, interactions of both types participate in formation of compact structures. It was shown previously [4] that macromolecules of unsubstituted poly-*C*-vinyltetrazoles have the conformation of double-stranded regular chains with the outer hydrophobic hydrocarbon surface; therefore, 5-VT copolymers are poorly soluble in water.

Figures 1a and 1b show that, with increasing content of VT in the reaction mixture, the equilibrium degree of swelling decreases.

At VT concentration less than 30 wt % relative to AA and 0.1–0.7 wt % content of MBAA, the resulting hydrogels hold their shape in the swollen state and have sufficient elasticity.

As known, hydrogels in electrolyte solutions behave as three-dimensional semipermeable membranes. Depending on the solution composition (e.g., concentration and nature of polyvalent metal salt), various distributions of ions in the system hydrogel–solution can occur [5].

Variation of the degree of swelling with time in nickel chloride solutions of various concentrations is shown in Fig. 2. It is seen that the hydrogels exhibit high degrees of swelling in solutions of salts of polyvalent metals with the concentration less than 10^{-2} M. In this case, the degree of equilibrium swelling of tetrazole-containing hydrogel is higher in a solution with a very low concentration of salt (10^{-5}–10^{-4} M) than in distilled water. This can be explained by the structured state at the interface of the salt solution and hydrogel [6].

Along with sorption of water molecules, the hydrogel forms complexes with metal ions, as suggested by coloration of the swollen copolymer. Complex formation of tetrazole-containing hydrogels with metal ions involves deprotonation of the NH group of the heterocycle [7]. It can be assumed that, in complex formation of tetrazolate ions with nickel chloride, polychelate complexes are formed.

With increasing salt concentration to 10^{-1} M, the gels studied are collapsed, which is explained by additional cross-linking of the polymeric chains by the metal ions. It was shown previously that, with excess metal ions in the solution surrounding the copolymer, a complex with three tetrazole units per metal ion is formed.

The complex formation and sorption characteristics of tetrazole-containing copolymers make them promising as flocculants in treatment of wastes from various

This work was financially supported by the Foundation for Basic Technical Sciences of the Education Ministry of the Russian Federation (project no. TOO-9.2-2078).

CONCLUSIONS

(1) The kinetic features of swelling of new hydrogels based on sodium acrylate and *N,N*-methylenebisacrylamide modified with 5-vinyltetrazole in the stage of radical polymerization in distilled water at 20°C show that the concentrations of the cross-linking

agent and 5-vinyltetyrazole in the monomer mixture affect the equilibrium degree of swelling of the resulting copolymers.

(2) Tetrazole-containing hydrogels in nickel salt solutions with the concentration less than 10^{-2} M exhibit a high water-absorbing power (up to 300 g per gram).

(3) High sorption power of the gels makes them promising for treatment of industrial wastewaters and in agriculture.

Received August 13, 2002

Abstract—Petroleum sorption on expanded graphite prepared from residual graphite hydrosulfate at 300–900°C was studied as influenced by pretreatment of the sorbent with water.

Expanded graphite is a highly efficient sorbent for petroleum and its derivatives; its sorption capacity for petroleum and industrial oil determined by the direct sorption procedure is about 80 [1–5] and 70 g g^{-1} [6, 7], respectively. The sorption capacity for petroleum and industrial oil form their aqueous emulsion is about 20 g g^{-1} [7, 8], i.e., it is lower by a factor of 3.5–4.

This sharp decrease in the sorption capacity cannot be due to competitive water sorption, since expanded graphite surface is mainly hydrophobic. Even if water is sorbed in the first steps, it should be desorbed from the sorbent by such a hydrophobic liquid as oil or petroleum. The lowering of the sorption capacity in an aqueous emulsion as compared to the direct sorption experiment is likely due to structural transformations of expanded graphite under the action of water. To check this assumption, in this work we studied the influence of pretreatment of expanded graphite with water on its sorption properties with respect to petroleum.

We used residual graphite hydrosulfate prepared from GT-1 natural flake graphite with the ash content of 5.68 wt % (Zaval'evskoe deposit). The graphite consists of mainly 0.630–0.315- (74.3 wt %) and 0.315–0.200-mm fractions (22.1%). The sample was treated with stirring with a 50% aqueous solution of chromium(VI) oxide (13 cm^3/100 g graphite) for 10 min and then with 95.8% sulfuric acid (42 cm^3/100 g graphite) for 10 min. After that, water (500 cm^3 per 100 g of the initial graphite) was added at room temperature and the reaction mixture was kept for 24 h. The crude product was filtered off and washed on the filter with water (8 dm^3 per 100 g of the initial graphite). The product was dried at 105°C to constant weight. Two batches of expanded graphite were prepared from the resulting graphite hydrosulfate.

The samples of the first batch were prepared by flash heating of residual graphite hydrosulfate in a muffle at a temperature ranging from 300 to 900°C. The samples were kept at 300–500°C for 5 min and then at 600–900°C for 2 min. The samples of the second batch were prepared by keeping samples of the first batch in water for 30 min. Then the liquid phase was carefully removed by filtration and drying at 105°C to constant weight.

We measured the specific surface area S_{sp} (m^2 g^{-1}), specific volume V_{sp} (cm^3 g^{-1}), and specific sorption of industrial oil W_{sp} (g g^{-1}) for all the samples of expanded graphite. The latter parameter was determined by the direct sorption method. The BET specific surface area was determined by low-temperature argon adsorption. The specific volume was calculated as the reciprocal of the bulk density of the sorbent.

We measured the sorption capacity of the expanded graphites for heavy oil [ρ = 0.873 g cm^{-3} (20°C)] from Lisichansk refinery. To a weighed portion of expanded graphite (~0.2 g) in a glass vessel, excess oil (25 g) was carefully added and the system was kept for 60 min to complete the sorption. Then the vessel was covered with a perforated metal foil and nonsorbed oil was allowed to drain down for 1 day. The oil sorption was determined gravimetrically. The sorption capacity of each sample was calculated as arithmetic mean of seven measurements.

When expanded graphite was treated with water, the following transformations were visually observed. Expanded graphite nonwetted with water was gradually saturated with water for 10 min, with its volume decreasing sharply. However, the vermiculite structure of graphite particles was retained. After drying, the black color of the initial expanded graphite changed to

1070-4272/03/7607-1179$25.00

Properties of expanded graphite samples prepared from residual graphite hydrosulfate

T, °C	S_{sp}, $m^2\ g^{-1}$		V_{sp}, $cm^3\ g^{-1}$		W_{sp}, $g\ g^{-1}$	
	batch 1	batch 2	batch 1	batch 2	batch 1	batch 2
300	9.6	5.0	52	35	17.9	14.8
400	12.1	7.3	122	66	28.2	18.5
500	30.7	12.7	149	74	31.3	23.2
600	41.2	15.1	179	75	38.5	24.7
700	55.4	22.4	222	79	48.2	26.4
800	47.8	21.9	250	86	57.1	28.0

gray with metallic luster. Separation of a negligible amount of small particles up to 0.1 mm in diameter was observed after both aqueous treatment and drying.

The specific surface area, specific volume, and sorption capacity for oil of the initial graphite samples expanded at T = 300–900°C (batch 1) and those of water-treated samples (batch 2) are summarized in the table. The influence of water treatment on the properties of expanded graphite is shown in Figs 1a–1c.

As seen from the table and Figs. 1a–1c, the specific surface area, specific volume, and sorption capacity for oil of all the samples linearly increase with increasing the preparation temperature. The parameters of all the samples decrease by a factor of 1.6–2.7, 1.5–3.0, and 1.2–2.0, respectively, after the samples were wetted with water and dried. The higher the preparation temperature of the samples, the more pronounced is the decrease. The temperature dependences of the specific surface area, specific volume, and sorption capacity for oil for the water-treated samples remain linear but their slopes decrease by factors of 2.5, 5, and 3.5, respectively.

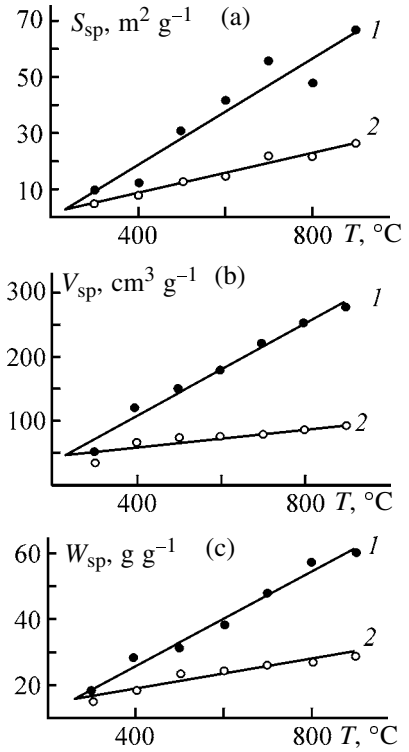

Fig. 1. (a) Specific surface area S_{sp}, (b) specific volume V_{sp} and (c) sorption capacity for petroleum W_{sp} of (*1*) the initial expanded graphite samples (batch 1) and (*2*) the samples treated with water (batch 2).

Thus, the morphology of expanded graphite particles profoundly changes after the water treatment, probably owing to a transformation of the honeycombed structure of expanded graphite under the action of forces of surface tension of water. This is confirmed by the fact that, as the preparation temperature of expanded graphite decreases and hence the strength of its honeycombed structure increases, straight lines shown in Figs. 1a–1c approach each other and cross at the point corresponding to the onset temperature of expansion of the residual graphite hydrosulfate (230–250°C).

The reasons for decrease in the specific surface area of expanded graphite are not so apparent. This cannot be due to collapse of water-filled pores during drying, since collapsed graphite layers will be expanded again with liberated water vapor. This also cannot be explained by collapse of empty pores when the specific volume of expanded graphite decreases under the action of forces of surface tension of water. This assumption is confirmed by the facts that the specific volume of expanded graphite decreases by a factor of 3 and its specific surface area remains the same after gentle mechanical treatment in the absence of water (mechanical stirring of dry expanded graphite for 45 min). We suggest that the specific surface area decreases owing to removal from the graphite structure of small fragments with the most developed surface.

A strong decrease in the sorption capacity for petroleum of expanded graphite treated with water is due to a decrease in its specific volume and specific surface area (Fig. 1c).

Thus, the substantial decrease in the sorption capacity for petroleum of expanded graphite treated with water is caused by morphological transformation of graphite particles, decreasing the specific surface area and specific volume of expanded graphite. These transformations can also be responsible for a sharp decrease in the sorption capacity of expanded graphite for petroleum and oil in going from direct sorption to sorption from an aqueous emulsion.

Abstract—The structure of asphaltene compounds formed by homogeneous pyrolysis of 2-naphthol was studied.

Although asphaltenes of various origins were studied in numerous works [1–15], their nature is not understood in detail. At the same time, asphaltenes play an important role in formation of liquid products of high-temperature coking of coals; they largely affect the structure and reactivity of coke and also of pyrocarbon prepared by pyrolysis of individual hydrocarbons and their mixtures.

To optimize processing of fossil fuels and high-temperature pyrolysis, it is quite necessary to study in detail the thermal degradation of the raw materials, including asphaltenes whose content in tars from "primary" decomposition of the organic matter of fuels reaches 30 wt %.

In this work we studied the structure of asphaltene compounds formed by homogeneous pyrolysis of 2-naphthol (800°C, 4.5 s).

EXPERIMENTAL

Asphaltenes were isolated as described in [16]. The molecular structure of asphaltenes was characterized by IR, UV, ^{1}H NMR, and ^{13}C NMR spectroscopy, elemental and quantitative functional analysis, and cryoscopy.

We found that the asphaltenes are a complex mixture of relatively high-molecular-weight polyfunctional compounds in which the prevailing structural fragments are fused aromatic rings and heterocomponents. Oxygen is present, in particular, in the forms of five-membered heterocycles inside fused aromatic structures [like naphtho(benzo)furans] and of quinoid groups (mainly 1,4-quinones). Phenolic hydroxyls are present, but alcoholic hydroxyls are not detected at all. Methoxy groups are present in small amounts. Among alkyl substituents in the rings, methyl groups prevail, but the degree of substitution is low. The mean size of fused systems is four rings.

To elucidate the structural features of asphaltene compounds in detail, we separated them into fractions by extraction with acetone, adsorption liquid chromatography, and preparative thin-layer chromatography (TLC).

Preparative TLC of asphaltene fractions was performed on standard Silufol plates (20 × 20 cm). The optimal separation of asphaltene fractions was attained in the following systems (the volume ratio is given in parentheses): fraction 1.1.1, hexane–diethyl ether–acetone (5 : 5 : 1); fraction 1.2, hexane–diethyl ether–ethyl acetate (10 : 10 : 1); fraction 2.1, heptane–diethyl ether (1 : 1); and fraction 2.2, hexane–diethyl ether (1 : 1).

The bands were developed under UV light (λ 254 and 366 nm). The nonluminescent bands were developed by treatment with solutions of various agents and also by chromatography on Silufol UV-254 plates in which the sorbent contained a luminescent additive, 0.05% sodium fluorescein. In this case, the nonluminescent bands were revealed by quenching of the green luminescence of sodium fluorescein.

The extracts, close-cut fractions, and even individual asphaltene compounds were characterized by a set of physicochemical methods.

We found that fractions 1.1.1 and 1.2 have a mixed hydroaromatic nature; they contain aromatic rings and heterocyclic groups. Their spectra exhibit absorption bands ν characteristic of fused aromatic systems (3030–3080, 1500–1600, 1450–1525 cm^{-1}). The aromatic rings are bonded with hydrogenated groups,

1070-4272/03/7607-1182$25.00

as suggested by strong bands at 2925, 2850, 1470, and 720–725 cm^{-1}.

It should be noted that the degree of aromaticity of fraction 1.1.1 is lower compared to 1.2. The content of cycloalkanes (ν 1611 cm^{-1}) in these fractions is similar and low. The content of methoxy groups (ν 2815–2830, 3050–3150 cm^{-1}) is also similar. However, in the quantitative content of other functional groups, fractions 1.1.1 and 1.2 differ appreciably. Fraction 1.2 is characterized by higher, compared to 1.1.1, intensity of the bands of phenolic hydroxyls (3850–3670, 1140–1230, 1410–1310 cm^{-1}) and heterocyclic oxygen (845–870, 3125–3165, 1030–1075 cm^{-1}). The shape and position of the quinoid bands (1600–1670, 1635–1655 cm^{-1}) suggest the presence of one (on the average) quinoid group in the ring.

The IR spectra of fractions 2.1 and 2.2 show that their major structural elements are fused aromatic rings and heterocycles (3030–3080, 1500–1600, 1450–1525 cm^{-1}), and also hydrogenated rings, as indicated by the absorption bands of the CH_2 group (2925, 2850, 1470, 720–725 cm^{-1}). The degree of aromaticity of fraction 2.2 is higher than that of 2.1. The bands at 3580–3670, 1140–1230, and 1310–1410 cm^{-1} suggest the presence of phenolic hydroxyls in both fractions, with their content in fraction 2.1 being higher by a factor of 15. The presence of quinoid groups is confirmed by the bands at 1660–1670 and 1635–1655 cm^{-1}; on the average, one quinoid group is present per ring. Quinoid groups have the structure of conjugated cyclohexanones and cyclopentanones. The content of alkoxy groups (2815–2830, 3050–3150 cm^{-1}) is low, and heterocyclic oxygen (845–870, 3125–3165, 1030–1075 cm^{-1}) prevails in fraction 2.1. It is localized in five-membered heterocycles fused with aromatic fragments to form structures of the benzo(naphtho)furan type (3125–3165, 1015–1030, 845–870, 740–810 cm^{-1}). Among alkyl substituents in rings, methyl groups prevail (2910, 2850, 1450, 1380 cm^{-1}). The pattern in the range 700–820 cm^{-1} suggests that the "acene" mode of fusion prevails over the "phene" mode.

Studies of the asphaltene compounds isolated by preparative TLC showed the following.

Fraction 1.1.1 was separated into 14 components, with their yield ranging from 3.2 to 14.3%. The content of elements (%) varies in the following ranges: C, from 80.0 to 88.1; H, from 6.4 to 7.6; and O, from 5.5 to 25.6%. The content of functional groups (g-equiv mol^{-1}) varies in the following ranges: quinone groups (QG), from 0.08 to 0.21; phenolic groups (PG), from 0.06 to 0.21; alkoxy groups (AG), from 0.01 to 0.16; and heterocyclic oxygen (O_c), from 0.04 to 0.48. The molecular formulas are $C_{11.75}H_{12.92}O_{1.00}$–$C_{18.81}H_{25.06}O_{5.39}$.

Fraction 1.2 was separated into 14 components, with their yield ranging from 4.3 to 12.8%. The content of elements (%) varies in the following ranges: C, from 63.6 to 93.0; H, from 6.3 to 9.1; and O, from 0.1 to 30.1%. The molecular weight *M* varies from 169 to 394. The content of functional groups (g-equiv mol^{-1}) varies in the following ranges: QG, from 0.01 to 0.40; PG, from 0.02 to 0.40; AG, from 0.05 to 0.22; and O_c, from 0.09 to 0.33. The molecular formulas are $C_{12.94}H_{18.35}O_{0.74}$–$C_{20.87}H_{24.80}O_{7.43}$.

Fraction 2.1 was separated into six components. Their yield varies from 2.8 to 28.3%. The content of elements (%) varies in the following ranges: C, from 80.3 to 87.5; H, from 6.0 to 9.5; and O, from 4.8 to 10.6%. *M* varies from 236 to 295. The content of functional groups (g-equiv mol^{-1}) varies in the following ranges: QG, from 0.65 to 1.00; AG, from 0.30 to 0.60; and O_c, from 0.27 to 0.35 g-equiv mol^{-1}. The molecular formulas are $C_{16.06}H_{21.79}O_{1.59}$–$C_{20.95}H_{18.10}O_{1.41}$.

Fraction 2.2 was separated into 14 components. Their yield varies from 2.0 to 18.6%. The content of elements (%) varies in the following ranges: C, from 77.6 to 90.6; H, from 5.7 to 15.2; and O, from 0.5 to 10.0%. *M* varies from 189 to 496. The content of functional groups (g-equiv mol^{-1}) varies in the following ranges: QG, from 0.12 to 0.37 and O_c, from 0.07 to 0.14. The molecular formulas are $C_{14.44}H_{11.15}O_{0.28}$–$C_{38.56}H_{30.75}O_{0.16}$.

Additionally we found that the components of fraction 1.2 have a hybrid naphthenoaromatic nature, with the cycloalkane structures prevailing. In fraction 1.1.1, aromatic structures and oxygen-containing heterocycles prevail. Fraction 2.1 mainly contains fused aromatic structures with the linear fusion mode, substituted by phenolic, methoxy, and methyl groups. Oxygen is also present in the form of cyclohexanone, cyclopentanone, and furan rings. The total number of rings in structures is 3–5.

Components of fraction 2.2, as those of fraction 2.1, consist mostly of three or four rings fused mainly in the linear mode; only one compound contains eight rings. The degree of aromaticity of the components is high, as confirmed by the C : H ratio. The calculation results obtained using the Van Krevelen [17] and Lillard [18] structural-group analysis procedures are well consistent with the suggested formulas.

CONCLUSIONS

(1) The structure of asphaltene compounds formed by homogeneous pyrolysis of 2-naphthol was studied in detail by IR, UV, ^{1}H NMR, and ^{13}C NMR spectroscopy, elemental and quantitative functional and structural-group analyses, cryoscopy, extraction, and adsorption liquid and preparative thin-layer chromatography.

(2) Asphaltene compounds have a hybrid naphthenoaromatic nature. The linear fusion mode prevails; the number of rings varies from 2 to 8. The rings contain phenolic, quinoid, alkoxy, and methyl substituents. The content of heterocyclic oxygen is high.

OBITUARIES

Karl Samoilovich Minsker (1929–2003)

On May 23, 2003, Karl Samoilovich Minsker, an outstanding scientist, prominent specialist in chemistry of macromolecular compounds, petrochemistry, and technical chemistry, doctor of chemistry, professor, academician of the Academy of Sciences of the Republic of Bashkortostan, and Honored Scientist of the Russian Federation and the Republic of Bashkortostan, died in the age of seventy-three.

K.S. Minsker graduated from the Lomonosov Institute of Fine Chemical Technology in Moscow. He started working at the chemical plant in Dzerzhinsk, Gor'kii oblast, as head of shift. From 1953 till 1967, he worked at Dzerzhinsk Chemical Research Institute (now Kargin Research Institute of Polymer Chemistry and Technology), where made a career from junior researcher to head of laboratory. The initial period of Minsker's scientific activities is closely associated with Academician G.A. Razuvaev. In 1968, Minsker was invited to Ufa to organize at Bashkir State University a chair of macromolecular compounds. Simultaneously, from 1968 till 1983, he headed laboratory of ionic polymerization at the Institute of Chemistry, Bashkir Branch of the USSR Academy of Sciences. In 1978, Minsker organized and headed the Problem Research Laboratory of Degradation and Stabilization of Halogen-Containing Polymers at Bashkir State University.

Under Minsker's supervision, a quantitative theory of degradation of chlorine-containing polymers was set up, and quite a number of high-performance additives to polymers and formulations for materials and articles, mainly based on polyvinyl chloride, were developed. A fundamental phenomenon of modification of Ziegler–Natta catalysts with electron-donor compounds in polymerization of olefins was described for the first time, which is presently the main classical way to control the activity and selectivity of industrial catalytic systems. An original theory of the mechanism of stereoregulation in polymerization of olefins and dienes on Ziegler–Natta catalysts was developed. Important fundamental aspects of the mechanism of cationic polymerization of olefins were revealed. A new section of chemical physics and theoretical technology, concerned with occurrence of fast processes in turbulent flows, was developed, which made it possible to create and put in industrial practice a number of resource- and energy-saving highly efficient processes based on small-size tubular turbulent reactors.

Among Minsker's disciples are 54 candidates and 11 doctors of science. He published more than 1100 printed works, including 16 monographs and books, and was holder of 25 foreign patents and more than 300 inventor's certificates and RF patents. Minsker was honored with titles "Man of the Year 1994–1995" (American Biographic Institute) and "International Man of the Year 1995–1996" in science and education (International Biographic Centre, Cambridge, England). He was awarded a medal "For Achievements in the XX Century, 1999–2000" (International Biographic Centre, Cambridge, England), a State Prize of the Republic of Tatarstan in Science and Technology (2001), and Academician Kargin Prize of the Russian Academy of Sciences, and was more than once a laureate of the All-Union Exhibition Center (VDNKh) and the Russian Exhibition Center.

The blessed memory of Karl Samoilovich Minsker will be forever preserved in the hearts of his numerous disciples and colleagues and his people.

A. A. Berlin, G. E. Zaikov, V. P. Zakharov, R. Akhmetkhanov, and staff members of the Chair of Macromolecular Compounds, Bashkir State University

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

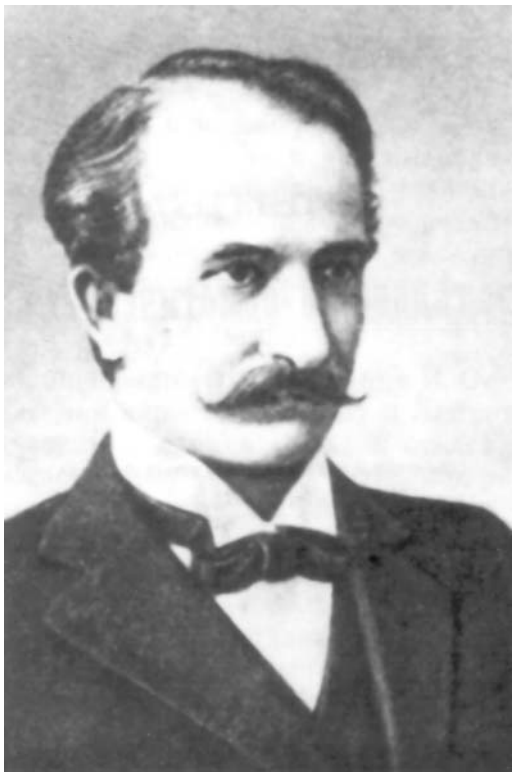
Academician Pavel Ivanovich Walden (on 140th Anniversary of His Birthday)

In the early XX century, two positions were provided at the St. Petersburg Academy of Sciences for ordinary academicians in chemistry. Since 1886 these positions were occupied by F.F. Beilstein (1838–1906) and N.N. Beketov (1827–1911). After Beilstein's death, his position remained vacant for a certain time, and in 1916, P.I. Walden, professor of chemistry of Riga Polytechnic Institute, was elected member of the Academy of Sciences. In a representation signed by a number of scientists, including Beketov, V.I. Vernadsky, and A.P. Karpinsky, Walden's achievements were noted, in the first place, in stereochemistry of organic compounds. As an exception, Walden was allowed to temporarily remain in Riga and to come to St. Petersburg only to take part in sessions of the Academy of Sciences. World War I, which began in August 1914, resulted in that Walden did not move to Petrograd.

Walden's life and scientific activities have been the subject of a great number of publications, including a detailed scientific biography [1], and other studies and recollections [2–9]. In a brief essay, only the main events of the scientist's life and his close association with St. Petersburg colleagues will be recalled.

Pavel Ivanovich (Paul) Walden was born on July 26, 1863, in a peasant's family in Latvia, not far from the town of Cecis. In 1876, he graduated with distinction from the Cecis regional school, and in 1882, finished with the same amount of success his secondary education at Riga modern school. In December 1882, Walden became a student of Riga Polytechnic School (Riga Polytechnicum), founded in 1862. The teaching was in German, actually Walden's native language, even though he is commonly considered to be a Latvian [2, 8]. Later, in 1896, the school was reorganized into State Riga Polytechnic Institute with teaching in Russian. Riga Polytechnicum had reputation of an exemplary educational institution with high level of specialist training and was a prominent research center.

Nearly simultaneously with Walden's entry into Riga Polytechnicum, the position of a professor of chemistry at this institution was occupied by young



Wilhelm Ostwald (1853–1932, 1909 Nobel Prize laureate), who returned to his native city from Derpt (now Tartu, Estonia) where he studied, and then taught chemistry. Ostwald started to deliver all courses of theoretical and technical chemistry, much extended the volume of laboratory works; he demanded that students should present and defend a degree thesis devoted to research. In September 1885, having become an assistant (not on permanent staff) of a professor of physics, T. Grönberg (1845–1910), Walden found an opportunity to do experimental research. By that time, he, following Ostwald's example, decided to prepare himself to work as chemist researcher.

In 1887, the first Walden's scientific publication, concerned with comparative assessment of reactions proposed for qualitative detection of nitric acid, appeared in *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva* (*Zh. Russ. Fiz.-Khim. O–va.*, 1887, vol. 19, no. 5, pp. 274–1295). By recommendation of

1070-4272/03/7607-1186$25.00 © 2003 MAIK "Nauka/Interperiodica"

N.S. Kurnakov, N.A. Menshutkin, and I.F. Schroeder, the young scientist was made a member of the Russian Physicochemical Society. In the same year appeared joint publication by Ostwald and Walden, which was devoted to variation of the molar electrical conductivity of acids and bases with their dilution (*Z. Phys. Chem.*, 1887, vol. 1, no. 10, pp. 529–549).

In 1888, Walden graduated with distinction from the Department of Chemical Technology, Riga Polytechnicum, and was given a rank of chemist-engineer. By that time, Ostwald moved to Leipzig, to become head of the chair of physical chemistry at Leipzig University. Professor K.A. Bischof (1855–1908), who replaced Ostwald in Riga, was an organic chemist. Walden accepted his proposition to remain assistant at the chair of chemistry (senior assistant since 1890 and associate professor since 1892) [9]. He commenced his rather intensive pedagogical and scientific activities at the Riga Polytechnicum (Polytechnic Institute), which continued till 1919.

Walden took the most active part in studies in the field of stereochemistry of organic compounds, the scientific direction developed by Bishof. A detailed analysis of the stereochemical research carried out in those years at the Riga Polytechnic Institute and other scientific centers of Russia has been made by Stradins [6]. During the period of time from 1889 till 1900, Walden published 57 papers concerned with stereochemistry in German journals and in *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva*. He, in particular, was the first to demonstrate the possibility of spatial displacement of atomic groups about an asymmetric carbon atom, which leads to transition from one state to a mirror-opposite state (Walden inversion) [1, 6, 10, 11]. In other words, according to Walden, an optically active compound may be transformed into the corresponding isomeric antipode, bypassing the optically inactive form.

Despite his extensive and labor-consuming studies in organic chemistry and stereochemistry, Walden did not terminate research in the field close to Ostwald's interests, did not break off scientific relations with him, and more than once went to Leipzig. In September 1891, he defended with excellence at Leipzig University his doctoral dissertation "On Affinities of Certain Organic Acids and Relationship of the Affinities with the Constitution of the Acids." The thesis contained material on dissociation constants of a great number of organic acids. In summer of 1892, Walden was appointed lecturer (associate professor) of physical chemistry at the Riga Polytechnicum. His further career required a scientific degree from a Russian university. After passing the appropriate examinations, Walden defended in spring of 1893 his master's dissertation "An Experience of Study of Osmotic Phenomena on Sediment Films" at Novorossia University (Odessa), where known chemists, such as P.G. Melikishvili (1850–1927) and N.D. Zelinsky (1861–1953), were working at that time. Already in 1894, the young scientist obtained an established position of a professor of analytical chemistry at the Riga Polytechnicum. Also, Walden continued intensive research both in organic chemistry and in physical chemistry. In these same years, the scientist actively extended his scientific contacts, visited a large number of scientific centers, including St. Petersburg, Derpt (Tartu), Kiev, and universities in German cities (Freiberg, Halle, Göttingen). His scientific and personal relations with Ostwald remain especially close. In 1903, Walden wrote the first Ostwald's biography [12].

Studies in the field of stereochemistry served as a basis for Walden's doctoral dissertation, defended by him on March 7, 1899, at St. Petersburg University. Professors D.P. Konovalov (1856–1929) and N.A. Menshutkin (1842–1907) were his official opponents. After defending the dissertation, Walden focused his entire attention on physicochemical research: He studied the electrical conductivity of solutions of various substances in highly polar solvents. This direction of the scientist's research was considered in detail in [1, 13–16]. During the period from 1900 till 1934, Walden studied the ionizing capacity of about 50 solvents, introduced into scientific practice the concepts of solvation and solvolysis, established a relationship between the equivalent electrical conductivity at infinite dilution and viscosity (Walden rule), and revealed a number of other dependences. The Walden rule stimulated construction of models of solutions, based on the concept of ion motion in a continuous medium [16].

The experience of work of the Riga Polytechnic Institute, the first Russia's higher-school institution of this type, was of interest for organization of the Polytechnic Institute in St. Petersburg. Walden was invited to become a member of the Chief Commission, headed by the minister of finance S.Yu. Witte (1849–1915) and dealing with building schedule and curricula. It was also assumed that Walden would take positions of the dean of the metallurgical department and a professor of general chemistry. As noted by a known historian of chemistry, B.N. Menshutkin (1874–1938), Walden was confirmed as dean on July 27, 1901, but already in October of the same year reported that he could not accept this appointment and recommended that N.A. Menshutkin should be ap-

pointed the dean, which was done on November 1, 1901. Already at the beginning of 1902, Walden was elected director of the Riga Polytechnic Institute and confirmed in this position for four years, beginning on April 15, 1902. In view of student disturbances in autumn of 1905, Walden resigned as director and was appointed dean of the chemical faculty beginning in January 1, 1906.

As already noted, Walden was elected ordinary member (academician) of St. Petersburg Academy of Sciences in "technology and chemistry adapted to art and handicraft." After the death of Academician Beketov in November 1911, Walden was appointed head of the Chemical Laboratory, which was the only chemical research institution of the Academy of Sciences at that time. With the beginning of World War I, regular Walden's visits to Petrograd became difficult, and N.S. Kurnakov (1860–1941, elected academician in December 1913) became the actual head of laboratory.

In *Izvestiya Imperatorskoi Akademii Nauk* (Transactions of Imperial Academy of Sciences), Walden published, as an academician, 14 papers on electrochemistry of nonaqueous solutions and related problems. In December 1907, he took part in meetings of the First Mendeleev Congress and presented a report "On Mendeleev's Works Concerned with Solutions." Walden's reports at the Second Mendeleev Congress in December 1911 were devoted to the problem of mass conservation in chemical reactions and to the development of chemistry in Russia. During the period of time from 1907 till 1914, Walden took part in quite a number of large-scale Russian and international conferences and was elected honorary member of numerous academies and scientific societies. Walden's friendship with Ostwald continued and scientific relations with prominent chemists of that time, S. Arrhenius (1859–1927, 1903 Nobel Prize winner), J. van't Hoff (1852–1911, 1901 Nobel Prize winner), E. Fischer (1852–1919, 1902 Nobel Prize winner), W. Ramsay (1852–1916, 1904 Nobel Prize winner), and H. Tammann (1861–1938), were maintained. Twice, in 1913 and 1914, Walden was nominated for Nobel Prize. As noted in the monograph [1], the years of Walden's life preceding World War I were the summit of his scientific career and scientific creative activities.

In July 1915, the Riga Polytechnic Institute, and Walden together with it, were evacuated to Moscow. During the period from 1915 till 1918, the scientist had no laboratory of his own in Moscow and had virtually no opportunity to carry out research. He finished the book *Ocherk istorii khimiii v Rossii* (Study in the History of Chemistry in Russia) (1915) and delivered lectures on physical chemistry and history of chemistry not only to students in Riga, but also to those at Moscow University and other metropolitan educational institutions. During these years, Walden took part in the work of the Commission for Study of Natural Productive Forces (KEPS), organized in February 1915 by the initiative of Academician V.I. Vernadsky (1863–1945) and a number of other scientists. In the same year, the Military-Chemical Committee, presided by Kurnakov, was organized at the Russian Physicochemical Society. Walden was appointed head of the Moscow department of the Committee. The Committee and its Moscow department carried out much work on development of means for military-chemical protection and organization of manufacture of a number of chemical products.

On January 1, 1917, Walden was confirmed as rector of the Riga Polytechnic Institute. Brest peace treaty (March 1918) envisaged return of the institute to Riga occupied by German troops. Part of lecturers and students decided to remain in Russia, to become the basis of a new institute in Ivanovo-Voznesensk (now Ivanovo). The main part of professors and students of the Riga Polytechnic Institute, led by Walden, returned to Riga in August 1918.

The political instability in Latvia, nationalistic tendencies exhibited by the authorities, and lack of conditions for scientific work of full value, all this resulted in that, in early summer of 1919, Walden sent his family to Germany and soon himself accepted the invitation of Rostock University to take a position of professor of inorganic chemistry. However, Walden's relationships with Latvia and Russia were not terminated at once. In summer of 1924, he came to Riga by invitation of the Latvian University to deliver lectures on the most recent advances in chemistry. Despite the propositions made, Walden had not dared to move back to Latvia. He also declined an invitation to take the chair of inorganic chemistry at Petrograd University, which became free because of the death of L.A. Chugaev (1873–1922). Nevertheless, his scientific contacts with Russian scientists continued, and quite a number of Walden's works were published in Russian, including the monograph *Teorii rastvorov v ikh istoricheskoi posledovatel'nosti* (Theories of Solutions in Their Historical Succession) (Petrograd, 1921) and brochures *Iz istorii khimicheskikh otkrytii* (Excerpts from History of Chemical Discoveries) (Leningrad, 1925), *Proshloe i nastoyashchee stereokhimii* (Past and Present of Stereochemistry) (Leningrad, 1925), and *Khimiya i zhizn'* (Chemistry and Life) (Petrograd, part I, 2nd ed., 1922; part II, 1919; part III,

1921). The publication of Walden's works was initiated by Professor M.A. Blokh (1882–1941), a known chemist and historian of chemistry, who graduated from the Riga Polytechnic Institute in 1908 [1].

In December 1927, Walden was unanimously elected honorary member of the Academy of Sciences of the USSR. His personal meeting with Russian colleagues occurred only in September 1934, when Walden came to Leningrad to the VII Jubilee Mendeleev Congress devoted to 100th anniversary of Mendeleev's birthday as head of a representative German delegation. The delegation included H. Wieland (1877–1957, 1927 Nobel Prize winner), A. Stock (1876–1946), O. Hahn (1879–1968, 1944 Nobel Prize winner), and other known scientists. Walden made a report "Electrolytes and Solvents" and delivered speech of welcome on behalf of all foreign participants of the Congress. In his report on the trip, Walden highly appreciated the success in chemical education and industrial development, achieved in the Soviet Union by that time [1, 5].

In Rostock, Walden continued his studies of nonaqueous solutions and processes of association in these solutions, commenced in Riga in the prewar years. During the period of time from 1923 till 1934, he published, together with his disciples, more than 50 original papers; however, the interest of physical chemists in classical investigations into the nature of solutions diminished, with the main attention given to other problems. Nevertheless, Walden rather actively delivered lectures and reports in various cities of Germany and other countries. He spent the entire academic year of 1927/28 in the United States, mainly delivering lectures at the Cornell University (Ithaca, NY).

In 1934, at the age of seventy, Walden resigned and concentrated his entire attention on studies in history of chemistry [1, 4]. He made a great effort to write a monograph devoted to history of organic chemistry, covering the period from 1880 till 1940. The book was published in Germany in 1941. After that the monographs *Three Millennia of Chemistry* (1944) and *History of Chemistry* (1947) were published. As noted in [4], a historical analysis of a problem served to Walden as substantiation of the concepts developed by him.

During the night of April 24/25, 1942, as a result of bombardment of Rostock by British aircraft, Walden's house was burnt, with a large library, archive materials, manuscripts, and scientists' letters lost. After that, Walden moved to Berlin, and then to Frankfurt am Main. The town of Tübingen and Tübingen University became the scientist's last refuge. In 1950, Walden became honorary doctor of the Tübingen University and honorary professor. The scientist delivered lectures on history of chemistry to the age of 90, till July 1953.

Pavel Ivanovich (Paul) Walden died on January 22, 1957, at the age of ninety-three. The world scientific community lost a first-rate scientist who had been honored with a great number of honorary titles and awards, made an outstanding contribution to the development of chemical science, and was a prominent historian of chemistry.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Acid Decomposition of Eudialyte and Certain Rare-Metal Concentrates from Kola Peninsula

V. N. Lebedev, T. E. Shchur, D. V. Maiorov, L. A. Popova, and R. P. Serkova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received April 18, 2003

Abstract—Specific features of decomposition of eudialyte concentrate by acids were studied. The structure of eudialyte crystals was analyzed by processing the kinetic characteristics obtained.

Eudialyte $Na_{12}Ca_6Zr_3Fe_3[Si_3O_9]_2 \cdot [Si_9O_{24}(OH)_3]_2$, i.e., sodium zirconosilitate with complex structure, means, in translation, "readily decomposable"; however, as a rule, the degree of its decomposition by various acids is 65–75% [1–3]. It is only possible to extract zirconium(IV) into solution rather completely under rigorous conditions with a manyfold excess of an acid or with fluoride ions introduced [4–6]. This is attributable to blocking of the mineral by silica, formation of secondary zirconium(IV) compounds, presence of "acid-insoluble zirconium," etc. A high degree of extraction with a minor excess of an acid has been reported [7]; however, no details of the procedure used were given (it may be assumed that readily decomposable forms of eudialyte containing a minimum amount of niobium and titanium were subjected to treatment).

The aim of the present study was to analyze reasons for the low degree of breakdown of the eudialyte concentrate (EC) from the Novozero deposit.

Eudialyte found in various deposits is, presumably, inhomogeneous not only in its composition, but also in structure of a unit crystal. This is rather probable because the coefficients of impurity cocrystallization in the formation of the mineral are different, and the strength of a crystal depends on its structural perfection. To verify this assumption, we obtained kinetic characteristics of decomposition of eudialyte concentrates of varied origin by diferent acids.

EXPERIMENTAL

Eudialyte concentrates from two batches[1] were used in the experiments. The composition of the concentrates is listed in Table 1.

The decomposition was carried out in a temperature-controlled beaker with a stirrer at a stoichiometric acid consumption, with its initial concentration maintained constant in each stage of decomposition. Narrow fractions of the concentrates were decomposed with 2 N H_2SO_4 at 40°C under the conditions in which no coagulation of silicic acid occurred within the recorderd intervals of time. The main monitoring parameter was the weight of dry undecomposed residue, and in certain experiments, zirconium(IV) content was determined. In sampling, a precipitate was filtered off and washed with water on a filter and by repulping under vigorous stirring. The precipitate was dried also with stirring to destroy the possible silica films. Then, weighed precipitate was treated under the initial conditions, i.e., with a new portion of the acid with the same concentration at the same consumption. The decomposition rate was estimated by the ratio of the weight loss to weight under decomposition within a unit time in relation

[1] EC-1 batch was obtained on a pilot installation of the Mining Institute, Kola Scientific Center, Russian Academy of Sciences, from the ore of the rock deposit Kedykvyrpakh, and EC-2, at GIREDMET, "Sevredmet" site from the ore from the Alluaiv deposit.

Table 1. Elemental composition of eudialyte concentrates

Batch	Contents of oxides, wt %										
	Zr + Hf*	Si	Na	Ca	Sr	Fe^{3+}	Fe^{2+}	Mn	Ti	Nb	Ln
EC-1	10.5–12.5	51.4	13.8	5.8	1.6	3.7	0.9	2.0	1.1	0.68	2.4
EC-2	9.8–12.2	45.7	12.8	5.1	1.7	3.8	0.9	2.0	1.9	0.5	1.8

* For other components, average values are given.

to the amount of the decomposed mineral. The content of the components in the concentrates and insoluble residues were determined by X-ray fluorescence analysis, and that in solutions, by the atomic-absorption method.

The data obtained in the experiments on decomposition are presented in Figs. 1 and 2. The specific decomposition rate W (g g^{-1} h^{-1}) and mass loss Δm (%) were found using the formulas

$$W = (m_n - m_{n+1})/\tau m_n,$$

$$\Delta m = (m_0 - m_n)/m_0.$$

Here m_0, m_n, and m_{n+1} are, respectively, the masses of the initial and current samples during decomposition (g), and τ is the time of decomposition (h).

The specific rate of zirconium(IV) transfer into solution is given, also as a function of mass loss, in

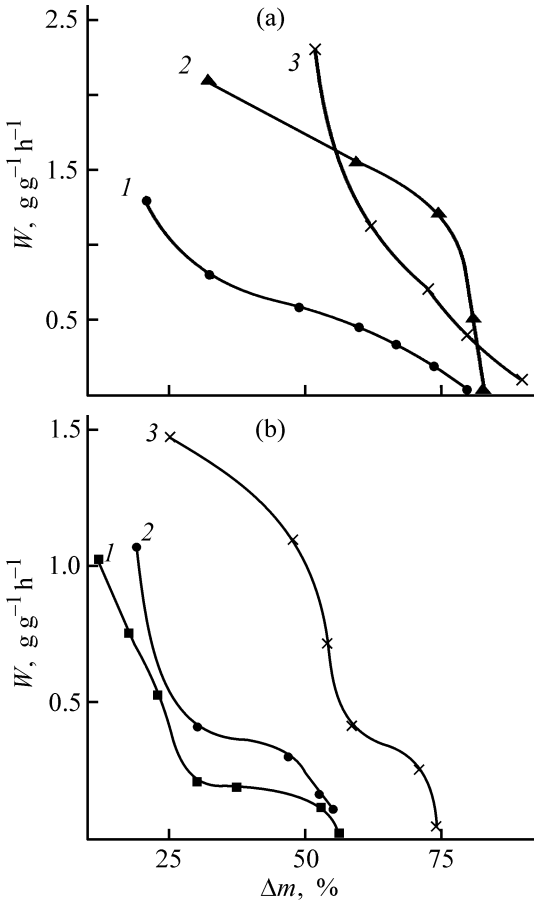

Fig. 1. Specific rate W of (a) EC-1 and (b) EC-2 decomposition with acids vs. the degree of decomposition. Fraction +0.063–0.16 mm. (Δm) Mass loss; the same for Figs. 2 and 3. Acid: (*1*) HNO_3, (*2*) H_2SO_4, (*3*) HCl.

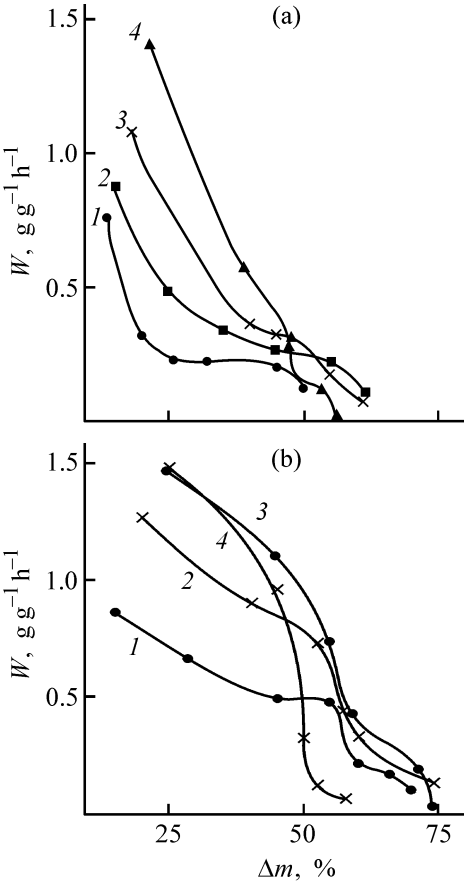

Fig. 2. Specific rate W of EC-2 decomposition with (a) HCl and (b) H_2SO_4 vs. the grain size and degree of decomposition. Fraction size (mm): (*1*) >0.315, (*2*) 0.2–0.16, (*3*) 0.06–0.16, (*4*) <0.06.

Table 3. Content of components in insoluble residues from decomposition with sulfuric acid

Residue of EC	Content of oxides, wt %					Mass ratio of oxides		Residue of EC	Content of oxides, wt %					Mass ratio of oxides	
	Zr	Si	Nb	Ti	Fe	Nb/Zr	Ti/Zr		Zr	Si	Nb	Ti	Fe	Nb/Zr	Ti/Zr
EC-1	6.9	52.5	1.2	0.69	2.6	0.17	0.1	EC-2	8.3	54.2	1.2	4.5	4.6	0.18	0.54

Fig. 3. An example of how the mass loss rate and the rate of zirconium(IV) transfer into solution in an experiment on decomposition of the EC-2 fraction –0.3 + 0.2 mm with sulfuric acid are calculated is given in Table 2.

Since we studied concentrates, rather than a monomineral fraction, a correction for ballast impurities was made when determining zirconium in the insoluble residue (Fig. 3). It follows from Table 2 that the mass of the insoluble residue was 6.1 g, and the ZrO_2 content, 8.1 wt %. Consequently, the content of insoluble impurities is 32.5 wt % (on assumption that eudialyte contains 12 wt % ZrO_2) or 2 g per 25 g of a portion being decomposed. As follows from the run of the curves, the error associated with ballast impurities is small. Thus, the following conclusions can be made on the basis of the kinetic characteristics.

(1) The decomposition rate decreases in the course of decomposition with acids irrespective of the grain size, which confirms the heterogeneity of the eudialyte structure.

(2) For both the concentrates and all the fractions, decomposition occurs the most readily in the experimental conditions under the action of sulfuric acid, with the decomposition rate of EC-1 being higher in the case of hydrochloric acid only in the initial stage. The decomposition parameters are the worst in the case of nitric acid. The concentrate from the Alluaiv deposit is more stable against acids, probably because of an increased content of titanium(IV), presumably strengthening the crystal lattice, in the concentrate. Hydrochloric acid and, the more so, nitric acid show poorer performance in decomposition of a concentrate with increased titanium(IV) content, since compounds with titanium are less characteristic of these acids.

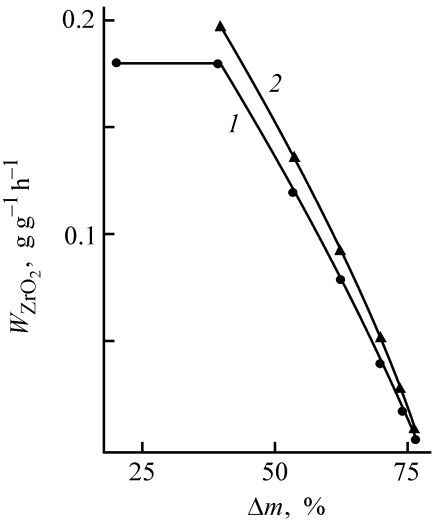

Fig. 3. Specific rate of zirconium(IV) transfer into solution W_{ZrO_2} from (*1*) EC-2 and (*2*) eudialyte vs. the degree of decomposition.

* Ratio of the content of an oxide to that of ZrO_2. ** Treatment at 90°C.

The irregularity of the mineral structure is confirmed by the composition of insoluble residues. The mass ratio of niobium and titanium oxides to ZrO_2 in the insoluble residues from EC decomposition with hydrochloric acid is 2–3 times that in the initial concentrate (Table 3). In spite of a prolonged treatment with acids, the insoluble residues retain the eudialyte structure. Their complete decomposition with sulfuric acid at 40°C only occurs at a concentration of 4 M; at 80°C the process is more intense, but is complete at a concentration of 3 M (Fig. 4). Therefore, the residues should be decomposed separately under more rigorous conditions, probably with introduction of fluoride ions into the reaction system. The processing technology of such concentrates must involve double decomposition: first, the secondary precipitate is treated under rigorous conditions with a concentrated acid, and then this solution is used to decompose the readily soluble part of eudialyte.

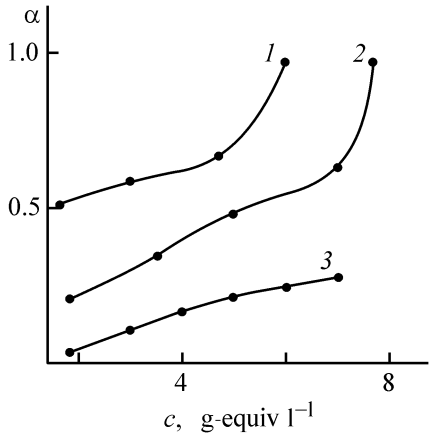

Fig. 4. Degree $\alpha = c/c_0$ of decomposition of insoluble residue vs. acidity of medium and temperature. c and c_0 are current and initial concentrations of acid. Acid: (*1, 2*) H_2SO_4, (*3*) HCl. Temperature (°C): (*1*) 80, (*2*) and (*3*) 40.

The irregularity of structure is also confirmed by the composition of the leaching solution. The contents of components in the second and the last portions of leaching solutions are listed in Table 4 (the first portion was not analyzed because of the primarily dissolving nepheline). With the decomposition of the concentrate, the ratio of the main (by mass) eudialyte components (silicon and sodium) to zirconium in solutions decreases; however, sodium is presumably leached first, with silicon retained in the eudialyte structure to a greater extent. Titanium is leached from EC-2 with hydrochloric acid in minor amounts under the experimental conditions, which is also confirmed by its increasing concentration in the insoluble residue. The leaching of titanium and niobium with sulfuric acid varies between batches. Presumably, part of these elements can strengthen the structure of the mineral, and part, be sorbed on a zeolite. The other components are leached to almost the same extent as zirconium.

Table 5. Distribution of elements in decomposition of rare-metal concentrates

Product	Decomposition technique	Degree of decomposition, %	Content of oxides, wt %					Ta/Ti(Zr) mass ratio
			Ti	Nb	Ta	Ca	Zr	
Loparite	HNO_3 + HF	80	39.6	8.8	0.62	4.5	–	0.016

Baddeleyite	CaO + $CaCl_2$	95	0.12	0.54	0.3		98.9	0.003
Residue			0.1	0.36	0.23		97.3	0.002

When other rare-metal concentrates (loparite, perovskite, sphene, and baddeleyite) are treated with acids, 5–20% of the concentrate occasionally remains undecomposed in spite of the rigorous conditions of the process. This is the most pronounced in the case of loparite, whose sulfuric acid processing resulted in extraction of the most valuable product tantalum by no more than 90%. This was attributed to hydrolysis of tantalum or its binding into phosphates. We assumed the same irregularity of the concentrate composition and checked whether the composition of insoluble deposits coincides with that of the initial concentrate. Undecomposed deposits were analyzed after separation of hydrolyzed forms by decantation and treatment of the insoluble residue with a mixture of hydrofluoric and sulfuric acids.

It was found (Table 5) that, in most cases, the content of tantalum in the insoluble residue is increased, which seems to strengthen the crystal lattice of the mineral. The only exceptions are sphene and baddeleyite residue from sintering. Stronger structural units seem to be present in sphene [8], and in the case of baddeleyite, the pretreatment and quality of stock are more important, since the decomposition conditions are rather rigorous.

CONCLUSIONS

(1) It was found by analyzing kinetic characteristics of acid decomposition of eudialyte concentrates that the structure of eudialyte crystals is irregular, and the presence of niobium and titanium in it is a probable reason for the low degree of decomposition. This also accounts for the lower degree of decomposition with nitric and hydrochloric acids, compared with sulfuric acid. The eudialyte concentrate from the Alluaiv deposit, containing 1.9 wt % TiO_2 is decomposed with hydrochloric acid to an extent of 65–70% under the chosen conditions, whereas the concentrate containing 1.1 wt % TiO_2 (with loparite accounting for about 50% of this amount) is decomposed by 95–97%. In all probability, the increase in the efficiency of eudialyte decomposition upon introduction of fluoride ions is to greater extent due to lattice destruction via binding of such strong acceptors of fluoride ions as titanium(IV), niobium(V), and tantalum(V).

(2) An analysis of residues formed in decomposition of other rare-metal concentrates, such as loparite, perovskite, and baddeleyite, demonstrated that the fraction of tantalum in relation to the main substance is increased. To improve the efficiency of processing of such concentrates, it is necessary to create a separate line for treatment of insoluble residues.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Fabrication of Low-Dimension CdSe Structures by Atomic Layer Epitaxy

D. P. Mikhaevich and Yu. K. Ezhovskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received November 25, 2002; in final form, June 2003

Abstract—Formation of thin cadmium selenide films on semiconductor and dielectric matrixes of (100) and (111) orientation from atomic-molecular beams was considered. Temperature ranges in which thin CdSe films are formed were determined. Conditions for layer-by-layer growth of nanostructures were established.

The development of new synthesis techniques and study of the formation of thin layers are among first-priority problems in the development of controlled synthesis of surface nanostructures. It is of importance, for theoretical and applied purposes, to have an opportunity to predict the results of a synthesis and the structural perfection of layers being formed.

Recently, the atomic-layer epitaxy (ALE) [1, 2], which makes it possible to obtain high-quality submicrometer dielectric layers, has attracted special interest abroad. This technique, which in better known in Russia as the method of chemical assembling, is based on macromolecular concepts of solids [3]. The method enables synthesis of thin film structures and nanostructures, in particular, by chemical reactions of surface functional groups of a matrix with gaseous reagents, to give surface chemical compounds.

Monomolecular or thicker layers of a compound to be synthesized can be grown by a series of successive chemical reactions on the matrix surface. To perform chemical assembling, it is necessary that the substrate temperature T_s should satisfy the relationship: $T_A, T_B < T_s < T_{AB}$, where T_A, T_B, and T_{AB} are, respectively, the critical condensation temperatures of components A, B, and compound AB.

It is necessary to note that such a layer can be grown without formation of three-dimensional nuclei, which allows synthesis of rather thin (<10 nm) solid films. Performing the process under nonequilibrium conditions, which can be easily attained by using a significant excess of a reagent and rapidly removing gaseous reaction products, yields a stable structure. The reaction of polycondensation and addition from atomic-molecular beams (molecular layering and atomic layer epitaxy, respectively) can be used as surface reactions [4]. In the latter case atomic or molecular beams of components in a vacuum are used. The most suitable for this purpose are $A^{II}B^{VI}$ compounds, owing to the sufficiently high vapor pressure at elevated temperatures and low critical condensation temperatures of their components [5]. Among compounds of this kind, cadmium selenide, which exhibits high photoconductivity and the shortest photoresponse time, is of special interest. Ultrathin CdSe films (nanostructures) are also of interest for fabrication of various optoelectronic systems.

EXPERIMENTAL

Low-dimension structures were fabricated by successive exposures of a substrate to molecular beams of cadmium and selenium, obtained by evaporation of the respective substances from Knudsen cells in an oil-free vacuum at a residual pressure of 5×10^{-3} Pa. Single-crystal (100) GaAs wafers of AGChT-23-17 brand, glass, and (0001) mica were used as substrates. The exposure duration was varied for each reagent within the range of 0.5–6 s. The calculated component fluxes across the support plane were determined from evaporation temperatures [5] and geometric parameters of the evaporator–substrate system. At fluxes R of 5×10^{14}–5×10^{16} $cm^{-2}\ s^{-1}$ and exposure duration exceeding 0.5 s, the layer thickness was determined only by the number of cycles and substrate temperature. It is seen from Fig. 1 that the duration of exposure to component beams, required to ensure the maximal filling of the surface under fixed condi-

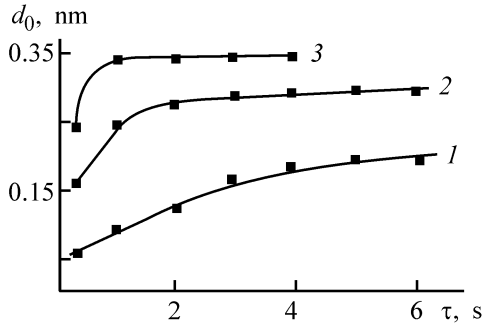

Fig. 1. Growth constant d_0 of CdSe films synthesized on (100) GaAs surface at 373 K vs. duration τ of exposure to components. R_{Cd}, R_{Se} (cm^{-2} s^{-1}): (*1*) 2.79×10^{14}, 1.38×10^{14}; (*2*) 9.3×10^{14}, 4.6×10^{14}; (*3*) 3.72×10^{15}, 1.84×10^{15}.

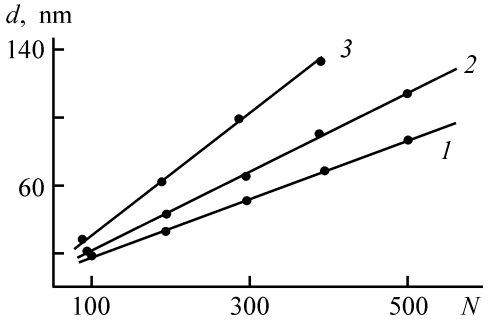

Fig. 2. Thickness of CdSe films d on mica surface vs. the number of exposure cycles N. $R_{Cd} = 9.3 \times 10^{14}$, $R_{Se} = 4.6 \times 10^{14}$ cm^{-2} s^{-1}; $\tau = 3$ s. T_s (K): (*1*) 458, (*2*) 423, and (*3*) 373.

tions of component evaporation ($R_{Cd} = 3.72 \times 10^{15}$ and $R_{Se} = 1.84 \times 10^{15}$ cm^{-2} s^{-1}) should be no less than 3 s. Therefore, the time of 3 s was chosen as exposure duration.

The thickness of the films synthesized was measured by the interference method and ellipsometry. Layer thicknesses less than 100 nm were determined from the results of ellipsometric measurements of the polarization parameters Δ and Ψ. These parameters, which characterize the surface properties, were recorded on a laser ellipsometer at a wavelength λ = 623.8 nm and light beam incidence angle θ = 68°30′. The thickness was computed in terms of the single-layer model by Drude's equation [6]. The measurement inaccuracy was no greater than 3%. Layer thicknesses exceeding 100 nm were measured by the interference method on an MII-4 interferometer.

An analysis of the experimental data on the kinetics of surface filling demonstrated that the curves covering both monomolecular and polymolecular sorption are well described by the equation

$$d_0 = d_{0(\max)}[1 - \exp(-\tau/t)] + \alpha t. \quad (1)$$

Here d_0 is a proportionality factor corresponding to the averaged layer thickness per exposure cycle; $d_{0(\max)}$, the maximum increase in layer thickness per exposure cycle; τ, the duration of contact with a reagent; t, the time constant of the process; α, a coefficient characterizing the contribution of the polymolecular adsorption, which is very close in its meaning to the condensation coefficient, $\alpha = f(R, T_s)$.

A comparison of the experimental data obtained with the calculated amount of a component, which is necessary for monomolecular filling of the surface of a given crystallographic orientation, demonstrated that the latter value is exceeded by more than a factor of 10. This points to the occurrence of a chemical reaction between the chalcogen and the metal by the Ridil–Ili mechanism. In this case, the surface reaction rate V depends on the surface filling θ and is given by the expression

$$V = k\theta R_+. \quad (2)$$

Here k is a dimensionality coefficient.

At nearly limiting filling ($\theta \to 1$), $V \to kR$, i.e., the rate of a reaction occurring under discrete exposure conditions depends only on fluxes of the substances being evaporated.

A study of the dynamics of layer growth demonstrated that, at fixed substrate temperature, the layer thickness increases in proportion to the number of cycles of exposure to molecular flows of the components. For all the substrates used, the dependences are linear (Fig. 2) and well described by the equation

$$d = d_0 N. \quad (3)$$

Here d is the film thickness, and N is the number of cycles of substrate exposure to component flows.

In atomic layer epitaxy, d_0 is named the growth parameter. It characterizes the structure of a growing layer and depends on the mechanism of its formation.

The linearity of the dependence $d = f(N)$ indicates that equal amounts of the surface compound are synthesized in each reaction cycle and, hence, the nanostructure grows uniformly. This allows control of the layer by only by the number of cycles of support surface exposure to component vapors.

Analysis of how the growth parameter depends on the substrate temperature, $d = f(T_s)$ (Fig. 3), gives

a notion of the layer formation mechanism. For example, three characteristic portions can be distinguished in Fig. 3 for all substrate types. In the low-temperature region, in which d_0 is large, the selenium vapor pressure is comparable with the cadmium vapor pressure, and the critical condensation temperatures of these substances at fixed flux are higher than the experimental temperatures, which results in the condensation of the metal and the chalcogen [7]. In this case, CdSe layers are formed through reaction between components within an adsorbed polymolecular layer. This is also indicated by values of the d_0 parameter, which significantly exceed interlayer spacings for various orientations of the crystal structure of this material. Such a film growth mechanism is accompanied by the formation of fragments of the crystalline phase of the compound, which gives polycrystalline layers [8].

At higher temperatures the value of d_0 is virtually constant, falling within the range $(0.29-0.33) \pm 0.01$ nm for the substrates under study. The calculated interlayer spacings for the sphalerite structure of CdSe are 0.303 and 0.349 nm for the (100) and (111) orientations, respectively. Comparison of the experimental d_0 values with the above-indicated calculated interlayer spacings suggests that the predominant orientation is (100) for GaAs and (111) for the glass substrate. These conclusions were confirmed by an electron-diffraction study of the structure of the layers being formed, with thickness exceeding 100 nm. It was shown that, with increasing temperature, a predominant orientation (texture) appeared in the films and transformed into a well-oriented structure. Thus, it may be assumed that the films grow by the layer mechanism with limiting, nearly monolayer filling of the surface in the indicated temperature range through chemisorption of each of the components.

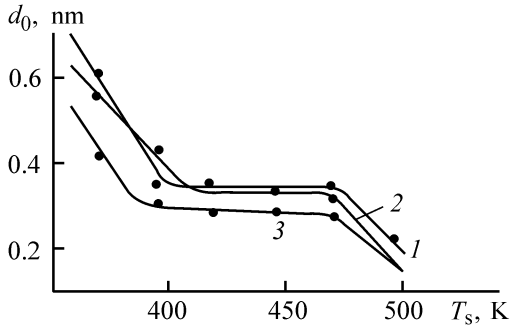

Fig. 3. CdSe film growth constant d_0 vs. substrate temperature T_s (K). Substrate material: (*1*) glass, (*2*) (100) GaAs, (*3*) mica.

With account taken of the significant degree of hydroxylation of the matrices indicated [7–9], the formation of a chalcogenide layer can be represented as the following surface reactions:

$$\begin{array}{l}=A-OH\\ \quad|\\ =A-OH\end{array} + Cd \rightarrow \begin{array}{l}=A-O-Cd\\ \quad|\\ =A-O-Cd\end{array} + 0.5Se \rightarrow \begin{array}{l}=A-O-Cd\\ \quad|\\ =A-O-Cd\end{array}\!\!\diagdown\!\!Se + 2Cd \rightarrow \begin{array}{l}=A-O-Cd\diagdown\\ \quad|\\ =A-O-Cd\diagup\end{array}\!\!Se\!\!\begin{array}{l}\diagup Cd\\ \diagdown Cd\end{array} \quad \text{etc.},$$

where A stands for surface atoms of GaAs and Si substrates.

It should be noted that, when chalcogenide structures are formed by alternating exposures of the matrix surfaces to metal and chalcogen vapors, the chemisorption of the metal on the surface hydroxy groups is predominant. The chemisorption of a chalcogen is of the dissociative nature and, as established for the case of growth of zinc sulfide nanostructures [10], is the rate-determining stage of the process.

A sharp decrease in d_0 values with increasing substrate temperature is due to partial surface filling, resulting from significant desorption of the compound components. In this case, the film growth in the initial stage may occur with the formation of two-dimensional nuclei on surface hydroxy clusters and their subsequent three-dimensional development to give a layer with critical thickness. Comparison of the calculated and experimental d_0 values allows evaluation of the degree of surface filling. It is about 0.7 for gallium arsenide at 523K, which corresponds to the degree of surface hydroxylation for this material [8]. Under these conditions, well-oriented structures were formed.

CONCLUSION

Analysis of the pattern of formation of cadmium selenide layers on the matrices under study suggests that, in all the cases, the layers grow by mechanisms successively replacing one another. These mechanisms are typical of all cyclic processes of chemical assembling. The component vapor pressure is a key factor in the low-temperature region, in which condensation processes predominate, and the degree of surface hydroxylation, at the high temperatures.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Optical Properties of Porous Glass Modified with Vanadium(V) Oxide

V. N. Pak and S. V. Sukhanov

Hertzen Russian State Pedagogical University, St. Petersburg, Russia

Received May 22, 2003

Abstract—Porous glasses modified with vanadium(V) oxide were obtained by impregnation with aqueous NH_4VO_3 solutions and by subsequent thermal decomposition of the salt. Changes in the charge-transfer spectra, resulting from an increase in the content of the deposited oxide and from water sorption, and also the possibility of using vanadium-containing glass for visual monitoring of air humidity were considered.

A wide variety of optical materials can be obtained from xerogels of silicic acid by introducing transition metal ions into these materials [1–6]. In particular, procedures for synthesizing transparent silica films including V(IV) and V(V) oxo anions have been studied [4–6]. Optical media of this kind can also be obtained on the basis of porous glasses (PG) modified with appropriate additives [7]. One of advantages gained in this case is the accessibility of components introduced into the porous space of the glasses to gases and vapors, and, consequently, the possibility of using modified PG as optical sensors. Also important is the problem of controlling the light absorption in the visual and UV regions by selecting a modifier and varying the size of particles introduced into open (through) pores of a glass. In this study, we analyzed the possibility of solving these problems for the example of PG modified with vanadium(V) oxide.

The porous glass used in this study was obtained by leaching a sodium-borosilicate glass of composition (mol %): $0.07Na_2O \cdot 0.23B_2O_3 \cdot 0.70SiO_2$, which was subjected to thermal pretreatment (3 days at 530°C with subsequent annealing for 3 h at 480°C) [8, 9]. The specific surface area of the PG (80 $m^2\ g^{-1}$) was determined from low-temperature adsorption of argon, and the pore volume (0.16 $cm^3\ g^{-1}$) and the predominant pore radius (4.5 nm), from the isotherm of water adsorption and parameters of the adsorption hysteresis loop [8–10]. Glass plates 1.0–1.2 mm thick were subjected to additional polishing; the resulting light transmission in the visual and near UV spectral ranges is shown in Fig. 1.

It should be noted that the possibility of obtaining transparent PG plates is limited not only by the range of small pore radii, but also by difficulties in ensuring optical homogeneity and, in particular, a constant refractive index across the plate thickness. Vanadium(V) oxide was deposited on the walls of through channels in PG by impregnating the glass with aqueous solutions of ammonium vanadate and by subsequent dehydration at 120°C and thermal decomposition of the

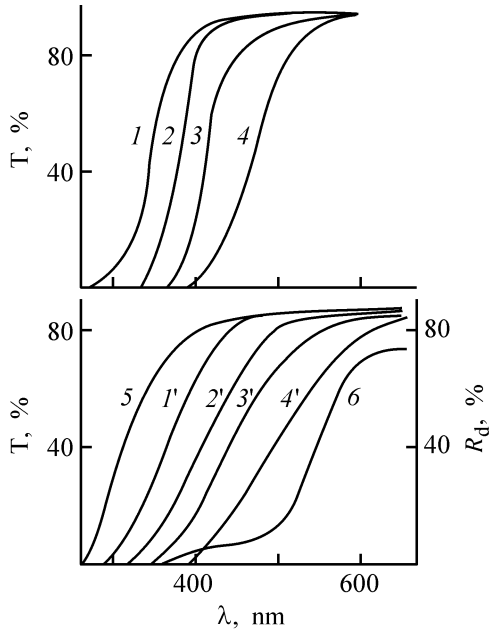

Fig. 1. Transmission spectra of (*1*–*4*) aqueous solutions of NH_4VO_3, (*1*'–*4*') PG plates impregnated with these solutions and dried at 120°C, (*5*) starting glass; (*6*) spectrum of diffuse reflection from polycrystalline V_2O_5. salt by calcination at 400°C. The transmission spectra of impregnation solutions and modified glasses were recorded on an SF-56 automated spectrometer. When studying the dependence of the spectra on the air humidity, we placed glass samples in desiccators over sulfuric acid solutions with concentrations providing a relative water vapor pressure $p/p_0 = 0.2–0.8$. The spectrum of polycrystalline vanadium oxide V_2O_5 was recorded on an SF-16 spectrometer with a spherical photometer, relative to MgO as optical reference.

The transmission spectra of aqueous solutions of NH_4VO_3 (Fig. 1), obtained in quartz cuvettes with optical thickness $l = 1$ cm, are uniformly shifted to longer wavelengths with the concentration increasing from 0.001 to 0.05 M. It appears impossible to determine the peak positions of the bands observed (even with l decreased to 1 mm), since the extinction coefficients in the charge-transfer spectra of anionic oxo vanadium species in solutions are on the order of $\varepsilon_{max} \approx 10^4$ [11].

The observed shift of the bands has been rather reliably interpreted qualitatively [11, 12] as resulting from stepwise association of the VO_4^{3-}, HVO_4^{2-}, and VO_3^- monomers into polynuclear vanadate anions under the action of increasing concentration and changing pH of solution. However, attempts to establish particular anionic species and their proportions meet substantial difficulties even under strong dilution conditions [11, 12]. The "concentration" sequence of the solution spectra (Fig. 1, curves *1–3*) is also reproduced in the case of PG plates impregnated with the solutions and dried to constant weight at 120°C. In this case, however, a noticeable long-wavelength shift of band edges is observed, which results in that modified glasses turn weak to intense yellow.

To a first approximation, it would be expected that thermal decomposition of ammonium vanadate on the silica surface of the glass in air must yield small-size particles of the higher oxide V_2O_5. Experiments with powdered polycrystalline NH_4VO_3 showed that the thermolysis of the salt is complete only at temperatures close to 400°C. The spectrum of the thus obtained orange-red V_2O_5, recorded in reflected diffusely scattered light, is shown in Fig. 1.

In this context, it is rather significant that the spectra of modified glasses treated in the range 120–400°C remain almost unchanged. This suggests that the decomposition of small salt particles on the silica surface is complete even at the temperature of glass dehydration and yields small-size vanadium oxide particles having the form of clusters with individual features of their electronic structure. These features differ from those of bulk V_2O_5 and are to some extent "inherited" from their precursors, anions in the impregnating solutions.

The recorded charge transfer spectra are formed as a result of electron excitation from nonbonding (pseudoatomic) $2p$ orbitals of oxygen to vacant $3d$ orbitals of vanadium(V). With a certain probability, their red shift is determined by the build-up of negative effective charge on oxygen with increasing size of vanadium oxide clusters. Indeed, in this case, the donor $2p$ orbitals of oxygen must be destabilized and the splitting of acceptor $3d$ states of vanadium(V) must increase, which results, in the end, in a decrease in the energy of $2p^n(O) \rightarrow 3d(V)$ transitions.

The content of vanadium(V) oxide in the glass is too small for reliable quantitative determination and can only be estimated using the glass porosity. The amount of NH_4VO_3 in PG, provided by impregnation, is found in this case as $Q = c\varepsilon\gamma$, where c is the solution concentration; ε, the volume of glass pores; γ, the coefficient characterizing the filling of the pore space, which usually does not exceed 0.9 [9, 13]. Therefore, to the concentrations of the impregnating solutions used (0.001, 0.005, 0.025, and 0.05 M) correspond the estimated $VO_{2.5}$ contents in the glass, equal to 0.14, 0.70, 3.5, and 7.0 μmol g^{-1}, respectively. With account of the well-developed PG surface (80 $m^2 g^{-1}$), it follows that its filling with small-size particles of vanadium(V) oxide is vanishingly small. For example, for a set of modified glasses, the free "landing area" per vanadium atom is $20–10^3$ nm^2.

Let us consider spectral consequences of water adsorption by modified PG (Fig. 2). Samples containing 0.14, 0.70, and 3.5 μmol g^{-1} of vanadium(V) oxide are similar in their behavior, which shows itself in a uniform shift of bands and visually observed intensification of the yellow coloration of the plates in transmitted light with increasing humidity. The changes in the electronic spectra definitely point to the coordination (ligand) character of water sorption by vanadium oxide clusters. Strong hindrance to desorption serves as additional evidence in favor of the coordination mechanism. For example, pure PG looses adsorbed water completely after 2 h of heating at 120°C, whereas the dehydration of modified glasses, which sorbed water at $p/p_0 = 0.8$, requires heating for the same period at a temperature not lower than 250°C. Only in this case, it becomes possible to restore the initial spectrum corresponding to the dehydrated state. The observed spectral shifts, accompanying water sorption, are, therefore, due to an in-

crease in the coordination number of a part of vanadium(V) atoms in oxide clusters. This results in that the splitting of 3*d* states increases to form lower states, to which electrons from oxygen are transferred.

The twofold increase in the content of vanadium oxide, from 3.5 to 7.0 μmol g^{-1}, results in a sharp change in the properties of modified glasses. Exposure of a sample to a humid atmosphere results in this case not only in a substantial shift of the spectral band, but also in a sharp loss of transparency in the range 500–800 nm (Fig. 2). So serious consequences, determined by the coordination addition of water, may be related to partial reduction of vanadium(V) in the oxide clusters to vanadium(IV). A process of this kind has been observed earlier [14, 15] on the surface of vanadium containing silica gels obtained by the molecular deposition method. A substantial transfer of the electron density of an unshared electron pair of oxygen of water to vacant 3*d* orbitals of vanadium is the reason why the V(V) → V(IV) transition occurs. The stabilization of the V(IV) valence state is believed [14, 15] to be attained in this case through cation interactions leading to delocalization of $3d^1$ electrons. This is the reason for the absence of the EPR signal and "leveling-off" of the band associated with the *d*–*d* transition (λ_{max} = 750–760 nm) typical of V(IV) in a pseudo-octahedral oxygen environment [14, 15]. It is this factor that, in all probability, determines the possibility of mild reduction of vanadium oxide clusters in PG. The increase in the size of these clusters, achieved by raising the content of vanadium oxide in PG to 7.0 μmol g^{-1}, makes the reduction process thermodynamically possible. It is important in this case that the nature and magnitude of the absorption in the visible range are clearly controlled by humidity (Fig. 2).

At pressures p/p_0 = 0.2–0.6, a relatively uniform shift of the band and a decrease in transmission in the range 500–800 nm are observed (Fig. 2). A substantial decrease in transparency is achieved by raising the humidity to p/p_0 = 0.8, which ensures water condensation in pores with predominant radius of 4.5 nm. The observed spectral consequences of water sorption are completely reversible. As in the preceding cases, complete dehydration requires raising the temperature to 250°C. However, in this case, the time expended for restoration of the initial spectrum is almost twice that necessary for dehydration of glasses with lower content of vanadium oxide. The fact that, with increasing humidity, the color of modified PG containing 7.0 μmol g^{-1} of vanadium changes rather uniformly from bright yellow to brown, and further to dark brown and the possibility of multiple thermal regeneration of the glass open up certain prospects for its use as a visual indicator of humidity.

Abstract—The influence exerted by composite layers formed by microarc oxidation with subsequent treatment with polymers (ultradispersed polytetrafluoroethylene and polytrifluorochloroethylene) on the intensity of salt deposition was studied.

Scaling is a problem common to widely diverse fields of technology, which deal with heating, cooling, and evaporation of water and brines. Formation of a deposit layer with low heat conductivity coefficient on heat-transfer surfaces makes lower the overall heat transfer coefficient. This, in turn, diminishes the thermal load. With seawater used as cooling agent and heat flux of 0.2–1 MW m^{-2}, a salt layer is deposited onto the surface of heat exchanger tubes. This layer markedly lowers the heat conductivity and, consequently, impairs the operation efficiency and makes shorter the service life of heat-exchange apparatus.

The main components of scale precipitating from seawater are calcium carbonate $CaCO_3$, magnesium hydroxide $Mg(OH)_2$, and calcium sulfate in the form of gypsum $CaSO_4 \cdot 2H_2O$, semihydrate $CaSO_4 \cdot 1/2H_2O$, and anhydrite $CaSO_4$. The chemical composition of salt deposits is largely determined by the temperature of a heat-exchange surface: mainly $CaCO_3$ is deposited at 60–70°C, $Mg(OH)_2$ at 70–100°C, and anhydrous $CaSO_4$ or its crystal hydrates at temperature exceeding 100°C.

Especially difficult to remove is scale composed of $CaSO_4$. $CaSO_4$ precipitates on heating surfaces at virtually any wall temperature. The solubility of $CaSO_4$ is strongly affected by seawater components. It increases in the presence of chloride ions, compared with that in distilled water, and evaporation of water in the evaporator makes higher the concentration of Ca^{2+} and SO_4^{2-} ions, i.e., leads to an increase in the probability of formation of sulfate deposits.

Despite the pronounced scientific interest in this problem [1–5], no sufficiently effective method for protecting heat exchanger apparatus from salt deposition has been developed so far. The chemical composition of salt deposits is largely determined by the tube surface temperature. In the opinion of the author of [4], service and design measures play only an auxiliary role an cannot eliminate scale deposition completely. However, the state of the surface (chemical composition, roughness, electrical and semiconducting properties) may strongly affect the intensity of salt deposition. Since the surface layers obtained on metals and alloys by microarc oxidation (MAO) in aqueous electrolyte solutions markedly modify the state of the surface [6–14], there is good reason to believe that the effect of MAO layers on the rate of salt deposition will be discovered.

As is known, phosphates are used to diminish the permanent and temporary hardness of water with the aim of making lower the amount of scale. This leads to formation of poorly soluble compounds, which precipitate and take no part in scale formation. MAO layers obtained in phosphate electrolytes contain 4 to 10 wt % phosphorus. According to X-ray photoelectron spectroscopy [9], the state of phosphorus in coatings formed in a phosphate electrolyte is close to that in PO_4^{3-}. In seawater, phosphate ions pass into solution, which lowers the hardness of water in the near surface layer and may affect the intensity of scale formation. The above process occurs at a low rate, which may ensure a prolonged protection.

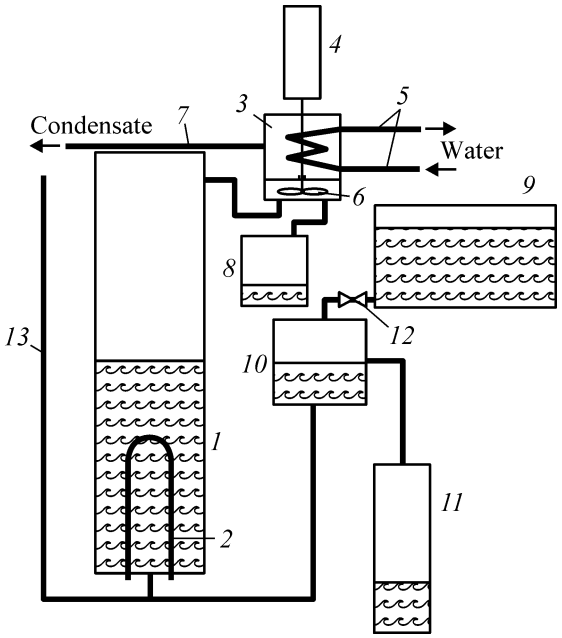

Fig. 1. Schematic of the evaporator installation.

As shown in [10, 12], the charge carrier concentration in a film may strongly affect the process of salt sorption, which is the initial and, occasionally, the key stage of salt deposition. At the same time, there is no published evidence (with the exception of several papers published by the authors of the present study) that MAO coatings affect scale formation.

In particular, the influence exerted by MAO and composite layers (fabricated on the basis of MAO coating with subsequent deposition of polytetrafluoroethylene, PTFE) on heat-exchange surfaces on the intensity of scale formation both in the case of electric heating and on a real heat-exchange installation. According to the results obtained, MAO coatings have virtually no effect on the heat conductivity of walls of a tube in a heat-exchange apparatus, but diminish substantially the rate of salt deposition onto its surface. The best protective properties are exhibited by an MAO layer treated with PTFE. After 96 h of operation of the installation, the scale layer on such a coating is 2 times thinner than that on the unprotected material, and the heat flux increases by 16% over the level for untreated titanium. The protective properties of MAO layers untreated with a polymer are weaker, but the scale layer on such coatings is more friable, compared with that on unoxidized tubes, and can be easily removed by the flow of a cooling agent [12]. In the authors' opinion, the method of combined protection (MAO + PTFE) is practically promising and requires further development.

EXPERIMENTAL

In this study, the antiscale properties of MOA coatings were tested on an evaporator installation intended for desalination of seawater.[1] The electric heater of the installation is subject to scale formation on its surface and, consequently, requires an appropriate protection.

During the experiment, natural seawater was taken from Amur Bay (Sea of Japan). The salinity of the water was approximately 30‰.

The evaporator installation is shown schematically in Fig. 1. In a steam generator *1*, seawater is heated to the boiling point by an electric heater *2* (ac feed voltage 220 V) mounted on the removable part of the heat generator's casing. Steam is fed into the bottom part of the foam disintegrator constituted by a casing *3* and motor *4*. In the upper cavity of the disintegrator casing, there is a coil *5* serving for steam condensation. In the lower cavity, there is an impeller *6* serving to separate the steam and liquid (foam). Steam arrives from the lower cavity, through the annular clearance between the impeller shaft and the partition edge, into the upper cavity of the disintegrator, and condenses there on the coil. The calculated velocity of steam upflow in a steam generator of the given design does not exceed 0.1 m s^{-1}, which corresponds to carry-over of drops less than 0.2×10^{-3} mm in diameter. This evaporation mode ensures a sufficient degree of purification. The distillate is collected in the pan and delivered therefrom through a pipe *7* into a collector vessel for the distillate. Coming in contact with the rotating impeller, the moisture and sludge contained in the steam are thrown by the centrifugal force to the walls and then flow down into a depression on the bottom, and then arrive through a tube with a siphon trap into the collecting tank *8*. Cooling tap water is fed through tubes *5* into the coil of the foam disintegrator and is then discharged into the drain.

Seawater is delivered from a tank *9* into the feeding-compensating tank *10* and arrives therefrom into the steam generator. The excess amount of water is discharged into the collecting tank *11*. The water level in the steam generator is maintained by means of its free supply from the tank *10* by the principle of communicating vessels. A fine-adjustment valve *12* is introduced into the feeding line between the tank for seawater and the feeding-compensating tank in

[1] Manufactured by Kaluzhskii turbinnyi zavod Open Joint-Stock Company.

order to minimize the discharge of excess seawater into the tank *11*. As seawater is consumed, its fresh portions are introduced into the tank *9* from an additional vessel.

All the basic members of the steam generator, foam disintegrator, compensating-feeding tank, and electric heater, which come in contact with one another and also with steam and water, are made of titanium alloys. This precludes corrosion processes and, consequently, ensures that no foreign substances capable of changing the scale formation pattern are produced and come into the heating zone. A glass tube serves as level indicator *13*. All elements of the installation are assembled on a stand made of construction steel.

The tests were carried out using an electric heater with rated power of 5.5 kW ($R \approx 8.7 \pm 0.1$ ohm) and varied state of the working surface: with natural oxide layer (without surface treatment), sample no. 1; with MAO coating formed in a phosphate electrolyte, no. 2; with MAO coating formed in a phosphate electrolyte and treated with finely dispersed PTFE with subsequent heat treatment, sample no. 3; with MAO coating formed in a phosphate electrolyte and treated with finely dispersed polytrifluorochloroethylene (PTFCE), no. 4. A PTFCE powder was dissolved in mesitylene at its boiling point (~165°C) in amount of about 260 g l^{-1}. Then the resulting solution was deposited onto the electric heater in two layers with a brush, with subsequent drying in air at room temperature for 24 h. This yielded a solid transparent polymeric coating of thickness not exceeding 20 μm. As a result of thermal treatment of a MOA layer with deposited PTFCE, a thin polymeric film was formed on the surface. This film raised the hydrophobicity of the coating and diminished its roughness. The preparation procedures and the quality of the sample nos. 1–3 under study were in complete correspondence with those in the case of surface layers studied previously in [12].

According to an estimate made, the heat flux across the heat-exchange surfaces was 0.2 MW m^{-2}. The time of testing of an electric heater in the boiling mode, with boiled-out water replenished with "fresh" seawater, was 27 h. In testing a single electric heater, 220 l of seawater was consumed. The degree of evaporation was approximately 10. Electrical conductivity measurements with an OK 102/1 conductometer demonstrated that G of the initial seawater was 25×10^{-3} S cm^{-1}, whereas the electrical conductivity of the brine formed in the steam generator after the tests was $(130–145) \times 10^{-3}$ S cm^{-1}. The change in electrical conductivity by more than a factor of 10 can be attributed to transfer of a part of salts responsible for the value of G from the dissolved state into scale and sludge.

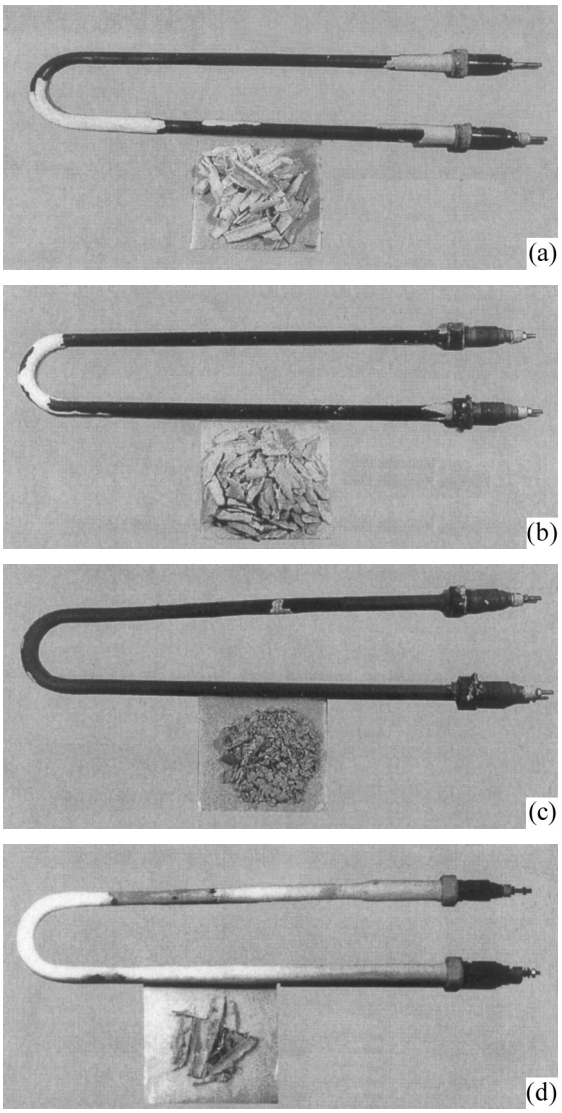

Fig. 2. Amount of scale formed on the surface of the electric heater in 27 h of operation of the evaporator installation. Total mass of scale (g): (a) 218, (b) 197, (c) 30, and (d) 171. Electric heater: (a) no. 1, (b) no. 2, (c) no. 3, and (d) no. 4.

On dismounting the electric heater after the tests, it was found that most part of scale (especially in the case of a sample with an MAO coating) fell off to the bottom of the removable part of the steam generator. The outward appearance of electric heater nos. 1–4 after tests for salt deposition is shown in Figs. 2a–2d. After drying the salt deposits (in air at 100°C for 1 h), the total mass and thickness of scale were measured and its phase composition was evaluated. Gravimetric measurements were done on an analytical balance with an error not exceeding 0.5%. The thickness was measured with a thickness gage. The sludge formed during the experiment and

present in the brine in the steam generator and in the boil-over from the foam disintegrator (sludge tank *8*) was also studied after filtering and drying. An X-ray phase analysis was performed on a DRON-2.0 diffractometer (Cu_{K_α} radiation). Fragments of scale were taken for study from the inner (adjacent to the electric heater) surface of the deposit and its outer surface. Also, scale was studied in the form of powder, which is a thickness-averaged sample. The measurement results are listed in Table 1 and shown in Fig. 2.

The experimental data obtained in this study confirm the conclusion [12] that MAO coatings affect the salt deposition process. The strongest protective effect is exhibited by an MAO layer treated with PTFE. The amount of scale formed on its surface is only 14% of that on an unprotected (with natural oxide layer) electric heater. An MAO coating untreated with PTFE lowers the rate of scale formation by approximately 10%.

The protective properties of layers obtained by the MAO method in phosphate electrolytes are due to several factors. On the one hand, the low concentration of charge carriers ($N_D = 9.8 \times 10^{17}$ cm^{-3}) in the coating material ensures its low sorption activity and, consequently, low concentration of crystallization centers. On the other hand, the egress of phosphate ions from an MAO coating into seawater, with the subsequent formation of poorly soluble salts removed as sludge from the heat-exchange zone, also leads to a decrease in the rate of salt deposition onto the coating surface.

According to the results of an X-ray fluorescence analysis, the in sludge collected in the steam generator after tests of electric heaters with MAO coatings contains trace amounts of phosphorus, which are absent in a similar sample taken after tests of an unprotected electric heater. A phase analysis confirmed the previously obtained data [4], which indicate that $CaSO_4$ is present in scale formed on the heating surface of desalting installations under virtually any temperature conditions. A minor amount of $CaCO_3$ in an aragonite crystal modification, which was found on the inner surface of the scale layer adjacent to the surface of electric heater treated by the MAO method, is, in all probability, a result of heat loss on MAO layers in the initial stage of scale formation. $Mg(OH)_2$, present in the sludge as a suspension, is actually not contained in scale at all.

Owing to its morphology, an MAO coating acts as a container retaining in its pores particles of finely dispersed PTFE, thereby creating the effect of an unwettable (hydrophobic) surface and making less pronounced its roughness. According to the experimental results obtained, this factor markedly diminishes the rate of scale formation (Table 1, Fig. 2c). Treatment of unoxidized titanium with PTFE is inefficient because of the poor adhesion of the polymer to the metal.

The mass of scale deposited onto the surface of an electric heater with an MAO layer treated with PTFCE is 171 g. This amount is smaller than that on an electric heater without a coating (m = 218 g), but much exceeds the mass of scale on an electric heater with an MAO coating obtained in a phosphate electrolyte and treated with ultradispersed PTFE (m = 30 g). The inner surface of the scale layer has dark coloration, which is probably due to destruction of PTFCE in the tests (as a result of scale formation the electric heater overheats, with fluoroplastic-3 melting and decomposing).

The experimental data obtained in this study, combined with the results of an analysis of physicochemical properties of PTFCE (Table 2), suggest that the protecting capacity of the given polymer is low when it is used as a component of a composite scale-protecting layer formed by the method described above.

The low melting (T_m) and decomposition (T_d) points of PTFCE, compared with PTFE (Table 2), are responsible for partial destruction of the polymer. This leads to carbonization of the inner surface of

the polymer layer and its subsequent swelling, which results in a higher rate of scale formation.

To confirm the correctness of the study and to verify the conclusions concerning the effect of composite layers on the rate of scale formation, the content of the main scale-forming elements distributed in the liquid and solid phases and present in different parts of the evaporator installation was determined.

The material balance of the evaporation process for the main chemical elements (Ca, Mg, Na, K, Cl) contained in seawater was calculated for an uncoated electric heater. The content of an element in scale (on the surface of electric heater no. 2), in the distillate, in the brine from the steam generator *1*, and in the fraction from the foam disintegrator (sludge tank *8*) was determined. The content of Ca, Mg, Na, and K was determined by atomic-absorption analysis with a Nippon Jarrell Ash AA-780 atomic-absorption and flame-emission spectrophotometer. The results obtained in studying the distribution of the main elements contained in seawater among material flows are listed in Table 3.

The convergence of the material balance demonstrates the reliability results obtained by various methods, including X-ray phase analysis, according to which the main compound contained in scale is $CaSO_4$ and its semihydrate (Ca content of about 30%).

CONCLUSIONS

(1) Composite layers strongly affect the rate of salt deposition at tenfold evaporation of seawater and heat flux of 0.2 MW m^{-2}. With polytetrafluoroethylene contained in a protecting layer deposited onto the surface of titanium electric heaters preliminarily subjected to microarc oxidation, the rate of scale formation can be lowered by 86%.

(2) Polytetrafluoroethylene deposited onto a layer formed by microarc oxidation changes the surface

morphology (diminishes the surface roughness) and raises its hydrophobicity. Owing to its branched porous structure, the resulting coating acts as a sublayer improving the polymer adhesion to the substrate. At the same time, this layer itself exhibits scale-protecting properties owing to its specific semiconducting and electrochemical properties, which diminishes the rate of salt deposition by approximately 10%.

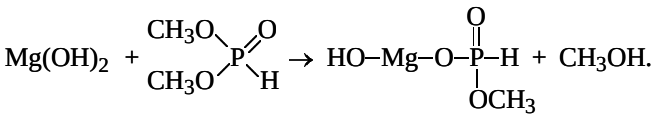
Abstract—The kinetic of the reaction between magnesium hydroxide and dimethyl phosphite in nitrobenzene was studied.

Analysis of the patent and technical literature shows that metal hydroxides and, in particular, aluminum and magnesium hydroxides are widely used as fire-retardant additives in developing polymeric composites with lowered combustibility. However, introduction of such additives impairs the physicomechanical properties of composites [1].

In order to diminish the influence of this important disadvantage and, simultaneously, to enhance the flame-quenching properties of a fire retardant, aluminum hydroxide has been modified with dimethyl phosphite and the kinetics of this reaction has been studied [2]. In continuation of these investigations, the kinetics of the reaction of modification of magnesium hydroxide with dimethyl phosphite in the liquid phase with nitrobenzene used as solvent:



EXPERIMENTAL

The kinetics was studied in the temperature range 126–146°C in a three-neck reactor with rabble, thermometer, and condenser to remove methanol. The ±0.2°C accuracy of temperature control was provided by an ultrathermostat. The reaction course was monitored by sampling at certain intervals of time, with the concentration of dimethyl phosphite determined by titration with 0.1 N alkali solution on a pH-340 pH-meter. The reaction was stopped by cooling a sample to 2–5°C.

The overall and partial reaction orders were determined by graphical differentiation of the kinetic curves at the initial instant of time (see table). The results of kinetic studies were processed using the least-squares method.

Since magnesium hydroxide entering into the reaction is in the solid state, its concentration is determined by solubility and remains constant during the entire process. It is impossible to determine the true reaction order with respect to $Mg(OH)_2$ under these conditions. The apparent reaction order with respect to this reactant is zero.

The kinetic curves obtained in a set of experiments in which the initial concentration of dimethyl phosphite and the amount of solvent used remained constant and that of $Mg(OH)_2$ in the reaction mass varied are virtually identical (Fig. 1a). The deviations observed lie within the experimental error. This con-

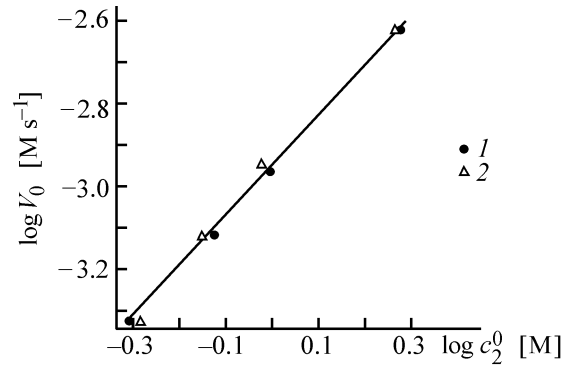

Fig. 2. $\log V_0$–$\log c_2^0$ dependence for reaction of magnesium hydroxide with dimethyl phosphite. (*1*) The partial reaction order with respect to dimethyl phosphite and (*2*) the overall reaction order with respect to the same reactant are determined.

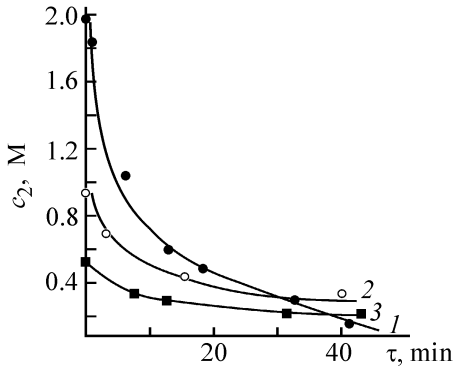

Fig. 3. Variation with time τ of the concentration c_2 of dimethyl phosphite in its reaction with magnesium hydroxide in nitrobenzene at equimolar ratio of the reactants and temperature of 146°C. c_2^0 (M): (*1*) 2.004, (*2*) 0.989, and (*3*) 0.506.

firms the zero apparent reaction order with respect to magnesium hydroxide and also indicates that the reaction occurs in solution, rather than on the surface of the solid reagent, since raising the content of $Mg(OH)_2$ in the reaction mass would accelerate the process because of the larger contact area.

The reaction order with respect to $(CH_3)_2HPO_3$ was determined by measuring the initial reaction rates at fixed amounts of magnesium hydroxide and varied (within 0.5–1.0 M) initial concentration of dimethyl phosphite (Fig. 1b). A knowledge of the partial reaction order with respect to dimethyl phosphite makes it possible to plot the dependence $\log V_0 = f(\log c_2^0)$ (Fig. 2), where V_0 is the initial reaction rate and c_2^0 is the initial concentration of dimethyl phosphite. It can be seen from Fig. 2 that the slope of the dependence of the logarithm of the initial rate on the logarithm of the initial dimethyl phosphite concentration is close to unity, which indicates the first reaction order with respect to this reagent. With account of the pseudo-zero order with respect to magnesium hydroxide, the overall reaction order is unity.

The calculations performed yielded the parameters of the linear equation

$$\log V_0 = \log k + n_1 \log c_1^0 + n_2 \log c_2^0, \qquad (1)$$

where k is the reaction rate constant, and n_1 and n_2 are the reaction orders with respect to magnesium hydroxide and dimethyl phosphite.

Under the experimental conditions, the $Mg(OH)_2$ concentration in solution, c_1^0, was maintained constant, and, consequently, $n_1 \log c_1^0 = \text{const}$. Then Eq. (1) takes the form

$$\log V_0 = (-2.9805 \pm 0.0200) + (1.1198 \pm 0.12304)\log c_2^0.$$

Consequently, the more accurate partial reaction order with respect to dimethyl phosphite is $n_2 = 1.12 \pm 0.12$.

The overall reaction order was confirmed in a set of experiments in which the initial concentration of dimethyl phosphite was varied within 0.5–2.0 M at fixed equimolar ratio of the starting reagents (Fig. 3). The calculations performed yielded the dependence

$$\log V_0 = \log k_{app} + n \log c_2^0 = (-2.9947 \pm 0.23) + (1.16 \pm 0.10)\log c_2^0,$$

which confirms the overall first reaction order under the experimental conditions and makes it possible to

find the apparent rate constant k_{app}, which is a function of the concentration of magnesium hydroxide in the liquid phase.

To determine the activation energy of the reaction, kinetic curves were measured at temperatures of 126, 136, and 146°C. In these experiments, the initial concentrations of the starting reagents remained constant (see table).

Using the method of graphical differentiation of kinetic curves at the initial instant of time in studying the kinetics of the chemical reaction at low solubility of $Mg(OH)_2$ in nitrobenzene makes it possible to state that the contribution from the heat effect of hydroxide dissolution is insignificant.

The reaction rate constant is described by the Arrhenius equation: the dependence $\log k_{app} = f(1/T)$ is described by a linear equation in integral form

$$\log k_{app} = (0.406 \pm 0.066) + (1417.79 \pm 26.89)/T;$$

$$r = 0.999, \quad S = 0.012.$$

CONCLUSIONS

(1) The reaction of magnesium hydroxide with dimethyl phosphite in nitrobenzene is first-order with respect to dimethyl phosphite, with the overall reaction order close to unity; the process occurs in solution, rather than on the surface of magnesium hydroxide.

(2) The reactions of magnesium and aluminum hydroxides with dimethyl phosphite have equal partial and overall orders.

Abstract—Kinetics of oxidation of some organic acids by ammonium nitrate was studied. Temperature dependences of the rate constants of acid oxidation were determined.

Gas-generating formulations for household purposes have been intensively developed in recent years. Systems of this kind can be created using the principles on which design of solid mixture fuels is based. The fuel system proposed must have an acceptable thermal stability and retain its working properties during a rather prolonged test at elevated temperatures. A possible way to solve this problem is to use mixtures of ammonium nitrate (AN) with organic substances and, in particular, oxalic acid.

It has been established previously that thermal decomposition of AN into ammonia and nitric acid proceeds via its equilibrium dissociation. The rate of the process in decomposition of a pure salt is determined by the rate of oxidation of the NH_4^+ ion by a molecule of nitric acid [1]: the rate grows with increasing content of nitric acid in the system. The content of HNO_3 in molten pure AN does not exceed 0.1% of the total content of NO_3^- ions in the salt, and, therefore, the stability of pure AN is sufficiently high for this compound to be used in the mixtures under consideration. Introduction of organic acids into AN can raise the equilibrium concentration of HNO_3 and, correspondingly, impair the stability of AN. However, organic acids in aqueous solutions are much weaker than nitric acid, with the difference in p*K* values between nitric and organic acids constituting 3 units and more [2]. Therefore, it would be expected that the increase in the concentration of HNO_3 will be small, and the thermal stability of the mixture, sufficient.

The aim of the present study was to analyze the kinetics and mechanism of the reaction of oxidation of various organic, mainly dibasic acids by ammonium nitrate in order to elucidate the general pattern and distinctions of this reaction for different acids and to assess the possibility of practical use of mixtures of this kind.

EXPERIMENTAL

The kinetic pattern of heat release in thermal interaction of AN mixtures with oxalic, malonic, succinic, pimelic, malic, tartaric, citric, maleic, and benzoic acids in a 1 : 1 molar ratio was studied. Also, separate experiments were carried out for mixtures of AN with decane and polyethylene for comparison purposes. The 1 : 1 ratio of the amounts of oxalic acid and AN corresponds to equivalent of the oxidizing agent and the fuel. For all other mixtures there exists an excess of the fuel, but the equal number of moles allows easier comparison of the positions of acid–base equilibria. For a mixture of AN with succinic acid, additional experiments were carried out at the stoichiometric ratio of the components for the oxidation reaction. Chemical reagents of chemically pure and analytically pure grades were used.

The experiments were performed on a DAK-1-1 automated dynamic microcalorimeter [3] in sealed glass ampules having no cool parts, which allows preservation of all the products in the reaction zone. If not specified otherwise, a two-component mixture of the compositions mentioned above exists in the form of a homogeneous liquid phase at any of the temperatures studied. The rate of the reaction between the solid phases is below the detection limit of the calorimeter. The mixture of AN with oxalic acid shows a sufficiently high reaction rate even at 70°C, and that with malonic acid, at 85°C; for other acids the rate becomes comparable only above 100°C, when the liquid phase appears in the system.

Figure 1 shows as an example kinetic curves of heat release for the mixture of AN with oxalic acid; for malonic, succinic, pimelic, tartaric, and benzoic acids the curves are mainly similar and differ only in the heat release rate and the range of temperatures

1070-4272/03/7608-1214 $25.00 © 2003 MAIK "Nauka/Interperiodica"

studied. The rate is the highest at the beginning of the process and then decreases fast; the reaction order much exceeds the second order. The kinetic equation has the form

$$dQ/dt = k_1 Q_f(1 - \eta)^2,$$

where Q and Q_f are the running and full heats of reaction ($J\ mol^{-1}$), and $\eta = Q/Q_f$ is the extent of the process.

The running heat of the process, Q, was found by integrating numerically the obtained time dependence of the heat release rate. Since the reaction was not brought to complete termination of heat release because of its extremely long duration, the full heat of the process, Q_f, was determined by extrapolation of the $(dQ/dt)^{0.5}$ dependence from Q to zero value of dQ/dt. For most of the acids studied, the Q_f values are close to 4200 $J\ g^{-1}$. For pure AN, the heat of thermal decomposition is much lower, 1460–1670 $J\ g^{-1}$ under the experimental conditions. Oxidation of the organic component makes a major contribution to the full heat of the process. In this case, NH_4^+ ions also become involved in the oxidation reaction under the action of more active intermediate reaction products, e.g., nitrogen oxides. At the same time, in the case when the reaction proceeds to completion to give CO_2, H_2O, and N_2 in a mixture of AN with oxalic acid, more than 5430 $J\ g^{-1}$ must be released, i.e., the oxidation under the experimental conditions is incomplete. In this series of acids, a strong difference in the experimental heat of oxidation is only observed for malonic acid: the heat of its oxidation by AN is approximately 830 $J\ g^{-1}$.

In the case of deviation from the equimolar ratio of the components, the two-component mixture exists at certain temperatures in the form of solutions of constant composition, which are saturated either with organic acid or with AN, in equilibrium with the corresponding solid phase. The apparent heat release rate dQ/dt is, in the general case, given by the formula

$$dQ/dt = k_{eff} Q_f \alpha V c_{RCOOH} c_{NH_4NO_3},$$

where k_{eff} is the effective rate of oxidation of an organic acid by AN ($M^{-1}\ s^{-1}$); Q_f, the full heat effect ($J\ mol^{-1}$); V, the mixture volume (l); α, the fraction of the melt volume relative to the total volume of the mixture; c_{RCOOH}, $c_{NH_4NO_3}$, the concentrations of organic acid and AN in the melt, respectively (M).

Figure 2 shows the dependence of the initial heat release rate by 1 g of a mixture of oxalic acid and AN at 89.2°C as a function of the mole fraction of oxalic acid. At small mole fractions of oxalic acid, the system is two-phase, the product of reagent concentrations in solution is constant, the volume fraction of the melt grows with increasing mole fraction of oxalic acid, and, correspondingly, the initial heat release rate grows somewhat. On reaching a certain mole fraction of oxalic acid in a mixture, the system becomes homogeneous, which corresponds to α equal to unity.

The heat release rate grows with increasing product $c_{RCOOH} c_{NH_4NO_3}$ at approximately constant V. The maximum of $c_{RCOOH} c_{NH_4NO_3}$ is reached in the equimolar

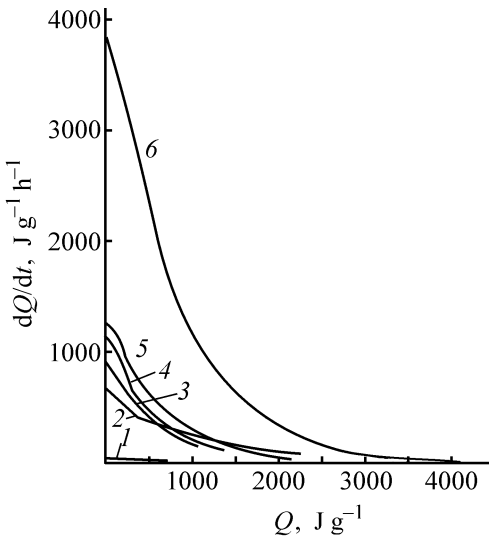

Fig. 1. Heat release rate dQ/dt vs. Q in equimolar mixture of oxalic acid with AN. T (°C): (*1*) 70.4, (*2*) 86.2, (*3*) 89, (*4*) 91, (*5*) 100, and (*6*) 106.

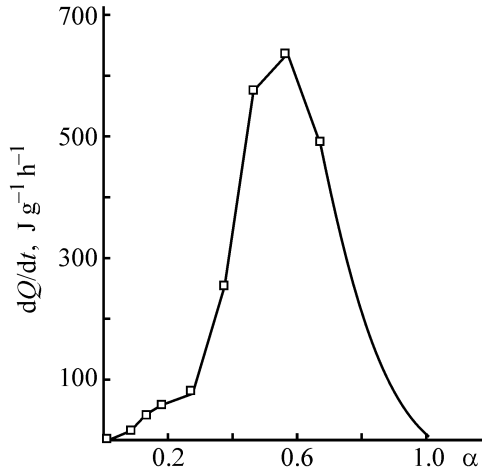

Fig. 2. Initial heat release rate dQ/dt in a mixture of oxalic acid with AN vs. mole fraction α of $(COOH)_2$ at 89.2°C.

mixture; with the mole fraction of oxalic acid increasing further, the product of concentrations starts to decrease, which leads to fall in the heat release rate. Then the mixture again becomes two-phase; the subsequent fall in the melt volume at constant product of the reactant concentrations leads to further decrease in the heat release rate.

Oxidation of maleic, malic, and citric acids by AN obeys a kinetic law different from that described by an equation of a second-order reaction. Oxidation of maleic acid is described by an equation of a first-order autocatalityc reaction with full heat of the process, Q_f, approximately equal to 5230 J g^{-1}:

$$dQ/dt = k_1 Q_f(1 - \eta) + k_2 Q_f(1 - \eta)\eta.$$

In oxidation of malic acid by AN, the heat release rate varies in the course of the process in a complicated way (Fig. 3). In the first stage, whose duration grows with increasing temperature, self-acceleration by the equation of a first-order autocatalytic reaction is observed. After the maximum rate is reached, it starts to fall by the equation of a first-order reaction to a certain level, which remains virtually constant until the conversion becomes 0.8–0.85, and then the rate again falls to complete termination of heat release.

Oxidation of citric acid by AN follows the first-order reaction law to conversion of 0.9–0.95?, after which the rate also falls abruptly to virtually zero value. The full heats of oxidation of malic and citric acids by AN are approximately equal to 4180 J g^{-1}.

The following values of $k = (dQ/dt)_{t=0}/Q_f V c_{NH_4NO_3} = k_{eff} c_{RCOOH}$ were obtained at different temperatures for all of the AN mixtures with organic acids, analyzed in this study:

Temperature dependences of k_1 are presented in the table. Owing to strong differences in the rates of heat release by the mixtures studied, different temperature ranges were used in the experiments. For convenience of comparison, rate constants are given for all the mixtures at 100°C, together with published values of pK for the acids studied, determined in aqueous solutions at room temperature [2]. The table also lists the times in which the reactions proceed to 1% extent, calculated using the dependences corresponding to the established kinetic pattern of the process. The temperature dependence of the constant k_2 (s^{-1}) of the autocatalytic stage, which is necessary for calculating the time of oxidation of maleic acid, is given by the expression

$$k_2 = 1.3 \times 10^8 \exp(-10.8 \times 10^3/T).$$

T, °C	100	138	145	148
k_2, s^{-1}	2.7×10^{-5}	5.7×10^{-4}	9.4×10^{-4}	7.7×10^{-4}
T, °C	151	152	165	
k_2, s^{-1}	1.9×10^{-8}	1.1×10^{-3}	1.5×10^{-3}	

The rate of thermal decomposition of pure AN at 200–250°C is determined by the rate of oxidation of the NH_4^+ ion by a molecule of nitric acid formed in dissociation of the onium salt [4]:

$$dQ/dt = k_{NH_4^+} Q_f V c_{NH_4^+} c_{HNO_3},$$

where $k_{NH_4^+}$ is the rate constant of oxidation of the ammonium ion by nitric acid, and V is the volume of the system.

In principle, the NH_4^+ ion is difficult to oxidize, with rather high temperatures necessary for achieving fast rates of AN decomposition. The temperature dependence of the initial heat release rate in decomposition of pure AN can be obtained from the data of [5]:

$$(dQ/dt)_{t=0} = 3.2 \times 10^{18} \exp(-23.8 \times 10^3/T).$$

Previously, it has been established in studying the possible ways to oxidize NH_4^+ ions with concentrated solutions of nitric acid that, at temperatures below 150–160°C and NHO_3 content exceeding that in an AN melt, the mechanism of the oxidation reaction undergoes a change. Oxidation by molecular nitric acid is replaced by oxidation by nitrogen(V) oxide formed in the equilibrium

$$2HNO_3 \rightleftarrows N_2O_5 + H_2O;$$

$$K_{deh} = a_{H_2O} a_{N_2O_5} / a_{HNO_3}^2. \quad (1)$$

Because of the lower activation energy of oxidation by nitrogen(V) oxide, the reaction rate decreases more slowly than in the case of oxidation by nitric acid, with the result that N_2O_5 makes major contribution to the apparent heat release rate in the low-temperature region. At the same time, in decomposition of AN proper, the low equilibrium concentration of HNO_3, which is additionally lowered because of the ioniza-

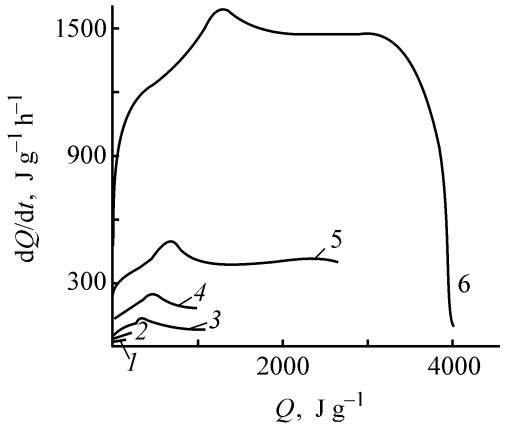

Fig. 3. Heat release rate dQ/dt vs. Q in equimolar mixture of malic acid with AN. T (°C): (*1*) 122.4, (*2*) 127.2, (*3*) 137.1, (*4*) 139, (*5*) 145, and (*6*) 158.5.

tion by impurity water, results in that the mechanism of AN decomposition with oxidation of ammonium ions by molecular HNO_3 is preserved in the entire temperature range studied, above and below the melting point [6].

In two-component systems constituted by AN and an organic acid, the rates of heat release much exceed those in thermal decomposition of pure AN. Extrapolation of the temperature dependence of the heat release rate in thermal decomposition of an AN melt [5] to 100°C yields a value of 8.1×10^{-10} W g^{-1}. In a mixture of AN with oxalic acid, the heat release rate at 100°C exceeds by 9 orders of magnitude the extrapolated value. The difference between the heat release rate in decomposition of crystalline AN, which is more stable than the melt, and the heat release rate in decomposition of a two-component mixture at this temperature will be even more pronounced.

Comparison of the rate constants of interaction between AN and various acids shows that the differences in the rates of heat release are very significant and constitute several orders of magnitude under analogous conditions. They are mainly associated with differences in the pK_a values in aqueous solution. The lower this value and, correspondingly, the higher the constant of proton ionization, the higher the oxidation rate. The highest heat release rate is observed for a mixture with oxalic acid, and the lowest, for that with benzoic acid.

The increase in the reaction rate in the two-component mixture is accounted for by two factors: (1) oxidation of an acid molecule, which occurs with much higher rate constant as compared with oxidation of the NH_4^+ ion; (2) increase in the content of nitric acid upon addition of an organic acid to AN. Mixtures of AN with polyethylene or decane, which do not affect the position of the acid equilibrium in the system, are oxidized at higher rate than NH_4^+ because of their higher intrinsic rate constant of oxidation.

The dependence of the heat release rate by a mixture of AN with an organic acid on the pK value of the acid is probably determined by the reaction of protonation of the NO_3^- anion by organic acid, which leads to an increase in the concentration of HNO_3:

$$NO_3^- + RCOOH \rightleftarrows HNO_3 + RCOO^-;$$

$$K_{ch} = a_{HNO_3} a_{RCOO^-} / a_{NO_3^-} a_{RCOOH}, \qquad (2)$$

where K_{ch} is the equilibrium constant equal to the ratio between the constants of proton ionization of an organic acid, K, and nitric acid, K_{HNO_3} in a melt; a_{HNO_3}, a_{RCOO^-}, $a_{NO_3^-}$, a_{RCOOH}, the activities of the respective species; $RCOO^-$, the anion of the organic acid.

It follows from the pK_a values of the acids, determined in aqueous solutions, that occurrence of reaction (2) in the forward direction is thermodynamically unfavorable: the pK value for HNO_3 in aqueous solution is 1.64 [2], whereas that for the weakest of the organic acids considered, oxalic acid, is higher by three units. The increase in the concentration of HNO_3 molecules cannot be significant at such pK values, and the oxidation rate must be independent of pK. It has been shown previously [7] that introduction of orthophosphoric acid (pK 2.1 in aqueous solution) into AN makes higher the HNO_3 concentration in the melt and the rate of AN decomposition, which the constant of the equilibrium

$$H_3PO_4 + NO_3^- \rightleftarrows HNO_3 + H_2PO_4^-$$

in an AN melt at 233.5°C found to be approximately 60. Such a change in the relative strength of HNO_3 may be due to the low dielectric constant of the ionic melt of AN and to selective complexation between HNO_3 molecules and ions of the melt (complex ion $2HNO_3 \cdot NO_3^-$ has been described in the literature [8]).

Apparently, a similar situation occurs in melts of AN with organic acids. The pK values for organic acids and HNO_3 must change as compared with those in aqueous solutions, and the strength of organic acids must increase with respect to that of HNO_3. The relative pK values of organic acids are mainly preserved, which is manifested in the rates of their interaction with AN, although the absolute values themselves are probably changed.

In a mixture system, the rates of heat release that are close to those in decomposition of pure AN are observed at much lower temperatures and higher HNO_3 concentrations than those in decomposition of pure AN. Such conditions probably favor occurrence of an oxidation reaction involving N_2O_5, as is the case in oxidation of the NH_4^+ ion with concentrated HNO_3 solutions. Thus, introduction of an organic acid, which is oxidized at lower temperatures than those in decomposition of an AN melt and makes higher the HNO_3 concentration, leads to a difference in the mechanisms by which are oxidized pure AN, in which HNO_3 is oxidizing agent, and a two-component system, with N_2O_5 acting as oxidant:

$$dQ/dt/Q_f V = k_{eff} c_{RCOOH} c_{NH_4NO_3}$$
$$= k'_{N_2O_5} a_{RCOOH} a_{N_2O_5} / \gamma^*_{TS}, \qquad (3)$$

where $k'_{N_2O_5}$ is the rate constant of the reaction of oxidation of an organic acid by nitrogen(V) oxide in the gas phase, and γ^*_{TS} is the activity coefficient of the activated complex in the melt [9].

At small degrees of protonation of nitrate ions, at which the activities a_{RCOO^-} and a_{HNO_3} can be considered equal, the following expression is obtained for a_{HNO_3} from equilibrium (2):

$$a_{HNO_3} = (Ka_{RCOOH}a_{NO_3^-}/K_{HNO_3})^{1/2}. \quad (4)$$

Expressing $a_{N_2O_5}$ in terms of the constants of dehydration equilibrium (1) with the use of (4) and substituting it into expression (3) for the rate yields an equation which has, after its logarithm is taken, the form

$$\log(dQ/dt/Q_fVc_{NH_4NO_3}) = \log k_1 = \log k(k_{eff}c_{RCOOH})$$
$$= \log k_{N_2O_5} + \log K_{deh} + pK_{HNO_3} - pK$$
$$+ \log(a_{RCOOH}a_{NO_3^-}/a_{H_2O}\gamma_{N_2O_5})$$
$$+ \log(c_{RCOOH}/c_{NH_4NO_3}),$$

where $k_{N_2O_5} = k'_{N_2O_5}\gamma_{RCOOH}\gamma_{N_2O_5}/\gamma^*_{TS}$ is the rate constant of oxidation of an organic acid by nitrogen(V) oxide in a melt [9], and γ_{RCOOH} and $\gamma_{N_2O_5}$ are the activity coefficients of RCOOH and N_2O_5 in the melt.

In accordance with the mechanism of oxidation by nitrogen(V) oxide, the rate must increase in proportion to the constant of proton ionization of the organic acid if the term with activity ratio is assumed to be constant. Figure 4 shows the logarithm of the rate constant of interaction between various organic acids and AN at 100°C as a function of the pK value of these acids. The relationship observed between the logarithm of the rate constant of heat release in the reaction of AN with organic acids and their pK value in aqueous solutions is close (with only a certain scatter of experimental data, caused by difference in chemical structure between the acids studied) to that assumed for the given mechanism, with a slope of the straight line approximately equal to –1. The constant of proton ionization of organic acids in aqueous solutions decreases, in going from oxalic to pimelic acid, by a factor of $10^{3.2}$, and heat release rate, by a factor of $10^{3.4}$.

Probably, owing to the higher activation energy, the rate constant of oxidation of organic acids by molecular HNO_3 will exceed the rate constant of oxidation by nitrogen(V) oxide at temperatures much higher than those used in the experiments, and, as

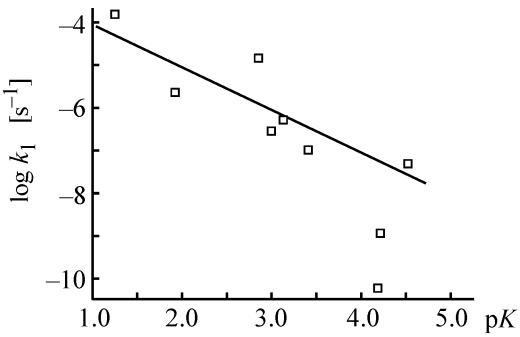

Fig. 4. log k_1 vs. pK value of organic acids. (k_1) Rate constant of interaction between AN and organic acids and (K) constant of acid dissociation of organic acid.

in the case of AN decomposition, HNO_3 will play the part of an oxidizing agent.

Thus, the main factor responsible for the difference in the rates of oxidation of organic acids by AN is their strength. At the same time, certain differences associated with the chemical structure of an acid are observed. The oxidation rate of an organic acid is determined by presence in it of fragments that can sufficiently rapidly react with a N_2O_5 molecule. In the compounds under study, these are hydrogen atoms of $–CH_2–$ groups and hydrogen atoms in α position in the –OH group. The rate of heat release by a mixture of AN with pimelic acids is 7 times that for a mixture with succinic acid, although the constant of proton ionization of pimelic acid is 2 times smaller, which is due to the presence in its molecule of a greater number of oxidizable $–CH_2–$ groups. The pK values of benzoic and succinic acids are close, and the rates differ by a factor of 18, with benzoic acid exhibiting the lowest heat release rate because of the high stability of hydrogen atoms in the benzene ring against oxidation.

The mixtures studied, constituted by AN and organic acids, strongly differ in stability, with equimolar mixtures of AN with succinic or benzoic acid being the most stable. For succinic acid, the rates of its interaction with AN were measured for the mixture components taken in stoichiometric ratio, which corresponds to mole fraction of AN equal to 0.875:

T, °C	191	195.8	200.6	204.4	214.4	221.6
$k_1 \times 10^6$, s^{-1}	7.5	14	18	25	53	78

The activation energies of reactions in equimolar and stoichiometric mixtures are the same, and the preexponential factor in the stoichiometric is 2.2 times lower. At the temperatures studied, the stoichiometric mixture of AN with succinic acid is a homogeneous

solution, and the decrease in the rate in this mixture is due to deviation from equimolarity of the amounts of AN and succinic acid.

CONCLUSIONS

(1) The thermal stability of two-component liquid mixtures of ammonium nitrate and an organic acid is determined both by the ability of an acid (determined by its strength) to transfer a proton to a nitrate ion and thereby to make higher the HNO_3 concentration in the system and by the rate constant of oxidation of the organic acid.

(2) In contrast to thermal decomposition of pure ammonium nitrate, the role of oxidizing agent in mixed systems constituted by ammonium nitrate and an organic acid is played by N_2O_5 formed in dehydration of nitric acid.

(3) Of the whole set of systems under study, constituted by ammonium nitrate and an organic acid, the most stable are mixtures with succinic and benzoic acids.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Properties of Systems $Ba(HCOO)_2$–$M(HCOO)_2$–H_2O (M = Ca or Mg) at 25°C

V. Z. Vasileva

Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

Received December 6, 2002

Abstract—The systems $Ba(HCOO)_2$–$Ca(HCOO)_2$–H_2O and $Ba(HCOO)_2$–$Mg(HCOO)_2$–H_2O were studied at 25°C by the solubility method. The effect of the ionic radii of doubly charged metals on the formation of double salts containing barium formate was considered.

Barium formate and its binary compounds possess interesting physical and chemical properties: $Ba(HCOO)_2$ and $BaCd(HCOO)_4 \cdot 2H_2O$ are nonlinear optical materials [1, 2], $Ba_2Cu(HCOO)_6 \cdot H_2O$ is paramagnetic material [3], and $BaY(HCOO)_5 \cdot 4H_2O$ and $Ba_2Cu(HCOO)_6 \cdot 4H_2O$ are suitable starting compounds for synthesis of superconductors [4, 5]. A study of salt systems containing barium formate is of interest because they show promise for practical application.

Barium formate is known to form double salts with formates of some doubly charged metals. $Ba_2M(HCOO)_6 \cdot 4H_2O$ (where M is Ni, Co, Cu, or Zn) (2 : 1 : 4) and $BaM(HCOO)_4 \cdot 2H_2O$ (where M is Cd) (1 : 1 : 2) [6, 7] were obtained by the preparative method. All these double salts (except that containing cobalt) were separated from the corresponding ternary water–salt systems [4, 8–10]. The double salt $Ba_2Fe(HCOO)_6 \cdot 4H_2O$ was separated from the $Ba(HCOO)_2$–$Fe(HCOO)_2$–H_2O system at 25°C. It was established that it is isostructural to the double salts of the isomorphic series. It is also known that manganese formate does not form a compound with barium formate. The $Ba(HCOO)_2$–$Mn(HCOO)_2$–H_2O system at 25°C is simple eutonic [11]. It was of interest to elucidate whether or not barium formate forms double salts with calcium and magnesium formates.

To determine the mutual solubility of the components and the possibility of formation of new phases from barium, calcium, and magnesium formates, we studied the systems $Ba(HCOO)_2$–$Ca(HCOO)_2$–H_2O and $Ba(HCOO)_2$–$Mg(HCOO)_2$–H_2O at 25°C. The systems have not been studied previously. Data on the solubility of barium, calcium, and magnesium formates were taken from [12, 13].

EXPERIMENTAL

The starting substances were obtained by reacting barium, calcium, and magnesium carbonates (all analytically pure) with a 50% solution of analytically pure formic acid, followed by recrystallization. According to chemical, derivatographic, and X-ray phase analyses, the resulting compounds have the compositions $Ba(HCOO)_2$ [14], α-$Ca(HCOO)_2$ [15], and $Mg(HCOO)_2 \cdot 2H_2O$ [16].

The solubility was studied by Khlopin's method of isothermal elimination of supersaturation [17]: aqueous solutions of two components of the system, taken in various proportions, were prepared at 80–90°C. Then the solution was cooled in a thermostat to the working temperature and vigorously stirred to constant concentration of a saturated solution (i.e., to attainment of equilibrium). The temperature was maintained constant to within ±0.1°C. The equilibration time was 15–20 h. After the suspension was filtered, the resulting liquid phase and the wet solid phase (residue) were analyzed. The Ba^{2+}, Ca^{2+}, and Mg^{2+} content in the liquid phases and residues was determined complexometrically [18]: the sum of Ba^{2+} and Ca^{2+} ions and of Ba^{2+} and Mg^{2+} ions was determined by back titration with zinc sulfate solution in ammonia solution in the presence of Eriochrome Black T indicator, Ca^{2+} was analyzed at pH 11 (NaOH solution) in the presence of calcone indicator, Mg^{2+} was analyzed in ammonia buffer solution after precipitating barium sulfate with a sulfuric acid solution, and the Ba^{2+} content was calculated as the difference between the two determinations. The solid phase composition was determined

by Schreinemaker's method of residues [19] and confirmed by chemical, thermal, and X-ray phase analyses. Thermal analysis was performed on an MOM-12 derivatograph (Hungary), and X-ray phase analysis, on a DRON-3 diffractometer (Cu_{K_α} radiation, Ni filter).

The results of a study of the system $Ba(HCOO)_2$–$Ca(HCOO)_2$–H_2O at 25°C are presented in Table 1, and the solubility isotherm is plotted in Fig. 1a. The system is simple eutonic at this temperature. The crystallizing solid phases are $Ba(HCOO)_2$ [14] and α-$Ca(HCOO)_2$ [15]. The composition of the eutonic solution is (wt %) 15.03 barium formate and 10.23 calcium formate. As either of the components is added, the solubility of the other decreases owing to salting-out.

Data on the solubility in the $Ba(HCOO)_2$–$Mg(HCOO)_2$–H_2O system are presented in Table 1 and Fig. 1b. The solubility isotherm is represented by the crystallization branches of anhydrous barium formate [14] and magnesium formate dihydrate [16], which intersect at the eutonic point of compositions (wt %): 17.27 $Ba(HCOO)_2$ and 7.39 $Mg(HCOO)_2$. The components exert the mutual salting-out effect. For example, the solubility of barium formate in the system decreases from 23.21 to 17.27 wt %, and that of manganese formate, from 11.99 to 7.39 wt %.

A study of the two systems showed that neither double salts nor mixed crystals are formed at 25°C. Thus, when barium formate is crystallized, the zinc and magnesium impurities are concentrated in the mother liquor. Barium formate free of calcium and

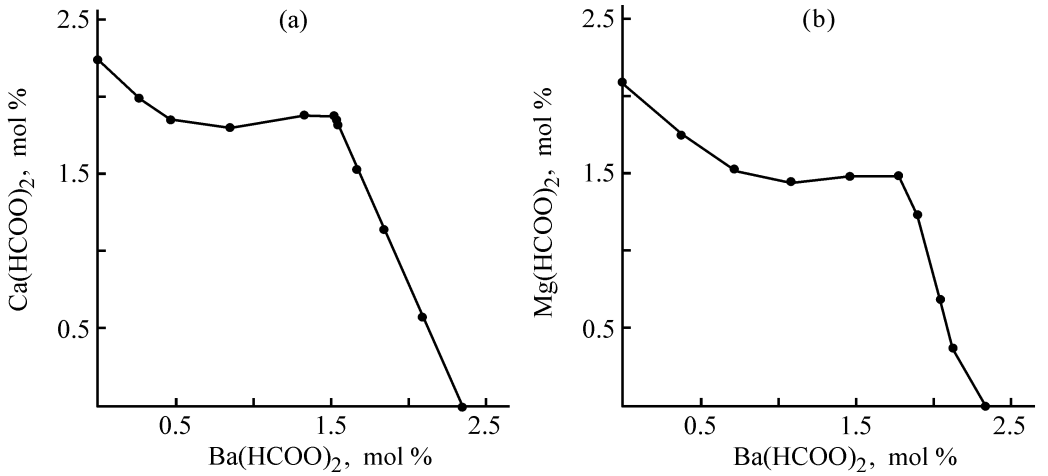

Fig. 1. Solubility isotherms of the systems (a) $Ba(HCOO)_2$–$Ca(HCOO)_2$–H_2O and (b) $Ba(HCOO)_2$–$Mg(HCOO)_2$–H_2O at 25°C.

magnesium impurities can probably be prepared by recrystallization.

Table 2 summarizes data on the compositions of double salts formed in the $Ba(HCOO)_2$–$M(HCOO)_2$–H_2O system (where M is Ni, Co, Cu, Zn, Fe, Mn, Cd, and Ca) at 25°C and lists the M^{2+} ionic radii [20]. As can be seen, barium formate yields double salts of stoichiometric composition $Ba_2M(HCOO)_6 \cdot 4H_2O$ (2 : 1 : 4) and $Ba_2M(HCOO)_4 \cdot 2H_2O$ (1 : 1 : 2) with formates of doubly charged metals. Barium formate gives the first structural type (2 : 1 : 4) with Ni, Co, Cu, Zn, and Fe formates. Only the double salt of copper has crystal structure [3]. All these double salts crystallize in the triclinic system, space group $P\bar{1}$, and have close unit cell parameters, i.e., they are isostructural.

The composition of a double salt and the M^{2+} ionic radius correlate. The structural type (2 : 1 : 4) is formed at ionic radii larger than 0.69 and smaller than 0.75Å. These conditions are satisfied by nickel(II), cobalt(II), copper(II), zinc(II), and iron(II) ions. In the systems $Ba(HCOO)_2$–$Mg(HCOO)_2$–H_2O (this study) and $Ba(HCOO)_2$–$Mn(HCOO)_2$–H_2O [11] no double salts are formed. This is because the Mg^{2+} radius (0.65Å) is probably too small, whereas the Mn^{2+} radius (0.80Å) is too large to make this structure stable. Apparently, the decisive factor influencing the formation of double compounds of the (2 : 1 : 4) structural type containing barium formate is the M^{2+} radius. The double salt of the second type [(1 : 1 : 2)] (only $BaCd(HCOO)_4 \cdot 2H_2O$ is known) crystallizes from aqueous solution at 25°C with the ionic radius increasing further. According to the data obtained in this study, no double salt is formed in the $Ba(HCOO)_2$–$Ca(HCOO)_2$–H_2O system. The ionic radii of Cd^{2+} and Ca^{2+} are very close (0.97 and 0.99Å, respectively). All the data presently available for the water–formate systems, including calcium formate, confirm the formation of anhydrous salts [21]. This fact is accounted for by strong dehydrating action of calcium formate. Probably, no double salt containing crystallization water is formed between barium and calcium formates for this reason.

Table 2. Composition of double salts formed in the $Ba(HCOO)_2$–$M(HCOO)_2$–H_2O systems

M^{2+}	Ionic radius, Å	Double salt composition
Mg^{2+}	0.65	Pure salts
Ni^{2+}	0.69	$Ba_2Ni(HCOO)_6 \cdot 4H_2O$ [6–8]
Co^{2+}	0.72	$Ba_2Co(HCOO)_6 \cdot 4H_2O$ [6, 7]
Cu^{2+}	0.72	$Ba_2Cu(HCOO)_6 \cdot 4H_2O$ [4, 6, 7]
Zn^{2+}	0.74	$Ba_2Zn(HCOO)_6 \cdot 4H_2O$ [6, 7, 9]
Fe^{2+}	0.75	$Ba_2Fe(HCOO)_6 \cdot 4H_2O$
Mn^{2+}	0.80	Pure salts [11]
Cd^{2+}	0.97	$Ba_2Cd(HCOO)_6 \cdot 2H_2O$ [6, 7, 10]
Ca^{2+}	0.99	Pure salts

CONCLUSIONS

(1) The systems $Ba(HCOO)_2$–$M(HCOO)_2$–H_2O (where M is Ca or Mg) were studied at 25°C and the formation of pure salts was established.

(2) Barium formate can be prepared by crystallization from an aqueous solution of impurity-free magnesium and calcium salts.

(3) A correlation between the composition of double barium salts and the M^{2+} ionic radius was estab-

lished. Double salts of the (2 : 1 : 4) type are formed at the ionic radii within 0.69–0.75Å. Above 0.80Å, another structural type (1 : 1 : 2) is formed.

SORPTION AND ION-EXCHANGE PROCESSES

Demineralization of Industrial Activated Carbons in an Extractor for Removing Components from Solid Materials

Received December 30, 2003; in final form, May 2003

Abstract—The possibility of exhaustive demineralization of industrial carbon sorbents by multiple treatment in the sequences acid–water–ammonia and alkali–water–acid–water was assessed. The influence exerted on the degree of demineralization by the process mode and composition of the alkaline solution was studied.

All the industrial activated carbons contain inorganic components in varied, and occasionally significant amounts. They pass into carbons from a starting material or are introduced into the charge before activation, which is carried out to improve the capacity and selectivity of sorbents or catalytically active carbons. The content of these mineral components [determined as ash according to the GOST (State Standard) 12596–67] may be as high as 20% of the carbon weight, and thus they can strongly affect the properties of the material [1–7]. Certain fraction of mineral components can leave the sorbent, strongly polluting the solution. Ash components affect the total porosity of the material [4, 8], creating nonuniform sorption profile in its bulk and, thus, changing the sorption of various (e.g., organic) compounds [7]. Therefore, the requirements to the sorbent purity are very stringent in some application fields (such as medicine, production of ultrapure compounds, nuclear industry, and drinking water supply).

Demineralization of carbon sorbents is of particular scientific and practical importance; it can be described as extraction in a solid–liquid system. Moreover, demineralization of carbon sorbents is (to some extent) similar to leaching of rocks that are difficult to break down. Acidic procedures are often used in demineralization of graphite carbon materials; for partial leaching the material is treated with nitric, hydrochloric, or sulfuric acids; for exhaustive leaching, with hydrofluoric acid or its mixtures with other mineral acids [3, 4, 8, 9]; which is followed by washing with hydrochloric acid and water.

Extraction in the solid–liquid system can be intensified by changing temperature, pressure, and particle size of the material and by applying external force fields [10–12].

We studied demineralization of carbon sorbents by their treatment with boiling reagents in the sequences acid–water–alkali–water and alkali–water–acid–water in several cycles and analyzed the effect exerted on the demineralization by intermittent and continuous stirring of a solid granular material.

EXPERIMENTAL

In this study we used SKT-6A activated carbon, because its sorption capacity is the highest among the Russian commercial activated carbons. We also studied AG-3 carbon, which is widely used in solvent recuperation and drinking water treatment. The reagents were 20% NH_4OH, KOH, and NaOH aqueous solutions, distilled water, and azeotropic hydrochloric acid. The treatment in the sequences acid–water–alkali–water and alkali–water–acid–water was performed using NH_4OH and KOH (or NaOH), respectively. The treatment time with each reagent was 4 h, so that the total cycle took 16 h. Since the multiple treatment is more efficient than a single-cycle treatment, we performed several complete treatment cycles in each sequence and with each sample.

Demineralization was carried out in a modified Soxhlet extractor [13–16] with water or acid condensates. The acid (as well as wash waters) can be distilled and recycled; as a result, the discharge of waste water would be only 1–2 volumes per sorbent volume, which is smaller than that in the existing flowsheets by a factor of 20 [3, 7, 9].

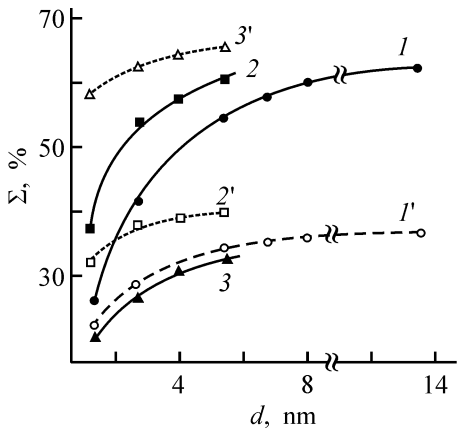
* $\alpha = [(c_{st} - c_{res})/c_{res}] \times 100$, $K_{pur} = c_{st}/c_{res}$.

To break the stagnation zones in the large-scale pilot extractor and to diminish the effect of filtration, the bed of the solid sorbent was intermittently or continuously fluidized with bubbling nitrogen. In the case of intermittent fluidization, the gas was bubbled through the sorbent bed for 5–10 min after every hour of unit operation. Both the intermittent and continuous fluidization were performed in the three-phase spouted bed mode [13, 15, 19]. In the course of treatment, the ash content in the solid phase was determined according to the GOST 12596–67; the samples were taken after each cycle of water treatment. The liquid phase was also sampled for microscopic dispersion analysis of particles carried away from the carbon sorbent by a liquid flow.



Integral size distribution curves of dispersed (*1*–*3*) carbon and (*1'*–*3'*) mineral particles. (Σ) Total content of the dispersed particles and (*d*) dispersed particle size. Sorbent treatment with: (*1*, *1'*) water, (*2*, *2'*) azeoropic hydrochloric acid, and (*3*, *3'*) aqueous ammonia.

The data on the degree of demineralization after each cycle of treatment of SKT-6A carbon with ammonia (alkali) without stirring are listed in Table 1. As seen, for SKT6A carbon, the alkaline demineralization is more efficient than the acid treatment. It should be noted, however, that acid pretreatment improves alkaline demineralization (and alkaline, vice versa, promotes acidic demineralization), because these reagents remove different mineral components from the aluminosilicate crystallites. The high efficiency of the alkaline treatment is also confirmed by data of microscopic dispersion analysis, which also indicate that some fraction of the mineral components is removed as disperse particles without dissolution (see figure).

A microscopic examination of the SKT-6A ash after three complete treatment cycles showed that the residual inclusions mainly consist of 30–90-nm coarse transparent plate-like crystals (resembling silica) and smaller steel-gray crystals.

An analysis of the wastewater after the alkali–water–acid–water treatment using KOH or NaOH showed that, after 12-h settling a carbon dust sediment was formed on the chamber bottom, and its layer was covered with a layer of light-colored mineral particles. The solution after filtration was dark green. With pH decreasing from 14 to 12–11, a significant amount of a white jelly-like precipitate appeared with significant decolorization of the solution. With pH decreasing further, to 6–4, the solution color was restored with partial dissolution of the precipitate. The residual fraction of this precipitate is probably silicic acid. This suggests that the compounds forming hydroxo complexes {$[Ni(OH)_3]^-$, $[Fe(OH)_4]^-$, $[Mn(OH)_3]^-$, $[Al(OH)_4]^-$, etc.} and fulvic acids, which are not precipitated with alkalis, are removed from activated carbons along with hydroaluminosilicates. This can account for the incomplete decolorization of the solution. Humic acids should be removed from carbon sorbents in preparing ultrapure compounds, especially ultrapure alkali metal hydroxides and salts, and also substances eluted with alkali solutions [19].

* Treatment with NaOH solution.

** Treatment with NH_4OH solution.

The degree of demineralization of the SKT-6A activated carbon, as influenced by the number of extraction cycles in various treatment modes, is given in Table 2. As seen, the content of mineral components in an extractor with a fixed sorbent bed, operating in the plug-flow mode, strongly changes along the apparatus height. This may be due to filtration of the washed-out dispersed particles in the sorbent bed and by the fact that, when flowing within the sorbent bed, the reagents are saturated with reaction products and thus the driving force of the extraction process becomes weaker. In the absence of fluidization, the ash content of the sorbent at the top and bottom of the extractor differed by a factor of 1.5; with intermittent stirring, by a factor of 1.15, whereas at continuous fluidization no difference was observed. Thus, stirring ensures uniform treatment of the sorbent in the apparatus volume. As seen from Table 2, at intermittent and continuous fluidization, the main fraction of mineral components (probably from the transport pores) are removed in the first two cycles. Upon subsequent treatment, the degree of demineralization increases to a lesser extent, because the process rate is limited by the rate of internal diffusion in the micropores, with decreasing total amount of the mineral inclusions. In this case, the process rate is almost independent of pulsation and fluidization.

Demineralization with KOH solution in various modes of acid treatment was studied with SKT-6A and AG-3 carbons; in the case of NaOH solution, only SKT-6A carbon was used. In all the cases, the sorbent was treated with boiling alkali solutions; the solid : liquid ratio (s : l) was 1 : 5. The results obtained are listed in Table. 3

As seen from Table 3, positive results of the alkaline treatment are manifested both in subsequent boiling in the acid and in the acid treatment in the inter-

Table 4. Total pore volume of SKT-6A carbon as influenced by the degree of demineralization in static treatment in the sequence KOH–H_2O–HCl–H_2O

* After thermal treatment.

mittent washing mode; the results of treatment with NaOH are nearly similar to those with KOH (within experimental error), with subsequent boiling in the HCl solution. Alkali solution removes only 20–25% of the ash in a single cycle, and its main fraction is recovered with acid. In alkali treatment, mineral components are converted into acid-soluble compounds; without this preliminary treatment no more than 27% of the ash are removed with acid in a single cycle.

In the experiments, the carbon sorbent bed came to a boil when treated with acid with the maximum gas evolution observed in the starting period, which is due to heat release in dissolution of the mineral components. Since liquid does not flow in micropores (molecular diffusion mechanism), the main fraction of this heat is consumed for steam generation, and, due to low thermal conductivity of the carbon, only insignificant heat fraction is transferred to the particle surface and dissipated in the core of the liquid flow. The decline in the gas evolution in the course of demineralization is due to a decrease in the amount of reacting compounds (impurities) and difficult access of acid to them.

In high-temperature treatment of the carbon (carbonization, graphitization, activation), the structure of mineral inclusions may undergo partial transformation with displacement of some ions (e.g., Na^+, K^+, Ca^{2+}, Mg^{2+}) to the surface of the resulting crystallites. In the course of demineralization, these elements are removed first. The main body of the crystallites loses contact with pore walls and can be damaged by the disjoining hydraulic pressure, especially when blast waves arise upon detachment of gas bubbles from the pore ends. As a result, mineral particles are removed into the solution in a finely dispersed state; this process is also promoted by peptization.

Our experimental data on the total pore volume determined according to GOST 17219–71 well agree with published data and show that, with decreasing ash content in the SKT-6A activated carbon by 70–80%, the total pore volume increases by 0.17–0.30 cm^3 per gram carbon (Table 4).

CONCLUSIONS

(1) Multiple treatment in the sequence alkali–water–acid–water ensures demineralization of industrial carbon sorbents; the efficiency decreases in the order KOH > NaOH > NH_4OH.

(2) Demineralization of carbon sorbents involves both dissolution of mineral components and their removal as finely dispersed particles.

(3) The three-phase fluidized bed mode provides more uniform treatment of the sorbent in the apparatus volume and is especially efficient in the first two treatment cycles.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis and Thermal Swelling of Residual Graphite Hydrosulfates Obtained Using the $Na_2Cr_2O_7$–H_2SO_4 System

A. P. Yaroshenko, M. V. Savos'kin, A. N. Magazinskii, and O. B. Savsunenko

Received August 13, 2002; in final form, March 2003

Abstract—The influence exerted by the conditions of synthesis of residual graphite hydrosulfate in a system constituted by concentrated sulfuric acid and saturated aqueous solution of sodium dichromate on the properties of the final product was studied in a wide range of reagent consumptions. The swelling coefficient and the loss of the product were analyzed as functions of the intercalate content in the product.

Previously, method for preparing high-quality residual graphite hydrosulfate, including treatment of natural flaky graphite with a 50-wt % aqueous solution of CrO_3 and then with H_2SO_{4con}, hydrolysis of the obtained graphite hydrosulfate, and washing and drying of the final product, has been developed [1–7]. The product obtained effectively swells at a relatively low temperature (500°C) and is used for fire prevention and in metallurgy.

However, this method uses an aqueous solution of CrO_3, which is an extremely volatile and toxic compound. In addition, this aqueous solution is highly corrosive, even with respect to stainless steel.

In this study, we analyzed the possibility of replacing CrO_3 with less toxic sodium dichromate and the properties of the residual graphite hydrosulfates obtained in this case.[1]

Natural flaky graphite of GT-1 brand[2] with ash content of 5.68 wt % was subjected to oxidation. Mainly two graphite fractions were present: 0.630–0.315 mm (74.3 wt %) and 0.315–0.200 mm (22.1 wt %). We used a solution in distilled water, containing 67.7 wt % $Na_2Cr_2O_7$ (ρ = 1.65 g cm^{-3}), as oxidant and chemically pure H_2SO_4 with concentration of 95.8 wt % (ρ = 1.835 g cm^{-3}).

The residual graphite hydrosulfate was synthesized at room temperature by the following procedure. An aqueous solution of $Na_2Cr_2O_7$ was added to 25 g of the starting graphite under agitation. After 10 min, H_2SO_4 was introduced into the reactor, and the reaction mass was agitated for another 10 min. Then, water (500 cm^3) was added and the mixture obtained was agitated and allowed to stay for 24 h to be hydrolyzed. During this period, small gas bubbles (CO_2 and probably CO) continuously evolved from the solid-phase layer. Then, the solid phase was filtered off on a paper filter in a water-jet-pump vacuum and washed with 2 l of water. The wet product was dried at 100–110°C to humidity not exceeding 1.0 wt %. The consumption of the aqueous solution of $Na_2Cr_2O_7$ per 100 g of graphite was varied within the range 2–20 cm^3, and that of H_2SO_{4con}, within 20–48 cm^3. The coefficient of swelling at 500°C in a shock heating mode, K_s^{500} (cm^3 g^{-1}), and the mass loss at 500°C were determined for all the 92 samples synthesized. The intercalate m_i (wt %) in the product was calculated from the values of the product yield on the assumption that no phase oxidation of graphite occurs at room temperature [8, 9], i.e., the whole amount of carbon is transferred from the graphite skeleton to the final product.

To determine the swelling coefficient of the products obtained, a weighed portion (m = 0.2–0.3 g) of the product was introduced into a stainless steel cell, preliminarily placed in a muffle furnace heated to 500°C, and kept there for 5 min to complete swelling. The cell with swollen graphite was withdrawn from the furnace and its contents were carefully transferred from the cell to a glassy volumetric flask and the volume V (cm^3) occupied by swollen graphite was measured. The swelling coefficient was determined as

[1] The term "residual graphite hydrosulfate" is used in this study for nonstoichiometric compounds formed upon modification of graphite hydrosulfate with water.

[2] Graphite from the Zaval'evsk deposit, Ukraine.

arithmetic mean of the ratio $K_s^{500} = V/m$ in three parallel runs.

The synthesis method developed in this study allows preparation of high-quality residual graphite hydrosulfate even at total consumption of the reagents of 60–80 mass fractions per 100 mass fractions of graphite.

The process involves graphite oxidation by chromium(VI) and intercalation of the resulting positively charged graphite matrix by hydrosulfate anions solvated by sulfuric acid molecules. In the limiting case, graphite hydrosulfate of the second degree of intercalation, with composition $C_{48}^{+} \cdot HSO_4^{-} \cdot (2.0–2.5)H_2SO_4$, is formed in this stage.[3] The content of sulfur(VI) in the residual graphite hydrosulfate obtained can be diminished from 11 wt % in the starting graphite hydrosulfate to 2.0 wt % by hydrolysis and washing with water. Apparently, this is due to the replacement of sulfuric acid molecules, solvating the hydrosulfate anion, with water molecules. In this case, the total content of the intercalate in the product obtained is as high as 25–35 wt %. The product obtained effectively swells at relatively low temperature, which makes it especially attractive for use as fire retardant. At 500°C, the swelling coefficient is as high as 250 $cm^3\ g^{-1}$.

Figure 1 shows how the swelling coefficient of the residual graphite hydrosulfates obtained depends on the consumption of oxidant (sodium dichromate aqueous solution) and concentrated sulfuric acid. This dependence is a hilly surface with a small plateau at the vertex at K_s^{500} = 200 $cm^3\ g^{-1}$, at oxidant and sulfuric acid consumptions per 100 g of graphite equal to, respectively, 11–13 and 40–44 cm^3. Outside the plateau, at lower and higher reagent consumptions, a decrease in the swelling coefficient is observed.

At oxidant consumption lowered to 8 cm^3/100 g graphite, the swelling coefficient of graphite is only about 20 $cm^3\ g^{-1}$, i.e., decreases by an order of magnitude. The decline in the swelling coefficient with decreasing consumption of sulfuric acid is described by a more gently sloping dependence, which, to a first approximation, is linear. Outside the plateau, at higher reagent consumption, a slight decrease in the swelling coefficient is observed. However, this decrease has a different origin. The decrease in K_s^{500} with increasing sulfuric acid consumption is due to the formation of a difficultly agitated viscous mass, whereas that with increasing oxidant consumption is associated with a decrease in the acidity of the intercalating solution because of its dilution with water introduced with the oxidant solution.

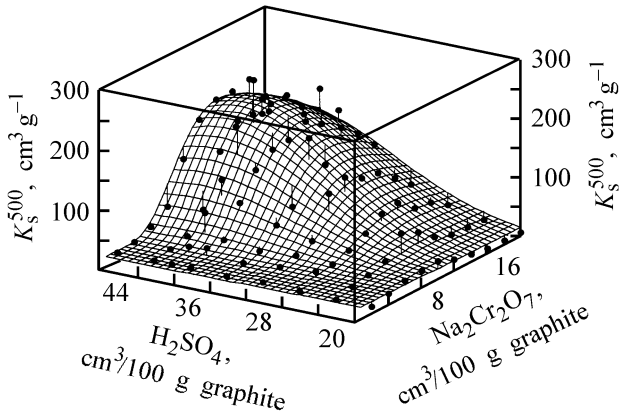

Fig. 1. Swelling coefficient of residual graphite hydrosulfate at 500°C, K_s^{500}, vs. the consumptions of $Na_2Cr_2O_7$ aqueous solution and concentrated H_2SO_4 in the synthesis stage.

The multiple parametric regression method was used to demonstrate that, at the reagent consumptions studied, the surface shown in Fig. 1 is described (with correlation coefficient r = 0.915) by the following empirical equation containing only two quadratic terms:

$$K_s^{500} = -23.24 + 0.4805AB - 0.4944A^2, \quad (1)$$

where A and B are, respectively, the oxidant and H_2SO_4 consumptions.

In setting-up Eq. (1), data corresponding to 10 samples obtained at the maximum consumption of sulfuric acid (48 cm^3/100 g graphite) were excluded from the regression because of the formation of a difficultly agitated viscous mass and the resulting uncontrollable conditions of product synthesis.

According to Student's t criterion, all the regression coefficients of Eq. (1) are significant. It is noteworthy that the regression analysis revealed nonsignificance of the linear terms, i.e., the swelling coefficient is determined by the product of the reagent consumptions, rather than by the consumptions themselves. This is due to a rise in the Cr(VI) oxidation potential with increasing solution acidity [10].

In all probability, the last, negative term of Eq. (1) reflects a decrease in the oxidation potential of dichromate ions in the intercalating mixture owing to its dilution with water introduced into the reaction mass together with the oxidizing solution.

[3] Graphite hydrosulfate has general formula $C_{24n}^{+} \cdot HSO_4^{-} \cdot mH_2SO_4$, where n is the degree of intercalation of the graphite compound, indicating the number of graphite layers between the adjacent intercalate layers.

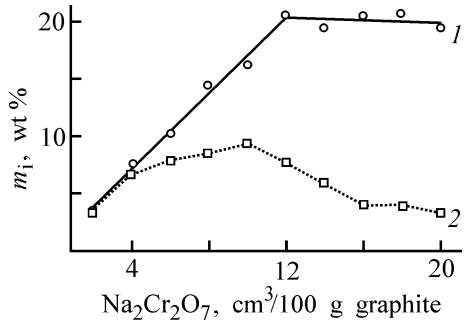

Fig. 2. Intercalate content m_i in residual graphite hydrosulfate vs. the consumption of $Na_2Cr_2O_7$ aqueous solution at constant consumption of H_2SO_4. Sulfuric acid consumption (cm^3/100 g graphite): (*1*) 44 and (*2*) 20.

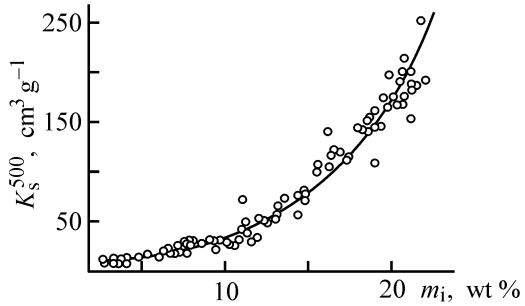

Fig. 3. Swelling coefficient of residual graphite hydrosulfate at 500°c K_S^{500} vs. intercalate content m_i. $K_S^{500} = 6.96\exp(0.160\,m_i)$, $r^2 = 0.968$.

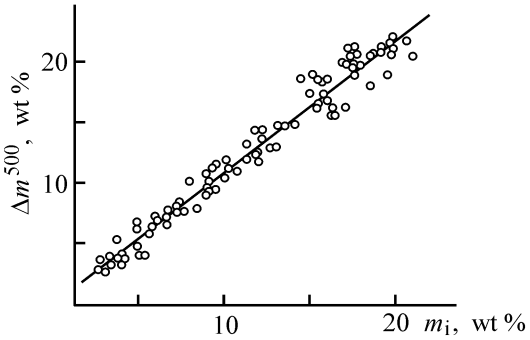

Fig. 4. Mass loss in swelling of residual graphite hydrosulfate at 500°C Δm^{500} vs. intercalate content m_i. $\Delta m^{500} = 1.099\,m_i - 0.061$; $r^2 = 0.966$.

The dependences of the intercalate content in the product synthesized at sufficiently high and relatively low acidities of the intercalating solution on the oxidant consumption (Fig. 2) clearly show that the stage of oxidation of the graphite skeleton governs the composition of the residual graphite hydrosulfate formed.

Raising the consumption of the aqueous oxidizing solution from 2 to 12 cm^3/100 g graphite at high acidity of the intercalating solution leads to a linear increase in the intercalate content in the final product (Fig. 2, curve *1*). In this case, the oxidation potential of the intercalating solution is so high that it ensures synthesis of a compound of the second degree of intercalation at 12 cm^3 of oxidizing solution consumed per 100 g of graphite, despite that the amount of the water introduced into the reaction mass with oxidizing solution grows. Raising the consumption of the aqueous oxidizing solution further does not lead to any increase in the intercalate content, which is indicated by a sharp bend and the following leveling-off of the dependence. This can be accounted for by an insufficient, despite the oxidant accumulation in the system, oxidation potential of the intercalating solution to give an intercalation compound of the first stage. Apparently, at lower consumption of the oxidizing solution, the graphite intercalation compounds of higher stages, which contain less intercalate, are formed.

At low amount of sulfuric acid in the reaction mass, raising the consumption of the oxidizing solution leads initially to an increase in the parameter m_i. However, the dilution of the intercalating solution with water introduced together with the oxidant results in a deviation from the linear dependence and gives rise to a maximum at a consumption of the oxidizing solution of 10 cm^3 per 100 g graphite (Fig. 2, curve *2*). Further increase in the oxidant consumption leads to a steady decrease in the intercalate content in the final product.

It follows from Fig. 2 that the intercalate content m_i in the final product can serve as a general characteristic of the efficiency of graphite intercalation, despite its being a complex process depending on a wide variety of parameters. It is the intercalate content that determines, in the end, the capacity of the final product for swelling under heating (Fig. 3).

The swelling coefficient of the residual graphite hydrosulfate depends on the intercalate content in it exponentially over the entire range of the reagent consumptions, with a correlation coefficient $r^2 = 0.968$. Such a behavior shows that the intercalate efficiency grows in the course of swelling, as its content in the product increases. This may be due to a change in the degree of intercalation of the residual graphite hydrosulfate with increasing intercalate content or to a change in the nature of the intercalate in the filled layers of the skeleton of residual graphite hydrosulfate.

It was found that, in swelling of the resulting products at 500°C, virtually the whole amount of the intercalate is removed from the structure of the residual graphite hydrosulfate, as evidenced by the linear relationship between the mass loss in swelling and the intercalate content m_i, with a slope close to unity (Fig. 4).

CONCLUSIONS

(1) High-quality residual graphite hydrosulfate can be obtained at extremely low consumption of the reagents by oxidation of graphite with a concentrated aqueous solution of sodium dichromate in the presence of sulfuric acid, with the subsequent hydrolysis of graphite hydrosulfate. The product obtained can be effectively swollen at relatively low temperature, which makes it especially attractive for use as fire retardant.

(2) An empirical equation, according to which the swelling coefficient is primarily determined by the product of the reagent consumptions, was suggested on the basis of an analysis of the experimental dependence of swelling coefficient on the reagent consumption in synthesis.

(3) Its was shown that the intercalate content in the final product is the general characteristic of the intercalation efficiency, and it is this value that determines, in the end, the swelling efficiency.

Received July 26, 2002; in final form, February 2003

Abstract—The chemical composition, specific surface area, and pore structure of a schungite sorbent were studied as influenced by the conditions of thermal treatment.

It is known [1–3] that schungite rocks from Karelia are used as sorbents in treatment of waste and reused water. Schungite rocks consist of various minerals (e.g., quartz, aluminosilicates, carbon, etc.) and show promise as complex sorbents combining the properties of carbon and silicate materials.

The sorption properties of schungite rock can be improved by thermal treatment [4]. However, data on how the heating conditions affect the schungite properties are scarce, the possible modes of thermal treatment for schungite modification have not been substantiated.

Samples of schungite sorbents (SSs) were prepared by crushing and sieving a schungite rock from Zazhoginskoe deposit to size grade of 2.5–0.5 mm. The thermal transformations were studied in air in the 20–1000°C temperature range using a 3434-S (model 907) derivatograph (10 deg min^{-1} heating rate, 50-mg sample weight, platinum crucibles, and α-Al_2O_3 reference).

The thermal oxidative treatment of the schungite sorbent was performed at three temperatures corresponding to the characteristic points in the DTA curve of the initial sample (Fig. 1): maximum of the exothermic peak at 528°C and two inflection points of the curve at 411 and 750°C at which structural transformations of the material occur. As seen from the TG curve, a pronounced weight loss by the material begins at about 500°C.

The thermal treatment of the SS samples (35–40 g) were performed in a muffle furnace in air for 1, 2, 3, 4, and 8 h. The rate of heating of the muffle furnace to a given temperature was 5 deg min^{-1}; the temperature was controlled with an accuracy of ±3°C.

The treated samples are denoted as SS-411, SS-528, and SS-750, in accordance with heat treatment temperatures.

Data on the effect of thermal treatment on the chemical composition of schungite sorbents are listed in Table 1.

As seen, the content of carbon in the samples decreases with increasing temperature, whereas the content of silicon and aluminum oxides grows. We assume that the rapid weight loss at temperatures higher than 500°C (Fig. 1) is due to burning-out of carbon, whose content decreases by a factor of 1.4 and 3.4 for SS-528 and SS-750, respectively.

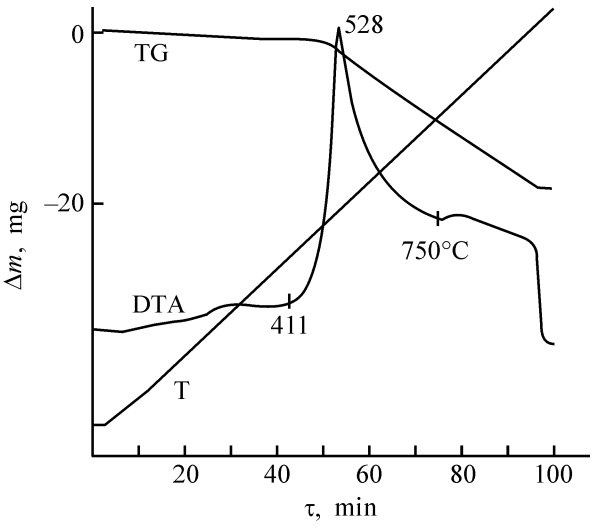

Fig. 1. TG and DTA curves of the initial schungite sorbent: (Δm) weight change and (τ) time.

Table 1. Chemical composition of the initial and thermally treated SS samples

Sample	Composition, wt %									
	C	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	MnO	K_2O	Cr_2O_3	TiO_2
Initial	31.00	54.50	4.62	2.04	1.50	0.66	0.02	1.15	0.03	0.22
SS-411	28.10	59.10	4.87	0.89	0.28	0.66	0.01	1.40	<0.02	<0.02
SS-528	21.80	64.81	5.00	0.79	0.28	0.64	<0.01	1.37	<0.02	<0.02
SS-750	9.12	77.35	6.74	1.84	0.28	0.88	0.01	1.90	<0.02	<0.02

The dependences of the sample weight loss on the duration of thermal treatment at the chosen temperatures are shown in Fig. 2.

For SS-411 sample, the weight loss is insignificant (about 3%) and occurs during the first hour of thermal treatment. SS-528 loses up to 6% of its weight during the first hour, on further heating the rate of weight loss decreases, and after 4-h annealing the total weight loss reaches 15% relative to the initial weight of the sample. The dependence for SS-750 sample is steeper: the weight loss in 1 and 4 h is 8 and 20%, respectively.

As seen from Table 2, the duration of thermal treatment at various temperatures affects the specific surface area S_{sp} of the sorbents, determined by the BET procedure from thermal desorption of argon adsorbed at low temperature [5]. Annealing of schungite at 411 and 528°C makes S_{sp} greater, and its value depends on the heating time. For example, the specific surface area of schungite increases by a factor of 1.5 and 3 after heating at 411°C for 1 and 8 h, respectively.

After heating the schungite sorbent at 528°C for 1 h, S_{sp} was the greatest; with increasing annealing time at this temperature, S_{sp} gradually decreased. On heating the schungite sorbent at 750°C for 1 h, S_{sp} remained unchanged and decreased by nearly a factor of 3 after a 4-h treatment.

The pore structure of the sorbent was studied using the samples with the largest specific surface area at each treatment temperature: SS-411 (8 h), SS-528 (1 h), and SS-750 (1 h).

It is known that the micro-, meso-, and macropores on the surface of solids affect their sorption, diffusion, mechanical, capillary, and other properties and determine the features of sorption processes. According to the IUPAC classification [6], pores with average size smaller than 2 nm, 2–50 nm, and greater than 50 nm are micro-, meso-, and macropores, respectively.

Real solids may contain a set of pores ranging from macropores through meso- and micropores to "subatomic" pores as gaps between the cleavage planes or dislocations and point defects.

Table 2. Specific surface area of the SS samples as influenced by thermal treatment duration τ (S_{sp} of the initial sample 9.0 $m^2 g^{-1}$)

Sample	S_{sp} ($m^2 g^{-1}$) at indicated heating time τ, h				
	1	2	3	4	8
SS-411	13.8	20.3	24.2	25.2	28.0
SS-528	29.3	22.8	16.4	17.2	
SS-750	9.0			3.2	

Data on the pore structure, obtained by sorption of iodine and acetone using known procedures [7, 8], are listed in Table 3.

As seen, the sorption capacity for iodine increases at 411 and 528°C, which indicates that the micropore structure of the material is developed by thermal treatment; in the case of SS-411, nearly a two-fold increase in comparison with the initial sample is observed. With the temperature increasing to 528 and 750°C, the interpore partitions break down and mesopores are formed. As a result, the sorbent porosity increases by a factor of 1.5 (acetone sorption). In the case of SS-750 sample, the sorption capacity for iodine (i.e., the content of micropores) decreases.

Mercury porosimetry is the best suitable for evaluating the size of macro- and coarse mesopores. The measurements were performed on a 2000 Macropore Unit Model 120 high-pressure mercury porosimeter,

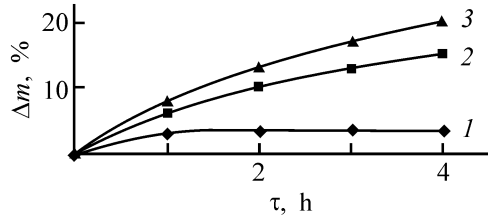

Fig. 2. Weight loss by the samples (Δ*m*) vs. the annealing time τ. (*1*) SS-411, (*2*) SS-528, and (*3*) SS-750.

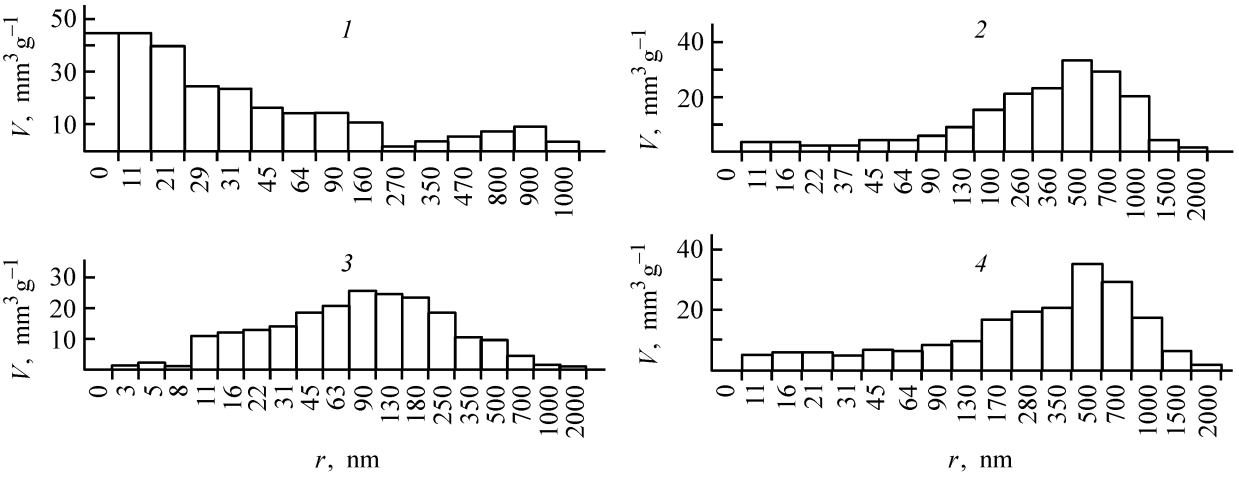

Fig. 3. Pore volume V distribution with respect to pore radius r. (*1*) Initial SS, (*2*) SS-411, (*3*) SS-528, and (*4*) SS-750.

using the procedures described in [9]. The principle of operation of this unit is based on the behavior of a nonwetting liquid (mercury) in the sample capillaries (bottles and cylinders).

The total pore volume and typical pore size in the initial and thermally modified samples, determined by mercury porosimetry, are listed in Table 3.

These data show that the total pore volume of SS-411 and SS-750 sorbents is greater by more than an order of magnitude than that of the initial sample, and a macroporous structure is formed. In SS-528 sorbent, the mesopore structure is predominant, and its total pore volume is smaller by almost a factor of 2.

The distribution of pore volumes with respect to the pore radius is illustrated by histograms Fig. 3.

Table 3. Properties of the SS samples after thermal treatment.

Properties	Initial SS	SS-411	SS-528	SS-750
Treatment temperature, °C	–	411	528	750
Treatment duration h	–	8	1	1
Sorption capacity for iodine, mg g^{-1}	11.4	23.17	16.07	9.84
Porosity for acetone, vol %	33.9	21.05	33.58	31.33
Total pore volume, cm^3 g^{-1}	0.025	0.289	0.175	0.300
Typical pore size, nm	13	596	106	596

The initial SS sample is characterized by approximately bidisperse structure with the first maximum in the mesopore range (11–21 nm), extending as a shoulder to the macropore range (64–160 nm) and the second diffuse maximum at 800 nm covering the 350–1000 nm macropore range.

As seen from Fig. 3, SS-411 and SS-750 have similar pore volume distributions in the 500–700 nm range, with a shoulder at 130–350 nm and a small maximum in the mesopore range (11–16, 21 nm). These data suggest that prolonged heating (8 h) of the SS sample at 411°C yields the same macro- and mesopore structure as treatment for 1 h at 750°C.

At a smaller total pore volume, the pore size distribution in SS-528 is more symmetrical with a maximum at 90–180 nm, a broad shoulder at 31–11 nm, and insignificant amount of fine 3–8-nm mesopores.

The development of the sorbent pore structure in the course of thermal treatment and its rather complex variation with heating may be probably due to removal of water vapor from sorbent pores at low temperatures and burning-out of schungite carbon at high temperatures. To understand in detail the mechanism of formation of the pore structure upon thermal treatment of a schungite sorbent, additional studies are required.

As seen from the above data, the schungite sorbent can be modified by thermal oxidative treatment in air, which raises the specific surface area and allows control of the pore structure. The changes in the chemical composition, specific surface area, and pore structure on heating of the schungite sorbent should be taken into account when choosing the modes of thermal oxidative modification and thermal regeneration of the sorbents.

CONCLUSIONS

(1) Thermal oxidative treatment of schungite sorbents in air raises the specific surface area and allows development of the sorbent pore structure.

(2) During thermal oxidative treatment at 528 and 750°C, the content of carbon in the schungite sorbent decreases by a factor of 1.4–3.4.

(3) The specific surface area of the schungite sorbents increases upon heating at 411 and 528°C and depends on the treatment duration.

(4) The total pore volume at any temperature of thermal treatment of the schungite sorbent increases by an order of magnitude (mercury porosimetry), and the pore size distribution depends on the treatment temperature.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Hexacyanoferrate(II, III) Anions on Nickel(II) Hydroxide

O. V. Nagornyi, A. S. Kolyshkin, and V. V. Vol'khin

Perm State Technical University, Perm, Russia

Received April 17, 2003

Abstract—$Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ anions are sorbed from aqueous solutions of their potassium and cesium salts on β-$Ni(OH)_2$ by the mechanism of anion exchange with hydroxy groups. Alkali metal cations (K^+, Cs^+) are also partly sorbed on nickel(II) hydroxide in the form of anionic complexes $(K,Cs)_zFe(CN)_6^{(n-z)-}$, where $n = 3$ or 4 ($0 < z < n$). The chemical composition of the new phase appearing in contact of nickel(II) hydroxide with aqueous potassium and cesium hexacyanoferrates(II, III) was determined by X-ray phase analysis and IR spectroscopy.

Inorganic ion exchangers are successfully used for treatment of industrial wastewater and natural waters to remove toxic metal ions and radionuclides [1, 2]. As compared to organic ion exchangers, these sorbents exhibit higher selectivity and have lower price [1, 3]. However, all the commercially available inorganic sorbents are mainly cation exchangers. Only a few types of inorganic anion exchangers have been prepared up to now [4], and the mechanism of their sorption activity is poorly understood. These factors hinder progress in the practical use of these sorbents.

In this study, we analyzed sorption of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ anions on β-$Ni(OH)_2$. Toxic hexacyanoferrate(II, III) anions get into wastewater from units for treatment of industrial wastes to remove cyanides [5].

EXPERIMENTAL

Nickel(II) hydroxide has two crystalline modifications: α-$Ni(OH)_2$ and β-$Ni(OH)_2$ [6, 7]. The α-$Ni(OH)_2$ modification has the hydrotalcite lattice with the interplanar spacing d_{003} from 0.7 to 0.8 nm. The interlayer space in this structure is occupied by H_2O molecules and anions (e.g., NO_3^-, CO_3^{2-}). In the β-$Ni(OH)_2$ lattice, the interplanar spacing decreases to $d = 0.46$ nm which hinders penetration of foreign anions into the interlayer space. Therefore, the mechanism of anion-exchange sorption on β-$Ni(OH)_2$ is simpler, and we chose this modification of nickel hydroxide as a sorbent. In our experiments, β-$Ni(OH)_2$ was prepared by hydrolysis of $Ni(NO_3)_2$ in aqueous solution by the method reported in [8]. However, we failed to obtain nickel hydroxide free of foreign anions.

The initial nickel hydroxide and that after treatment with aqueous solutions containing hexacyanoferrate(II, III) anions were characterized by powder X-ray diffraction and IR spectroscopy. The X-ray diffraction measurements were carried out on a DRON-2.0 X-ray diffractometer with monochromatic radiation (Cu_{K_α}, primary beam). The IR spectra (KBr pellets) were recorded on Specord 75-IR and UR-20 spectrometers. The chemical composition of solid samples (after preliminary dissolution) was determined on an AAS-30 atomic-absorption spectrophotometer. The content of hexacyanoferrate(II, III) anions in solutions was determined by volumetric titration [8, 9].

Sorpion of hexacyanoferrate(II, III) anions on nickel hydroxide from aqueous solutions was studied by a common technique under both dynamic and static conditions [10]. The sorption kinetics was studied at constant $Fe(CN)_6^{n-}$ and OH^- concentrations. These studies were carried on a laboratory setup including a pH meter (an IPL-102 ionometer), a buret for automatic titration, and a controlling computer. In the course of sorption experiments, the solid and liquid phases were vigorously stirred to ensure their uniform distribution in the reaction vessel. The sorption rate was estimated by the titration time.

Sorption of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ on β-$Ni(OH)_2$ under dynamic conditions was studied on a column about 10 cm high. The $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$ content in the initial solutions was 1.0×10^{-3} M. The maximal total sorption capacity of the sorbent in our experiments was 0.33 mg-equiv g^{-1} for $Fe(CN)_6^{3-}$ and 0.32 mg-equiv g^{-1} for $Fe(CN)_6^{4-}$. In

1070-4272/03/7608-1238 $25.00 © 2003 MAIK "Nauka/Interperiodica"

the course of sorption, the pH of the sorbate increases, which shows that the sorption occurs by the mechanism of anion exchange $Fe(CN)_6^{n-} \rightleftarrows OH^-$. Hexacyanoferrate(II, III) anions were desorbed from nickel hydroxide by passing 1 M NaOH through the column. The degree of desorption was 70–80%.

The equivalence of the anion-exchange sorption was studied under the came conditions, taking into account the joint sorption of anions and cations. We found no significant difference in the sorption characteristics of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ anions and, therefore, only the data on sorption of $Fe(CN)_6^{4-}$ are listed in the table. In the first experimental series, the sorption was studied from a 1.0×10^{-3} M $K_4[Fe(CN)_6]$ solution. In the second experimental series, the liquid phase additionally contained $CsNO_3$ (4×10^{-3} M). The data on sorption of anions and cations, obtained by the chemical analysis of two first 50-ml fractions of the solution, are listed in the table.

These results show that not only $Fe(CN)_6^{4-}$ anions, but also alkali metal cations are sorbed on $Ni(II)(OH)_2$. Sorption of these cations (especially Cs^+) decreases the amount of OH^- anions displaced from nickel hydroxide by $Fe(CN)_6^{4-}$. As can be seen from the table, in both the experimental series, the difference in the first filtrate fraction between the amounts of $Fe(CN)_6^{4-}$ and alkali metal cations sorbed on nickel(II) hydroxide is approximately equal to the amount of the OH^- anions displaced from the sorbent. At the same time, in the second filtrate fraction, the amount of displaced OH^- anions was considerably less than this difference. We believe that this is due to the fact that, in the course of sorption, not only OH^- groups, but also other foreign anions entering into the composition of the sorbent are displaced by $Fe(CN)_6^{4-}$ into the filtrate. In our numerous experiments, we found that the molar ratios of desorbed OH^- anions and sorbed hexacyanoferrate(II, III) anions $OH^-/Fe(CN)_6^{4-}$ and $OH^-/Fe(CN)_6^{3-}$ do not exceed 3.4 and 2.2, respectively.

The kinetic curves of sorption of $Fe(CN)_6^{3-}$ on nickel(II) hydroxide at pH 9 and 10 are shown in Fig. 1.

The kinetic curve of sorption of $Fe(CN)_6^{3-}$ at pH 10 is typical of diffusion-controlled ion-exchange sorption with diffusion in transport pores of granules as the limiting stage. This kinetic curve shows that the sorption rate is high initially and then decreases virtually to zero. In the kinetic curve obtained at pH 9, an inflection point appears, after which the sorption rate becomes constant. Such a shape of the kinetic curve suggests that, in the initial stage of ion-exchange sorption, nuclei of a new phase originate, and further sorption gives a separate phase.

Joint sorption of $Fe(CN)_6^{4-}$ anions and K^+, Cs^+ cations on nickel(II) hydroxide

Experimental series no.	Sorbed ions, mg-equiv				Desorbed OH^-, mg-equiv
	$Fe(CN)_6^{4-}$	K^+	Cs^+	$(I^+ + I^-)^*$

	0.180	0	0.062	0.118	0.045

* $(I^+ + I^-)$ Difference between the amounts of sorbed $Fe(CN)_6^{4-}$ and alkali metal cations

To elucidate the nature of this new phase and conditions of its formation, the sorption was studied at a solid to liquid phase ratio of 1 : 50 and hexacyanoferrate(II, III) concentration of 0.1 M under static conditions. In these experiments, the effect of sorption on the structure and chemical composition of nickel(II) hydroxide was studied by X-ray phase analysis (Fig. 2) and IR spectroscopy (Fig. 3).

The powder X-ray diffraction pattern (Fig. 2, curve *1*) shows that the initial sorbent mainly consists of β-$Ni(OH)_2$. This result is confirmed by the IR spec-

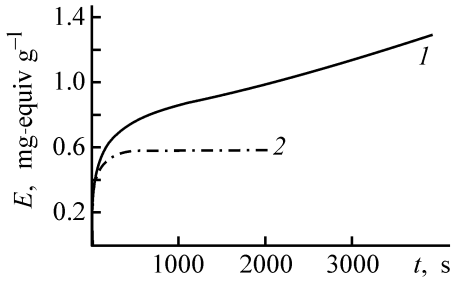

Fig. 1. Kinetic curves of sorption of $Fe(CN)_6^{3-}$ on nickel(II) hydroxide at (*1*) pH 9 and (*2*) pH 10. (*E*) Sorption of $Fe(CN)_6^{3-}$ on nickel(II) hydroxide and (*t*) time.

trum of a Ni(II) hydroxide sample (Fig. 3, curve *1*). The spectra of the initial sorbent contain the band of OH stretching vibrations ν(OH) at 3640 cm^{-1}, the band of the stretching vibrations of hydrogen-bonded OH groups at 3425 cm^{-1}, and the band of OH bending vibrations $\nu_2(H_2O)$ at 1635 cm^{-1}. The band at 1460 cm^{-1} is apparently due to $\nu_3(CO_3)$ vibrations. The bands at 1350 and 1000 cm^{-1} can be assigned to $\nu_3(NO_3)$ (D_{3h}) and N–O (C_{2v}) vibrations. These spectroscopic data show that the initial nickel hydroxide contains foreign CO_3^{2-} and NO_3^- anions. However, the powder X-ray diffraction pattern of our sample of nickel(II) hydroxide (Fig. 2, curve *1*) shows no changes in the interplanar spacing (00*l*) as compared to the standard values. This fact suggests that the foreign anions present in our nickel(II) hydroxide are impurities.

The powder X-ray diffraction patterns in Fig. 2, (curves *2* and *3*) show that sorption of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ anions on nickel hydroxide is accompanied by formation of a new phase, mixed Ni, K hexacyanoferrate(II, III) with cubic structure (*Fm*3*m* space group). For comparison, Fig. 2 (curve *4*) shows an X-ray diffraction pattern of mixed Ni, K hexacyanoferrate prepared by a common technique [12]. These results show that, upon sorption of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ anions, all the main reflections of mixed Ni, K hexacyanoferrate appear in the powder X-ray diffraction pattern of nickel(II) hydroxyde. At the same time, the initial β-$Ni(OH)_2$ phase is retained in significant amount even after contact of the sorbent with a hexacyanoferrate(II, III) solution for several days.

A study of the sorption of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ anions from aqueous solutions of their potassium salts on β-$Ni(OH)_2$ under static conditions showed that mixed Ni, K hexacyanoferrate(II) and Ni, K hexacyanoferrate(III) phases are formed only at pH < 11.0 and <9.7, respectively. These processes are accompanied by an increase in pH, and, when alkalization reaches the above-noted levels, the formation of new phases stops. Although the phase formation stops, sorption of hexacyanoferrate(III) under these conditions continues by a common anion-exchange mechanism. This process can be observed, e.g., under dynamic conditions.

The IR spectrum of nickel(II) hydroxide containing sorbed $Fe(CN)_6^{3-}$ anions (pH > 10) (Fig. 3, curve *2*) shows an absorption band at 2100 cm^{-1} which can be assigned to ν_6 vibrations of "free" $Fe(CN)_6^{3-}$ anions with terminal N atoms. At the same time, in sorption at pH < 9.7 (Fig. 3, curve *3*), two separate bands appear at 2170 and 2100 cm^{-1}, which are typical of the bridging –CN– groups in the structure of Ni, K hexacyanoferrate(III) [12] (Fig. 3, curve *4*). The bands of the bridging –CN– groups are also observed in the IR spectra of nickel(II) hydroxide containing sorbed $Fe(CN)_6^{4-}$ anions. However, this spectrum is characterized by more complicated splitting of the absorption bands, pesumably due to partial oxidation of hexacyanoferrate(II) to hexacyaoferrate(III) by atmospheric oxygen.

Thus, $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ anions are sorbed from aqueous solutions of their potassium and cesium salts by a complicated mechanism involving anion exchange and formation of a new phase. The contribution of anion exchange to the overall sorption of $Fe(CN)_6^{4-}$ can be described by the reaction equation

$$Ni(OH)_{2-x}(CO_3)_{x/2} + y\,Fe(CN)_6^{4-} \rightleftarrows Ni(OH)_{2-x-4y}(CO_3)_{x/2}[Fe(CN)_6]_y + 4y\,OH^-. \quad (1)$$

The exchangeable OH^- anions are located on both the surface planes of β-$Ni(OH)_2$ crystals and in defective sites in which the interlayer spaces at the surface of crystallite blocks are expanded [6]. Along with anions, K^+ and Cs^+ cations are also sorbed on nickel hydroxide. We believe that these cations are sorbed in the form of $K_z[Fe(CN)_6]^{(n-z)-}$ anionic complexes, where $n = 3$ or 4 and $0 < z < n$. The possibility of joint ion-exchange sorption of Na^+ and SO_4^{2-} on double Zn–Cr(III) hydroxide was reported in [13]. Thus, ion-exchange sorption of $Fe(CN)_6^{4-}$ anions from aqueous solutions of their potassium and cesium salts on

nickel(II) hydroxide gives a new multicomponent phase whose chemical composition can be expressed by the formula

$$Ni(OH)_{2-x-(4-z)y}(CO_3)_{x/2}[K_zFe(CN)_6^{4-}]_y$$

This formula shows that the sorption is accompanied by displacement of $(4-z)y$ OH^- anions from the sorbent into the liquid phase.

As the anion-exchange capacity of nickel hydroxide is exhausted owing to a decrease in the amount of the OH^- anions available for ion exchange, the foreign anions present in nickel(II) hydroxide can get involved in the exchange. It should be noted that nitrate anions of $Ni_2(OH)_3NO_3$ basic salt are strongly bound to the nickel cation by covalent bonds and, therefore, are unexchangeable [11], so these anions are not included into the formula reflecting the sorbent composition. At the same time, it is known that carbonate anions of the basic salts are typical exchangeable groups [14]. Since the diffusion coefficient of CO_3^{2-} is considerably lower than that of OH^- anions, carbonate anions must be displaced from the sorbent after exhaustion of hydroxy anions.

Sorption of $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ is accompanied by formation of nuclei of a mixed Ni, K(Cs) hexacyanoferrate(II, III) phase. At K(Cs) hexacyanoferrate(II, III) concentration in the initial aqueous phase equal to 1.0×10^{-1} M, these initial nuclei are converted into separate phases at pH < 9.7 and <11.0 for $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$, respectively. The main mechanism by which the new phase is formed (e.g., in sorption of $Fe(CN)_6^{4-}$) can be described by the following chemical reaction:

$$(2-x)Ni(OH)_2 + 2xM^+ + Fe(CN)_6^{4-} \longrightarrow M_{2x}Ni_{2-x}[Fe(CN)_6] + 2(2-x)OH^-, \quad (2)$$

where M is K^+ and Cs^+, $0 < x < 2$ (predominantly $x = 1.3$–1.5).

In going from Na^+ to Cs^+, the formation of mixed Ni, M hexacyanoferrates(II, III) increases with strengthening of the ion-exchange sorption of these cations [12]. Although the new phase is formed very slowly, it has time to build its own structure, e.g., when the sorption is performed in the batch mode. To ensure the most favorable conditions for phase formation under these conditions, pH must be lower than its maximum permissible level.

CONCLUSIONS

(1) $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ anions are sorbed on nickel(II) hydroxide mainly by ion-exchange substitution of hydroxy groups. Sorption of hexacyanoferrate(II, III) anions is accompanied by ion-exchange sorption of alkali metal cations present in the sorbate and ion exchange of the foreign anions present as impurities in nickel(II) hydroxide.

(2) In sorption of hexacyanoferrate(II, III) anions on nickel(II) hydroxide, a new phase of Ni-M hexacyanoferrate(II, III) is formed, where M is alkali metal cation. At the initial hexacyanoferrate(II, III) concentration of 1.0×10^{-1} M, this phase is formed at pH lower than 9.7 and 11.0 for $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$, respectively.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Oxidation and Contact Corrosion of Silver and Copper in Pores of Palladium Coating

E. P. Grishina

Institute for Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received December 3, 2002; in final form, June 2003

Abstract—Cyclic voltammetry and graphical calculation of corrosion currents in short-circuited systems Ag–Pd and Cu–Pd in a 38% H_2SO_4 solution were applied to study the mechanism and evaluate the intensity of corrosion of silver and copper anodes at base of pores of a cathode coating, palladium black, in an aqueous solution of sulfuric acid.

Silver and copper are used as cathode materials in manufacture of tantalum electrolytic capacitors (TEC) [1–3]. These two metals have high electrical conductivity and corrosion stability in unoxidizing acids [4]. Palladium or platinum black is deposited onto the inner surface of the case (cathode) [2, 3], which results in that the anode capacity of the capacitor is utilized to fuller extent [1]. The resulting bimetallic system, which is constituted by the metal and the porous coating in sulfuric acid (working electrolyte of TEC), is a short-circuited galvanic cell.

Theoretically, in comparison of the standard potentials E^0 of the metals, a contact of silver with palladium can be characterized as corrosion-safe, since $\Delta E^0 = 0.987 - 0.799 < 0.400$ mV [5]. A contact of copper with palladium is inadmissible ($\Delta E^0 = 0.987 - 0.337 > 0.400$ mV). In both cases, the support metal, being more electropositive than palladium, may suffer corrosion destruction, which leads to changes in the working parameters of a capacitor or to its failure [6, 7].

Since irreversible steady-state potentials E_{st} of these metals are established in the working electrolyte of a capacitor (38% H_2SO_4 solution), the actual pattern of the process and the risk run in using one or another cathode material may differ significantly from those predicted. Experimental studies of short-circuited electrochemical systems of this kind are scarce, and there is no published evidence concerning the corrosion-electrochemical behavior of Ag–Pd and Cu–Pd systems.

The aim of this study was to analyze the mechanism and evaluate the intensity of corrosion of silver and copper anodes at base of pores of a cathode coating, palladium black, in a 38% aqueous solution of sulfuric acid.

EXPERIMENTAL

As objects of study were used stationary silver [Sr999 GOST (State Standard) 6836–80] and copper (M0b, vacuum-smelted, GOST 859–78) electrodes. Palladium plating electrolytes were prepared from $PdCl_2$ (30 g l^{-1}, for coating of silver) or $PdSO_4$ (0.64 g l^{-1}, for coating of copper) from pure or chemically pure reagents and twice-distilled water.

Potentials were measured and polarization measurements performed as in [8]. A 38% H_2SO_4 solution served as working electrolyte, the working temperature range was 20–60°C (temperature control accuracy ±0.1°C). The electrode capacity C was measured with an R 5021 ac bridge at a frequency of 1 kHz in a 38% H_2SO_4 solution, with platinum-plated platinum as counter electrode. The loss of mass from the electrode, Δm, was determined gravimetrically on a VLR 200 balance. The corrosion currents of the short-circuited electrochemical system constituted by a metal and porous coating were found graphically by a procedure described in [5].

The values of E_{st} of silver and palladium, measured at 20°C in a 38% H_2SO_4 solution, are 0.44–0.45 and 0.82–0.83 V, respectively; with ΔE_{st} close to the critical value ΔE_{cr}. At the same time, the potential of Pd with palladium black deposited on it electrochemically (Pd/Pd) is less positive and, depending on the current density j_{Pd} of palladium plating, falls with-

in the range 0.675–0.690 V. Under the conditions of contact between a silver substrate and palladium black, comparison of E_{st} of silver and Pd/Pd electrodes is more adequate.

The steady-state potential of palladium-plated silver, $E_{Ag/Pd}$, depends on j_{Pd} (Table 1). $E_{Ag/Pd}$ occupies an intermediate position between E_{st} for Ag and Pd because of the presence of through pores in the coating and low voltage drop in these pores [5]. The rise in $E_{Ag/Pd}$ with increasing j_{Pd} points to a decrease in the number of through pores. Simultaneously decreases the surface capacity C, and the color of palladium black changes from gray to black. Presumably, finely crystalline palladium deposits having much more developed structure and weakly shielding the substrate surface are formed at low current densities.

The mechanism of the anodic process on Ag and Cu was studied by cyclic voltammetry, since this method allows recording of the electrochemical response of the substrate metal in the presence of through pores in a coating.

In anodic polarization of silver in sulfuric acid, there occurs an EC process [8]

$$2Ag + SO_4^{2-}(HSO_4^-) \rightleftarrows Ag_2SO_4 + 2e\ (+H^+) \quad (1)$$
$$\downarrow$$
$$2Ag^+ + SO_4^{2-}$$

This process is manifested in a cyclic voltammogram (CVA) as two conjugated current peaks: anodic in electrochemical formation of a resistive porous Ag_2SO_4 layer, and cathodic in its reduction. Figure 1 shows CVA of Ag and Ag/Pd electrodes in a 38% H_2SO_4 solution. These voltammograms are characterized by identical positions of the anodic and cathodic current peaks, with the electrochemical response of Pd not distorting the pattern of a redox process involving Ag. At any temperatures and potential sweep rates V, the main features of the anodic behavior of silver in sulfuric acid [8, 9]: number and position of anodic and cathodic peaks in CVA and linear dependence of the current density j_m^a and anodic peak potential E_m^a on $V^{0.5}$, are preserved for the bimetallic system. This indicates that the mechanisms of anodic oxidation of

silver as individual metal and silver in contact with a porous palladium coating coincide.

The decrease in j_m^a in polarization of the Ag/Pd electrode can be attributed to two factors. The first and, presumably, foremost is the shielding of a part of the silver surface by palladium, since the current is a function of the potential and the electrochemically active part of the electrode surface under potentiodynamic conditions of polarization. The second factor is the appearance of additional hindrance to migration of the reacting anions (SO_4^{2-}, HSO_4^-) within pores of the palladium coating (limiting stage of the process [9]).

The intensity of Ag corrosion in a short-circuited Ag/Pd system is characterized by the corrosion current, which can be determined from polarization corrosion diagrams (Fig. 2). In the given case, cathodic potentiostatic polarization curves reflect the polarization behavior of palladium black. The anodic portion of the polarization diagram is obtained by connecting the point on the potential axis, which corresponds to E_{st} of Ag, and that on the cathodic polarization curve of palladium, corresponding to E_{st} of Ag/Pd.

Table 2. Loss of metal, Δm, in anodic polarization of silver and palladium-plated (at j = 10 mA cm^{-2}) silver electrodes (Q = 1.5 A s cm^{-2})

Metal	Δm (mg cm^{-2}) at j^a, mA cm^{-2}			
	0.5	5	50	250
Ag	1.55–1.60	1.45–1.60	0.75–1.0	0.80–0.85
Ag/Pd	0.55–1.15	0.75–1.15	0.45–1.15	0.35–0.45

In the system constituted by silver and palladium black, the support metal is polarized to a greater extent than the coating metal, which may be due to the significant difference between E_{st} and the equilibrium potential of the anodic reaction (1) on silver. The value of j_{cor} grows with increasing current density of palladium plating (Table 1) because the potential of the coating becomes more positive and the polarization of the cathodic process is enhanced. The cathodic process occurs in the kinetic mode (effective activation energy A_{eff} = 36.6 kJ mol^{-1}), and the rate of the anodic process is limited by the transport stage (A_{eff} = 14.4 kJ mol^{-1}), which is, presumably, migration of the salt-forming anion into the reaction zone [9].

The shielding action of the Pd coating also tells upon the cathodic loss of metal, Δm, making it much smaller (Table 2). Under these conditions, a potential corresponding to the occurrence of process (1) is established at the anode. The decrease in the loss of metal is due to an increase in the anodic current density on the silver surface not shielded by palladium and to passivation of this surface.

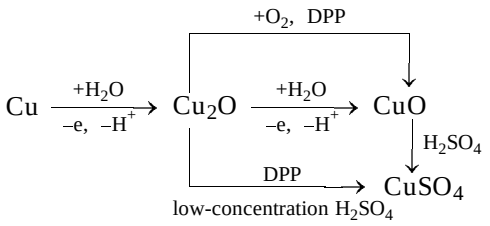
Thus, the safest in regard to corrosion is the contact of silver with palladium coatings deposited at low current densities. However, account should be taken of the circumstance that TEC must remain in working state at elevated temperatures (up to 85°C) and under the action of anodic currents. Palladium black formed at lower cathodic current densities is more subject to anodic dissolution than that deposited at the potentials of hydrogen ion discharge [10]. Therefore, in choosing the palladium-plating mode, preference should be given to medium current densities in the J range considered.

Change of silver for copper in TEC is rather attractive because of the comparatively low cost of the latter metal [2, 3, 11]. The rather significant difference between the steady-state potentials of Cu and Pd results in contact deposition of the more noble palladium on copper in the form of a black. The black deposited in this way does not have sufficient adhesion to the substrate, which reflects on the electrochemical characteristics of the bimetallic system.

The difference of E_{st} of Cu and Pd in a 38% H_2SO_4 solution is 0.44 V, which is much lower than the theoretical value, but exceeds somewhat ΔE_{cr}.

Figure 1 shows CVA of copper and palladium-plated copper electrodes in 38% H_2SO_4 solution. As also in the case of silver, redox processes on both

the electrodes coincide. In contrast to silver, anodic oxidation of copper in H_2SO_4 solutions is a more complex multistage process including electrochemical and chemical stages. For example, depending on the concentration of acid and dissolved oxygen, anodic oxidation of copper may proceed by an ECC or EEC mechanism (E and C stand for, respectively, electrochemical and chemical stages of the electrode process), but the primary product of electrochemical reaction is, invariably, copper(I) oxide forming a resistive porous layer [12]:



(2)

where DPP is the disproportionation process.

In potential cycling, the palladium coating flakes off the copper substrate, which is due to the formation of a Cu_2O layer. The large number of through pores reflects on the experimental values of the capacity C and E_{st} (Table 1), and the E_{st} of the Cu/Pd electrode remains inchanged.

When in contact with palladium, copper undergoes corrosion oxidation with very low polarization, whereas the cathode of the galvanic pair is strongly polarized (Fig. 2). The corrosion currents exceed by approximately a factor of 3 that in the Ag/Pd system. The A_{eff} in corrosion of copper in the given system is 16.3 kJ mol^{-1}. Apparently, the primary product of copper oxidation in corrosion will be Cu_2O, whose further chemical conversion into soluble products will proceed at a rate depending on external factors, temperature and concentration of acid, presence of dissolved oxygen.

CONCLUSIONS

(1) According to the results obtained, the anodic processes occurring in pores of the palladium coating at the Ag–electrolyte and Cu–electrolyte phase interfaces are virtually identical to those on individual metals and consist in anodic formation of, respectively, Ag_2SO_4 and Cu_2O passivating films.

(2) Combined, the contact coating with poor adhesion and the more negative value of E_{st} make the Cu/Pd system less reliable than the Ag/Pd system, as regards their use as cathodes in tantalum electrolytic capacitors. At the same time, the reliability of the Cu/Pd system can be, undoubtedly, much improved by using a number of technological procedures, and its corrosion stability can be made close to that of Ag/Pd.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion Resistance of Construction Materials in Liquid Bromine Trifluoride

G. N. Amelina, I. I. Zherin, and S. N. Lozhkomoev

Tomsk Polytechnic University, Tomsk, Russia

Received October 16, 2002; in final form, June 2003

Abstract—Results obtained in studying gravimetrically and electrochemically the corrosion resistance of the most widely used construction metals and alloys in liquid bromine trifluoride BrF_3 under steady-state conditions are presented.

Halogen fluorides are rather strong oxidizing and fluorinating agents, which can be used in gas and liquid phases both individually and in mixtures with one another. Therefore, corrosion of construction materials is a topical problem in working with this class of compounds. Among liquid halogen fluorides, BrF_3 is one of the most corrosive. This is mainly due to its susceptibility to self-ionization and high electrical conductivity ($8.02 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$), which exceeds by many orders of magnitude that of other halogen fluorides. For this reason, BrF_3 is a strong ionizing solvent and complexing agent [1]. The whole set of these properties indicates that not only chemical, but also electrochemical corrosion may occur in solutions containing BrF_3. Consequently, a contact with an electrochemically different material can strongly affect the corrosion rate, i.e., contact corrosion may occur.

Published data on this issue are rather incomplete and refer only to the gravimetric method for determining the corrosion rates of steels and alloys not manufactured in Russia [2]. It was of interest to study in sufficient detail the corrosion resistance of various widely used stainless steels in liquid BrF_3. Particular attention is required by corrosion of metals brought in contact, which depends of the potentials of the metals in the given medium.

In this context, the aim of this study was to determine the rates and potentials of corrosion of a number of construction metals that are of particular practical interest: NP2 nickel, GOST (State Standard) 492–73; M2 copper GOST 859–66; steels: 12Kh18N10T, 08Kh18N10T, 14Kh17N2, 08Kh18N11M3G2F [metal for EA-400/10U electrodes, TU (Technical Specification) 5.965-4027–72], 04Kh20N9 (metal for OZL-36 electrodes, GOST 9466–75), 04Kh19N11M3 (GOST 2246–70, wire for welding). Also, their electrochemical compatibility was to be assessed.

The stability of construction materials brought in contact with fluorinating agents is based on the formation of a dense passivating film on the surface of a material. Nickel and copper–nickel and chromium–nickel alloys are materials the most resistant to BrF_3. The results of corrosion tests of metals in liquid bromine trifluoride, reported by the Argonne National Laboratory [2], indicate that nickel, monel, *K*-monel, and inconel exhibit enhanced corrosion resistance and can be used in BrF_3. Copper is less stable than nickel or monel. Static tests for 20 weeks at 125°C and dynamic tests for 650 h at 70°C demonstrated that, in the second case, the corrosion rate of a number of materials increases by a factor of 4–20. High-alloy chromium-nickel steels with austenitic structure (such as Kh18N10T) are widely used in chemical machine building [3]. Their suitability for operation in BrF_3 is difficult to judge, but experience shows that their corrosion rate much exceeds that of nickel, monel, *K*-monel, and inconel.

Metal corrosion may proceed, in the overwhelming majority of corrosive media, by the chemical and electrochemical mechanisms [4–6].

A real corrosion process is characterized by steady-state or corrosion potential E_c [7]. The current density i_c and the potential of corrosion can be found graphically from a polarization diagram in the form of a dependence of the rates of anodic and cathodic processes on potential [4]. The processes occurring when two dissimilar metals are brought in contact in an ionizing

1070-4272/03/7608-1246 $25.00 © 2003 MAIK "Nauka/Interperiodica"

solvent with relatively high electrical conductivity can be represented as processes in a galvanic cell in which a more negative metal starts to act as anode, and the more positive, as cathode. The rate of contact corrosion of the anode in the pair is determined by polarization characteristics of the contacting metals, ratio of their areas, and the ohmic resistance of the system [3, 4]. The corrosion potentials of construction metals and alloys and their polarization characteristics in liquid BrF_3 could not be found in the literature.

EXPERIMENTAL

When gravimetric or electrochemical methods are used to determine the corrosion resistance of metals, the metal surface should be subjected to standard pretreatment and thoroughly polished. The strongest smoothing of the surface microprofile is achieved with electrochemical polishing [8]. Preliminarily, samples were polished with fine emery paper, washed, degreased, and dried.

As cathode in electrochemical polishing served a hollow perforated lead cylinder with height of 50 mm, inner diameter of 30 mm, and wall thickness of 5 mm. Electrically polished samples were washed with 3% phosphoric acid solution, degreased with acetone, and dried. To rule out the possibility of formation of an oxide film on the surface of electrically polished samples in storage, the polishing was done immediately before the beginning of each corrosion test.

Table 1. Polishing modes and electrolyte compositions

Material	i_a, A cm^{-2}	T, °C	τ, min	Electrolyte composition, wt %
Steel:				
08Kh18N10T	0.30	80	20	60 H_3PO_4, 20 H_2SO_4, 20 H_2O
12Kh18N10T	0.45	80	15	
04Kh19N11M3	0.45	80	15	
04Kh20N9	0.45	80	15	
08Kh18N11M3G2F	0.45	80	15	
14X17H2	0.30	80	20	
M2 copper	0.35	35	15	70 H_3PO_4, 6 CrO_3, 24 H_2O
NP2 nickel	0.30	30	20	

The polishing modes and electrolyte compositions chosen in the study are listed in Table 1.

The steady-state (corrosion) potentials and corrosion rates were found from polarization characteristics of the metals and alloys using the potentiostatic

method for measuring steady-state polarization curves. The potentials were measured by the Nernst–Glazer method [9]. As reference and, simultaneously, auxiliary electrode served the nickel case of the electrolytic cell. The experimental setup is shown schematically in Fig. 1.

A certain potential was applied to a working electrode under study and the current was monitored with a P-5827M potentiostat *1* and F136 microvoltnanoammeter *2*. The prescribed temperature in the thermostat was maintained with an electric heater *3*, KSM3 automatic bridge *4*, resistance thermometer *5*, and attachment *6* for position control. The argon feed was controlled with an RM-A 0.063G UZ rotameter *7*; discharged argon was purified to remove fluorine-containing gases on a column with lime chemical absorber *8*. To eliminate the influence exerted on the sample corrosion products by products of decomposition of bromine trifluoride (Br_2, BrF), the space over the surface of liquid BrF_3 was purged, through pipes (Fig. 2) with argon dried on an NaA zeolite in the column *9* to the dew point of –50°C.

The electrolytic cell is shown schematically in Fig. 2. The cylindrical case *1*, serving simultaneously as auxiliary and reference electrodes is made of NP2 nickel. Polarization characteristics were determined for working electrodes *2* having the form of cylinders 3 mm in diameter and 20 mm high.

Potentiostatic standardization of the initial state of the surface was done by keeping the working electrode in BrF_3 at a constant anode potential. This potential was chosen experimentally: if the anode current did not stabilize for a long time, the potential was raised to a value at which sufficiently fast current stabilization was observed (0.5–1.0 h). Then the working electrode was subjected to electrochemical aging to improve the reproducibility of electrochemical measurements [10]. After the measurement results became reproducible, the polarization characteristic of the working electrode was determined. The current was measured beginning with potentials of potentiostatic standardization +2…+4 V (depending on a material), with the potential shifted in discrete steps to negative values (–1.8…–2.4 V). Each time the potential of the working electrode was changed after the current attained a steady-state value. The duration of a run in which the polarization characteristic of a working electrode was determined was 6–20 h.

The polarization characteristics of construction materials (typical dependences are shown in Fig. 3) were used to find graphically the steady-state potential of the corrosion process and the corresponding logarithm of the current density of anodic dissolution.

The relationship between the corrosion current density i_{cor} (A cm^{-2}, steady-state current density of anodic dissolution) and the mass factor of the corrosion rate, K_m (g cm^{-2} h^{-1}) is described by the equation

$$i_{cor} = K_m nF/A, \quad (1)$$

where n is the degree of oxidation of a metal; F = 26.8 A h mol^{-1}, the Faraday number; A, the atomic mass of the metal (g mol^{-1}).

Table 2. Results of electrochemical and gravimetric* studies of the corrosion resistance of construction materials in liquid BrF_3 (temperature $16 \pm 1°C$)

Material	E_{cor}, V	i_{cor}, μA cm^{-2}	K_p, mm yr^{-1}	Corrosion resistance on a ten-point scale, GOST (State Standard) 13819–68	
				point	resistance group
NP2 nickel	0.00	1.86×10^{-1}	$\frac{2.0 \times 10^{-3}}{2.3 \times 10^{-3}}$**	2	Highly resistant

* Gravimetric measurements were done for NP2 nickel, M2 copper, and 12Kh18N10T and 04Kh19N11M3 steels.

** K_p found electrochemically, numerator, and gravimetrically, denominator.

The corrosion depth factor K_p (m yr^{-1}, corrosion permeability) is related to K_m and i_{cor} by

$$K_p = \frac{K_m \times 8.76 \times 10^4}{\rho_M} = \frac{i_{cor} A \times 8.76 \times 10^4}{n \times 26.8 \rho_M} = \frac{i_{cor} A}{n \rho_M} \times 3268.7, \quad (2)$$

where ρ_M is the metal density, and 8.76×10^4 is the conversion factor.

The values of E_{cor} and i_{cor}, determined for metals and alloys from their polarization characteristics (Fig. 3), and the corresponding values of K_p are listed in Table 2.

Among the alloyed construction steels studied, 12Kh18N10T steel has the highest corrosion resistance. The corrosion rate K_p of this steel is 4 times smaller than that of 14Kh17N2 steel and 25 times smaller than that of 08Kh18N10T steel. The corrosion resistance of 04Kh19N11M3 and 04Kh20N9 steels in liquid BrF_3 exceeds that of 12Kh18N10T and 08Kh18N11M3G2F steels by respectively, factors of 16 and 450. For alloyed steels, intercrystallite and pitting corrosion in an electrically conducting liquid is not improbable. This kinds of corrosion were beyond the scope of this study.

The corrosion rate of NP2 nickel is an order of magnitude lower than that of 12Kh18N10T steel, and, therefore, this brand of nickel is the most preferable construction material to be used in liquid BrF_3. The corrosion rate of copper in BrF_3 exceeds that of nickel and 12Kh18N10T steel by factors of 20 and 2.5, respectively.

To verify the electrochemically obtained data and to distinguish the electrochemical component in the overall corrosion process, the corrosion rates of the metals and alloys were determined in liquid bromine trifluoride under steady-state conditions by means of gravimetry in the course of 152 days.

NP2 nickel, M2 copper, 12Kh18N10T steel, and 04Kh20N9 steel (metal of OZL-36 welding electrode) were chosen for gravimetric determination of the cor-

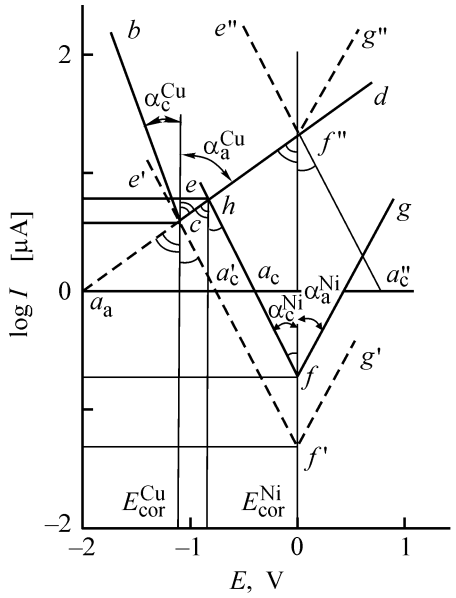

Fig. 4. Schematic E–log I dependences obtained in liquid BrF_3 (16 ± 1°C) on M2 copper at S = 1 cm^2 (*bcd*) and NP2 nickel with varied surface area. S^{Ni} (cm^2): (*e'f'g'*) 0.25, (*efg*) 1, (*e"f"g"*) 24.

rosion rate. Cylindrical samples 20 mm long and 3 mm in diameter (15 samples) were used. The temperature of bromine trifluoride was 16 ± 1°C. The results obtained are listed in Table 2.

It can be seen from Table 2 that the corrosion rates determined by gravimetry are somewhat higher than those found electrochemically, which points to the existence of a chemical component in the overall corrosion process. The average conversion factor of electrochemically determined corrosion rates with respect to the true corrosion rates is 1.2. Such an increase in corrosion permeability (Table 2) does not change the corrosion characteristics (corrosion severity and group of corrosion resistance) of the materials in question.

The compatibility of construction materials brought in contact in liquid bromine trifluoride can be judged from the corrosion potentials determined relative to a nickel (NP2) reference electrode (Table 2). Corrosion becomes stronger in contact with a more electronegative metal or alloy, and weaker or zero, in contact with a more electropositive material.

The most corrosion resistant 12Kh18N10T steel can be welded using 04Kh19N11M3 welding wire and OZL-36 electrode made of 04Kh20N9 steel. The weld metal will be protected from corrosion by the construction metal. The increase in corrosion of the construction itself will be insignificant because its surface area is many times the weld area. The corrosion rate of the metal of EA-400/10U electrodes is more than an order of magnitude lower under steady-state conditions than that of the welding wire and the metal of OZL-36 electrodes (Table 2), and the corrosion potential is more negative than that of 12Kh18N10T steel by 0.59 V, i.e., the weld metal will undergo anodic dissolution. The dissolution rate will be low in the case of a uniform corrosion over the weld surface, but occurrence of pitting and intercrystallite corrosion cannot be ruled out.

The polarization dependences obtained by extrapolation of real polarization curves can be used to determine the current of the anodic component of corrosion for a pair of contacting metals at any ratio of their surface areas. The steady-state potentials E_{cor} (V), necessary for graphical construction, and the corresponding current densities i_{cor} (μA cm^{-2}) of anodic dissolution are listed in Table 2. The constants appearing in the Tafel equation for the cathodic and anodic processes, b_c = tan α_c and b_a = tan α_a (Fig. 3), found from the polarization curves for the metals are given below:

Material	b_c, V	b_a, V
NP2 nickel	0.57	0.55
M2 copper	0.42	1.45
Steel:		
12Kh18N10T	0.52	1.42
08Kh18N10T	0.82	1.17
14Kh17N2	0.52	1.72
04Kh20N9	0.79	0.52
08Kh18N11M3G2F	0.41	0.98
04Kh19N11M3	0.90	0.69

The dependences of the logarithm of current on potential, obtained for both the constituents of a pair of contacting metals, were recalculated in accordance with their areas and plotted in a common polarization diagram as logarithm of current against potential.

Figure 4 shows polarization curves for copper and nickel samples with surface area S^{Cu} = 1 cm^2 (*bcd*) and S_1^{Ni} = 1 (*efg*), S_2^{Ni} = 0.25 (*e'f'g'*), and S_3^{Ni} = 24 cm^2 (*e"f"g"*). At area ratios of the contacting metals S^{Cu} : S^{Ni} = 1 : (0.25–24), the anodic process occurs at copper, and cathodic, at nickel. The corrosion rate and the common corrosion potential of the system were determined from the intersect of the anodic component for copper and cathodic component for nickel, i.e., the corrosion potential changed from point *c* to point *f"* on varying the nickel area.

At $S^{Cu} : S^{Ni} = 1 : (<0.25)$ the common corrosion potential of the system takes the value equal to the corrosion potential of copper ($E_{cor}^{Cu} = -1.12$ V). The current of the anodic process of copper dissolution remains invariable and equal to I_{cor}^{Cu}. For the condition of equality of the rates of the anodic and cathodic processes to be satisfied at decreasing nickel area, it is necessary to take into account the current of the cathodic process occurring at copper (at $S^{Ni} < 0.25$ cm^2, $\Sigma I_c = I_c^{Ni} + I_c^{Cu} = I_a^{Cu} = I_{cor}^{Cu}$).

At $S^{Cu} : S^{Ni} = 1 : (>24)$, the common potential of the system takes a value equal to the nickel corrosion potential ($E_{cor}^{Cu-Ni} = 0.00$ V). For the condition of equality of the rates of anodic and cathodic corrosion processes to be satisfied in this case with increasing nickel area, it is necessary to take into account the anodic dissolution of nickel, since the current of the cathodic process on nickel remains invariable and equal to I_{cor}^{Ni}.

Graphical construction (Fig. 4) yielded an equation for calculating the logarithm of the current of the anodic component of corrosion for a pair of contacting metals. For example, at $S^{Cu} : S^{Ni} = 1 : 1$ (dependences *bcd* and *efg*), $\log I^{Cu}$ is determined by the altitude of the triangle $a_a h_a c$:

$$\log I^{Cu} = \frac{a_c - a_a}{\tan\alpha_a^{Cu} + \tan\alpha_c^{Ni}} = \frac{a_c - a_a}{b_c^{Ni} + b_a^{Cu}}, \quad (3)$$

where a_c and a_a are constants equal numerically to the potentials at current density equal to unity for the cathodic process occurring at nickel (*ef*) and anodic process at copper (*cd*).

The constants were found from the equations

$$E_{cor}^{Cu} - a_a = \log I_{cor}^{Cu} \tan\alpha_a^{Cu}, \quad (4)$$

$$a_a = E_{cor}^{Cu} - \log I_{cor}^{Cu} \tan\alpha_a^{Cu}, \quad (5)$$

$$E_{cor}^{Ni} = a_c - \log I_{cor}^{Ni} \tan\alpha, \quad (6)$$

$$a_c = E_{cor}^{Ni} + \log I_{cor}^{Ni} \tan\alpha_c^{Ni}. \quad (7)$$

The current densities of anodic dissolution in steady state, i_{cor}, necessary for determining the current $I_{cor} = i_{cor}S$ and E_{cor} are listed in Table 2, and the values $\tan\alpha_a^{Cu} = b_c^{Cu}$ and $\tan\alpha_c^{Ni} = b_c^{Ni}$ are given in text. Use of these data and Eqs. (5) and (7) at $S^{Cu} : S^{Ni} = 1 : 1$ yielded $a_a = -1.12 - \log(0.186 \times 1) \times 1.45 = -2.00$ V and $a_c = 0.00 + \log(4.07 \times 1) \times 0.57 = -0.42$ V. According to Eq. (3),

$$\log I^{Cu} = \frac{-0.42 + 2.00}{0.57 + 1.45} = 0.782, \quad I^{Cu} = 6.06\ \mu A,$$

$$i_{Cu} = I^{Cu}(S^{Cu})^{-1} = 6.06 \times 1^{-1} = 6.06\ \mu A\ cm^{-2}.$$

At $S^{Cu} : S^{Ni} = 1 : (\leq 0.25)$, $i^{Cu} = i_{cor}^{Cu} = 4.07\ \mu A\ cm^{-2}$, at $S^{Cu} : S^{Ni} = 1 : (\geq 24)$, $i^{Cu} = 24.00\ \mu A\ cm^{-2}$).

Thus, at area ratio $S^{Cu} : S^{Ni} = 1 : (0.25–24)$, the current density of anodic dissolution of copper grows on bringing the metals in contact from the steady-state value ($4.07\ \mu A\ cm^{-2}$) to the maximum value ($24.00\ \mu A\ cm^{-2}$) by a factor of 6.

For an arbitrary pair of contacting metals, Eq. (3) takes the form

$$\log I^a = \frac{a_c^c - a_a^a}{b_c^c + b_a^a}. \quad (8)$$

The limiting conditions for the area ratio of the metals for expression (8) are determined from graphical constructions similar to those in Fig. 4. The internal resistance of a system in contact was taken to be zero. The given calculation procedure is inferior in precision to that using the real polarization dependences, but is much simpler and sufficiently reliable.

CONCLUSIONS

(1) Polarization characteristics of the most widely used construction materials in liquid BrF_3 were determined. These characteristics make it possible to calculate the rate of contact corrosion of the materials studied at varied ratio of contacting surface areas.

(2) It was found that nickel and copper can be recommended as construction materials that can work in liquid BrF_3, but contact between these materials is inadmissible because of their electrochemical incompatibility. Among high-alloy steels, 12Kh18N10T steel, which is compatible with 04Kh20N9 and 04Kh19N11M3 steels, is the most resistant. However, the alloyed steels studied can only be recommended for work in liquid BrF_3 after carrying out additional tests for pitting and intercrystallite corrosion.

Received April 10, 2003

Abstract—The catalytic activity of composites constituted by a porous metallic or ceramic support, intermediate layers of oxide nature, and perovskite coatings, including those doped with silver, was studied in reactions of deep oxidation of CO and organic compounds of various classes. The relationship between the catalytic activity of a composite and its composition and nature of substances being oxidized was analyzed.

Reactions of deep oxidation of organic substances and carbon monoxide CO are used in developed countries to protect the environment, prevent discharge of toxic wastes formed in chemical industry, fuel and energy industry, etc. Catalysts based on platinum metals, and also lower-cost complex-oxide catalysts of, e.g., perovskite type, containing lanthanum, transition metals (manganese, cobalt, iron, chromium), and other elements are widely used for this purpose.

One of techniques for effective use of catalysts consists in developing composite catalysts including a foamed, e.g., foamed-metal, support [1], an intermediate, or transition layer, and a complex-oxide coating [2–7]. In contrast to compact elements, catalytic elements of this kind allow economic use of materials, ensure good contact with a gas flow at moderate gasdynamic resistance, and exhibit fire-extinguishing properties.

An important issue in the development and use of catalysts is that the properties of the composites obtained are rather closely associated with the mutual influence of their components, which is manifested in mechanical and chemical-thermal stabilization of the systems. Among the possible effects are mutual doping via diffusion interaction of components, formation of new phases, and promotion of the catalytically active layer by underlying surfaces [8].

The present study is concerned with the relative activities of composite catalysts of varied composition and platinum-containing catalysts on foamed-nickel or mullite-silica supports in reactions of oxidation of CO and organic substances of varied nature: *n*-heptane, benzene, ethanol.

EXPERIMENTAL

The catalysts were prepared by impregnating supports with solutions of polymer-salt formulations [9, 10]. As starting substances served lanthanum(III) nitrate hexahydrate and silver nitrate of chemically pure grade, manganese(II) nitrate hexahydrate and strontium nitrate of analytically pure grade, "pure" cobalt(II) nitrate hexahydrate, and polyvinyl alcohol of 11/2 brand. Solutions of salts necessary for synthesizing the catalysts were prepared, and then a solution of polyvinyl alcohol was added. Supports made of K-20 foamed-nickel supports with thickness of 20 mm, pore diameter in the range 1.8–3.5 mm, density of 0.3–0.4 g cm^{-3}, and air permeability of 5.5×10^{-8} m^2 were submerged in the resulting working solution. Then the supports were removed from the solution, excess amounts of the solution were allowed to flow down, and the supports were dried and subjected to pyrolysis and thermal treatment at 650°C for 4 h. The procedure was repeated again and again until

*** Slow cooling to indicated temperature instead of normalizing annealing.

the required amount of a catalyst was obtained on a support. Coatings on mullite-silica foamed materials with about the same porosity and permeability were deposited in a similar way. The specific surface area of the composite catalysts was monitored by the method of low-temperature sorption of nitrogen with thermal desorption, using Sorpty-1750 and Sorptomatic-1900 instruments. Part of supports were preliminarily covered with aluminum oxide deposited from an alkaline aluminate solution and stabilized with lanthanum oxide. The mass fraction of such an intermediate layer was 10–12%. An X-ray phase analysis was made on a standard DRON-3 diffractometer with Cu_{K_α} radiation. Local analysis of the distribution of element concentrations was performed with a Jeol-Super-probe 733 microanalyzer.

The catalytic activity in oxidation of carbon monoxide (CO) to carbon dioxide was studied on a setup comprising a gas tank, furnace, and system for uniform supply of the gas mixture into a catalytic reactor. The gas tank was filled with a gas mixture of air, carbon monoxide, and inert carrier-gas (nitrogen or argon). The oxidizing and reducing agents were taken in a ratio 1 vol % O_2 : 0.3 vol % CO, with the inert gas the rest. This mixture was passed at a rate of 30 l h^{-1} through a quartz tube with a catalyst at a prescribed temperature (measured with a ChA_{68} thermocouple directly in the reaction zone). Preliminarily, the content of CO in the mixture was monitored, the gas mixture was also analyzed at the outlet of the catalytic unit with an IMR-3000P gas analyzer or with indicator tubes of the TI SO-1.0 type, combined with an AM-5.M aspirator.

The catalytic activity in oxidation of organic compounds (*n*-heptane, benzene, and ethanol) was determined at their content of 5 g m^{-3} and gas flow rate of 15 l h^{-1} through the reactor with a catalyst. The specific load on the catalytic reactors did not exceed 1000 h^{-1}. The mass fraction of the active component in the catalytic compositions was 4–10%. As reference samples served Pt–Pd–Rh samples with content of 0.7–1.3 wt % on foamed-nickel supports with a sublayer of aluminum oxide stabilized with lanthanum oxide.

Heterogeneous catalysts of the system La–Ag–Mn–O [10–13], in which perovskite phases are formed and a minor amount of metallic silver is contained, are rather active in reactions of oxidation of CO and organic substances [2–7]. In particular, catalysts with empirical formula $La_{0.75}Ag_{0.25}MnO_{3\pm y}$ stand out. These catalysts were chosen as an object of study. It was found that the perovskite phases obtained in the above system do contain silver [11] even upon annealing at temperatures exceeding its melting point. This is confirmed by processing of the results of an X-ray phase analysis of samples annealed at 600–1100°C and having an empirical formula $La_{1-x}Ag_xMnO_{3\pm y}$ (x in the range from 0.1 to 0.3) by full-profile Ritwild's analysis (Fullprof software) with calculation of the occupation numbers of the lanthanum sublattice (Table 1).

For equilibrium with respect to oxygen to be attained, the samples were subjected to normalizing annealing (Table 1), since oxygen nonstoichiometry strongly affects characteristics of the samples. Raising the total content of silver in the system to, e.g., $x = 0.5$, does not increase its content in the perovskite. Above the melting point of silver, there occurs evaporation of the existing metallic form; silver contained in the perovskite is not removed in the process,

which is confirmed by chemical analysis of the samples. At 1100–1200°C, depending on composition, the perovskite phase starts to decompose, with secondary silver appearing and possing into the gas phase [11]. After annealing at 1400°C for 24 h with slow cooling, a diffusion zone is present around silver grains, in which the metal is contained in a complex oxide (Fig. 1).

The contradiction between the low magnetic moment of the manganese ion and the occurrence of doping of the lanthanum sublattice with silver, noticed in [10], is eliminated, since it is more correct to compare properties of silver-doped samples not with samples of composition $LaMnO_{3\pm y}$, as it has been done previously, but with lanthanum-deficient $La_{1-x}MnO_{3\pm y}$, where x corresponds to the amount of silver introduced into the system. Such a composition would be formed upon consumption in the course of synthesis of the whole amount of lanthanum and manganese if silver were not incorporated in the perovskite. It can be seen that silver-substituted and lanthanum-deficient kinds of perovskite have different lattice constants (Table 1). The constants were calculated in terms of the $R\bar{3}c$ space group (hexagonal packing). Also of interest are perovskite catalysts containing no silver; the most active of these are compositions containing manganese and cobalt. Their activity increases because of the substitution of lanthanum by, e.g., strontium ions.

The efficiency in CO oxidation of four variants of catalysts on foamed nickel, with the complex-oxide coating constituting 3–4% of the total mass of the composite catalyst, was studied. The results obtained are presented in Fig. 2 and Table 2. The highest efficiency was observed for composite no. 1. This fact can be explained as follows. The active complex-oxide in the system La–Ag–Mn–O is a heterogeneous mixture, and catalysts for heterogeneous reactions, which have complex composition, frequently exhibit higher activity. Presence of silver in the perovskite structure favors generation of additional defects, which makes higher the catalytic activity of the perovskite phase itself in oxidation-reduction processes.

The composition $La_{0.84}Sr_{0.16}Mn_{0.8}Co_{0.2}O_{3\pm y}$ also exhibited high efficiency under the positive influence exerted by the presence of cobalt ions characterized by low energy of bonding to oxygen [8, 14]. Doping of the perovskite $LaMnO_{3\pm y}$ with strontium also gives rise to additional defects of the type $[M^{4+}]$, with, however, one defect of this type formed per each Sr^{2+} ion, and two defects, per Ag^{+} ion. Composite

Table 2. Characteristics of catalysts on foamed nickel in oxidation of carbon monoxide

Catalyst no.	Coating/sublayer	Total specific surface area, $m^2 g^{-1}$	Combustion temperature, °C
1	$La_{0.75}Ag_{0.25}MnO_{3\pm y}/Al_2O_3$	3.0	150
2	$La_{0.84}Sr_{0.16}Mn_{0.8}Co_{0.2}O_{3\pm y}/Al_2O_3$	2.6	160
3	$La_{0.75}Ag_{0.25}MnO_{3\pm y}/LaMnO_{3\pm y}$	1.9	185
4	$La_{0.75}Ag_{0.25}MnO_{3\pm y}/–$	0.5–0.8	180

no. 2 contains a virtually homogeneous perovskite phase. For this reason, it is somewhat inferior in efficiency to composite no. 1.

Efficiency measurements at relatively low specific load on the catalysts and temperatures close to the combustion point demonstrated that an Al_2O_3 sublayer (intermediate support) strongly affects the efficiency. The possible reason is that the specific surface area of the composites grows, also possible are other mechanisms of this effect. The aluminum oxide layer isolates the perovskite from the nickel substrate and hibnders the mutual diffusion of nickel and manganese ions between the support and the complex-oxide layer [15].

The possibility of a diffusion interaction was confirmed by modeling the system $LaMnO_{3\pm y}$ by means of contact annealings (850°C, 20 h) of ground-together plates of the corresponding materials. The component exchange between the support and coating occurs within a zone comparable in thickness with the zone of nickel oxide formation via oxidation (Fig. 3), being equal in this case to about 4–6 μm. At the same time, this value is comparable with the layer thickness of the catalytic coating.

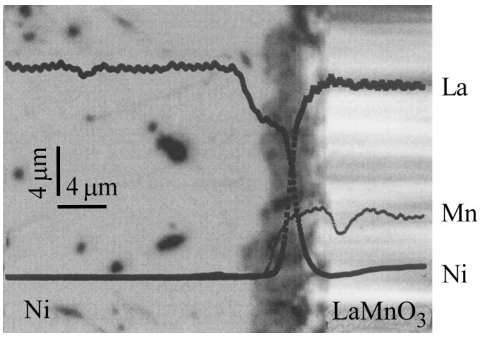

Fig. 3. Element concentration profile in the zone of contact between nickel and $LaMnO_{3\pm y}$ along a line perpendicular to the interface in arbitrary units of characteristic X-ray emission intensity.

Perovskites containing manganese and cobalt are the most active catalysts in CO oxidation, since the bonding energy of oxygen in the structure of oxides is the lowest for these metals [8, 14], which facilitates oxygen desorption from the catalyst surface and accelerates the oxidation process. For this reason, doping of a catalyst with nickel in synthesis and operation of this catalyst may presumably depress its activity (sample no. 3). Use of an intermediate $LaMnO_{3\pm y}$ layer (economically doped sample no. 4) is less effective than that of an Al_2O_3 layer. The properties of sample nos. 3 and 4 are about the same (Fig. 2), despite the differences in specific surface area, which, in the authors' opinion, does not play a key role. In this case, no reliable diffusion barrier appears (compared with the case of aluminum oxide), and the total amount of silver on the surface of sample no. 4 may be lower because of the equalization of its concentration in perovskite layers. Also possible, in the presence of an Al_2O_3 layer, is a promoting effect of aluminum oxide on the catalyst [8].

The promoting influence can also be exerted by a spinel of the $MnAl_2O_4$ type, formed in the zone of contact between compounds containing Mn, Co, and Al_2O_3. The formation of this complex oxide of brown color was recorded by X-ray phase analysis in modeling two methods for obtaining a catalytic coating on an aluminum oxide sublayer. The spinel appeared upon annealing between 650 and 850°C if the aluminum oxide powder was impregnated with a manganese oxide solution with addition of polyvinyl alcohol or upon pyrolysis (with subsequent annealing) of similar solutions containing manganese and aluminum nitrates simultaneously. A similar compound of blue color ($CoAl_2O_4$) is formed in the cobalt-containing system.

Compositions without Al_2O_3 sublayer were advantageous from the standpoint of mechanical strength of the catalytic coatings. The adhesion strength of a coating was evaluated by compressing a catalyst on foamed-nickel support, with its volume decreasing by a factor of 2–4, and then subjecting it to vibration. Up to 5–10% of the deposited composite detached from catalysts with an Al_2O_3 sublayer at the interface between the sublayer and the support. For sample nos. 3 and 4, the loss of deposited composite was no more than 1–2%. Thus, direct interaction of the catalytic layer with the support ensured its better adhesion. This result is important for catalysts intended for operation under nonsteady conditions, e.g., for neutralization of automobile exhaust gases.

The problem of deep oxidation of organic substances is frequently encountered under conditions of

Table 3. Relative activities of composite catalysts in oxidation of organic substances*

stationary arrangement of thermocatalytic devices, when it is possible to use as catalyst supports ceramic foamed materials having somewhat lower mechanical strength than foamed metals. In oxidation of organic substances, the catalytic activity strongly depended on the nature of these compounds and on the composition of composite catalysts. As an example, Fig. 4 shows temperature dependences of the efficiency of some samples. The data obtained can be summarized to give the corresponding series in Table 3.

Complex-oxide catalysts were in all cases more efficient in alcohol oxidation than the samples containing noble metals. The highest activity was observed for the sample containing no silver. Benzene is the most readily oxidized on catalyst no. 4 (Table 3). Of the compounds studied, it is aromatic hydrocarbon that is the most readily oxidized on noble metals. Such a situation may be due to different abilities of organic substances to be sorbed on the catalyst surface: noble metals tend to adsorb aromatic compounds, whereas the oxygen-containing alcohols show higher affinity for oxide materials.

The activity of the catalysts in oxidation of heptane is intermediate, but this compound better reacts with oxygen in the presence of silver-containing catalysts. Catalysts of this type are also sufficiently active in oxidation of natural gas components [6]. Sample no. 1 (Table 3, Fig. 4) exhibits higher activity than no. 2 in oxidation of alcohol and heptane and is comparable with sample no. 2 in oxidation of benzene, despite the smaller total specific surface area of catalyst no. 1. Catalysts of composition $La_{0.75}Ag_{0.25}MnO_{3\pm y}$ on foamed nickel without a sublayer were more active than the same composition with an intermediate aluminum oxide layer (Fig. 4, Table 3). Probably, the effect of promotion by aluminum oxide is absent, and, by contrast, doping a catalyst with silver is favorable, in the case of oxidation of organic substances. Moreover, it is known that nickel exerts strong catalytic influence on those reactions of organic compounds, which involve addition or elimination of a hydrogen atom.

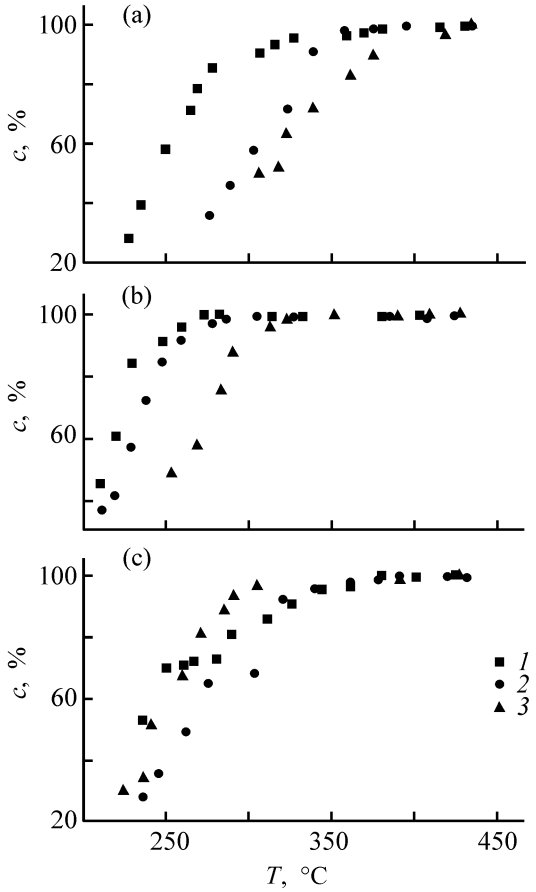

Fig. 4. Conversion *c* vs. temperature *T* in reactions of deep oxidation of organic substances on various catalysts. (*1*) Ethanol, (*2*) *n*-heptane, and (*3*) benzene. (a) $La_{0.75}Ag_{0.25}MnO_{3\pm y}$ catalyst on nickel support with Al_2O_3 sublayer, (b) the same without sublayer, and (c) catalyst based on platinum metals.

The data in Table 2 support the assumption that, in CO oxidation, too, the difference in specific surface area between the catalysts may be not a decisive factor at relatively low loads on a catalyst. Surely, it is desirable to compare catalysts with the same surface area for making more correct conclusions. It can be seen that, depending on the nature of compounds being oxidized and catalysts, manifestations of selectivity in the corresponding reactions in mixtures would be expected. To improve the efficiency of oxidation of a sum of toxic compounds, catalytic elements of different types and compositions can be combined [16].

It should be noted, to conclude, that one more type of perovskite catalysts with a silicon carbide SiC support was tested. This catalyst is of interest for developing elements heated by electric current to the working temperature because of their intrinsic electrical resistance. Measurements demonstrated that their activity is comparable with that of sample nos. 2 and 5 (Table 3) in oxidation of alcohol, sample nos. 4 and 5 in oxidation of heptane, and sample nos. 1 and 2 in oxidation of benzene.

CONCLUSION

Catalysts constituted by a porous support, intermediate oxide layer, and complex-oxide coating are proposed for use to protect the atmosphere from noxious substance discharges. Their activity is comparable with that of catalysts based on platinum-group metals. The catalytic activity is strongly affected by the nature and composition of the substances being oxidized and the catalysts, with an important role played by the interaction between the underlying surface with a catalytic coating. In particular, the perovskite structure is doped with silver in silver-containing perovskite compositions. Oxidation of CO is the most efficient just on perovskite catalysts of this kind with a sublayer of aluminum oxide, and that of *n*-heptane, on a similar catalyst without aluminum oxide sublayer. Alcohol and benzene are more readily oxidized, on a catalyst based on a mixture of cobaltite, manganite, lanthanum, and strontium.

CATALYSIS

Conjugated Oxidation of Carbon Monoxide and Reduction of Nitrogen(II) Oxide on Pt-containing Ceramic Catalyst with Modifying Additives

Yu. A. Aleksandrov, K. E. Ivanovskaya, and I. A. Vorozheikin

Lobachevskii State University, Nizni Novgorod, Russia

Received March 20, 2003

Abstract—A Pt-containing catalyst for conjugated oxidation of CO and reduction of NO was developed with the use of a synthetic porous ceramic as a support. The catalyst is modified with oxides of a number of metals to improve its efficiency.

The presently topical problem of catalysis is a search for effective catalysts for purification of exhaust gases of combustion engines [1]. The most promising are catalysts for conjugated oxidation of CO and hydrocarbons and reduction of nitrogen oxides. As shows analysis of published data, most of catalysts for the given process, containing no noble metals, have been tested only in laboratory and are rapidly deactivated in prolonged operation even under these conditions [2]. Cu- and Co-containing zeolites, intensively developed in Japan in recent years, have also proved inefficient when tested under industrial conditions [1]. In this context, development of new Pt-, Pd, or Rh-containing catalysts optimized by making lower the content of noble metals, simplifying the technology of catalyst manufacture, and using modifiers [3] remains a topical task.

Previously, catalysts for deep oxidation of CO have been obtained on supports in the form of a synthetic porous ceramic (SPC) with large specific surface area (~90 $m^2 g^{-1}$). The catalysts based on SPC are distinguished by simplicity of fabrication.

The aim of this study was to develop SPC-based Pt-containing catalysts modified with some promising additives and to test the activity of the catalysts in reaction of conjugated oxidation of CO and reduction of NO. To compare the activities of catalysts on SPC and conventional supports, a catalyst with equivalent amount of platinum supported by γ-Al_2O_3 was prepared. The activities of the catalysts studied were also compared with that of Pt-containing catalysts for the process in question, fabricated on various alumina-borosilicate and silica supports [7].

Since published evidence points to the positive influence exerted by addition of alkaline-earth, rare-earth, and transition metals on the activity of catalysts for purification of exhaust gases of combustion engines, Pt-containing catalysts modified with equal amounts of Na, Ce, and V compounds were prepared. Vanadium was introduced directly into SPC in the form of V_2O_5 in preparing a ceramic, since it was established earlier [8] that catalysts based on SPC + V_2O_5 exhibit higher activity than SPC-based catalysts.

EXPERIMENTAL

The catalysts were prepared by impregnating a support with aqueous solutions of H_2PtCl_6, $NaNO_2$, and $Ce(NO_3)_3 \cdot 6H_2O$ in amounts (percent relative to support mass) Pt 0.7 and 1.4, Ce 8, and Na 8. The impregnation was repeated 3 or 4 times. First, Pt(IV) was deposited, and then modifying additives were deposited onto a dried and calcined Pt catalyst. As mentioned above, vanadium(V) was introduced directly into SPC in the form of V_2O_5 in amount of 8% relative to the support mass. All the catalysts prepared in this way were dried in air at 100°C and then calcined in a flow of helium at 500–650°C.

The catalytic activity of the samples was studied in reactions of conjugated oxidation of CO and reduction of NO to N_2 in a pulsed microcatalytic installation (pulse volume 2 cm^3, flow rate F of carrier gas 1 $cm^3 s^{-1}$). The reaction products were analyzed by gas chromatography, with katharometer as detector and carrier-gas helium. N_2, NO, and CO were separated on a column with 5-Å NaX molecular sieves (200 × 3 mm, 50°C). IR spectra of samples of the

1070-4272/03/7608-1260 $25.00 © 2003 MAIK "Nauka/Interperiodica"

1.4% Pt/(SPC + V_2O_5) catalyst in Vaseline oil were recorded on a Specord 75-IR spectrophotometer. The spectra in Fig. 1 were obtained by subtracting the base absorption spectrum of Vaseline oil.

The compositions of the catalysts prepared are listed in Table 1.

The activity of the catalysts in the reaction of conjugated oxidation of CO and reduction of NO was studied using the pulsed method with chromatographic analysis of the reaction products. The temperature dependence of the conversion α of CO into CO_2 and NO into N_2 on the catalysts studied is shown in Fig. 2.

Complete reduction of NO to N_2 could not be observed on any of the catalysts. Complete reduction of NO with propane has not been achieved, either, on industrial catalysts [9], which is probably due to incomplete reduction of NO to N_2O.

As a comparative characteristic of catalyst activity was chosen the temperature at which a conversion of 0.5 is achieved. The following activity series of the catalysts studied in oxidation of CO and reduction of NO were obtained for α = 0.5: IV > VI = II > I > V > III and IV > VI > II > III ≈ I > V, respectively.

It can be seen that the highest activity in the reaction of conjugated oxidation-reduction of a CO + NO mixture is exhibited by catalysts IV and VI, i.e., V(V) and Ce(III) are effective modifying additives. Raising the amount of Pt from 0.7 to 1.4% also makes higher the activity of the SPC-based catalyst. Introduction of Na ions into an SPC-based Pt-containing catalyst impairs its activity.

Thus, the results obtained suggest that metal oxides with low oxygen– metal bonding energy are effective additives to catalysts for conjugated oxidation of CO and reduction of NO. However, the bonding energy in a modifying oxide must exceed the energy of bonding between oxygen and a noble metal (in the given case, the oxygen–sodium bonding energy is lower than that for oxygen and platinum, and, therefore, addition of sodium ions is inefficient).

and various fiber glass supports [7] shows that SPC-based catalysts compare well in efficiency with the latter in the comparable temperature range.

Table 2 lists kinetic parameters of the reaction of CO oxidation to CO_2 and NO reduction to N_2 on Pt-containing catalysts. The parameters were calculated using the procedure described in detail in [8].

To determine the composition of a catalyst and elucidate the mechanism of reactions occurring at its surface, the IR spectrum of one of the most active catalysts [1.4% Pt/(SPC + V_2O_5)] was analyzed before and after its treatment with carbon monoxide at 500°C (Fig. 1).

The IR spectrum of the catalyst (Fig. 1, curve *1*) contains a strong broad band and several low-intensity bands in the frequency range 800–400 cm^{-1}. These latter can be assigned to vibrations of silicate groups contained in the ceramic. The low-intensity band peaked at 900 cm^{-1} and broad bands in the range 1700–1200 cm^{-1} are associated with vibrations of phosphate groups, and the strong band at 1200–900 cm^{-1} most probably results from superposition of vibrations of phosphate and silicate groups. The bands peaked at 1000, 955, 915, 880, and 840 cm^{-1} correspond to vibrations of the V=O bond (spectrum of vanadium-containing catalyst was compared with that of SPC).

Figure 1 (curve *2*) also shows the spectrum of a Pt-containing catalyst pretreated with carbon monoxide at 500°C. This temperature corresponds to the maximum conversion of CO into CO_2 and NO into N_2 on the given catalyst at the following composition of the reaction mixture (vol %): 6NO + 12CO + 82He. When a reaction mixture containing 12 vol % CO and 88 vol % He was passed through the 1.4% Pt/(SPC + V_2O_5) catalyst, complete oxidation of CO to CO_2 by oxygen contained in the catalyst was observed initially, but then the conversion of CO into CO_2 started to decrease gradually. The run was terminated when CO ceased to oxidize completely. Comparison of curves *1* and *2* shows that passing carbon monoxide through the catalyst at 500°C leads to a decrease in the intensity of the band corresponding to vibrations of the V=O bond. The data obtained suggest that CO is oxidized by oxygen from V_2O_5. This hypothesis is also supported by a change in the catalyst color on passing CO through it from red-yellow to dark gray, which corresponds to transition of V(V) to a more reduced form.

Thus, it may be assumed that, in passing a CO + NO mixture through a 1.4% Pt/(SPC + V_2O_5) catalyst, CO is adsorbed on active centers of the catalyst and is oxidized by their oxygen. NO is adsorbed on the same centers, but subsequent dissociation of NO to give a nitrogen molecule requires a sufficient number of active centers reduced by carbon monoxide. Experiments with catalysts based on SPC and SPC + V_2O_5 demonstrated that the key role in the reactions of conjugated oxidation-reduction is played by a noble metal, since only oxidation of CO occurs in its absence. It may be assumed that the function of a noble metal is to catalyze dissociation of an adsorbed NO molecule.

CONCLUSIONS

(1) A Pt-containing catalyst supported by an original synthetic porous ceramic was developed and tested in the reaction of conjugated oxidation of CO and reduction of NO.

(2) The catalyst was modified with oxides of a number of metals. It was found that the Pt-containing catalysts developed compare well in efficiency with the known Pt-containing catalysts on various supports.

(3) An analysis of IR spectra of one of the catalysts yielded data on its composition and allowed an assumption concerning the mechanism of the reaction of conjugated oxidation of CO and reduction of NO.

Abstract—The possibility of obtaining suspensions with very small particle radius and low polydispersity coefficient in tubular turbulent apparatus though specific hydrodynamics of reagent motion in fast chemical reactions was studied.

Chemical technology widely employs processes for obtaining suspensions by the condensation method in the course of a chemical reaction involving precipitation. In many cases, it is necessary to obtain homogeneous finely dispersed suspensions, in particular, in preparing highly active heterogeneous and microheterogeneous Ziegler–Natta catalytic systems for polymerization of olefins and dienes, antiagglomeration agents for synthetic caoutchoucs, pigments for paints, etc.

Under industrial conditions, fast chemical reactions are frequently carried out with suspensions obtained by mixing starting homogeneous reagents in the turbulent mode effected by blades of centrifugal pumps. However, this may lead, with high probability, to failure of moving elements of the pumps and to their clogging, and in the case of corrosive media, special corrosion-protective coatings are to be deposited the working surfaces of apparatus.

Chemical reactions used to prepare finely dispersed suspensions are commonly of ion-exchange type and, as a rule, proceed at high rate. Therefore, it is apparently advisable to use in this case a new type of chemical technological apparatus: small-size high-throughput tubular turbulent apparatus of jet type [1]. The specific features of operation of these apparatus have been studied sufficiently well, and they are widely used in industry [2] to perform fast homogeneous chemical reactions. However, there have been no publications concerned with the possibility of their use for carrying out fast chemical reactions combining homogeneous fluid flows with suspension formation.

The aim of this study was to analyze the possibility of using tubular turbulent apparatus of diffuser-confuser design for obtaining homogeneous finely dispersed suspensions by the condensation method in a fast chemical reaction and to compare their efficiency with that of volume apparatus with mechanical agitation.

As model served the following fast chemical reaction

$$H_2SO_4 + BaCl_2 \rightarrow BaSO_4\downarrow + 2HCl.$$

Three methods were used to synthesize suspensions: (1) reaction of barium chloride with sulfuric acid in a volume mixing apparatus (70%-filled 500-cm^3 three-necked vessel) with a rotating rabble operating as a centrifugal pump and creating high-intensity turbulent flows in the axial direction of the reaction volume (Fig. 1a); (2) method similar to variant 1 but differing in that a deflector partition is installed within the volume of the reaction mixture (Fig. 1a), which results in higher power consumed for agitation and intensifies the turbulent mixing of flows [3]; (3) reaction of the starting reagents (aqueous solutions of H_2SO_4 and $BaCl_2$) directly in a six-section tubular turbulent apparatus of diffuser-confuser design (diameter of diffuser 24 mm, that of confuser 10 mm, section length 48 mm) at linear flow velocity of the reagents $V \approx 0.5$ m s^{-1} (Fig. 1b). In order to make greater the ratio of nucleation and crystal growth rates, so that systems as finely dispersed as possible could be obtained, concentrated (0.52 M) and diluted (0.03 M)

1070-4272/03/7608-1264 $25.00 © 2003 MAIK "Nauka/Interperiodica"

aqueous solutions of, respectively, $BaCl_2$ and H_2SO_4 were used.

Dispersion analysis of the $BaSO_4$ suspensions obtained was made by the method of sedimentation in a gravitational field on a torsion balance by the conventional procedure [4]. To diminish the probability of particle interaction in the course of sedimentation, diluted solutions of $BaSO_4$ suspensions were obtained (~0.35 wt %). The results of sedimentation analysis were processed by means of graphical differentiation of the sedimentation curves (Fig. 2). For this purpose, the sedimentation dependences of the mass of precipitate, m, on time τ were approximated with a sigmoid three-parameter function of the type

$$m(\tau) = \frac{a}{1 + \exp\left(-\frac{\tau - x_0}{b}\right)}. \quad (1)$$

The coefficients a, b, and x_0 in Eq. (1) and the error in approximation of the experimental sedimentation curves (Fig. 2) are listed in the table.

In this case, in accordance with the Svedberg–Oden equation [4], the mass m_i of a fraction of suspension particles with radius $r > r_i$, sedimented by instant of time τ_i, was calculated as

$$m_i = \frac{a}{1 + \exp\left(-\frac{\tau_i - x_0}{b}\right)} - \tau_i \frac{\exp -\frac{\tau_i - x_0}{b} \; a}{b\left[1 + \exp\left(-\frac{\tau_i - x_0}{b}\right)\right]^2}. \quad (2)$$

A microscopic analysis of the suspensions obtained demonstrated that $BaSO_4$ particles show clearly pronounced anisometry (have the form of rods with length to diameter ratio of about 4, which accounts for the sigmoid shape of sedimentation curves with an inflection). At the initial instant of sedimentation, rotation of a rod-like particle is possible, which gives rise to an additional resistance to its motion and leads to slowing down of sediment accumulation. In addition, nonspherical particles are oriented in the motion direction in free sedimentation in such a way that the highest resistance to motion is created. This also makes slower the sedimentation of solid particles in a fluid and hinders determination of their true dimensions. Because of this circumstance, the equivalent radius r_e (radius of a spherical particle sedimenting at the same velocity) was determined from the results of sedimentation analysis.

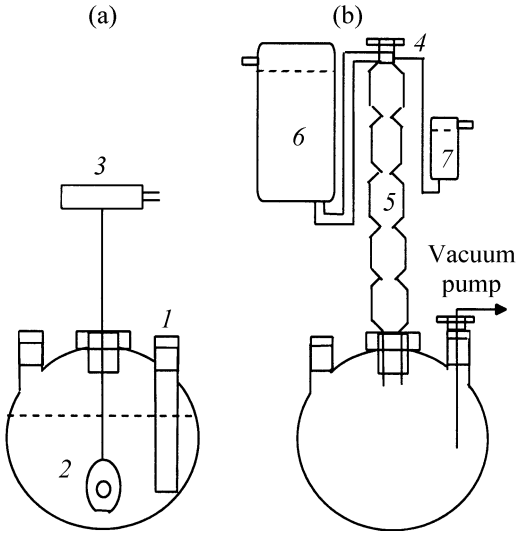

Fig. 1. Schematic of experimental setup. Suspension synthesis: (a) in a volume apparatus of mixing (variants 1 and 2) and (b) in tubular turbulent apparatus. (*1*) Deflector partition; (*2*) rabble operating as centrifugal pump; (*3*) electric drive of rabble; (*4*) three-way valve; (*5*) tubular turbulent apparatus; (*6*, *7*) vessels for, respectively, H_2SO_4 and $BaCl_2$ solutions.

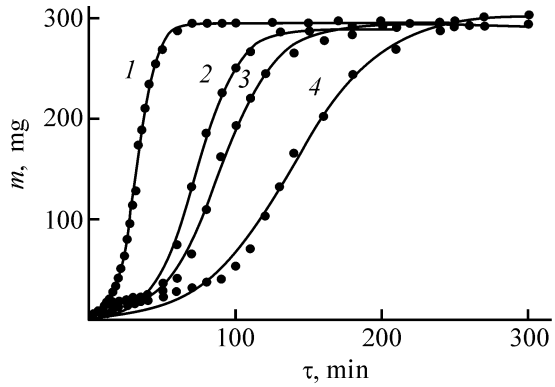

Fig. 2. Sedimentation curves for $BaSO_4$ particles. (m) Sediment mass and (τ) time. Agitation rate N (rpm): (variant 2) (*1*) 300, (*2*) 1500, and (*3*) 2500; (*4*) tubular apparatus. Points, experiment; lines, approximating function.

It can be seen from Fig. 2, that, with increasing agitation rate, the sedimentation curves shift to the range of smaller particles (longer sedimentation time), i.e., the mean particle radius decreases with increasing intensity of turbulent mixing in the reaction zone. In view of the fact that the differential particle size distribution of the dispersed phase, $F(r_e)$, is a typical distribution function of a random variable, the most

probable (integral-average) radius r_{mp} of suspension particles was calculated using the relation

$$\tau_{mp} = \frac{\int_0^\infty r_e F(r_e) dr_e}{\int_0^\infty F(r_e) dr_e}. \quad (3)$$

It can be seen (Fig. 3) that, in the case when volume apparatus of mixing (variants 1 and 2) are used to obtain suspensions, r_{mp} decreases with increasing agitation rate N (from $r_{mp} = 4.6$ μm without agitation to $r_{mp} = 1.2$ μm at $N = 5000$ rpm). In the given case, the reaction mixture is sufficiently diluted under the experiment conditions and raising the intensity of turbulent agitation cannot intensify significantly the mass transfer and, as a consequence, make higher the growth rate of crystals and, in the end, their size. A noticeable decrease in the particle radius of the dispersed phase occurs because of the high rate of micromixing, whose intensity grows when dissipation of the specific kinetic energy of turbulence, ε, becomes stronger with increasing agitation rate [5].

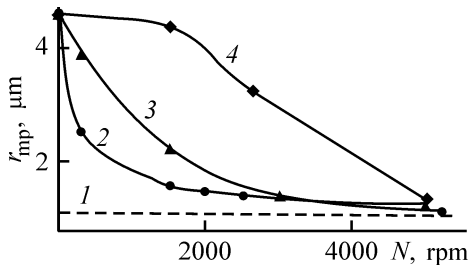

Fig. 3. Most probable radius r_{mp} of $BaSO_4$ particles vs. agitation rate N. (*1*) Tubular turbulent apparatus; volume apparatus of mixing: (*2*) variant 1, (*3*, *4*) variant 2, (*4*) after preliminary forming without agitation and aging for 90 min; the same for Fig. 4.

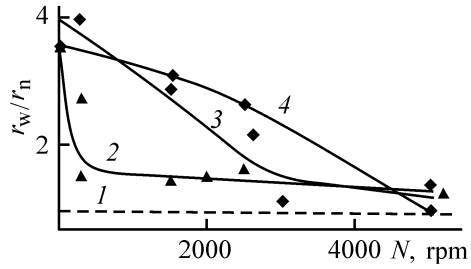

Fig. 4. Polydispersity coefficient r_w/r_n of $BaSO_4$ particles vs. agitation rate N.

At high rate of micromixing, the ratio of nucleation and crystal growth rates grows, which leads to an increase in the number of nuclei of the new phase and to a decrease in r_{mp}. This is, in particular, observed with the deflection partition (variant 2), which makes higher the intensity of turbulent mixing in the volume apparatus. In this case, the relative rate at which r_{mp} decreases with increasing rotation rate N of the rabble is higher than that in variant 1. It is noteworthy that, with the agitation rate in the volume apparatus (variants 1 and 2) increasing up to the maximum possible in laboratory ($N \approx 5000$ rpm), r_{mp} approaches the particle size ($r_{mp} \approx 1.1$ μm) of a suspension obtained in a tubular turbulent apparatus with high intensity of turbulent agitation ensured exclusively by the channel geometry and hydrodynamic energy of the flow [1].

In order to evaluate the degree of polydispersity of the suspensions obtained on the basis of the sedimentation curve (Fig. 2), the weight-average (r_w) and number-average (r_n) radii of particles were calculated:

$$r_w/r_n = \frac{\Sigma r_i n_{wi}}{\Sigma r_i n_{ni}}, \quad (4)$$

where n_{wi} and n_{ni} are the weight and number fractions of particles with radius r_i.

For a homogeneous suspension, the polydispersity coefficient $r_w/r_n = 1$. With increasing intensity of agitation in formation of solid particles in the system by variant 1, the polydispersity coefficient decreases from $r_w/r_n = 2.8$ without agitation to $r_w/r_n = 1.55$ at $N = 5000$ rpm (Fig. 4). The homogeneity of the suspension obtained by variant 2 remains virtually unchanged ($r_w/r_n \approx 1.77$) with increasing intensity of turbulent agitation. Carrying out a fast reaction with precipitation in a tubular turbulent apparatus makes it possible to obtain suspensions with rather high homogeneity: $r_w/r_n \approx 1.48$ (Fig. 4).

Naturally, it seemed appropriate to analyze the characteristics of suspensions subjected to hydrodynamic treatment after preliminary aging without agitation, rather than at the instant of formation. For this pur-

pose, the starting reagents (aqueous solutions of H_2SO_4 and $BaCl_2$) were brought into reaction in the absence of agitation, with aging for 90 min and subsequent turbulent agitation of the resulting suspensions by variant 2 in a tubular turbulent apparatus.

It was found that, in this case, the mean particle radius does not grow with suspension aging (Fig. 3, curve *4*). No sharp decrease in the radius of solid particles obtained without agitation (Fig. 3, curve *4*) with respect to that in suspensions obtained at varied rotation rates of the rabble (Fig. 3, curves *2* and *3*) is observed with increasing intensity of turbulent agitation of a mixture containing the preliminarily formed suspension. This was also demonstrated in [6]. However, highly dispersed particles with $r_{mp} = 1.2$ μm are formed under high-intensity hydrodynamic treatment in a volume apparatus (N = 5000 rpm). Use of a tubular turbulent apparatus for treatment of a mixture aged for 90 min yields dispersed systems with even smaller particles with $r_{mp} \approx 1.1$ μm (Fig. 3, curve *1*).

A similar situation is observed for the polydispersity coefficient r_w/r_n of the suspensions obtained (Fig. 4). Use of a tubular turbulent apparatus both at the instant of suspension synthesis and in treatment of a preliminarily obtained, and aged for 90 min, dispersed system yields rather uniform particles with polydispersity coefficient $r_w/r_n \approx 1.48$ (Fig. 4, curve *1*).

Thus, it was found that it is advisable to use small-size high-throughput tubular turbulent apparatus when performing fast chemical reactions to obtain homogeneous highly dispersed suspensions. In this case, the residence time of the reaction mixture in the apparatus is 2–3 s, which makes lower the probability of secondary processes. As a result, it is necessary to use tubular turbulent apparatus for obtaining Ti–Al, V–Al, Nd–Al, and other highly active microheterogeneous Ziegler–Natta catalytic systems in (co)polymerization of olefins and dienes (*cis*-1,4-isoprene, ethylene-propylene, *cis*-1,4-butadiene, and other caoutchoucs), antiagglomeration agents (M^{2+} stearates) for synthetic caoutchoucs, pigments (in particular, those based on TiO_2), and other homogeneous highly dispersed suspensions formed in interaction of homogeneous fluid flows. Apparently, apparatus of this type compare well in efficiency of suspension synthesis with pump-type or other energy-intensive equipment.

CONCLUSION

Use of tubular turbulent apparatus of diffuser-confuser design both directly in synthesis and in treatment of a finished $BaSO_4$ suspension makes it possible to obtain finely dispersed systems with mean equivalent particle radius of the dispersed phase, $r_{mp} \approx 1.1$ μm, and polydispersity coefficient $r_w/r_n \approx 1.48$, which is ensured in a volume apparatus with mechanical stirrer only at agitation rates exceeding 2000 rpm.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of Radial Mixing in a Continuous Flow-through Apparatus

N. A. Dul'kina, A. B. Golovanchikov, G. V. Ryabchuk, and E. A. Selezneva

Volgograd State Technical University, Volgograd, Russia

Received May 22, 2003

Abstract—The structure of flows was studied experimentally in continuous flow-through apparatus in various flow modes.

In studying the structure of flows in continuous flow-through apparatus and reactors, it is commonly assumed that there is no concentration gradient in the radial direction [1, 2], i.e.,

$$\partial c/\partial r = 0. \quad (1)$$

However, this assumption is only valid for low-viscous media in the case of a turbulent flow and geometric simplex [3]

$$l/d > 100. \quad (2)$$

In industrial tubular apparatus and reactors, the media being processed have considerable viscosity and the length of the tubes commonly exceeds their diameter by only an order of magnitude, since these geometric dimensions are chosen in accordance with the results obtained in solving simultaneously the equations of material and heat balance [4]. The authors of the present communication studied experimentally the dependence of the indicator concentration on tube radius.

The experimental setup had the form of a hollow tube with inner diameter of 58 mm and length of 1 m, i.e., with a geometric simplex $l/d = 17.3$ (Fig. 1). Service water with kinematic viscosity $\nu = 1.1 \times 10^{-6}$ m^2 s^{-1} was pumped through the tube. Three concentration transducers were mounted in the middle of the tube at $x = l/2$ (at the flow axis $r = 0$, in the middle of the radius $r = R/2$, and at the inner wall $r = R$).

The experiments were carried out as follows. Water was fed into the tube inlet at a prescribed flow rate. Then, at instant of time $\tau = 0$, an indicator, 1 ml of a concentrated solution of common salt, was introduced into the flow in pulsed mode. Preliminarily, the concentration transducers were calibrated using balance resistance bridges. The ratio between the volume of the indicator and that of the fluid in the tube was less than 0.04, i.e., satisfied the requirement that the indicator should not affect the structure of the main flow [1, 2]. The concentration curves obtained are shown in Fig. 2.

As seen from the concentration curves, no concentration equalization occurs in the laminar flow. Molecular diffusion cannot ensure, even for such a low-viscous fluid as water, a uniform distribution of the reaction mass along the radius. In the intermediate mode (Fig. 2b), the influence of convective mass transfer on the concentration equalization along the radius is noticeable. Turbulent pulsations and vortices (Fig. 2c) well equalize the concentration along the radius. In this case, there is no need for static or dynamic mixers, even though the longitudinal mixing gives no way of describing the concentration curve of the turbulent flow by the "one-seventh" law valid for a developed turbulent flow with Re > 10^5 [5]:

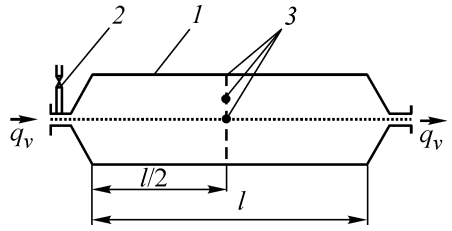

Fig. 1. Schematic of the setup used to determine the dependence of the indicator concentration on radius. (*1*) Tube, (*2*) pipe for introduction of indicator, and (*3*) concentration transducer. l = 1 m is the pipe length.

1070-4272/03/7608-1268 $25.00 © 2003 MAIK "Nauka/Interperiodica"

$$\left.\begin{aligned} v &= v_0(1 - r/R)^{1/7}, \\ C &= 14(\theta_0^7/\theta^9)[1 - (\theta_0/\theta)^7], \end{aligned}\right\} \quad (3)$$

where $v_0 = (120/98)v_{av}$; v_{av}, the average flow velocity; C, the response function of the turbulent flow; $\theta = \tau/\tau_{av}$, dimensionless time; τ, running time; τ_{av}, the average residence time equal to the ratio of the apparatus volume to the flow rate through the apparatus; $\theta_0 = \tau_0/\tau_{av}$, the relative residence time at the flow axis; τ_0, the residence time at the flow axis.

At the same time, in the case of Poiseuille's velocity profile, the response function [second equation in the system (4)] is "broadened" for the laminar flow, too, by molecular diffusion in a low-viscous fluid. This occurs both in the longitudinal and in the radial directions:

$$\left.\begin{aligned} v &= 2v_c[1 - (r/R)^2], \\ C &= 1/(2\theta^3). \end{aligned}\right\} \quad (4)$$

To equalize the concentrations in the radial direction and to diminish the effect of reverse mixing, it is necessary to decelerate the flow along the axis of an apparatus or reactor and to raise the velocity in the peripheral zone. In addition radial mixing is to be simultaneously ensured in both the zones.

Both these tasks can be accomplished in a continuous ribbon screw mixer (Fig. 3). This mixer comprises a cylindrical casing *1*, drive *2*, charging orifice *3* displaced toward the drive *2*, discharging unit *4* at the opposite end of the casing *1*, ribbon screw actuator in the form of a twin screw mixing element with internal coil *5* and external ribbon coils *6*. A planetary mechanism *7* with central tooth gear *8* and pinions *9* engaged with the gear is mounted coaxially with the drive and with the internal ribbon coil *5*. The pinions *9* are mounted in line with the external ribbon coils *6*.

The rotation of the ribbon coils gives no way of mounting static concentration transducers within the casing. However, comparison of the response function of a tubular apparatus with that of the apparatus with the ribbon screw mixer described here shows that, at an adequate choice of the ratio of the angular velocities ω_1 and ω_2, the variance of the response function decreases by a factor of 3–4 in the case of a laminar flow (Fig. 4). A characteristic feature of the flow structure in the apparatus of the design proposed is the presence of two concentration peaks, which is accounted for by the existence of a central and peripheral zones. Undoubtedly, the reduction gear and three

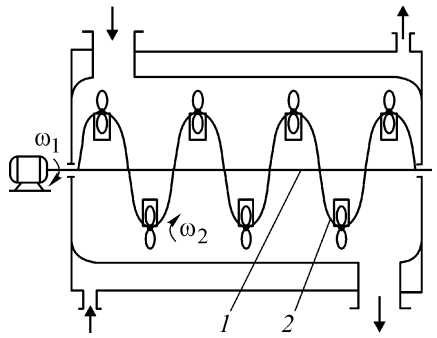

Fig. 5. Schematic of mixing reactor.

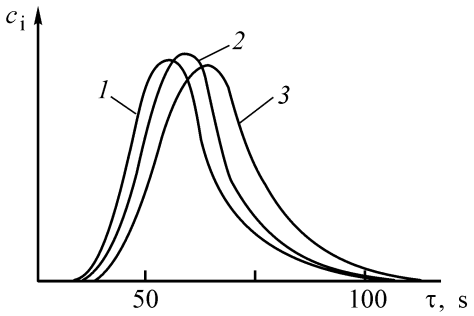

Fig. 6. Indicator concentration c_i vs. time τ after indicator introduction in the case of a laminar flow (Re = 530) and Reynolds number of the stirrer, Re_s = 340.

ribbon screws make the apparatus design more complex.

To simplify the design, a mixing reactor with a single screw, ensuring longitudinal flow with good radial mixing, can be used. The schematic of the design suggested is shown in Fig. 5 [6]. Analysis of the response curve of this apparatus shows (Fig. 4, curve *3*) that the variance decreases by a factor of 1.2–1.3, i.e., is lower than that in the ribbon screw mixer described above. However, the last design is simpler in fabrication and operation. Moreover, with a radial slit cut in the ribbon of screw *2* as far as the shaft *1*, concentration transducers can be easily mounted in accordance with Fig. 1.

The result obtained in studying the dependence of the indicator concentration on the flow line radius are shown in Fig. 6. Comparison of the concentration curves in Fig. 6 with similar curves for a hollow tube shows that a screw with propeller agitators at coil crests equalized the concentrations along the radius and makes the variance of the curves lowr by a factor of 1.6–1.8.

Compared with the screw of the conventional design, the variance of the response curves is virtually unchanged, but the dependence of the concentration curves on radius is preserved (as shown in Fig. 2a, even though the curves themselves become narrower and higher).

Thus, in the case of a turbulent flow, auto-equalization of the flow concentrations along the radius is caused by pulsations and vortices, but ideal plug flow cannot be ensured at $l/d \approx 20$.

Mounting screw mixers of special design in continuous apparatus makes it possible to make the flow close to the ideal plug flow (variance < 0.1) and to ensure the ideal mixing along the radius in the case of a laminar flow.

CONCLUSIONS

(1) Analysis of experimental response curves obtained for the internal volume of the apparatus shows that, to intensify the radial mixing and to level the velocity profile along the radius, it is necessary to mount additional mixing devices, especially at low flow velocities of the reaction mass and its high viscosity.

(2) On the basis of analysis of the response curves obtained, new designs of flow-through continuous apparatus are suggested.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of Drop Size Distribution in Multistage Bubble Extractor

Received June 6, 2002; in final form, January 2003

Abstract—Results obtained in determining experimentally the mean volume-surface drop diameter of the dispersed phase in a multistage bubble extractor are presented.

The experience gained in designing and introducing into industrial practice fluid extractors with pneumatic agitation shows that bubble extractors of the mixing-settling type are the most efficient under the conditions of multistage counterflow extraction [1]. Particularly important for apparatus of this kind is that data obtained on pilot installations and even in laboratory are quite reliable and can be used to pass to industrial conditions [2].

In carrying out extraction processes in bubble extractors, one of liquid phases is dispersed into drops under the action of the inert gas used for agitation. As a rule, the dispersed phase is a polydisperse system of drops whose size distribution (or interfacial area) affects, first, the rate of mass exchange across the phase boundary and, second, the rate and extent of phase separation in the settling part of each stage of the extractor.

Theoretical description of mass transfer in a polydisperse system of drops involves severe difficulties, and, therefore, to simplify calculations, most of researchers replace the polydisperse system with a monodisperse one, with particle size equal to mean particle size of the polydisperse system. This allows relations obtained for a single drop to be used when calculating the mass-transfer coefficients [3].

Passing from a polydisperse to monodisperse system for calculating the coefficients of mass transfer from drops into the continuous medium was substantiated in [4], where it was shown theoretically that relations for an isolated drop can be used if the drop diameter is replaced with a volume-surface mean drop diameter in the polydisperse system.

The specific area of the phase boundary can be calculated using the relation [5]

$$F_{sp} = 6\varphi/d_{vs}, \quad \varphi = V_d/(V_c + V_d), \qquad (1)$$

where φ is the volume fraction of the dispersed phase; V_c and V_d, the flow rates of the continuous and dispersed phases ($m^3\ s^{-1}$); d_{vs}, the mean volume-surface drop diameter (m).

The severity of difficulties encountered in attempts to describe analytically the disintegration of drops in fluid–fluid systems for any method used to supply external energy forced authors of numerous studies to take an empirical approach to this problem [6].

The mean volume-surface drop diameter was determined under the conditions of pneumatic agitation in a particular industrial process of double extraction of caprolactam [7] on a three-stage model bubble extractor. The drop diameters were found photographically [8] on a special-purpose laboratory installation.

The model extractor had the following geometric dimensions (mm): inner diameter of the glass casing 104, diameter of the external pipe of the mixer 50, diameter of the internal pipe of the mixer 33, section (extraction stage) height 400.

In the experiments, the flow rates of fluids and the inert gas were varied within the following ranges

Table 1. Physicochemical properties of fluids

Model section no.	Continuous phase		Dispersed phase		σ, N m^{-1}	φ
	ρ_c, kg m^{-3}	$\mu_c \times 10^3$, Pa s	ρ_d, kg m^{-3}	$\mu_d \times 10^3$, Pa s		
1	880	0.88	1036	2.8	2.77	0.193
2	868	0.62	1028	1.4	5.6	0.138
3	859	0.53	1023	1.00	10.8	0.096

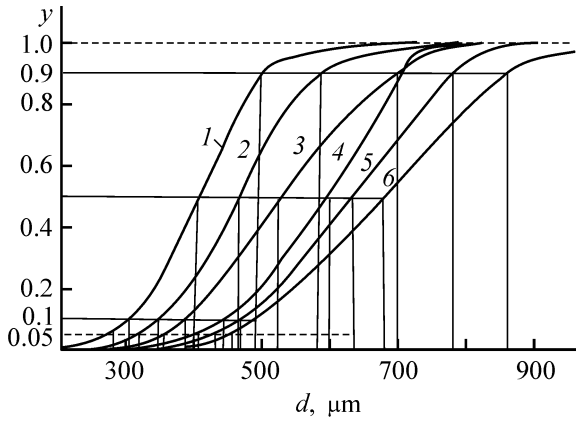
(l h^{-1}): light fluid 80–240, heavy fluid 25–80, inert gas (nitrogen) 77–306. The physicochemical properties of the fluids studied are listed in Table 1.

The sizes of all drops were measured using a microscope, with a calibrated wire 1 mm in diameter, placed in the settling zone of an extractor stage, serving as a scale for determining the true sizes of drops.

In each run, data for 250–600 drops were calculated, depending on dispersity.

The whole range of drop sizes obtained was divided into intervals of 10 μm and the mean diameter d_i and number of drops in each interval were determined. Further, the total volume of drops in a group, volume of drops smaller than d_i in size, and, finally, volume fraction of drops smaller than d_i were determined.

The figure shows the drop size distributions, depending on physicochemical properties of fluids and conditions of their dispersion in a stage of the bubble extractor.



Distribution y of drops over sizes d in pneumatic dispersion. $\bar{w}_g$ (m s^{-1}): (*1, 4*) 0.1, (*2, 5*) 0.05, and (*3, 6*) 0.025. τ_{av} (s): (*1–3*) 10.6 and (*4–6*) 5.3.

Previously, a relation for determining the admissible diameter of drops carried away from the settling zone, in calculating the diameter of a bubble extractor, has been obtained by processing of experimental data [9]:

$$d_5 = 4.96 \times 10^{-6} (\sigma^{0.35} \varphi^{0.8}) / (\bar{w}_g^{0.2} \tau_{av}^{0.45} \mu_c^{1.1}), \quad (2)$$

where d_5 is the drop diameter corresponding to relative drop volume fraction of 5%; σ, the interfacial tension (N m^{-1}); $\bar{w}_g$, the reduced gas flow velocity in the mixer (m s^{-1}); τ_{av}, the average residence time of fluids in the mixer (s); μ_c and μ_d, the viscosities of the continuous and dispersed phases (Pa s); ρ_c and ρ_d, the densities of the continuous and dispersed phases (kg m^{-3}).

Analysis of the type of variation of the parameters appearing in relation (2) shows that they are totally dependent on the mechanism of drop disintegration [5, 6, 8].

The mean volume-surface drop diameter d_{vs} from the logarithmic probability equation for the upper limit is given by the expression [10]

$$d_{vs} = d_{max} / [1 + a \exp(0.25\beta \cdot \beta)], \quad (3)$$

where d_{max} is the maximum drop diameter in the emulsion (m); a and β are constant distribution parameters.

According to [11], it is recommendable to take β = 0.725 and to determine the distribution parameter a from the equality

$$a = (d_{max} - d_{50}) / d_{50}, \quad (4)$$

where d_{50} is the drop diameter corresponding to relative drop volume fraction of 50%.

In its turn, d_{max} can be found from the relation

$$d_{max} / d_{50} = [d_{50}(d_{90} + d_{10}) - 2 d_{90} d_{10}] / (d_{50}^2 - d_{90} d_{10}), \quad (5)$$

where d_{90} and d_{10} are the drop diameters corresponding to volume drop fractions of 90 and 10%.

The results obtained in processing the experimental data from the figure by relations (3)–(5) are listed in Table 2.

The data in Table 2 suggest that the mean volume-surface drop diameter d_{vs} in a multistage bubble ex-

Table 2. Results of experimental data processing

Parameter	Curve no. in figure					
	1	*2*	*3*	*4*	*5*	*6*
d_{90}, μm	490	585	690	710	780	870
d_{50}, μm	400	470	530	600	640	682
d_{10}, μm	305	350	395	438	465	490
d_{max}, μm	730	870	980	816	975	1360
a	0.825	0.85	0.9	0.36	0.52	1.0
d_{vs}, μm	376	442	480	578	610	635
d_5, μm	278	310	360	420	435	470
K	1.35	1.35	1.34	1.37	1.37	1.35

tractor can be calculated using the dependence obtained for d_5 [9] with a constant $K = 1.35$ introduced:

$$d_{vs} = 1.35\,d_5 = 6.7 \times 10^{-6}\left(\sigma^{0.35}\varphi^{0.8}\right)/\left(\overline{w}_g^{0.2}\tau_{av}^{0.45}\mu_c^{1.1}\right) \quad (6)$$

Thus, the experimentally determined curve of the drop volume distribution over drop size can be used to determine with sufficient accuracy important parameters of a fluid–fluid system, such as the admissible diameter of carried-away drops, d_5, necessary for calculating the dimensions of the settling zone of an apparatus, and the mean volume-surface drop diameter d_{vs}, depending on physicochemical properties of fluids and conditions of pneumatic agitation in the mixing zone of the bubble extractor.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Optimization of Oxidative Method for Synthesis of 1,3-Diformyl-2,4,6-triethylbenzene

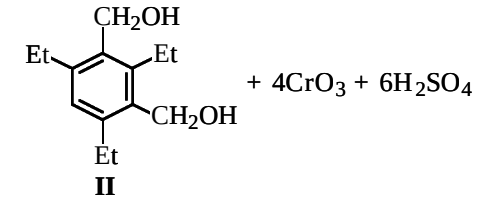
Abstract—Oxidation of 1,3-diformyl-2,4,6-triethylbenzene with chromium anhydride in diluted H_2SO_4 to form 1,3-di(hydroxymethyl)-2,4,6-triethylbenzene was studied.

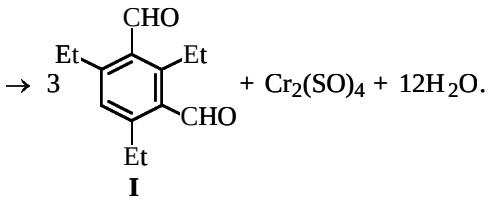
Synthesis of nitrile oxides [1], which are used as efficient cross-linking agents, has become industrially important for production of polymeric formulations containing porophore-like compounds. 1,3-Di(nitrile oxide)-2,4,6-triethylbenzene, whose stability is ensured by three alkyl substituents screening the nitrile oxide groups, is among such compounds.

The synthesis of the above compound includes the stage of preparation of 1,3-diformyl-2,4,6-triethylbenzene (**I**) as an intermediate [1]. This stage may proceed with the formation of the largest amount of impurities and is, in the end, responsible for the quality and yield of the target product. Industrially, compound **I** is commonly obtained by oxidation of 1,3-di(hydroxymethyl)-2,4,6-triethylbenzene (**II**) with Cr(VI) in an aqueous solution of sulfuric acid, with the yield of the reaction product not exceeding 50–55% [2].



II

$$+ 4CrO_3 + 6H_2SO_4 \rightarrow 3$$



I

$$+ Cr_2(SO)_4 + 12H_2O.$$

As is known [3], transformation of a hydroxymethyl compound into a formyl compound can be accompanied by further oxidation of aldehyde groups to carboxy groups [3]. Dimerization and polymerization, involving the initial and final products of this stage [4], and also oxidation of alkyl groups to aldehyde and carboxy groups, may proceed simultaneously [5]. The rates of the above reactions are comparable, and their extent depends on the reaction conditions, i.e., component ratio, temperature, and time.

Therefore, when formylation is performed under nonoptimal conditions, the reaction product may contain a wide variety of impurities, from the starting diformyl compound to dicarboxylic acid and triethylbenzene. In addition, Cr(VI) is apparently transformed not only into chromium(II) sulfate removable by washing with water, but also into water-insoluble chromium(III) oxides. The presence of these latter in the reaction mass hinders isolation of the target product and results in its contamination.

In this study, the optimal conditions of formylation of compound **I** were determined to obtain the target product in maximum yield with high content of the main substance.

The complex composition and instability of the final reaction product make a kinetic study of the process difficult. For this reason, we solved this problem using the mathematical experiment design [7–9], which allows construction of a mathematical model of the process and its optimization with minimum experimental effort [10–12].

EXPERIMENTAL

The whole set of tests was performed under identical conditions on an installation consisting of a 500-ml

1070-4272/03/7608-1274 $25.00 © 2003 MAIK "Nauka/Interperiodica"

jacketed glass reactor with bottom drain (see figure). The apparatus was equipped with a four-blade high-speed agitator, thermometer, and a thermocouple connected to a KSP-4 recorder. The jacket of the reactor was connected to a U-2 thermostat and a cold-water line by two heat-transfer-agent circuits, which ensured control of the reactor temperature in the range from 10 to 90°C. The volume of the reaction mass was constant in all the tests (400 ml). Calculated amounts of compound **II** and diluted H_2SO_4 were charged into the reactor. The mixture was agitated for 30 min to create a uniform suspension and warmed to 25°C (fixed temperature of the reaction onset), and then a 50% aqueous solution of CrO_3 was added. After that, the reaction mass was heated to the required temperature for 5–10 min and kept at 53–55°C for 60 min.

In the first stage of the study, the reaction mass was allowed to stay for 1 h. In the second stage, the reaction mass was heated, on adding a CrO_3 solution, to a temperature determined from the disign matrix of a full factorial experiment (FFE) and kept at this temperature for a time also determined by the FFE matrix. Then, cold water was fed into the reactor jacket to cool the reaction mass to 15–20°c, and the target product **I** was extracted with carbon tetrachloride. The extraction was done with three portions of the solvent: the volume of the first portion was numerically equal to the mass of compound **II** taken for the reaction. The volumes of the second and third portions were half the above mass. The extraction time was 10–15 min, and the separation time, 20–30 min. The layers were separated in a separating funnel. Since the target product **I** is unstable, the joint extract was immediately used for preparing 1,3-diformyl-2,4,6-triethylbenzene dioxime (**III**) (reaction proceeds in quantitative yield [5, 6]) by the known procedure [3]. The oximes were formed in a 1000-ml three-necked flask equipped with a high-speed agitator rotating at fixed rate and a thermometer.

Water was poured into the reactor, and NaOH (sol) was added under agitation. After NaOH was dissolved, the extract containing aldehyde **I** and then $(NH_2OH_2) \cdot H_2SO_4$ were added. The pH of the reaction mass was measured every 10–15 min and adjusted to 6.5–7.0 with NaOH(sol) or $(NH_2OH_2) \cdot H_2SO_4$. The reaction mass was heated to 45–50°C and kept at this temperature for 1 h. After that, NaOH(sol) was added in an amount necessary for oxime **III** to be transformed into the corresponding disodium salt. The reaction mass was kept at 45–50°C for another 1 h, cooled to 20–25°C, poured into a separating funnel, and allowed to settle for 0.5 h. The lower

(organic) layer was separated, whereas the aqueous solution of disodium salt of oxime **III** was placed in the reactor again and its pH was adjusted to 6.5–7.0. For a sediment of product **III** to be formed, the solution was kept at room temperature for 1 h. The sediment was filtered off, washed with water, and dried at 50–55°C in a thermostat to constant mass. The mass of the substance, its boiling point, and the content of the main substance were determined by liquid chromatography (LC).

A quantitative analysis was done on a Milikhrom liquid chromatograph with a 64 × 2-mm KAKh-2 column packed with Separon-C_{18} (grain size 5 μm). As eluent served a mixture of dioxane, acetonitrile, and water (volume ratio 1 : 4.5 : 4.5).

An analysis of an *a priory* information about formylation made it possible to reveal a number of influencing factors (independent variables), examine them, and arrange them in order of increasing priority for the problem to be solved. To these factors we assigned, in the first place, the relative amounts of the starting components and the process temperature and time.

As optimization criterion (response function) served the yield of the target product, with account taken of the content of main substance in the target product, i.e., its quality.

In the first stage of the study, a FFE was carried out (Table 1, run nos. 1–8). To eliminate, to the maximum possible extent, the effect of interaction, the following three factors, determining the relative amounts of the starting components, were used originally: x_1, the excess of CrO_3 with respect to its amount re-

* Calculations were based on the data of Table 1.

quired by stoichiometry (%); x_2, the H_2SO_4 amount [mol mol^{-1} of initial compound **II**]; x_3, the acidity of the reaction mass in terms of H_2SO_4 concentration in the total amount of water used in the process (%).

The levels of factors and their variation ranges were chosen on the basis of an *a priory* information. The other formylation factors, i.e., the temperature of the beginning of introduction of a Cr_2O_3 solution, time of introduction, and also exposure temperature and time, were also fixed on the basis of *a priory* information at the levels considered to be optimal. The systematic experimental error was compensated for by the randomization method. The reproducibility of the experiment was estimated (Table 2), the coefficients of the regression equation (1) were calculated, the significance of the regression coefficients was determined, and the adequacy of the model was verified:

$$y = 58.31 + 0.83x_1 - 0.94x_2 + 5.94x_3 + 1.36x_1x_2 - 1.59x_1x_2x_3. \quad (1)$$

The high value (5.94) of the coefficient of x_3 shows that the factor x_3 (H_2SO_4 concentration) strongly affects the optimization parameter, i.e., the yield of the target product **I**. The sign "+" means that, with the given factor increasing, the optimization parameter increases too, in good agreement with the data of [13, 14], according to which the oxidizing capacity of Cr(VI) strongly depends on the acidity of the reaction mass and on the ability of Cr(VI) ions to form complex compounds. Thus, the sulfuric acid concentration in the oxidizing system affects rather strongly the oxidation direction and the purity of the target product.

Application of the steep-ascent method failed to find a maximum in the region studied. This may be a consequence of the possible curvature of the response surface, which is indicated, despite the formal adequacy, by the significance coefficients of the double and triple interaction terms. For adequate mathematical description of the process, we used the second-order regression equation derived using the orthogonal central composition design (OCCD). The OCCD matrix is standard for all the three factors [8] and is not randomized. The design of the first order, the FFE matrix, was completed to the OCCD plan by runs carried out at the center points (Table 1, run nos. 10–15). The results of its realization are listed in Table 1. These data were used to determine the coefficients of the second-order regression equation (2) and to estimate the significance of the equation coefficients and its adequacy.

$$y = 60.43 - 0.95x_2 + 4.69x_3 + 1.36x_1x_2 - 1.59x_1x_2x_3 - 2.77x_3^2. \quad (2)$$

* The melting point of recrystallized sample is 121°C.

The equation is adequate to the experimental data within the range of the influencing parameters, studied here.

The second-order model developed was optimized using Box's complex method [12], which made it possible to calculate the coordinates of the maximum of the target function.

The data of Table 3 show that the maximal yield is achieved at the boundary of the factor space. An attempt to perform the experiment at the point obtained in optimization (Table 3, run no. 1) failed owing to the impossibility to separate the reaction mass in extraction.

Apparently, at large excess of chromium anhydride and stoichiometric amount of sulfuric acid (Table 3, run no. 1), we presumably obtain a considerable amount of water-insoluble chromium(III) oxide, which serves as emulsifier, facilitates formation of a stable emulsion, and impedes layer separation.

As a result, only inconsiderable portion of a poor-quality final product could be separated from the reaction mass in this run (Table 3, run no. 1). With the amount of chromium anhydride diminished to a nearly stoichiometric value under otherwise invariable conditions (Table 3, run no. 2), the yield of the raw product increased, but its quality remained poor (content of the main substance 74%).

In the next run (Table 3, run no. 3), at a minimum excess amount of chromium anhydride and the same x_3 factor (H_2SO_4 concentration), the amount of sulfuric acid increased [to x_2 = 3.0 mol mol^{-1} of initial compound **II**] with respect to stoichiometric amount (2.0 mole). The comparatively poor quality of the raw product at its sufficiently high (69%) yield can be apparently accounted for by the insufficient amount of chromium anhydride, which is confirmed by the presence of unreacted bishydroxymethyl derivative of triethybenzene in the reaction mass.

In the next run (Table 3, run no. 4), chromium anhydride was taken in a 3.5% excess with respect to the stoichiometry at the same amount of sulfuric acid and its same concentration in the reaction mass. As a result, a 99.5% pure product was obtained in 69% yield (recalculated to 100% content of the main substance). In run nos. 5 and 6 (Table 3), we studied whether an increase in the x_3 factor (H_2SO_4 concentration) outside the factor space to, respectively, 22 and 26% affects the yield of the target product. The raw product was obtained in rather high yield, but with drastically impaired quality. This result can be accounted for by the fact that, under these conditions, the rate of side oxidation reactions and the fraction of their products in the raw product grow, in good agreement with the data on how the oxidation depth and the purity of the target product depend on the sulfuric acid concentration [13, 14].

The first stage of the study resulted in the following conclusion: to perform formylation with high yield and to obtain a high-quality product, it is necessary to use CrO_3 in a 3–4% excess with respect to the stoichiometry, and H_2SO_4 in an amount of 3 mole per 1 mole of initial compound **II**, and to maintain its concentration in the reaction mass within the range 14–15 wt %.

In the second stage, a mathematical model of formylation was constructed, which describes the relationship between the process temperature and time, on the one hand, and the optimization parameter (response function), i.e., the yield of the target product, on the other (with account taken of the content of initial substance in it).

Table 4. Results of realization of FFE design matrix

Run no.	Content of main substance, %	Yield, %
1	91	56
2	90	49
3	87	56
4	89	41
5	94	60

The FFE was also performed. As indicated above, the yield of the target product was used as response function, with account taken of the content of main substance in it. We chose two influencing parameters, z_1 and z_2, i.e., the reaction temperature (°C) and reaction time (min), respectively. The level of factors and their variation range were chosen on the basis of an *a priory* information. The FFE standard matrix for two factors was randomized.

The results of FFE are listed in Table 4. These data were used to calculate the coefficients of the regression equation, determine their significance, and verify the adequacy of the model. A first-degree regression equation adequately describing the response surface was obtained:

$$y = 61.57 + 5.47z_1 + 2.06z_2 - 2.25z_1z_2. \quad (3)$$

Analysis of Eq. (3) shows that the coefficient of the z_1 factor exceeds that of z_2, which confirms the positive effect exerted by a rise in temperature. The significant coefficient of the pair-interaction term, having "minus" sign, indicates that for the optimization parameter to grow, the z_1 factor must increase, rather than decrease.

To optimize the process, we used the steep-ascent method. However, it failed to find a maximum in the region studied. This may be a consequence of the curvature of the response surface, as evidenced, despite the formal adequacy, by the significant coefficients of the pair-interaction term and by the difference between the free term of the regression equation and the yield at the center of the design (Table 4, run no. 5).

The use of Box's complex method for optimizing the resulting first-order equation made it possible to avoid additional experiments to search for local extrema. This enabled calculation of the coordinates of the maximum of the target function.

The maximum yield is achieved at the boundary of the factor space. An experiment with factors calculated by Box's method, a 10-min exposure time and a 69.5–70.0°C temperature, were carried out. As a result, the product containing 99.5% main substance was obtained in 70% yield, which is rather close to Box's value (71%).

The recommended relative amounts of the reagents, and the process temperature and time worked very well under pilot plant conditions: oxime **III** was obtained with high content of the main substance (95–98%) in good yield (66–68%), close to the expected value. This result shows that the process conditions chosen ensure predominant oxidation of the initial compound **II** to dialdehyde **I**.

CONCLUSIONS

(1) Synthesis of 1,3-diformyl-2,4,6-triethylbenzene from 1,3-di(hydroxymethyl)-2,4,6-triethylbenzene by oxidizing the latter with CrO_3 in diluted H_2SO_4 was studied using a mathematical method of experiment design. The model of the process was constructed and optimized.

(2) Under the optimal process conditions [CrO_3 taken in 3–4% excess with respect to stoichiometry, and H_2SO_4 in an amount of 3.0 mol mol^{-1} of initial compound **II**, 14–15 wt % H_2SO_4 concentration in the reaction mass, and 10-min keeping of the reaction mass at 69.5–70°C the yield of the final product is as high as 67–70%.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antimicrobial Activity of *N,N*-Disubstituted 3-Allyloxy-1-amino-2-propanethiols

M. A. Allakhverdiev and A. B. Askerov

Baku State University, Baku, Azerbaijan
Sumgait State University, Baku, Azerbaijan

Received March 25, 2003

Abstract—3-Allyloxy-1,2-epithiopropane was synthesized; its treatment with amines yielded *N,N*-disubstituted 3-allyloxy-1-amino-2-propanethiols, which were tested for antimicrobial activity.

Among products of thiirane ring opening, 1,2-amino thiols are of great practical importance [1–5]. For example, an aminoethanethiol moiety is a structural fragment of coenzyme A, playing a major role in the vital activity of living bodies [6]. Amino thiols and their derivatives are physiologically active compounds; they are widely used in medicine. Also they find growing application as effective components of polymeric materials enhancing the radiation resistance of polymers, suppressing oxidation and corrosion processes, etc.

In this context, we prepared in this study *N,N*-disubstituted 3-allyloxy-1-amino-2-propanethiols and tested them as antimicrobial additives to lubricating oils. As starting compound we used 3-allyloxy-1-chloro-2-propanol which, in turn, was prepared in 73% yield by treatment of epichlorohydrin with allyl alcohol; this yield is appreciably higher than that with concentrated sulfuric acid as catalyst (54%) [7]:

$$CH_2{=}CHCH_2OH + \underset{\diagdown O \diagup}{CH_3CHCH_2Cl} \xrightarrow{ZnCl_2} CH_2{=}CHCH_2OCH_2\underset{OH}{\underset{|}{C}}HCH_2Cl.$$

I

Dehydrochlorination of **I** in the presence of KOH gave 3-allyloxy-1,2-epoxypropane **II** in 85% yield:

$$\mathbf{I} + KOH \xrightarrow[-KCl\ -H_2O]{} CH_2{=}CHCH_2OCH_2\underset{\diagdown O \diagup}{CH{-}CH_2}.$$

II

Treatment of **II** with thiourea in the presence of sulfuric acid gave thiirane **III** in 79% yield:

$$\mathbf{II} + \underset{\underset{S}{\|}}{NH_2CHNH_2} \xrightarrow[-(NH_2)_2CO]{H_2SO_4} CH_2 + CHCH_2OCH_2\underset{\diagdown S \diagup}{CHCH_2}.$$

III

Previously thiirane **III** has been prepared in 30% yield by the reaction of 1,2-epithio-3-chloropropane with allyl alcohol in the presence of KOH [8]. Apparently, an oxathiolane ring is readily formed in the presence of sulfuric acid, which increases the yield of the target product.

We found that, with catalytic amounts of sulfuric acid, the procedure is simplified and the yield of **III** is increased.

Reactions of thiirane **III** with various primary and secondary amines yielded *N,N*-disubstituted 3-allyloxy-1-amino-2-propanethiols **IV**–**XII** (see table):

$$\mathbf{III} + HNR^1R^2 \rightarrow CH_2{=}CHCH_2OCH_2\underset{SH}{\underset{|}{C}}HCH_2NR^1R^2,$$

IV–**XII**

where $R^1 = R^2 = C_2H_5$ (**IV**); $R^1 = R^2 = C_4H_9$ (**V**); $R^1R^2 = (CH_2)_5$ (**VI**); $R^1R^2 = (CH_2)O$ (**VII**); $R^1R^2 = (CH_2)_2O(CH_2)_2$ (**VIII**); $R^1 = H$, $R^2 = C_6H_5$ (**IX**); $R^1 = H$, $R^2 = C_6H_5CH_2$ (**X**); $R^1 = R^2 = H$ (**XI**); $R^1 = H$, $R^2 = C_3H_7$ (**XII**).

The yields of the target products increase when the amine is taken in excess (i.e., when it acts also as a solvent). Access of air decreases the yield of amino thiols because of the oxidation and polymerization of the starting thiirane **III**. Therefore, amino thiols **IV**–**XII** were prepared in sealed ampules at a thiirane : amine ratio of 1 : 2.

Amino thiols **IV**–**XII** are colorless liquids turning yellow on storage. The purity of all the compounds was checked by thin-layer chromatography; the composition was confirmed by elemental analysis, and the structure was determined by IR and ^{1}H NMR spectroscopy.

The IR spectra of compounds **IX**–**XII** containing a secondary amino group exhibit narrow absorption bands at 3375–3395 cm^{-1}, characteristic of the N–H bond. A very weak band at 2560–2580 cm^{-1} in the spectra of **IV**–**XII** is due to S–H stretching vibrations, and a band at 1060–1070 cm^{-1}, to C–N vibrations. The stretching vibrations of the C=C bonds in the aromatic ring and allyloxy group are manifested at 1420–1440, 1490–1500, 1600–1610, and 1650–1680 cm^{-1}.

The ^{1}H NMR spectra of **IV**–**XII** in the range 4.15–5.90 ppm contain multiplets from allyloxy group protons. In the range 6.9–8.1 ppm, compounds **IX** and **X** have signals due to nonequivalent protons of the aromatic rings. The proton signals of methylene groups bound to the nitrogen atom (amino thiols **IV**–**VIII**) are observed at 2.25–2.40 ppm. The methine proton appears as a broadened multiplet at 2.8–3.4 ppm due to coupling with the adjacent methylene protons. The two methylene groups at the oxygen atom give signals at 4.1–4.3 ppm.

It is known [9] that reactions of asymmetric thiiranes with amines follow the Krasuski rule, i.e., the ring opening occurs so that the thiol group in the 1,2-amino thiol molecule appears at the most substituted carbon atom. In the reactions of **III** with amines, this reaction pathway was confirmed by ^{1}H NMR spectroscopy. Namely, the ^{1}H NMR spectra of amino thiol **VI** were recorded before and after benzoylation. In the spectrum of **VI**, the methine proton appears as a quintet at 2.9 ppm due to coupling with the two adjacent methylene groups. Benzoylation of **VI** with benzoyl chloride (to give 3-allyloxy-1-piperidino-2-benzoylthiopropane **XIII**) shifts the methine proton signal down-field by 1.3 ppm (to 4.25 ppm) owing to the inductive effect of the benzoyl group.

A similar benzoylation experiment was performed with a primary thiol, 1-octanethiol. In the ^{1}H NMR spectrum of 1-octanethiol, the protons of the methylene group bound to the SH group appears as a triplet at 2.55 pm, and, upon benzoylation to give benzoyl octyl sulfide **XIV**, this triplet is shifted downfield to 3.00 ppm ($\Delta\delta$ 0.45 ppm). Published data [10] on acylation of primary and secondary hydroxy groups show that, upon acylation, the signals of the α-CH protons are shifted downfield by 0.5 ppm in primary alcohols and by 1.0–1.15 ppm in secondary alcohols. The 1.35 ppm shift observed in **VI** suggests that, in 1,2-

amino thiols **IV**–**XII**, the thiol groups are located at the secondary carbon atom.

The amino thiols obtained were tested as antimicrobial additives to DS-II lubricating oil and to Solidol (lubricating grease). We found that all compounds **IV**–**XII** added in amount of 0.5–1.0 wt % ensure long-term protection of DS-II and Solidol from biodamage. The width of the suppression zone, with industrially used sodium pentachlorophenolate taken as reference, was 0.7–1.3 cm for bacteria and 0.7–1.4 cm for fungi, i.e., the compounds exhibit antibacterial and fungicidal activity, with the fungicidal properties being somewhat more pronounced.

We revealed no clear correlation between the structure and antimicrobial activity of **IV**–**XII**. However, we found that phenyl and benzyl substituents (compounds **IX** and **X**) appreciably enhance the antimicrobial activity.

EXPERIMENTAL

The IR spectra were recorded on a Specord 75-IR spectrophotometer; liquid samples were prepared as thin films, and solid samples, as KBr pellets. The ^{1}H NMR spectra were recorded at 27°C on a Bruker AV spectrometer (300 MHz, CCl_4, internal reference HMDS).

3-Allyloxy-1-chloro-2-propanol I. A mixture of 7.2 g (0.12 mol) of allyl alcohol, 7.2 g (0.08 mol) of epichlorohydrin, and 0.2 g of zinc chloride was heated for 4 h at 95–100°C, after which it was cooled and vacuum-distilled. Yield of alcohol **I** 9 g (73%); bp 105–106°C (20 mm Hg), n_D^{20} 1.4619. Published data [7]: bp 86.5°C (9 mm Hg), n_D^{20} 1.4635.

3-Allyloxy-1,2-epoxypropane II. Finely ground KOH (11.2 g, 0.2 mol) was added to a solution of 15 g (0.1 mol) of alcohol **I** in 50 ml of anhydrous diethyl ether; the reaction mixture warmed up. After heating at 30°C for 2 h, the mixture was cooled, the ether layer was separated, and the residue was treated with three portions of anhydrous diethyl ether. The ether solutions were combined, the solvent was distilled off, and the reaction product was distilled at ambient pressure. Yield of oxirane **II** 9 g (79%), bp 122–123°C, n_D^{20} 1.1476. Published data [11]: bp 121–123°C, n_D^{20} 1.4159.

3-Allyloxy-1,2-epithiopropane III. A 3-ml portion of dilute sulfuric acid (0.5 mol of H_2SO_4 in 350 ml of water) was added to 7.6 g (0.1 mol) of thiourea. The mixture was cooled to 5–10°C, and 11.4 g (0.1 mol) of oxirane **II** was added dropwise over a period of 30 min with vigorous stirring, with the reaction temperature maintained at 5–10°C. After that, the mixture was stirred for an additional 1 h at room temperature and hydrolyzed with a solution of 10.6 g (0.1 mol) of sodium carbonate in 45 ml of water. The aqueous layer was separated from the organic layer and treated with two 20-ml portions of diethyl ether. The combined organic phases were dried over sodium sulfate. The solvent was distilled off, and the product was vacuum-distilled. Yield of thiirane **III** 10.3 g (73%), bp 79–81°C (12 mm Hg), n_D^{20} 1.4892, d_4^{20} 1.0215.

Found, %: S 24.56; MR_D 36.80.
$C_6H_{10}OS$.
Calculated, %: S 24.63; MR_D 36.88.

3-Allyloxy-1-diethylamino-2-propanethiol IV. A mixture of 14.6 g (0.2 mol) of diethylamine and 13 g (0.1 mol) of thiirane **III** was heated in an ampule at 80–90°C for 8 h. The ampule was cooled and opened; excess diethylamine was distilled off in a water-jet-pump vacuum. The reaction product was vacuum-distilled. Yield of amino thiol **IV** 14 g (68%), bp 94–95°C (2 mm Hg), n_D^{20} 1.4735. TLC: R_f 0.68 (hexane–isopropyl alcohol, 5 : 1).

Found, %: C 59.23, H 10.24, N 6.78, S 15.49.
$C_{10}H_{21}NOS$.
Calculated, %: C 59.07, H 10.41, N 6.89, S 15.77.

Amino thiols **V**–**XII** were prepared similarly.

3-Allyloxy-2-benzoylthio-1-piperidinopropane hydrochloride XIII. Freshly distilled benzoyl chloride (14 g, 0.1 mol) was added dropwise with cooling to 0–5°C to a solution of 10.7 g (0.05 mol) of 3-allyloxy-1-piperidino-2-propanethiol **VI** in 50 ml of anhydrous diethyl ether. The colorless crystalline precipitate was filtered off, washed several times with anhydrous diethyl ether (total volume 100 ml), and recrystallized from anhydrous acetone. Yield of **XIII** 14.7 g (83%), mp 96–97°C.

Found, %: C 61.27, H 6.42, N 3.68, S 9.27.
$C_{18}H_{21}NO_2S \cdot HCl$.
Calculated, %: C 61.44, H 6.30, N 3.98, S 9.11.

CONCLUSIONS

(1) 3-Allyloxy-1,2-epithiopropane was prepared by the reaction of 3-allyloxy-1,2-epoxypropane with thiourea in the presence of sulfuric acid. This compound was brought into reactions with amines to

obtain *N,N*-disubstituted 3-allyloxy-1-amino-2-propanethiols. The yields were high in all the steps.

(2) The *N,N*-disubstituted 3-allyloxy-1-amino-2-propanethiols prepared exhibit antibacterial and fungicidal activity in lubricating materials.

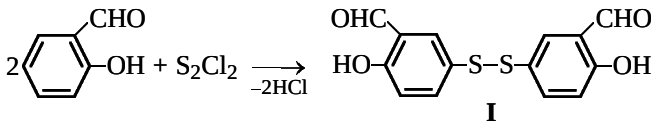
Abstract—Bis(4-hydroxy-3-formylphenyl) and bis[3-alkyl(aryl)iminomethyl-4-hydroxyphenyl] disulfides were prepared. Their reaction with cumylperoxy radicals was studied, and the inhibiting effect on the cumene oxidation was examined.

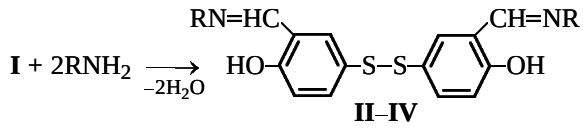
We has show previously [1] that bis[3-alkyl(aryl)-aminomethyl-4-hydroxyphenyl] sulfides effectively inhibit cumene oxidation. Proceeding with studies aimed at preparing various classes of organosulfur compounds and elucidating the mechanism of their inhibiting effect [2–4], we prepared in this work aromatic disulfides with azomethine fragments and evaluated their antioxidative performance in oxidation of cumene.

The starting compound, bis(4-hydroxy-3-formylphenyl) disulfide, was prepared by the reaction of salicylaldehyde with S_2Cl_2 in the presence of zinc as catalyst:



I

Subsequent condensation of **I** with primary aliphatic and aromatic amines gave the corresponding bis[3-alkyl(aryl)iminomethyl-4-hydroxyphenyl] disulfides **II**–**V** in high yields:



II–**IV**

where R = CH_3 (**II**), *tert*-C_4H_9 (**III**), C_6H_5 (**IV**), $C_6H_5CH_2$ (**V**).

The purity of **II**–**V** was checked by thin-layer chromatography, and the composition and structure were confirmed by elemental analysis and by IR and ^1H NMR spectroscopies.

The IR spectrum of **I** contains characteristic absorption bands of the hydroxy group at 3320 cm^{-1}. The IR spectra of **II**–**V** contain azomethine bands at 1639–1640 cm^{-1}, and the hydroxyl band is shifted to 3165 cm^{-1}.

In the ^1H NMR spectra of **II**–**V**, we have not revealed, in contrast to the spectrum of **I**, the broadened signal of the formyl proton (10.37 ppm). The spectra contain proton signals of radicals R at the N atom; the signals of nonequivalent protons of two symmetrically arranged benzene rings give a doublet at 7.0 and 7.4 ppm. The signals of the hydroxyl protons are shifted downfield by 0.4 ppm relative to **I**, giving a doublet at 10.9–11.6 ppm. This may be due to weaker intramolecular hydrogen bonding between the hydroxy group and azomethine nitrogen atom, compared to the carbonyl oxygen atom in **I**.

To evaluate the antioxidative performance of **I**–**V** in elementary steps of inhibition of cumene oxidation, we studied the reactions of these compounds with cumylperoxy radicals (CPR) and cumyl hydroperoxide (CHP).

The capability of disulfides **II**–**V** to terminate oxidation chains in reactions with peroxy radicals was evaluated for the example of cumene oxidation at 60°C, initiated by azobis(isobutyronitrile) (AIBN), in the presence of **II** (Fig. 1).

From the induction period, we calculated the stoichiometric coefficient of inhibition, *f*, equal to the number of oxidation chains terminating in molecule of the inhibitor and its transformation products:

$$f = \tau v_i / [In]_0,$$

where v_1 is the initiation rate (under the examined conditions, $v_1 = 2 \times 10^{-7}$ l mol^{-1} s^{-1}, and $[In]_0$ is the initial inhibitor concentration.

1070-4272/03/7608-1284 $25.00 © 2003 MAIK "Nauka/Interperiodica"

From the kinetics of oxygen uptake, we calculated the rate constants of the reactions of the inhibitors with CPR, k_7 [5, 6]. For this purpose, the kinetic curves of oxygen uptake were transformed from the coordinates $[O_2]$–τ to the coordinates $[O_2]^{-1}$–τ^{-1}:

$$k_7 = \tan\alpha\, k_2[RH]v_i/f[In]_0,$$

where $\tan\alpha$ is the slope of the straight line in the coordinates $[O_2]^{-1}$–τ^{-1}; k_2 = 1.51 l mol^{-1} s^{-1}, rate constant of chain initiation [1, 2]; [RH] = 6.9 M, concentration of the substance subject to oxidation; and v_i, initiation rate (under our conditions, $v_i = 2 \times 10^{-7}$ l mol^{-1} s^{-1}).

The high antioxidative performance of **II**–**V** was also confirmed by experiments on cumene autooxidation at 110°C (Fig. 2), and the kinetic parameters of the reaction were determined (Fig. 2). As seen from Table 1, the parameters f for **II**–**V** vary in the range from 1.8 to 2.4, and the rate constant k_7 of the reaction of inhibitors with peroxy radicals, from 1.92×10^4 to 2.72×10^4 l mol^{-1} s^{-1}. The products of transformations of **II**–**V** in reaction with CPR also show a certain inhibiting effect: The oxidation rate after the induction period is somewhat lower than the rate of uninhibited oxidation (Fig. 1).

We found that all the compounds **I**–**V** actively decompose CHP.

The kinetic curve of CHP decomposition in the presence of **I**–**V** is typical of autocatalytic reactions (Fig. 3). The autocatalytic character of the kinetic curves shows that decomposition of CHP is effected not by compounds **I**–**V** themselves, but by products of their transformation in the first, slow, step of the reaction with CHP.

To determine the reaction order, we studied how the initial rate of catalytic decomposition of CHP depends on the reactant concentrations. We found that the reaction is first-order with respect to both inhibitor and CHP.

To determine the reaction stoichiometry, CHP was taken in excess. The stoichiometric coefficient ν was calculated by the formula

$$\nu = \frac{[ROOH]_0 - [ROOH]_\infty}{[In]_0},$$

where $[ROOH]_0$ and $[ROOH]_\infty$ are, respectively, the initial and final CHP concentrations, and $[In]_0$ is the initial inhibitor concentration.

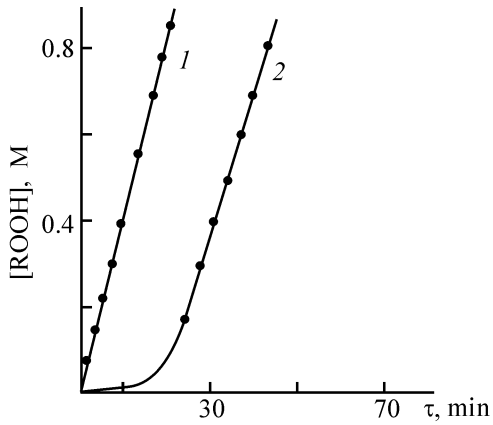


Fig. 1. Variation of CHP concentration [ROOH] with time τ in initiated oxidation of cumene (*1*) in the absence and (*2*) in the presence of **II**. [AIBN] = 2×10^{-2}, [In] = 3×10^{-4} M; 60°C.

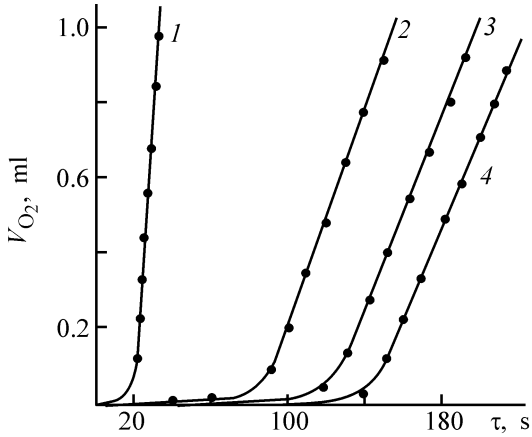

Fig. 2. Volume V_{O_2} of oxygen taken up in autooxidation of cumene at 110°C vs. time τ. Inhibitor added ([In] = 5×10^{-6} M): (*1*) none, (*2*) **II**, (*3*) **III**, and (*4*) **V**.

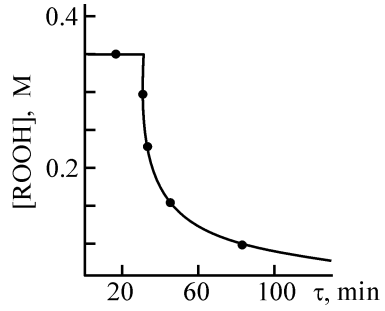

Fig. 3. Variation with time τ of the CHP concentration [ROOH] in the course of decomposition in the presence of inhibitor **I** ([In] = 5×10^{-5} M, 110°C).

As seen from Table 1, one inhibitor molecule (with its transformation products) decomposes more than 10^4 CHP molecules.

Table 1 shows that the coefficient f increases from 1.6 to 1.8–2.4 in going from disulfide **I** to **II**–**V**.

Table 1. Parameters of reactions of **I**–**V** with CPR and those of catalytic decomposition of CHP

Compound	f	$k_7 \times 10^{-4}$, l mol^{-1} s^{-1}	ν	Compound	f	$k_7 \times 10^{-4}$, l mol^{-1} s^{-1}	ν
I	1.6	1.92	18000	**IV**	2.2	2.5	26000
II	2.4	2.72	24000	**V**	2.1	2.4	20000
III	1.8	2.12	38000				

Table 2. Characteristics of compounds **II**–**V**

Compound	Yield, %	mp, °C	Found, %/Calculated, %				Formula
			C	H	S	N	
II	55	144–145	57.42/57.81	5.19/4.85	19.80/19.29	8.91/8.43	$C_{16}H_{16}N_2O_2S_2$
III	60	127–128	63.72/63.44	6.46/6.77	15.79/15.39	7.25/6.73	$C_{22}H_{28}N_2O_2S_2$
IV	75	119–120	68.10/68.41	4.67/4.41	13.60/14.05	6.39/6.14	$C_{26}H_{20}N_2O_2S_2$
V	80	131–132	62.65/69.40	5.15/4.99	13.61/13.23	5.33/5.78	$C_{28}H_{24}N_2O_2S_2$

This may be due to the presence of the N=C bond, which also terminates oxidation chains. A similar trend is observed with the parameter ν. The highest ν, 38000, is exhibited by *tert*-butyl-substituted disulfide **III**.

Table 1 shows that f and k strongly depend on the radical R in **II**–**V**. As compared to the related sulfides (ν = 5680–9000), disulfides **II**–**V** have higher ν, i.e., their inhibiting power is considerably higher; the k_7 and f values are, by contrast, somewhat higher for sulfides [f = 1.36–6.00, k_7 = (1.99–7.96) × 10^{-4} l mol^{-1} s^{-1}] [1].

EXPERIMENTAL

The IR spectra were recorded on a Specord 75-IR spectrophotometer, and the ^{1}H NMR spectra, on a Bruker spectrometer (300 MHz); the chemical shifts (ppm) are given in the δ scale relative to internal TMS.

Cumyl hydroperoxide was purified as described in [7], with the subsequent distillation; chlorobenzene and cumene were purified by a common procedure based on sulfonation of impurities with concentrated sulfuric acid [8, 9]. The CHP concentration was determined by iodometric titration [7] of intermittently taken samples. Experiments on CHP decomposition were performed in chlorobenzene at 110°C in a glass bubbler in an inert gas atmosphere; the CHP concentration was varied within 0.16–0.64 M, and the concentrations of **I**–**V**, within 10^{-5}–5×10^{-3} M.

Experiments on initiated oxidation of cumene were performed on a manometric unit [9]; as initiator served AIBN (initiation rate constant at 60°C 10^{-5} l mol^{-1} s^{-1} [10]). The initiator concentration was 2×10^{-2} M in all the experiments, and the concentration of **I**–**V**, (1–5) × 10^{-4} M.

Bis(4-hydroxy-3-formylphenyl) disulfide I. A solution of 6.7 g (0.05 mol) of S_2Cl_2 in 20 ml of CCl_4 was added with stirring to a solution of 12.2 g (0.1 mol) of salicylaldehyde in 30 ml of absolute CCl_4. The mixture was allowed to stand for 24 h, after which the solvent was distilled off and the residue was triturated with benzene. Yield of disulfide **II** 6.5 g (72%), mp 105°C.

Found, %: C 54.49, H 3.68, S 20.56.
$C_{14}H_{10}O_2S_2$.
Calculated, %: C 54.90, H 3.29, S 20.93.

Bis[3-alkyl(aryl)iminomethyl-4-hydroxyphenyl] disulfides II–**V**. A three-necked 100-ml flask equipped with a stirrer, reflux condenser, and dropping funnel was charged with a solution of 0.05 mol of disulfide **I** in 30 ml of anhydrous CCl_4, and 0.1 mol of appropriate amine was added dropwise over a period of 5 h

with stirring and cooling with ice. Then the mixture was stirred for 5 h at 30–40°C. The reaction product was washed with water and dried over Na_2SO_4; the solvent was distilled off, and the residue was recrystallized. The yields, melting points, and elemental analyses of **II**–**V** are listed in Table 2.

CONCLUSION

Bis(4-hydroxy-3-formylphenyl) disulfide was prepared; its reactions with primary amines gave the corresponding bis[3-alkyl(aryl)iminomethyl-4-hydroxyphenyl] disulfides. These disulfides inhibit cumene oxidation and catalytically decompose cumyl hydroperoxide.

Abstract—The birefringence of thin films of poly(1-trimethylsilylpropyne) with 55 : 45 ratio of units with *trans* and *cis* configurations of the –C=C– bonds was studied by the method of an oblique polarized beam. The surface birefringence coefficients were determined for films of various thicknesses. A theory of birefringence in the surface layers of polymer films was suggested, based on the assumed exponential decrease in the orientation order parameters of the molecular chain fragments with increasing distance from the film surface.

Recent studies suggest that polymers hold much promise for preparation of membranes. The relationships between the permeability coefficients of membranes, on the one hand, and the chemical structure, preparation and treatment conditions, free polymer volume, etc., on the other, have been studied. However, correlations often exhibit deviations inconsistent with the generally accepted views [1–4].

Published data show that studies of polymer membranes pay little attention to the scaling effect, i.e., the difference in the physical properties of polymers in the bulk and surface layers [5, 6]. The influence of the orientation ordering of the molecular chains relative to the surface on the membrane and film permeability has also been studied inadequately.

In this study, we analyzed the structure and properties of the surface layers of poly(1-trimethylsilylpropyne) (PTMSP) films by the method of oblique polarized beam [5–7]. It is known that PTMSP membranes are highly permeable to gas and liquid molecules. However, there are no published data on the factors responsible for the unprecedentedly high permeabilities.

Here, we studied, with the aim to explain these effects, the structure and orientation order of the chain molecules of PTMSP in the surface layers of thin polymer films.

The PTMSP samples were prepared in the presence of $TaCl_5$ catalyst, using an alkylating agent [8]. Polymerization was performed in a glass reactor equipped with a magnetic stirrer under argon atmosphere. All manipulations (drying the monomer and solvent, dosing the catalyst, charging the reactants, and performing the polymerization) were carried under high-purity argon. Powdered tantalum pentachloride (0.1–0.4-g portions) was sealed into glass ampules under argon. The sealed ampules containing the catalyst were kept at $\leq +4°C$. The catalyst was charged by opening the glass ampule. The amount of catalyst was determined as the difference between the weights of the ampule with and without the catalyst. Based on the weighed portion of the catalyst, we calculated the weights of the other components. After charging the catalyst, the solvent was introduced, and the resulting mixture was stirred for 30 min until complete dissolution of the catalyst at the polymerization temperature. Next, the monomer, 1-trimethylsilylpropyne, was added under vigorous stirring, and the resulting mixture was stirred for 24 h. When the polymerization was complete, a sixfold (by volume) excess of methanol was added to the jelly-like reaction mass. The precipitated polymer was washed with straight methanol, dissolved in toluene, and reprecipitated with methanol. The polymer was filtered off on a Schott filter and dried in air for 24 h at room temperature, whereupon the polymer dissolution, reprecipitation, and drying runs were repeated. The resulting polymer was additionally vacuum-dried at room temperature for 8 h to constant weight, and then the polymer yield was determined.

1070-4272/03/7608-1288 $25.00

The chemical structure of the polymer macromolecule was studied by ^{13}C NMR spectroscopy of PTMSP solutions in $CDCl_3$, whose signal served as reference for assigning the chemical shifts of the carbon atoms (the ^{13}C NMR spectra were recorded on a Bruker MSh-300 instrument at 75.47 MHz, with accumulation for 12 h).

According to the ^{13}C NMR data, PTMSP is a random copolymer with 55 : 45 ratio of units with *trans* and *cis* configurations of the –C=C– bonds.

An X-ray diffraction study showed the glassy structure of the sample studied.

The molecular weight of the PTMSP sample was determined by the method of molecular hydrodynamics. The hydrodynamic measurements were carried out in hexane at 25°C (density $\rho_0 = 0.774$ g cm^{-3}, viscosity $\eta_0 = 0.859 \times 10^{-2}$ P), and viscosity measurements of the PTMSP solution, in cyclohexane in an Ostwald viscometer; the solvent flow time was 105 s. The intrinsic viscosity $[\eta] = 1.3 \times 10^3$ cm^3 g^{-1} was determined by extrapolating the experimental η_{sp}/c values to zero concentration.

The forward diffusion coefficient $D_0 = 0.55 \times 10^{-7}$ cm^2 s^{-1} was estimated from the time dependence of the smearing of the diffusion boundary formed by layering of the solution under the solvent in a glass cell. The measurements were carried out at polymer concentrations c of $(3–5) \times 10^{-4}$ g cm^{-3}.

High-speed sedimentation was studied on an MOM-3180 analytical centrifuge in a two-sector cell; an artificial boundary was created. The sedimentation coefficient was determined from the shift of the sedimentation boundary with time. The measurements were carried out in the polymer concentration range $(6–8) \times 10^{-4}$ g cm^{-3}. The sedimentation coefficient $S_0 = 5.6 \times 10^{-13}$ s^{-1} was determined by plotting the concentration dependence of $1/S$.

Using the S_0, D_0, and $[\eta]$ values obtained, we calculated the molecular weight $M_{SD} = 10.5 \times 10^5$ by the Svedberg formula

$$RTS_0/[D_0(1 - \nu\rho_0)].$$

Here, ρ_0 is the solvent density; R, gas constant; $T = 298$ K, absolute temperature; and $(1 - \nu\rho_0) = 0.24$, floatability factor.

To study the birefringence of the PTMSP sample, we produced films with various thicknesses by casting a polymer solution (in toluene and CCl_4) on cellophane, followed by drying to constant weight. The film thickness was determined by the geometric method, with the density taken to be $\rho = 0.82$ g cm^{-3}.

The properties of the surface layers of the polymer films are determined not only by the chemical composition of the surface but also by its physical structure, including the orientation order of the chain molecules near interfaces. As quantitative measure of the orientation order of the molecular fragments relative to the surface serves the orientation order parameter

$$S = \frac{1}{2}\left(3\overline{\cos^2\vartheta} - 1\right). \quad (1)$$

Here, ϑ is the angle between the direction of the chain molecule fragment and the normal to the film surface.

In the case of the lacking predominant orientation of the molecular chains relative to the film surface, $\overline{\cos^2\vartheta} = 1/3$ and $S_0 = 0$. For $S \neq 0$, when the polarized beam passes at an angle i to the film normal, a birefringence arises in the film, with the phase difference between the ordinary and extraordinary beams [5–7] given by

$$\delta = B(1 - \cos 2i). \quad (2)$$

Here, B is the surface birefringence coefficient.

It can be shown that, when S is independent of the film thickness, the surface birefringence coefficient is [7]

$$B = -\frac{\pi N_A \rho}{n\lambda}\frac{a_{\parallel} - a_{\perp}}{M_0}\left(\frac{n^2+2}{3}\right)^2 SH. \quad (3)$$

Here, ρ is the polymer density; n, refractive index; N_A, Avogadro number; λ, wavelength; $(a_{||} - a_{\perp})$, difference between the main polarizabilities of the monomer unit; and M_0, molecular weight of the monomer unit.

It is seen that, in terms of the model of a film characterized by a uniform orientation order, the coefficient B is proportional to the film thickness H. However, in real films, the local value of the orientation order parameter decreases with increasing distance from the surface [6, 9, 10]. It can be shown that this decrease is described by the exponential law [10]

$$S = S_0 \exp(-H/H_0). \quad (4)$$

Here, S_0 is the order parameter near the surface, and H_0, the effective thickness of anisotropic surface layer of the polymer film.

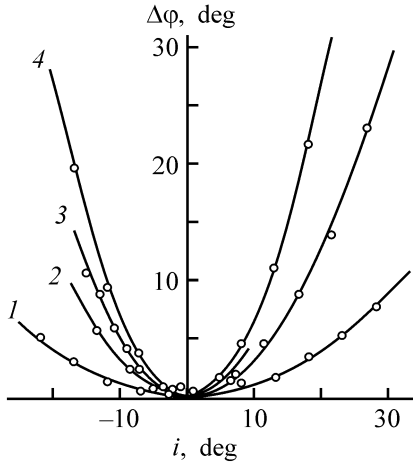

Fig. 1. Variation of φ with the beam incidence angle *i* onto the polymer film surface. Film thickness $H \times 10^3$, cm: (*1*) 0.48, (*2*) 1.55, (*3*) 2.78, and (*4*) 3.28; the same for Fig. 2.

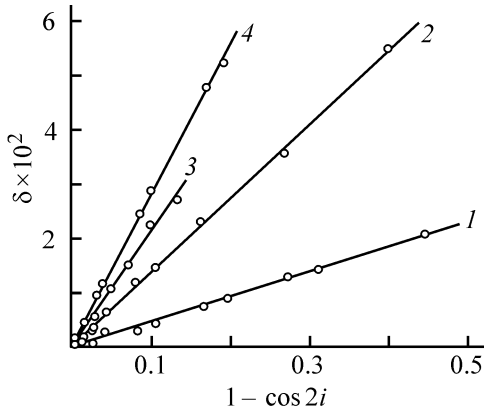

Fig. 2. Variation of the optical phase difference δ with $(1 - \cos 2i)$.

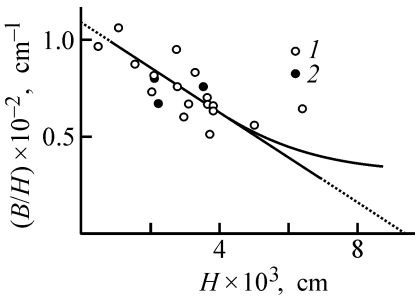

Fig. 3. Variation of the experimental *B*/*H* values with the film thickness *H*. The films were prepared from solutions in (*1*) toluene and (*2*) CCl_4.

In this case, the surface birefringence coefficient is given by [10]

$$B = B_0(1 - \exp(-H/H_0), \qquad (5)$$

where

$$B_0 = -\frac{\pi N_A \rho}{n^3 \lambda} \frac{a_\parallel - a_\perp}{M_0} \left(\frac{n^2 + 2}{3}\right)^2 S_0 H_0. \qquad (6)$$

By expanding the exponent into a series and retaining two terms, we obtain

$$\frac{B}{H} = -\frac{\pi N_A \rho}{n^3 \lambda} \frac{a_\parallel - a_\perp}{M_0} \left(\frac{n^2 + 2}{3}\right)^2 S_0 \left(1 - -\frac{H}{H_0}\right). \qquad (7)$$

Based on formula (7), we can propose a new method for determining the orientation order parameter S_0 near the film surface and the effective thickness H_0 of the anisotropic surface layer from the experimental *B*/*H*-vs.-*H* dependence.

Formula (7) suggests that $S_0 \sim \lim(B/H)$ at $H \to 0$, and $H_0 = 1/2 \lim H$ at $B/H \to 0$.

The birefringence in the PTMSP films was measured using a visual scheme of recording the optical phase difference δ [5, 6]. The film was inserted between crossed polarization prisms. For determining the optical phase difference δ created by the polymer film, we placed the compensator (by rotating the limb) in the position corresponding to equal illuminances of the two halves of the vision field (penumbra asimuth). In this case, $\delta = \delta_0 \sin 2\Delta\varphi$, where $\Delta\varphi = \varphi - \varphi_0$ is the difference in the readings of the compensator at normal incidence of the polarized beam onto the film and at an angle *i*, and $\delta_0 = 0.076$ is the phase difference created by the compensator.

By way of example, Fig. 1 presents typical experimental dependences of Δφ on the angle *i* of beam incidence onto the polymer film surface, and Fig. 2, the dependences of δ on $(1 - \cos 2i)$ for the same films. The latter dependences are described by straight lines; from their slope, we determined the magnitude and sign of the surface birefringence coefficient for each film.

Figure 3 shows how the experimental *B*/*H* values vary with film thickness *H*. With increasing film thickness, *B*/*H* tends to decrease, and the *B*/*H* vs. *H* dependence asymptotically approaches the abscissa axis.

For thin PTMSP films ($H < H_0$), the *B*/*H*-vs.-*H* dependence can be described by a portion of a straight line, in accordance with formula (7). Extrapolation of this plot to $H = 0$ yields $B/H = 1.15 \times 10^2$ cm^{-1}. Using this value, we estimated S_0 by formula (7) at –0.49. Extrapolation of the *B*/*H*-vs.-*H* plot at small *H* values to $B/H \to 0$ gives the effective thickness of the anisotropic surface layer $H_0 = 1/2 \lim H = 4.7 \times 10^{-3}$ cm.

The parameter of the orientation order near the interface of the PTMSP polymer film is characterized by $S_0 = -0.49$, which is close to the analogous value $S = -0.5$ corresponding to ideal planar ordering of the chain molecule fragments relative to the surface.

This is a characteristic feature of the structure of the surface layers formed by rigid-chain polymers at interfaces. The conclusion about enhanced thermodynamic rigidity of the molecules studied is consistent with the results of independent hydrodynamic [11] and optical [12] studies of PTMSP.

Notably, the anisotropic surface layer characterized by high degree of orientation order is very thick. The H_0 thickness exceeds by 4 orders of magnitude the transverse dimensions of the PTMSP molecules.

The negative sign of the orientation order parameter $S_0 = -0.49$ suggests that the fragments of the chain molecules of PTMSP at interfaces are predominantly oriented parallel to the film surface. The revealed characteristics will presumably exert a decisive effect on the structure and permeability of PTMSP membranes.

CONCLUSIONS

(1) The birefringence of films of poly(1-trimethylsilylpropyne) with 55 : 45 ratio of units with *trans* and *cis* configurations of the –C=C– bonds was determined by the method of oblique polarized beam. The fragments of the chain molecules of poly(1-trimethylsilylpropyne) are predominantly oriented parallel to the film surface. The orientation order parameter S_0 was estimated at –0.49, which corresponds to the ideal planar order of the fragments of poly(1-trimethylsilylpropyne) molecules at interfaces.

(2) The effective thickness of the surface layers of thin films of poly(1-trimethylsilylpropyne) H_0 was estimated at 4.7×10^{-3} cm, which exceeds by 4 orders of magnitude the thickness of the chain molecule.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Poly(methyl Methacrylate) Containing Metal Sulfoxide Complexes

G. V. Leplyanin, E. M. Battalov, and Yu. I. Murinov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received January 28, 2003

Abstract—The uniformity, light fastness, heat resistance, radiation hardness, and antistatic properties of poly(methylmethacrylate) prepared in the presence of metal sulfoxide complexes were studied.

Synthesis of polymers, in particular poly(methyl methacrylate) (PMMA) containing metal compounds is of both scientific and practical interest. Introduction of metals substantially broadens the field of polymer application. Kinetic features of MMA polymerization in the presence of sulfoxides and their metal complexes, oxychlorides, and mineral acids were well understood [1]. At the same time, properties of poly(methyl methacrylate) containing various metal sulfoxide complexes have been studied insufficiently.

EXPERIMENTAL

To remove stabilizer, methyl methacrylate was shaken with 10% KOH, washed with water to neutral reaction, dried over calcined calcium chloride, and distilled twice in a vacuum [2]. Poly(methyl methacrylate was prepared from a fraction with bp 42°C (100 mm Hg), d_4^{20} = 0.936, and n_D^{20} = 1.4130.

Azobis(isobutyronitrile) (AIBD) was recrystallized repeatedly from methanol and dried in a vacuum at room temperature to constant weight (mp 103°C, dec.). The initiator was stored at 5°C.

Sulfoxides[1] were recrystallized from hexane. Their purity was monitored by IR spectroscopy and elemental analysis for sulfoxide sulfur (potentiometric titration). The content of the main compound was 98.5–99%. Physicochemical properties of purified sulfoxides agreed well with published data. Petroleum sulfoxides (PSOs) are a mixture of mono-, bi-, and tricyclic, mainly saturated, sulfoxides.

The concentration of paramagnetic centers was determined on an RE-1301 radiospectrometer at liquid nitrogen temperature. The light fastness was estimated by a change in the color intensity of organic glass exposed for 20 h to the light of a PRK-2 lamp at a distance of 14 cm. Antistatic properties were de-

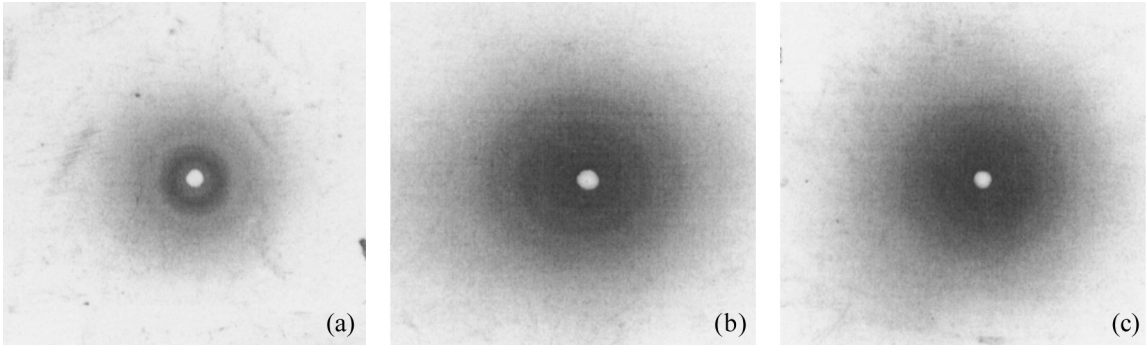

Fig. 1. Debye patterns of organic glass prepared (a) without additives and (b, c) in the presence of 1×10^{-3} M uranyl nitrate complex.

[1] Sulfoxides and their metal complexes were prepared at the laboratory of Physical Chemistry, Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences.

$Th(NO_3)_3$	240	362		

termined by measuring the discharge rate of an electroscope connected to a plate of organic glass containing a radioactive isotope and charged with static electricity. To study thermal oxidative degradation, a sample was heated in air at a rate of 5°C min^{-1} in an MOM derivatograph (Hungary).

The organic glasses prepared in the presence of the metal sulfoxide complexes are X-ray-amorphous. The Debye patterns of the organic glass (a) with no additives and (b, c) containing uranyl nitrate sufoxide complex are shown in Fig. 1. Polymers modified with other metal complexes are also X-ray-amorphous. Hence, the distribution of the metal compounds in PMMA is uniform and the organic glass is optically homogeneous. The physicochemical properties of plates and blocks of organic glass modified with the metal compounds meet the existing requirements to organic glass. However, the softening point of the glass with high content of metal complexes (5–10 wt %) is 5–10°C lower than that of the unstabilized glass, owing to the plasticizing effect of the additive.

Metal sulfoxide complexes turned out to be effective stabilizers of photochemical and thermal oxidative degradation. The degradation temperature in air of a PMMA sample with additive concentration of 2.5–3.0 wt % is 20–50°C higher than that of an unstabilized glass. Data on heat resistance and light fastness of PMMA samples modified with metal complexes are listed in Table 1. It can be seen that, modification of organic glass with metal complexes noticeably increases the service life of these materials.

A study of the radiation hardness of the organic glasses modified with the metal complexes showed that the number of paramagnetic centers in the polymer decreases at high radiation doses (Fig. 2).

Good dielectric properties of most of plastics favor ectrostatic charging of their surface. To decrease static electrization of polymers, antistatic agents are introduced into the bulk of these materials or applied on their surface. Conducting materials, film-forming compounds, and surfactants are used as these agents.

However, introduction of antistatic agents strongly deteriorates the physicochemical properties, in particular, dielectric properties, of the polymers. Introduction of antistatic agents in the course of polymerization substantially deteriorates the most important properties of polymers, such as high electrical resistance, moisture and weather resistance, and transparency. The optical properties of optically homogeneous organic glasses are most strongly affected by antistatic agents. As a result, only a few compounds are used as antistatic additives to polymers. Among them are substances based on soaps, sulfonated organic compounds (cyclohexylammonium dodecyl sulfate), and alkylammonium salts of organic and mineral acids (e.g., triethanolammonium phenylcarboxylates). The use of phosphates as antistatic agents has also been reported.

Polymers with antistatic properties can be prepared by polymerization of MMA in the presence of sulfoxide complexes of salts of radioactive metals. The concentration of radioactive compounds has no effect on the physicochemical properties of an organic glass and should be at the level providing safe handling of polymeric articles. Salts of α- and β-emitters, e.g., uranium, thorium, plutonium, zinc, cobalt, etc., can be used for this purpose.

Introduction of radioactive compounds into PMMA provides fast electrostatic leakage from the polymer surface owing to external and internal ionization, which is confirmed by electrization experiments.

We took the rate of electroscope discharge as a measure of ionization. A plate of organic glass charged with a definite quantity of static electricity by friction against a cloth was connected to the contact of an electroscope. The rate of electroscope discharge was proportional to the rate of charge leakage from the polymeric plate. The measurements were performed at 60% relative humidity of air and 18–21°C (Table 2). As seen from Table 2, introduction of metal complexes

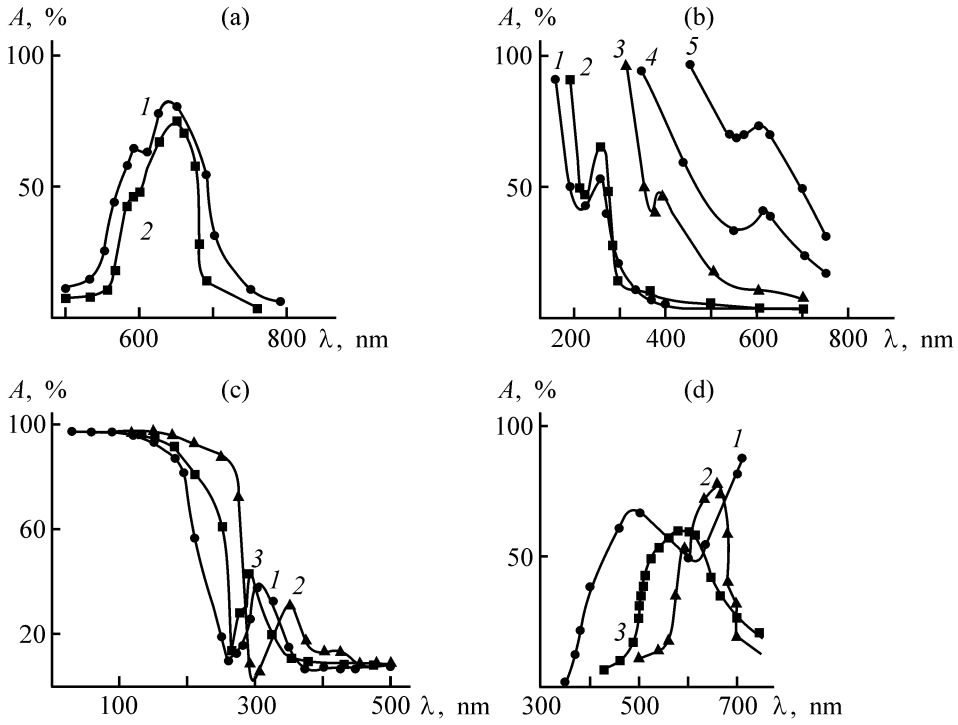

Fig. 3. Transmission spectra of PMMA containing metal sulfoxide complexes: (*A*) transmission and (λ) wavelength. (a) (*1*) MMA + $CoCl_2 \cdot 2PSO$, (*2*) PMMA + $CoCl_2 \cdot 2PSO$ (8.0×10^{-3} M); (b) PMMA + additive ($3.0 \cdot 10^{-2}$ M): (*1*) $Tb(NO_3)_4 \times 3DPSO$, (*2*) $Dy(NO_3)_3 \cdot 3PSO$, (*3*) $TeCl_4 \cdot 2PSO$, (*4*) $ZrOCl_2 \cdot 2PSO$, and (*5*) $CdCl_2 \cdot 2PCO$; (c) (*1*) $CuCl_2 \times 2DPSO$, (*2*) $CuCl_2 \times 2DCPSO$, and (*3*) $CuCl_2 \cdot 2DBSO$; (d) (*1*) $Cu(NO_3)_2 \cdot 2PSO$, (*2*) $CoCl_2 \cdot 2PSO$, and (*3*) $CoCl_2 \cdot 2PSO$ + $Co(NO_3)_2 \cdot PSO$ (8.0×10^{-2} M).

slightly decreases the surface and bulk resistivity of the organic glass. Only the bulk resistivity is proportional to the additive concentration. The rate of electrostatic leakage is proportional to the concentration of radioactive element in a sample.

The proposed metal complexes can be used as effective antistatic agents for preparing optically homogeneous transparent organic glasses with good antistatic properties and high softening points. Clearly, these glasses should be used under conditions excluding prolonged contact with human body).

The electronic spectra of polymers modified with the metal complexes are similar to those of the same complexes in the initial monomer, which indicates stability of these complexes to peroxide initiators. The transmission spectra of PMMA samples containing some of these complexes are shown in Fig. 3. The transmission depends on the nature of metal and sulfoxide. It should be noted that most of metal sulfoxide complexes are readily soluble in MMA and negligibly affect MMA polymerization.

CONCLUSION

Colored organic glasses containing metal sulfoxide complexes are transparent and resistant to heat, light, and radiation; they exhibit good antistatic properties meeting the existing requirements. Introduction of these additive does not affect the process of organic glass production.

Received April 1, 2003

Abstract—Hydrolysis of 2-hydroxyethyl methacrylate in aqueous solutions, as influenced by pH, temperature, and substrate concentration, was studied. In concentrated solutions, the monomer forms associates, which promotes its hydrolysis.

(Co)polymers derived from 2-hydroxyethyl methacrylate (HEM) are used in production of coatings, adhesives, membranes, and eye contact lenses thanks to such valuable properties as nontoxicity, biocompatibility, transparency, etc. In some cases, these (co)polymers are prepared in aqueous solutions at various pH values [1]. It is known that amino-containing analogs of HEM, in particular, *N*,*N*-dimethylaminoethyl methacrylate (DMAEM), are prone to hydrolysis, especially in alkaline solutions. Studies of hydrolysis of such compounds revealed some specific features [2–4]. Lavrov *et al.* [5] showed that polymers derived from HEM also undergo base hydrolysis at elevated temperatures.

In this study, we examined the influence of pH, temperature, and concentration of HEM on its hydrolysis. We found that the monomer is hydrolytically stable in neutral solutions in a broad range of concentrations (10–90%) and temperatures (20–90°C). In acidic or alkaline solutions, HEM undergoes gradual hydrolysis to methacrylic acid and ethylene glycol:

$$CH_2{=}C(CH_3)COOCH_2CH_2OH + H_2O \rightarrow CH_2{=}C(CH_3)COOH + HOCH_2CH_2OH.$$

Accumulation of methacrylic acid alters the pH of the medium, which affects the hydrolysis rate. In base hydrolysis, the catalyst concentration decreases in the course of the process, and in acid hydrolysis it grows.

In alkaline solutions, hydrolysis is very fast even at room temperature in both dilute and concentrated HEM solutions. For example, at the initial monomer content of 20 or 80 wt % (20°C), the solution becomes neutral within several minutes after adding NaOH (0.4–1.0 mg-equiv g^{-1}), and the maximal degree of hydrolysis corresponds to the amount of the initially added alkali.

In acidic solutions, the pattern is quite different: The reaction is considerably slower, and its rate depends on temperature and on the concentrations of the monomer and catalyst. Figure 1 shows the characteristic kinetic curves illustrating how the HEM concentra-

tion varies in the course of acid hydrolyhsis. Figure 2a illustrates the influence of the catalyst (H_2SO_4) concentration on the initial hydrolysis rate v_0. As expected, v_0 is a linear function of the acid concentration, and the reaction order with respect to acid is close to unity. Figure 2b illustrates the temperature dependence of the initial reaction rate. The slope of the straight line in Fig. 2b corresponds to an activation energy of 65.14 ± 1.54 kJ mol^{-1}.

An increase in the initial monomer content results in a noticeable acceleration of the acid hydrolysis (Fig. 2c). It is interesting to compare the concentration dependences of the hydrolysis rates for the hydroxyl- and amino-substituted methacrylic acid esters: HEM and DMAEM. These monomers differ only in the kind of acceptor substituents in the alcoholic moiety. The inductive constants σ^* of the –OH and $-N^+H(CH_3)_2$ groups are 1.60 and 4.38, respectively [6, 7]. Therefore, it could be expected that acid hydrolysis of protonated DMAEM would be faster than that of HEM. However, actually in moderately concentrated solutions at equal molar concentrations of the monomers and equal acidity, hydrolysis of HEM was considerably faster. For example, at 80°C, free acid concentration of 0.4 mg-equiv g^{-1}, and DMAEM · $0.5H_2SO_4$ concentration of 1.5 mg-equiv g^{-1}, there was no appreciable hydrolysis in 4 h, whereas the degree of hydrolysis of HEM under the same conditions was 30% (Fig. 1, curves *4*, *6*). Furthermore, previous studies of DMAEM hydrolysis [4] have shown that, as the amino ester concentration is increased, the hydrolysis rate in both acidic and alkaline solutions decreases. In acidic aqueous solutions of HEM, the hydrolysis, by contrast, accelerates with increasing HEM concentration, with an inflection observed in the concentration dependence of the initial hydrolysis rate at a conte4nt of approximately 40% (Fig. 2c).

Analysis of the viscosity–concentration relationship for DMAEM [4] revealed association of the monomer in concentrated solutions. To evaluate the tendency for HEM to associate, we examined the concentration dependence of the viscosity of its aqueous solutions (Fig. 3). The nonlinear growth of the viscosity with concentration suggests association of the monomeric molecules, and inflections observed in some cases are apparently due to rearrangements of the associates. In acidic solutions, the ester shows a stronger tendency toward association. It should be noted that, under similar conditions of hydrolysis and viscosity measurements (80°C, $[H^+]$ = 0.4 mg-equiv g^{-1}), the concentration at which the hydrolysis sharply accelerates corresponds to one of the two inflections in the concentra-

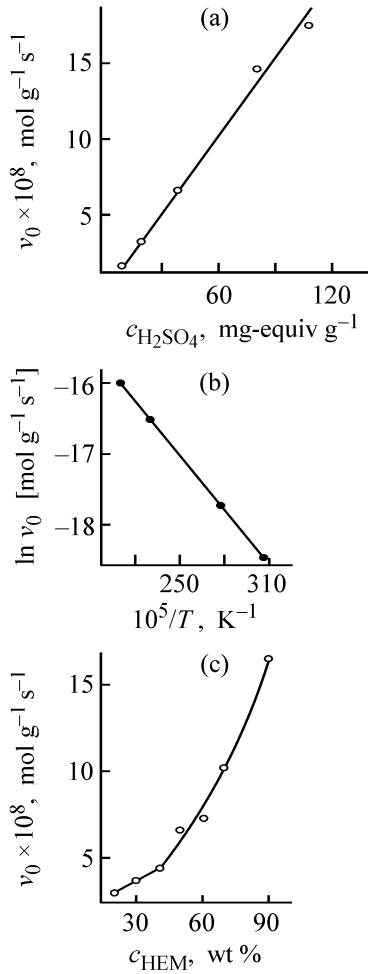

Fig. 2. Influence of the (a) H_2SO_4 concentration $c_{H_2SO_4}$, (b) temperature T, and (c) HEM content c_{HEM} on the initial rate of HEM hydrolysis v_0. (a) $[HEM]_0$ = 50 wt %, 80°C; (b) $[HEM]_0$ = 50 wt %, $[H^+]$ = 0.4 mg-equiv g^{-1}; and (c) $[H^+]$ = 0.4 mg-equiv g^{-1}, 80°C.

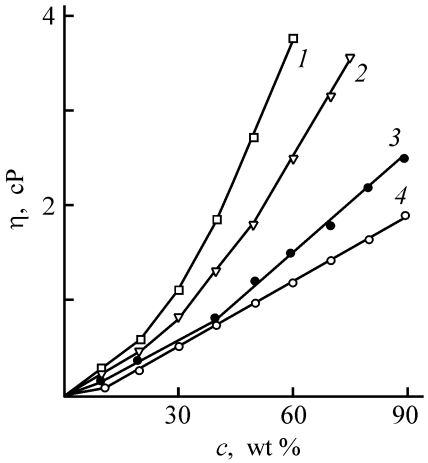

Fig. 3. Viscosity η of aqueous solutions of HEM vs. the monomer content c at various acidities. (*1*, *3*) $[H^+]$ = 0.4 mg-equiv g^{-1} and (*3*, *4*) no acid added. T, °C: (*1*, *2*) 25 and (*3*, *4*) 80.

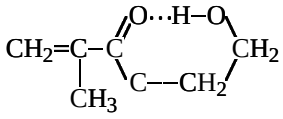
tion dependence of the viscosity (Fig. 2c; Fig. 3, curve *3*). Thus, our results suggest that, similarly to DMAEM, the specific features of HEM hydrolysis are related to association of the monomer. In associates of DMAEM and its salts, charged and fairly bulky ammonium groups hinder access to the ester reaction center, and association decreases the hydrolysis rate. In electrically neutral HEM containing hydrophilic OH groups, the associates of the monomer must be less hydrophobic and must incorporate more water molecules. Presumably, packing of HEM and water molecules in the associates leads to higher accessibility of the carbonyl carbon atom as compared to dilute HEM solutions in which HEM, apparently, has a cyclic structure with an intramolecular hydrogen bond:



EXPERIMENTAL

The hydrolytic stability of HEM was studied at 20–90°C and monomer content of 10–90 wt %. Radical polymerization was prevented by adding hydroquinone (0.5 wt % relative to the monomer). The reaction course was monitored by alkalimetric titration and gas–liquid chromatography. The content of C=C bonds was determined by bromide–bromate titration. Gas–liquid chromatography was performed on a Tsvet-100 chromatograph equipped with a flame-ionization detector; a 1000×3-mm stainless steel column was packed with Chromaton N-AW + 8% dioctyl sebacate; the carrier gas was N_2 (flow rate 2×10^{-3} $m^3 h^{-1}$); the vaporizer temperature was 180°C, and the column temperature, 120°C. The viscosity of aqueous solutions of monomers was measured with an Ubbelohde viscometer (d_c 0.56 and 0.34 mm) at 25 and 80°C.

CONCLUSIONS

(1) Hydrolysis of 2-hydroxyethyl methacrylate in alkaline solutions is very fast at both low and high concentrations of the monomer.

(2) Acid hydrolysis of 2-hydroxyethyl methacrylate is considerably slower, and its rate grows with increasing temperature and monomer and acid concentrations.

(3) Viscosity–concentration dependences for aqueous solutions of 2-hydroxyethyl methacrylate suggest association of the monomeric molecules. Sharp acceleration of the hydrolysis in concentrated acidic solutions is presumably due to association.

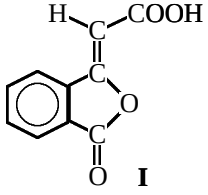
Abstract—Procedures were developed for preparing unsaturated phthalides: phthalideneacetic acid and methylene phthalide, which are promising monomers for radical polymerization. The structures of the monomers were studied, and their copolymerization with methyl methacrylate was performed.

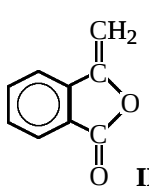
Much attention is given today to polymeric materials whose components change the structure and physicochemical properties, depending on external conditions (pressure, temperature, acidity of the medium, etc.). Of particular interest in this respect are phthalides showing ring–chain isomerism [1]. Phthalide-containing polymers exhibit unique electrical [2] and optical [3] properties, high heat resistance, and high softening points [4]. These polymers are most often prepared by polycondensation. However, their high heat resistance is combined with high glass transition and flow points, and also with poor solubility in the majority of industrially used organic solvents.

In contrast to phthalide-containing polymers, many vinyl polymers, in particular, polyacrylates have low glass transition and flow points and good solubility, but poor heat resistance. These polymers are most often prepared by radical polymerization. Therefore, it seems appropriate to modify vinyl polymers, such as poly(meth)acrylates, polystyrene, etc., with phthalides, and development of procedures allowing modification in the stage of synthesis is an urgent problem.

Phthalides can be incorporated into a polymeric molecule in the course of radical polymerization both via their involvement in chain initiation or transfer [3] and through (co)polymerization of unsaturated phthalides. With the aim to prepare poly(methyl methacrylate) modified with phthalide-containing compounds, we prepared two phthalide-containing monomers: phthalideneacetic acid **I** and methylene phthalide **II**:



I



II

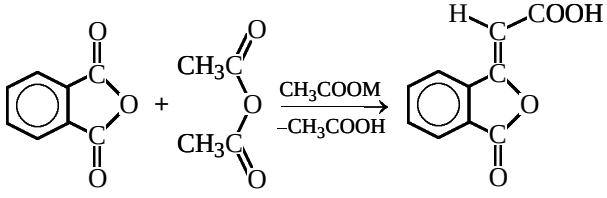
The monomeric purity is the necessary condition for their application.

EXPERIMENTAL

Phthalic anhydride was recrystallized from absolute ethanol before use; mp 239°C. Acetic anhydride was distilled; bp 140°C. The polymerization initiators, azobis(isobutyronitrile) (AIBN) and benzoyl peroxide (BP), were repeatedly recrystallized from methanol and vacuum-dried to constant weight.

Methyl methacrylate (MMA) was purified to remove the stabilizer by shaking with 5–10% KOH, washed with water to neutral reaction, dried over $CaCl_2$, and double-distilled in a vacuum. The fraction with bp 42°C (13.3 kPa) was used for polymerization.

Phthalideneacetic acid. Published data on synthesis of **I** and **II** are contradictory. Phthalideneacetic acid was prepared for the first time at the end of the XIX century [5–8], but its properties have been studied poorly. In this study, we prepared **I** by the Perkin–Gabriel reaction from phthalic and acetic anhydrides in the presence of a metal acetate:



The reaction was performed in several steps. First, a flask was charged with phthalic anhydride (2–3% excess relative to the reaction stoichiometry), acetic anhydride, and potassium acetate (20–30% excess relative to phthalic anhydride). The mixture was heated for 1.5 h on a boiling water bath. Then a tenfold vol-

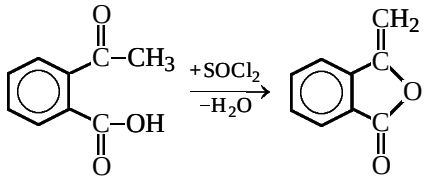
ume of hot water was added, and the hot mixture was filtered. The precipitate was washed with hot water and ethanol. A light brown product was obtained; it was washed with a small amount of hot glacial acetic acid. After cooling and filtration, a yellow substance was obtained; its melting point, 249°C, is reasonably consistent with published data [6, 7]. The product was repeatedly recrystallized from glacial acetic acid in the presence of activated carbon. Colorless lustrous plates were obtained; mp 280°C (with decomposition). Further recrystallizations did not increase the melting point. The product was identified by IR, ^{13}C NMR, and ^1H NMR spectroscopy and by elemental analysis (Table 1).

Methylene phthalide. Synthesis of methylene phthalide and its polymers has been attempted by numerous researchers. However, either the suggested procedures gave the monomer in low yield (10–15%) or the product was unsuitable for polymerization because of the presence of inhibiting impurities.

In this study, to prepare and purify methylene phthalide, we chose the procedure described in [9]. It involved high-vacuum dehydration of acetophenone-*o*-carboxylic acid:



The product sublimes and is condensed as colorless needles, mp 56°C (yield about 60%); it is hygroscopic and sublimes in a vacuum at about 300°C (1–5 mm Hg). Some characteristics of **II** are listed in Table 1.

The kinetics of bulk polymerization was monitored gravimetrically [10]. The temperature was maintained at 60 ± 0.5°C. The composition was calculated from the analytical data.

The UV spectra (solutions in CH_3COOH) were recorded on a Shimadzu UV–VIS–NIR 3100 spectrometer using a 1-cm quartz cell. The IR spectra (mulls in mineral oil) were recorded on a Specord M-80 spectrophotometer (Germany). The ^1H and ^{13}C NMR spectra were taken on a Bruker AM-400 spectrometer (300 MHz, CD_3OD, internal reference hexamethyldisiloxane).

The temperature of the decomposition onset was determined by the method of tangents with an MOM Q-1500D derivatograph (Hungary); sample weight 100 mg, heating rate 5 deg min^{-1}.

The probabilities of addition of propagating radicals with different structures of terminal units to comonomer molecules were calculated as described in [10].

The overwhelming majority of studies concerned phthalideneacetic acid are limited to its synthesis. In most cases, the acid was immediately subjected to thermal decarboxylation in a vacuum to obtain methylene phthalide [7, 8]. The properties and structure of the acid remained unknown, like those of methylene phthalide. Therefore, we first examined the structures of these compounds.

The ^1H NMR spectrum of **II** (Table 1) shows that the methylene hydrogen atoms (α-position relative to the phthalide ring) are nonequivalent (*cis* and *trans* arrangement relative to the oxygen atom of the phthalide ring).

In the case of phthalideneacetic acid, two isomers with the *cis* and *trans* arrangement of the carboxy group relative to the oxygen atom of the phthalide ring are possible. The nuclear Overhauser effect (η = 8%) observed on the aromatic proton (8.28 ppm, 3-position) upon irradiation at the frequency of the olefinic proton signal (6.32 ppm) unambiguously suggests steric proximity of these protons, i.e., the *cis* structure of the product. In other words, the synthesized phthalideneacetic acid is a pure *cis* isomer. Furthermore, the chemical shift of the carboxyl proton signal is unusually small, which may be due to interaction of this proton with the oxygen atom of the phthalide ring. Unfortunately, we failed to follow the changes in the chemical shift of this signal depending on the solvent polarity because of extremely low solubility of **I** in other solvents. However, the chemical shift varies with temperature: 25°C, 4.00 ppm; 30°C, 4.72 ppm; and 40°C, 5.73 ppm. This indicates that the intramolecular hydrogen bond in the acid molecule becomes weaker.

Table 3. Characteristics of copolymerization of MMA with unsaturated phthalides at 70°C [initiator azobis(isobutyronitrile), 0.5 wt %] and decomposition (onset) temperatures of the copolymers

90	0.0704	77.7	240

The molecular geometry of **I** and **II** was optimized by PM3 calculations. The results (Table 2) show that the oxygen atom deviates from the ring plane by approximately 2°; the bond angle at the ring oxygen atom is 108°, and the C–O bond length, 1.44 Å. An important result is that the phthalideneacetic acid molecule, in contrast to the methylene phthalide molecule, has functional groups that extend from the molecular plane; this must affect the electrical properties of **I** at elevated pressures and temperatures.

Unfortunately, we failed to prepare the homopolymer of phthalideneacetic acid by radical polymerization. However, we obtained copolymers of **I** with MMA. Some data on the reaction and copolymer compositions are listed in Table 3. It is seen that the copolymerization rate decreases with increasing content of **I** in the reaction mixture. This may be due to the fact that the purity of **I** is insufficient for radical polymerization. Therefore, we additionally performed repeated chromatographic purification of the mono-

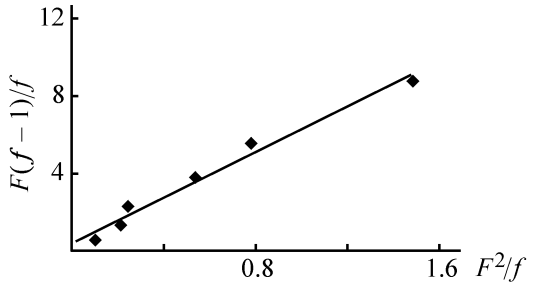

Fig. 1. Determination of the constants of MMA copolymerization with phthalideneacetic acid by the Fineman–Ross method.

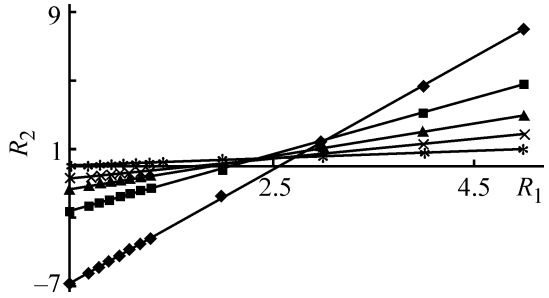

Fig. 4. Determination of the constants of MMA copolymerization with methylene phthalide by the Mayo–Lewis method.

mer. A certain increase in the copolymerization rate was, indeed, observed but attempted preparation of the homopolymer failed.

The constants of copolymerization of MMA with **I** were determined by the Fineman–Ross method [10] (Fig. 1) to be 0.36 ± 0.06 and 5.80 ± 0.08, respectively. Calculation of the probabilities of monomer addition to propagating radicals of various structures shows (Fig. 2) that incorporation of MMA into the chain is much more probable than incorporation of **I**.

At the same time, the copolymerization constants show that the monomers interact with each other (the product of the constants is significantly greater than unity), probably owing to their high polarity. Using the *Q*–*e* scheme, we calculated the parameters $e = 1.26$ (parameter characterizing the polarity of **I**) and $Q = 0.79$ (parameter characterizing the conjugation in the propagating radical with the radical center localized in the phthalideneacetic acid unit) [10]. Phthalideneacetic acid is close to MMA in the value of *Q* ($Q_{\mathrm{MMA}} = 0.74$) but significantly exceeds it in polarity ($e_{\mathrm{MMA}} = 0.40$), being in this respect close to acetonitrile ($e = 1.20$).

In contrast to phthalideneacetic acid **I**, methylene phthalide polymerizes in the presence of radical initiators, such as BP or AIBN. The reaction was performed in DMF in the presence of 3.7×10^{-3} M BP. The polymerization noticeably accelerated after reaching 30% conversion of the monomer (gel effect), suggesting the radical mechanism of the reaction. The polymer was precipitated with acetone and reprecipitated several times. Dry poly(methylene phthalide) has a high glass transition point (305°C), and its softening is accompanied by decomposition (as indicated by significant weight loss). We failed to prepare films from this polymer (under conditions similar to those used with other polymers) for studying electrical properties; therefore, it seems necessary to prepare copolymers of **II**, primarily with MMA.

A study of copolymerization of MMA with **II** showed that, with increasing content of **II**, the process decelerates but does not fully stop (Table 3), which allows preparation of the copolymer with different monomer ratios. Figure 3 shows that the copolymer is enriched in MMA units at any composition of the monomer mixture, and the ratio of the copolymerization constants meets the condition $r_1 > 1$ and $r_2 < 1$.

The copolymerization constants were determined by the Mayo–Lewis method [10] (Fig. 4) to be 2.69 ± 0.05 (for MMA) and 0.70 ± 0.07 (for **II**). In this case, too, the product of the copolymerization constants is

greater than unity, suggesting mutual interaction of the monomers; however, it is apparently weaker than that with **I**.

Methylene phthalide is characterized by $Q = 1.35$ and $e = +1.20$. It is somewhat more polar than **I**, but its growing radical is more active in chain propagation.

As expected, the copolymers show higher heat resistance, compared to poly(methyl methacrylate) (Table 3). However, with increasing content of phthalideneacetic acid, the decomposition onset temperature starts to decrease, probably owing to decarboxylation.

CONCLUSIONS

(1) Procedures were developed for synthesis and purification of phthalideneacetic acid and methylene phthalide, promising monomers for radical polymerization.

(2) The structures of the phthalides were studied; phthalideneacetic acid has the *cis* structure.

(3) (Co)polymerization of unsaturated phthalides with methyl methacrylate was performed; the copolymerization constants and *Q*–*e* parameters were calculated; the activity of **I** and **II** as monomers was evaluated.

(4) The methyl methacrylate copolymers obtained show enhanced heat resistance.

ACKNOWLEDGMENTS

The authors are grateful to S.N. Salazkin (Nesmeyanov Institute of Organometallic Compounds, Russian Academy of Sciences, Moscow) for valuable advices.

The study was supported financially by the Russian Foundation for Basic Research (project no. 98-03-33 322).

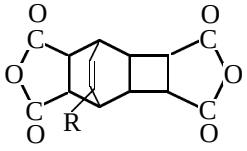
Abstract—*p*-Xylylenediamine was prepared by hydrogenation of terephthalodinitrile; the conditions ensuring high yield of this monomer were found. The influence exerted by the catalyst and solvent on the diamine yield was examined. Single-step polycondensation of *p*-xylylenediamine with tricyclodecenetetracarboxylic dianhydrides in the presence of catalytic amounts of isonicotinic acid gave a series of new polyimides consisting of aliphatic and aromatic fragments.

Polyalkanimides show promise as materials for electrical and radio engineering [1, 2]. The interest in these polymers is not occasional. Occupying an intermediate position between aromatic and aliphatic derivatives, they combine the advantages of both. Introduction of methylene units into the backbone decreases the melting point, enhances the resistance to hydrolysis, and imparts to the polymers other valuable properties allowing their processing with commercially available equipment [2].

A series of polyalkanimides (PAIs) derived from pyromellitic dianhydride and aliphatic diamines (deca- and dodecamethylenediamines, and also their mixtures) have been prepared; these materials shown long service life at temperatures of up to 200°C [2, 3]. At the same time, PAIs can also be prepared from *p*-xylylenediamine (*p*-XDA) and other anhydrides.

In this study, we prepared dianhydrides of cyclodecenetetracarboxylic acids: tricyclo[4.2.2.$0^{2,5}$]dec-7-ene-3,4,9,10-tetracarboxylic dianhydride (product of photochemical addition of maleic anhydride to benzene, AB) and its 7-fluoro (AFB) and 7-chloro (ACB) derivatives, which are starting compounds for preparing a wide set of heat-resistant polymers, including polyimides [4, 5]:



where R = H (AB), F (AFB), Cl (ACB).

It is known that the prospects for application of polymeric materials are determined by numerous factors, with the availability of the starting monomers being of major importance. We have developed a procedure for preparing *p*-XDA in quantitative yield, which allowed us to begin studies of synthesis of new PAIs derived from *p*-XDA and alicyclic dianhydrides.

Here we report the features of synthesis of *p*-XDA and polyimides derived from it.

EXPERIMENTAL

The starting compounds and solvents were purified by common procedures. The IR spectra were recorded on a Specord IR-25 spectrometer. The monomer samples were prepared as KBr pellets, and the polymer samples, as 3–5-μm films. The reduced viscosities of 0.5% solutions of polyimides were measured with an Ubbelohde viscometer at 25°C in DMSO. The TG and DTA curves were recorded simultaneously on an MOM derivatograph (Hungary) at a heating rate of 8 deg min^{-1}. From the TG curves, we calculated the temperatures of the onset of weight loss and of 5, 10, and 50% weight loss (T_0, T_5, T_{10}, and T_{50}, respectively).

The physicomechanical (tensile strength σ, relative elongation *l*) and dielectric (dielectric loss tangent tan δ, relative dielectric permittivity ε') characteristics were studied under standard conditions by published procedures [6, 7].

p-Xylylenediamine was prepared by catalytic reduction of terephthalodinitrile (TDN)[1] in a high-pressure kinetic unit [8] allowing monitoring of the hydrogen uptake in unit time [9]. As catalysts we used promoted catalytic alloys whose base component was Raney nickel; the catalysts were prepared by leaching of the corresponding alloys with Ni : Al ≈ 1 : 1. A 0.5-l long-necked stainless steel vessel was shaken at a frequency of 600–700 one-side rockings per minute. A 0.5-g portion of the catalyst was loaded under the layer of the solvent (50 ml of methanol preliminarily saturated with ammonia under cooling; nitrile : ammonia ratio 1 : 3). Then 1.43 g of TDN was added. Hydrogenation was performed until the H_2 uptake stopped.

p-XDA was identified by elemental analysis, melting point, and IR spectra.

Found, %: C 70.26, H 8.84, N 19.92.
$C_8H_{12}N_2$.
Calculated, %: C 70.60, H 8.09, N 20.57.

IR spectrum, ν, cm^{-1}: 1500 (benzene ring); 1670, 3420 (–NH_2 groups); 2920 (–CH in –CH_2 group); mp 34.5–35°C (published data [8]: 35°C).

AB, AFB, and ACB were prepared by published procedures [10, 11] and purified by three- or fourfold 1.5–2.0-h treatment with hot acetone under stirring. The precipitate of the monomers was filtered off and vacuum-dried in an oven to constant weight at 80–90°C.

AB: equivalent weight 68.5 (calculated 68.5), mp 250–252°C; AFB: equivalent weight 73.04 (calculated 73.04), mp 312–314°C; ACB: equivalent weight 77.12 (calculated 77.12), mp 302–304°C. The elemental analyses were consistent; the melting points agreed with published data [10, 11]. The solvents [dimethylformamide, DMF; dimethylacetamide, DMA; *N*-methyl-2-pyrrolidone, MP; dimethyl sulfoxide, DMSO] were dried over 4-Å molecular sieves.

The polyimide derived from AB and *p*-xylylenediamine was prepared as follows. A three-necked flask equipped with a stirrer and an inlet tube for inert gas was charged with 13.71 g (0.05 mol) of AB, 5.20 g (0.05 mol) of *p*-XDA, 0.09 g (5 wt % relative to the sum of the monomers) of isonicotinic acid, and 56.9 ml of DMA. The mixture was heated on an oil bath (50°C) for 15 min with stirring, after which the temperature was raised to 110°C over a period of 20 min, and the mixture was stirred for additional 2 h. After cooling to room temperature, the polyimide was precipitated with chemically pure acetone, and the precipitate was washed with two portions of acetone and vacuum-dried in an oven at 80–90°C to constant weight.

Table 1. Conditions of TDN hydrogenation on Raney nickel catalysts (H_2 pressure 4.0 MPa; 60°C)

Composition of starting alloy before leaching (weight ratio)	τ, min	*p*-XDA yield, wt %
Ni : Al = 50 : 50	140	73–75
Ni : Ti : Al commercial (TU*-59-83–75), prescribed content: Al, 50–53.5; Ni, 44–46.5; Ti, 2.2–2.8	50	90–92
N-5 catalyst		
Ni : M : Al:		
47.5 : 2.5 : 50.0	41	94–95
45.0 : 5.0 : 50.0	32	97–98

* Technical Specifications.

Table 2. Conditions of TDN hydrogenation in various solvents (H_2 pressure 4.0 MPa; 60°C)

Solvent (saturated with NH_3)	Ni–Ti catalyst (~3% Ti)		N-5 catalyst	
	τ, min	*p*-XDA yield, wt %	τ, min	*p*-XDA yield, wt %
Methanol	50	90–92	32	97–98
Ethanol	62	89–91	41	96–97
Propanol	69	90–91	48	96–97
Butanol	71	90–91	53	96–97

The elemental composition of the precipitated polymer corresponds to the theoretical value. Polyimide films were prepared by casting 25% solutions of the polyimides in DMA on glass plates. To remove the solvent, the films were predried by vacuum heating in an oven at 80°C for 0.3 h, after which they were heated to constant weight at 150°C for 1 h.

Polyimides derived from *p*-XDA and halogenated dianhydrides were prepared similarly. Yield 98.5–99.0%, degree of imidization about 100%.

Catalytic hydrogenation of nitriles involves a set of parallel-consecutive reactions [8, 12–14]. The reduction of TDN was performed on the catalysts listed in Table 1. The results are given in Tables 1 and 2.

[1] Terephthalodinitrile was kindly submitted by P.B. Vorob'ev and L.F. Gabdullina (Bekturov Institute of Chemical Sciences, Ministry of Education and Science of the Republic of Kazakhstan).

Table 1 shows that Ni–Ti and N-5 catalysts are more active, compared to straight Raney nickel. The yield of the target product is 90–92% on Ni–Ti and as high as 97–98% on N-5. Therefore, the subsequent experiments were performed with N-5 catalyst.

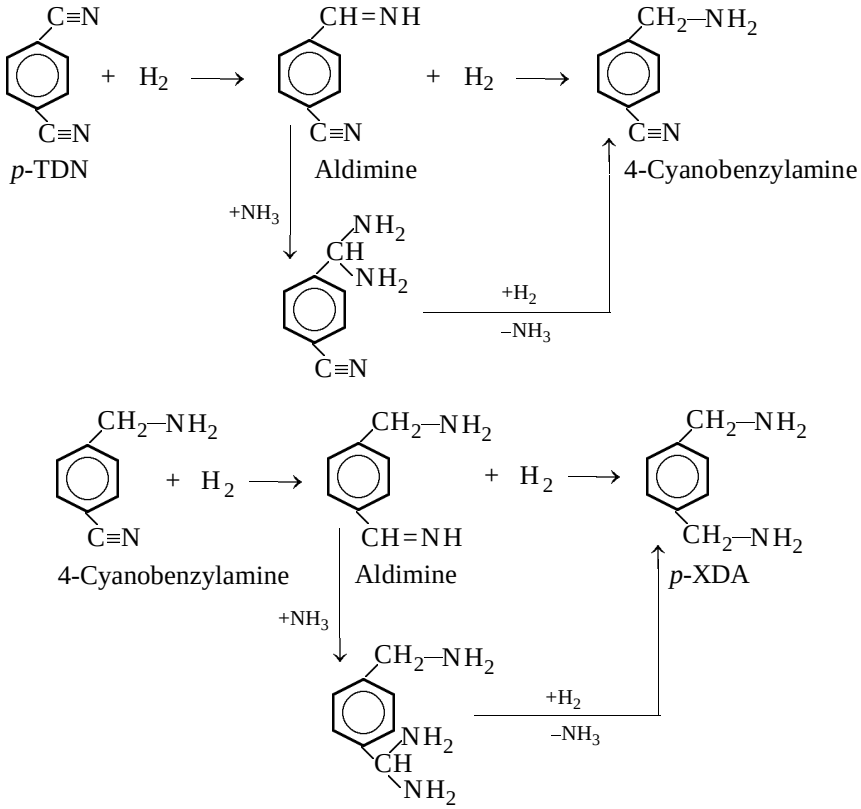
Published data on hydrogenation of aromatic dinitriles demonstrate a significant solvent effect on the process; the best results are attained in alcohols [14].

In this study, we examined the influence exerted by the nature of a solvent on hydrogenation of TDN on N-5 catalyst in the presence of ammonia. The results are listed in Table 2. It is known that the highest rate of formation and highest yield of the product are attained at the stoichiometric ratio of the reactants on the catalyst surface [15]; this fact was taken into account in our experiments.

Table 2 shows that the most favorable ratio of the reactants on the catalyst surface in alcohol is attained at the nitrile : ammonia ratio of 1 : 3.

It is known that the products of hydrogenation of phthalonitriles contain amino nitriles [14, 16, 17]. This fact suggests consecutive reduction of the nitrile groups. The hydrogenation rate on N-5 catalyst decreases with time; the hydrogen uptake corresponds to the reaction stoichiometry [18]. Hydrogenation starts and proceeds at a high rate until 2 mol of H_2 is taken up per mole of the dinitrile; after that, the rate of hydrogen uptake somewhat decreases, and the remaining 2 mol of H_2 is added at a lower rate [17, 18].

Hydrogenation of TDN can be described by the following scheme:



This scheme suggests that, initially, one of the nitrile groups is hydrogenated to give the amino nitrile (cyanobenzylamine), and only after that *p*-XDA is formed.

Bizhanov [19] believes that the growth of activity of Raney nickel catalysts is associated with an increase in the content of the $NiAl_3$ phase relative to the Ni_2Al_3 phase. Thus, the yield of the target product and the reaction rate depend on both the synthesis conditions and the catalyst used. The activity and selectivity of N-5 catalyst may be due to its high enrichment in firmly bound adsorbed hydrogen; its amount is 2–3 times higher than that on straight Raney nickel [19].

Tricyclodecenetetracarboxylic dianhydries are the starting monomers for preparing various heat-resistant

polymers, including polyimides [20, 21]. No data are, however, available on synthesis of high-performance polyimides from *p*-XDA and the above dianhydrides, because of the lack of efficient synthesis procedures. In this study, we developed such procedures. The polyimides were prepared by single-stage polycondensation of the components in polar aprotic solvents (amides) in the presence of catalytic amounts of isonicotinic (pyridine-4-carboxylic, INA) acid, which is known [5] to appreciably intensify polycondensation, like other pyridinecarboxylic acids.

It is known that polyheterocycles prepared in solution are more soluble than the same polymers prepared by solid-phase imidization of polyamido acids. Among the chosen solvents (DMF, DMA, MP, DMSO), the best results were obtained with DMA; the polyimides prepared in this solvent have the highest viscosity. For example, η_r of 0.5% solution of the fluorinated polyimide prepared in various solvents under the optimal conditions is as follows (dl g^{-1}): 0.45 in DMF, 0.53 in MP, 0.75 in DMSO, and 1.23 in DMA. Therefore, all the subsequent syntheses were performed in DMA.

A study of the reactions of *p*-XDA with alicyclic dianhydrides showed that the fluorinated dianhydride (AFB) is more reactive in acylation, which is due to the high electronegativity of the fluorine atom at the endocyclic double bond; as a result, the anhydride groups become more electrophilic. AB and ACB are less reactive [10].

It should be noted that PAIs with fairly good characteristics, derived from an alicyclic dianhydride, were prepared for the first time. The syntheses were performed at 110–120°C for 2.0–2.5 h. All the reactions occurred under homogeneous conditions and gave PAIs in almost quantitative yields, with degrees of imidization of about 100%. The viscosity of the polymers was as high as 0.94–1.23 dl g^{-1}.

The optimal conditions for preparing PAIs are listed in Table 3; for comparison, we also give data for the two-stage synthesis of the polyimide from AFB and *p*-XDA (polymer no. 4). Table 3 shows that the single-stage procedure ensures higher η_r of the polyimide.

The compositions and structures of the polyimides were confirmed by elemental analysis and IR spectroscopy. The IR spectra of the polyimides contain absorption bands at 1775 and 1715 (carbonyl groups of imide rings), 1365–1370 (>N–), and 715–725 cm^{-1} (imide ring); the PAI derived from AFB also exhibits C–F vibration band at 1260–1300 cm^{-1}, and the PAI derived from ACB, a C–Cl band at 860 cm^{-1}. No bands characteristic of uncyclized amido acid fragments were detected.

The structural features of polyimides derived from tricyclodecenetetracarboxylic dianhydrides (presence of the alicyclic structure and, in the case of AFB and ACB, also of halogen atoms) are responsible for some specific properties; for example, the glass transition points T_g decrease somewhat. Comparison of the glass transition points of PAIs, determined by dielectric measurements [22], showed that they are within 265–280°C; T_g of the halogenated polymers is 10–15°C lower, compared to the PAI derived from AB; introduction of Cl decreases T_g to a greater extent, compared to F (Table 4, polymer nos. 1, 2).

We evaluated the heat resistance of the new polymers. As seen from Table 4, decomposition of all the three PAIs in air (onset temperature T_0) starts at 325–340°C, with the nonhalogenated polymer being somewhat less heat-resistant. Decomposition under Ar starts at higher temperatures.

Table 4 shows that, for the polyimides prepared, the interval between T_g and T_0 is 45–70°C, which allows processing of the polymers by pressure molding.

The relatively high viscosity characteristics and good solubility of the polymers in DMA allowed us to prepare films with strength of 70–80 MPa and 30–40% elongation. The modulus of elasticity ranges from 2700 to 3400 MPa depending on the modifying additive (triphenyl phosphate, dimethyl phthalate, dibutyl phthalate, dimethyl terephthalate, etc.).

The dielectric loss tangent at f = 1 kHz, T = 25°C, and zero moisture content is 0.002–0.004; relative dielectric permittivity, 3.22–3.35. The relative dielectric permittivities of the new PAIs are relatively low, especially of those containing an F atom, which is due to the alicyclic structure of the anhydride ring and to the effect of the electronegative halogen atom. The relative dielectric permittivities of aromatic polyimides containing aliphatic and aromatic fragments are higher.

CONCLUSIONS

(1) Conditions were found for preparing *p*-xylylenediamine in quantitative yield by hydrogenation of terephthalodinitrile in lower aliphatic alcohols in the presence of promoted catalysts containing Raney nickel as base component and obtained by leaching of the corresponding alloys with Ni : Al ≈ 1 : 1. The catalysts used in this study are 3–4 times more active than straight Raney nickel.

(2) A series of new (including fluoro and chloro derivatives) polyimides were prepared by condensation of *p*-xylylenediamine with tricyclodecenetetracarboxylic dianhydrides in polar aprotic solvents (amides). These polymers exhibit high, for this class of materials, physicomechanical and dielectric characteristics and high heat resistance.

Abstract—The influence of single- and double-charged cations on degradation of metal 2-acrylamido-2-methylpropanesulfonate-*N*-vinylpyrrolidine copolymers in aqueous solutions in the presence of potassium peroxodisulfate, $K_2S_2O_8$, at 50 and 70°C was studied by viscosimetry.

Degradation of polymers in solutions in the presence of radicals is used to control the molecular weight (MW) and molecular-weight distribution (MWD) of polymers and to prepare partially degraded polymers with the best molecular characteristics, providing their best performance [1]. Previously [2] we have studied the main features of radical degradation of copolymers of sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS) with *N*-vinylpyrrolidine (N-PV) in aqueous solutions. These polymers exhibit good flocculating [3], adhesion, and antistatic activity [4] and have cross-linking and complexing properties.

As shown previously [1], degradation of polyelectrolytes in aqueous solutions is strongly affected by electrostatic interaction between charged macromolecules and the product of persulfate decomposition, SO_4^{-*} radical ions. Since the strength of such electrostatic interactions depends on the degree of binding of cations with polyanions, the cation nature must affect degradation of copolymers of H-AMS salts with N-VP in aqueous solutions containing persulfate anions. In this study, we analyzed the influence of M cations (M = Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, and Ba^{2+}) on the degradation of M-AMS–N-VP copolymers in aqueous solutions in the presence of potassium peroxodisulfate (PP).

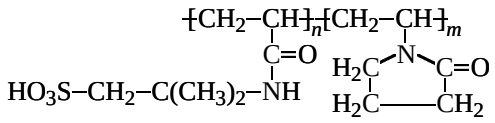
EXPERIMENTAL

We studied Na-AMS–N-VP copolymers prepared by radical coplymerization of the monomers in aqueous solutions.

We used H-AMS (Lubrizol 2404) purchased from Lubrizol Corporation (UK), mp 185°C; N-VP purchased from Merck (Germany) and purified by vacuum sublimation in the presence of 0.1% KOH, n_D^{20} = 1.5119; and distilled water. Other chemicals were of chemically pure and analytically pure grades. Potassium peroxodisulfate $K_2S_2O_8$ was twice recrystallized from water. The main compound, determined by redox titration was 97.8%. Sodium 2-acrylamido-2- methylpropanesulfonate (Na-AMS) was prepared by neutralization of an aqueous solution of H-AMS with NaOH.

Copolymerization of Na-AMS with N-VP was performed by the procedure described in [6]. The copolymer was precipitated from an aqueous solution with acetone, filtered off, washed with acetone, and dried in a vacuum at 50°C to constant weight. The parameters of the copolymers studied are listed in the table.

Properties of H-AMS–N-VP copolymers



Sample no.	[η], $cm^3\ g^{-1}$	Content of indicated units, mol%	
		H-AMS	N-VP
1	180	89.0	11.0
2	380	78.1	21.9

The content of ionic groups in the copolymer was calculated from the sulfur content [7]. The intrinsic viscosity of polymer solutions, [η], was determined on a VPZh-3 viscometer (d_c = 0.56 mm) by isoionic dilution of a 0.5 M NaCl solution at 30°C.

To convert Na-AMS–N-VP copolymer into the H-form, its solution was passed through a column packed with KU-2 × 8 cation exchanger. The cation exchanger was pretreated in accordance with GOST (State Standard) 10896–78. Single- and double-charged metal salts of the copolymers were prepared by potentiometric titration of solution of H-AMS–N-VP copolymers with KOH or LiOH solution, or by treatment of the copolymer solution with an $Mg(OH)_2$, CaO, or $Ba(OH)_2$ suspension to pH 7 with cooling and stirring. The insoluble residue was filtered off.

Degradation in 0.1% aqueous solutions was initiated by thermolysis of PP initiator at 50 and 70°C. The reaction kinetics was monitored by viscometry [8]. The degradation was performed in a glass reactor equipped with a jacket for temperature control, a magnetic stirrer, a thermometer, a connecting pipe for sampling to measure [η], and a VPZh-3 capillary viscometer (d_c = 0.56 mm) for determining the viscosity of the reaction mixture [8]. A polymer solution placed in the reactor was brought to the required temperature, and PP initiator was added. This time was taken as the degradation onset. The time τ_1 of efflux of the reaction solution was measured intermittently. The reduced viscosity of the solution η_{sp}/c_c, where c_c is the copolymer concentration, was calculated. The $\eta_{sp}/c_c = f(\tau)$ curve, where $\tau = \tau_2 + \tau_1/2$ and τ_2 is the time elapsed from the onset of degradation till the beginning of measurements of the viscosity of the reaction solution, was plotted.

The acidity of the solution was measured with a pH-121 pH meter using an ESL-65-07 glass working electrode and an EVL 1M3 silver chloride reference electrode.

The dependence of the reduced viscosity η_{sp}/c_c of aqueous solutions of Na-AMS–N-VP copolymer (sample no. 3) and various PP concentrations at 50°C on the degradation time is shown in Fig. 1. The fact that the viscosity of the copolymer solution prepared in the absence of the initiator does not change with time indicates that the copolymer is stable under the experimental conditions. Introducing PP and raising its concentration lead to formatiom of SO_4^{-*} radical anions in the reaction solution to deincrease in η_{sp}/c_c owing to macromolecular degradation (curves *2*–*4*). As seen from Fig. 1, the initial η_{sp}/c_c (τ = 0) decreases with increasing PP concentration. This is due

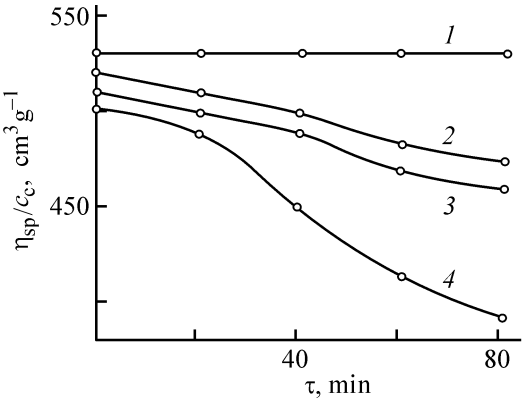

Fig. 1. Reduced viscosity η_{sp}/c_c of aqueous solutions of Na-AMS–N-VP copolymer (sample no. 3) with different PP concentrations vs. the degradation time τ. c_c = 0.1%, 50°C; the same for Fig. 4. [PP]/[copolymer]: (*1*) 0, (*2*) 0.04, (*3*) 0.06, and (*4*) 0.08.

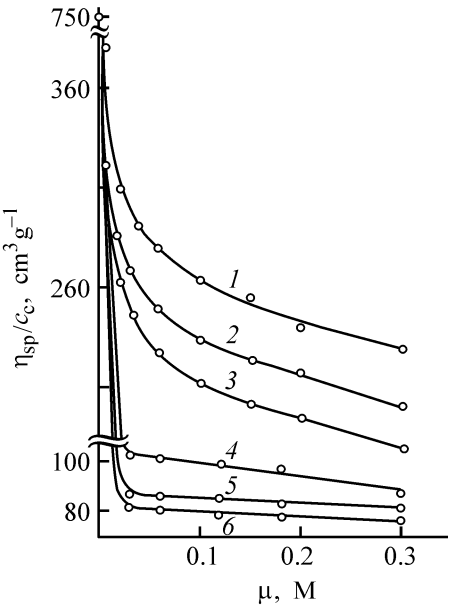

Fig. 2. Reduced viscosity η_{sp}/c_c of aqueous solutions of H-AMS–N-VP copolymer (sample no. 1) vs. the ionic strength μ produced by (*1*) KCl, (*2*) NaCl, (*3*) Li_2CO_3, (*4*) $BaCl_2$, (*5*) $CaCl_2$, and (*6*) $MgCl_2$. c_c = 0.1%; 30°C.

to a dual effect of PP additive: on the one hand, it initiates the copolymer degradation, and, on the other hand, it is a salt making higher the ionic strength μ of the solution.

The dependence of η_{sp}/c_c (c_c = const) of aqueous solutions of H-AMS–N-VP copolymer (sample no. 1) on μ produced by various salts is shown in Fig. 2. It can be seen that η_{sp}/c_c decreases with increasing μ. This is due to weakening of electrostatic repulsion of sulfonate groups along the polymeric chain, which decreases the effective size of macromolecular glob-

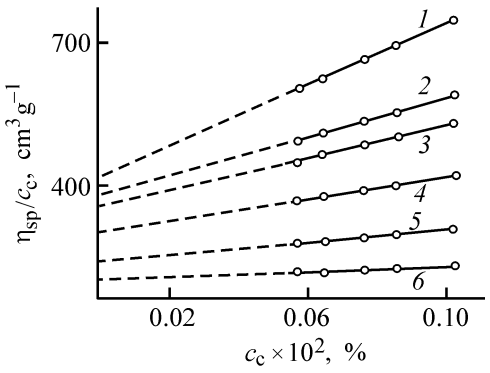

Fig. 3. Reduced viscosity η_{sp}/c_c in 0.5 M NaCl at 30°C of samples taken (*1*) 0, (*2*) 20, (*3*) 40, (*4*) 60, (*5*) 90, and (*6*) 120 min after the onset of degradation of the Na-AMS–N-VP copolymer (sample no. 4) vs. copolymer concentration c_c. Degradation conditions c_c = 0.1 %, 50°C, [PP]/[copolymer] = 0.08.

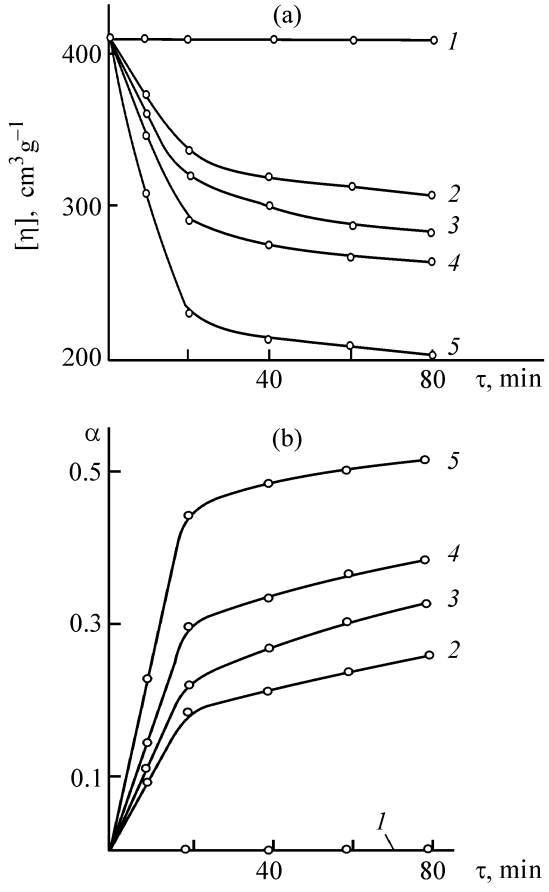

Fig. 4. Viscosity [η] vs. (a) number of ruptures per single macromolecule α and (b) degradation time τ of Na-AMS–N-VP copolymer (sample no. 4) at different PP concentrations. [PP]/[copolymer]: (*1*) 0, (*2*) 0.01, (*3*) 0.02, (*4*) 0.04, and (*5*) 0.08.

ules $(r^2)^{1/2}$. The decrease in η_{sp}/c_c of copolymer solutions at the instant of PP addition (τ = 0) with increasing PP concentration (Fig. 1) has a similar origin.

To estimate the MW of the copolymers in the course of their degradation, we determined [η], since, in accordance with the Mark–Houwink equation, MW ~ [η]. The viscosity was determined from the $\eta_{sp}/c_c = f(c_c)$ dependence obtained by isoionic dilution (0.5 M NaCl, 30°C) of samples of the reaction solution taken in the course of copolymer degradation. Typical $\eta_{sp}/c_c = f(c_c)$ dependences shown in Fig. 3 are linear. The viscosity was determined by extrapolation of these curves to c_c = 0, i.e., $[\eta] = \lim(\eta_{sp}/c_c)$.

The dependence of [η] on the time of Na-AMS–N-VP copolymer degradation is shown in Fig. 4a. In the absence of PP, [η] is constant with time (curve *1*). As the PP concentration and the reaction time increase, the viscosity falls owing to a decrease in the MW of the copolymer, caused by rupture of the macromolecule backbones (Fig. 4a, curves *2*–*5*). The number of ruptures per macromolecule was calculated from the data presented in Fig. 4a by the equation

$$\alpha = ([\eta]_0 - [\eta]_\tau)/[\eta]_\tau, \quad (1)$$

where $[\eta]_0$ and $[\eta]_\tau$ are viscosities of Na-AMS–N-VP copolymer before degradation and after degradation for time τ, respectively.

The dependence of α on the time of Na-AMS–N-VP copolymer degradation is shown in Fig. 4b. The number of ruptures grows with increasing initiator concentration and reaction time. However, the fact that the maximum α does not exceed 0.5 indicates that no low-molecular-weight products are formed.

We studied the influence of the cation nature on the degradation of Na-AMS–N-VP copolymer. These experiments were performed with samples no. 2 (see table) under the same degradation conditions at 70°C. The dependence of [η] in the presence of metal cations on the degradation time is shown in Fig. 5. The viscosity of all the samples decreases with time owing to macromolecular degradation. The viscosity at definite degradation time becomes lower with decreasing cationic radius in the following order: $K^+ > Na^+ > Li^+$ and $Ba^{2+} > Ca^{2+} > Mg^{2+}$. Similar dependences were obtained for degradation at 50°C and with copolymer samples having another ratio of AMS and N-VP units.

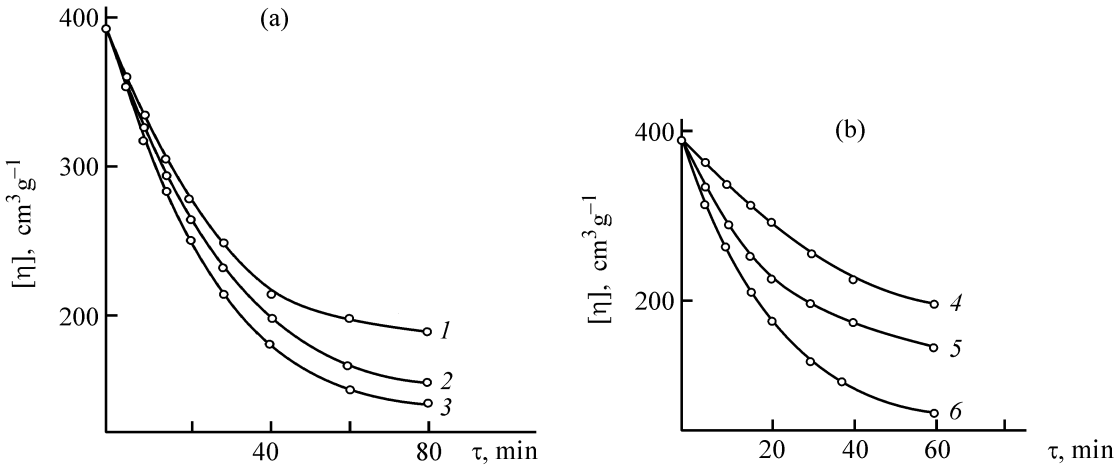

Fig. 5. Viscosity [η] of H-AMS–N-VP copolymer solution (sample no. 2) containing (*1*) K^+, (*2*) Na^+, (*3*) Li^+, (*4*) Ba^{2+}, (*5*) Ca^{2+}, and (*6*) Mg^{2+} ions vs. degradation time τ. c_c = 0.1%, 70°C. [PP]/[copolymer]: (a) 0.005 and (b) 0.02.

To understand the influence of metal cations on the degradation of copolymers of H-AMS salts with N-VP, we considered the following ionic equilibria in aqueous solutions:

$$\underset{\mathbf{I}}{A^-X^+} \rightleftarrows \underset{\mathbf{II}}{A^-} \;||\; \underset{\mathbf{III}}{X^+} \rightleftarrows A^- + X^+. \qquad (2)$$

where A^- is sulfonate anion of the macromolecule; X^+ is the cation; **I**, **II**, and **III** are the contact ion pair, solvent-separated ion pair, and free ions, respectively.

Previously we have found that the degree of binding of cations with polyanions of H-AMS– N-VP copolymers in aqueous solutions increases in the following order: $K^+ < Na^+ < Li^+$ [9] and $Ba^{2+} > Ca^{2+} > Mg^{2+}$ [9, 10]. Ionic equilibrium (2) is shifted to the left with increasing μ and degree of binding of the cations with the polysulfonate anions. This weakens the strength of intra- and intermolecular interactions between similarly charged species in the reaction system, thus changing the reactivity of the charged macromolecules with respect to SO_4^{-*} radical anions. The weakening of electrostatic repulsion between similarly charged groups fixed along the polymeric chain makes smaller the effective size of macromolecular globules $(r^2)^{1/2}$, thus decreasing η_{sp}/c_c (μ = const) in the order $K^+ > Na^+ > Li^+$ and $Ba^{2+} > Ca^{2+} > Mg^{2+}$ (Fig. 2). An increase in the degree of binding of cations with polysulfonate anions in the course of degradation of H-AMS–N-VP copolymers weakens the electrostatic repulsion between SO_4^{-*} radical anions and sulfonate groups of the macromolecules. As a result, the degradation of the macromolecules becomes more pronounced and [η] of copolymer solutions (τ = const) decreases in the order $Li^+ > Na^+ > K^+$ (Fig. 5a) and $Mg^{2+} > Ca^{2+} > Ba^{2+}$ (Fig. 5b).

CONCLUSIONS

(1) The viscosity [η] of aqueous solutions of metal 2-acrylamido-2-methylpropanesulfonate-*N*-vinylpyrrolidine copolymers subjected to radical degradation at 50 and 70°C can be controlled by varying the nature of metal cations, initiator concentration, and degradation time.

(2) The viscosity of degraded copolymers [η] decreases in the order $Li^+ > Na^+ > K^+$ and $Mg^{2+} > Ca^{2+} > Ba^{2+}$ owing to a decrease in electrostatic repulsion of SO_4^{-*} radical anions of the initiator, with charged macromolecules, with the degree of binding of the cations with the macromolecular anions increasing in the order $K^+ < Na^+ < Li^+$ and $Ba^{2+} < Ca^{2+} < Mg^{2+}$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Low-Waste Process for Preparing Ketopantolactone, with Electrochemical Recovery of Bromine

L. V. Kaabak, N. P. Stepnova, A. V. Khudenko, and A. P. Tomilov

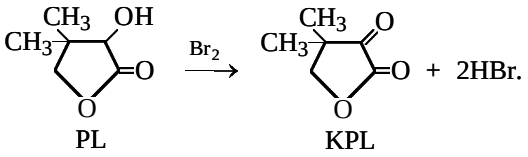
State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received January 17, 2003

Abstract—The process parameters of dehydrogenation of pantolactone with bromine in chloroform and the possibility of bromine recycling by electrolysis of hydrogen bromide formed in the synthesis of ketopantolactone were studied.

Ketopantolactone (KPL) shows promise for pharmaceutical industry. The known methods for its preparation are based on oxidative dehydrogenation of pantolactone (PL).

There are published data on oxidation of PL with oxygen in the presence of a catalyst [1, 2], as well as with calcium hypochlorite [3–5], potassium bromate [6, 7], bromine [8–10], and organic peroxides [11]. These data show that PL is catalytically oxidized at 180–300°C and elevated pressure, which requires complex equipment; the target product undergoes partial tarring. With chlorine or calcium hypochlorite, abundant nonutilizable wastewater is formed. The reaction with bromine as dehydrogenating agent proceeds by the scheme:



PL KPL

This scheme suggests formation of an equivalent amount of hydrogen bromide, which is suitable for high-yield recovery of recyclable bromine. This option was recognized as the most promising and was technologically developed.

In [10], dehydrogenation of PL with bromine in refluxing carbon tetrachloride was recommended; the reaction is complete within 5–8 h. In [9], this period was reduced to 1 h by adding a minor amount of water to the reaction mixture.

Presently, carbon tetrachloride is considered unsuitable as solvent for environmental reasons and its production is to be closed [12]. Therefore, we replaced carbon tetrachloride with chloroform in our experiments. Next, the possibility of recovery of bromine from an aqueous solution of hydrogen bromide formed in the synthesis was analyzed.

The initial experiments on dehydrogenation of PL in chloroform failed. The reaction was incomplete even after refluxing the PL solution in chloroform with bromine for 14 h, probably because of the lower boiling point of $CHCl_3$, compared to CCl_4. The situation was substantially improved by introducing minor amounts of water to the reaction mixture: When 10 ml of water was added to 60 ml of chloroform, the reaction was complete after heating for 3.5 h. However, further increase in the content of water decreased the weight of the target product. For example, upon adding 60 ml of water, the yield of KPL after refluxing for 5 h was only 48%, and at water content below 10% the reaction was decelerated and HBr evaporated.

An important role is also played by the PL concentration in chloroform. Table 1 shows that, at the PL : chloroform ratio of 1 : 7.5, the KPL yield remains fairly high, but falls dramatically with the amount of chloroform decreasing further; the reaction does not go to completion despite longer heating time. Thus, we developed a procedure for preparing KPL in 92–95% yield.

All the above-described experiments were performed in a 150-ml reactor charged with 4 g of PL. To test the suitability of the process for large-scale application, we carried out an experiment in a 2-l reactor charged with 100 g of PL, 900 ml of chloroform, 160 ml of water, and 137 g of bromine. The very first run showed that, on passing to a larger reactor,

Table 1. Influence of the PL concentration in chloroform on the yield of KPL (4 g of PL, 5.27 g of Br_2)

$CHCl_3$, ml	Water, g	PL : $CHCl_3$ ratio	Yield of KPL, %
40	1.0	1 : 10	82.8*
30	5.5	1 : 7.5	91.8
20	5.0	1 : 5.0	80.0
10	2.5	1 : 2.5	30.0**

* 7-h refluxing. ** The reaction was incomplete in 8 h.

Table 2. Influence of the electrolysis mode on the degree of bromine recovery (anolyte volume 500 ml)

HBr charge, g	*I*, A	*Q*, A h	Br_2 obtained	
			g	%
196	10	58	112	64
217	10 → 5	78	197	87
213	10 → 5	71	176	86
213	10 → 5 → 2	72	194	91

the reaction is significantly decelerated: Upon refluxing of the mixture for 3 h 50 min, only 47% of the charged PL reacted. Upon further refluxing for 3 h 30 min, PL was 75% converted. Our attempt to accelerate the reaction by illuminating the reaction mixture with a 300-W incandescent lamp was successful: Upon 45-min illumination, PL fully entered into the reaction, and the yield of isolated KPL was 85%.

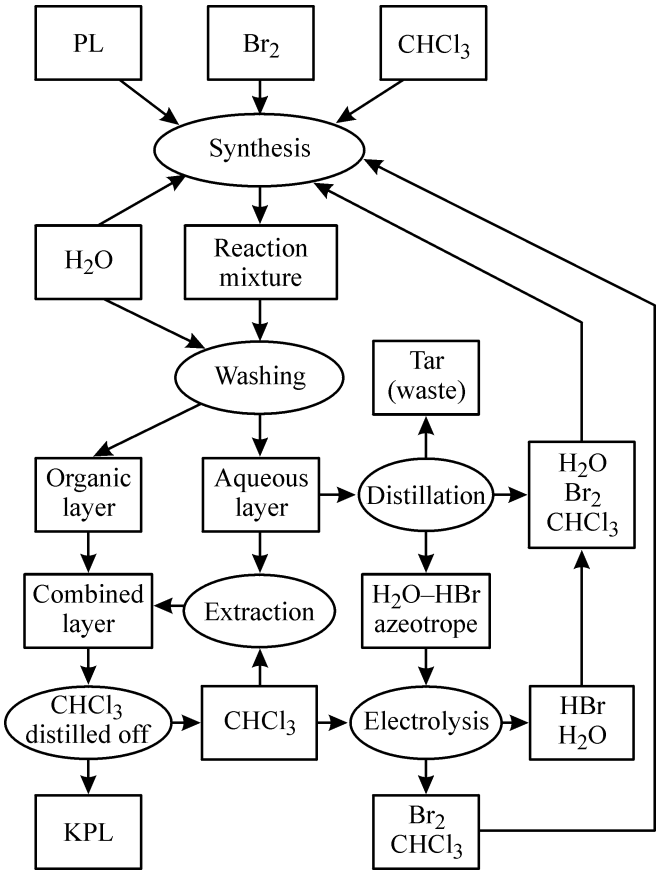
Further experiments showed that, under intensive illumination, the reaction was complete within 15–20 min, but the yield of KPL decreased to 70–79%. Thus, illumination intensifies not only oxidative dehydrogenation but also side reactions, which have, most probably, the radical nature. By varying the power of the light source and the distance separating it from the reactor, we empirically chose the conditions at which the reaction was complete within 2 h and the yield of KPL based on the reacted PL was within 82–85%.

To free the HBr solution from organic impurities, the aqueous layer was distilled on a film evaporator. First, water containing unchanged bromine and chloroform dissolved in the aqueous layer was distilled off at 100–102°C. Then the vapor temperature increased, and the HBr–H_2O azeotrope containing 48% hydrogen bromide was distilled off at 123–124°C. The bottoms contained ca. 8 g of a thick tar composed, most probably, of the products of side reactions accompanying the dehydrogenation of PL. The distilled-off aqueous phase, containing bromine and chloroform, was recycled, and the HBr–H_2O azeotrope was subjected to electrolysis for recovery of bromine.

Bromine was recovered in the cathode chamber of a filter-press electrolyzer under permanent extraction of the evolving bromine with chloroform. Electrolysis was performed in the batch mode, the current lowered stepwise. The initial current density was 0.25 A cm^{-2}; after 50% of the calculated amount of electricity *Q* was passed, it was decreased to 0.10 A cm^{-2}, and the remaining 15% of the electricity was applied at a current density of 0.05 A cm^{-2}. In this mode, it is possible to recover over 90% of the bromine present in solution in the form of bromide ions. The effect of a stepwise decrease in the current density is clearly illustrated by Table 2. It is reasonable to utilize the depleted anolyte containing 3–5% HBr instead of water in further KPL synthesis.

In the experiments utilizing the generated bromine-containing solutions, the yield of KPL was 83 and 88%. A control run with pure reactants under the identical conditions gave an 85% yield.

The general flowsheet of the suggested process is shown below.



Flowsheet of the KPL synthesis involving bromine recovery.

EXPERIMENTAL

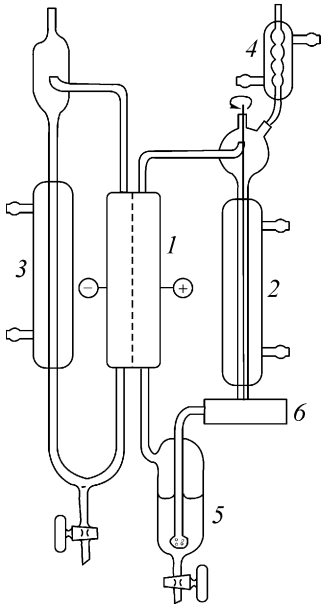
In this study, we used *DL*-pantolactone (mp 74–77°C). The other reactants (bromine and chloroform) were of chemically pure grade.

Into a 2-l flask equipped with a reflux condenser and a stirrer, 100 g of PL, 960 ml of chloroform (870 ml of recycled and 90 ml of fresh), 150 ml of water (or depleted anolyte), and 137 g of bromine were introduced. The reaction mixture was illuminated with a 300-W incandescent lamp and refluxed for 2 h. The reaction was regarded as complete when no traces of PL were revealed by gas chromatography. The reaction mixture was transferred into a separatory funnel; for better separation of the aqueous layer, 40 ml of water was added. The separated organic layer was washed with 40 ml of water. This water was combined with the separated aqueous layer, which was a concentrated solution of hydrogen bromide. The resulting aqueous layer was treated with chloroform (2 × 30 ml). The extract was combined with the organic layer, and chloroform was distilled off. The hot bottoms were transferred into a beaker for crystallization. After 1 h, the crystalline KPL precipitate had a constant weight of 83.7 g, mp 64–66°C. The waste was ca. 350 ml of an aqueous hydrogen bromide solution containing 127 g of HBr and 11.7 g of bromine.

Distillation of the aqueous layer on the film evaporator yielded 84 ml of a fraction containing water, bromine, and chloroform, 255 ml of the HBr–H_2O azeotrope, and 8 g of the bottoms containing the reaction by-products.

The HBr–H_2O azeotrope mixture was electrolyzed in a filter-press electrolyzer with the anode and cathode spaces separated by a NAFFION-403 membrane. A stainless-steel plate served as cathode, and DEZ-3 graphite used in chlorine production, as anode. Prior to being used, graphite was impregnated with a paraffin–polyethylene melt. The electrodes and the membrane were separated by 4 mm. The catholyte circulation was effected by a gas lift system, and anolyte circulation, by a rotary pump. The solution leaving the anolyte entered a backup reservoir where it passed through a chloroform layer. The bromide formed on the anode was dissolved in a chloroform layer. When the required concentration was reached, the solution of bromine in chloroform was fed to synthesis of KPL. The figure presents the general view of the setup for bromine recovery.

The anode chamber of the electrolyzer was charged with 500 ml of a 33.4% solution of HBr containing



Schematic of the setup for electrochemical recovery of bromine: (*1*) electrolyzer, (*2*) anode circuit cooler, (*3*) cooler at the cathode off-gas line, (*4*) reflux condenser, (*5*) backup reservoir, and (*6*) rotary pump.

213.4 g of the bromide ion. As anolyte was used 150 ml of a HBr solution of the same concentration. Chloroform (80 ml) was poured into the backup reservoir. Electrolysis was performed in three steps at current densities of 0.25, 0.10, and 0.05 A cm^{-2}, respectively. The anolyte temperature during electrolysis was kept within 12–15°C. After each step, the solution of bromine in chloroform was discharged from the backup reservoir, and a fresh portion of chloroform (88 ml) was added. A total of 188.4 g of bromine dissolved in 240 ml of chloroform was obtained in our experiment. Waste anolyte consisted of 490 ml of the aqueous solution of HBr containing 24.7 g of HBr. Bromine was recovered to 88%. The waste anolyte

was used in the synthesis instead of water. The electrolysis mode and bromine yields in each step are presented in Table 3.

CONCLUSIONS

(1) Pantolactone can be dehydrogenated with bromine in chloroform.

(2) At the pantolactone : chloroform : water ratio of 1 : 7.5 : (0.85–0.90) in the reaction mixture, ketopantolactone can be prepared in 82–85% yield. The process can be accelerated 3–4-fold by illuminating the reaction mixture.

(3) A method for electrochemical recovery of bromine and its recycling was developed. Three percent of bromine is lost in the developed scheme.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

2,2,4-Trimethyl-1,2-Dihydroquinoline Hydrochloride as Coagulant for Butadiene-Styrene Latices

S. S. Nikulin, V. N. Verezhnikov, T. N. Poyarkova, and Zh. V. Shmyreva

Abstract—Coagulating action of 2,2,4-trimethyl-1,2-dihydroquinoline hydrochloride in separating butadiene-styrene rubber from latex is studied, and the properties of vulcanizate based on rubbers prepared by this procedure are examined.

The use of nitrogen-containing compounds in separation of rubber prepared by emulsion copolymerization allows, in some cases, a considerable decrease in the consumption of coagulating agents [1]. Of special interest in this regard are polymeric quaternary ammonium salts and, in particular, poly(*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride) (PDDAC), which, as shown in a series of publications [2–4], demonstrates high performance in separating rubber from latices when taken both separately and in combination with other coagulating agents.

The possibility of using PDDAC in a real process was confirmed in pilot tests [3]. However, industrial application of this reagent is limited by its short supply and considerably higher cost as compared to such commonly used coagulant as NaCl. Therefore, searching for new more readily available coagulants allowing not only reduction of the mineral salt consumption or its exclusion from the process at all, but also improvement of the performance characteristics of the resulting products (rubbers, rubber stocks and vulcanizates) is a topical task.

Desired nitrogen-containing compounds for separating rubber from latex must have a dual function, operating as a coagulant and antioxidant (stabilizer of polymer), provided that, in the course of coagulation, they will enter the composition of the resulting rubber crumb and will not be removed from the system. The antioxidant properties of a coagulant will allow lower consumption or complete elimination of expensive antioxidants, which are introduced into the latex prior to the coagulation stage in production of emulsion rubber. This should compensate to a considerable extent for the expenses for acquisition of an expensive nitrogen-containing coagulant, making rubber separation from the latex more cost-efficient.

In [5], it was suggested to use for salt-free coagulation of latices of butadiene-styrene and butadiene-acrylonitrile rubbers, a coagulant, poly(*N*-3,5-di-*tert*-butyl-4-hydroxytolyl) ethylenimine synthesized by the Mannich reaction, which also exhibits stabilizing properties for rubber. A similar bifunctional polymeric coagulant was also described in [6].

In this context, low-molecular-weight cationic reagents, such as 2,2,4-trimethyl-1,2-dihydroquinoline (DHQ), which can inhibit oxidation processes [7] and increase the stability of polymers against ozone aging [8], may be promising. The initial dihydroquinoline is a condensation product of such readily available organic compounds as aniline and acetone [9, 10].

Previously [11] we reported on a study of the kinetics of coagulation and coagulating performance of DHQ hydrochloride (DHQHC) in separating rubber from latex of emulsion polybutadiene (EPB) produced by the industry in limited amounts. It was of interest to assess the efficiency of DHQ salts in separating butadiene-styrene rubber as the most widely used rubber of general purpose.

The goal of this study was to estimate the coagulating efficiency of the water-soluble organic ammonium salt, DHQHC, in separating commercial butadiene-styrene rubbers from latices.

DHQ salts were prepared as in [9, 10].

Surface tension, 10^3 J m^{-2}	63.7	56.5
Radius*, nm	50.8	46.7

* Radius of the latex globules was estimated by the Rayleigh equation from optical data [12].

Rubbers were separated from latices in a coagulation unit comprising a stirred vessel placed in a thermostat. The vessel was filled with a latex (25 ml) and allowed to stand for 10–15 min at a prescribed temperature. Then calculated amount of aqueous DHQHC (c = 3.0–5.0 wt %) was introduced with continuous stirring into the latex, and the system was acidified with aqueous sulfuric acid (c = 1.0–2.0 wt %). The coagulation efficiency was monitored visually by the transparency of serum (aqueous phase remaining after rubber separation from latex) and also by the weight of the resulting coagulum.

A reference sample was separated from the latex by coagulation with NaCl (200–250 g kg^{-1} rubber). The reference and test rubber samples were separated from the serum and dried in an oven at 75–80°C.

In the first stage, it was appropriate to make a preliminary estimate of the coagulation performance of one of the above-indicated salts. Therefore, we studied the influence of the DHQHC concentration on the amount of coagulum at various concentrations of the disperse phase. The results obtained are given in Fig. 1.

The results show that, if DHQHC is used as a coagulant, the disperse phase concentration affects the rubber separation from the latex only slightly over the investigated concentration range. With increasing c_d, the rubber separation curves shift to higher DHQHC concentrations. The optimal coagulation concentration (OCC), defined as the DHQHC concentration corresponding to flattening out of the curve, grows insignificantly with increasing c_d (Fig. 2). At the same time, as demonstrated earlier [13], c_d is one of the most important parameters in coagulation with NaCl. In this case, decreasing the concentration of the disperse phase in the latex results in abruptly increasing coagulant consumption. The lack of a significant effect of c_d on the coagulation is an important advantage of DHQHC as a coagulant, since, in real processes, c_d may vary over a rather wide range, which, naturally, is reflected in the coagulant consumption.

With DHQHC as a coagulant, rubber separation from the latex must proceed preferentially by the neutralization mechanism through DHQHC interaction with anionic emulsifiers and latex stabilizer (Leukanol) to give insoluble complexes. In this case, the precipitation curves must have extrema caused by recharging of particles at concentrations exceeding the optimal value, corresponding to neutralization of their surface charge [13, 14]. At the same time, the precipitation curves in Fig. 1 show no peak or latex restabilization branch corresponding to the assumed recharging of the particles and increase in the positive surface charge at an excess of the coagulant.

To clarify the question of particle recharging upon introduction of excess DHQHC into the latex, we measured the electrophoretic mobility of the latex as influenced by the DHQHC concentration. The electrophoretic velocity was determined by the moving boundary technique, using a Chaikovskii apparatus [15]. The electrokinetic potential ξ was estimated by the Helmholtz–Smoluchowski equation

$$\xi = \eta U/\varepsilon\varepsilon_0 H,$$

where η is the viscosity of water (1×10^{-3} Pa s); U, mean electrophoretic velocity (m s^{-1}); ε, dielec-

tric constant; ε_0, permittivity of free space (8.85×10^{-12} F m^{-1}); H, electric gradient (V m^{-1}).

The results of the electrophoretic measurements suggest no recharging of the latex particles near OCC, and, therefore, the lack of the latex restabilization effect (no maximum in the φ–c curves).

Previously, we have reported a similar phenomenon observed in coagulation of latex of emulsion polybutadiene with DHQHC [11]. In both cases, the lack of the latex restabilization effect in the presence of an excess coagulant is, evidently, an indication of a small adsorption activity of DHQHC at the aqueous phase–polymer interface (in the absence of the electrostatic interaction with anions of the emulsifier). This is indirectly confirmed by the fact that such an anomaly was not observed with colloidal cationic surfactants as coagulants, for example, with cetylpyridinium bromide [13, 14] demonstrating high surface activity. However, the suggested interpretation requires further experimental verification.

A chemical analysis of rubbers separated from latices with DHQHC showed that the reference and test samples are identical in all basic parameters. However, it should be pointed out that the test rubber samples contain virtually no organic acid soaps, which is an important advantage. Also, these samples are characterized by lower weight loss for drying and lower ash content (Table 1).

Mechanical tests of vulcanizates based on SKS-30 ARK and SKS-30 ARKPN rubbers showed that the test rubber samples separated from the latex with DHQHC are close in all the basic parameters to the reference samples separated with NaCl (Table 2).

It follows from Table 2 that the vulcanizates based on the rubber separated from the latex with DHQHC demonstrate a slight increase in the heat aging resistance, suggesting that DHQHC and products of its interaction with components of the emulsion system, remaining in the rubber after its separation from the latex, act as antioxidants, even though to a small extent.

CONCLUSIONS

(1) It was demonstrated in studying the coagulation effect of 2,2,4-trimethyl1,2-dihydroquinoline in separating butadiene-styrene rubbers from latices that the disperse phase concentration affects only slightly the rubber separation from the latex over the range investigated.

(2) Properties of rubbers, rubberstocks, and vulcanizates obtained in this study from the experimental samples differ only slightly from those of reference samples obtained by the conventional procedure using NaCl.

Abstract—Initial flocculation rate of SKN-26SM butadiene-acrylonitrile rubber and the polymer yield are studied in relation to the concentration of the cationic polyelectrolyte, poly(dimethyldiallylammonium chloride), at various NaCl concentrations and, in experiments on rubber separation, also at various temperatures.

In previous studies [1, 2] we have demonstrated that, in separating polymers from synthetic latices with a cationic polyelectrolyte (CPE), the maximum flocculating effect, typical of high-molecular-weight flocculants, is observed only at relatively low rubber concentrations (c_d < 10–50 g l^{-1}). At higher c_d, the flocculation curves φ–c_{CPE} (φ is the polymer coagulation efficiency, wt %) no longer show a restabilization branch, so that the initial rise in φ with increasing c_{CPE} ends in attainment of a constant limiting value corresponding to complete polymer separation. A similar effect was observed in [3] when studying flocculation of kaolin suspensions with copolymers of acrylamide and quaternary ammonioalkyl acrylates. Such a behavior is associated with the observed adsorption layers of the flocculant macromolecules are formed on the surface of disperse phase particles [1–3] and with processes occurring in these layers [4–7].

It may be suggested that the occurrence (or lack) of the latex flocculation optimum depends not only on the disperse phase concentration, but also on other factors influencing the flocculation conditions, such as ionic strength and temperature. There are only a few experimental studies concerned with this problem. Gregory [8] measured the flocculation rate of a polystyrene latex under the action of a cationic polyelectrolyte and demonstrated that introduction of an inorganic salt extends the flocculation range as a result of decreased range of electrostatic repulsive forces. Matsumotu and Adachi have shown [9] that, at high ionic strength, flocculation in emulsifier-free polystyrene latex under the action of a cationic polyelectrolyte proceeds by the nonequilibrium flocculation mechanism [6, 7]. Finally, there is no information in the literature concerning the effect of temperature on the flocculation efficiency in colloid dispersions and, in particularly, in latices.

In this study, we analyzed the effects of the NaCl concentration and temperature on the flocculation rate and the efficiency of rubber separation from butadiene-acrylonitrile latex under the action of the cationic polyelectrolyte, poly(dimethyldiallylammonium chloride) (PDDAC). This reagent shows promise for industrial production of rubber from synthetic latices [10, 11]. It has been demonstrated that its flocculating performance is influenced by inorganic electrolytes [10, 11], but the mechanism of this effect has not been considered yet.

EXPERIMENTAL

In the study, we used commercial latex of SKN-26SM butadiene-acrylonitrile rubber (content of bound acryloacrylonitrile in the copolymer 30.5%). As emulsifier in the synthesis of latex, we used suing soap based on tall oil. The polymer content in the latex was 27.5 g l^{-1}; surface tension, 36.7 mJ m^{-1}; and pH 8.5.

As flocculants we used the PDDAC sample described in [2] and also its two fractions separated by

fractional precipitation from an aqueous solution with acetone. The viscosity-average molecular weights M_v of the initial sample and two fractions were 11.5×10^4, 2.3×10^4, and 17.4×10^4, respectively. Sodium chloride (chemically pure grade) was used without additional purification.

The viscosity of PDDAC solutions was determined in 0.1 M NaCl using an Ostwald viscometer. The M_v was estimated by the Mark–Houwink equation with $K = 1.12 \times 10^4$ and $\alpha = 0.82$ [12]. The turbidity of dilute latex solutions was measured at room temperature with an NFM nephelometer. The procedures for nephelometric determination of the initial rates of flocculation and rubber separation from the latex under the action of a flocculant were described elsewhere [2, 13].

The dependences of the initial flocculation rate of 10^4-fold diluted latex on the flocculant concentration at various NaCl concentrations are shown in Fig. 1. The initial flocculation rate was estimated as the turbidity 1 min after flocculation was started (τ_1) [6].

Figure 1 also shows τ_1 as a function of the NaCl concentration in the absence of PDDAC. The bend in this curve at $c_{NaCl} = 0.2$ M corresponds to the threshold of rapid coagulation of the latex [14].

In the absence of NaCl, the flocculation curves τ_1–c_{CPE} show clearly pronounced peaks (flocculation optimum) typical of the flocculating action of polyelectrolytes. The occurrence of flocculation optimum is caused by neutralization of the surface charge of the particles by adsorbed macrocations of the reagent, followed by recharging and restabilization of the sol through adsorption of the excess polymer and increase in the positive charge on the particles and also via formation of sufficiently thick layers of a hydrophilic polymer [15]. The occurrence of recharging of latex particles in flocculation with cationic polyelectrolytes has been more than once confirmed by measuring the electrophoretic mobility of the particles [1, 2, 16].

It should be pointed out that the flocculation rate at the optimum virtually coincides with the rate of

rapid coagulation of the latex by NaCl (Fig. 1). Therefore, at the optimal flocculating concentration (OFC) of the polyelectrolyte, flocculation must proceed as rapid coagulation.

With increasing NaCl concentration, the flocculation rate tends to grow, which is the most clearly pronounced in the restabilization range. For the lower-molecular-weight PDDAC sample, this results in virtually total suppression of the restabilization effect (at c_{NaCl} = 0.2 M). In this case, the flocculation rate approaches a value close to that with NaCl, although the coagulation rate is lower by about a factor of 3 at the indicated NaCl concentration in the absence of the polyelectrolyte,.

The NaCl concentration has a similar effect on the rubber separation efficiency in flocculation (Fig. 2). The flocculation curves have peaks which become less pronounced with increasing c_{NaCl}, virtually disappearing on reaching some critical value c^{∞}_{NaCl}. With increasing disperse phase concentration c_d, the peak in the flocculation curves disappears at lower salt concentration: at c_d of 10 and 30 g l^{-1} c^{∞}_{NaCl} is about 0.4 and 0.1 mM, respectively. Therefore, raising the ionic strength suppresses the latex restabilization effect in the course of flocculation, which is reflected in an increase both in the flocculation rate and in the efficiency of rubber separation from the latex.

This phenomenon can be interpreted taking into account two possible contributions to latex stabilization after reaching the flocculation optimum. One of these is enhancement of electrostatic stabilization, caused by increasing positive charge on the particles at concentrations above OFC [1, 2, 16]. Raising the NaCl concentration results in compaction of the diffuse electric double layer and also in weakening of the electrostatic repulsive forces, which impede agglutination of the particles upon collisions.

It should be pointed out that the range of electrostatic stabilization is restricted to relatively low salt concentrations. Simple calculation shows that, for a 1–1 electrolyte, the thickness of the electrical double layer decreases to about 1 nm even at a concentration of about 0.1 M and it loses its diffuse nature and, therefore, the electrostatic stabilization. At the same time, as seen from Figs. 1 and 2, further rise in c_{NaCl} makes the flocculation rate and rubber separation efficiency still higher. Evidently, this is a result of action of another factor, namely, nonelectrostatic interaction (repulsion) between the latex particles [17, 18]. The origin of this interaction is associated with the formation of hydrate shells of considerable thickness on the surface of latex particles, modified with the adsorption layer of the emulsifier. This phenomenon is known as secondary hydration [19]. The overlap of these shells controls the structural component of the disjoining pressure [20, 21]. In the case of the investigated butadiene-acrylonitrile latex under study, not only the secondary hydration, but also direct interaction of the polar acrylonitrile groups of the polymer with the environment may contribute significantly to the increase in the latex stability against the coagulating action of the electrolyte. This conclusion is confirmed by the industrial practice: NaCl consumption for separating acrylonitrile rubbers is higher by a factor of 3–5 than that for butadiene-styrene rubbers, the composition of the aqueous phase being nearly the same [22].

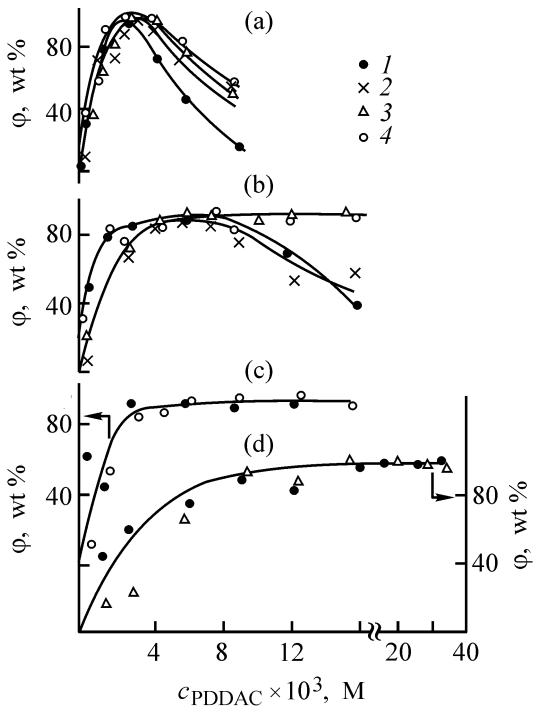

Fig. 3. Polymer separation efficiency φ vs. the PDDAC concentration c_{PDDAC}. $M_v = 17.4 \times 10^4$. T (°C): (*1*) 20, (*2*) 40, (*3*) 60, and (*4*) 80. Disperse phase concentration in latex (g l^{-1}): (a) 20, (b) 30, (c) 50, and (d) 80.

It is known [23, 24] that the thickness of hydrate shells of latex particles considerably decreases with increasing electrolyte concentration. Therefore, the observed increase in the flocculation efficiency at high NaCl concentrations (c_{NaCl} > 0.05–0.1 M) is associated with progressive breakdown and thinning of the hydrate shells under the action of the electrolyte. This allows the particles to approach one another more closely, thus increasing the probability of bridging between them.

Figure 3 shows the rubber separation curves (under the effect of PDDAC with $M_v = 17.4 \times 10^4$) at a tem-

perature of 20 to 80°C and various rubber concentrations in the latex. At relatively low disperse phase concentrations (c_d 20 and 30 g l^{-1}), raising the temperature provides an effect similar to that produced by increasing ionic strength: in the restabilization range, the rubber separation efficiency tends to grow. At c_d = 30 g l^{-1}, the restabilization effect is totally suppressed starting from 60°C, and the flocculation curves flatten out, which corresponds to complete separation of the rubber from the latex. At higher latex concentrations (c_d 50 and 100 g l^{-1}), when the restabilization effect is lost, temperature has no effect on the flocculation efficiency.

Finally, raising the temperature or ionic strength weakens the restabilization effect to the point of its elimination, provided that the disperse phase concentration is sufficiently high (c_d = 30 g l^{-1} in our case).

One of possible reasons for the observed effect is, evidently, a rise in particle mobility and in frequency and energy of their collisions with increasing temperature. In this context, heating is similar to raising the disperse phase concentration.

To conclude, the efficiency of rubber separation from a latex through flocculation with a cationic polyelectrolyte can be raised by adding an inorganic salt and elevating the temperature. In both cases, the net effect consists in weakening of the restabilization effect at flocculant concentrations exceeding OFC. From the practical standpoint, this suggests, among other things, the possibility of making less stringent the requirements to the precision of flocculant dosage as compared to that commonly needed for dilute dispersions, when efficient separation of the dispersed phase is only achieved in a narrow range of flocculant concentrations in the vicinity of OFC.

CONCLUSION

Raising the ionic strength by adding NaCl results in higher flocculation rate and completeness of coagulation of SKN-26SM butadiene-acrylonitrile rubber through weakening of the restabilization effect in the system with excess flocculant. For dilute latices, similar effect is observed at elevated temperature.

Abstract—2-Vinylphenothiazine was prepared, and its polymerization was studied. The possibility of using 2-vinylphenothiazine and its polymer as antioxidant in industrial rubber formulations was examined.

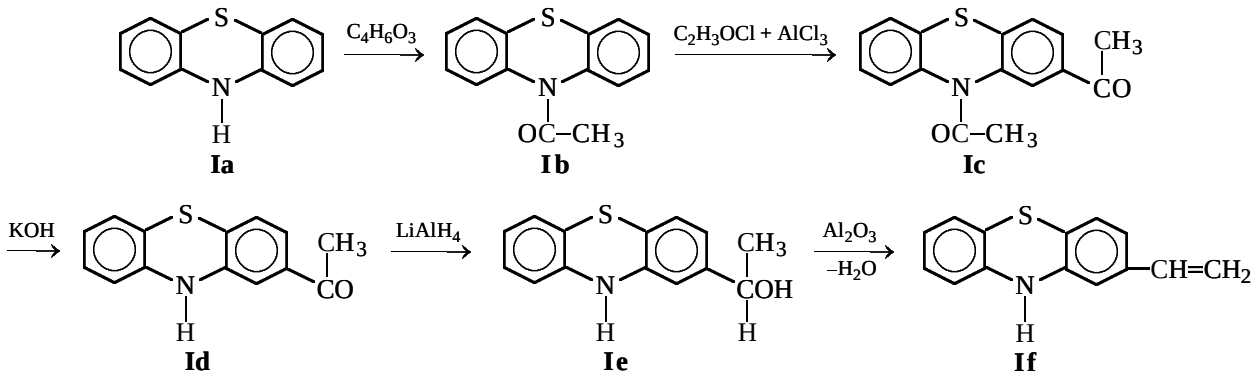
Nitrogen- and sulfur-containing heterocyclic compounds attract much researchers' attention. Among these compounds, phenothiazine and its diverse derivatives found extensive applications. Many phenothiazine derivatives have valuable properties and are used in pharmacy, in photographic and polygraphic industry for fabricating photographic materials, as inhibitors, antioxidants, etc. [1–5].

Vinyl derivatives of phenothiazine, especially 2-vinylphenothiazine (2-VPT), are of particular interest. However, their synthesis and preparation of polymeric materials from them have been studied poorly. First experiments on radical polymerization of 2-VPT failed, which was due to easy abstraction of hydrogen from the amino group and inhibition of the polymeric chain propagation by the resulting radical [6, 7]. Therefore, experiments on preparation of polymeric materials from 2-VPT were initially performed in an acylating solvent (acetic anhydride) and resulted in preparation of poly-2-vinyl-10-acetylphenothiazine. Saponification of this compound with an alcoholic alkali yielded poly-2-VPT. Later studies demonstrated the feasibility of preparing poly-2-VPT by direct radical polymerization of monomeric 2-VPT. However, it remains unclear from the available data how the polymerization conditions affect the degree of conversion of 2-VPT into the polymer.

In this study, we analyzed radical polymerization of 2-VPT in the bulk and in solution, evaluated the resistance of the polymer to thermal oxidative degradation, and examined the properties of polymeric compounds containing 2-VPT and its polymers.

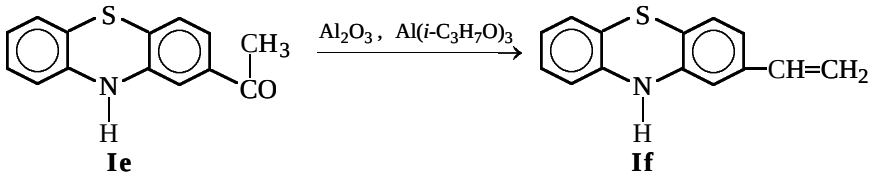
EXPERIMENTAL

2-Vinylphenothiazine was prepared from phenothiazine (mp 182–184°C) as follows [6, 8, 9]:



Scheme 1.

1070-4272/03/7608-1327 $25.00 © 2003 MAIK "Nauka/Interperiodica"



Scheme 2.

Acylation of phenothiazine (**Ia**) with refluxing acetic anhydride at 140°C for 5 h gave 10-acetylphenothiazine **Ib** in 97% yield [6]. Acylation of **Ib** with acetyl chloride in the presence of $AlCl_3$ produced 2,10-diacetylphenothiazine **Ic** [8, 9], which was then saponified with an alcoholic solution of KOH to give 2-acetylphenothiazine **Id** [6, 8]. The yield of 2-acetylphenothiazine after recrystallization from ethyl acetate was 80–95%. Compound **Id** was reduced with $LiAlH_4$ in ether within 12 h to 2-(1-hydroxyethyl)phenothiazine **Ie** in 65–74% yield [8, 10]. Dehydration of **Ie** in the presence of Al_2O_3 in a vacuum at 220–240°C gave 2-VPT (**If**) in 20–30 wt % yield (Scheme 1).

According to Scheme 2, 2-VPT can be prepared in 15–23 wt % yield in a single step under conditions of high-vacuum (10^{-3} mm Hg) high-temperature (220°C) sublimation of a mixture of 2-acetylphenothiazine (**Id**), triisopropoxyaluminum, and Al_2O_3.

The structure of the product (mp 178–180°C) was confirmed by IR, UV, and ^1H NMR spectroscopy, and also by elemental analysis.

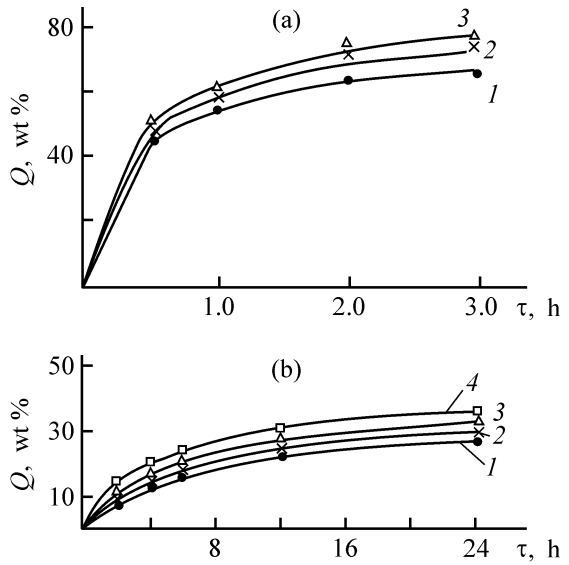


Fig. 1. Yield of poly-2-VPT *Q* vs. the time τ of polymerization (a) in the bulk and (b) in solution at various temperatures. *T*, °C: (a) (*1*) 185, (*2*) 210, and (*3*) 245; (b) (*1*) 70, (*2*) 80, (*3*) 90, and (*4*) 100.

Found, %: C 74.60; H 4.95; N 6.20.
$C_{14}H_{11}NS$.
Calculated, %: C 74.67; H 4.90; N 6.20.

High-temperature radical polymerization of 2-VPT was performed in the bulk in evacuated (10^{-3} mm Hg) and sealed glass ampules. The product was dissolved in THF or benzene and precipitated with a 5–10-fold amount of ethanol.

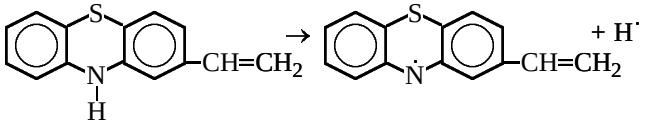
Radical polymerization of 2-VPT in benzene was performed in the presence of azobis(isobutyronitrile) at 70–100°C. The initial concentrations of the monomer and initiator in solution were 3.4×10^{-1} and 1.04×10^{-2} M, respectively.

We found (Fig. 1a) that, in the examined range of reaction times, the yield of poly-2-VPT steadily grows with temperature. The optimal reaction time is 2–3 h. Heating above 240°C is not appropriate, because the polymer yield does not increase further, but degradation becomes noticeable.

According to gel permeation chromatography, the synthesized poly-2-VPT had $\overline{M}_n$ = 2040, $\overline{M}_w$ = 4280, $\overline{M}_z$ = 9950, and $\overline{M}_w/\overline{M}_z$ = 2.1. Elemental analysis gave consistent results for the C, N, and H content, suggesting the absence of degradation in the course of high-temperature polymerization.

Found, %: C 74.6; H 4.95, N 6.2.
$(C_{11}H_{14}NS)_n$.
Calculated, %: C 74.7; H 4.9; N 6.2.

In polymerization in solution, the polymer yield also increased with temperature (Fig. 1b); however, it remained much lower than in that bulk polymerization in the same period of time. This is most probably due to easy abstraction of hydrogen from the amino group of the monomer or polymeric unit with the formation of a free radical terminating the polymeric chain and thus decreasing the yield and molecular weight of the polymer:



The low molecular weights of the polymers prepared by various procedures are due to the presence of the labile N–H bond in the phenothiazine group. It should be noted, however, that poly-2-VPT prepared in solution has a somewhat higher molecular weight ($\overline{M}_n$ = 3000–4000). This may be due to the fact that generation of radicals is more intense in thermal polymerization in the bulk, performed at higher temperature (185–245°C) than polymerization in solution (70–100°C). This results in higher concentration of initiating species, higher initiation rate, and hence increased conversion of the monomer, especially in the initial step. However, the high concentration of radicals in high-temperature bulk polymerization, on the other hand, results in more active chain termination, compared to polymerization in solution at a lower temperature. Therefore, the molecular weight of the polymer prepared in the bulk is lower.

Poly-2-vinylphenothiazine prepared by polymerization of 2-VPT in solution was largely similar to poly-2-VPT prepared in the bulk.

The structure of the poly-2-VPT samples obtained was confirmed by IR, UV, and ^{1}H NMR spectroscopy. The IR spectrum of poly-2-VPT (Fig. 2) shows no bands at 900 and 990 cm^{-1}, characteristic of monomeric 2-VPT. The UV spectrum of the polymer is similar to that of the starting 2-VPT. The spectrum contains a band at 258 nm (ε = 28100) characteristic of the π→π* transition in the conjugated system and a band at 320 nm (ε = 3500) related to the lone electron pairs of the N and S atoms. In the ^{1}H NMR spectrum of the polymer (Fig. 3), the signals at 5.15, 5.65, and 6.62 ppm, belonging to the vinyl protons of the monomer, disappear, and a broad unresolved signal of the CH and CH_2 protons of the polymeric chain appears at 0.75–2.7 ppm. The spectrum also contains signals from aromatic protons at 6.75–7.72 ppm and NH proton at 8.2 ppm.

The X-ray diffraction patterns of the polymers show that they are X-ray-amorphous.

The inhibition of radical polymerization by phenothiazine suggests that thermal oxidative degradation of polymers can be hindered by introduction of phenothiazine fragments into macromolecules. Also, a study of thermal oxidative degradation of poly-2-VPT prepared at low temperature in solution could show whether or not thermal degradation of poly-2-VPT can occur directly in the course of high-temperature polymerization of the monomer in the bulk. Figure 4 shows that poly-2-VPT starts to degrade in air only at high temperatures (350–380°C) exceeding by more than 100°C the polymerization temperature (≤250°C). A minor weight loss at lower temperatures is due to desorption of low-molecular-weight compounds (water, solvent, monomer). At 500°C, the weight loss slightly exceeds 30 wt %.

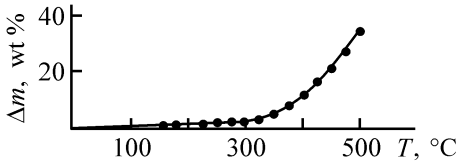

Fig. 4. Weight loss Δ*m* of poly-2-VPT on heating in air vs. temperature *T*.

The absence of degradation in poly-2-VPT at temperatures of up to 350°C confirms the possibility of high-temperature polymerization of monomeric 2-VPT in the temperature range examined. The high resistance of poly-2-VPT to thermal oxidative degradation is due to the presence, in each unit of the polymer, of the phenothiazine substituent containing the labile N–H group whose homolysis products inhibit degradation of polymeric molecules.

Fedotova *et al.* [10] has shown that introduction of phenothiazine and its derivatives into various polymers by mechanical blending enhances their resistance to thermal oxidative degradation. However, phenothiazine and its alkyl derivatives tend to exude on the surface of finished industrial rubber items, which is a major drawback, since this decreases the stability and may promote cleavage of multilayered articles. To minimize exudation, it is appropriate to modify the phenothiazine molecule with a reactive functional group capable of forming valence bonds with rubber

macromolecules in the course of stock preparation and vulcanization. It can be expected that 2-VPT will be grafted via its vinyl group to polymeric chains and will act as a nonexuding chemically bound antiaging agent. To verify this assumption, we introduced 2-VPT and poly-2-VPT into the polymeric matrix in the course of rubber stock preparation, with the subsequent vulcanization.

Rubber stocks were prepared on 320×160-mm laboratory rollers at 65 ± 5°C by common procedures and vucalnized in a mold at 143°C. Tests were performed by standard procedures. The results obtained with 2-VPT and poly-2-VPT additives were compared with those obtained using known antiaging agents: Neozon D, Quinol ED, and phenothiazine.

The resistance of vulcanized rubbers to three kinds of aging was evaluated. The resistance to thermal aging was determined at 100°C over a period of 72 h by the aging coefficients with respect to relative elongation. The resistance to ozone aging was determined at 50°C, working ozone concentration of 5×10^{-5} vol %, and static elongation of 10%. The resistance to dynamic loads was evaluated under conditions of repeated extension (dynamic strain 200%) from the number of cycles till failure.

The experimental results listed in the table show that, in all the main parameters, the vulcanized rubbers containing 2-VPT and poly-2-VPT are not inferior to those containing Neozon D and Quinol ED and even surpass them in the resistance to dynamic loads and to ozone.

Thus, phenothiazine, 2-VPT, and poly-2-VPT are good agents against ozone aging. However, in vulcanizates based on SKD rubber, 2-VPT at its high content is more active than unsubstituted phenothiazine. This is due to weaker exudation of 2-VPT on the surface and to its better compatibility with the rubber, since it can add to the diene rubber molecules via vinyl group in the course of compounding.

CONCLUSIONS

(1) Experiments on radical polymerization of 2-vinylphenothiazine in the bulk at high temperatures and in solution in the presence of azobis(isobutyronitrile) as radical initiator demonstrated an inhibiting effect of phenothiazine-containing units on the degradation processes in the polymers.

(2) 2-Vinylphenothiazine and its polymer can be used as antioxidants in industrial rubber formulations.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Composite Hardener for Epoxy Adhesives

S. L. Selektor, M. Yu. Semyachkin, and V. V. Arslanov

Institute of Physical Chemistry, Russian Academy of Sciences, Moscow, Russia

Received December 26, 2002; in final form, April 2003

Abstract—A new composite hardener for epoxy adhesives, based on a heteropoly acid, was suggested, and its formula was optimized. The curing kinetics and the physicomechanical and adhesion properties of the cured material were studied. The advantages of the new material over traditional epoxy adhesives were demonstrated, and the ways to control its characteristics were found.

Wide use of binary epoxy adhesives cured by polyamines is due to the possibility of room-temperature curing. However, the high toxicity of polyamines makes topical a search for new, less toxic and more environmentally safe, hardeners. Among such hardeners are heteropoly acids (HPAs) and their salts, which are active catalysts for polymerization of epoxy oligomers [1, 2]. The problem is that, in the presence of even small amounts of such compounds introduced as aqueous solution, the polymerization is so vigorous that the formulation warms up to temperatures exceeding the decomposition point of epoxy materials [2]. Furthermore, it should be noted that even dilute HPA solutions are aggressive liquids with low pH. These facts have prevented application of aqueous HPA solutions as initiators of curing of epoxy adhesives.

In this study, to solve these problems, we suggest a composite hardener containing, along with HPA and water, an additional third component introduced to dissipate the excess heat, decelerate the initiated polymerization, and improve the compatibility of the oligomer and hardener. As such "inhibiting" component we chose high-molecular-weight polyvinyl alcohol (VRP-1), a polymer forming stable highly viscous aqueous solutions well compatible with heteropoly compounds (HPCs).

EXPERIMENTAL

To verify our suggestions, we chose a formulation of ED-20 epoxy resin, phosphotungstic acid (HPW), and a gel-like aqueous solution of VRP-1; the weight ratio of the resin and VRP-1 solution was 9 : 1 in all the systems.

To optimize the adhesive formula and curing conditions, we studied the curing kinetics in the range 18–90°C at varied content of the initiator (HPW, 1.5–6.8 wt %). The curing kinetics was monitored by sol–gel analysis and by microhardness measurements. The sol–gel analysis was performed by extraction with acetone at room temperature to constant weight (for no less than 18 h). The microhardness of polymeric films was measured with a PMT-3 hardness gage with a pyramidal diamond indenter.

The adhesion strength was evaluated by exfoliation of A99 aluminum foil at an angle of 180° with an Instron-1121 universal tensile-testing machine. Immediately before applying the adhesive, the surface of the aluminum support was etched with 10% NaOH at 60°C for 2 min, with subsequent brightening in 20% HNO_3 and washing with distilled water. Similar tests were performed with the same ED-20 epoxy resin cured with traditionally used polyethylenepolyamine (PEPA) added in amounts of 10 wt parts per 100 wt parts of the resin. The films formed were cured for a day at 18–20°C ("cold" curing), or for 30 min at 90°C (formulations with HPW) or 3 h at 100°C (formulations with PEPA) ("hot" curing). Cold curing was continued until the sol fraction content no longer decreased.

The deformation and strength properties of the composites were studied with an Instron-1121 machine in the extension mode at a clamp velocity of 10 mm min^{-1}. Samples were prepared as strips of aluminum foil with an applied adhesive layer [3, 4]. The strength characteristics of the foil itself were determined in preliminary experiments. The modulus of elasticity E_{met}, calculated from the initial linear

portion of the σ–ε diagram (σ is the specific load, kg cm^{-2}; ε, relative elongation) was 3.43 MPa; the breaking load σ_{met}^{lim} was 2.6 kg per centimeter of the sample width at the place of break.

Similar measurements performed with a two-layered system showed that the sample is broken at loads considerably exceeding the strength of the metallic support, but, at the onset of failure, the deformations correspond to the portion of the σ–ε curve in which the support behaves according to the Hooke law (range of elastic strain), rather than to the range of plastic strain [5]. In this case, the stress distribution in the two-layer system can be regarded as additive, and the breaking load of the polymer layer can be calculated as the difference between the breaking load for the coated sample and the load required for extension of the uncoated foil of the same width to the extent at which the coating failed:

$$P_{pc} = P_s - P_{met} = P_s - \varepsilon_s E_{met} S_{met}.$$

Here P_{pc} is the breaking load for the polymer coating, N; P_s, ultimate load on the failure diagram for the two-layered sample, N; P_{met}, load required to deform the metal sample to ε_s, N; E_{met}, modulus of elasticity of the metal, Pa; ε_s, relative deformation of the two-layered sample at break; and S_{met}, cross section of the metal sample, m^2.

The influence of the curing time and temperature on the sol fraction content φ (%) in the formulations containing various amounts of the initiator is shown in Fig. 1. As expected, with increasing curing temperature, the gelation considerably accelerates: its duration decreases from several hours in cold curing to several minutes at 90°C. The kinetic curves (Fig. 1) can be divided in several portions corresponding to various steps of gelation. In cold curing, the sol–gel analysis reveals a short incubation period preceding the avalanche-like autocatalytic process. Such a delay is indicative of a slow diffusion of the initiator from the bulk of an emulsion drop to the phase boundary. At elevated temperatures, this step is complete in several seconds. In the next step, in all the cases, the sol fraction content rapidly decreases, which is characteristic of the relay mechanism of initiated gelation in the bulk of the material (Fig. 1, region *A*).

The influence of the initiator content on the curing kinetics is manifested to the greatest extent at room temperature: As the HPW concentration is raised from 3.3 to 5.0 wt %, the rate at which the sol fraction content decreases ($-d\varphi/d\tau$) in the initial linear portions of the curves (Fig. 1, region *A*) grows by approximately a factor of four (from 0.31 to 1.18). At 90°C, the rate ratio does not exceed 2, and gelation is mostly complete within 1.5–2 min.

In region *C*, the sol fraction content decreases very slowly at all the temperatures, which may be due to diffusion hindrance preventing further curing in the bulk of the material.

In the transition region *B* between regions *A* and *C*, the rate at which the sol fraction content decreases first falls abruptly and then grows again. This may be due to significant conformational limitations arising in the material and to the high level of internal stresses accompanying fast cross-linking; after their relaxation, the gelation slightly accelerates again.

The multistep course of network polymer formation is noted by Irzhak *et al.* [6]; they believe that the process rate in each particular step is governed by the ratio of the rate constant of the proper chemical reaction between the functional groups and those of various relaxation processes (local or segmental) involving these groups. Ivanov [2] believes that the decisive factor affecting the cross-linking kinetics of

an epoxy oligomer in the presence of an emulsified aqueous HPA solution is the HPA concentration in this solution, rather than the total amount of the solution. Unfortunately, this conclusion was based on data for a relatively narrow range of concentrations and curing temperatures. For the emulsions in question, the dependence of the gelation rate on the concentration of the initiator solution is determined by the ratio of the rates of the chemical step (polymerization) and HPW diffusion. The HPW diffusion should be considered in an emulsion drop, in the non-cross-linked resin, and in cured regions of the forming polymer. The last factor is the most important for high curing temperatures.

A comparative analysis of the sol fraction content in fully cured formulations showed that, although the gelation accelerates with increasing initiator concentration in cold curing (Fig. 1a), the degree of curing as a function of the initiator content passes through a maximum. As the HPW content is raised from 3.2 to 4.8%, the residual sol fraction content first decreases from 23 to 17% and then grows to 24%. The degree of curing in the case of hot curing varies similarly.

Such a behavior of the system confirms the existence of considerable diffusion limitations arising directly in the course of gelation. Apparently, at high initiator concentrations, fast polymerization in the regions adjacent to the phase boundaries in the emulsion (between epoxy resin and thickened aqueous HPW solution) results in formation of a densely cross-linked network preventing the initiator diffusion into the bulk of the resin. Such a concept accounts for the revealed [2] increase in the degree of polymerization of the formulations with decreasing HPA concentration in the initial solution and with increasing total amount of this solution in the system. The role of diffusion limitations decreases in the first case owing to lower initial rate of the chemical reaction at the phase boundary between the epoxy oligomer and the aqueous solution of the initiator, and in the second, owing to the increased contact surface area. The weaker influence of the initiator concentration on the curing rate at elevated temperatures suggests that, as expected, the activation energy of polymerization considerably exceeds that of diffusion. As a result, the rate of the chemical reaction of polymerization grows with increasing temperature faster than the diffusion rate, so that the diffusion limitations become more significant.

Evaluation of the activation energy of polymerization from the results of a sol–gel analysis for the formulation containing 3.8 wt % HPW gives a value of 60 kJ mol^{-1}, consistent with data of [2]. As the HPW concentration is raised, the activation energy decreases somewhat.

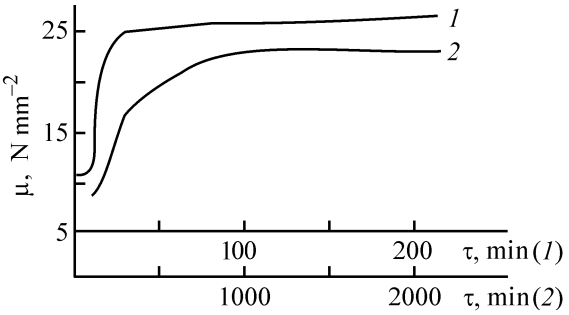

Fig. 2. Variation of the microhardness μ of the formulation containing 3.8 wt % HPW with curing time τ. Curing temperature, °C: (*1*) 20 and (*2*) 90.

The validity of the suggested curing scheme is supported by the results of the microhardness measurements. Figure 2 shows that, at both curing temperatures, there are intervals in which the microhardness grows steeply. In cold curing, the interval of the steep growth of microhardness (Fig. 2, curve *1*; up to 200 min) corresponds to completion of fast gelation (Fig. 1a). In hot curing, the microhardness starts to grow steeply only after fast gelation is complete. Such a "delay" in the microhardness growth at elevated temperatures may be due to the increasing role of diffusion limitations in both curing and extraction of the sol fraction. Deceleration of the diffusion is due to formation of densely cross-linked zones around drops of the emulsified initiator solution. These zones must appreciably hinder the cross-linking in the bulk of the nonpolymerized resin and also the extraction of the sol fraction from this volume during tests. At the same time, the presence of separate densely cross-linked zones does not affect noticeably the microhardness of the material. For the microhardness to increase, such zones must grow together to form a rigid framework.

To reveal the influence of the HPW concentration on the structure of the forming polymeric material, we analyzed how the microhardness of the fully cured films depends on the initiator content. We found that the microhardness of the films cured at 90°C decreases with increasing HPW concentration, whereas for the films cured at 20°C the dependence passes through a minimum.

The dependences observed may be due to the fact that, at low HPW concentrations, the growth of local polymerization zones noticeablly accelerates as the HPW content is raised. This considerably restricts the

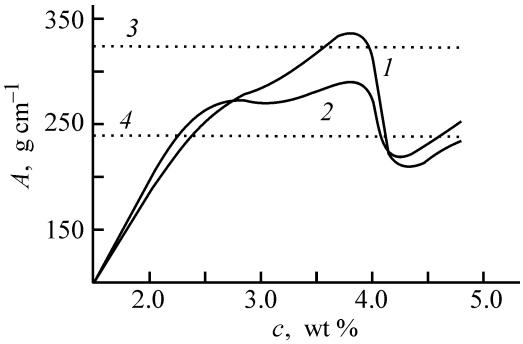

Fig. 3. Strength *A* of adhesion joints epoxy polymer–aluminum vs. the HPW content *c* in compounds cured at (*1*) 90 and (*2*) 20°C. (*3, 4*) Epoxy polymer cured with PEPA at 100 and 20°C, respectively.

conformational mobility of the cross-linking macromolecules and results in formation of a more defective polymer structure with decreased microhardness. In hot curing, this trend keeps in the entire concentration range, whereas in cold curing the microhardness starts to increase at an HPW concentration of 4.0 wt %. This growth is due to the fact that, at high concentrations of the hardener and relatively low reaction rates, the increase in the density of cross-linking of the gel fraction acquires decisive importance. In this case, apparently, the structure of the polymer becomes still less uniform, since in the entire examined range of curing temperatures the sol fraction content grows with increasing initiator concentration.

It is notable that, at all the temperatures, the sol fraction content passes through a minimum at an HPW concentration ot 3.8–4.1 wt %, i.e., at the concentration at which the microhardness also passes through a minimum. This is due to the fact that the microhardness is determined not by the overall gel fraction content but by the uniformity of distribution of the chemical bonds in the three-dimensional network of the polymer. The coincidence of the characteristic points in the concentration dependences of the microhardness and residual sol fraction content suggests that there is a threshold in the concentration region in the vicinity of these points.

It should be noted that epoxy materials cured with amines show strong structural nonuniformity, too [6–8]. Some authors speak of clusters with a high degree of ordering [8], and other authors, of a developed globular structure consisting of more densely packed regions (globules) and regions with nonuniform packing and taut chains (interglobular space) [7]. These are, however, different descriptions of the same fact: nonuniform distribution of network points in the bulk of the epoxy material.

In addition, Nielsen [8] indicates that, in some ranges, the dependence of the elastic characteristics of network polymeric materials in the glassy state on the mean concentration of network points is inverse. This is attributed to weakening of intermolecular physical interactions in formation of a rigid chemically cross-linked three-dimensional network significantly restricting the segmental mobility of macromolecules. Although Nielsen discusses the dynamic modulus of elasticity of thickly cross-linked polymers [8], it is commonly believed [9] that the microhardness also belongs to parameters characterizing the elastic properties of polymeric materials. Furthermore, in many studies, attempts are made to calculate the modulus of elasticity from the results of microhardness measurements with indenters of various shapes [9].

Thus, the study of the curing kinetic showed that it is possible to control the gelation rate, degree of gelation, and properties of the resulting material by varying the temperature and initiator concentration.

Since the main criteria in evaluating the service properties of an adhesive formulation are the strength and durability of the adhesion joint, the adhesive formula was optimized on the basis of adhesion tests. Figure 3 shows that the adhesion strength is a nonmonotonic function of the initiator concentration. At both curing temperatures, the highest adhesion strength was attained with 3.8 wt % HPW. In both cases, the adhesion strength at the maximum exceeds that attained with the amine hardener. The same formulation appeared to be the most stable in tests in water; its performance in the case of hot curing appeared to be similar to that of the aminecured compound, and in the case of cold curing it showed much better performance.

The increase in the strength of adhesion joints in the ascending branch of the strength-vs.-initiator concentration dependence is due to a rise in the cohesion strength and plasticity of the adhesive material and also to activation of the aluminum surface under the action of the HPW solution having low pH. The descending branch of the curve may be associated with acceleration of polymerization involving functional groups of the epoxy oligomer and taking them out of adhesion interaction with the polar surface of the metal. Furthermore, fast gelation largely restricts the conformational mobility of the macromolecules and segments of the polymeric network, preventing their interaction with active centers of the surface. Thus, the best service properties are shown by the adhesive containing 13.5 wt % HPW solution in VRP-1,

at a 29 wt % content of HPW in this solution (i.e., 3.8 wt % HPW in the formulation).

To refine the parameters of preparation and application of the adhesive suggested, we studied the properties of the material with the optimal initiator content in more detail. The results of a detailed sol–gel analysis for various curing temperatures are shown in Fig. 1, curve *3*. As already noted, the curing occurs in distinct steps (transition region *B*), which is due to relaxation of stresses arising in the material in the first step of gelation. A prolonged experiment showed that the sol fraction content in the samples cured at 90°C became ultimately the same as that upon curing at 60°C. Presumably, the initiated polymerization reaches the co-called topological limit in both cases [7, 8].

To confirm the significant role of relaxation of internal stresses in the curing kinetics and formation of the supramolecular structure of the adhesive, we studied its physicomechanical properties and their variation on adding the plasticizer. A calculation of the strength characteristics of the adhesive with the optimal HPW content from the results of mechanical tests showed that the material cured at room temperature has an approximately three times greater relative elongation than the hot-cured compound. The modulus of elasticity differs by approximately a factor of 5. For the cold-cured compound, E was as low as 670 MPa. For the hot-cured compound, $E = 3.1 \times 10^3$ MPa, which is close to E for the amine-cured compound. However, the breaking stress of the amine-cured compound appeared to be almost twice that of the HPW-cured compound. The fact that the modulus of elasticity of the hot-cured compound virtually coincides with that of the PEPA-cured epoxy resin suggests similar structures of these network polymers, and the different strength parameters may be due to increased defectiveness of the network formed by fast polymerization in the presence of the catalyst (HPW).

It is known that the density n_c of the chemical points of a polymeric network can be evaluated from the modulus of elasticity measured in the absence of intermolecular interactions; theoretically, this is the case in the hyperelastic state only. Therefore, the minimum in the microhardness of the considered formulation at a 3.8 wt % HPW content was due to substantial weakening of such interactions; this allowed us to estimate n_c from the measured tensile modulus of elasticity. Such approaches are widely used [10]. The mean density of network points was calculated from the formula [6]

$$n_c = 3E/\gamma RT,$$

where γ is the front factor taking into account the deviation of the network from the ideal state.

For epoxy materials, the experimentally determined value of γ is 1.4–1.9 [6]. We assumed a value of 1.9 (the most defective structure). The density of the network points in the hot-cured compound, determined by this procedure, was 2.3×10^3 m^{-3}, which virtually coincides with the n_c values obtained for epoxy polymers cured with amines under the same conditions.

As a rule, addition of a plasticizer to a polymeric material must increase its elasticity but decrease the strength and the modulus of elasticity [11]. However, plasticizers added in low concentrations make the material less defective and decrease the concentration of stresses at microcrack apices [1, 3, 7, 12–14]. This, in turn, must enhance the fatigue strength and durability. The relatively low cohesion strength of the compound in hand is apparently due to the high level of internal stresses arising from nonuniform gelation in slow relaxation. In this case, it can be expected that the presence of a plasticizer facilitating relaxation of stresses and enhancing the conformational mobility will strengthen the material under static conditions, too. As in [12], the dependence of the material strength on the amount of the additive must pass through a maximum, since weakening of intermolecular interactions at high plasticizer content will result in a gradual decrease in the strength characteristics. We emphasize that, in a system with a high level of internal stresses, the increase in the strength of the plasticized material relative to the initial material would be expected at relatively high plasticizer concentrations, too.

To check the validity of these assumptions, we measured the strength and relative deformation of a plasticized adhesive. As plasticizer we used glycerol, which, being a low-molecular-weight polar organic compound, is well compatible with the epoxy resin and VRP-1. Glycerol was added simultaneously with the curing agent; the glycerol : resin weight ratio was 1 : 10. The resulting compound appeared to be heterophase, which was manifested in the turbidity of the cured films (without plasticizer, the material became transparent upon curing).

As expected, the results of mechanical tests showed that the strength and modulus of elasticity of the material increased by more than a factor of 3 upon plasticization; for the hot-cured compound, the modulus of elasticity was 9.3×10^3 MPa, and the breaking stress, 11.1 MPa. The relative deformation of the films remained approximately the same. Note that the

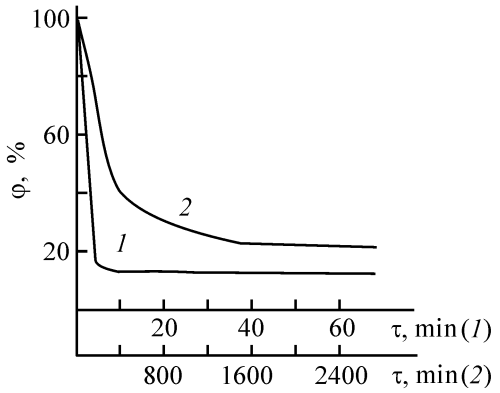

Fig. 4. Sol fraction content φ vs. time τ of curing of a compound containing 3.8 wt % HPW and glycerol. Curing temperature, °C: (*1*) 20 and (*2*) 90.

similarly measured strength of ED-20 resin cured with PEPA appeared to be 15.4 MPa, i.e., the strength of the plasticized formulation approaches that of traditional compounds.

Furthermore, the results of sol–gel analysis (Fig. 4) and microhardness measurements made with the plasticized adhesive in the course of curing show that the plasticizer inhibits somewhat the gelation and, what is especially important, smoothens inflections in the kinetic curves (Fig. 4), associated with relaxation of internal tensions (Fig. 1, range *B*). It is interesting that the residual content of the sol fraction in plasticized compounds virtually coincides with that in the glycerol-free compounds, i.e., addition of the plasticizer affects the uniformity of sol fraction distribution in the polymer bulk, rather than the overall gel fraction content.

CONCLUSIONS

(1) Introduction of a water-soluble polymer into epoxy resin hardeners based on aqueous solutions of heteropoly acids appreciably inhibits curing, decreases the heat release, and allows preparation of adhesives ensuring high strength and stability of adhesive joints; this approach opens up prospects for development of a new generation of hardeners.

(2) Curing of ED-20 epoxy resin under the action of phosphotungstic acid occurs in steps: the three-dimensionally cross-linked network is formed by intergrowth of the initially formed densely cross-linked local zones, with the transition (intergrowth) zones being the most defective and the least densely cross-linked.

(3) The mechanical properties of the adhesive developed can be controlled by introducing plasticizing additives.

Received April 14, 2003

Abstract—A two-stage procedure for production of powdered cellulose II, based on polymorphous transformation of native cellulose I and hydrolytic dispersion of the fiber with a single reagent, nitric acid, was proposed.

A search for new procedures for production of powdered cellulose (PC) forms with improved characteristics is an urgent task. The most commonly used modification of PC is microcrystalline cellulose (MCC) produced by partial acid hydrolysis of cellulose fiber to the so-called limiting degree of polymerization (DP). The vast majority of studies in this field are aimed to improve the conditions of hydrolytic cleavage of native fiber (cellulose I), characterize the recovered MCC-I, and determine the fields of its application [1–3].

At the same time, some publications [4, 5] reported similar data on cellulose II produced in the form of powder from the native fiber, using hydrolytic dispersion. According to [5], the polymorphous transition from cellulose I to cellulose II results in increased dispersity and whiteness of the final products, which is important, e.g., for pharmaceutical applications. The polymorphous transformation is usually effected by mercerization of native cellulose with 15–20% aqueous sodium hydroxide. Thus, to produce powdered cellulose II from native fiber, both alkaline and acidic reagents are used, which is inconvenient for technology.

Here, we discuss the possibility of polymorphous transformation and hydrolytic dispersion of cellulose with a single reagent, nitric acid. The structural and sorption characteristics of powdered samples of various morphologies, prepared by the acidic process, are presented in comparison with the similar characteristics of the samples produced by the traditional procedure and also of MCC-I.

EXPERIMENTAL

Purified wood sulfite cellulose of the Raikord brand (96% α-cellulose, DP = 1500) was used as the starting material for production of powdered forms.

The working 68.5% HNO_3 solution was prepared from commercial 72% HNO_3 of ultrapure grade. The acid concentration was checked by the solution density at 20°C. Along with the acid, 18% NaOH was used. Production of all powdered forms of cellulose was completed by repeated washing of the final products to neutral reaction of the wash waters, removal of water with acetone, and drying at room temperature. After drying, the samples were additionally milled in a mortar to a dispersity allowing sifting through a 100-μm sieve.

Variations of physical and chemical characteristics of cellulose in polymorphous transformation by the nitric acid procedure were judged from the IR spectra recorded on a Specord 75-IR spectrophotometer. Samples were prepared as described in [6]. The content of bound nitrogen in the samples was determined by the Kjeldahl procedure [7].

The degree of polymerization of powdered cellulose forms was estimated from the viscosity of nitrate ester solutions according to the procedure [8] tested on the samples of cellulose with known DP.

X-ray diffraction patterns were recorded on an HZG-4a diffractometer (Cu_{K_α} radiation, Ni filter). The samples in the form of flat discs were prepared by cold pressing. The crystallinity index of the samples

1070-4272/03/7608-1337 $25.00 © 2003 MAIK "Nauka/Interperiodica"

was determined from the diffraction patterns obtained under similar conditions [9].

The morphology of structural elements of the powders was studied with an EM-125K transmission electron microscope. PC particles were dispersed by ultrasonic treatment (UZDN-2T unit, 22 kHz, maximum power). As a result, a slightly opalescent suspension was obtained. A drop of this suspension was applied to the surface of freshly painted mica, and the dispersion medium was evaporated. The samples for microscopic examination were prepared using platinum-carbon replicas.

The surface of powder particles and cross sections of the fibers were studied using an S-520 Hitachi scanning electron microscope. The cross sections were obtained on a manual microtome using a razor blade. The surfaces to be studied were gold-plated in a gas-plasma discharge.

The procedure for determining the water-retaining capacity (WRC) of cellulose was described in [10]. The sorption of iodine was evaluated by the procedure described in [11], and that of Congo Red, by the procedure described in [12].

The nitric acid procedures for production of powder forms of cellulose II, discussed here, are based on the ability of HNO_3 to form the Knecht addition compound (KC) with cellulose at a concentration of 68–69%, and also to promote hydrolysis of cellulose fiber at low concentrations and elevated temperature.

KC has been known for a long time [13], but up to now its chemical composition and structure have not been determined reliably. Under the action of water, cellulose is regenerated from KC produced on the basis of native cellulose, which enables a purely acidic scheme for processing of native fiber to powdered forms of cellulose II.

HCl, as a rule, and, less commonly, H_2SO_4 are used for hydrolytic cleavage of cellulose fiber [14]. Among published data, there are only a few evidences for the use of HNO_3 for this purpose [15, 16], although its catalytic activity is rather high. When studying sucrose hydrolysis in solutions of some acids, Ostwald revealed the highest catalytic activity of HCl, which was then taken as a reference. According to similar experimental data on hydrolysis of cellulose in 2 N solutions of various acids, the catalytic activity of HNO_3 at 100°C is close to the activity of HCl (0.95 against 1), while that of H_2SO_4 is 0.57 [17]. Apparently, the development of studies on using HNO_3 for production of MCC has been restrained by the well-known ability of this acid to chemically modify cellulose.

Two samples of cellulose II in the powdered form were prepared by the unconventional procedure using nitric acid only. In production of a sample with microcrystalline structure (MCC-IIn), wood cellulose was first treated for 3 h at the temperature of thawing ice and a liquid-to-solid ratio of 20 ml of 68.5% nitric acid per gram. This treatment must provide complete intracrystallite swelling of native cellulose, so that under subsequent action of water it must completely transform via KC into cellulose II. It is wood cellulose with its inherent moderate crystallinity that is the most appropriate material for completion of these transformations under the action of 68–69% HNO_3 and then water. In the case of cotton cellulose characterized by relatively coarse and perfect crystallites, phase transitions cellulose I $\rightarrow$ KC and KC $\rightarrow$ cellulose II occur partially [18].

Nitric acid at a concentration of 68–69% exerts a weak nitrating effect on cellulose [18, 19]. To decrease the nitrating activity of nitric acid, the treatment was carried out at low temperature, which, however, increased the duration of complete conversion of cellulose into KC [19]. Cellulose swollen in 68.5% HNO_3 was squeezed out to approximately three fold overweight. In squeezing, no less than 60% of the initial amount of HNO_3 is released. After appropriate concentrating and loss compensation this acid can be reused for the polymorphous transformation of cellulose. Water was added in amount required for formation of 2.0–2.5 N HNO_3 from the concentrated acid sorbed with the fiber to the squeezed pulp. As a result of dilution, cellulose II is regenerated from KC. It was hydrolyzed to the limiting DP with boiling 2.0–2.5 N HNO_3 for 1 h at a liquid-to-solid ratio of approximately 10 ml g^{-1}.

The second sample (PC-IIn) was prepared by the purely acidic scheme based on cellulose prehydrolyzed to the limiting DP. Hydrolysis was performed with boiling 2.5 N HNO_3 at a liquid-to-solid ratio of 10 ml g^{-1} for 1 h. The resulting MCC-I was washed and dried by the above procedure. A part of this material was converted into cellulose II with 68.5% HNO_3.

With the aim to compare the characteristics of powdered forms of cellulose II produced by the purely acidic scheme, we also prepared MCC-IIt and PC-IIt samples of similar structure by the conventional scheme. In the conventional scheme, the polymorphous transformation of native cellulose was carried out by usual mercerization with 18% aqueous NaOH for 1 h at the temperature of thawing ice and liquid-to-

solid ratio of 20 ml g^{-1}. The conditions of hydrolysis, washing, and drying of all the prepared samples were the same, with only the procedures for transformation of cellulose I to cellulose II being different.

The yield of the final products is governed mainly by the loss of the material in hydrolysis of cellulose fiber to the limiting DP. This loss is the most noticeable in the case of hydrolysis of cellulose II, whose crystal structure is less perfect that that of cellulose I. The MCC-IIn and MCC-IIt samples are produced in 72–75% yield, based on the weight of the initial cellulose, with the yield of MCC-1, PC-IIn, and PC-IIt samples being 83–85%.

The IR spectra of all the prepared samples show signs of oxidative transformations (range 1700-1800 cm^{-1}). Weak absorption bands of nitrate ester groups (1650, 1280, 850, and 750 cm^{-1}) appear only in the spectrum of the PC-IIn sample produced by treatment with 68.5% HNO_3 in the final stage of the process. According to the results of chemical analysis, this sample contains approximately eight nitrate ester groups in 100 cellulose units. In production of MCC-IIn, hydrolytic cleavage of the cellulose fiber follows its treatment with HNO_3. As a result of hydrolysis, most of nitrate ester groups added in the first stage are removed from the fiber together with amorphous binder [18]. Comparison of the spectrum of MCC-I with the spectra of the other samples shows that the intensities of the absorption bands at 1430, 1111, and 890 cm^{-1} vary in conformity with the well-known manifestations of cellulose I and cellulose II in the IR spectra [20].

The X-ray diffraction patterns of the samples are shown in Fig. 1. Comparison of the reflection positions in powder patterns 2 and 4 with those in the powder patterns of similar samples subjected to the conventional mercerization (3 and 5) shows that, under the action of 68.5% HNO_3, the polymorphous transition is virtually complete. However, some "residual nativity" apparently remains in MCC-IIn, since in its powder pattern the reflection (002) is the strongest, which is not characteristic of cellulose II (powder patterns 3 and 5) and is characteristic of cellulose I (powder pattern 1). This conclusion can also be made on the basis of electron microscopic data, which are considered below.

If account is taken of the fact that, the polymorphous transformation of fibrous cellulose in 18% aqueous NaOH occurs under conditions of much stronger swelling than that in 68–69% HNO_3 [19], the retention of some elements of structural organization typical of native cellulose after acid treatment seems to be quite logical. In polymorphous transformation under the action of HNO_3, the cellulose fiber undergoes decrystallization to a noticeably greater extent than in usual mercerization with an NaOH solution. This difference in crystallinity is preserved after hydrolysis of cellulose to the limiting DP. The crystallinity index of MCC-IIn is 0.44, while that of MCC-IIt is 0.57 (see table). Polymorphous transformation of MCC-I under the action of HNO_3 is accompanied by the deepest decrystallization, whose plausible reasons were discussed in [18]. PC-IIn is characterized by powder pattern 4 typical of cellulose II with very low degree of structural ordering (crystallinity index 0.23 against 0.45 in PC-IIt).

Some characteristics of powdered forms of cellulose

Sample	DP	Crystallinity index	WRC	WRC*	Sorption of I_2, mg g^{-1}
			%		
MCC-I	170	0.67	58	56	19.9
MCC-IIn	50	0.44	107	73	76.3
MCC-IIt	50	0.57	105	65	27.0
PC-IIn	150	0.23	155	83	261.4
PC-IIt	160	0.45	208	100	119.1

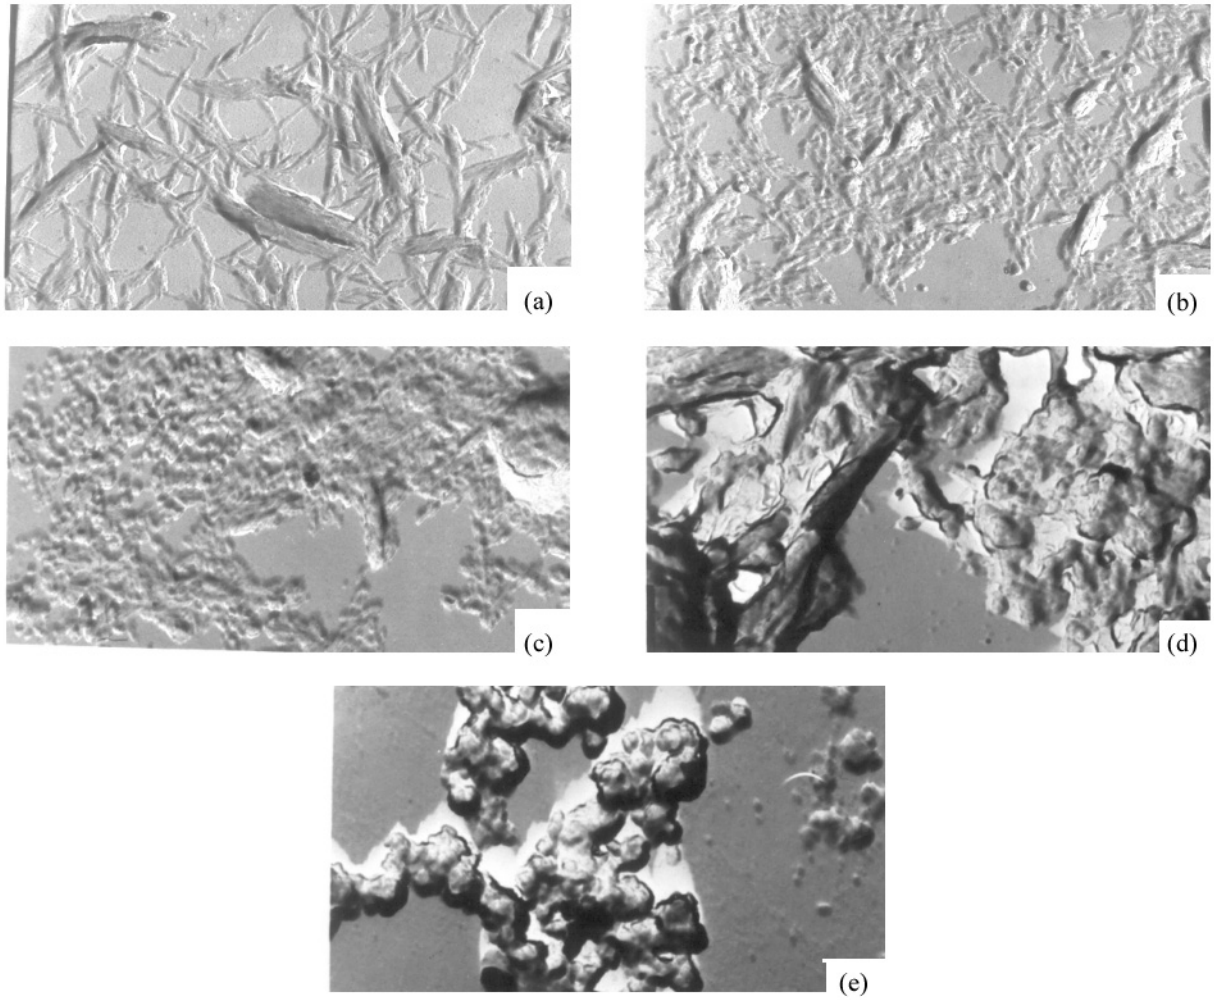

Fig. 2. Electron micrographs of fragments produced by ultrasonic dispersion of powdered forms of cellulose. Magnification 11 000. (a) MCC-I, (b) MCC-IIn, (c) MCC-IIt, (d) MCC-IIn, and (e) PC-IIt.

Figure 2 shows electron micrographs of fragments formed after desintegration of the prepared samples by ultrasonic dispersion. In the case of MCC-I (Fig. 2a), the well-known asymmetric aggregates of needle-shaped microcrystallites are well defined. At present, it is well established that this "needle morphology" is typical of microcrystallites recovered from native cellulose fiber [14]. Based on the average limiting DP of MCC-I equal to 170, the length of anhydroglucose unit of cellulose (5.15 Å), and elongated conformation of macromolecules in microcrystals, we can conclude that the average longitudinal size of microcrystals of this native material is approximately 900 Å.

In passing from cellulose I to cellulose II, the dispersity and morphology of crystallites change significantly (Figs. 2b, 2c). The average limiting DP of both MCC-IIn and MCC-IIt is approximately 50 (see table), which suggests a more than threefold decrease in the length of crystallites, compared to MCC-I. Because of the small sizes and increased tendency to aggregation during preparation of suspensions, individual microcrystals of MCC-IIn and MCC-IIt are difficult to distinguish.

Micrographs of the sample prepared through the stage of intensive swelling of the initial cellulose in alkaline solution (MCC-IIt) show no clearly pronounced indications of the asymmetric shape of microcrystals. A similar electron micrograph of cellulose II microcrystals obtained by acid hydrolysis from viscose fiber can be found in [14]. At the same time, comparison of micrographs 2b and 2c shows that, despite the equality of the limiting DP and, hence, the equality of the microcrystal lengths MCC-IIn show, in contrast to MCC-IIt, clearly pronounced elements of asymmetric aggregation of microcrystals,

characteristic of native MCC. In our opinion, this morphologic feature of MCC-IIn is due to relatively weak swelling of the initial cellulose when polymorphous transformation is performed with 68–69% HNO_3 instead of the conventionally used NaOH solution. We believe that, after the phase transition under the action of HNO_3, crystallites of the cellulose fiber keep "elements of memory" about the morphology of its native precursor.

In production of PC-IIn and PC-IIt (Figs. 2d, 2e) by polymorphous transformation of MCC-I (Fig. 2a) by both alkaline and acidic reagents, the average DP (170) characteristic of native microcrystals remains virtually the same, while the crystallite size and crystallinity of the material as a whole decrease significantly (see table). The length of crystallites is not governed by DP (DP is greater). Microcrystalline structure of cellulose I is transformed into the usual amorphous crystalline structure of cellulose II with low DP. This leads to an abrupt change in the morphology of fragments (compare Figs. 2a–2c with Figs. 2d, 2e). The extremely strong tendency for PC-IIn and PC-IIt particles to aggregate results mainly in the formation of coarse friable fragments in the form of micrometer-sized islets with irregular shape. In the case of PC-IIn, coarse fragments are composed of smaller aggregates of, as a rule, fibril-like type (Fig. 2d), and in the case of PC-IIt, of lump-like type (Fig. 2e). This is also due to different degrees of MCC-I swelling in acidic and alkaline media used for the phase transformation.

The prepared powdered forms of cellulose II differ from native MCC in the significantly higher hydrophilicity and sorption activity (see table). The hydrophilicites of cellulose powders was evaluated by two characteristics. One of these, WRC, characterizes a sample of the final product, washed to neutral reaction and not subjected to drying, and corresponds to the maximum attainable value of WRC. The second characteristic, WRC*, characterizes the ability of a dried sample in the usual air-dry state to retain water. For MCC-I, whose crystallites are similar to crystallites of the initial fiber not subjected to significant transformations in recovery, these characteristics are close. For MCC-II and, especially, PC-II samples, these characteristics are significantly different, which reflects the negative influence of drying on the hydrophilicity of cellulose II.

Microcrystalline forms of cellulose II, produced by both procedures, have comparable hydrophilicities, being markedly inferior in this regard to amorphous-crystalline forms. The most hydrophilic is the sample

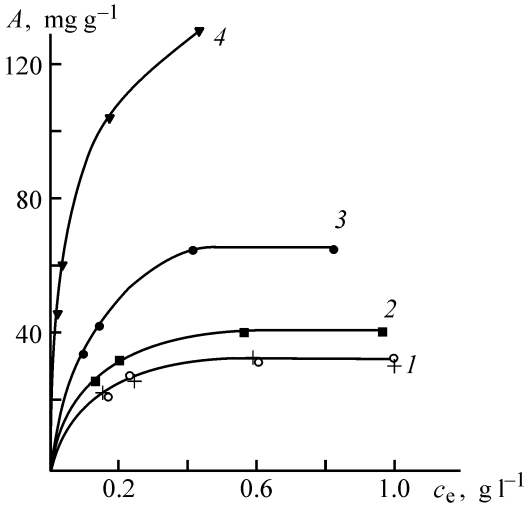

Fig. 3. Isotherms of sorption of Congo Red with powdered cellulose forms. (*A*) sorption and (c_e) equilibrium concentration. (*1*) MCC-I and MCC-IIt, (*2*) MCC-IIn, (*3*) PC-IIt, and (*4*) PC-IIn.

prepared by the conventional procedure and having amorphouscrystalline morphology (PC-IIt), despite that its crystallinity index is greater than that of the similar sample prepared by the purely acidic scheme (PC-IIn). There is no strict correlation between the crystallinity index and hydrophilicity of the samples, whereas the influence of the morphology factor of the water-retaining capacity is appreciable. This influence is especially noticeable in the case of moistening of samples during preparation (WRC characteristic). Drying of the final products even at room temperature noticeably levels out the differences in hydrophilicity between the samples of microcrystalline and amorphous-crystalline morphology (WRC* characteristic).

Powdered forms of cellulose II, prepared by the purely acidic procedure, surpass the conventional analogs in the ability to sorb iodine by more than a factor of 2 (see table). Here, the samples of amorphous-crystalline morphology have the highest sorption power. The sorption of iodine by these samples is 3–4 times greater than that of the samples of microcrystalline morphology. Similar features are observed in the case of sorption of Congo Red (Fig. 3). The isotherms of Congo Red sorption by MCC-I and MCC-IIt coincide within the measurement error (Fig. 3, curve *1*). It should be noted that the values of iodine sorption by these samples are very close. The MCC-IIn sample sorbs the dye somewhat more actively than the two above-mentioned dyes; however, the difference in the values of limiting sorption is small (Fig. 3, curves *1* and *2*). Thus, with respect to sorption of bulky molecules, the microcrystalline forms of cellu-

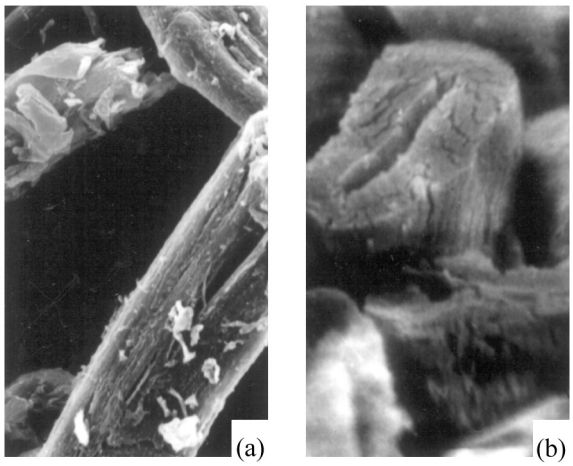

Fig. 4. SEM micrographs of (a) surface of PC-IIn particles and (b) cross section of cotton fibers after treatment with 68.5% HNO_3. Magnification 1250.

lose I and cellulose II produced by various procedures are characterized by close values of limiting sorption. Congo Red, as well as iodine, is most efficiently sorbed by PC-IIn (Fig. 3, curve *4*), which considerably exceeds all the other samples in this respect.

Within the same morphological form of the powdered material, there is a correlation between its crystallinity index and sorption capacity for both iodine and Congo Red. The lower the sorbent crystallinity, the higher its activity (see table, Fig. 3). However, the highest sorption characteristics of PC-IIn, compared to the other samples, are apparently caused by not only its low crystallinity. It was found that, in contrast to the conventional procedure, polymorphous transformation of cellulose by nitric acid is accompanied by appearance of a great number of longitudinal microcracks. These microcracks are readily seen on both the side surface and cross sections of fibrous fragments (Fig. 4). The formation of microcracks must enhance the sorption power of the material. In preparation of the MCC-IIn sample, the effect of microcracking is eliminated in hydrolytic degradation of fiber to aggregates of microcrystals in the final stage of the process. In the case when the final stage of the process is polymorphous transformation of preliminarily dispersed fiber (PC-IIn) with 68.5% HNO_3, this effect is observed. Apparently, along with low crystallinity of PC-IIn, this effect is responsible for the high sorption power of this sample.

CONCLUSIONS

(1) The ability of native cellulose to undergo phase transformation through formation of a Knecht compound in the reaction with 68.5% HNO_3 and the hydrolytic activity of boiling dilute solutions of this acid allow production of powdered forms of cellulose II without the conventional mercerization of cellulose with alkali solutions. The order of procedures performed with the same reagent governs the morphology of the final products, their degree of polymerization, hydrophilicity, and sorption power.

(2) Contrary to similar samples subjected to the conventional mercerization, powdered forms of cellulose prepared by the acidic procedure retain some elements of structural organization typical of the native cellulose. This is accounted for by the fact that the phase transition of cellulose in nitric acid occurs at considerably lower swelling than that in an alkaline medium.

(3) The discussed powdered forms of cellulose II have considerably lower crystallinity than their analogs, and values of sorption of Congo Red and iodine by these samples are more than 2 times greater, which is especially noticeable for the amorphous-crystalline samples. The phase transformation of cellulose in nitric acid is accompanied by the formation of a developed system of longitudinal microcracks in the fiber, which, in combination with the lowered crystallinity of the samples, provides their high sorption power.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Oxidative Delignification of Flax Fiber[1]

S. N. Petrova, I. Yu. Volkova, and A. G. Zakharov

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received March 12, 2003

Abstract—Oxidative delignification of flax fiber at 98°C was studied. The intermediate material was produced in moderate yield with high degree of delignification. The optimum conditions of the process were determined.

Use of annual plants as a raw material for production of cellulose is highly promising, since plant resources, renewable every year, contain as well as wood material, a sufficient amount of cellulose (Table 1). This does not exert any negative influence on the environment and assists to preservation of woodland. Here, we studied delignification of intermediate flax fiber, which can serve as an excellent source of cellulose, since, as regards its chemical composition, it occupies an intermediate position between long-stemmed flax (high-grade flax fiber) and wood.

As a rule, alkaline and alkaline-peroxide treatments are used for refining of cellulose-containing materials. Hydrogen peroxide is an efficient oxidizing agent and modifier of chromophore groups of lignin. It is well known [5, 6] that transition metal compounds catalyze oxidative delignification by H_2O_2. They react with H_2O_2 to form intermediate peroxo complexes Cat–O, which, in turn, transport active oxygen from hydrogen peroxide to the substratum by the scheme

$$H_2O_2 + Cat \rightleftarrows H_2O + Cat\text{–}O,$$

$$L + Cat\text{–}O \rightleftarrows L_{ox} + Cat,$$

where L and L_{ox} are lignin and products of its oxidation, respectively [5, 7].

Sulfuric acid promotes the activity of peroxo complexes and stabilizes the peroxide solution, but, simultaneously, it causes noticeable hydrolytic degradation of polysachharides [8]. At the same time, oxidized lignin is poorly soluble in acid medium; therefore, alkaline extraction is necessary for its complete recovery.

EXPERIMENTAL

Flax fiber was subjected to two-stage treatment: oxidative treatment with an H_2O_2 solution in the presence of $(NH_4)_2MoO_4$ and H_2SO_4 as catalyst (for 60 min) and alkaline extraction with 4% NaOH (120 min). Both stages were carried out at 98°C. The H_2O_2 con-

tent was varied from 1 to 8 wt %, and $(NH_4)_2MoO_4$ content, from 0 to 4 wt %. The H_2SO_4 content was varied in direct proportion to that of $(NH_4)_2MoO_4$. The following characteristics of the process were evaluated: degree of delignification (DD), degree of carbohydrate removal (DCR), characteristic of process selectivity (PS), and extent the process optimization (PO) [9].

In the sample produced we determined the content of Classon lignin by sulfuric acid procedure with 72% H_2SO_4 [10], and the degree of polymerization (DP), by viscometric method [11]. Changes in the structure of flax fiber during treatment were studied by IR spectroscopy. The IR spectra were recorded on an Avatar E.S.P. IR Fourier spectrometer in the range 4000–400 cm^{-1}. The samples were prepared from milled fibers in KBr pellets.

Preliminary tests showed that, in treatment of flax fiber in alkaline and alkaline-peroxide solutions, an intermediate product with residual lignin content of 6 and 4%, respectively, can be obtained. For more exhaustive delignification, the fiber was treated in two stages, using a catalytic additive. Samples of flax cellulose were obtained with average yield of 53–68%, with the residual lignin content of 0.22–7.3% (Table 2). The evaluated characteristics of the process are listed in Table 3 and shown in Fig. 1. With increasing content of the catalyst in the solution and constant concentration of H_2O_2, the degree of delignification grows and degree of polymerization decreases. For example, with the content of $(NH_4)MoO_4$

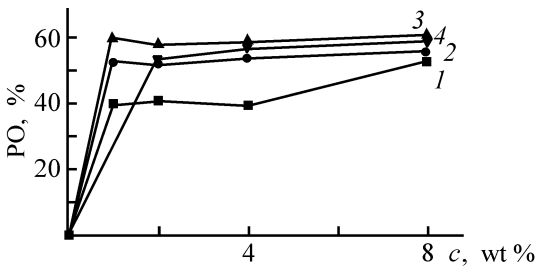

Fig. 1. Extent of the process optimization PO vs. the content c of hydrogen peroxide. Content of $(NH_4)_2MoO_4$ (wt %): (*1*) 0, (*2*) 1.04, (*3*) 2.08, and (*4*) 4.16.

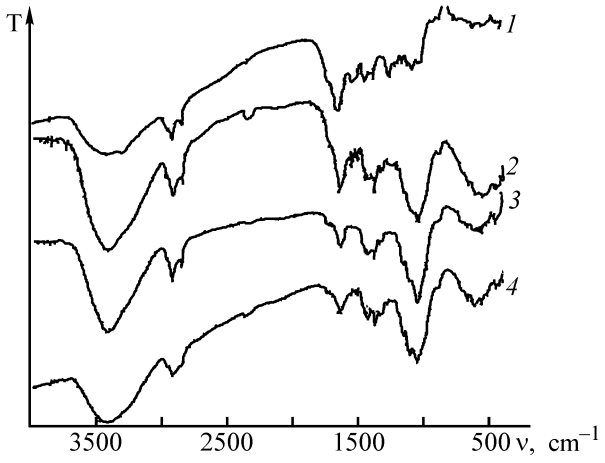

Fig. 2. IR spectra of the samples: (T) transmission and (ν) wave number. (*1*) Alkaline lignin, (*2*) initial flax fiber, (*3*, and *4*) flax fiber after chemical treatment (Table 2, sample nos. 2 and 4).

increasing from 0 to 4 wt % at 4 wt % content of H_2O_2, the degree of delignification increases from 66 to 95%, the degree of carbohydrate removal is about 40%, and DP decreases from 2900 to 530. At constant content of the catalyst, the degree of delignification grows with increasing content of H_2O_2. In this case, the degree of polymerization remains virtually constant (Table 3). Addition of the catalyst significantly accelerates the delignification of the flax fiber. For example, in treatment of a cellulose-containing material with a 1% H_2O_2 solution at the lowest content of the catalyst (1.04 wt %), the degree of delignification may reach 82.5%, while in refining without a catalyst, even in a 8% H_2O_2 solution, the degree of delignification is only 75%.

The most favorable conditions of refining of cellulose-containing material are those at which the removal of lignin is at a maximum and dissolution of carbohydrates is at a minimum. In this context, we evaluated the extent of the process optimization PO = DD PS/100 (Fig. 1). It is seen that, even at H_2O_2 content in the solution of 1 wt %, the extent of the process optimization is high. The dependence of this characteristic on the catalyst concentration passes through a maximum and, at the $(NH_4)_2MoO_4$ content higher than 2 wt %, PO decreases. This is apparently caused by predominance of dissolution of carbohydrates over degradation of lignin with a parallel increase in the H_2SO_4 concentration in the solution.

Structural transformations of flax fiber in the course of delignification were also judged from IR data (Fig. 2). For comparison, we recorded the IR spectrum of alkaline lignin produced by precipitation from the solution after alkaline extraction (Fig. 2, curve *1*). In the course of delignification, the intensities of the bands at 1050 (bending vibrations of OH groups of cellulose) and 1160 cm^{-1} (vibrations of the pyranose ring of cellulose) [3, 12, 13] increase, whereas the intensity of absorption in the range of 1450–1600 cm^{-1}, related to skeleton vibrations of the aromatic ring, and that of the band at 1270 cm^{-1}, characterizing guaiacyl structural units of lignin [14], decrease. A decrease in the splitting of the band in the range of stretching vibrations of CH bonds of methyl and methylene groups (2850–2920 cm^{-1}) also suggests removal of lignin-like structures. From the ratio of the optical densities of the absorption bands D_{1370}/D_{2900}, we estimated the crystallinity index [15, 16], which was equal to 0.84, 0.87, and 0.90 for the initial flax and purified fibers (Fig. 2), respectively. This is apparently caused by the fact that chemical modification of the plant material involves, along with removal of lignin, dissolution of the low-molecular-weight fractions of cellulose and hemicellulose.

CHEMISTRY OF FOSSIL FUEL

Transformations of Acids in the Course of Ozonolysis of Oxygen-containing Derivatives of Cycloparaffins

A. M. Syroezhko and O. Yu. Begak

St. Petersburg State Technological Institute, St. Petersburg, Russia

Mendeleev Russian Research Institute of Metrology, Federal State Unitary Enterprise, St. Petersburg, Russia

Received March 20, 2003

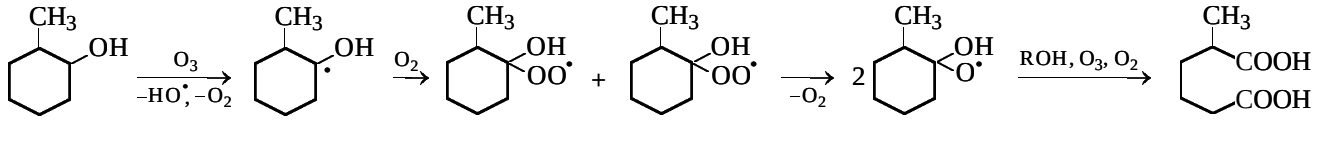
Abstract—Transformations of monocarboxylic, dicarboxylic, and keto acids in the course of low-temperature ozonolysis were studied using the corresponding ^{14}C-labeled compounds.

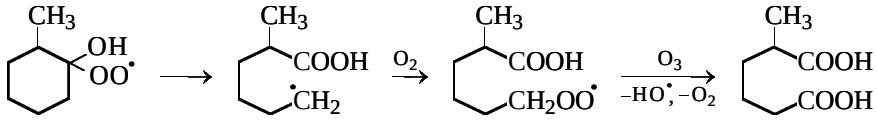
Deep oxidation of cyclohexane [1], methylcyclohexane [2], and their oxygen-containing derivatives (alcohols, ketones, esters, lactones) [2] results in accumulation of monocarboxylic, dicarboxylic, and keto acids, which are actively oxidized by ozone–oxygen mixtures.

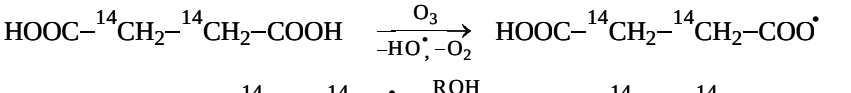
In this study, we analyzed transformations of [2,3-^{14}C]succinic, [2,4-^{14}C]glutaric, [1,2-^{14}C]-α-ketoglutaric, and [1-^{14}C]caproic acids in 2-methylcyclohexanol under conditions of its oxidation at 80°C ([O_3] = 4 vol %).

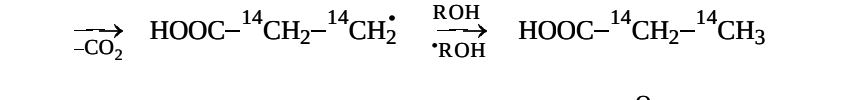
Procedures for radiochromatographic analysis of the acids are described in [3, 4]. Calculations [2] show that, under these conditions, the hydroxy peroxy radical derived from 2-methylcyclohexanol does not react with the C–H bonds of the acids in hand and of 2-methylcyclohexanol. However, alkyl and alkoxyl radicals and ozone abstract the most labile hydrogen atoms from 2-methylcyclohexanol, labeled acids under consideration, and intermediate oxidation products, including radicals. The radioactive products of ozonolysis of [2,3-^{14}C]succinic acid are [2,3-^{14}C]propionic acid, [2-^{14}C]acetic acid, and $^{14}CO_2$.

[2,3-^{14}C]Succinic acid is 21.5% decarboxylated in 3 h at 32.5% overall conversion. Ozone attacks the acid at both the methylene chain and the functional group:

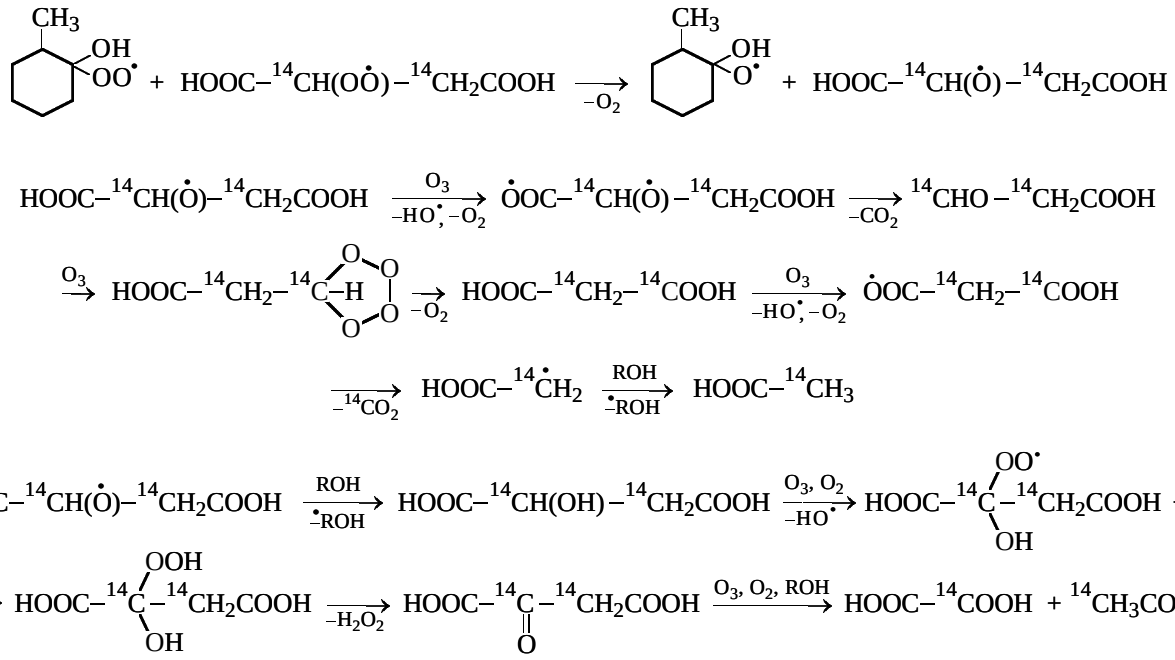




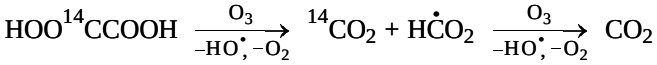




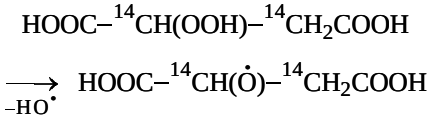
1070-4272/03/7608-1348 $25.00 © 2003 MAIK "Nauka/Interperiodica"



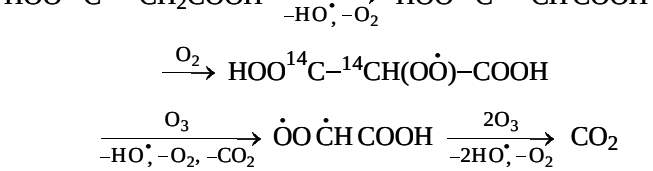
At 32.5% conversion of [2,3-^{14}C]succinic acid, the total activity of acetic and propionic acids is 10.1%. Hence, the major amount of $^{14}CO_2$ is formed in further ozonolysis of [^{14}C]oxalic acid:



The probability of recombination of the alkoxyl and hydroxy radicals to form intermediate hydroperoxide is low. However, 2-methylcyclohexanol reacts with ozone to form unstable 1-hydroxy-1-hydrotrioxy-2-methylcyclohexane whose thermolysis generates hydroperoxy radical $HO_2^{\cdot}$ [5, 6]. Recombination of the hydroperoxy and peroxy radicals yields α-hydroperoxysuccinic acid. Its decomposition generates the corresponding α-oxyl radical:



The probability of reaction of this radical with the ozone molecule via O–H bond in the carboxy group is low, since this radical reacts with a high rate constant [7] with alcohol molecules present in excess. However, occurrence of the reaction of the radical with ozone to even a small extent will result in formation of CO_2 by oxidation of the intermediately formed malonic acid:



[2,4-^{14}C]Glutaric acid transforms with 30.2% conversion into $^{14}CO_2$ and [2,4-^{14}C]butyric (1.2%), [1,3-^{14}C]succinic (13%), [1-^{14}C]oxalic (0.41%), [1-^{14}C]acetic (0.8%), and [1-^{14}C]propionic (0.45%) acids within 180 min. The composition and activity ratio of the acids show that all the methylene groups of glutaric acid are attacked by ozone. However, the α-methylene groups are attacked predominantly. Note that CH and OH acids can also be attacked by alkoxyl radical.

Under the ozonolysis conditions, [1,2-^{14}C]-α-ketoglutaric acid is 42.5% consumed in 180 min; $^{14}CO_2$ and ^{14}CO are formed in 18.1 and 2.1% yields, respectively. The liquid radioactive products are [1-^{14}C]acetic (0.3%), [1-^{14}C]propionic (1.8%), [1-^{14}C]succinic (13.0%), and [1-^{14}C]oxalic (7.1%) acids. Ozone attacks α-ketoglutaric acid at the α-positions to the carbonyl and carboxy groups and also directly at the O–H bond of the carboxy group. Detection of ^{14}CO shows that ozonolysis involves cleavage of C–C bonds throughout the carbon chain of the keto acid. Experiments with [1-^{14}C]caproic acid showed that it transforms in 180 min with 30.5% conversion into

$^{14}CO_2$, [1-^{14}C]acetic acid (7%), [1-^{14}C]proionic acid (3.5%), [1-^{14}C]butyric acid (3.4%), and small amounts of formic acid:

$$CH_3(CH_2)_4{-}{}^{14}CO_2H \xrightarrow[-HO^{\bullet},\,-O_2]{O_3} CH_3(CH_2)_4{}^{14}CO\dot{O}$$

$$\xrightarrow[-{}^{14}CO_2]{} CH_3(CH_2)_3\dot{C}H_2 \xrightarrow[-\dot{R}OH]{ROH} CH_3(CH_2)_3CH_3$$

$$CH_3(CH_2)_3CH_2{}^{14}CO_2H \xrightarrow[-HO^{\bullet},\,-O_2]{O_3} CH_3(CH_2)_3\dot{C}H{-}{}^{14}CO_2H$$

$$\xrightarrow{O_2} CH_3(CH_2)_3{-}\underset{\displaystyle OO^{\bullet}}{\underset{|}{C}}H{-}{}^{14}CO_2H + \text{  }$$

$$\xrightarrow[-O_2]{} CH_3(CH_2)_3{-}\underset{\displaystyle O^{\bullet}}{\underset{|}{C}}H{-}{}^{14}CO_2H + \text{  }$$

$$\xrightarrow[-HO^{\bullet},\,-O_2,\,-{}^{14}CO_2]{O_3} CH_3(CH_2)_3CHO \xrightarrow{O_3} CH_3(CH_2)_3{-}\text{  }$$

$$\xrightarrow[-O_2]{} CH_3(CH_2)_3CO_2H$$

By a similar scheme, ozone attacks the remote (β, γ, and δ relative to the carboxy group) methylene groups of caproic acid.

The ratio of the amounts of pentane and valeric acid shows that the probability of ozone attack at the α-position to the carboxy group is 3.6 times higher compared to the attack at the O–H bond of [1-^{14}C]caproic acid. [^{14}C]Formic acid and $^{14}CO_2$ can be formed from the intermediate hydroperoxide by the scheme

$$CH_3(CH_2)_3CH(O\dot{O}){-}{}^{14}CO_2H + HO_2^{\bullet}$$

$$\xrightarrow[-O_2]{} CH_3(CH_2)_3{-}CH(OOH){-}{}^{14}CO_2H$$

$$\xrightarrow[-\dot{O}H]{} CH_3(CH_2)_3{-}\underset{\displaystyle O^{\bullet}}{\underset{|}{C}}H{-}{}^{14}CO_2H$$

$$\xrightarrow[-HO^{\bullet},\,-O_2,\,-{}^{14}CO_2]{O_3} CH_3(CH_2)_3{-}CHO \xrightarrow{O_3} CH_3(CH_2)_3{-}\text{  }$$

$$\xrightarrow[-O_2]{} CH_3(CH_2)_3{-}CO_2H$$

$$CH_3(CH_2)_3{-}CH(OOH){-}{}^{14}CO_2H$$

$$\xrightarrow{T,\,O_3,\,ROH} H{}^{14}COOH + CH_3(CH_2)_3COOH$$

CONCLUSIONS

(1) In ozonolysis (80°C) of [2,3-^{14}C]succinic, [2,4-^{14}C]glutaric, [1,2-^{14}C]-α-ketoglutaric, and [1-^{14}C]-caproic acids, ozone attacks the O–H bond of the carboxy groups and all the methylene groups of the aliphatic chain, predominantly those in the α-position relative to functional groups.

(2) Under the conditions examined, peroxy radicals are inactive in cleavage of the C–H and O–H bonds. The reactions involve ozone, oxygen, and alkyl, alkoxyl, hydroxy, and hyroperoxy radicals.

CHEMISTRY OF FOSSIL FUEL

Improving the Cetane Number of Diesel Fuels

O. Yu. Begak and A. M. Syroezhko

St. Petersburg State Technological Institute, St. Petersburg, Russia

Mendeleev Russian Research Institute of Metrology, St. Petersburg, Russia

Received March 27, 2003

Abstract—Effect of paraffins C_{10}–C_{13}, C_{14}–C_{17}, C_{18}–C_{23}, *tert*-butyl hydroperoxide, cumyl hydroperoxide, and isopropyl nitrate as cetane number improvers for summer- and winter-grade diesel fuels[1], added in amount of 0.4–5 wt %, is studied.

In recent years, the share of diesel fuel (DF) and, correspondingly, its total annual production volume have been growing steadily [1]. This is associated, in particular, with the fact that, in diesel engines, the compression ratio is higher, and the fuel consumption, lower by 25–30%, than in carburetter engines [2].

The cetane number (CN) is the most important characteristic of DF. It is a measure of the ignitability, which, in turn, determines the power, ecological, and economical characteristics of an engine. With increasing CN, the NO_x and CO contents in the exhaust decrease.

The cetane number depends on the group and fraction composition of DF. The cetane number of domestic summer-, winter-, and arctic-grade diesel fuels is 47–51, 45–49, and 38–40, respectively. At the same time, the requirements to the quality of DF, inprosed by the World Fuel Charter become more stringent; CN from 48 for DF of the first group to 55 for DF of the third group [3]. Now, advanced diesel engines are being designed, meant for DT with CN = 58–60 [4].

The goal of this study was to select cetane number improvers for commercial diesel fuels from the Kirishi Refinery and to analyze the effect of these additives on the performance of DF.

EXPERIMENTAL

Samples of diesel fuels (DTZ-0.2 minus 35,[2] DTL-0.2-40, and DTL-0.2-62) and also of paraffins C_{10}–C_{13}, C_{14}–C_{17}, and C_{18}–C_{23} were provided by the Kirishi Refinery.

The paraffin fraction C_{18}–C_{23} was treated to remove arenes by urea dewaxing, recrystallization from acetone, or acid–base purification, followed by carbamide urea. The quality of the resulting product was controlled by n_D^{20} [5] using reference data [6]. The recrystallization proved to be the most efficient treatment technique.

Paraffin fraction C_{18}–C_{23} had after recrystallization the minimal refraction intercept (difference between the refractive index and half of the relative density) typical of paraffins (1.04–1.0461). For arenes, the refraction intercept is much higher (1.0592–1.0627).

The arene content in the test samples of DF was determined using the aniline point technique [7], sulfonation, or directly from ^1H and ^{13}C NMR spectra.

n-Alkanes were determined from the ^1H and ^{13}C NMR data and also by the urea dewaxing method [9]. The cloud and pour points of DF were determined as in [10], with a mixture of acetone and dry ice as a coolant. The ^1H and ^{13}C NMR spectra were recorded on a Bruker AM-500 instrument (500 MHz) with $Si(CH_3)_4$, C_6D_6, and $CDCl_3$ as internal references.

The CN of the initial DF samples and those modified with cetane number improvers was determined on an IDT-69 device. Isopropyl nitrate was prepared in accordance with TU (Technical Specifications) 6-14-944–73 [11]. Physical characteristics of *tert*-butyl hydroperoxide and cumyl hydroperoxide used were consistent with reference data [12].

[1] Fuel from the Kirishi Refinery was studied.

[2] Pour point below –35°C.

$DI = [(1.8t_{an} + 32)(141.5 - 131.5\rho_4^{15})]/100\rho_4^{15}$	49.2	48.6	49.4

* (DI) Diesel index; (ν_{20}) kinematic viscosity, $m^2\ s^{-1}$; (ρ_4^{15}) relative density of diesel fuel; (c_p, c_n, c_a) content of carbon (wt %) in paraffins, naphthenes, and arenes, respectively.

The effect of the cetane number improvers is shown in Table 1. All the additives used appeared to be quite efficient, yielding a 2 to 17 cetane number benefit for both summer- and winter-grade diesel fuels. This implies that addition of butyl or cumyl hydroperoxide in amount of only 0.3–0.5 wt % is sufficient to raise CN by 5–6 points. It should be pointed out that addition of 3–5 wt % paraffin fractions C_{10}–C_{13}, C_{14}–C_{17}, and even C_{18}–C_{23} appeared to be efficient too.

In the ^{1}H NMR spectra of the DF samples we observed four groups of signals: 6.8–9.2 ppm [hydrogen atoms of aromatic ring (H_a)], 2.0–3.2 ppm [hydrogen atoms of the methine, methylene, and methyl groups in the α position to the aromatic ring (H_α)]; 1.05–2.0 ppm [hydrogen atoms of the methine and methylene groups of alkyl chains and naphthene rings in position more distant than α-position to the rings (H_β)]; and 0.5–1.0 ppm [hydrogen atoms of the methyl groups in position more distant than α and β positions, i.e., at a considerable distance from the aromatic ring (H_γ)].

Typical ^{13}C NMR spectra of diesel fuel show the signals of carbon atoms of the aromatic rings at 110–155 ppm and those of aliphatic and naphthenic structures at 14.1095–32.0658 ppm. The hydrogen atom distribution in the investigated DF samples is given below. Signal intensity (%): DTL-0.2-40: H_a 2.3, H_α 5.64, H_β 57.76, and H_γ 34.3; DTZ-0.2-35: H_a 2.3, H_α 5.7, H_β 60.4, and H_γ 31.6. The carbon atom distribution is as follows. Signal intensity (%): DTL-0.2-40: C_{ar} 23.1, C_{naph} 15.6, and C_{aliph} 62.3; DTZ-0.2-35: C_{ar} 27.6, C_{naph} 14.2, and C_{aliph} 58.2.

In addition to experimental determinations, we estimated the cetane numbers by various theoretical methods (Table 2). The most consistent estimated values were obtained from the NMR data and by using the DI–CN nomogram.

Table 3. Cloud (T_{cl}) and pour (T_p) points of unadditized diesel fuels and those modified with paraffin fractions C_{10}–C_{13}, C_{14}–C_{17}, and C_{18}–C_{23}

DF	Additive, wt %	T_{cl}, °C	T_p, °C	DF	Additive, wt %	T_{cl}, °C	T_p, °C
DTL 0.2-40	–	–8	–14	DTL-0.2-40	C_{18}–C_{23}, 2 + IPN, 1	–6	–31.5
DTL 0.2-62	–	–7	–14	DTZ-0.2 minus 35	C_{14}–C_{17}, 5	–30	–46
DTZ-0.2 minus 35	–	–26	–53	DTZ-0.2 minus 35	C_{10}–C_{13}, 5	–27	–60.2
DTL-0.2-40	C_{10}–C_{13}, 3	–6	–32	DTZ-0.2 minus 35	C_{14}–C_{17}, 3	–29	–51.5
DTL-0.2-40	C_{14}–C_{17}, 3	–5	–30	DTZ-0.2 minus 35	C_{10}–C_{13}, 3	–36	–64

The use of paraffin-containing fractions may deteriorate the cold flow properties of diesel fuel. We measured the cloud and pour points of the DF samples modified with paraffin fractions (Table 3). It was demonstrated that, in these parameters, the investigated summer- and wintergrade diesel fuels with paraffin-containing cetane number improvers meet the existing requirements.

CONCLUSIONS

(1) Paraffin fractions C_{10}–C_{13}, C_{14}–C_{17}, and C_{18}–C_{23} taken in amount of 3–5 wt % demonstrate properties of cetane number improvers. The cloud and pour points of diesel fuels with these additives meet the requirements of GOST 305–82.

(2) Isopropyl nitrate, *tert*-butyl hydroperoxide, and cumyl hydroperoxide used in amount of about 0.5 wt % are efficient cetane number improvers for diesel fuels.

Thermal Disproportionation of Hypophosphorous Acid

G. T. Shechkov, I. A. Pevneva, and O. A. Meshkova

Polzunov Altai State Technical University, Barnaul, Russia

Received April 18, 2003

Abstract—Thermal disproportionation of hypophosphorous acid was studied to find the reaction order, the rate constant and activation energy of the process, and also the temperature ranges in which the reaction rate is the highest.

The use of red phosphorus is based on its capability to be oxidized (manufacture of matches, getters, fire-retardants, and components of pyrotechnic formulations) [1–3]. The oxidation yields phosphorous acids (hypophosphorous H_3PO_2, phosphorous H_3PO_3, and phosphoric H_3PO_4) and phosphine PH_3. The formation of these products may result both in retrogradation of properties of phosphorous composites and in shortening of guaranteed shelf lives of articles based on red phosphorus.

However, the kinetics and temperature ranges of transformation of phosphorus acids have not been analyzed in studies devoted to phosphorus oxidation [2–4]. The main goal of the present study was to analyze the fundamental aspects of phosphine formation in disproportionation of hypophosphorous acid of varied concentration and to determine the temperature ranges and kinetic parameters of the process

$$3H_3PO_2 \rightarrow 2H_3PO_3 + PH_3. \quad (1)$$

We studied 50% hypophosphorous acid of reagent grade, TU (Technical Specification) 6-09-1462–76. The acid was diluted with twice-distilled water and concentrated by recrystallization, as described in [5].

The disproportionation was monitored by evolution of PH_3 in the temperature range $(30–160) \pm 1.5$°C in a glass reactor connected to an AGB-67M automated gas burette.

The acid (5 g) was placed in a glass dish mounted on a quartz hook fastened to a ground tap wrench by a fiberglass thread. A sample was rapidly (10 s) introduced into the reactor with a furnace, using the tap wrench.

The sensitivity of the installation was 0.001 to 1 ml, depending on a burette volume. The error in measuring the gas volume was ±5%. A solution of calcium chloride served as a locking liquid.

Analysis for PH_3 was carried out on an LKhM-80 chromatograph by the technique described in [6]. Gas samples (1 ml) were taken from the reactor at intervals of 10–15 min through a hermetic tap made of special rubber. Polysorb-1 served as absorbent. The flow rate of the carrier gas was 24 ml min^{-1}; column temperature, 60°C; measurement error, ±3%. Phosphine for constructing a calibration plot was obtained by hydrolysis of aluminum phosphide and analyzed both chemically and chromatographically.

A thermal analysis of H_3PO_2 was carried out with 200-mg samples on an MOM Q-1500D (Hungary) derivatograph in standard ceramic crucibles at a heating rate of 10 deg min^{-1}.

We revealed low- (30–90°C) and high-temperature (110–200°C) regions of phosphine evolution in disproportionation of H_3PO_2. At low temperatures, the acid reacts with water to give hydrogen, which was detected by mass-spectrometry:

$$H_3PO_2 + H_2O \rightarrow H_3PO_3 + H_2. \quad (2)$$

At high temperatures (>110°C) the disproportionation process (1) occurs at the highest rate at 130–160°C, being complete at 190°C. The process is complicated by gas-phase oxidation of phosphine, beginning at 120°C and ending in combustion of the gas mixture above 160°C.

Kinetic curves of disproportionation are S-shaped. The rate of H_3PO_2 disproportionation grows with the concentration of the acid increasing from 30 to 90%, the disproportionation being of the autocatalytic nature. This feature seems to be associated with

1070-4272/03/7608-1354 $25.00 © 2003 MAIK "Nauka/Interperiodica"

the dependence of the rate of tautomeric regrouping of H_3PO_2 from the inactive form, containing phosphorus(V), to the active form, containing phosphorus(III). The rate constant of the regrouping is extremely low, $k = 10^{-12}$ s^{-1} [4]. Raising the concentration, temperature, and time presumably removes diffusion hindrances for this regrouping.

At 110 and 140°C and process duration of 40–160 min the evolution of phosphine occurs in the kinetic mode and further passes to the diffusion mode. With the temperature increasing to above 140°C, the process passes to the diffusion mode within 40–120 min. The disproportionation reaction in the kinetic mode at high temperatures (110–170°C) is first-order with rate constant $k = 1.96 \times 10^{-5}$ s^{-1} and activation energy of 85 ± 2 kJ mol^{-1}. The transition of the reaction of phosphine evolution from the kinetic to diffusion mode results from the accumulation of the more thermally stable products H_3PO_3 and H_3PO_4, which are formed upon PH_3 oxidation:

$$4PH_3 + 5O_2 \rightarrow 2P_2O_5 + 6H_2, \quad (3)$$

$$P_2O_5 + 3H_2O \rightarrow 2H_3PO_4. \quad (4)$$

A pronounced endothermic effect is observed in the derivatograms at 135°C. It is determined by the equilibrium the endothermic processes of dehydration and disproportionation of H_3PO_2 and also by the exothermic oxidation of the evolving phosphine. The overall activation energy of dehydration, hydration, and disproportionation of H_3PO_2 below 100°C is 44 ± 1 kJ mol^{-1}.

According to the derivatographic data, the activation energy of H_3PO_2 disproportionation in the range 110–140°C is 69.8 ± 2 kJ mol^{-1}, in satisfactory agreement with the activation energy obtained from the kinetic data (85 ± 2 kJ mol^{-1}).

The forming H_3PO_3 disproportionates in the range 190–270°C, with simultaneous oxidation of the evolving PH_3. According to the derivatographic data, the maximum rate of PH_3 oxidation is observed in the range 280–300°C. The corresponding activation energy is 207 ± 10 kJ mol^{-1}.

Stability of Phosphorus Trihalide Solutions Used in Polarography

L. M. Kisil', I. M. Osadchenko, and A. P. Tomilov

State Research Institute of Organic Chemistry and Technology, Moscow, Russia

Received January 15, 2003

Abstract—The behavior of PCl_3 and PI_3 solutions in acetonitrile containing no more than 0.02 wt % H_2O in storage at room temperature was studied.

Previously [1, 2] we have studied the polarographic behavior of phosphorus trihalide solutions. It was shown that their stability depends on the water content in the solvents.

In this study, we analyze the stability of phosphorus trihalide solutions in acetonitrile, used in polarography.

Since phosphorus trihalides are readily hydrolyzed by water and react with protic organic solvents, their polarographic behavior is studied in aprotic solvents [1–4].

As shown previously, polarograms of phosphorus trihalides at 20–25°C in dimethylformamide and acetonitrile dried by the procedure described in [4] show well defined waves.

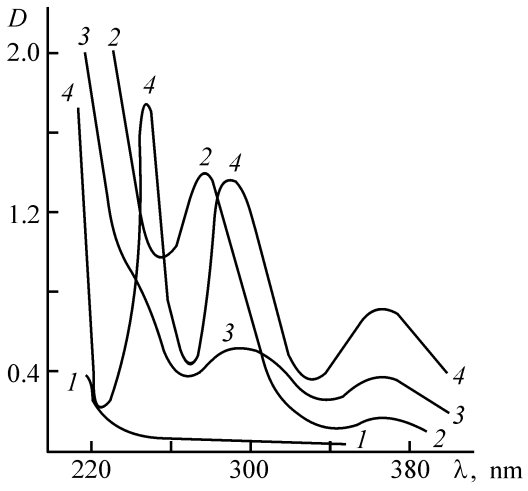
The stability of phosphorus trihalides in acetonitrile solutions with composition similar to that used in polarographic studies [1] (no more than 0.02% H_2O) was monitored by UV spectroscopy. The absorption spectra of straight acetonitrile and acetonitrile solutions of PCl_3, PI_3, and HCl (HCl is the main hydrolysis product of PCl_3 in water) are shown in the figure. The PCl_3 spectrum contains two bands peaked at 298 and 365 nm. The PI_3 spectrum contains three bands at 250, 293, and 370 nm. As seen from the figure, no appreciable amount of HCl is formed in the PCl_3 solution, i.e., PCl_3 is not hydrolyzed in acetonitrile solution during the experiment.

The UV spectrum of acetonitrile solution of PCl_3 did not change during its storage for a week. This indicates that PCl_3 is not hydrolyzed noticeably in acetonitrile containing up to 0.02% water, i.e., acetonitrile purified by the procedure described in [4] is suitable as a solvent for polarography. This is confirmed by the fact that the polarogram of PCl_3 in acetonitrile containing no more than 0.02% water does not change after storage of this solution at +3 to +5°C for 7 days. After longer storage, especially at room temperature, the limiting current decreases and a wave appears at more negative potentials. For example, the limiting current of reduction of a 0.23 M PCl_3 solution containing 0.08 M tetraethylammonium perchlorate as a supporting electrolyte decreases from 1.298 to 1.200 μA in 12 days.

When the water content is higher than 0.02%, the half-wave potential of PCl_3 reduction is shifted to the cathodic region:

Water content, %	0.02	0.03	0.06	0.10
$-E_{1/2}$, V	0.915	0.930	0.960	1.920

At water content of 0.06%, a second wave appears at $E_{1/2}$ = –1.93 V (relative to bottom Hg). This is due to reaction of PCl_3 with H_2O present in the solvent.



UV spectra of (*1*) straight acetonitrile and acetonitrile solutions of (*2*) HCl, (*3*) PCl_3, and (*4*) PI_3. (*D*) Optical density and (λ) wavelength.

1070-4272/03/7608-1356 $25.00 © 2003 MAIK "Nauka/Interperiodica"

When H_2O is added in concentration exceeding the initial PCl_3 concentration by a factor of 4 (0.38 mM), the first wave becomes weaker, and a wave with $E_{1/2}$ = –1.068 V and another wave at more negative potentials appear. The current of the last wave grows with increasing water content.

Since HCl and H_3PO_3 are the main hydrolysis products of PCl_3, we studied their polarographic behavior in acetonitrile solutions. We found that HCl is reduced in acetonitrile solution of tetraethylammonium perchlorate with $E_{1/2}$ = – 1.06 V (relative to bottom Hg), which agrees with published data [5]. In addition, a wave with $E_{1/2}$ = –0.50 V due to reduction of CH_3CNH^+ cation [6] is observed. The reduction of phosphorus acid under these conditions is also characterized by two waves with $E_{1/2}$ = –1.95 and –2.74 V (relative to saturated calomel electrode) [7]. The total current of both waves is proportional to the H_3PO_3 concentration. Since the current of the waves decreases by a factor of 2 after addition of the maximum amount of water, 50% of PCl_3 is hydrolyzed. Thus, PCl_3 hydrolysis by H_2O in acetonitrile solutions is hindered as compared with the aqueous solution, owing to solvation of PCl_3. This fact is confirmed by IR spectroscopy. The bands in the range 2400–2700 cm^{-1} can be assigned to the $HCl \cdot CH_3CN$ solvate (the band of pure HCl lies at 2480 cm^{-1} [8]).

Since PI_3 is difficulty soluble in acetonitrile, PI_3 was dissolved in benzene at +3°C and the resulting solution was added to an acetonitrile solution of tetraethylammonium perchlorate. Benzene solutions of PI_3 are stable at low temperature in the dark. No visible changes in these solutions were observed after their storage for 10–12 h. In 1–2 days, a lemon yellow PI_3 solution in benzene acquires a Bordeaux shade, probably owing to liberation of iodine. When this solution is kept at 35°C for a long time, it gets turbid, and a yellow precipitate is formed. The half-wave potentials of these solutions are shifted to the negative range by –1.0 to –2.6 V (the polarogam of the initial PI_3 solutions contains two waves with $E_{1/2}$ = –0.04 and –0.42 V [1]).

Thus, solutions of phosphorus trihalides in purified and dried acetonitrile are stable and can be used in polarography.

Calorimetric Study of Specific Heat of Anabasine Nitrate and Glaucine Hydrobromide

B. K. Kasenov, Sh. B. Kasenova, Zh. K. Tukhmetova, S. M. Adekenov, A. Zh. Turmukhambetov, and A. Zh. Abil'daeva

Institute of Phytochemistry, Ministry of Education and Science of the Republic of Kazakhstan, Karaganda, Kazakhstan

Received April 24, 2003

Abstract—The results obtained in studying the isobaric specific heat of alkaloid derivatives, anabasine nitrate and glaucine hydrobromide, in the temperature range from 198 K to the melting point are presented.

Studying the thermochemical and thermodynamic properties of natural compounds and, in particular, alkaloids, is theoretically and practically important for physical chemistry of natural compounds, directed synthesis of biologically active substances with prescribed properties, and determination of new constants to be loaded as input information arrays into fundamental databases and reference books.

Previously, thermodynamic characteristics (enthalpies of dissolution, formation, combustion, and melting; specific heat in the temperature range from 198 K to T_{decomp}) of anabasine alkaloid hydrochloride have been studied [1]. The present communication reports the results obtained in studying the temperature dependence of specific heats of anabasine nitrate and glaucine hydrobromide in the temperature range from 198 K to melting point (T_m).

Analytically pyre anabasine nitrate $C_{10}H_{14}N_2HNO_3$ with melting point of 176–177°C was synthesized by reacting anabasine hydrochloride and silver nitrate (both of analytically pure grade). The compound obtained was identified by IR and NMR spectroscopies.

Glaucine hydrobromide $C_{21}H_{25}NO_4HBr$ of pharmaceutical purity is an antitussive preparation with melting point of 237°C.[1]

The specific heats of the compounds were measured with an IT-S-400 calorimeter. Liquid nitrogen served as cooling agent. The duration of measurements in the whole temperature range, including data processing, did not exceed 2.5 h. The rated maximum error of the instrument was ±10%.

A sample to be studied, placed in a metallic ampule of the measuring cell, was continuously heated by heat flow through a heat flow meter. The time lag of the ampule temperature with respect to the base temperature was measured after each 25°C.

Table 2. Coefficients of equations describing the dependence $C_p^0 \sim f(T)$ for the alkaloid derivatives

Compound	a	$b \times 10^3$	$c \times 10^{-5}$	T, K
Anabasine nitrate	152 ± 10	733 ± 49	–(54 ± 4)	198–398
Glaucine hydrobromide	223 ± 16	884 ± 63	13.4 ± 0.9	198–323
	2766 ± 197	–(6945 ± 496)	–	323–348
	2132 ± 152	–(1934 ± 138)	–(1344 ± 96)	348–448

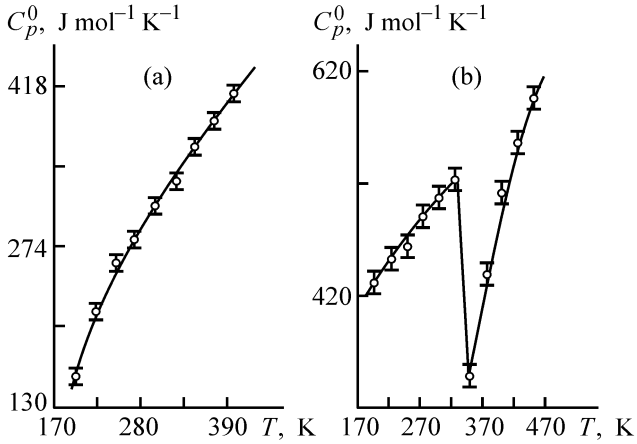
Preliminarily, the measuring instrument was calibrated by determining the heat conductivity K_t of the heat flow meter [2]. For this purpose, five parallel runs with empty ampule, and the same number with a copper sample, were carried out. Similarly, five parallel runs were done at each temperature for each of the compounds under study; the results obtained were averaged and processed by methods of mathematical statistics [3].

At each temperature, the root-mean-square deviation $\bar{\delta}$ was determined for averaged values of specific heat; the random error $\mathring{\Delta}$ was found for molar heat.

The instrument operation was tested by determining the specific heat of α-Al_2O_3: the experimental value $C_p^0(298.15) = 76.0$ J mol^{-1} K^{-1} is in satisfactory agreement with the reference value of 79.0 J mol^{-1} K^{-1} [4].

Table 1 lists experimental values of the specific and molar heat for anabasine nitrate (M = 225.24) and glaucine hydrobromide (M = 436.09). The dependence $C_p^0 \sim f(T)$ is plotted in the figure.

Mathematical processing of the experimental data yielded equations describing the temperature dependences of the specific heat of the compounds $C_p^0 = a + bT + cT^2$, J mol^{-1} K^{-1}, whose coefficients are listed in Table 2.



Specific heat C_p^0 of (a) anabasine nitrate and (b) glaucine hydrobromide vs. temperature T.

The error in determining the coefficients in the specific heat equations were found from mean random errors for the whole temperature range.

As seen from Table 1 and the figure, the specific heat of glaucine hydrobromide shows an anomalous peak at 323 K, then falls at 348 K, and then again starts to increase. This is presumably due to a second-order phase transition. In view of this circumstance, three equations describing the dependence $C_p^0 \sim f(T)$ in each portion of the curve (Table 2) were derived for this compound.

The coefficients b and c of the equation describing the dependence $C_p^0 \sim f(T)$ for glaucine hydrobromide in the temperature range 348–448 K have negative sign, which, at first glance, seems paradoxical. With increasing temperature, the contribution from the specific heat component associated with coefficient b grows, and that from the component associated with coefficient c falls. The strong decrease in the component associated with coefficient c leads to an increase in the specific heat, which is confirmed by the good agreement between the experimental and calculated data.

CONCLUSION

The temperature dependences of the specific heat of anabasine nitrate and glaucine hydrobromide were studied in the temperature range from 198 K to the melting (decomposition) point. Equations describing the dependence $C_p^0 \sim f(T)$ were derived from the experimental data obtained for each of the compounds.

BRIEF COMMUNICATIONS

Thin Near-Surface Layer in a Resist Film

V. I. Trigub, A. V. Plotnov, and A. N. Kiselev

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received October 16, 2002

Abstract—The structure of the near-surface layer of a polymer film of a resist was studied by atomic-force microscopy.

Lavrishchev *et al*. [1] provided indirect evidence for the presence of a near-surface layer in the (co)polymer film of a resist. They demonstrated that the time required for complete removal of the solvent from the resist film depends on the drying method. We experimentally confirmed the presence of a thin near-surface layer in a resist film [2] and revealed periodic changes in the thickness of copolymer films based on methyl methacrylate and methacrylic acid during their heat treatment at constant temperature, which suggests the presence of a near-surface layer [3]. However, the thickness of the near-surface layer of the (co)polymer films applied as resists in lithography has not been estimated as yet because of the small thickness of resist films (no greater than 1 μm) [4].

A thin near-surface layer in a film of a (co)polymer-based resist must give rise to a barrier effect precluding diffusion of the solvent from the resist film during heat treatment [4, 5]. This effect makes it necessary to revise the conditions of formation of resist films by centrifugation and heat treatment.

The aim of this study was to reveal and analyse the thin near-surface layer in a polymethyl methacrylate (PMMA) film by atomic-force microscopy. A film of the positive electron-sensitive resist was formed on a KDB-4 silicon substrate by centrifugation from a 4.5% diglyme solution of PMMA with molecular weight M = 638400, modified with organohydridedisilane [6]. The viscosity of the electron-sensitive resist was 46.7 cSt, and the rate of its application to the substrate, 850 rpm. After centrifugation, the resist film was dried at 170°C for 30 min in an oven in air. The thickness of the resist after the heat treatment was 1.0 μm. The thin near-surface layer was microprobed on a Topometrix-TMX-2100 atomic-force (AFM) microscope by recording the lateral force acting on the probe during scanning (lateral force measurement, LFM) [7]. The LFM method implies a study of the force of friction between the surface and the probe sliding over it. During scanning, the probe is subject to the friction force from the sample surface

$$F_{\text{fr}} = kN. \quad (1)$$

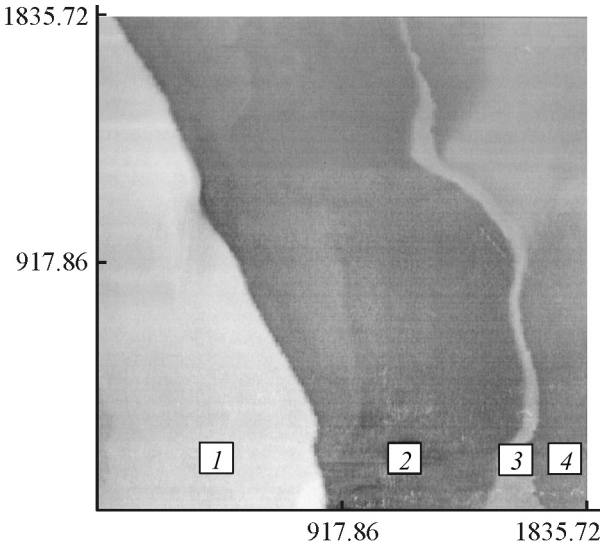
Here, N is the response force exerted by the sample on the probe, and k, local friction coefficient.

The greater the coefficient h of friction between the probe and the surface section directly contacting the probe, the lighter the section being scanned on the AFM image (i.e., the denser the sample section).

The local friction coefficients k for the probe in Eq. (1) substantially differ from the dry friction coefficients of various materials, as the domain of contact between the probe and the sample is as small as 0.1–1.0 nm.

The near-surface layer of the PMMA resist film was sought by studying the fracture of a silicon substrate with resist applied to its surface. The substrate was fractured at liquid nitrogen temperature by the known procedure [8], which prevented plastic deformation of the resist edge during fraction. However, the facial edges of the sample cannot be studied in an atomic-force microscope because of a force field jump [9]. This undesirable effect can be eliminated by coating the PMMA film with an FP-383 photoresist film [10] by centrifugation at 550 rpm. After centrifugation, the FP-383 resist was heat-treated in an oven at 70°C for 20 min. The resulting FP-383 photoresist film was 7.2 μm thick. The fracture was studied in air in the contact mode. The AFM image of the fracture of the silicon substrate with a double resist coating is shown in the figure. It is seen that the near-surface layer of the PMMA resist along the fracture boundary is 17.2 to 204.7 nm thick. Dark and light domains in

1070-4272/03/7608-1360 $25.00 © 2003 MAIK "Nauka/Interperiodica"



AFM image of the surface fracture (the size is given in nanometers): (*1*) silicon, (*2*) PMMA, (*3*) thin near-surface PMMA layer, and (*4*) FP-383.

the AFM image correspond to less dense and denser materials, respectively. The boundary layer of the PMMA/FP-383 composite has darker color and is situated between domains *3* and *4* (see figure).

CONCLUSIONS

(1) A thin near-surface layer is formed during preparation of a resist film from a polymethyl methacrylate solution in diglyme by centrifugation followed by heat treatment at 170°C.

(2) The density of the near-surface layer exceeds that of the bulk polymer.

(3) The density of the near-surface thin layer of the polymethyl methacrylate film varies from 17.2 to 204.7 nm.

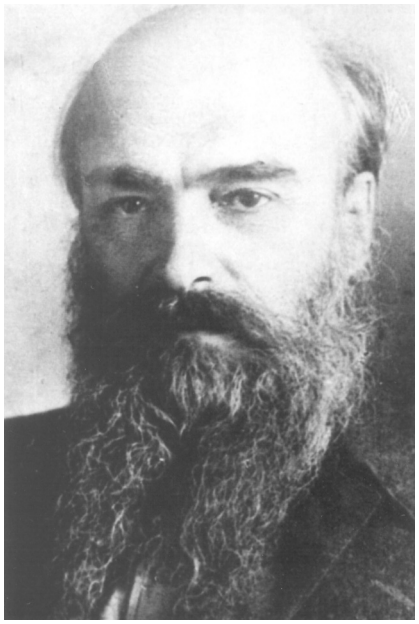
In Memory of Professor Ivan Yakovlevich Bashilov (To 50th Anniversary of His Death)

Professor Ivan Yakovlevich Bashilov, a talented scientist and engineer and one of founders of Russia's industry of radioactive and rare metals, passed away on August 20, 1953, in Krasnoyarsk.

I.Ya. Bashilov was born on November 29, 1892, at the town of Kashin in Tver Province, into a large family of an office worker of the uyezd treasury. Allready beginning at the age of 12, Bashilov had to make money for his education himself. Having finished Tver Gymnasium with gold medal in 1911, Bashilov entered the metallurgical department of Emperor Peter the Great Polytechnical Institute in St. Petersburg. The Polytechnical Institute, opened in October 1902, had among its lecturers quite a number of prominent scientists and possessed excellently equipped laboratories, and, therefore, fast acquired a reputation of one of the best technical higher school institutions not only in Russia, but in Europe too. Among those who taught at the metallurgical department were N.S. Kurnakov (1860–1941, academician since 1913), F.Yu. Levinson-Lessing (1861–1939, academician since 1925), V.A. Kistyakovskii (1865–1952, academician since 1929), A.A. Baikov (1870–1946, academician since 1932), and other known scientists.

When still being a student, Bashilov started to work at the Permanent Commission for Study of Russia's Productive Forces (KEPS), which was organized in February 1915, on the initiative of Academician V.I. Vernadskii (1863–1945) and a number of other scientists, at the Academy of Sciences for studying the natural resources of Russia and their industrial use. Bashilov worked under supervision of a prominent geochemist A.E. Fersman (1883–1945, academician since 1919), who was Vernadskii's closest associate.

In 1920–1921, under sever conditions of civil war, Bashilov studied, together with V.G. Khlopin (1890–1950, academician since 1939), the technology for recovery of radium from domestic raw materials (copper-vanadium ores from the Southern Fergana deposit) by recommendation of the Radium board of the Academy of Sciences. When being head of the Pilot radium plant (now in Mendeleevsk, Tatarstan, Russia), Bashilov developed a technology for recovery of all valuable components: radium, uranium, vanadium, and



copper, from the starting ore. By December 1, 1921, the first Russia's high-activity radium preparations were obtained [1–5]. In 1922, the Radium Institute was created in Petrograd, and Vernadskii was appointed its first director. The Pilot plant joined the Institute, and Bashilov became a member of its Scientific Council.

In 1925, the facilities for recovery of radioactive metals were amalgamated with those for recovery of other rare metals at one of Moscow plants. Bashilov was appointed manager of the chemical department of the Trust of rare elements in Moscow.

In 1927, Bashilov was sent, as a prominent specialist, to a business trip to Germany and Czechoslovakia for familiarization with activities of chemical plants manufacturing radioactive preparations, rare metals, and their compounds [4, 5]. To the decennial anniversary of the Soviet power, the Radium Institute published Bashilov's monograph *Tekhnologiya radioaktivnykh rud* (Technology of Radioactive Ores, Leningrad, 1927, 96 pp.). Later, other his books were published: *Redkie elementy i ikh ispol'zovanie* (Rare Elements and Their Use, Moscow, 1930, 150 pp.)

1070-4272/03/7608-1362 $25.00 © 2003 MAIK "Nauka/Interperiodica"

and *Vvedenie v tekhnologoyu redkikh elementov* (Introduction to Technology of Rare Elements, Moscow–Leningrad, 1932, 275 pp.). In December 1928, Bashilov became, after many years' break, an external student of the Polytechnical Institute, and, in january of 1929, backed his graduation thesis work "A Study of Processing of Radium-containing Ores," to be qualified as engineer-metallurgist.

In the autumn of 1930, Ivan Yakovlevich was invited by the Scientific Council of the 2nd Moscow State University (later Lomonosov Institute of Fine Chemical Technology) to organize a chair and deliver a course of lectures on chemistry and technology of rare elements [6]. In 1931, Bashilov received an academic degree of a professor. At that same time, he was appointed scientific supervisor of the State Research Institute of Rare Metals (Giredmet, Moscow) and, simultaneously, headed the laboratory of radium at the same institute. In 1937, the degree of a doctor of technical science was conferred on Bashilov.

In the beginning of 1938, the Commission for problems associated with further development of the domestic radium industry was created at the Academy of Sciences of the USSR under Academician Vernadskii's supervision. The commission included, together with Academicians Khlopin and Fersman, also Professor Bashilov. In June 1938, Bashilov, a prominent specialist in the technology of rare and radioactive metals, was nominated a candidate for election into the Academy of Sciences of the USSR. However, on August 21 of the same year, he was arrested by Peoples' Commissariat for Internal Affairs (NKVD) and, on February 14, 1939, sentenced to five years of penal servitude for "counterrevolutionary activities" [5]. Till the beginning of 1943, the scientist served his sentence in Kotlas camps (Arhangelsk Province).

After the end of his term of imprisonment in June 1943, Bashilov was deported, by the order of deputy Peoples' Comissar A.P. Zavenyagin (1901–1957), to Krasnoyarsk, where NKVD was completing the construction of a plant for manufacture and refining of platinum metals. As raw materials served concentrates obtained in processing of sulfide copper-nickel ores from the Norilsk deposit. The scientist was well aware of the complexity of the task, because he had never dealt with platinum-group metals before that. By a twist of fate, Bashilov, chief specialist in the technology of processing of uranium ores, had to work, in the year when the development of the atomic industry was commenced in the country, on refining of platinum-group metals. Being undoubtedly important, this problem was more familiar to quite a number of representatives of the scientific school created in Russia by L.A. Chugaev (1873–1922) and N.S. Kurnakov (1860–1941, academician since 1913).

Owing to his natural capacities and experience, Bashilov fast familiarized himself with a production technology new to him. Already in the beginning of 1945, he was awarded the "Sign of Honor" order, and became, together with others, a laureate of the Stalin (State) Prize (1948) for the development and implementation of new methods for purification of platinum metals.

Soon, the plant started to work using the already well-established technology, and there was no need any more for services of such a high-skilled specialist. He clearly perceived that his knowledge and experience remained uncalled for. His appeals to the government to let him work somewhere to better purpose remained unanswered, he was denied exculpation. Of no avail, either, was his address to the president of the Academy of Sciences of the USSR, despite their long-standing friendship.

Bashilov was much respected by plant workers of any rank, he was highly cultured and attentive and benevolent to those surrounding him.

Ivan Yakovlevich Bashilov died of a heart attack exactly 15 years after his arrest. He was buried in Krasnoyarsk at Pokrovsko-Troitskoe Cemetery. In November 1996, a black-stone monument was erected over his grave, on which an inscription "Now look at my deeds" was carved, together with his bas-relief. Also carved were symbols of chemical elements, to whose manufacture technology Professor Bashilov contributed in different years: uranium, radium, vanadium, ruthenium, rhodium, and iridium.

The charge imposed on Bashilov by a Special Council of NKVD on February 14, 1939, was dismissed by the Supreme Court of the USSR on January 30, 1957.

All those who were lucky to work with Bashilov, or knew him, preserve the dearest memory of this fine man. The most detailed biographic evidence concerning the scientist can be found in a book by V.R. Polishchuk [5], who could see over the personal archive of scientist's daughter, I.I. Bashilova. The book published in connection with the 55th foundation anniversary of the Krasnoyarsk plant of nonferrous metals includes numerous personal reminscences of staff members of the plant about Bashilov.

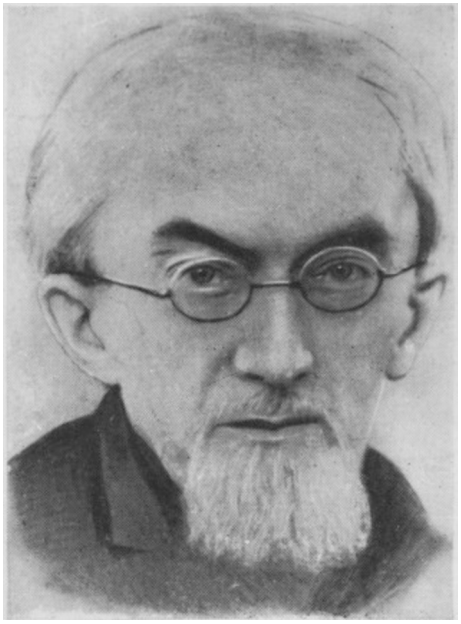
Professor Semen Petrovich Vukolov (To His 140th Birthday Anniversary)

One of the closest pupils and co-workers of D.I. Mendeleev, professor Semen Petrovich Vukolov, who is among the most prominent specialists in explosives and powders, made a major contribution to the improvement of the fighting efficiency of the Russian Navy and to training of engineers-chemists specialized in this field.

S.P. Vukolov was born on September 6 (August 23), 1863, in the Don region at Starocherkasskaya stanitsa (Cossack village). Having received primary education at a local school, he entered Novocherkassk Gymnasium, wherefrom he graduated with gold metal in 1882. When still studying at the gymnasium, he, mostly on his own, mastered German, French, and English languages. In 1882, Vukolov entered, and in 1887 graduated from, the natural department of the physicomathematical faculty at St. Petersburg University. His acquaintance with D.I. Mendeleev (1834–1907) largely determined all the subsequent activities of the young scientist. Having graduated from the university, Vukolov worked for two years in Paris, at the laboratory of professor L.J. Troost (1825–1911), known for his studies in the field of inorganic chemistry. In these years, Vukolov published in Transactions of the Paris Academy of Sciences his first papers: "On Solubility of Gases" and "On Solubility of Carbon Dioxide in Chloroform," and took active part in the preparation of the Brokhaus–Efron Encyclopedia.

In 1890, the Naval Ministry assigned the honored professor Mendeleev to supervise research aimed to develop smokeless powder for naval guns. In August 1891, the scientific-and-technological laboratory was created at the Naval Ministry for solving this problem, and Vukolov occupied the position of junior assistant of the head of the laboratory (in 1906–1918, senior assistant; in 1918–1928, head of laboratory). In one and a half years, smokeless powder for firearms of all the necessary calibers was obtained and tested. The outstanding Mendeleev's contribution to this work was described by Vukolov in detail in an article devoted to the centennial anniversary of Mendeleev's birthday [1]. By 1894, a simple and convenient technological process for industrial manufacture of smokeless powder was developed [2].



Together with working at the laboratory, Vukolov took part, in the summer of 1899, in a business trip with Mendeleev and other specialists to the Urals for studying the natural and economic conditions of operation of metallurgical plants. As a result of the expedition, quite a number of suggestions on development of metallurgical industry, transport, and economy of the Ural region was made. Mendeleev's memorandum concerning the results of the trip, submitted to the Minister for Finance S.Yu. Vitte (1849–1915), in particular, reads: "The industrial impact of Russia on the entire western Siberia and steppe center of Asia may and must involve the Ural region." The results of the expedition were summarized in a three-volume publication "Ural's Iron Industry in 1899."

By Mendeleev's recommendation, Vukolov took part in the expedition on ice-breaker Ermak (1901), aimed to study magnetic phenomena in the Arctic Ocean. Vukolov went in business trips to England, Germany, France, and the United States to make acquaintance with plants manufacturing explosives and was a participant of international congresses on applied chemistry in London (1909) and New York (1912). By 1911, he had the rank of senior state councilor.

1070-4272/03/7608-1365 $25.00 © 2003 MAIK "Nauka/Interperiodica"

After smokeless powder was put into industrial production, the functions of the Scientific-technological laboratory were extended, largely on Vukolov's initiative, to all kinds of ammunition for the Navy. Technologies for manufacture of trinitrotoluene and tetryl were developed, and these, new by that time, explosives were tested and methods for their use in various kinds of ammunition were studied [3].

In the prewar years (1911–1914), Vukolov and coworkers studied underwater explosions and designed special devices for this purpose. During the war (1914–1918), the efforts of the Laboratory and the associated pilot shops were completely concentrated on the supply of ammunition for the Navy. These works revealed the Vukolov's vigor and talent. In particular, lead azide was used for the first time in Russia in manufacture of caps for various kinds of shells for naval artillery. The scientific and technological results of the activities of the Laboratory were analyzed in [3, 4].

Already the first months of the war revealed the weakness of the military chemical industry of Russia. The available resources of nitric and sulfuric acid were insufficient for satisfying the dramatically increased demand for powders and explosives; benzene, toluene, and other necessary components could not be manufactured in required amount. In February 1915, "Commission for Procurement of Explosives" was organized at the Chief Artillery Department of the Military Ministry. The commission was headed by a professor of the Artillery Academy, lieutenant-general V.N. Ipat'ev (1867–1952, academician since 1916). Vukolov became a member of this commission [5]. He took active part in setting up production of the necessary raw materials at plants of southern Russia, and explosives in Revel (Tallinn), Petrograd, and Kineshma. As is known, a rapid rise in manufacture of explosives and chemical warfare, and other most important chemical industrial products, occurred in Russia already by the end of 1916 [5, 6]. Vukolov's activities during the years of war were honored by a number of state awards, and also by French Legion of Honor.

In 1919–1923, Vukolov was deputy head of the "Special Technical Commission for Inspection of Powders and Explosives" and dealt with problems of accounting and storage of the naval ammunition. From 1919 till 1928, he headed a department at the State Institute of Applied Chemistry, worked in a number of other scientific institutions, and taught at Leningrad University and Naval Academy.

In 1929, about 100 officers of the Russian Navy, allegedly members of a "counterrevolutionary organization at the Naval Department of the Workers'and Peasants' Red Army" were arrested. Vukolov was among them: he was arrested on 27.07.1929 and sentenced on 30.04.1931 to 3 years of imprisonment [7]. However, in January 1932, he was freed and rehabilitated. In 1932–1935, Vukolov worked as senior engineer at the Research Institute of Navy. Simultaneously, in 1932, he created a chair of explosives at the Leningrad Institute of Chemical Technology and headed it till the end of his life. The scientific degree of a doctor of chemical science was conferred on him in 1935, and the rank of a professor, in 1938.

Semen Petrovich Vukolov died on October 10, 1940, in Leningrad. Till the last days of his life he devoted all his energies to pedagogical and research activities. His pupils remember this excellent person who loved his country.

BOOK REVIEWS

Reznik, D.I., Ermakov, G.P., and Shneerson, Ya.M., *Nikel'* (Nickel), 3 vols., Moscow: Nauka i Tekhnika Ltd., 2003, vol. 3, 608 pp.

The final volume of the three-volume monograph (parts VIII–XV, chapters 27–55)[1] contains a vast body of material concerning mainly the nature and processing methods of sulfide copper-nickel ores. Also considered are refining of nickel, recovery of noble and rare metals in processing of nickel and copper-nickel ores, and evidence about world's manufacture and consumption of nickel.

The share of sulfide copper-nickel ores in the total output of nickel ores is 60 – 64%. The main components of the ores are such minerals as pyrrhotine, pentlandite, chalcopyrite, and magnetite. Their various ratios give rise to a wide variety of relative contents of copper and nickel in ores from different deposits. To accessory components are referred cobalt, platinum metals, gold, silver, selenium, and tellurium, which are present in minor amounts. In some deposits, the cost of accessory components, e.g., platinum and palladium, exceeds that of nickel and copper. The authors describe deposits of sulfide copper-nickel ores in the Kola Peninsula and Norilsk region, a deposit discovered in Voronezh province in 1977, and foreign deposits and mines in Canada, Australia, and China (part VIII, ch. 27).

The ninth part of the monograph discusses a wide variety of problems associated with smelting of sulfide copper-nickel raw materials. It considers in detail the blast smelting of a relatively rich lump ore at the Severonikel' combine (beginning in 1938) and Norilsk mining-and-smelting combine (since 1942) and foreign combines, and also autogenous blast smelting of sulfide copper and copper-nickel raw materials (ch. 28). By 1978, the blast smelting was replaced at domestic plants with other processes in order to diminish the discharge of sulfur dioxide into the atmosphere. The authors note that it is possible now to revert to blast smelting by using oxygen-enriched blast and passing to autogenous processes without coke. The same part of the monograph considers reverberatory smelting of sulfide copper-nickel ores and concentrates (chapter 29), electric smelting of copper-nickel raw materials (ch. 30), impoverishment of molten converter slags in electric furnaces (ch. 31), smelting of sulfide concentrates in suspended state (ch. 32), autogenous smelting of copper-nickel ore in a unit with top oxygen blast (ch. 33), smelting in a liquid bath (ch. 34), and other kinds of smelting of sulfide concentrates (ch. 35). The authors emphasize that the development of new smelting processes was due to the necessity to catch and utilize sulfur dioxide, diminish the energy consumption for smelting by using heat released in oxidation of sulfides, and raise the output capacity of smelting units to compensate for the low content of nickel in concentrates.

The tenth part of the monograph contains detailed evidence about conversion of copper-nickel mattes and cooling of converter matte. The aim of conversion (ch. 36) is to remove iron from matte in order to obtain converter matte in which nickel, copper, cobalt, and noble metals are concentrated in the sulfide and, partly, metallic form. In slow cooling of molten converter matte, there occurs separate crystallization of copper and nickel sulfides, which makes it possible to obtain nickel and copper concentrates (ch. 37).

The eleventh part discusses hydrometallurgical techniques for processing of sulfide copper-nickel materials. It describes the following methods: autoclave leaching of rich sulfide concentrates, mattes, and converter mattes in ammonia medium (ch. 38); leaching in sulfuric acid medium (ch. 39); autoclave leaching of intermediate products formed in pyrometallurgical processes (ch. 40); chloride techniques for processing of sulfide nickel concentrates (ch. 41); leaching of sulfide nickel-cobalt concentrates (ch. 42).

The twelfth part of the book is devoted to methods for processing of nickel-pyrrhotine concentrates. These concentrates are obtained by flotation isolation of copper and nickel (pentlandite) concentrates by additional flotation and magnetic separation (ch. 43). Industrial processing of pyrrhotine concentrates is presently done only at single plant in Norilsk. Also

[1] Information about the first two volumes was published previously in Zhurnal Prikladnoi Khimii (2001, vol. 74, no. 4, p. 691 and no. 7, p. 1211). The numbering of parts and chapters is the same through all the three volumes.

1070-4272/03/7608-1367 $25.00 © 2003 MAIK "Nauka/Interperiodica"

described are theoretical foundations of the oxidizing and autoclave leaching of nickel-pyrrhotine concentrates (ch. 44).

The thirteenth part discusses methods for nickel refining: liquid extraction (ch. 45), autoclave technology for manufacture of metallic nickel powders (ch. 46), carbonyl technology for nickel refining (ch. 47),[2] and electrolysis of nickel (ch. 48).[3] Electrolysis is the final procedure in the technological scheme for processing of nickel raw materials, which makes it possible, in addition to obtaining the metal, to solve the problem of recovery of cobalt and platinum group metals into semi-products for further refining. All industrially implemented variants of nickel electrolysis are considered: refining of raw metallic anodes, refining of sulfide anodes, and electric extraction of nickel from sulfuric acid and chloride solutions.

The fourteenth part of the monograph[4] presents information on recovery of platinum group metals, gold, silver, and rare elements in processing of nickel and copper-nickel ores. It describes the following issues: behavior of noble metals in processing of oxidized nickel ores (ch. 49) and sulfide copper-nickel ores (ch. 50); technology for recovery of noble metals and rare chalcogens from electrolyte sludge and other products enriched with these elements (ch. 51).

The final, fifteenth part of the monograph presents statistical data on the scale of manufacture and consumption of nickel. In 2002, the world's output of nickel was 1091 thousand tons, of which Russia produced 236.6 thousand tons, thus occupying the first place with 21.7% of the world's output. The consumption of nickel in Russia was only 31.3 thousand tons (2.7% of the world consumption) (ch. 52). Chapters 53, 54, and 55 present evidence concerning the largest world's plants processing sulfide copper-nickel raw materials and consider the ranges of use of nickel and the trends of prices for nickel, cobalt, and copper at London Metal Exchange in the last 10 years.

Each part of the monograph has its own reference list. The third volume presents a total of 423 references, mainly to publications by domestic authors. The third volume, as also the whole monograph, has clearly pronounced technological orientation. A detailed analysis of production processes at Russian and foreign plants of nickel industry is made. The information value of this capital publication is very high. The authors of the monograph, and I.D. Reznik in the first place, are well aware of the entire history of the development of the domestic nickel industry, which imparts an interesting aspect to the presentation and makes it possible to trace the dynamics of technological changes at the largest plants of the country.

The book gives an exhaustive description of the nickel industry of Russia and other countries. It may be of use for a wide audience of specialists associated with nickel industry and also for graduate students, masters, and postgraduate students specialized in metallurgy of heavy nonferrous metals.

REVIEWS

Reaction Medium and Kinetics of *N*-Vinylsuccinimide Copolymerization

Dedicated to the memory of Prof. Sergei Nikolaevich Ushakov

N. A. Lavrov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 28, 2003

Abstract—Studies in the field of radical copolymerization of *N*-vinylsuccinimide were summarized, and the effect of the reaction medium on the process kinetics was examined. Factors governing the relative activity of the monomers were revealed, and ways to control the reactivity of *N*-vinylsuccinimide in binary copolymerizations were suggested.

September 16, 2003 is the 100th anniversary of Prof. Sergei Nikolaevich Ushakov's birthday. Prof. Ushakov, Corresponding Member of the USSR Academy of Sciences, Honored Scientist of the RSFSR, Honored Inventor of the RSFSR, winner of State Prizes, Doctor of Engineering, contributed much to foundation of the Chair of Chemical Technology of Plastics at the St. Petersburg State Technological Institute (formerly Lensovet Leningrad Technological Institute), Institute of Macromolecular Compounds (Russian Academy of Sciences), and Research Institute of Polymerization Plastics, and also to many other major events in the Soviet science. Ushakov's scientific interests were very diverse. His monographs became reference books for many generations of engineers and researchers, and the results of research work, published in numerous papers, were further developed by his disciples and followers. About 50 years ago, S.N. Ushakov together with A.F. Nikolaev initiated studies in the field of synthesis and application of polymers based on dicarboxylic acid *N*-vinylimides [1–4]. These studies were subsequently continued; their results were published in more than 100 papers, and several tens of inventor's certificates and patents were received. Two doctoral [4, 5] and more than ten candidate's dissertations were defended on this problem at the Chair of Chemical Technology of Plastics, St. Petersburg State Technological Institute.

Among the compounds prepared, polymers derived from *N*-vinylsuccinimide (VSI) aroused the greatest scientific and practical interest; they showed promise for biology and medicine. To expand the assortment of VSI-based polymers, copolymerization of VSI with other monomers was studied. This paper summarizes the results of these studies and analyzes the effect of the reaction medium on the kinetics of synthesis of VSI copolymers, relative activity of the monomers, and compositional uniformity of the copolymers.

The electron-donor substituent in the VSI molecule increases the electron density on the vinyl double bond, which is confirmed by the negative Alfrey–Price parameter e ($e = -0.34$). The increased electron density on the double bond suggests the possibility of preparing VSI polymers by cationic polymerization; however, this method found no application because of the low molecular weight of the products obtained. VSI (co)polymers are mainly prepared by radical (co)polymerization. It should be noted that the conjugation between the lone electron pair of the nitrogen atom and the π electrons of the vinyl group is relatively weak ($Q = 0.13$), which is responsible for fairly low activity of VSI monomer in binary radical copolymerization with other monomers (see table).

The table shows that VSI copolymers are chiefly prepared by copolymerization in the bulk, in organic solvents, and in water. The initiators used are quite traditional: benzoyl peroxide (BP), azobis(isobutyronitrile) (AIBN), and various redox systems.

In binary copolymerizations, VSI is more active than VA and vinyl *n*-butyl ether but less active than styrene and acrylic monomers. Dicarboxylic acid *N*-vinylimides are more active in copolymerizations than many other *N*-vinyl compounds, as noted, e.g., in copolymerization of VSI with *N*-vinylpyrrolidone (VP) and *N*-vinylcarbazole (see table) and of *N*-vinylphthalimide (VPI) with VP: $r_1 = 1.284 \pm 0.04$, $r_2 = 0.35 \pm 0.002$ [22].

It is known that binary radical copolymerization kinetics is affected by various factors. Analysis of the

published data reveals the following factors causing deviations from the classical theory of radical copolymerization and affecting the reactivity of monomers and radicals, the rate constants of elementary reactions, and the overall copolymerization kinetics:

(a) occurrence of a dynamic equilibrium between the forward (polymerization) and reverse (depolymerization) reactions [23–25];

(b) homoassociation of monomers [24] and effect of the solvent polarity on the monomer speciation;

(c) solvation of radicals with solvent molecules, shielding the reaction center [23];

(d) dependence of the rate constants of elementary reactions on the composition of the starting monomeric mixture [24];

(e) selective solvation of macroradicals with monomers [26];

(f) dependence of the copolymerization kinetics and copolymer composition on the initiator concentration [23];

(g) possible interaction of monomers with each other to form a complex [24];

(h) presence of components (solvents, initiators, complexing agents, etc.) forming complexes with monomers [23–25, 27–30];

(i) chain transfer to copolymer macromolecules [24];

(j) effect of penultimate unit, along with the terminal unit, on the copolymerization kinetics [23, 24, 31];

(k) variation of the composition of the forming copolymer with variation of the initiation rate [32];

(l) influence of the heterophase mode of the process on the elementary reactions [23, 24, 33, 34];

(m) influence of the degree of polymerization on the elementary steps of the process [23, 24, 34]; polymerization systems in viscous media can be considered as microheterophase [23];

(n) influence of pH in copolymerization of ionizable monomers [35]; changes in the reaction kinetics under conditions of heterogeneous copolymerization on a solid surface [25, 32];

(o) changes in the reaction kinetics in an emulsion [23, 25];

(p) influence of the solvent composition on the macromolecule conformation [24];

(q) hydrophobic interaction arising in polymer solutions when copolymerization is performed in aqueous-organic media [36];

(r) effect of selective sorption of monomers on the copolymer composition [37].

It should be taken into account that several factors can act simultaneously.

The structural features of VSI and conomomer molecules and the results obtained in experiments on VSI homopolymerization [38] suggest that the VSI copolymerization kinetics will also show deviations from the classical theory. Firstly, VSI and some comonomers, owing to the features of their structure and charge distribution [39], can interact with components of the medium to form intermolecular complexes. In this case, by the reaction medium is understood the whole set of components participating in the process (comonomers, solvents, initiators, etc.). Secondly, the presence of bulky substituents in VSI and comonomer molecules and different polarities of the monomers will result in the fact that addition of monomers to a propagating radical will be influenced by the structure of not only terminal but also penultimate unit of the macrochain. Thirdly, the heterophase mode of the process performed in some solvents, e.g., benzene, may result in that the active center gets immured in the condensed polymer phase. Because of occlusion of macroradicals, the chain termination can occur by the monomolecular mechanism. The access of monomers to the active centers is thus hindered; the diffusion rates of the monomers, especially of those of different polarity, can differ significantly. Therefore, the compositions of the copolymers obtained under conditions of homophase and heterophase copolymerization can differ significantly. The rate of the heterophase copolymerization is usually higher than that of the homophase process. Fourthly, in copolymerization with monomers tending to homoassociation, e.g., with 2-hydroxyethyl methacrylate (HOEMA), the relative activities of the monomers and the compositions of the copolymers can depend on the polarity of the medium. The kinetics of VSI copolymerization can also be influenced by other factors, in particular, by solvation, sorption, macromolecule conformation, etc. Some trends can be expected theoretically; as for experimental data, the following facts have been proved.

N-Vinylsuccinimide can enter into intermolecular interaction with comonomers, e.g., maleic anhydride (MA), and with some solvents: dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and acetic anhydride. Hopff and Becker [18] revealed no complexation of VSI with MA, but in later studies [40, 41] equimolar donor–acceptor complexes of VSI and some other *N*-vinyl monomers (VP, VPI) with MA were detected; this resulted in formation of copolymers of a fixed composition corresponding to the composition of the complex. If the ratio of the starting components was not equimolar, copolymerization yielded an alternating copolymer of the equimolar composition and a homopolymer of the *N*-vinyl monomer, if this monomer was in excess; if MA was in excess, its homopolymer was not formed, and excess MA was recovered unchanged. The compositions of the copolymers prepared in DMF and benzene were similar; this fact was accounted for in [40, 41] by the incapability of the MA–solvent interaction to compete with the donor–acceptor interaction of MA with the

N-vinyl monomer; the possibility of interaction of *N*-vinyl monomers with solvents was not considered in [40, 41]. It was only noted that the solvent affected the copolymerization rate: in benzene, the reaction was faster than in DMF. The causes of this trend were not discussed in [40, 41]; they may be associated with occlusion of the macroradicals, since the process should be heterophase. The difference between the results obtained in [18, 40, 41] may be due to different experimental procedures. In particular, Nikolaev *et al*. [40, 41] first obtained the monomeric complexes and then performed the polymerization. They noted that the donor–acceptor interaction increased in the order MA–VPI < MA–VSI < MA–VP.

The kinetics of copolymerization of VSI with various monomers in solvents was studied in more detail. Complexation of VSI with DMSO was proved by IR spectroscopy [15] and refractometry [42]. The donor–acceptor interaction may involve various groups [39], but interaction of the C=O groups of VSI with the S=O group of DMSO seems to be preferable. Experiments on copolymerization of VSI with *n*-butyl acrylate, VA, HOEMA, methyl methacrylate, and styrene showed that DMSO strongly affects the copolymerization constants (see table).

Interaction of VSI molecules with electron-donor DMSO molecules results in redistribution of the electron density in the monomer molecule and increase in the electron density on the double bond; as a result, the relative activity of VSI decreases compared to polymerization in the bulk or in an inert solvent, dichloroethane. As a result, the copolymerization constants of VSI with VA become closer, and it appears feasible to prepare copolymers with better alternation of the units [43, 44]. The copolymerization constants and the probability of formation of particular microstructures in the copolymer chains depend on the molar ratio of VSI and DMSO (see table). However, in copolymerization of VSI with acrylic monomers, a decrease in the relative activity of VSI results in that the copolymers become less uniform in the composition; therefore, to obtain copolymers with better alternation of the units, the reaction should be performed in an electron-acceptor solvent, e.g., acetic anhydride [45]. Dipole–dipole interaction of monomers with the solvent and solvation effects should be expected in (co)polymerization of VSI in water, but these processes have been studied insufficiently.

Complexation of VSI with a solvent affects the copolymerization constants calculated taking into account both the terminal and penultimate units of the macrochain [46]. Experiments on copolymerization of VSI with HOEMA showed that the penultimate unit only slightly affects the reactivity of the macroradical with the VSI terminal unit, but with the HOEMA terminal unit the effect of the penultimate unit is significant: the VSI penultimate unit decreases, and HOEMA unit enhances the reactivity of such macroradicals toward HOEMA monomers. The occurring processes affect the microstructure of the forming copolymers.

Heterophase copolymerizations in benzene are of applied interest. The processes are fast and allow preparation of copolymers in the form of finely dispesred powders, which simplifies their isolation. Although benzene, like DMSO, is an electron-donor solvent, copolymerization of VSI with HOEMA in benzene yielded copolymers with better alternation of the units than in DMSO. This may be due to a stronger tendency of DMSO to form complexes with VSI, owing to the presence of vacant orbitals on the sulfur atom. Therefore, in DMSO, VSI is less active in copolymerization than in benzene (see table). However, when comparing the copolymerization kinetics of VSI with HOEMA in benzene and DMSO, it should be taken into account that, in nonpolar solvents (dielectric permittivity: benzene 2.28, DMSO 46.45), HOEMA tends to associate, which affects its activity, i.e., the copolymerization of VSI with HOEMA in benzene is complicated by the effect of at least four factors, which are difficult to rank with respect to the extent of their influence.

To complete consideration of experimental data on VSI copolymerization kinetics, one more way to control the relative activity of the monomers should be noted: complexation of the comonomer (rather than VSI) with the components of the medium. This approach was used in experiments on copolymerization of VSI with VA in aqueous solution in the presence of the initiating system manganese tris(acetylacetonate)–acetic acid [17]. It is known that manganese tris(acetylacetonate) forms a complex with VA monomer in the initiation step, which enhances the relative activity of VA. Under these conditions, the copolymerization constants of VSI with VA become closer (see table), which results in formation of the copolymer with better alternation of the units.

Thus, studies commenced on Ushakov's initiative started a comprehensive research on radical copolymerization of VSI. A correlation was elucidated between the structure of the monomers, kinetic parameters of copolymerization, and nature of the reaction medium; factors affecting the VSI reactivity were revealed, and their total effect was analyzed; ways to control the VSI reactivity and prepare VSI copoly-

mers of preset structure and properties, suitable for various applications, were outlined [47].

CONCLUSIONS

(1) The reaction medium strongly affects the relative activity of *N*-vinylsuccinimide in radical copolymerization and the microstructure of the resulting copolymers. The major factors affecting the reaction kinetics are complexation of *N*-vinylsuccinimide or comonomer with components of the medium, homophase or heterophase mode of the process, features of the influence of the penultimate unit on addition of monomers to the propagating radical, and polarity of the medium (affecting the reactivity of monomers that form homoassociates).

(2) Electron-donor solvents enhance the activity of the *N*-vinylsuccinimide radical and decrease the relative activity of the monomer in binary copolymerizations.

(3) Heterophase copolymerization in benzene allows preparation of *N*-vinylsuccinimide copolymers at a higher rate, with isolation of the reaction products as finely dispersed powders.

Abstract—A group of crystalline and amorphous calcium–magnesium phosphates were prepared by exchange in solution of sodium orthophosphate and calcium and magnesium chlorides at pH 8–12. The behavior of the phosphates on heating to 1000°C was studied.

Calcium phosphates are components of preparations and materials for modern stomatology and orthopedics [1–4]. Among them, the most widely used compound is hydroxyapatite $Ca_5(PO_4)_3OH$, which is a mineral base of human and animal bone tissues [4–8]. This compound is mainly used in the crystalline form. Its amorphous form, which has not yet been obtained pure, should exhbit considerably higher bioactivity.

Hydroxyapatite is sparingly soluble in water. Therefore, chemical methods of its preparation include exchange reactions in a solution between phosphates and calcium salts [4]. Amorphous phosphates, which can be considered as apatite-related compounds, are precipitated in the presence of substances preventing crystal nucleation and growth. As crystallization inhibitors can serve different substances, e.g., soluble carbonates, fluorides, diphosphates, etc. [4, 9, 10]. Of great interest are magnesium salts, whose behavior in the course of the phosphate precipitation has been considered elsewhere [5, 9–15]. A method has been patented [16], according to which crystallization of the precipitated apatite is prevented by adding soluble magnesium(II) salts in the ratio Mg/Ca = 0.001–1. The presence of Mg^{2+} ions opens new ways to control properties of calcium-containing medical preparations [17]. Moreover, amorphous calcium–magnesium phosphates are interesting precursors for bioceramics.

The goal of this study was to refine the Mg/Ca ratio ensuring formation of amorphous substances from Na_3PO_4 aqueous solutions containing $CaCl_2$ and $MgCl_2$ and to gain insight into the behavior of the precipitated phosphates on heating.

EXPERIMENTAL

We used $CaCl_2$, $MgCl_2$, and sodium hydrophosphate Na_2HPO_4 (analytically pure grade). 5% aqueous solutions containing the required amounts of both chlorides were slowly added dropwise to a solution of Na_2HPO_4 at vigorous stirring. Preliminarily, the Na_2HPO_4 solution was adjusted to pH 12.0 to neutralize acids released upon the hydroxyapatite formation. After most of the substance was precipitated, pH was decreased to 8.0, and then a 5% NaOH solution was added to maintain pH at this level up to the synthesis completion. The precipitates were washed with distilled water (pH 8) to fully remove Cl^- ions, decanted, and filtered through a glass frit. The substances were dried in air at room temperature and studied by IR spectroscopy and X-ray phase and thermal analyses. The IR spectra were recorded on a Specord M80 spectrometer from KBr pellets, and X-ray diffraction patterns were taken on a DRON-3 diffractometer (CuK_α radiation). The thermal analysis of 0.2-g samples heated in platinum crucibles in air at a rate of 10 deg min^{-1} was done with a MOM Q-1500 thermal analyzer (Hungary) using aluminum oxide as reference.

The chemical analysis of the precipitates revealed phosphorus(V), calcium(II), and magnesium(II) in ratios used in the synthesis. According to the X-ray phase analysis (Fig. 1), the substance precipitated with calcium chloride from an Na_3PO_4 solution is crystalline hydroxyapatite [9]. In the diffraction patterns of substances precipitated with calcium chloride in the presence of small amount of $MgCl_2$, the reflections become less intense and more diffuse with growing

1070-4272/03/7609-1375$25.00

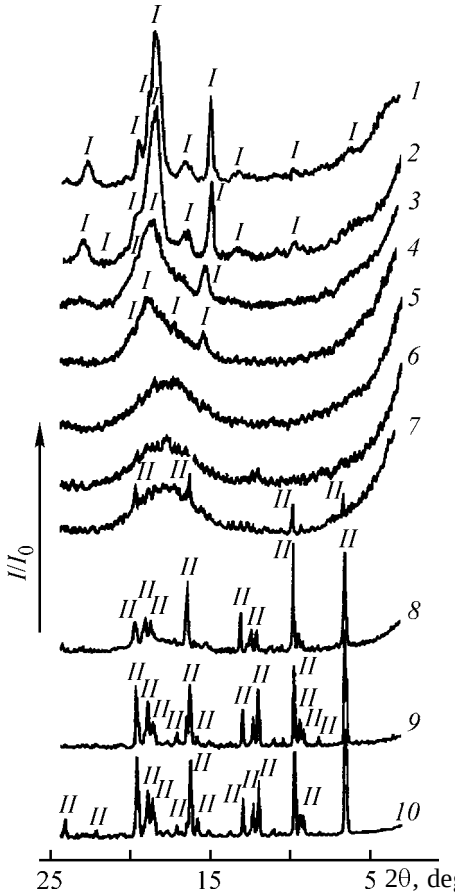

Fig. 1. X-ray diffraction patterns of phosphates precipitated from aqueous solutions containing $CaCl_2$ and $MgCl_2$: (I/I_0) relative reflection intensity and (2θ) diffraction angle; the same for Fig. 4. $MgCl_2/(MgCl_2 + CaCl_2)$ molar ratio: (*1*) 0, (*2*) 0.05, (*3*) 0.10, (*4*) 0.20, (*5*) 0.25, (*6*) 0.35, (*7*) 0.40, (*8*) 0.50, (*9*) 0.80, and (*10*) 1.00. (*I*) $Ca_5(PO_4)_3OH$ and (*II*) $Mg_2OHPO_4 \cdot 3H_2O$.

$MgCl_2/(MgCl_2 + CaCl_2)$ ratio. This means that the less crystalline precipitate is formed. The diffraction patterns of the substances precipitated from solutions at $0.25 \le MgCl_2/(MgCl_2 + CaCl_2) \le 0.35$ suggest that they are amorphous to a maximal extent. The substances formed from solutions with larger amounts of $MgCl_2$ contain the crystalline component $Mg_2OHPO_4 \cdot 3H_2O$, along with the amorphous phase. These data show that formation of crystalline phosphates is inhibited in a narrow range of the $MgCl_2/(MgCl_2 + CaCl_2)$ molar ratios (0.25–0.35), which is considerably narrower than that reported in [16].

One of the reasons why the precipitated calcium–magnesium phosphates are amorphous is that the types of calcium– and magnesium–oxygen polyhedra forming the phosphate structure are different. It is known that the number of oxygen atoms bound to Ca^{2+} ions can reach 12, whereas that for Mg^{2+} ions is commonly four [18]. Owing to such differences, the Ca^{2+} and Mg^{2+} ions present simultaneously in certain ratios in a solution containing PO_4^{3-} ions cannot form surroundings typical of crystalline hydroxyapatite and basic magnesium phosphate. Instead of them, products with the random distribution of cations among PO_4 groups are formed.

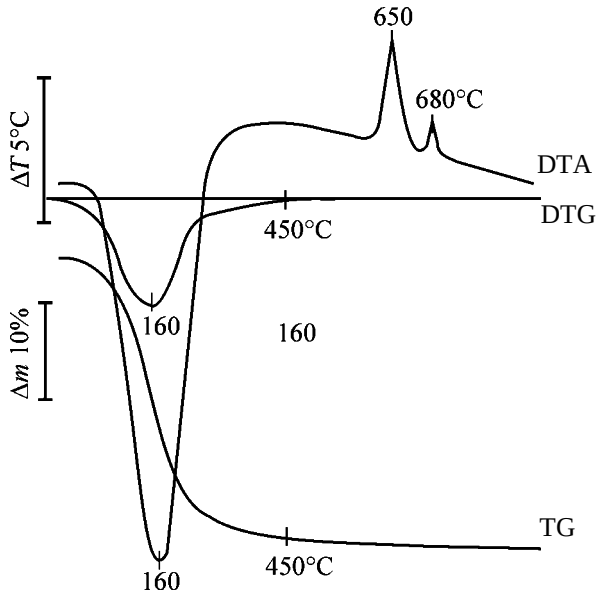

Fig. 2. Thermogram of calcium–magnesium phosphate precipitated at the atomic ratio Mg/(Mg + Ca) = 0.35.

The precipitated calcium–magnesium phosphates dried to constant weight at room temperature are hydrates. Their IR absorption spectra contain strong absorption bands belonging to the O–H stretching vibrations of water molecules. The water of crystallization is lost even on weak heating. Figure 2 shows for the sample whose composition corresponds to the atomic ratio Mg/(Mg + Ca) = 0.35 that the dehydration becomes more active with increasing temperature, with the maximal rate attained at about 160–170°C, and is mainly complete at 400–450°C. The water content in phosphates, as estimated from the thermal analysis data, depends on the sample composition. Figure 3a shows that, with an increase in the magnesium(II) content in the substance, the water content increases to the maximal value, which is reached in the most amorphous products, and then decreases.

Dehydration is an endothermic reaction, and the endothermic peaks in the DTA curves reflect the water content in the substances (Fig. 3b). The endothermic peaks are the strongest for the phosphates with the atomic ratio Mg/(Mg + Ca) $\approx$ 0.35.

The DTA curves of calcium–magnesium phos-

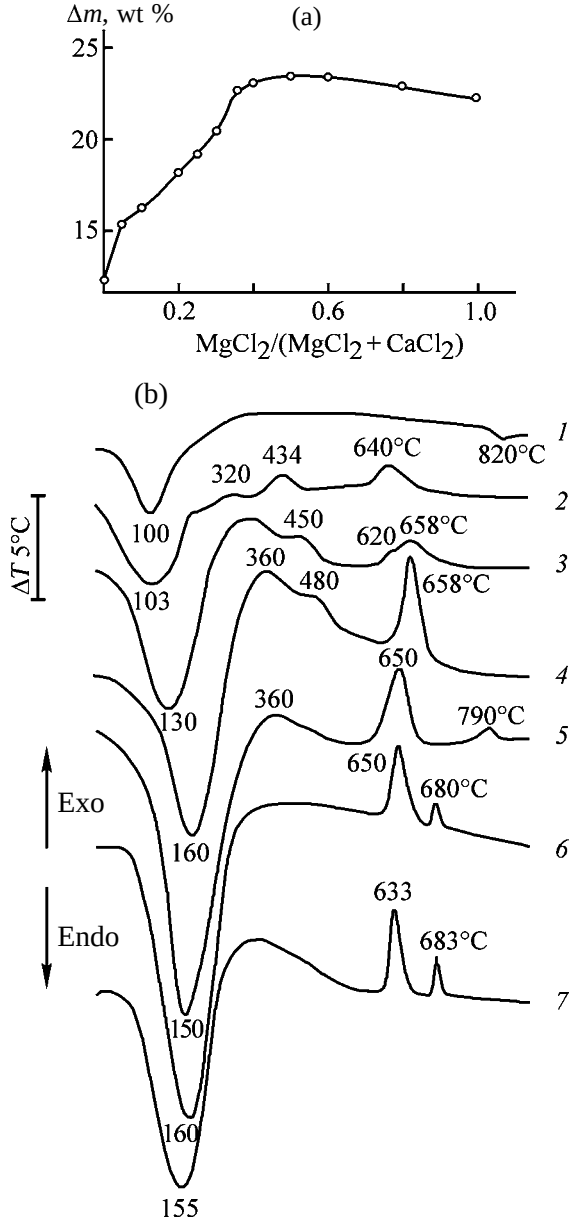

Fig. 3. (a) Weight loss Δm due to dehydration, as determined by thermal analysis, and (b) DTA curves of the precipitated calcium–magnesium phosphates. Mg/(Mg + Ca) atomic ratio: (*1*) 0, (*2*) 0.05, (*3*) 0.10, (*4*) 0.20, (*5*) 0.25, (*6*) 0.35, and (*7*) 0.40.

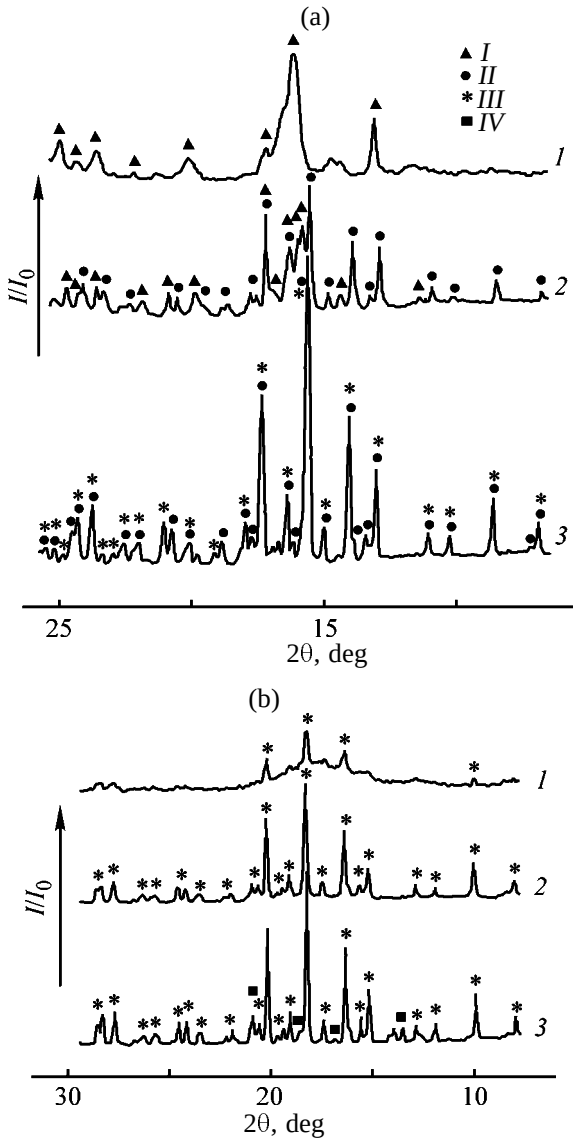

Fig. 4. Diffraction patterns of the thermal dissociation products of phosphates precipitated from solutions containing $CaCl_2$ and $MgCl_2$. $MgCl_2/(MgCl_2 + CaCl_2)$ molar ratio: (a) 0.05 and (b) 0.35. *T*, °C: (a) (*1*) 600, (*2*) 640, and (*3*) 900–1000; (b) (*1*) 580, (*2*) 650, and (*3*) 680–1000. (a) (*I*) $Ca_5(PO_4)_3OH$, (*II*) β-$Ca_3(PO_4)_2$, and (*III*) $Ca_7Mg_2(PO_4)_6$. (b) (*III*) $Ca_7Mg_2(PO_4)_6$ and (*IV*) $Ca_3Mg_3(PO_4)_4$.

phates also contain several exothermic peaks, showing that the thermal transformations are accompanied by heat evolution. An exception is hydroxyapatite, for which only one weak endothermic peak with a minimum at about 820°C is observed. The X-ray phase analysis showed that, at this temperature, apatite partially transforms into β-$Ca_3(PO_4)_2$, and the relative content of this salt somewhat increases with temperature. As known, hydroxyapatite is thermally stable and dissociates only above 1300–1450°C [18–20]. Therefore, the forming β-$Ca_3(PO_4)_2$ can originate from an impurity of a nonstoichiometric compound in the precipitated substance, in which a part of PO_4^{3-} ions is replaced by HPO_4^{2-} ions. Such apatites can dissociate above 700°C to form $Ca_3(PO_4)_2$ [4].

The apatite structure formed with $CaCl_2$ in the presence of a small amount of $MgCl_2$, in particular, at the ratio $MgCl_2/(MgCl_2 + CaCl_2) = 0.05$, remains unchanged up to nearly 600°C. Above this tem-

perature, i.e., when the exothermic transformation at 640°C starts, a part of apatite transforms into $Ca_3(PO_4)_2$ (Figs. 3b, 4a). Interestingly, when a minor amount of Mg^{2+} ions is present in the precipitated phosphate, the temperature of the appearance of β-$Ca_3(PO_4)_2$ decreases from 820 to 640°C, and its content in the heat-treated products increases. Another salt, $Ca_7Mg_2(PO_4)_6$, appears on heating to 900–1000°C.

The structural transformations in amorphous calcium–magnesium phosphates are appreciable at about 580°C, i.e., at temperatures of the onset of the exothermic peaks in the corresponding DTA curves (Figs. 3b, 4b). The crystalline $Ca_7Mg_2(PO_4)_6$ phase appears in the products after the exothermic transformations at about 650°C are complete, and another calcium–magnesium salt, $Ca_3Mg_3(PO_4)_4$, is detected after passing the second exothermic effect (~680°C).

The substances precipitated from solutions at $MgCl_2/(MgCl_2 + CaCl_2) \geq 0.50$ also undergo thermal transformations: the two above-indicated calcium–magnesium phosphates whose relative content depends on the composition are formed above 500°C.

CONCLUSIONS

(1) Crystalline or amorphous substances are precipitated from a sodium orthophosphate solution containing calcium and magnesium chlorides, depending on their relative content.

(2) The crystalline compounds are formed from solutions containing excess of either of two chlorides, whereas amorphous products are formed within the narrow range of molar ratios $MgCl_2/(MgCl_2 + CaCl_2) = 0.25–0.35$.

(3) All the precipitated calcium–magnesium phosphates are hydrates. They lose water of crystallization when heated to 400°C, with the amorphous form preserved, and, depending on composition, they transform into $Ca_5(PO_4)_3OH$, β-$Ca_3(PO_4)_2$, $Ca_7Mg_2 \cdot (PO_4)_6$, and $Ca_3Mg_3(PO_4)_4$ when heated above 500°C.

Abstract—Regular trends in the phase formation in the course of oxidation of aqueous $FeSO_4$ solutions and(or) $Fe(OH)_2$ suspensions under steady-state conditions (pH_0 = const, T = const) with atmospheric oxygen were studied within broad ranges of pH, temperature, total concentration $c^0_{Fe(II)}$, and air space velocity.

The oxidation of aqueous solutions of iron(II) salts and(or) suspensions of iron(II) hydroxide with atmospheric oxygen [system $Fe(II)R_n$–H_2O–H^+/OH^-–O_2, where R is Cl^-, NO_3^-, or SO_4^{2-}] underlies industrial processes of synthesizing inorganic pigments, ion-exchange materials, and catalysts based on Fe(III) oxide compounds, including hydrated compounds [1–4]. It was found [2–11] that the phase composition and crystal size of the resulting products depends on both thermodynamic [temperature T and pH of reaction medium, concentration of Fe(II) ions in solution and(or) $Fe(OH)_2$ in suspension, etc.] and kinetic (average oxidation rate $\tilde{V}$) parameters of the synthesis. It was shown [4–6] that, at $\tilde{V} \approx$ const, the phase composition changes in the sequence $\gamma(\delta)$-FeOOH $\rightarrow$ α-FeOOH $\rightarrow$ Fe_3O_4 as the temperature increases, with the average crystal size d in these phases changing in parallel with temperature; at $T \approx$ const, the dependences of the phase composition and crystal size on $\tilde{V}$ are opposite to those mentioned above [6, 11]. The phase composition and crystal size depend on a number of parameters, and there is still no common opinion on what of these parameters is decisive [2, 4–7], which does not allow optimization of the synthesis of products with reproducible properties.

The goal of this work was to refine regular trends in phase formation in the course of oxidation of aqueous $FeSO_4$ solutions and(or) $Fe(OH)_2$ suspensions with atmospheric oxygen (system $FeSO_4$–H_2O–H^+/OH^-–O_2) at quasi-constant temperatures and pH of the reaction medium.

EXPERIMENTAL

The starting reagents were aqueous solutions of $FeSO_4$ (1.7 M, preliminarily reduced with iron powder) and NaOH (6.2 M), both of chemically pure grade.

The oxidation was carried out in a 3 dm^3 reactor equipped with a bubbler with a sprayer for air supply, a stirring device, systems of electrical heating and thermostatic control (± 2°C), a dosing unit for continuous supply of the NaOH solution, and also with systems for continuous monitoring of the redox potential and pH of the medium (pH-340 pH-meter–millivoltmeter). To measure redox potential and pH values, we used, respectively, platinum and hydrogen electrodes coupled with a silver chloride reference electrode. Calculated amounts of an $FeSO_4$ solution and distilled water were charged to the reactor and heated to a specified temperature, and an NaOH solution was fed to adjust the required pH_0 of the reaction medium. After that, we started to feed air into the reactor at a constant rate, and also to feed an NaOH solution to maintain a quasi-constant pH_0 value (± 0.25 units, range $3.5 \le pH_0 \le 8.5$). In some experiments, intermediate samples of suspensions were taken during the oxidation, and the compositions of the liquid and solid phases were determined. The process was completed when the redox potential, which remained constant in the initial stage of the oxidation, started to increase sharply with time τ.

On completion of the oxidation, we determined the residual concentration $c^{\tau_0}_{Fe(II)}$ (τ_0 is the oxidation duration) in the suspension. The total initial concentration of iron(II) $c^0_{Fe(II)}$ in $FeSO_4$ solution and(or) in $Fe(OH)_2$ suspension was varied from 0.25 to 0.8 M (taking into account dilution of the initial $FeSO_4$ solution with NaOH solution); air space velocity V_a, from 125 to 600 $dm^3\ h^{-1}$ per 1 dm^3 of $FeSO_4$ solution

1070-4272/03/7609-1379$25.00

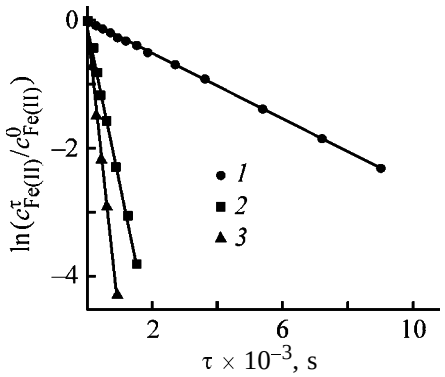

Fig. 1. Oxidation kinetics in the system $FeSO_4$–H_2O–H^+/OH^-–O_2. T = 20°C, $c^0_{Fe(II)}$ = 0.25 M, V_a = 600 dm^3 h^{-1}; the same for Fig. 2. [$c^0_{Fe(II)}$, $c^{\tau}_{Fe(II)}$] Total initial and current Fe(II) concentrations; (τ) time. pH_0: (*1*) 3.5, (*2*) 7.0, and (*3*) 11.0.

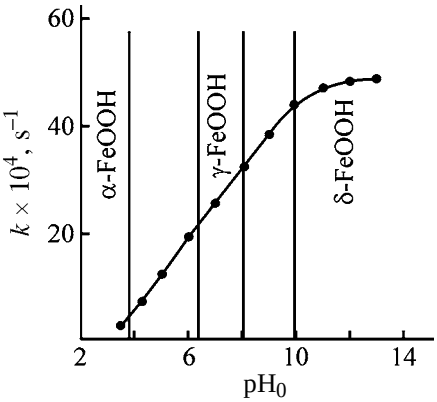

Fig. 2. Rate constant k of the oxidation of $FeSO_4$ solution and(or) $Fe(OH)_2$ suspension and phase composition of the forming precipitate vs. pH_0 of the reaction medium.

and(or) $Fe(OH)_2$ suspension; and temperature and pH_0 of the reaction medium, from 15 to 80°C and from 3.5 to 13, respectively. The resulting samples were separated on a Büchner funnel from the mother solution, washed with water until the absence of sulfate ions in the filtrate, dried to a constant weight at a temperature of about 70°C, and crushed.

The phase composition and crystal size of samples were evaluated by X-ray phase analysis (DRON-3 X-ray diffractometer; filtered FeK_α radiation) and by transmission electron microscopy (UEMV-100K electron microscope), and their chemical composition and $c_{Fe(II)}$ in solution, by volumetric chemical analysis and thermogravimetry (MOM derivatograph, Hungary). The mean crystal size d in the precipitate formed was calculated by a standard technique based on physical broadening of the diffraction peaks $\Delta 2\theta$.

In the first series of experiments, we varied pH_0 of $FeSO_4$ solution and(or) $Fe(OH)_2$ suspension at equal values of the other parameters: $c^0_{Fe(II)} = 0.25 \pm 0.02$ M, $V_a = 600 \pm 50$ dm^3 h^{-1}, and $T = 20 \pm 2$°C. It follows from the experimental data that the dependences of the current concentrations $c^{\tau}_{Fe(II)}$ on time τ can be linearized in the coordinates $\ln[c^{\tau}_{Fe(II)}/c^0_{Fe(II)}]$–$\tau$ (Fig. 1). Therefore, the oxidation is described by the kinetic equation

$$c^{\tau}_{Fe(II)} = c^0_{Fe(II)} \exp(-k\tau), \quad (1)$$

where k is the oxidation rate constant. The values of k were calculated by Eq. (1) from the experimental $c^0_{Fe(II)}$, $c^{\tau_0}_{Fe(II)}$, and τ_0 values.

The dependence of the oxidation rate constant on pH_0 is given in Fig. 2, which shows that, in the range $3.5 \le pH_0 \le 10$, k linearly increases with pH_0 from 2.6×10^{-4} to 4.9×10^{-3} s^{-1}, and as pH_0 increases further to 13.0, the rate constant remains constant within the limits of the experimental error. The results obtained qualitatively agree with the data of [2], indicating that the oxidation rate constant groups as pH of aqueous solutions of Fe(II) salts increases. At the same time, the experimental factor by which k changes when pH of the $FeSO_4$ solution and(or) $Fe(OH)_2$ suspension is changed by unity is considerably (by a factor of approximately 10) smaller than that reported in the monograph [2], which can be caused by different reaction conditions, e.g., different concentrations of Fe(II) ions in solution.

The phase composition and crystal size of the forming precipitate (Fig. 2) also depend on pH_0. In particular, in the ranges $3.5 \le pH_0 \le 4$, $7 \le pH \le 8$, and $10 < pH_0 \le 13$ iron(III) hydroxide–oxides of the α, γ, and δ modifications are formed. Their average crystal size is about 10, 4, and 9 nm, respectively. Samples obtained at $4 < pH_0 < 7$ are two-phase (α- + γ-FeOOH), and, as pH_0 increases, the weight fraction of the γ-FeOOH phase in the precipitates changes in parallel. The phase composition of samples at pH_0 ~9 is not constant: in this pH region, various combinations of iron(III) hydroxide-oxides of α, γ and δ modifications and Fe_3O_4 phases can form.

In the second series of experiments, we varied the temperature and pH_0 of the reaction medium, air space velocity V_a, and total concentration $c^0_{Fe(II)}$. The influence of these parameters on the oxidation rate constant and also on the phase composition and crystal size of the precipitate formed in the system $FeSO_4$–H_2O–H^+/OH^-–O_2 is illustrated by the table. It follows from the table (experiment nos. 1–8) that, at the other parameters fixed, k changes in parallel with temperature, with the relative change of the mean oxi-

dation rate η [$\eta = k(T_2)/k(T_1)$, $T_2 > T_1$] decreasing monotonically with an increase in pH_0 3.8 to 7.5.

The temperature dependence of k is apparently responsible for the deviation of the sequences of phase formation in the $FeSO_4$ solution in the range $3.8 < pH_0 < 5.5$ from that found in [4, 5], according to which at a fixed oxidation rate the α-FeOOH phase is formed at higher temperatures than γ-FeOOH. This dependence is broken in run nos. 1–3 (table), which is most likely due to a change in the rate constant of the oxidation of the $FeSO_4$ solution. As pH_0 is increased further, η decreases with temperature growth, and the phase formation sequence takes its usual form: γ- → α-FeOOH → Fe_3O_4 [4, 5], which is illustrated by run nos. 6–8 (table).

An increase in $c^0_{Fe(II)}$ in $FeSO_4$ solutions ($pH_0 < 5.5$) does not exert a significant influence on the average rate of Fe(II) oxidation, but results in an increase in the mean crystal size and in the weight fraction of the high-temperature phase in binary mixtures (table, run nos. 12 and 13).

Vice versa, in the range $5.5 < pH_0 < 8.5$ corresponding to partial precipitation of Fe(II) ions from the solution at $c^0_{Fe(II)} > 0.3$ M, k sharply decreases with increasing $Fe(OH)_2$ content in suspension (table, run nos. 14–17). This is due to a change in the flow characteristics of the suspensions during oxidation. According to [12, 13], in this pH_0 range the phase known in the literature as "green rust II" forms as an intermediate compound. It consists of crystals with a pronounced platelike habit, which results in a sharp increase in the viscosity of suspensions. As a consequence, on the one hand, the solubility and diffusion coefficient of oxygen in the reaction medium decrease, and, on the other, the specific surface area of the gas phase decreases because of the coalescence of air bubbles [14]; this results in decreased oxidation rate constant, increased mean crystal size, and decreased temperature at which the α-FeOOH phase is formed.

Thus, it follows from the table that the phase composition and crystal size of products formed in the system $FeSO_4$–H_2O–H^+/OH^-–O_2 largely depend on the rate of oxidation of the $FeSO_4$ solution and(or) $Fe(OH)_2$ suspension, and the rate constant k, in turn, depends on temperature and pH_0 of the reaction medium, total concentration $c^0_{Fe(II)}$, and air space velocity. In this case, in the entire examined range of variation of the synthesis parameters, the influence of the oxidation rate on the phase composition and particle size of iron(III) oxides is opposite to the influence of temperature. The observed dependence of the phase composition and particle size of the precipitate forming in the system $FeSO_4$–H_2O–H^+/OH^-–O_2 on the oxidation conditions agrees, on the whole, with the published data for similar systems [2, 5, 6, 11]. This suggests that the crystal growth during oxidation of aqueous solutions of iron(II) salts and(or) $Fe(OH)_2$ suspen-

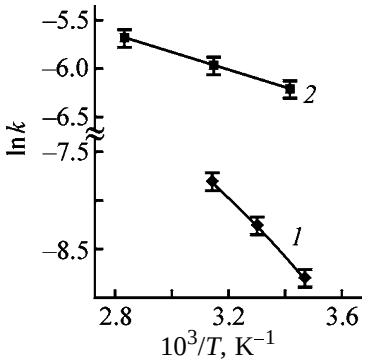

Fig. 3. Temperature dependence of $\ln k$. $c^0_{Fe(II)}$ = 0.25 M. pH_0: (*1*) 3.8 and (*2*) 7.5. Air space velocity, $dm^3\ dm^{-3}\ h^{-1}$: (*1*) 220 and (*2*) 440.

sions, especially at low temperatures, proceeds under conditions of high oversaturation. It results in decreased mean crystal size, increased crystal defectiveness, and formation of phases with disordered crystal structure, e.g., of δ-FeOOH (Fig. 2).

Note that the temperature dependences of the oxidation rate constant, at equal other parameters (table, run nos. 1–3 and 6–8), are satisfactorily linearized in the coordinates $\ln k - 1/T$ (Fig. 3). This points to the activation nature of formation of Fe(III) oxides, accompanied by elementary reactions of the oxidation of iron(II) hydroxoaqua complexes in solution, subsequent hydrolysis of iron(III) hydroxoaqua complexes, and their passing from solution to the condensed state (incorporation of the complexes in the lattice of the forming phases). Figure 3 shows that the apparent activation energy E_a decreases from 25 ± 2 to 7.5 ± 0.7 kJ mol^{-1} as pH_0 increases from 3.8 to 7.5. As pH corresponding to complete hydrolysis of Fe(III) ions in aqueous solutions (~2.4 [1, 2]) is much lower than pH_0 in our experiments, we can assume that the oxidation of iron(II) hydroxoaqua complexes is the limiting stage. In this case, the revealed dependences of k (Fig. 2) and E_a (Fig. 3) on pH_0 can be interpreted from the standpoint of changing degrees of hydrolysis (n values) and relative fractions of various iron(II) hydroxoaqua complexes of the composition $[Fe(OH)_n]^{2-n}_{aq}$ ($0 \le n \le 3$) in solution.

In fact, as shown in [15], Fe(II) ions in aqueous solutions are present as hydroxoaqua complexes with n 0 ($1.5 < pH < 9$), 1 ($4.5 < pH < 12$; the maximum of their weight fraction is reached at pH ~7), 2 ($6.5 < pH < 9.5$; the maximum at pH ~9), and 3 ($pH > 8$). Therefore, at pH_0 3.8, only iron(II) aqua complexes with $n = 0$ are oxidized, and at pH_0 7.5 there are three types of hydroxoaqua complexes with n 0, 1, and 2, with $[Fe(OH)]^+_{aq}$ ($n = 1$) being the major species. Quantum-chemical calculations performed in [16] showed that, as n increases, the energy of the lowest unoccupied $7a_{1g}$-like orbital of iron(II) hydroxoaqua complexes monotonically decreases, and the band gap ΔE_g becomes narrower. Consequently, the reactivity of iron(II) hydroxoaqua complexes increases, which is probably responsible for a decrease in the apparent activation energy of the oxidation.

CONCLUSIONS

(1) The dependences of the oxidation rate constant k and of the phase composition and crystal size of the precipitate formed in the system $FeSO_4$–H_2O–H^+/OH^-–O_2 on the thermodynamic [temperature, pH, total concentration $c^0_{Fe(II)}$] and kinetic (air space velocity) parameters were found for the steady-state oxidation mode (pH_0 = const). The ranges of parameters corresponding to the formation of the Fe_3O_4 and α-, γ-, and δ-FeOOH phases were revealed.

(2) In the range $3.5 < pH_0 \le 7.5$, all other conditions being equal, k changes in parallel with pH_0, whereas the apparent activation energy E_a changes in the opposite direction.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Formation in the System FeOOH–$Zn(OH)_2$–H_2O under Hydrothermal Conditions

D. G. Kleshchev, A. V. Tolchev, and V. Yu. Pervushin

South-Ural State University, Chelyabinsk, Russia

Received March 18, 2003

Abstract—Sequence of chemical transformations occurring in the system FeOOH–$Zn(OH)_2$–H_2O in the course of heat treatment at 125–200°C was studied by X-ray phase analysis, electron microscopy, and chemical analysis.

Finely dispersed zinc ferrite (average crystal size from several tens to hundreds of nanometers) with a spinel structure is a promising anticorrosive pigment [1, 2] and a catalyst of chemical reactions of ammonia oxidation, CO_2 and H_2O decomposition, methane synthesis, etc. [3, 4]. Conventional processes for synthesizing ferrites are based on solid-phase reactions of iron oxides, hydroxides, carbonates, and(or) other salts with those of the corresponding metal [4–7], which occur actively in air at a high (above 700°C) temperature. Activation of the mass transfer by calcination of a charge results in agglomeration of particles, occurring in parallel with a chemical reaction and causing polydispersity of the ferrites. Furthermore, ferrites with a spinel-type structure obtained by a ceramic technology can dissolve a significant amount of Fe_2O_3 [5], which results in the formation of a heterogeneous product with irreproducible physicochemical properties.

According to [4, 8], metal(II) ferrites can be obtained by joint hydrolysis of M(II) and Fe(III) ions in aqueous solutions. Chemical transformations of nonequilibrium oxides and hydroxides of *p* and 3*d* metals in solutions are accompanied by active mass exchange between the solid and liquid phases; therefore, we can expect that $ZnFe_2O_4$ will be formed by heat treatment of a mixture of $Zn(OH)_2$ and FeOOH suspensions, in particular, under hydrothermal conditions [9, 10].

The goal of this work was to study regular trends in the phase formation in the system FeOOH–$Zn(OH)_2$–H_2O and to reveal factors affecting the phase composition and crystal size of the resulting product.

EXPERIMENTAL

The starting reagents were aqueous solutions of $FeSO_4$ (chemically pure grade), $ZnSO_4$ (chemically pure grade), and NaOH [GOST (State Standard) 2263–79] of concentrations 1, 6, 2.1, and 6.5 M, respectively. The solutions were preliminarily filtered under pressure to remove mechanical impurities; in addition, the $FeSO_4$ solution was preliminarily reduced with iron powder.

Single-phase (according to X-ray phase analysis and electron microscopy) iron(III) hydroxide-oxides of α (acicular crystals, average size about 0.5 μm, form factor f = 4) and δ (ellipsoidal crystals, average size about 0.1 μm, form factor f = 2) modifications were obtained according to [9] by oxidation of 1 M $FeSO_4$ aqueous solutions (pH 4.5) or $Fe(OH)_2$ suspensions (pH 9.5) with atmospheric oxygen at 25°C. A calculated amount of $ZnSO_4$ solution was added with stirring to FeOOH suspensions at room temperature, then NaOH solution was added, and the reaction mixture was subjected to hydrothermal treatment in autoclaves equipped with stirrers. In laboratory experiments, the hydrothermal treatment was carried out in 0.07 dm^3 autoclaves, whereas enlarged laboratory samples were prepared in 3 dm^3 autoclaves. After the hydrothermal treatment, samples of the resulting product were separated by filtration under pressure from the mother solution, washed to remove water-soluble salts, dried to constant weight at 110°C, and crushed.

The following parameters were varied in the experiments: FeOOH : $Zn(OH)_2$ molar ratio in the initial suspensions, from 1.6 : 1 to 2.4 : 1; pH of suspensions, from 9.0 to 12.0; and temperature T and dura-

tion τ of hydrothermal treatment, from 125 to 200°C and from 0.5 to 4 h, respectively.

The phase composiiton and crystal size of samples were evaluated by X-ray phase analysis (DRON-3 X-ray diffractometer; filtered FeK_α radiation) and by transmission electron microscopy (UEMV-100K electron microscope). The chemical compositions of solutions and also of intermediate and final products of the synthesis were studied by volumetric chemical analysis. Weight fractions of phases contained in two- and three-phase samples were determined qualitatively from the ratios of integral intensities β_i of nonoverlapping diffraction peaks. The unit cell parameter a of zinc ferrite was determined from reflections with Miller indices (800) and (733) using annealed polycrystalline MgO as an independent reference. The average crystal size d of intermediate and final products was calculated by Selyakov–Scherrer's formula [11] from physical broadening of the diffraction peaks $\Delta 2\theta$. The curve of size distribution of $ZnFe_2O_4$ crystals was plotted on the basis of electron-microscopic data. For this purpose, the average linear size of no less than 200 nonoverlapping crystals was measured in micrographs of the samples. The pigment parameters of samples were determined as described in [12].

The X-ray patterns of samples of the initial suspensions contain only one group of diffraction maxima, which should be assigned to the corresponding modification of iron(III) hydroxide–oxide [13]. Therefore, zinc hydroxide formed by base hydrolysis is in the amorphous state in suspension.

Depending on the parameters of hydrothermal treatment, the X-ray patterns of all the samples after the treatment contain from one to three different sets of reflections, which can be assigned to $ZnFe_2O_4$, α-Fe_2O_3, and ZnO phases [13]. We point out that the formation of iron and zinc oxides upon the hydrothermal treatment agrees with our previous data on the chemical transformations of FeOOH and $Zn(OH)_2$ in solutions [14, 15].

It follows from the experimental data systematized in the table that the kinetics of $ZnFeO_4$ formation depends on three main parameters: heat treatment

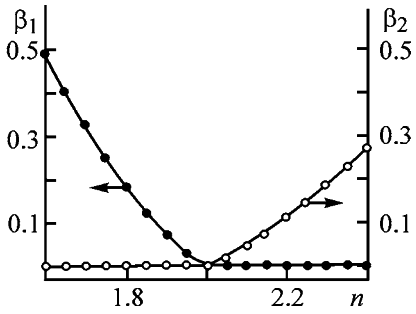

Fig. 1. Ratios of the integral intensities of hematite (012) and zinc ferrite (220) reflections (β_1), and also of zincite (100) and zinc ferrite (220) reflections (β_2) as functions of the molar ratio α-FeOOH/$Zn(OH)_2$ n in the suspension. Hydrothermal treatment conditions: pH 10, T = 200°C, τ = 4 h; the same for Fig. 2.

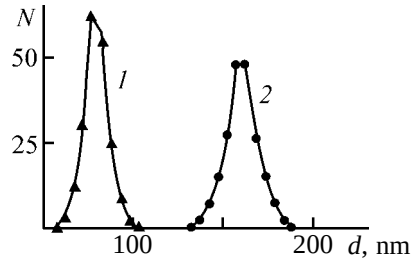

Fig. 2. Size distribution curves for single-phase samples of $ZnFe_2O_4$ synthesized from (1) δ- and (2) α-FeOOH. (N) Number of crystals with size within a $d \pm \Delta d$ range; (d) average size of this fraction of crystals; Δd = 2.5 nm.

temperature, pH of suspension, and phase composition of FeOOH, whereas the phase composition of the samples depends also on the molar ratio FeOOH and $Zn(OH)_2$ in the initial suspension (Fig. 1). In particular, at a fixed phase composition of FeOOH, the rate of $ZnFe_2O_4$ formation monotonically increases with temperature and pH of the suspension, and, when α-FeOOH is used, with the other parameters being the same, the lower temperature boundary of the $ZnFe_2O_4$ formation increases approximately by 25°C as compared to δ-FeOOH. This may be due to the fact that transformations of α-FeOOH, compared to δ-FeOOH, yield larger crystals of α-Fe_2O_3 with a lower reactivity (compared to small crystals) [10].

An increase in the rate of the $ZnFe_2O_4$ formation with increasing pH agrees with the data of [9] that an alkaline medium initiates chemical transformations of nonequilibrium compounds of p and 3d metals. At the same time, when suspensions with pH > 10 are subjected to a hydrothermal treatment, a part of Zn(II) ions remains in solution because of amphoteric nature of zinc compounds [16]. The concentration of Zn(II) monotonically increases with increasing pH, reaching 5–7 g dm^{-3} (in terms of ZnO) at pH 12. This can explain the presence of an α-Fe_2O_3 impurity in $ZnFe_2O_4$ samples prepared by hydrothermal treatment of suspensions with such pH, even in the case of stoichiometric ratio of the components (see table).

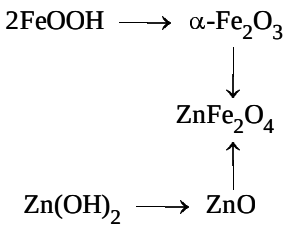
To determine the homogeneity region of the forming $ZnFe_2O_4$, we subjected α-FeOOH and $Zn(OH)_2$ suspensions with pH ~ 9 and various molar ratios n to a hydrothermal treatment at 200°C for 4 h. Figure 1 shows that almost single-phase $ZnFe_2O_4$ samples are formed at $n \approx 2$ (some of them contain small amounts of α-Fe_2O_3 or ZnO impurity phase, which results from inaccurate dosage of the components). Samples obtained at $n < 2$ and $n > 2$ are two-phase: $ZnFe_2O_4$ + ZnO and $ZnFe_2O_4$ + α-Fe_2O_3, respectively. In this case, as n deviates from the stoichiometric value, the weight fraction of ZnO or α-Fe_2O_3 phase in the samples increases.

Therefore, the composition of zinc ferrite formed by hydrothermal treatment of aqueous solutions is close to the stoichiometric composition $ZnFe_2O_4$. This conclusion is confirmed by X-ray phase and chemical analyses. These data show that, within the limits of experimental error, single-phase samples of $ZnFe_2O_4$ have the same unit cell parameter a (a = 0.8441 ± 0.0002 nm) and chemical composition (in terms of oxides they contain 33.1 ± 0.5 wt % ZnO and 64.9 ± 0.5 wt % Fe_2O_3). Using the results of the chemical analysis, we have calculated the molar ratio η of zinc and iron(III) oxides in single-phase samples of $ZnFe_2O_4$ (η = 1 : 1), which corresponds to the stoichiometric composition of ferrites.

According to the electron microscopy, $ZnFe_2O_4$ crystals have an isometric shape with clear signs of faces, and their average size d_{av} depends on the above-listed parameters and, to the greatest extent, on the FeOOH crystal size. In particular, for equal conditions of heat treatment (hydrothermal treatment temperature and pH of suspension), d_{av} of $ZnFe_2O_4$ samples obtained from α-FeOOH is approximately twice as high as that of samples synthesized from δ-FeOOH. The increase in the temperature and pH of the suspension results in the growth of the average size of $ZnFe_2O_4$ crystals. Single-phase $ZnFe_2O_4$ samples, as well as other pigments obtained by the hydrothermal procedure [10, 14], are monodisperse, i.e., they are characterized by a narrow size distribution of crystals (Fig. 2), which predetermines their high quality. We found that the main pigmental characteristics of $ZnFe_2O_4$ samples basically depend on d_{av}, and their values monotonically decrease as d_{av} increases. In particular, as d_{av} increases from 75 ($ZnFe_2O_4$ sam-

ple synthesized from δ-FeOOH) to 160 nm (sample obtained from α-FeOOH), the covering power changes from 15 to 9 g m^{-2}, the oil-absorption power, from 35 to 20 g/100 g pigment, and the content of volatile and water-soluble substances, from 0.7 to 0.4 and from 0.5 to 0.2 wt %, respectively.

The table shows that, at relatively low temperatures of hydrothermal treatment, α-Fe_2O_3 and ZnO phases are formed in an earlier stage of the treatment as compared to $ZnFe_2O_4$. Therefore, the formation of the equilibrium phase (zinc ferrite) in the system $FeOOH–Zn(OH)_2–H_2O$ is preceded by the stage of the formation of the α-Fe_2O_3 and ZnO phases, which are metastable in this case, and the whole combination of processes occurring in the system $FeOOH–Zn(OH)_2–H_2O$ can be presented by the scheme



Let us consider possible causes of this phenomenon. According to [9, 10, 14, 15], the transformations of α(δ)-FeOOH and $Zn(OH)_2$ in solutions proceed by the dissolution–precipitation mechanism. This mechanism includes the following elementary stages: (a) dissolution of crystals of a nonequilibrium phase with the formation of hydroxoaqua complexes of the metal ions, which are in equilibrium under specified thermodynamic conditions [17]; (b) reaction between hydroxoaqua complexes yielding nuclei of a new phase and polynuclear crystal-forming complexes, which serve as "building material" for the growing crystals; (c) incorporation of the hydroxoaqua complexes in the surface layer of the nuclei, which is complicated by dehydration, olation, oxolation, and(or) dehydroxylation [9, 15].

The experimental dependences of the formation rate and average size of $ZnFe_2O_4$ crystals on pH of suspension, and also the absence of eligibility in the morphology and size of crystals of the nonequilibrium (α-Fe_2O_3 and ZnO) and forming ($ZnFe_2O_4$) phases (in particular, ZnO crystals are platelike and $ZnFe_2O_4$ crystals are isometric) suggest that the chemical reaction of α-Fe_2O_3 with ZnO in solutions also proceeds by the dissolution–precipitation mechanism.

The dissolution–precipitation mechanism involves a directed mass transfer of a crystal-forming substance from the crystals of a dissolving phase to the nuclei of a forming phase. The nucleation probability and the mass transfer intensity are proportional to the equilibrium concentration c_{CFC} of crystal-forming complexes in solution. Under conditions of low solubility of α(δ)-FeOOH and $Zn(OH)_2$ at relatively low temperatures of the heat treatment, the nuclei of a new phase are formed by the heterogeneous mechanism [18], and the mass transfer proceeds stochastically [19] with equal probabilities of the detachment and incorporation of crystal-forming complexes. In this case, the formation of one or another phase is determined by the probability of formation of the corresponding nuclei.

Oxides, hydroxide–oxides, and hydroxides of *p* and 3*d* metals have similar structural motives. In particular, the crystal lattices of α(γ, δ)-FeOOH and α-Fe_2O_3 phases can be reproduced by oriented incorporation of the same binuclear crystal-forming complex (CFC-1) of the composition $Fe_2(OH)_6 \cdot 4H_2O$ [9, 15]. Therefore, it is most likely that nuclei of α-Fe_2O_3 and ZnO are formed by reactions between hydroxoaqua complexes and(or) crystal-forming complexes of the corresponding metals. The mechanism of the formation of nuclei of $M(II)Fe_2O_4$ phases with a spinel structure, e.g., magnetite, is more complicated. For example, they can be formed by reaction of one crystal-forming complex CFC-1 with two $MFe(OH)_5 \cdot 6H_2O$ complexes (CFC-2) [9]. As a consequence, the probability of the formation of $ZnFe_2O_4$ nuclei at low concentrations c_{CFC} is much less than that of the nuclei of α-Fe_2O_3 and ZnO phases. Therefore, chemical transformations of nonequilibrium FeOOH and $Zn(OH)_2$ in the initial stage of heat treatment proceed toward formation of oxides of the corresponding metals.

The following processes seem to proceed subsequently in systems containing α-Fe_2O_3 and MO. The α-Fe_2O_3 and ZnO phases, which have nonzero solubility, are in equilibrium with the corresponding hydroxoaqua complexes and(or) crystal-forming complexes in solution. As a result of random reactions of the complexes, the nuclei of the equilibrium phase $ZnFe_2O_4$ are formed in this system. Iron(III) and zinc(II) crystal-forming complexes start to get incorporated into the formed nuclei from solution, which results in a decrease in their concentrations to the level lower than c^0_{CFC} and, as a consequence, in the dissolution of α-Fe_2O_3 and ZnO crystals.

The value of c^0_{CFC} changes in parallel with the increase in temperature or pH of the suspension. As c_{CFC} increases, on the one hand, the duration of the latent period of the nucleation stage decreases, and, on the other hand, the intensity of the mass transfer

in the disperse system increases. These trends are manifested as an increase in the rate of $ZnFe_2O_4$ formation and in the average size of its crystals, which agrees with the experimental data.

CONCLUSIONS

(1) Formation of the equilibrium phase ($ZnFe_2O_4$) upon hydrothermal treatment of the system FeOOH–$Zn(OH)_2$–H_2O is preceded by chemical transformations of iron(III) hydroxide–oxides and zinc hydroxide to the corresponding oxides.

(2) The main factors (temperature, pH of suspension, and phase composition of FeOOH) affecting the rate of the $ZnFe_2O_4$ formation and the average size of its crystals have been revealed.

Abstract—The effect of bismuth(III) nitrilotriacetate $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4, CN_3H_6) and mixed-ligand bismuth(III) complex with ethylenediaminetetraacetate and thiourea $KBi(Edta) \cdot 2tu$ on an association of sea bacteria, seaweed (*Ulva fenestrata*), and biofouling was studied. The minimal concentrations of some of these complexes suppressing bacterial growth were determined.

Metal complexonates are widely used in various fields of science and industry, analytical chemistry, and medicine [1, 2]. Complexonates of Group I and II metals and transition metals were studied most extensively. Data on nontransition metal complexonates are scarce. Previously we prepared anionic bismuth(III) complexes with anions of nitrilotriacetic acid (H_3Nta) and alkali metal, ammonium, and guanidinium cations, $M_3Bi(Nta)_2 \cdot nH_2O$ [3], and mixed-ligand Bi(III) complex with anions of ethylenediaminetetraacetic acid (H_4Edta) and thiourea, $KBi(Edta) \cdot 2tu$ [4]. The crystal structures of $(NH_4)_3Bi(Nta)_2$ [5, 6] and $KBi(Edta) \cdot 2tu$ [7] were determined.

The biological properties of many complexones are understood well. Their molecules do not degrade or transform in a biological medium. These compounds form stable complexes with many metals. They have long been used in toxicology as antidotes [1, 8]. Although some bismuth compounds (nitrates, citrate complexes, basic bismuth gallate, etc.) are used in medicine [2, 9, 10], the biological properties of bismuth(III) are not clearly understood. At the same time, bismuth(III) as well as antimony(III) are thiol poisons, since they selectively react with thiol (–SH) groups of biological molecules, mainly of enzymes, other proteins, and some amino acids [8, 11].

Bismuth(III) chloride and nitrate complexes exhibit bactericidal properties with respect to *Helicobacter pylori* bacteria [12, 13], and $Bi(Nta) \cdot 2H_2O$ and Bi(HEdta), with respect to *Escherichia coli* [14]. No data on bioligical properties of $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, Cs, NH_4, and CN_3H_6) and $KBi(Edta) \cdot 2tu$ are reported.

In this work we studied the biological effect of the above bismuth(III) complexes on an association of sea bacteria (sea bacteriocenosis), seaweed (*Ulva fenestrata*), and macrobiofouling.

The bismuth complexes $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4, and CN_3H_6) and $KBi(Edta) \cdot 2tu$ were prepared by the procedure in [3, 4]. All these complexes are readily soluble water at room temperature.

The biocidal activity of the bismuth complexes in the solid state and in aqueous solution with respect to sea bacteria was estimated by a conventional procedure based on diffusion of a complex in agar containing the test object [15]. The experiments were performed as follows. Fish-peptone agar was poured in a Petri dish. A bacterial suspension isolated form seawater[1] was placed in solidified agar plates. Hollow glass cylinders (0.8 cm in diameter and 1 cm high) were placed upright on the pretreated surface. Either 10^{-3} mol of solid compounds to be studied or 10^{-3}–10^{-4} M solutions of these compounds in distilled water were introduced into the cylinders. The Petri dishes with bacterial inoculation were incubated at 28°C for 48 h. The compound toxicity was estimated from the diameter of the zone of suppressed bacterial growth (ZSBG, cm), around the place of the compound introduction. The stimulating influence of a substance was manifested in more intense bacterial

growth around the cylinder with examined compound as compared to the remaining surface of the agar plate.

The effect of the bismuth(III) complexes on *U. fenestrata* seaweed can be estimated from the oxygen content in the system, which depends on the main metabolic processes, photosynthesis and respiration. The experimental procedure was described in [16]. Thalluses of freshly collected seaweed (5 g) were placed in 1-l aquariums filled with seawater to the top. A 0.01-g portion of a test compound (as determined in preliminary experiments) was added. The reference aquarium was free of the Bi(III) complexes. Some of the aquariums with seaweed were kept at 22–24°C for 24 h under a daylight (photosynthesis), and the others were kept in the dark (respiration). After that, the oxygen content in the seawater was determined by the Winkler procedure [17].

The biofouling was studied in June–October, 2002. To prepare antifouling coatings, the complexes were crushed to fine powders and introduced into a methyl methacrylate solution in amount of up to 50 wt % with respect to dry methyl methacrylate. A suspension of the Bi(III) complexes in a methyl methacrylate solution was applied to one side of Plexiglas plates and dried until it ceased to be sticky. The coated and noncoated plates were fixed in benches which were immersed in sea.[2] The number of each species on the plates was determined visually at intervals of two weeks.

After the completion of the experiment, the biological material was scraped off with a spatula made from an inert material, dried at room temperaure to constant weight, and weighed. The total biomass was determined with respect to the reference sample.

The biological properties of bismuth(III) complexes with Nta^{3-} and $Edta^{4-}$ are presented in Tables 1–3.

$Bi(Nta)_2 \cdot 2H_2O$, $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4, CN_3H_6), and $KBi(Edta) \cdot 2tu$ are toxic with respect to associates of sea bacteria (Table 1). The precursors of these complexes, $Bi(OH)_3$, H_3Nta, and H_4Edta, have no effect on vital functions of the bacteria. The bactericidal properties of $M_3Bi(Nta)_2 \cdot nH_2O$ differ from those of $KBi(Edta) \cdot 2tu$: ZSBG ranges from 0.5 to 2.5 cm. The most toxic among the examined compounds is $Na_3Bi(Nta)_2 \cdot 4H_2O$.

$(NH_4)_3Bi(Nta)_2$, unlike the other complexes, stimulate bacterial growth: bacterial biomass is accumulated around a cylinder with this complex.

It is difficult to explain why the biological effect or $M_3Bi(Nta)_2 \cdot nH_2O$ is opposite to that of $(NH_4)_3 \cdot Bi(Nta)_2$. This may be due to the structural difference of these complexes {only the $(NH_4)_3Bi(Nta)_2$ structure is known [5, 6]} or to different outer-sphere cations.

[2] Fedorov Bay, Peter the Great Gulf, 2-m depth.

The coordination polyhedron of bismuth(III) in the structure of $(NH_4)_3Bi(Nta)_2$ is a distorted cube (coordination number CN = 8). The Bi–O and Bi–N distances are 2.42×6 and 2.60×2 Å, respectively. Mononuclear complex anions $[Bi(Nta)_2]^{3-}$ and ammonium cations are bonded by hydrogen bonds to form a framework structure.

Among the examined complexes, $KBi(Edta) \cdot 2tu$ is the least toxic with respect to sea bacteriocenosis (Table 1). The coordination number of Bi(III) in the crystal structure of this complex is also 8 [7]. The complex anions $[Bi(Edta)(tu)_2]^-$ are bonded via K^+ cations and with the N–H···O hydrogen bonds into a three-dimensional framework. The bismuth atom forms four Bi–O bonds (2.36–2.48 Å) and two Bi–N bonds (2.46, 2.48 Å) with the Edta anions and two Bi–S bonds (3.09 and 3.22 Å) with the thiourea ligands.

The minimal $M_3Bi(Nta)_2 \cdot nH_2O$ concentration suppressing bacterial growth (MCSBG) in aqueous solutions is 10^{-2} M. In the presence of solutions of these complexes, the diameter of ZSBG varies from 1.4 to 1.6 cm. However, colonies of some bacteria grew even in the ZSBG, which indicated that these bacteria were stable to the Bi(III) complexes. A solution of $KBi(Edta) \cdot 2tu$ is the most toxic; the diameter of ZSBG is 2.5 cm; the MCSBG is 10^{-3} M.

We studied the effect of the bismuth complexes on strains of *p. Psedomonas sp*., *Bacillus sp*., and *Cytophaga sp*. A change in the pigmentation of their colonies, loss of mobility, and induction of sporulation of spore-forming bacteria in the region of substance diffusion indicate morphological and physiological transformations of bacterial cells.

The oxygen content determined in seawater of aquariums with *U. fenestrata* seaweed in the presence and in the absence of the Bi(III) complexes is presented in Table 2.

Some of the examined Bi(III) complexes, as in the case of sea bacteria, inhibit vital functions of seaweed, and the others stimulate their growth.

Analysis of the oxygen content in the aquarium seawater shows that $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, NH_4, CN_3H_6) slightly stimulate the photosynthesis. The activity of these complexes as compared to the blank experiment increases in the following order: $NH_4^+ < Na^+ < CN_3H_6$. The complexes $M_3Bi(Nta)_2$ (M = K, Rb, Cs) exhibit algicidal properties. They inhibit photosynthesis, thus decreasing the oxygen content in the aquarium seawater as compared to the dark experiment. The inhibiting effect decreases in the order $K^+ > Rb^+ > Cs^+$. The complex $KBi(Edta) \cdot 2tu$ also inhibits photosynthesis.

The complexes also affect seaweed respiration. $(CN_3H_6)_3Bi(Nta)_2 \cdot 3H_2O$ and $KBi(Edta) \cdot 2tu$ stimulate respiration by a factor of 1/2 as compared to the blank experiment. As a result, the oxygen content in the seawater decreases (Table 2). The other complexes $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4) almost completely suppress energy metabolism of the plants: in the presence of these complexes, the oxygen content in the seawater strongly increases as compared to that in the blank experiment.

The biocidal properties of $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4, CN_3H_6), and $KBi(Edta) \cdot 2tu$ with respect to macrobiofouling are presented in Table 3. The study of the dynamics of macrobiofouling on the uncoated plates showed that three types of animals are present in the biomass: *Balanus improvisus*, *Hydrodes ezoensis*, and *Conopeum seurati*. No seaweeds were found in the biofouling.

Analysis of biofouling of plates coated with the Bi(III) complexes revealed the compounds with biocidal properties. All the examined complexes are moderatly toxic or exhibit repellent properties with respect to *Conopeum seurati* cortical pearlwort.

The average biomass grown on the reference plates is 0.08 g cm^{-2}. The biomass grown on the plates correlates with the toxicity of the examined complexes with respect to macrophytes. The most toxic are $M_3Bi(Nta)_2$ complexes (M = Na, K, and Rb) (Table 3).

The ratios of species growing on the plate surface differ. Probably the toxic and repellent properties of the complexes with respect to macrophytes are selective.

CONCLUSIONS

(1) The bismuth(III) complexes exhibit biological activity with respect to sea bacteria and green weeds. The sensitivity of these organisms to the complexes is different.

(2) The biological effect of $(NH_4)_3Bi(Nta)_2$ on sea bacteriocenosis is similar to that on *U. Fenestrata* seaweed. This complex stimulates both bacterial growth and photosynthesis. On the contrary, $KBi(Edta) \cdot 2tu$ inhibits these processes. The biological effect of the other complexes depends on their composition and the biological species.

(3) $Bi(Nta)_2 \cdot 2H_2O$, $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Cs, CN_3H_6), and $KBi(Edta) \cdot 2tu$ inhibit growth of

sea bacteria; $M_3Bi(Nta)_2 \cdot nH_2O$ (M = K, Rb, Cs) and KBi(Edta)·2tu inhibit photosynthesis; and $M_3Bi \cdot (Nta)_2 \cdot nH_2O$ (M = Na, K, Rb, Cs, NH_4) inhibit respiration.

(4) $(NH_3)_3Bi(Nta)_2$ stimulates growth of sea bacteria; $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, NH_4, CN_3H_6) stimulate photosynthesis; and $(CN_3H_6)_3Bi(Nta)_2 \cdot 3H_2O$ and KBi(Edta)·2tu stimulate respiration.

(5) The Bi(III) complexes are moderately toxic or exhibit repellent properties with respect to organisms growing on Plexiglas plates. The antifouling properties of $M_3Bi(Nta)_2 \cdot nH_2O$ (M = Na, K, Rb) are the most pronounced.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of High-Purity Silicon Tetrafluoride by Thermal Dissociation of Na_2SiF_6

A. D. Bulanov, D. A. Pryakhin, and V. V. Balabanov

Abstract—The possibility of preparing high-purity silicon tetrafluoride by the thermal dissociation of pure grade Na_2SiF_6 was studied. The impurity composition of the product was studied by IR and atomic emission spectroscopy and by mass spectrometry.

High-purity silicon tetrafluoride SiF_4 is used for preparing fluorine-doped amorphous hydrogenated silicon [1] and ion implantation of silicon and fluorine into gallium arsenide [2]. Because SiF_4 has no intrinsic absorption bands, it is also used as doping additive to decrease the refractive index of quartz glass, which is very important in manufacture of quartz fibers [3]. Also, silicon tetrafluoride is a convenient compound for centrifugal separation of silicon isotopes [4].

The methods for preparing SiF_4 can be subdivided into four groups.

(1) Reaction of elemental silicon with fluorinating agents F^-, SF_6, UF_6, NF_3 [5–10], which is a complex procedure requiring sophisticated equipment.

(2) Fluorination of silicon dioxide [11–15]. This, however, involves problems with hydrolysis of SiF_4 by the reaction by-product, H_2O.

(3) Fluorination of silicon tetrachloride [16–22]. With $SiCl_4$ as the initial compound, it is necessary to treat SiF_4 to remove impurities of mixed fluorochlorosilanes.

(4) Preparation of SiF_4 from hexafluorosilicic acid H_2SiF_6 and hexafluorosilicates of alkali (Li, K, Na) and alkaline-earth (Ba, Ca) metals [23, 24]. It is possible to decompose H_2SiF_6 [25–27] or metal hexafluorosilicates [28–30] with concentrated acids (H_2SO_4 or H_3PO_4). However, silicon tetrafluoride obtained by acid treatment has low purity.

Thermal dissociation of metal hexafluorosilicates is the preferential method [31, 32]. The method is economical and environmentally safe. It was found [33] that SiF_4 obtained by this method from Na_2SiF_6 is relatively pure, because solid sodium fluoride sorbs impurities. The content of the impurities in Na_2SiF_6 and SiF_4 obtained from it is presented in the table [34]. The relative intensity of ions in the mass spectrum of SiF_4 is as follows [34]: SiF_3^+ 96.9, $Si_2OF_6^+$ 3.04, and $SO_2F_3^+$ 0.076.

The dissociation pressure of Na_2SiF_6 within 298–968 K has been determined in [35]. A study [36] of the effect exerted by CO_2, SiO_2, ZrO_2, and HfO_2 on the Na_2SiF_6 thermal dissociation showed that addition of SiO_2 considerably decreases the dissociation rate. The thermal dissociation of K_2SiF_6 in the liquid phase (K_2SiF_6–KCl eutectic) is slower than in the solid

phase [37]. The influence of the H_2O partial pressure on the K_2SiF_6 thermal dissociation was studied in [38]. It was found that the SiF_4 being formed reacts with H_2O even at a low partial pressure of water vapor to form various gaseous and X-ray amorphous solid fluorosiloxanes.

EXPERIMENTAL

In this study, SiF_4 was prepared by thermal dissociation of pure grade sodium hexafluorosilicate Na_2SiF_6. In this case, the yield of SiF_4 approaches 100%, whereas in the case of the K_2SiF_6 thermal dissociation it is considerably lower owing to K_3SiF_7 formation [39]. Moreover, NaF formed in this reaction can be used for sorption purification of SiH_4 to remove SiF_4 impurity in the course of preparation of silane from silicon tetrafluoride.

The impurity content in pure grade Na_2SiF_6, as determined by laser mass spectrometry, is presented below:

Impurity element	Content, at. %	Impurity element	Content, at. %
B	1×10^{-1}	Cl	1×10^{-3}
C	3×10^{-2}	S	2×10^{-3}
Mg	4×10^{-3}	Ca	3×10^{-2}
Al	4×10^{-4}	Cr	5×10^{-5}
P	2×10^{-2}	Fe	2×10^{-3}

The content of Sc, Ti, V, Mn, Co, Ni, Cu, Zn, Ga, Ge, As, Se, Br, Rb, Sr, Y, Zr, Nb, Mo, Ru, Rh, Pd, Ag, Cd, In, Sn, Sb, Te, I, Cs, Ba, Hf, Ta, W, Re, Os, Ir, Pt, Au, Hg, Tl, Pb, and Bi impurity ions and lanthanides is below the detection limit of this method (1×10^{-4}–2×10^{-5} at. %).

A setup for the silicon tetrafluoride synthesis is shown schematically in the figure. The synthesis was performed in a stainless steel reactor *1* equipped with a resistance heater *2*. The temperature of the heater was adjusted to within ±0.5°C with an R-133 precision temperature controller and a U-013 power amplifier and measured with a Chromel–Alumel thermocouple *3*. A stainless steel boat *4* charged with about 3-kg portion of Na_2SiF_6 was placed into the reactor. The salt was preliminarily dried at 250°C in a vacuum or in a nitrogen flow. Moisture and gases released during preliminary evacuation of Na_2SiF_6 were condensed in a trap *5* cooled with liquid nitrogen.

The thermal dissociation of the salt was performed at 500–620°C in a vacuum. Since the Na_2SiF_6 thermal dissociation is a reversible reaction and the degree of dissociation is pressure-dependent, the forming SiF_4 was fed continuously into a 4-l metallic cylinder *6* cooled with liquid nitrogen.

The pressure in the reactor and the rate of the SiF_4 flow from the reactor into the receiving cylinder were monitored with vacuum gage *7* and rotameter *8*, respectively. To remove suspended particles, SiF_4 was allowed to pass through a Petryanov cloth filter *9*; *10–17* are stopcocks. The SiF_4 yield in the process approached 100%. Up to 1.5 kg of SiF_4 can be obtained on this installation in one process cycle.

The SiF_4 thus obtained was analyzed for the content of molecular impurities by mass spectrometry and IR spectroscopy [40]. Both methods revealed hexafluorodisiloxane as the major impurity. Its content in SiF_4 amounts to several percents, which agrees with the data of [34]. The mass spectrum contained no lines assignable to the BF_3 impurity. The content of metallic impurities in the silicon tetrafluoride obtained, which were concentrated by distilling off the matrix and then analyzed by atomic emission spectroscopy, is presented below:

Impurity	Content, wt %	Impurity	Content, wt %
Al	1×10^{-8}	Mn	3×10^{-10}
Ni	$<2\times10^{-8}$	Ca	7×10^{-8}
Co	$<7\times10^{-8}$	Pb	$<2\times10^{-8}$
Ag	$<3\times10^{-10}$	Sn	$<2\times10^{-8}$
Cd	$<3\times10^{-8}$	Cu	2×10^{-9}
Fe	7×10^{-7}	Ga	$<4\times10^{-9}$
Cr	3×10^{-8}	Sb	$<1\times10^{-7}$
Mg	1×10^{-7}	In	$<1\times10^{-8}$

To perform further isotopic enrichment and use SiF_4 as a doping additive in manufacture of quartz fibers, it was additionally purified by distillation.

CONCLUSION

High-purity SiF_4 was obtained by thermal dissociation of pure grade Na_2SiF_6. IR spectroscopy and mass

spectrometry revealed hexafluorodisiloxane as the major molecular impurity in SiF_4. According to the data of atomic emission spectroscopy, the SiF_4 prepared contains about 10^{-7} wt % metallic impurities.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Nanolayers of Double Fe(III) and Ni(II) Hydroxide by Ionic Layer Deposition on Quartz and Silicon Surfaces

V. P. Tolstoi and I. V. Samsonova

St. Petersburg State University, St. Petersburg, Russia

Received January 9, 2003

Abstract—Conditions for the synthesis of nanolayers of double Fe(III) and Ni(II) hydroxides by ionic layer deposition on quartz and silicon surfaces were determined. The layers synthesized were studied by X-ray photoelectron spectroscopy, ellipsometry, and UV-Vis and IR Fourier transmission spectroscopy.

It is known that metal hydroxides are effective sorbents and ion exchangers. The method of ionic layer deposition (ILD) opens up new opportunities, as it allows deposition of nanolayers of hydroxides on a surface of an inert support with a preset specific surface area. Conditions for the synthesis of FeOOH by ILD were determined previously [1].

The goal of this work was to study conditions for ILD of nanolayers consisting of hydroxides of two metals. Hydroxides of Fe(III) and Ni(II) were chosen as the objects of the study. We expected that a layer of Fe(III) hydroxide could be obtained by the technique from [1] involving the following successive steps: sorption of Fe^{2+} from a solution of Mohr's salt on the support surface, removal of excess solution by washing with water, oxidation of the sorbed ions with a solution of $H_2O_2(OH^-)$, and removal of excess H_2O_2 solution by washing with water. One such sequence of treatments formed one ILD cycle. Upon multiple repetition of ILD cycles, the thickness of the layer proportionally increased. When synthesizing a layer of double Fe(III) and Ni(II) hydroxide, it is possible to combine oxidation of sorbed Fe(II) ions and sorption of Ni(II) ions and to prepare a layer of the double hydroxide by a minimal number of treatments of the surface with chemicals, using an ammonia solution of an Ni(II) salt. In such solutions, on the one hand, Fe(II) is catalytically oxidized to Fe(III) with oxygen dissolved in water, and, on the other, a layer of Fe(III) hydroxide is formed on the surface and Ni(II) ions are sorbed on this layer [2]. It is also known [3] that the double-charged metal ions sorbed on Fe(III) hydroxide from ammonia solutions are not removed from the surface on washing the sample with water.

EXPERIMENTAL

Melted quartz of KU grade and single-crystalline silicon of the KEF-7.5 grade ([100] orientation), polished to class 14 of surface finish, were used as supports for the synthesis. The quartz supports were washed in acetone and kept at 90–100°C for 10 min in concentrated nitric acid and then washed with water, a KOH solution with pH 9, and again water. The single-crystalline silicon substrates were etched in HF, heated in concentrated HNO_3 for 0.5 h to 90–100°C to form a surface layer of silicon oxide, and

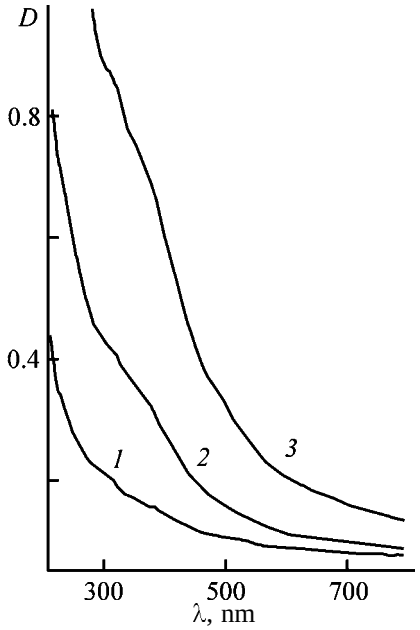

Fig. 1. UV-Vis transmission spectra of nanolayers of Fe(III) and Ni(II) hydroxide synthesized on the surface of melted quartz by (*1*) 10, (*2*) 20, and (*3*) 30 ILD cycles. (*D*) Optical density and (λ) wavelength.

1070-4272/03/7609-1396$25.00

washed with distilled water, a KOH solution with pH 9, and again water.

The reagents for the synthesis were a freshly prepared solution of Mohr's salt $(NH_4)_2[Fe(SO_4)_2]\cdot 6H_2O$ and an ammonia solution of $NiSO_4$ (pH 8.0–8.5) with concentrations of 0.01 M. The ammonia solution was prepared by dissolving a weighed sample of an Ni(II) salt in an 0.1 M solution of $(NH_4)_2SO_4$ with preliminarily added 25% solution of NH_4OH in an amount of 0.15–0.25 ml per 50 ml of the ammonium salt solution [4]. Excess reagents were washed off from the surface with water. The time of treating the supports in reagent solutions and water was 0.5 min.

We used IR Fourier and UV-Vis transmission spectroscopy, X-ray photoelectron spectroscopy, and ellipsometry. The UV-Vis transmission spectra were recorded on a Perkin–Elmer Lambda-9 spectrophotometer at a scan rate of 50 nm min^{-1} and a slit program of 2 nm; the IR Fourier spectra, on a Perkin–Elmer 1760X spectrophotometer (50 scans); and the X-ray photoelectron spectra, on a Perkin–Elmer 5400 spectrometer using MgK_α excitation radiation. The ellipsometric measurements of the thickness of the synthesized layers were carried out on an ellipsometer with a light incidence angle of 45° and λ = 632.8 nm.

As seen from the UV-Vis transmission spectra (Fig. 1), performing 10, 20, and 30 ILD cycles on a quartz plate gives rise to a broad absorption band in the range 200–450 nm with the integral intensity increasing with increasing number of cycles. According to the ellipsometry measurements, one cycle of the treatment of a support results in formation of an approximately 0.7-nm-thick layer on the support surface. According to X-ray photoelectron spectroscopy (Fig. 2), the layer consists of Fe(III), Ni(II), and oxygen atoms, which are characterized by peaks in the spectrum with maxima at 711.9, 855.9, and 531.1 eV, respectively. The positions of the first two peaks allows their assignment to 2*p* electrons of Fe(III) and Ni(II) in the corresponding hydroxides [5]. The concentration ratio Fe(III)/Ni(II) in the layer, determined from the intensities of their peaks, is 1/0.4. Sulfate ions, which could enter into the layer from solutions of the reagents, are absent. The layer also contains H_2O molecules and OH^- groups incorporated into metal hydroxides, which can be identified in the IR Fourier spectrum of the layer (Fig. 3) by the bands of stretching vibrations at 3800–3000 cm^{-1} and of bending vibrations at 1640 and 1560–1392 cm^{-1}, respectively. A broad absorption band in the region of 1000–400 cm^{-1} and a narrow band at 370 cm^{-1} are also seen in the spectrum. According to [6, 7], these spectra can be assigned to amorphous double Fe(III) and Ni(II) hydroxide. In view of all the data obtained in this work, its formula can be presented as $FeNi_{0.4}(OH)_{3.8}\cdot nH_2O$.

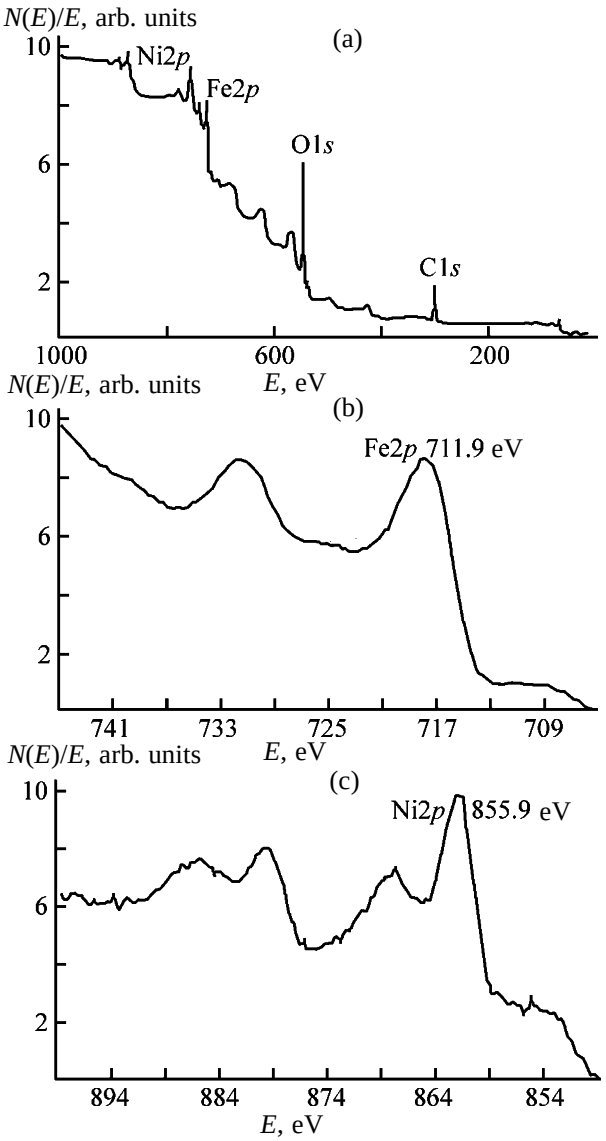

Fig. 2. X-ray photoelectron spectra of a nanolayer of Fe(III) and Ni(II) hydroxide synthesized on the surface of single-crystalline silicon by 20 ILD cycles: [*N*(*E*)/*E*] intensity and (*E*) binding energy. (a) Total spectrum, (b) Fe region, and (c) Ni region.

CONCLUSION

Repeated alternate treatment of a silica surface with a solution of Mohr's salt and an ammonia solution of $NiSO_4$ by the ionic layer deposition technique yields nanolayers of double Fe(III) and Ni(II) hydroxide on

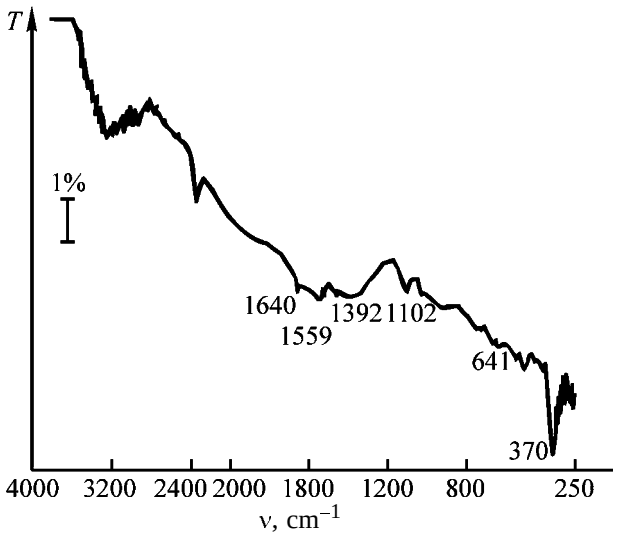

Fig. 3. IR Fourier transmission spectra of a nanolayer of Fe(III) and Ni(II) hydroxide synthesized on the surface of single-crystalline silicon by 20 ILD cycles: (*T*) transmission and (ν) wave number.

the support surface. The concentration ratio Fe/Ni in the layer is 1/0.4, and its thickness can be preset by the number of ionic layer deposition cycles, with one treatment cycle giving an 0.7-nm-thick layer on the surface.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Liquid–Vapor Equilibrium in the Isobutanol–*n*-Butanol–Butyl Butenyl Ether Ternary System, Azeotropy in Butyl Alcohols–Butyl Butenyl Ether–Water Systems, and Separation of Their Components by Distillation

M. N. Rogov, I. I. Sabylin, and A. P. Khvorov

Abstract—Liquid–vapor equilibria and azeotropy in isobutanol–*n*-butanol–butyl butenyl ether ternary system and in isobutanol-butyl butenyl ether and *n*-butanol–butyl butenyl ether binary systems were studied experimentally and calculated, as well as azeotropy in butyl alcohols–butyl butenyl ether–water systems under atmospheric and reduced pressure. Recovery of commercial butyl alcohols by distillation of alcohol–ether fractions was studied.

To decrease losses of commercial products in oxosynthesis of butyl alcohols, recovery of butyl alcohols by distillation of the alcohol–ether fraction should be optimized by mathematical simulation. The simulation requires knowledge of parameters of the liquid–vapor equilibrium and azeotropy in isobutanol–*n*-butanol–butyl butenyl ether ternary system and in binary systems of these compounds.

Oxosynthesis of butyl alcohols yields alcohol–ether fractions as a by-product in amount of 10–15% of the produced butyl alcohols. The content of butyl alcohols in these fractions is 50–70%.

This fraction is used today as a fuel component. Feasibility study shows that recovery of more that 50% of saleable butyl alcohols gives a profit with fast pay-back of investments.

The alcohol–ether fraction contains also saturated C_8 ethers (dibutyl ether, diisobutyl ether, butyl isobutyl ether) and the corresponding C_8 vinyl ethers.

Unsaturated C_8 ethers are formed in the step of C_{12} acetal degradation when butyric aldehydes are hydrogenated to form butyl alcohols. The acetals are present in the raw material to be hydrogenated as by-products of propylene hydroformylation [1].

The liquid–vapor equilibria in butyl alcohol–saturated C_8 ether systems have been extensively studied [2–6]. These processes are simulated well by UNIFAC group procedure [7]. At the same time, no data on the equilibria in butyl alcohol–unsaturated C_8 ether systems are reported. Hence, equilibria in these systems cannot be simulated.

To study the liquid–vapor equilibria in the latter systems, we prepared unsaturated C_8 ether, butyl butenyl ether (BBE).

The synthesis of BBE involves two steps. The first is preparation of C_{12} acetal, dibutyl butyral, from *n*-butyric aldehyde and *n*-butanol purified by distillation.

C_{12} acetal was distilled under reduced pressure and thermolyzed on calcium phosphate catalyst at 200–220°C under atmospheric pressure to form *n*-butanol and BBE.

The unsaturated C_8 ether was isolated by distillation. The boiling point at 760 and 100 mm Hg is 145.4°C and 83.7°C, respectively; density d_4^{20} = 0.773 kg m^{-3}; refractive index n_D^{20} = 1.3974.

No physicochemical properties of this ether are reported in available handbooks. All the other chemicals used in this work were thoroughly purified; their physicochemical parameters were consistent with the published data [8].

The liquid–vapor equilibrium was studied on a circulation unit connected with a manostat. The design of the unit provided minimal consumption of chemicals. The vapor condensed in a receiver was

analyzed by gas chromatography with an accuracy of 0.5 mol %.

The boiling point of the solutions was measured in the course of the experiment with an accuracy of 0.2°C.

The experimental parameters of the liquid–vapor equilibrium in the *n*-butanol (NB)–BBE and isobutanol (IB)–BBE binary systems at 760 and 100 mm Hg are summarized in Table 1, and the parameters for the ternary system at 760 and 100 mm Hg, in Table 2. The differences between the experimental and calculated (NRTL equation [9]) concentrations of the components in the vapor phase and boiling points of the solution components Δy_i and ΔT and the average absolute deviations $\lvert\overline{\Delta y}\rvert$ and $\lvert\overline{\Delta T}\rvert$ are also presented in Tables 1 and 2. The parameters of the liquid–vapor equilibrium in the ternary system were calculated from the NRTL equation parameters, which, in turn, were calculated from the data on the liquid–vapor equilibrium in the binary systems.

As seen from Tables 1 and 2, the calculated parameters agree well with the experimental results.

n-Butanol and BBE form an azeotrope. Under a pressure of 760 mm Hg, the BBE content in the azeotrope is 10.5 mol % (16.9 wt %) and its boiling point is 116.8°C. Under a pressure of 100 mm Hg, the

BBE concentration in the azeotrope is 22.4 mol % (33.3 wt %), and its boiling point is 66.2°C.

No azeotrope was found in the isobutanol–BBE system under atmospheric pressure. However, under reduced pressure (100 mm Hg), the compounds do form an azeotrope [bp 60.2°C, BBE concentration 12.9 mol % (20.4 wt %)].

Calculation by the azeotrope search program showed that ternary azeotropes were formed in the IB–NB–BBE ternary system neither at 760 nor at 100 mm Hg. The study of this system on a high-performance column by the procedure in [10] confirmed this assumption.

In this work we studied phase equilibria in distillation of systems containing saturated butyl alcohols and unsaturated butyl ethers to determine initial parameters for a mathematical model of distillation of commercial butyl alcohols from these systems.

It is known [11] that ternary azeotropes are formed in systems consisting of water, butyl alcohols, and saturated butyl ethers; however, for the similar systems with unsaturated butyl ethers, no data are reported.

In this work we determined the compositions and boiling points of ternary azeotropes in H_2O–IB–BBE and H_2O–NB–BBE systems at a pressure from 100 to 760 mm Hg.

These experiments were performed on a laboratory 50-mm column 150 cm high, packed with $2 \times 3 \times 3$ mm three-edged spirals made from 0.4-mm Nichrome wire.

The column efficiency determined with the IB–NB system [12] was 68–70 TP.

The azeotrope composition was determined by the procedure in [10]. The gaseous distillate was condensed, homogenized with acetone, and analyzed

760	89.1	35.7	33.0	31.3	0.95

chromatographically. The results of these experiments are presented in Table 3.

As shown above, the BBE : NB weight ratio strongly increases with decreasing pressure: at 760 and 100 mm Hg it is 0.20 : 1 and 0.50 : 1, respectively. Addition of water to the IB–BBE and NB–BBE systems also increases this ratio (Table 3). Thus, we suggest that butyl alcohol–butyl ether systems can be efficiently separated by distillation under reduced pressure in the presence of water as a separating agent.

Industrial alcohol–ether fractions formed in production of butanols by oxosynthesis have the following composition (wt %): IB 30–50, NB 20–40, saturated buthyl ethers 4–11, unsaturated butyl ethers 5–12, butyl formates 3–7, butyric aldehydes 1–3, and water 1–5.

We studied distillation separation of butanol form an industrial alcohol–ether fraction[1] of the following composition (wt %): IB 39.29, NB 33.34, saturated buthyl ethers 9.87, unsaturated butyl ethers 11.26, butyric aldehydes 2.08, butyl formates 2.74, and water 1.42.

A five-component system containing (wt %) IB 44.2, NB 33.3, dibutyl ether (DBE) 9.8, BBE 11.3, and water 1.4 was used as a model.

To simulate the distillation process, we used parameters of the NRTL equation for the binary system under a pressure of 760 and 100 mm Hg. The parameters calculated by the procedure in [13] are summarized in Table 4.

The saturated vapor pressure of pure components was calculated by the Antoine equation in the following form:

$$\log P = A - \frac{B}{C + T},$$

where P is the saturated vapor pressure (mm Hg), T is the temperature (°C), and A, B, C are the Antoine constants.

The parameters of the Antoine equation for IB, NB, water and DBE taken from [14] were brought to the above form of the equation. The BBE parameters were determined in this work by treatment of the experimental temperature dependence of saturated vapor pressure of BBE (Table 5).

The separation parameters of the model system were computed by the program for calculation of distillation parameters, developed on the basis of the concept in [15, 16].

To recover high-grade NB [GOST (State Standard) 5208–81] and high-grade IB [GOST 9536–79], the content of butyl alcohols and unsaturated compounds in the product should be no less than 99.4 wt % and no more than 0.02 wt %, respectively.

The distillation parameters at which butyl alcohols are separated to the highest extent at the indicated column efficiency and 760 and 100 mm Hg from the alcohol–ether fraction meeting the GOST requirements are presented in Table 6.

As seen from Table 6, under reduced pressure the yield of butyl alcohols is higher at smaller reflux ratios.

On an industrial scale, we suggest to recover butyl alcohols on a 23600-mm column 1000 mm in diameter, equipped with 40 valve single-flow plates.

To check the adequacy of calculation of the quality and the yield of butyl alcohols recovered from the alcohol–ether fraction, we performed a pilot experiment on this column.

The initial alcohol–ether fraction was fed to the 21st plate from the top, and the separating agent (steam) was fed to the 36th plate (in the initial mixture, H_2O : BBE = 1 : 1). The column was sprayed with the organic phase from the florentine with the reflux ratio of 9–10.

Table 4. Parameters of NRTL equation

System	760 mm Hg			100 mm Hg		
	τ_{12}	τ_{21}	α_{12}	τ_{12}	τ_{21}	α_{12}
NB–BBE	0.9776	0.1242	0.4	2.1047	–0.1230	0.4
IB–BBE	1.9805	–0.6088	0.3	3.2272	–0.7412	0.3
NB–DBE	1.2734	–0.0729	0.4	1.3068	0.2524	0.4
IB–DBE	3.4845	–1.9043	0.1	0.9872	0.3085	0.4
H_2O–IB	3.5987	0.4653	0.4	3.4984	0.5140	0.4
H_2O–NB	3.5864	0.4951	0.4	3.6000	0.5757	0.4
H_2O–BBE	5.6281	–0.9681	0.1	5.3635	–0.7941	0.1
H_2O–DBE	5.7557	–1.1372	0.1	5.6131	–0.9847	0.1
DBE–BBE	–0.2111	0.2288	0.1	1.3457	–1.0773	0.1

The composition of the fraction obtained by separation from the bottoms was as follows (wt %): H_2O 0.07, IB 50.01, NB 49.88, saturated butyl ethers 0.02, and unsaturated butyl ethers 0.01. Commercial isobutanol and *n*-butanol were recovered by distillation of this fraction on a column with 90 valve plates at a reflux ratio of 12.

Commercial IB was taken off from the seventh plate form the top, and NB, from the bottoms. The quality of the commercial alcohols met the GOST requirements. The yield of IB and NB based on their potential content in the head ether fraction was 75 and 90.3%, respectively.

The yield of high-grade butyl alcohols, calculated on the basis of the developed model, agreed well with the results of the experimental run on the industrial distillation column.

Thus, the experimental and calculated data of this work can be used to design a process for recovery of commercial butyl alcohols from side alcohol–ether fraction at the Salavatnefteorgsintez Joint-Stock Company.

CONCLUSIONS

(1) Liquid–vapor phase equilibria in isobutanol–*n*-butanol–butyl butenyl ether ternary system and in binary systems of these compounds were studied experimentally at 760 amd 100 mm Hg. *n*-Butanol and butyl butenyl ether form an azeotrope at 760 and 100 mm Hg; no azeotropes were found in the isobutanol–butyl butenyl ether system at 760 mm Hg, but at 100 mm Hg this system has an azeotrope. No ternary azeotrope was found in the three-component system. The average absolute error of calculating the equilibrium composition of the ternary system by the NRTL equation from the equilibrium compositions of the binary systems of the components is 1 mol %. The boiling point of the equilibrium ternary system was calculated by this procedure with an absolute error of 0.6–0.8°C. Thus, the calculation results are quite adequate.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Saturated Vapor Pressure over the Melts of the $NaNO_2$–$NaNO_3$ System

V. I. Glazov, G. P. Dukhanin, and M. Kh. Dkhaibe

Volgograd State Technical University, Volgograd, Russia

Received July 26, 2003

Abstract—The partial pressures of sodium nitrite and sodium nitrate over the system $NaNO_2$–$NaNO_3$ were determined at 798, 823, and 848°C. For sodium nitrate, *A* and *B* coefficients of the Clausius–Clapeyron equation, partial molar heats of vaporization, activities, and activity coefficients were calculated as functions of composition.

Molten nitrites and nitrates of alkali metals and systems based on them are used as high-temperature heat carriers in vulcanization of extruded rubber articles, in heat treatment of metals, and for preparing heat-resistant lubricants [1]. For this reason, study of physicochemical properties of nitrite–nitrate molten salt systems is of both theoretical and applied importance.

In this work, proceeding with studies [2–5] on physicochemical properties of nitrite–nitrate salt melts, we measured the saturated vapor pressure of the system $NaNO_2$–$NaNO_3$ at 798, 823, and 848 K. The experimental procedure and method of determining saturated vapor pressure of individual molten salts have been reported previously [2].

The mass spectrometry data [6, 7] for vapors of alkali metal nitrites and nitrates show that the vapor phase coexisting with nitrite–nitrate melts consists of monomeric molecules. This made it possible to calculate the saturated vapor pressure over pure components and their mixtures from the content of the components in a given volume of the vapor. As previously, the content of the sodium cations in the condensed vapor phase was determined by flame photometry [25], and the concentration of NO_2^- anions, by permanganate titration [8]. The content of $NaNO_2$ and $NaNO_3$ was calculated from these data.

The results of measurements of the vapor pressure over the sodium nitrite and sodium nitrate melts at 798 and 848 K are plotted in Fig. 1. As seen, the concentration dependence of the saturated vapor pressure in the $NaNO_2$–$NaNO_3$ system exhibits negative deviations from Raoult's law, decreasing with increasing temperature. Under isothermal conditions, the vapor

848	0.045 / 0.45	0.98 / 0.49	0.24 / 0.60	0.34 / 0.67	0.44 / 0.74	0.72 / 0.9	0.85 / 0.95

pressure over the binary melts monotonically decreases as the content of sodium nitrate in the mixture increases. For component concentrations less than 5 mol %, the saturated vapor pressure as a function of composition is adequately described by Raoult's law. In the region of the equimolar concentrations of the components, the extent of the negative deviations increases.

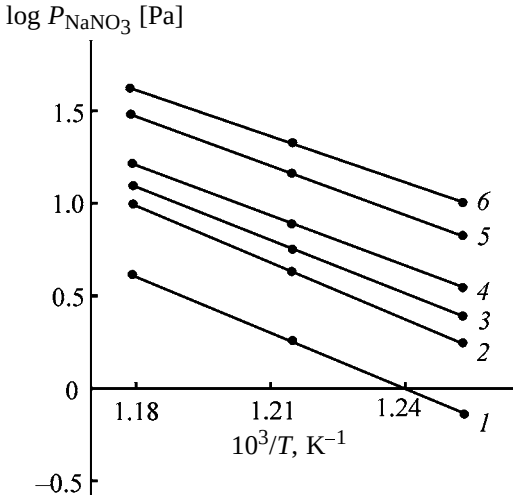

Fig. 2. Vapor pressure of sodium nitrate P_{NaNO_3} in the system $NaNO_2$–$NaNO_3$ vs. temperature T. $NaNO_3$ content in melt, mol %: (*1*) 20, (*2*) 40, (*3*) 50, (*4*) 60, (*5*) 80, and (*6*) 100.

Because the vapor pressures of sodium nitrite and sodium nitrate differ greatly, the total saturated vapor pressure over the system is determined by the $NaNO_3$ partial pressure.

The temperature dependence of the vapor pressure of the components over the melts of various compositions is adequately described by the Clausius–Clapeyron equation $\log P = B - A/T$. The coefficients of the equation are given in Table 1. Figure 2 shows the $\log P = f(1/T)$ plots for different concentrations of sodium nitrate in the melt.

The partial molar heats of vaporization of sodium nitrate from the melts of various compositions were calculated from the slopes of the straight lines

$$\Delta H = 2.3RA,$$

where R is the universal gas constant (8.314 J mol^{-1} K^{-1}).

With decreasing concentration, the heat of vaporization of sodium nitrate increases, i.e., the strength of interaction between the particles increases. The experimental data and results of their processing are presented in Table 1.

The coefficient of the linear correlation of $\log P$ with $1/T$ varies from 0.78 (at low concentrations) to 1.

The experimentally determined saturated vapor pressures over the pure components P_i^0 and their partial pressures P_i in the system were used to calculate the activities ($a_i = P_i/P_i^0$) and the activity coefficients ($\gamma_i = a_i/N_i$) for sodium nitrate in the binary system [9] (N_i is mole fraction of $NaNO_3$ in the melt). The calculation results are presented in Table. 2.

As seen, the activity of sodium nitrate exhibits negative deviations from the mole fraction. Therefore, the calculated activity coefficients are less than unity.

In the system $NaNO_2$–$NaNO_3$, the extent of deviations of the vapor pressure from ideality is larger than in the previously studied system $NaNO_2$–KNO_3 [5]. This may be explained by formation of a continuous series of solid solutions of $NaNO_2$ and $NaNO_3$ and of the chemical compound $NaNO_2 \cdot NaNO_3$ [10, 11].

Studies of N.S. Kurnakov's school [12] have shown that, when a solid ionic compound is melted, a part of ions can form complex species in equilibrium with simple ions. Therefore, the partial pressures of the components in the system decrease, the vapor pressures of the components exhibit considerable deviations from Raoult's law, and, consequently, the activity is not equal to concentration.

CONCLUSIONS

(1) The partial pressures of sodium nitrite and sodium nitrate over the system $NaNO_2$–$NaNO_3$ at 798, 823, and 848 K were determined. For sodium nitrate, the coefficients A and B of the Clausius–Clapeyron equation and the partial molar heats of vaporization were calculated.

(2) The saturated vapor pressure exhibits negative deviations from Raoult's law, indicative of certain interaction of the components in a melt.

(3) The activities and activity coefficients of sodium nitrate were calculated as functions of composition and temperature. The activity of sodium nitrate shows negative deviations from the mole fraction. As a result, the activity coefficient is less than unity.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Influence of Crystallization Conditions in Production of Citric Acid on the Properties of Forming Calcium Sulfate

K. A. Pavlov and B. A. Dmitrevskii

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 3, 2003

Abstract—The boundaries of phase equilibria involving calcium sulfate crystal hydrates in a citric acid solution were calculated. The influence exerted by an excess amount of sulfuric acid on the stability of calcium sulfate crystal hydrates in citric acid solutions was considered. The possibility of achieving a hemihydrate mode of citric acid extraction from calcium citrate was studied.

Acid calcium sulfate suspensions are formed in sulfuric acid extraction of citric acid ($C_6H_8O_7$) from calcium citrate $Ca_3(C_6H_5O_7)\cdot 4H_2O$ [1, 2]. The solubility and stability of calcium sulfate ($CaSO_4$) modifications predetermines important parameters of the $C_6H_8O_7$ manufacture process, such as concentration and purity of the product acid, throughput of the stages of suspension filtration and calcium sulfate washing, washing efficiency, conditions of acid evaporation, $CaSO_4$ properties in hydration and dehydration processes, $CaSO_4$ transportability, content of total and crystallization water, and impurity background. All these characteristics are comparatively rarely discussed in the literature.

Citric acid plants mainly employ a semicontinuous extraction process with varying $H_2SO_4 : C_6H_8O_7$ ratio, which predetermines the presence of crystals with different microgranulometric characteristics in citrogypsum. It was found, in particular, that about 60% of the total amount of crystals are isolated parallelogram-shaped crystals 70 μm long and 15 μm wide. Separate finer and coarser gypsum crystals with dimensions of 30×10 and 400×300 μm are found, together with fine crystals of calcium oxalate and shielded crystals of calcium citrate. Such an inhomogeneity of the solid phase is accounted for by the method of $C_6H_8O_7$ extraction from solid $Ca_3(C_6H_5O_7)\cdot 4H_2O$ in a heterogeneous system.

Data on the concentration and temperature boundaries of mutual phase transformations of calcium sulfate crystal hydrates are important for practical use of crystallization processes occurring in sulfuric acid and nitric–sulfuric acid extraction of phosphoric [3] and, apparently, citric acids. Analysis for the content of these compounds in phosphoric and nitric acid solutions was a subject of numerous papers [4, 5]. No published data of this kind could be found for citric acid, and, therefore, these boundaries were determined tentatively by a prognosis graphical-analytical calculation. The points in which calcium sulfate dihydrate ($CaSO_4\cdot 2H_2O$) and hemihydrate ($CaSO_4\cdot 0.5H_2O$) coexist in equilibrium are commonly found by studying their solubility and determining graphically the intersection points of the solubility isotherms of gypsum and calcium sulfate hemihydrate, or by comparing the water vapor pressures over the corresponding solutions with the dissociation pressure of the reversible reaction

$$CaSO_4\cdot 2H_2O(s) \rightleftarrows CaSO_4\cdot 0.5H_2O(s) + 1.5H_2O(vapor). \quad (1)$$

To make a rough prognosis of the conditions (acid concentration, temperature) of phase equilibrium between gypsum and hemihydrate in acid solutions, parameters of dehydration by reaction (1) yielding water vapor were compared with water vapor pressures over solutions of phosphoric [6], nitric, and citric acids.

The dehydration parameters and the equilibrium content of the acid were found on the assumption that dissolved $CaSO_4$ affects only slightly the equilibrium pressure over solution, $P_{H_2O(sol)}$, which is close (equal) to the dehydration pressure $P_{H_2O(dehydr)}$.

To find the acid concentration in a eutonic solution saturated with $CaSO_4\cdot 2H_2O$ and $CaSO_4\cdot 0.5H_2O$, the dependence $P_{H_2O} = f(c_{acid})$ was plotted for each isotherm-polyconcentrate of an acid, and an isobar of P_{H_2O} over gypsum at the same temperature was

1070-4272/03/7609-1408$25.00

drawn to its intersection with the isotherm. Figure 1 exemplifies the construction for 80°C. Table 1 compares the dihydrate–hemihydrate equilibrium conditions for solutions of the three acids, obtained by this method also for other temperatures. The isotherms $P_{H_2O} = f(c_{acid})$ for citric acid emerge from the point corresponding to the water vapor pressure over water and intersect the isobar of water vapor pressure over a solution saturated with citric acid [7]. The isotherms for nitric (HNO_3) and phosphoric (H_3PO_4) acids were plotted using experimental data, and the isotherm for $C_6H_8O_7$ is represented by a prognosis line *3* [6].

It should be noted that the water vapor pressures over solutions of nitric [8, 9] and phosphoric [6] acids are well represented in the literature and the calculated conditions of phase transformation are close to those found experimentally. It is possible that the prognosis data on the content of $C_6H_8O_7$ may be somewhat overestimated. However, these data also indicate that appearance of a more stable phase, $CaSO_4$ hemihydrate, is possible at 80–90°C at citric acid concentrations in the extraction solution exceeding 40%. At 100°C, occurrence of the dihydrate–hemihydrate phase transformation would be expected at a lower concentration of citric acid, which, according to some data [10], stabilizes calcium sulfate hemihydrate.

As already mentioned, the fact that citric acid is a foodstuff results in that it is difficult to use various control agents to affect the crystallization process. Therefore, the main way to control the crystallization process is to vary the temperature and concentration characteristics.

The quality of the forming $CaSO_4$ crystals is the most important characteristic of the crystallization process. The shape and size of calcium sulfate crystals formed in extraction determine the filtering properties of a layer of this material and, consequently, the efficiency of its washing. These parameters of the crystals depend on the temperature and acid concentration, extent and conditions of supersaturation elimination, and relative amounts of Ca^{2+} and SO_4^{2-} ions in solution.

The necessity for controlling the crystallization process predetermines the choice of specific schemes for introduction of raw materials, circulation solutions, and suspensions into the reaction mass, cooling of the reaction mass, and its separation into zones with different temperature and concentration characteristics. For example, with the temperature raised from 30 to 80°C, the length of gypsum crystals increases by a factor of 10–15, and their width, by a factor of 3–5.

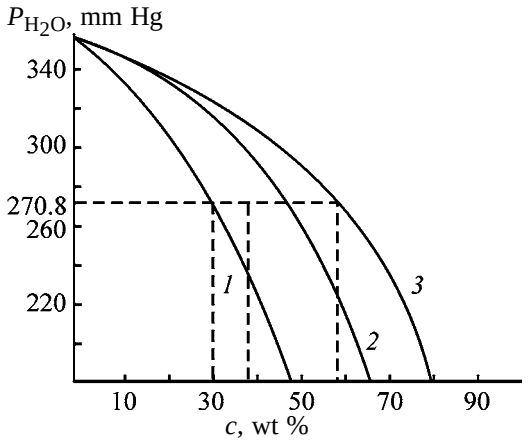

Fig. 1. Graphical illustration of how the acid concentrations are found for the dihydrate–hemihydrate equilibrium at 80°C. (P_{H_2O}) Water vapor pressure and (*c*) acid concentration. System: (*1*) $CaSO_4$–HNO_3–H_2O, (*2*) $CaSO_4$–H_3PO_4–H_2O, and (*3*) $CaSO_4$–$C_6H_8O_7$–H_2O.

Combined dihydrate–hemihydrate extraction techniques, in which calcium sulfate first crystallizes in the form of a metastable phase, $CaSO_4 \cdot 0.5H_2O$, and then transforms into a more stable phase, $CaSO_4 \cdot 2H_2O$, have been implemented, and they showed very good performance in manufacture of H_3PO_4.

As seen from Fig. 1, $CaSO_4$ must crystallize in the form of gypsum in extraction of citric acid under industrial conditions. However, hemihydrate is to be formed on raising the concentration to 55% and temperature to 90°C.

Isotherms–polybars of water vapor over H_2SO_4 solutions exhibit curvilinear behavior (Fig. 2*I* a). Now a polybar will be plotted for the dehydration reaction in the range from 60 to 100°C. The A_{60}–A_{100} line is the locus of points with equal water vapor pressures over gypsum in its conversion into the hemihydrate and over an acid solution. Owing to the relatively low $CaSO_4$ solubility in acid solutions [12], it is assumed that $CaSO_4$ has virtually no effect on the water vapor

Table 1. Parameters of equilibrium dehydration of gypsum into hemihydrate by reaction (1)

pressure over a solution in water–acid systems. Plotting the A_{60}–A_{100} line on a graph of temperature against H_2SO_4 concentration yields a polythermal diagram of mutual transformations of calcium sulfate crystal hydrates in sulfuric acid (Fig. 2*II* b).

Whereas the concentration dependence of P_{H_2O} over solution has been described in sufficient detail [9], there are only two experimental points in each isotherm for $C_6H_8O_7$ solutions: water and saturated acid solution (Fig. 2*II* a, B_{60}–B_{100} line); the vapor pressure over citric acid solutions is calculated using the similarity theory. The reason for such a choice is the structural similarity of the molecules of both acids, i.e., three stages of dissociation of hydrogen ions, with the first constant K_1 at 25°C equal to 7.6×10^{-3} for phosphoric acid and 7.45×10^{-4} for citric acid [9].

Table 2. Calculated citric acid concentrations $c_{c.a}$ at which the water vapor pressure at 60°C is equal to the indicated water vapor pressure $P_{w.p}$ over phosphoric acid solution with indicated concentration $c_{p.a}$

$P_{w.p}$, kPa	$c_{p.a}$, %	$c_{c.a}$, %
19.62	10	13.2
18.97	20	26.4
17.80	30	39.7
16.04	40	52.6
13.67	50	66.1
12.39	55.6	73.5

Two expressions follow from the similarity theory [13]:

$$c'/c'' = C_c, \quad p'/p'' = C_p, \tag{2}$$

where c' is the $C_6H_8O_7$ concentration; c'', H_3PO_4 concentration; p', water vapor pressure over $C_6H_8O_7$ solution; p'', water vapor pressure over H_3PO_4 solution; C_c and C_p, similarity constants.

Taking the constant C_p to be unity, i.e., equating the water vapor pressures for both the acids, gives for the constant C_p at 60°C a value of 73.5/55.6 = 1.32, where 73.5 stands for the concentration of a saturated solution of $C_6H_8O_7$, and 55.6, for the corresponding concentration of an H_3PO_4 solution, at which the water vapor pressure over solution (12.39 kPa) is

equal to the water vapor pressure over a $C_6H_8O_7$ solution [7].

Using the resulting constant C_c, it is possible to calculate from data on H_3PO_4 [9] the corresponding concentrations for citric acid (Table 2). Thus, the calculated curve of water vapor pressure over a citric acid solution at 60°C is plotted (Fig. 2*II* a). Similar calculations for temperatures of 80, 90, and 100°C yield isotherms–polybars for $C_6H_8O_7$. The A_{60}–A_{100} line is the locus of points corresponding to equal water vapor pressures over gypsum in its conversion into hemihydrate and over a citric acid solution. Plotting the A_{60}–A_{100} line as a graph of temperature against $C_6H_8O_7$ concentration gives a calculated polythermal diagram describing mutual transformations of $CaSO_4$ crystal hydrates in $C_6H_8O_7$ (Fig. 2*II* b).

The prognosis calculations performed, combined with published data on solubility and phase transformations of calcium sulfate crystal hydrates in the systems $CaSO_4$–H_2SO_4–H_2O and $CaSO_4$–$C_6H_8O_7$–H_2O, make it possible to plot a polythermal diagram of mutual phase transformations $CaSO_4 \cdot 2H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O$ in citric–sulfuric acid solutions (Fig. 3).

Figure 3 shows isotherms connecting the points that correspond to the compositions of the sulfuric and citric acid solutions in which gypsum and calcium sulfate hemihydrate are in equilibrium at a given temperature. The short-dash lines represent isoconcentrates corresponding to mixtures of solutions containing equal amounts of $C_6H_8O_7$ and H_2SO_4. The intersection points of the isotherms and isoconcentrates characterize the composition of solutions in which gypsum and calcium sulfate hemihydrate are simultaneously in metastable equilibrium at a given temperature, i.e., the points at which the water vapor pressure over an acid solution and that of $CaSO_4 \cdot 2H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O$ dissociation are equal. The line with constant total concentration of $C_6H_8O_7$ + H_2SO_4, equal to 50%, intersects the isotherms of phase transformations at 60 and 80°C. Consequently, to the metastable equilibrium $CaSO_4 \cdot 2H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O$ at 60°C corresponds a solution containing 32% citric acid and 18% sulfuric acid. Gypsum must be more stable in solutions with a lower content of sulfuric acid, and hemihydrate, in those with higher content of H_2SO_4.

Thus, to obtain at the output of the extraction process a high concentration of citric acid, 50% and more at 80°C, and to ensure crystallization of gypsum, it is necessary to maintain the content of sulfuric acid in solution at a level not exceeding 1%. At H_2SO_4 content higher than 1%, crystallization of calcium sulfate hemihydrate or recrystallization of gypsum into hemihydrate may begin. Similarly, performing the process in the hemihydrate mode requires a ≥5% excess of sulfuric acid in order to prevent the process from passing to the range of joint crystallization of gypsum and hemihydrate, which may lead to formation of poorly filterable fine crystals.

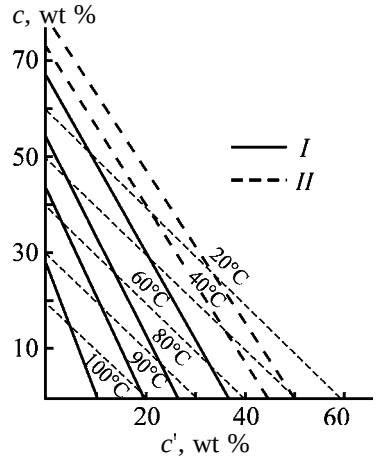

Fig. 3. Polythermal diagram of equilibrium transformations $CaSO_4 \cdot 2H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O$ in the system $CaSO_4$–H_2SO_4–$C_6H_8O_7$–H_2O: (*c*) citric acid concentration and (*c*') sulfuric acid concentration. (*I*) Isotherms of phase transformations and (*II*) compositions of solutions with constant total concentration.

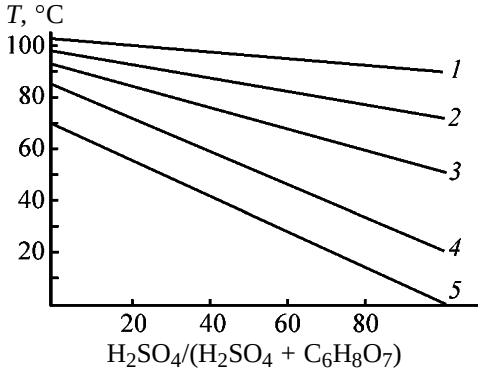

Fig. 4. Concentration ratio and total concentration of sulfuric and citric acids in solutions of the system $CaSO_4$–H_2SO_4–$C_6H_8O_7$–H_2O vs. temperature *T* of equilibrium transformations $CaSO_4 \cdot H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O$. [$H_2SO_4/(H_2SO_4 + C_6H_8O_7)$] Fraction of sulfuric acid in the total amount of acids. Total concentration of acids (%): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, and (*5*) 60.

The temperatures of phase transformations in solutions of sulfuric and citric acids can be calculated in the same way. As seen in Fig. 4, the temperature of equilibrium phase transformations depends linearly on

Table 3. Calcination of the calcium sulfate samples obtained

$c_{c.a}$, %	Amount of moisture, %, removed at indicated temperature, °C			Total amount of crystal hydrate water, %	Mass fraction	
	20–90	90–160	160–600		gypsum	hemihydrate
30	17.56	19.02	0.92	20.3	88.3	11.7
40	5.08	15.74	1.5	17.1	64.7	35.3
50	8.39	10.8	1.64	12.29	31.22	68.78
Reagent	0.26	19.98	0.89	20.7	93.7	6.3

the ratio of acids in the mixture. With increasing mass fraction of H_2SO_4, the temperature of the phase transition of gypsum into calcium sulfate hemihydrate becomes lower.

The extraction of citric acid from calcium citrate and hydrocitrate was studied, and the possibility of performing dihydrate–hemihydrate extraction was assessed.

A study of extraction from calcium citrate demonstrated that the crystallization of calcium sulfate always begins with the formation of hemihydrate crystals, which disappear by the middle of the process, at citric acid content not exceeding 50%, to give place to gypsum crystals. When the content of citric acid is raised to >50%, the extraction process begins in a similar way and a stable hemihydrate appears by the end of the process, with the amount of the hemihydrate the greater, the higher the content of the acid. In this case, crystals of calcium sulfate hemihydrate precipitate from the mother liquor several hours after its filtration.

Presumably, citric acid present in high concentration decelerates crystallization and recrystallization of calcium sulfate and phase transitions in this material, which results in that the extraction takes much longer time. Such an increase in the process duration may be technologically unacceptable. Attempts to make the extraction process shorter markedly impair the filtration characteristics.

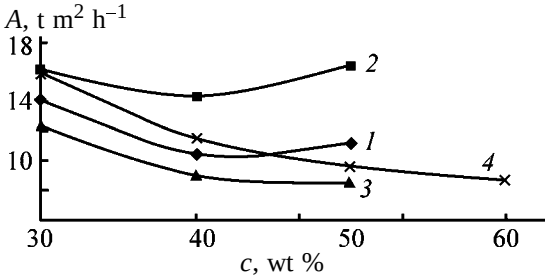

Fig. 5. Effect of a calcium sulfate seed on the throughput *A* of main filtration. (*c*) Content of citric acid. Decomposition of citrate: (*1*) without seed and (*2*) with seed; that of hydrocitrate: (*3*) without seed and (*4*) with seed.

When extraction is performed in the crystallization region of calcium sulfate hemihydrate, the throughput of the main filtration in terms of citric acid increases by a factor of 2, from 1.79 to 3.57 t $(m^2\ h)^{-1}$. Introduction of a seed (mixture of gypsum and hemihydrate, obtained in preceding experiments) improves the quality of hemihydrate crystals and also makes it possible to avoid formation of fine crystals. When the extraction process was carried out in the hemihydrate mode with a seed, the throughput of filtration increased to 4.81 t $(m^2\ h)^{-1}$.

Experiments on calcination of the resulting calcium sulfate samples at different temperatures confirmed that calcium sulfate is mainly present in the form of hemihydrate already at a citric acid content of 50%. For comparison, the results obtained in calcination of reagent-grade gypsum are presented (Table 3).

A study of the extraction of citric acid from calcium hydrocitrate ($CaC_6H_6O_7 \cdot 4H_2O$) under similar conditions demonstrated that mainly gypsum (up to 60%) crystallizes in the existence range of the hemihydrate in the presence of a seed. This may be due to a steeper, compared to the case of $Ca_3(C_6H_5O_7)_2 \cdot 4H_2O$, rise in the content of citric acid in solution in decomposition of $CaC_6H_6O_7 \cdot 4H_2O$; as already mentioned, concentrated citric acid decelerates mutual transformations of the crystal hydrates. Introduction of a seed (mixture of gypsum and an intermediate product, similar to that used in the preceding experiments) improves the crystallization of gypsum and stabilizes this material: no hemihydrate formation is observed. Gypsum exists, in the beginning, as a stable phase and then, with increasing content of $C_6H_8O_7$ in solution, becomes metastable, but is not dehydrated to hemihydrate. Citric acid exerts a stabilizing influence on the solid phase, irrespective of whether or not it is stable under the given conditions. The key factor in this case is what phase existed in the system previously.

Generalization of the data on the throughput of the main filtration reveals two well-pronounced dependences (Fig. 5).

In extraction of citric acid from calcium citrate, an extremum is observed at citric acid content of 40%, with the decrease and increase in throughput around the extremum being due to, respectively, an increase in viscosity and transition to the hemihydrate region of extraction.

In extraction from calcium hydrocitrate, no extremum is observed, since the process does not pass to the hemihydrate mode because of the stabilizing action of citric acid, and calcium sulfate precipitates in the form of gypsum.

On the basis of the experimental data obtained, a procedure for continuous extraction of citric acid from calcium citrate was proposed, together with ways to raise the concentration of the production acid after the extraction stage. It was established that citric acid lowers the rate of phase transformations, which is particularly noticeable at its contents exceeding 40%. In this case, the degree of decomposition of calcium citrate may decrease to 30%, thereby making greater the loss of the target product.

CONCLUSIONS

(1) In extraction of citric acid, calcium sulfate precipitates in conformity with the Ostwald rule first as a metastable crystal hydrate, which is then transformed into a more stable hydrate form; an excess amount of sulfuric acid also shifts the process to the region of joint crystallization of gypsum and the hemihydrate and markedly impairs the quality of the resulting crystals.

(2) Citric acid markedly decelerates hydration and dehydration of calcium sulfate. Gypsum was obtained in 60% citric acid at 90°C and did not undergo dehydration during 90 min of extraction. The lowest throughput of filtration is characteristic of the region with citric acid content ranging from 40 to 50%, i.e., the zone of joint crystallization of gypsum and calcium sulfate hemihydrate, which is confirmed by a prognosis calculation of the metastable equilibrium boundaries.

(3) A method for decomposition of calcium citrate in solution was developed, which makes it possible to carry out the extraction process itself in a homogeneous system. It was established that, at high content of the acid (>50%), calcium sulfate crystallizes predominantly in the form of the hemihydrate $CaSO_4 \cdot 0.5H_2O$.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Properties of Natural Aluminosilicates (Clay, Loam, Sandy Loam, Zeolite)

S. A. Evtyukhov and V. G. Berezyuk

Ural State Technical University, Yekaterinburg, Russia

Received May 22, 2002

Abstract—Sorption of Ni^{2+}, Cu^{2+}, Mn^{2+}, Fe^{3+}, and Cr^{3+} from model solutions with natural sorbents (clay, loam, sandy loam, zeolite) was studied. The optimal conditions of sorption were determined. The effect of pH and electrolytes on the sorption efficiency was studied.

A study of sorption properties of natural materials was performed with soil samples (clay, loam, sandy loam, zeolite) collected near Nizhni Tagil and Revda towns (Sverdlovsk oblast) in which the environmental situation is presently very bad. As zeolite sample we took clinoptilolite of the Kholinsk deposit (Buryatia). The compositions of aluminosilicates studied were as follows (SiO_2 and Al_2O_3, wt %): clinoptilolite 65.7 and 11.5; clay 70.1 and 18.2; loam 65.8 and 24.3; and sandy loam 86.8 and 5.6, respectively. Estimation of the sorption power of soils would allow prediction of the danger of groundwater pollution with metals from sewage percolating through soils and monitoring of the features of sorption processes in such technologies as underground and heap leaching [1, 2].

Sorption was studied under static conditions by the method of separate samples. A sorbent sample (m_s, g) was immersed in 100 ml of a model solution with a known metal concentration, and the mixture was agitated with a shaker. The time in which the sorption equilibrium was attained was determined in preliminary experiments. As a rule, the time of contact of the sorbent and solution was no more than 30 min. The required pH was adjusted with 1 N H_2SO_4 or 0.1 N NaOH. The completeness of metal recovery was monitored by the standard methods [3]. Sorption of metal ions was performed with both nonfractionated and fractionated zeolite. The 0.5–1.5-mm fraction proved to be optimal.

To choose metal ions that make the major contribution to the groundwater pollution in the region in question, we collected information on the quantitative and qualitative composition of sewage from industrial plants. The typical pollutants are copper, nickel, manganese, and iron compounds, bichromates, sulfates, and oil products. A study of leaching of clay, loam, and sandy loam in various media showed that the main metal pollutants of the groundwater are Ni^{2+}, Cu^{2+}, Fe^{3+}, and Cr^{3+}. In our experiments, we used $NiSO_4$, $CuSO_4$, $MnSO_4$, $NH_4Fe(SO_4)_2$, $KCr(SO_4)_2$, Na_2SO_4, $Cd(NO_3)_2$, and $Al_2(SO_4)_3$.

The sorption efficiency was estimated by the process time t and degree of metal recovery from the solution S (%):

$$S = (C_{in} - C_{eq}) \times 100/C_{in},$$

where C_{in} and C_{eq} are the initial and equilibrium metal concentration, respectively, mg l^{-1}.

The data were treated by standard methods [4].

The sorption efficiency substantially depends on pH. The effect of pH was studied within the pH range 0.7–8.5. The results are shown in Figs. 1 and 2. In acidic media (pH < 3.0–3.5), the recovery of all the metals studied decreases because of the competitive effect of the acid. At pH > 4.0–4.5, hydrolyzed metal species are formed, which are well sorbed with the sorbent (the recovery with zeolite reaches 98–99.5% and with soils, 65–85%).

Sorption of Ni(II) reaches 98% (pH > 4.0); that of Cu(II), 99.5% (pH > 5.5); and that of Fe(III), 75% (pH ~ 3.0) and more than 90% (pH > 7.5).

Chromium can exist in solution as Cr^{3+} (in acid medium), as hydroxo complexes, or as chromate or bichromate ions [5]; its behavior is rather complex. In neutral and weakly alkaline media, Cr^{3+} is hydrolyzed to chromium(III) hydroxide. The recovery of Cr^{3+} amounts to 96–97% at pH > 2.9.

The recovery of Mn is affected by the features of conversion of manganese compounds into MnO_2

1070-4272/03/7609-1414$25.00

(90% recovery is reached in neutral solutions). The maximum of Cu(II) sorption was 63% on sandy loam, 80–83% on clay and loam, and 87% on zeolite . At larger amounts of the sorbent, the sorption maximum shifts to the acid region. The static capacity of clinoptilolite (g kg^{-1}) was determined to be 1.71 for Ni(II), 1.59 for Cu(II), 0.61 for Cr(III), 1.95 for Fe(III), and 2.31 for Mn(II).

Let us perform the quantitative treatment of the experimental data for Cu(II) assuming that copper sorption with natural sorbents proceeds by the ion-exchange mechanism. Ion exchange in soils was discovered more than 150 years ago. Now, the sorption is considered as the main mechanism of interaction of heavy metals with inorganic components of soils [2]. Heavy metals form with clay minerals both exchangeable and nonexchangeable species.

The ion-exchange equilibria are often described by the equations derived from the law of mass action [6]:

$$\log\varepsilon = A - (Z_1/Z_2)\log a_s, \quad (1)$$

where ε is the distribution coefficient of Cu(II) between the sorbent and solution [i.e., $S/(1 - S)$, where S is the degree of Cu(II) recovery from the solution]; Z_1 and Z_2 are charges of the copper ion and competing cation, respectively; a_s is the activity of the competing cation in the solution; and A is the constant depending on the concentration of electrolyte cations in the solid phase, exchange constant, and activity coefficients of the ion being recovered and the competing ion in the solid phase and solution. This equation is general for all cases of the ion exchange. When the sorption indeed occurs by ion exchange, the $\log\varepsilon$–$\log A_s$ dependence is a straight line with the slope equal to Z_1/Z_2, i.e., to the ratio of the real charges of the exchanging ions.

When the competing ion is hydrogen ion, Eq. (1) transforms into

$$\log\varepsilon = B + Z\text{pH}, \quad (2)$$

where Z is the charge of the cation being recovered and B is the constant similar to constant A for the case of the presence of hydrogen ions as the only competing ions in the system.

The pH dependences of copper sorption, shown in Fig. 2, were treated by Eq. (2), and the Z values obtained are listed in Table 1.

Table 1 shows that the experimental data are described by curves with two linear sections and a bend

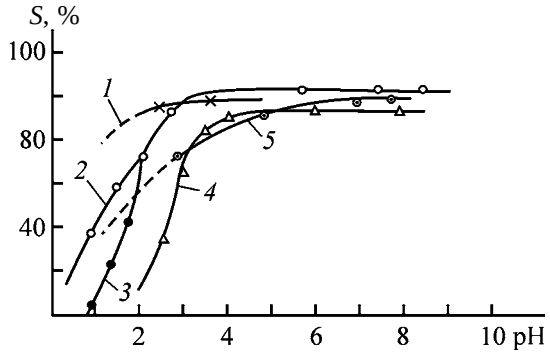

Fig. 1. Degree of metal sorption on clinoptilolite as a function of pH. C_M = 50 mg l^{-1}, m_s = 10 g, t = 30 min. (*S*) Degree of metal sorption from solution; the same for Fig. 2. (*1*) Cr^{3+}, (*2*) Cu^{2+}, (*3*) Ni^{2+}, (*4*) Mn^{2+}, and (*5*) Fe^{3+}.

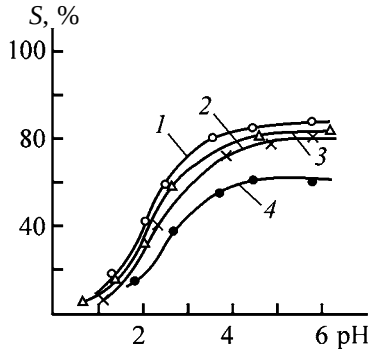

Fig. 2. Degree of Cu^{2+} sorption on natural sorbents as a function of pH. C_{Cu} = 100 mg l^{-1}, m_s = 5 g, t = 30 min. (*1*) Zeolite, (*2*) clay, (*3*) loam, and (*4*) sandy loam.

at pH 2.3–2.5. Within the pH range 0.7–2.3, the Z values are close to 1. In this case, the equivalent exchange of Cu^{2+} with Ca^{2+}, Mg^{2+}, Mn^{2+}, and other cations can occur. When copper exists as single-charged complex ions $CuCl^+$, $CuOH^+$, $CuHCO_3^+$, etc., the equivalent exchange of these ions with H^+ ion is possible.

Within the pH range 2.5–5.5, the $\log\varepsilon$–pH dependence remains linear, but in this case the other proc-

Sorbent	Z for indicated pH range	
	0.7–2.3	2.5–5.5
Zeolite	0.94	0.34
Clay	0.91	0.28
Loam	0.81	0.39
Sandy loam	0.72	0.25

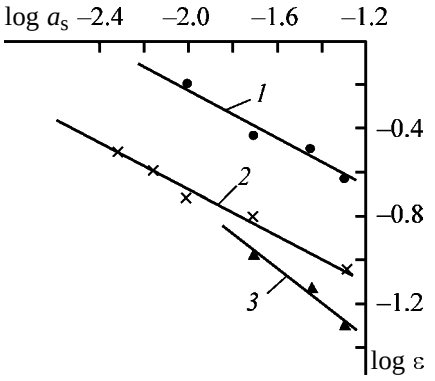

Fig. 3. Coefficients of Cu(II) distribution between clay and solution as a function of activity of competing salt cations in sorption. (ε) Coefficient of Cu(II) distribution between clay and solution and (a_s) activity of competing cations in the solution. (*1*) Na_2SO_4, (*2*) $Cd(NO_3)_2$, and (*3*) $Al_2(SO_4)_3$.

esses are superimposed on the ion-exchange mechanism such as hydrolysis of copper and other metals; the amount of H^+ ions in the system decreases, and copper complex species with the total fractional charge are formed. The contribution of the chemisorption to the interaction of copper cation with natural sorbents also increases.

We also studied the effect of Na_2SO_4, $Cd(NO_3)_2$, and $Al_2(SO_4)_3$ on the sorption Cu(II) at pH 2.25–2.31, when the interaction of Cu^{2+} with the sorbents follows the ion-exchange mechanism. The salt concentration range was 0.005–0.05 M. The experiments showed that the presence of a competing electrolyte in the solution decreases the Cu^{2+} sorption. The experimental data were treated by Eq. (1). The results are shown in Fig. 3 and Table 2. The dependences in Fig. 3 are straight lines, in accordance with assumption on ion-exchange character of interaction of Cu^{2+} with natural sorbents. As seen, suppression of Cu^{2+} sorption with cations increases in the order Na^+ < Cd^{2+} < Al^{3+}. This indicates that the competing effect of the cations added is the stronger, the higher their charge and the smaller their radius.

Table 2. Angular coefficients Z_1/Z_2 of Eq. (1) in sorption of Cu(II)

Sorbent	Salt	Z_1/Z_2
Zeolite	Na_2SO_4	0.53
	$Cd(NO_3)_2$	0.67
	$Al_2(SO_4)_3$	0.42
Clay	Na_2SO_4	0.57
	$Cd(NO_3)_2$	0.45
	$Al_2(SO_4)_3$	0.66
Loam	Na_2SO_4	0.50
	$Cd(NO_3)_2$	0.65
	$Al_2(SO_4)_3$	1.10
Sandy loam	Na_2SO_4	0.44
	$Cd(NO_3)_2$	0.55
	$Al_2(SO_4)_3$	0.75

Figure 2 shows that, in the presence of aluminum sulfate, the exchange between Cu^{2+} and Al^{3+} is approximately equivalent ($Z_1 : Z_2 = 2 : 3$) only for clay. In the other cases, the equivalent exchange was not observed. In accordance with the law of mass action, an increase in salt concentration leads to a decrease in the Cu(II) sorption in the case of ion exchange. When the electrolyte concentration in the solution increases, the ions undergo dehydration to a growing extent and, as a result, the nature of the ions involved in the ion exchange changes. In the process, the exchange "constant" is variable and depends on the degree of hydration (it increases with a decrease in the degree of hydration of ions). Thus, in the case of ion-exchange type of interaction between copper ion and the sorbent, an increase in the ionic strength of the solution, on the one hand, decreases this interaction because of competition and, on the other hand, increases interaction because of the corresponding increase in the exchange constant as a result of the cation dehydration. The real result is the sum of both processes. Such readily interpretable factor as the degree of hydration, which characterizes the deviation of the system with ion exchange from the ideal behavior, is used for a long time to explain the experimental results [7].

Under the experimental conditions (Table 2), the effect of competition of the electrolyte ions prevails over the effect their dehydration; as a result, the dependence

$$\log \varepsilon = f(\log a_s) \quad (Z_1/Z_2 \cong 0.4-0.6).$$

becomes flatter.

A decrease in the degree of hydration of ions with an increase in the electrolyte concentration results in a change in the order of sorbability, which is reflected in the Z_1/Z_2 value (Table 2). As the sorption conditions, e.g., acidity or sorbent mass, are varied, the features of the ion-exchange interaction (i.e., the ratio of charges of exchanging species Z_1/Z_2) change, and under definite conditions Z_1/Z_2 reaches the theoretical value. Thus, equations derived from the law of mass action are valid for ion-exchange sorption of Cu(II) with natural sorbents.

CONCLUSIONS

(1) Optimal conditions of sorption of Ni(II), Cu(II), Mn(II), Fe(III), and Cr(III) on clinoptilolite (95–99% recovery), and Cu(II) compounds on soils (sandy loam, loam, and clay; 77–96% recovery) were found.

(2) The equations derived from the law of mass action well describe the dependence of Cu(II) distribution between the sorbent and solution on the concentration of competing components (acid, salt).

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of $Zn(OAc)_2$ from Aqueous Solutions on the Surface of Activated Carbons Modified with Acetic Acid

Hoang Hyu Bin', H. J. Abanto-Chavez, I. A. Kozhemyakina, Hoang Kim Bong, and O. N. Temkin

Lomonosov Moscow State Academy of Fine Chemical Technology, Moscow, Russia

Received August 4, 2003

Abstract—Adsorption of zinc acetate on the surface of activated carbons modified with acetic acid was studied as a function of the process temperature, initial concentration of the salt, and pH of the initial solution.

Studies of adsorption of zinc acetate from aqueous solutions on the surface of HNO_3-treated activated carbons under conditions of solution circulation with a linear velocity of 12–15 cm s^{-1} through a fluidized bed of the support showed that the adsorption process in the dynamic mode substantially differs from that in the static mode [1, 2]. The dependences of the amount of adsorbed zinc acetate on the process temperature and velocity of solution circulation pass through extrema. The sorption catalysts obtained [2, 3] demonstrated high activity in the synthesis of vinyl acetate [4, 5]. The activity and stability in time of the catalysts prepared in the extreme mode of repeated cyclic changes of the synthesis temperature (175–205–230°C) [4] exceeded the parameters of the commercial catalyst produced by Montecatini Company (MAVC) [4].

The study of other methods of modification of activated carbons (AC) showed that oxidation with hydrogen peroxide and treatment with dilute acetic acid at elevated temperatures give similar results. The technological simplicity of the latter method makes it attractive for commercial production of catalysts of vinyl acetate synthesis.

EXPERIMENTAL

Activated carbon (AGN-2) taken as 1–3-mm particles was dried at 260–280°C and treated with 2–3 wt % acetic acid at the solution to activated carbon volume ratio of 3 : 1. The solution was continuously fed through an AC layer in the reactor for 120 min by a circulation pump at a velocity V = 6–7 cm s^{-1} at 60 ± 5°C. Then, carbon was filtered and heated at 90–95°C for 2 h. The AGN-2 parameters before and after treatment are listed in Table 1.

The catalyst was prepared under conditions of circulation of the zinc acetate solution in alternating directions (from top to bottom and vice versa) and at various solution flow velocities (within the 12–31 cm s^{-1} range). 12 cm^3 of carbon was weighed on an analytical balance and placed in a reactor. The reactor was a glass tube with filters from both sides to restrict displacement of the carbon. Then, the zinc acetate solution was circulated through a mobile carbon bed using circulation pump. The velocity of the solution flow through the reactor was monitored with a rheometer. The variation of the concentration in time was determined by a differential interferometric method. The measurement error was 5%. The best results were obtained at V = 15 cm s^{-1} as in [2, 4]. The catalyst was prepared at 25–85°C.

The specific surface area and the volume and distribution of pores of the supports and catalysts were determined from the adsorption isotherms of vapors of C_6H_6, CH_3COOH (25°C), and liquid nitrogen (78 K) at the initial pressure of 10^{-5}–10^{-6} mm Hg. Adsorption was performed by the method described in [6]. The specific surface area was calculated by the BET

Table 1. Parameters of the pore structure of AGN-2 (AGN-3) activated carbon before and after treatment with acetic acid

	cm^3 g^{-1}				
Initial	0.630	0.275	0.040	0.315	870.5
After treatment with acetic acid	0.638	0.281	0.049	0.308	868.7

1070-4272/03/7609-1418$25.00

method. The differential curves of pore size distribution were calculated from the data of adsorption of CH_3COOH vapor by the Kelvin–Kiselev equation [7].

The catalyst activity was determined in a flow reactor (for details, see [4, 8]) at 175, 205, and 230°C at a constant space velocity of the C_2H_2 + CH_3COOH + N_2 mixture (volume ratio C_2H_2 : CH_3COOH : N_2 = 4 : 1 : 1) of 4.2 h^{-1}.

The comparison of the characteristics of the initial activated carbon AGN-2 and that treated with acetic acid (Table 1, Fig. 1) shows that the pore structure of AC weakly changes after the treatment. The mesopores are somewhat widened, and their volume slightly increases (in Fig. 1, the peak heights and areas increase, and a third peak appears).

The shape of the adsorption kinetics curves at the initial concentration c_0 = 13.5 wt % and temperatures of 25 and 50°C (Fig. 2a, curves *1*, *2*) indicates that the adsorption process is complex, including monomolecular and polymolecular adsorption. An abrupt increase in the concentration of the adsorbed salt, followed by a new plateau, is observed in all the kinetic curves of $Zn(OAc)_2$ adsorption from aqueous solutions at c_0 = 13.5 wt % and 25–50°C after 80–90 min. Interaction of carbon with water is weak [in aqueous solutions of $Zn(OAc)_2$], since carbon is hydrophobic. This fact complicates penetration of the hydrated $Zn(OAc)_2$ molecules from aqueous solution into the carbon interlayer space, the more so as the size of $Zn(OAc)_2$ molecules and particularly of their associates is relatively large for micro- and supermicropores. With time, the surface is gradually coated with a monolayer of zinc acetate associates. After formation of such a layer, the adsorption accelerates (after 80–90 min), and polymolecular adsorption occurs with formation of several layers of the active component as a result of intermolecular interactions. This hypothesis accounts for the most important characteristics of both types of curves of $Zn(OAc)_2$ (Fig. 2) and acetic acid adsorption on activated carbons.

It should be noted that, at a higher zinc acetate concentration (19.6 wt %) and 25–50°C (Fig. 2b, curves *1*, *2*), no inflection was observed. The adsorption reaches a plateau within 60 min, and the plateau lies substantially higher than for the concentration of 13.5 wt %. At higher salt concentrations, the steps of monomolecular and polymolecular adsorption coalesce. At 75°C (Figs. 2a, 2b, curves *3*), maxima appear in the kinetic curves, probably due to the fact that the rapidly sorbed species of zinc acetate (associates, colloidal particles) increase the concentration of the adsorbed salt above the equilibrium concentration. With time, these species again pass into the solution, and the adsorption equilibrium is attained.

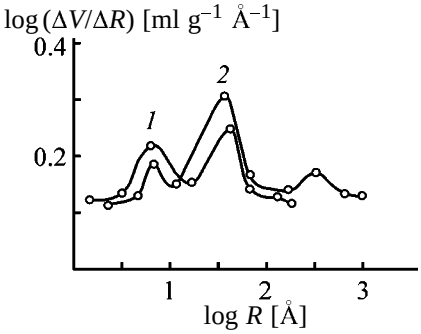

Fig. 1. Differential curves of pore volume distribution in size, $\log(\Delta V/\Delta R)$ vs. $\log R$, for activated carbon AGN-2, plotted from the isotherms of benzene vapor adsorption: (*1*) before treatment and (*2*) after treatment with 10% CH_3COOH.

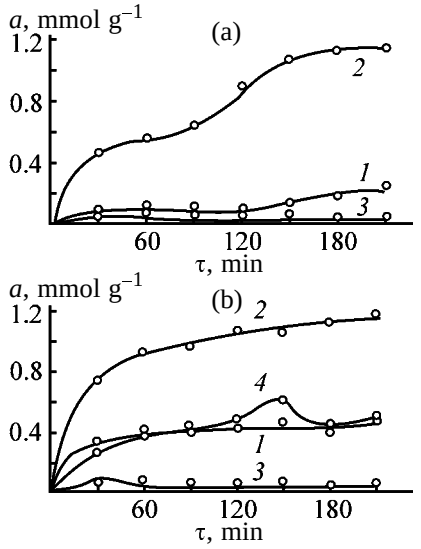

Fig. 2. Variation with time τ of zinc acetate adsorption a from aqueous solutions with CH_3COOH-treated AC at V = 15 cm s^{-1}. T (°C): (*1*) 25, (*2*) 50, and (*3*) 75; (*4*) initial AGN-2. Initial concentration of zinc acetate c_0 (%): (a) 13.5 and (b) 19.6.

The comparison of the kinetic curves of zinc acetate adsorption at 50°C and salt concentration in the solution of 19.6 and 13.5 wt % on activated carbons treated with acetic acid and untreated shows that adsorption in 60 min on treated carbons is substantially (by a factor of 2.5) greater (Fig. 2b, curves *2*, *4*), and the total amount of the adsorbed salt is two times greater (in 2 h at c_0 = 19.6 wt %).

Within the 25–85°C temperature range, the temperature dependence of the amount of the salt adsorbed on carbons treated with acetic acid passes through a pronounced maximum (Fig. 3). The amount of the acetate adsorbed reaches a maximum at 50°C.

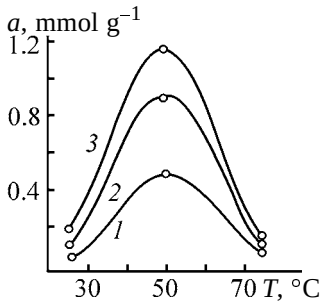

Fig. 3. Adsorption of $Zn(OAc)_2$ a from aqueous solutions on activated carbons treated with acetic acid as a function of temperature of catalyst application T. c_0 = 19.6 wt %, V = 15 cm s^{-1}. τ (min): (*1*) 30, (*2*) 120, and (*3*) 210.

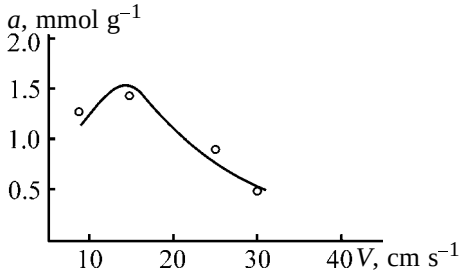

Fig. 4. Limiting adsorption capacity of $Zn(OAc)_2$ a on AGN-2 activated carbon treated with acetic acid as a function of velocity of solution circulation V. T = 50°C, c_0 = 19.6 wt %, pH_{init} 5.6, adsorption time 240 min.

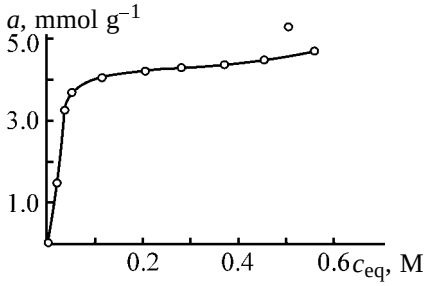

Fig. 6. Isotherm of acetic acid adsorption a on AGN-2 activated carbon at 50°C. (c_{eq}) Acetic acid equilibrium concentration; the same for Fig. 8.

Similar temperature dependences were observed previously for zinc acetate adsorption on the AC surface treated with nitric acid [2, 5] and for mercury chloride adsorption on AC [6, 9]. The dependence of the limiting adsorption capacity for zinc acetate on the velocity of the salt solution circulation also passes through a maximum (Fig. 4), which is attained at the velocity of 15 cm s^{-1}. This velocity was used when studying the temperature (Figs. 1, 3) and pH (Fig. 5) dependences of adsorption. All the isotherms of zinc acetate adsorption within the pH range 2.9–13 correspond to the Langmuir type (Fig. 5). Unexpectedly, the pH dependence of the adsorption capacity passes through a maximum (a_{max} at pH 5.6).

The study of the adsorption of acetic acid at 50°C showed (Fig. 6) that the adsorption capacity for the acid exceeds by a factor 2–3 the maximal capacity for zinc acetate (Fig. 6). Since a substantial part of acetic acid, apparently, exists on the AC surface at the temperature of catalyst drying (90–95°C) in the adsorbed state, the maximum in the pH dependence of the limiting capacity for $Zn(OAc)_2$ can be explained by preferred adsorption of neutral salt species or associates with formation of the surface complexes $H[Zn(OAc)_3]$. Adsorption of such complexes at pH 2.9 (additions of acetic acid) is lower, while increase in the pH above 8 eliminates the adsorbed acid from the AC surface, which also decreases the limiting capacity for zinc acetate. The salt species that are hydrolyzed at pH > 8 are neutralized by the desorbed acetic acid:

$$AcOH_{ads} + [Zn(OAc)(OH)] \rightleftarrows Zn(OAc)_2 + H_2O. \quad (1)$$

Therefore, pH of the solution (in the range of pH > 8) does not change in the course of adsorption. Adsorption of neutral $Zn(OAc)_2$ species at pH < 5 also does not change pH of the solution in time.

Adsorption of the neutral species is not probably single adsorption process. The maximum in the temperature dependence suggests the occurrence of the endothermic processes (decomposition of associates, ion exchange with surface acidic groups) increasing the adsorption capacity within the 25–50°C temperature range. Within this temperature range, the contribution of hydrolysis also increases [formation of Zn(OAc)(OH) and the other species]. Probably, the constancy of pH during adsorption is explained by adsorption of hydrolyzed species at simultaneous binding of acetic acid with the AC surface, i.e., by reaction (1).

Within the 25–75°C temperature range, the temperature dependence of the specific surface area S_{sp}

U_3	75	0.135	0.157	0.095	0.062	1.986	8.67	74.37	107.6
U_4	85	0.105	0.105	0.060	0.045	1.043	9.05	52.8	72.8

* Amounts of adsorbed salt at the initial concentration of 19.6 wt% and adsorption time of 4.5 h are presented. U_0 is the catalyst prepared by supporting $Zn(OAc)_2$ aqueous solution on the initial AGN-2 AC.
** Parameters of the Dubinin–Radushkevich equation.

has a maximum at 50°C (Fig. 7); upon adsorption, S_{sp} of AGN-2 decreases from 900 to 168 $m^2\ g^{-1}$.

It should be noted that the pretreatment of the support with acetic acid is the main factor determining the amount of the adsorbed salt and the surface area; the presence of the acid is important specifically in the instant of adsorption. Under optimal temperature conditions of salt application (50°C) and pH 5–6, both the specific surface area of the catalyst and its activity in the vinyl acetate synthesis are maximal (Table 2) and substantially exceed these parameters for the support untreated with the acid. It follows from Table 2 that the total volume of the catalyst pores W^Σ and S_{sp} (Fig. 7) pass through a maximum at 50°C; in spite of a large amount of the salt adsorbed, this indicates more uniform distribution of the salt under these conditions, providing very large specific surface area of the catalyst.

As seen from Fig. 8, at the $Zn(OAc)_2$ equilibrium concentration $c_{eq} < 0.45$ M, all the adsorption isotherms are of the Langmuir type, i.e., the equilibrium adsorption is formation of a monolayer. With increasing c_{eq}, the adsorption passes through a maximum, and the adsorption isotherms acquire a previously unknown shape.

At $c_{eq} < 0.4$ M, the adsorption isotherms are described by the equation

$$a = \frac{a_\infty b_i c_{eq}}{1 + b_i c_{eq}}, \qquad (2)$$

where a_∞ is maximal content of $Zn(OAc)_2$ in the AC unit weight after impregnation (mmol g^{-1}); a, adsorption (mmol g^{-1}); c_{eq}, equilibrium concentration of the salt in the solution (M); and b_i, adsorption constant.

The b_i values are 2.18×10^{-3}, 6.40×10^{-3}, and 1.85×10^{-3} at 25, 50, and 75°C, respectively, having a maximum at 50°C.

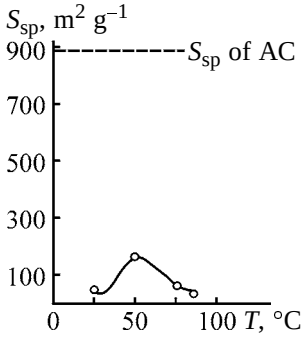

Fig. 7. Specific surface area S_{sp} of the catalyst as a function of the temperature of $Zn(OAc)_2$ application T from aqueous solutions on AGN-2 activated carbon treated with acetic acid.

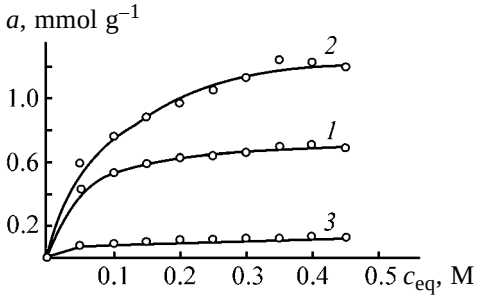

Fig. 8. Isotherm of $Zn(OAc)_2$ adsorption from aqueous solutions on AGN-2 activated carbon treated with acetic acid. Application temperature (°C): (*1*) 25, (*2*) 50, and (*3*) 75.

CONCLUSIONS

1. The study of the adsorption power of CH_3COOH-treated AC with respect to zinc acetate showed that the amount of the adsorbed salt, specific surface area, and catalytic activity in the synthesis of vinyl acetate pass through maxima at the temperature of zinc acetate application of 50°C.

2. The adsorption capacity of CH_3COOH-treated AC at 50°C passes through a maximum at pH 5–6.

3. The adsorption isotherms of zinc acetate on AC treated with acetic acid do not follow the Langmuir law.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation and Characteristics of a Cation Exchanger Based on Oxidized Anthracite

N. V. Sych, N. T. Kartel', and M. F. Kovtun

Institute of Sorption and Endoecological Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received October 28, 2002; in final form, July 2003

Abstract—The features of anthracite oxidation as influenced by temperature and time were determined. Physicochemical and sorption characteristics of the resulting cation exchanger were studied.

Many sorts of natural coals, similar to activated coals, exhibit cation-exchange characteristics, which can be enhanced by oxidative and thermal treatment [1–4]. Oxidation of ordinary activated coals at heating to 400–450°C in air yields so-called oxidized coals [1, 5] having a pronounced capability for selective ion exchange owing to the presence of surface acidic groups substituting metal cations for hydrogen ions. They are also capable to form surface complexes with metal ions and are catalytically active in some reactions. These characteristics can be efficiently used for thorough purification of process solutions, selective recovery and concentration of impurities [6], and production of high-purity substances.

It was of interest to study the possibility of production of cation exchangers based on anthracite, cheap natural coal with inexhaustible resources, high content of carbon, and low ash content.

The goal of this work was to determine the optimum temperature–time conditions of anthracite oxidation and to study physicochemical and sorption characteristics of the resulting cation exchanger.

Experiments were performed with anthracite of the A type,[1] crushed to particles with the size of 0.5–3.0 mm.

Initially anthracite was activated with steam at 850°C to the burn-out of 20, 40, and 60%. The resulting samples were oxidized in humid air at 270, 320, and 370°C to 20–30% burn-out. To estimate the efficiency of oxidation of activated anthracite, the initial (fossil) coal was also subjected to oxidation.

During oxidation, the burn-out was determined at certain time intervals, and the static exchange capacity (SEC) was determined.

In some cases, we measured pH values of oxidized samples and the volume of sorption pores with respect to benzene and methanol [7], studied the sorption activity with respect to iodine and methylene blue (MB), measured the specific surface area S_{sp} with respect to argon, and analyzed oxygen-containing groups by titration with bases of various strength (Boehm method) [8]. According to this method, the total content of oxygen-containing carboxy and phenolic groups was determined from sorption of 0.1 N NaOH solution, the content of weakly and strongly acidic groups, from sorption of 0.1 N Na_2CO_3 solution, and the content of strongly acidic carboxy groups, from sorption of 0.1 N $NaHCO_3$ solution. The content of phenolic and weakly acidic carboxy groups was determined from the corresponding difference in the SEC values.

It is well known [3] that the exchange capacity of a carbon cation exchanger is affected by the chemical nature of the raw material, its porosity, and specific surface area, i.e., by factors governing the accessibility of reaction centers at which ionogenic groups are formed. Coals and, in particular, anthracite are peculiar natural compounds with undeveloped porosity. The specific surface area of fossil anthracite is small (0.7–1.0 $m^2 g^{-1}$); therefore, it is preactivated to develop the porous system and uncover new active centers accessible for atmospheric oxygen. In turn, owing to formation of various acidic groups containing coordination-unsaturated oxygen atoms and bonded to the system of conjugated bonds at the surface of oxidized carbons, the subsequent reactions of carbons with some metal cations involve not only exchange of hydrogen ions for cations but also formation of more or less stable surface complexes in which functional groups of carbons serve as ligands.

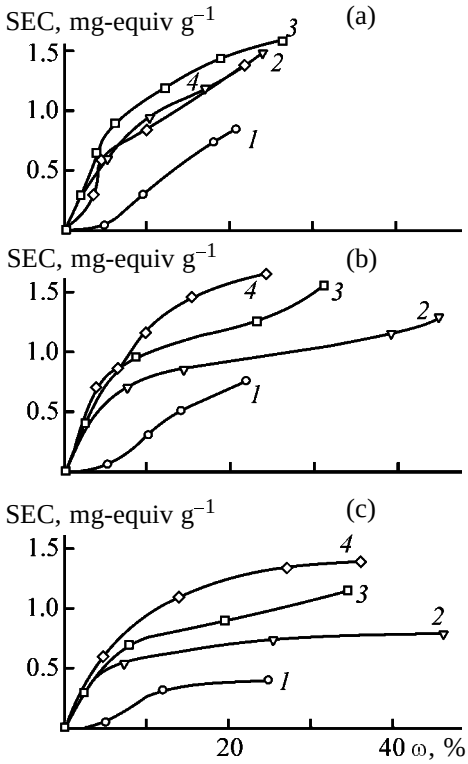

Fig. 2. SEC as a function of burn-out ω in oxidation of the (*1*) initial sample of anthracite and samples preactivated to the burn-out of (*2*) 20, (*3*) 40, and (*4*) 60%. Oxidation temperature, °C: (*1*) 270, (*2*) 320, and (*3*) 370.

A kinetic study of SEC growth with heating is important for understanding the course of anthracite oxidation, in particular, for determining the optimal temperature interval of stability of oxygen-containing groups participating in cation-exchange processes.

The kinetic curves shown in Figs. 1a–1d indicate that the rate of accumulation of functional groups in all the considered cases increases with heating. Thus, the degree of oxidation characterized by SEC equal to 1.0 mg-equiv g^{-1} is attained in several tens hours at 270°C, in 6–8 h at 320°C, and in 2–4 h at 370°C. Preactivation exerts no significant effect on the shape of the kinetic curves: they are linear in the initial portion, with subsequent tendency to saturation. For the initial anthracite, the curves are concave, which is caused by inefficient oxidation in the initial portion of the curve, evidently owing to low development of the surface. For the samples of anthracite preactivated to 20–60% burn-out, the reached values of SEC are close to each other. In oxidation of the initial anthracite, the SEC is considerably lower; in this case, the material expands.

Figures 2a–2c show that formation of protonogenic groups at the surface of anthracites in their oxidation is accompanied by different weight loss (burn-out) depending on the treatment temperature. At 270°C, the samples of preactivated anthracite are characterizad by abrupt increase in SEC, whereas for the initial anthracite accumulation of SEC is decelerated and the reached values of burn-out are considerably lower. At higher oxidation temperature, the difference between the initial and activated samples becomes more pronounced. The higher the burn-out in activation, the higher the reached values of SEC at similar burn-out values.

It is also seen from Fig. 2 that the range 270–320°C is optimal for oxidation of activated anthracite. Apparently, at higher temperatures, burning of carbon is intensified and, correspondingly, the fraction of surface functional groups decreases.

As subjects for sorption studies, we took the samples of activated and oxidized anthracites whose characteristics are listed in the table.

The characteristics of the sorbing materials were estimated by sorption of Cu^{2+}, Pb^{2+}, Cd^{2+}, Zn^{2+}, Cr^{2+}, Co^{2+}, Mn^{2+}, Fe^{3+}, and Ni^{2+} ions from the Ringer solution containing NaCl 9.0, KCl 0.42, $CaCl_2$ 0.24, and $NaHCO_3$ 0.15 g l^{-1} as a salt background. The sorption tests were carried out at pH 4 under static conditions at the ratio solid : liquid = 1 : 100 and contact time of no less than 6 h at continuous stirring. The concentration of ions in the model solution simulating a multicomponent system containing Ca^{2+} ions before and after attainment of the sorption equilibrium was determined by the standard procedure on an S-115M-1 atomic absorption spectrophotometer.

Knowing the filtrate concentration before (c_0) and after (c_s) sorption, the weighed portion of the sorbent m, and the volume of the sample solution V, we evaluated the sorption A and the distribution coefficient K_d of metal ions by the formulas

$$A = (c_0 - c_s)V/m, \qquad K_d = A/c_s \times 100.$$

The sorption isotherms presented in Fig. 3 show that the samples of oxidized anthracite have, as expected, a higher ability to sorb ions of heavy metals than the initial activated analogs.

The sorption efficiency in each case was evaluated by comparison of the K_d values for activated and oxidized samples under standard conditions: c_{eq} = 1 mg l^{-1} and c_{eq} = MPC (maximum permissible concentration) of the studied cations (Fig. 4). According to GOST (State Standard) 2874–82, the MPC values in drinking water are as follows: Cu^{2+} 1.0, Pb^{2+} 0.03, Zn^{2+} 5.0, Cr^{3+} 0.05, Mn^{2+} 0.1, Fe^{3+} 0.3, Co^{2+} 0.1, Ni^{2+} 0.1, and Cd^{2+} 0.001 mg l^{-1}. With respect to the sorbability, the cations can be ranked in the following order: for activated anthracite at c_{eq} = 1 mg l^{-1}, $Fe^{3+} > Cu^{2+} > Pb^{2+} \cong Cd^{2+} > Mn^{2+} > Ni^{2+} > Zn^{2+} > Cr^{3+} > Co^{2+}$; at c_{eq} = MPC, $Fe^{3+} > Cd^{2+} > Cu^{2+} > Pb^{2+} > Mn^{2+} > Ni^{2+} > Co^{2+} > Zn^{2+} > Cr^{3+}$; for oxidized anthracite at c_{eq} = 1 mg l^{-1}, $Cu^{2+} = Pb^{2+} > Fe^{3+} > Cd^{2+} > Mn^{2+} > Ni^{2+} > Co^{2+} > Zn^{2+} > Cr^{3+}$, and at c_{eq} = MPC, $Cd^{2+} > Pb^{2+} > Fe^{3+} = Cu^{2+} > Mn^{2+} > Ni^{2+} > Co^{2+} > Zn^{2+} > Cr^{3+}$.

The diagram of the K_d values (Fig. 4) shows that the maximal sorption selectivity is observed for Cu^{2+}, Pb^{2+}, and Cd^{2+} cations. In this case, the sorption power of oxidized samples increases in sorption of Cu^{2+} by a factor of 3.5, Cd^{2+}, by a factor of 6, and Pb^{2+}, by a factor of 18. For the other cations, K_d increases by a factor of 2–3. This activity series of the ions makes especially promising the use of anthracite cation exchanger for purification of water to remove toxic heavy metals and also for recovery of microimpurities of Zn^{2+}, Cr^{3+}, Co^{2+}, Mn^{2+}, and Ni^{2+} ions in conditioning of process solutions.

CONCLUSION

(1) The efficiency of oxidation of anthracite with humid air and the resulting values of static exchange capacity are governed by temperature conditions of the process and also the degree of preactivation of anthracite. The optimal temperature range to attain

Physicochemical and porosimetric characteristics of carbons used in sorption studies

the maximal static exchange capacity is 270–320°C at 40–60% burn-out of preactivated samples.

(2) Sorption studies showed that oxidation of activated anthracite increases the volume of sorption pores, specific surface area, and, as a consequence, sorption activity with respect to tested substances. In addition, oxidized anthracite is an effective carboxylic cation exchanger with respect to multicharged metal ions.

(3) The series of activity of Cu^{2+}, Pb^{2+}, Cd^{2+}, Zn^{2+}, Cr^{3+}, Co^{2+}, Mn^{2+}, Fe^{3+}, and Ni^{2+} ions in sorption with activated and oxidized anthracite samples under standard conditions (c_{eq} = 1 mg l^{-1} and c_{eq} = MPC) were established. Fairly high selectivity of sorption of Cu^{2+}, Pb^{2+}, and Cd^{2+} ions with oxidized anthracite from multicomponent salt solution was revealed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Topical Problems Associated with Utilization of Lead Battery Scrap

A. G. Morachevskii

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received July 23, 2003

Abstract—The review summarizes data on the present state of organization of collection and processing of lead battery scrap, the most important variety of lead-bearing secondary raw materials. Hydrometallurgical procedures ensuring recovery and refining of lead with the highest environmental safety are considered in detail. The review is based on publications of 1997–2002.

In the last decade, much attention has been given to collection and processing of lead-bearing secondary raw materials, and in the first place to utilization of spent lead batteries. This problem is becoming increasingly important in economical and environmental regard from year to year [1]. At present, lead batteries are the most widely used secondary chemical power source. These batteries include starter (used for electric start of combustion engines), traction (feeding electric motors of vehicles), and stationary (used in radioelectronic devices and as emergency power sources) batteries. There is no serious alternative to lead batteries in transportation. The rise in manufacture of electromobiles also leads to increasing demand for batteries [2].

According to the International Lead and Zinc Study Group (ILZSG), the main amount of consumed lead is expended for manufacture of lead batteries (%): 72.1 in 1997, 74.2 in 1998, and 74.9 in 1999 [3]. It should be noted for comparison that only 45% of lead was expended for manufacture of lead batteries in 1973 [4]. A considerable amount of lead was spent at that time for production of tetraethyllead (antiknock additive to motor fuel) [5]. Beginning in 1996, tetraethyllead has not been used in any of foreign countries [6].

At present, world's annual output of lead exceeds 6 million tons: 5999 thousand tons in 1998, 6277 thousand tons in 1999, and 6532 thousand tons in 2000 [3]. The monograph [7] gives somewhat smaller figures for the manufacture of refined lead: 5634 thousand tons in 1998 and 5620 thousand tons in 1999. Globally, the fraction of lead produced from secondary raw materials is no less than 55%, being as high as 85–100% in some countries. For reference, not so long ago, in 1986, the manufacture of refined lead from ore exceeded its production from secondary raw materials: the total output was 4009 thousand tons, amount produced from primary raw material was 2179 thousand tons, and that from secondary raw materials, 1830 thousand tons [7]. According to Besser's data [3], 88% of lead manufactured in Russia in 2000 was obtained by processing secondary raw materials (battery scrap, cable sheaths, wastes from battery plants). The main and the most difficultly processed kind of lead-bearing secondary raw materials is battery scrap. The average service life of lead batteries is, depending on the battery purpose and working conditions, 3–5 years, and the extent of recovery of the metal from these batteries is determined by processing technology, occasionally being very high.

Despite that Russia occupies the fourth place in the world as regards its total lead resources (after the United States, Australia, and Kazakhstan), the quality of Russia's deposits is, on the whole, inferior to that in foreign countries [7]. Under present-day conditions, gross investment in the development of the ore base of Russia's lead industry is hardly expectable. Only one third of the exhausted resources of lead is reproduced [8]. In 2001, the manufacture of lead in the form of concentrates was 31.5% of the level of 1990 [7].

Metallurgical plants for ore processing, which remained in the territory of Russia after the geopolitical changes of 1991, Elektrotsink Joint-Stock Company (Vladikavkaz) and Dal'polimetall Joint-Stock Company (Primorskii krai), are equipped with outdated apparatus and do not undergo any reconstruction. Lead is manufactured at the Elektrotsink plant by the

1070-4272/03/7609-1427$25.00

classical scheme of blast smelting, with stock agglomeration done by an imperfect method. The smelting of lead at the Dal'polimetall combine is done with the use of reactive furnace smelting [7].

All over the world, measures are taken for organizing efficient collection of batteries and improving the flowsheet of their utilization. It should be constantly kept in mind that, being economically important, these problems are of profound environmental significance. As regards its impact on living bodies, lead belongs to highly toxic substances, which requires that batteries should be collected to the maximum possible extent [9–14]. In addition to lead, battery scrap contains such toxic substances as antimony and sulfuric acid electrolyte. Spent lead batteries are an important source of environmental pollution with lead in our country [12]. According to expert estimates, dumps, transport yards, and other places all over the territory of Russia contain up to 1 million tons of lead in battery scrap [10], with this figure increasing by 50–60 thousand tons annually. According to other estimates [15], the amount of battery scrap may increase, at the existing state of battery collection and processing, by 150–200 thousand tons every year. Absolutely unacceptable are storage of spent batteries in garages and their removal to dumps, irrespective of the type of wastes to be stored there.

Already in 1998, the developed countries achieved a high level of battery scrap collection (%): UK more than 90, Germany 95, Italy 85, US up to 98, France ~90, Sweden nearly 100, and Japan ~90 [15, 16]. An important role in utilization of lead batteries is played by international and national regulations in this field, effective system for scrap collection and processing, environmental consciousness of citizens, and understanding of the importance of the problem at all levels of the society. In the United States, utilization of batteries is stimulated and supported by the federal administration [17], an infrastructure is created for collection and utilization of batteries, and all battery components find new application. At the same time, there is no system for collection and utilization of spent batteries in Russia, including its central regions, and the efficiency of the existing procedures is poor [18]. Vasin [19] studied the present state of the system for collection of spent batteries in the Moscow region and made an attempt to assess the damage inflicted on the nature by unprocessed batteries.

The Russia's system for processing of nonferrous scrap metals is affected by shortcomings of licensing of this kind of activities [20]. According to the available estimates, up to 70% of the turnover of nonferrous scrap metal and wastes is illegal [21]. One of manifestations of the illegal turnover of scrap and waste are illegal plants. During the years in which Russia has been passing to market economy, small plants appeared which smelt various metals from scrap and waste using low-level technology, without due systems for gas purification and appropriate regulations of storage and disposal of wastes. The products manufactured at plants of this kind have extremely poor quality, but their cost is lower than that at licensed plants with higher-level technology. All these factors largely refer to processing of lead-bearing secondary raw materials.

The lead branch of the nonferrous metallurgy in Russia should be based, in the first place, on utilization of secondary raw materials, have regional structure, and use environmentally safe technologies.

The presently existing flowsheets for processing of lead batteries were analyzed in [15, 22–27]. All the processing plants in the developed countries deal with spent batteries with undischarged electrolyte, in conformity with the existing regulations. The system for collection and transportation of such batteries does not assume any intermediate yards or areas for their opening and crushing. Discharge and utilization of the electrolyte, and other operations, are carried out directly at the plants processing the battery scrap. Unfortunately, the regulations operative in Russia make it possible to receive all kinds of lead batteries "..with discharged electrolyte." Thus, utilization of a toxic electrolyte containing suspended lead oxides and sulfides, which belong to substances of the first degree of hazard, is not subject to any regulations [3].

Two fundamentally different technologies are used in processing of lead battery scrap. The first of these includes preliminary treatment of the battery scrap: crushing and separation of organic components (ebonite, polypropylene, polyethylene, polyvinyl chloride) from lead-containing fractions, oxysulfate and metallic. The last two fractions are processed using various techniques to give the corresponding commercial products.

The second technology consists in smelting of a stock composed of unprocessed batteries with removed electrolyte, fluxes, and fuel. This process yields lead bullion, which should be refined. The organic components burn out, and sulfur passes partly into matte and partly into the gas phase. Chlorine contained in polyvinyl chloride reacts with lead to give lead chloride passing into dust, which requires further processing to recover lead. The process is mainly

carried out in blast furnaces. Irrespective of a technology adopted, plants usually perform the whole set of procedures for scrap processing, from separation of electrolyte and its processing to manufacture of lead, its alloys, and some intermediates. Each of the two technologies has its own advantages and disadvantages. According to a review [15], no more than 10–15% of the world's manufacture of secondary lead from spent batteries was accounted for by smelting of unprocessed lead battery scrap in blast furnaces by 1998.

In view of the existing tendency toward use of chlorine-free separators, the amount of dusts obtained in blast furnaces will decrease. Replacing ebonite with other materials in fabricating battery cases makes lower the total content of sulfur in the battery scrap, diminishes the amount of the forming mattes, and decreases the content of sulfur in the gas phase. Despite these positive tendencies, construction of blast furnaces and gas-purification systems requires gross investment, necessitates processing of the forming intermediate products (dusts and mattes), leads to formation of lead bullion with high content of antimony, and contradicts the present-day conservation trends. In 1997–1998, a German company Warta assembled a blast furnace for processing of lead-bearing secondary raw materials at Kursk battery plant [28]. Unfortunately, it was impossible to find in the literature any data concerning the results obtained with this installation. In the author's opinion, lead battery scrap is a specific kind of secondary raw materials, whose processing must differ significantly in equipment-related and technological regard from that of any type of lead-containing ores. From the standpoint of environment protection and investment in construction of regional plants for utilization of lead batteries, it is hardly advisable to employ technologies that involve smelting of unprocessed battery scrap in blast furnaces. In view of the present-day situation in Russia, there is no reason to create new plants for joint processing of ore and secondary raw materials.

In the case of preliminary cropping of batteries, irrespective of the way in which this is done, the key issue is the method for lead recovery from the oxysulfate fraction. The active pastes from the positive and negative plates of a battery fall into this fraction. On the average, an active paste washed with water contains (wt %) Pb 73.5, Sb 0.3, As up to 0.004, Cu 0.1, Fe 0.05, and SO_4^{2-} 16.7 [14]. The main components of the active paste are $PbSO_4$ and PbO_2, and, to a lesser extent, $PbO \cdot PbSO_4$, Pb_2O_3, and Pb. With account taken of the fact that lead oxides are rather easily reduced to metal by any carbonaceous reducing agent at relatively low temperature (720–740°C), it seems appropriate to convert lead sulfate into lead hydroxide or carbonate by a simple hydrometallurgical procedure (desulfation or desulfurization). In this case, the problem of sulfur utilization is solved completely, with sulfur passing into the aqueous phase in the form of a soluble sulfate. The desulfation process is employed in quite a number of flowsheets at plants in Western countries, its environmental advantages being indubitable. Physicochemical and technological studies of the desulfation process were considered in detail in a review [29]. The best suitable reagents for the desulfation process are aqueous solutions of sodium hydroxide or carbonate [27, 30]. The reaction, which is not subject to any essential kinetic hindrance and is sufficiently fast, is based on much lower solubility products (SP) of lead(II) hydroxide or carbonate, compared to lead sulfate. For example, SP = $10^{-7.8}$ for $PbSO_4$ and varies with temperature only slightly. At the same time, SP for $Pb(OH)_2$ and $PbCO_3$ is, respectively, $10^{-15.3}$ (20°C) and $10^{-13.1}$ (25°C) [29].

Desulfation gives commercial sodium sulfate conforming to quality standards as regards its content of heavy metals [31]. Utilization of sulfur in the form of sodium sulfate has also been recommended by Zaikov and co-authors [32]: in processing of anodic sludges formed in manufacture of copper foil, lead(II) sulfate is converted into carbonate.

An important factor affecting the extent and rate of desulfation is the degree of crushing of the active paste being processed. A factor hindering the desulfation process in repeated use of a mother liquor is accumulation of Na_2SO_4. It was also noted in [11] that the most advanced method for utilization of sulfur is desulfation to give commercial sodium sulfate, gypsum plaster, etc. Mention has been made of the advisability of using potassium carbonate for desulfation of active paste from lead battery scrap [33]. This conclusion is substantiated by the fact that K_2CO_3, being a by-product of alumina manufacture from nepheline raw materials, is produced by the Russian industry in sufficient amounts and the market of potassium sulfate is less saturated than that of sodium sulfate. It was noted in [27] that use of K_2CO_3 can be substantiated not only economically. It is known that no double salt similar to $NaPb_2(CO_3)_2OH$ is formed with potassium carbonate, which facilitates desulfation.

Industrial instrumentation of the desulfation process poses no difficulties. Further processing of the desulfated material consists in thermal decomposition of lead carbonate and concomitant compounds (basic

lead carbonates) and subsequent reduction of lead oxides. Investigations have shown [34] that decomposition of $PbCO_3$ onsets under usual conditions already at 280°C, being complete at 510°C. Reduction of lead(IV) oxide contained in the desulfated paste by solid carbonaceous reducing agents onsets at 380–390°C and is complete at 400–410°C. It should be kept in mind that the saturated vapor pressure of lead at 1000 K is as low as 1.45 Pa (1.09×10^{-2} mm Hg) [35].

An alternative process for recovery of lead from battery scrap, based on dissolution of lead sulfate in aqueous NH_4OH and subsequent recovery of lead by cementation with metal powders, was proposed in [36]. The process was performed in autoclaves at 100°C at a stirring rate of 300 rpm. The effect of various factors on the course of the process was analyzed.

The apparatus for reduction of the desulfated paste and the choice of reducing agents may vary depending on the production scale, investment, and availability of one or another type of equipment. Preliminary briquetting of the starting material with coal powder has no effect on the reduction process. An important conclusion is that lead(II) oxide is reduced with sufficient rate and completeness at a temperature not exceeding 720–740°C.

As already noted, desulfation must be preceded by processing of lead battery scrap in one or another way. According to [15], already by 1998, more than two thirds of waste lead batteries were utilized in the world's practice after preliminary processing. According to the available evidence, the flowsheet with preliminary scrap processing is adopted at the Verkhneivinskii plant of nonferrous metals [37]. Mechanized battery scrap processing is used at the Ryaztsvetmet plant [38].

Let us consider some other flowsheets developed or being developed in Russia with account of the domestic economic capacity. The Gintsvetmet State Research Center of the Russian Federation (Moscow) proposed a technology for processing of battery scrap and other kinds of lead-bearing secondary raw materials with the use of soda-free smelting. The scheme includes mechanized scrap processing, melting of the metallic fraction in a melting kettle, electrothermal smelting of the oxysulfate fraction, refining of lead bullion, and processing of a number of intermediate products, with their subsequent transfer to the corresponding plants (copper matte, arsenic-containing alloy, slag). The main equipment was designed for a plant with output capacity of 15 000 t of lead per year.

A decision has been made, on the basis of an analysis of technologies for cropping battery scrap into fractions, that it is appropriate to accept the offer of an Italian company, Engitec Impianti SpA. The CX-compact installation designed by this company is environmentally safe, has small size, and separates battery scrap into five fractions: metallic, oxysulfate, polypropylene, polyvinyl chloride, and ebonite. The main characteristics of the installation were reported in [23], with references given to publications with detailed description of the CX-compact installation. According to the available data [15], the installation designed in Italy has found wide use in numerous countries.

The central place in the technology proposed by the Gintsvetmet Institute is occupied by matte- and soda-free electric smelting. To smelting are directed, together with the oxysulfate fraction, oxide dross obtained in melting of the metallic fraction in melting kettles and dusts caught in cleaning gases formed in the course of the smelting itself. The theory and technology of the process have been described in a number of reports, beginning in 1988 [38–43]. The authors proceed from the assumption that melts are vigorously agitated in electric smelting by convective flows generated at the electrodes. This creates conditions for reactive smelting; sulfides completely react with oxides and sulfates to give molten lead, rapidly flowing down [40].

The lowering of the temperature of slag melting and, correspondingly, that of the process as a whole is due to the fixed $FeO : SiO_2 : CaO$ ratio and increased content of lead silicates in the slag. No soda is introduced into the stock. Dosing of a reducing agent (coke breeze) controls reduction of sulfates to sulfides, but only in amount necessary for their reaction with oxides to occur. Release of sulfur dioxide into the gas phase shifts the reaction equilibrium and favors complete consumption of the sulfides, which rules out matte formation.

In [39], the experience of utilization of lead-bearing secondary raw materials at the Ryaztsvetmet plant with the use of electric smelting was summarized. The results obtained were compared with the parameters characteristic of other methods for battery scrap processing: smelting in shaft and short-drum-type furnaces. Here, only the results obtained using the Gintsvetmet technology are considered. In this case, the stock contains battery scrap (80–90%), coke (3–4%), and slag-forming materials (5–10%). The smelting products contain 92–94% lead bullion, 3–5% slag, and 4–7% dust. The extent of lead recovery from the raw

materials being processed into lead bullion is as high as 95%. The process temperature is 1100°C [40].

In [40, 42], mention was made of quite a number of advantages of soda-free matte-free electric smelting over battery scrap processing in shaft or short-drum furnaces: the amount of forming waste gases is 3–5 times smaller; also lower is discharge of lead-containing dust into the atmosphere; the technology is virtually waste-free.

A comparative analysis of the feasibility of industrial methods for battery processing was also made in [25, 26]. In the opinion of Koshelev and co-authors [25], certain advantages are observed in the case of melting of unprocessed batteries in a blast furnace; the technology was assessed on the basis of the results obtained at a plant in Germany. Also promising is application of the Vanyukov process to melting of unprocessed battery scrap (melting in a liquid bath). In this case, a continuous operation mode, complete burning of organic components, and high economical and environmental characteristics are achieved. A detailed critical analysis of this standpoint was presented by Besser [26].

Of interest are publications concerned with relatively low-temperature processes of melting of lead-containing materials [44, 45]. One of these [44] suggests processing of the oxysulfate fraction of lead battery scrap by low-temperature soda smelting, with the system Na_2CO_3–NaCl, in which a eutectic mixture exists at 634°C (36.5 mol % NaCl), recommended as salt flux. Sodium sulfate forming in exchange reaction between lead sulfate and soda does not lead to any rise in the melting point of the complex salt system. A carbonaceous reducing agent is introduced after exchange processes in the system are complete, at about 700°C. Thus, the reaction between lead sulfate and sodium carbonate occurs in a salt melt. The possibility of achieving, in principle, a high recovery of lead in the form of metal at minimum amount of noxious substances (sulfur dioxide, chlorine, lead chloride, lead vapor) discharged into the atmosphere was noted in [44].

In [45], melting of lead-containing materials in a lead bath under a layer of sodium hydroxide flux at 550°C was suggested. Experiments were carried out on laboratory scale. A 0.05-kg amount of NaOH is consumed in the bath per 2.5 kg of wastes (lead-rich materials, lead battery scrap). The extent of lead recovery is 98 and 75% in smelting with and without flux, respectively. Spent flux can be used for desulfation of the active paste from lead battery scrap.

An extensive series of recent investigations at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, in Yekaterinburg was devoted to physicochemical foundations of processing of lead-containing materials with the use of carbonate melts [46–55]. The method of thermodynamic modeling was widely used in these studies to determine the possibility of occurrence of one or another high-temperature process and to assess tentatively the behavior of impurities. The essence of the technique was described in detail in [56].

A detailed thermodynamic analysis of the possibility of reducing PbO, $PbCl_2$, PbS, and $PbSO_4$ under equilibrium conditions with carbon in carbonate melts of various compositions yielded data on the effect of temperature and other factors on the extent of lead recovery [48, 54]. The monograph [55] mainly discusses two issues: processing of various kinds of lead-containing raw materials, including the active paste of lead batteries, in carbonate melts at temperatures of up to 1000°C and electrochemical processing of oxidized wastes in hydroxide melts. A thermodynamic analysis and laboratory and pilot-plant tests demonstrated that use of molten carbonates ensures nearly 100% reduction of lead compounds, nearly theoretical consumption of a reducing agent, small volume of waste gases, and dramatic decrease in the amount of the forming dust. It should, however, be mentioned that no detailed flowsheet is given in the monograph [55] and other publications of its authors for the case of lead battery scrap. Electrochemical processing of lead oxide with the use of an alkali–carbonate electrolyte can hardly compete with the rapidly occurring pyrometallurgical reduction of lead(II) oxide with any carbonaceous reducing agent at 720–740°C [57, 58]. Use of ionic melts in the technology for processing of lead-bearing secondary raw materials has been described in detail previously [59, 60].

Quite a number of recent investigations have been devoted to physicochemical foundations and technologies of lead refining. In [61, 62], the possibility was demonstrated for lead purification to remove antimony by introducing aluminum into the melt at 700–720°C with subsequent slow cooling of the metal to 340–350°C. Experiments and theoretical calculations produced well-consistent results. Samples taken in the course of cooling contain AlSb intermetallic compound. The content of antimony in lead can be diminished to 0.005 wt %. For deeper purification of lead to remove antimony and some other impurities, it is advisable to use a method based on anodic polarization of a metal being refined in molten sodium hydroxide. In large-scale experiments, 35 kg of a metal

to be refined was charged into the electrolyzer and the yield of refined metal was 99.0–99.5% in terms of charged metal at a process temperature of 340–370°C. The content of antimony can be diminished to 0.001%. Simultaneously, it is possible to remove aluminum, tin, arsenic, and iron, which are not found in lead after anodic polarization, at detection limit of 1×10^{-3}%, irrespective of their initial content [64].

Omel'chuk and co-authors used for selective extraction of tin, bismuth, antimony, and arsenic impurities from lead the method of cathodic refining with molten sodium hydroxide [65]. As is known [59, 60], the method consists in that sodium is deposited on the surface of the refined metal acting as cathode, with the corresponding intermetallic compounds formed. Here, it should be emphasized that deposition of sodium and compound formation constitute a single electrochemical event. Under certain conditions (temperature, current density, etc.), these compounds pass from the cathodic metal into electrolyte. By varying the electrolysis conditions, it is possible to control the order in which the alloy components are extracted. According to the authors' data [65], the method of cathodic refining makes it possible to extract such components as bismuth, antimony, tin, and arsenic virtually completely from lead-based alloys. Highly important for processes of electrochemical refining with the use of ionic melts as electrolyte, and also for other refining techniques involving intermetallic compounds, are their thermodynamic characteristics, and also the thermodynamic properties of the corresponding liquid phases.

The general principles underlying various kinds of intermetallic processes applicable to removal from lead of such impurities as bismuth, antimony, arsenic, and tellurium were considered in [66]. Some investigations have been concerned with thermodynamic properties of liquid alloys and solid phases in the sodium–tellurium system [67], sodium bismuthide (Na_3Bi) [68], liquid alloys in the systems sodium–bismuth and lead–sodium–bismuth [69, 70], and liquid and solid phases in the system sodium–antimony [71]. The pseudobinary system $Pb–Bi_2Mg_3$ was studied using the calorimetric method, integral excess Gibbs energies at 973, 1023, and 1073 K were calculated, and the phase diagram of the system was described [72]. Data on binary systems of edge components were used to calculate in terms of various geometric models the thermodynamic characteristics of liquid alloys in the system lead–magnesium–bismuth [73].

As is known [4, 35], the classical method for bismuth elimination from lead bullion is based on physicochemical interactions in the system Pb–Bi–Ca–Mg–Sb. In [74], alloying processes in the systems Pb–Ca, Bi–Ca, and Pb–Bi–Ca were analyzed and the process of lead purification to remove bismuth at its small content by adding calcium was discussed. Another study [75] considered and compared published data on the phase diagram and thermodynamic properties of the system Ca–Sb and discussed, with account of the results obtained, the equilibrium in the system Ca–Pb–Sb.

A number of investigations have been devoted to analysis of electrochemical processes involving aqueous electrolyte solutions and to study of the nature of solutions of lead compounds in various media, which are of interest for technological practice. In [76], the processes of lead refining and anodic dissolution of Pb–Sn–Sb alloys with an electrolyte based on hydrosilicofluoric acid were discussed. In lead refining, the current efficiency by lead is as high as 99% at current density of 100 A m^{-2} and specific electric power consumption of 30–40 kW h t^{-1}. Nikitin and co-authors proposed a process for lead refining to ultrahigh purity by anodic dissolution in a perchlorate electrolyte with introduction into the anodes of components binding impurities. The theoretical foundations and general principles of this refining technique were considered in detail in [35, 77].

Lebedev [79] studied recovery of lead from anodes in which the total content of antimony, bismuth, and tin may be as high as 12 wt %. The electrolysis is carried out in a sulfamic electrolyte. The metal obtained on the cathode corresponds, as regards its chemical composition, to S1, S2, and S3 brands with the content of the base component of 99.985, 99.95, and 99.90%, respectively.

The solubility of lead sulfate in the quaternary systems $PbSO_4–NaCl–HCl–H_2O$ and $PbSO_4–NaCl–H_2SO_4–H_2O$ has been determined [80]. It was shown that introduction of HCl intensifies chloride leaching of lead. Yurkinskii and co-authors [81, 82] have studied complexation of lead(II) with hydroxide ions under various conditions. In electrolysis of impurity-free alkaline solutions of lead (25 g l^{-1} lead, 100 g l^{-1} alkali, temperature 50°C, current density 100 A m^{-2}), a finely dispersed powder of lead is obtained with a high current efficiency at the cathode, and lead dioxide PbO, at the anode (current efficiency 22.4%) [83].

Analysis of reports published in 1997–2002[1] points to the impelling need, from the economical and en-

[1] Information about patents and inventor's certificates can be found in [1] and is not considered in this review.

vironmental viewpoints, for cardinal improvement of the state of affairs with collection and utilization of lead battery scrap in Russia. At the same time, there is no doubt that processing of lead-bearing secondary raw materials must be the primary source of lead in Russia. There is no reason to expect large-scale manufacture of lead from ore in the near future. The massive import of batteries from abroad and the work of domestic battery plants indicate that there is no danger of any deficiency of lead-bearing secondary raw materials, provided that they are collected properly. Only the already accumulated amount of battery scrap and other kinds of lead-bearing secondary raw materials will be sufficient for satisfying Russia's need for lead for many years to come [84].

Efficient organization of a State-supported system for collection of spent lead batteries in each region of Russia is necessary. Also rather important is improvement of the system for licensing of plants that process battery scrap and other lead-containing materials, irrespective of the scale of production at these plants [20, 85].

As a long ago as 1993, and later [22, 23, 57], we pointed to the advisability of a regional approach to setting up comparatively small-scale plants for processing lead battery scrap and other kinds of lead-bearing secondary raw materials (10–15 thousand tons of lead and lead alloys per year). This conclusion was based on the environmental hazard of these widely occurring technological wastes, which should not be transported to large distances.

A similar position was maintained by Kolotyrkin and Tkachek [86]. In their opinion, lead batteries should be utilized by small plants (100–150 thousand batteries per year, or 2500–3000 t of lead processed annually). Pashchenko [87] noted the necessity for creating a great number of plants for battery scrap processing, each with annual capacity of up to 3.0–3.5 thousand tons of the metal, in regions with gross consumption of batteries and mass flows of secondary raw materials.

It seems rather important to solve two mutually related problems: to choose the optimal capacity of a separate plant for processing of lead-bearing secondary raw materials and to select the flowsheet for processing of battery scrap as the main and most difficultly processed kind of secondary raw materials. With account of the vast territory of Russia, existence of remote regions, transport difficulties, high cost and environmntal unsafety of the transportation of lead battery scrap, the above problems cannot have a unique solution. Specific features of our country do not allow simple copying of the foreign experience, but this experience cannot be disregarded, either.

To supply large consumers of lead, and battery plants in the first place, with a sufficient amount of lead and its alloys and compounds, the unit capacity of a subsidiary plant for processing of not only secondary raw materials, but also the waste formed in manufacture of batteries must correlate with the demand and capacity of the main plant, battery manufacturer. Another approach can be used in estimating the unit capacity of a plant for processing of battery scrap in one or another region, irrespective of whether or not it has lead consumers. In this case, the minimum investment and sufficient environmental safety can be achieved by constructing plants with annual capacity of 10–15 thousand tons of lead or lead–antimony alloy.

Despite the quite acceptable difference in the flowsheets used at plants for processing of lead-bearing secondary raw materials, characterized by different output capacities and specific factors, general approaches can be formulated, which ensure environmental safety and feasibility of production.

In view of the dissimilar chemical natures of lead compounds and different types of impurities in ore and in battery scrap, it seems inappropriate to process these two kinds of raw materials simultaneously in the same apparatus. At the same time, joint processing of battery scrap with wastes formed in manufacture of batteries and other kinds of lead-bearing secondary raw materials is quite acceptable.

In choosing one or another flowsheet or separate operation, account should be taken of the fact that their environmental hazard is associated with the following factors: discharge of lead into the atmosphere, discharge of sulfur compounds, discharge of products formed in burning of the organic fraction (separators, battery cases), amount of wastewater containing heavy metals, amount of unutilizable slag, and content of heavy metals in the slag.

Simultaneously, account should be necessarily taken of the economical factors affecting the choice of technology. To these factors belong expenses for purification of process and ventilation gases to remove noxious substances to below the required level, cost of fuel and electric power, and expenditure for disposal of unutilizable products. The content of lead in waste gases and the total volume of these gases can be diminished dramatically by lowering the temperature of the main reducing process. This can be done if lead oxides, rather than sulfur-containing compounds of

lead (sulfates, sulfides), are reduced. Simultaneously, this leads to a pronounced saving of energy resources. Sulfur contained in the active paste of lead batteries in the form of lead sulfate can be completely utilized in desulfation. Preliminary disassembly of batteries rules out appearance of products formed in burning of organic compounds in waste gases. The problem of possible reuse of polypropylene, ebonite, and polyvinyl chloride after appropriate processing was considered in detail in [88]. According to the authors' data, processed polypropylene can be reused in fabrication of battery cases, and ebonite, in road building; however, the latter technology requires additional ecological-hygienic expertise. Polyvinyl chloride is to be disposed of.

The following sequence of operations seems to be the most appropriate in processing lead battery scrap, irrespective of the production scale:

(i) crushing of battery scrap into the metallic, oxysulfate, and organic fractions;

(ii) desulfation of the oxysulfate fraction;

(iii) reduction of lead oxides with solid reducing agents at relatively low temperatures;

(iv) refining of lead to give metal of highest-quality brands.

In those cases when small plants with annual metal output capacity of 5–7 thousand tons are the matter in question, lead battery scrap can be processed preliminarily in a simplified way, with the use of small-scale mechanization. The possible final products of such plants are lead antimonide obtained in remelting of the metallic fraction in a melting kettle and lead bullion formed in reduction of lead oxides. In the case of insufficient energy resources, mother liquors can be processed to give commercial barium sulfate, rather than be evaporated to give sodium sulfate. Water is recycled in the course of the process.

It should be emphasized the recommendations aimed to diminish the environmental hazards in battery scrap processing are based on the assumption that processing of lead-bearing secondary raw materials differs fundamentally from ore smelting because of the specific features of their chemical composition. It is inadvisable to use in processing of secondary raw materials such procedures as blast smelting, smelting in electrothermal furnaces, or other high-temperature processes.

Of particular interest among foreign plants is that in Freiberg (Germany), specialized in processing of lead battery scrap [89]. The plant was completely modernized in 1997 and processes annually 3.0 million starter batteries, to produce 35 thousand tons of lead and lead alloys, and also 3.5 thousand tons of chemically pure sodium sulfate and 2 thousand tons of polypropylene. Organic substances that cannot be utilized are burned, in conformity with all environmental safety regulations, on a special installation. The extent of lead recovery is 99%, and that of polypropylene exceeds 90%; sulfuric acid and sulfate ions from the battery paste are utilized in the form of sodium sulfate. Lead discharge into the atmosphere is about 7 g per ton of lead, and that into wastewater, less than 1 g per ton of lead. As regards all the process parameters, the plant belongs to the most modern plants for utilization of lead batteries. Its flowsheet envisages battery shredding and separation into fractions and desulfation of the active paste with sodium hydroxide. The grid material is melted in a short-drum furnace to give a lead–antimony alloy. The products obtained upon desulfation are subjected to reductive smelting, also in a short-drum furnace. Lead bullion is directed to refining. The lead–antimony alloy is either refined or serves for preparing necessary formulations. Sodium sulfate crystallizes from solutions used in desulfation; it is then dehydrated and delivered to a storehouse for subsequent selling; the content of lead in this product does not exceed 10 ppm. All steps of battery scrap processing at the plant are controlled from a single center. Further operation of the plant was considered in [90].

The set of the main operations in the flowsheet of the plant is in full agreement with the above recommendations. Owing to the presence of a special installation for burning of ebonite and separators, the amount of plant's wastes is very small. Crushing and separation of battery scrap, desulfation of the active paste, and reduction of lead(II) oxide—all these operations must form the basis of any flowsheet for processing of lead battery scrap. However, reagents for desulfation and refining processes can be varied to give different final products.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Synthesis of Complex Oxide Systems by Cathodic Deposition of Molybdenum Oxide from Aqueous Solutions in the Presence of Nickel(II) and Thiosulfate Ions

V. M. Nagirnyi, R. D. Apostolova, A. S. Baskevich, and E. M. Shembel'

Received February 27, 2002; in final form, June 2003

Abstract—Cathodic processes occurring in electrolytic deposition of molybdenum oxide from aqueous solutions of sodium molybdate in the presence of nickel(II) and thiosulfate ions were studied. Conditions for formation of cathodic deposits in the form of complex oxide systems Mo–Ni and Mo_4O_{11}–MoS_2 were determined.

The interest in electrolytic oxide materials is due to their enhanced electrochemical activity and the possibility of creating thin-film ballast-free cathodes for lithium power cells by direct deposition of an oxide material in the form of a compact coating on a metallic support [1–3]. Previously, the possibility of electrolytic synthesis of molybdenum oxide with nonstoichiometric composition in high yield by cathodic deposition from ammonium molybdate solutions has been demonstrated [4]. With account of the modern tendency toward development of high-performance cathode materials for lithium batteries on the basis of complex multicomponent oxide systems, it seemed appropriate to study the possibility of obtaining these materials in quantitative yield by electrolytic deposition of molybdenum oxide in the presence of nickel(II) and thiosulfate ions.

According to the results of preliminary experimental tests, cathodic deposits formed under certain electrolysis conditions from sodium molybdate solutions containing $NiSO_4$ are homogeneous mixtures of molybdenum oxide, nickel (NiO), and a single-phase compound of the type $NiO \cdot Mo_4O_{11}$, $Ni_xM_{4-x}O_{11+y}$. The presence of an electrolytic oxide system Mo–Ni creates certain prerequisites for formation of a sulfide phase (NiS, MoS_2, etc.) in joint deposition at the cathode of molybdenum and nickel oxides in the presence of thiosulfate ions, which may be promoted by the catalytic activity of nickel compounds [5]. This is confirmed by X-ray diffraction patterns of deposits obtained by electrolysis from solutions containing mixtures of the compounds mentioned above. Of interest is a study of cathodic processes and of the preparation conditions and properties of cathodic deposits formed by electrolytic deposition of molybdenum oxide in the presence of nickel(II) and thiosulfate ions.

As base for the study served Na_2MoO_4 solution, which, in contrast to $(NH_4)_2MoO_4$, rules out formation of complexes and molecular ammonia in the course of electrolysis. The solutions were prepared from chemicals of pure and analytically pure grades and distilled water. The electrolysis was performed in a temperature-controlled 0.2 dm^3 cell. As cathode samples served smooth $10 \times 10 \times 0.3$-mm 12Cr18Ni9Ti steel plates with current lead in the form of a thin strip of the same steel. As anodes were used smooth plates of technical-grade VT-1 titanium with $S_c : S_a = 1 : 5$. The materials to be studied were obtained in the form of compact coatings on both sides of the cathode. The experiments were carried out in two-component solutions of Na_2MoO_4 and $NiSO_4$ at their total concentration of 0.12–0.14 M and concentration ratios of 7 : 1 to 1 : 12 (here and hereinafter, molar ratios). The first digits refer to the base component, and the second, to the doping component.

To analyze the influence exerted by the total concentration of the solutions on the nature of the processes under study, experiments at higher concentrations (up to 0.17–0.19 M) were also carried out at a temperature of 85 ± 3°C chosen on the basis of preliminary tests. The efficiency of the cathodic process was evaluated by the conventional current efficiency CE_{conv} (wt %) on the assumption that the whole useful current is expended for formation of molybdenum oxide, whose formula is Mo_4O_{11} according to X-ray structural analysis. In this compound, molybdenum is

1070-4272/03/7609-1438$25.00

pentavalent, and, therefore, Mo_4O_{11} can be regarded as doubled oxide Mo_2O_5 with one coordinated oxygen atom. The latter compound is formed in accordance with the standard equation by a two-electron reaction and, therefore, the electrochemical equivalent can be taken to be

$$[Mo_2O_3]/(2 \times 26.8) = 272/(2 \times 26.8) = 5.07 \text{ g (A h)}^{-1}.$$

Polarization curves j_c–E were measured in a special U-shaped cell on the initial surface of the 12Cr18Ni9Ti steel cathode with the roughness corresponding to ∇ 7–8 at $S_c : S_a = 1 : 5$ ($S_c = 1$ cm^2) and on a film of cathodic deposit, formed preliminarily at j_c = 0.5–50 A cm^{-2}. The nonworking parts of the cathode surface were insulated with an acid-and-alkali-resistant varnish. The potentials were measured relative to a silver chloride reference electrode (E = +0.225 V) with an Shch-4315 digital instrument. The phase composition of the deposits and their approximate quantitative composition were determined by X-ray diffraction analysis on a DRON-2 installation [6].

The dependences of CE_{conv} on the current density j_c in electrolysis of two-component solutions of Na_2MoO_4 and $NiSO_4$ with varied Mo : Ni molar concentration ratios and pH values are shown in Fig. 1. The shape and relative positions of the curves indicate that the ratio of solution component concentrations and the pH value exert a desicive influence on the efficiency and nature of the cathodic processes under study.

At increased pH values (5.5–6.0) and concentration ratios Mo : Ni ≤ 1 in solution, the maximum values of CE_{conv} do not exceed 25%, with the quantitative formation of deposit on the cathode limited to the range j_c = 1.5–5.0 A cm^{-2}, which becomes narrower with increasing relative concentration of nickel(II) ions. In the limiting case (Mo : Ni = 1 : 12), the stability of the electrolysis process is disturbed and mainly hydroxide and metallic nickel start to deposit at the cathode (Fig. 1, curve *2*). The dependence CE_{conv}–j_c for the concentration ratio Mo : Ni = 7 : 1 (Fig. 1, curve *1*) is shifted to higher j_c and has a maximum at j_c > 10 mA cm^{-2}. Deposits of black color with bluish tint, characteristic of molybdenum oxide, are formed on the cathode, which indicates that mainly this compound is contained in the cathodic product. Lowering the solution pH to 3.0–3.5 makes the range of "effective" current densities much wider, with a simultaneous increase in the current efficiency by the cathodic deposit (Fig. 1, curves *1*'–*4*'). The corresponding curves become nearly linear and are arranged in order of increasing CE_{conv} with decreasing relative concentration of nickel ions in solution. The outward appearance of the cathodic deposits changes when passing to higher current densities and molybdate ion contents, and the deposits show tendency toward increasing compactness and susceptibility to brittle failure. In this case, the deposit changes its color from dark gray to bluish black, characteristic of molybdenum oxide deposits.

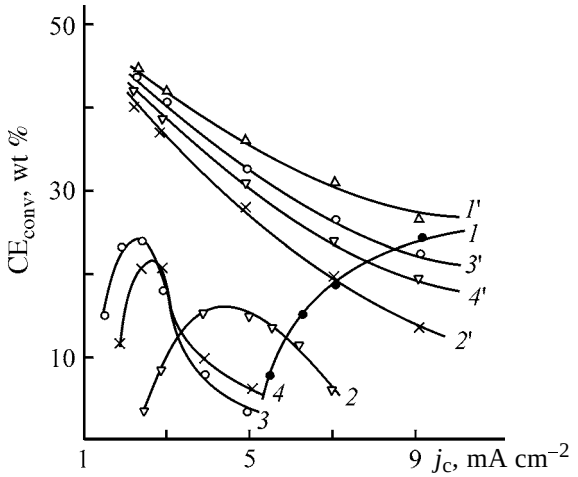

Fig. 1. Conventional current efficiency CE_{conv} vs. current density j_c for cathodic deposits formed in electrolysis of mixed solutions of Na_2MoO_4 and $NiSO_4$. Total concentration 0.12–0.14 M, T = 85°C; the same for Figs. 2 and 4. Mo : Ni concentration ratio: (*1*, *1*') 7 : 1, (*2*, *2*') 1 : 12, (*3*, *3*') 1.5 : 1, and (*4*, *4*') 1 : 1.3. pH: (*1*–*4*) 5.5 and (*1*'–*4*') 3.5.

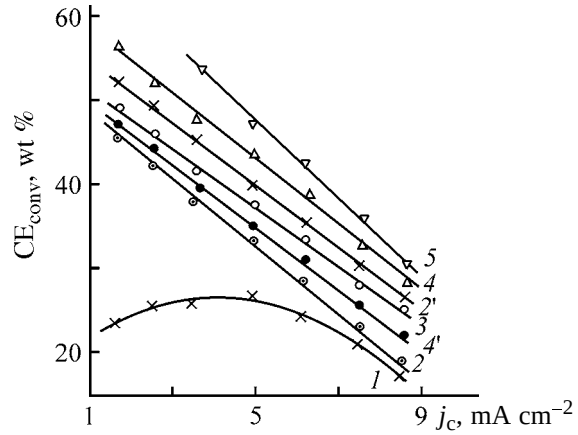

Fig. 2. Conventional current efficiency CE_{conv} vs. current density j_c for cathodic deposits formed in electrolysis of mixed solutions of Na_2MoO_4 and $NiSO_4$ in the presence of 0.01 M $Na_2S_2O_3$. Mo : Ni concentration ratio: (*1*) 1 : 12, (*2*, *2*') 7 : 1, (*3*) 1 : 2.7, (*4*, *4*') 1 : 1.3, and (*5*) 1.5 : 1. pH: (*1*–*5*) 5.5 and (*2*', *4*') 3.5.

Adding $Na_2S_2O_3$ (0.004–0.02 M) to the solutions under study leads to a dramatic increase in the efficiency of the cathodic process in weakly acidic solutions (pH 5.5) at any concentration ratio Mo : Ni (Fig. 2). In this case, nearly all the dependences are

strictly linear in a rather wide range of j_c, irrespective of the solution pH (Fig. 2). The only exception is the dependence for Mo : Ni = 7 : 1 in a solution with pH 5.5, having a maximum at j_c = 3.5 mA cm^{-2}. The corresponding curves are arranged in order of increasing CE_{conv} with decreasing relative concentration of nickel ions in solution at Mo : Ni = 1 : 2.7 to 1.5 : 1. However, at Mo : Ni = 7 : 1, the conventional current efficiency is much lower than that at the inverse ratio of the main components in solution, Mo : Ni = 1 : 12 (Fig. 2, curves *1* and *2*). Lowering the solution pH to 3.5, conversely, makes the tendency toward increase in CE_{conv} at Mo : Ni $\leq$ 1 more pronounced.

Changing the total concentration of the molybdenum and nickel salts from 0.8 to 0.16 M has no pronounced effect on the dependences under consideration or outward appearance of the deposits formed. However, other combinations with higher total content of the main components in solution are, in principle, also possible, including those with thiosulfate ions, for which the properties of the cathodic deposits, characteristic of the conditions under study, are preserved.

In a single-component solution of Na_2MoO_4 (0.1–0.12 M), addition of $Na_2S_2O_3$ at the molar concentration ratio of these compounds of 10 : 1 to 10 : 4 also affects somewhat the value of CE_{conv} and the outward appearance of molybdenum oxide deposits. At the same time, the presence of thiosulfate ions in a nickel sulfate solution (0.005–0.06 M) totally suppresses deposition of nickel hydroxide on the cathode, irrespective of the thiosulfate ion concentration and electrolysis parameters. Possibly, this is the reason why the dependences measured at different Mo : Ni concentration ratios in solution (1 : 12 and 7 : 1) are dissimilar. For example, in the first case, i.e., at high relative concentration of nickel ions in solution, deposition of nickel oxide is nearly completely suppressed and mostly molybdenum oxide and molybdenum sulfide are deposited on the cathode, which leads to an increase in CE_{conv}. In the second case, the codeposition of nickel oxide lowers the rate of formation of the cathodic deposit, which leads simultaneously to equalization of its values at different current densities.

An apparent factor determining the nature of the processes under consideration is the ratio of the amounts of molybdenum and nickel oxides simultaneously deposited at the cathode, and also hydrogen, in the presence of thiosulfate ions and without them. Here, account should be taken of the fact that, when the cathodic deposit is formed, deposition of nickel oxide is preceded by that of nickel hydroxide because of the alkalization of the near-cathode layer:

$$H_2O + e \rightarrow 1/2H_2 + OH^-.$$

In joint deposition and in interaction with the simultaneously deposited molybdenum oxide, nickel hydroxide may lose a water molecule:

$$Ni(OH)_2 + Mo(oxid) \rightarrow NiO + Mo(oxid)\cdot H_2O, \quad (1)$$

$$Mo(oxid)\cdot H_2O + e \rightarrow Mo(oxid) + 1/2H_2 + HO^-. \quad (2)$$

Also possible is simultaneous direct discharge of nickel hydroxide with the loss of a water molecule to give nickel oxide. This can account for the strong influence of the solution pH on the efficiency of the cathodic process, all other electrolysis conditions being the same.

At increased pH values (5.5–6.0) the rate of nickel hydroxide formation at small current densities exceeds that of the joint reaction of molybdenum oxide deposition, and the limiting diffusion current is reached already at relatively low values of j_c (Fig. 1). The deposits formed in this case are inhomogeneous mechanical mixtures of nickel oxide, nickel hydroxide, and molybdenum oxide, and at molybdenum to nickel concentration ratios Mo : Ni < 1 nickel hydroxide and metallic nickel are deposited predominantly (as fine dendrites). Lowering the solution pH decelerates alkalization of the near-cathode layer and thereby changes the ratio of formation rates of nickel hydroxide and molybdenum oxide in such a way that the latter becomes higher and, correspondingly, reactions (1) and (2) proceed at all Mo : Ni concentration ratios. However, hydrogen evolution, whose rate grows with increasing current density, becomes predominant in the overall cathodic process at higher relative concentrations of nickel ions. This correlates with the corresponding decrease in CE_{conv} (Fig. 1, curves *1*'–*4*').

A similar type of the overall cathodic process is also possible in the presence of thiosulfate ions in solutions with pH 5.5–6.0. However, the mechanism of separate and joint reactions is more complex in this case (Fig. 2). This should, presumably, be attributed to the influence exerted by products formed in reduction of thiosulfate ions at the cathode, and sulfur and its compounds in particular. For example, hydrogen sulfide can "acidify" the near-cathode layer, which leads to a decrease in the rate of nickel hydroxide formation, observed in acid solutions (pH 3.0–3.5), and to the corresponding increase in the rate of the reactions occurring in parallel. This is manifested to

a greater extent at molar concentration ratio Mo : Ni ≥ 1 in solution (Fig. 2, curves *2*' and *4*').

The aforesaid is in satisfactory agreement with current–voltage characteristics of the cathodic processes under study, measured at different compositions and pH values of the solutions used (Fig. 3). A common feature of all the j_C–E dependences is the presence of two transition steps connecting three ascending portions (Fig. 3). For each pH value, the lower and upper transition steps are arranged so that the j_C values corresponding to these steps decrease as the relative concentration of nickel ions in solution is made lower. The curves are arranged in the same order with respect to cathode potentials. In this case, a decrease in pH leads to a shift of the corresponding curves (Fig. 3, curves *4* and *5*) relative to their analogs for solutions with increased pH 5.5 (Fig. 3, curves *1* and *3*) to more negative potentials. In the same solution, the process occurs at a stronger cathodic polarization on a surface with preliminarily deposited film of a cathodic deposit (Fig. 3, curves *1* and *1*'); however, the steps in the corresponding curve are smoothed in this case (Fig. 3, curve *1*').

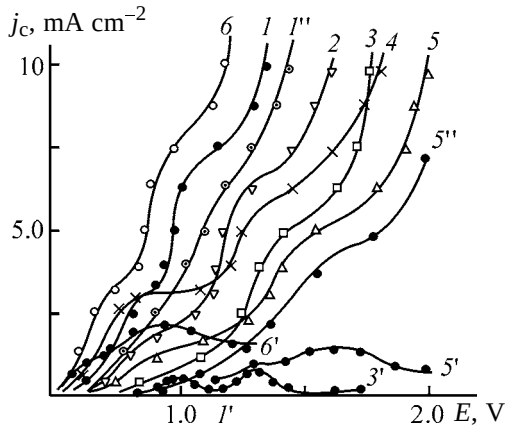

Fig. 3. Cathode potential E vs. current density j_C in electrolysis from mixed solutions of Na_2MoO_4 and $NiSO_4$. pH: (*1*, *1*', *1*'', *2*, *3*, *3*', *6*, *6*') 5.5 and (*4*, *5*, *5*', *5*'') 3.5. Overall cathodic processes, Mo : Ni concentration ratio: (*1*, *5*) 1 : 12; (*1*'') 1 : 12, on a preliminarily formed deposit film; (*2*) 1 : 1.3; (*3*, *4*) 7 : 1; and (*6*) 1 : 12, 0.01 M $Na_2S_2O_3$. Partial processes of cathodic deposit formation, Mo : Ni concentration ratio: (*1*', *5*') *1* : 12; (*3*') 7 : 1; and (*6*') 1 : 12, 0.01 M $Na_2S_2O_3$. Hydrogen evolution, Mo : Ni concentration ratio: (*5*'') 1 : 12.

In the presence of thiosulfate ions at equal Mo : Ni concentration ratios in solution, the curves are shifted to lower cathode potentials so that they remain parallel to the initial lines (without $S_2O_3^{2-}$ ions; Fig. 3, curve *6*), with a simultaneous increase in the current densities corresponding to the transition steps. The partial curves of cathodic deposit formation exhibit a gradual rise to a certain limiting plateau (Fig. 3) with a noticeable step-like transition at lowered intensity of alkalization of the near-cathode layer (Fig. 3, curves *5*' and *6*'). With the cathode potential increasing further, the polarizing current decreases to a certain constant minimum value. The extremum points of the partial curves coincide with the point of transition from the second step in the overall curves to the upper ascending portions. The partial curve of hydrogen evolution lies to the right from the corresponding overall curve, nearly in parallel to this curve, which points to the key role of this process in the kinetics of the overall cathodic process (Fig. 3, curve *5*').

The behavior of the j_C–E dependences under consideration (Fig. 3) indicates that the nature of the cathodic process changes with polarizing current. The step-like dependence of this current on the cathode potential is apparently due to a change in the rate ratio of the individual reactions simultaneously occurring at the cathode. The lower portions of the curves are mainly associated with the formation of nickel hydroxide, accompanied by hydrogen evolution and deposition of molybdenum oxide. In the partial curves (Fig. 3, curves *1*', *3*' and *5*', *6*'), this is manifested by the initial gently sloping and ascending portions. Reaching the limiting current of nickel ion diffusion leads to enhancement of the cathodic polarization and gives rise to the corresponding transition plateaus. The polarizing current corresponding to the extremum points of the lower transition plateaus is closely associated with the relative concentration of nickel ions in solution for each pH value. In solutions with lowered pH value (3.0–3.5), the alkalization of the near-cathode layer is slower, which decelerates nickel hydroxide formation and leads to higher limiting diffusion currents.

The rise in the cathodic polarization after reaching the extremum points of the lower transition step in the curves shifts the cathode potential to negative values, which leads to preferential deposition of molybdenum oxide, whose rate becomes a key factor in the transition region and second ascending portions of the overall curves. To the same factor correspond the steep rise portions and limiting plateaus of the partial curves. In this case, the overall cathodic process becomes more complex because of the simultaneous occurrence of nickel oxide deposition and hydrogen evolution. The limitation of the rate of molybdate ion diffusion toward the cathode surface with increasing polarizing current leads to the subsequent enhancement of the cathodic polarization, with predominance of the rate

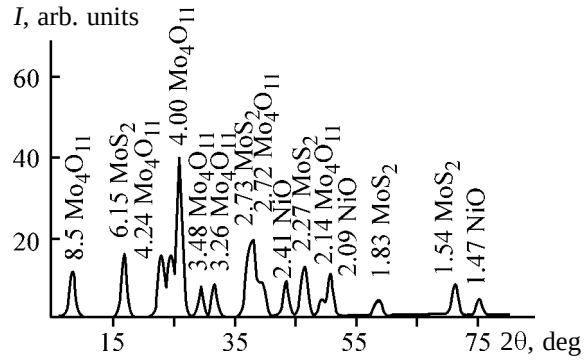

Fig. 4. X-ray diffraction pattern of the cathodic deposit in electrolysis of the solutions under study. Concentration ratio Mo : Ni = 1.5 : 1, pH 5.5, in the presence of 0.01 M $Na_2S_2O_3$. (*I*) Intensity and (2θ) Bragg angle.

of hydrogen evolution, and makes the lower plateaus of the partial curves more pronounced. This circumstance presumably accounts for the fact that the cathodic processes under consideration occur in an acid medium with pH 3.0 (Fig. 3, curves *4*, *5*, *5*') at higher cathodic polarization than in the case of solutions with lower acidity (pH 5.5).

At the same time, all the j_c–E curves in Fig. 3 are shifted with respect to one another to higher cathode potentials with increasing relative concentration of molybdate ions in solution. This is possibly due to strong cathodic polarization of the discharge of MoO_4^{2-} ions and to high hydrogen overvoltage on the surface of the cathodic deposit formed at a sufficient rate in the range corresponding to the second and third portions of the curves. Correspondingly, the transition plateaus between these portions are arranged in order of decreasing current densities corresponding to these plateaus because of the change in the relative rates of hydrogen evolution and molybdenum oxide deposition, with a steady increase in the latter. This is also indicated by a relative increase in the limiting currents of cathodic deposit formation for different pH values (Fig. 3, curves *1*', *3*', *5*') and in the length of the second ascending portions of the overall curves, which lie higher in the above sequence (Fig. 3, curves *1–3* and *4*, *5*).

The shape and relative positions of the overall and partial j_c–E curves for a solution containing $Na_2S_2O_3$ (Fig. 3, curves *6* and *6*') are in agreement with the suggested possible mechanism of influence exerted by thiosulfate ions on the kinetics of the cathodic process, which is manifested in a decrease in the cathodic polarization of the overall process. Together with the possible role played by thiosulfate ions in the "acidification" of the near-cathode layer of the solution owing to formation of hydrogen sulfide in discharge of $S_2O_3^{2-}$ ions and to an increase in the contribution of hydrogen evolution to the overall process, a certain contribution to the mechanism under consideration can be made by simultaneous deposition of sulfur at the cathode. Adsorption of sulfur on the electrode surface presumably makes lower the energy barrier to discharge of molybdate ions, by analogy with a similar phenomenon in electrolytic deposition of metals [7]. This is also confirmed by the relatively high peak in the corresponding partial curve (Fig. 3, curve *6*').

According to the results of an X-ray diffraction analysis, the deposits under study are multiphase systems with clearly pronounced phases of molybdenum oxide Mo_4O_{11}, nickel oxide NiO, and molybdenum sulfide (Fig. 4). The oxide phase of molybdenum, which is virtually independent of the solution composition and electrolysis parameters, predominates (88–95 wt %). The content of nickel oxide NiO and molybdenum sulfide MoS_2 in the deposits may vary within 0.5–3 and 1–9 wt %, respectively, with the greater values corresponding to higher content of the components in solution.

The structure and bonding in the systems under study cannot be described unambiguously on the basis of the available experimental data. However, with account taken of the inevitable interaction, on the molecular level, of the phases codeposited at the cathode in the course of electrolysis, it may be assumed that the materials obtained are homogeneous mixtures with a tendency toward ordered chemically interrelated structure. To obtain deposits with the optimal, under the experimental conditions, content of the doping phases, MoS_2 and NiO, the concentration ratio of the molybdenum and nickel salts in solution (total concentration 0.08–0.14 M) must fall within the range from 2 : 1 to 1 : 3 at $Na_2S_2O_3$ concentration equal to the lower concentration of the main component.

CONCLUSION

A study of the efficiency and current–voltage characteristics of the cathodic processes, and also of the phase composition of the cathodic deposits formed in electrolysis of mixed solutions of sodium molybdate and nickel sulfate (total concentration 0.08–0.14 M) in the presence of sodium thiosulfate (0.01–0.012 M) in relation to their composition and electrolysis conditions, revealed the possibility of obtaining in quantitative yield materials in the form of multiphase systems composed of a homogeneous mixture of nickel and

molybdenum oxides and sulfides. Stable electrolysis conditions are achieved at $85 \pm 3°C$, j_c = 3.5–7.5 mA cm^{-2}, pH 5.0–6.0, molar ratio of the components in the range from 2 : 1 to 1 : 3, and thiosulfate concentration of 0.01–0.012 M.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Modifying Additives to Electrolytes for Anodic Treatment of Alloys in Development of Resource-Saving Technologies

E. A. Fedorova

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received November 6, 2002; in final form, April 2003

Abstract—The effect of modifying additives on the processes of anodic treatment of alloys was studied and the role of adsorption effects in development of resource-saving technologies for metal working was established.

A topical problem of modern technologies for anodic treatment of metal articles consists in imparting certain functional properties to their surfaces at high output capacity and good environmental safety. The vast practical experience accumulated in this field mainly refers to treatment of surfaces of technically "pure" metals and high-alloy steels [1–3]. Solutions for electrochemical polishing (ECP), most widely used for this purpose, still include highly toxic phosphoric–sulfuric–chromic acid electrolytes. There is virtually no effective environmentally acceptable substitute for these solutions [2].

It has been established previously that the quality of anodic treatment of alloys in the conventional electrolytes becomes poorer with decreasing degree of steel alloying in the order 12Cr18Ni10Ti > 95Cr18 > 40Cr13 > 12Cr13 > 08kp [4] and with increasing degree of alloying of aluminum and titanium alloys in, respectively, the series AMg < AMts < D16 [5] and VT6 < VT8 < VT16 [6]. Introduction of modifying adamantane additives into the phosphoric–sulfuric acid solution for ECP, or their combination with glycerol or alkali metal cations in a phosphoric acid electrolyte, makes faster the smoothening of the microroughness of the alloy surface [4–6].

When selecting additives, two quantities are taken into account [3]: surface tension of the electrolyte with additive and the anodic polarization of a process, which, however, cannot serve as the only criteria in development of resource-saving technologies.

Here we analyze the influence exerted by additives introduced into modified electrolytes for ECP on the processes and results of anodic treatment of alloys in order to predict the electrolyte compositions and develop resource-saving technologies.

EXPERIMENTAL

Anodic treatment of alloys with varied degree of alloying was performed with electrolytes of different compositions (M): phosphoric acid (PA) 11 H_3PO_4; phosphoric–sulfuric acid (PSA) 10 H_3PO_4, 3.7 H_2SO_4; phosphoric–sulfuric acid glycerol (PSAG) 14 H_3PO_4, 0.5 H_2SO_4, 1.2 $C_3H_8O_3$ at 303–333 K for steels and aluminum alloys; hydrofluoric–sulfuric acid (HFSA) 11.5 H_2SO_4, 5.5 HF; and hydrofluoric–sulfuric acid glycerol (HFSAG) 11.5 H_2SO_4, 5.5 HF, 2.0 $C_3H_8O_3$ at 293 K for titanium alloys. Data on the elemental composition of the surface of steel and aluminum and titanium alloys, according to the results of electron-probe microanalysis, are listed in Tables 1–3.

As modifying additives were studied organic compounds with varied steric structure and different functional groups: linear [triethanolamine $N(C_2H_4OH)_3$] and heterocyclic (hexamethylenetetramine $C_6H_{12}N_4$) amines; alicyclic hydrocarbons of the adamantane series with the general formula $C_{10}H_{16-n}R_n$, where R is H (Ad, adamantane), OH (hydroxyadamantane),

Table 1. Elemental composition of steel surface

* Numerator, data for the initial sample; denominator, for a sample subjected to anodic treatment in PSA electrolyte, J_a = 12 A dm^{-2}, T = 333 K, τ = 5 min.

Br (bromoadamantane), $NHCOCH_3$ (acetylaminoadamantane), and C_2H_4–$NH_2 \cdot HCl$ (Re, remantadine), and also their combinations with glycerol (Gl) or alkali metal cations.

Adsorption effects at the electrolyte–alloy interface in the initial and anodically polarized states were studied with a number of independent methods by measuring the contact angle for a drop of electrolyte [7], surface hardness by Rebinder [8], contact potential [5], and potential decay (with the differential pseudocapacitance determined) [9], and also using the potentiostatic and potentiodynamic methods at potential sweep rates of 0.01–0.02 V s^{-1} with correction for the ohmic voltage drop in a film [10].

The anodic polarization of the electrodes was done with P5848, ON-405, and PI-50-1 potentiostats, LKD-4 recorder, three-electrode glass (for steels and aluminum alloys) or fluoroplastic (for titanium alloys) cell, and saturated silver chloride reference electrode. The potentials are given relative to standard hydrogen electrode.

The elemental composition of the surface of the initial and polished samples was determined with a Philips SEM-515 scanning electron microscope (the Netherlands) with an EDAX-9900 energy-dispersive detector (the United States).

Changes in the functional properties of the alloy surface after anodic treatment were evaluated by substructure parameters: microscopic deformation ε and density of dislocations inside subgrains (ρ_e, cm^{-2}) and at their boundaries (ρ_L, cm^{-2}), determined on a DRON-3M diffractometer in CuK_α radiation by the approximation method, and also by surface roughness R_a (μm) and relative smoothening Y (%) [11].

X-ray diffraction analysis of the substructure parameters of the initial surface of the alloys demonstrated that raising the degree of alloying of aluminum and titanium alloys leads to an increase in the microscopic deformation level and density of dislocations, which are chaotically distributed and form subgrain boundaries. Each structural component of the alloys dissolved in the conventional electrolytes in a certain range of potentials at its own rate on applying anodic polarization, which was reflected in a change in the elemental composition of the alloy surface after anodic treatment (Table 1).

Partial replacement of water in PSA and HFSA ECP solutions with glycerol made less pronounced the selective etching of the alloying components of the alloys. In glycerol-containing electrolytes, the rates of anodic dissolution of aluminum alloys (evaluated by the etched layer thickness δ, μm) decreased, and the relative smoothening Y (%) of the article surfaces did

not exceed 50% (Table 4). Also, a dependence of δ on the chemical composition of the surface layer of the alloys was clearly observed (Tables 1–4): with increasing degree of alloying, the rates of anodic dissolution became higher and the quality of the anodic treatment of article surfaces was impaired (Table 4).

The required functional properties of the alloy surfaces were achieved, with the microscopic deformation of the alloy surfaces eliminated (Table 5) and relative smoothening increased to 65–70%, only upon introduction into the electrolytes of modifying additives of the adamantane series, or when the solution contained simultaneously alkali metal cations and adamantane additives, or glycerol and adamantane additives.

The run of the isotherms of the surface tension σ_s (N m^{-1}) of the electrolytes with additives demonstrates that the chosen modifying additives of the adamantane series act as surfactants at the interface between the polishing electrolyte and vapor (Fig. 1, curve *1*). After anodic treatment, adamantane preserves its surface-active properties (Fig. 1, curve *2*). The observed slight increase in the surface tension of the electrolyte points a decrease in the surfactant concentration at the electrolyte–vapor interface, probably, because of the adsorption of the additives onto the electrode surface.

The behavior of the modifying additives in polishing electrolytes on the initial surface of the alloys is reflected in kinetic dependences of electrolyte drop spreading over the surface of 12Cr18Ni10Ti steel (Fig. 2). These curves exhibit two clearly pronounced "plateaus" characterized by quasi-equilibrium contact angles θ_0 and θ (Fig. 2), which made it possible to evaluate the surface energy of viscous spreading, ΔG^S and the spreading factor *S* (Table 6).

Comparison of the Gibbs energies of spreading of supporting electrolytes (ΔG^S = 14 mJ m^{-2}) and those with modifying additives (ΔG^S = 4–6 mJ m^{-2}) indicates that the additives introduced exert hindering action. This is also confirmed by the values of the spreading factor (Table 6).

The relationship between the surface tension and the surface concentration Γ in adsorption at low concentrations of additives is described by the Gibbs adsorption isotherm looking as follows in the integral form:

$$-\int_{\sigma_0}^{\sigma} d\sigma = RT\, d\ln c, \quad (1)$$

where σ_0 is the surface tension at the electrolyte–vapor interface, and σ is the interfacial tension at the electrolyte–alloy interface; for adsorption of an additive on the solid surface, $\sigma_0 \equiv \sigma_{a-v}$ and $\sigma \equiv \sigma_{a-a.l.}$, where σ_{a-v} and $\sigma_{a-a.l.}$ are the surface tensions at the interfaces between the alloy and the vapor and between the alloy and the adsorption layer, respectively; c is the concentration of the additive (M).

Using a combination of Young equations

$$\cos\theta_0 = (\sigma_{a-v} - \sigma_{e-a})/\sigma_{e-v} \quad (2)$$

(σ_{e-a} and σ_{e-v} are the surface tensions at the electrolyte–alloy and electrolyte–vapor interfaces, respectively), on the assumption that

$$\sigma_{a-v} = \text{const}, \quad d\sigma_{a-v}/dC = 0, \quad (3)$$

and taking into account Eq. (1), one can obtain a formula for calculating the surface concentration:

$$\Gamma_{a-a.l.} = \frac{d(\cos\theta)\sigma_{e-v}}{dc}\frac{c}{RT}. \quad (4)$$

Graphical differentiation of the curve describing the dependence $\sigma_{e-v}\cos\theta = f(\ln c)$ was used to calculate the maximum surface concentration of adamantane, $\Gamma_{max} = 5.0\times10^{-11}$ mol cm^{-2}, and remantadine, $\Gamma_{max} = 9.0\times10^{-11}$ mol cm^{-2}. This indicates that the adsorption occurs by the chemisorption mechanism to give associates of etching products of the alloy components [Fe(III), Fe(II), Cr(III), Cr(VI), Ni(II), Ti(IV), Al(III), and Mg(II)] with adamantane and remantadine. As a result, adsorbed molecules of the additives and their associates with metal ions are accumulated, in addition to metal phosphates and sulfates, in the viscous near-surface layer.

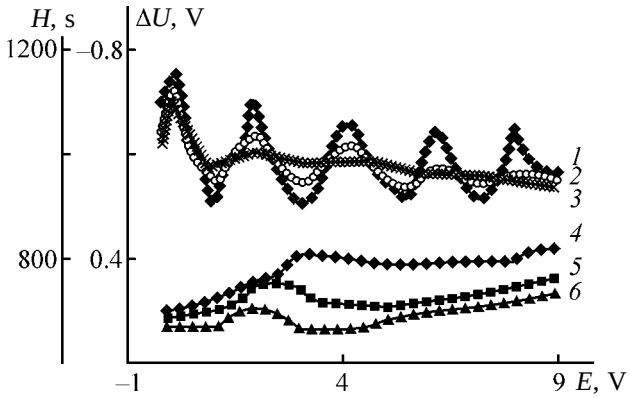

Fig. 4. (*1–3*) Work of surface formation H and (*4–6*) contact potential difference ΔU vs. anode potential of titanium (VT16) electrode at 293 K. Solution (M): (*1, 4*) H_2SO_4 11.5, HF 5.5, KF 0.52, and $C_3H_8O_3$, 2.0; (*2, 5*) the same + $C_6H_{12}N_4$ 0.02; (*3, 6*) the same as (*1, 4*) + $C_{10}H_{15}$–C_2H_4–$NH_2\cdot HCl$ 0.02.

Introduction of adamantane $C_{10}H_{16}$, hexamethylenetetramine $C_6H_{12}N_4$, remantadine $C_{10}H_{15}$–C_2H_4–$NH_2\cdot HCl$, and K_2SO_4 into the supporting electrolytes leads to a dramatic decrease in the work of anode surface formation near the maxima and to a slight increase in the hardness at its minima (Figs. 3, 4). This effect was particularly pronounced in solutions with additives belonging to the adamantane series or in the case of simultaneous presence of $C_{10}H_{16}$ and K_2SO_4 in solution.

The observed change in the contact potential difference ΔU (V) with increasing positive potential at the anodically oxidized alloys and growing oxidation time (Fig. 4), which reflects an increase in the electron work function λ_i [5], indicates that charged anodic films with excess negative charge are formed on the surface of anodically polarized alloys. After opening the circuit in air, these charges recombine, i.e., leak to the metal base. The presence of an excess negative charge in oxide films in anodic polarization of the titanium electrode correlates with the existence of several electrocapillary curves of the work of surface formation (Fig. 4).

Addition of adamantane, and especially introduction of a combination of K_2SO_4 and $C_{10}H_{16}$ additives into the supporting electrolyte, make the adsorption pseudocapacitance of the D16 alloy lower (Fig. 3).

The fact that modifying additives make lower the work of surface formation at peaks of the electrocapillary curves (Figs. 3, 4), the electron work function (Fig. 4), and the adsorption pseudocapacitance (Fig. 3) is a direct confirmation of adsorption of these additives on the surface of anodically polarized alloys in a wide range of potentials, including the potentials of electropolishing, under conditions of competitive adsorption of anions and radical anions (e.g., HSO_4'), radical hydrogen peroxide species HO_2', PO_4''', etc.

The chemisorption of adamantane molecules on the surface of an alloy being polished is also confirmed by results of mass-spectrometric analysis of an extracted solution obtained upon cathodic reduction of an oxide layer formed on the surface of the 12Cr18Ni10Ti steel in an electrolyte with addition of adamantane. Species characterized by m/z = 135 were found in the solution being analyzed, which corresponds to the presence of a highly stable adamantyl cation $C_{10}H_{15}^+$ in the solution. Thus, adamantane molecules may be incorporated into the surface anodic oxide layer (AOL) and affect its properties.

The electron work function of an anodically polarized VT16 alloy became lower in the presence of hexamethylenetetramine and, especially, remantadine in a glycerol-containing solution (Fig. 4). It may be assumed that species of modifying additives, e.g., remantadine, are chemisorbed on the surface of the titanium alloy and thereby give rise to impurity states with positive effective charge in the band gap of *n*-type titanium oxide TiO_2 [12], which leads to an increase in the free electron concentration in the oxide.

The facilitation of transport processes in the AOL may lead to an increase in the rate of metal ionization, compared to a glycerol-containing electrolyte without surfactant, which was confirmed experimentally for the example of aluminum alloys (Table 4). Automated correction for the ohmic voltage drop across the film made it possible to evaluate the resistance of the AOL on the D16 alloy to decrease from 440–480 to 237–

250 Ω cm^{-2} in the presence of 0.02 M of remantadine in a PSAG solution.

In a PSA electrolyte, the rates of anodic dissolution of the aluminum alloys decreased upon introduction of adamantane additives.

The ohmic resistance of AOL formed on 12Cr-18Ni10Ti steel in aqueous PA and PSA electrolytes with modifying additives increased, especially in the transpassive region, in the case when a film of reaction products was already formed on the anode surface. The film resistance related to unit surface area of a steel being treated increased from 15 to 25 and 29 Ω cm^{-2}, respectively, in the presence of adamantane and bromoadamantane in the PSA electrolyte and to 28 Ω cm^{-2} upon joint introduction of K_2SO_4 and adamantane additives into an aqueous PA polishing solution.

The observed hindrance of the anodic dissolution of the alloys by $C_{10}H_{16}$ (Table 4) and K_2SO_4 + $C_{10}H_{16}$ (Table 7) additives in aqueous PA and PSA ECP electrolytes will extend the working life of alloy–electrolyte process media in the case of chemical and electrochemical stability of the additives in the solutions.

A quantitative analysis by ascending chromatography for adamantane in a PSA electrolyte used for anodic treatment of steels and for remantadine in PSAG electrolyte used for aluminum alloys demonstrated that the content of the additives in the solutions remained virtually unchanged after passing 250 and 120 A h l^{-1} of electricity, respectively.

Measurements of the surface tension of polishing solutions with the surfactant additives under study demonstrated that reaching the original value of σ_s corresponds for adamantane additives to passing 260–320 A h l^{-1} of electricity, this value being lower for other types of additives (Fig. 5). This indicates a higher electrochemical stability of compounds of the adamantane series.

The established pattern of the anodic behavior and state of the surface of the alloys under study in the presence of modifying additives to electrolytes for anodic treatment revealed the following basic directions of research for developing resource-saving technologies: (1) extending the working life of process media constituted by an alloy being treated and an electrolyte; (2) lowering the energy expenditure for anodic treatment; (3) decelerating accumulation of metal ions in electrolytes; (4) improving the quality of surface treatment of alloys with heterogeneous composition by introducing modifying additives possessing such basic properties as inhibition of metal ionization, faster formation of a viscous near-electrode layer via interaction of additive molecules with prod-

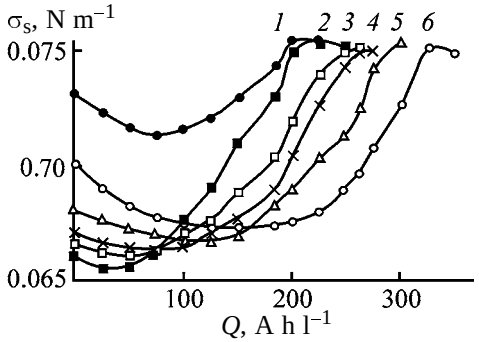

Fig. 5. Surface tension σ_s of PSA electrolyte in the course of its exhaustion. (Q) Quantity of electricity passed. Additive: (1.0 g l^{-1}): (*1*) $C_6H_{12}N_4$, (*2*) $N(C_2H_4OH)_3$, (*3*) $C_{10}H_{15}NHCOCH_3$, (*4*) $C_{10}H_{15}Br$, (5) $C_{10}H_{15}OH$, and (*6*) $C_{10}H_{16}$.

ucts of chemical and anodic dissolution of alloys, and improvement of the quality of the anodic oxide film via adsorption of additive molecules on the alloy surface at high positive potentials.

The rates of accumulation of metal ions in solutions were also lowered (1) by modifying the electrolyte compositions by replacing the solvent in aqueous solutions with a more viscous component (e.g., glycerol) decelerating the selective etching of microscopic areas on the article surface, (2) by excluding sulfuric acid from the PSA electrolyte in order to deposit poorly soluble phosphates of the metals contained in the alloys in the course of electrolysis, and (3) by binding the soluble components of the alloys into complexes stable in electrolytes for anodic treatment.

Development of resource-saving technologies should also involve studies concerning regeneration of spent ECP electrolytes and purification of washing and waste water to recover valuable components.

Adamantane and its derivatives proved to be versatile additives for virtually any brand of the alloys studied; they have high efficiency already at a low content in solution (0.2–2.0 g l^{-1}), low expenditure [$3-4\times10^{-3}$ g $(A\ h)^{-1}$], and chemical and electrochemical stability in anodic treatment, ensuring low energy expenditure in this process (0.8–4.0 A h l^{-1}) and long working life of alloy–electrolyte process media.

The highest working capacity of up to 400–420 A h l^{-1}, exceeding that of the presently employed electrolytes by a factor of 2, is observed for a PA solution with modifying additives of an alkali metal sulfate and adamantane compounds for anodic treatment of steels and Al alloys. This electrolyte is characterized by long working life of the solution because of the lowered current efficiency in anodic dissolution of alloys and simplicity of regeneration, shorter duration and lower energy intensity of the process, less expensive solution components, and lower expenditure for neutralization of spent solutions.

CONCLUSIONS

(1) The concept for choice of modifying additives of organic substances to electrolytes for polishing of alloys with varied degree of alloying on the basis of the whole set of their physicochemical properties was formulated.

(2) The effect of adsorption on the macro- (changes in the structure of the viscous near-electrode layer by the additives) and microscopic levels (changes in the properties of the surface anodic oxide films) in anodic treatment of alloys in electrolytes with modifying additives was established.

(3) It was shown that adamantane and remantadine additives to alloy polishing electrolytes lead to formation of impurity states with positive effective charge in the band gap of semiconducting oxide films. This facilitates or hinders (depending on the conduction type of the film) migration of ions across the film and improves the quality of treatment by smoothing the microroughness and eliminating microscopic deformations of the surface of metal articles.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics of Reaction of Nickel(II) Hydroxide with Sulfuric Acid

A. I. Demidov and M. S. Kokhatskaya

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received July 17, 2003

Abstract—Changes in the concentrations of nickel(II) sulfate and sulfuric acid in the course of the dissolution of nickel(II) hydroxide powder in sulfuric acid of various concentrations at 25, 50, and 75°C were evaluated from variation of the electrolyte resistance. The rate constant and activation energies of the dissolution were calculated.

Leaching with ammonia or an acid is widely used in reprocessing of solid nickel-containing waste [1–4]. Owing to the high solubility of nickel sulfate, the acid leaching of nickel hydroxide from spent nickel–iron batteries is more efficient than ammonia leaching. The acid leaching involves transformation of nickel compounds into sulfate form and treatment to remove impurities; in the process, nickel sulfate is not separated from a solution [4].

The goal of this work was to develop a method of studying the reaction of $Ni(OH)_2$ in solutions with H_2SO_4 and to choose a canonic equation which would describe adequately the experimental data. For this purpose, the nickel(II) hydroxide powder was dissolved in sulfuric acid solutions of different concentrations (0.1–0.5 N) at 25, 50, and 75°C. We used in the study the following chemicals: $Ni(OH)_2$ intended for manufacture of alkaline batteries containing no less than 58.5–59.0% Ni in terms of dry substance and chemically pure grade H_2SO_4. The study was performed in a temperature-controlled conductometric cell at vigorous agitation of the solution with a magnetic stirrer. The solution volume was 100 ml, and the weighed portion was varied from 0.5 to 2.5 g. No less than seven replicate tests were performed.

Let us consider the reaction of $Ni(OH)_2$ with H_2SO_4:

$$Ni(OH)_2 + H_2SO_4 \rightarrow NiSO_4 + 2H_2O. \qquad (1)$$

In the course of the nickel hydroxide dissolution in sulfuric acid, very mobile hydrogen ions are replaced for less mobile nickel ions. As a result, in the course of the process the electrical conductivity of the solution changes. In view of this fact, the total specific electrical conductivity of a solution χ_Σ can be calculated by the equation

$$\chi_\Sigma = \chi_{H_2SO_4}(1 - x) + \chi_{NiSO_4}x, \qquad (2)$$

where x is the fraction of $NiSO_4$ at the total amount of the reactants accepted as unity; $\chi_{H_2SO_4}$ and χ_{NiSO_4} are the specific electrical conductivities of H_2SO_4 and $NiSO_4$, respectively [5].

To determine the nickel sulfate and sulfuric acid concentrations in a solution, the solution resistance in the course of the dissolution was measured over a period of 30 min with a step of 30 s using an E7-15 immitance meter. A change in the resistance upon dissolution of nickel hydroxide in sulfuric acid at 50°C is presented in Fig. 1. Then, the resistance was recalculated to the specific electrical conductivity:

$$\chi_\Sigma = K/R_t,$$

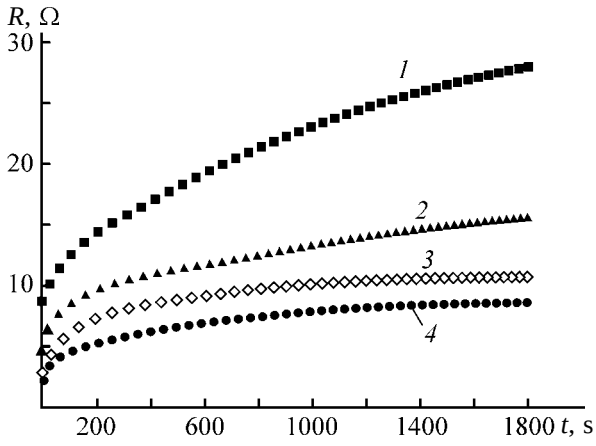

Fig. 1. Variation of the resistance R with time t in the course of nickel hydroxide dissolution in sulfuric acid solutions of different concentrations at 50°C. Concentration, g-equiv l^{-1}: (*1*) 0.1, (*2*) 0.2, (*3*) 0.4, and (*4*) 0.5; the same for Fig. 2.

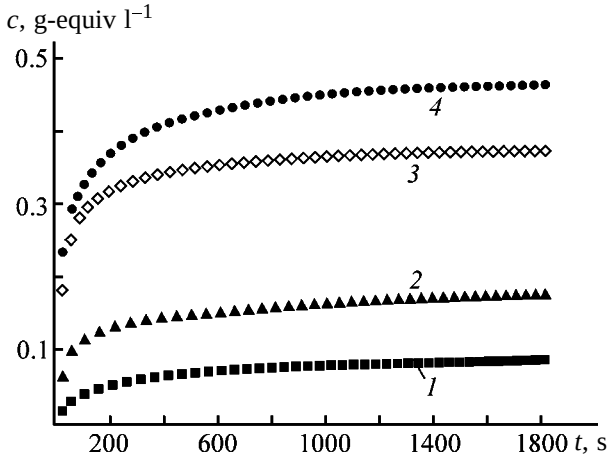

Fig. 2. Variation of the nickel sulfate concentration c with time t in the course of nickel hydroxide dissolution in sulfuric acid solutions of different concentrations at 50°C.

where K is the cell constant (0.260 – 0.277 cm^{-1}), and R_t is the solution resistance at time t.

The nickel sulfate concentration was determined from the χ_Σ value, found experimentally and calculated by Eq. (2). Variation of the nickel sulfate concentration with time at 50°C is shown in Fig. 2.

Table 2. Degree of nickel recovery α upon dissolution of $Ni(OH)_2$ in H_2SO_4 solutions

Solution no.	$c_{H_2SO_4}$, g-equiv l^{-1}	α, %, at indicated temperature, °C		
		25	50	75
1	0.1	65	92	97
2	0.2	61	89	96
3	0.4	64	94	96
4	0.5	78	93	97

The results obtained were compared with the data of the spectrophotometric analysis. The results of conductometric and spectrophotometric determinations of the nickel sulfate concentration at the end of the experiment are given in Table 1. As seen, the values of the nickel sulfate concentration calculated conductometrically agree well with the spectrophotometric data. This allows the conductometric method to be used for determining the nickel concentration in solution at any time.

The obtained values of the running and initial concentrations of sulfuric acid were used to calculate the degree of nickel dissolution at any time:

$$\alpha = (c_0 - c)/c_0,$$

where α is the degree of nickel dissolution; c_0 and c are the initial and running concentrations of sulfuric acid, respectively.

The calculated degrees of nickel dissolution by the end of the experiment are given in Table 2.

The experimental data were processed by different kinetic equations [7–9]. However, the experimental plots could be linearized only using an equation of the Erofeev–Kolmogorov type:

$$\alpha = 1 - \exp(-kt^n),$$

where α is the degree of dissolution; k, rate constant; t, time; and n, exponent taking into account the reaction order and a change in the surface area in the course of dissolution of the nickel hydroxide powder.

Writing Eq. (1) in the ionic form

$$1/2Ni(OH)_2 + H^+ \rightarrow 1/2Ni^{2+} + H_2O, \qquad (3)$$

we obtain:

$$-\frac{dc_{H^+}}{dt} = k' c_{H^+}, \qquad \frac{dc_{H^+}}{c_{H^+}} = k' dt, \qquad (4)$$

where k' is the parameter dependent on the area of the $_{solid}$ substance surface.

Let us integrate Eq. (4):

$$\ln c_{H^+} = -k't + \text{const}.$$

At the beginning of the process (at $t = 0$),

$$\text{const} = \ln c_0,$$

where c_0 is the initial concentration of hydrogen ions in a solution.

Then

$$\ln(c_{H^+}/c_0) = -k't,$$

$$1 - c_{H^+}/c_0 = 1 - \exp(-k't),$$

$$1 - c_{H^+}/c_0 = \alpha.$$

Consequently,

$$\alpha = 1 - \exp(-k't). \quad (5)$$

A change in the area of the solid particle surface in the course of the reaction can be described by the equation

$$S = \text{const}\, t^m, \quad m < 0,$$

then

$$k' = kt^m.$$

Substitution of k' into Eq. (5) yields the Erofeev–Kholmogorov type equation:

$$\alpha = 1 - \exp(-kt^{m+1}).$$

Taking $n = m + 1$, we obtain

$$\alpha = 1 - \exp(-kt^n). \quad (6)$$

The experimental data show that $0.135 < n < 0.916$ for the concentration and temperature intervals studied.

Applicability of Eq. (6) was verified by the linearity of the dependence $\ln[-\ln(1-\alpha)] = f(\ln t)$ obtained by taking two times the logarithm of the initial equation [9]. The $\ln[-\ln(1-\alpha)] = f(\ln t)$ dependences are plotted in Fig. 3. The rate constant k is calculated from the equation

$$\ln k = \ln[-\ln(1-\alpha)] - n(\ln t).$$

Linearization of the experimental graphs (3) shows that Eq. (6) adequately describes the kinetics of dissolution of the nickel hydroxide powder in sulfuric acid.

Then, the straight lines obtained were approximated by the direct least-squares method. As a result, $\ln k$ was determined. The rate constant was found, and the activation energy of the reaction was calculated after taking antilogarithm. The activation energy was

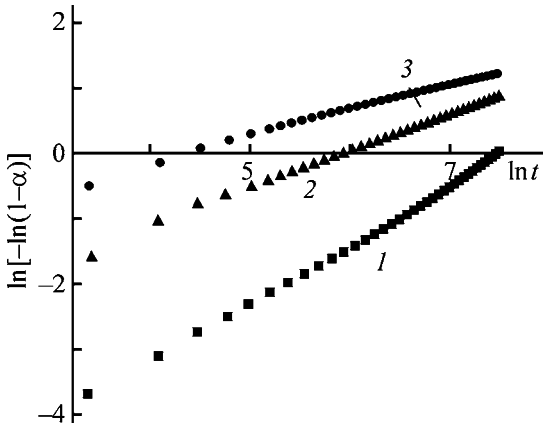

Fig. 3. The $\ln[-\ln(1-\alpha)]$–$\ln t$ dependence for nickel hydroxide dissolution in 0.1 N sulfuric acid at various temperatures. Temperature, °C: (*1*) 25, (*2*) 50, and (*3*) 75.

calculated by the formula

$$\Delta E = \frac{RT_1T_2\ln(k_2/k_1)}{T_2 - T_1},$$

where R is the universal gas constant (8.314 J mol^{-1} × K^{-1}); k_1 and k_2 are the rate constants at temperatures T_1 = 298.15 and T_2 = 348.15 K, respectively.

The final results of the calculation are presented in Table 3.

Table 3. Rate constant k and activation energy ΔE of the process

$c_{H_2SO_4}$, g-equiv l^{-1}	k, s^{-1}, at indicated temperature, °C			ΔE, kJ mol^{-1}
	25	50	75	
0.1	0.00101	0.03196	0.16740	88
0.2	0.00171	0.13921	0.33367	91
0.4	0.00895	0.29561	1.21531	85
0.5	0.00977	0.21541	0.77260	75

The values of the activation energy show that the dissolution of nickel hydroxide powder in 0.1–0.5 N sulfuric acid in the temperature range 25–75°C is kinetically controlled.

CONCLUSIONS

(1) The nickel sulfate and sulfuric acid concentrations at each time were determined from the results of measurement of the solution resistance in the course of dissolution. The values of the nickel sulfate concentration at the end of the experiment agree well with the data of the spectrophotomertic analysis.

(2) The obtained dependences are described by the Erofeev–Kholmogorov type equation. Within 25–75°C, the dissolution of nickel(II) hydroxide powder in 0.1–0.5 N sulfuric acid is kinetically controlled.

CATALYSIS

Deactivation of Iron–Gallium Oxide Catalyst for Ammonia Oxidation

N. I. Zakharchenko

Zhukovsky National Aerospace University, Kharkov, Ukraine

Received January 29, 2003

Abstract—An iron–gallium oxide catalyst (97.0 wt % Fe_2O_3, 3.0 wt % Ga_2O_3) was studied in high-temperature oxidation of ammonia. Reasons for the deactivation of the catalyst at elevated temperature were analyzed.

Catalytic oxidation of ammonia to nitrogen(II) oxide is the basis of the industrial method for manufacture of nitric acid [1]. In view of the high cost, shortage, and unrecoverable loss of commercial catalysts in industrial processes (platinum, rhodium, and palladium alloys), a search for effective nonplatinum catalysts is a topical problem. Iron(III) oxide is a promising base for catalysts of this kind; it is used industrially as a component of the second stage of a combined system for ammonia oxidation [1]. Commonly, high activity and selectivity with respect to nitrogen(II) oxide are preserved and the thermal and chemical stability of iron(III) oxide is improved using various modifying additives and, in particular, metal oxides [1–8].

Gallium(III) oxide (Ga_2O_3) is used as a modifying additive for iron-containing catalysts with varied content of modifying agent [1, 7, 8], but these catalysts are deactivated at elevated temperatures, with their selectivity with respect to nitrogen(II) oxide decreasing [1, 7]. Reasons for the deactivation of iron–gallium oxide catalysts are virtually unknown [1, 7]. The present study is concerned with deactivation of a highly selective iron–gallium catalyst (97.0 wt % Fe_2O_3, 3.0 wt % Ga_2O_3) in high-temperature oxidation of ammonia.

The catalyst was prepared by thermal decomposition in air of a mixture of hydrated iron nitrate [$Fe(NO_3)_3 \cdot 9H_2O$] and gallium nitrate [$Ga(NO_3)_3 \cdot 9H_2O$] of chemically pure grade, taken in calculated amounts, using a procedure described in [9]. The temperature of finishing thermal treatment of the catalyst grains was 1143 K.

An X-ray phase analysis was made on a Siemens D-500 powder diffractometer (CuK_α radiation, graphite monochromator) in the path of the diffracted beam. The phases manifested in the diffraction patterns were identified using a JCPDS file shipped with the diffractometer.

IR absorption spectra were measured on a Perkin–Elmer 577 spectrophotometer at 200–2000 cm^{-1} using KBr technique. The selectivity of the catalysts with respect to NO (S_{NO}) was determined on a flow-through installation with a quartz reactor 2×10^{-2} m in diameter, using the procedure described in [1]. The height of the bed of catalyst grains of size $(2 \times 3) \times 10^{-3}$ m was $(4–12) \times 10^{-2}$ m; content of ammonia in the ammonia–air mixture (AAM), ~10.0 vol %; time of contact, 6.89×10^{-2} s (normal conditions, n.c.), the optimal value according to previously obtained data; pressure, 0.101 MPa. The testing temperature was close to the optimal value for a single-component iron oxide catalyst (1103 K): in separate tests, it was varied within the range 1103–1173 K. The composition of the products of ammonia oxidation on the catalysts was determined using the known technique [10], by analyzing the gas mixture for the content of NH_3, O_2, N_2, NO, and N_2O before and after the catalysts. The sensitivity limit of this analytical procedure was (vol %) 3.0×10^{-3} for NH_3, 3.5×10^{-3} for NO, and 5.0×10^{-3} for O_2, N_2, and N_2O.

The specific surface area of the catalysts was measured by the method of low-temperature adsorption of nitrogen and calculated by the BET equation, using a standard procedure [11].

The binding energies of the surface oxygen to the catalysts were found from the temperature dependence of the equilibrium oxygen pressure over the surface of the compounds, using the procedure described in [12].

The basic characteristics of the iron–gallium catalyst are listed in Table 1.

According to the results of an X-ray diffraction analysis, the unused catalyst is a solid solution of

1070-4272/03/7609-1455$25.00

Table 1. Basic parameters of a catalyst for ammonia oxidation containing (wt %) 97.0 Fe_2O_3 and 3.0 Ga_2O_3

Run no.	Parameter (designation)	Numerical value

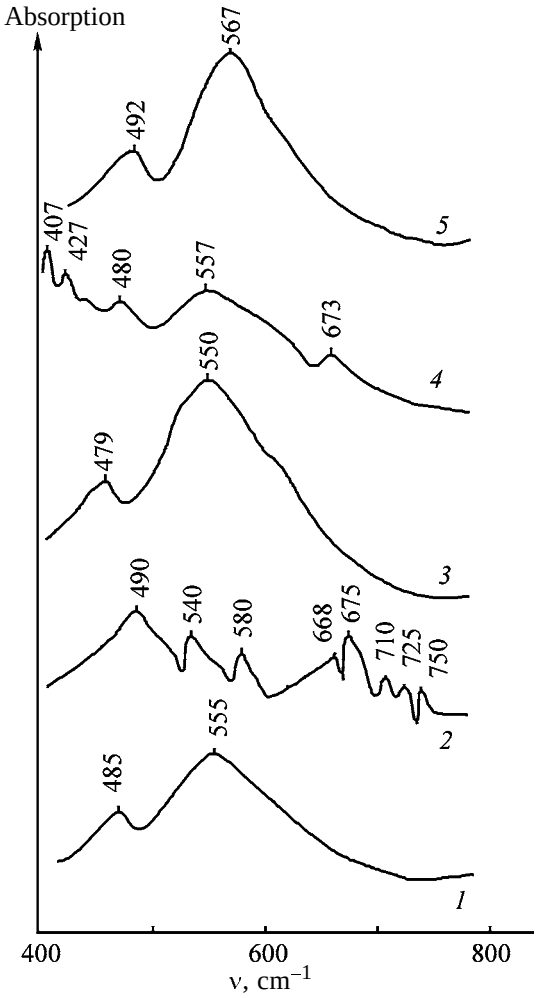

Fig. 1. IR absorption spectra of (*1*) α-Fe_2O_3, (*2*) β-Ga_2O_3, (*3*) unused iron–gallium catalyst, (*4*) surface (ferromagnetic) layer of iron–gallium catalyst upon operation, and (*5*) iron–gallium catalyst (nonmagnetic fractions) upon operation. (ν) Wave number.

gallium(III) oxide in hematite (α-Fe_2O_3), with the structure of the α-Al_2O_3 (corundum) type, i.e., $(Fe_xGa_{1-x})_2O_3$. The X-ray diffraction patterns of the fresh catalyst are characterized by main lines with interplanar spacings of 0.3682, 0.2693, 0.2511, 0.2214, 0.1846, 0.1695, 0.1484, and 0.1454 nm. These values are typical of the rhombohedral structure of α-Fe_2O_3 [3], but are shifted to greater reflection angles, which corresponds to a decrease in the lattice constant a of iron oxide from 0.5434 to 0.5423 nm. No gallium oxide lines were found in the catalyst, which points to the formation of a solid solution of gallium(III) oxide in hematite. IR spectra of unused catalyst contain absorption bands at 479 and 550 cm^{-1}. These values are typical of iron(III) oxide (485, 555 cm^{-1}) (Fig. 1), but are shifted to lower frequencies, which is accounted for by replacement, in solid formation, of a part of Fe^{3+} ions in the structure of hematite by havier Ga^{3+} ions. No β-Ga_2O_3 bands were found in the IR spectra of the catalyst, probably because of the fact that the absorption bands characteristic of gallium(III) oxide are close to those of hematite (Fig. 1), but the content of gallium oxide is insufficient for clear manifestation of the absorption bands of Ga_2O_3.

Studies of how the catalyst selectivity depends on the working time (Fig. 2) indicate that the iron–gallium catalyst exhibits higher stability than α-Fe_2O_3. The catalyst selectivity at 1103 and 1173 K decreased by 1.7 and 4.5%, respectively, after 90 h of operation. At the same time, the selectivity of iron(III) oxide decreased under the same conditions by 2.3 and 6.4%, respectively (Fig. 2). Raising the process temperature leads to stronger deactivation of both iron–gallium and iron oxide catalysts (Fig. 2). X-ray diffraction patterns of the surface layers of an iron–gallium catalyst that

Table 2. Binding energy of the surface oxygen of catalysts, q_S, and their selectivity with respect to nitrogen(II) oxide, S_{NO}

Run no.	Catalyst	Working time of catalyst, h	q_S,* kJ mol^{-1} O_2	S_{NO}, %, at 1173 K

5	Fe_3O_4	3	226.5	4.1

* q_S in the oxidized state of the catalyst surface.

worked at 1173 K contain lines of a rhombohedral solid solution of gallium(III) oxide in hematite, together with weak lines with interplanar spacings of 0.4850, 0.2970, 0.2430, 0.2102, 0.1713, 0.1615, and 0.1487 nm, typical of magnetite (Fe_3O_4) [3]. In this case, magnetite and the iron–gallium catalyst do not form solid solutions, being present as a mixture of separate phases.

The formation of magnetite is confirmed by IR data. The IR spectra of the surface layers of a catalyst after operation (magnetic fractions) contain absorption bands at 407, 427, 481, 558, and 673 cm^{-1} (Fig. 1), characteristic of magnetite [13]. According to [9, 14], magnetite suppresses the catalyst selectivity, being a low-active phase: the selectivity of magnetite is 7.0% at 1073 K.

Only two nitrogen compounds were found in the products formed in ammonia oxidation on the catalyst under study: N_2 and NO; no breakthrough of ammonia was detected. Thus, the overall conversion of the starting substance is 100.0%.

High-temperature catalytic oxidation of ammonia proceeds by two concurrent pathways [1, 15]:

$$4NH_3 + 5O_2 = 4NO + 6H_2O, \quad (1)$$

$$4NH_3 + 3O_2 = 2N_2 + 6H_2O. \quad (2)$$

The redox mechanism of the reactions [15] predetermines the relationship between the selectivity and the binding strength of chemisorbed oxygen to the catalyst surface [12, 15]. As measure of strength of oxygen binding to the catalyst can serve the heat of chemisorption [12, 15]. For catalysts of certain nature and, in particular, metal oxides, there exists the optimal energy of oxygen binding to the catalyst surface, at which the selectivity with respect to nitrogen(II) oxide is the highest [12, 15, 16]. Deviation from the optimal oxygen binding energies leads to lower catalyst selectivity with respect to NO, and to higher selectivity with respect to N_2.

The experimental binding energies of surface oxygen of the iron–gallium catalyst and its constituents are listed in Table 2.

The energies of oxygen binding to the surface of the forming magnetite and of the catalyst after its operation surpass the corresponding characteristics of the iron–gallium catalyst before operation.

In the formation of a product of deeper oxidation of ammonia, i.e., nitrogen(II) oxide, a greater number of oxygen–catalyst bonds is ruptured than that in the formation of molecular nitrogen. This means that the selectivity of the catalyst with respect to NO must decrease with increasing binding energy of adsorbed oxygen, which is, indeed, observed for magnetite and used catalyst, in which Fe_3O_4 was found.

Gallium(III) oxide is characterized, as a constituent of the iron–gallium catalyst, by high binding energy of oxygen to the surface (231.5 kJ mol^{-1} O_2), which is comparable with a similar characteristic for magnetite (226.5 kJ mol^{-1} O_2): the selectivities of these two phases with respect to NO are close (1.9 and 4.1%, respectively) and rather low.

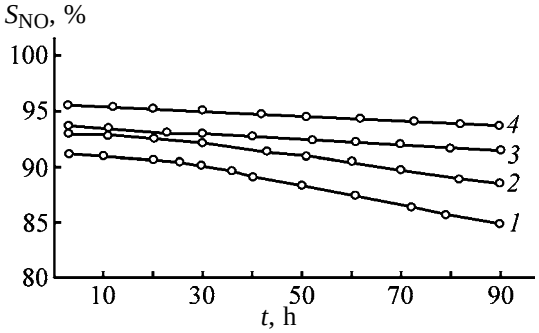

Fig. 2. Catalyst selectivity with respect to nitrogen(II) oxide, S_{NO}, vs. working time t: (*1*) α-Fe_2O_3, 1173 K; (*2*) Fe_2O_3–Ga_2O_3 (3.0 wt % Ga_2O_3), 1173 K; (*3*) α-Fe_2O_3, 1103 K; and (*4*) Fe_2O_3–Ga_2O_3 (3.0 wt % Ga_2O_3), 1103 K.

Table 3. Changes in chemical composition and mass of catalysts for ammonia oxidation in their operation at 1173 K

Run no.	Catalyst	Chemical composition, wt %			Content of Ga_2O_3 in $(Fe_xGa_{1-x})_2O_3$ solid solution, wt %	Mass loss by catalyst, %
		Fe_2O_3	Ga_2O_3	Fe_3O_4		
1	Unused iron–gallium	97.00	3.00	–	3.00	–
2	Iron–gallium after 90 h of operation	94.52	2.56	2.92	2.64	0.5
3	Unused β-Ga_2O_3	–	100.00	–	–	–
4	β-Ga_2O_3 after 20 h of operation	–	100.00	–	–	7.1

The product of phase transformations of the catalyst (magnetite) may be formed both in the redox reaction of ammonia oxidation [1–3, 5, 6, 15, 17] and in direct interaction of the parts of the catalyst surface that are characterized by low catalyst–oxygen binding energies with a strong reducing agent in the reaction medium, in accordance with the equation

$$9(Fe_xGa_{1-x})_2O_3 + 2xNH_3 = 6xFe_3O_4 + 9(1 - x)Ga_2O_3 + xN_2 + 3xH_2O. \quad (3)$$

The deficiency of Fe^{3+} ions in the surface layers of the catalyst (magnetite formation) leads to a local increase in the content of gallium(III) oxide in a hematite-based solid solution and a decrease in the selectivity of the catalyst with respect to NO (Table 2). According to X-ray phase analysis, no gallium(III) oxide was found as a separate phase, i.e., there was no decomposition of the solid solution. Gallium(III) oxide, as a component of a solid solution, may undergo, under the action of a strong reducing agent (ammonia) at high temperature (1073–1173 K), phase transformations in accordance with the reaction equation

$$3Ga_2O_3 + 4NH_3 = 3Ga_2O + 2N_2 + 6H_2O. \quad (4)$$

The transformation product, Ga_2O, readily sublimes at 1073–1173 [18] and thereby enters the gas flow of reagents. With account of the transformations of gallium(III) oxide, the equation describing reaction (3) can be written as follows:

$$9(Fe_xGa_{1-x})_2O_3 + 2(6 - 5x)NH_3 = 6xFe_3O_4 + 9(1 - x)Ga_2O + (6 - 5x)N_2 + 3(6 - 5x)H_2O, \quad (5)$$

where $0 \le x \le 1$.

The thermodynamic probability of reduction by ammonia of iron(III) oxide [19] as a component of the $(Fe_xGa_{1-x})_2O_3$ solid solution by the equation

$$9Fe_2O_3 + 2NH_3 = 6Fe_3O_4 + N_2 + 3H_2O \quad (6)$$

is higher than that of gallium(III) oxide reduction [18] and grows with increasing temperature. After 90 h of operation of an iron–gallium catalyst at 1173 K, magnetite was found in amount of 2.92 wt % (Table 3). For the iron oxide catalyst, the content of Fe_3O_4 in the surface layers was 4.80 wt % under the same testing conditions [9]. The intensity of phase transformations of the catalyst, $(Fe_xGa_{1-x})_2O_3$ solid solution, to give magnetite is somewhat lower than that of individual iron(III) oxide.

Processes (4) and (5) may lead to mass loss by catalyst because of Ga_2O sublimation. Indeed, its mass decreased by 0.5% after 90 h of catalyst operation at 1173 K. Hematite, magnetite, and gallium(III) oxide are nonvolatile thermally stable compounds in air at the testing temperatures [20]. To confirm the transformation of gallium(III) oxide, a component of the iron–gallium catalyst, in the course of high-temperature oxidation of ammonia, a mixture of substances after the catalyst was passed through columns cooled by a mixture of solid carbon dioxide and acetone (temperature of cooling mixture 213–203 K). The dramatic decrease in the temperature of the reaction products made it possible to minimize the interaction in the gas phase between gallium(I) oxide and oxidizing agents contained in the reaction mixture, nitrogen(II) oxide and oxygen, by the equations [18]

$$Ga_2O + 2NO = Ga_2O_3 + N_2, \quad (7)$$

$$Ga_2O + O_2 = Ga_2O_3. \quad (8)$$

In particular, process (7) may lead to nitrogen defixation, as in the side reaction of ammonia oxidation at short time of contact, in accordance with the equation

$$4NH_3 + 6NO = 5N_2 + 6H_2O, \quad (9)$$

i.e., to a decrease in the catalyst selectivity with respect to NO. Under the experimental conditions, Ga_2O vapor condensed on column walls, and water was frozen to ice (other substances contained in the

reaction mixture were carried away by the gas flow). After shutting down the reactor, the columns were purged with inert gas (Ar) and heated to T = 473 K to remove water. A film was found on the column walls. The substance of this film was identified by X-ray diffraction analysis as gallium(I) oxide. The IR spectra of this compound contain absorption bands at 472 and 809 cm^{-1}, characteristic of Ga_2O [21].

A low content of gallium(III) oxide in the solid solution leads to relatively small loss of mass by the iron–gallium catalyst at 1173 K. Chemical analyses performed using the procedure described in [22] demonstrated that the content of Ga_2O_3 in the $(Fe_xGa_{1-x})_2O_3$ solid solution decreased in the course of catalyst operation from 3.00 to 2.64 wt % (Table 3).

In tests of individual gallium oxide (β-Ga_2O_3) as a catalyst for ammonia oxidation, a pronounced decrease in its mass, by 7.1% after 20 h of operation at 1173 K, was observed (Table 3). X-ray phase and IR spectral analyses demonstrated that, under the action of the reaction medium, β-Ga_2O_3 undergoes, similarly to the iron–gallium catalyst, phase and chemical transformations to give volatile gallium(I) oxide. Thermal treatment of β-Ga_2O_3 at the same temperature in air did not lead to any decrease in the oxide mass, i.e., the catalyst is nonvolatile and thermally stable under these conditions. Consequently, the mass deficiency of the β-Ga_2O_3 catalyst under the conditions of high-temperature oxidation of ammonia is associated with the influence of the redox reaction medium, redox mechanism of the reaction [1–3, 5, 6, 15, 17], and processes (4) and (5).

The thermodynamic probability of oxidation of the forming low-active compound Fe_3O_4 by oxygen from AAM by the equation

$$4Fe_3O_4 + O_2 = 6Fe_2O_3 \quad (10)$$

is lower than that of processes (3) and (6) and decreases with increasing reaction temperature [19, 23]. It becomes possible that Fe_3O_4 is accumulated in the surface layers of the catalyst at elevated temperature. Being a volatile product of phase transformations of the catalyst, gallium(I) oxide sublimes from its surface, which makes lower the content of Ga_2O_3 in the iron–gallium catalyst (Table 3). High-temperature redox processes in which new phases (Fe_3O_4, Ga_2O) are formed and the catalyst surface is regenerated are unbalanced and result in accumulation of the low-selectivity compound (magnetite) and changes in the composition of the $(Fe_xGa_{1-x})_2O_3$ solid solution. With increasing temperature, the unbalance of the phase transformations of the catalyst becomes more pronounced.

Table 4. Changes in structural and catalytic properties of iron–gallium catalyst (3.0 wt % Ga_2O_3) in the course of its operation at 1173 K*

t, h	S_{NO}, %	s, $m^2\ g^{-1}$	n, nm	$X \times 10^{-3}$, $m^3\ h^{-1}\ m^{-2}$
3	93.0	8.7	120	9.58
11	92.8	7.4	134	8.15
20	92.5	6.1	150	6.72
30	92.1	4.8	170	5.29
43	91.3	3.7	200	4.08
51	90.9	3.1	220	3.42
60	90.3	2.7	237	2.97
70	89.7	2.3	253	2.53
82	89.0	1.9	270	2.09
90	88.5	1.7	280	1.87

* t is the time of operation, and n, the rms particle size.

In addition, the catalyst undergoes, under the action of elevated temperature, recrystallization with a decrease in the specific surface area (Table 4) from 8.7 to 1.7 $m^2\ g^{-1}$ (90 h of operation at 1173 K) and, consequently, in the number of active centers on the surface [1]. The size of catalyst particles grows from 120 to 280 nm.

A study of an iron–gallium catalyst subjected to thermal treatment in air at 1173 K (90 h) demonstrated that the specific surface area of the catalyst decreases by 7.5 $m^2\ g^{-1}$, i.e., within the same limits as in the case of a catalyst operating in an ammonia–air medium (Table 4), but the selectivity of this catalyst decreases by only 0.6%. No phase transformations were observed in the catalyst treated in air. The energy of oxygen binding to the surface of a catalyst treated in air increases only slightly (from 134.3 to 136.0 kJ mol^{-1} O_2), which leads to an insignificant decrease in its selectivity. In the IR spectra of the deactivated catalyst (Fig. 1), the absorption bands at 492 and 567 cm^{-1}, characteristic of "metal–oxygen" vibrations, are shifted to higher frequencies, compared to the similar absorption bands (479 and 550 cm^{-1}) of unused catalyst. Changes of this kind are also observed for a catalyst subjected to thermal treatment in air. Such a shift of absorption bands is accounted for by a decrease in the metal–oxygen bond length (an increase in the force constant of the bond), which is observed in recrystallization of solids [24], and leads to an increase in the energy of binding of adsorbed oxygen to the catalyst surface. The reaction occurs under conditions that are far from being critical, i.e.,

is limited by diffusion of ammonia toward the outer surface of the catalyst. Therefore, the specific surface area has no significant influence on the selectivity of the iron–gallium catalyst with respect to nitrogen(II) oxide [1–3, 5, 6, 17], i.e., the decrease in selectivity at 1173 K is mainly due to phase and chemical transformations of the catalyst. Under critical conditions of the reaction (catalyst "decay"), recrystallization processes and decrease in the specific surface area of the catalyst diminish its limiting load, i.e., activity, from 9.58×10^3 to 1.87×10^3 m^3 NH_3 $(h\,m^2)^{-1}$ (90 h of operation).

CONCLUSIONS

(1) A study of factors responsible for deactivation of an iron–gallium oxide catalyst (97.0 wt % Fe_2O_3, 3.0 wt % Ga_2O_3) in high-temperature oxidation of ammonia demonstrated that the catalyst undergoes phase and chemical transformations leading to formation of low-selective magnetite and volatile gallium(I) oxide. The deactivation process is accompanied by structural changes: recrystallization and decrease in the specific surface area of the system.

(2) Data on the deactivation of the catalyst can be used in developing theoretical and practical foundations for design of high-performance catalysts for ammonia oxidation.

CATALYSIS

Conjugate Conversion of Methanol and Lower Alkanes C_3–C_4 on Zeolite-Containing Catalysts

L. M. Koval', S. S. Safronova, E. B. Chernov, V. V. Bolotov, and N. V. Zhukova

Tomsk State University, Tomsk, Russia

Received December 17, 2002; in final form, May 2003

Abstract—Simultaneous conversion of methanol and lower alkanes C_3–C_4 on high-silica zeolites of ZSM-5 type of various compositions (SiO_2/Al_2O_3 30, 50, 90) was studied. The catalytic activity of zeolite catalysts and their physicochemical properties (acidity, sorption capacity, and pore structure) were evaluated.

Efficient utilization of cheap hydrocarbon resources such as natural and casing-head gas, gas condensate, and light paraffins in production of gasoline, lower olefins, arenes, and other valuable products is still urgent. Simultaneous conversion of methanol and lower alkanes C_3–C_4 into olefins and arenes is a new promising approach. Implementation of this process predominantly depends on the development of new heat-resistant catalysts [ZSM-5 high-silica zeolites (HSZ)] catalyzing conversion both of hydrocarbons into arenes and of methanol into alkenes.

This work was aimed to study the conjugate conversion of methanol and lower alkanes on high-silica zeolite catalysts of various compositions as influenced by the process parameters (temperature and space velocity) and to evaluate the relationship between the catalytic, acid, and sorption properties of these zeolites.

EXPERIMENTAL

High-silica zeolites were prepared by hydrothermal synthesis from aluminosilica gels in the presence of hexamethylenediamine upon heating at 448 K for 4–6 days; then the zeolites were decationized with 25% aqueous NH_4Cl at 363 K for 2 h, dried, and calcined in air at 823 K for 8 h. The acid properties of the zeolite-containing catalysts were determined by temperature-programmed desorption (TPD) of ammonia according to the procedure given in [1]. The sorption and structural properties of the resulting zeolites were studied on a vacuum unit equipped with a McBain quartz balance. The sorbates were benzene and methanol; the pore size distribution was calculated from the desorption isotherms of benzene.

The conjugate conversion of methanol and lower alkenes (wide-cut fraction) into hydrocarbons on the zeolite-containing catalysts was performed at 673–873 K and atmospheric pressure on a flow-type unit with a fixed catalyst bed (4 cm^3) at space velocities of methanol and lower alkanes of 1 and 240 h^{-1}, respectively. The gaseous and liquid reaction products were analyzed by chromatography at programmed heating from 323 to 493 K. The yield of the conversion products of methanol and propane–butane mixture and the number of the acid centers in the catalysts were determined by this method with an accuracy of ±2.5%.

We studied the conjugate conversion of methanol and lower alkanes on HSZ (SiO_2/Al_2O_3 30) as influenced by temperature and space velocity of the raw materials. Table 1 shows the data on the composition of hydrocarbon fraction obtained by methanol conversion on H-ZSM-5 at 644 K and 1 h^{-1} space velocity of methanol [2], by conversion of lower alkanes on H-ZSM-5 at 873 K and space velocity of propane–butane mixture of 100 h^{-1} [3], and by simultaneous conversion of methanol with lower alkanes on the H-ZSM-5 type zeolite in the 673–823 K range and alkanes : methanol space velocity ratio of 240 : 1.

The choice of the temperature range was governed by the fact that the lower temperature limit corresponds to the efficient conversion of methanol and the upper limit, to activation of lower alkanes [4]. The experimental data show that the conjugate conversion yields the same set of the reaction products as the individual processes, and the yield of the products is intermediate. The conjugate conversion at 823 K yields significant amounts of olefins (about 30 wt %) and at 623 K, large amounts of *i*-butane (25.4 wt %), alkylbenzenes (about 40 wt %), and low amount of naphthalenes (1.9 wt %). With increasing temperature, conversion of lower alkanes increases. As the conversion of the propane–butane mixture increases from 38 to 65%, the yields of hydrogen, methane (from 3 to

Hydrocarbon	*T*, K	Conversion products, wt %						
		n-butane	butenes	benzene	toluene	xylenes	arenes C_{9+}	naphthalenes
Methanol	644	5.6	0.5	1.7	10.5	17.2	11.6	0.2
Methanol + alkanes C_3–C_4	673	–	4.5	2.4	13.5	23.7	9.0	1.9
	723	–	4.6	3.8	14.7	13.2	6.5	1.7
	773	–	2.4	1.6	6.3	12.7	2.6	1.0
	823	–	3.7	1.3	5.3	4.6	1.9	1.1
Alkanes	823	–	–	8.5	10.1	3.9	1.8	4.2

31 wt %), ethane, ethylene, and propylene (from 3 to 12–14 wt %) grow significantly, whereas the selectivity with respect to aromatic hydrocarbons decreases from 47 to 12 wt %.

Thus, at high temperatures lower alkanes are activated and their cracking accelerates. High temperature accelerates the removal of the reaction products from the surface, increasing the fraction of lower gaseous hydrocarbons which have no time to participate in subsequent oligomerization, cyclization, etc.; as a result, the yield of arenes decreases.

The yields of the conversion products as influenced by the ratio of the space velocities of methanol and lower alkanes at 773, 823, and 873 K are listed in Table 2. The space velocity of the propane–butane mixture was constant (240 h^{-1}), and the space velocity of methanol was 0.4, 0.9, and 1.7 h^{-1}. The increase in the space velocity of methanol to 1.7 h^{-1} does not noticeably affect the overall conversion of the propane–butane mixture, and its change does not exceed ±5%. However, methanol clearly affects the distribution of the products of conjugate conversion.

Methanol increases the selectivity with respect to alkenes C_2–C_4, and at 773 K their fraction increases from 3.3 in the absence of methanol to 15.6 wt % (methanol space velocity 0.4 h^{-1}). Although at different temperatures the effect of methanol on the degree of conversion and selectivity is different, some trends can be revealed.

With increasing space velocity of the methanol supply from 0.4 to 1.7 h^{-1}, the selectivity with respect to alkenes C_2–C_4 increases from 15.6 to 21.3 wt % at 773 K, from 17.5 to 35 wt % at 823 K, and to a still greater extent at 883 K. The selectivity with respect to aromatic hydrocarbons C_6–C_{10} increases also, the selectivity with respect to arenes varies within the 15.6–27.7 wt % range at 773 K, and with increasing temperature their yield decreases. At the same time, the increase in the methanol content increases the selectivity with respect to arenes and alkenes and decreases the yield of lower alkanes C_1–C_2, on the average, from 60 to 30 wt % in the entire temperature range studied.

The dependence of the selectivity with respect to aromatic hydrocarbons C_6–C_{10}, alkenes C_2–C_4, and alkanes C_1–C_2 on the silica ratio (*M*), i.e., the silica–alumina ratio in the zeolite, is shown in Table 3. At 773 K, with increasing silica ratio, the selectivity with respect to alkenes C_2–C_3 increases from 13.3 to 22.4 wt % and the selectivity with respect to aromatic hydrocarbons remains almost constant and varies within 23–25 wt % range. The conversion of the initial alkanes C_3–C_4 at 773 K with increasing content of alumina in the zeolite increases from 66 to 73 wt %. At 823 and 873 K, with decreasing alumina content (silica ratio 30 and 90), the selectivity with respect to alkenes C_2–C_3 decreases from 34.12 to 17.1 wt %. The content of aromatic hydrocarbons increases from 13.54 to 24.90 wt % with increasing silica ratio

from 30 to 50 and remains approximately the same (23.3 wt %) for the sample with M = 90. The conversion of the starting lower alkanes strongly increases with increasing temperature above 773 K, but its dependence on the silica ratio is ambiguous; at 823 K the conversion increases from 77 to 90 wt % with increasing silica ratio, but at 873 K this increase is insignificant, from 85 to 89 wt %.

The catalytic activity of the zeolites in question in conversion of methanol and lower alkanes C_3–C_4 is due to the presence of acid centers on their surface. Thus, it was of particular interest to reveal a correlation between their acid properties and catalytic parameters. There are no generally accepted views on how the acidity of the zeolite surface centers correlates with the silica ratio. It was shown that, with increasing SiO_2/Al_2O_3 ratio in the zeolite framework, the strength of the acid centers increases [3, 5, 6], remains unchanged [7], and decreases [8]; i.e., there is no direct correlation of the concentration and strength of the acid centers with the HSZ silica ratio. This suggests that we can only determine the optimal silica ratio ensuring the highest catalytic activity of the sample in the process studied.

The concentration of the acid centers in HSZ and their strength were determined by temperature-programmed desorption of ammonia (Table 4). The TPD spectra show the presence of two acid centers; the low-temperature form is assigned [9, 10] to the weak acid, predominantly Lewis, centers, and the high-temperature maximum belongs to the strong acid centers (predominantly Brønsted proton centers). The amount of desorbed ammonia in the temperature range studied, which is determined by the number of the acid centers of both types, and the positions of the maxima in the ammonia TPD spectra, indirectly characterizing the strength of the acid centers occurring on the HSZ surface, are given in Table 5.

Table 4. Structural parameters of HSZs

Catalyst	Limiting sorption capacity	Volume of intermediate pores	Volume of micropores	Coefficient in the Dubinin–Radushkevich equation		Diameter of mesopores, nm, in maximum		
	$cm^3\ g^{-1}$			$B_1 \times 10^8$	$B_2 \times 10^8$	1	2	3
H-HSZ-30	0.09	0.03	0.06	0.31	3.34	20	35	75
H-HSZ-50	0.09	0.03	0.06	0.32	2.87	17	35	–
H-HSZ-90	0.08	0.03	0.05	0.30	1.97	13	32	80

As seen from Table 5, with increasing silica ratio from 30 to 90 the total concentration of the acid centers decreases from 1.17 to 0.48 mmol l^{-1}, which is due to a decrease in the content of alumina in the zeolite framework. In accordance with low-temperature shifts of the desorption peaks, the strength of the acid centers of both types decreases with increasing silica ratio. The HSZ sample with *M* = 30 is characterized by the highest concentration of the acid centers on its surface with predominance of low-temperature acid centers (type I : type II = 1 : 0.75). For this zeolite sample, the alkene : arene ratio is 3 : 1 at 823–873 K. For the samples with *M* 50 and 90, the concentration ratio of the acid centers of both types is similar (type I : type II = 0.75 : 1). Moreover, the strength of the acid centers of both types in these samples is also similar, which causes their nearly equal catalytic activity with respect to aromatic hydrocarbons in the entire temperature range (773–873 K) and difference in the selectivity with respect to alkenes from the

Table 5. Acid properties of HSZs

Catalyst	T_{max}, K		Content of acid centers, mmol g^{-1}	
	1	2	1	2
H-HSZ-30	476	765	0.67	0.50
H-HSZ-50	467	722	0.28	0.38
H-HSZ-90	471	712	0.20	0.28

sample with a lower silica ratio (*M* 30) and a higher content of stronger acid centers of type I, providing dehydrogenation of the starting alkanes and oligomerization of alkenes.

Thus, the activity of the zeolite catalysts and their selectivity with respect to aromatic and olefin hydrocarbons in the course of conjugate conversion of methanol and lower alkanes C_3–C_4 predominantly depends not on the total content of the acid centers, but on the concentration of the strong acid centers on the catalyst surface, which activate the alkane molecules and promote dehydrogenation and subsequent aromatization of hydrocarbons.

As seen from the data on the pore structure (Table 4), the sorption capacity for benzene of all the zeolites in question is similar and comprises 0.08–0.09 $cm^3\ g^{-1}$, and the greatest contribution to the total pore volume is made by micropores (0.04–0.06 $cm^3\ g^{-1}$). The greatest volume of micropores was found in zeolite with *M* 30 and 50 (0.06 $cm^3\ g^{-1}$). According to the theory of the volume filling of micropores (TVFM), the zeolite samples studied contain two types of micropores with different size, corresponding to the parameters B_1 and B_2 in the TVFM equation indirectly characterizing the micropore size. The parameter B_1 for zeolites with various silica ratios varies insignificantly in the $(0.30-0.32)\times10^{-8}$ range. The parameter B_2 with increasing silica ratio from 30 to 90 decreases from 3.34×10^{-8} to 1.97×10^{-8}, i.e., with increasing silica ratio the size of the zeolite micropores decreases. Similar trend in the decrease of the zeolite pore size was found in [11]. Analysis of the structural parameters of zeolites and their acid properties showed that the micropore size (characterized by B_2) varies in parallel with the total concentration of the acid centers.

The data on the methanol sorption on the zeolites with various silica ratios showed that H-HSZ-30 zeolite with the greater total volume and size of micropores has greater sorption capacity for methanol. The isotherms of the methanol sorption calculated from the Dubinin–Astakhov equation with two exponents [12] suggest that the zeolite contains two type of micropores with different characteristic energies. This confirms our above conclusions on the pore structure, made from the data on the benzene sorption. The increase in the characteristic energy with increasing silica ratio indicates that the micropore size decreases.

Thus, study of the catalytic activity of zeolites with various silica ratios in the course of conjugate conversion of methanol and lower alkanes C_3–C_4 and analysis of their sorption, structural, and acid properties showed that the sample (*M* 30) exhibiting a high selectivity in alkene formation is characterized by the higher content and greater strength of the acid centers and exhibits high sorption capacity for methanol, probably due to the larger micropore size.

CONCLUSION

(1) The yield of alkenes in conjugate conversion of methanol and lower alkanes C_3–C_4 increases with the temperature and space velocity of the methanol supply.

(2) The highest catalytic activity is shown by the zeolite sample with the silica ratio of 30, which is characterized by the maximal concentration and strength of the acid centers and by coarser micropores.

(3) The zeolite samples with smaller pores and lower concentration and strength of the acid centers (silica ratio 50 and 90) can be used in synthesis of alkylaromatic hydrocarbons at low temperature.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Water Purification with Titanium Compounds To Remove Fluoride Ions

E. P. Lokshin and M. L. Belikov

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received April 18, 2003

Abstract—Sorption of fluoride ions from water by titanium compounds was studied. The possibility of deep purification of fluorine-containing wastewater with water-soluble oxotitanium(IV) sulfates was analyzed and the optimal conditions of this process were determined.

Millions of cubic meters of wastewater are formed at a number of mining plants at the Kola Peninsula because of the presence of villiaumite in the ore. These effluents are characterized by increased concentration (up to 10 mg l^{-1}) of fluoride ions. Part of wastewater finds its way to fish farming ponds without being purified. Liquid effluents with increased content of fluoride ions are also present in some other regions of Russia. According to the existing regulations, the concentration of fluoride ions must not exceed 1.4 mg l^{-1} in drinking water reservoirs and 0.75 mg l^{-1} in fishery ponds.

Fluoride ions can be recovered by precipitation, sorption, and electrochemical methods.

It has been recommended to purify solutions from hydrometallurgical processing of tungsten raw materials using the lime method, although purification to the MPC (maximum permissible concentration) was not achieved [1]. At an F^- concentration in weakly mineralized water of 12 mg l^{-1}, introduction of 8 g l^{-1} of CaO and subsequent carbonation for 90 min diminished the concentration of fluoride ions to 1.25 mg l^{-1}, and introduction of 10 g l^{-1} of CaO, to 0.37 mg l^{-1} [2]. A high purification efficiency was achieved by addition of a considerable excess of compounds promoting "salting-out" of the forming fluorite and their subsequent sorption with de-ashed pyrocarbon [3] or zeolites [4].

The use of aluminum sulfate (in amount corresponding to 0.95 g l^{-1} in terms of alumina) at pH 6–7 and settling time not exceeding 0.5 h made it possible to diminish $[F^-]$ from 9.3 to 1.5 mg l^{-1} [5]. The efficiency of removal of fluoride ions increases in the presence of soluble salts of calcium [6]. Sodium and calcium aluminates sorb fluoride ions, with the orthoform being the most effective among calcium aluminates [7, 8]. The use of aluminosilicate materials for precipitation of fluoride ions failed to offer any additional advantages [9, 10].

The disadvantages of the techniques mentioned above are as follows.

Sorbents saturated with fluoride ions cannot be regenerated and reused, and their disposal may lead to migration of fluoride ions into the environment.

Additional water purification to remove aluminum(III) is necessary if water is to be discharged into drinking water or fishery reservoirs; according to GOST (State Standard) 2874–82, the maximum permissible concentration of aluminum ions in drinking water is 0.5 mg l^{-1}.

The fluoride ion can be precipitated in the form of fluoroapatite by introducing soluble compounds of calcium and the phosphate ion into a solution with pH 6–11.5 [1]. However, purification by this method takes a long time (the concentration of fluoride ions in a 100-ml portion of solution decreased from 10 to 1.2–1.8 mg l^{-1} in 5 h, and to 0.1–0.6 mg l^{-1} in 35 h). In addition, although it has been reported that deep purification is achieved at the stoichiometric consumption of reagents [11], it has been shown that this method leads to secondary contamination of water with foreign ions because of the high consumption of chemicals.

It has been suggested to use a sorption–precipitation method for purification of wastewater to remove fluoride ions by its treatment with lime milk to pH 8–

1070-4272/03/7609-1466$25.00

11 and subsequent introduction of adsorbents, water-soluble titanium fluorides (potassium, sodium, and lithium hexafluorotitanates) [12]. A report of the high efficiency of this technique (residual concentration of fluoride ions of 0.3 mg l^{-1} at initial concentration of 3–5 g l^{-1}) seems to be doubtful because of the unclear mechanism of F^- sorption by hexafluorotitanates of alkali metals, which are readily hydrolyzable in alkaline media, with the release of fluoride ions.

The residual concentration of fluoride ions in the case of their sorption from wastewater by $CaSO_4$ synthesized in the presence of sulfocarbon in a solution being purified was 5 mg l^{-1} and more [13].

Purification of water with rare-earth metals as precipitants or adsorbents [14] fails to ensure sufficiently complete removal of fluoride ions, since the solubility of rare-earth metal fluorides is not low enough [15] and, moreover, strongly depends on the pH value and ionic composition of the solution.

The use of anion-exchange resins of various brands in the OH^- form in an equivalent mixture with KU-2 cation-exchange resin in the H^+ form made it possible to recover sodium fluoride from neutral and weakly alkaline solutions containing 5.6–8.0 g l^{-1} of fluoride ions to an extent of 98–99.5% (28–40 mg l^{-1}); however, the residual concentration of F^- remained high [16].

A chelate ion-exchange resin modified with cerium can be used for removal of fluoride ions from solutions [17]. A common disadvantage of ion-exchange techniques is the necessity for thorough preliminary removal of suspended particles from solutions and difficulties encountered in processing large amounts of solutions.

Use of electrochemical methods [18] gives no way of processing large amounts of wastewater and involves gross energy expenditure.

Thus, the known techniques show various disadvantages and, therefore, cannot be used for industrial purification of wastewater discharged into drinking water reservoirs. Moreover, these techniques, as a rule, do not involve processing of solid products saturated with fluorides ions. These products, in turn, act, when stored, as a source of environment contamination with fluorine.

The aim of this study was to develop a method not only involving deep purification of wastewater to remove F^-, but also enabling utilization of fluoride ions and regeneration of the sorbent.

EXPERIMENTAL

Sorption of fluoride ions with hydrated oxotitanium(IV) hydroxide was performed from NaF solutions with fluoride ion concentration of 1.0 g l^{-1}, in which the initial pH_{in} value was adjusted to 4, 5, and 6 with hydrochloric acid.

Hydrated oxotitanium(IV) hydroxide was obtained by dissolving a weighed portion of $TiOSO_4 \cdot 2H_2O$ [TU (Technical Specification) 6-09-01-279–85] in water and separating the precipitate formed in hydrolysis from the liquid phase by centrifugation. Then the precipitate was washed with water until washing water containing no SO_4^{2-} ions was obtained.

The obtained hydrated oxotitanium(IV) hydroxide was used to sorb F^- from 30 ml of NaF solution under continuous agitation with a magnetic stirrer. In the process, the concentration of fluoride ions and the pH value were monitored with ion-selective electrodes and I-160 pH meters. After the equilibrium was attained (in 40–60 min), the solution was separated by centrifugation from the precipitate and a fresh portion of an NaF solution with the same initial pH was added to the precipitate. In each stage, the solution to sorbent mass ratio α was 50. The procedure was repeated until the sorption activity of the precipitate started to decrease steeply. The atomic ratio of the total amount of sorbed F^- and TiO_2 was calculated. The value of K_d was found from the equation

$$K_d = \frac{\alpha_{F^-} \alpha_1}{100 - \alpha_{F^-}}, \quad (1)$$

where α_{F^-} is the fraction of sorbed F^- relative to the total amount brought in contact with the adsorbent (%), and α_1 is the mass ratio of the total amount of solution brought in contact with the sorbent and of the sorbent itself.

The experimental results obtained are listed in Table 1.

Fluoride ions are sorbed by oxotitanium(IV) hydroxide from aqueous solutions by the reaction

$$TiO_{1+x}(OH)_{2-2x} + yF^- = TiO_{1+x}(OH)_{2-2x-y}F_y + yOH^-. \quad (2)$$

Reaction (2) proceeds to such a full extent that it is used for quantitative determination of OH^- groups bound to titanium [19]. It has been established [19] that the efficiency of sorption of fluoride ions depends on how hydrated titanium dioxide is prepared and on

the anionic and cationic composition of the solution from which F^- sorption is carried out. As a result of olation and oxolation processes, oxotitanium(IV) hydroxide may have, depending on synthesis conditions, different numbers of hydroxo groups per titanium atom. Although it has been reported that $Ti(OH)_4$ can be obtained [20], this is not the case because of the high rates of olation and oxolation. Neutralization of $TiCl_4$ with ammonia or ammonium carbonate at room temperature gives $TiO(OH)_2$ [21]. However, this form is also unstable, and oxotitanium hydroxide, $TiO_{1+x}(OH)_{2-2x}$, species with $x < 1$ are gradually formed. By boiling of $TiCl_4$–HCl–H_2O and $TiOSO_4$–H_2SO_4–H_2O mixtures, air-dry products of the composition $TiO_{2-x}(OH)_{2x}$, with $x = 0.04 \pm 0.05$ and 0.05 ± 0.01, respectively, have been obtained, and neutralization of $TiCl_4$ with potassium hydroxide at room temperature yields a product with $x = 0.225 \pm 0.05$ [22]. In the last case, part of OH^- groups was probably converted into OK^- groups as a result of sorption of potassium cation.

Table 1 shows that hydrated oxotitanium(IV) hydroxide effectively sorbs fluoride ions from aqueous solutions. In accordance with reaction (2), sorption must be accompanied by an increase in the solution pH; however, the final pH_{fin} of a solution decreased in first stages of its use in sorption. This can be attributed to the fact that precipitates formed in hydrolysis of oxotitanium(IV) sulfate [23] contain a considerable amount (up to 8 wt %) of sulfate groups.

Therefore, the sorption of fluoride ions may be accompanied, together with reaction (2), by liberation of H^+ and, as a consequence, by a decrease in pH. The fact that a decrease in pH was observed in the first stages of sorption indicates that liberation of sulfuric acid occurs more easily than reaction (2). In later sorption stages, pH either stabilizes (run no. 1) or grows.

If it is assumed [24] that residual sulfate groups in hydrated oxotitanium(IV) hydroxide are present in the form of the acid $HOTiO–OSO_2OH$, then sorption of fluoride ions can be represented, in addition to reaction (2), by the reactions

$$HOTiO–OSO_2OH \rightarrow HOTiO–OSO_2O^- + H^+, \quad (3)$$

$$NaF \rightarrow Na^+ + F^-, \quad (4)$$

$$HOTiO–OSO_2O^- + F^- \rightarrow (HO)TiOF + SO_4^{2-}. \quad (5)$$

Reactions (3)–(5) must result in that the concentration of hydrogen ions in solution grows and sulfate ions pass into solution. After the acid $HOTiO–OSO_2OH$ is exhausted, sorption of fluoride ions proceeds by reaction (2) leading to the observed increase in pH.

Table 1 shows that K_d first decreases somewhat and then grows with increasing solution pH_{in}. With pH_{in} varying within the range 4–6, β changes only slightly in the first stages of sorption, but then it decreases by a factor of approximately 1.5 with the pH_{in}

increasing from 4 to 5–6, which points to a dramatic decrease in the number of sorption-active groups.

After regeneration of a sorbent "saturated" with fluorine by treating the sorbent with a 0.107 N sodium hydroxide solution and then washing it thoroughly with water, the sorption activity of the sorbent decreased dramatically: Under the experimental conditions, the residual concentration of F^- was 0.65 g l^{-1}, instead of 0.01–0.035 g l^{-1} in the case of a fresh sorbent. The possible reasons for such a behavior are as follows: conversion of OH^- groups into ONa^- groups and their inability to exchange for fluoride ions, intensification of olation–oxolation reactions in the alkaline medium, and disappearance of sulfate groups from the solvent.

Thus, even though freshly prepared hydrated oxotitanium(IV) hydroxide sorbs F^- rather effectively, its recycling after regeneration with alkaline solutions is inefficient.

The experimental data obtained suggest that $TiOSO_4 \cdot H_2O$, which is readily obtained in processing titanium-containing mineral raw materials, can be used directly for sorption of fluoride ions from aqueous solutions.

In studying sorption of fluoride ions by oxotitanium(IV) sulfate, account was taken of the fact that wastewater from a number of mining plants of the Kola industrial region commonly shows alkaline reaction because of the presence of NaF. Although sulfate ions will find their way into water instead of fluoride ions, their maximum permissible concentration in the aqueous phase (MPA) is relatively high (500 mg l^{-1}); however, the expenditure of oxititanium(IV) sulfate should be kept within the limits allowing discharge of purified water into water reservoirs.

In the experiments, a certain amount of $TiOSO_4 \cdot 2H_2O$ was introduced into solutions with prescribed concentration of F^-. The resulting mixture was agitated, with the pH value monitored continuously. Hydrolysis of titanyl(IV) sulfate occurred in the solution, and the forming precipitate sorbed fluoride ions. The concentration of F^- was also monitored continuously, if the pH value of the mixture allowed this. In those experiments in which the equilibrium pH value did not correspond to a value that enabled F^- concentration measurements, the solid phase was separated before determining the concentration, and the pH of the filtrate was adjusted to 4.1–4.3 with a sodium hydroxide solution. In performing the sorption at constant pH, this constant prescribed value was maintained, when necessary, by adding dropwise a concentrated (250 g l^{-1}) NaOH solution. After F^- sorption terminated, the precipitate formed was separated, and the residual content of titanium(IV) in the purified solution was determined spectrophotometrically using a titanium(IV) peroxo complex.

Table 2. Sorption from solutions containing 10 mg l^{-1} of F^- (pH_{in} 6.70) with pH maintained at 4–4.5

Parameter	$TiOSO_4 \cdot 2H_2O$ expenditure, mg l^{-1}

K_d, cm^3 g^{-1}	4290	10 000	24 620

* pH value was maintained constant during sorption by introducing NaOH.

A study of the influence exerted on the sorption efficiency by expenditure of solvent at pH maintained at 4–4.5 (the strongest sorption was observed at this pH value) demonstrated that deep purification of wastewater to remove F^- can be achieved with oxotitanium(IV) sulfate (Table 2). In this case, titanium completely passes from the solution being purified into the precipitate. Deeper purification can be achieved at higher expenditure of oxotitanium sulfate (smaller β).

At higher concentrations of F^- in the initial solution, greater expenditure of the sorbent may be required. Table 3 shows that, with increasing amount of introduced $TiOSO_4 \cdot 2H_2O$, pH_{fin} and efficiency of F^- sorption decrease and there occurs secondary contamination with titanium(IV) of the solution being purified. This contamination becomes more pronounced with decreasing pH.

With the pH_{fin} increasing from 4.5 to 5 at a constant $TiOSO_4 \cdot 2H_2O$ expenditure (200 mg l^{-1}), β decreases more steeply (Table 4) than in the case when hydrated oxotitanium(IV) hydroxide is used for sorption (Table 1).

The optimal pH_{fin} value of sludge is 4–4.5, since, in this case, the values of β and K_d are sufficiently high and the introduced titanium is completely precipitated from the solution.

The purification efficiency is virtually independent of whether the sorbent is added in several portions (Table 5) or in one portion (Table 2, 800 mg l^{-1}). However, the 5-fold drop in β at decreasing initial

Parameter	Stage						
	1	2	3	4	5	6	7
Final concentration of F^-, mg l^{-1}	7.0	3.4	2.8	1.8	1.45	1.1	0.5
pH_{in}	6.7	4.0	4.15	4.18	4.06	4.20	4.15
$TiOSO_4 \cdot 2H_2O$ introduced, mg l^{-1}:							
in a stage	100	200	100	100	100	100	100
total	100	300	400	500	600	700	800
β:							
in a stage	0.310	0.185	0.063	0.102	0.036	0.036	0.062
total	0.310	0.227	0.186	0.169	0.147	0.136	0.128
K_d, $cm^3\ g^{-1}$:							
in a stage	4290	5280	2175	5520	1332	6220	12 015
total	4290	6461	6445	9102	9830	12 000	23 750

concentration of fluorine in solution (Table 5, stages 1 and 7) indicates that sorbent portions brought in contact with a solution with low F^- concentration are not saturated with the fluoride. The total expenditure of the sorbent can be lowered if the process is carried out in a step-like counterflow mode, with a solution richer in fluoride ions purified using the sorbent already brought in contact with an F^--depleted solution.

At $TiOSO_4 \cdot 2H_2O$ expenditure of 800 mg l^{-1}, which is sufficient for deep purification of wastewater containing 10 mg l^{-1} of F^-, only 423 mg l^{-1} of SO_4^{2-} ions is introduced into water at the permissible concentration of 500 mg l^{-1}. Using $TiOSO_4 \cdot H_2O$ instead of $TiOSO_4 \cdot 2H_2O$ has no effect on the process of wastewater purification.

To conclude, it should be noted that 94.2–97.5% of fluoride ions are distilled off from titanium-containing sulfuric acid solutions already at 100°C [25]. This

enables treatment of the isolated solid product with sulfuric acid to give HF gas, which can be used for manufacture of various fluorine-containing compounds, and water-soluble titanium sulfates, suitable for reuse in wastewater purification.

CONCLUSIONS

(1) Wastewater can be efficiently purified to remove fluoride ions with titanium(IV) compounds and, in particular, with hydrated oxotitanium sulfates. The lowest F^- concentration achieved in this case, 0.5–0.6 mg l^{-1}, is lower than that required by regulations for fishery ponds. The optimal conditions of the purification process were determined.

(2) In the optimal modes of the purification process, wastewater is not contaminated secondarily with titanium compounds and the concentration of the introduced sulfate ions in purified water does not exceed the permissible level.

(3) Processing of the resulting solid product containing titanium and fluorine, with sorbent regeneration and manufacture of usable fluorine compounds, will enable purification of fluorine-containing wastewater without any necessity for disposal of sorbents saturated with fluoride ions.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Ozonation of Fulvic Acids of Natural Waters in Aqueous Solutions

G. V. Slavinskaya and V. F. Selemenev

Voronezh State University, Voronezh, Russia

Received March 26, 2003

Abstract—Ozonation of fulvic acids of natural waters in aqueous solutions was studied.

It is known that water chlorination gives rise to its contamination with carcinogenic organic impurities [1]. Therefore, ozone is widely used today as oxidant instead of chlorine in water treatment. Ozonation is used for treating drinking and ultrapure water, for breakdown of organic impurities in wastewater, etc. [2–6]. Ozonation of natural waters is actively studied to elucidate the possibility of water decontamination from ozonation products by various techniques, including coagulation and sorption.

Taking into account that fulvic acids (FAs) are, as a rule, the main organic impurity present in natural waters, we studied in this work their ozonation in aqueous solutions.

EXPERIMENTAL

Fulvic acids were isolated from Neva water by the technique reported in [8]. The ozonation of fulvic acid solutions was carried out in a glass column of bubble type 70 mm in diameter at pH 7.1 typical of Neva water. The experiments on water treatment by coagulation with iron sulfate combined with liming were carried on the same column at pH 9. The air–ozone flow containing 6.8–10.0 mg dm^{-3} ozone was generated by an ozonizer with the performance of 2 g O_3 min^{-1} at the air flow rate of about 1 dm^3 min^{-1}. The difference between the ozone concentration in the aqueous solution before and after its reaction with FAs was determined by the method reported in [9].

As seen from Fig. 1, on ozonation of neutral FA solutions, the color index measured at 350 nm (an SF-46 spectrophotometer) decreases to a lesser extent than on ozonation of weakly alkaline FA solutions.

The color of fulvic acids is due to the fact that these molecules contain a polycyclic aromatic core and peripheral chains, with a common system of conjugated double bonds giving a continuous absorption band in the range 200–350 nm [10]. On oxidation with ozone, this chromophoric molecular system is broken down.

The FA degradation is manifested in the electronic absorption spectra (Fig. 2) as a decrease in the optical

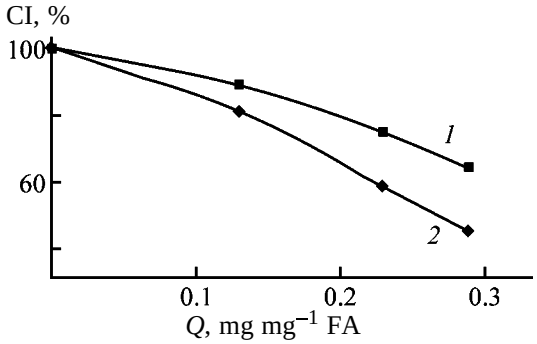

Fig. 1. Residual color index CI as a function of the ozone amount Q that reacted with FAs at pH (*1*) 7 and (*2*) 9.0.

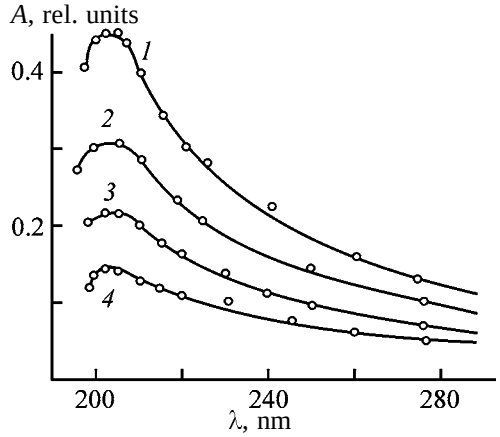

Fig. 2. Electronic absorption spectra of FAs (*1*) before and (*2*) after ozonation. Q (mg mg^{-1} FA): (*1*) 0, (*2*) 0.13, (*3*) 0.23, and (*4*) 0.29. (*A*) Optical density and (λ) is wavelength.

1070-4272/03/7609-1472$25.00

density at invariable shape of the spectra. These spectra show that, on ozonation, only a certain fraction of FA molecules degrade.

The effect of ozonation on the molecular-weight distribution of FAs was studied by gel chromatography on a column 10 mm in diameter packed with Molselect G-50 gel (gel bed height 300 mm, sample volume 0.1 ml). Water was used as eluent. The gel chromatograms of the initial FAs and those after ozonation have two elution bands (Fig. 3). The first elution band (*I*) belongs to the high-molecular-weight fraction of FAs (HMWF). This fraction, due to its steric features, cannot penetrate into gel and, therefore, is eluted first. The second elution band belongs to low-molecular-weight fraction of FAs (LMWF). Figure 3 shows that, after ozonation, the relative content of HMWF (band *I* in gel chromatograms *1*' and *2*') decreases and, correspondingly, the LMWF content (band *II*) increases. These gel chromatograms also show that, with increasing pH from 7.1 to 9.0, the degree of HMWF degradation increases from 20 to 60%. We found that the initial molecular weight of HMWF (8900) does not noticeably change after ozonation. At the same time, the LMWF molecular weight decreases from the initial value of 6400 to 5300 and 4000 after ozonation in neutral and alkaline media, respectively. The decrease in the molecular weight of organic compounds to values <5000 on ozonation was noted in [12].

To elucidate how ozonation affects the FA structure, the IR spectra of both HMWF and LMWF were recorded on a Specord UV Vis-235 spectrophotometer (KBr pellets) before and after ozonation. These studies showed that, after ozonation, the bands of the C–H stretching vibrations at 2950 and 2880 cm^{-1} disappear. Taking into account that the intensity of the absorption band of the bending vibrations of the methyl groups of FAs at 1460 cm^{-1} also decreases after ozonation [13, 14], we can suggest that the disappearance of the above-noted C–H stretching bands after ozonation is caused by degradation of the methyl groups.

Another effect of FA ozonation is transformation of a sharp absorption band of skeletal C–C vibrations of the benzene rings at 1510 cm^{-1} into a weak absorption peak. This fact shows that, on ozonation, some fraction of the aromatic rings is broken down. The strengthening of the absorption bands at 1720 and 1400 cm^{-1} shows that ozonation results in an increase in the content of carbonyl groups.

It should be noted that, after ozonation, LMWF contains not only products of FA reaction with ozone

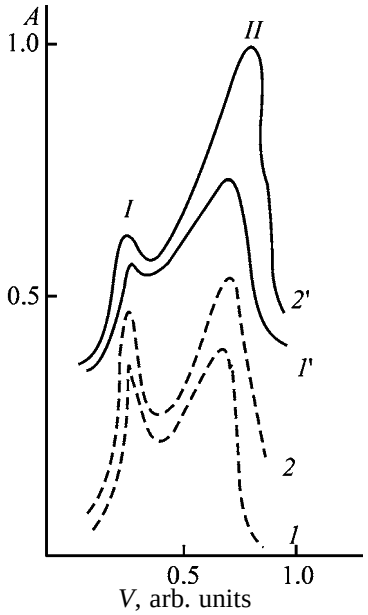

Fig. 3. Gel chromatogram of FA (*1*, *2*) before and (*1*', *2*') after ozonation at (*1*, *1*') pH 7.1 and (*2*, *2*') pH 9.0. (*A*) Optical density of eluate and (*V*) eluate volume.

but also low-molecular-weight species formed by HMWF degradation. Therefore, the IR spectra reflect the total amount of low-molecular-weight fractions of both origins. The amount of the COOH groups increases owing to oxidation of the terminal methyl groups of FA molecules, which is manifested in disappearance of the absorption bands at 2950 and 2880 cm^{-1}.

The possibility of oxidation of the peripheral hydrocarbon groups of FAs into carboxy groups was analyzed by Orlov [10]. In our case, the IR spectrum of the initial FAs contains no absorption band at 3030 cm^{-1} typical of benzene rings with more than four substituents, but contains the bands of C–C vibrations at 1620, 1500 and 1450 cm^{-1} characteristic of less substituted benzene rings. The substituents can be oxidized with ozone to form benzenepolycarboxylic acids.

We also determined the elemental composition, weight content, and permanganate oxidizability (PO) of the ozonation products. To compare the weight content of FAs in the initial solution and that after ozonation, we used the completely dimeneralized FAs. The effect of ozonation of FA solution on the amount of their dry residue (after drying of FA solution under an Infratherm lamp at 34–36°C) is demonstrated in Table 1.

These results show that, after ozonation of FA solution, the weight content of FAs decreases insig-

nificantly. However, under the same conditions, the elemental composition of FAs substantially changes. It was found that, on ozonation, the carbon content in FAs decreases, whereas the content of H, N, and O increases. We believe that enrichment of FAs in nitrogen is caused by formation of nitrogen oxides in the ozonizer from atmospheric nitrogen. The relatively small loss of carbon suggests that carbon is oxidized not only to CO_2, but also to various oxygen-containing hydrocarbon groups (not only carboxy, but also keto, aldehyde, ether, and alcoholic groups). The permanganate oxidizability shows that ozonation decreases the content of readily oxidizable fractions by 40%.

The content of the carboxy groups in FAs before and after ozonation was determined by potentiometric titration from a single sample. Based on the titration curves, we calculated both the ionization constants of the COOH groups of FAs by the Henderson–Hasselbach equation and the equivalent weights of fulvic acids before and after ozonation (Table 2).

Table 2 shows that the COOH group content in FAs increases after ozonation by 50%. Ozonation increases both the dissociation constant of the carboxy groups (K_a) and the electrical conductivity χ. At the same time, the equivalent weight of FAs decreases owing to degradation.

To elucidate what products are formed upon ozonation of FAs, the ozonized FAs solutions were fractionated by high-performance liquid chromatography (HPLC). Fractionation was performed on an Milikhrom multicolumn chromatograph equipped with a spectrophotometric detector sensitive in the range 190–260 cm^{-1} and a 2 × 62-mm column packed with Silosorb-600 sorbent with particle size of 5×10^3 nm. Amino acids contained in the fulvic acids were determined by the method described in [15]. A fulvic acid solution (5–10 μl) was introduced into the chromatographic column and eluted with a water–acetonitrile (40 : 60)–0.35 NH_4OH mixture until the optical density A in the measuring and reference cells became equal.

Table 2. Effect of ozonation on FA properties

O_3 reacted, mg O_3 mg^{-1} FA	C_{CO_2H}, mg-equiv g^{-1}	FA equivalent weight	pK_a*	$\chi \times 10^{-4}$, Ω^{-1} cm^{-1}
0	4.15	242	4.2	3.87
0.13	6.46	148	3.7	7.17
0.23	6.62	138	3.5	7.82
0.29	6.68	153	3.6	9.90

* Determination accuracy ±0.05.

Under these conditions, a chromatogram contains four elution bands, the first of which refers to amino acids. In the chromatograms of ozonized FAs, the height of all the elution bands decreases irrespective of pH, and this decrease was the more pronounced, the greater amount of ozone reacted with FAs. This chromatographic analysis showed that FA ozonation results in their degradation. However, we found no new elution bands in the chromatograms, i.e. the chomatographic method used is incapable of detecting the products of FA degradation.

CONCLUSIONS

(1) On reaction with ozone, both the high- and low-molecular-weight fractions of fulvic acids are broken down. The products of fulvic acid ozonation have lower degree of aromaticity and lower molecular weight. At the same time, the content of carboxy groups in them increases. This factor can favor sorption of the products of fulvic acids degradation on anion exchangers by the anion-exchange mechanism.

(2) In ozonation of fulvic acids, the degree of their degradation increases in going from neutral (pH 7.1) to alkaline (pH 9) solutions. After ozonation, the weight content of fulvic acids decreases by 7–8% in neutral (pH 7.1) and by 17–18% in alkaline (pH 9.0) solutions.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Regeneration of Exhausted Chrome Tanning Solutions from Leather Production as a Method Preventing Environmental Pollution with Chromium

V. P. Panov, E. M. Gyul'khandan'yan, and A. S. Pakshver

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received February 5, 2003

Abstract—Photochemical degradation of organic impurities in exhausted chrome tanning solutions is studied. A method for regeneration of these solutions is proposed, allowing reduction of chromium loss with wastewater.

Leather production in the volume of water consumption and, correspondingly, in the volume of water supply ranks first among the branches of light industry. Since tanneries are arranged mostly near water basins used as sources of drinking and industrial water, the problem of preventing pollution of these basins with leather production discharges is very topical.

After tanning of hide (skin after removal of the hair side), 22 to 35% of the chrome tanning agent remains in exhausted tanning solutions, which corresponds to a residual chromium concentration of 3–8 g l^{-1} (recalculated to Cr_2O_3). According to published data, more than 25 000 t of Cr(III) is discharged to the environment with leather production wastes all over the world, whereas the discharge from metallurgical works is about 1500 t [1–4].

One of the promising ways to reduce the discharge of chrome tanning agents and, correspondingly, the Cr(III) consumption is recycling of chrome tanning solutions. Recovery of chromium(III) from exhausted tanning solutions by precipitation requires large amounts of alkaline reagents and sulfuric acid for dissolution. The resulting Cr(III) hydroxide sludge is poorly settled and filtered, being contaminated with residual proteins.

Presently growing efforts are devoted to developing methods of waste treatment without phase transfer, for example, ultrafiltration on various membranes allowing separation of solutes, fats, and protein residues [5]. However, to provide reasonable service life for the membranes, the solutions should be pretreated to thoroughly remove suspended materials prior to ultrafiltration. Wide application of the method is also limited by high cost and batch process mode.

The problem of recycling of tanning solutions may be solved only after solving the problem of removal of organic impurities from them, for example, by degradation. Recent studies demonstrate high efficiency of liquid-phase oxidation of organic impurities under the combined effect of active oxygen, hydroxy radicals formed in UV treatment of the solutions after addition of hydrogen peroxide, and ozone. In this case, degradation of organic acids, particularly, amino acids proceeds more rapidly by two orders of magnitude than with the use of an oxidant only [6, 7].

There is no information in the literature on the effect of UV irradiation on Cr(III) complexes with amino acids. It may be expected that photolysis will break down such complexes, providing mineralization of the amino acids. As a result, the chrome tanning agent will be regenerated.

In this work we studied photochemical degradation of organic impurities with simulated and actual exhausted tanning solutions. The process was monitored by the chemical oxygen demand (COD) using the standard procedure. The amino acid concentration was determined by paper partition chromatography using water–acetone–*n*-propanol–acetic acid (1 : 2 : 1.5 : 0.2) as a mobile phase and polarography. Experiments on determination of COD of solutions containing such amino acids as glycine, β-alanine, *DL*-proline, and arginine showed that, under the COD determination conditions (boiling in 18 N sulfuric acid for 2 h), the degree of mineralization of organic impurities ranges

1070-4272/03/7609-1476$25.00

from 86 to 94%, which was then taken into account in interpretation of the results.

In the experiments we used a photoreactor with UV irradiation from the top (monochromatic radiation at λ = 254 nm, dose rate 30 W l^{-1}, irradiation time 120 min) and supply of hydrogen peroxide.

In the simulated solutions, the concentrations of glycine and β-alanine (recalculated to COD) were 670 mg O_2 l^{-1} each. After addition of the tanning agent to a Cr_2O_3 concentration of 4 g l^{-1}, COD increased to 2440 mg O_2 l^{-1} as a result of the presence of organic impurities in it. The experiments showed that photolysis of amino acids in aqueous solutions proceeds slowly, but considerably accelerates in the presence of the chrome tanning agent (Fig. 1). Evidently, in acid solutions, Cr(III) compounds behave as catalysts [8]. The results obtained demonstrate a possibility of a sufficiently exhaustive photochemical degradation of organic impurities.

Even stronger acceleration of the UV degradation of organic impurities is realized in the presence of H_2O_2. After addition of H_2O_2, COD, determined by the standard procedure, increased, since H_2O_2 acts as a reducing agent with respect to $K_2Cr_2O_7$ (potassium bichromate is the commonly used oxidant in COD determinations). The stoichiometric amount of hydrogen peroxide (relative to the initial COD of the solution) was estimated as

$$M_{H_2O_2} = COD_0 M_{exp(H_2O_2)}/M_{exp(O_2)}.$$

After addition of H_2O_2 in amount of 50, 100, and 150% relative to the stoichiometric amount into the solution with COD_0 = 4200 mg O_2 l^{-1}, COD increased to 6000, 8050, and 10 000 mg O_2 l^{-1}, respectively. Similar trends were also observed in the corresponding aqueous H_2O_2 solutions. Without UV treatment, COD of the chrome tanning solutions remained practically unchanged in 60–120 min at 20–25°C. After addition of H_2O_2 (60–130% against the stoichiometry) to the initial tanning solution (Cr_2O_3 concentration 3.5 g l^{-1}, COD 1370 mg O_2 l^{-1}), UV treatment resulted in decreasing COD (Table 1).

The most significant change in COD was observed in the first 60 min of UV treatment. In this time, the degree of degradation of organic impurities approaches 55–70% (75–85% in 2 h). The residual content of organic impurities is quite acceptable for reuse of exhausted tanning solutions. It appeared inexpedient to increase the amount of H_2O_2 above 100%, since, with increasing amount, the residual COD does not noticeably decrease.

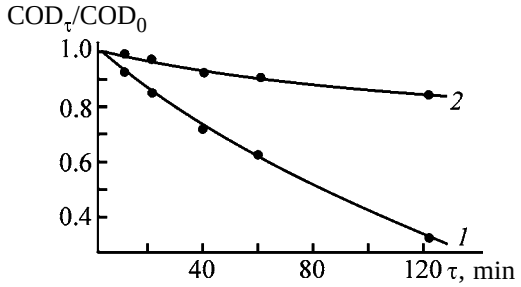

Fig. 1. Relative decrease in the COD (COD_τ/COD_0) in the course of photochemical treatment (*1*) with and (*2*) without chrome tanning agent. (τ) Irradiation time.

UV treatment of 2.6×10^{-2} M glycine solutions with introduction of H_2O_2 (100% against the stoichiometry of glycine mineralization to CO_2, H_2O, and NH_3) provides a 60–65% decrease in COD in 10–20 min. After introduction of Cr(III) (4 g l^{-1} recalculated to Cr_2O_3) into the solutions, COD decreased by 80–85%.

To estimate the efficiency of the photochemical degradation of organic impurities in exhausted chrome tanning solutions, we carried out experiments with actual industrial waste formed after tanning of pig hide. The initial Cr(III) concentration was 3.9 g l^{-1} (recalculated to Cr_2O_3), pH 3.7, and COD, 3700 mg O_2 l^{-1}. The experiments were performed at 293 K with addition of H_2O_2 (Table 2).

The results reveal complex interactions between components of the system. In the initial period of UV treatment, the radiation energy goes to degradation of organic impurities (photolysis in the absence of H_2O_2) or, in the presence of H_2O_2, to its photolysis. UV radiation may break down Cr(III) complexes with amino acids with formation of some intermediates, but without considerable change in COD. Actual solutions contain saturated organic compounds, whose degradation is hindered. After the initial (in the first 30–40 min) degradation of complex structures in the

40	2330	5020	4960
60	2220	4410	4100
90	2100	2820	1620
120	1850	1760	930

presence of H_2O_2, COD considerably decreases, as in simple photolysis.

The rate of the photochemical degradation of organic impurities depends on their nature, as demonstrated by the experiments on UV treatment of actual exhausted solutions after tanning of goatskin. The initial Cr(III) concentration was 4 g l^{-1} (recalculated to Cr_2O_3); COD, 1780 mg O_2 l^{-1}; radiation dose rate, 15 W l^{-1}. At an H_2O_2 dose of 25–70% against the stoichiometry, even in 30–60 min, the degree of degradation approached 50–70% (Fig. 2). Since for recycled solution there is no need in full mineralization of organic impurities, it is enough to perform the UV treatment for 60–90 min.

Under industrial conditions (70-l tanning drum), we performed experiments on tanning of goatskin with fresh and recycled tanning solutions, all other conditions being equal. Prior to the experiments, the exhausted solutions after UV treatment were conditioned with the fresh tanner. Six batches of hide were tanned. The quality of all the resulting leathers was practically the same. The shrinkage temperature of leather ranged from 108.2 to 110 and from 107.8 to 109°C with the use of the fresh and regenerated tanning solutions, respectively. The shrinkage test results met the technical regulations.

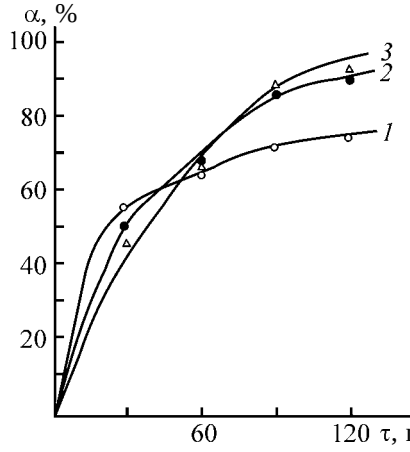

Fig. 2. Total degree of degradation of organic impurities and hydrogen peroxide α as a function of the UV treatment time τ. Amount of H_2O_2 added (% of stoichiometry): (*1*) 25, (*2*) 50, and (*3*) 75.

The results obtained provided a basis for developing a new method of regeneration of exhausted chrome tanning solutions from leather production [9]. In this method, the volume of the chrome tanning agent discharged or delivered to alkaline treatment stage can be reduced by a factor of 4–6.

CONCLUSIONS

(1) Exhausted chrome tanning solutions can be regenerated by UV treatment at a wavelength of 254 nm.

(2) Introduction of hydrogen peroxide in the solution considerably intensifies degradation of organic impurities (in actual systems, 60–90-min irradiation provides 50–75% degradation). Chromium(III) compounds were proved to accelerate degradation of organic impurities.

(3) The quality of leather produced with regenerated tanning solutions was demonstrated to be virtually the same as with a fresh tanning solution. The proposed regeneration method allows reduction in the chromium loss with wastewater by a factor of 4–6.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Contamination and Cleaning of a Microfiltration Membrane in Filtration of an Aqueous Extract of Dog-Rose

B. T. Sagdullaev, E. V. Safonova, and M. A. Khodzhaeva

Yunusov Institute of Chemistry of Vegetable Compounds, Academy of Sciences of the Republic of Uzbekistan, Tashkent, Uzbekistan

Received February 26, 2003

Abstract—The main factors responsible for decrease in the filtration flux (membrane throughput) in removal of pectin substances from an aqueous extract from dog-rose fruits and reasons for membrane contamination were studied. The method for membrane cleaning with distilled water and additional cleaning agents, aqueous solutions of NaOH and HNO_3, was optimized.

Microfiltration is one of baromembrane methods for solution separation, which is used to remove microparticles, bacteria, grease drops, yeast cells, and colloids from suspensions. This method is based on the sieve mechanism, i.e., the filtering membrane can catch from solutions particles and large dissolved molecules. This yields two products, retentate and permeate. The retentate is a suspension that cannot pass across the membrane, and, therefore, the retentate concentration grows in the course of the filtration process. The permeate is a solution that has passed across the membrane and contains no large molecules [1, 2].

According to the IUPAC classification (1985), microfiltration membranes have pores more than 50 nm in size [3].

Microfiltration is a promising and attractive method for concentration of macromolecules, desalination (mainly for removal of low-molecular-weight compounds from macromolecular solutions), fractionation of macromolecules, and clarification, pasteurization, and sterilization of juices, wines, beer, and dairy products, and also in manufacture of biologically active substances [4–6].

The main advantage of this method is its high throughput. However, the throughput (filtration flux) decreases in the course of filtration, which is mainly due to membrane contamination and concentration polarization [7]. Commonly, the filtration flux decreases upon contamination, but occasionally the membrane selectivity is also altered. These changes are observed during the entire process and even may make necessary membrane replacement [8].

The effect of factors responsible for membrane contamination has been poorly studied. In principle, all the components (with exception of the solvent) involved in filtration can contaminate the membrane. Physicochemical properties of individual components, membrane, and the bulk of the flow being filtered determine the nature and amount of contamination. Not infrequently, substances dominating in the contamination are present in trace amounts and their concentration has virtually no effect on the main components involved in the separation process. For example, the flux decreases in most of aqueous solutions through deposition of particles or microorganisms present in these solutions [9].

Certain difficulties are encountered in identifying the component making the main contribution to contamination and in determining the extent of this contribution.

Many researchers explain the fast decrease in the permeate flux by the occurrence of concentration polarization, which leads to formation of a gel layer [10, 11]. The simultaneous decrease in the flux is attributed to membrane contamination. However, the contamination may occur very rapidly, since the time necessary for adsorption of macromolecules on the membrane surface may be as short as several seconds. It should be noted that the factors responsible for the decrease in the membrane throughput include slow increase in the solution viscosity because of particle retention (in solution concentration), concentration polarization, and slow physicochemical changes in the structure of the membrane or substances [11].

The cleaning of membrane is one of the most im-

1070-4272/03/7609-1479$25.00

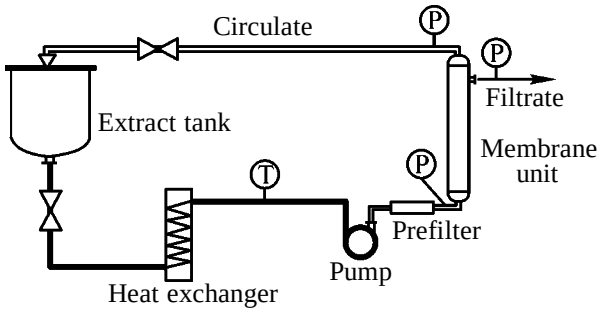

Fig. 1. Schematic of the microfiltration process.

portant processes for preservation of its properties (permeability and selectivity). Theoretically, the process of membrane cleaning must be effective, simple, and executable without disassembly of the membrane unit. In doing so, the membrane and filtering installation should not be damaged and the cleaning procedure must conform to all sanitary and hygienic regulations.

The present communication reports the results obtained in studying the effect of the main factors (transmembrane pressure and temperature) on the membrane contamination in removal of pectin substances from an aqueous extract from fruits of *Rosa canina L.* dog-rose and evaluates the efficiency of various cleaning agents.

EXPERIMENTAL

The experiments were carried out on an Alpma microfiltration installation (Germany) with two membrane units, each comprising nine cylindrical ceramic membranes (Fig. 1). The total effective filtration area was 2.2 m^2. Monolithic ceramic Kerasep membranes (France) had rated pore size of 0.2 μm. The overall diameter of the membrane with 19 channels (channel diameter 2.5 mm) was 20 mm. This membrane is thermally and chemically stable in contact with chemical cleaning agents at 20–85°C and pH 1–14, and also in sterilization with steam at 121°C (for 40 min).

The filtration flux across the membrane was ($l\ h^{-1}\ m^{-2}\ bar^{-1}$) 3600 for distilled water, 2000 for spring water, 500–1500 for contaminated water, and 80–250 for fruit juices. The effect of pressure on the flow rate of a fluid being filtered was studied under transmembrane pressure of 100–300 kPa, and the influence of solution temperature on the filtration process, at 25–50°C and constant pressure (200 kPa).

The experiments were carried out with an aqueous extract produced from dog-rose fruits used in manufacture of the Kholosas preparation. The total amount of extractive substances in the extract was 1.5 wt %, and the content of pectin substances, 0.047 wt %. The extract also contained a number of other compounds: flavonoids, several organic acids (citric, malic, ascorbic), pigments, mineral substances, etc.

The specific throughput of a filter is determined by the flux J [amount of substance (solution volume) that passes across a unit surface area in unit time, $m^3\ m^{-2}\ s^{-1}$].

The flux can be found as the ratio of the increasing volume of permeate, ΔV, collected in unit time Δt, to the area of the effective membrane surface, or mass-transfer area, S:

$$J = \frac{\Delta V/\Delta t}{S}. \quad (1)$$

The flux of pure solvent, J_w, passing across a clean (new) membrane can be expressed as

$$J_w = \frac{\Delta P}{\mu_p R_m}, \quad (2)$$

where ΔP is the transmembrane pressure (Pa); μ_p, permeate viscosity (Pa s); and R_m, membrane resistance to a flow of pure solvent (m^{-1}).

As already mentioned, the effect of contamination and concentration polarization is commonly regarded as an additional membrane resistance R_f, resulting from adsorption of particles on the surface of the membrane and within its pores [12].

Equation (2) can be used to account for the contamination effect by including the additional resistance R_f to the flow passing across the contaminating layer (Darcy law):

$$J_w = \frac{\Delta P}{\mu_p(R_m + R_f)}. \quad (3)$$

The value of R_f varies with pressure, solution concentration, and rate of solution circulation at low pressures; however, at its high values, pressure has no significant effect on the process [13].

At constant ΔP, μ_p, and R_m, the resistance R_f becomes a function of time.

Membrane cleaning is the most important procedure in all membrane processes. All membranes, including liquid membranes, are contaminated in operation, and, as a consequence, their throughput decreases to below the acceptable level. As a result, the substances contaminating the membrane must be removed from the surface and pores of the membrane by special cleaning techniques. The cleaning is done

to remove not only contaminating deposits, but also microorganisms to conform to hygienic regulations.

Frequently, additional maintenance of the membrane (chemical pretreatment) makes higher the permeate flux [14]. In this study, the microfiltration membrane was preliminarily treated by circulation of a 0.005 M solution of NaOH. This was done at a temperature of 50°C and transmembrane pressure of 0.5 bar for 0.5 h.

Immediately after the treatment of the membrane, experiments aimed to determine the flux J_w for pure solvent (water) were carried out. This value was used in calculating the maximum throughput and cleanness of the membrane.

Further, the membrane unit was subjected to contamination with an aqueous extract of dog-rose fruits, which was circulated for 30 min with continuous filtration. The decrease in the membrane throughput and appearance of a considerable amount of deposits on it were monitored by measuring the permeate flux J_p.

Additional chemical cleaning was performed after rinsing the system with distilled water for 15 min (without circulation) and 0.5% solution of NaOH for 40 min with full circulation (of permeate and retentate), at controlled temperature. The permeate flux in the course of cleaning was measured, and rinsing was done, using a volumetric cylinder and a stopwatch.

In parallel, experiments on membrane cleaning with 0.5% HNO_3 for 40 min and preliminary washing with distilled water for 15 min were carried out. The efficiency of the cleaning process was evaluated as the ratio of the flux J_c during cleaning to flux J_w of pure solvent determined on a clean (new) membrane (before its being contaminated).

The restoration of the initial flux J_r (%) was evaluated by the formula

$$J_r = (J_c/J_w) \times 100. \quad (4)$$

The extent of membrane contamination affects the permeate flux, which markedly decreases with increasing contamination. The flux is frequently high at the beginning of the filtration process and markedly decreases in the course of time [11]. In the present study, the contamination model is analyzed at different pressures and temperatures.

Figure 2a shows how the transmembrane pressure affects the flux decay. The data obtained indicate that the flux grows with the transmembrane pressure increasing from 100 to 300 kPa. However, after 15 min this difference becomes insignificant, and then, with the membrane becoming contaminated, changes in

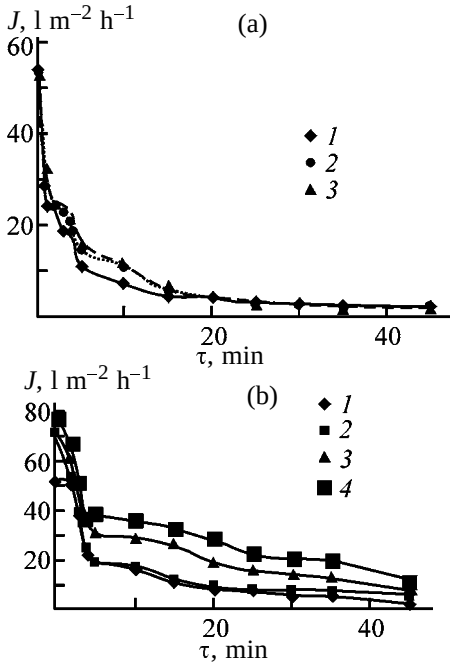

Fig. 2. Permeate flux J vs. time τ. (a) Transmembrane pressure (kPa): (*1*) 100, (*2*) 200, and (*3*) 300. (b) Permeate temperature (°C): (*1*) 25, (*2*) 35, (*3*) 40, and (*4*) 50 (transmembrane pressure 200 kPa).

pressure do not lead to the expected change in the flux. This phenomenon can be only accounted for by the individual properties of the membrane (morphology, chemical nature of its material) and the fluid being filtered.

Also, the effect of temperature on the flux was studied. The experiments were performed at different temperatures (from room temperature to 50°C) and constant transmembrane pressure of 200 kPa.

Figure 2b shows that the flux grows with increasing temperature, which can be accounted for by the effect of temperature on the solution viscosity and mass-transfer coefficient, with the resulting improvement of the transfer of high-molecular-weight components of the extract from the membrane surface into the common flow.

To determine the effective temperature in membrane cleaning, experiments were done at 25 to 65°C by washing with distilled water at low transmembrane pressure (50 kPa).

The optimal temperature for membrane cleaning was found to be 55°C, as shown in Fig. 3. Raising the temperature further leads to poor flux restoration. This is accounted for by better separation into constituents and/or dissolution of deposits on the membrane surface at higher temperatures. This gives rise to free fine particles, which can be more firmly fixed within the

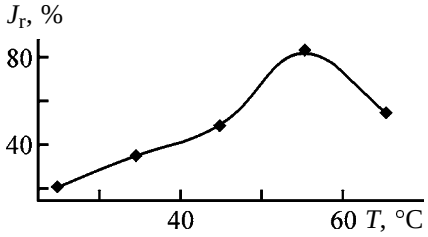

Fig. 3. Effect of temperature on the cleaning process: extent of restoration of the initial flux J_r.

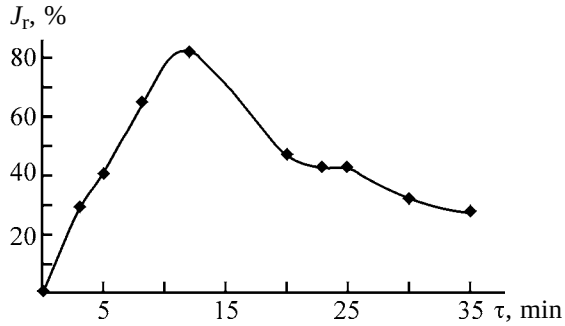

Fig. 4. Extent of restoration of the initial flux J_r vs. time τ of membrane cleaning.

pores of the membrane than coarser particles [15].

Figure 4 shows a typical curve of restoration of the flux of distilled water at 55°C The curve reaches a maximum (82%) in 12 min and then gradually descends. The appearance of the peak in the flux restoration curve can, probably, be accounted for by the mechanism described in [13]. After the cleaning procedure, coarse settled particles can be removed, and, therefore, a tendency toward increase in the flux is observed originally. However, at the same time, some fine particles formed upon dissolution of a part of large molecules may find their way into narrow pores and be adsorbed there.

It is also possible that, in rinsing a membrane with water, fine particles situated between coarse particles (or attached to them) are shifted deeper inside the pores. It should be added to the aforesaid that the peak width may be affected by hydration of particles within pores, which also leads to poorer restoration of the initial flux.

Additional cleaning of the membrane after its washing with distilled water demonstrated that the following values are achieved after 10 min: $J_r(\text{NaOH}) = 98.2\%$, $J_r(\text{HNO}_3) = 92.3\%$.

CONCLUSIONS

(1) The results obtained in studying the permeate flux in microfiltration of an aqueous extract of dog-rose fruits show that the membrane contamination is affected by the process pressure and temperature.

(2) The highest flux of the fluid being filtered is observed in the initial stage of filtration, and then the flux decreases.

(3) The main factor in membrane contamination is clogging of its pores.

(4) A contaminated membrane can be washed with distilled water, with 82% of its initial throughput restored in 12 min. Additional application of chemical cleaning agents for 10 min gives 98.2% for NaOH and 92.3% for HNO_3.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Comparative Assessment of the Solvating Powers of Solvents of Different Nature with Respect to Condensed Aromatic Hydrocarbons

S. M. Leshchev and A. V. Sin'kevich

Belarussian State University, Minsk, Belarus

Received January 8, 2003

Abstract—The solubilities of anthracene, tetracene, 1,2-benzanthracene, chrysene, pyrene, perylene, α,α'-dinaphtyl, rubrene, and decacyclene in solvents of different nature and polarity (hydrocarbons and halogenated hydrocarbons, alcohols, ketones, ethers, and esters) were determined at 20 ±1 °C. The distribution of benzene and naphthalene in the organic solvent–water system was studied. The Gibbs energy of transfer of aromatic hydrocarbons from *n*-octane to organic solvents was calculated.

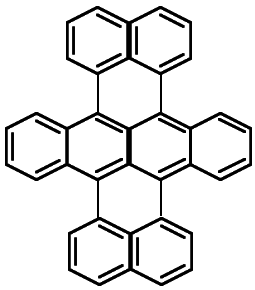
Condensed aromatic hydrocarbons (CAHs) and their derivatives, whose molecules contain fused benzene rings, are present as complex mixtures in oil, coal tar, and pyrolysis products of organic compounds. On the one hand, CAHs are valuable raw materials for chemical industry and on the other, highly toxic and hazardous environmental pollutants. Aromatic hydrocarbons are separated and isolated from various objects by liquid extraction and crystallization using selective solvents [1, 2].

By now, for CAHs, whose molecules contain up to four benzene rings, the relationships in extraction from hydrocarbon solutions with strongly polar organic solvents are fairly well understood [3]. However, there are virtually no published systematized data on the solubility of CAHs in weakly and moderately polar solvents miscible with liquid aliphatic hydrocarbons. Many of these solvents have low boiling points and are easily recovered, which makes them suitable for wide application in chemical and petrochemical industries. A systematic study of the relationships in solvation of CAHs with these solvents will enable, in turn, development of efficient methods of their separation, isolation, and concentration from various objects (soils, resins, asphaltenes, etc.).

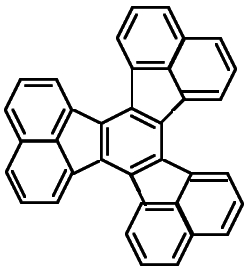
Therefore, this study was aimed at deriving systematized information about the solvency and solvating power of weakly and moderately polar solvents with respect to CAHs and about their dependence on the nature and structure of the solvent molecules.

EXPERIMENTAL

We used the following CAHs: anthracene, tetracene, 1,2-benzanthracene, chrysene, pyrene, perylene, α,α'-dinaphtyl, 5,6,11,12-tetraphenylnaphthacene (rubrene), and decacyclene purified be recrystallization. The structural formulas of decacyclene and rubrene are given below:



Rubrene



Decacyclene

As organic solvents we used pure grade *n*-octane purified by sulfuric acid extraction, as well as 2,2,5-trimethylpentane (isooctane), cyclohexane, cyclohexene, benzene, α-methylnaphthalene, chlorobenzene, carbon tetrachloride CCl_4, methylene chloride CH_2Cl_2, chloroform $CHCl_3$, 1,1- and 2,2-tetrachloroethane, methyl iodide, methylene iodide, diethyl ether (DEE), dibutyl ether (DBE), ethyl acetate, amyl acetate, acetone, methanol, propanol, and isopropanol (pure grade).

The solubilities of CAHs were determined by different procedures. In the case of liquids transparent at wavelengths corresponding to absorption of aromatic

substances, we used UV spectrophotometry, and in the case of volatile UV-absorbing liquids (benzene and acetone), gravimetry. We prepared saturated solutions of aromatic substances in the solvents studied. Next, into a preliminarily weighed clean dry weighing bottle, the required volume of saturated solution of the aromatic compound was introduced, whereupon the solvent was evaporated and the weighing bottle with the substance was weighed. For high-boiling UV-absorbing liquids (α-methylnaphthalene, chlorobenzene), we measured the volume of the liquid required for complete dissolution of the precisely weighed portion of a solid aromatic hydrocarbon.

All the experiments were run at 20 ± 1°C. Based on the data obtained, we calculated the Gibbs energies of transfer (hereinafter, energies of transfer) of hydrocarbons from *n*-octane to the solvents under study:

$$\Delta G_t^0 = -2.3RT\log\frac{S}{S_{oct}}, \quad (1)$$

where S and S_{oct} are the solubilities, mol l^{-1}, of an aromatic hydrocarbon in organic solvent and in *n*-octane, respectively.

The energies of transfer of benzene, which is unlimitedly soluble in the solvents under study, and naphthalene, whose solubility exceeded 1 mol l^{-1}, were calculated by the equation

$$\Delta G_t^0 = -2.3RT\log\frac{P}{P_{oct}}, \quad (2)$$

where P and P_{oct} are the distribution constants of naphthalene in the organic solvent–water and *n*-octane–water extraction systems, respectively.

We described in detail the procedures for studying the benzene and naphthalene distribution in [3, 4]. The parameters S and P were estimated accurately to within 10%, and ΔG_t^0, to within 0.42–0.83 kJ mol^{-1}.

Tables 1 and 2 list the parameters P and S for CAHs and their corresponding energies of transfer from *n*-octane to solvents of different nature and polarity, miscible with it. The ΔG_t^0 parameter is, evidently, a measure of the solvating power of a solvent with respect to CAH.

Table 2 suggests that the majority of the solvents have negative energies of transfer. The energies of

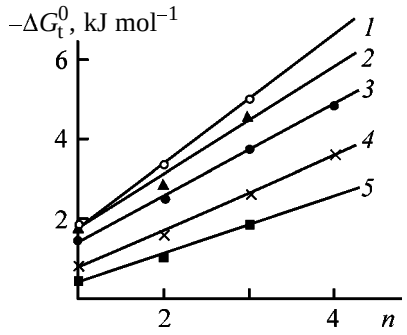
* I_{CH_2} is the methylene group increment.

transfer are positive only for isooctane (minor) and alcohols (relatively high). The energy of transfer from isooctane to octane is weakly dependent on the hydrocarbon structure, being 0.79 kJ mol^{-1} on the average.

The influence of the structure of aliphatic hydrocarbons on the intensity of the dispersion interactions of CAHs with hydrocarbons is distinct along the isooctane–octane–cyclohexane series. For example, a minor positive value of the ΔG_t^0 parameter characterizing transfer of the aromatic hydrocarbon from octane to isooctane suggests that branching of the molecule of aliphatic hydrocarbon decreases its solvating power. This is due to the so-called "voids" in the structure of the branched hydrocarbon. Cyclization of linear paraffin molecules (cyclohexane), on the contrary, affords a denser packing of the solvent molecules. This effect is particularly prominent in the case of molecules with a larger number of carbon atoms (rubrene, decacyclene). On the whole, the ΔG_t^0 parameter in the naphthalene–anthracene–1,2-benzanthracene series is weakly influenced by the hydrocarbon structure.

Solvents whose molecules contain polar segments or π bonds are typically characterized by large negative ΔG_t^0 parameters. Solvation by these solvents can proceed either via π complex formation or solvation of the protons in the aromatic rings. For example, upon introducing a multiple bond into the solvent molecule (series cyclohexane–cyclohexene–benzene), the solvation power of the solvent sharply increases. This is probably due to polarizability of the π systems and existence of instant dipoles in the molecules of aromatic hydrocarbons, which intensifies the dispersion interactions. The importance of π electrons in CAH solvation is indirectly supported by a sharp increase in the boiling and melting points of condensed hydrocarbons with increasing number of fused benzene rings. Hence, benzene with its polarizable π system is inferior (just insignificantly) in the solvating power only to chloroform and methylene chloride, despite its significantly lower polarity. Naturally, α-methylnaphthalene is a more active solvating agent for CAH than benzene (Table 2).

In unassociated solvents (chloroform, methylene chloride) characterized by a high density of the negative charge on the chlorine atoms and by strongly polarized bonds, evidently, there exist electrostatic



Variation of the energy of transfer ΔG_t^0 with the number of fused rings n in CAHs: (*1*) CH_2Cl_2, (*2*) $CHCl_3$, (*3*) benzene, (*4*) amyl acetate, and (*5*) CCl_4.

interaction forces between the solvent molecule dipoles and instant dipoles of the solute. The relative strength of such forces depends on the polarity and polarizability of the molecules. As a result, these solvents exhibit more negative energies of transfer than other weakly polar solvents. Shielding of the electron-accepting center and replacement of all the protons by chlorine atoms (CCl_4) is accompanied by a significant decrease in the solvating power of the solvent. At the same time, the chlorine atoms of halogenated hydrocarbons, evidently, make a significant contribution to the total energy of CAH solvation. Interestingly, this contribution sharply increases with increasing polarizability of the halogen-containing group (CH_3I). The factors responsible for a decrease in the solvating power on changing from CH_3I to CH_2I_2 will be discussed below.

The solvent polarity exerts an ambiguous effect on the energy of transfer. The dissolving power of a solvent with respect to CAH usually tends to decrease with increasing polarity of the solvent (alcohols and esters), and in the case of ethers it markedly increases. High polarity of organic solvent typically strengthens its three-dimensional structure [5], promoting "expulsion" of weakly polar CAH molecules.

As a measure of this "expulsion" we can take the increment of the methylene group I_{CH_2} into the logarithm of the distribution constant between the hydrocarbon and solvent. In the case of the solvents studied (except for alcohols, methylene iodide, ethyl acetate, and acetone), the increment of the methylene group is fairly small and does not exert the deciding influence on the pattern of variation of G_t^0 with the number of the aromatic rings in the hydrocarbon molecules. Interestingly, a significant difference in ΔG_t^0 for methyl iodide and methylene iodide is due specifically to the difference in the I_{CH_2} parameters, and methylene iodide is immiscible with aliphatic hydrocarbons, unlike methyl iodide. As to alcohols, significantly positive ΔG_t^0 values are due to both fairly high I_{CH_2} values and strong self-association of alcohols, which sharply weakens their solvating power.

Table 3. Coefficients in correlation equation (3)

Solvent	*a*	*b*
	kJ mol^{-1}	
Benzene	–2.79	–0.96
CCl_4	–2.04	–0.58
$CHCl_3$	–3.29	–1.13
CH_2Cl_2	–3.08	–1.33
Amyl acetate	–2.38	–0.75

The solvating and dissolving powers of a solvent with respect to such CAHs as naphthalene, anthracene, and tetracene (chrysene) can be estimated using the plots of the energy of transfer of aromatic hydrocarbons vs. the number of fused aromatic rings (see figure). This plot is linear for all the solvents studied by us. The figure shows that the solvating and dissolving powers of a solvent are the greater, the greater the section cut at the ordinate axis and the greater the slope. The ΔG_t^0 parameters can also be described by the equation

$$\Delta G_n^0 = a + bn, \quad (3)$$

where a is the energy of benzene transfer from *n*-octane to a solvent, kJ mol^{-1}; b, increment into the transfer energy upon adding to the benzene molecule each new aromatic ring; and n, number of fused aromatic rings.

Table 3 lists the coefficients from Eq. (3). It is seen that, among the most extensively studied solvents, the greatest solvating powers with respect to CAHs are exhibited by chloroform, methylene chloride, and benzene. For less extensively studied solvents, the anthracene transfer energy can serve as a measure of the solvating power. The linearity of the ΔG_t^0–n dependence, evidently, allows calculation of the energies of transfer from *n*-octane to a solvent for other condensed aromatic hydrocarbons using the ΔG_t^0 parameters for anthracene and benzene.

By contrast to polar solvents, the ΔG_t^0 parameters of CAHs for the majority of weakly polar organic solvents miscible with *n*-octane are independent, within the experimental error, of the type of connection of aromatic rings in these substances (tetracene–

Table 4. Energies of transfer of decacyclene and rubrene from *n*-octane to weakly polar organic solvents

* Using the additivity method, by Eqs. (4) and (5).

1,2-benzanthracene–chrysene), as well as of the degree of connectivity of the naphthyl substituents in molecules (α,α'-dinaphthyl, perylene). At the same time, in the case of solvents having the greatest solvating power with respect to CAHs (Table 2), as well as in the case of extraction of CAHs with strongly polar solvents, their solvating power markedly increases on going from linear to angular connection of rings in CAH molecules [3].

To elucidate the suitability of the method of increments for predicting the ΔG_t^0 parameters of complex aromatic hydrocarbons, we studied CAHs with complex structures, rubrene and decacyclene. Based on their solubilities, we calculated the energies of transfer of decacyclene and rubrene from *n*-octane to the solvents studied using the following equations:

$$\Delta G_t^0(\text{decacyclene}) = 3\Delta G_t^0(\text{naphthalene}) + \Delta G_t^0(\text{benzene}) - 6\times2.3RTI_{CH_2}, \quad (4)$$

$$\Delta G_t^0(\text{rubrene}) = \Delta G_t^0(\text{tetracene}) + 4\Delta G_t^0(\text{benzene}) - 4\times2.3RTI_{CH_2}, \quad (5)$$

where ΔG_t^0(decacyclene), ΔG_t^0(naphthalene), ΔG_t^0(benzene), ΔG_t^0(rubrene), and ΔG_t^0(tetracene) are the energies of transfer of the corresponding substance from *n*-octane to weakly polar organic solvent; the latter term characterizes the contribution from the hydrogen atoms to the energy of transfer [6].

Let us compare the experimental and calculated data. Table 4 shows that, for the solvents exhibiting the greatest solvating powers with respect to CAHs ($CHCl_3$, CH_2Cl_2, and benzene), the experimental values noticeably exceed the calculated ΔG_t^0 values.

This is probably due to the mutual influence of the groups constituting the molecules of substituted CAHs. This, in turn, weakens the solvation of decacyclene and rubrene by the CAHs with the greatest solvating powers.

At the same time, transfer of decacyclene and rubrene from *n*-octane to weakly polar solvents exhibiting nonspecific solvation powers with respect to CAHs (amyl acetate, CCl_4, cyclohexane, cyclohexene) can be adequately described using the additivity principle. Probably, specifically a relatively small affinity of these solvents for aromatic hydrocarbons, including decacyclene, prevents them from adequately responding to the change in the conjugation energy of π electrons in a substance molecule.

CONCLUSIONS

(1) Condensed aromatic hydrocarbons with simple structures exhibit virtually linear dependence of ΔG_t^0 on the number of aromatic rings in hydrocarbons. This suggests an independent, to a first approximation, solvation of individual rings. Thus, the additivity principle can be applied to predicting the solubilities of these hydrocarbons and their derivatives in weakly polar solvents.

(2) For solvents that have strong solvating power with respect to condensed aromatic hydrocarbons, the additivity principle is of a limited use. In this case, the calculational formulas should, evidently, be added with special correction terms to take into account the mutual influence of the groups in the molecules of the substances studied.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Effect of Humic Acids on the State of Disperse, Acid, and Vat Dyes in Aqueous Solutions

Yu. S. Vashurina, A. S. Pogorelova, and Yu. A. Kalinnikov

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received May 22, 2003

Abstract—Effect of humic acids (biopolymeric compounds of anionic type recovered from peat) on the state of disperse, acid, and vat dyes in aqueous solutions was studied; vat dye was studied in the form of water-soluble sodium salt of leuco acid.

The adsorption and diffusion processes occurring in aqueous solutions of organic dyes [1] in the course of textile dyeing can be controlled by addition of various synthetic textile-processing chemicals, which are environmentally hazardous and fairly expensive [2]. Hence, search for new readily available and environmentally safe compounds to improve the dyeing process is urgent.

As such compounds, we studied humic acids, biopolymeric compounds of irregular structure, which contain various functional groups [3] and can react with both hydrophilic [4–6] and hydrophobic [7–11] organic compounds. Humic acids are human safe and are already used as broad-spectrum medical products [12, 13]. The effect exerted by a humic sample recovered from peat of deep degradation [14] on the state of three organic dyes of different classes was studied by spectroscopy.

EXPERIMENRAL

In our work we used the following dyes: Disperse Red 2S (1-hydroxy-4-amino anthraquinone), Acid Green Anthraquinone N2S (sulfonated 1,4-dibutylphenylaminoanthraquinone), and Vat Goldish-Yellow KKh (brominated dibenzopyrenoquinone). The dyes were preliminarily treated to spectral purity by known procedures [15–17]. The humic preparation was used as an aqueous solution with pH 8.4; under these conditions, humic acids behave as anionic polyelectrolytes [18, 19], whose total charge is determined by complete dissociation of carboxy groups and partial dissociation of phenolic hydroxy groups. The content of carboxy and hydroxy groups in peat humic acids is 2.50–3.65 and 3.3–4.2 mg-equiv g^{-1}, respectively [3, 20–22]. The measurements were carried out at 20°C.

Since humic acids can affect dyes in both truly dissolved (I) and associated (II) form, we studied the disperse and acid dyes at two concentrations of humic acid. At the first, relatively low concentration c_I, the dyes occur in solution in the monomeric form; at this concentration, the Lambert–Bouguer–Beer law is obeyed. At the second, relatively high concentration c_{II}, significant deviations from the above law are observed, which suggests association of dyes. The vat dye, which was dissolved using large amounts of electrolytes [$NaHSO_3$ (reducing agent) and NaOH], occurs in the above solutions in the associated form.

The experimental dependences of the position of the long-wave absorption maximum in the spectrum of Disperse Red 2S on the concentration of humic acid c_{HA} in solution for both forms I and II are shown in Fig. 1a.

As seen, associates of 1-hydroxy-4-aminoanthraquinone, appearing in water in the absence of any additives with increasing its concentration by a factor of 35, slightly shift λ_{max} to longer waves by 1–2 nm. This effect of the dye association is well known and is predicted by physicomathematical simulation. It is known that the main shift of the absorption peak occurs upon formation of dimers, and it remains virtually constant with subsequent coarsening of the associates [23].

On adding humic acids into a disperse dye solution, the bathochromic shift of λ_{max} reaches 5–9 nm, which suggests interaction between the dye and additive. Moreover, the difference in λ_{max} of the monomeric I and associated II forms of the disperse dye in the presence of the biopolymeric compound shows that both forms of the dye-nonelectrolyte can interact with humic acids.

(λ_{max}) Wavelength of the absorption maximum of the dye and ($A_{\lambda_{max}}$) Optical density of solutions at the wavelength of absorption maximum of the dye; the same for Fig. 2. Dye form: (*1*) monomeric and (*2*) associated.

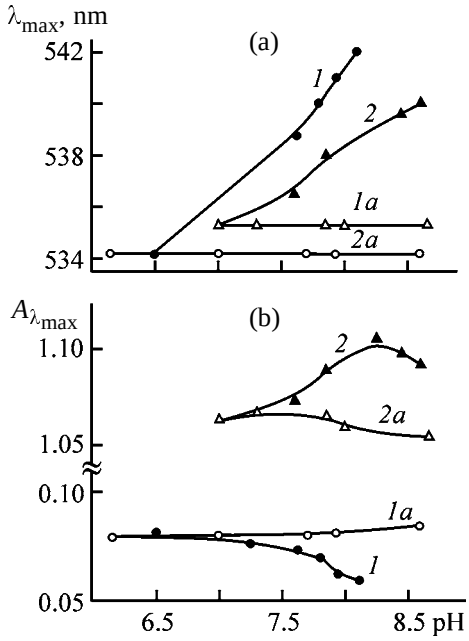

Fig. 2. (a) Position of the long-wave absorption maximum and (b) intensity of absorption of the aqueous solution of Disperse Red 2S dye as influenced by solution pH with addition of (*1*, *2*) humic acids and (*1a*, *2a*) sodium hydroxide. Dye form: (*1*, *1a*) monomeric and (*2*, *2a*) associated; the same for Fig. 3.

Hence, the decrease in the absorption intensity at low concentration of 1-hydroxy-4-aminoanthraquinone in aqueous solution (Fig. 1b, curve *1*) can be due to the dye–humic polymer heteroassociation, rather than to agglomeration of the monomers (homoassociation).

When the disperse dye in solution is initially associated, the resulting dependence (Fig. 1, curve *2*) reflects the sum of two simultaneously occurring processes differently affecting the parameter in question.

–	20	λ_{max_1} = 644.9, λ_{max_2} = 689.3	λ_{max_1} = 646.5, λ_{max_2} = 695.1
0.05–0.25	20	λ_{max_1} = 644.9 λ_{max_2} = 689.3,	λ_{max_1} = 646.5, λ_{max_2} = 695.1
–	70	λ_{max_1} = 644.9, λ_{max_2} = 689.3	λ_{max_1} = 644.9, λ_{max_2} = 691.2
0.05–0.25	70	–	–

The first of them is the interaction of the monomers of Disperse Red 2S dye with humic acids, which decreases the light absorption, and the second is related to breakdown of these associates, which, on the contrary, increases the extinction coefficients. These effects prevail in the ascending and descending sections of the experimental dependences, respectively.

As seen from Fig. 2, changes in the state of the disperse dye in aqueous solutions on adding weakly alkaline sample of humic acids are not due to increasing solution pH, because at similar alkalization of solution with sodium hydroxide (Fig. 2, curves *1a* and *2a*) no shift of λ_{max} and no significant changes in the adsorption of the dye solution are observed.

The effect of humic acids on the Acid Green Anthraquinone N2S dye (anionic-type dye-electrolyte) is illustrated in the table and in Figs. 3a and 3b. Addition of humic acids into the aqueous solutions of the anionic dye does not affect λ_{max} (see table). At the same time, association of the Acid Green Anthraquinone N2S dye in fairly concentrated solutions (c_{II}) causes the bathochromic shift of λ_{max}, reaching 6 nm.

These experimental results (table, Fig. 3a) suggest that there are no direct interactions of the acid anthra-

quinone dye with humic acids in neutral and weakly alkaline aqueous solutions in question, although anthraquinone derivatives tend to interact in aqueous solutions. The examples of such interaction are homoassociation of Disperse Red 2S and Acid Green Anthraquinone N2S and heteroassociation of Disperse Red 2S with humic acids. The lack of interaction of Acid Green Anthraquinone N2S with humic acids is obviously due to mutual repulsion of the anionic dye and anionic polyelectrolyte.

Humic acids, when added even in small amounts (0.025–0.075 g l^{-1}) into an aqueous solution of the associated acid dye, promote to some extent breakdown of the associates, which is confirmed by increasing absorption density of the dye solution. However, in contrast to the disperse dye, this phenomenon is most likely due to the fact that the polyelectrolyte breaks down the water structure, stabilizing the dye in the monomeric form [2].

The second rise in the dependence of the absorption density at the concentration of humic acids of 0.22–0.25 g l^{-1} is obviously due to the phenomenon actively discussed in papers concerning solubilization of hydrophobic organic compounds with humic acids [8, 10]. It is interpreted as micellization of an organic compound with a humic polymer, which undergoes conformational transformation at certain concentration in solution [24, 25] and becomes able to form micelles with possible incorporation of a foreign component into the micelle core.

As seen from Fig. 3b, the effect of humic acids is not associated with an increase in the solution pH on adding biopolymeric additives.

The leuco forms of the vat dye, which are unstable because of the possibility of the reverse oxidation and association, were studied spectrophotometrically by a specially designed procedure providing high reproducibility of the spectra. In this procedure we took into account changes in the state of the vat dye in humic acid free solutions in the course of the experiment. For this purpose, we alternately measured the absorption density of the blank solutions and dye solutions containing various amounts of humic acids; simultaneously we fixed the time τ of each measurement and then plotted the baseline *1* and experimental curves *2*, respectively (Fig. 4a). The desired dependence of the absorption density of the dye solution ΔA on the concentration of humic acids was determined by subtraction of $A_{\lambda_{max}}$ of the blank solutions from $A_{\lambda_{max}}$ of the polymer-containing liquid systems in

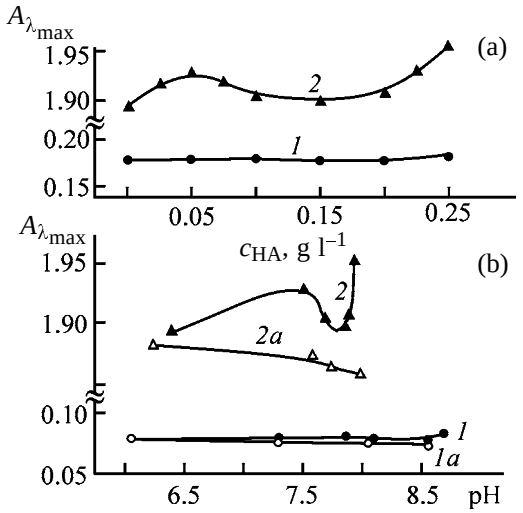

Fig. 3. Optical density of aqueous solutions of Acid Green Anthraquinone N2S dye as a function of concentration of (*1, 2*) humic acids and (*1a, 2a*) sodium hydroxide. ($A_{\lambda_{max}}$) Optical density of solutions at the wavelength of the dye absorption maximum and (c_{HA}) concentration of humic acid in aqueous solution (M).

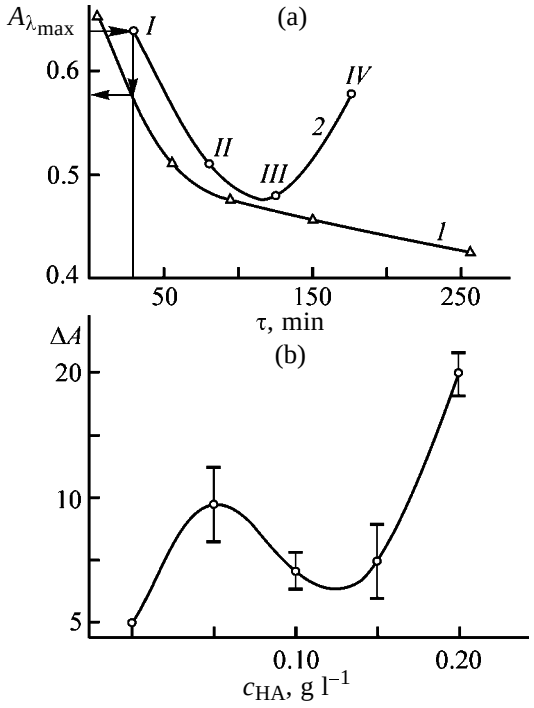

Fig. 4. (a) Experimental data on the absorption density of Vat Goldish-Yellow KKh dye and (b) their treatment to reveal the influence of the concentration of humic acids c_{HA} in aqueous solution. ($A_{\lambda_{max}}$) Optical density of solutions at the wavelength of the dye absorption maximum, (τ) time, and (ΔA) change in the absorption density. (a) c_{HA}, g l^{-1}: (*I*) 0.05, (*II*) 0.10, (*III*) 0.15, and (*IV*) 0.20.

the points corresponding to the moments of recording the absorption density in solutions containing humic acids (Fig. 4b).

As seen from Fig. 4b, the shape of the curve corresponding to the reduced vat dye is similar to the curve shown in Fig. 3a, characterizing the state of associated acid dye in solution, which suggests general similarity of the processes induced by humic acid additions in the aqueous solutions of the dyes in question. At the same time, changes in the absorption density of the vat dye solution are more pronounced. Obviously, the more hydrophobic the dye, the greater the role of structural factors in its hydration, and the deeper the breakdown of the dye associates in the presence of structure-breaking agents. The more hydrophobic the compound, the stronger its micellization with humic acids [7, 8].

Thus, we found that humic acids being added into aqueous solutions of synthetic textile dyes of various types promote various interactions, whose mechanism primarily depends on the molecular structure of the dyes and content of the additives. The latter factor can be used to control the state of the dye and thus to modify its characteristics. Thus, humic acids show promise for development of new formulations for textile dyeing.

CONCLUSIONS

(1) Disperse Red 2S dye (1-hydroxy-4-aminoanthraquinone) interacts with humic acids in aqueous solutions in both monomeric and associated forms.

(2) Humic acids being added into a solution of Acid Green Anthraquinone N2S dye (sulfonated 1,4-dibutylphenylaminoanthraquinone) break the dye associates, which is due to the breakdown of the water structure and possible incorporation of the dye molecules into the core of a micelle formed by the natural polymer.

(3) Changes in the spectral properties of the acid dye and reduced vat dye in the presence of humic acids are similar. The more pronounced spectral changes in the case of the vat dye are probably due to its high hydrophobicity and significant contribution of structural effects to its hydration.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Inhibiting Effect of Sulfur-Containing Alkylphenols on Oxidation of Vaseline Oil

Research Institute of Chemistry of Antioxidants, Novosibirsk State Pedagogical University, Novosibirsk, Russia

Received March 3, 2003

Abstract—A comparative study was made of antioxidative properties of sulfur-containing 2,6-di-*tert*-butylphenol derivatives in a model reaction of autooxidation of Vaseline oil.

Sulfur-containing derivatives of sterically hindered phenols occupy a prominent place among antioxidants used today to prevent oxidative degradation of various organic materials (polymers, fuels, lubricating oils, plastics, fibers) [1, 2]. The high antioxidant activity (AOA) of such compounds is due to the presence of two active fragments: phenolic and sulfur-containing, which show a synergistic effect [3, 4]. The relationship between the structure and antioxidative performance of sulfur-containing phenolic antioxidants (SPAOs) is complex, because the inhibiting properties of these compounds are governed by the structure of phenolic and sulfur-containing fragments, their number and mutual arrangement, and also by the properties of the substrate and oxidation conditions [5]. At the same time, elucidation of this relatioship is very important for theory and practice, as it would allow directed synthesis of more effective antioxidants.

In this work we studied the antioxidative activity of sulfur-containing alkylphenols **I**–**XVII** in a model reaction of autooxidation of Vaseline oil (see table) and analyzed the structure–activity relationship for these inhibitors. The inhibiting effect exerted by sulfur-containing alkylphenols on oxidation of Vaseline oil was evaluated by the induction period τ. As reference antioxidants we used Ionol, Probucol, TB-3, and SO-3.

We found that all the sulfur-containing alkylphenols **I**–**XVII** exhibit pronounced antioxidative activity, increasing the induction period of Vaseline oil oxidation by a factor of 5–30. A certain correlation is revealed between the structure of the antioxidant molecule (length of the alkyl chain separating the phenolic and sulfur-containing fragments; structure of substituent at the S atom; number of sulfide and phenolic fragments) and its inhibiting effect.

In the series of unsymmetrical sulfides **I**–**III** with different length of the *p*-alkyl chain, AOA grows with increasing number of methylene units separating the phenolic and sulfide fragments. This may be associated with changes in the antiradical activity [6].

The antioxidative activity of unsymmetrical sulfides **II** and **IV**–**IX** varies depending on the length and extent of branching of the aliphatic substituent at

Induction periods τ of Vaseline oil oxidation inhibited with antioxidants. Antioxidant concentration c_a = 2 μmol g^{-1}, 180°C

the sulfur atom. In going from *S*-methyl-substituted sulfide **IV** to *S*-ethyl derivative **V**, the antioxidative activity becomes appreciably stronger, in accordance with the increased electron density on the sulfur atom. However, with the length of the *S*-alkyl substituent increasing further in the series **VI**–**II**–**VII**, the inhibiting effecr becomes weaker. The lower AOA of sulfide **VII** is probably due to steric hindrance produced by the bulky octadecyl group. This group prevents access of hydroperoxides to the sulfur atom and thus decreases its antiperoxide activity.

The differences in the AOA of isomeric sulfides **II**, **VIII**, and **IX** may be due to resultant effect of two factors: different electron-donor powers of isomeric butyl radicals and susceptibility of the S–C bond to free-radical cleavage. On the one hand, in going from primary to secondary and then tertiary butyl radicals, the inductive effect increases, and the reactivity of the sulfide fragment toward a hydroperoxide should increase in parallel in the order **II**–**VIII**–**IX**. On the other hand, in the same series of sulfides, the S–C bond energy decreases, and this bond becomes more susceptible to thermal cleavage. As a result, sulfides **II** and **IX** exhibit similar AOA with respect to Vaseline oil.

Replacement of the aliphatic substituent at the sulfur atom in alkyl arylalkyl sulfides by phenyl or benzyl group (compounds **X** and **XI**, respectively) causes a decrease in AOA. Compounds **X** and **XI** inhibit oxidation by a factor of 1.6–2.0 more efficiently than TB-3 but by a factor of 2.0–2.5 less efficiently than Probucol and by a factor of 3.6–5.0 less efficiently than sulfides **II** and **V**–**IX**. The low inhibiting activity of **X** and Probucol, compared to **II** and **V**–**IX**, is probably due to the conjugation of the sulfur lone electron pair with the aromatic ring, weakening the antiperoxide activity of the sulfide group. In the case of sulfide **XI** and TB-3, the low AOA may be due to thermal decomposition of the primary products of their oxidation [7].

Thiol **XII**, as compared to the other sulfur-containing alkylphenols, showed poor AOA with respect to Vaseline oil, which may be due to thermal oxidative cleavage of the S–H bond and generation of thiyl radicals, which can participate in chain propagation [8, 9], lowering the inhibiting performance of **XII**:

$$RH + R'S^{\cdot} \rightarrow R'SH + R^{\cdot}.$$

Comparison of the antioxidative properties of sulfur-containing alkylphenols differing in the relative content of sulfur in the molecule showed that compounds **V**, **XIII**, and **XIV** with equal numbers of phenolic and sulfide fragments inhibit oxidation of Vaseline oil more efficiently than does SO-3 inhibitor containing two phenolic groups per sulfur atom. These differences are apparently due to the fact that, at equal concentration of phenolic groups, SO-3 deactivates a smaller number of hydroperoxide molecules than its analogs **V**, **XIII**, and **XIV** [3].

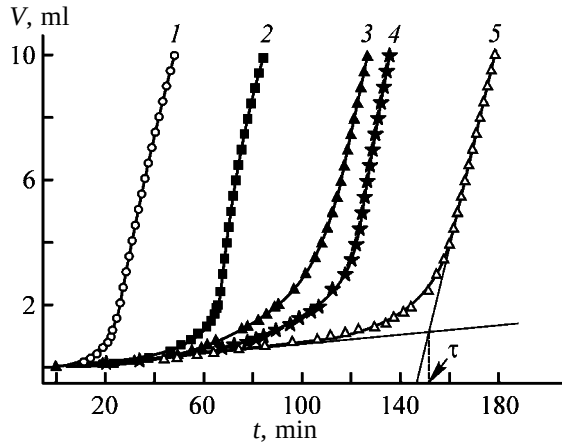
The significant contribution of the antiperoxide activity of the sulfur-containing fragment to the total inhibiting activity of sulfur-containing alkylphenols is confirmed by the fact that compounds **V**, **XIII**, and SO-3 surpass in AOA their analogs **XV**–**XVII** with partially oxidized sulfur-containing fragments.

Among the sulfur-containing alkylphenols studied, compounds **I**–**III**, **V**–**IX**, **XIII**, and **XIV** proved to be the most effective inhibitors of Vaseline oil oxidation; they surpass in the antioxidative power the multifunctional antioxidant Ionol and commercial SPAOs: Probucol, TB-3, and SO-3.

EXPERIMENTAL

Vaseline oil was purchased from Tatkhimfarmpreparaty (Kazan). Oxidation was monitored by the oxygen uptake, which was measured at 180°C and 1 atm with a gasometric unit similar to that described in [10]. The total volume of the sample being oxidized was 5 ml, and the concentration of antioxidants, 2 μmol g^{-1} oil. The kinetic curves were plotted, from which the induction period was determined as the interception point of secants to the curve portions corresponding to the initial and final rates of Vaseline oil oxidation. Four or five replicate runs were performed with each antioxidant; the figures in the table are average values with the rms deviation.

2,6-Di-*tert*-butyl-4-methylphenol (Ionol) was purchased from Acros Organics, and 2,2-bis(3,5-di-*tert*-butyl-4-hydroxyphenylthio)propane (Probucol), from Sigma. SPAOs {bis(3,5-di-*tert*-butyl-4-hydroxybenzyl) sulfide (TB-3); bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfide (SO-3); alkyl[ω-(3,5-di-*tert*-butyl-4-hydroxyphenyl)alkyl] sulfides **I**–**XI**; 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-1-propanethiol **XII**; bis-[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] disulfide **XIII**; tris[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-propyl] phosphorotrithioite **XIV**; ethyl [3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfoxide **XV**; *S*-[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propanethiosulfinate **XVI**; bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfoxide **XVII**} were prepared by previously developed



Kinetic curves of Vaseline oil oxidation in the presence of (*1*) thiol **XII**, (*2*) SO-3, (*3*) disulfide **XIII**, (*4*) thiophosphite **XIV**, and (*5*) sulfide **V**. (*V*) Volume of oxygen taken up and (*t*) time.

procedures [1, 3, 11–15]. The main substance content in the samples was 97–99%.

CONCLUSION

The antioxidative activity of sulfur-containing 2,6-di-*tert*-butylphenol derivatives depends on the structure of the sulfur-containing fragment and on the number and mutual arrangement of the sulfur-containing and phenolic fragments in their molecules; in some cases, it considerably surpasses the activity of the known commercial oxidation inhibitors.

Abstract—The properties of medical low-density polyethylene films with carbon coatings improving the biological compatibility of the polymer were studied by electron and scanning atomic-force microscopy, as well as by IR, Raman, visible, and UV spectroscopy.

A promising line in development of hemocompatible materials is modification of the polymer surface by deposition of coatings having the desired biochemical properties [1]. Understanding of the formation mechanism of hemocompatible surfaces requires studying the properties of the modifying coating.

Among the materials suitable for modification of medical polymers, in particular, low-density polyethylene (LDPE), is carbon [2] with its unique properties, above all, the occurrence in various chemical modifications: sp^3 (diamond), sp^2 (diamond-like), and *sp* (carbyne). Carbon is expected to be well compatible biologically with blood plasma proteins and living cells of the human body, because these cells consist, primarily, of organic, i.e., carbon-containing compounds. Lastly, it is possible to build on the surface of a polymer support the required cluster formations from carbon (nanostructured carbon), matching in the thermodynamic and geometric parameters a certain type of molecules of blood plasma proteins. This makes possible formation of a high-quality polymer–blood interface when using carbon as the modifying coating.

In this work, we studied LDPE-supported nanostructured carbon by physical methods.

EXPERIMENTAL

As the model material for the support we used a 50-μm-thick film of LDPE [GOST (State Standard) 10354–82]. Rectangular 25×20-mm pieces of the LDPE film were cut out in a such way that their longer sides made the same angle with the axis of film extension during its preparation.

Carbon coatings were deposited onto the polymer films in a working chamber of a UVNIPA-1 vacuum setup (manufactured by the Kvarts Kaliningrad Machine-Building Plant) by pulse plasma-arc spraying of a graphite target at the residual gas pressure of ca. 7.5×10^{-4} torr. The LDPE sample was fixed in a holder at a distance of 35 cm from the carbon target surface; the working surface of the polymer was perpendicular to the direction of propagation of the carbon ion flow.

The ignition electrodes in the UVNIPA-1 setup were used for initiating a ~0.01-s pulse electric-arc discharge on the surface of a cold in the bulk graphite cathode. The discharge produced carbon plasma whose ions were then accelerated in an electric field with a potential difference of 450 V and condensed on the working surface of the support. The sample surface was modified at various frequencies f of the pulses generated by the carbon plasma generator (0.1, 0.3, and 1 Hz).

The pulsed condensation of the carbon coating (with the pause being more than 10 times longer than the plasma discharge period) improves the heat removal from the carbon coating condensation zone. This makes less probable melting of the structural elements of the polymer matrix and favors stabilization of the surface modification process. The setup used by us provided the carbon film deposition rate of ~0.15 nm per pulse. We estimated the rate constant of the coating thickness growth by X-ray photoelectron spectroscopy using the procedure from [3]. For comparing the modified and initial LDPE film surfaces, a segment of the sample was shielded from the ion beam. The thickness of the deposited carbon films was 1.5–15 nm on the average, which corresponds to N = 10–100 pulses of the coating deposition.

The LDPE film surface morphology was examined by scanning probe atomic-force microscopy (AFM)

1070-4272/03/7609-1497$25.00

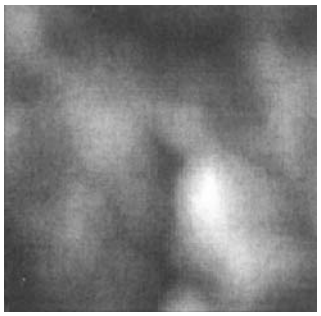

Fig. 1. Unmodified (with carbon) LDPE surface with a characteristic developed random structure.

using a Solver P4 NT-MDT microscope. We used a cantilever (Lukin Research Institute of Physical Problems, Federal State Unitary Enterprise) with the elasticity coefficient of 20 N m^{-1}, resonance frequency of ~132 kHz, and needle tip radius less than 10 nm. The measurements were run in the tapping mode in air at room temperature. The limiting resolution of the microscope was estimated from the minimal discernible film surface elements at 20–30 nm. The maximal scanning field was 6×6 μm in size.

The morphology of the surface of the modified films was preliminarily studied by raster electron microscopy (REM). We used an Camscan 4, Cambridge, microscope with a typical magnification of $\times 3500$–5400 corresponding to the examined fields with a size of tens of micrometers. Based on analysis of the features of REM relief image typical for this scale, we made express estimates of the performance of the process equipment when optimizing the parameters of the pulse process of carbon deposition.

Certain structural features of the LDPE films were analyzed by optical spectroscopy (IR, visible, and UV). We measured the transmission spectra of the samples under normal incidence of the light onto the surface. Polarization IR spectra at 500–4000 cm^{-1} were measured on a Michelson 100 (Bomem) IR Fourier spectrometer equipped with a cooled HgCdTe detector and a lattice polarizer on a KRS-5 plate (SPECAC). The UV and visible spectra of the samples at 200–900 nm were recorded with a U3000 Hitachi spectrophotometer.

The electronic structure of the carbon coatings was studied by Raman spectroscopy at 100–1800 cm^{-1}. These spectra were measured using a depolarized radiation from an argon laser at 488 nm (5 mW power) by the procedure from [4]. The focus spot was 50 μm in size. The Raman spectra obtained were typical for solid diamond-like films [4, 5].

We preliminarily compared the morphologies of the modified surfaces of LDPE samples by scanning electron microscopy [frequency of generation of the discharge pulses in plasma f = 1 Hz; number of pulses 10 and 50; carbon film thickness (one pulse corresponds to ~0.15 nm) 1.5 and 7.5 nm (samples I and II, respectively)]. The morphology of the samples proved to be globular-fibrillar for sample I and fibrillar for sample II; the fibrils were predominantly oriented along the image diagonal.

The procedure developed by us allows reliable reproduction of the morphology of the modified polymer surface. On the sample I surface, there were globular-fibrillar structures 0.5 to 2.0 μm in size, and on the sample II surface, fibrillar structures 3–4 μm in size. Presumably, the structures with a typical size close to that of thrombocyte will strongly influence the adhesion of thrombocytes.

The sample surface morphology was examined in more detail by AFM. The samples were divided into three groups comprising samples whose modified layer was formed at f of 0.1, 0.3, and 1.0 Hz. From each group we took samples with coatings obtained at different numbers of pulses N, 10, 50, and 100, corresponding to the coating thicknesses of 1.5, 7.5, and 15 nm, respectively.

For coatings with these thicknesses, the carbon layer is not continuous; it consists of clusters (islands) tens and hundreds of nanometers in size. The size of the carbon-free areas in the sample depends on the number of the carbon deposition pulses N and the frequency of their generation f. To ensure high-precision and linear measurements, we developed a method of active scanning and positioning. This implies the use of specific structures on the surface under study (in our case, carbon clusters) as the reference points in movings. This eliminates the effect of the thermal drift, nonlinearity, and nonorthogonality of the piezoscanner on the results of examining the nanostructures.

The image of the initial LDPE surface demonstrates a characteristic developed random structure (Fig. 1).

The image of the carbon-modified polyethylene surface obtained with the carbon plasma generator operating at f = 0.1 Hz reveals the presence of elongated carbon clusters, 70–200 nm in size on the average. It should be noted that, at N = 10, the length and width of a surface element are in a ratio of approximately 1 : 3; the distance separating the clusters is approximately equal to the size of the clusters, and at N = 50 this distance decreases to 20–100 nm.

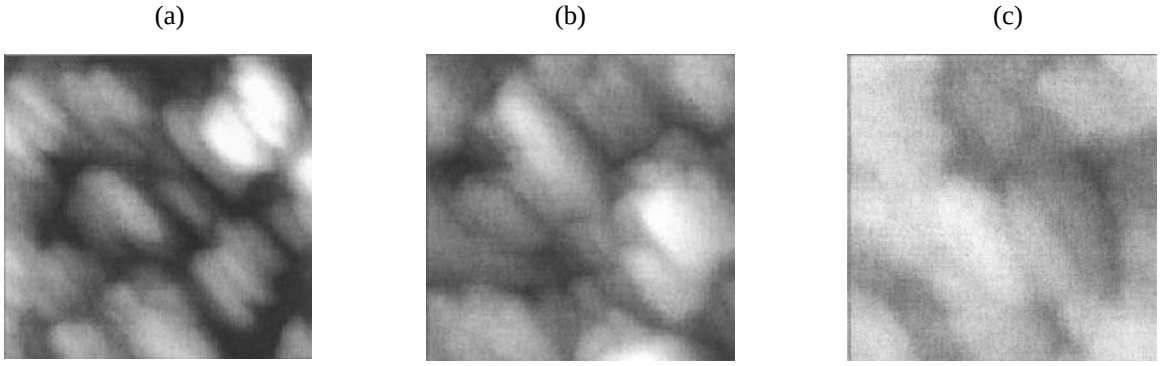

Fig. 2. Carbon-modified LDPE surface; the frequency of pulse generation by the carbon plasma generator 1 Hz. Number of pulses *N*: (a) 10, (b) 50, and (c) 100. Coating thickness, nm: (a) 1.5, (b) 7.5, and (c) 15.0.

The scans of the carbon-modified polyethylene surface obtained at f = 0.3 Hz reveal oval clusters 70–150 nm in size. The cluster length-to-width ratio is close to 2. The degree of filling of the polyethylene surface with the clusters increases relative to the case of f = 0.1, and the distance separating the clusters decreases to 10–70 nm.

The carbon coatings formed at f = 1 Hz exhibit a nanostructure with disk-like clusters 120–150 nm in size; the distance separating the clusters decreases to 5–20 nm.

Figure 2 presents the most typical images for different numbers of pulses.

The optical spectroscopic studies showed that the initial and modified polymer films obtained with 10, 50, and 100 pulses have different spectra within 200–900 nm. The transmission is inversely proportional to the number of the carbon deposition pulses or the thickness of the film formed. The transmission band edge is located at $\lambda \sim 200$ nm, which is due to strong light absorption by the polymer at $\lambda \leq 200$ nm.

Figure 3 shows the relative transmission T/T_0 spectra of the modified polymers (T_0 is the transmission of the initial samples of this polymer). It is seen that, with the growth of the carbon coating, the transmission tends to substantially decrease, especially in the UV range. Possible reasons for the characteristic decrease in transmission of the samples are light absorption and scattering on the carbon clusters. Analysis of the characteristic decrease in the relative transmission T/T_0 allowed estimation of the size of the carbon clusters. For example, the carbon clusters of the modified sample obtained at 100 pulses can be 100–200 nm in size. The sizes of the carbon clusters estimated from the spectral and AFM data agree well.

It should be noted that the samples modified at different pulse generation frequencies (0.1, 0.3, and 1.0 Hz) show similar trends in variation of the relative transmission T/T_0 spectra in the UV and visible ranges with the number of pulses.

In the middle IR range, we revealed a number of the most intense characteristic absorption bands of the CH_2 groups in the spectra of LDPE. The IR spectra of the modified polymer films are very close to that of the initial polymer film. The observed modulation of the baseline in the transmission spectrum is due to interference of the IR radiation in the polymer film, which complicates analysis of weak absorption bands in the differential spectra.

Studies of the optical properties of carbon films showed that the band gap for them can be estimated by the procedure from [6] at 2.1 eV; the extinction coefficient ε is determined as

$$æ = \alpha\lambda/4\pi,$$

where α = 0.06 is the absorption coefficient at λ = 550 nm.

These parameters also correspond to diamond-like films [7].

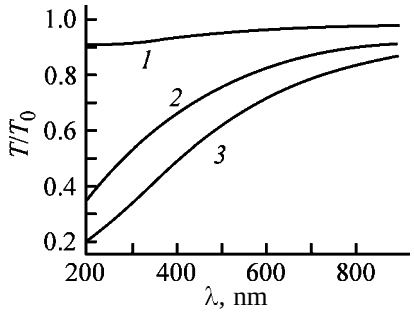

Fig. 3. Relative transmission T/T_0 of the LDPE films with carbon coatings of different thicknesses. (λ) Wavelength. Coating thickness, nm: (*1*) 1.5, (*2*) 7.5, and (*3*) 15.0.

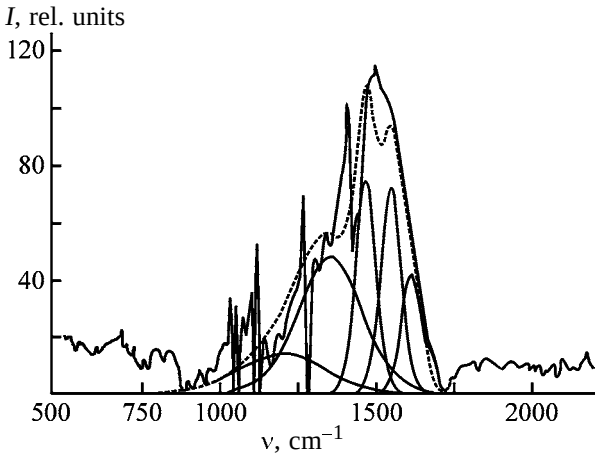

Fig. 4. Raman spectra of the carbon layers obtained by arc pulse-plasma spraying of graphite. N = 50, f = 1.0 Hz. (I) Intensity and (ν) wave number.

Comparison of the spectra of polyethylene before and after sputtering shows that the line positions and their relative intensities do not change significantly. There is only general decline in intensity, probably due to shielding of polyethylene by the carbon layer. It can be supposed that the surface processes associated with the film deposition produce no changes in the bulk of the polyethylene support.

To gain additional information about the structure of the modifying carbon coatings, we carried out mathematical analysis of their Raman spectra. Figure 4 presents the Raman spectrum of the modifying carbon coatings for N = 50 and f = 1 Hz (for other N and f, the spectra are similar). This analysis consisted in resolution of the experimental spectrum into three model subspectra determined as mixed Lorenzian–Gaussians by the relationship

$$F(x) = \text{peak height}/[1 + M(x - x_0)^2/\beta^2]$$

$$\times \exp(1 - M)\ln 2(x - x_0)^2/\beta^2,$$

where x_0 is the peak center position and β, a parameter equal approximately to the half of the full width at half maximum (FWHM).

Such spectra (Fig. 4) are characterized by two wave numbers: 1355 (D line) and 1580 cm^{-1} (G line) responsible for sp^3 diamond (1322 cm^{-1}) and sp^2 graphite (1580 cm^{-1}) electronic structures, respectively. For certain samples, we sometimes observed another peak with a wave number of 1200 cm^{-1} characterizing the disordering of the sp^3 electronic structure.

The characteristics of the Raman spectra of the samples after resolution are listed in the table.

These data were calculated from the parameter β by the iteration method. The parameter M determines the degree of mixing and is equal to 1 for pure Lorenzian and to 0 for pure Gaussian peaks. We varied such parameters of the model subspectra as intensity, Lorenzain-to-Gaussian ratio, and peak width with the aim to achieve the best agreement between the superposition of the model subspectra and the experimental spectrum. As the criterion of fitting quality we took the χ^2 parameter.

The Raman shift of one of the most intense lines is 1550 cm^{-1}. This suggests predominant graphite modification of the carbon layers under study with the sp^2 hybrid bond. This peak is also significantly shifted relative to the typical position of the G line (1580 cm^{-1}). This shift is due to the presence in the carbon layers of sp^3 bonds, along with sp^2 bonds, as well as to angular disorientation for sp^2 bonds [5, 6]. This disorientation is also confirmed by the presence in the resolved spectrum of a broadened peak at 1200 cm^{-1} [7].

The spectra of all the samples studied contained another broadened peak near 1350 cm^{-1}. It is also shifted to larger wave numbers from the typical position of the D peak (1332 cm^{-1}). This peak suggests the presence in the obtained layers of carbon with the sp^3 hybrid bond [7].

The presence in the resolved spectra of peaks at 1450 cm^{-1} confirms oxygen bonding with the deposited carbon.

The peak at 1615 cm^{-1} suggests the presence of C–H chemical bonds in the layers.

Analysis of the parameters of the Raman spectra such as the Raman shift and the height and width of the model subspectra using the data from [7] allows the following conclusions about the electronic structure of the layers formed on the polymer supports. These layers contain carbon with both sp^2 and sp^3 hy-

Characteristics of the Raman spectra after resolution (N = 50, f = 1.0 Hz)

Raman shift of the peak, cm^{-1}	Intensity, rel. units	FWHM, cm^{-1}
1200	15	300
1350	45	250
1450	75	100
1550	70	100
1650	40	75

bridizations. According to the general thermodynamic principles, the sp^2 states are integrated into small clusters. Among these, the most probable energetically are clusters in the form of six-membered rings, either single or fused. The average size of the clusters, most probably, does not exceed 2–3 nm. The sp^2 hybrid bonds inside the clusters exhibit disorientation in angles, and the rings have the shape of irregular hexagons. The clusters are linked by sp^3 hybrid bonds and randomly oriented with respect to one another.

This pattern corresponds to the cluster model of amorphous carbon substantiated in [8, 9].

CONCLUSIONS

(1) The optimal conditions for formation of a cluster structure on the polymer surface are the pulse generation frequency of 1–2 Hz and the deposition rate of the carbon-containing films of 0.1–0.2 nm s^{-1}.

(2) The following conditions can be recommended for deposition of a modifying coating onto medical polymers: process temperature no higher than 60°C; pulse generation frequency 1–2 Hz; pulse number 30–50; and thickness of the layer deposited during one pulse 0.15 nm.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Curing of Oligomers with Thermoreactive Norbornene, Chalcone, and Maleimide Groups

Abstract—Curing of powdered chalcone-containing oligoimides with terminal maleimide or norbornenedicarboxylic acid imide groups was studied by differential scanning calorimetry. The calorimetric characteristics of curing were discussed in relation to the chemical structure and conformational isomerism of the oligomers.

One of urgent problems in preparation of polymeric composites is development of high-heat-resistance reinforced plastics based on polyimides and related compounds, with the characteristics meeting the requirements of modern engineering. In this connection, it becomes necessary to elucidate relationships between curing conditions and structure of oligomers containing various thermoreactive groups, with the aim to find oligomers suitable as binders in high-heat-resistance composites.

In this work, we studied how the phase and aggregation state of a series of monomers and oligomers containing norbornenedicarboxylic acid imide, maleimide, and chalcone functional groups varies in the course of thermal cross-linking.

EXPERIMENTAL

The chemical structures of oligomers **1**–**6** and the corresponding monomers **1'**–**6'** are given below:

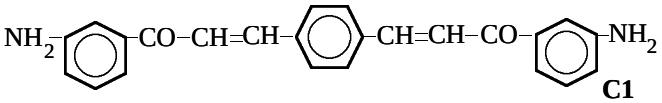
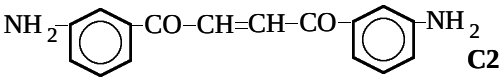
where P =  .

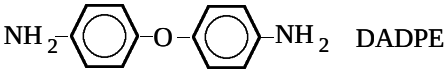
Monomers **1'**–**6'** were prepared by acylation of chalcone-containing diamines **C1** and **C2** with 4,4'-diaminodiphenyl ether (DADPE), maleic anhydride, or 5-norbornene-2,3-dicarboxylic anhydride, respectively:



C1

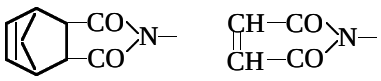


C2



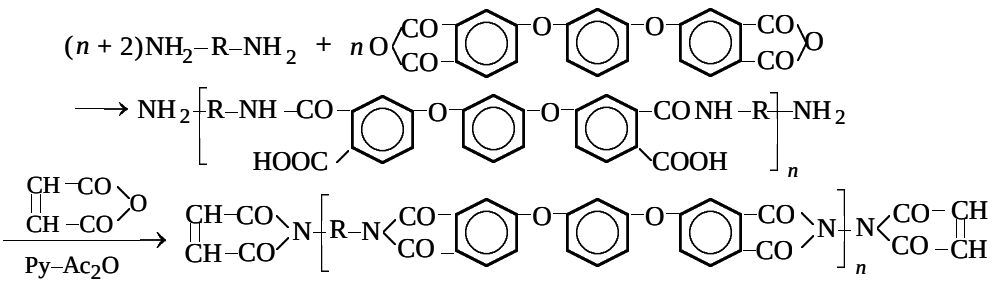
DADPE

Oligomers **1**–**3** and monomers **1'**–**3'** have the terminal norbornenedicarboxylic acid imide group (**a**), and oligomers **4**–**6** and **4'**–**6'**, maleimide group (**b**):



a **b**

Oligomers **1**–**6** were prepared from 1,4-bis[3-oxo-3-(3'-aminophenyl)-1-propenyl]benzene [1] (bischalcone **C1**), 1,4-bis(3'-aminophenyl)-2-butene-1,4-dione [2] (chalcone **C2**), DADPE, and 1,3-bis(3',4'-dicarboxyphenoxy)benzene dianhydride (DA-P) by the following scheme:



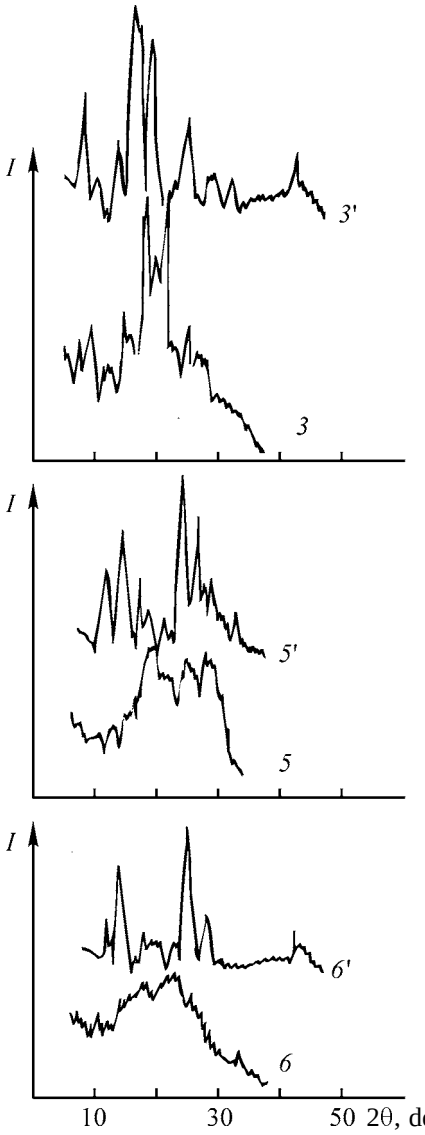


Fig. 1. Diffraction patterns of the monomers and oligomers of series III, V, and VI: (*I*) intensity and (2θ) Bragg angle. Curve numbers are monomer and oligomer numbers; the same for Figs. 2 and 3.

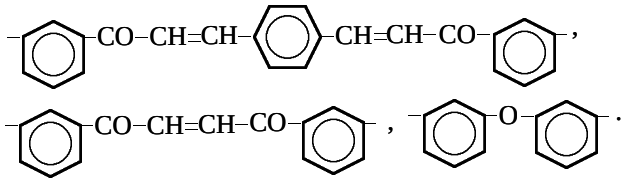
where R =



Dianhydride DA-P was added to a solution of appropriate diamine in dimethylformamide (DMF) at 20°C. The solution was stirred for 3 h, after which maleic or 5-norbornene-2,3-dicarboxylic anhydride was added. The oligomer concentration was 30 wt %. After 2 h, the imidizing mixture of acetic anhydride and pyridine (2 : 1 by volume) was added in a fivefold molar excess relative to the reactive units, and the solution was left overnight. Then the solution was stirred for an additional 2 h at 60–70°C, and the polymer was precipitated with methanol. The powders were vacuum-dried at 50°C. Monomers **1**'–**6**' were prepared similarly but without DA-P.

Compounds **1**–**6** and **1**'–**6**' were characterized by IR and electronic spectra. According to the IR spectra, the degree of imidization was 95–97%. The electronic spectra of **1**, **1**', **5**, and **5**' exhibited absorption with λ_{max} = 360 nm, characteristic of bischalcone **C1**, and those of **2**, **2**', **6**, and **6**', absorption with λ_{max} = 308 nm, characteristic of chalcone **C2**.

Curing of monomers and oligomers was monitored by calorimetric, X-ray diffraction, and thermomechanical methods. Calorimetric measurements were performed in the range 30–400°C with a DSM-2M calorimeter at a scanning rate of 16 deg min^{-1} and theshold sensitivity of 0.04 MW [3].

X-ray diffraction data were obtained with a DRON-2 diffractometer using Ni-filtered CuK_α radiation. Thermomechanooptical measurements were performed with a Boetius heating stage; the softening range was evaluated visually from changes in the powder particle shape and in the response on pressing.

In the initial state, powders of monomers **1**'–**6**' were highly crystalline substances; the phase state of oligomers **1**–**6** depended on their chemical structure: oligomers **2** and **4** were crystalline; **5** and **1**, mesomorphic; and the others, amorphous. Figure 1 shows the X-ray diffraction patterns of monomers **3**', **5**', and **6**' and of crystalline (**3**), mesomorphic (**5**), and amorphous (**6**) polymers.

The thermograms of oligomers and monomers of series I–VI are compared in Fig. 2. The monomers exhibit thermal effects in two ranges, with different signs of the effects: endothermic (melting of crystals) and exothermic (curing due to cross-linking of thermoreactive groups). The oligomers exhibit thermal effects in three ranges. The effects manifested at low and moderate temperatures are endothermic, and the high-temperature effects are exothermic. The low-temperature range, 50–150°C, is similar for all the oligomers; it corresponds to removal of residual solvents used in the synthesis of the oligomers. As it has no relation to the structure of the oligomers, it is not discussed further. The medium- and high-temperature ranges are different for different oligomers. The DSC curves of some oligomers, recorded on heating to 400°C , do not return to zero (baseline), suggesting

* Determined by a thermomechanooptical method.

incompleteness of double bond opening or instability of the process. Repeated scanning to a higher temperature (450°C) revealed no exothermic effects. Hence, curing that occurred in these monomers in the course of the first scanning to 400°C went to completion, and a new equilibrium state was formed.

The temperature ranges of the endothermic (ΔT_{endo}) and exothermic (ΔT_{exo}) effects exhibited by the monomers and oligomers, and also the softening ranges (ΔT_s) evaluated by a thermomechanooptical method are listed in the table. The lower boundary of the softening range corresponds to the onset of fusion of powder particles, followed by spreading and passing to the hyperelastic state at the upper boundary of this range.

Oligomer **5**, in contrast to the other oligomers, showed no softening range; caking and darkening of the powder started without fusion.

Comparison of the ranges ΔT_{endo} for monomers **1'**–**6'** and oligomers **1**–**6** shows that, in going from monomers to the corresponding oligomers, ΔT_{endo} shifts to lower temperatures in the case of **1**–**3** and **5**, remains virtually the same in the case of **6**, and shifts to higher temperatures in the case of **4**. Comparison of the temperature ranges in which the monomers exhibit endothermic effects (melting) with the softening ranges of the oligomers shows that softening of the oligomers occurs at lower temperatures than melting of the monomers. For example, softening of **3** is complete at 270°C, and melting of **3'**, at 330°C. These differences in the ranges of the endo- and exothermic effects are due to the influence of structural conformational isomerism: Oligomers have a larger number of rotational isomers than the corresponding monomers. In the case of oligomers, the softening range depends on both the chemical structure and the rotational isomerism (number of rotational isomers). Crystallization of oligomers **3** and **4** is due to greater, compared to the other oligomers, conformational freedom because of the presence of the DADPE fragment containing no thermoreactive double bonds, and mesomorphic structure of **1** and **5** is due to specific conformational features of the **C1** fragment, compared to **C2** in amor-

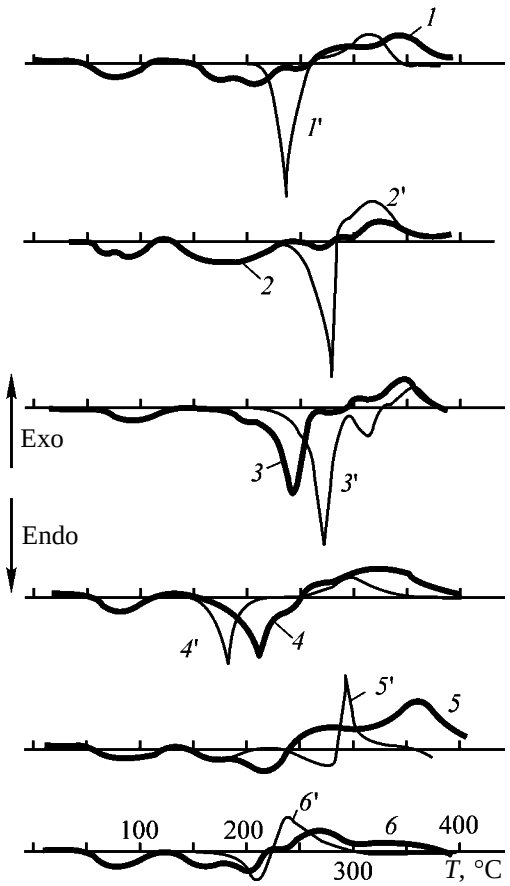

Fig. 2. Thermograms of monomers and oligomers of series I–VI. (*T*) Temperature; the same for Fig. 3.

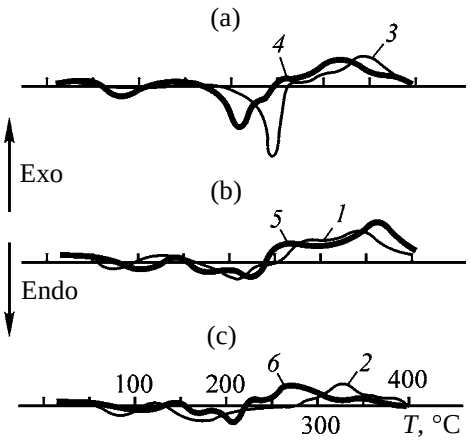

Fig. 3. Thermograms of oligomers (a) **3** and **4**, (b) **1** and **5**, and (c) **2** and **6**.

phous oligomers **2** and **6**. The maximum of the melting peak in the DSC curve of oligomer **3** (Fig. 2) is lower, compared to the corresponding monomer **3**', by 40°C, whereas in the case of **4** it is 25°C higher.

Crystalline oligomer **3** has the lattice similar to that of the monomer, as suggested by coincidence of several reflections, but more defective, as indicated by lower intensity of reflections. The lattice of **4** differs from that of **4**'.

Figure 3 shows the thermograms of the oligomers grouped with respect to the phase state: crystalline (**3**, **4**, Fig. 3a), mesomorphic (**1**, **5**, Fig. 3b), and amorphous (**2**, **6**, Fig. 3c). It is clearly seen that the energy characteristics of the curing transitions correlate with the phase state. The heats of endothermic transitions regularly decrease in going from crystalline (**3**, **4**; 42 kJ kg^{-1}) to mesomorphic (**1**, **5**; 26 kJ kg^{-1}) and amorphous (**2**, **6**; 21 kJ kg^{-1}) oligomers. The respective heats of exothermic transitions are 78, 161, and 51 kJ kg^{-1}. The considerably larger heat of the exothermic transition (curing) in the case of **1** and **5**, with the transition extending to 400°C, is due to the more pronounced conformational isomerism, compared to **2** and **6**.

Within each pair in Fig. 3, the oligomers differ only in the structure of the terminal group. Comparison of the thermograms of **3** and **4**, **1** and **5**, or **2** and **6** reveals the effect of the terminal group on curing. In the case of oligomers **3** and **4** containing the diphenyl oxide unit and no chalcone units, replacement of the terminal norbornenedicarboxylic acid imide group (Fig. 3a, curve *3*) by maleimide group (Fig. 3a, curve *4*) shifts the melting range, curing range, and maximum of the exothermic effect to lower temperatures by 50, 25, and 30°C, respectively.

In the compound with the bischalcone (**C1**) fragment, replacement of the norbornenedicarboxylic acid imide group (Fig. 3b, curve *1*) by the maleimide group (Fig. 3b, curve *5*) affects the melting range of the mesophase insignificantly, but considerably extends the curing range: Curing is not complete even at 400°C, whereas in the case of **1** (Fig. 3b, curve *1*) it is virtually complete at 400°C. In oligomers with the chalcone (**C2**) fragment, the norbornenedicarboxylic acid imide group (Fig. 3c, curve *2*), compared to the maleimide group (Fig. 3c, curve *6*), does not alter the range of transition from the amorphous to softened state but noticeably (by 50–60°C) shifts the exothermic effect to higher temperatures. Compound **6** with the maleimide group (Fig. 3c, curve *6*) exhibits the narrowest curing range and the lowest temperature in the maximum of the exothermic effect, 270°C.

The thermograms in Fig. 3 show that the temperature ranges of the exothermic effects of the oligomers with the norbornenedicarboxylic acid imide terminal groups (curves *1–3*) differ to a lesser extent compared to the oligomers with the maleimide terminal groups (curves *4–6*). For example, in the case of **4** the exothermic effect is complete at 400°C; in the case of **5**, it is not complete at this temperature; and in the case of **6**, it is complete even at 370°C, which is more favorable for using the oligomer as a binder. Therefore, we chose **6** for further experiments aimed to determine the activation energy of curing. For this purpose, we heated samples of **6** to 523, 533, 543, and 573 K at a rate of 32 deg min^{-1} and obtained the isotherms of heat release capacity Qt. The isotherms plotted in the coordinates Qt–t (Fig. 4a) and $\ln(Qt)$–t (Fig. 4b) show that curing at 523, 533, 543, and 573 K is a first-order reaction; its rate constant is $k = -\mathrm{d}[\ln(Qt)]/\mathrm{d}t$. Fig. 4c shows a plot of $\ln k$ vs. reciprocal temperature $1/T$. From this plot, we determined the activation energy $E_a = 8.314\,\mathrm{d}(\ln k)/\mathrm{d}(1/T) = 79$ kJ mol^{-1}. For cross-linking of bisbornenimide, Liu *et al.* report a somewhat higher value, 94 kJ mol^{-1}. This fact is consistent with our DSC data that oligomers **1** and **3** with the norbornenedicarboxylic acid imide terminal groups exhibit higher temperatures of the onset and end of the exothermic effect and higher heat of curing, compared to **6**.

We found that the course of cross-linking is influenced by preliminary pressing of oligomer powders: The exothermic effect starts at lower temperatures. We performed experiments with samples of oligomer powders compacted before curing at a pressure of 50 atm in a mold with a punch diameter of 10 mm. Upon pressing, the initially weakly colored powders

became yellow, dark yellow, and brown, and in some places even dark brown. The temperature of the onset of the exothermic effect decreased after pressing by the following values ΔT_{exo}:

Oligomer	ΔT_{exo}, °C
4	8
1	12
2	17
3	17
5	22
6	36

It is seen that, for **6**, ΔT_{exo} is as large as 36°C, whereas for **4** it only slightly exceeds the measurement error.

The dependence of ΔT_{exo} on the oligomer structure can also be explained by the influence of the concentration of thermoreactive bonds and by conformational features. As in the case of nonpressed powders, the conditions for cross-linking are optimal in **6**.

It should be noted that the influence of pressure on chemical processes was examined in numerous studies. Analysis of their results allows us to interpret the decrease in the temperature of the exothermic effect upon pressing as follows. It is well known that polymerization of many unsaturated organic compounds (olefins, dienes, organosilicon compounds, etc.) accelerates at high pressures. Many monomers that do not polymerize at atmospheric pressure (in particular, tri- and tetrasubstituted ethylenes, aliphatic aldehydes) polymerize at high pressure [5]. Application of a high pressure accelerates polymerization both in liquids and in powders. Furthermore, polymers prepared in the liquid phase at high pressures usually have higher molecular weight [6–8]. The pressure in the course of plastic deformation plays an initiating role in solid-phase polymerization of powders of acrylamide [9] and various heteroarylenes [10]. Solid-phase reactions are accelerate at high pressures also without plastic flow. For example, application of a high pressure considerably accelerated synthesis of the double salt syngenite–schoenite, which allowed its preparation at room temperature [11]. Acceleration of solid-phase reactions at high pressure is due to increase in the number of contacts between particles in the powder. The same factor is apparently responsible for a change in the powder color upon pressing and for a decrease in the curing temperature. In our case, the pressure was insufficient to initiate the reaction, but it decreased the reaction onset temperature.

Thermal and kinetic characteristics of curing of **6**: (a, b) isotherms of the heat release capacity *Qt*, plotted in the coordinates *Qt*–time *t* and ln(*Qt*)–*t*; (c) temperature dependence of the reaction rate constant *k* in the Arrhenius coordinates. *T*, K: (*1*) 523, (*2*) 533, (*3*) 543, and (*4*) 573.

CONCLUSIONS

(1) Curing of oligomers containing thermoreactive chalcone fragments with norbornenedicarboxylic acid imide and maleimide terminal units was studied. The formula of the oligomer exhibiting the best curing characteristics and showing promise as a binder was suggested, and the activation energy of curing of this oligomer was determined.

(2) Preliminary pressing of oligomers decreases the temperature of the exothermic effect of curing.

Abstract—Viscosity and gelation characteristics of aqueous solutions of sodium carboxymethyl cellulose produced from cotton and wood cellulose were studied.

Sodium salt of carboxymethyl cellulose (Na-CMC) is a cellulose ether (CE) produced on a large scale. This is due to its valuable characteristics and relatively easy production. It finds wide applications in petroleum, textile, food, and pharmaceutical industries as stabilizing agent, thickener, adhesive, and film-forming substance [1–3]. Dilute aqueous solutions of Na-CMC are efficiently structured by multivalent metal ions with formation of coordinatively cross-linked gels. These gels are widely used in gas-and-oil industry as viscoelastic systems in secondary treatment of oil wells and hydraulic fracturing of strata [4, 5]. All these characteristics of Na-CMC are governed by the degree of polymerization, degree of substitution, molecular-weight distribution, and uniformity of distribution of carboxy groups along the chain [3, 6]. In turn, these characteristics depend on the procedure of Na-CMC production and also on the raw materials used in production (such data are scarce).

The aim of this work was to study viscosity and gelation characteristics of aqueous solutions of Na-CMC produced from cotton cellulose in comparison with the characteristics of Na-CMC produced from wood cellulose (sulfite cooking).

EXPERIMENTAL

In the study we used three samples of Na-CMC produced from cotton cellulose (sample nos. 1–3) and two samples of Na-CMC of the 85/600 (sample no. 4) and 85/800 (sample no. 5) types produced from wood cellulose. The characteristics of the samples are listed in Table 1.

All the experiments were carried out at $22 \pm 2°C$. Viscosity characteristics of aqueous solutions of Na-CMC were studied on a Hoeppler ball viscometer.

To prepare gel-forming compositions, we used a solution of the polymer (2.0 wt %) in double-distilled water and solutions of chrome–potassium alum $KCr(SO_4)_2 \cdot 12H_2O$ (1.0–5.0 wt %), serving as a cross-linking agent. The initial pH 12.3 was adjusted with 0.2 wt % KOH. The concentration limits of gelation and the onset of syneresis were determined visually [7, 8]. The minimal concentrations of the polymer and cross-linking agent were determined from the loss of the solution fluidity under gravity in turning-over of the ampule in which the cross-linking occurred after combining the solutions of the polymer and chromium salt. The onset of syneresis was determined from the appearance of water drops at the gel–air boundary. The amount of water separated from the gel in syneresis was evaluated by weighing. The modulus of elasticity G of coordinatively cross-linked Na-CMC gels was determined by penetration using spherical indentors with various radii depending on the gel elasticity [9, 10]. The experiment was carried out at the values of imposed force initiating no creep of the system. According to the Herz theory [9], with the use of a spherical indentor the elasticity modulus of a gel is given by the relation

$$G = \frac{3F}{16h^{3/2}R^{1/2}},$$

where F is the force applied to the spherical indentor, R is its radius, and h is the depth of immersion into the gel.

1070-4272/03/7609-1509$25.00

Table 1. Characteristics of Na-CMC sample

Sample no.	Degree of polymerization	Degree of substitution, %	Content of the main substance, %	Viscosity of 2 wt % solutions, mPa s
1	580	74	60.6	350
2	540	49	71.6	202
3	780	66	59.0	790
4	588	81	49.2	280
5	800	81	49.6	580

To determine the concentration range of existence of gels in the system Na-CMC–Cr(III) salt, we obtained isothermal phase diagrams in the coordinates polymer concentration–concentration of cross-linking agent for three samples of Na-CMC synthesized from cotton cellulose (Fig. 1). Curves *1–3* correspond to solution–gel transitions for each system, and curves *1*'–*3*', to transitions from the gel to the system with phase separation, which corresponds to separation of water from the gel at the instant of its formation. Figure 1 shows that there is a critical concentration of polymer c_{cr} below which gelation does not proceed irrespective of the concentration of the Cr(III) salt. The c_{cr} value is an important characteristic of the system, since it governs the economical efficiency of using these systems in practice (in secondary treatment of oil wells, hundreds of cubic meters of the polymer solution are pumped into oil wells).

Figure 1 shows that c_{cr} in this system increases not only with decreasing molecular weight of the polymer

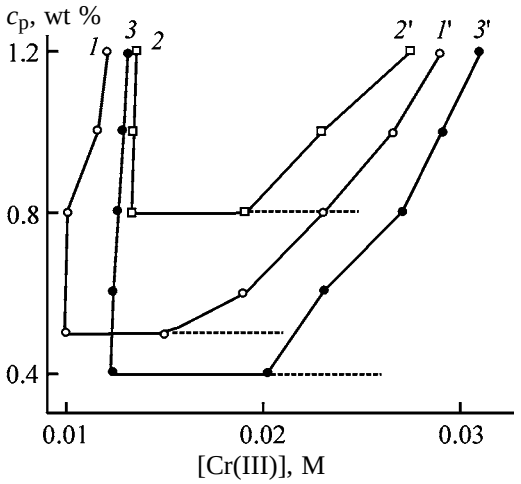

Fig. 1. Isothermal phase diagrams in the coordinates polymer concentration c_p–concentration of Cr(III) salt [Cr(III)] for Na-CMC sample nos. (*1*, *1*') 1, (*2*, *2*') 2, and (*3*, *3*') 3. (*1–3*) Transition solution–gel and (*1*'–*3*') phase separation of the system (instantaneous syneresis).

[10] but also with decreasing degree of substitution of Na-CMC at approximately the same degrees of polymerization. This fact can be explained in terms of the existing concept of the behavior of polyelectrolyte macromolecules in solution. With increasing degree of carboxymethylation of cellulose macromolecule, its total charge increases. This results in significant increase in the polymer rigidity and elongation of the polymer chain [11], which makes lower the polymer concentration in the solution required for gelation. On the whole, these data confirm the previous conclusion that the critical concentration of the polymer in the reaction with polyvalent metal ions is governed by the conformation of polymer macromolecules in the solution [12].

It should be also noted that, with increasing degree of substitution of Na-CMC, the critical concentration of the cross-linking agent [Cr(III) salt] required for the gelation decreases.

Long-term visual monitoring of the resulting gels revealed gradual syneresis, i.e., with time the solvent separates from the gel. The syneresis intensity is governed by the system composition. The rate of syneresis development and the volume of separated water are maximal for systems whose compositions correspond to the right part of the phase diagram (transition from the gel to the system with phase separation).

The stability of gels is characterized by dashed lines in the isothermal phase diagrams, corresponding to the same times of syneresis onset, i.e., time intervals from the onset of coordination cross-linking to visual observation of syneresis in the resulting gel. The results for Na-CMC sample nos. 1 and 2 are shown in Figs. 2a and 2b, respectively. Analysis of these data allows a conclusion that syneresis begins earlier for Na-CMC gels with the minimum degree of substitution (49%) than for the gel samples whose degree of substitution is more than 60%. For example, the stability of gels based on sample no. 2 does not

exceed 3 months, while for the most part of systems syneresis proceeds within a week (Fig. 2b).

Thus, our results show that the degree of carboxymethylation of Na-CMC is the important characteristic governing the gelation power of the system Na-CMC–Cr(III) salt. The decrease in the degree of substitution to 50% results in an increase in the minimal concentration of the polymer required for gelation, narrowing of the concentration range of the gel existence, and deterioration of the characteristics of the resulting gels (decrease in their stability in time and increase in the amount of released water).

The main part of this work was devoted to comparative analysis of viscosity and gelation characteristics of aqueous solutions of Na-CMC synthesized on the basis of wood (sulfite; sample nos. 4 and 5) and cotton cellulose (sample nos. 1–3). In the first stage, we studied the stability of aqueous solutions of various Na-CMC samples in storage. These studies are necessary for forecasting the efficiency of using one or another sample of Na-CMC in practice, e.g., in gas-and-oil industry as mud stabilizers and viscoelastic systems (gels) in secondary treatment of oil wells. The variation of viscosity characteristics of the solutions of three Na-CMC samples (2.0 wt %) in time in the relative coordinates is presented in Fig. 3.

Figure 3 shows that solution of sample no. 1 produced from cotton cellulose (degree of substitution 74%) is more stable in time: in 3 months, its viscosity decreases by a factor of only 2 (curve *1*), and the viscosity of solution of sample no. 4 (2 wt %), produced from wood cellulose, increases by more than an order of magnitude (curve *3*). This is apparently caused by the fact that commercial Na-CMC is extremely heterogeneous in the degree of cellulose carboxymethylation. The presence of weakly alkylated crystalline regions causes aggregation and association of Na-CMC macromolecules in the solution. Since the degree of crystallinity of cotton cellulose is higher than that of wood cellulose, Na-CMC produced from cotton cellulose contains greater number of crystalline regions preserving the structure of the initial cellulose. Therefore, apparently, moderately concentrated solutions of this cellulose are structured in a greater extent (Table 1) and retain the initial characteristics for a longer time.

It should be noted that this effect disappears with decreasing degree of substitution of Na-CMC. The viscosity of its 2 wt % solution decreases (Table 1) and its stability gets worse (Fig. 3, curve *3*). This fact can be explained by a decrease in the polymer solubility with increasing number of carboxymethyl groups

(*1*, *1*') 1, (*2*, *2*') 3, (*3*, *3*') 4, and (*4*, *4*') 5 of Na-CMC produced from cotton and wood cellulose. (*1*–*4*) Solution–gel transition and (*1*'–*4*') phase separation of the system (instantaneous syneresis).

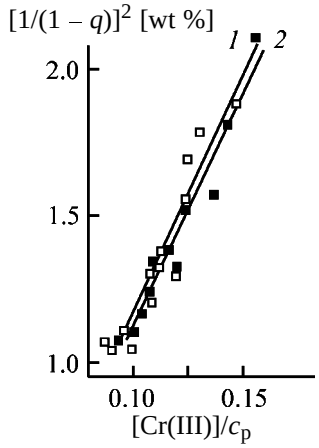

Fig. 5. The limiting relative amount of water q released in syneresis of gels as a function of weight ratio of components in the system $[Cr(III)]/c_p$ in the coordinates of relation (2) for samples nos. (*1*) 1 and (*2*) 4 of Na-CMC produced from cotton and wood cellulose.

in the chain (low-substituted cellulose ethers dissolve only in dilute alkali solutions).

Furthermore, we carried out a comparative analysis of the gel-forming power exhibited by solutions of Na-CMC of various origins in the presence of the Cr(III) salt, and also of the characteristics of the resulting gels (elasticity, stability in time, and syneresis intensity).

The concentrations corresponding to the transitions solution–gel and gel–phase separation for cotton and wood Na-CMC samples with the same molecular weights are close (Fig. 4). The critical concentrations of the polymers are also the same when the degree of substitution of cotton cellulose is more than 70% and increase from 0.3 to 0.4 wt % when the degree of substitution of Na-CMC produced from cotton cellulose is less than 70% (the degree of substitution of wood Na-CMC in both cases is higher, 81%). In this case, gelation of a solution of Na-CMC synthesized from cotton cellulose, with a degree of substitution more than 70%, requires a lower concentration of the cross-linking agent, which is important from both economical and environmental standpoints. This means that smaller amounts of the chromium ions fall into the interior of the Earth.

The stability of the resulting gels in time is approximately the same for cotton and wood Na-CMC at similar degrees of substitution [10]. A decrease in the degree of substitution abruptly deteriorates the stability of gels.

Figure 5 shows the syneresis results for the samples of cotton and wood Na-CMC with a close molecular weight, plotted in the coordinates of the relationship proposed previously [13]. This relationship was obtained considering a decrease in the size of the subchains (distances between cross-linking points) in the coordination cross-linking reaction. In this case, the number of subchains and the density of units in these subchains increase. Then, variation of the gel volume in syneresis V_0/V is given by

$$V_0/V = \nu^{1/2}, \quad (1)$$

where ν is the number of cross-links.

When

$$\nu \sim \frac{[Cr(III)]}{[Na\text{-}CMC]},$$

$$V_0/V \sim 1/(1-q)$$

(q is the relative amount of water released in syneresis), we obtain

$$[1/(1-q)]^2 = k\frac{[Cr(III)]}{[Na\text{-}CMC]} + \text{const}. \quad (2)$$

Figure 5 shows that the volumes of water released in syneresis of gels of cotton and wood cellulose are close (curves in Fig. 5 virtually coincide).

A study of the physicomechanical characteristics of gels is also important for their practical use, in particular, for predicting their behavior under various

Table 2. Modulus of elasticity *G* of 1.2% gels of Na-CMC

[Cr(III)], M	Sample no.	*G*, Pa
0.020	1	800

	4	1200
	5	1000

conditions. The modulus of elasticity is the main rheological characteristic of gels, since, by definition, gels are systems with lost fluidity.

The moduli of elasticity *G* of two gels based on various Na-CMC samples are listed in Table 2. The *G* value for the gels based on cotton Na-CMC is somewhat higher provided that the degree of substitution is more than 60%.

CONCLUSIONS

(1) Viscosity and gelation characteristics of aqueous solutions of sodium salt of carboxymetyl cellulose produced from cotton cellulose are governed by both molecular weight of the polymer and degree of carboxymethylation. A decrease in the degree of substitution to less than 50% results in an increase in the critical concentrations of the polymer and cross-linking agent required for gelation and in deterioration of the characteristics of the resulting gels.

(2) The viscosity of moderately concentrated solutions of cotton Na-carboxymethyl cellulose is higher and its values are more stable in time, as compared to wood Na-carboxymethyl cellulose.

(3) The gelation power, stability in time, and intensity of syneresis of coordinatively cross-linked gels of cotton and wood Na-carboxymethyl cellulose are similar. However, for formation of gel from solutions of cotton Na-carboxymethyl cellulose with the degree of substitution more than 70%, lower concentrations of the cross-linking agent are required.

(4) At close degrees of substitution, the elastic characteristics of the gels based on cotton Na-carboxymethyl cellulose are higher compared to the sample produced from wood cellulose.

Received January 20, 2003

Abstract—Modification of cellulose acetate with vapor of a mixture of water and a solvent in which cellulose derivatives form a lyotropic liquid-crystal phase, aimed at preparation of films, membranes, and biofilters, is studied. The resulting materials are capable of removing excess blood cholesterol with no concomitant decrease in the blood protein and electrolyte levels.

It is known that cellulose acetates provide a basis for production of a wide spectrum of film materials of various purposes from reverse osmosis to microfiltration [1]. The effect of such separating systems is based mostly on the pore size, and, in some cases, on the Donnan exclusion of counterions by fixed charges of the membrane.

Cellulose acetate films, membranes, and biofilters are used in mass-transfer apparatuses for treating blood or serum to remove metabolites and xenobiotics [2]. Plasma exchange therapy (plasmopheresis) is used to remove lipids, coarsely dispersed proteins, and toxins from blood. Membrane plasma filters mostly do not have a sufficient selectivity (in separating excess cholesterol from blood, vitally important protein substances and electrolytes are also retained) [3]. In some cases, in filtration of plasma, proteins coagulate, blocking the membrane pores, decreasing its performance, and even making it fully unusable [4, 5].

Therefore, it is a quite topical problem to develop filtering materials capable of retaining cholesterol, but not other vitally important blood components. This problem was tackled to be solved in various manners [6–8].

In this work we studied physicochemical modification of cellulose acetates with vapor of a mixture of water and a solvent in which cellulose derivatives form a lyotropic liquid-crystal phase. The method allows preparation of films, membranes, and biofilters capable of retaining excess cholesterol with no concomitant decrease in the blood protein and mineral salt level [9].

EXPERIMENTAL

In experiments we used powdered air-dry cellulose diacetate (CDA) of the wood or cotton origin. The content of bound acetic acid in the samples was 54.5–55.3%; viscosity-average molecular weight of wood and cotton CDA, 8.2×10^4 and 7.0×10^4, respectively; and their bulk density, 1.3–1.32 g cm^{-3}.

Modification of CDA was carried out under ambient conditions in a closed vessel partly filled with an aqueous–organic mixture. As a sorbate we used binary mixtures of distilled water and DMSO or dimethylacetamide (DMAA) (both of analytically pure grade). The water to organic solvent volume ratio varied from 90 : 10 to 99 : 1. An 0.5-mm sieve filled with powdered CDA was arranged at a distance of 5 cm over the surface of the liquid phase, and the polymer was exposed to solvent vapor. The amount of absorbed vapor was determined gravimetrically with a WT torsion balance to within 0.0002 g. The degree of vapor sorption was varied from 0 to 10 wt %. As the polymer was saturated with the sorbate vapor, it was sampled for film forming.

In the work we studied reference and modified CDA samples and also membranes prepared from them. As a solvent for the polymer we used the conventional process solvent, a mixture of acetone with water (95 : 5; analytically pure grade). The CDA concentration in the film-forming solutions was 3 and 5% for wood and cotton CDA, respectively. The membranes were formed under ambient conditions by solution casting onto finished glass plates using a

1070-4272/03/7609-1514$25.00

round glass draw plate, followed by solvent removal. The support plates were degreased with ethanol and acetone prior to use. The solvent removal was monitored by the sample weight. All the resulting membranes were milk-white in color. Their thickness was 90–110 μm.

The filtering properties of membranes were studied on a laboratory system with a separating cell of the plate-and-frame type. Cholesterol, total protein, and electrolytes in blood plasma before (penetrate) and after membrane filtration (permeate) were determined on a Humolize-2000 programmable photometer according to standard procedures.

Electrophoresis of proteins in a polyacrylamide gel was carried out by the Laemmli method on a vertical electrophoresis apparatus (plate size 12 × 12 cm, gel layer 0.1 cm). Plasma proteins were preliminarily separated into subunits. To a plasma sample, an equal volume of a buffer solution was added [0.125 M Tris-HCl (pH 6.8), 4% sodium dodecyl sulfate, 20% glycerol, and 5% β-mercaptoethanol]. The fix and finished gels contained 12.5 and 5% acrylamide, respectively. Electrophoresis was performed at a constant current strength (20 mA). When proteins approached the fix gel boundary, the current was increased to 30 mA. After completion of the process, the gel was stained with 0.25% Coomassie Blue R-250 in a mixture of 50% ethanol and 12% acetic acid, and then the polymer matrix was destained in an aqueous solution containing 50% ethanol and 12% acetic acid. As MW markers we used ovotransferrin (MW 78×10^3), albumin (66.3×10^3), ovalbumin (42.7×10^3), carbonic anhydrase (30×10^3), myoglobin (17×10^3), and cytochrome C (12.3×10^3).

The optical rotation of the reference and modified CDA samples (0.5 g dl^{-1}) was measured on an SM-2 rotary polarimeter (λ_{Na} = 589 nm) [11] to within 0.04°. A DNAS18-04.2 lamp was used as a light source. The optical activity expressed in [α] units (specific optical rotation) was determined to be +30° and +12° for wood and cotton CDA, respectively.

To obtain biofilters of a definite 3D structure, the initial polymer was modified with vapor of an aqueous-organic mixture (water–DMSO or water–DMAA at a component volume ratio from 90 : 10 to 99 : 1).

Selection of DMSO and DMAA was caused by the fact that they are classified with aprotic dipolar solvents [12] in which cellulose derivatives form lyotropic LC solutions [13]. Furthermore, it was demonstrated previously [14, 15] that DMSO and DMAA and their mixtures with water, being in the vaporous state, have

a significant effect on the structure formation in cellulose acetates, opening the door for preparation of a broad spectrum of polymeric materials of various purposes [16, 17]. It should be pointed out that the effect of solvent vapor on the structure of cellulose acetate is much stronger and more specific as compared to addition of equal amounts of the same liquids to the polymer solution [14, 15]. Note also that aqueous DMSO is widely used as a medicine (Pharmacopoeia Article "Dimexidum" 75-244-9). Figure 1 shows the results on filtration of blood plasma through membranes fabricated from modified CDA. The cholesterol (c_{Ch}) and

protein (c_{Pt}) concentrations in the permeate after filtration through the reference (commercial) CDA membrane are given on the ordinate axis. Figures 1a and 1b (curves *1*) show data obtained with wood CDA, and Figs. 1b (curves *2, 3*) and 1c, with cotton CDA.

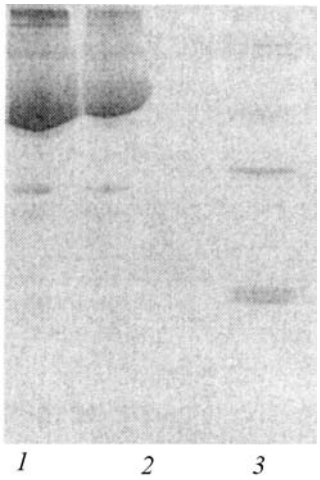

Fig. 2. Electrophoresis in polyacrylamide gel: (*1, 2*) protein fractions in the penetrate and permeate, respectively, and (*3*) markers.

As seen, the membranes fabricated from modified CDA (of both wood and cotton origin) demonstrate higher retaining capacity for cholesterol and lower retaining capacity for protein and electrolytes, as compared to the initial CDA membranes (Fig. 1). The degree of retention of cholesterol on the CDA membranes modified with H_2O–DMSO (90 : 10, 95 : 5, and 98 : 2) vapor is higher by 20–30% as compared to the reference membrane (Table 1). For the membranes modified with H_2O–DMAA (95 : 5) vapor, the effect is 30–33%, and with H_2O–DMSO (99 : 1), 14–16%. Data on the concentrations of electrolytes in the permeate (Table 2) show that c_{Na}, c_K, and c_{Ca} in blood plasma after filtration through modified CDA membranes are higher than those after filtration through the reference membrane. It is of primary importance that the modified membranes do not retain proteins (Figs. 1a, 1b). As an example, Fig. 2 shows data on electrophoresis of the initial plasma and plasma after filtration through a membrane from cotton CDA that sorbed 2.5 wt % of H_2O–DMSO (90 : 10) vapor. As seen, fractions 2 and 3 are practically identical in the protein composition.

For all the systems CDA–aqueous-organic vapor, the sorption of the sorbate vapor is very low, being no more than 5 wt % (Fig. 1, Table 1). Therefore, the content of an individual solvent (DMSO or DMAA) in any of the products formed is below 10^{-4} wt %. Nevertheless, even such a small absorption of the vapor by the polymer provides (if the modified structure of CDA is preserved in a membrane), on the one hand, selective separation of optically active components of blood plasma and, on the other hand, efficient retention of one of them (cholesterol) with no decrease in the content of another (protein) and also of electrolytes.

Cellulose acetates are classified with optically active polysaccharides. Shipovskaya and Timofeeva have demonstrated [14, 15] that solvents forming lyotropic mesophases with cellulose and its derivatives, being in the vaporous state, have a strong effect on the optical activity of cellulose esters. It was shown that modification of CDA with an aqueous-organic vapor in which one component is a mesogenic solvent initiates a change in the structure of the cellulose ester at the stereoisomeric level.

Figure 3 shows the dependence of the specific optical rotation [α] of the CDA solutions on the degree of modification of the polymer with the sorbate vapor. The reference samples of CDA in aqueous acetone are characterized by positive [α]: +30° and +12° for wood and cotton CDA, respectively. For the samples modi-

fied with vapor of a mixture of water and a specific solvent, we observed not only a change in the absolute value of the specific optical rotation, but also the inversion of the sign of [α].

Absorption of a small amount (up to 1–2 wt %) of the sorbate vapor on the wood CDA is accompanied by a considerable change in the optical activity, with [α] passing from the positive to the negative range (Fig. 3). Increasing degree of sorption of the sorbate vapor to 4–5 wt % results in further increase in negative [α]. At last, absorption of more than 5 wt % of H_2O–DMSO (90 : 10) vapor no longer changes the value and sign of [α] (plateau in curve *1*). Absorption of a large amount of H_2O–DMAA (90 : 10) decreases induced negative [α] (curve *2*). For cotton CDA, a significant change in the value and sign of [α] is observed after absorption of about 0.1 wt % of the sorbate vapor, and the [α]–c_s curve flattens out after absorption of 0.5 wt % of the vapor (curve *3*).

The results obtained (Figs. 1, 3 and Tables 1, 2) show a correlation between the filtering properties of the modified CDA membranes and the optical activity of the polymer. The membranes capable of selectively separating such optically active compounds as cholesterol and steroids (proteins) were obtained on the basis of CDA with a modified 3D structure characterized by a negative induced [α]. The correlation between the polymer structure and its optical activity follows a dose–effect regular trend, the most significant effect being observed at small amounts of the absorbed sorbate vapor.

It is worth noting that, in filtration of blood plasma through a modified CDA membrane, we observed a decrease in the concentration of the toxic metabolite, bilirubin, in the permeate and its selective separation from the protein fraction [18].

The authors are grateful to B.M. Zelikson for the interest in the work and valuable discussions of the membrane filtration data.

CONCLUSIONS

(1) Treatment of cellulose acetate with vapor of a mixture of water and a solvent in which cellulose derivatives form a lyotropic liquid-crystal phase provides physicochemical modification not only at the supramolecular level, but also at a delicate conformational level involving the stereochemical structure of the polysaccharide.

(2) The modification is a controllable process, as following a dose–effect regular trend. It can be interrupted at any stage of formation of the 3D structure of the polymer.

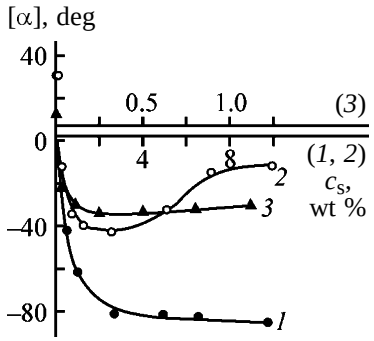

Fig. 3. Specific optical rotation [α] in CDA solutions as a function of the degree of sorption c_s of the sorbate vapor on the polymer. Sorbate: (*1*) H_2O–DMSO (90 : 10), (*2*) H_2O–DMAA (90 : 10), and (*3*) H_2O–DMSO (95 : 5). λ = 589 nm; T = 20°C.

(3) Films, filters, and membranes prepared from modified cellulose diacetate demonstrate an exceptional capability for retention of excess cholesterol with no concomitant decrease in the blood protein and mineral salt level.

(4) The membranes meet the requirements on the selectivity of removal of cholesterol from plasma and also on the predictability. To all appearance, they should be quite biocompatible (in using the modified cellulose diacetate films for filtration of plasma, the contact of the polymer surface with blood cells is excluded).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Color Stabilization of Polymers with Formulations Containing Di(hydroxyphenyl)methane Stabilizers

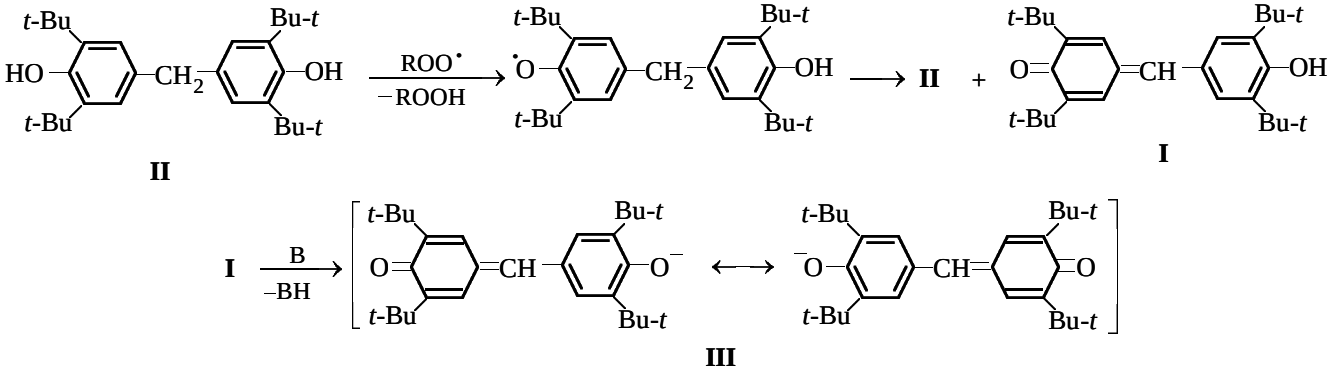
Kazan State Technological University, Kazan, Tatarstan, Russia

Received February 21, 2003; in final form, June 2003

Abstract—The possibility was examined of developing noncoloring stabilizing formulations based on di(hydroxyphenyl)methane stabilizers with addition of agents that decompose hydroperoxides without generation of radicals and thus inhibit formation of α-hydroxyphenylmethylenequinones, or of components that ensure transformations of these quinones into colorless products.

Preservation of the initial color (color stabilization) of polymeric products and articles is an important aspect of polymer stabilization. Variation of the polymer color due to aging is inadmissible for many items made from polyolefins, polyvinyl chloride, and colorless and colored rubbers. The mechanism responsible for changes in the polymer color are diverse [1] and can be subdivided into three main groups: (1) formation of chromophoric systems in the initial polymer, initiated by abnormal fragments (weak points) or polyvalent metal impurities; (2) degradation of macromolecules; and (3) oxidative transformations of additives, in particular, of stabilizers.

In chemically resistant polymers, color primarily originates from oxidation of phenolic stabilizers to give chromophoric products. The tendency to form such products depends on the stabilizer structure [2]. There are indications in the literature that the methylene bridge in di(hydroxyphenyl)methane stabilizers is responsible for coloration [3, 4], as their oxidative transformations yield colored methylenequinones [5]. For example, hydrogalvinoxyl **I**, oxidation product of bis(3,5-di-*tert*-butyl-4-hydroxyphenyl)methane **II**, has a long-wave absorption maximum at 398 nm, responsible for its yellow color:



Methylenequinones in which substituents at the α-C atom are weaker electron donors than 4-hydroxy-3,5-di-*tert*-butylphenyl absorb in the UV range only [6]; therefore, such antioxidants as 2,4,6-tris(3',5'-di-*tert*-butyl-4'-hydroxybenzyl)mesitylene (Ionox-330) and pentaerythritol tetrakis[β-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate] (Irganox 1010) do not cause the polymer coloration.

Furthermore, in some cases di(hydroxyphenyl)-methane stabilizers can cause deeper (violet) coloration of polymers [7, 8] owing to ready formation of

1070-4272/03/7609-1519$25.00

mesomeric anions of type **III** from α-hydroxyphenyl-substituted methylenequinones under the action of basic components present in polymeric formulations or on surface contact with bases [9].

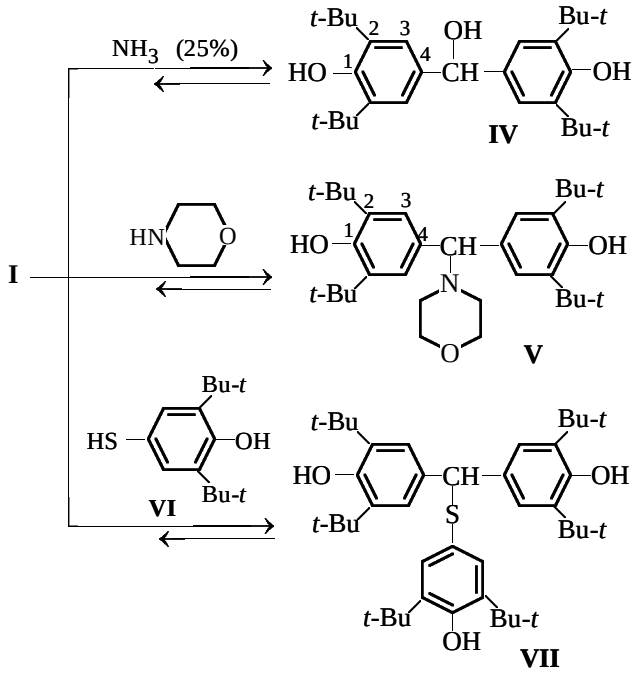
Thus, to develop noncoloring stabilizing formulations based on di(hydroxyphenyl)methane stabilizers, it is necessary to prevent accumulation of α-hydroxyphenylmethylenequinoid products, so as to avoid yellow coloration produced by these products themselves and to exclude formation of intensely colored mesomeric anions.

In this work, our examined the possibility of solving the problem by converting α-hydroxyphenylmethylenequinones into colorless products. It is known that sterically hindered methylenequinones are highly reactive toward nucleophilic agents [10] and readily form colorless addition products. It seemed appropriate to test for this purpose various commercially available alcohols, amines, mercaptans, or phosphites. In particular, it is well known that addition of phosphites eliminates coloration of polymers owing to conversion of colored quinoid compounds into colorless benzoid derivatives [11].

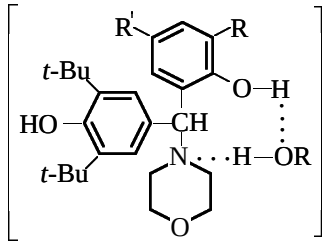
However, experiments with hydrogalvinoxyl **I** as a model α-hydroxyphenyl-substituted methylenequinone showed that prolonged contact at 20°C or refluxing of its solutions with mono- and diethanolamines, diphenylguanidine, diethylhydroxylamine, tri(2,4,6-di-*tert*-butylphenyl) phosphite, and dimethyl hydrogen phosphite did not result in decolorization. Upon dissolution of **I** in ethanol, a certain amount of the addition product did form, as indicated by thin-layer chromatography, but longer contact, refluxing, and addition of an acid did not result in exhaustion of **I**.

Individual adducts with morpholine (**IV**) and water (**V**) were obtained by reactions of **I** with excess aqueous ammonia and morpholine, respectively.

Products **IV** and **V** are stable in the crystalline form, but more or less rapidly decompose in chloroform, benzene, alcohol, acetone, and DMSO with regeneration of **I**. Decomposition occurs more actively in polar solvents and on adding an acid.



Komissarov *et al.* reported that substituted di(hydroxyphenyl)methane derivatives in which one of the hydroxy groups is in *o*-position relative to methine carbon atom reversibly dissociate in polar solvents [12, 13]. They believe that dissociation is due to concerted proton transfer involving a solvent molecule:



Our data show that the presence of protic solvents and *o*-position of one of hydroxy groups are not necessary conditions for such dissociation. Apparently, the driving force of the process is the high stability of the intermediate di(hydroxyphenyl)methyl carbocation **A**, promoting dissociation even in solvents uncapable of specific solvation:

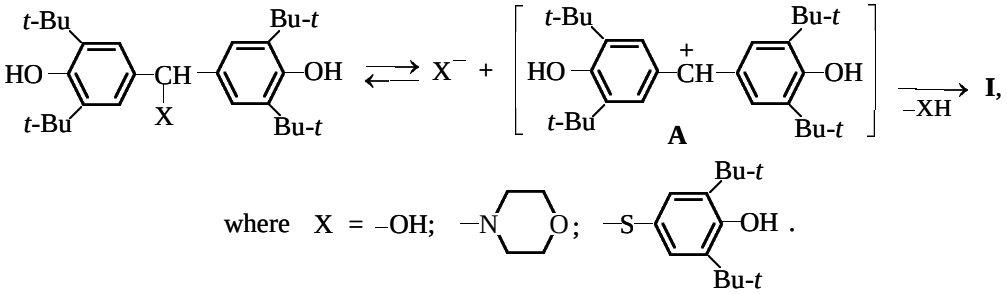


Table 1. Color stability of HDPE in the presence of stabilizers

Stabilizer	*c*, wt %	Color, points	
		after extrusion	after thermal aging (175°C, 8 h)
Irganox 1010	0.1	1	1
VIII	0.1	2–3	5
VIII + **VI**	0.05 ± 0.05	1	3

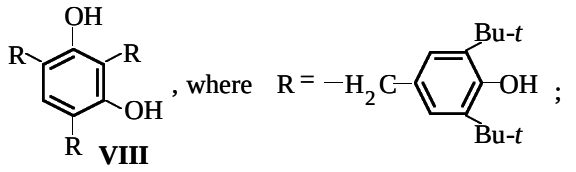
Table 2. Color stability and heat resistance of BR in the presence of stabilizers (170°C)

Stabilizer	*c*, wt %	Induction period of oxidation τ, min	Color (points) after oxidation for indicated time, h					
			initial	1	2	3	4	5
None	–	30	1	1	2	2–3	3–4	3–4
IX	0.2	120	1	1	1–2	2	2–3	2–3
X	0.2	325	1	5	5–6	6	7	8
IX + **X**	0.1 ± 0.1	185	1	2	3	3–4	4	4
	0.067 ± 0.133	220	1	2	2–3	3	4	4

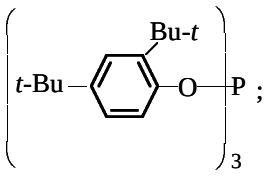
Adduct **VII** of **I** with 2,6-di-*tert*-butyl-4-mercaptophenol **VI** can be obtained even at equimolar ratio of the reactants. Adduct **VII** also partially dissociates in solutions to **I** and **VI**; however, in the solid phase, compound **VII** it is stable up to the melting point (192°C). This fact allows the use of mercaptophenol **VI** as a component of di(hydroxyphenyl)methane-based stabilizing formulations that do not impart color to polymers. The α-hydroxyphenylmethylenequinoid compounds formed by inhibited oxidation of the stabilizers can react with **VI** to give colorless products stable in the course of processing of the polymer melt and service of polymer items. For example, extrusion at 190°C of high-density polyethylene (HDPE) containing a di(hydroxyphenyl)methane stabilizer, 2,4,6-tris(3',5'-di-*tert*-butyl-4'-hydroxybenzyl)resorcinol **VIII**, is accompanied by coloration of the polymer. At the same time, with the stabilizing formulation consisting of **VIII** and **VI**, the initial color of the polymer can be preserved in the course of extrusion (Table 1).

Apparently, the intensity of accumulation of colored α-hydroxyphenylmethylenequinone can be substantially reduced by introducing compounds that decompose hydroperoxides without generation of free radicals. Such compounds, e.g., phosphorous acid esters, suppress degenerate branching of oxidation chains and hence inhibit consumption of phenolic stabilizers and formation of methylenequinones [14].

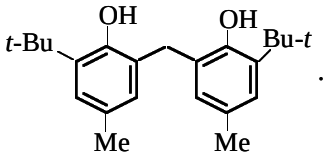
We examined the influence exerted by an aromatic phosphite, tris(2,4-di-*tert*-butylphenyl) phosphite **IX**, on the color stability and heat resistance of polymeric formulations based on butyl rubber (BR) and ethylene–propylene rubber (SKEPT), containing di(2-hydroxy-3-*tert*-butyl-5-methylphenyl)methane **X**, and of HDPE stabilized with 2,4,6-tris(3',5'-di-*tert*-butyl-4'-hydroxybenzyl)resorcinol **VIII**:



VIII



IX



X

Long-term tests of BR (exposure to air for 6 months at room temperature) showed that the samples containing phosphite **IX** did not change color, whereas the polymer stabilized only with **X** became light brown. The parameters of the color stability and heat resistance of BR in the course of oxidation at 170°C are listed in Table 2, showing an additive thermostabilizing effect of the mixed formulations and a significant color-stabilizing effect of phosphite **IX**. Similar trends are observed with the phenol **X**–phosphite **IX** formulation used for stabilization of SKEPT rubber (Table 3).

Table 3. Color stability and heat resistance of SKEPT rubber in the presence of stabilizers (150°C)

A combination of phenol **VIII** with phosphite **IX** in HDPE exhibits a small synergistic thermostabilizing effect and also enhances the color resistance of this polymer (Table 4). This formulation is not inferior or in performance to Irganox 1010.

Thus, addition of hydrolysis-resistant aromatic phosphite **IX** enhances the color stability of polymers stabilized with di(hydroxyphenyl)methane stabilizers. The color-stabilizing effect of phosphite **IX**, taking into account its inertness toward model α-hydroxyphenylmethylenequinone **I**, should be attributed to the capability of **IX** to suppress degenerate branching of oxidation chain by decomposing hydroperoxides without radical generation.

EXPERIMENTAL

In our study we used nonstabilized samples of commercial gas-phase HDPE (brand 289) and of BR-1675 rubber. SKEPT-40 ethylene–propylene rubber was treated with a 3 : 7 toluene–ethanol mixture for 9 h in a Soxhlet apparatus to extract additives. The stabilizers were added with stirring into 10% pentane solutions of the rubbers. After stirring for 40–60 min (to complete dissolution of the additive), the solvent was evaporated in a vacuum oven. Into HDPE, stabilizers were introduced with rollers (160±5°C, 5± 1 min) or from solutions, by thorough mixing with a polyethylene powder in a porcelain cup at room temperature to complete evaporation of the solvent, followed by drying in a vacuum oven to constant weight.

Extrusion of HDPE was performed with an IIRT capillary viscometer (capillary diameter 2.095± 0.005 mm) at 190±0.5°C and a load of 5 kgf, after keeping for 5 min in the heated device.

Thermal oxidation of polymeric compounds was performed on a manometric unit in oxygen at 150–195°C, P_{O_2} = 250 mm Hg. The sample weight was ~100 mg. The dependences $\Delta P_{O_2} = f(\tau_0)$ were plotted, and the induction periods of oxidation were determined from the slopes. The color of polymer samples was evaluated using a 10-point scale (1, white; 10, black) after thermal oxidation in air at 150–195°C.

The ^{1}H and ^{13}C NMR spectra were recorded on a Varian Gemini 200 spectrometer (working frequency 200 and 50 MHz for ^{1}H and ^{13}C, respectively) relative to residual protons of deuterated solvents.

Di(3,5-di-*tert*-butyl-4-hydroxyphenyl)hydroxymethane IV. To a solution of 1 g of hydrogalvinoxyl **I** in 50 ml of acetone, we added 30 ml of 25% aqueous ammonia and left overnight. The white precipitate was filtered off, washed with water, and dried. Yield 0.73 g (70%), mp 222–225°C (with decomposition).

^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.42 s (36H, CMe_3), 2.03 s (1H, OH), 4.41 s (1H, CH), 5.02 s (2H, OH), 7.13 s (4H, ArH). ^{13}C NMR spectrum ($CDCl_3$), δ_C, ppm: 30.5 (C*Me*$_3$), 34.5 (*C*Me$_3$), 64.1 (CH), 124.7 (C^3), 135.1 (C^4), 135.3 (C^2), 152.5 (C^1).

(3,5-Di-*tert*-butyl-4-hydroxyphenylthio)bis(3′,5′-di-*tert*-butyl-4′-hydroxyphenyl)methane VII. A 1-g portion of **I** and 0.56 g of mercaptophenol **VI** were dissolved in 5 ml of acetone. A white precipitate started to form immediately. The mixture was stirred for 0.5 h. The precipitate was filtered off, washed with acetone, and dried. Yield 1.4 g (90%), mp 190–192°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.30 s (18H, CMe_3), 1.41 s (36H, CMe_3), 5.04 s (2H, OH), 5.05 s (1H, OH), 5.19 s (1H, CH), 6.98 s (2H, ArH), 7.21 s (4H, ArH).

Found, %: C 78.51; H 9.82; S 4.61.
$C_{43}H_{64}O_3S$.
Calculated, %: C 78.13; H 9.76; S 4.85.

CONCLUSIONS

(1) Mercaptophenol **VI** forms colorless adducts with α-hydroxyphenylmethylenequinoid compounds and thus shows promised as a component of noncoloring stabilizing formulations based on di(hydroxyphenyl)methane stabilizers.

(2) Addition of aromatic phosphite **IX** as an agent decomposing hydroperoxides without radical generation and inhibiting formation of α-hydroxyphenylmethylenequinones enhances the color stability of polymers stabilized with di(hydroxyphenyl)methane stabilizers.

Electrodeposition of Nickel–Tungsten Alloy from Acetate Electrolyte

I. G. Kapralova, Yu. P. Perelygin, and T. K. Semchenko

Penza State University, Penza, Russia

Received April 28, 2003

Abstract—Deposition of coatings of nickel–tungsten alloys from acetate electrolyte was studied. The dependences of the relative content of components in the alloy on the electrolysis conditions were elucidated.

Electrolytic nickel–tungsten alloys are characterized by high wear resistance, elevated microrigidity, and corrosion resistance in a wide temperature range [1].

Electrolytic deposition of nickel–tungsten alloys is performed at elevated temperatures at high current densities over a wide range of pH from solutions containing tartrate, diphosphate, citrate, sulfamate, and sulfosalicylate ions in the absence and in the presence of ammonium ions, and borate ions in combination with hydrogen peroxide [2]. The rate of alloy deposition and the content of tungsten in the alloys can be increased by using current pulses [3].

It is of a certain scientific and applied interest to study the possibility of electroplating of nickel–tungsten alloys from acetate solution, since the acetate nickel–plating electrolyte has been studied fairly comprehensively and has some advantages over other known nickel–plating electrolytes.

We studied the deposition of nickel–tungsten alloy in a 200-ml rectangular cell using insoluble graphite or platinum anodes. The electrolyte had the following composition (g l^{-1}): nickel acetate (in terms of the metal) 50, sodium tungstate (in terms of the metal) 10, sodium acetate 100, and saccharin 1. The deposition was carried out at 20°C, current density of 10 A dm^{-2}, and pH 4.

The nickel content in alloys was determined by EDTA titration. The tungsten content was determined photocolorimetrically with potassium thiocyanate [7]. The internal stresses in coatings were evaluated by the method of flexible cathode [8], and the wear resistance, by the procedure described in [9]. The results were treated by the least-squares method using relationships given in [10] and the software from [11]. The correlation coefficient of the equations given below is 0.98–0.99.

An increase in the tungsten(VI) concentration in the electrolyte results in cracking of coating, increase in its luster, decrease in the current efficiency (CE) by the alloy, and increase in the tungsten content in the coating (see table). The correlation between the component ratio in the alloy and the ratio of the ion concentrations in the electrolyte is described by the Akhumov–Rozen equation [12]

$$\log[\mathrm{Ni}]/[\mathrm{W}] = 0.55 + 0.707\log[\mathrm{Ni}^{2+}]/[\mathrm{W}^{6+}].$$

Introduction of saccharin into the electrolyte (1 g l^{-1}) decreases the internal stresses in the alloy coating from 250 to 170 MPa, and addition of 1,4-butynediol (5 ml l^{-1}) further decreases the internal stresses to 18.6 MPa, with the coatings becoming semilustrous. The coating composition and current efficiency are affected by these additives insignificantly.

The influence of the cathodic current density, temperature, and pH of solution were studied using an electrolyte containing 10 g l^{-1} of tungsten.

An increase in the current density from 7.5 to 12.5 A dm^{-2} results in a decrease in the tungsten content in the alloy from 12 to 7% (Fig. 1a, curve *1*), with the current efficiency increasing from 26 to 50% (Fig. 1b, curve *1*). The dependence of the ratio between the component contents in the alloy on the cathodic current density i_c (A dm^{-2}) is described by the equation [10]

$$\log[\mathrm{Ni}]/[\mathrm{W}] = -0.15 + 1.15\log i_c.$$

As the temperature increases from 10 to 40°C, the content of the highmelting component in the alloy decreases from 20 to 4.5% (Fig. 1a, curve *2*), with the cathodic current efficiency increasing from 6.5 to 45% (Fig. 1b, curve *2*). The dependence of the component ratio in the alloy on temperature T (K) is described

1070-4272/03/7609-1524$25.00

Influence of tungsten(VI) content in the electrolyte on the coating morphology and deposition parameters

Component content				CE by alloy, %	Appearance of coating
in electrolyte, g l^{-1}		in alloy, %			
Ni(II)	W(VI)	Ni(II)	W(VI)		
50	5	95	5	32	Dull
50	10	91	9	30	Semilustrous
50	15	89	11	27	Semilustrous
50	20	88	12	22	Semilustrous

by the equation [10]

$$\log[\mathrm{Ni}]/[\mathrm{W}] = 8.2 - 2132/T.$$

The change in pH of the solution from 3 to 5 results in an increase in the current efficiency from 21 to 42% (Fig. 1b, curve *3*) and in a decrease in the tungsten content from 20 to 5% (Fig. 1a, curve *3*).

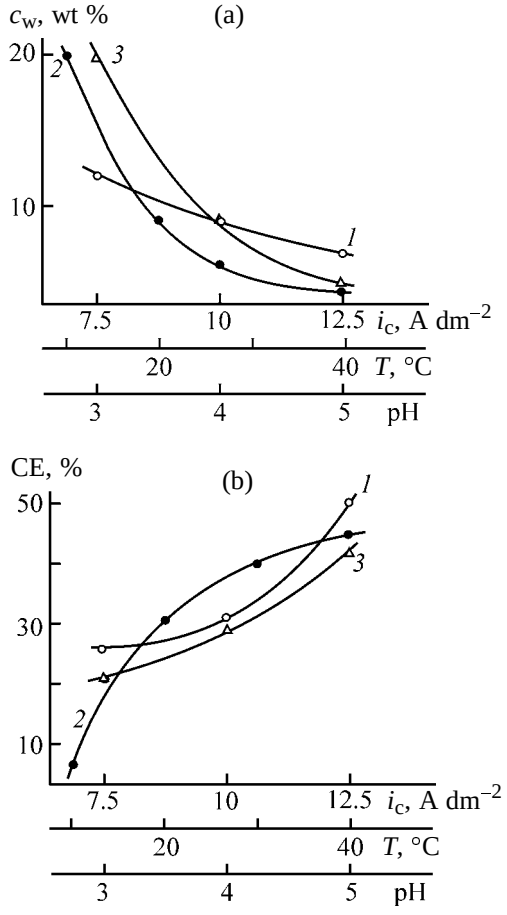

Fig. 1. Plots of (a) tungsten content c_W in the alloy and (b) current efficiency by the alloy vs. (*1*) current density i_c, (*2*) pH, and (*3*) temperature T.

The dependence of the component ratio on pH in the range under study is described by the equation [10]

$$\log[\mathrm{Ni}]/[\mathrm{W}] = -0.4 + 0.4\mathrm{pH}.$$

The alloy is not deposited to an appreciable extent from the electrolyte with pH less than 2, and a precipitate is gradually formed in this electrolyte.

An increase in the sodium acetate concentration from 100 to 150 g l^{-1} does not affect the alloy composition, but results in an increase in the current efficiency from 30 to 40%.

Thus, to obtain semilustrous coatings containing from 5 to 20% tungsten, we can recommend the electrolyte of the following composition (g l^{-1}): nickel acetate (in terms of the metal) 50, sodium tungstate (in terms of the metal) 5–20, sodium acetate 100–150; pH 3–5. The coating is deposited at 20–40°C and cathodic current density of 10–12.5 A dm^{-2} using insoluble platinum anodes. The current efficiency by the alloy under these conditions is 30–50%.

The wear resistance of the plated alloy containing 9% W exceeds the resistance of pure nickel by a factor of 10.

Kurnakov Institute of General and Inorganic Chemistry, Russian Academy of Sciences, Moscow, Russia

Received May 6, 2003

Abstract—A powder X-ray diffraction study of a polycrystalline sample of ethylenediamine-*N*,*N*'-bis(isopropylphosphonic) acid dihydrate (Phosphicine drug) isolated from aqueous solution showed that the product is single-phase. The diffraction pattern allows identification and detection of Phosphicine in mixtures with other substances. The thermal transformations of the compound were studied by differential thermal and thermal gravimetric analyses.

Ethylenediamine-*N*,*N*'-bis(isopropylphosphonic) acid, $H_2O_3P–C(CH_3)_2–NH–CH_2CH_2–NH–C(CH_3)_2–PO_3H_2$ (H_4L, Phosphicine) has very low toxicity and is used in medicine as antidote against toxic and radioactive metals [1, 2]. H_4L forms in aqueous solutions stable complexes with bi- and trivalent metal cations, showing selectivity with respect to Cu^{2+} ions [2–4]. The solid complexes $KLnL \cdot nH_2O$ [5] and $CuH_2L \cdot 2H_2O$ [6] were prepared; the structure of the copper complex was determined by single crystal X-ray diffraction [6].

In this work, we examined the possibility of identifying ethylenediamine-*N*,*N*'-bis(isopropylphosphonic) acid by powder X-ray diffraction.

EXPERIMENTAL

The powder X-ray diffraction patterns were taken on a DRON-3M diffractometer (Ni-filtered CuK_α radiation, 2θ 2°–60°). Thermal analysis was performed with an OD-103 derivatograph (quartz crucible, sample weight 100 mg) in air in the range 20–500°C at a heating rate of 2.5 deg min^{-1}. The temperature of the onset of H_4L decomposition was determined by the procedure described in [7].

$H_4L \cdot 2H_2O$ [TU (Technical Specification) 6-09-14-1806–75] was of pure grade. The substance was additionally purified by double precipitation from an alkaline solution with a mineral acid. For this purpose, $H_4L \cdot 2H_2O$ was dissolved in 10% NaOH, which was added dropwise, acidified with 1 M HCl to pH 2, and left overnight. After that, the crystalline precipitate was filtered off with a glass frit at reduced pressure, washed with water to negative reaction of wash waters for Cl^- and then with ethanol, and dried at room temperature to constant weight.

Found, %: C 27.8, H 7.4, N 8.0, P 18.2.
$C_8H_{26}N_2O_8P_2$.
Calculated, %: C 28.24, H 7.70, N 8.23, P 18.21.

Ethylenediamine-*N*,*N*'-bis(isopropylphosphonic) acid crystallizes from aqueous solutions at room temperature in the form of $H_4L \cdot 2H_2O$. Its experimental powder X-ray diffraction pattern coincides with that calculated from the single crystal X-ray diffraction data for this compound [8, 9] (see table), which indicates, in combination with the analytical data, that the polycrystalline sample is single-phase. The X-ray diffraction pattern contains no foreign reflections with the intensity $I \geq 0.5\%$.

$H_4L \cdot 2H_2O$ is poorly soluble in water, DMSO, DMF, acetic acid, ethanol, isopropanol, glycerol, acetone, chloroform, and benzene. It passes into solution under the action of 1 M solutions of ammonia, alkalis, sodium carbonate, sodium hydrogen carbonate, and mineral acids.

Thermal analysis shows that $H_4L \cdot 2H_2O$ starts to lose water of crystallization at 70°C. The first water molecule is eliminated fast at a relatively low temperature. Further dehydration (DTA_{min} 130°C) is slow; in particular, at 160°C in 1 h $H_4L \cdot 2H_2O$ loses 1.45 water molecules, and the constant weight loss value of 10.2% corresponding to the loss of 1.9 H_2O molecules is attained only after heating for no less than

* (*d*) Interplanar spacings corresponding to the reflections with the relative intensities $I \geq 1\%$.

5–6 h. Thermal decomposition of H_4L becomes noticeable rate even at 180°C (DTA_{min} 190, 205°C). Further heating is accompanied by a major weight loss due to release of gaseous pyrolysis products (DTA_{min} 340°C), with cleavage of the C–P bonds in the H_4L molecule. Medved' and Rudomino [10] reported for the compound the melting point of 235–236°C, but we revealed no endothermic effect in the DTA curve in this temperature region.

CONCLUSIONS

(1) Thermal analysis of ethylenediamine-*N*,*N*'-bis-(isopropylphosphonic) acid dihydrate showed that the compound has no well-defined dehydration, melting, and decomposition points suitable for identification.

(2) Powder X-ray diffraction allows reliable check of the phase purity of the compound and identification

of this compound in mixtures with other substances, in particular, in ready drug forms.

Synthesis of Monochloroacetic Acid from Ethylene Chlorohydrin

N. V. Svetlakov, V. G. Nikitin, and E. A. Nikolaeva

Kazan State Technological University, Kazan, Tatarstan, Russia

Received May 22, 2003

Abstract—The possibility of preparing monochloroacetic acid by oxidation of ethylene chlorohydrin with nitric acid was examined.

Monochloroacetic acid (MCAA) is widely used in production of polymers, pesticides, pharmaceuticals, etc. The main industrial and laboratory procedures for MCAA synthesis, and also its properties and application fields are described in [1]. The main industrial process for MCAA synthesis, chlorination of acetic acid, has a number of drawbacks; in particular, di- and trichloroacetic acids are formed as by-products, and their separation involves certain problems.

MCAA can be prepared by oxidation of ethylene chlorohydrin (ECH) with CrO_3 [2], but this procedure is of little promise for industrial use because of toxicity and high cost of the oxidant.

In this work, we prepared MCAA by oxidation of ECH with nitric acid, a readily available and relatively cheap oxidant used in industry for preparing carboxylic acids (e.g., oxalic, adipic) [3]. Oxidation of ECH was performed with 60–80% HNO_3; ECH was added at 20–25°C. The reaction was accompanied by slight warming-up and release of nitrogen oxides coloring the reaction mixture. After that, the temperature increased to 60–70°C, with vigorous evolution of nitrogen oxides.

ECH is oxidized with nitric acid to MCAA more difficultly compared to unsubstituted alcohols [3]. Presumably, oxidation of ECH with concentrated HNO_3 involves intermediate formation of ECH nitrates and nitrites [4, 5], which are relatively stable in an electrophilic medium. When kept in an acid solution, these ECH esters decompose to MCAA.

EXPERIMENTAL

The IR spectrum of MCAA in Vaseline oil was recorded on a UR-20 spectometer. The ^1H NMR spectrum of MCAA was taken in acetone-d_6 on a Tesla-497 spectrometer (working frequency 100 MHz) at room temperature against internal HMDS.

ECH was of pure grade; technical-grade 97% HNO_3 was diluted to the required concentration with distilled water.

To prepare monochloroacetic acid, ECH (17 g, 0.2 mol) was added with stirring at 20–25°C to 80% HNO_3 (63 g as calculated on 100% HNO_3, 1 mol). In the process, the temperature rose by 2–3°C, and nitrogen oxides (which were not analyzed) were released. After stirring for 0.5 h, the mixture became colorless owing to removal of nitrogen oxides. Then the stirring was stopped, and the temperature of the reaction mixture was controlled, so as to prevent self-heating above 60–70°C. After reaction completion, the mixture was stirred at 20°C to remove nitrogen oxides; unchanged HNO_3 and H_2O were distilled off in a water-jet-pump vacuum. The bottom residue was transferred into a beaker, in which it crystallized within 20–30 min. The crystalline precipitate was filtered off and dried in air; yield of MCAA 16.5 g (85%), mp 62°C [from chloroform; published data [1]: mp 63°C (α-modification)]. IR spectrum, ν, cm^{-1}: 1716, 2100–3250 (COOH). ^1H NMR spectrum, δ, ppm: 4.0 s (2H, CH_2Cl), 10.0 s (1H, COOH).

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

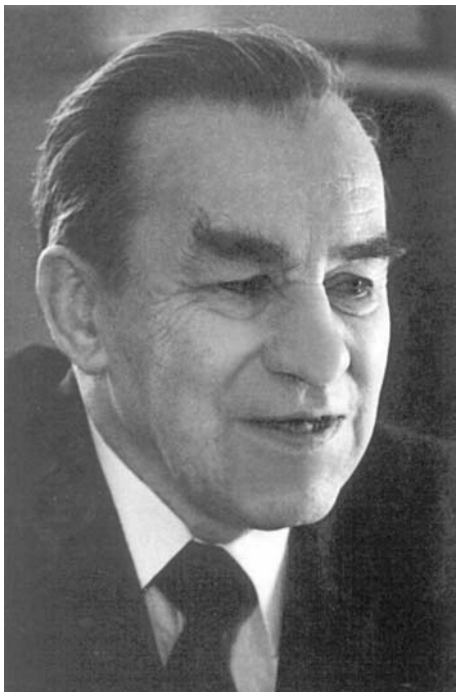
Professor Yakov Ivanovich Gerasimov

(to Centennial Anniversary of His Birthday)

Corresponding member of the Academy of Sciences of the USSR Yakov Ivanovich Gerasimov, a scientist, pedagogue, and research organizer, made an outstanding contribution to the development of physical chemistry and its most important branch, chemical thermodynamics, in our country. All his main scientific and pedagogical activities had been associated with the Moscow State University for more than 60 years.

Ya.I. Gerasimov was born on September 23, 1903, in Valdai, Novgorod province, into a doctor's family. Despite the early death of their father, the children were excellently educated and bred thanks to the efforts of their mother. Beginning in his childhood, the scientist-to-be was quite at home in English, French, and German, was familiar with history and literature, and practiced music. In 1920, he finished a secondary school in Rybinsk, Yaroslavl province, and in the same year entered the chemical division of the Physicomathematical Faculty of the Moscow University. Among the teachers with whom his was the closest were I.A. Kablukov (1857–1942) and A.V. Rakovskii (1879–1941). Kablukov was one of the first physical chemists and a contemporary of D.I. Mendeleev (1834–1907). He worked at A.M. Butlerov's (1828–1886) laboratory in St. Petersburg and W. Ostwald's (1853–1932) laboratory in Leipzig, was on friendly terms with S. Arrhenius (1859–1927) and well acquainted with van't Hoff (1852–1911), and made a major contribution to the development of the theory of solutions, thermochemistry, and other fields of physical chemistry and chemical engineering. He became an honorary member of the Academy of Sciences of the USSR in 1932. Particularly strong influence was exerted on the formation of Gerasimov's scientific view of the world by Rakovskii, whose main studies were concerned with problems of chemical thermodynamics and with heterogeneous equilibria. Rakovskii was the author of one of the best domestic textbooks of physical chemistry (1938) and became a corresponding member of the Academy of Sciences of the USSR in 1933.

Gerasimov graduated from the University in 1925; however, already beginning in 1923 he worked as laboratory assistant with Kablukov and performed



demonstrational experiments during his lectures. Later, Gerasimov made a scientific career from postgraduate student to professor (1942) and head of the chair of physical chemistry at the Moscow University (1952). He became candidate of chemistry in 1935 and doctor of chemistry in 1940. In October 1953, he was elected a corresponding member of the Academy of Sciences of the USSR (Division of Chemical Sciences, Physical Chemistry). In addition to working at the University, Gerasimov took an active part in research conducted at the Institute of Nonferrous Metals (Gintsvetmet), headed the Chemical Editorial Office at the State Publishing House for Foreign Literature, and delivered lectures at a number of higher school institutions in Moscow.

Gerasimov's scientific activities, commenced in 1925, were devoted to a wide variety of thermodynamic problems largely associated with the needs of the industrial practice. His studies of 1927–1934, concerned with equilibria in water–salt systems, were performed at laboratories of Moscow University and the Institute of Pure Chemical Reagents, where Rakovskii

1070-4272/03/7609-1531$25.00

worked. The first Gerasimov's publication was titled "On Synthesis of Chemically Pure Ammonium Bichromate" [*Trudy Instituta Chistykh Khimisheskikh Reaktivov* (Transactions of the Institute of Pure Chemical Reagents), 1927]. Rakovskii always demanded that the research techniques and results obtained should be highly reliable. This feature also became characteristic of his disciples [1].

Already in the early 1930s, Gerasimov commenced investigations in the field of thermodynamics of metallurgical systems and processes. Together with his co-workers, he studied heterogeneous equilibria involving sulfides and other compounds of zinc, lead, copper, nickel, and cobalt with hydrogen and carbon monoxide in order to obtain data on the thermodynamic characteristics of the corresponding processes. A number of original investigation techniques were developed. The results obtained in the series of metallurgical studies were summarized in Gerasimov's doctoral dissertation.

In 1932–1934, Gerasimov and A.N. Krestovnikov published a three-volume textbook *Khimicheskaya termodinamika v tsvetnoi metallurgii* (Chemical Thermodynamics in Nonferrous Metallurgy) presenting a vast body of reference data on thermodynamic properties of a large group of nonferrous metals and their most important compounds. Later (1960–1973), this book was much expanded (to seven volumes). The authors collected, treated, and critically assessed published evidence concerning the thermodynamic properties of hundreds of compounds that are of interest to chemists and metallurgists.

Of particular interest are reviews of topical publications, written by Gerasimov in different years: "Chemical Thermodynamics and Molecular Spectra" (*Usp. Khim.*, 1933, no. 4), "On Thermodynamics of Metal–Slag Equilibria" (*Stal'*, 1947, no. 1), "Activity of Metallic Oxides in Melts with Silica and Calcium Oxide" (*Stal'*, 1947, no. 5), and "Thermodynamic Properties of Solid and Liquid Metallic Melts and Their Relationship with Phase Diagrams" (*Zh. Fiz. Khim.*, 1967). All the reviews are characterized by rigorous and simple manner of presentation. Gerasimov was among those who initiated the introduction of statistical methods for calculation of thermodynamic quantities in our country.

Beginning in 1943, Gerasimov headed the laboratory of chemical thermodynamics at the chair of physical chemistry, Moscow State University. The main task of the laboratory during the postwar years was to search for heat-resistant materials and coatings, required by new technologies. In this context, wide-scale investigations of the thermodynamic properties of ferrites, tungstates, and molybdates were carried out. In the early 1950s, the emf method started to be used at the laboratory for studying the thermodynamic characteristics of liquid and solid metal alloys and, later, oxides and salts of rare metals. Solid electrolytes with anionic conduction (oxygen- and fluorine-ionic) found wide use together with molten and solid electrolytes with cationic conduction. The saturated vapor pressure was measured, and its molecular composition was studied, using versions of the Knudsen method. Rather advanced and diverse investigation techniques made it possible to expand substantially the variety of objects that could be studied. New data were obtained on the thermodynamic properties of quite a number of alkali metal containing alloys, chalcogenides, and alloys and compounds of rare-earth metals. The general goal of these studies was to create thermodynamic foundations of materials science. Calculation methods of chemical thermodynamics, combined with the known thermodynamic functions of substances, make it possible to prodict properties of a material synthesized from these substances. During the entire period of his scientific activities, Gerasimov always strove to introduce thermodynamic data into practice. This standpoint of the scientist was clearly reflected in his publications "Thermodynamics of Solutions at High Temperature and Its Use in Theoretical Metallurgy" (*Usp. Khim.*, 1945, no. 4) and "Chemical Thermodynamics and Some Promising Fields of Its Application" (in co-authorship with G.F. Voronin, *Vestn. Akad. Nauk SSSR*, 1970, no. 3). Gerasimov also wrote "Review of Research at the Laboratory of Chemical Thermodynamics, Chemical Faculty, Moscow State University" [2], in which particular attention was given to studies in the field of thermodynamics of intermetallic compounds and metal oxides, carried out at the laboratory in 1953. Studies of the preceding period of time were also briefly reviewed.

In 1981, Gerasimov was among those who were awarded a State Prize of the USSR for investigations in the field of thermodynamics.

During the entire period of his many-year pedagogical activities, Gerasimov paid much attention to improving the methods for teaching of physical chemistry at higher-school institutions of our country. He headed a group of authors, edited the whole manuscript, and wrote himself the chapters devoted to foundations of thermodynamics, thermodynamics of solutions, chemical equilibrium, and electrochemistry in creating a fundamental textbook *Kurs fizicheskoi khimii* (Course of Physical Chemistry) (two volumes, for chemical faculties of universities) published in two

editions (1963 and 1973) and translated into English, Spanish, Arabic, and Azerbaijani. Gerasimov paid much attention to methodological problems associated with teaching of physical chemistry. Of much interest are his papers "On the Object and Scope of Physical Chemistry" [3] and "On Some Fundamental Concepts of Thermodynamics" [4]. During many years, Gerasimov delivered a course of lectures in physical chemistry and special courses "Thermodynamics of Solutions" and "Selected Chapters of Thermodynamics." Together with V.A. Geiderikh, he wrote a book *Termodinamika rastvorov* (Thermodynamics of Solutions) (1980). Gerasimov translated into Russian or edited translations of numerous foreign publications. In particular, he was the scientific editor of translations of a two-volume course of physical chemistry by Moelwyn-Hughes (1962) and a monograph by A. Munster (1971).

A number of Gerasimov's papers were concerned with history of chemistry. These papers analyzed investigations of the solubility of carbon dioxide in salt solutions (1952) carried out by I.M. Sechenov (1829–1905), mutual solubility of liquids (1950) carried out by V.F. Alekseev (1852–1919), and adsorption and thermodynamics of irreversible processes (together with A.V. Kiselev, 1949) performed by Rakovskii.

During nearly 30 years, Gerasimov headed the largest chair of physical chemistry, which included 11 laboratories with more than 400 staff members. The scientist and pedagogue, he possessed exceptional personal qualities, being a good-wishing man adhering to his principles, with extensive life experience, and was greatly respected both in our country and abroad. Gerasimov conducted extensive scientific-organizational work. During many years, he headed the Scientific Council for chemical thermodynamics and thermochemistry of the Academy of Sciences of the USSR. For more than 25 years, till the end of his life, he was Editor-in-Chief of *Zhurnal Fizicheskoi Khimii* (Soviet, now Russian Journal of Physical Chemistry) published by the Academy of Sciences and a member of the editorial board of the international journal devoted to chemical thermodynamics (*Journal of Chemical Thermodynamics*). During 10 years he was a member of a committee of IUPAC. He knew personally, and maintained scientific contacts with most of the leading world's specialists in chemical thermodynamics.

For his services in the training of highly skilled scientists and pedagogues and in the development of the domestic science Gerasimov was honored with a number of State awards.

Yakov Ivanovich Gerasimov passed away on March 17, 1983 at the age of 79. The domestic chemical science suffered a grievous loss. In 1988, the Nauka publishing house published posthumously selected works of the scientist [5], prepared by staff members of the laboratory of chemical thermodynamics, Chemical Faculty, Moscow State University. The foreword of the collection of works mentioned that the main merit of Gerasimov and his school consists in that they developed experimental techniques for thermodynamic investigations and obtained, using these techniques, a large body of data on properties of various substances and materials of interest to science and technology.

All those who knew Yakov Ivanovich Gerasimov, a prominent scientist and excellent person, deeply respected and sincerely liked him.

OBITUARIES

Professor Aleksandr Leonovich Rotinyan (1913–1991)

Aleksandr Leonovich Rotinyan, a remarkable person and prominent scientist who tirelessly paved new ways in electrochemical science and technology, a talented pedagogue who supplied Russia's electrochemical school with highly skilled specialists, would be 90. During many years he had been a member of the Editorial Board of *Zhurnal Prikladnoi Khimiii* (Soviet, now Russian Journal of Applied Chemistry) and took an active part in its work.

Aleksandr Leonovich Rotinyan was born on August 13, 1913, in St. Petersburg. His father, Leon Aleksandrovich Rotinyan (1879–1964), was a lecturer at the chair of physical chemistry and theoretical electrochemistry at the St. Petersburg Polytechnic Institute. Later, Professor L.A. Rotinyan, a known physical chemist, delivered lectures at a number of higher-school institutions of Russia.

In 1935, A.L. Rotinyan graduated from the Chemical Faculty of the Yerevan Polytechnic Institute, and in 1938, finished his postgraduate education at the Leningrad Polytechnic Institute. A.L. Rotinyan's scientific and pedagogical activities, which he commenced as docent at the Novocherkassk Polytechnic Institute, were interrupted by the beginning of the war. From June 1941 till September 1945 he served in Soviet Army and participated in action at the Leningrad Front. His war merits are honored with Government awards.

During the period from 1945 till 1960, A.L. Rotinyan's activities were associated with the Gipronikel' research and design institute, where he made a career from senior researcher to deputy director for research work. There, extensive research and technological work were carried out under his direct supervision, with his most active personal involvement, in the fields of hydrometallurgy of nickel, kinetics of calcination processes, leaching, cementation, hydrolysis, hydration, and formation of difficultly soluble hydrates and basic salts that are in equilibrium with the solid phase.

The set of these investigations served as a basis for the development of an industrial process for manufacture of high-purity nickel suitable for preparing heat-resistant nickel-based alloys. Aleksandr Leonovich

was awarded, together with specialists from the Gipronikel' institute and Severonikel' combine, a 1949 State Prize of the USSR in science and technology. High-purity domestic nickel is manufactured up to now at two largest combines of the country by the technology suggested and introduced by Rotinyan and co-workers at the Severonikel' combine in 1947–1948.

The fundamental studies in the theory of joint discharge of ions in electrolytic deposition of metals, published by A.L. Rotinyan and V.L. Kheifets in 1952–1953, found use in various fields of chemical technology and led to further development of the theory. Highly important were studies, carried out in the same years, in the field of dissolution kinetics of solids with complex composition, and also development and introduction of a new intensified method for synthesis of nickel carbonyl. In 1952, A.L. Rotinyan became doctor of engineering.

Further scientific and pedagogical activities of Aleksandr Leonovich were associated with the Lensovet Technological Institute in Leningrad; he became a professor in 1960 and headed the chair of technology of electrochemical industries in 1969.

1070-4272/03/7609-1534$25.00 © 2003 MAIK "Nauka/Interperiodica"

The investigations carried out by A.L. Rotinyan and his disciples during 30 years were related to the most important directions of modern theoretical and applied electrochemistry. A major contribution to theory and practice was made by studies concerned with the mechanism and fundamental kinetic aspects of metal electrodeposition processes, considered with account of the acidity of the near-electrode layer, process stages, and ionic equilibria in solution. Investigations concerned with joint discharge of zinc and hydrogen ions at a zinc electrode, redox potentials of cobalt ions, and kinetics of electrodeposition of nickel–cobalt, iron–cobalt, and iron–nickel alloys were carried out at the institute. The method of a microscopic glass electrode, suggested by A.L. Rotinyan for measuring the acidity of the near-electrode layer, found use at numerous domestic and foreign laboratories.

Mention should be made of a series of investigations by A.L. Rotinyan and co-workers in the field of chemical power cells. These studies were aimed both to improve the already existing electric power sources and to develop new systems with the use of organic solvents. Aleksandr Leonovich supervised studies of main physicochemical properties of inorganic salts in aprotic organic solutions, equilibria in halide solutions of zinc and cadmium in dimethylacetamide and dimethylformamide, kinetics and mechanism of electrochemical reactions of lithium charging–discharge in ethers, and reduction of metal oxides and chalcogenides in organic solvents.

The concepts of the course of electrode reactions, suggested by A.L. Rotinyan, which are extensively used by researchers to solve widely varying problems of applied electrochemistry, served as a basis for the development of new directions in electrochemical technology.

A.L. Rotinyan was a talented pedagogue who trained a great number of engineers and candidates of science, working successfully in the industry and at higher-school institutions in our country and abroad. He was the author of more than 300 scientific papers, books, and inventions. A.L. Rotinyan took an active part in writing the textbook *Prikladnaya elektrokhimiya* (Applied Electrochemistry), which ran through three editions, and monographs *Teoreticheskaya elektrokhimiya* (Theoretical Electrochemistry), *Optimizatsiya proizvodstva khlora* (Optimization of Chlorine Manufacture), and *Osnovy metallurgii* (Foundations of Metallurgy).

Rather diverse and fruitful were A.L. Rotinyan's scientific-organizational activities. As a prominent specialist in applied electrochemistry he headed the Electrochemical Technology Section of the Scientific Council for Electrochemistry at the Academy of Sciences of the USSR, was a member of the Editorial Board of *Elektrokhimiya* (Electrochemistry) journal, supervised the permanent seminar on electrochemistry of the *Znanie* (Knowledge) society, and was Chairman of the Specialized Council for conferring scientific degrees at the Technological Institute.

Aleksandr Leonovich Rotinyan was a scientist with encyclopedic knowledge and a broad-minded person of high culture. His surprising intuition helped him to distinguish promising directions of research, which were invariably supported by him.

Any person who was acquainted with A.L. Rotinyan was subject to the charm of his vivid personality. Colleagues and disciples remember Aleksandr Leonovich as an exceedingly well-wishing person always ready to give help to those who addressed him and to support them.

A.L. Rotinyan died on March 30, 1991, at the age of 77. Aleksandr Leonovich belongs to those who will be always remembered by grateful disciples and colleagues.

INFORMATION

XI International Conference on Chemistry of Organic and Organoelement Peroxides

The 11th International Conference on Chemistry of Organic and Organoelement Peroxides was held from June 24 to 26, 2003 in Moscow. The conference was organized on the basis of the Semenov Institute of Chemical Physics, Russian Academy of Sciences (ICP RAS), Moscow and Emanuel Institute of Biochemical Physics, Russian Academy of Sciences (IBCP RAS), Moscow.

The Conference organizers were the Russian Academy of Sciences, ICP RAS, IBCP RAS, Russian Foundation for Basic Research (RFBR), and Lobachevsky State University (Nizhni Novgorod).

The conference participants were more than 450 scientists representing 52 research centers from Russia and CIS countries. The Conference was held in the form of a series of minisymposia on 5 dedicated topics. In the opening ceremony, V.L. Antonovskii, E.T. Denisov, and A.A. Berlin outlined the topicality of the problems concerning synthesis, properties, and applications of peroxides from the theoretical and applied standpoints. Peroxides were said to represent an important class of chemical compounds taking a great part in chemistry, biology, and medicine.

The motto of the Conference was "Chemistry of Peroxides on the Way to the Third Millenium," and the major attention was paid to results obtained in this area in the last four years. The problems considered at the conference included questions of theoretical chemistry (homolysis models, spin chemistry, catalysis, redox reactions, rearrangement, structure–reactivity relationship, transformation of the chemical energy to the light energy, chain reactions), polymer chemistry and technology (initiation of radical polymerization, cross-linking, functionalization), chemical industry (foundry, fuel additives, bleaching of fabrics and other materials, adhesive and varnish components, combustion, film coating); biology (normal and pathological processes; lipid oxidation; synthesis of steroids, prostaglandins, etc.; chemiluminescence of organisms), ecology (atmospheric processes, autooxidation, biochemical oxidation in water and soil), and synthesis (radical reactions, synthesis of alcohols and ketones, epoxidation).

The first session of the Conference was devoted to the problems of synthesis and reactivity of peroxides. The session included 20 oral and 26 poster presentations. Particular emphasis was made on such questions as interaction of peroxides with various organic and inorganic compounds, synthesis and reactivity of peroxides, determination of the rate constants of reactions of peroxy radicals with organic and inorganic compounds, photooxygenolysis, kinetics and mechanisms of oxidation of various chemical groups by peroxides, calculation of bond (dissociation) energy of various peroxides, and quantum chemical study of the structure and conformations of peroxides.

The second session covered the problems of physical and analytical chemistry of peroxides. The session included 8 oral and 17 poster presentations devoted to the kinetic features of decomposition of peroxides, calculation of the activation volume of thermal transformation of peroxides, effect of surfactants on decomposition of peroxides, new supramolecular model for the mechanism of peroxide decomposition, theoretical estimation of the formation enthalpies and dissociation energies of –O–O– bonds, quantum chemical calculation of the kinetic parameters of decomposition of organic and inorganic peroxides, and catalyzed and inhibited decomposition of peroxides.

The topic of the third session (28 oral and 31 poster presentations) was the study of peroxides as intermediate products of oxidation in chemical and biological processes. In this session, a particular attention was paid to oxidation of lipids with microbial lipoxygenase, the chain mechanism of decomposition of peroxides, effect of nanostructures in hydrocarbons on the oxidation mechanism, effects of antioxidants and peroxides on the plant cell growth as influenced by the physicochemical parameters of elementary reactions, development of supramolecular catalysts, and characterization of oxidation products.

The fourth session "Peroxides in Organic Synthesis, Polymer Processing, and Other Processes" included 6 oral and 28 poster presentations covering such problems as determination of explosive characteristics of organic peroxides, modification of polymeric surfaces with peroxides, synthesis of new initiators of radical telomerization, development of new

1070-4272/03/7609-1536$25.00

principles of homolytic phosphorylation, the use of peroxides in manufacture of mold cores and casting molds, the use of oligomeric peroxides for preparation of petroleum polymer epoxy resins, and application of functionalized peroxides as reagents for synthesis of peroxy monomers, surface-active initiators, and reactive surface modifiers.

Finally, the fifth session (13 oral and 12 poster presentations) covered the problems of ecology and the use of hydrogen peroxide for sterilization. The participants reported on new chemical disinfectant based on environmentally friendly hydrogen peroxide, new metal–containing catalysts based on hydrogen peroxide, reactions of hydrogen peroxide with metal porphyrins, photocatalyzed synthesis of organic compounds, general questions of applications of hydrogen peroxides in the environmental chemistry, etc.

The Conference showed that peroxides, as chemical compounds, continue to attract close attention of chemical researchers and practical persons, the biochemical, biological, and even medical aspects of peroxide research being of steadily growing interest.

The next 12th Conference will be held in 2006. The abstracts of the 11th Conference are available from the library of the Institute of Chemical Physics, RAS, and the proceedings will be published in 2004 in the United States (Nova Science Publishers, New York).

INFORMATION

14th Annual BCC Conference on Flame Retardancy "New Technological Achievements and Developments in the Field of Flame Retardancy of Polymer Materials" (FR Materials, Applications, Scientific and Technological Achievements, Market for FR Products)

The 14th Annual Conference on Flame Retardancy of Polymer Materials was held from June 2 to 4, 2003 in Stamford, Connecticut (the United States). The Conference was organized by the Business Communications Co (BCC).

The Conference covered the following topics:

(1) review of the current state of science and technology in FR;

(2) review of the applications and markets for FR products;

(3) recent developments in local and global standardization and in testing technology;

(4) problems of toxicity and environmental issues;

(5) halogen-based and non-halogen-based flame-retardant chemicals, synergism, intumescence, FR mechanisms, modeling, flame parameters, and inherently FR polymers.

(6) review of developments on fire control, containment, and FR enablement.

The 2003 highlights were as follows: nanomaterials, flame-retarding steel components, new fabric and vehicle FR developments, and news from Europe. The conference participants were about 100 scientists from the Unites States, Canada, Russia, the United Kingdom, Israel, France, Belgium, Germany, Italy, and Poland. Professor Menachem Lewin, who is the Program Chairman of this annual conference for already 14 years, in his opening remarks outlined that polymer combustion studies demonstrate a need in developing both theoretical and applied approaches in their close interlink. The reports presented at the Conference were discussed in five sessions. The first session "Review and Mechanism of Flame Retardancy" included six oral presentations. T.R. Hull (the United Kingdom) in his lecture reported on combustion studies in a purser furnace; T. Kashiwagi (the Unites States), on flame retardant mechanism of polymer clay nanocomposites; J.E.J. Staggs (the United Kingdom), on simulation of thermal degradation of linear polymers; and M. Nyden (NIST), on a unified reaction rate theory for large molecules in condensed phases.

Two other reports presented at this session were devoted to new developments in FR polyurethanes [S. Levchik (the Unites States)] and environmental aspects in polymer FR [G.E. Zaikov and S.M. Lomakin (Russia)].

The second session "Halogen- and Non-Halogen-Based FR Systems" included eight oral and one poster presentations. A.R. Horrocks (the United Kingdom) reported on the capacity of heavy metal ions to enhance the flame-retardant activity of ammonium polyphosphate; Dr. Shiow-Ching Lin (the Unites States), on fire resistance of fluoropolymers; and I. Finberg (Israel) and T. Geran (the United States), on development of fire-retarded plastics with reduced content or no presence of antimony trioxide.

The next four reports were devoted to applications of silicone-phosphonates [S. Gallagher (the United States)], enhanced performance of phosphate- and sulfonate-based intumescent agents [P.S. Rhodes (the United States)], improvement of the fire behavior of PVA-using binary and ternary mineral compositions [J.M. Lopez-Cuesta (France)], and use of iron compounds in non-halogen FR systems [E.D. Weil (the United States)]. Finally, K.K. Shen (the United States) reported on firebrake zinc borates as fire retardants in halogen-free polyolefins.

The poster presentation made by J. Hicks, P.J. Davies, A. Alderson, and A.R. Horrocks (the United States) provided information on the burning behavior of polyacrylonitrile fiber-forming polymers in the presence of phosphorus-containing FRs. The third session "Flame Retardancy of Nanocomposites" included six oral presentations. In the first one, S. Bourbigot and J.W. Gilman (NIST), C.A. Wilkie, and A.B. Morgan (both the United States) examined the problems of processing, characterization, thermal stability, and

1070-4272/03/7609-1538$25.00

flammability of polystyrene clay nanocomposites. The talk was followed by a fruitful discussion. Then S. Padbury (the United Kingdom) reported on the effect of P-containing flame retardant and nanoclays on behavior of polyamides 6 and 6.6. The next four talks were devoted to progress on nanostructurated flame retardants [G. Beyer (Belgium)], recent advances in fire retardancy based on nanocomposites [C.A. Wilkie (the United States)], fire performance of polystyrene/silica nanocomposites prepared by extrusion [G.L. Nelson (the United States)], and regulatory activity governing brominated flame retardants in Europe and the United States [T. Hull (the United Kingdom)]. The fourth session "Consumer Focus—Industrial Applications" included eight oral presentations. The first four talks were devoted to the thermal and fire behavior of polypropylene/flax biocomposites [B. Schartel (Germany)], the use of red phosphorus for flame proofing of polyolefins [N. Gatti (Italy)], ignitability of wood treated with different FRs [R. Kozlowski (Poland)], and cotton batting barriers for soft furnishings [S. Wolf, P.J. Wakelyn (the United States)]. In the next four reports, the authors discussed thermal stability and FR of rigid PU foams [K. Pielichowski (Poland)], new developments in durable flame retardant finishing of cotton textiles [C.Q. Yang (the United States)], halogen content analysis of fire redardants [R. Fehrenbach (the United States)], and new FR materials for military applications [U. Sorathia (the United States)].

The final fifth session "Testing Standards and Toxicity" included seven oral presentations. The first one entitled "How to Get Your Product CE-Labeled? First Experiences with Euroclasses" was presented by P.Vandervelde (Belgium). J.S. Stimitz (the United States) talked about properties of plastic materials for use in 42 volt automotive applications, and M.M. Hirschler (the United States), about fire hazard assessment of personal computers in a home and in a small office. The next four reports in this session were devoted to studies on the combustion behavior of polystyrene systems flame retarded with phosphorus [D. Price (the United States)], comparison of fire properties of automotive materials [M.L. Janssens (the United States)], the correlation of heat release calorimetry measurements [R. Filipczak (the United States)], and potential effects of combustion products of brominated fire-retardant chemicals on egress time in home fire scenarios [T.A. Thomas (the United States)].

The 14th Conference on Flame Retardancy of Polymer Materials showed that the problems considered are of great importance for science and technology. The next 15th Conference will be held in Stamford, Connecticut (the United States) in 2004.

BOOK REVIEWS

Motov, D.L., *Fizikokhimiya i sul'fatnaya tekhnologiya titano-redkometall'nogo syr'ya* (Physical Chemistry and Sulfate Technology of Titanium–Rare-Metal Raw Materials)

Apatity: Kol'skii Nauchnyi Tsentr Ross. Akad. Nauk, 2002, part 1, 189 pp.; part 2, 163 pp.

In the Kola Peninsula, there are unique deposits of titanium–rare-metal raw materials. Of particular importance among titanium-containing minerals are perovskite, sphene, and titanomagnetite, and also loparite, which is a complex titanium–rare-metal raw material. Of chief interest among zirconium minerals are eudialyte and baddeleyite. For all of the titanium-containing ores found in the Kola Peninsula there are rather efficient dressing schemes yielding various concentrates of required composition.

The main industrial products produced by one or another scheme for processing of complex titanium or zirconium raw materials are titanium dioxide for various purposes, titanium tetrachloride, technical-grade niobium pentoxide with admixtures of titanium and tantalum, niobium and titanium pentoxides for manufacture of the metals, concentrates of rare-earth elements, and zirconium dioxide as refractory material.

The choice of a technique for processing of titanium–niobium raw materials is largely determined by the kind of titanium products to be manufactured. D.L. Motov's monograph, devoted to physicochemical foundations and technology of sulfuric acid processing of titanium–rare-metal raw materials, comprises two parts. The first part covers the physicochemical foundations of sulfuric acid technology for recovery of titanium, zirconium, and hafnium compounds from titanium–rare-metal raw materials and also the results of development of flowsheets for integrated sulfuric acid processing of loparite, sphene, and titanomagnetite. The second part discusses sulfuric acid processing of other kinds of raw materials: of titanate (perovskite), titanosilicate (leucoxene), and zirconium (eudialyte, baddeleyite) types.

Using methods of physicochemical analysis, the author obtained a vast body of reference-type data on solubility in the systems MeO_2–SO_3–H_2O (Me = Ti, Zr, Hf) at temperatures ranging from 20 to 300°C, and also on more complex equilibria. Sulfate and sulfatometallate compounds isolated in studying the systems are characterized using chemical, crystal-optical, X-ray phase, and thermogravimetric analyses.

The process characteristics of breakdown of loparite, perovskite, and sphene concentrates with sulfuric acid or its mixture with ammonium sulfate are described. In processing of loparite, titanium can be separated from niobium and tantalum. The first part of the monograph also presents results obtained in studying and optimizing sulfuric acid processing of sphene, which is one of the most important minerals of the Khibins. In addition to being a component of apatite–nepheline ores, sphene forms in the Kola Peninsula separate ore deposits. Processing of sphene can give various pigments.

The second part of the monograph considers methods of integrated processing of titanate and titanosilicate raw materials to obtain titanium dioxide pigment. Zirconium (hafnium) compounds can be recovered from eudialyte of complex composition, whose ores are mainly found in the Lovosero massif, and from baddeleyite, natural zirconium dioxide, which is an admixture mineral in one of iron-ore deposits in the Kola Peninsula. The final section of the second part contains evidence concerning certain fields of application of titanium and zirconium compounds.

Motov's monograph, published in an edition of only 100 copies, is packed with experimental material and flowsheets. The book is intended for a relatively small audience of readers specialized in processing of the above-mentioned kinds of raw materials or in use of the products obtained.

BOOK REVIEWS

Habashi, F., *From Alchemy to Atomic Bombs: History of Chemistry, Metallurgy, and Civilization*

Quèbec City (Canada): Laval University, 2002, 357 pp.

The book written by F. Habashi, a know Canadian scientist working in the field of nonferrous metallurgy, considers in a sufficiently popular form a wide variety of problems associated with the development of chemistry, physics, and metallurgy from the ancient times till the present days. Particular value and attractiveness is imparted to the book by the richest illustrative material, photographs of scientists, various events, commemorable places, process schemes, etc. (the book contains 223 illustrations, 30 of these colored). All the photographs and drawings are of extremely high quality. Separate sections of the book had been published, mainly in not readily available Canadian journals.

The book comprises 11 small chapters and has author and bibliographic indexes. Chapter 1 (Mythology, pp. 1–22) presents evidence of historical-mythological nature and pays much attention to the origin of the names of metals, associated with various mythological characters (from cobalt, 1735, to promethium, 1945; a total of 15 metals). Chapter 2 (The Four Elements, pp. 23–46) describes the concepts of Empedocles (ca. 490–430 BC), an ancient Greek philosopher who recognized four elements: fire, air, water, and soil, naming them "roots of all." Also considered are the viewpoints of other philosophers: Aristotle (384–322 BC), Galen (130–201), Agricola (1494–1555), and the philosophy of Zoroaster prophet. Chapter 3 (Alchemy, pp. 47–100) is devoted to the origin and development of alchemy. Chapter 4 (The Alchemists, pp. 102–154) presents brief biographic evidence concerning a large number of scientists who were, to varied extent, on the standpoint of alchemy both in Arab countries and, later, in West Europe. To these belong Ibn Sina (Avicenna) (980–1036), T. Paracelsus (1493–1541), van Helmont (1577–1644), R. Boyle (1627–1691), G.E. Stahl (1660–1734), and other scientists.

Chapter 5 (Reform in Chemistry, Mineralogy and Metallurgy, pp. 155–182) includes materials characterizing the reform in natural sciences in the XVIII and XIX centuries. Special attention is given to the works of A. Lavoisier (1743–1794), who was the first to cast doubt on the theory of phlogiston. Together with a number of other scientists, Lavoisier developed principles of a new chemical nomenclature, published his "Elementary Course of Chemistry," and made a number of major discoveries. The chapter recognizes the merits of J. Dalton (1766–1844), reforming activities of J.J. Berzelius (1779–1848), and works of F.A. Kekulé (1829–1896), S. Cannizzaro (1826–1910), and quite a number of other outstanding scientists of the XIX century.

Chapter 6 (Discovery of Electricity, pp. 183–210) is devoted to the investigations which led to the discovery of electricity 200 years ago. L. Galvani (1737–1798), A. Volta (1745–1827), M. Faraday (1791–1867), S. Arrhenius (1859–1927) are mentioned among others. H. Davy (1778–1829), R. Bunsen (1811–1899), and H.E. Saint-Claire Deville (1818–1881) are named fathers of electrometallurgy. Chapter 7 (Classification of the Elements, pp. 211–234) discusses studies concerned with the classification of elements. Mention is made of the discovery of the Periodic law by D.I. Mendeleev (1834–1907) and later studies in this field. Chapter 8 (The Modern Physics: Discovery of X-rays, pp. 235–272) is devoted to the advances in physics, beginning with the end of the XIX century. The attention is focused on the discovery by W.K. Röntgen (1845–1923). Chapter 9 (Radioactivity: Chemistry and Physics United, pp. 257–272) describes the development of investigations into radioactivity from H. Becquerel (1852–1908) to G. Seaborg (1912–1999). Chapter 10 (Uranium Fission, pp. 273–294) briefly describes the history of discovery of uranium fission. The author, in particular, gives a list of outstanding scientists who emigrated from Germany, Austria, Italy, and Denmark in 1933–1943. These include 20 Nobel Prize Laureates in physics or chemistry. Chapter 11 (Atomic Bombs, pp. 295–338) is devoted to the history of development of nuclear warfare in the United States.

Habashi's book is of indubitable interest, it is well written and could possibly be a useful textbook in

1070-4272/03/7609-1541$25.00 © 2003 MAIK "Nauka/Interperiodica"

studying the history of science. Unfortunately, the contribution of Russian scientists to the development of the world civilization is reflected to an apparently insufficient extent. Only Mendeleev's discovery of the Periodic law is described in comparatively full detail. Also mentioned are investigations by V.N. Ipat'ev (1867–1952), who developed, in about 1900, the principles of the process of metal recovery from aqueous solutions with hydrogen at high temperature and pressure. Mention is also made of the explanation by N.N. Semenov (1896–1986) in 1928 of the oxidation of phosphorus vapor by water vapor in terms of the concept of branched chain reactions, for which he was later (in 1956) awarded a Nobel Prize, together with C. Hinshelwood (1897–1967). There are no other mentions of the investigations by Russian scientists. At the same time, judging from the topics covered by the book and its structure, it would seem quite appropriate to describe rather diverse investigations by M.V. Lomonosov and the discovery of electroplating by B.S. Jacobi (1838) and to mention studies of reduction of metal oxides by N.N. Beketov, A.S. Popov's investigations concerned with practical application of electromagnetic waves, and V.E. Grum-Grzhimailo's hydraulic theory of flame motion.

Received June 20, 2003

Abstract—Results obtained in studying the structure of olefin and diene molecules, and complexes of these, in the ground and lower excited states by RHF, ROHF, GVB/DN, and 6-31G* quantum-chemical methods are presented. Attention is paid to the identity of the main structural and electronic parameters of triplet T_1 and singlet S_1 states forming a reactive fourfold spin-degenerate diradical equilibrium excited state $(S \cdot T)_1$ having the lowest energy. A new mechanism of cyclodimerization of ethylene and tetrafluoroethylene and anionic polymerization of dienes, involving the $(S \cdot T)_1$ states, is suggested.

INTRODUCTION

The rapid development of computers and their accessibility to a great number of chemists enable the introduction of mathematical modeling techniques into chemical practice and technology. In this context, the problem of adequate quantum-chemical description of elementary processes determining the course of chemical reactions and properties of their products is topical. A key issue in the theory of chemical reactions is elucidation of the mechanism of formation/rupture of a chemical bond. The necessity for using new theoretical approaches in combination with a quantummechanical calculation becomes apparent.

The concepts of intermediate species of diradical nature are increasingly frequently invoked in analyzing the mechanism of thermal and photochemical reactions [1, 2]. In particular, it is believed [1] that the reaction of formation/cleavage of a four-membered ring in the cyclobutane molecule

$$\boxed{\text{H}} \rightleftarrows H_2C{=}CH_2 + H_2C{=}CH_2 \qquad (1)$$

passes through two intermediate states, each involving diradical species. Here, two permanent components of the conventional scheme of a chemical reaction are represented. These are the intermediate state characterizing the active stage of the reaction and intermediate products formed in the reaction.

According to the results of a quantum-chemical calculation [1], the energy of the diradical state in reaction (1) is 4 kcal mol^{-1} lower than the experimental activation energy of cyclobutane decomposition (62.5 kcal mol^{-1}). At the same time, the calculations carried out in [4] demonstrate that the diradical state has much lower energy: it lies 20 kcal mol^{-1} lower than the top of the activation barrier for cyclobutane decomposition (see below).

Analysis of published evidence shows clearly the ambiguity of definition of the notion of "diradical." Some researchers, following the classical theory of chemical structure, understand by radicals and diradicals chemical compounds with subvalent (valence-deficient) atoms [5, 6]. In this sense, free radicals are tetramethylene $^{\cdot}CH_2CH_2CH_2CH_2^{\cdot}$ (including two trivalent terminal carbon atoms) [1], carbenes $:CH_2$, $:CF_2$ and carbon oxide $:CO$, which contain bivalent carbon atoms, but not the O_2 molecule whose oxygen atoms have normal valence.

Others regard as radicals and diradicals paramagnetic species whose spin multiplicities are other than unity. The authors of [7] make the notion of diradicals narrower by attributing to them those bifunctional systems in which two radical centers have independent properties. A similar definition of this notion assumes a small singlet–triplet splitting and/or quasi-degeneracy of singly occupied electron levels [8]. This is the case for tetramethylene, excited states of the n-π^* type, and charge-transfer complexes. However, carbenes do not satisfy this requirement and cannot be considered diradicals in this sense. In this context, it becomes necessary to reconsider the properties and

1070-4272/03/7610-1543 $25.00 © 2003 MAIK "Nauka/Interperiodica"

structure of diradical species with high chemical activity.

In the general case, one has to consider the diradical nature of molecules (case of locally excited states) and complexes of molecules (case of excited excimer or exciplex states). These cases differ in the localization of radical centers: within a single molecule (local excitation) or within several, commonly two, molecules (excimers or exciplexes). The diradical states of photoexcited species (molecules or complexes of these) are well known and will not be specially discussed here (see, e.g., [9]). As for the thermal electronic excitation, the forming excited species have been poorly studied experimentally and not at all theoretically. Mention should be made here of only few studies [4, 10, 11] carried out by the authors of the present review.

When considering the quasi-degeneracy of the triplet and singlet states of ethylene, Salem [8] understands by the latter the ground state S_0 with changed (orthogonal) configuration. However, this means that, according to the commonly accepted concept, not only reactants and products, but also all intermediates formed in the chemical process must belong to the potential surface of this state. The properties of these species, e.g., absorption spectra, must correspond to the ground electronic state. However, experimental data cast doubt on this common viewpoint. In particular, studies of perfluoro-olefins [12–15] revealed absorption by intermediates in the visible spectral range, whereas the starting perfluoro-olefins absorb in the state S_0 in the vacuum ultraviolet range.

This review presents experimental and calculated data on the reactivity of olefins and dienes and gives their theoretical interpretation in terms of the concept of thermal electronic excitation in an elementary chemical process [16]. Two types of chemically active species, which are thermally generated in the dark and possess diradical properties, are considered. To the first type belong excited olefin molecules (ethylene and its derivatives), in which closely spaced (~1.5 Å) radical centers are localized on carbon atoms of a degraded double bond. The second type comprises electronically excited complexes: excimers between identical molecules (of, e.g., olefins) or exciplexes between different molecules (e.g., butadiene molecule and the corresponding anion). In species of the second type, free valences are distributed among atoms of the interacting molecules and valence-deficient atoms are spaced by several angstroms. The common feature of all the species is that they are in an electronically excited state of local or intermolecular nature.

THEORY AND CALCULATION PROCEDURES

Bond indices and free valence indices of atoms. Chemical bonds between atoms are characterized by equilibrium internuclear spacings and indices [17, 18]

$$I_{AB} = \sum_{a\in A}\sum_{b\in B}(PS)_{ab}(PS)_{ba}, \quad (2)$$

where a and b are the numbers of orbitals belonging to atoms A and B.

The matrix P in formula (2) is constituted by expansion coefficients of the electron density $\rho(r)$ [19] in partial products of atomic orbitals (AO) $\chi_a(r)$ $\chi_b^*(r)$:

$$\rho(r) = \sum_A\sum_B\sum_{a\in A}\sum_{b\in B}\chi_a(r)P_{ab}\chi_b^*(r) = \chi(r)P\chi^+(r), \quad (3)$$

$S = \int \chi^+(r)\chi(r)d^3r$ is a metric matrix, and $\chi(r)$ is a row of basis AO.

The diagonal elements of the matrix product PS are identified with electron occupancies of AO [20, 21]:

$$n_a = (PS)_{aa}. \quad (4)$$

Comparison of the sum of bond indices with the valence index

$$V_A = \sum_{a\in A}(2n_a - n_a^2) - \sum_{a\neq a'\in A}(PS)_{aa'}(PS)_{a'a} \quad (5)$$

suggested in a monograph [22] makes it possible to define the free valence of each atom as the difference [23]

$$F_A = V_A - \sum_{B(\neq A)} I_{AB}. \quad (6)$$

The total valence of a molecule or radical is defined as a sum of atomic valences, minus a doubled sum of indices of intraradical chemical bonds [24]

$$V_{mol} = \sum_{a\in mol}(2n_a - n_a^2) - \sum_{a\neq a'\in mol}(PS)_{aa'}(PS)_{a'a}$$
$$= \sum_A(V_A - \sum_{B(\neq A)} I_{AB}) = \sum_A F_A = F_{mol}, \quad (7)$$

where a and a' are the numbers of all the basis AO χ.

According to formula (7), the free valences F_A are additive quantities characterizing the distribution of the total valence of a chemical compound (free radical, diradical, excited molecule) among the constituent atoms A.

Occupancies of molecular orbitals (MO) and the valence of a molecule. In the RHF approximation, the ground N-electron state S_0 of a molecule is characterized by a set of molecular orbitals with integer occupancies $n_i = 2$ ($i = 1, 2, 3, N/2$), which is named electronic configuration. In this case, the free

valence of the molecule as a whole and the free valence of each atom are zero: $V_{mol} = F_{mol} = 0$ and $F_A = 0$. The ROHF approximation is the simplest method for describing the triplet state T_1, in which the single-determinant wave function Ψ is the eigenfunction of the operator of squared N-electron spin. In this case, the electronic configuration of a molecule includes, together with doubly occupied orbitals ($n_i = 2$ for $i = 1, 2, \ldots, N/2 - 1$), also two singly occupied orbitals ($n_i = 1$ for $N/2$, $N/2 + 1$), and the total valence satisfies the relation $V_{mol} = F_{mol} = 2$. In the ROHF approximation, the free atomic valences F_A [23] coincide with spin occupancies of atoms, n_A^s [25]. In the GVB approximation for an excited singlet state S_1 described by two-determinant wave function, the free valence is expressed in terms of a pair of occupancies $n_{N/2} + n_{N/2+1}$ of active natural MO:

$$V_{mol} = F_{mol} = 2n_{N/2} - n_{N/2}^2 + 2n_{N/2+1} - n_{N/2+1}^2 = 2n_{N/2}n_{N/2+1}. \quad (8)$$

The atomic components F_A of the total valence (7) can be used to evaluate the relative reactivities of the atoms and reveal reaction centers in excited molecules, free radicals, and diradicals.

It is noteworthy that the above-mentioned indices of chemical bonds and free valence indices differ from the indices in the output file of GAMESS software (version 6.2) [26]. The point is that, immediately after publication of [23] in 1984, its author redefined, following the concept of [27–29], the chemical bond index by including into it an additional term [30] given by

$$I'_{AB} = I_{AB} + \sum_{a\in A}\sum_{b\in B}(QS)_{ab}(QS)_{ba}. \quad (9)$$

Here, matrix Q is constituted by expansion coefficients of the spin density $\rho^s(r)$ [19] in pair products of atomic orbitals $\chi_a(r)\chi_b^*(r)$:

$$\rho^s(r) = \sum_A\sum_B\sum_{a\in A}\sum_{b\in B}\chi_a(r)Q_{ab}\chi_b^*(r) = \chi(r)Q\chi^+(r), \quad (10)$$

with the spin density normalized in accordance with the equality

$$\int \rho^s(r)\,d^3r = \sum_A\sum_{a\in A}(QS)_{aa} = 2M_S, \quad (11)$$

and the diagonal elements of the matrix product QS yielding the above-mentioned spin occupancies $n_A^s = (QS)_{aa}$ and $n_A^s = \sum_{a\in A} n_n^a$.

It is this variant of the theory that is implemented in the GAMESS software; however, the free valence indices by Mayer, found from formula (6) with modified indices I'_{AB}, yield in the aggregate a value different from the free valence of the whole molecule (free radical). In this context, the original variant of the theory [18, 22, 23] seems to be preferable and was used to analyze the reactivities of organic electronically excited molecules in [4].

Basis orbitals and optimization procedures. The molecular orbitals were represented in 6-31G* or DH (Dunning & Hay [31]) basis sets. The configuration of the triplet states T_1 is obtained via energy minimization in the ROHF approximation without symmetry-related limitations. For singlet excited states S_1, it is advisable to use the GVB method in the modes of energy minimization (with fixed occupancies of the active natural MO $n_{N/2} = n_{N/2+1} = 1$) or saddle point search (with these occupancies varied at $n_{N/2} + n_{N/2+1} = 2$). It seems natural to take as the starting nuclear configuration that of the corresponding triplet state T_1. As demonstrated below, the structural parameters of these two states are, indeed, very close.

LOCALLY EXCITED DIRADICAL STATES OF OLEFINS

In the gas phase, tetrafluoroethylene (TFE) C_2F_4 (**I**-F), hexafluoropropylene C_3F_6 (**II**-F), *trans*-perfluorobutene-2 2-C_4F_8 (**III**-F), perfluorobutene-1 1-C_4F_8 (**IV**-F), and and a number of other floroderivatives show much higher thermal stability, compared with ethylene and its derivatives. On heating perfluoroolefins to "prepyrolysis" temperatures of 700–1500 K, Buravskii and Kolbanovskii [13] confirmed for the first time the existence of previously unknown species (intermediates) with diradical properties. They also established the monomolecular type of the reaction in which intermediates are formed [13]. This fact indicates that the intermediates are identical in their empirical formula to the starting compounds and, consequently, can be designated as $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, and 2-$C_4F_8^*$.

The method of kinetic spectroscopy revealed two absorption bands of intermediates in the UV and visible ranges (nm): $C_2F_4^*$ 236.5 and 500; $C_3F_6^*$ 240 and 477.5; 1-$C_4F_8^*$ 242.5 and 460, which do not coincide with the characteristic absorption bands of the starting compounds: C_2F_4 188 and C_3F_6 185. Special-purpose experiments, in which the same intermediates were generated from different starting compounds, revealed their direct involvement in the formation of new chemical compounds. For example, the intermediate of tetrafluoroethylene, $C_2F_4^*$, decomposes into two

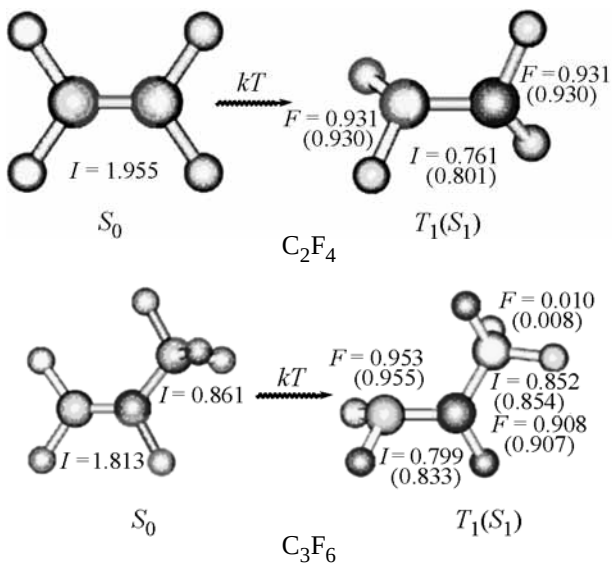

Fig. 1. Structure of C_2F_4 and C_3F_6 molecules in the ground singlet (S_0) and excited triplet (T_1) states; I are bond indices, and F, free valence indices of carbon atoms (ROHF/DH); values of the same parameters for a singlet excited state S_1 (GVB/DH) are given in parentheses.

tetrafluoromethylenes, which add to $C_2F_4^*$ to form hexafluoriopropylene [12]:

$$C_2F_4 \rightarrow C_2F_4^* \overset{kT}{\rightleftarrows} :CF_2 + CF_2, \qquad (12)$$

$$C_2F_4^{\cdot} + :CF_2 \rightleftarrows C_3F_6^* \rightleftarrows C_3F_6. \qquad (13)$$

The authors of [15] believe that the intermediates $C_2F_4^*$, $C_3F_6^*$, 1-$C_4F_8^*$, and 2-$C_4F_8^*$ are previously unknown, low-lying excited singlet states of the respective perfluoro-olefins, which are formed in the monomolecular reaction on heating these latter in the gas phase. However, quantum-chemical calculations in terms of the method of the intermediate state [32], available in the literature, give no way of making any conclusion about the structure of intermediates.

The new concept of the nature of intermediates of perfluoro-olefins as electronically excited molecules in a triplet state was described in [33]. This viewpoint follows from the general concept of thermal electronic excitation in chemical reactions [16]. The role of triplet excited molecules and complexes in polymerization–depolymerization reactions was considered in [10, 34, 35]. In elucidating the mechanism of chemical reactions involving triplet molecules, a question necessarily arises as to how the triplet T_1 states are transformed in the course of a chemical process into a singlet ground state S_0 of the stable reaction product. This question cannot be answered without taking into account the singlet excited states S_1. In this context, the procedure for quantum-chemical calculation of singlet states S_1 was reconsidered in [4].

The energy of triplet states, $E(T_1)$, is, as a rule, lower than the energy of singlet states, $E(S_1)$ [7]. The difference of the energies, $E(S_1) - E(T_1)$, which is named singlet–triplet splitting, is high for π–π^* (up to 80 kcal mol^{-1}), but low for n-π^* states and charge-transfer states (5–10 kcal mol^{-1}). For ethylene C_2H_4, the value of $E(T_1)$ is 82.1 (experimental value [7]) or 81.8 kcal mol^{-1} (ROHF/6-31G** calculation for the vertical transition $T_1 \leftarrow S_0$), and the experimental singlet–triplet splitting is 69.2 kcal mol^{-1} [7].

The energy of the nonequilibrium singlet excited states S_1 of olefins in the case of a vertical transition can be found from absorption spectra, but the energies of excited states for equilibrium, relaxed states S_1 are mostly determined from quantum-chemical calculations. Excited olefin molecules are characterized by rotation about the unsaturated bond C=C

$$R^1HC{=}CHR^2 \xrightarrow{h\nu,\ kT} R^1HC^{\cdot}{-}C^{\cdot}HR^2 \qquad (14)$$

to give diradical structures, which either relax $C^{\cdot}-C^{\cdot}$ nonradiatively into the ground singlet state S_0, or are involved in chemical reactions as diradical species. It is the conformational instability of planar olefin structures in the excited state that gives rise to an effective channel of nonradiative energy dissipation.

Structure of triplet states of olefins and perfluoro-olefins. It is known that the triplet, so-called phantom states of ethylene and its derivatives, e.g., stilbene [36, 37], have a perpendicular configuration. Via these states occurs *cis–trans*-isomerization, i.e., rotation about the C=C bond by 180°. Triplet states of ethylene and other olefins have diradical nature, irrespective of whether they have perpendicular (in relaxed state) or planar (in the case of a vertical transition) configuration. The decrease in the index of the C=C bond in a triplet excitation has electronic origin and is not related directly to a transition of a molecule to the perpendicular configuration. For example, the index of the C=C bond of ethylene, I = 1.91, decreases to I = 0.79 in the vertical transition $T_1 \leftarrow S_0$ without any change in the planar structure. As a result of relaxation of the T_1 state, its energy decreases, the chemical bond energy grows, and the bond index increases to I = 0.92. In this regard, the excited state of ethylene differs fundamentally from the ground state, for which the molecular energy increases, the chemical bond becomes weaker, and the C=C bond index decreases when the planar structure is distorted.

Table 1. Geometric parameters of molecules and diradicals C_2X_4 (**I**-X) and C_3X_6 (**II**-X) in equilibrium configurations in the states S_0, S_1, and T_1, calculated by RHF/DH, GVB/DH, and ROHF/DH methods

* Experimental data of [38–40] given in parentheses.

The molecules of perfluoro-olefins C_2F_4, C_3F_6 (Fig. 1, Table 1), 1-C_4F_8, and 2-C_4F_8 (Fig. 2, Table 1) have planar structure in the ground singlet state, except in the 1-C_4F_8 molecule, in which the CF_3 group lies outside the plane of the central fragment $\rangle C{=}C\langle$. In the triplet state T_1, these molecules undergo rotation about the $^{\bullet}C-C^{\bullet}$ bond and take a nearly perpendicular configuration. In this case, fluoro-olefins are characterized by a significant decrease in the F–C–C angle at radical $C^{\bullet}$ centers from 123°–125° (S_0) to 114°–116° (T_1), whereas for unsubstituted olefins, the decrease in the H–C–C angle upon transition to the triplet state is small, from 121°–121.9° (S_0) to 121.1°–121.4° (T_1).

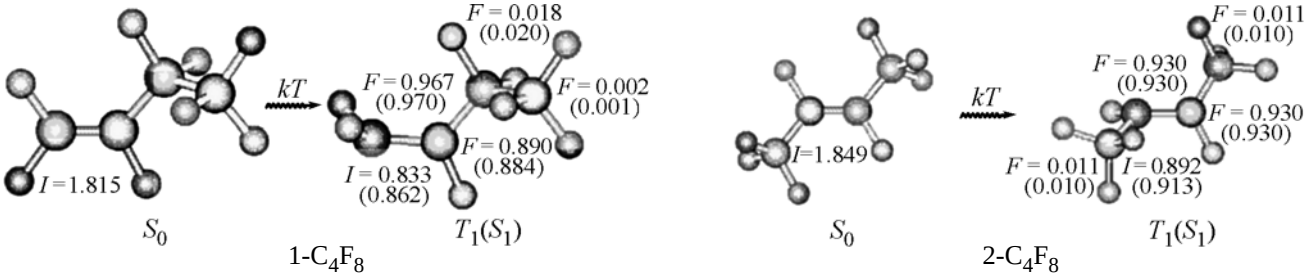

Fig. 2. Structure of 1-C_4F_8 and 2-C_4F_8 molecules in the ground singlet (S_0) and excited triplet (T_1) states; F are free valence indices of carbon atoms (ROHF/DH); values of the same parameter for a singlet excited state S_1 (GVB/DH) are given in parentheses.

* Occupancies n_1 and n_2 fixed in the course configuration optimization.

The experimental data available for the ground state of the molecules [38–40] are in satisfactory agreement with the values calculated by the RHF/DH or RHF/6-31G* method (Table 1). Previously, the structure of unexcited molecules of ethylene and its fluoroderivatives has been studied in detail by *ab initio* methods, including the MP2 technique [41].

In the triplet state, the free valence indices F_A (Figs. 1 and 2), which are equal to spin occupancies, are located at carbon atoms of a degraded double CC bond, with the distribution of F_A weakly dependent on the type of a substituent at this bond (F or C). In the triplet state, olefin molecules become diradicals, with all the ensuing consequences in spectral and chemical regard.

Structure of singlet excited states S_1. In calculating a singlet excited state S_1, there arises the problem of a variational collapse, which can be eliminated by using the GVB method with fixed occupancies of active natural MO at $n_1 = n_2 = 1$ or with variation of these occupancies at $n_1 + n_2 = 2$. Both the approaches give identical results for geometric parameters, energies, and occupancies. The geometric characteristics of olefin molecules in the S_1 state (Table 1), calculated under these assumptions, are close to the corresponding parameters of the molecules in the triplet states. This gives reason to maintain that the 3*D* structure of olefin molecules in the lower excited states T_1 and S_1 is the same. It should be noted that optimization at $n_1 = n_2 = 1$ reveals a minimum on the potential surfaces for T_1 and S_1 (absence of imaginary frequencies in the vibrational spectrum), whereas occupancy variation at $n_1 + n_2 = 2$ localizes the saddle point on the S_1 surface at the same energy (presence of a single imaginary frequency in the spectrum).

A quantum-chemical calculation yielded unexpectedly close energies of the singlet and triplet states (Table 2); the triplets lie below singlets (by

Table 3. Quantum-chemical total energies E_{tot}, squared total spins $<S^2>$, and enthalpies ΔH of lower excited states of perfluoro-olefins (UHF/DH) with account of the energy Δ_{vib0} of zero vibrations and thermochemical corrections for temperatures 0–700 K

IV-F	27.7	2.015	–0.4	27.3	27.2	27.7	27.3	27.3	27.3	18

1–3 kcal mol^{-1}), in agreement with the general experimental pattern. The uncommon nature of this result is emphasized by the fact that the singlet–triplet splitting $E(S_1)$–$E(T_1)$ for vertical transitions in olefins, e.g., ethylene, is gigantic (3 eV). The dramatic, nearly 30-fold decrease in the $E(S_1)$–$E(T_1)$ splitting on passing to the equilibrium excited state S_1 is, apparently, a consequence of the elimination of the exchange interaction between π-electrons as a result of a structural transformation of the ethylene molecule from planar to perpendicular configuration.

The values of n_1 and n_2 in the optimal configuration are 1.000 for all the eight olefin molecules studied, **I**–**IV** and **I**-F–**IV**-F (Table 2 lists data for 6 molecules). The valences V_{mol} of the molecules in the singlet (S_1) and triplet (T_1) states take the maximum possible, for a two-determinant wave function, value of 2.000. The exception is provided by those S_1 states which were calculated by the GVB//T_1 method for an equilibrium triplet configuration. However, V_1, n_1, and n_2 are close to their optimal values in these cases, too, which confirms that the molecular structures in the S_1 and T_1 states are identical.

Energies of equilibrium excited states of olefins and perfluoro-olefins. A specific feature of perfluoro-olefins (Table 2) is that the excitation energies are low and lie within the thermally accessible range (~1 eV). Another important point is that the energies of singlet (S_1) and triplet (T_1) states coincide, i.e., there exist fourfold degenerate states of olefins, $(S \cdot T)_1$, of diradical nature. Also, as substituents are introduced at the double bond of perfluoro-olefins, a certain increase in the energy of the S_1 and T_1 states is observed. The corresponding levels for unfluorinated olefins (Table 2) lie at approximately twice higher energies, being virtually independent of the type of a substituent at the double bond.

In Table 3, the calculated electronic excitation energies of the molecules are corrected for the energies of zero vibrations and thermochemical contributions (vibrational, rotational, etc.), which become noticeable at elevated temperatures. The resulting enthalpies of excitation can be directly compared with experimental enthalpies of formation of intermediates (excited species) [15]. The best agreement between experiment and calculation is observed for the simplest representative of perfluoro-olefins, TFE (Table 3): 18 and 19.8 kcal mol^{-1} at 700 K. Replacing the fluorine atoms in the TFE molecules with perfluoroalkyl substituents leads to a noticeable increase in the calculated enthalpy of excitation; however, no dependence of the experimental enthalpy of formation of intermediates on the type of substituent was observed in [15].

THERMOEXCIMERS IN CYCLODIMERIZATION OF ETHYLENE AND PERFLUOROETHYLENE

An important consequence of the concept [16] of electronic excitation as a necessary stage of a chemical reaction is the conclusion that the reaction structure (intermediate in terms of [15]), which precedes the formation/rupture of a chemical bond, has radical (diradical) nature. For the reaction of TFE cyclodimerization

$$C_2F_4 + C_2F_4 \overset{kT}{\rightleftarrows} C_2F_4^* + C_2F_4 \rightleftarrows C^{\bullet}F_2{-}C^{\bullet}F_2...CF_2{=}CF_2 \overset{kT}{\rightleftarrows} C^{\bullet}F_2{-}CF_2{-}CF_2{-}C^{\bullet}F_2 \overset{kT}{\rightleftarrows} \boxed{F} \quad (15)$$

this means that the formation of stable perfluorocyclobutane F is preceded by a number of radical stages, with the direct processes of binding of two unexcited molecules

$$C_2F_4 + C_2F_4 \rightleftarrows \boxed{F} \quad (16)$$

not occurring at all. In single-stage reactions of the type (16), radical stages are concealed and cannot be revealed experimentally because of their short lifetime.

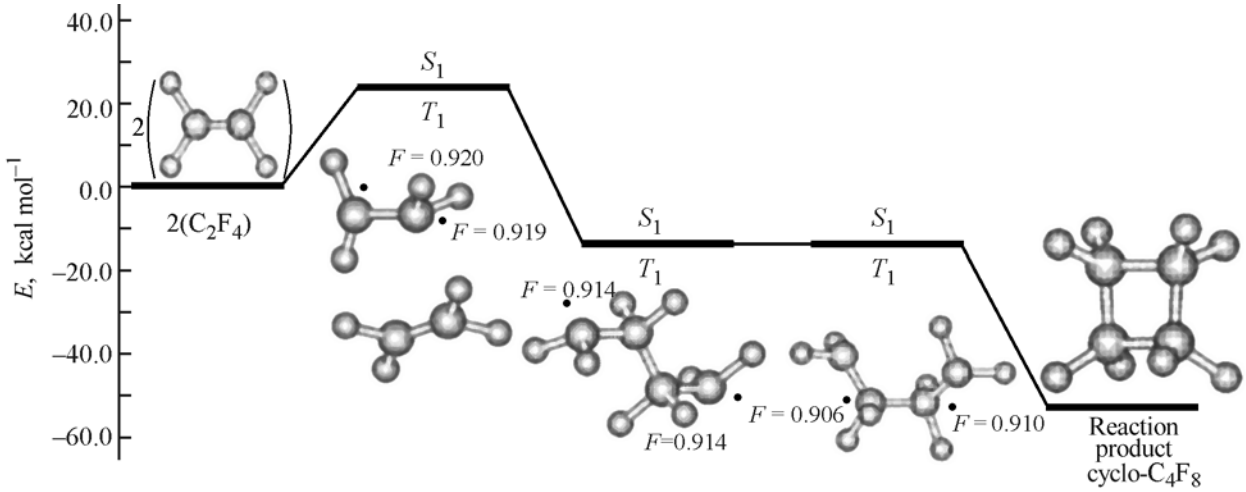

Fig. 3. Energy diagram of the reaction of C_2F_4 cyclodimerization (RHF, ROHF, GVB/DH); *F* are free valence indices of terminal carbon atoms. (*E*) Energy; the same for Figs. 4, 7, and 8.

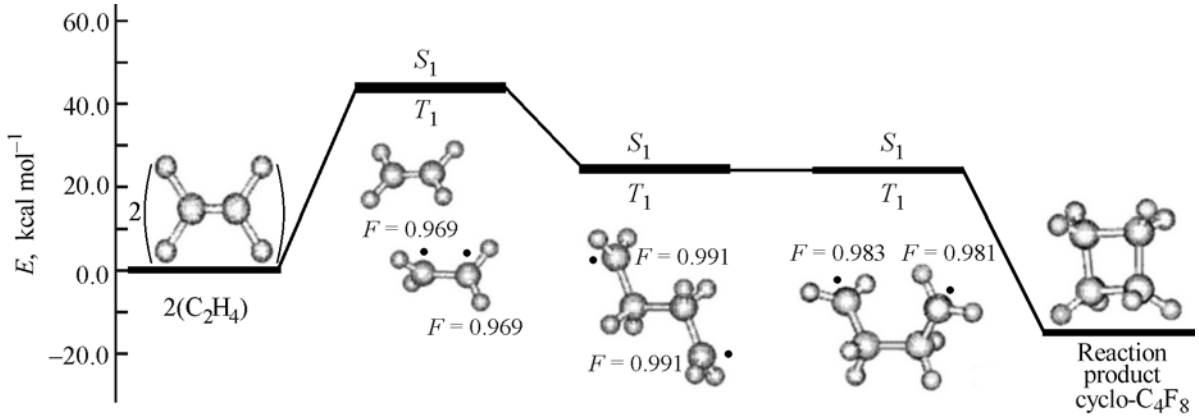

Fig. 4. Energy diagram of the reaction of C_2H_4 cyclodimerization (RHF, ROHF, GVB/DH); *F* are free valence indices of terminal carbon atoms.

In view of the concepts of diradical nature of the $(S \cdot T)_1$ states and new experimental data [12, 14, 15], the mechanism of TFE cyclodimerization was reconsidered in [4, 33, 42]. Direct experimental confirmation of the radical nature of the reaction of TFE cyclodimerization [14, 15] is of great importance for understanding of the mechanism of this and many other reactions.

Thermal cyclodimerization of TFE is similar to the corresponding photochemical reaction of anthracene (A) dimerization, which proceeds via the excimer state AA^* [43]. In either case, a complex, named excimer, is formed between the excited and unexcited molecules. In TFE dimerization (Fig. 3), the potential barrier of the reaction is determined by the enthalpy of formation of the complex (thermoexcimer) TFE TFE^*, which can be calculated as triplet energy. A collision of TFE^* and TFE molecules (quenching of TFE^*) leads to formation of intermediate perfluorotetramethylene C_4F_8.

The diradical C_4F_8 was first recorded as a stable species, presumably in *trans*-configuration, by its absorption spectrum (230 nm) in the millisecond time range [14]. The lifetime of its hydrogen analogue C_4H_8 is much shorter, being equal, depending on the pumping energy, to 300–800 fs [1], but in the case in question, the diradical C_4H_8 has *cis*-configuration. The diradicals C_4F_8 (C_4H_8) are relaxed electronically excited singlet (S_1) and triplet (T_1) states of the final product of the reaction, cyclobutane. The theoretical activation energies E_a of the cleavage of a four-membered ring

are the same for cyclo-C_4F_8 and cyclo-C_4H_8 (39 kcal mol^{-1}) (Figs. 3 and 4). The difference in the optimized geometric parameters of singlet and triplet diradicals is negligibly small; for example, the lengths of the central bond C–C in the *cis*-C_4F_8 di-

radical coincide for the S_1 and T_1 states, being equal to 1.547 Å. The energies of these states are also rather close (with the difference not exceeding 0.1 kcal mol^{-1}). The radical centers in the molecules of tetramethylenes are localized at terminal carbon atoms and are characterized by free valences close to unity. The total valence of the diradicals in the ROHF approximation is exactly 2 for the triplet state and varies within 1.890–1.990 for the equilibrium singlet state (GVB/DH method).

If the activation energy $E_a(\rightarrow)$ of forward cyclization is taken to be equal to the triplet energy of TFE, 20.7 kcal mol^{-1} (Table 3), and the enthalpy ΔH, to be 52.7 kcal mol^{-1} (experimental value 53.1 kcal mol^{-1} [44]), then the calculated activation energy of the reverse reaction $E_a(\leftarrow) = 20.7 + 52.7 = 73.4$ kcal mol^{-1}. The experimental activation energy of reaction (16) of perfluorocyclobutane decomposition into two TFE molecules (79.2 ± 1 kcal mol^{-1} [12]) exceeds somewhat the calculated value obtained by the authors of this review. At the same time, [12] presents data of other authors, according to which $E_a^{exp}(\leftarrow)$ vary within 74.4–75.6 kcal mol^{-1}.

It is assumed that the reaction proceeds in accordance with Eq. (15): upon encounter of TFE and TFE* molecules, the excited complex $^{1,3}(C^{\bullet}F_2–C^{\bullet}F_2...CF_2=CF_2$ transforms into the diradical $C^{\bullet}F_2–CF_2–CF_2–C^{\bullet}F_2$ with electronic structure $(S \cdot T)_1$. *trans*-1,4-Diradical has nonplanar structure ($\angle$CCCC = 163.9°) with terminal radical centers on which a free valence $F = 0.914$ is concentrated. The $C^{\bullet}F_2–CF_2$ and $CF_2–CF_2$ bond lengths are, respectively, 1.523 and 1.552 Å. 1.4-Diradical readily assumes the *cis*-configuration, then undergoes internal conversion $S_0 \leftarrow\sim\sim S_1$, and, on the way to the ground singlet state S_0, is stabilized in the form of the reaction product, perfluorocyclo-butane. The C–C bond length in a symmetric (D_{2d}) nonplanar molecule of cyclo-C_4F_8 is the same as that in the molecule of cyclo-C_4H_8 (1.559 Å).

It may be assumed that the reversible reaction (1) of ethylene cyclodimerization can be described in a similar way. In this case, all the levels in the energy diagram (Fig. 4) lie much higher than the corresponding levels for the reaction of TFE dimerization (Fig. 3). For example, the heats of formation of cyclobutane and perfluorocyclobutane are 15.2 and 53.0 kcal mol^{-1}, respectively. In the case of ethylene, the heats of formation of 1,4-biradicals are positive, being negative for TFE, and, therefore, 1,4-perfluorodiradicals must be much more stable than their

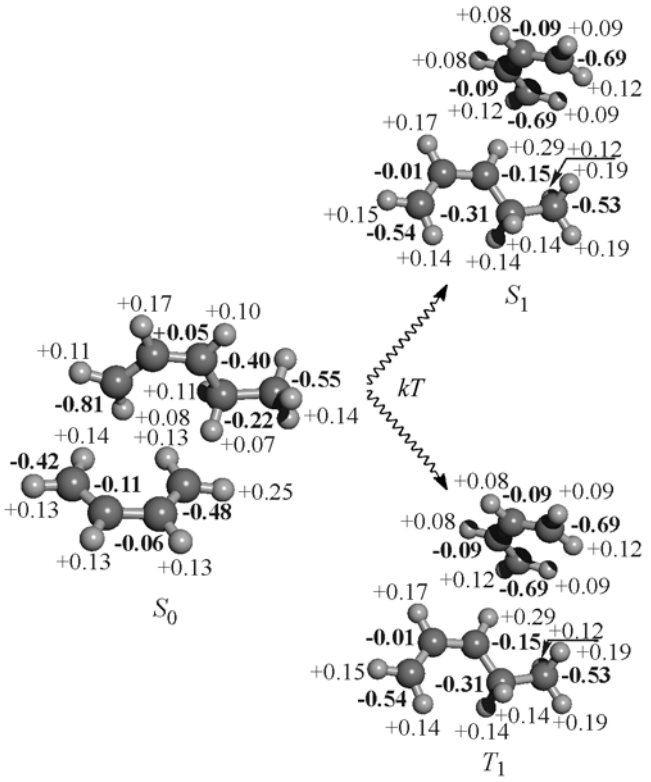

Fig. 5. Distribution of charge among atoms in a complex of *cis*-2-penten-1-yl anion with *cis*-butadiene in singlet ground (S_0, RHF/DH), singlet excited (S_1, GVB/DH), and triplet excited (T_1, ROHF/DH) states.

hydrogen analogues. The calculated activation energy of the reaction of cyclobutane decomposition into two ethylene molecules (59.1 kcal mol^{-1}) is in satisfactory agreement with the experimental value of 62.5 kcal mol^{-1} [3].

Thus, a new mechanism of the reaction of ethylene and TFE dimerization, including thermal electronic excitation of a complex of molecules of the excimer type, was suggested in [4, 33, 42]. Alternative analysis of the reaction [1, 15] in terms of the transition state method fails to provide an adequate quantitative description and to account for the properties of experimentally observed electronically excited olefin intermediates.

ELECTRONICALLY EXCITED COMPLEXES (THERMOEXCIPLEXES) OF BUTADIENE

The above radical mechanism of ethylene dimerization can be extended to the case of polymerization, whose elementary stage includes local triplet excitation of the ethylene molecules within the reaction complex constituted by a free radical and ethylene

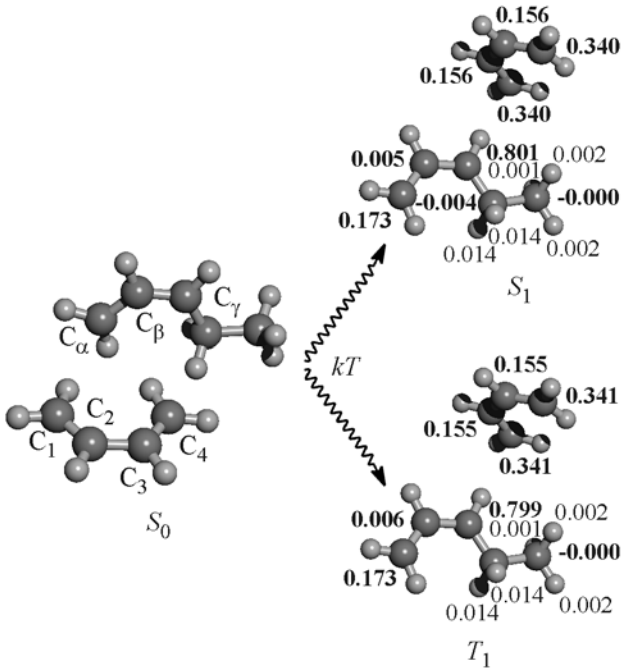

Fig. 6. Distribution of free valence indexes among atoms in a complex of *cis*-2-penten-1-yl anion with *cis*-butadiene in singlet, S_1 (GVB/DH), and triplet, T_1 (ROHF/DH), excited states and structure of the complex in the singlet ground state S_0 (RHF/DH).

molecule. The general pattern of the process was discussed in [45], but rigorous nonempirical calculation of complexes of uncharged radical species by the existing methods fails to produce satisfactory results. More adequate results are obtained for anionic polymerization of dienes (butadiene, isoprene) [11, 35, 46–51], which have been extensively studied by spectral and quantum-chemical methods previously [52–62]. Because of this circumstance, an example of a theoretical analysis of reaction complexes of butadiene with the corresponding anionic and lithium species in terms of the concept of thermal electronic excitation is given below.

Quasi-degenerate singlet (S_1) and triplet (T_1) states of reaction complexes. Modeling of elementary stages of anionic polymerization of butadiene is possible for a particular case of complexes formed by butadiene CH_2=CH–CH=CH_2 with 2-penten-1-yl anion CH_3–CH_2–CH=CH_2^- (V-an). Figure 5 illustrates a complete transfer of an electron (Δq = 0.98) between reactant molecules upon excitation of the complex into a singlet (S_1) or triplet (T_1) state. It is important that both the excited states are characterized by identical charge distributions among atoms of the 2-pentene-1-yl radical and the anion-radical of butadiene.

Another important issue is the virtually absolute identity of the free valence indices F_A for the triplet (T_1) and singlet (S_1) excited states (Fig. 6). The values of F_A coincide with spin occupancies calculated for the triplet state as a sum of atomic contributions to boundary orbitals. In a similar way are found free valence indices for the excited singlet state S_1. Also close are the geometric parameters of the complex 2-penten-1-yl anion...butadiene (Table 4) in the states T_1 and S_1, with the optimized structure of the complexes corresponding to a minimum on the potential-energy surface, which is confirmed by absence of imaginary frequencies in the vibrational spectrum.

Finally, mention should be made of the singlet-triplet splitting, which is negligibly small (0.17 kcal mol^{-1}).

*** Data from Table 1.19.

The close energies of the S_1 and T_1 states, combined with the above-mentioned coincidence of charges, free valence indices, and geometric parameters, suggest the existence of a fourfold degenerate diradical state of the complex, $(S \cdot T)_1$, with low energy, which is directly involved in the events of rupture and formation of a chemical bond.

Structure of complexes formed by free anions and butadiene. Now a system constituted by a V-an anion in *cis*-conformation and *cis*-butadiene (bd) will be considered in more detail. In a real polymerizing system containing "living" (polybutadien)yl-lithium and butadiene, anions are formed in noticeable amounts in polar electron-donor solvents (D), e.g., THF, as a result of dissociation of ion pairs:

$$\sim\sim\sim C^- Mt^+ \overset{D}{\rightleftarrows} \sim\sim\sim C^- Mt^+ \cdot D. \qquad (17)$$

The difference between the energies of *cis*- and *trans*-isomers of butadiene is 3.34 kcal mol^{-1} (RHF/DH), and, consequently, the fraction of *cis*-isomer in solution is insignificant (<1%). However, *cis*-butadiene forms more stable complexes, compared with the *trans*-form, and is more active in polymerization. Therefore, the review only presents data for *cis*-butadiene and the role played in polymerization by *trans*-butadiene is considered in [35]. An RHF/DH calculation shows that the free *cis*-2-penten-1-yl anion has π-allyl structure with approximately equal C_α–C_β and C_β–C_γ bond lengths (Table 4). However, the charges on atoms C_α and C_γ are different, being equal to, respectively, –0.81 and –0.42. In the optimized structure of the complex (Fig. 5), the molecular planes are mutually perpendicular, which points to a predominating role of interaction between local centers, whereas the overlapping of boundary orbitals, which requires a planar orientation of the 2-penten-1-yl anion and butadiene, is less important.

The transition of the V-an anion from the free state into a complex with butadiene has no essential influence on its geometric parameters (Table 4) or on charges (q_α = –0.81, q_γ = –0.41). It would be expected, on the basis of the prevailing concept of charge control, that butadiene should mainly add to the C_α atom to give 1,4-unit in the polymer chain. This assumption is not, however, confirmed by experiment, which demonstrates the predominant formation of 1,2-units in the electron-donor THF solvent (Table 5). Figure 7 shows the energy levels found for the gas phase and solution in inert *n*-heptane. It can be seen that the heats of formation of the *cis*-V-an...*cis*-bd complex in the S_0 states are significantly different for these two cases: 4.8 and 1.0 kcal mol^{-1}, respectively. Consequently, complexes with 2-penten-1-yl and, presumably, other anions are unstable in an inert solution.

In the electronically excited state of the complex (S_1 or T_1), there occurs complete transfer of an elec-

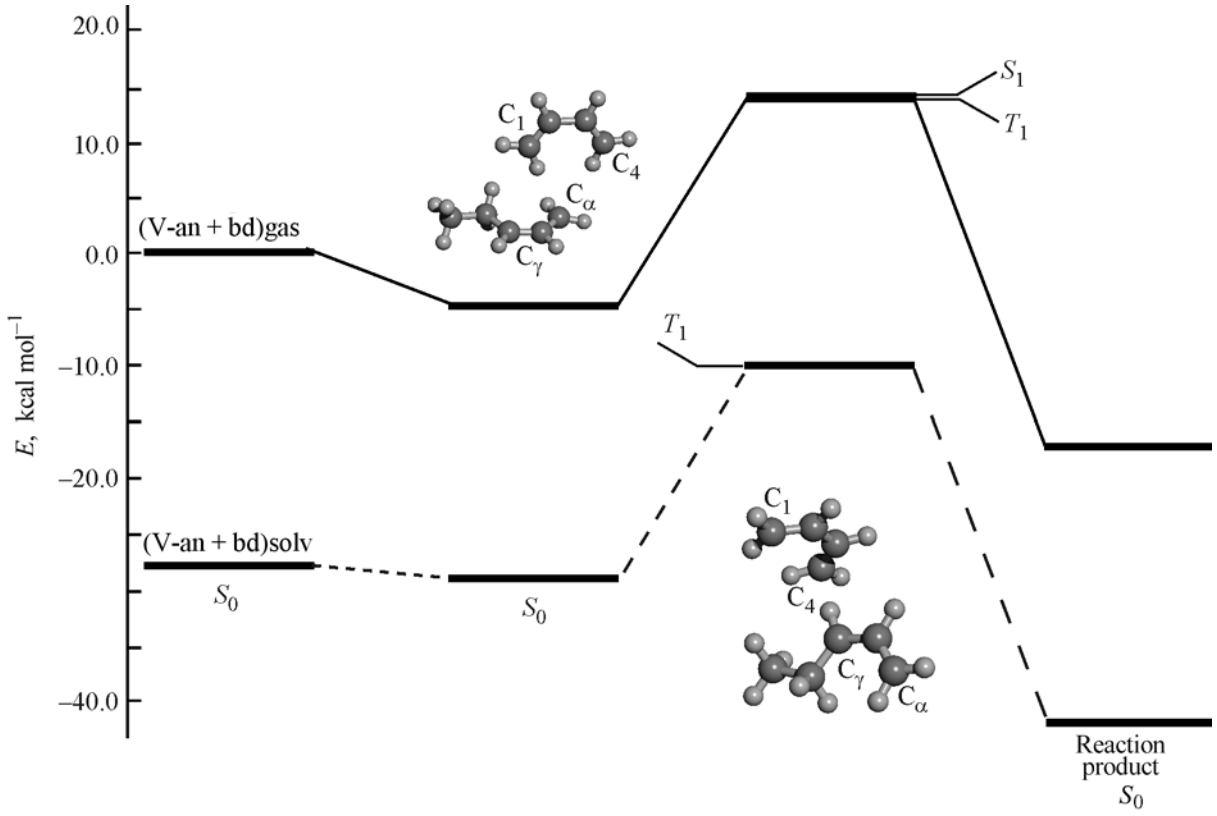

Fig. 7. Energy diagram of the reaction of *cis*-penten-1-yl anion with *cis*-butadiene (solvent taken into account in the RSM approximation; RHF, ROHF, and GVB/DH methods). *Solid lines*, gas phase; *dashed lines*, solution in *n*-pentane; energy levels of the starting reagents V-an+bd, reaction product, and complex in the ground (S_0) and excited (S_1 and T_1) states are shown.

tron from the anion to the butadiene molecule to give a free chain radical and anion-radical of the monomer, which can be judged from the distribution of charge density and free valence indices (Figs. 5 and 6). The highest chemical activity for the complex shown in Fig. 6 is exhibited by the C_γ atom of the 2-penten-1-yl radical (F_A = 0.80) and atoms C_1 and C_4 of the anion radical of butadiene (F_A = 0.34). It is these carbon atoms that are the most closely spaced in the reagent molecules (R = 4.20 Å) and, in principle, can form a chemical bond through spin coupling, which must give rise to 1,2-units in polybutadiene. This theoretical prediction is in full agreement with experimental data (Table 6) [35, 52, 54, 62, 64].

Table 6. Charges q on C_α and C_γ carbon atoms in *cis*- and *trans*-2-penten-1-yl anion, calculated by semiempirical and *ab initio* methods (RHF, definition of q by Mulliken)

RHF/6-311G**	0.504	0.407	0.483	0.402

The activation energy of the electron-transfer reaction, which determines the potential barrier for the overall reaction of addition of a butadiene molecule to V-an, can be calculated as the energy of the diradical state $(S \cdot T)_1$ relative to the level of free reagents. For the system shown in Fig. 7, this value is 14.2 kcal mol^{-1} in the gas phase and 17.9 kcal mol^{-1} in an inert medium of heptane.

Structure of complexes formed by 2-penten-1-yl-lithium with butadiene. A polymer mostly composed of 1,4-*cis*(*trans*)-units is formed in polymeriza-

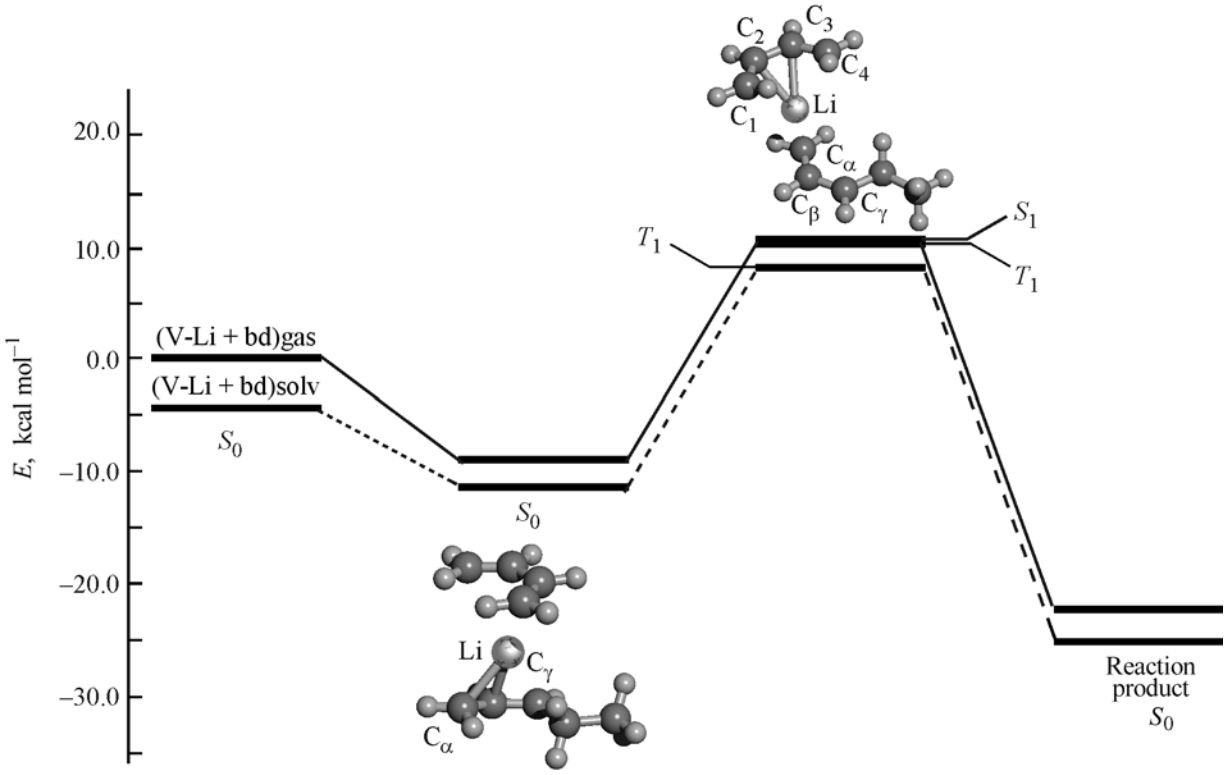

Fig. 8. Energy diagram of the reaction of *cis*-penten-1-yl-lithium with *cis*-butadiene (solvent taken into account in the RSM approximation; RHF, ROHF, and GVB/DH methods). *Solid lines*, gas phase; *dashed lines*, solution in *n*-pentane; energy levels of the starting reagents V-Li+bd, reaction product, and complex in the ground (S_0) and excited (S_1 and T_1) states are shown.

tion of butadiene in hydrocarbon solvents (hexane, heptane) in the absence of free anions (Table 5). It is commonly believed that chain grows under these conditions on monomeric and associated forms of the organolithium compound, and the 1.4-structure is fixed in the terminal unit of the active center as a result of incorporation of bd at the C_α–Mt bond [52–62]. Calculation of a model complex by the RHF/DH method yields a nearly α-alkyl structure (Fig. 8, Table 4), and the distribution of atomic charges differs only slightly from that in the V-an...butadiene complex considered above: q_α = –0.73, q_γ = –0.38.

The complex of *cis*-2-penten-1-yl-lithium with *cis*-butadiene has in the ground state such a structure (Fig. 8, Table 4) that the monomer molecule is oriented toward the Li atom, with inequality of charges on C_α and C_γ atoms preserved (–0.73 and –0.35, respectively). In the triplet excited state of the complex, charge transfer to the butadiene molecule (Δq = –0.52) is accompanied by a shift of the Li^+ cation, which is situated at equal distances from the terminal carbon atoms (2.30 Å), but closer to the central atoms (2.20 Å) of the anion-radical of butadiene. The resulting process is that the Li atom is transferred and two radical species are formed: 2-penten-1-yl radical and a radical of butadiene-lithium. The chemical bond is formed in the singlet state in the course of relaxation of the diradical state of the complex: $(S \cdot T)_1 \rightsquigarrow S_0$

In accordance with the free valence indices, the terminal atoms C_1 and C_4 of *cis*-butadiene-lithium ($F_1 = F_4 = 0.34$), which are closer to the carbon atom C_α (F_α = 0.17), at 4.40 and 4.55 Å, than to C_γ (F_γ = 0.80), 4.94 and 5.30 Å, in the triplet state of the complex. These data predict, in agreement with experiment (Table 5), preferable formation of a chemical bond between the α-carbon atom of the chain radical and one of the atoms C_1 or C_4 of butadiene, to give 1,4-units in the chain of polybutadiene.

As a theoretical parameter characterizing the reactivity of the system 2-penten-1-yl-lithium...butadiene can be taken the calculated energy of the excited level $(S \cdot T)_1$, which is 10.4 kcal mol^{-1} for the gas phase and 12.6 kcal mol^{-1} for a solution in heptane (Fig. 8). In contrast to the case of the anionic complex, the enthalpy of formation of this complex in

the ground state changes, on passing from the gas phase to a heptane solution, only slightly, from 9.1 to 7.0 kcal mol^{-1}. Comparison of the given system with the V-an...butadiene complex shows a higher chemical activity of the lithium forms, compared with the anionic ones. This theoretical conclusion is in an apparent contradiction with the widely accepted opinion that the chemical activity of anions is at the maximum possible level.

On principles of charge and spin control over polymerization reaction. Data on atomic charges are commonly obtained from quantum-chemical calculations. However, it is known that calculated charges are rather sensitive to a calculation procedure, and in the case of nonempirical methods, to a basis. In numerous theoretical studies in the field of anionic polymerization, carried out in the 1970s–1990s [53, 57, 59, 65], calculations were mostly performed using semiempirical methods, which yield charge distribution for free anions, $|q(C_\gamma)| \geq |q(C_\alpha)|$, satisfying the charge control principle. Indeed, vinyl $-CH=CH_2$ and $-C(CH_3)=CH_2$ units are generated in the polymer chain in polymerization of butadiene and isoprene in electron-donor solvents, in which formation of free anions is observed, through addition of the monomer to the C_γ atom carrying the highest amount of negative charge (Table 6).

At present, *ab initio* methods, which provide a more adequate description of the geometric configuration and electronic characteristics of molecules, compared with semiempirical methods, are widely used. However, the *ab initio* techniques yield exactly the opposite charge distribution (Table 6): $|q(C_\alpha)| > |q(C_\gamma)|$, and, consequently, calculations of this kind are in contradiction with the principle of charge control in the formation of the microscopic structure of polydienes. This contradiction can be accounted for in two ways: (1) *ab initio* methods are not quite correct in evaluation of charges on atoms, and (2) the very principle of charge control is inadequate.

In terms of the approach used in [11, 35, 48–51], there is no need to invoke the charge control principle. The properties of reaction complexes in the electronically excited state are controlled by the distribution of free valence indices, rather than by that of atomic charges, and these distributions are not in agreement with each other. Moreover, the probability of formation of a chemical bond depends on the configuration of the excited complex, i.e., on the proximity of the potentially active centers of interaction.

CONCLUSION

The known processes, such as dimerization of ethylene or anionic polymerization of butadiene, can be explained in a novel way, and in agreement with experimental data, in terms of the concept of thermal electronic excitation in an elementary chemical process. This is done by considering a real physical process, electronic excitation of a molecule or a reaction complex to low-lying states S_1 or T_1 of radical or diradical nature. It is assumed that the events of rupture/formation of a chemical bond occur at the atom with sufficiently large free valence index, rather than at the atom with the greatest negative charge.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Sulfuric Acid Technology for Processing of Eudialyte Concentrate

V. N. Lebedev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received April 18, 2003

Abstract—Sulfuric acid decomposition of eudialyte was studied, and a technological process including two-stage treatment with sulfuric acid, separation and washing of an insoluble residue, successive hydrolytic precipitation of zirconium and iron-manganese concentrates from solution, and recovery of rare-earth elements from the insoluble residue by leaching, was considered. It was found that zirconium(IV) is recovered from a complex carbonate precipitate in the form of a basic sulfate.

Eudialyte from the Lovozero deposit finds no use because of the low content of rare metals [content in the concentrate (wt %): 10–12 ZrO_2, 2–2.5 Ln_2O_3, 0.7–0.9 Nb_2O_5] and the lack of any efficient technology for obtaining high-quality zirconium products, even though the amount of zirconium and rare-earth elements (REE) contained in this deposit is hundreds of times that in the rest of the world [1, 2]. Technological variants including decomposition with sulfuric, hydrochloric, or nitric acids, in which all the components of the eudialyte concentrate (EC) were used and utilized, have been suggested, but it was reported that only processing of about 1 million tons of EC can be costeffective [3].

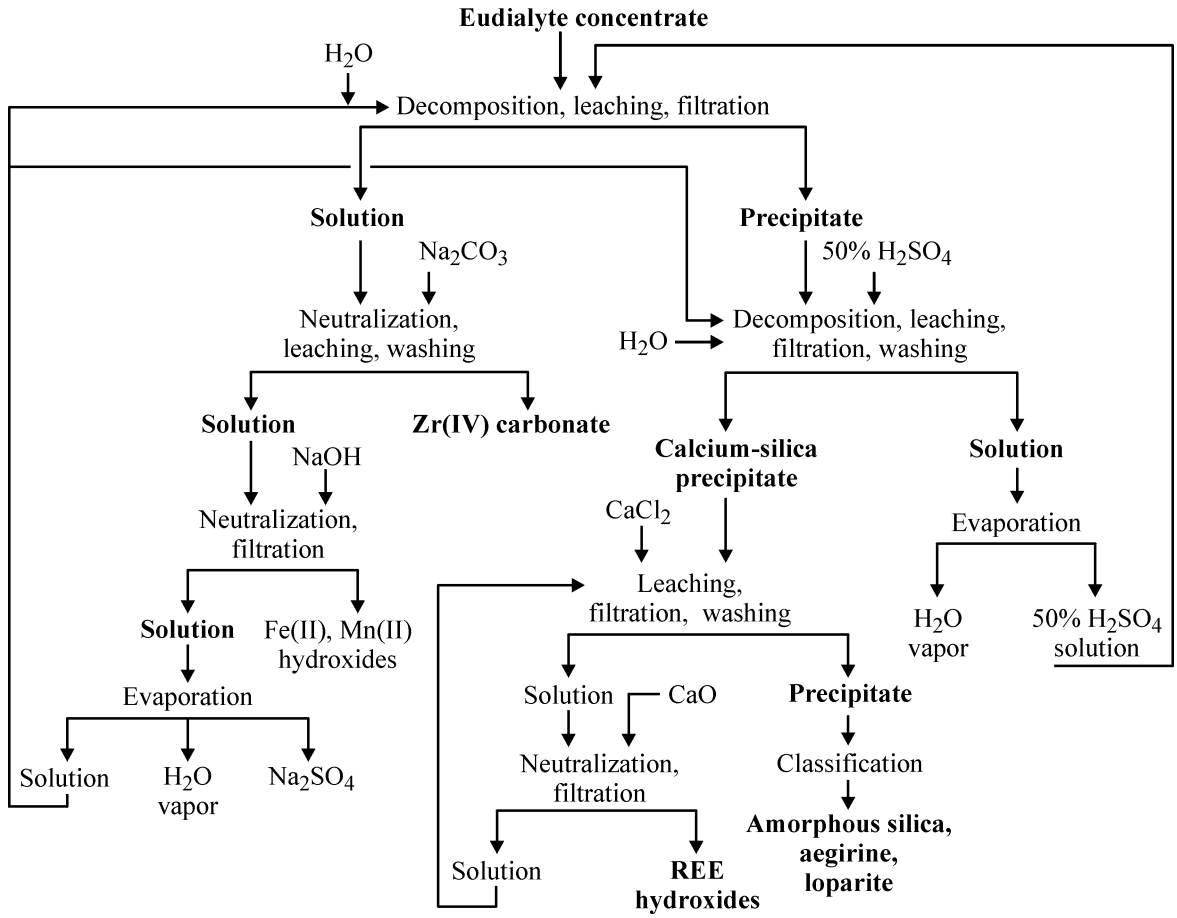
The key issue of the technology is the integrated use of the concentrate components and the maximum recovery of zirconium(IV) at the minimum consumption of the acid, since the neutralizing components, ammonia and soda, are much more expensive than, e.g., sulfuric acid. In the acid technologies for processing of rare-earth raw materials, the whole amount of acid used for decomposition is to be neutralized to recover the components and utilize wastes.

As a rule, the degree of EC decomposition with acids is not too high, 65–80 wt % [4–6]. The best performance is ensured by use of H_2SO_4, but sufficiently high recovery can be only achieved at a 8–10-fold excess of acid [7–9] or by introduction of 6 mol of the fluoride ion per 1 mol of zirconium(IV) at a threefold excess of sulfuric acid [10]. Sufficiently high recovery at small excess is achieved by using the method described in [11]. Presumably, this occurs because of the additional concentrate decomposition in drying, since the concentration of the acid increases upon water evaporation, and this creates conditions for more complete decomposition at elevated temperature. However, this method is hardly acceptable because of the necessity for drying of a large amount of a gel-like sulfation product.

Use of sulfuric acid has a number of advantages. These are the following: low cost, volatility, and corrosion activity of the acid; separation of some ballast components together with the insoluble residue; higher, compared with that achieved with other acids, degree of decomposition. It has been suggested to recover zirconium(IV) from solution by neutralization [12], extraction [10], and precipitation of zirconium(IV) phosphate [8, 9]. In the case of phosphate precipitation, the amount of impurities captured into the precipitate is large, and processing of zirconium(IV) phosphate into required products is difficult. In the author's opinion, no selective recovery of zirconium has been achieved in studies concerned with extractive processing of solutions. Presumably, the only remaining acceptable technique is precipitation by solution neutralization.

The amount of niobium(V) passing into solution in decomposition with 30–50% sulfuric acid is 40–50%. To achieve a more complete recovery, it has been suggested to introduce hydrogen peroxide in the course of decomposition and leaching [13] or to decompose eudialyte at 180–230°C with 50% acid [14]. True,

1070-4272/03/7610-1559 $25.00 © 2003 MAIK "Nauka/Interperiodica"



the above conditions more refer to decomposition of loparite contained in EC as impurity. Taking into account the necessary deficit of acid in the technology, high recovery of niobium(V) can be hardly expected.

The amount of rare-earth elements, which constitute a second in importance component of eudialyte, passing into a calcium-silica precipitate in sulfuric acid decomposition is 75–90% [11]; at high dilution the amount of yttrium passing into solution may be 50% [10].

The present communication is concerned with the main procedures used in the integrated sulfuric acid technology of eudialyte [15]. These are the following: sulfuric acid decomposition, formation of a precipitate of zirconium(IV), titanium(IV), niobium(V), iron(III), and aluminum (III) carbonates; formation of an iron-manganese precipitate by neutralization with an alkali; recovery of sodium sulfate by evaporation (see scheme). The recovery of REE from the calcium-silica precipitate by leaching with a calcium nitrate or chloride solution has been studied earlier [16].

EXPERIMENTAL

The EC used in the experiments had the following composition (wt %): ZrO_2 10.5, SiO_2 51.4, Fe_2O_3 4.4, Al_2O_3 4.7, TiO_2 1.1, Ln_2O_3 2.4, MnO 2.0, CaO 5.7, Na_2O 12.4, Nb_2O_5 0.6. In the total REE (wt %, oxides): La 12, Ce 31, Pr 3.9, Nd 14.5, Sm 3.1, Eu 0.79, Gd 2.9, Tb 0.66, Dy 3.68, Ho 1.32, Er 2.32, Tu 0.53, Yb 1.9, Lu 0.43, Y 18.7. An interesting feature of this batch of EC was the high, up to 2.5 wt %, content of loparite, with this content being as high as 40 wt % in coarse fractions.

The eudialyte concentrate was decomposed in a fluoroplastic vessel with a stirrer in a thermostated water bath. The sludge obtained after decomposition and leaching was filtered in a vacuum across a Lavsan filter. The composition of the precipitates obtained was analyzed by X-ray fluorescence method, and that of solution, by atomic-absorption spectroscopy.

It has been suggested, to prevent passing of silicon into solution, to dehydrate the sulfate mass in EC decomposition with sulfuric acid [11, 14] or to per-

*** Decomposition [11].

form decomposition at elevated temperature in an excess amount of acid, with slow charging of the concentrate [5, 6]. A method for decomposition with concentrated acid, with gradual dilution of the resulting sludge, has been suggested [12]. The results of the experiments on decomposition are listed in Table 1.

As follows from the data obtained, the degree of ZrO_2 decomposition is low and increases with the consumption of the acid. A virtually unfilterable sludge is formed at stoichiometric consumption of the acid. The rate of filtration is directly related to the acidity of the system and, as a result, to the content of silicic acid in solution. The concentration of SiO_2 in solution changes from 5.5 g l^{-1} at acid consumption of 100% relative to stoichiometry to 0.15 g l^{-1} at 200%. Even though the introduction of the fluoride ion within the limits studied, improves the process characteristics, it fails to ensure complete decomposition of the concentrate, with better effect achieved on raising the expenditure of the acid. It has been shown previously [17] that eudialyte is nonuniform in composition and more severe conditions are necessary for decomposition of the remaining 20–30% of the concentrate, compared with those for the primary concentrate. Therefore, a 10-fold excess, or threefold in the presence of fluoride ions, of the acid is necessary for complete decomposition.

The excess amount of the acid in the production solution could be neutralized with EC, with the two-stage decomposition thus used. In treatment with eudialyte, up to 0.4–0.6 N is neutralized; however, silicic acid passes into solution under these conditions. A two-stage decomposition with precipitation of silica was achieved with decomposition under spontaneous drying of the precipitate in the first stage and an excess of acid, sufficient for precipitation of silica, in the second. The decomposition was carried out in both stages with approximately 50% acid at overall consumption of 105% relative to stoichiometry. After secondary decomposition and leaching, the solution was filtered, evaporated to 50%, and used to decompose a fresh portion of the concentrate. The reaction proceeded vigorously to give a dry mass. In leaching of this mass, the concentration of silicic acid in solution was 0.03–0.05 g l^{-1} of SiO_2. After three cycles of decomposition (100-g portion of eudialyte in each cycle), the production solution (370 ml) contained 36.1 g l^{-1} of ZrO_2 at acidity of 0.9 N. The solution obtained after secondary decomposition of the precipitate formed in the first stage (370 ml) contained 13.8 g l^{-1} of ZrO_2 at acidity of 5.1 N, and the washing solution (140 ml), 6.3 g l^{-1} at 2.9 N. A 84.5-g portion of insoluble residue contained 1.5% ZrO_2, which corresponds to recovery of 88%. The results obtained in recovery by two-stage treatment are close to those for the technique described in [11]; however, it seems that solution evaporation is simpler technologically and less energy-consuming than drying of the whole amount of the sulfate mass.

Two-stage decomposition at minimum consumption of acid ensures a sufficiently high recovery, but REE can pass into solution in acid treatment of a sec-

ondary precipitate. To retain REE in the precipitate, it is necessary to create a sodium sulfate salt background in the acid solution, which can be easily done by diluting the acid with mother liquors obtained by evaporation of sodium sulfate solutions. The necessary sodium sulfate concentrations are substantiated in Table 2. It can be seen that presence of minor amounts of sodium sulfate in acid solutions is sufficient for REE precipitation, and washing with weakly acidic solutions (0.2–0.5 N) is to be restricted.

It was recommended in [11] to recover zirconium(IV) from solution by precipitation with ammonia after separation of iron aluminum ammonium alum by freezing, with preliminary oxidation of iron. Precipitation with soda was carried out without separation of alum, since utilization of sodium sulfate is more feasible, whereas separation of alum is expensive and poorly efficient. The precipitation was done from solutions obtained in the runs mentioned in Table 1. Dry soda was introduced until a precipitate appeared, and then the pH value was adjusted with a 10% Na_2SO_4 solution to 4.8–5.0. The precipitates formed were washed by single repulpation at s : l = 1 : 2 and dried. The yield of dry residue was 12.5–16 g per 100 g of EC. The composition of the precipitates is listed in Table 3.

Treatment with a solution of weak acid can be used to raise the content of zirconium in the precipitate via removal of aluminum, and part of iron and silicon, by washing. However, iron and manganese contained in the precipitate are partly oxidized in the course of precipitation, and removal of their oxidized forms by washing is impossible. Humid precipitate is easily dissolved in acids, and, therefore, zirconium can be recovered selectively by any conventional technique. For example, after dissolving the precipitate in hydrochloric acid, separating the insoluble residue, and heating the solution to boiling at acidity of 20 g l^{-1}, zirconium precipitates as a basic sulfate with the following composition (after calcination, wt %): ZrO_2 92.7, TiO_2 3.7, Nb_2O_5 2.6, Fe_2O_3 0.1, MnO_2 0.05. The extraction of zirconium into the precipitate was 93.5%. Presumably, repulpation ensured the necessary ratio between zirconium and the sulfate ion. The main difficulty in precipitate processing is the presence of silicic acid hindering the filtration.

The order in which the evaporation and neutralization procedures are performed must determine the requirements to the quality of sodium sulfate. For glass manufacturing purposes, sodium sulfate is to be isolated after separation of iron and manganese, even though the content of iron(II) did not exceed 0.01 wt % in direct evaporation after washing precipitated sodium sulfate with cold water. If sodium silicate solution is to be obtained, the requirements should be less stringent. The fraction of recycled sodium sulfate may be as high as 100%, and this does not diminish the solubility of the main components. The amount of sodium sulfate extracted from the system can be easily controlled because of its high temperature gradient of solubility, from 4 wt % at 0°C to 33 wt % at 33°C.

After separation of the zirconium product, the solution was neutralized to pH 9.5, and the precipitate was filtered off and washed with water on the filter. The amount of dry precipitate was 2.3–4.1 g, and the content of MnO_2, 40–50 wt % at a yield of 55–70%.

CONCLUSIONS

(1) A study of sulfuric acid decomposition of the eudialyte concentrate led to a conclusion that a two-

stage process, ensuring a 88% recovery of zirconium(IV) at minimum consumption of the acid, is necessary.

(2) A method for two-stage decomposition was developed, which ensures that silicic acid passes into the precipitate because of a spontaneous dehydration in the first stage and high acidity in the second.

(3) A scheme of integrated sulfuric acid processing of eudialyte was suggested and the main technological procedures involved were verified in large-scale laboratory experiments.

Received November 25, 2002; in final form, July 2003

Abstract—Evaporation of chromium ore and concentrates was studied using high-temperature differential mass-spectrometry. The data obtained, concerning the component vapor pressures in evaporation of complex oxide systems in the range 1700–2100 K, can be used to calculate the evaporation loss in melting and to assess the possibility of utilization of the sublimates formed.

Melting of a chromite raw material (CRM) [1] involves processes that occur at high-temperatures (2000–2100 K) and are poorly understood as regards the composition of the vapor phase in equilibrium with a melt. It is of indubitable scientific interest to study the evaporation of such a complex oxide system as molten ore or concentrate.

Experimental data on the composition and vapor pressure over the individual oxides of chemical elements present in the systems studied are summarized and classified in a monograph [2].

Chromium oxide Cr_2O_3 evaporates congruently [3], in accordance with the reactions:

$$Cr_2O_{3(solid)} = 2Cr_{(gas)} + 3O_{(gas)}, \quad (1)$$

$$Cr_2O_{3(solid)} = 2CrO_{(gas)} + O_{(gas)}, \quad (2)$$

$$Cr_2O_{3(solid)} = CrO_{2(gas)} + CrO_{(gas)}. \quad (3)$$

The ratio of partial pressures of Cr, CrO, and CrO_2 within the temperature range 1850–2010 K is 100 : 6 : 3.

Iron forms with oxygen three oxides: Fe_2O_3, Fe_3O_4, and FeO. When heated to 1200–1500, Fe_2O_3 and Fe_3O_4 dissociate, with molecular oxygen passing into a vapor and FeO accumulating in condensed phase. Wustite evaporates congruently at 1700–1850 K with dissociation into atomic iron and oxygen [4]:

$$FeO_{(solid)} = Fe_{(gas)} + 1/2O_{2(gas)}. \quad (4)$$

The partial pressure of FeO does not exceed 3% of the total pressure.

Silicon oxide SiO_2 evaporates congruently in the temperature range 1800–2000 K with dissociation into gaseous silicon monoxide and oxygen [2]:

$$SiO_{2(solid)} = SiO_{(gas)} + 1/2O_{2(gas)}. \quad (5)$$

When heated, magnesium and aluminum oxides dissociate virtually completely into gaseous oxygen and atomic metal vapor [2]:

$$MgO_{(solid)} = Mg_{(gas)} + 1/2O_{2(gas)}, \quad (6)$$

$$Al_2O_{3(solid)} = 2Al_{(gas)} + 3/2O_{2(gas)}. \quad (7)$$

In addition, the oxides AlO, Al_2O, and Al_2O_2 are present in minor amounts (2–3%) in a vapor over aluminum oxide.

The evaporation of CRM was studied using high-temperature differential mass-spectrometry, which is one of the most informative methods for physicochemical analysis of multicomponent systems. The method enables direct qualitative and quantitative determination of the vapor composition in a wide range of temperatures and compositions of the condensed phase.

The study was carried out on an MS-1301 mass-spectrometer. A sample was evaporated from a Knudsen cell heated by electron bombardment. The temperature was measured to within ±5°C with an EOP-66 optical pyrometer. The instrument was preliminarily

1070-4272/03/7610-1564 $25.00 © 2003 MAIK "Nauka/Interperiodica"

calibrated against vapor pressure of gold [5]. The ionizing energy was 25 eV, which made it possible to partially suppress dissociative ionization and to simplify interpretation of mass-spectra. The partial vapor pressures of the components were determined by comparing ion currents, with gold as reference. The vapor pressure of gold, p_{Au} (Pa), was calculated by the formula [5]:

$$\log p_{Au} = -18\,013/T + 10.8772. \quad (8)$$

The experimental procedure employed was described in detail in [6].

The composition of the samples studied is listed in Table 1.

Sample no. 1 was evaporated at 1700–2100 K from a tungsten Khudsen cell. Fe^+, Cr^+, CrO^+, CrO_2^+, SiO^+, Mg^+, Al^+, Al_2O^+, AlO^+, $Al_2O_2^+$, WO_2^+, and WO_3^+ ions were observed in the mass-spectrum in the course of evaporation. The vapor mass-spectra and the dependences of ion current on the time and temperature of sublimation, and also the fact that the energies at which the ions appeared, which are equal to the ionization energies of the corresponding molecules [7], showed that the vapor over a sample studied contains the following molecules: Fe, Cr, CrO, CrO_2, SiO, Mg, Al, Al_2O, AlO, Al_2O_2, WO_2, and WO_3 in different temperature intervals. The CrO and CrO_2 pressures constitute 3–5% of the chromium pressure and depend on temperature and oxygen pressure. Tungsten oxides are formed in the interaction of the chamber wall material with a sample. Molecular and atomic oxygen is also present in the vapor, but direct measurements of partial oxygen pressures are impossible because of the high-intensity background at *m*/*e* 16 and 32 and the fact that O_2 and O are not condensed on cool parts of the mass-spectrometer. At the same time, these pressures can be estimated using reference data [8] on the equilibrium constants of the reactions:

$$WO_{3(gas)} = WO_{2(gas)} + O_{(gas)}, \quad (9)$$

$$WO_{3(gas)} = WO_{2(gas)} + 1/2O_{2(gas)}. \quad (10)$$

Figure 1a shows how the partial pressures of the components over the chromium concentrate vary with time and temperature. The atomic iron and oxygen are major vapor components within 1700–1850 K. The iron vapor pressure at 1700 K is 0.2 Pa and remains virtually unchanged for a long time. The iron vapor pressure increases by an order of magnitude with temperature raised to 1850 K, and, in the course of an isothermal exposure, decreases as the condensed phase becomes depleted of iron oxide. Atomic chromium and SiO, whose partial pressures increase somewhat, appear in the vapor at this temperature, and a minor amount of atomic magnesium, at the end of the isothermal exposure. With the temperature raised to 2000K, the Fe, Cr, Mg, and SiO pressures increase, and, in addition, atomic aluminum appears in the vapor. In the course of the isothermal exposure, the partial pressure of atomic iron decreases rapidly, and that of chromium, magnesium, and silicon monoxide, first increases and then starts to decrease gradually. In the process, the aluminum vapor pressure remains constant (0.03–0.04 Pa). With the temperature raised to 2100K, the Cr, Mg, and SiO pressures first increase and then decrease to the background level, with first magnesium totally removed

Table 1. Initial composition of samples studied

Sample no.	Content, mol %

Table 2. Activities of Cr_2O_3 at various compositions of condensed phase (sample no. 1)

T, K	$a_{Cr_2O_3}$	$\gamma_{Cr_2O_3}$	Content, mol %				
			FeO	Cr_2O_3	MgO	SiO_2	Al_2O_3
1850	0.031	0.09	11.1	32.8	38.8	6.7	10.7
1850	0.038	0.11	7.6	34.1	40.3	6.9	11.1
1850	0.11	0.29	5.9	37.3	44.6	–	12.3
2000	0.35	0.91	2.3	38.4	46.2	–	13.1

from the sample, and then chromium and silicon monoxide. Atomic aluminum is the last component to evaporate from residues of chromium concentrate at 2200–2300 K. In this temperature range, no ion signals corresponding to atomic iron, magnesium, chromium, and SiO were recorded.

The method of differential mass-spectrometry was used to determine the activity of chromium(III) oxide in the condensed phase. Pure Cr_2O_3 served as reference. Transition from the working chamber to the reference chamber and back took 20–30 s, which enabled sufficiently fast measurement of ion current intensities and determination of the partial pressures of components over a sample and reference. The Cr_2O_3 activity was calculated by the formula:

$$a_{Cr_2O_3} = \frac{p^2(Cr)\,p^3(O)}{p_0^2(Cr)\,p_0^3(O)}, \qquad (11)$$

where p and p_0 are the partial vapor pressures of the components over the sample and reference, respectively.

The partial pressures of atomic oxygen were replaced, according to Eq. (9), with the $p(WO_3)/p(WO_2)$ ratio. Then

$$a_{Cr_2O_3} = \frac{p^2(Cr)\,p^3(WO_3)\,p_0^3(WO_2)}{p_0^2(Cr)\,p_0^3(WO_3)\,p_0^3(WO_2)}, \qquad (12)$$

The activities, activity coefficients, and the corresponding concentrations of the components, calculated from the evaporation curves, are listed in Table 2.

Sample nos. 2–4 were evaporated from a double molybdenum chamber, with gold used as reference. The Cr_2O_3 activity for these samples of initial composition (3.5×10^{-4}, 5.5×10^{-4}, and 7.5×10^{-4}, respectively) was determined as it was done for sample no. 1 with account of the change of the chamber material (Mo instead of W). The activity coefficients are 2.9×10^{-3}, 2.6×10^{-3}, and 2.6×10^{-3}, respectively.

Figure 1b demonstrates the dependence of the partial vapor pressures of the components over sample no. 3 on the evaporation time and temperature. Atomic iron and oxygen are major vapor components at 1700–1800 K. The vapor pressure of iron is as high as 0.25 Pa at 1800 K and remains virtually unchanged for a long time. With the temperature raised to 1950 K, the iron vapor pressure increases by approximately an order of magnitude, and Cr, SiO, and Mg appear in the vapor phase. In the course of isothermal exposure, the partial pressures of Fe and SiO decrease to virtually the background value, the Mg vapor pressure decreases somewhat, and the Cr vapor pressure increases slightly. After the temperature is raised to 2080 K, the vapor pressures of Cr and Mg increase and then decrease in the course of isothermal exposure. On further heating to 2200 K, the vapor pressure of chromium remains at the minimum level, whereas that of magnesium increases and then decreases to a background value in the course of exposure. The last component evaporating from residues of chromium concentrate at 2200–2400 K is atomic aluminum. The evaporation of sample no. 2 and 4 occurred similarly.

In the system studied, negative deviation from ideal behavior was observed, proportional to the content of iron oxide in the condensed phase.

CONCLUSIONS

(1) It was established that, first, iron and then chromium, silicon, magnesium, and aluminum, evaporate from the chromite raw material under heating. The vapor pressure of these components at 1700–2100 K was determined.

(2) The activity of chromium(III) oxide in the condensed phase was calculated. It was shown that the system shows negative deviation from ideality, proportional to the content of iron(II) oxide in the condensed phase.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Seed on Supersaturation and Scale Growth in Flow-through Crystallizers and Evaporating Apparatus

O. D. Linnikov

Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received March 28, 2003

Abstract—The problem of choosing the most effective concentration of seed crystals for controlling the supersaturation and scale growth rate in flow-through crystallizers and evaporating apparatus is considered theoretically. Equations describing these processes are derived and compared with published experimental data.

Seed crystals are widely used in crystallization and evaporating processes. The size of crystals obtained in crystallization can be controlled by changing the seed concentration. Addition of seed crystals to an industrial or natural mineralized water being evaporated makes it possible to diminish scale formation [1]. For example, the method for preventing scale formation by using seed crystals has been employed during many years for thermal desalination of Caspian Sea water [1, 2]. There is evidence of successful application of a seed to diminish formation of calcium sulfate scale [3–5]. The method of seed crystals can also be used to prevent formation of calcium carbonate scale in geothermal power engineering [6]. In spite of such a wide application of seeds, their most effective concentration in various processes is selected empirically in many instances. In this study, the problem is analyzed theoretically.

The rate of scale growth is known to decrease in the presence of seed crystals. Seed crystals remove scale-forming salts from solutions. Consequently, solution supersaturation also decreases in the presence of seed crystals. Let us consider how introduction of a seed affects the solution supersaturation.

In the simplest case, for a solution volume v in an apparatus and total surface area of seed crystals equal to S, the average growth rate of crystals V is independent of time and supersaturation and the following mass M of a scale-forming salt will be removed during time τ_0 from the solution:

$$M = SV\rho_T\tau_0. \quad (1)$$

Here ρ_T is the density of the scale-forming salt (kg m^{-3}) and τ_0 is the residence time of the solution in the apparatus (s).

The concentration of the solution is given by

$$c = \frac{c_i v - M}{v} = \frac{c_i v - SV\rho_T\tau_0}{v} = c_i - \frac{SV\rho_T\tau_0}{v}, \quad (2)$$

where c_i and c are the initial and running salt concentrations in the solution (kg m^{-3}).

The concentration of the scale-forming salt in solution is seen to be a linear function of the total surface area of seed crystals, S, and the residence time of the solution in apparatus, τ_0.

However, in the general case, the growth rate of seed crystals depends on the concentration of a scale-forming salt in solution (solution supersaturation). The growth rates of seed crystals, V, and scale, V_R, are described by the equations:

$$V = k(c - c_0)^n, \quad (3)$$

$$V_R = k_R(c - c_0)^m. \quad (4)$$

Here k and k_R are average growth rate coefficients of seed crystals and scale, respectively; V and V_R, the average growth rates of seed crystals and scale (m s^{-1}); c_0, the solubility of the scale-forming salt in solution (kg m^{-3}); n and m, the growth rate orders.

Commonly, n = 1–2 and m = 1–2. Therefore, four combinations of n and m can be considered: 1) $n = m = 1$; 2) $n = 1$, $m = 2$; 3) $n = m = 2$ and 4) $n = 2$, $m = 1$.

(1) $n = m = 1$. In this case, the following mass dM of the scale-forming salt will be removed from the solution during a time dτ:

$$dM = SV\rho_T d\tau. \quad (5)$$

1070-4272/03/7610-1568 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Taking into account the equality $dM = -vdc$ and substituting Eq. (3) into expression (5), we obtain:

$$-\frac{dc}{d\tau} = \frac{S\rho_T}{v}k(c - c_0) = \frac{S}{v}K(c - c_0). \quad (6)$$

Here $K = k\rho_T$ is the growth rate coefficient of seed crystals ($m\ s^{-1}$).

After integration, we have:

$$\ln\frac{c - c_0}{c_i - c_0} = -\frac{S}{v}K\tau_0. \quad (7)$$

From Eq. (7) follows formula (8) relating the solution supersaturation to the total surface area of seed crystals and to the residence time of the solution in an apparatus:

$$\Delta c = c - c_0 = (c_i - c_0)\exp\left(-\frac{S}{v}K\tau_0\right) = \Delta c_i\exp\left(-\frac{S}{v}K\tau_0\right). \quad (8)$$

Here $\Delta c = c - c_0$ is the solution supersaturation ($kg\ m^{-3}$) and $\Delta c_i = c_i - c_0$ is the initial supersaturation (of a solution free of seed crystals) ($kg\ m^{-3}$).

Substitution of (8) in expression (4) gives the equation for the rate of scale growth ($m = 1$):

$$V_R = k_R\Delta c = k_R\Delta c_i\exp\left(-\frac{S}{v}K\tau_0\right). \quad (9)$$

(2) $n = 1$, $m = 2$. In this case, the dependence of the solution supersaturation on the total surface area of seed crystals and on the duration of solution residence in the apparatus remains unchanged and is described by formula (8). Therefore, substitution of (8) into Eq. (4) yields

$$V_R = k_R\Delta c_i^2\exp\left(-\frac{S}{v}K\tau_0\right). \quad (10)$$

It can be seen that, on the whole, the dependence of the rate of scale growth on the residence time of the solution in an apparatus and on the total surface area of seed crystals remains nearly the same.

(3) $n = m = 2$. At $n = 2$, Eq. (3) takes, after integration and transformations, the form

$$\Delta c = \frac{\Delta c_i}{1 + K\Delta c_i\frac{S}{v}\tau_0}. \quad (11)$$

It is noteworthy that the growth rate coefficient of seed crystals, K, in Eq. (11) has the dimensionality $m^4\ s^{-1}\ kg^{-1}$.

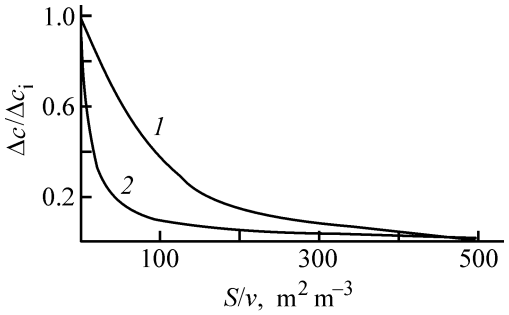

Fig. 1. Dependence of $\Delta c/\Delta c_i$ ratio on specific surface area S/v of seed crystals in solution (theoretical curves). $\tau_0 = 100$ s. (*1*) $n = 1$, $K = 1 \times 10^{-4}$ m s^{-1}; (*2*) $n = 2$, $K = 1 \times 10^{-4}$ $m^4\ s^{-1}\ kg^{-1}$, $\Delta c_i = 10$ kg m^{-3}.

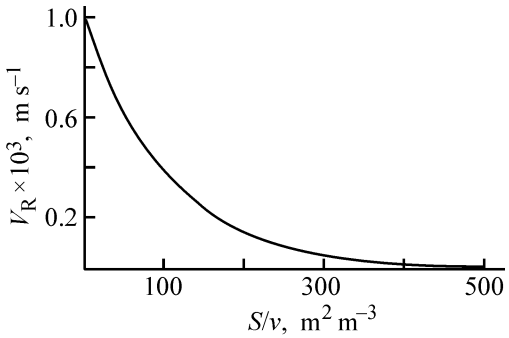

Fig. 2. Influence of specific surface area S/v of seed crystals in solution on scale growth rate V_R [theoretical curve according to Eq. (9)] $K = 1 \times 10^{-4}$ m s^{-1}, $k_R = 1 \times 10^{-4}$ $m^4\ s^{-1}\ kg^{-1}$, $n = m = 1$, $\Delta c_i = 10$ kg m^{-3}, $\tau_0 = 100$ s.

Substitution of (11) in expression (4) gives ($m = 2$)

$$V_R = \frac{k_R\Delta c_i^2}{\left(1 + K\Delta c_i\frac{S}{v}\tau_0\right)^2}. \quad (12)$$

(4) $n = 2$, $m = 1$. If $n = 2$, the solution supersaturation is described by Eq. (11). Therefore, the expression for the scale growth rate has the form

$$V_R = \frac{k_R\Delta c_i}{1 + K\Delta c_i\frac{S}{v}\tau_0}. \quad (13)$$

Theoretical curves describing the dependence of the $\Delta c/\Delta c_i$ ratio on the specific surface area of seed crystals in solution, S/v, in accordance with Eqs. (8) and (11), are shown in Fig. 1. It is seen that, if $K = 1 \times 10^{-4}$ m s^{-1} for $n = 1$ or $K = 1 \times 10^{-4}$ $m^4\ s^{-1}\ kg^{-1}$ for $n = 2$ (typical values), then the solution supersaturation decreases dramatically with the specific surface area of seed crystals increasing from 0 to 100–200 $m^2\ m^{-3}$. Further increase in the specific surface area of seed crystals to above 100–200 $m^2\ m^{-3}$ does not lead to any significant additional decrease in the ratio $\Delta c/\Delta c_i$. A similar dependence takes place for the scale growth rate (Fig. 2).

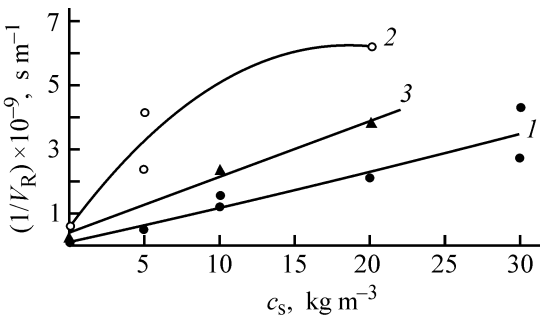

Fig. 3. Experimental data of [4], plotted in the coordinates of Eq. (16). T = 70°C. Δc_i (kg m^{-3}): (*1*) 1.50, (*2*) 0.68, (*3*) 1.09. *Points*, experimental data; *lines*, theoretical curves [calculation by Eq. (16)].

It is of interest to compare the obtained theoretical dependences with published data [4–6]. Formation of scale in the form of calcium sulfate (sulfate scale) was studied by Kaldaeva [4]. The effect of calcium sulfate seed crystals on the scale growth was studied. It was found that the growth rates of seed and scale crystals are described by Eqs. (3) and (4) for $n = m = 2$. The plot constructed on the basis of the data obtained in [4] in Fig. 3 is similar to the curve in Fig. 2 of the present study. The experimental data from Fig. 3 of [4] are listed in Table 1.

Table 1. Experimental data on the rate of sulfate scale growth for various concentrations of seed crystals, c_s, and solution temperatures (from Fig. 3 of [4])

T, °C	Δc_i, kg m^{-3}	c_s, kg m^{-3}	$V_R \times 10^9$, m s^{-1}
50	0.95	0	2.40
		5	0.45
		5	0.37
		10	0.38
		10	0.32
70	0.68	0	1.68
		5	0.42
		5	0.24
		20	0.16
	1.09	0	3.35
		10	0.42
		20	0.26
	1.50	0	6.72
		5	2.40
		5	2.28
		10	0.84
		10	0.65
		20	0.47
		30	0.36
		30	0.23

To compare Kaldaeva's experimental data [4] with Eq. (12), we transform this equation to

$$\frac{1}{V_R} = \frac{\left(1 + K\Delta c_i \frac{S}{\nu}\tau_0\right)^2}{k_R \Delta c_i^2} = \frac{1}{k_R \Delta c_i^2} + \frac{2K\tau_0}{k_R \Delta c_i}\left(\frac{S}{\nu}\right) + \frac{(K\tau_0)^2}{k_R}\left(\frac{S}{\nu}\right)^2. \quad (14)$$

Assuming that seed crystals have a near-spherical shape and taking into account that

$$\frac{S}{\nu} = \frac{S_{cr}}{m_{cr}} c_s = \frac{\pi d_{cr}^2}{\frac{1}{6}\pi d_{cr}^3 \rho_T} c_s = \frac{6}{d_{cr}\rho_T} c_s, \quad (15)$$

where c_s is the concentration of seed crystals in solution (kg m^{-3}); d_{cr}, the average diameter of seed crystals (m); $S_{cr} = \pi d_{cr}^2$, the average surface area of a single seed crystal (m^2); $m_{cr} = 1/6(\pi d_{cr}^3 \rho_T)$, the average mass of a single seed crystal (kg), we finally obtain

$$\frac{1}{V_R} = \frac{1}{k_R \Delta c_i^2} = \frac{12K\tau_0}{k_R \Delta c_i d_{cr}\rho_T} c_s + \frac{36(K\tau_0)^2}{k_R (d_{cr}\rho_T)^2} c_s^2. \quad (16)$$

Equation (16) is a parabolic regression. Typical dependencies obtained by processing the experimental data of Table 1 are shown in Fig. 3 in the coordinates of this equation. It is seen that Kaldaeva's experimental data [4] are satisfactorily approximated by Eq. (16).

Data obtained with calcium carbonate seed crystals used to prevent scale formation in geothermal power engineering have been reported by Akhmetov [6]. The effect of seed crystals on the concentration of Ca^{2+} ions in a solution passed through an apparatus was studied. The experimental results of [6] are listed in Tables 2 and 3. The data in the last column of Table 2 suggest that the $CaCO_3$ solubility in the solution under study was about 50 mg l^{-1}.

To analyze Akhmetov's experimental data [6], we transform Eqs. (8) and (11). After substituting formula (15), we obtain

$$\Delta c = \Delta c_i \exp\left(-\frac{S}{\nu}K\tau_0\right) = \Delta c_i \exp\left(-\frac{6}{d_{cr}\rho_T}K\tau_0 c_s\right), \quad (17)$$

$$\Delta c = \frac{\Delta c_i}{1 + K\Delta c_i \frac{S}{\nu}\tau_0} = \frac{\Delta c_i}{1 + \frac{6K\Delta c_i}{d_{cr}\rho_T}\tau_0 c_s}. \quad (18)$$

A verification of Eqs. (17) and (18) demonstrated that the data of [6] are best described by expression

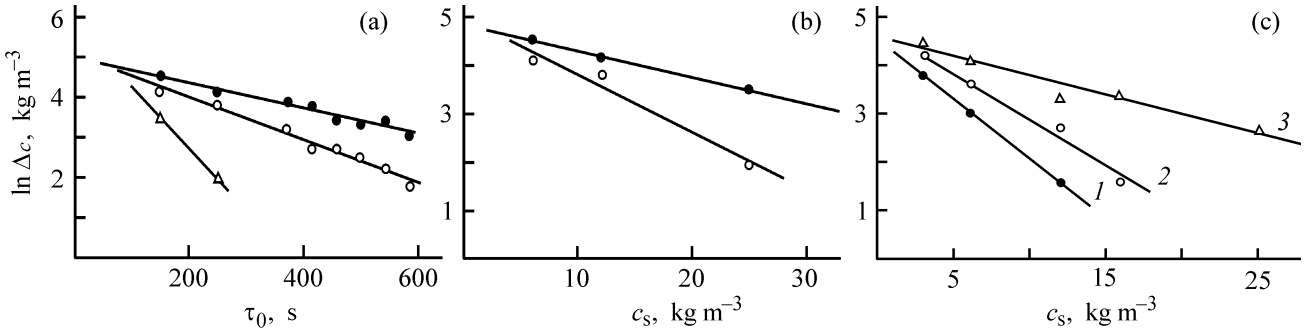

Fig. 4. Experimental data of [6] in the coordinates of modified Eq. (17). (a) c_s (kg m^{-3}): (*1*) 6, (*2*) 12, and (*3*) 25. (b) τ_0 (s): (*1*) 149 and (*2*) 249. (c) $d_{cr} \times 10^6$ (m): (*1*) 56, (*2*) 82, and (*3*) 150.

(17). Akhmetov's experimental data [6] (Tables 2 and 3 of the present study) are shown in Figs. 4a–4c in the coordinates of modified Eq. (17) (after taking logarithms). It is seen that all the experimental data well fall on straight lines. This confirms the applicability of expression (17) and indicates that the equation describing the seed crystal growth is first-order [formula (8)]. The data in Fig. 4c can be used to estimate the growth rate coefficient of seed crystals, *K*, under the experimental conditions of [6], by using formula (17). For example, calculation gives $K = 7.75 \times 10^{-6}$ m s^{-1} for $d_{cr} = 56 \times 10^{-6}$ m, $K = 8.94 \times 10^{-6}$ m s^{-1} for $d_{cr} = 82 \times 10^{-6}$ m, and $K = 6.64 \times 10^{-6}$ m s^{-1} for $d_{cr} = 150 \times 10^{-6}$ m. Hence the average *K* is 7.69×10^{-6} m s^{-1}.

Table 2. Concentration of Ca^{2+} ions, *c*, in solution as a function of its residence time in an apparatus (Fig. 2 of [6]), $T = 98°C$

τ_0, s	$c \times 10^{-3}$ (kg m^{-3}) at c_s, kg m^{-3}		
	6	12	25
149	143	113	83
249	111	95	57
371	99	75	50
414	93	65	51
457	80	65	50
500	78	62	56
543	81	59	54
586	71	56	48

Table 3. Influence of average diameter of seed crystals on the concentration *c* of Ca^{2+} ions in solution (Fig. 3 of [6]), $\tau_0 = 586$ s, $T = 98°C$

c_s, kg m^{-3}	$c \times 10^{-3}$ (kg m^{-3}) at $d_{cr} \times 10^6$, m		
	56	82	150
3	96	118	140
6	70	87	111
12	55	65	79
16	51	55	80
25	52	58	65

Unfortunately, verification of other equations of the present study seems to be impossible because of the lack of required published experimental data. Nevertheless, the results obtained can be used for carrying out approximate calculations in designing industrial apparatus and for choosing the optimal concentrations of seed crystals to prevent scale formation, and also for controlling the mass-crystallization processes.

To conclude, it should be noted that Eqs. (1)–(13) were derived on the assumption that the total surface area of seed crystals much exceeds the scale surface area. Therefore, the mass of scale-forming salt deposited on the scale surface could be neglected.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Relations and Electrical Properties of Phases in Systems Na_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ (A = Mg, Mn, Co, Ni; R = Cr, Fe)

I. Yu. Kotova and N. M. Kozhevnikova

Baikal Institute of Nature Management, Siberian Division, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia

Received March 28, 2003

Abstract—The subsolidus region of ternary salt systems Na_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ was studied. It was established that phases $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, $0 \le x \le 0.2$–0.3 of variable composition with rhombohedral lattice ($R\bar{3}c$) and ternary molybdates $NaA_3R(MoO_4)_5$ of triclinic crystal system ($P\bar{1}$) are formed in the system. The electrical characteristics of ternary molybdates and the effect of the cation nature on the homogeneity region of the phases and type of conduction were studied.

The interest in oxygen-containing compounds of molybdenum is caused by their wide application in both new and traditional fields of science and engineering. Matrixes for fixation of long-lived isotopes, phosphors, laser materials, ferroelectrics, piezoelectrics, catalysts for organic synthesis, superionics, high-temperature binders and other materials have been obtained on the basis of composite oxides with various cations and a tetrahedral anion [1–3]. In this context, a physicochemical analysis of systems of this kind, synthesis of new compounds, and a study of their structure and properties, including electrical properties, are being carried out.

It is necessary to note that the rhombohedral phases are of particular interest because they exhibit a crystal-chemical similarity with compounds of the NASICON type, which are characterized by superionic properties [3–9], and the possibility of iso- and heterovalent substitutions in the rhombohedral skeleton enables smooth variation of properties of materials based on them.

The aim of this study was to analyze phase relations in the systems Na_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$, (A = Mg, Mn, Co, Ni; R = Cr, Fe) and the type of conduction in ternary molybdates.

EXPERIMENTAL

Starting components for a study of the systems were molybdates of double-charged metals, sodium, iron(III), and chromium(III), synthesized by the solid-phase technique, specifically, by sintering the oxide of a corresponding metal, Na_2CO_3, $Fe(NO_3)_3 \cdot 9H_2O$, and molybdenum trioxide, taken in stoichiometric ratio. The compounds $NaR(MoO_4)_2$ (R = Cr, Fe) were synthesized at 550–650°C in the course of 100–150 h. All the starting compounds were preliminarily calcined, for their full dehydration, at temperatures 100–200°C lower than their melting points. The annealing was carried out in the range 550–750°C. The duration of calcination at each temperature was 100–200 h. Nonequilibrium samples were annealed additionally. To determine the homogeneity regions, ternary molybdates were obtained from preliminarily synthesized neutral molybdates. The value of x was varied from 0 to 1.00 in steps of 0.1. The annealing was done in the range 550–750°C, with intermediate grinding after every 20–30 h. The duration of calcination at each temperature was 150–250 h.

The phase composition was monitored, as equilibrium was attained, by means of X-ray diffraction analysis with a DRON-2.0 diffractometer and a chamber-monochromator of the Guignet–de-Wolf type (Cu_{K_α} radiation, Ge as internal standard). A differential thermal analysis was carried out on an MOM OD-103 derivatograph (rate of temperature rise 10 deg min^{-1}, sample weight 0.3–0.4 g).

Electrical measurements in the range 200–600°C were carried out in the heating–cooling mode, using 0.15–0.2-cm-thick dense ceramic discs sintered at

$NaMgFe(MoO_4)_3$	9.375(4)	23.226(5)	294.6	2.477	790
$Na_{0.7}Mg_{0.7}Fe_{1.3}(MoO_4)_3$	9.391(2)	23.292(3)	296.5	2.498	790

600–700°C, with platinum electrodes deposited onto their surface. An E8-4 bridge was used for ac measurements at a frequency of 10 kHz, with an R5025 capacitance box (accuracy ±5%) which extended the measurement range of the dielectric loss tangent. A voltage of 60 mV was used in dc measurements. The electronic and ionic transfer numbers were determined by Vest and Tallan's method [10].

The systems Na_2MoO_4–$AMoO_4$ (A = Mg, Mn, Co, Ni) and Na_2MoO_4–$R_2(MoO_4)_3$ (R = Cr, Fe) were studied in [11–15], and, therefore, were not analyzed additionally here.

To study interactions in the system Na_2MoO_4–$MgMoO_4$–$R_2(MoO_4)_3$, mixtures of neutral and binary molybdates were prepared in a specified stoichiometric ratio, including the compositions corresponding to intersection points for all the sections existing in the system. The samples were annealing in the range 300–700°C. An analysis of the data obtained in studying the phase composition of the compounds lying at the intersection points and at the points located in the plane of the triangle Na_2MoO_4–$MgMoO_4$–$R_2(MoO_4)_3$ demonstrated that the phase relations in the subsolidus region for the iron-containing systems at 600°C and for the chromium-containing systems 650°C are characterized by the following quasibinary sections: $MgMoO_4$–$NaMg_3R(MoO_4)_5$; $Na_{2-2x}Mg_{2+x}(MoO_4)_3$, $0.4 \le x \le 0.5$–$NaMg_3R(MoO_4)_5$; $NaMg_3R(MoO_4)_5$–$R_2(MoO_4)_3$; $NaMg_3R(MoO_4)_5$–$Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$, $0 \le x \le 0.3$; $Na_{2-2x}Mg_{2+x}(MoO_4)_3$–$Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$; $Na_{2+2x}Mg_{1-x}(MoO_4)_2$, $0 \le x \le 0.2$–$Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$; Na_2MoO_4–$Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$; $NaR(MoO_4)_2$–$Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$; $Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$–$R_2(MoO_4)_3$ (Fig. 1).

According to the results of X-ray phase analysis, the ternary compounds $NaMg_3R(MoO_4)_5$ and $NaMgR(MoO_4)_3$ show no noticeable homogeneity region along the section $NaR(MoO_4)_3$–$MgMoO_4$ (R = Cr, Fe), whereas the homogeneity region in the plane of the triangle along the section $NaMgR(MoO_4)_3$–$R_2(MoO_4)_3$ is 9.8 mol % wide.

Along the section $NaMgR(MoO_4)_3$–$R_2(MoO_4)_3$, phases of variable composition, $Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$, $0 \le x \le 0.3$, are formed. They are solid solutions of subtraction, based on the ternary molybdate $NaMgR(MoO_4)_3$. According to the X-ray data (positions of reflections and their relative intensities in X-ray diffraction patterns), these solid solutions are isostructural to the ternary sodium–zinc–scandium molybdate [16] having a rhombohedral lattice (space group $R\bar{3}c$, $Z = 6$) (Table 1).

Taking into account that the starting compounds have the same formulas and structures, it would be expected that the phase relations in the systems containing manganese, cobalt, and nickel molybdates must be similar to those in the system under study: Na_2MoO_4–$MgMoO_4$–$R_2(MoO_4)_3$ (R = Cr, Fe). Therefore, the study of phase formation in these ternary systems was restricted to an analysis of samples whose composition corresponded to the intersection point of the lines $AMoO_4$–$NaR(MoO_4)_2$ and $Na_{2-2x}A_{2+x}(MoO_4)_3$, $0.4 \le x \le 0.5$–$R_2(MoO_4)_3$; $AMoO_4$–$NaR(MoO_4)_2$; $Na_{2+2x}Mg_{1-x}(MoO_4)_2$, $0 \le x \le 0.2$–$R_2(MoO_4)_3$.

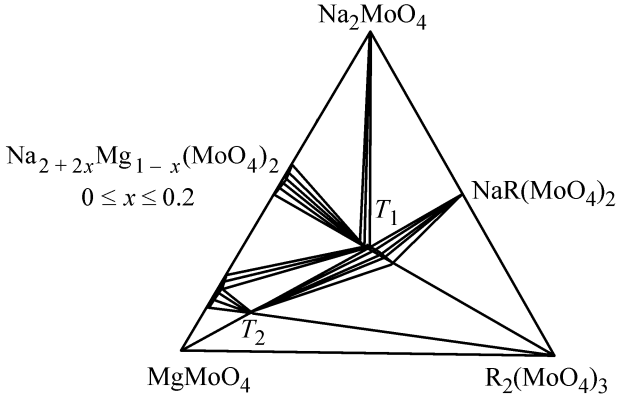

Fig. 1. Phase relations in the systems Na_2MoO_4–$MgMoO_4$–$R_2(MoO_4)_3$ (R = Cr, Fe). (T_1) $Na_{1-x}Mg_{1-x}R_{1+x}(MoO_4)_3$ and (T_2) $NaMg_3R(MoO_4)_5$.

It was found that at 650–700°C the compounds $NaAR(MoO_4)_3$ (A = Mn, Co, Ni; R – Cr, Fe) are formed, together with phases of variable composition on their base, with various homogeneity regions in the series of both double- and triple-charged elements. In spite of the fact that all molybdates of doublecharged elements A (Mg, Mn, Co, and Ni) have the same symmetry (structural type of α-$MnMoO_4$), the homogeneity region depends on the nature of an element. When small double-charged ions (Ni^{2+}) and highly polarizing cations (Co^{2+}) are introduced into the skeleton, the region of existence of rhombohedral phases is narrowed down to $x = 0.2$. The phases with A = Mg have the widest region of existence, $0 \le x \le 0.3$. It is necessary to note that the individual manganese-, cobalt-, and nickel-containing phases at $x = 0-0.1$ could not be isolated by varying the temperature and annealing time. Alongside with the phases $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, the binary molybdate $NaR(MoO_4)_2$ is present in the annealed samples. This structural type (skeleton) is the most favorable for magnesium compounds.

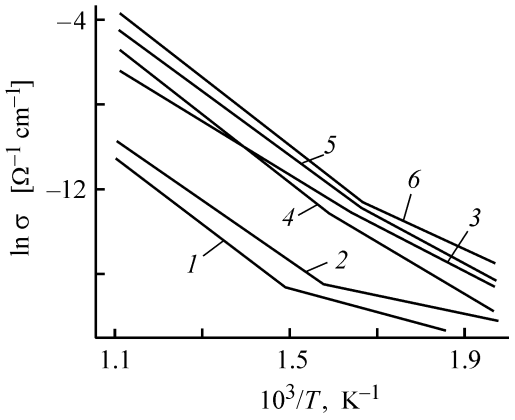

Fig. 2. Dependence of electrical conductivity σ on temperature *T*. (*1*) $NaMg_3Cr(MoO_4)_5$, (*2*) $NaMg_3Fe(MoO_4)_5$, (*3*) $NaMgCr(MoO_4)_3$, (*4*) $Na_{0.7}Mg_{0.7}Cr_{1.3}(MoO_4)_3$, (*5*) $NaMgFe(MoO_4)_3$, and (*6*) $Na_{0.7}Mg_{0.7}Fe_{1.3}(MoO_4)_3$.

It was found in [17] that the widest homogeneity regions are observed in aluminum molybdates, in which manganese and magnesium are double-charged elements and $x = 0.5$. Introduction of such ions as Cr and Fe, which are larger than Al, into the rhombohedral skeleton makes the homogeneity region narrower: $x = 0.3$.

According to the results of X-ray phase analysis, the formation of ternary compounds in $3Co(Ni)MoO_4$–$NaR(MoO_4)_2$ (R = Cr, Fe) mixtures begins at 600–650°C, and in $3Mg(Mn)MoO_4$–$NaR(MoO_4)_2$ (R = Cr, Fe), at 550–600°C. The ternary molybdates of 3 : 1 composition were obtained as single-phase products at 650–700°C and calcination time of 150–200 h.

The compounds $NaA_3R(MoO_4)_5$ were synthesized from neutral molybdates at 1 : 6 : 1 ratio of the starting components, 700–750°C, and calcination time of 200–300 h. Ternary molybdates are formed in synthesis from neutral molybdates in a number of successive stages. Binary molybdates $NaR(MoO_4)_2$ and $AMoO_4$ were revealed as intermediate products. The results obtained suggest that, when a ternary molybdate is synthesized by the reaction of $AMoO_4$ with a binary molybdate of single- and three-charged elements, the equilibrium is attained faster, and at a lower temperature, as compared with reaction mixtures of Na_2MoO_4, $AMoO_4$, and $R_2(MoO_4)_3$.

An X-ray study of the synthesized compounds $NaA_3R(MoO_4)_5$ (A = Mg, Mn, Co, Ni; R = Cr, Fe) demonstrated that they are isostructural to each other and crystallize in the triclinic crystal system ($P\bar{1}$, $Z = 2$), which places them in a new structural family [18] (Table 2).

Table 3. Electrical characteristics of $NaA_3R(MoO_4)_5$

Compound	300°C		600°C		*E*, eV
	σ, Ω^{-1} cm^{-1}	t_e	σ, Ω^{-1} cm^{-1}	t_e	
$NaMg_3Fe(MoO_4)_5$	1.82×10^{-8}	0.28	1.20×10^{-5}	0.62	6.07
$NaMn_3Fe(MoO_4)_5$	1.39×10^{-8}	0.25	1.40×10^{-5}	0.64	5.97

Table 4. Electrical characteristics of phases of variable composition, $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, $0 \le x \le 0.3$, R = Cr, Fe

Compound	300°C		600°C		*E*, eV
	σ, Ω^{-1} cm^{-1}	t_e	σ, Ω^{-1} cm^{-1}	t_e	
$NaMgCr(MoO_4)_3$	6.25×10^{-8}	0.75	2.15×10^{-3}	0.72	2.43
$Na_{0.7}Mg_{0.7}Cr_{1.3}(MoO_4)_3$	1.62×10^{-8}	0.80	1.01×10^{-2}	0.79	2.33
$NaMgFe(MoO_4)_3$	9.09×10^{-8}	0.78	8.26×10^{-3}	0.75	2.26
$Na_{0.7}Mg_{0.7}Fe_{1.3}(MoO_4)_3$	1.06×10^{-7}	0.80	1.47×10^{-2}	0.81	2.17

It was found that the total conductivity of ternary molybdates $NaA_3R(MoO_4)_5$ varies within the limits 10^{-8}–10^{-5} Ω^{-1} cm^{-1} as temperature increases from 200 to 600°C. There is only a single bend in the $\ln\sigma$–$1/T$ curves (Fig. 2), which is associated with transition from impurity conduction to that of the intrinsic type. On the basis of temperature dependences of the electrical conductivity and transfer numbers, a conclusion was made that the ternary molybdates exhibit mixed ionic-electronic conduction, with the ionic component predominant up to 360°C (t_e = 0.25–0.35) and the electronic component much exceeding it in the range 360–600°C (t_e = 0.62–0.67). The activation energies *E* of the electronic conductivity of the compounds are shown in Table 3. With increasing radii of double- and triple- charged cations, the conductivity becomes higher.

In all the cases, the dielectric constant and the dielectric loss tangent grow exponentially without anomalies with increasing temperature.

With increasing temperature, the total conductivity of rhombohedral phases $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ varies within the limits 10^{-8}–10^{-2} Ω^{-1} cm^{-1}.

The predominantly ionic conduction (t_i = 0.72–0.81) is characteristic of the compounds obtained. It was found that the conductivity grows in the series of solid solutions with *x* increasing from 0 to 0.3 and with increasing radius of triple-charged cation (Fig. 2 and Table 4), which is associated with the structural features of NASICON-like phases, whose structure is a three-dimensional porous skeleton composed of apex-connected MoO_4 tetrahedra and MO_6 octahedra of double- and triple-charged cations. The Na^+ cations are situated within the spacious voids of the skeleton, which are combined into a system of communicating channels [16]. Hetero-charge substitution $Na^+ + M^{2+} = M^{3+} + \square$ in the series of solid solutions results in the formation of additional vacancies in the sodium sublattice, which affects the mobility of sodium cations, i.e., the possibility of their freer motion in the voids along the conduction channels. With *x* increasing from 0 to 0.3, the electrical conductivity grows from 8.26×10^{-3} to 1.47×10^{-2} for iron-containing phases and from 2.15×10^{-3} to 0.01×10^{-2} Ω^{-1} cm^{-1} for chromium-containing phases. It was found that the large sizes of both the octahedra and the tetrahedra lead to high ionic conductivity [3]. At 600°C, the electrical conductivity of $NaMgCr(MoO_4)_3$ ($r_{Cr^{3+}}$ = 0.62 Å) and $NaMgFe(MoO_4)_3$ ($r_{Fe^{3+}}$ = 0.65 Å) is 2.15×10^{-3} and 8.26×10^{-3} Ω^{-1} cm^{-1}, respectively.

The dielectric constant ε and the dielectric loss tangent tanδ depend on temperature exponentially for $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$. The absence of extrema in the curves for the dielectric constant and dielectric loss tangent indicates the absence of phase transitions and ferroelectric properties in NASICON-like ternary molybdates.

Comparison of the results obtained in this study with the data of [19] shows that the highest conductivity among sodium and potassium ternary molybdates $MAR(MoO_4)_3$ and phases of variable composition on their base, $M_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$, $0 \le x \le 0.6$–0.2

(A = Ni, Mg, Co, Mn; R = Al, In, Sc, Yb, Lu) is observed for sodium-containing rhombohedral phases, which makes them promising materials for solid electrolytes.

CONCLUSIONS

(1) A study of phase relations in the subsolidus region of the systems Na_2MoO_4–$AMoO_4$–$R_2(MoO_4)_3$ (A = Mg, Mn, Co, Ni; R = Cr, Fe) demonstrated that ternary molybdates $NaA_3R(MoO_4)_5$ and $NaAR(MoO_4)_3$ and phases of variable composition on their base with different homogeneity regions are formed.

(2) The electrical characteristics of $NaA_3R(MoO_4)_5$ and $Na_{1-x}A_{1-x}R_{1+x}(MoO_4)_3$ were studied. It was found that $NaA_3R(MoO_4)_5$ have low conductivity (10^{-8}–10^{-5} Ω^{-1} cm^{-1}) with predominant electronic component. The rhombohedral phases of variable composition have predominantly ionic conduction. The conductivity in the homogeneity region grows steadily with increasing concentration of vacancies in the sodium sublattice and also with increasing size of the triple-charged cation (Cr → Fe).

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption Properties of Natural Carbonaceous Adsorbents and Thermally Expanded Graphite

Received May 13, 2002; in final form, March 2003

Abstract—Structural and sorption characteristics of natural carbonaceous sorbents and thermally expanded graphite were examined. Acid–base sites on the sorbent surface were characterized qualitatively and quantitatively. The performance of the materials in wastewater treatment to remove anionic surfactants was studied.

Search for, and characterization and practical application of efficient and sufficiently cheap natural sorbents for treatment of natural and waste water is a topical problem [1, 2]. For this purpose, natural and synthetic carbonaceous sorbents are widely used [3, 4]. The use of carbonaceous adsorbents from domestic deposits or those modified by domestically developed processes appears to be the most expedient from the cost-effectiveness standpoint. Therefore, we started studies of natural porous coal, natural graphite, and thermally expanded (foamed) graphite (TEG) for water treatment.

Natural porous coal is a young coal, precursor of brown coal, whose deposits are found in the Donets Basin (Ukraine). Natural graphite was taken from the Zaval'e deposit (Kirovograd oblast, Ukraine).

TEG samples were prepared using the procedure described in [5]. Chemically enriched natural graphite of GAK-2 brand {GOST (State Standard) 0273–78 [6]} was treated with a mixture of concentrated sulfuric acid and 30% hydrogen peroxide for 30 min. Hydrolysis of the intercalate (graphite bisulfate) yields oxidized graphite, which is subjected to thermal treatment in a gas furnace at 627°C. Finally, TEG is treated in a roasting apparatus at 427° under nitrogen for 30 s to remove residual sulfur compounds.

As the first stage of the study, we analyzed the structural and sorption characteristics of the above-indicated materials, including the nature and amount of functional groups on their surface and adsorption capacity for some anionic surfactants.

EXPERIMENTAL

Low-temperature (77 K) static adsorption of nitrogen on the test sorbents was carried out on an ASAP 2000 M instrument (Micromeritics, the United States). The sample pretreatment temperature was 393 K. From the isotherms obtained using the ASAP software, we determined the BET specific surface areas S_{N_2}, total pore volume V_Σ, volume of micropores W_0, and pore size distribution.

To gain better insight into the structure of the carbonaceous materials and to estimate the hydrophilicity of their surface, we measured the adsorption–desorption isotherms of *n*-hexane and water vapor, using a vacuum adsorption system with a McBain–Bakr quartz spring balance at 298 K (temperature of preliminary vacuum treatment of samples, 393 K). Using the BET equation, we determined from the adsorption isotherms the nominal monolayer capacity and the effective specific surface area of the sorbents. From the hexane desorption isotherms obtained at relative pressures P/P_s = 0.3–0.9, we estimated the pore size distribution of the samples by the Kelvin–Thomson equation.

Acidic and basic reactive groups on the sorbent surface were determined by conductometric back titration [7]. Weighed portions (0.5 and 0.1 g) of the sorbents were placed in 20 ml of CO_2-free distilled water and allowed to stand for 24 h at 293 K in flasks with ground-glass stoppers, with intermittent stirring. Then 1 ml of 0.1 M KOH or HCl was added, and

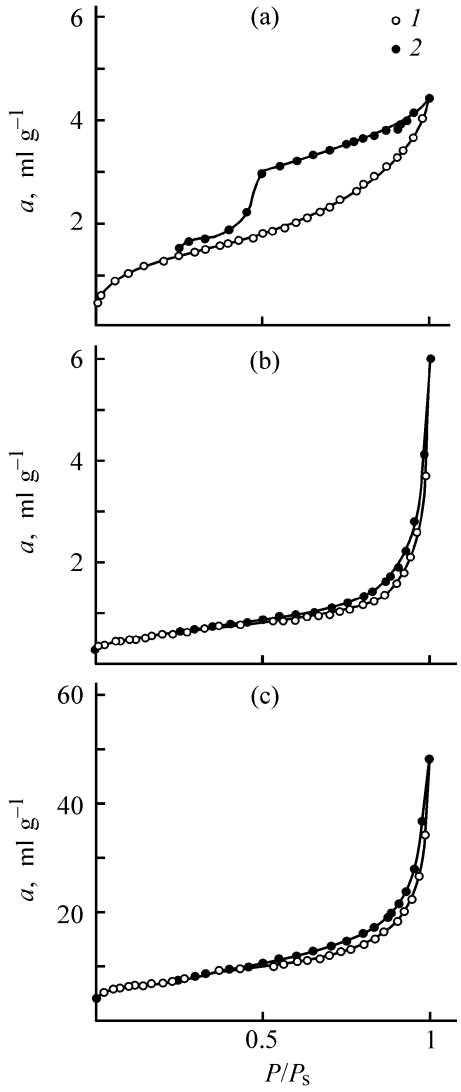

Fig. 1. Isotherms of (*1*) sorption and (*2*) desorption of nitrogen at 77 K: (a) natural coal, (b) natural graphite, and (c) TEG. (*a*) Adsorption and (P/P_s) relative pressure; the same for Figs. 2 and 3.

the suspensions were titrated with 0.1 M HCl or KOH, respectively. The volumes of the standard solutions were measured with a standardized 1-ml burette equipped with a special microdoser. The electrical conductivity of the suspensions was measured with a P5021 ac bridge in a temperature-controlled conductivity cell with flat Pt electrodes and a magnetic stirrer. Contact with the atmosphere was enabled through an absorption tube filled with soda lime. From the conductometric titration curves, the amount of acidic and basic centers (μg-equiv g^{-1}) was estimated as

$$n_{H^+(OH^-)} = \frac{c_{HCl(KOH)}V_1 - c_{KOH(HCl)}V_2}{m} \times 10^3,$$

where $c_{HCl(KOH)}$ is the acid or alkali concentration (M); V_1, the volume (ml) of the acid or alkali added to the suspension; V_2, the volume (ml) of the titrant consumed for titration of free acid or alkali; m, the sorbent weight (g).

The amount of active centers was determined to within 5%.

The nature and strength of the active sites on the sorbent surface were determined by potentiometric titration over the pH range 2.3–10.8, using the single-portion method [8]. The portions were 0.5 g for natural coal and graphite samples and 0.1 g for TEG samples. The total solution volume was 40 ml in each case. As supporting electrolyte served 1 M KCl. All solutions were prepared in CO_2-free distilled water. The contact time of the sorbents with 0.1 M KOH or 0.1 M HCl in 1 M KCl was 24 h at 273 K. For natural coal in KOH, the contact time was 15 min because of the instability of sorbents and ion exchangers based on natural coal in alkaline solutions [9]. The pH in the systems was measured on an EV-74 universal ion meter with ESL-05G working glass electrode and EVL-1MZ immersible saturated Ag/AgCl reference electrode. The glass electrode was calibrated once a week against three standard buffer solutions. The measurements were conducted at 273 K in a hermetically sealed temperature-controlled cell equipped with a magnetic stirrer. Contact with the atmosphere was enabled through an absorption tube packed with soda lime. The potentiometric titration curves were plotted in the coordinates pH–V, where V is the volume (ml) of the acid or alkali added to the system. From the titration curves, we estimated at fixed pHs (9.0 and 9.8) the exchange capacity of the sorbents E (μg-equiv g^{-1}) to within 5%.

We examined the performance of the adsorbents under study in recovery of anionic surfactants. As a typical anionic surfactant we selected Sulfonol [sodium dodecylbenzenesulfonate $C_{12}H_{25}C_6H_4SO_3Na$; MW 348, CMC 420 mg l^{-1} (1.2×10^{-3} M)]. To obtain Sulfonol adsorption isotherms on the carbonaceous sorbents, we prepared 8–10 aqueous Sulfonol solutions with concentrations of 2.5–100 mg l^{-1} (7.1×10^{-6}–2.6×10^{-4} M). Weighed portions of dry sorbents were placed in these solutions and equilibrated for 5 days. Then the solid phase was separated by centrifugation at 6000 rpm, and the equilibrium Sulfonol concentrations were determined spectrophotometrically at λ = 227 nm ($\varepsilon = 44 \times 10^3$ cm^{-1}) on a Specord UV-VIS instrument.

The low-temperature nitrogen adsorption isotherms of the sorbents studied are presented in Fig. 1. It fol-

Table 1. Specific surface area S, total pore volume V_Σ, micropore volume W_0, nominal monolayer capacity a_m, and effective pore radius r_{ef} of carbonaceous adsorbents

lows from the type of the isotherms that all the sorbents have a nonuniform porous structure. In particular, the sharp rise at $P/P_s < 0.05$ suggests the presence of micropores in the structure of carbonaceous materials. However, the observed volume W_0 of micropores is rather small (Table 1), suggesting that they do not contribute significantly to the adsorption capacity of the sorbents. At relative pressures P/P_s of 0.20 to 0.98, a capillary–condensation hysteresis loop is observed, caused by the presence of mesopores in the sorbent structure. Indeed, the pore size distribution curves demonstrate domination of mesopores with effective radii of about 1.2, 2.0, and 22.5–25 nm. The platelike shape of particles of carbonaceous materials suggests a slotlike shape of the mesopores, which is also supported by the shape of the hysteresis loop of type *B* [10].

The adsorption–desorption isotherms of *n*-hexane and water on the carbonaceous adsorbents studied are similar to the corresponding isotherms obtained for nitrogen. Initially ($P/P_s < 0.1$) all the isotherms are convex toward the ordinate. Then, in the isotherms of the initial and thermally expanded graphite, a hysteresis loop is observed, which closes at $P/P_s \sim 0.02$. For natural coal, the hysteresis loop in the isotherms of adsorption of hexane and water is considerably broader than for the other sorbents, extending to $P/P_s = 0$. This is associated with swelling of the sorbent texture (submicroscopic structure). The ability of some sorts of bituminous coals and hard and soft brown coals to swell was reported in [9]. For the same reason, Lishtvan *et al.* [11] observed the adsorption isotherms of water and hydrocarbon vapor on brown coals and peat with an anomalous hysteresis loop.

We have demonstrated previously [12] that the presence of a considerable amount of hydrophilic centers on the surface of coal stacks is an important factor responsible for significant adsorption of water. The results showed that the limiting adsorption of water on mesoporous coal exceeds that of hexane by about a factor of 3, suggesting considerable amount of hydrophilic centers on the sorbent surface.

The reverse was observed with the initial and thermally expanded graphite: the amount of adsorbed hexane is much higher than that of water (Figs. 2, 3), which is a clear indication of highly hydrophobic surface of both the graphite samples.

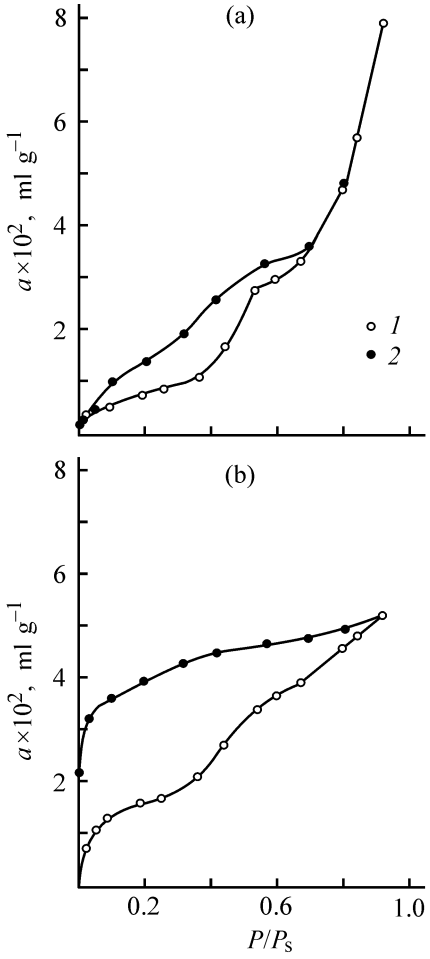

Fig. 2. (*1*) Adsorption and (*2*) desorption isotherms of hexane vapor at 298 K: (a) TEG and (b) natural coal; the same for Fig. 3.

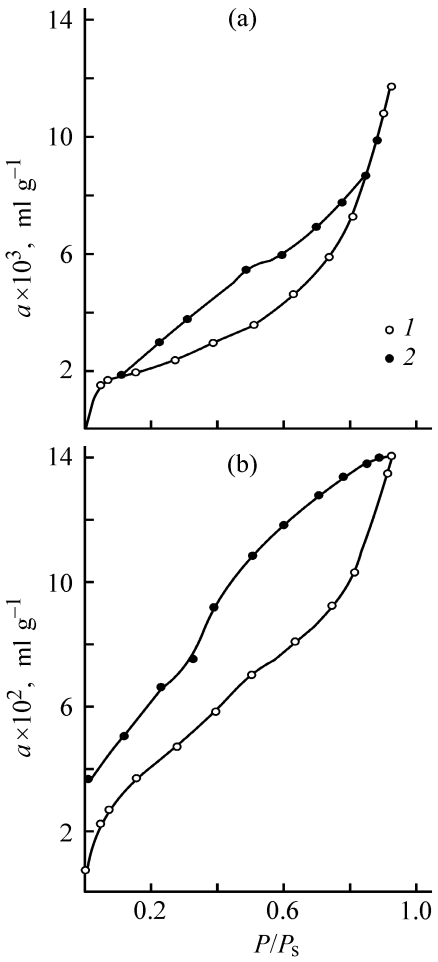

Fig. 3. (*1*) Adsorption and (*2*) desorption isotherms of water vapor at 298 K.

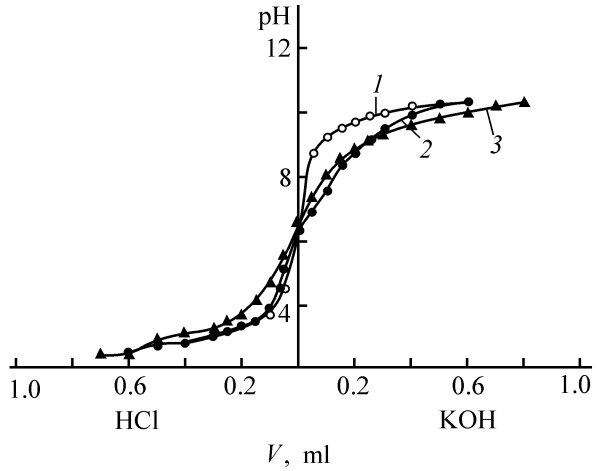

Fig. 4. Potentiometric titration curves. (*V*) Titrant volume. (*1*) Blank experiment, (*2*) TEG, and (*3*) natural graphite.

It follows from the potentiometric titration curves (Fig. 4) that all the carbonaceous adsorbents studied are weakly acidic polyfunctional cation exchangers: the titration curves demonstrate nearly the same smooth slopes over a wide pH range and also weakly pronounced inflections.

In the acidic range, the titration curve of the initial graphite runs slightly above the titration curves obtained in the blank experiment and with TEG. In the range from pH 3.5–3.7 to 9.0–9.5, pH increases more sharply, which is probably due to gradual (as pH increases) involvement in dissociation of surface carboxy and phenolic hydroxy groups [9, 13, 14]. From comparison of the titration curves of the adsorbents with the result of the blank experiment [15], we estimated their total exchange capacity E (μg-equiv g^{-1}): TEG 160–170 (pH 9.0) and initial graphite 60 (pH 9.5). These results are well consistent with the conductometric data discussed below.

It should be noted that data on conductometric titration of the initial graphite revealed the presence of some basic functional groups that are neutralized with 0.1 HCl. It may be suggested that these are the surface OH groups, which is supported by the conductometric titration data on the concentrations of acidic (c_{H^+}) and basic (c_{OH^-}) centers in the sorbents studied. Natural coal contains acidic centers only (c_{H^+} = 140 μg-equiv g^{-1}); the initial graphite, both acidic (c_{H^+} = 60 μg-equiv g^{-1}) and basic centers (c_{OH^-} = 20 μg-equiv g^{-1}); and TEG, acidic centers only (c_{H^+} = 160 μg-equiv g^{-1}). As seen, only the initial graphite contains basic centers. Most likely, it is this fact that is responsible for the above-mentioned higher run of the acidic branch in the potentiometric titration curve of the initial graphite relative to the curve obtained in the blank experiment.

Water molecules, as known [16], interact with acids and bases and, therefore, the adsorption method gives the total amount of active centers.

Estimation of the concentration of active centers on the sorbent surface from the specific surface area determined from the hexane adsorption (Table 1) gives 2.8×10^{19}, 1.6×10^{19}, and 0.64×10^{19} m^{-2} for natural coal, initial graphite, and TEG, respectively. As expected, the amount of active centers is the highest in mesoporous coal, exceeding that in graphitized thermal black [17].

The number of water molecules bound to an active center was estimated from the nominal monolayer capacity, determined by the BET equation (Table 1), to be 14, 1.05, and 0.6 for the coal, initial graphite, and TEG, respectively. Evidently, the high concentration of active centers in the mesoporous carbon enables association of water molecules on its surface

Table 2. Limiting adsorption, a_{max}, and degree of Sulfonol recovery, α, from aqueous solutions with different concentrations c_0

Sorbent	a_{max}, mg g^{-1}	α, %, at indicated c_0, mg l^{-1}

Natural graphite	3.1	35	21
TEG	31.0	99	84

even at low P/P_s. The cluster mechanism of water adsorption on hydrophilic centers of carbonaceous sorbents is supported by data reported in [18].

The concentration of active sites strongly influences the adsorption of water, mainly at low coverage of the sorbent surface [19]. It should be borne in mind, however, that formation of clusters of water molecules near active hydrophilic centers favors swelling of the porous carbon texture under water vapor and, as a result, influences the adsorption of water at higher coverage.

It follows from the shape of the sorption–desorption isotherm of hexane on mesoporous coal (inflection in the adsorption branch at $P/P_s \approx 0.5$) and also from the residual amount of hexane after a short-time vacuum treatment of a sample (~2×10^{-2} ml g^{-1}) that this material swells under hexane vapor too, as a capillary-condensation film of the hydrocarbon is formed in its pore space. From the inflection point in the sorption branch, we estimated the minimum halfwidth of slotlike mesopores. We obtained 2.5 and 2.9 nm for natural coal and TEG, respectively, which is comparable with the values obtained by the Kelvin–Thomson equation (Table 1).

The isotherms of Sulfonol adsorption on the sorbents studied are shown in Fig. 5. All the isotherms demonstrate a clearly pronounced convexity toward the ordinate at low coverage.

Compared with the initial graphite and porous coal, the adsorption on TEG is higher by an order of magnitude (28.0 against 2.5–3.0 mg g^{-1} at c_S = 40 mg l^{-1}). In this case, adsorption is mainly controlled by the dispersion interaction of the alkyl chain of Sulfonol with the carbon surface.

From the results of the adsorption experiments, we estimated the degree of Sulfonol recovery at two Sulfonol concentrations (Table 2). The results obtained show that the degree of Sulfonol recovery decreases in the order TEG > natural coal > initial graphite.

It should be noted out that TEG ensures virtually total recovery of Sulfonol at its concentration in water of up to 20 mg l^{-1}. At c_S = 70 mg l^{-1}, the degree of recovery is 84% (Sulfonol MPC in discharged water is 0.5 mg l^{-1}).

CONCLUSIONS

(1) Natural carbonaceous sorbents have a nonuniform porous structure with predominance of slotlike mesopores. The size of the slotlike mesopores was determined.

(2) The sorbents studied are weakly acidic polyfunctional cation exchangers.

(3) The concentration of active hydrophilic sites on the surface of natural carbonaceous sorbents is estimated, and it is shown that adsorption of the water molecules on the natural coal surface proceeds by the cluster formation mechanism. Natural coal is capable of swelling in water and *n*-hexane vapors.

(4) Thermally expanded graphite shows promise as a sorbent for recovery of anionic surfactants from wastewaters.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemically Deposited Zinc–Nickel Alloys

T. V. Gaevskaya, T. V. Byk, and L. S. Tsybul'skaya

Research Institute of Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received May 6, 2003

Abstract—The mechanism of formation of a zinc–nickel alloy under the conditions of normal and anomalous electrochemical codeposition (accompanied by enrichment of the deposit with nickel or zinc) were studied. The manner in which the composition, structure, and properties of the zinc–nickel alloy vary with the electrolyte composition (nature of ligands and molar ratio of codeposited metals) and deposition conditions (potential and current density) was determined.

The increasing requirements to the functional properties of zinc coatings created a need for development of processes for electrodeposition of zinc alloys [1–4]. One of promising ways to improve the corrosion resistance of zinc coatings is their alloying with nickel, which makes it possible to decrease the thickness of a coating at its same protecting capacity, raise its thermal resistance, and, in some cases, avoid use of toxic cadmium. To solve numerous topical problems concerning the deposition of functional coatings, it is necessary to study the specific features of formation, structure, and properties of electrochemically deposited zinc–nickel coatings.

Despite the great number of studies concerned with this problem, a number of issues are controversial and insufficiently studied. For example, it is not understood completely, in which cases there occurs anomalous codeposition of Zn and Ni, which consists in predominant deposition of the more electronegative metal (Zn) into the alloy [5–13]. The available published evidence and experimental data on the composition of zinc–nickel-plating electrolytes give no way of elucidating properly the ways to control the chemical and phase composition, microstructure, and properties of the alloy by varying the electrolyte composition and deposition conditions. Data on the conditions under which phases of nonequilibrium composition are formed and on structural and phase transformations occurring upon heat treatment of electrolytic zinc–nickel coatings cannot be found in the literature, either.

The aim of this study was to analyze the electrochemical deposition of Zn and Ni from both simple and complex electrolytes, establish the effect of solution composition on the deposition rate, determine the chemical and phase composition of a zinc–nickel alloy, and reveal the relationship between the structure and properties of zinc–nickel coatings.

EXPERIMENTAL

A zinc–nickel alloy was deposited onto a copper or stainless steel support at 20°C from weakly acid chloride solution (I) of composition (M): $ZnCl_2$ 0.09–0.36, $NiCl_2$ 0.09–0.36, and NH_4Cl 3.0, at pH 4.5 ± 0.2, and from electrolyte (II) containing (M): ZnO 0.05–0.15, $NiCl_2$ 0.05–0.20, NH_4Cl 3.0, and $Na_4P_2O_7$ 0.3, at pH 6.5 ± 0.2. The Zn(II) and Ni(II) concentrations in electrolyte (I) were varied within 0.09–0.36 M at constant total concentration of the metal ions (0.45 M) and Zn(II)/Ni(II) ratio of 0.25 to 4.0. The Zn(II) and Ni(II) concentrations in electrolyte (II) were varied from 0.05 to 0.15 M, with their total concentration in the solution of 0.2 M and Zn(II)/Ni(II) ratio in the range from 0.3 to 3.0. The current density was varied within the range from 0.05 to 4.0 A dm^{-2}. The content of Zn and Ni in an alloy was determined by atomic-emission spectroscopy on a SPECTRO FLAME MODULA multiple-element emission spectrometer. The analysis error did not exceed 1%.

The rate of electrochemical deposition of the zinc–nickel alloy was estimated gravimetrically. The polarization dependences of the steady-state cathode current on the electrode potential, used in studying the deposition of a zinc–nickel coating, were measured with a P-5827M potentiostat. As working electrode was used 1-cm^2 copper plate degreased and etched in a dilute (1 : 1) HCl solution; a silver chlo-

ride electrode served as reference, and platinum electrode, as auxiliary electrode.

The microstructure of the films was studied by X-ray diffraction analysis (DRON-3 diffractometer, Cu_{K_α}-radiation). X-ray diffraction patterns were measured at a scanning rate of 1 deg min^{-1} at angles $2\theta = 10°–85°$. The crystal lattice parameters and sizes of coherent domains were determined by the method of Cauchy's approximating function. The structural and phase transformations were studied on zinc–nickel films heated for 1 h in a vacuum at temperatures of 200 to 800°C at a step of 200°C.

The corrosion resistance of the zinc–nickel coatings (thickness 6.5 ± 0.5 μm) was determined by measuring the polarization curves of anodic dissolution of a coating and cathodic evolution of hydrogen. The polarization curves were obtained with a PI-50-1.1 potentiostat in the potentiodynamic mode at potential sweep rate of 2 mV s^{-1}, with fresh portions of a 3% NaCl solution (50 ml) and a new working electrode used. The potentials are given relative to a saturated silver chloride reference electrode. The auxiliary electrode was made of platinum; as working electrode served a steel plate onto which zinc–nickel alloy of varied chemical composition was electrodeposited. The measurements were done at 20 ± 1°C with natural aeration (without stirring the solution). The results were represented as E–log i plots. The linear portions of the cathodic and anodic curves were extrapolated to the stationary potentialof the metal to determine the corrosion current density i_{cor} (μA cm^{-2}) and the dissolution potential E_d (V).

The dependences of the nickel content c_{Ni} in the alloy and the deposition rate V on the Zn(II)/Ni(II) ratio are shown in Figs. 1a and 1b for the electrolytes studied. The curves consist of two portions: (*I*) Zn(II)/Ni(II) = 0.25–1.0 and (*II*) Zn(II)/Ni(II) = 1.0–4.0. Each of these is characterized by a certain type of variation of the nickel content and deposition rate. For electrolyte (I), the Ni content in the forming alloy decreases from 51.6 to 14.0 at.% and the deposition rate increases from 11.2 to 15.9 μm h^{-1}, as the Zn(II)/Ni(II) ratio grows from 0.25 to 1.0 (portion *I*). With the Zn(II)/Ni(II) ratio increasing from 1.0 to 4.0, the deposition rate remains virtually unchanged, whereas the amount of codeposited nickel decreases from 14.0 to 5.0 at.% (portion *II*). It was established that, for electrolyte (I), the ratio c_{Ni}/c_{Zn} of metal concentrations in the alloy is considerably lower than the Ni(II)/Zn(II)ratio in solution. This indicates that the codeposition of Zn and Ni from the solution studied has anomalous character.

For electrolyte (II), the deposition rate increases from 2.2 to 10.0 μm h^{-1} and the Ni content in the coatings decreases from 76.4 to 30.2 at.% with the Zn(II)/Ni(II) ratio growing from 0.3 to 1.0 (Fig. 1, portion *I*). As in the case of electrolyte (I), an increase in the Zn(II)/Ni(II) ratio to 3.0 has no effect on the deposition rate of the alloys, but, at the same time, leads to further decrease (to 12.0 at.%) in the amount of codeposited nickel in them (Fig. 1, portion *II*). It should be noted that, at comparatively low Zn concentration in the solution, when the Ni content in the alloy becomes as high as 76.4 at.%, the zinc–nickel alloy is deposited at a very low rate (2.2 μm h^{-1}). Probably, despite that the hydrogen overvoltage on the alloy of the given composition is nearly the same as that on pure nickel, the potential of its deposition is close to the deposition potential of pure Zn. As a result, the cathodic deposition of such an alloy is accompanied by more intense hydrogen evolution, compared with that observed in a pure solution of nickel salt, and it is this circumstance that leads to a decrease in the deposition rate of the alloy.

To compare the processes in which zinc–nickel alloys are formed from solutions (I) [at molar ratio Zn(II)/Ni(II) = 0.5] and (II) [at molar ratio Zn(II)/Ni(II) = 3.0], a potentiostatic study was carried out in the potential range from 0 to –1.4 V. The chosen Zn(II)/Ni(II) ratio ensured deposition of alloys of the same chemical composition (~20 at.% Ni) under the conventional electroplating conditions (at i_c = 1 A dm^{-2}).

The potentiostatic cathodic polarization curves in Fig. 2 show that the cathodic current density in deposition of a zinc–nickel alloy from solution (I) starts to grow even at –0.75 V (curve *1*), whereas in the case of solution (II), it starts to increase at a more negative potential equal to –0.95 V (curve *2*). It should be noted that, in the case of solution (I), the polarization curve (Fig. 2, curve *1*) shows an inflection in the potential range –1.0…–1.1 V, which, in all probability, is due to a relatively low efficiency of nickel(II) reduction from the given electrolyte. The reduction of zinc(II), which fills the working surface, hinders nickel reduction.

The study of the effect of deposition potential on the chemical composition of zinc–nickel coatings formed demonstrated that the shift of the potential to the cathodic region, from –0.75 to –1.3 V, leads to a decrease in the Ni content from 75.3 to 14.6 at.% in the coatings obtained from solution (I) (Fig. 3, curve *1*). The deposition of zinc–nickel coatings from solution (II) at –0.75 V was not performed, since, according to the potentiostatic curves obtained, the current density is virtually zero under these conditions, and no zinc–nickel alloy is formed. Therefore, for the initial deposition potential from a given solution was taken the potential corresponding to the onset of formation of a zinc–nickel alloy ($E = -0.95$V). With potential varied from –0.95 to –1.3 V, the Ni content in the coatings obtained from solution (II) decreased from 89.2 to 21.2 at.% (Fig. 3, curve *2*). The dashed lines *1*' [for solution (I)] and *2*' [for solution (II)] in Fig. 3 divide the alloy deposition process into two regions of normal and anomalous codeposition. These lines indicate that normal deposition (predominantly Ni is deposited into the alloy) in the case of solution (II) (virtually the entire curve *2* lies above dashed line *2*'), and anomalous deposition (predominantly zinc is included in the alloy), in the case of solution (I) (virtually the entire curve *1* lies below dashed line *1*').

The influence of the current density on the chemical composition of zinc–nickel coatings deposited from the above two electrolytes was studied at Zn(II)/Ni(II) = 0.5 for electrolyte (I) and Zn(II)/Ni(II) = 3.0 for electrolyte (II). Figure 3b shows that raising the current density from 0.05 to 0.25 A dm^{-2} leads to a dramatic decrease in the Ni content in the coatings; with the current density raised further, to 4.0 A dm^{-2}, a slight increase, from 17.7 to 22.3 at.%, in the nickel content was observed in the case of solution (II) (Fig. 3b, curve *2*) and a more considerable increase, from 14.2 to 28.0 at.%, in the case of solution (I) (Fig. 3b, curve *1*).

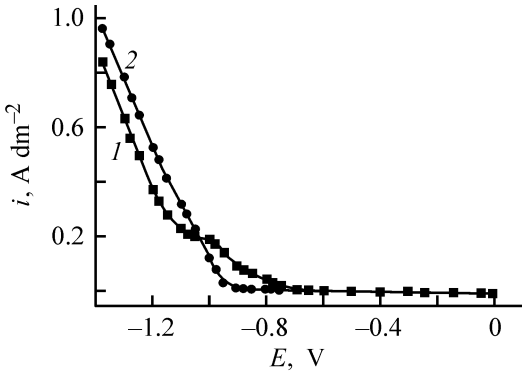

Fig. 2. Potentiostatic cathodic polarization curves for deposition of zinc–nickel alloy from (*1*) solution (I) and (*2*) solution (II). (*i*) Current density and (*E*) deposition potential. Zn(II)/Ni(II) molar ratio: (*1*) 0.5 and (*2*) 3.0; the same for Figs. 3, 4.

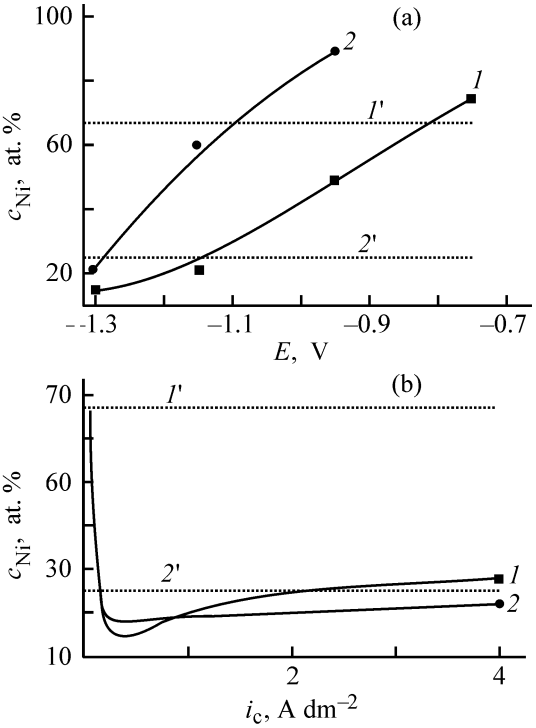

Fig. 3. Nickel content c_{Ni} in the alloy vs. (a) deposition potential E and (b) current density i_c for (*1*) solution (I) and (*2*) solution (II). The lines separating the regions of normal and anomalous deposition of the zinc–nickel alloy: (*1*') for solution (I) and (*2*') for solution (II).

Zinc-enriched coatings (with Ni content lower than that in solution) can be obtained from solution (I) over virtually the entire range of current densities studied. At the same time, alloys with content of Ni close to that in solution (region of normal deposition above dashed line *2*') and those with Ni content lower than that in solution (region of anomalous

Table 1. Structure of Zn–Ni films deposited from electrolytes (I) and (II)

deposition below *2'* line) are deposited from solution (II).

It is not well understood, especially for solution (I), why the Ni content grows with current density increasing from 0.25 to 4.0 A dm^{-2} (Fig. 3b). The possible reason is the higher surface activity of zinc ions, compared with nickel ions [7]. This results in a predominant discharge of zinc ions at the cathode at low current densities (0.25 A dm^{-2}), to which corresponds a dramatic decrease in the Ni content in the alloys. As the rate of zinc ion reduction increases, the concentrations of ions in the dense part of the double layer are redistributed: the concentration of zinc ions decreases owing to diffusion hindrance, whereas that of nickel ions increases. As a result, with current density increasing to 4.0 A dm^{-2}, the alloy is enriched with nickel.

Thus, the anomalous deposition of the Zn–Ni alloys, accompanied by their enrichment with zinc, occurs under steady-state conditions of electrochemical deposition (i_c = 1.0 A dm^{-2}) in the case of solution (I), irrespective of the concentrations of ions of metals being codeposited. At the same time, in the case of solution (II), it occurs solely at Zn(II)/Ni(II) ≥ 1. Irrespective of the composition of zinc- and nickel-plating solutions, the mechanism of codeposition of Zn and Ni can be changed from anomalous to normal by varying the deposition conditions (potential or current density). For example, under certain conditions [at Zn(II)/Ni(II) = 0.3 in solution and i_c = 1.0 A dm^{-2}; or at Zn(II)/Ni(II) = 3.0 and E = –0.95… –1.3 V or i_c = 0.05–0.15 A dm^{-2}], the codeposition of Zn and Ni from solution (II) occurs by the normal mechanism. Presumably, the codeposition from the above electrolyte is favored by the lower difference between the redox potentials of zinc(II) and nickel(II) [14].

An X-ray diffraction study demonstrated that the composition of an electroplating solution strongly affects the structure of zinc–nickel films. The Zn–Ni alloys obtained from solution (I) with low Ni content (up to 2 at.%) are isostructural to crystalline Zn, with the crystal lattice parameter in agreement with the published value. The alloys containing 5.0 to 14.0 at.% Ni consist of two phases: crystalline Zn and Ni_5Zn_{21} intermetallic compound (γ-phase), with the fraction of crystalline Zn decreasing and that of the γ-phase increasing when the content of Ni becomes higher. With the nickel content in the films growing from 20.7 to 51.6 at.%, the phase of crystalline Ni appears, along with the above intermetallic compound, and the fraction of the γ-phase decreases, whereas the fraction of crystalline Ni increases (Table 1).

The zinc–nickel alloys deposited from solution (II) containing 12.0 to 76.4 at.% Ni have homogeneous structure (Table 1). In contrast to the case of solution (I), neither crystalline Zn, nor the γ-phase appear in the alloy containing 12.0 at.% Ni, with only a single δ-phase formed, Ni_3Zn_{22} intermetallic compound with composition corresponding to a Ni content in the alloy equal to 12.0 at.%.

An increase in the content of Ni in the films to 19 at.% leads to formation of the Ni_5Zn_{21} intermetallic compound with crystal lattice parameter corresponding to the published value. At Ni content in the films of up to 33.4 at.% Ni, a solid solution of Ni in Ni_5Zn_{21} is formed, and at higher Ni content (68.0 and 76.4 at.%), an equilibrium solid solution of Zn in Ni (α-phase). An X-ray phase analysis demonstrated that, with increasing Ni content in the films, the grain size decreases from hundreds of nanometers (100–150 nm for Zn) to several nanometers (2–5 nm for zinc–nickel alloy containing 76.4–89.2 at.% Ni).

The data on how the composition of films changes in the course of their growth from solutions (I) and (II) demonstrated that the composition of a zinc–nickel film is inhomogeneous across its thickness (Fig. 4). The content of Ni decreases with the thickness of a deposited film increasing to 1 μm, with the composition remaining comparatively unchanged at thicknesses exceeding 1 μm. This is probably due to the fact that, in the initial stage, mostly Ni is deposited as a more inert metal. Then, the forming Ni monolayer can capture zinc adatoms, which results in prephase deposition of Zn and its subsequent predominant deposition into the alloy [8–13]. It was shown that the change in the Ni content observed in the course of film growth, is accompanied by a change in the phase composition of the films. For example, the films less than 0.3 μm thick consist of an X-ray-amorphous solid solution of Zn in Ni and a minor amount of finely crystalline Zn.

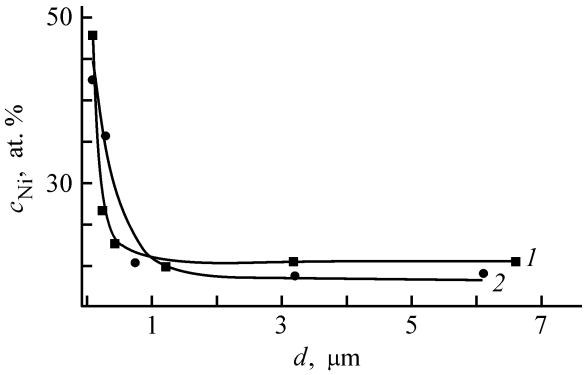

Fig. 4. Nickel content c_{Ni} in the alloy vs. coating thickness d for (*1*) solution (I) and (*2*) solution (II).

It was found that, at low current densities (i_c = 0.05 A dm^{-2}) and low polarization potentials (E = –0.75…–1.15 V), X-ray-amorphous or poorly crystallized solid solutions of Zn in Ni are formed. Presumably, this is due to the nonequilibrium conditions of alloy electrocrystallization. Probably, the hydrogen evolution, accelerated at higher content of Ni in the alloy, also plays a certain role. A combination of the processes of growth of the metallic phase and its hydrogenation impede the normal growth of crystallites.

A study of the structural and phase transformations in the zinc–nickel films of varied composition, heat-treated in a vacuum, demonstrated the complexity of the occurring processes. On heating the initial samples of Zn–Ni films at 200–800°C in a vacuum, there appear phases not revealed at room temperature: $NiZn_3$ intermetallic compound and a solid solution of Ni in Zn. On being heated at 400–800°C, the alloys are enriched with Ni, which is probably due to the formation of the initial zinc–nickel films under nonequilibrium conditions. As a result, evaporation of Zn from intermetallic compounds of various compositions (Ni_5Zn_{21}, NiZn, and Ni_3Zn_{22}) with the subsequent formation and dissociation of nonstoichio-

Table 2. Effect of the chemical and phase composition of Zn–Ni coatings on their corrosion resistance

Solution	c_{Ni}, at.%	Phase composition	E_p, V	i_{cor}, μA cm^{-2}
(I)	–	Zn (crystalline)	–1.00…–1.02	12.0
	5.0–14.0	Zn (crystalline) Ni_5Zn_{21} (γ-phase)	–0.98…0.96	5.0–5.5
	20.7–51.6	Ni (crystalline) Ni_5Zn_{21} (γ-phase)	0.88…–0.85	2.0–2.5
(II)	12.0	Ni_3Zn_{22} (γ-phase)	–0.70	0.8–1.0
	19.0	Ni_5Zn_{21} (δ-phase)	–0.70	0.1–0.2
	33.4	Solid solution of Ni in Ni_5Zn_{21}	–0.68	0.3–0.4
	68.0–76.4	Solid solution of Zn in Ni (α-phase)	–0.65…–0.63	0.2–0.3

metric compounds, and also that from solid solutions, occur at lower temperatures, compared with those indicated by the phase diagram of a zinc–nickel metallurgical alloy [15].

An electrochemical study demonstrated that, with increasing Ni content in the alloy, the potentials of the onset of dissolution of zinc–nickel coatings in a 3% NaCl solution are shifted toward anodic potentials, and the corrosion currents, as a rule, decrease (Table 2).

It was established that the corrosion-electrochemical behavior of zinc–nickel film coatings depends not only on the chemical, but also on the phase composition. The lowest corrosion currents (0.1–0.2 μA cm^{-2}) are characteristic of single-phase films [compositions with a single intermetallic compound Ni_5Zn_{21} (γ-phase) or Ni_3Zn_{22} (δ-phase), a solid solution of zinc in nickel (α-phase), or a solid solution of nickel in Ni_5Zn_{21}]. The heterogeneous phase composition of a coating (crystalline Zn or Ni present along with the γ-phase) leads to a decrease in its corrosion resistance (Table 2).

CONCLUSIONS

(1) The conditions for occurrence of normal or anomalous codeposition accompanied by enrichment of the deposit with, respectively, nickel or zinc were determined from the results obtained in a study of the influence exerted by the solution composition (nature of ligands and molar ratio of codeposited metals) and deposition conditions (potential and current density) on the chemical composition and deposition rate of Zn–Ni films. This opens up opportunities for varying widely the Ni content in the coatings (from less than 2 to 90 at.%).

(2) The influence exerted by the composition of a solution for electrodeposition of zinc–nickel films on their microstructure and phase composition were studied [formation of films with homogeneous phase composition (Ni_5Zn_{21} and Ni_3Zn_{22} intermetallic compounds and solid solutions of Zn in Ni and Ni in Ni_5Zn_{21}) from electrolyte (II) under varied deposition conditions and formation of two-phase films (Ni_5Zn_{21} in a mixture with crystalline Zn or Ni) from electrolyte (I)]. The conditions for formation of nonequilibrium X-ray-amorphous solid solutions of Zn in Ni at low current densities (i_c = 0.05 A dm^{-2}), low polarization potentials (E = –0.75…–1.15 V), or small film thicknesses (less than 0.3 μm) were determined.

(3) It was shown that zinc–nickel alloy coatings of homogeneous composition (Ni_5Zn_{21} intermetallic compound, solid solutions of Zn in Ni and Ni in Ni_5Zn_{21}) exhibit enhanced corrosion resistance.

Abstract—The possibility of depositing black cobalt coatings from fluoride-containing electrolytes based on cobalt sulfate was studied.

Black cobalt coatings, which are not general-purpose coatings [1], are, nevertheless, in sufficient demand by various industries.

Black cobalt has light absorption coefficient of 92–96%, and, therefore, it is occasionally used instead of black chromium coatings [2]. Owing to their high corrosion resistance, cobalt oxide compounds are used as protecting decorative coatings for iron [3]. In recent years, such compounds have received rather wide acceptance as components of a nickel-based cathode material [4–6] in chemical power sources and also in solar cells [7]. In additiion, they are also used as an effective and selective catalyst for a number of reactions [8].

Cobalt oxide compounds are conventionally obtained by the thermal method [9] and also by electrochemical deposition from electrolytes based on cobalt sulfate, acetate, chloride, or nitrate [10]. At the same time, with electrolytes containing fluoride ions as ligands, the technology for obtaining oxide compounds of a number of transition metals can be substantially simplified through use, under these conditions, of a bifunctional electrochemical system electrode | film | electrolyte [11], whose central phase contains low- or high-charged forms of a metal in question. At the electrolyte | film interface, the film itself is formed through electrolytic reduction of ions of the discharging metal (or electrolytic oxidation of the metal) to an intermediate oxidation state and dissolution of the film in the electrolyte. At the electrode | film interface, the film substance is consumed for its further reduction to metal or oxidation to the highest oxidation state. As a result of these simultaneous processes, the film is permanently in the state of dynamic equilibrium. As a rule, such oxide compounds have reproducible composition; depending on the process conditions, they can be obtained either as compact film coatings, usually black, or as powders [12].

The aim of this study was to synthesize electrochemically cobalt compounds of oxide nature, to identify their composition, and to analyze their properties.

EXPERIMENTAL

Deposits of black cobalt were obtained on cathodes made of 1Kh18N10T steel, in a 250-ml polyethylene cell. The deposition rate ($g\ A^{-1}\ h^{-1}$) was determined from an increase in the precipitate weight during electrolysis. In the experiments, solutions containing chemically pure $CoSO_4$ and $(NH_4)_2SO_4$, and also various concentrations of special-purity hydrofluoric acid, were used. A solution containing 1.0 M of chemically pure Na_2SO_4 served as supporting electrolyte.

The deposits were obtained as powders and as thin films adhering to a support. In the first case, the deposit was separated from the cathode (scraped off), thoroughly washed with distilled water to remove trace amounts of the electrolyte, and dried to constant weight over phosphorus(V) oxide in a desiccator under inert atmosphere. The dried deposit consisted of a stable compound, which did not change its composition upon further storage in air. In the second case, 7–10-μm-thick compact films were obtained, which ruled out any contact of the supporting electrolyte with the cathode material, since the coating was nonporous. The electrodes covered by black cobalt films were washed with distilled water and then dried in air to constant weight.

The composition of the electrochemically synthesized cobalt oxide compounds was subjected to chem-

0.6	83.5	55.0	16.0	2.0	5.8

* $O_{2\,tot}$ is the total content of O_2, determined from NAA data.
** According to DTG data.

ical phase analysis, which made it possible to determine the total amount of cobalt and its content in the form of metal [13].

A thermogravimetric analysis was carried out on an Orion derivatograph, with samples heated in air to 1000°C at a rate of 5 deg min^{-1}.

The total content of oxygen (including that contained in H_2O molecules and OH^- groups) was determined by neutron activation analysis (NAA) [14]. The relative error of the method was 1.5%.

The porosity of the coatings was found by placing a filter paper impregnated with a mixture of $K_3Fe(CN)_6$, KCl, and NH_4Cl on their surface (in this case, a black cobalt coating was deposited on St.3 steel).

The microhardness of black cobalt coatings was determined on a PMT-3 hardness gage with indenter load of 20 g.

Chronovoltammograms were recorded using a PI-50-1 pulsed potentiostat and a PDA1-004 laboratory compensation X–Y recorder at a potential sweep rate of 0.002–0.1 V s^{-1}, with compensation of the I-R error. In the experiments, a three-electrode glass cell

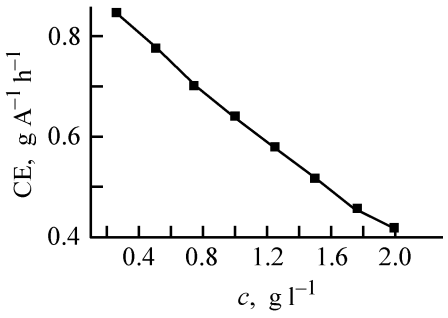

Fig. 1. Current efficiency (CE) by the composite product vs. concentration c of hydrofluoric acid in the electrolyte.

was used, in which a platinum plate of area 4 cm^2 served as auxiliary electrode. A plate of stainless steel, with area of 0.5 cm^2, pressed-in in Teflon was used as working electrode. The current density was related to the geometric surface area of the electrode. Before a measurement, the working electrode was scraped with fine emery paper, polished with filter paper, degreased with Vienna lime, and activated in diluted HCl, which ensured good reproducibility of the results obtained. A saturated calomel electrode served as reference. The potentials are given relative to a standard hydrogen electrode. All the experiments were carried out at 20 ± 0.1°C.

The optimal composition of the electrolyte and optimal conditions of electrolysis were determined in preliminary experiments. Electrolyte composition (g l^{-1}): $CoSO_4 \cdot 7H_2O$ (in terms of the metal) 10, $(NH_4)_2SO_4$ 25, and HF (40%) 1.0. The cathode current density was 40–60 A dm^2, the electrolyte temperature was 18–25°C. The duration of electrolysis was determined by the necessity for obtaining either a powder or a compact film.

Raising the current density and electrolysis duration favors deposition of a powder-like deposit. At a current density of 40–60 A dm^2, 7–10-μm-thick compact films are electrodeposited within 5 minutes. This electrolyte and these electrolysis conditions were selected as basic experimental conditions.

The dependence of the current efficiency by the composite deposit containing cobalt oxide compounds on the concentration of hydrofluoric acid is shown in Fig. 1. The amount of black cobalt, i.e., the current efficiency by the product decreases almost linearly with increasing concentration of fluoride ions in the electrolyte.

The composition of the compound is mainly determined by the concentration of fluoride ions. Raising their concentration in the electrolyte results in an increase in the content of both the total cobalt, Co_{tot}, and metallic cobalt, Co_{met}, and, correspondingly, in a decrease in the content of the oxide phase (see table). It follows from these data that the composition of the compound obtained can be rather easily controlled by varying the concentration of fluoride ions, which changes the amount of oxygen in the product and thus determines the degree of deviation from its stoichiometric composition.

The resulting films are black, being comparable with black chromium coatings in their light absorption. At the same time, the microhardness of black cobalt films varies within 250–300 MPa, which is

much lower than that of black chromium films. It is necessary to point out that, even at small coating thickness not exceeding 4–6 μm, no pores are found in the coating, i.e., the films are rather dense.

The chronovoltammogram characterizing the electrolytic reduction of cobalt(II) ions, accompanied by deposition of its oxide compounds, is shown in Fig. 2. Raising the concentration of fluoride ions at constant concentration of cobalt(II) ions and fixed solution pH leads to a shift of the chronovoltammograms in the negative direction along the potential axis. In this case, the limiting current at potentials of 1.25 to 0.5 V also decreases. A similar phenomenon has been observed in formation of complexes, whose dissociation is strongly hindered kinetically [15, 16], and also in partly complexed systems, which arise when minor amounts of ligands forming complexes with metal ions are added to a system [17].

As noted above, in this case, the content of metallic cobalt in the deposits increases, and the amount of the oxide phase decreases (see table); the color of the deposit changes to dark gray. Black cobalt is deposited in the range of electropositive potentials.

Raising the potential sweep rate leads to an increase in the limiting currents of electrolytic reduction of cobalt(II) ions in the solution of optimal composition. The dependence of I on $V^{1/2}$ is approximated by straight lines (Fig. 3), which points to the diffusion kinetics of the process characterized by this part of the polarization curve. At constant rate of polarization variation, $|dE/d\tau|$, the limiting current in the chronovoltammogram is proportional to the initial concentration of cobalt(II) ions in the electrolyte, which is attributable to direct discharge of the reacting species under diffusion limitation without any preliminary chemical stages.

The contribution of diffusion and migration to the total mass transfer of electrically active species was estimated by measuring the polarization of an electrode in solutions containing or not containing a supporting electrolyte. When the supporting electrolyte was added to the solution, the limiting currents in the electrolytes with various concentrations of fluoride ions decreased to virtually the same value (Fig. 2). This suggests that a substantial contribution to the mass transfer in electrolytic reduction of cobalt(II) ions is made by the migration component, whose presence predetermines the comparatively high limiting current densities in the electrolyte in electrolytic reduction of cobalt(II) ions from the fluoride-containing electrolyte.

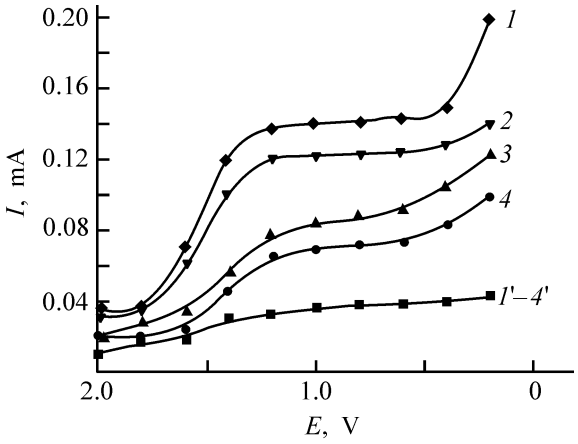

Fig. 2. Chronovoltammograms of electrolytic reduction of Co(II) ions at potential sweep rate of 5 mV s^{-1}. (I) current and (E) potential. Concentration of hydrofluoric acid in the electrolyte (g l^{-1}): (*1*) 0.05, (*2*) 0.1, (*3*) 0.2, (*4*) 0.4, (*1'–4'*) the same in the presence of a supporting electrolyte.

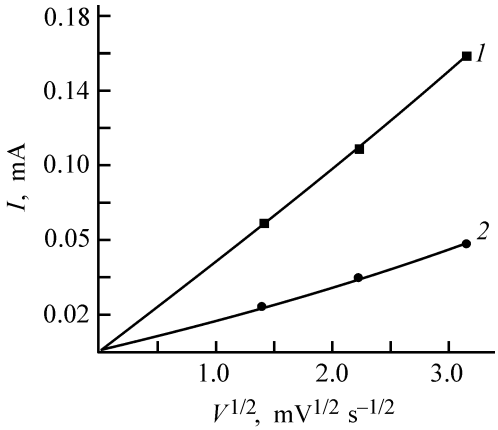

Fig. 3. Limiting current I in the chronovoltammogram of the solutions containing 0.05 g l^{-1} of hydrofluoric acid (*1*) in the absence and (*2*) in the presence of a supporting electrolyte vs. the potential sweep rate $V^{1/2}$.

CONCLUSIONS

(1) Conditions for obtaining black cobalt (composed of cobalt oxide compounds) in the form of compact films or powder were developed.

(2) It was established that the current efficiency and the composition of black cobalt are determined by the concentration of fluoride ions in an electrolyte.

(3) It was found that the electrodeposition of black cobalt occurs at positive potentials and is controlled by diffusion and migration processes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrolytic Recovery of Cadmium from Cyanide Washing Solutions on Filtering Carbon-Graphite Electrodes

V. K. Varentsov

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received April 17, 2003

Abstract—Electrorecovery of cadmium(II) on filtering carbon-graphite electrodes from washing cyanide solutions formed in cadmium-plating of articles in a cyanide electrolyte was studied. The effect of the dilution factor of the supporting electrolyte on the run of cathodic polarization curves, pH value, and solution resistivity was analyzed. The influence exerted by the efficiency of cadmium(II) recovery on the carbon-graphite electrodes was studied in relation to current density, solution flow rate, cadmium(II) concentration in solution, dilution factor of the supporting electrolyte, and material of the carbon-graphite electrode. The possibility of dissolution of cadmium deposited onto a filtering carbon-graphite electrode via anodic dissolution or because of the operation of a short-circuited electrochemical system constituted by the carbon-graphite electrode, cadmium, and cyanide solution was considered.

Cadmium coatings are used in various industries (machine-building, electronic, radio, etc.). Despite the attempts to replace these coatings, they remain irreplaceable in some cases because of their special properties [1]. The necessity for substituting cadmium-plating electrolytes is due to the high toxicity of cadmium compounds. The best performance, especially in deposition of coatings on articles of complex configuration, is exhibited by cyanide cadmiumplating electrolytes. The fact that complex Cd(II) compounds are rather stable leads to difficulties in selecting methods for detoxication of washing solutions, wastewater, and spent electrolytes. In most cases, the methods used in industry and recommended for implementation fail to ensure high degree of solution purification and recycling of recovered cadmium [2, 3]. It should be noted that cadmium is a rare metal and its cost is rather high. Therefore, it is necessary to develop, together with methods for detoxication of cadmium-containing solutions, also techniques ensuring recycling of cadmium. Of indubitable interest in this context are electrochemical methods and, in particular, electrolysis with filtering carbon-graphite electrodes, which make it possible to detoxicate solutions and obtain compact pure metal reusable in fabrication of soluble anodes for electroplating baths or in electrolyte preparation [4, 5]. The present communication reports on a study of electrorecovery of Cd(II) from cyanide solutions that model washing water in relation to solution composition, electrolysis conditions, and type of a carbon filtering cathode.

EXPERIMENTAL

An industrial cadmium-plating electrolyte of composition ($g\ l^{-1}$): CdO 50, NaCN 90, Na_2SO_4 30, NaOH 5, $NiSO_4$ 1, dextrin 1, was chosen for study. The supporting electrolyte contained all the above components except cadmium. To obtain a necessary concentration of Cd(II), the supporting electrolyte was diluted by a factor of *n* and a certain amount of the industrial cadmium-plating electrolyte of the above composition was added. The electrolytic cell employed and the installation for electrochemical studies with filtering carbon-graphite electrodes (FCE) were described in [5]. The cathode was made of an NTM-100 material, its overall surface area was 30 cm^2; as anode served a grid made of platinum-plated titanium, as anolyte was used a 2% solution of Na_2SO_4. The electrode spaces were separated by an ion-exchange membrane of the MK-40 type.

The electrical conductivity of solutions was measured with a VM-503 ac bridge, and the pH value, with an OR-265/1 pH-meter. Polarization curves were measured on a cadmium microelectrode 1 mm in diameter with surface freshened in the electrolyte so-

lution, using the procedure and setup described in [6] and an RA-2 polarograph, with potential sweep rate of 120 mV min^{-1}.

The efficiency of Cd(II) electrorecovery was evaluated by the following parameters: degree of recovery $\alpha = (c_0 - c_\tau)/c_0$ and current efficiency by cadmium

$$CE = [(c_0 - c_\tau)V \times 26.8]/(I\tau M_{eq}),$$

where c_0 and c_τ are the initial and final concentrations of cadmium in solution (g l^{-1}); V, the solution volume; I, the current at which electrolysis is carried out (A); τ, the experiment duration (h); 26.8 A h mol^{-1}, the Faraday constant; M_{eq}, the molar mass of the metal equivalent.

The influence exerted by the solution composition and the solution flow rate on the electrolytic recovery of Cd(II) was studied in the direct-flow mode. The solution from which Cd(II) was recovered was passed a single time through a cell with a carbon-graphite cathode and sampled at the outlet of this cell. The samples were analyzed for the content of Cd(II) by the atomic-absorption method.

In accordance with the previously suggested approach, which was used in the development of methods for recovery of metals from washing solutions formed in electrodeposition processes [4], polarization studies were carried out and the effect of dilution of the supporting cadmium-plating electrolyte on its electrical conductivity and pH value was studied, in order to assess the feasibility of Cd(II) electrorecovery. Investigations of this kind were necessitated by the fact that articles are washed in a non-flow-through bath. This leads to gradual accumulation of metal ions and components of the supporting electrolyte in the washing solution. If a working electrolyzer is connected to the washing bath, there will occur permanent recovery of Cd(II) introduced with the articles, with the result that components of the cadmium-plating electrolyte accumulate in the washing bath.

It is known that the efficiency of electrorecovery of metals on FCE is determined not only by the current mode, but also by the ratio of electrical conductivities of the electrolyte (χ) and the carbon filtering electrode (χ_{FCE}), by potentials of metal deposition and hydrogen evolution, and by the length of the plateau of the limiting diffusion current of metal deposition.

It can be seen from Fig. 1 that, with the supporting electrolyte diluted, the electrical resistivity of the solution decreases and the pH value varies within unit range (from 12 to 11 upon 100-fold dilution of the supporting electrolyte). The polarization curves in Fig. 2 demonstrate that, with the solution diluted, the stationary zero-current potential shifts in the positive direction and the plateau of the limiting current of Cd(II) electrodeposition becomes longer. Analysis of the data in Figs. 1 and 2 indicates that cadmium(II) can be electrolytically recovered from washing solutions formed in cadmium-plating of articles in a cyanide electrolyte.

The dependences of the degree of recovery and current efficiency by cadmium on the dilution factor of the supporting electrolyte at constant initial concentration of cadmium(II), shown in Fig. 3, indicate that the solution composition strongly affects the efficiency of cadmium electrodeposition. The best process parameters are obtained at supporting electrolyte dilutions by a factor of 5 to 15. Making this parameter greater or smaller leads to a decrease in the degree of Cd(II) recovery and current efficiency by Cd(II). With the dilution factor changing from 22 to 100 the process parameters decrease only slightly.

The plot describing the dependence of the degree of Cd(II) recovery on current density (Fig. 3b) shows that Cd(II) recovery grows with the current density increasing to 500–1000 A m^{-2}. With the current den-

sity increasing further (to 5000 A m^{-2}), the degree of Cd(II) recovery not only fails to increase, but even decreases somewhat, whereas the current efficiency falls dramatically. For example, the current efficiency is approximately 36% at 1000 A m^{-2}, and only about 4% at 5000 A m^{-2}. Under these conditions, the main amount of electricity is apparently consumed for hydrogen evolution. Therefore, it is appropriate to perform electrolytic recovery of Cd(II) at current densities not exceeding 1000 A m^{-2}.

Figure 3c shows the results characterizing the effect of Cd(II) accumulation in the washing solution on the parameters of the process of Cd(II) electrorecovery. It is of interest that the degree of Cd(II) recovery is the highest under the chosen process conditions at Cd(II) concentrations of about 100 mg l^{-1}. Apparently, the fraction of current consumed for concurrent processes, the main of which is reduction of hydrogen ions, is higher at lower initial concentrations of Cd(II), which is confirmed by a decrease in the current efficiency by cadmium. At Cd(II) concentrations exceeding 100 mg l^{-1}, the decrease in the degree of cadmium(II) recovery is presumably due to a shift of the place at which cadmium is deposited on the FCE to the front side of the electrode. As a result, the fraction of the electrode surface onto which cadmium is deposited decreases.

The parameters of Cd(II) electrorecovery largely depend on the rate at which the solution flows through the electrode (Fig. 3d). Making the solution flow rate lower, which is equivalent to longer residence time of the solution within the electrode, leads to a significant increase in the degree of Cd(II) recovery. For example, the degree of Cd(II) recovery is as high as 95% at a solution flow rate of 0.01 ml s^{-1} and a single pass of the solution through the electrode volume. With the solution flow rate increasing to 0.4 ml s^{-1}, the degree of recovery falls to 5%.

The possibility of using various nonwoven fibrous carbon materials (FCM) for recovery of Cd(II) was studied. The results obtained are listed in the table, whence follows that all the materials considered can be used in electrorecovery of Cd(II) from cyanide solutions. Preferable materials are Mtilon and VVP-66-95 wad. The characteristics of the materials represented in the table were described in [5].

The maximum amount of cadmium, which can be precipitated without impairing the output capacity of the process was 10–15 kg kg^{-1} of the material. In order to assess the possibility of recycling of the recovered cadmium (to be used as the material of a soluble anode in a cadmium-plating bath) and FCM regeneration, cadmium deposited onto FCE was dissolved in a cyanide electrolyte. The dissolution was done at anode current density of 0.5 A m^{-2}, with cadmium dissolved without any difficulties.

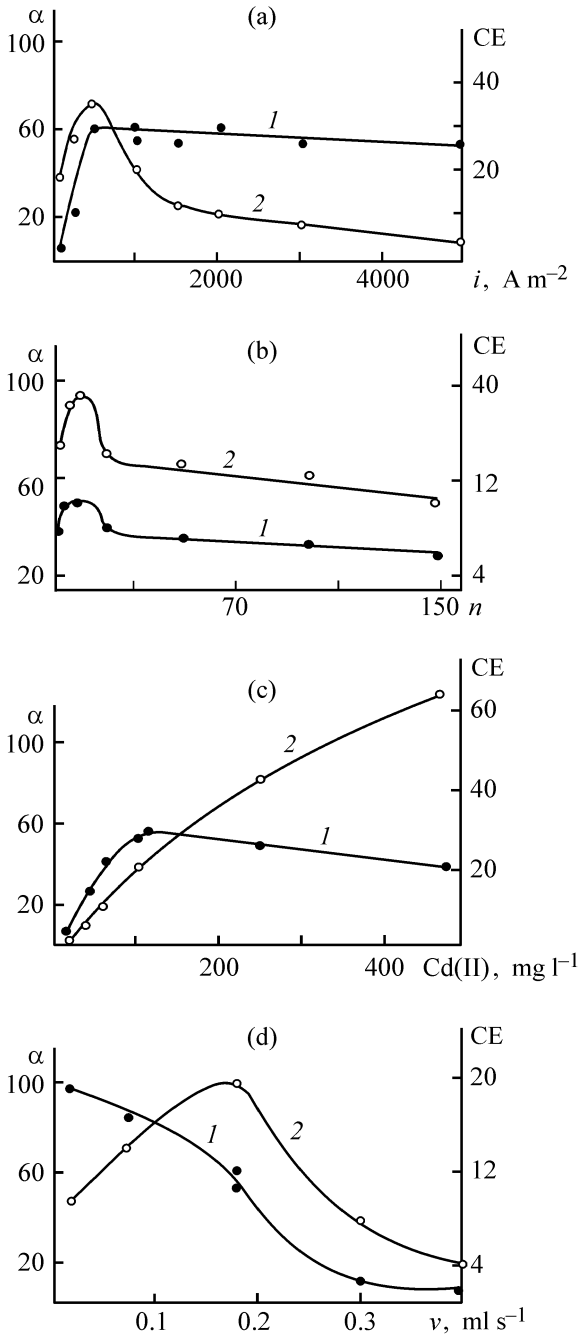

Fig. 3. (*1*) Degree of recovery, α, and (*2*) current efficiency CE by cadmium vs. (a) current density *i*, (b) dilution factor *n* of the supporting electrolyte, (c) initial Cd(II) concentration in solution, and (d) solution flow rate v. Initial Cd(II) concentration in solution 100 mg l^{-1}, cathode current density 500 A m^{-2}, solution flow rate 0.2 ml s^{-1}.

In addition, it was established that effective dissolution of cadmium in flowing electrolyte is pos-

KNM	68	7.8	63.3

sible without applying any external voltage because of the operation of a short-circuited electrochemical system constituted by cadmium, electrolyte solution, and FCM. The possibility of cadmium dissolution through operation of this short-circuited system is ensured by the substantial difference in standard potential between the cadmium and carbon-graphite electrodes, which varies within the range 0.8–1.1 V (depending on the electrolyte composition).

In both cases, cadmium deposited on an FCM dissolves both in the cadmium-plating electrolyte and in the supporting electrolyte containing no Cd(II), to give a cadmium-plating electrolyte. In all cases, the carbon electrode can be reused without impairing the characteristics of the Cd(II) electrorecovery process.

In order to verify the results obtained, an experiment modeling the electrorecovery of Cd(II) in the case of an automated cadmium-plating line was carried out. The operation parameters of the automated line, washing procedure, and the main galvanic process were taken from industry. Into a solution circulated between the electrolyzer and the tank at a rate of 0.2 ml s^{-1} were introduced, at regular intervals of time (20 min), portions of the cadmium-plating electrolyte of composition mentioned above. The electrorecovery of Cd(II) was carried out at current densities in the range 500–1000 A m^{-2}, the rise in the Cd(II) concentration in solution, modeling a single washing of articles, was varied from 42 to 115 mg l^{-1}. The suggested process modes ensure that the concentration of Cd(II) in solutions in the catching bath is maintained constant at 20–40 mg l^{-1}. This indicates that the whole amount of Cd(II) introduced with articles into the washing bath is recovered between successive article washings.

On the basis of the results obtained, tests were performed at a machine-building plant. The electrolytic recovery of Cd(II) was done from the solution of a catching bath. The suggested modes ensured a more than 99% recovery of Cd(II), which makes it possible to recommend the process of electrolytic recovery of Cd(II) from washing cyanide solutions onto filtering carbon electrodes for industrial use.

CONCLUSIONS

(1) A study of the effect of dilution of the supporting cadmium-plating cyanide electrolyte on the cathodic polarization curve, pH value, and electrical resistivity of the solution led to a conclusion that effective recovery of Cd(II) from washing solutions formed in cadmium-plating of articles in a cyanide electrolyte is possible.

(2) It was shown that the efficiency of Cd(II) electrorecovery, characterized by the degree of Cd(II) recovery and current efficiency, from solutions modeling washing cyanide solutions depends on current density, solution flow rate, dilution factor of the supporting electrolyte, initial concentration of cadmium(II) in solution, and the type of a FCM used.

(3) By varying the parameters mentioned above, a high degree of Cd(II) recovery can be achieved; the amount of cadmium deposited onto a carbon-graphite electrode without impairing the efficiency of its recovery is 10–15 g g^{-1} of fibrous carbon material.

(4) Dissolution of cadmium deposited onto a filtering carbon-graphite electrode, caused by anodic polarization and by operation of a short-circuited electrochemical system in the cadmium-plating or supporting electrolyte, enables recycling of cadmium and multiple use of the fibrous carbon material.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Modification with Manganese of Anodic Layers Containing Tungsten Oxides

I. V. Lukiyanchuk, V. S. Rudnev, E. S. Panin, T. A. Kaidalova, and P. S. Gordienko

Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received April 14, 2003

Abstract—The influence exerted by addition of manganese(II) acetate or potassium permanganate to an electrolyte with $Na_2H[PW_{12}O_{40}]$ on the content of manganese in tungsten-containing anodic-spark layers on aluminum alloy was studied.

The method of anodic-spark deposition makes it possible to form on the surface of rectifying metals a coating based on the components of a metal (alloy) being treated and of the electrolyte. One of ways to obtain anodic-spark layers of complex composition is to use electrolytes with complex anions, e.g., isopolyoxoanions (IPA) and heteropolyoxoanions (HPA) or to create conditions for their formation in solution [1–3].

It is known [4–6] that polyoxoanions can react both with a metal being anodized, so that it passes into solution, and with cations and anions of the electrolyte. Incorporated into negatively charged complexes, all the components mentioned can be delivered to the anode surface. High-temperature interactions of the components of the anodic film and electrolyte, including thermolysis of compounds at the anode, are possible in the vicinity of spark and microarc discharges. The coatings contain conversion products insoluble in a given electrolyte: salts, oxides, or glasses on their base.

In [7], formation of coatings on an AMtsM alloy in an electrolyte with $Na_2H[PW_{12}O_{40}]$[1] was studied, and anodic layers containing crystalline $WO_{2.9}$ were obtained.

The aim of the present study was to analyze specific features of manganese incorporation into coatings formed in the $Na_2H[PW_{12}O_{40}]$ electrolyte and to determine how presence of manganese in the cation or anion of a salt being added affects the coating composition.

[1] In [7], the salt composition was erroneously indicated as $N_2H[PW_{12}O_{42}]$.

Anodic layers on samples of AMtsM aluminum alloy (97% Al, 1–1.6% Mn) were formed galvanostatically at a current density of 1–10 A dm^{-2} in the course of 10 min. Sample preparation, electrochemical cell design, systems for cooling and stirring the electrolyte, thyristor unipolar power source, and methods for determining the phase and elemental composition have been described previously [7, 8]. The electrolytes were prepared from distilled water and the reagents $Na_2H[PW_{12}O_{40}] \cdot 9H_2O$ (chemically pure), $Mn(CH_3COO)_2 \cdot 4H_2O$ (analytically pure), and $KMnO_4$ of pure grade. All the electrolytes were prepared by pouring solutions together at room temperature. The base electrolyte no. 1 contained 83×10^{-3} M of $Na_2H[PW_{12}O_{40}]$, which corresponds to overall concentration of tungsten in solution equal to 0.1 M. Into electrolyte nos. 2 and 3, 8.3×10^{-3} M of, respectively, $Mn(CH_3COO)_2$ and $KMnO_4$ were introduced.

The parameters of the electrolytes (pH value and resistivity æ) before and after their use for anodic-spark treatment of aluminum alloy, and also the phase and elemental composition of the coatings formed, are listed in the table. It should be noted that, according to microprobe analysis, a chemically polished sample prepared for anodic-spark treatment contains (wt %): 98 Al and 1.22 Mn, and the X-ray diffraction pattern of the sample contains, in addition to aluminum peaks, low-intensity peaks of $Al(OH)_3$.

Introduction of manganese compounds changes the color of the initial electrolytes (no. 1 colorless, no. 2 yellow, no. 3 red-violet) but does not affect significantly the pH of the electrolytes. At the same time, permanganate ions (electrolyte no. 3) are unstable in an acid medium. When the electrolyte is allowed to

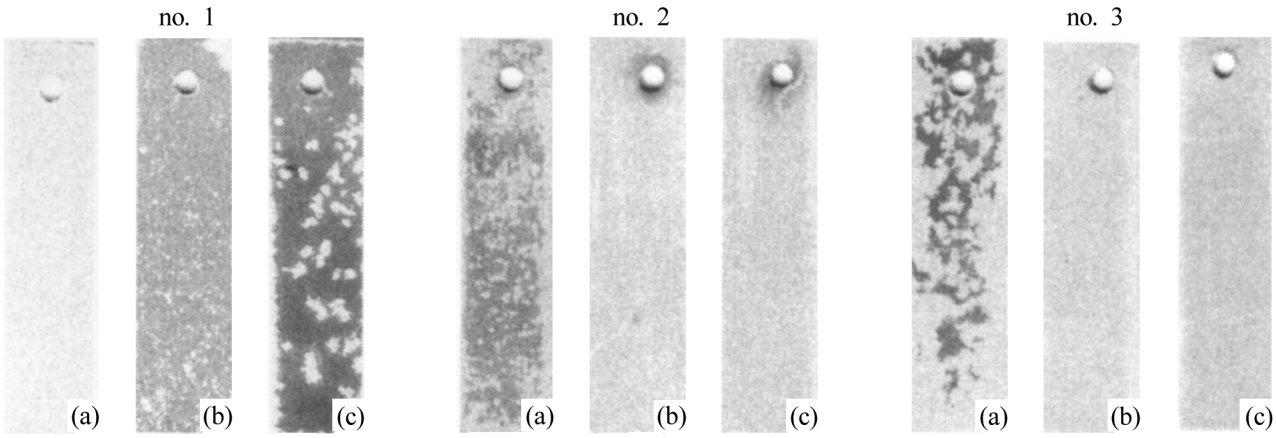
** Numerator, pH value and æ for the initial electrolyte; denominator, the same after anodizing.

stand, a bulky white precipitate, turning brown in air, is formed. After an anodic-spark treatment of the AMtsM alloy, X-ray phase analysis of the precipitate formed in electrolyte no. 3 shows the presence of β-$Na_{0.7}MnO_2$, $Na_2W_4O_{13}$, and $WO_{2.9}$.

As follows from the table, introduction of manganese compounds in a cationic or anionic form has no effect on the phase composition of coatings formed on the AMtsM alloy. In both cases, the X-ray diffraction pattern shows peaks corresponding to the $WO_{2.9}$ phase. At the same time, a change is observed in the outward appearance and color of the coatings, the latter being the same in electrolyte nos. 2 and 3 (see figure). In electrolyte no. 1, mat black layers are formed, with green point-like areas chaotically scattered over them. At the same time, in electrolyte nos. 2 and 3, beige coatings are formed on the surface of a shining and transparentprimary (prespark) anodic oxide film. In all probability, the change of coloration from green to beige is due to incorporation of manganese into the tungsten oxide lattice. Green and beige areas are formed in all the three electrolytes by the island mechanism, similarly to the case of anodic-spark deposition of coatings in a vanadate-phosphate electrolyte [1, 9]. First, nuclei of the new phase appear, and then they gradually expand to fill the increasing fraction of the surface area. In the process, the sparking is concentrated on the periphery of a growing area of the new phase.

The elemental composition of green and beige coatings is independent of the current density. The difference of beige coatings from green ones consists in an increase in the content of manganese to 0.8–1.7 wt % (table lists average values for coatings obtained in



Outward appearance of coatings formed on aluminum alloy in electrolyte nos. 1–3. Current density (A dm^{-2}): (a) 1, (b) 2, (c) 10.

the current density range under study). The fact that introduction of manganese compounds into the base electrolyte leads to an increase in the concentration of the transition metal in anodic-spark layers indicates that the metal is incorporated into the coatings from the electrolyte, rather than from the substrate.

The incorporation of manganese is presumably due to thermolysis of compound manganese-containing HPA or colloid particles at the electric breakdown channels. The latter is possible for the $KMnO_4$-containing electrolyte, in which a precipitate is formed.

The approach considered can also be presumably applied to modification of tungsten-containing coatings with other transition metals, which is promising for obtaining functional coatings, e.g., catalytically active structures, on the support surface.

CONCLUSIONS

(1) Anodic films formed on an AMtsM aluminum alloy in an electrolyte with $Na_2H[PW_{12}O_{40}]$ (8.3×10^{-3} M) contain crystalline $WO_{2.9}$. Addition of 8.3×10^{-3} M of $Mn(CH_3COO)_2$ or $KMnO_4$ to the electrolyte has no effect on the phase composition, but leads to incorporation of up to 1.7 wt % Mn into the coatings and to a change in the coating coloration from green to beige. The latter points to the presence of manganese in the tungsten oxide lattice.

(2) The layer containing tungsten oxides, both with and without manganese inclusions, is formed on the anode surface by the island mechanism: areas of new phase appear on the film surface, expand, and merge to give a new layer.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of Composition and Structure of Aluminozirconium Hydroxides Obtained by Coprecipitation in Membrane Electrolyzer

R. G. Romanova, A. A. Lamberov, and E. V. Petrova

Kazan State Technological University, Kazan, Tatarstan, Russia

Received March 25, 2003

Abstract—Fundamental aspects of formation of aluminum and zirconium hydroxides in their coprecipitation under the action of products of electrode reactions in a membrane electrolyzer were studied. The influence exerted by precipitation conditions (temperature and pH value) on the phase composition and porous structure of coprecipitated systems was analyzed.

Coprecipitated aluminozirconium hydroxides (AZH) and oxides are used as supports for high-efficiency catalysts for important catalytic processes, such as isomerization, reforming, etc. The use of zirconium dioxide is due to its ability to create stable systems with developed surface.

Previously, the structure and acid-base properties of aluminum hydroxides and oxides synthesized in a membrane electrolyzer have been studied. It has been found that aluminum hydroxides precipitated in the anode chamber of the electrolyzer differ significantly from those obtained by the conventional technologies both in phase composition and porous structure and in distribution of acid-base centers over their surface [1–4].

The formation of a heterogeneous phase in precipitation of poorly soluble compounds is a complex process including stages of salt hydrolysis to give low-molecular forms of hydroxo complexes, their polycondensation, and subsequent precipitation of a hydroxide, first as primary particles and then as disordered aggregates and the crystalline phase [5].

The processes of formation of binary hydroxides in coprecipitation are more complex and may lead to crystallization in two directions: to give individual phases or heteronuclear spinel structures. In the case of precipitation in an electrochemical cell, the formation of the hydroxide structure is complicated by the effect of electric field on dispersed systems, which leads to quite a number of nonequilibrium electric surface phenomena changing fundamentally the characteristics of the heterogeneous phase. Polynuclear particles formed under real conditions determine the structure and surface characteristics of the resulting systems based on poorly soluble hydroxides. In this context, it seemed a topical task to study the fundamental aspects of formation of binary systems in their precipitation in a membrane electrolyzer.

The aim of this study was to analyze the influence exerted by conditions of coprecipitation by products formed in electrode reactions on the composition and structure of aluminozirconium hydroxides.

EXPERIMENTAL

The precipitation was performed in the anode chamber of a membrane electrolyzer [1] by continuous introduction of sodium aluminate into a $ZrO(NO_3)_2$ solution. Platinum served as anode, and Kh18N9T steel, as cathode. The anode and cathode spaces were separated by an MK-40 cation-selective membrane. The precipitation was done at pH ranging from 6 to 10 at temperatures of 303–343 K. The suspension obtained upon precipitation was subjected to electrochemical purification to remove sodium ions and aged in mother liquor for 48 h. The $ZrO_2 : Al_2O_3$ molar ratio in the hydroxides synthesized varied from 1 : 0.73 to 1 : 1.85.

The content of sodium and aluminum ions was determined by flame photometry and complexometry. Analysis for zirconium(IV) was carried out by X-ray fluorescence method on a VRA-20 instrument. A sam-

ple was preliminarily mixed with an inert substrate in 1 : 15 ratio and pelletized. As inert substrate served boric acid of chemically pure grade. Reference samples with known content of zirconium(IV) were prepared in a similar way using zirconium dioxide of special-purity grade. The content of water in the samples was found from calcination loss at 1123 K.

The crystal structures were studied on a DRON-3M diffractometer with Fe$_{K_\alpha}$ radiation and graphite monochromator in the secondary beam. As reference were used structures represented in the Inorganic Crystal Structure Database (ICSD for WWW).

The pore structure was determined by the method of low-temperature adsorption of nitrogen. The adsorption measurements for determining the specific surface area, pore volume, and pore diameter distribution were carried out on Micrometrics ASAP-2400 instrument. For analysis, a 0.8–1.0-g portion of a preliminarily powdered catalyst was taken and placed in the ampule of the analyzer. The sample was heated to 523 K and kept under vacuum with residual pressure of 0.1 mm Hg for 4 h, the ampule was filled with helium and weighed, and adsorption–desorption of nitrogen was carried out. The adsorption–desorption isotherms were measured at 77 K, with degassing to residual pressure of 0.03 mm Hg. In calculations, the density of nitrogen in normal liquid state was taken to be 0.808 g cm^{-3}, and the molecular cross section for nitrogen, 0.1620 nm^2. The measurement accuracy of pore volume and pore size distribution was ±13%, and that of specific surface area, ±3%.

Thermochemical studies were carried out with a Perkin–Elmer TGS-2 thermogravimetric analyzer and SETARAM DCK 111 differential scanning calorimeter.

As can be seen from Table 1, the rate of precipitation of aluminozirconium hydroxides at 303 K with electrochemically generated protons depends on the acidity of the medium only slightly in the pH range 6–9. In a more alkaline medium (pH 10), an excess content of hydroxide ions accelerates the hydrolysis process, with the result that precipitation is faster by a factor of 1.8.

Raising the temperature also makes the precipitation rate higher because of the increasing mobility of reacting particles. However, this leads to a strong effect of the pH value on the rate of AZH precipitation, which manifests itself in the appearance of a maximum at pH 8. The anomalously high precipitation rate under these conditions is probably due to formation of particles of a heterogeneous phase, which have uncharged surface (point of zero charge, p.z.c.), with the result that fast coagulation of the precipitate occurs.

As shown in [6], the point of zero charge strongly depends on the anionic composition of a solution and lies at pH 8.8–9.3 for zirconogels obtained from $ZrO(NO_3)_2$. The true state of the neutrality of heterogeneous particles is determined by the distribution of hydroxonium and hydroxy ions between the charged gel surface and electrolyte solution. In the presence of a directed electric field, a certain contribution is

also made by particle orientation along the external field vector and by polarization coagulation, which, in the end, determine the real $pH_{p.z.c.}$ and, correspondingly, the rate of formation of the heterogeneous phase. A lower $pH_{p.z.c.}$ is observed for gels susceptible to polymerization [6], and, therefore, it may be stated that electrical-surface phenomena occurring in electrochemical precipitation favor formation of polymer particles.

It can be seen from Table 2 that the composition of hydroxides obtained in the anode chamber of the membrane electrolyzer also depends on precipitation conditions. The loss upon calcination of the hydroxides at 1123 K is 28–40%, which corresponds to 2.44–4.18 mol of water per 1 mol of metal oxide. It should be noted that the ratio $M_xO_y : H_2O = 1 : \sim 4$ is only observed at 303 K in the pH range 6–9. With increasing precipitation temperature, this ratio tends to 1 : 3.

It is significant that the content of water in the samples synthesized grows with increasing mole fraction of zirconium dioxide. For example, with the $ZrO_2 : Al_2O_3$ changing from 1 : 1.53 to 1 : 0.73, the amount of water per 1 mol of oxide increases from 3.81 to 4.18 mol. Virtually in the whole range of temperatures studied, the dependence of the molar content of water in AZH on the precipitation pH shows extremal behavior with a weak maximum at pH 8–9.

It should be noted that the precipitation temperature affects the AZH composition. For example, for the hydroxides obtained at pH 6, the content of water in their composition decreases rather substantially, from 3.81 to 2.44 mol, with the precipitation temperature increasing from 303 to 343 K. At the same time, performing the precipitation process at pH 8–9 leads to a pronounced decrease in the amount of water only with temperature increasing from 303 to 323 K, with further rise in temperature virtually not affecting the AZH composition. For the hydroxides obtained at pH 10, the mole fraction of water in their composition decreases somewhat with increasing precipitation temperature.

Analysis of published data [6–8] shows that the amount of water molecules in zirconogels obtained in precipitation with chemical reagents mainly depends on the precipitation pH, being equal to 0.7–1.8 mol per molecule of zirconium dioxide. The authors of [8] synthesized aluminozirconium hydroxides of composition $(ZrO_2 + Al_2O_3) : H_2O = 1 : 1.6$, which are similar to the samples used in the present study, by treating oxo zirconium and aluminum nitrate solutions with a 3 N ammonia solution. The content of water in individual aluminum hydroxides prepared in electrochemical precipitation [2] varied with temperature and precipitation pH in the range 1.29–1.6 mol mol^{-1} Al_2O_3. The experimental results obtained (Table 2) show that binary aluminozirconium hydroxides synthesized under the action of electrochemically generated protons are distinguished by higher content of water, compared with individual and complex hydroxides obtained in chemical precipitation.

Thermogravimetry and differential scanning calorimetry (DSC) were used to study thermal decomposition of the samples synthesized. It can be seen from

the derivatograms obtained (Fig. 1) that the mass loss by AZH samples occurs stepwise in two or three stages and is accompanied by endothermic effects at 400, 590–600, and 700 K. Thermal decomposition below 400 K results in removal of water from the xerogel of zirconium hydroxide, and that at 553–603 K, probably, leads to decomposition of aluminum hydroxide of bayerite modification, with release of structural water. Intermicellar moisture is first removed from broad pores, and then from fine pores within secondary crystals. At 688–700 K, finely crystalline pseudoboehmite decomposes. The DSC curves obtained for AZH samples are mainly characterized by two peaks (Fig. 2). The peak at temperatures of the first endothermic effect has complex broadened structure, and the peak in the range of temperatures of the second endothermic effect shows a clearly pronounced narrow dip. For some of the samples, a third low-intensity broadened endothermic peak is observed. The thermogravimetric and DSC data obtained were used to calculate the corresponding heat effects to be 45–107 kJ mol^{-1}.

The electrical-surface phenomena occurring in the process of formation of a heterogeneous phase in an electric field determine the structure and composition of the resulting systems and, in particular, the content of counter ions, whose role is played by sodium ions in coprecipitation of AZH. As shown previously [4], immediately after precipitation the residual content of Na_2O in electrochemically synthesized individual aluminum hydroxides grows with increasing pH and precipitation temperature, being equal to 0.66–5.5%. One of advantages of the electrochemical method for synthesis of hydroxides is the possibility of purification of the systems obtained to eliminate simultaneously the undesirable impurity ions, which are removed, already in the process of synthesis, from the precipitation chamber into the opposite chamber of the membrane electrolyzer through electromigration. To purify the hydroxides completely, it is suggested to subject the suspension to an additional "finishing" treatment consisting in that the electrolysis process is continued after the precipitation is complete. As the criterion of completeness of the purification process serves a decrease in the current density to a constant value, with the pH value in the anode chamber becoming 4–4.5. It has been shown previously that carrying out a finishing treatment of aluminum hydroxides makes the content of Na_2O as low as 0.01–0.08 wt %.

It can be seen from Table 2 that the residual content of sodium ions in precipitation of binary aluminozirconium hydroxides depends on electrolysis con-

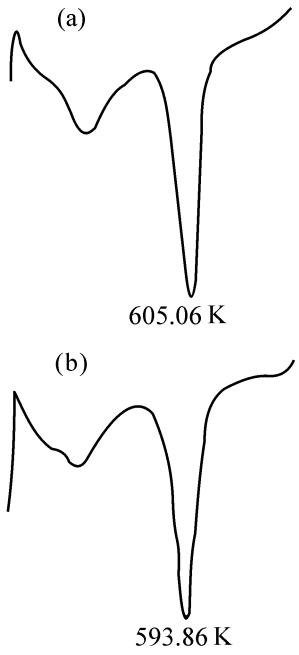

Fig. 2. DSC curves for AZH samples. T_{sc} = 293.2–773.2 K, sensitivity 1 mV, heating rate 20 deg min^{-1}, recorder chart motion velocity 5 mm min^{-1}.

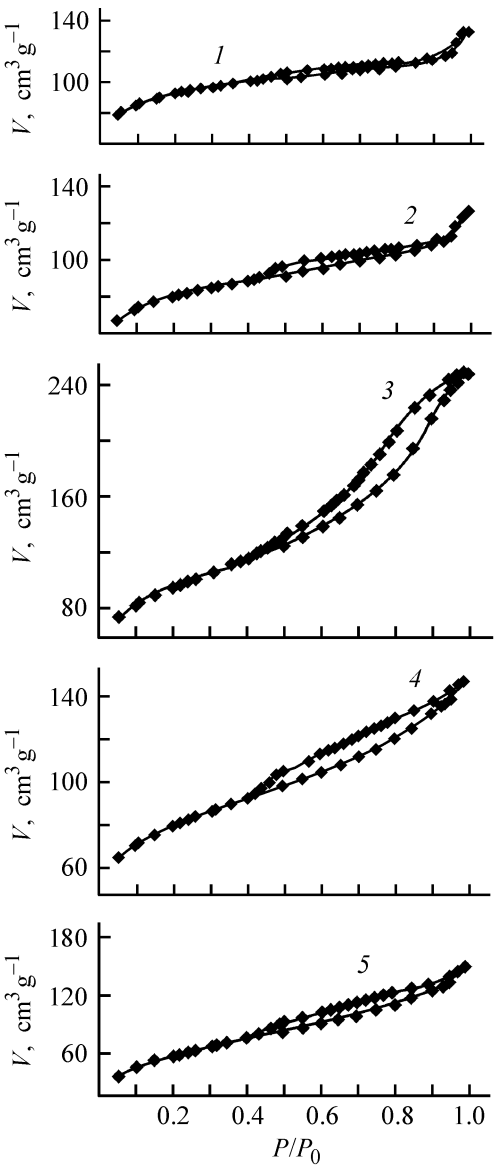

Fig. 3. Adsorption isotherms of sample nos. (*1*) 4, (*2*) 8, (*3*) 10, (*4*) 12, and (*5*) 130. (*V*) Micropore volume and (P/P_0) relative pressure.

ditions and varies within the range 0.34–3.12 wt %. However, in contrast to the case of individual aluminum hydroxides, the content of Na_2O in AZH samples changes stepwise with increasing temperature and pH value. Similar dependences are observed for samples synthesized at 323 and 343 K: the hydroxides obtained at pH 8 contain the minimum amount (0.56 and 0.34 wt %), and those synthesized at pH 9, the maximum (2.51 and 2.04 wt %) amounts of Na_2O. These dependences are in conformity with the concept of the point of zero charge of the surface, which favors formation of a heterogeneous phase with minimum sorption capacity for ions (Na^+ in the case in question). A reverse dependence is observed at 303 K: AZH synthesized at pH 8 contain the maximum amount, and those obtained at pH 9, the minimum amount of Na_2O. Probably, the point of zero charge of AZH-based systems is shifted to pH 9 at not-too-high temperatures.

It should be noted that, depending on temperature, the content of sodium impurity ions in precipitates obtained at one and the same pH value varies differently. For example, the content of sodium ions grows with increasing precipitation temperature at pH 6, and, by contrast, decreases steeply with temperature increasing from 303 to 323 K at pH 8. For AZH obtained at pH 10, the precipitation temperature affects the content of sodium ions only slightly, whereas for samples synthesized at pH 9, the temperature dependence of this content shows a maximum at 323 K. Comparison of the experimental data obtained with the results of previous studies [1–4] shows that the pattern of mass transfer of sodium ions into the cathode chamber from a suspension of binary hydroxides is more complex than that in the case of similar suspensions of individual hydroxides.

A study of the samples by the method of low-temperature nitrogen adsorption demonstrated that the AZH synthesized are characterized by microporous structure with pore diameter of about 10 Å and mesopores with a maximum in the pore volume distribution over pore radii at 38 Å. At room temperature, the pore structure of the precipitate is mainly represented by micropores, which is indicated by isotherms of nitrogen adsorption, characterized by high adsorption at low relative pressures and nearly horizontal plateau up to $P/P_0 = 0.9$ (Fig. 3).

The micropore volumes calculated using the Dubinin–Radushkevich method for samples obtained under varied conditions were 0.15 to 0.12 $cm^3\ g^{-1}$. Raising the precipitation temperature leads to a certain decrease in the fraction of micropores (by approximately 15%) and to a simultaneous increase in the mesopore volume by nearly a factor of 2. The change in the pore structure results in a significant transformation of the adsorption isotherm: the slope of the curve at $P/P_0 = 0.2–0.9$ increases and the hysteresis loop becomes much wider.

It should be noted that the most developed porous structure is formed in precipitation at low pH values, with the samples obtained containing a great number of both meso- and micropores. In this case, broad bands appear in the curve of pore volume distribution over effective diameters in the form of bends at 50 and 78 Å, which points to the formation of larger-diameter pores of varied nature. These samples have the greatest specific surface area calculated by the BET

method. For example, S_{sp} is 317 $m^2 g^{-1}$ for a sample synthesized at pH 6 and temperature of 343 K, whereas for AZH obtained at pH 9–10 and 343–363 K, the specific surface area is in the range 250–277 $m^2 g^{-1}$, with the pore volume varying within 0.2–0.4 $cm^3 g^{-1}$.

The X-ray diffraction patterns of the hydroxides obtained show reflections corresponding to aluminum hydroxides of the bayerite and pseudoboehmite modifications. After calcination of the samples at 873 K, the γ-Al_2O_3 phase is revealed by X-ray diffraction analysis, the ZrO_2 phase being X-ray-amorphous under these conditions. Studies of the thermal decomposition of the systems obtained also confirm this phase composition. Comparison of the structural parameters of the AZH synthesized with those of individual hydroxides obtained under similar conditions indicates that the processes in which the structure of individual and coprecipitated hydroxides is formed are different.

CONCLUSION

The experimental study demonstrated that the conditions of precipitation in synthesis of aluminum and zirconium hydroxides with electrochemically generated reagents make it possible to vary widely both the composition and the porous structure of the systems obtained, which opens up new opportunities for development of supports and catalysts with prescribed structural characteristics.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Influence of Zinc Intercalation on Processes in Nickel Oxide Electrode and on Service Life of Nickel–Zinc Battery

Z. P. Arkhangel'skaya, T. B. Kas'yan, and M. M. Loginova

Akkumulyatornaya Kompaniya Rigel', Open Joint-Stock Company, St. Petersburg, Russia

Received May 28, 2003

Abstract—The dependence of capacity and service life of a nickel–zinc battery on the mechanism of zinc transfer and the rate of zinc intercalation into nickel oxide electrodes differing in the conductivities of the active paste and porous structures was studied.

The problem of raising the service life of nickel–zinc (NZ) batteries, which permanently attracts attention, is mostly solved by using various methods for making lower the solubility of zinc at the negative electrode. It is a common practice to use for this purpose electrolytes with as low KOH concentration as possible and F^- and CO_3^{2-} ions added to the electrolyte and $Ca(OH)_2$, $Sr(OH)_2$, and other additives to the active paste of the zinc electrode. These additives form with zinc oxide, complex compounds sparingly soluble in alkaline solutions [1–3]. This makes it possible to slow down the processes leading to intraelectrode transfer of zinc in the negative electrode and to "loss of its shape," a factor limiting the service life of NZ batteries.

It can be seen from [1–5] that, presently, the service life of NZ batteries is 300–400 cycles, and the Evercell company achieved a service life of 600 cycles [3].

So far, all attempts to raise further the service life of NZ batteries have failed, which is still attributed to the necessity for improving the negative electrode. At the same time, it was determined in [6] that the decrease in the capacity of NZ batteries after 300–400 cycles is due to impaired working capacity of the nickel oxide electrode (NOE) on a metal-ceramic (MC) support. The authors failed to reveal the reason for its degradation, since the assumption that the structure of the active paste degrades was not confirmed.

A decrease in the capacity of a NZ battery, associated with deteriorated chargeability of an NOE on an MC support after 250 cycles, was also noted in [7]. The observed dramatic rise in the potential in anodic polarization and increase in oxygen evolution were accounted for by nonuniform distribution of current over the NOE surface, which results in an unbalance in the degree of charging of different areas on the surface of the positive and negative electrodes, and, as consequence, in the loss of shape by the zinc electrode and in its local passivation.

Data indicating that processes occurring on NOE can strongly affect the working capacity of the zinc electrode and limit the service life of an NZ battery have been obtained recently using a compacted NOE made of spherical nickel hydroxide containing cobalt hydroxide as additive on a foamed-nickel (FN) support [8]. In a battery with NOE on an FN support, the intraelectrode mass transfer in the zinc electrode is strongly decelerated, and its shape is retained after up to 200–250 cycles. This is accounted for by the increased conductivity of active paste [spherical $Ni(OH)_2$], which affects the uniformity of the current distribution both within the active paste and over the surface of the zinc electrode.

It was also revealed that accumulation of zinc in an FN-supported NOE as a result of interelectrode mass transfer, occurs in the course of direct incorporation of zinc into the structure of $Ni(OH)_2$, with the stages of its deposition within pores in the form of $Zn(OH)_2$ or ZnO bypassed.

The results obtained suggest that incorporation of zinc also occurs in an MC-supported NOE, but is not manifested clearly, being preceded by deposition of ZnO within the porous space of the electrode.

EXPERIMENTAL

This study considers processes associated with zinc incorporation and their influence on the efficiency of NOE and the service life of an NZ battery for the case of NTs-25 batteries with positive electrodes on FN and MC supports. The batteries differed only in the positive electrodes. All other elements and the design were the same.

It is of interest to study simultaneously the intercalation processes on two types of electrodes in view of the fundamental difference in their structural parameters and active paste conductivities. The electrode with an MC support contains the active paste in the form of a $Ni(OH)_2$ layer covering the surface of deep pores of the support. At low active paste conductivity, the anodic and cathodic processes on the electrode occur in the inner-diffusion mode and are accompanied by a considerable change in the concentration of hydroxide ions and by decomposition of hydroxo zincate ions present in the electrolyte.

By contrast, the active paste of NOE on an FN support is composed of densely compacted $Ni(OH)_2$ particles with radius of 10 to 30 μm. The closed pores have the same size. Therefore, their contribution to current transport in the electrolyte is insignificant.

The active paste of NOE on an FN support contains cobalt hydroxide as an additive (5–6%), which is transformed in the course of battery forming into the compound $Ni_{1-x}Co_xOOH$ exhibiting electronic conduction [9]. Owing to these features, the electrochemical processes in the electrode mainly occur on its outer surface, with the current flowing within the electrode, predominantly in the solid phase. Also, Zn is introduced in amount of 2–4%, i.e., an amount not affecting adversely the working capacity of the electrode [10], into spherical Ni(OH) to preclude formation of the γ-phase.

The basic parameters of the batteries studied are listed in Table 1.

In all the batteries, the same sets of separators and the same amounts of the electrolyte containing (M): 7 KOH + 1 LiOH, were used. This made it possible to determine the characteristics of interest under the comparable conditions.

The batteries with MC-supported NOE were formed in two cycles, with a charging capacity C equal to $1.0\,C_{theor}$ imparted in each cycle. The batteries with NOE on an FN support were also formed in two cycles, with capacities $1.0\,C_{theor}$ and $1.4\,C_{theor}$ imparted in the first and second cycle, respectively. The cycling was done in the following mode: a two-or-three stage charging with decreasing current to a voltage not exceeding 1.98 V in each stage, and discharge with a 5 A current to a voltage of 1.2 V.

Table 1. Basic parameters of NTs-25 batteries with NOE of different types (thickness 0.9–1.0 mm, electrolyte volume 105 ml)

NOE support	Theoretical capacity of NOE (+) for $Ni^{2+} \rightleftarrows Ni^{3+}$ transition, A h	Theoretical capacity ratio of electrodes (–)/(+) in battery
FN	50	2.0/1
MC	33	3/1

In the course of cycling, the charging and discharge capacities, KOH and $Zn(OH)_4^{2-}$ concentrations in the electrolyte, content of zinc in the active paste of both types of electrodes, and cobalt content in the NOE on an FN support were monitored.

In some tests, the solubility of zinc present in the NOE was determined. This made it possible to determine the amount of zinc incorporated, since, according to the data of [11], the solubility of zinc incorporated into the NOE structure in KOH solutions is two orders of magnitude lower than that of ZnO. For dissolution, a 5 M KOH solution was used, with concentration close to that established in the electrolyte of the battery. The electrolyte volume exceeded by about a factor of 10 that necessary for zinc dissolution. The dissolution time was, in accordance with the data of [11], 7 days.

In battery cycling, the primary attention was given to elucidating the dynamics of zinc incorporation into the active paste of the electrodes studied. Because approximately the same charging capacities were imparted to both types of batteries in cycling, the accumulation was estimated in grams per cycle (Fig. 1) and then recalculated to percentage content in the active paste of the NOE studied.

It was established that the accumulation of zinc in the $Ni(OH)_2$ electrode on an FN support occurs at a rather high rate in the initial cycles, is decelerated by approximately a factor of 2 after 60–70 cycles, and then continues at a constant rate (Fig. 1). By the 200th cycle, 18 g of zinc was accumulated in the positive electrodes of the battery, and then the process virtually terminated. Analyses showed that the main part of the accumulated zinc (85–87%) is not dissolved

in KOH, i.e., the accumulated zinc is incorporated into $Ni(OH)_2$.

The incorporation of zinc into the structure of $Ni(OH)_2$ in MC electrodes is accompanied by deposition of ZnO within the electrode pores in charging. In the course of discharges, when the concentration of hydroxide ions in the pores increases dramatically, zinc partly dissolves again [12]. In the process, part of zinc from the zincate complex formed is incorporated into the structure of $Ni(OH)_2$ (Fig. 1, curve *2*), and another part returns into the electrolyte. Since the forming zincate ions are present directly in the reaction zone, the incorporation of zinc into $Ni(OH)_2$ occurs at a higher rate than that into the FN-supported electrode, being complete after 60–70 cycles, i.e., simultaneously with the termination of ZnO deposition. At more intense incorporation of zinc into the NOE on an MC support, the amount of zinc accumulated, in the end, in this electrode is smaller than that in the NOE on an FN support. The total amount of zinc incorporated into the MC-supported electrode and accumulated in its pores in the form of ZnO is represented by curve *3* in Fig. 1.

In both the electrodes, the intercalation slows down as 10–12% zinc is accumulated (Fig. 2), i.e., an amount which can be incorporated into β-$Ni(OH)_2$ before the onset of its destruction through transformation into the α-form [10]. The variation of the zinc content (%) in the FN-supported NOE is represented by curves *1* and *1*' in Fig. 2. Curve *1* shows the content of zinc accumulated in the electrodes of the battery in the course of cycling, and curve *1*', the total amount of zinc, including that contained initially in the initial paste (3.2%). With this correction, the maximum percentage content of zinc in both types of electrodes is virtually the same.

The difference in the dynamics of zinc incorporation into the active paste of the electrodes considered does not affect the manner in which the KOH concentration in the electrolyte varies (Fig. 3). A considerable initial decrease in the concentration of OH^- ions is mainly due to transfer of carbonate ions from the electrodes into the electrolyte [13]. After this process is complete, the concentration of KOH in charged and discharged batteries stabilizes at about the same level. It is noteworthy that the decrease in the KOH concentration to the steady-state value occurs in parallel with a decrease in the rate of zinc incorporation into the FN-supported NOE.

However, the specific features of processes occurring in the FN-supported NOE studied are clearly manifested in the variation of the concentration of zincate ions (Fig. 4). After a battery is formed, the

MC	1	7.0	–	–	–	60–100	150–300
	Up to 60	4.0	12.6	12.0	0.21		
	60–200	3.7	12.6	12.1	~0		

zinc(II) concentration in the electrolyte of the charged battery is 40 g l^{-1}. Further cycling of the battery to 60th cycle is accompanied by a decrease in the concentration to a virtually zero value (2–3 g l^{-1}) at a rate of 0.6 g per cycle, with 0.14 g of Zn incorporated. After 200 cycles, 18 g of Zn is incorporated into the FN-supported NOE, i.e., approximately 0.09 g Zn per cycle, which corresponds to an average loss of zinc(II) of 0.9 g l^{-1} from the electrolyte (the electrolyte volume in the battery is 0.1 l, Table 2).

The deficit is compensated for by the diffusion flow from the zinc electrode into the NOE. With increasing number of cycles, the diffusion flux becomes greater owing to an increase in difference between the zincate ion concentrations in the zone of zinc electrode and in the zone of NOE. As a result, the average concentration of zinc in the electrolyte decreases.

After 60 cycles, when the Zn(II) concentration in the electrolyte of a charged battery decreases to the minimum value, a quasi-equilibrium state is attained at a constant diffusion flux. With the difference in the zincate ion concentrations in the zones of the negative and positive electrodes increased to the maximal value, the loss of zincate ions (in electrolyte volume), which disturbs equilibrium in the system operating in the reversible mode, is compensated for by the zinc electrode. In the process, the intercalation of zinc proceeds at a constant rate (about 0.06 g per cycle) during a long period (200 cycles) till termination of the process (Table 2).

The concentration of zincate ions in batteries with positive MC electrodes is higher than that in batteries with FN electrodes. Being controlled in the absence of diffusion by the very event of electrochemical intercalation, the concentration decreases in the initial cycles because of the deposition of zinc oxide within NOE in charging and only its partial return into the electrolyte in discharge (Fig. 4). For the same reason, the steady-state concentration in further cycling is higher than that in a battery with an NOE on an FN support. Part of zinc from $Zn(OH)_4^{2-}$ ions formed in pores of MC electrodes is incorporated into the NOE structure at a rate exceeding that of incorporation into an NOE on an FN support by, on the average, a factor of 2 (Table 2).

The correlation between the beginning of decrease in the charging capacity of an NZ battery and incorporation of 10–12% Zn into an NOE on an FN support is illustrated by Fig. 5. As noted in [8], this hinders the anode process at NOE and leads to a decrease in the charging capacity to the minimum value of $0.6C_{ther}$ in approximately 100 cycles [8].

In estimating the service life of the NZ battery under consideration, having an FN-supported NOE, account is taken of the possibility of making it longer (by about 50–100 cycles) by using an electrolyte

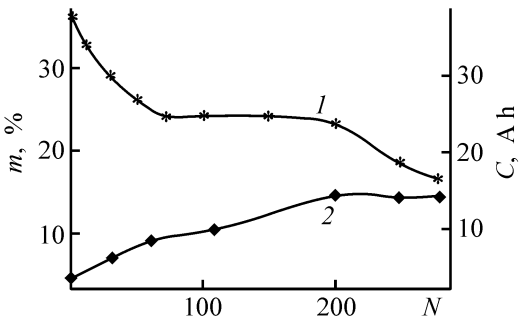

Fig. 5. Variation of (*1*) charge capacity *C* of NTs-25 battery and (*2*) the zinc amount in NOE with FN support in cycling. (*m*) Content of zinc in the active paste of NOE, including that in the initial $Ni(OH)_2$, and (*N*) number of cycles.

with lower initial KOH concentration (Table 2). It is also appropriate to use spherical $Ni(OH)_2$ containing the minimum amount of zinc, which can also prolong the service life by 50–100 cycles.

Thus, the service life of the battery under study, with an NOE on an FN support, may be as long as 400–500 cycles, provided that the influence of other known negative factors (such as growth of zinc dendrites and disintegration of separators) is suppressed by the known methods.

CONCLUSIONS

(1) The service life of a nickel–zinc battery is limited by a decrease in its capacity, associated with incorporation of zinc into the $Ni(OH)_2$ structure in amounts hindering the electrochemical processes in the battery. The number of cycles ensured by a battery without any decrease in capacity and the total service life depend on the conditions of transfer of zincate ions into the intercalation zone.

(2) In batteries with a nickel oxide electrode on a metal-ceramic support, the incorporation of zinc is facilitates by deposition of ZnO within the pores of the electrode operating in the inner diffusion mode and considerable changes in the KOH concentration in the pores. Therefore, the incorporation occurs at the maximum rate, which is limited solely by the electrochemical process itself.

(3) In batteries with a nickel oxide electrode on a foamed-nickel support, operating in the outer-diffusion mode, the rate of zinc incorporation is twice lower, since it is limited by transport of zincate ions into the reaction zone.

(4) With a nickel oxide electrode on a foamed-nickel support used instead of a metal-ceramic electrode, the service life of a nickel zinc battery can be prolonged from 150–300 cycles to 400–500 cycles, with stable capacity ensured during 300 cycles.

Abstract—A procedure for preparing new lithium salts with large organic anions, which can be used as additives to nonaqueous electrolytes of high-capacity chemical power sources, was developed. The electrochemical properties of the salts were studied.

Solutions of inorganic lithium salts in pure aprotic solvents or their mixtures are widely used as electrolytes in lithium power sources intended for different purposes.

Recently researchers' efforts have been focused on development of procedures for preparing new, cheap, nontoxic, moisture- and heat-resistant, and chemically and electrochemically stable salts readily soluble in aprotic solvents [1]. This is due to necessity for improvement of the performance of primary and, especially, secondary lithium-metal and lithium-ionic batteries.

The physicochemical properties of lithium organic salts depend on their chemical structure: the nature of the atom to which lithium is bonded and the type of this bond [2]; the nature and size of the anion; the degree of delocalization of the negative charge, which affects the stability of the salt anion [1].

The anion affects the properties of a nonaqueous electrolyte and of lithium power sources for the following reasons. In aprotic solvents, anions are solvated by dipole–dipole interactions which depend on mutual polarization of the anion and the solvent molecules. As the size of the organic anion increases, the polarization becomes stronger, thus enhancing the interaction between the anion and the solvent molecule [3].

Among the known lithium organic salts, lithium salt of bis(trifluoromethanesulfonyl)imide $LiN(SO_2CF_3)_2$ is the most promising as electrolyte for lithium power sources [4–15]. Liquid solutions of this salt have high electrical conductivity and are electrochemically stable up to 4.8 V (relative to lithium reference electrode) [2].

The lithium salt of bis(trifluoromethanesulfonyl)-imide and its structural analogues $LiN(SO_2CF_2CF_3)_2$, $LiN(SO_2C_4F_9)_2$, $LiN[(CF_3SO_2)(C_4F_9SO_2)]$ are also used for preparing polymeric electrolytes. The anion size in these lithium organic salts can strongly affect the structural and electrochemical properties of polymeric electrolytes derived from these salts [4].

Lithium salt of bis(trifluoromethanesulfonyl)imide $LiN(SO_2CF_3)_2$ was prepared from bis(trifluoromethanesulfonyl)imide, which is a relatively strong NH acid forming a stable N-anion owing to the presence of two electron-acceptor trifluoromethanesulfonyl groups. Bis(trifluoromethanesulfonyl)imide is not readily available, since substitution of chlorine atoms in the trichloromethyl groups with fluorine [16] requires special equipment and conditions that are difficult to provide in a common chemical laboratory. Alternative components of polymeric electrolytes are lithium salts of aromatic bis(sulfonyl)imides and, in particular, bis(*p*-nitrobenzenesulfonyl)imide $(p\text{-}NO_2C_6H_4SO_2)_2NH$, which is also a relatively strong acid, pK_a 3.2 (aqueous solution) [17].

The structure and acid properties of *N*,*N*'- bisarenesulfonyl substituted imides of iminosulfinic acids are similar to those of aromatic bis(sulfonyl)imides [18]. These compounds inhibit thermooxidative degradation of polymers [19], which is important for electrolytes derived from halogen-containing polymers (polyvinyl chloride, polyvinylidene chloride, polyvinylidene fluoride, etc.).

In this study, we prepared lithium salts of *N,N'*-bis-(benzenesulfonyl)pentanesulfinamidine and *N,N'*-bis-(*p*-toluenesulfonyl)pentanesulfinamidine and analyzed these salts as additives to liquid and polymeric electrolytes of lithium power sources.

EXPERIMENTAL

N,N'-Bis(benzenesulfonyl)pentanesulfinamidine and its lithium salt were prepared by the following procedures.

***N,N'*-Bis(benzenesulfonyl)pentanesulfinamidine (Ia).** To a solution of dipentyldisulfide (0.001 mol) in acetone (10 ml), sodium salt of *N*-chlorobenzenesulfonamide (0.0042 mol) was added. The mixture was shaken for 30 min, allowed to stand for 12–15 h to negative reaction for available chlorine, and filtered. The solvent was evaporated, and the residue was treated with 10% $NaHCO_3$ (20 ml) and filtered. Compound **Ia** (0.18 g, 43.9%) was isolated from acidified filtrate. The product was identified by melting point (mixing with an authentic sample) and by IR spectroscopy.

Compound **Ib** was prepared similarly in 45.4% yield.

Lithium salt of *N,N'*-bis(benzenesulfonyl)pentanesulfinamidine (IIa). To a solution of **Ia** (0.001 mol) in acetone (10 ml), equimolar amount of LiOH dissolved in a minimal volume of methanol or water was added. The reaction mixture was shaken for several minutes and filtered. The solvent was removed in air. The residue was dried to constant weight in a desiccator over $CaCl_2$. Compound **IIa** was obtained in the form of a colorless powder decomposing at 88–90°C.

Found (%): N 6.34

$C_{17}H_{21}N_2O_4S_3Li$.

Calculated (%): N 6.66.

Salt **IIb** was prepared similarly in quantitative yield in the form of a colorless powder decomposing at 147–150°C.

Found (%): N 6.12

$C_{19}H_{25}N_2O_4S_3Li$.

Calculated (%): N 6.25.

The IR spectra (KBr pellets) were recorded on a UR-20 spectrophotometer.

The dissociation constant pK_a of **IIa** in a 1% methanol solution was determined by potentiometric titration at 24 ± 2°C on a pH-121 millivoltmeter with an automated titration unit. Glass ESP/41-G-04 electrode served as working electrode, and a silver chloride electrode, as reference electrode. A 0.1 M solution of **Ia** was titrated with 0.1 M KOH.

The electrical conductivity of these salts in nonaqueous electrolytes was measured and the range of electrochemical stability of these solutions was determined. The behavior of the modified electrolytes in model secondary lithium power sources Li–MnO_2 and Li–V_6O_{13} was studied.

The electrical conductivity of solution of the lithium salts in aprotic organic solvents was measured by impedance spectroscopy in a temperature-controlled glass electrochemical cell with parallel platinum electrodes. The measurements were performed at a working frequency of 80 kHz and temperature of 24 ± 2°C. The electrolyte conductivity χ (S cm^{-1}) was calculated by the equation

$$\chi = KG,$$

where G is the conductance of the electrolyte in the cell (S), and K is the cell constant determined using 0.01 M aqueous solution of KCl (cm^{-1}).

The range of electrochemical stability of the lithium salts was determined by cyclic voltammetry under potentiodynamic conditions. The experiment was performed under an argon atmosphere in a three-electrode Teflon cell of disc design, containing working, reference, and auxiliary electrodes. The reference and auxiliary electrodes were made of metallic lithium. A platinum plate with surface area of 8.0×10^{-3} cm^2 was used as working electrode. The electrode potential was set with a PI-50-1.1 potentiostat and a PR-8 programmer. The sweep rate was 20 mV s^{-1}. The cyclovoltammograms were recorded on a PDA-1 *XY*-recorder in the potential range from 1.1 to 4.6 V.

Polymeric electrolytes (PEs) were prepared on glass supports from THF solutions containing a polymer, lithium salt, and additive (synthesized lithium salt with organic cation). The PE films were dried for 24 h at room temperature and for 48 h in a vacuum at 45°C.

Charging–discharge cycling of the model lithium power sources with polymeric electrolytes containing the synthesized lithium organic salts was performed in the geometry of 2325 disc battery. The electrode structure was obtained by layer-by-layer application of the polymeric electrolyte between lithium anode and cathode. The thickness of the polymeric electrolyte and the lithium anode was 0.03 and 0.8 mm, respec-

tively. The cathode was prepared from a mixture of chemically synthesized MnO_2 or V_6O_{13} (80 wt %), carbon (5 wt %), graphite (5 wt %), and F-4D fluoroplastic binder (10 wt %).

N,*N*'-Bis(benzenesulfonyl)pentanesulfinamidines were obtained using the known modified procedure [20]. Dipentyl disulfide was oxidatively iminated with sodium *N*-chloroarenesulfonamide in acetone by the reaction

$$(C_5H_{11}S)_2 + 4ArSO_2NNaCl \xrightarrow[-4NaCl]{} C_5H_{11}-S(=NSO_2-Ar)-NHSO_2-Ar$$

Ia, **Ib**

Compounds **Ia** and **Ib** were indetified by melting points (mixing with known samples), by determining the neutralization equivalent, and by IR spectroscopy. These compounds are relatively strong NH acids (pK_a of **Ia** is 2.91), which can be titrated with an alkali in alcoholic solution in the presence of Methyl Red as indicator. The equivalent weight determined by titration agrees with the calculated data. The IR spectra of Ia and Ib contain the bands of stretching vibrations of the SO_2 (1160–1158 and 1310–1335 cm^{-1}) S=N (753–765 cm^{-1}), CH_3 (2925–2950 cm^{-1}), CH_2 (2841–2850 cm^{-1}), and CH (ar.) (1485–1533 cm^{-1}) groups. Two strong bands in the range 3250–3360 cm^{-1} are assigned to N–H stretching vibrations. This type of absorption by the N–H bonds is due to prototropic tautomerism in the N–S–N triad, which has been found previously in *N*,*N*'-bis(arenesulfonyl)sulfinamidines [18].

The lithium salts were prepared by neutralization of appropriate pentanesulfinamidines with equimolar amounts of LiOH in acetone–methanol–water mixture [21]:

$$\textbf{Ia}, \textbf{Ib} + LiOH \xrightarrow[-H_2O]{} \left[C_5H_{11}-S(=NSO_2-Ar)-NSO_2-Ar\right]^- Li^+$$

IIa, **IIb**

where Ar = Ph (**a**), *p*-MeC_6H_4 (**b**).

The solvents were evaporated in air, and the residue was dried in a desiccator over $CaCl_2$. **IIa** and **IIb** were obtained in the form of colorless hygroscopic powders or oily substances decomposing in a wide temperature range.

The composition and structure of salts **IIa** and **IIb** was confirmed by elemental analysis and IR spectroscopy. The IR spectra of these compounds contain the bands of stretching vibrations of the SO_2 (1160–1165 and 1310–1330 cm^{-1}) and S=N (1030–1040 cm^{-1}) groups and bands of other groups. The NH bands are absent.

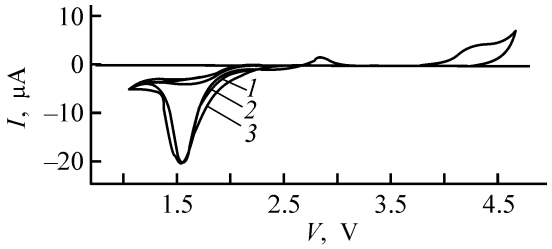

Fig. 1. Cyclic voltammogram of 0.5 M solution of lithium salt **IIa** in PC. Sweep rate 20 mV s^{-1} (*I*) Current and (*V*) voltage.

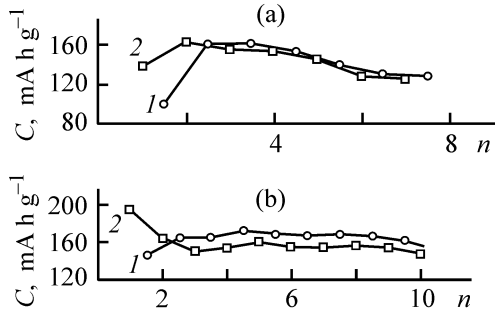

Fig. 2. Specific capacity *C* of Li/PE/MnO_2 system in a 2325 battery vs. the number of charging–discharge cycles. PE composition: (a) c-PVC : PC : $LiCF_3SO_3$ = 19.2 : 75.1 : 5.7 and (b) c-PVC : PC : $LiCF_3SO_3$: **IIa** = 18.1 : 72.5 : 3.1 : 6.3. (*n*) Cycle no. $I_{charge} = I_{discharge}$ = 100 μA.

Salts **IIa** and **IIb** are readily soluble in aprotic solvents.

The conductivity of a 0.24 M solution of **IIa** in dimethylformamide and 0.5 M solution of **IIb** in propylene carbonate (PC) is 6.0×10^{-3} and 5.2×10^{-4} S cm^{-1}, respectively.

Cyclic voltammograms of a 0.5 M solution of **IIa** in PC, recorded on a platinum electrode under potentiodynamic conditions, are shown in Fig. 1. As seen from Fig. 1, this compound is stable under conditions of repeated potential sweeping in the range 1.1–4.6 V.

Since this additive is electrochemically stable in a wide potential range, it can be used in lithium power sources with different discharge voltages: 3.8 (lithium–ionic systems), 2.8 (lithium–metal secondary systems with oxide cathode), and 1.8 V (lithium–metallic systems with sulfide cathode).

We used salt **IIa** as a modifying additive to PE based on chlorinated polyvinyl chloride (c-PVC) or vinylidene fluoride–hexafluoropropylene copolymer.

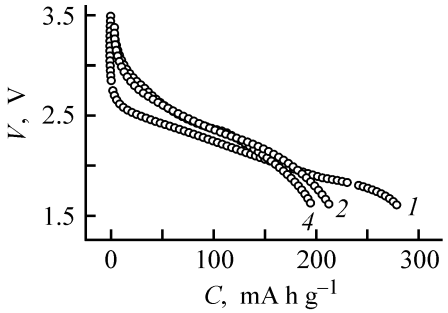

Fig. 3. Discharge curve of the Li/PE/V_6O_{13} system. Polymeric electrolyte based on microporous vinylidene fluoride–hexafluoropropylene copolymer modified with lithium salt **IIa**. I_{charge} = 120, $I_{discharge}$ = 290 μA. (*V*) Voltage, and (*C*) specific capacity. *Digits at the curves* correspond to the cycle numbers.

Power sources with plasticized and microporous PEs modified with lithium salt of *N,N'*-bis(benzenesulfonyl)pentanesulfinamidine **IIa** have good charging–discharge parameters and are stable under conditions of repeated cycling of the Li–MnO_2 (Figs. 2a, 2b) and Li–V_6O_{13} (Fig. 3) systems. It should be noted that addition of **IIa** makes longer the shelf life of the Li-V_6O_{13} system. The discharge curves of a model lithium power source with a V_6O_{13} cathode, stored for 1 month, are shown in Fig. 3.

CONCLUSIONS

(1) Lithium salts of *N,N'*-bis(benzenesulfonyl)pentanesulfinamidine and *N,N'*-bis(*p*-tolyenesulfonyl) pentanesulfinamidine were synthesized.

(2) The electrical conductivity of nonaqueous solutions of these salts is relatively high even at low salt concentration . The conductivity of a 0.24 M solution of **IIa** in dimethylformamide and 0.5 M solution of **IIb** in propylene carbonate is 6.0×10^{-3} and 5.2×10^{-4} S cm^{-1}, respectively.

(3) Solutions of the lithium salts in propylene carbonate are electrochemically stable at potentials of 1.1 to 4.6 V relative to lithium reference electrode.

(4) The lithium salt of *N,N'*-disubstitued pentanesulfinamidine can be used as additive to polymeric electrolytes to stabilize the discharge properties and decrease the self-discharge of lithium power sources.

ACKNOWLEDGMENTS

The authors are grateful to O.V. Kolomoets and I.M. Maksyuta for studying the conductivity and electrochemical stability of the electrolytes.

CATALYSIS

Direct Single-Stage Conversion of Synthesis Gas to Dimethoxymethane: Influence of the Sequence of Metal Introduction into Cu, Pd-Zeolite Catalysts on the Degree of Cu and Pd Reduction and Catalyst Acidity

N. V. Vlasenko and Yu. N. Kochkin

Pisarzhevskii Institute of Physical Chemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received March 25, 2003

Abstract—The influence of the sequence of Cu and Pd introduction into zeolite matrice when preparing Cu, Pd-zeolite catalysts on their acidity and degree of metal reduction was studied. The mutual influence of Cu and Pd on their reducibility was analyzed. The selectivity of Cu, Pd-zeolite catalysts in conversion of synthesis gas to different products was elucidated.

Dimethoxymethane (DMM) is a promising additive to diesel oil [1]. It is known [2] that this compound can be prepared in high yield by condensation of methanol with formaldehyde at 150-180°C and a pressure of 1 MPa. Another promising route to this product is the single-stage conversion of synthesis gas. Thermodynamic calculations showed that this route is feasible under fairly mild conditions (180–220°C, pressure above 0.5 MPa). In this process, Pd, Cu-containing zeolites can be used as catalysts. Under these conditions, DMM can be prepared in a single stage combining three reactions: hydrogenation of synthesis gas to methanol, dehydrogenation of methanol to formaldehyde, and DMM formation by condensation of methanol with formaldehyde.

It is known [4, 5] that, in preparing supported catalysts, the most uniform distribution of metals on the support surface is achieved with ion-exchange supports by ion-exchange sorption of metals, e.g., from aqueous solution of their ammine complexes [4, 5]. To obtain catalytically active surface, a metal-containing precursor is calcined and then reduced with hydrogen [6, 7]. In this treatment, the support surface is dehydroxylated and deammonated, and the reduced metals can be oxidized by reaction with the support.

A catalyst prepared by this technique is a polyfunctional system containing catalytically active metallic and free acid sites. Owing to the mutual influence of these sites, the metal atoms can modify the acid sites and, in turn, the acid sites can affect the valence state of the metal [4]. For reduced catalysts containing several metals, their chemical composition is controlled not only by interaction of the metals with the support surface, but also by interactions between different metals. Thus, the features of physicochemical processes occurring during catalyst preparation are responsible for the state of the catalyst surface, and, ultimately, for the activity of the catalytic sites. The mutual influence of copper and palladium has been mainly studied for catalysts prepared by simultaneous application of these metals on a support surface [8, 9]. In these studies, due attention was not given to the influence of the sequence of the metal application. However, it is known that this factor can affect substantially the catalyst properties [10].

In this study, we analyzed how the sequence of introduction of Cu and Pd in a zeolite catalyst designed for single-stage conversion of synthesis gas to dimethoxymethane affects both the catalyst acidity and the degree of reduction of the metals.

EXPERIMENTAL

When preparing Cu, Pd-zeolite catalysts, we used Ps(60) and Ps(200) Pentasil zeolites as supports. The Ps(60) and Ps(200) zeolites have the $SiO_2 : Al_2O_3$ ratio of 60 an 200 and the cation-exchange capacity (CEC) of 0.20 and 0.57 mg-equiv g^{-1}, respectively.

1070-4272/03/7610-1615 $25.00 © 2003 MAIK "Nauka/Interperiodica"

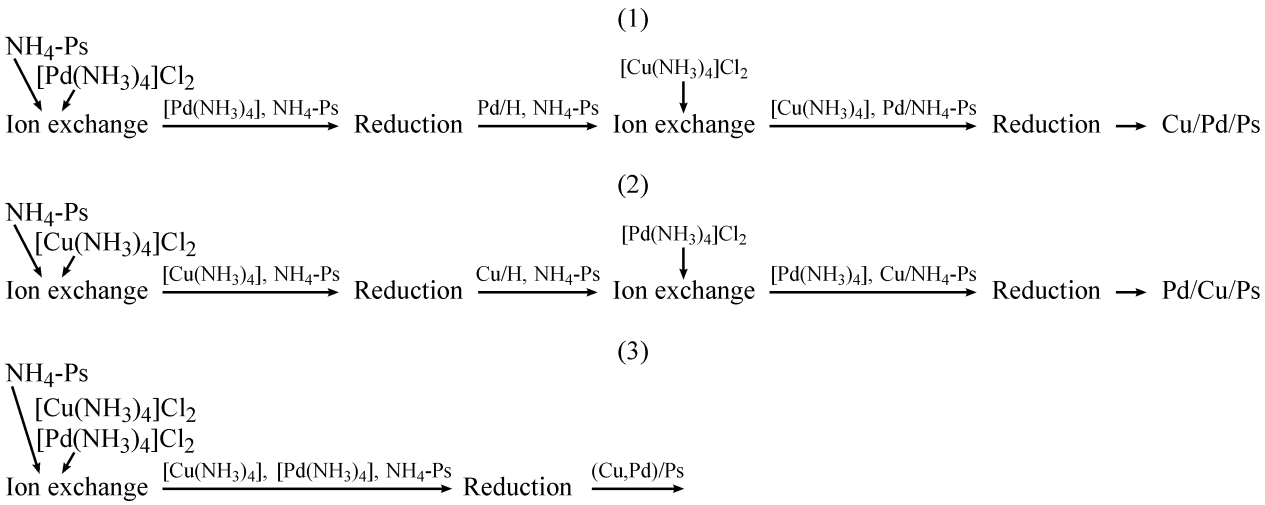

Fig. 1. Scheme of preparing Cu, Pd-containing Pentasils.

These Pentasils were converted to the NH_4 form and then modified with Pd and Cu by ion exchange with aqueous $Pd(NH_3)_4Cl_2$ and $Cu(NH_3)_4Cl_2$. This procedure was carried out in the course of 3 days, which was followed by washing the metal-containing Pentasil to remove Cl^- and drying at 100–110°C for 6 h. The resulting catalyst precursor was reduced with hydrogen at its flow rate of 50 ml min^{-1} and temperature of 300°C for 5 h.

Figure 1 shows the sequence of procedures in preparing Cu, Pd-containing Pentasils. The catalyst designations used in this study reflect the sequence of procedures used in their preparation. For example, the designation Pd/Cu/Ps(200) means that the sequence of procedures was as follows: copper introduction, copper reduction, palladium introduction, and palladium reduction. The designation (Pd,Cu)/Ps(200) means that both metals were introduced simultaneously and then the Pd, Cu-containing Pentasil was reduced with hydrogen. Along with bimetallic catalysts, we also prepared those containing copper or palladium only.

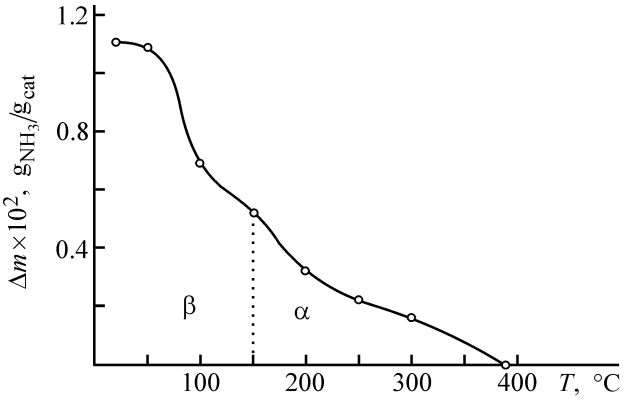

Fig. 2. Amount Δm of ammonia sorbed on a sample of the starting Pentasil Ps(200) vs. temperature T. Ranges corresponding to acid centers: (β) low-temperature and (α) high-temperature.

All the catalyst samples were prepared separately. Because the procedure used does not ensure an absolutely reproducible metal content, the catalyst samples were characterized by the degree of metal reduction [percentage of reduced metal relative to its total content in the catalyst).

The acidity of the metal-containing catalysts based on Pentasil was determined by ammonia sorption Δm (g_{NH_3}/g_{cat}) at different temperatures [11]. The content of acid centers in the catalysts was calculated assuming that one acid center sorbs one ammonia molecule [12].

The metal content in the catalysts was determined by the standard technique [13, 14]. The content of oxidized and reduced forms of metals was determined by difference in their leaching with aqueous inorganic acids. In order to elucidate where the metals are localized in the zeolite matrice, we studied how introduction of the metal into the zeolite affects the distribution of the acid sites. To determine the total content of the acid ion-exchange sites in the zeolite, the initial Pentasil sample in the NH_4^+ form was converted to its acid form by heating at 500°C for 3 h. In these experiments we used Pentasil Ps(200).

Our data on the total concentration of acid centers and the concentration of low(β)- and high-temperature (α) centers are listed in Table 1. The temperature ranges corresponding to these acid centers and the concentrations of low (β)- and (α) high-temperature centers were determined from the curves of NH_3 thermal desorption from H-Pentasil (Fig. 2). These curves

(Pd,Cu)/Ps(60)	0.18	0.44	0.62	0.33	0.07	0.40	70.97	17.50

have two separate temperature ranges 50–150 and >150°C corresponding to desorption of ammonia from two different types of acid centers.

Table 1 shows that introduction of metals into a Pentasil, as a rule, decreases the total content of high-temperature acid centers α. This data are consistent with the known fact [15] that, in cation exchange, cations are primarily sorbed on the strongest acid centers. In our experiments, the prevailing sorption of metals on strong acid centers is indicated by the fact that the complete desorption of ammonia from metal-containing zeolites (especially bimetallic catalysts) occurs at lower temperature than desorption from the starting H-Pentasil (Table 1).

We found that the content of the β-centers in the metal-containing Pentasils exceeds that in the starting H-Pentasil. We suggest that, in the course of ion exchange, the sorption of a metal on the α-centers gives rise to new β-centers. This process is similar to the known phenomenon of partial conversion of α centers into β centers in thermal treatment of the starting Pentasil in a hydrogen atmosphere (Table 1). The relative increase in the content of the β-centers on thermal treatment is, however, less pronounced than that upon introduction of metals.

The amount of reduced (M^0) and oxidized (M^{n+}) metals present in the reduced metal-containing catalysts based on Ps(60) and Ps(200) was determined by chemical analysis. This analysis showed that, in all the cases, the degree of reduction of palladium exceeds that of copper (Table 2), and the degree of reduction of both metals grows with increasing aluminosilicate ratio of the catalyst. This trend is more pronounced for palladium than for copper.

We found that the degree of metal reduction in the catalysts decreases in the following order. For Pd: Pd > Pd/Cu > Cu/Pd > (Pd,Cu) [Ps(200)], (Pd,Cu) ≈ Pd > Pd/Cu > Cu/Pd [Ps(60)], and for Cu: Cu/Pd > Pd/Cu > (Pd,Cu) > Cu [Ps(200)]; Pd/Cu > (Pd,Cu) > Cu/Pd > Cu [Ps(60)].

These series for both Pd and Cu are generally similar, except for the position of the (Pd,Cu) cat-

alyst for the Pd series and that of the Cu/Pd catalyst for the Cu series. We found that the Cu content in the (Pd,Cu) supported by Ps(200) and in the Cu/Pd catalyst supported by Ps(60) is 112 and 115%, respectively, of the IEC of the corresponding zeolites. We believe that, under these conditions, zeolite is completely coated with copper, which hinders the palladium reduction. These processes affect the ranking of (Pd,Cu)/Ps(200) and Cu/PdPs(60) catalysts. If the catalysts with superequivalent copper content are disregarded, the metal reducibility must decrease (irrespective of the Pentasil type) in the following order. For Pd: (Pd/Cu) ≈ Pd > Pd/Cu > Cu/Pd and for Cu: Cu/Pd > Pd/Cu > (Pd,Cu) > Cu.

These revised sequences reflect the mutual influence of palladium and copper on their reducibility in preparing the bimetallic catalysts. It should be noted that, in preparing catalysts containing only palladium (Pd/Ps) or copper (Cu/Ps), palladium is completely reduced whereas copper is reduced to the minimun extent. For bimetallic catalysts, copper binds palladium and palladium promotes the copper reduction owing to the mutual influence of the metals.

We believe that the mutual influence of palladium and copper is associated with the difference in their interaction with hydrogen. It is known that palladium dissolves hydrogen by the mechanism of its atomization and irreversible chemisorption of hydrogen atoms. It is possible that activated hydrogen reduces copper to metal in Pd, Cu catalysts. In contrast to palladium, metallic copper sorbs hydrogen reversibly. It is known [16] that introduction of copper into a Pd-containing catalyst decreases its sorption power for hydrogen, which, in turn, makes lower the degree of palladium reduction. The data reported in [7] show that oxidized forms of palladium and copper are stabilized by the formation of a bimetallic compound in which bulkier palladium atoms are incorporated into the copper crystal lattice.

Our preliminary studies on catalytic features of Pd, Cu-zeolite catalysts showed that all the catalytic systems under consideration actively catalyze conversion of synthesis gas to methanol, dimethyl ether, dimethoxymethane, and methyl formate under fairly mild conditions (120–225°C, 1 MPa). The ratio between different products is strongly dependent on the catalyst type.

In conversion of synthesis gas, the primary product is methanol [3]. We found that, with the use of catalysts with high degree of palladium reduction [Pd/Cu/Ps(200), Pd/Cu/Ps(60)], this process stops after CO conversion to methanol, i.e., these catalysts are selective for methanol synthesis (up to 90%).

At low temperatures (<160–180°C), methanol is mainly converted to dimethyl ether. The selectivity of the catalysts for this product increases with decreasing degree of copper reduction, suggesting that, in this case, oxidized copper is the catalytic species.

Dimethoxymethane is formed at 180°C and higher temperatures along with methyl formate as a by-product. The selectivity of catalysts for DMM synthesis increases in the order Cu/Pd/Ps(60) < Pd/Cu/Ps(60) < Pd/Cu/Ps(200), (Pd,Cu)Ps(200). The selectivity of Pd/Cu/Ps(200) and (Pd/Cu)/Ps(200) catalysts is 12%. The Cu/Pd/Ps(200) and (Pd,Cu)Ps(60) catalysts are inert in DMM synthesis. Our experiments showed that Pentasil (Ps200) modified with Pd and Cu by their successive (first Cu, then Pd) or simultaneous introduction into the zeolite matrice is the most promising catalyst for single-stage production of DMM from synthesis gas.

CONCLUSIONS

(1) When preparing Pd, Cu-containing zeolite catalysts, their chemical composition, acidity, and catalytic activity are mainly controlled by the sequence of introducing the metals into the zeolite matrice.

(2) Introduction of Pd and Cu into the zeolite matrice makes the concentration of strong acid centers lower and that of concentration of weak acid centers higher. Simultaneous introduction of Pd and Cu decreases the content of strong acid centers to the greatest extent, as also does introduction of Cu before Pd or introduction of Cu only.

(3) The valence state of Pd and Cu in Pd, Cu zeolite catalysts is controlled by the mutual influence of these metals; palladium is mainly converted to metal, whereas Cu is predominantly preserved in the oxidized form. For bimetallic catalysts, copper hinders palladium reduction, whereas palladium promotes copper reduction.

ACKNOWLEDGMENTS

Abstract—Complexes of fullerene C_{60} with poly-*N*-vinylpyrrolidone were prepared by various procedures in the presence of additional agents in solution (systems C_{60}–poly-*N*-vinylpyrrolidone and ternary system C_{60}–tetraphenylporphyrin–poly-*N*-vinylpyrrolidone) and in the solid phase (C_{60}–polyvinylpyrrolidone and C_{60}–KBr–poly-*N*-vinylpyrrolidone). Formation of a donor–acceptor bond in the system C_{60}–poly-*N*-vinylpyrrolidone was studied by ^{13}C NMR. The conditions under which the ternary complex C_{60}–tetraphenylporphyrin–poly-*N*-vinylpyrrolidone with fullerene content varied from 1 to 5 wt % can be obtained were found.

One of research lines in chemistry of fullerenes is preparation of their water-soluble derivatives. This problem has attracted deep interest after discovery of the biological activity of C_{60} [1, 2]. However, these studies are complicated by the fact that fullerene is virtually insoluble in water.

Various methods for C_{60} conversion into the water-soluble state, including covalent addition of hydrophilic groups to its molecule, have been suggested [3, 4]. It was found that, for efficient use of fullerene, it is necessary to obtain its water-soluble derivatives in which C_{60} occurs in the form of a monomer and distortion of its structure is at a minimum. In fullerene derivatives with covalent bonding, the structural distortion is too strong.

In this context, it is of interest to prepare such water-soluble derivatives of C_{60} in which fullerene is retained by nonvalent interactions. One way to produce water-soluble systems is complexation of C_{60} with poly-*N*-vinylpyrrolidone (PVP).

The interactions in this system are poorly understood, and the content of fullerene in complexes with PVP can be only varied in a narrow range (up to 1%).

The goal of this study was to prepare PVP-based water-soluble fullerene-containing systems with varied content of fullerene, optimize conditions for preparing systems with various fullerene concentrations, and examine the influence of the state of the polymer and fullerene on the complex composition.

EXPERIMENTAL

We used fullerene C_{60} produced by the Fullerene Technologies (Russia) with 99.5% content of the main substance, *meso*-tetraphenylporphyrin produced by Sigma (USA) with 99.5% purity, and commercial PVP with molecular weights of 8000 and 12 000, containing no high-molecular-weight fractions.

Complexes C_{60}–PVP were synthesized from a solution by the procedure described in [6] and also by a solid-phase reaction involving dispersion of powdered C_{60} and PVP in a vacuum (10^{-6} mm Hg). For solid-phase experiments, PVP was initially dried in a vacuum at 140°C, and then fullerene was added under the conditions of a vacuum system. In some runs, KBr was also added simultaneously with C_{60}. To recover the water-soluble fraction, the product was dissolved in water and a filtered solution was dried lyophilically. Ternary water-soluble complexes C_{60}–tetraphenylporhyrin (TPP)–PVP were also prepared by a two-stage procedure [7].

The content of fullerene and porphyrin in the water-soluble product was determined from the electronic spectra of sample solutions in chloroform, using the extinction coefficients of the absorption bands of fullerene (λ = 258 nm) and porphyrin (λ = 419 nm).

The electronic spectra of the sample solutions were recorded on a Specord M40 spectrophotometer. The ^{13}C NMR spectra of aqueous solutions of complexes

1070-4272/03/7610-1620 $25.00 © 2003 MAIK "Nauka/Interperiodica"

were recorded on a Bruker-500 spectrometer at room temperature, and spectra of solid samples, on a Bruker CXP-100 spectrometer operating at 25.18 MHz (rotation rate of the samples, 3–4 KHz). Chemical shifts were related to tetramethylsilane. Solutions of complexes in D_2O were preliminarily kept at 80°C for 1 h.

Homogeneous mixing of hydrophobic C_{60} molecules with a hydrophilic polymer and preparation of complexes with high content of C_{60} involve considerable difficulties caused by the absence of a common solvent for the components. In particular, this process is complicated by fullerene aggregation both in individual solvents and in a solvent-precipitant mixture [8, 9], which apparently takes place in synthesis of complexes (the complexes are synthesized by the procedure described in [6], by combining equal volumes of solutions of C_{60} in benzene and PVP in chloroform, the latter solvent being a bad solvent for fullerene).

With the aim to improve the quality of C_{60} retained by the polymer in water, we used various procedures for preparation of complexes. To decrease the degree of fullerene aggregation in the initial solution, we prepared complexes from a solution of the initial components both in an individual solvent (benzene) and in its mixture with the minimum amount of a precipitant (chloroform) (Table 1). The resulting product contains greater amount of C_{60} (1.7%) than the product prepared by the traditional procedure (less than 1%), but is significantly less soluble in water than the initial polymer. It is apparent that true solutions of PVP in benzene are not formed. Hence, fullerene reacts with the aggregated polymer to give a stable complex of several PVP macromolecules with fullerene.

It was found that the efficiency of the reaction of fullerene with the polymer in solution increases when interpolymer complexes are formed [10]. Apparently, in this case, association of PVP in benzene in the absence of fullerene association is favorable for the reaction with C_{60}, but intermolecular complexes do not form true solutions in water.

Another procedure decreasing the fraction of aggregated fullerene in solution is synthesis of complexes in the presence of a third agent, TPP, which also forms water-soluble complexes with PVP. It has been shown previously that this procedure allows preparation of water-soluble complexes with higher fullerene content than that in the binary system C_{60}–PVP [11]. In the first stage of synthesis, binary complex C_{60}–TPP is prepared by the procedure involving evaporation of benzene from a mixture of fullerene and porphyrin solutions and thermal treatment of the resulting solid residue [7]. In cocrystallization from organic solvents, fullerene and porphyrin form chain structures or complexes in which fullerene molecules are separated by porphyrin rings [12, 13]. The assumption that this C_{60}–TPP complex shows a weaker tendency to aggregate in solution than the initial fullerene is confirmed by comparative studies by the neutron scattering method [7]. Fundamental distinctions in the scattering patterns of C_{60} solutions and solutions of C_{60}–TPP complexes, suggesting the absence of coarse aggregates in the latter case, were found. At the same time, mixing of the TPP and C_{60} solutions did not result in a decrease in the fullerene aggregation [7].

Table 1. Composition of C_{60}–PVP complexes prepared under various conditions

Complex no.*	Reaction conditions	Solvent	C_{60} content in the water-soluble fraction, %
1	In solution	Toluene : chloroform = 1 : 1	0.8
2	″	Benzene : chloroform = 1 : 1	0.7
3	″	Benzene : chloroform = 2 : 1	0.7
4	″	Benzene	1.7
5	In solid phase	–	2.1
6	″	–	2.3

* Initial substance: complex nos. 1–5, C_{60} and PVP; complex no. 6, C_{60}, PVP, and KBr.

When three components, C_{60}, TPP, and PVP, are combined simultaneously, there is no increase in the C_{60} content in the composition of the ternary complex. As seen from Table 2, the polymer predominantly binds porphyrin, which is less hydrophobic than C_{60}. Based on these data, we prepared ternary water-soluble complexes C_{60}–TPP–PVP by a procedure involving two stages: preliminary complexation of C_{60} with TPP and further mixing of the resulting product with the polymer.

The conditions of synthesis of the C_{60}–TPP complex, in particular, thermal treatment in a vacuum, were optimized. NMR data suggest for solid samples that the intensity and duration of thermal treatment of the complex affect the extent to which the electron density is shifted from TPP to fullerene. This is seen from the chemical shifts of the corresponding nuclei in the NMR spectra (Table 3). A higher heating temperature promotes efficient reaction of the components. At the same time, it was found that, above 200°C,

Table 2. Synthesis of fullerene complexes with PVP and TPP

Complex no.	Synthesis conditions	Solvent	Composition of water-soluble product, wt%	
			C_{60}	TPP

C_{60}–TPP complex synthesized at 100°C (**I**)	143.21	142.51	134.89	–	–
C_{60}–TPP complex synthesized at 200°C (**II**)	143.02	142.52	134.84	–	–
PVP–C_{60}–TPP synthesized from complex:					
I	142.00	144.64	–	174.31	40.91
II	140.23	148.75	–	173.14	40.91

C_{60} reacts with TPP, presumably via the N–H groups of the porphyrin ring. This is suggested by changes in the electronic spectrum of the solution of the complex in benzene: a decrease in the intensities of the characteristic bands of fullerene and porphyrin and appearance of a new absorption band peaked at 360 nm. Thus, we found that the optimum temperature of thermal treatment of the solid C_{60}–TPP complex prepared in the first stage is 200°C.

As seen from Table 2, we synthesized from the C_{60}–TPP complex prepared at the optimal temperature water-soluble systems with significant amount of C_{60}. It is possible that the state of components in the ternary water-soluble complex C_{60}–TPP–PVP is governed by the composition and structure of binary systems C_{60}–TPP. This conclusion is in good agreement with the results of NMR studies of ternary systems in solids state. In the spectra of the water-soluble system C_{60}–TPP–PVP, the C_{60} signal is shifted upfield, and the signal assigned to the porphyrin ring, downfield, i.e., the electron density in the complexes is redistributed due to the interaction of the components. In the NMR spectra of the ternary system based on the C_{60}–TPP complex (heating temperature 200°C), the shift of the signals is more pronounced (Table 3).

It should be noted that, in this case (in the absence of solvent, water), the signals of carbon atoms of PVP, both carbonyl and methylene, adjacent to the nitrogen atom in the ring, are also shifted upfield.

The presence of a significant amount of water, both sorbed and chemically bound [14], in the initial polymer inhibits the reaction of C_{60} with PVP. As shown previously [14], a water molecule in the complex with PVP acts as an acceptor of the electron density from the carbonyl groups of polymer. Thus, water can compete with fullerene in complexation. This is also suggested by comparative solid-state

NMR studies of the initial (moist) PVP, PVP dehydrated by thermal treatment, and PVP–C_{60} system prepared from thermally treated PVP (Table 4). The presence of both water and C_{60} molecules in the system results in a similar effect: downfield shift of the ^{13}C NMR signal of carbonyl group, i.e., shift of the electron density, resulting in deshielding of the carbon atom. Considering that water molecules interact with virtually each carbonyl oxygen and the fraction of PVP units interacting with C_{60} is no more than 5% of the total number of units, it is conceivable that the acceptor power of fullerene is significantly higher. Nevertheless, removal of adsorbed water must favor interaction of C_{60} with PVP.

With the aim to eliminate the influence of water contained in the polymer on the interaction of C_{60} with PVP, compounds C_{60}–PVP were prepared in the solid phase. The reaction in the absence of solvent excludes formation of C_{60} solvates, i.e., competition of solvent and PVP for the interaction with C_{60}.

As a result of thermal treatment of the polymer in a vacuum (at 140°C), not only adsorbed water, but also a significant part of chemically bonded water molecules are removed [14]. In this case, the electron-donor power of carbonyl groups increases, which is confirmed by the NMR studies: upfield shift of the carbonyl carbon signal upon thermal treatment (Table 3).

As the third component, we added KBr. It was shown that the presence of a salt facilitates dispersion of coarse fullerene crystallites [15]. We studied the influence of KBr on dispersion and found that the presence of KBr accelerates the complexation. In this case, higher concentrations of fullerene are attained in aqueous solutions than in binary systems C_{60}–PVP prepared by a similar procedure (Table 1). In the solid-state NMR spectra of C_{60}–PVP and C_{60}–KBr–PVP systems, we revealed no changes suggesting formation of donor–acceptor bonds between fullerene and the polymer. Presumably, fullerene is not dispersed to molecular species during mechanical treatment and is retained in aqueous solution only by hydrophobic interaction between the C_{60}–KBr compound formed and PVP. It is possible that the contact of C_{60} with KBr prevents formation of donor–acceptor complexes in the system C_{60}–KBr–PVP.

It was of importance to compare the behavior of solid-phase compounds and complexes prepared in organic solvents. Comparative studies of aqueous solutions of these samples were carried out by light scattering and neutron scattering methods. It was found that the characteristics of the aggregation observed (size and concentration of structured particles found in concentrated solutions by neutron scattering and their behavior upon dilution, studied by light scattering in more dilute solutions) does not depend on the sample preparation procedure and is governed only by the fullerene content in these samples [15, 16]. Thus, the proposed procedure for preparing C_{60}–PVP compounds in the solid phase offers advantages over the synthesis in solutions, since it allows preparation of systems similar in their behavior in aqueous solutions to complexes with higher content of C_{60} less strongly bound to the polymer.

after heating*	184.00	47.28	44.89	36.31	33.87	20.14	32.57	23.00

* Aqueous solutions of the samples were heated for 1 h at 80°C.

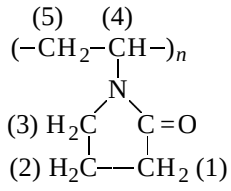
We studied complexation in the systems C_{60}–PVP prepared from organic solvents, by NMR in the solid state and in solution.

In the system C_{60}–PVP, an ESR signal was recorded [17]. This signal was assigned to electron transfer from the carbonyl group of PVP to the C_{60} molecule to give a fullerene radical anion. This signal appeared in the spectrum of the solid product after thorough removal of solvents in a vacuum upon prolonged heating.

Solid-state NMR spectra of the system C_{60}–PVP prepared similarly after removal of organic solvents show that fullerene occurs in the form of a solvate with toluene (see figure). This is suggested by the signal of toluene bound to C_{60} (δ 128 ppm). At the same time, the C_{60} signal is broadened and split into several peaks, which is caused by hindered rotation of the fullerene molecule. During lyophilic drying of C_{60}–PVP, toluene is completely removed and the signal of C_{60} is shifted upfield (by approximately 0.5 ppm), which suggests a shift of the electron density from the carbonyl group of the polymer to the C_{60} molecule in complexation.

Data of NMR in solid state, obtained for C_{60}–TPP–PVP complexes (Table 3), also suggest that carbonyl groups of the polymer are involved in interactions in the ternary system and the interaction of the polymer with fullerene is of donor–acceptor nature, as discussed above.

In the NMR spectra of the complexes in D_2O solutions, we found new signals of the polymer, assigned to the carbonyl carbon atom and C_2 and C_5 atoms (Table 5) according to their integral intensities:



The latter signals appear in the spectrum immediately after the dissolution of the sample. The new signal of the carbonyl carbon atom appears in the spectrum after heating of the solution. These data suggest that, in the solution of the ternary complex, fullerene initially interacts with the hydrophobic part of the polymer molecule. After heating, carbonyl groups additionally interact with the carbon atoms of PVP carbon chain and C_{60} molecule to give a donor–acceptor complex. This specific character of formation of donor–acceptor bonds is apparently observed in the porphyrin-free system, too.

The new signal in the ^{13}C NMR spectrum of PVP in the complex, assigned to the C_5 atom, is shifted upfield relative to the initial signal. This position of the signal can be also accounted for by displacement of water molecules because of the appearance of hydrophobic fullerene–PVP bonds. Similar upfield shifts were observed for ternary complexes with TPP (Table 3) by the solid state NMR spectroscopy.

The results obtained suggest that in dissolution of fullerene-containing PVP in water, bonds between components are finally formed. In this case, substitution of a large C_{60} molecule with more pronounced acceptor power for water molecules results in a redistribution of the electron density in the PVP unit. Although PVP, as a whole, is an electron donor with respect to fullerene, C_2 and C_5 carbon atoms increase somewhat the electron density in complexation with fullerenes.

Thus, after passing into aqueous solution, additional bonds between polymer chains and fullerene molecules, both donor–acceptor and hydrophobic, are formed, which favors retention of C_{60} in water. In this case, only small fraction of fullerene molecules form donor–acceptor bonds with the polymer.

CONCLUSIONS

(1) Water-soluble formulations C_{60}–poly-*N*-vinylpyrrolidone and C_{60}–KBr–poly-*N*-vinylpyrrolidone were prepared by solid-phase reaction in a vacuum. Synthesis of the product in the presence of KBr results in increased content of C_{60} in its composition as compared with the binary system C_{60}–poly-*N*-vinylpyrrolidone. In this case, C_{60} is less firmly bound to the polymer. Removal of the hydrate shell of poly-*N*-vinylpyrrolidone upon thermal treatment promotes interaction of the components in the complex.

(2) Water-soluble complexes C_{60}–poly-*N*-vinylpyrrolidone were prepared in solution in the presence of tetraphenylporphyrin, an agent promoting molecular dispersion of C_{60} in the course of complexation. The optimal conditions of preparation of ternary complexes with high content of fullerene were found.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electrochemical Synthesis of Thin Films of Polymers Derived from [NiSalen] and [NiSalphen]

G. A. Shagisultanova and L. P. Ardasheva

Herzen State Educational University, St. Petersburg, Russia

Received April 8, 2003

Abstract—Electrochemical synthesis of conducting polymeric Ni(II) complexes with *N,N'*-bis(salicylidene)-ethylenediamine and *N,N'*-bis(salicylidene)-*o*-phenylenediamine was studied. The kinetic of this process was examined. The possibility of preparing the polymeric films with a definite thickness ranging from 0.01 to 2 μm was assessed.

It is known that electrochemical oxidative polymerization of Ni(II) complexes with *N,N'*-bis(salicylidene)ethylenediamine (Salen) and *N,N'*-bis(salicylidene)-*o*-phenylenediamine (Salphen) and their derivatives in weakly or moderately electron-donor solvents gives thin conducting films [1–8].

Electrochemical synthesis of polymeric transition-metal complexes with structurally different macrocyclic ligands, including those of the Salen type, has been the subject of numerous recent studies [2, 9–15]. The resulting polymers with controllable thickness have high redox conductivity; their reduced and (or) partially oxidized forms exhibit photoelectric activity [9–15].

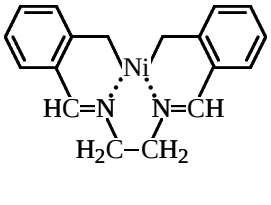
Thus, a wide variety of conducting polymeric Cu(II), Pt(II), Co(II), Pd(II), and Ni(II) complexes insoluble in water and organic solvents have been grown on solid supports and studied. The parameters of the electrochemical synthesis and the kinetics of polymer formation have been analysed. The charge diffusion coefficient D_{ct} in the polymer bulk, which characterizes the rate of charge transfer in the polymer in a solution of a supporting electrolyte, has been calculated [2, 9–12]. The suggested mechanism of polymer formation is based on existence of a single resonance structure of the initial monomers and transformation of this structure into another structure with redistribution of the electron density in the macrocycle [16].

Although orangometallic polymers have been studied extensively, optimization of their synthesis and analysis of their structure, stability, and properties remain a topical task.

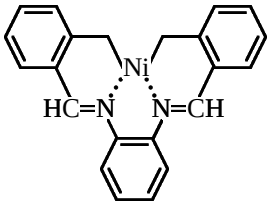
In this study, we analyzed in detail the electrochemical (potentiostatic conditions) synthesis of polymers derived from [NiSalen] and [NiSalphen] and determined the kinetic parameters of this process.

EXPERIMENTAL

The complexes [NiSalen] and [NiSalphen] were synthesized by the procedure in [17]



[NiSalen]



[NiSalphen]

Electrochemical measurements were performed on a PI-50-1 pulsed potentiostat in the potentiostatic and potentiodynamic modes with linear potential sweep at a rate of 0.01 to 0.5 V s^{-1}, using a PR-8 programmer. We used an three-electrode electrochemical cell with separated compartments. Platinum wire (99.99% Pt) with surface area of 0.25 cm^2, sealed in glass, served as working electrode; a platinum gauze was an auxiliary electrode. All potentials were measured relative to a silver chloride electrode filled with a saturated NaCl solution.

The monomer concentration in the working solution was 1 mM. The supporting electrolyte was 0.1 M solution of tetraethylammonium perchlorate (Et_4NClO_4) in acetonitrile (CH_3CN) dried by the procedure de-

1070-4272/03/7610-1626 $25.00 © 2003 MAIK "Nauka/Interperiodica"

scribed in [18]. The solution was deaerated with high-purity argon.

The film thickness was calculated by the procedure described in [19].

The cyclic voltammogram measured by single potential sweep in an acetonitrile solution of [NiSalen] is shown in Fig. 1. Comparison of the peak current with those measured in propylene carbonate $C_3H_6CO_3$ in a single potential sweep cycle [2, 9] confirmed that the deposition rate of the polymer in CH_3CN is higher than that in $C_3H_6CO_3$. Probably, diffusion of the monomer to the near-electrode space in more viscous $C_3H_6CO_3$ is slower.

As a rule, the intensity of anodic and cathodic peaks grows with increasing the number of potential sweep cycles in solutions of nickel(II) complexes. The cathodic peak current in acetonitrile solution of [NiSalen] increases during five cycles of potential sweep from 0.0 to 1.6 V at a rate of 0.001 V s^{-1} and then decreases rapidly [7]. However, this phenomenon cannot be interpreted unambiguously. Vilas-Boas *et al.* [7] suggest that the decrease in the peak current in the course of polymerization may be due both to "superoxidation" caused by irreversible oxidation of the ligand at high potentials and to lowering of the complex concentration near the working electrode.

Stable multilayer poly[NiSalen] films with thickness ranging from 0.01 to 2 μm can be prepared by potential sweep from 0.0 to +1.2 V at a rate of 0.05 V s^{-1}.

As in our previous study [2], a dark yellow film insoluble in water and organic solvents is deposited on the electrode surface, which confirms the formation of stable solid oxidation products of [NiSalen] in the course of continuous potential sweep. A yellow-brown conducting film of poly[NiSalphen] was prepared similarly.

Polymeric [NiSalen] and [NiSalphen] were deposited in the potentiostatic and potentiodynamic modes. Potentiodynamic synthesis was performed by cyclic sweeping of the potential of the working electrode in a solution of the initial monomer in a certain range for each complex: 0.0–1.2 V for [NiSalen] and 0.0–1.3 V for [NiSalphen]. The potentiostatic synthesis is performed at a constant accumulation potential determined experimentally. The accumulation potential, at which the deposition rate of the electrochemically active polymer is the highest was considered to be the optimal. The potentionstatic accumulation mode has an advantage over, the potentiodynamic procedure in that it allows rapid deposition of thick films. In this study, [NiSalen] and [NiSalphen] were polymerized

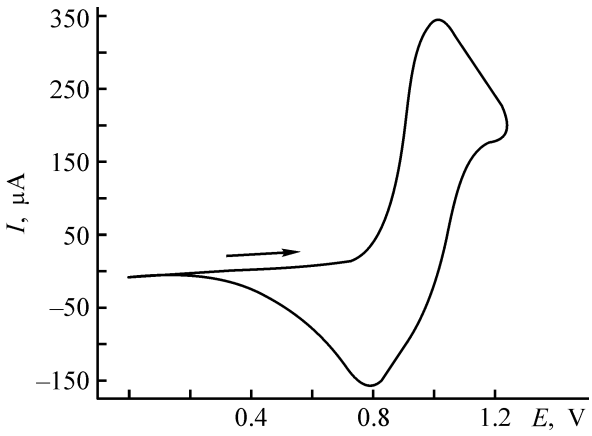


Fig. 1. Cyclic voltammogram of anodic polymerization of [NiSaen] in 0.1 M Et_4NClO_4 in CH_3CN (first cycle). $c_{complex} = 1 \times 10^{-3}$ M, $V_s = 0.05$ V s^{-1}. (*I*) Current and (*E*) potential; the same for Fig. 2.

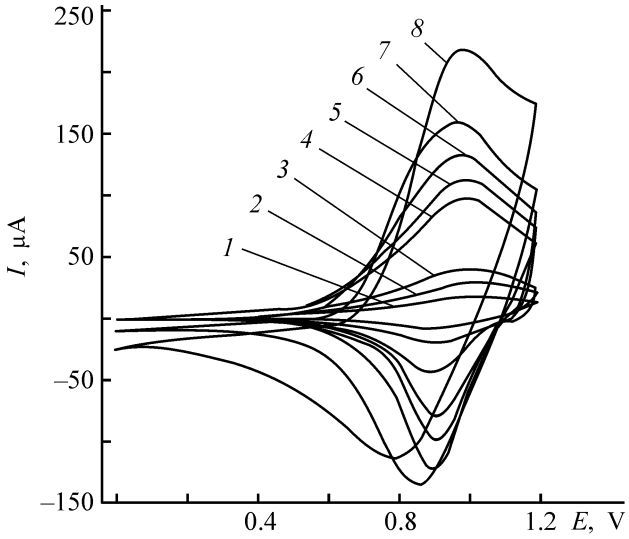

Fig. 2. Cyclic voltammograms illustrating solid-phase redox processes in poly[NiSalen] films deposited in (*1*) 0.5, (*2*) 1.0, (*3*) 2.0, (*4*) 5.0, (*5*) 7.0, (*6*) 10.0, (*7*) 17.0, and (*8*) 43.0 min in the potentiostatic mode at $E_a = 1.1$ V. CH_3CN, Et_4NClO_4, $V_s = 0.01$ V s^{-1}; the same for Figs. 3 and 4.

mainly in the potentiostatic mode at a potential of 1.1 ± 0.05 V.

The electrodes coated with [NiSalen] and [NiSalphen] were immersed in a solution of the supporting electrolyte, and their potential was swept in the ranges 0.0–1.2 and 0.0–1.3 V, respectively. The cathodic and anodic waves in the cyclic voltammograms characterize electron transfer in the bulk of the polymer. Cyclic voltammograms recorded at the potential sweeping of the electrode coated with poly [NiSalen] films of varied thickness (sweep rate 0.01 V s^{-1}) in a solution of pure supporting electrolyte are shown in Fig. 2.

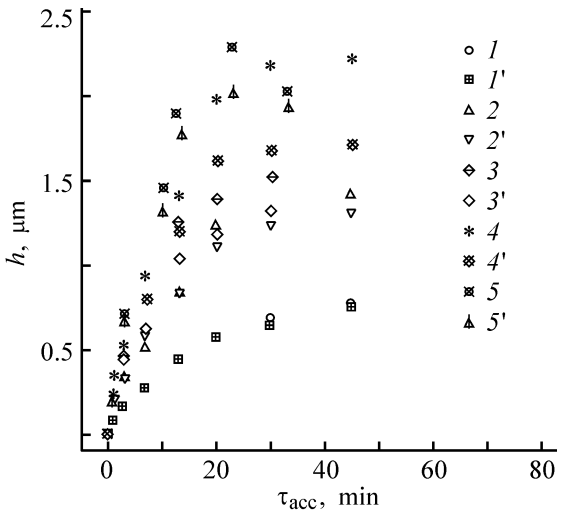

Fig. 3. Thickness h of poly[NiSalen] films deposited from solutions with monomer concentration of (*1*, *1*') 0.5, (*2*, *2*') 0.75, (*3*, *3*') 1.0, (*4*, *4*') 1.5, and (*5*, *5*') 2 mM vs. the accumulation time τ_{acc}. The film thickness was calculated from the quantity of electricity spent for (*1*–*5*) oxidation and (*1*'–*5*') reduction of the polymer.

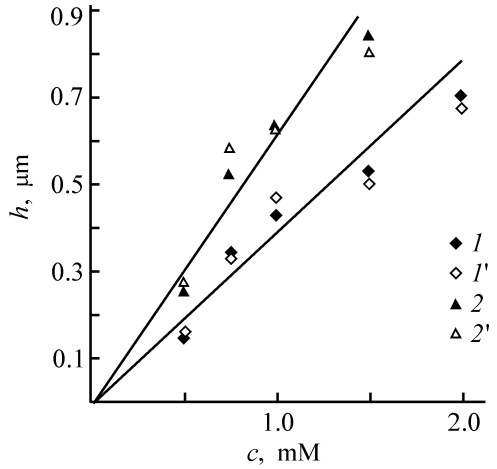

Fig. 4. Thickness h of poly[NiSalen] films grown for (*1*, *1*') 3 and (*2*, *2*') 7 min vs. the monomer concentration in the solution c. The film thickness was calculated from the quantity of electricity spent for (*1*, *2*) oxidation and (*1*', *2*') reduction of the polymer.

It can be seen that the anodic peak at $E_a \approx 0.6$ V appears and is shifted to positive potentials with an increasing deposition time and, hence, the film thickness. The shift of the first oxidation potential at $E_a \approx 0.6$ V (sweep rate 0.01 V s^{-1}) is the most pronounced at the thickness of poly[NiSalen] film larger than 0.7-μm. This peak disappears upon further growth of the film. In this case, the cyclic voltammogram contains a single wave at $E_a \approx 0.95$ V (Fig. 2). We suggest that the characteristics of redox processes in thick polymer layers differ from those for thin films. Thus, the shift and the subsequent disappearance of the first anodic peak at $E_a \approx 0.6$ V in cyclic voltammograms can be regarded as a quantitative characteristic of the transition from thin to thick polymeric films, which differ in structure and physicochemical properties.

There exist two forms of the polymeric substance: yellow-brown oxidized, which turns dark brown with increasing thickness of a polymeric film, and yellow reduced. These forms determine the electrochromic properties of a polymer. The oxidized form is deposited in the potentiostatic mode (0.5–60 min, E = 1.05 V) and can be rapidly converted to the reduced form by potentiostatic reduction at E = 0.0 V in a solution of pure supporting electrolyte. The reduction time τ_{red} is equal to the time of oxidative polymerization. The oxidized form is spontaneously reduced in a solution of the supporting electrolyte within 30–120 min (depending on the film thickness) after the applied voltage is switched off. The thicker the film, the slower its spontaneous reduction. It should be noted that the cathodic potential never reaches 0.0 V in the course of spontaneous reduction of the polymer. Our experimental results show that the limiting, so-called equilibrium potential of spontaneous reduction is equal to the potential at which the anodic wave in the cyclic voltammograms starts to grow, i.e., at which the electrostimulated oxidation of the reduced form starts. Along with spontaneous reduction, spontaneous oxidation of the polymer was observed. The polymer reduced under potentiostatic conditions at E = 0.0 V is oxidized in a pure supporting electrolyte after the applied voltage is switched off. The potential of the electrode coated with the polymeric film increases to a value equal to the potential recorded by the end of the spontaneous reduction. Thus, the so-called intermediate redox form is formed both by spontaneous reduction and by spontaneous oxidation of the polymer. The potential of this form depends on the film thickens and the nature of a supporting electrolyte.

Our experimental results show that polymer thickness h is one of the most important parameters determining the rate of charge transfer in the polymer.

To calculate the thickness h of a polymeric film, we recorded cyclic voltammograms at slow potential sweep (0.01 V s^{-1}). Under these conditions, the film is deposited by the adsorption mechanism ensuring reduction or oxidation of all molecular fragments of the polymeric chain. The dependence of h of poly[NiSalen] on the time of accumulation in the potentiostatic mode at different concentrations of the complex in solution is shown in Fig. 3. On the whole, the polymer formation accelerates with increasing

monomer concentration in solution. In the initial deposition steps (up to 7 min), the dependence of h on the monomer concentration at constant accumulation time is linear (Fig. 4). Upon further electrode polarization in a solution of the nickel complex (for more than 15–20 min), polymerization decelerates and the curve flattens out. When the films are deposited from highly concentrated solutions, h passes through a maximum and then decreases. At low monomer concentration, the curve flattens out owing to a decrease in the monomer concentration near the electrode. The influence of the concentration on the rate of polymer growth is the most pronounced in going from 0.5 to 0.75 mM monomer solutions. At higher monomer concentration (up to 2 mM), the dependence of the thickness of polymeric film on the monomer concentration becomes less steep, being, on the whole, nonlinear (Fig. 4).

It should be noted that the dependence of the thickness of polymeric film grown from a solution with monomer concentration of 2.0 mM on the accumulation time passes through a maximum. Since the curves measured in the first deposition steps are similar for all monomer concentrations, we suggest that, in 20 min, the polymerization is decelerated and the curve flattens out. However, it can be seen from Fig. 3 that at the monomer concentration of 2 mM the curve has ascending and descending portions, which reflects the decrease in the electrical conductivity of the polymer. At high monomer concentration in the working solution, the polymerization accelerates and a film with a high content of structural defects grows [20], which makes lower the redox conductivity of the polymer.

We calculated the polymer thickness from the area under the cathodic (h_c) and anodic (h_a) portions of the cyclic voltammograms (Fig. 3). As seen from Fig. 3, the thicknesses of poly[NiSalen] films calculated from the areas under the cathodic and anodic portions become different when the thickness reaches 0.7 μm. The thicknesses of these films, calculated from the anodic portion are higher than those calculated from the cathodic portion. Thus, the calculated thickness of the oxidized conducting polymeric film grown at any monomer concentration is slightly larger than that of the reduced film. The higher the monomer concentration in the working solution, the greater the difference between the currents of anodic and cathodic portions of the cyclic voltammograms and hence, the greater is the difference between h_a and h_c. The decreased activity of the polymer films in reduction is due to the presence of residual oxidized fragments in the polymer, which are electron traps or have a "frozen" charge [21, 22].

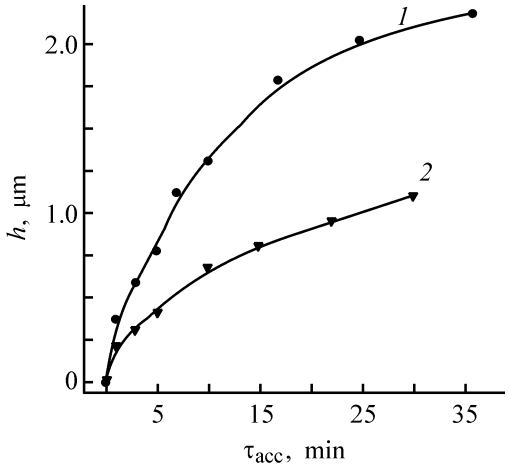

Fig. 5. Thickness h of (*1*) poly[NiSalen] and (*2*) poly[NiSalphen] vs. the accumulation time τ_{acc}. CH_3CN, Et_4NClO_4, E_a = 1.1 V, continuous growth.

The dependences of the thickness of poly[NiSalen] and poly[NiSalphen] films on the time of accumulation on the electrode at the optimal potentials are shown in Fig. 5 (curves *1*, *2*). It can be seen that the poly[NiSalen] film is thicker than the poly[NiSalphen] film grown under the same conditions. Probably, polymerization of [NiSalphen] on the electrode surface is sterically hindered owing to the presence of the third phenyl ring in the ligand.

We examined the possibility of stepwise growth of polymer films. An electrode coated with the polymer for a definite time was immersed in a pure supporting electrolyte and a cyclic voltammogram was recorded. Then the electrode was placed in the monomer solution and the polymerization runs (up to 15 steps dependening on the experimental conditions) were continued. We found that a polymeric film can be grown stepwise. The thickness of the thus obtained polymeric film was close to that of the film grown in a single step during the same time.

CONCLUSIONS

(1) Electrochemical synthesis of polymeric nickel(II) complexes in the potnetiostatic mode was studied. The best accumulation potential providing fastest growth of the electroactive layer is 1.1 ±0.5 V.

(2) The redox conductivity of the polymer may decrease with increasing monomer concentration in the working solution.

(3) The polymeric film can be grown by both continuous and stepwise deposition, which is of practical importance.

Received April 8, 2003

Abstract—New experimental data on physicochemical properties of polymeric nickel(II) complexes with *N*,*N*'-bis(salicylidene)ethylenediamine and *N*,*N*'-bis(salicylidene)-*o*-phenylenediamine (including redox conductivity, photoactivity in a solution of a supporting electrolyte, and electrochemical stability) were obtained. The rate of charge transport in the polymeric matrix was studied as a function of the polymer film thickness.

Electrochemical synthesis and study of thin-layer metal-containing polymers attracts much researchers' attention [1]. The electrochemical synthesis allows preparation of conducting polymers on solid supports as solid and uniform films with controllable thickness. Transition metal complexes with macrocyclic ligands of various compositions and structures, which are structural units in the synthesis of these polymers, determine the variety of their properties [1–10], e.g., redox conductivity, photosensitivity, sensor and catalytic properties.

It has been found previously [6, 11] that, when immersed in a solution of a supporting electrolyte, polymers based on transition metal complexes with ligands of the *N*,*N*'-bis(salicylidene)ethylenediamine (Salen) type in the reduced and (or) partially oxidized state are photoelectroactive and can exhibit a positive photovoltaic effect [6, 11]. The maximum positive change in the potential of the electrode with the polymer layer applied by electrochemical synthesis was first found for poly[PdSalen] and amounted to 450 mV [12]. The photoelectroactivity is the major property required of polymers to be used in accumulation and conversion of the energy of light.

Thus, these polymers are promising materials in production of sensors, electro- and photocatalysts, and solid-phase galvanic cells.

In the preceding publication [13], we considered the optimal conditions of the synthesis and the kinetic aspects of formation of polymers based on Ni(II) complexes with *N*,*N*'-bis(salicylidene)ethylenediamine (Salen) and *N*,*N*'-bis(salicylidene)-*o*-phenylenediamine (Salphen). In this study, we analyzed the electro- and photoinduced charge transfer in poly[NiSalen] and poly[NiSalphen] and the electrochemical stability of these polymers.

EXPERIMENTAL

The method of the electrochemical measurements was described in [14].

The photoelectric measurements were performed on a device including an irradiation source (DRSh-1000 lamp), a potentiometric recorder, and a photoelectrochemical cell. A cell with parallel-plate windows was the working part of a two-electrode Pyrex glass cell. The samples were irradiated with focused polychromatic light; the IR light was cut off by two water filters. A silver chloride electrode filled with a saturated NaCl solution was used as reference. A platinum (99.99% Pt) wire with surface area of 0.25 cm^2 sealed in the glass served as indicator electrode. The electrode was coated with a layer of the polymer studied, which was deposited in the course of the electrochemical synthesis. A 0.1 M solution of tetraethylammonium perchlorate Et_4NClO_4 in acetonitrile CH_3CN was used as a supporting electrolyte.

The capability for reversible electroinduced charge transfer is one of the major properties of Ni(II) polymers studied and the related polymeric compounds.

Among conducting polymers, two main groups are distinguished. To the first group belong polymers with electrons delocalized over very extended polyconjugated systems. These are mainly organic polymers containing no metal [9, 15–17]. The second

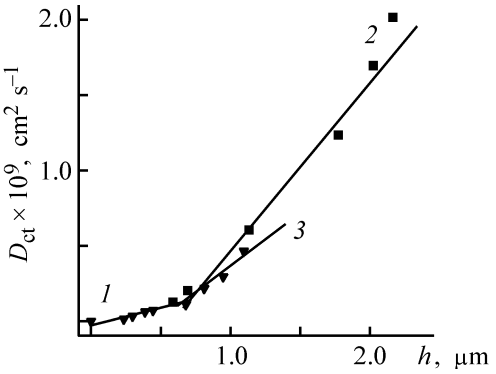

Fig. 1. Charge diffusion coerfficient D_{ct} vs. the thickness h of (*1, 2*) poly[NiSalen] and (*1, 3*) poly[NiSalphen] films. CH_3CN, Et_4NClO_4, E_{acc} = 1.1 V.

group includes so-called redox polymers, in which the electronic conductivity is due to electron hopping between low-mobility redox centers incorporated into a polymeric matrix with low electronic conductivity [1, 18, 19]. Two types of redox polymers are distinguished. The first of them are redox polymers, which can be prepared by electrochemical oxidation or reduction of individual coordination compounds of transition metals with organic ligands [1, 3]. The second type includes the so-called composites consisting of an organic polymeric matrix with metal ions (mainly of variable valence) and separate molecules of metal complexes incorporated into its internal voids by various procedures.

It is known that the conductivity of organic polyconjugated polymers is several orders of magnitude higher than that of the redox polymers and is essentially independent of the polymer chain length, but is determined by conformation and morphology of macromolecules, i.e., by the supramolecular structure of a substance [15].

As a quantitative characteristic of the rate of charge transfer in the polymer phase bulk, we used the charge diffusion coefficient D_{ct} (cm^2 s^{-1}) calculated by Randles-Shevchik equation

$$I_p = (2.69 \times 10^5) n^{3/2} S (D_{ct})^{1/2} V_p^{1/2} c_0,$$

where I_p is the peak current (A); n, number of electrons transferred in an elementary event; S, electrode surface area (cm^2); V_p, potential sweep rate (V s^{-1}); c_0, concentration of the electrochemically active species in the polymer film (mol cm^{-3}) [20].

Depending on the nature of the limiting stage, the D_{ct} values characterize the electron self-exchange between the heterocharged fragments or diffusion of the supporting electrolyte ions in the polymer phase. It is known [20] that D_{ct} varies within the range 10^{-13}–10^{-8} cm^2 s^{-1} when the rate-determining stage is the rate of the diffusion of the supporting electrolyte ions and is higher than 10^{-7} cm^2 s^{-1} when the rate of charge transfer in the polymer phase is limited by the rate of the electron exchange between the heterocharged fragments in the polymer chain.

We calculated the D_{ct} values from cyclovoltammograms (CVAs) recorded at high potential sweep rates (≥0.1 V s^{-1}) under the conditions of incomplete oxidation or reduction of the polymer film. In this case, the redox reactions in the polymer phase proceed in the semi-infinite diffusion mode, when the dependence of currents of voltammogram peaks on $V_p^{1/2}$ is linear.

Vilas-Boas *et al*. [21] calculated, using several independent methods, the diffusion coefficient in the polymer based on the Ni(II) complex with *N,N'*-bis-(salicylidene)butane-2,3-diamine (Salt-Me) prepared by potentiodynamic synthesis and found that D_{ct} grows with increasing polymer film thickness, especially for thin films. The maximum thickness of films of poly[NiSalt-Me] films deposited on the electrode in [21] was attained after 50 potential sweep cycles and was calculated to be 0.6 μm. In our experiments, a similar thickness of poly[NiSalen] and poly[NiSalphen] was attained within 3–7 min in the potentiostatic mode (E_{acc} = 1.1 V, initial concentration of the metal complex in the solution 1 mM).

We found that, for poly[NiSalen] and poly[NiSalphen], D_{ct} is limited by the rate of motion of counterions in the polymer bulk and grows with increasing thickness of the conducting layer (Fig. 1). For a 1.5–2.0 μm thick poly[NiSalen] film, D_{ct} was relatively high for complexes with ligands of this type: 10^{-9} cm^2 s^{-1}.

The D_{ct} values corresponding to various thicknesses of the polymeric conducting substance, calculated both for highest peak of the anodic current in CVAs at E_a ~ 0.95 and 1.05 V and for the corresponding cathodic current at E_c ~ 0.85 and 0.92 V for poly-[NiSalen] and poly[NiSalphen], respectively, are listed in Table 1.

As seen, the D_{ct} values characterizing the rates of diffusion of counterions in polymer oxidation are lower than the D_{ct} values characterizing reduction. For thin poly[NiSalphen] films, this difference reaches 100% and decreases with increasing film thickness. The above difference for oxidation and reduction may be due to the fact that the polymers in the reduced

state have a more compact structure. Direct measurements of the polymer film thickness showed that the oxidized polymer film is 60% thicker than the reduced polymer film [22]. The IR and XPES data indicate that ions of the supporting electrolyte and solvent molecules are virtually absent in the bulk of the polymer in the reduced state [23].

Thus, a decrease in the rate of penetration of ions and solvent molecules into the polymer in the reduced state in the course of its oxidation may be associated with a decrease in the volume of the free space in the bulk of the reduced form of the polymer in comparison with the oxidized form because of the denser molecular packing. At the same time, the oxidized form contains inner free space sufficient for exit of molecules of the supporting electrolyte. As a result, D_{ct} increases for the reduction process. The obtained experimental data on the effect of the polymer film thickness on D_{ct} are in agreement with data of [21].

As seen from Table 1, the D_{ct} values for poly[NiSaphlen] are somewhat lower than those for poly[NiSalen] at the same thickness. The difference between the D_{ct} values for these polymers is greater in the case of anodic processes, as compared with cathodic processes. Presumably, owing to existence of an additional phenyl ring, poly[NiSalphen] has a smaller volume of the free space than poly[NiSalen].

However, with increasing thickness of the conducting polymeric film to h = 2.0 μm (poly[NiSalen]) the D_{ct} values calculated from the anodic and cathodic branches of CVAs become close. Nevertheless, the subsequent increase in the time of the positive polarization of the electrode gives another dependence. Namely, for poly[NiSalen] (h = 2.17 μm), anodic D_{ct} exceeds cathodic D_{ct}. With increasing thickness, less compact films are probably formed, the volume of the free space in the layers adjacent to the electrolyte–polymer phase boundary grows, and ions of the supporting electrolyte and solvent molecules penetrate into the film bulk with weaker hindrance than that in thinner films of the polymer. However, in this case, exit of counterions from deeper near-electrode layers of the polymeric phase is complicated because of structural heterogeneities accumulating with film growth.

For poly[NiSalphen], the pattern of variation of D_{ct} for anodic and cathodic processes with increasing film thickness is similar. However, we can assume that, even in poly[NiSalphen] with relatively large h (~1 μm), the volume of the free space is smaller than that in the similar poly[NiSalen], since the D_{ct} values remain unequal, similar to those in the thin-layer samples.

It should be noted that the rise in the redox conductivity of the polymeric supramolecules with increasing film thickness is untypical of the known conducting materials, although we have also noted in previous studies that the redox activity of polymers based on transition metal complexes with Salen type ligands grows with increasing thickness of the conducting polymer [11–14, 24, 25]. The effect of the redox activity growth with increasing thickness of polymeric copper aminophthalocyanines was noted in [16]. Alpatova *et al*. [16] suggest that, with increasing thickness of the polymer film, the system of conjugated π bonds develops, and, as a result, hopping mechanism of the electron transport typical of redox polymers transforms into the polaronic mechanism characteristic of polymers with conjugated bonds.

The absence of conductivity in solvents with high donor power is a characteristic feature of the metal-free conducting organic polymers with developed π system (e.g., in dimethyl sulfoxide and dimethylformamide with potential sweep within the range of pos-

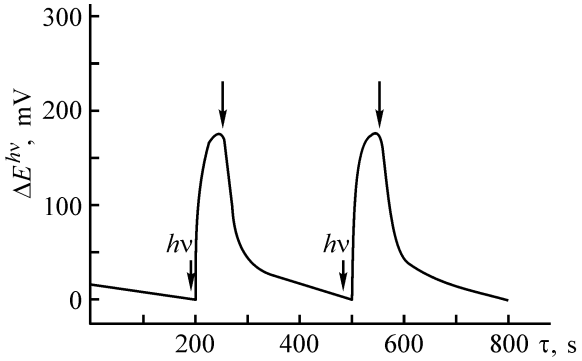

Fig. 2. Typical curve of variation of the potential $\Delta E^{h\nu}$ of the electrode with applied poly[NiSalphen] layer under the action of polychromatic light. h_{film} = 0.29 μm, CH_3CN, Et_4NClO_4; source of light, DRSh-1000 lamp. (τ) time.

itive values). It has been found [26–28] that solid-phase redox reactions are also untypical of polymers based on metal complexes with Salen type ligands, immobilized on an electrode immersed in a solvent with high donor power.

In Fig. 1, we can distinguish three linear sections with different slopes. The first (straight line *1*) with small slope is independent of the ligand structure and reflects the dependence of D_{ct} on h in the initial stages of film thickness growth, i.e., for relatively thin layers of poly[NiSalen and poly[NiSalphen]. Straight line *2* reflects further increase in D_{ct} with h for poly[NiSalen], and straight line *3* for poly[NiSalphen]; the more pronounced growth of D_{ct} with increasing thickness of the electroactive layer and, hence, the greater slope is observed for poly[NiSalen]. It should be noted that the boundary thickness of polymer films at which the slope of the curve changes lies at about of 0.7 μm.

Thus, the observed rise in the rate of charge diffusion in the polymer phase with increasing film thickness is probably caused by the change in its morphology and in the number of physicochemical characteristics, including the porosity of the polymeric substance [15].

When discussing the influence of the polymer film thickness on the character of the electroinduced charge transfer, we should take into consideration that the simultaneous increase in the thickness of the conducting layer and in the potential rate results in electrochemical overvoltage associated with deceleration of the redox reactions in the solid phase. As known, this phenomenon is characterized by an increase in the difference of the potentials corresponding to the anodic and cathodic processes and, as a result, is reflected in CVAs in that the anodic and cathodic peaks are shifted and move away from each other. For poly[NiSalen], the shift of the potential of the cathodic peak is greater than that for the anodic peak: from E_c ~ +0.92 V (accumulation time τ_a = 0.5 min) to E_c ~ +0.85 V (τ_a = 17 min) at sweep rate of 0.01 V s^{-1}. Similar changes in CVAs and shifts of the anodic and cathodic peaks with increasing thickness have been described previously for related polymeric systems [24, 25]. Probably, the overvoltage is caused by a decrease in the rate of penetration and exit of the supporting electrolyte ions in the course of oxidation and reduction of thick polymer films when relatively high potential sweep rates are used. It is assumed that thick polymeric films contain large amounts of structural defects, microheterogeneities, and cross-links. In turn, this causes slower motion of counterions in the free volume of the polymer.

Thus, the D_{ct} values and differences of the potentials of the anodic and cathodic processes are the basis for a quantitative correlation between the thickness of the polymer film formed on the electrode surface and the degree of reversibility of the solid-phase redox reactions.

It was established for the first time that, in the supporting electrolyte solution under continuous irradiation with polychromatic light, the change in the potential $\Delta E^{h\nu}$ (mV) of the electrode coated with a polymeric film of poly[NiSalen] or [NiSalphen] is positive and reaches several tens of millivolts.

The maximum value of $\Delta E^{h\nu}$ amounted to 250 and 190 mV for [NiSalen] and [NiSalphen], respectively. A typical curve of the potential change, recorded when an electrode coated with electrochemically immobilized poly[NiSalphen] is irradiated with polychromatic light, is shown in Fig 2.

The photovoltaic effect was found only for the polymer in the reduced or partially oxidized state. Thus, only chain fragments that exist in the ground electronic state and are characterized by the maximum aromaticity of phenyl rings can be photodetectors [23]. Previously, Orlova [12] has assumed that photoexcitation of the reduced form of the polymer is accompanied by charge transport and accumulation of oxidized fragments, similar to those proceeding under the action of the electric potential. Hence, the presence of charge-compensating ions in the polymer phase is the necessary condition for maintaining the macroneutrality of the polymer under photoexcitation.

Multiple alternation for each polymer of photoexcitation and dark phase, resulting in that the potential of the electrode in the supporting electrolyte spontaneously returns to its initial value, showed that the max-

60	0.45	0.45	0	0.75	0.75	0

imum value of $\Delta E^{h\nu}$ is reached in the first irradiation run. Later on, $\Delta E^{h\nu}$ decreases, and after 5–7 irradiation runs it becomes constant (Table 2).

We experimentally found that $\Delta E^{h\nu}$ passes through a maximum with increasing thickness of the polymer film (Table 2) and is independent of the oxygen presence in the supporting electrolyte solution.

It was also found that the polymeric films are photostable and keep the initial thickness of the conducting substance after irradiation is terminated.

The stability (including electrochemical stability, whose criterion is the ability of a polymeric system to keep the redox conductivity under the action of external factors) is the major property making organometallic polymers promising as novel materials.

The results obtained in studying the polymer stability, estimated as preservation of the thickness of the electroactive substance after continuous potential sweep, prolonged exposure to the supporting electrolyte solution, and action of air, are listed in Table 3.

It can be seen that the most rapid and substantial decrease in the thickness of the conducting polymer films is caused by continuous potential sweep. When the potential of an electrode coated with polymeric film in the pure supporting electrolyte is varied relatively slowly within the 0.05–0.01 V s^{-1} range, the electrochemical degradation accelerates and the redox conductivity of the polymeric substance decreases, especially for thick films. In addition, the degrading action of the solvent should be noted. This conclusion follows from the decrease in the conductivity of the polymer after prolonged exposure to a solution of pure supporting electrolyte.

In air, the reduced form of the polymer is substantially more stable as compared with the oxidized form. The latter may contain chain fragments with unpaired electrons. Their high chemical activity may favor reactions with air components, which, in turn, may result in irreversible structural distortions in the system of the conjugated bonds responsible for conducting properties of the polymeric substance.

CONCLUSIONS

(1) The rate of charge transfer in poly[NiSalen] and poly[NiSalphen] is determined by the mobility of the supporting electrolyte ions and grows with increasing thickness of the polymer film. In contrast to thin films, the D_{ct} value for thick films of the electroactive substance ($h > 0.7$ μm) depends on the ligand structure.

(2) Poly[NiSalen] and poly[NiSalphen] immobilized on an electrode immersed in an electrolyte solution are capable of photoinduced charge transfer. The photovoltaic effect depends on the irradiation intensity and film thickness and is independent of the presence of oxygen in the supporting electrolyte solution. The maximum values of $\Delta E^{h\nu}$ for poly[NiSalen] and poly[NiSalphen] are 250 and 190 mV, respectively.

(3) The reduced forms of the polymers are substantially more stable in air as compared with oxidized forms.

Dipole Structure and Electrooptical Properties of Poly-*N*-vinylpyrrolydone in Nonaqueous Solvents

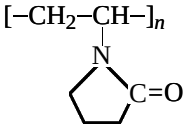
N. P. Evlampieva, T. A. Dmitrieva, and E. I. Ryumtsev

Research Institute of Physics, St. Petersburg State University, St. Petersburg, Russia

Received May 12, 2003

Abstract—Electrooptical Kerr effect and dielectric polarization were studied for poly-*N*-vinylpyrrolidone solutions in chloroform and in mixed chloroform–CCl_4 solvent. The results were compared with those for an analogue of the monomeric unit of poly-*N*-vinylpyrrolidone, low-molecular-weight compound *N*-methylpyrrolidone.

Poly-*N*-vinylpyrrolidone (PVP) is one of the major synthetic polymers used in medicine and pharmacology; it exhibits extremely valuable properties. PVP is biologically inert, fairly stable thermally and chemically, nontoxic for living bodies, and capable of complexing with diverse compounds in aqueous media. This made PVP suitable for extensive use in production of drugs, medical preparations, and cosmetics [1].



PVP

Studies of the properties of biologically active molecular complexes of PVP with fullerene C_{60} [2] and PVP derivatives with covalently bound C_{60} [3] revealed a very strong dependence of the electrooptical properties of these compounds on their composition and type of bonding between fullerene and PVP. However, there are no published data on specific features of the electrooptical behavior of PVP in solutions. Therefore, we studied the Kerr effect of PVP in nonaqueous media. The solvents were chosen so as to eliminate the influence of aggregation phenomena and enable correlation of the molecular structure of PVP, which has been extensively studied by various methods [1], with the electrooptical properties of PVP and its derivatives.

In this study, we analyzed by the methods of electrooptical Kerr effect and dielectric polarization two PVP samples with different molecular weights (MWs) (Table 1) in chloroform and mixed 1 : 1 (by volume) chloroform–carbon tetrachloride (CCl_4) solvent. The PVP-1, 2 samples were synthesized at the Institute of Macromolecular Compounds, Russian Academy of Sciences. The analogue of the monomeric unit of PVP, *N*-methylpyrrolidone (MP) produced by Sigma S0760, was studied by the Kerr effect method in chloroform

only. The solvents used had the following characteristics: refractive index $n_0 = 1.4456 \pm 0.0005$, dielectric constant $\varepsilon_0 = 4.813 \pm 0.001$, and density $\rho_0 = 1.4891 \pm 0.0008$ g cm^{-3} for chloroform and $n_0 = 1.4536 \pm 0.0004$, $\varepsilon_0 = 3.364 \pm 0.003$, and $\rho_0 = 1.5358 \pm 0.0008$ g cm^{-3} for the chloroform–CCl_4 mixture. The characteristics of the solvents were determined at 21°C by the standard methods; the Kerr effect and the dielectric constant in polymer solutions were measured at 21°C as well.

The birefringence of solutions subjected to pulse electric field [(Kerr effect), hereinafter, bire-fringence in electric field, BE] was measured by the compensation method [5] at rectangular pulse duration of 1 ms. The parameters of the setup and the measurement cell corresponded to those described in [6]. The equilibrium (i.e., independent of the frequency and duration of electric pulses) electrooptical properties of the samples were characterized by the specific Kerr constant K

$$K = \lim_{\substack{c \to 0 \\ E \to 0}} (\Delta n - \Delta n_0)/E^2 c. \qquad (1)$$

Here, $(\Delta n - \Delta n_0)$ is the difference between the birefringences of the solution of concentration c and of the solvent, and E, the electric field intensity in the measurement cell.

In the solvents used, PVP exhibited a minor negative intrinsic (minus the contribution from the solvent) electrooptical effect proportional to the squared electric field intensity, in accordance with the Kerr law for molecular-dispersed media. Figure 1 shows the plots of the optical birefringence Δn against the squared electric field intensity, E^2, for PVP-1 sample. It is seen that the difference in Δn between the solution and solvent is small, though exceeding the measurement error. Figure 2 shows the same dependences for MP solutions in chloroform. Since the electrooptical Kerr effect is positive for MP and negative for chloroform, the sign of the electrooptical effect of the solution changed with the MP concentration in chloroform (Fig. 2).

The specific Kerr constant of the samples was determined, in accordance with Eq.(1), from the $K = f(c)$ plot (Fig. 3). Here, each K value is the slope of the $\Delta n = f(E^2)$ plot estimated at a certain concentration of the solution. Thus, for PVP-1 sample we obtained the Kerr constants $K = -(0.80 \pm 0.07) \times 10^{-10}$ g^{-1} cm^5 (300 V)$^{-2}$ in chloroform and $K = -(0.20 \pm 0.05) \times 10^{-10}$ g^{-1} cm^5 (300 V)$^{-2}$ in the mixed solvent. These constants were identical, within the experimental error, to those of the second sample,

PVP-2, which is typical of polymers in the Gaussian region of properties [5]. The fourfold difference between the specific Kerr constants in chloroform and the mixed solvent is due to the difference in the internal field factors for these solvents, which depend on the dielectric constant and refractive index of the medium subjected to electric field [5]. The results of the electrooptical measurements are summarized in Table 1.

The dielectric constant ε of the PVP solutions in the mixed solvent was measured in a cylindrical titanium capacitor with intrinsic capacitance of 92.62 pF at 700 kHz. We used an E12-1 instrument for capacitance measurements. The mixed solvent for dielectric measurements was formulated specially for decreasing the ε_0 parameter. The refractive indices of the solutions n were determined on an IRF-23 refractometer. The resulting increments of the dielectric constant $(\varepsilon - \varepsilon_0)/c$ and of the squared refractive index $(n^2 - n_0^2)/c$ for the solutions were used for calculating the specific dielectric polarization μ^2/M of the samples [7]:

$$(\mu^2/M) = 27kT[(\varepsilon - \varepsilon_0)/c - (n^2 - n_0^2)/c]/[4\pi N_A(\varepsilon_0^2 + 2)^2]. \quad (2)$$

Here, μ is the dipole moment; M, molecular weight; k, Boltzmann constant; T, absolute temperature; and N_A, Avogadro number.

Poly-*N*-vinylpyrrollidone belongs to carbon-chain polymers whose polar properties are determined by the pendant radical (for PVP, by polar pyrrolidone ring) with the dipole moment not rigidly bound to the backbone. A similar dipole structure is characteristic of comb-shaped mesomorphic polyacrylates [8].

With poly(alkylphenoxycarbonylphenyl methacrylates) (PAPCPM) as examples, Tsvetkov *et al.* [9] showed, for the first time, that, for interpreting the dielectric and electrooptical properties of polymers with polar –C=O group situated in close proximity of the backbone, it is necessary to distinguish the contributions from the dipole moment components of the pendant groups that are parallel and perpendicular to the chain propagation direction. The perpendicular components for PAPCPM (Fig. 4) are not ordered along the backbone (Fig. 4, vector **h**) and do not contribute to the total dipole moment of the macromolecule.

A specific feature of polymers containing polar pendant substituents is the difference (occasionally not only in magnitude but also in sign) between the electrooptical properties of the low-molecular-weight

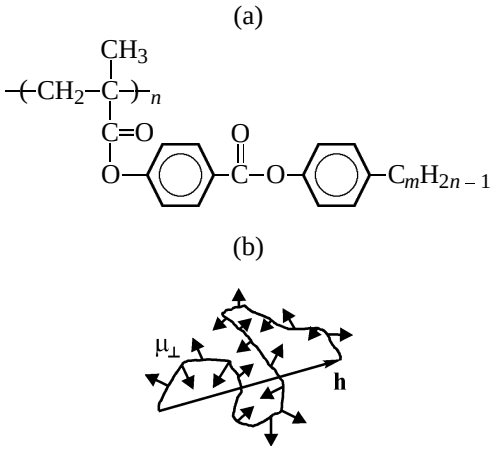

Fig. 4. (a) Chemical and (b) dipole structures of PAPCPM molecules.

structural analogue of the pendant substituent and the polymer proper, measured in the same solvents [5, 8]. This is mainly due to long-range interaction of pendant groups in the polymer chain, manifested in their mutual orientation. Strongly interacting polar and optically anisotropic groups in the pendant chain of the PAPCPM molecule are responsible for intramolecular ordering. As a result, the optical anisotropy of polarizability of the PAPCPM monomeric unit in the direction perpendicular to the chain propagation direction exceeds that in the chain propagation direction. This is responsible, in turn, for a negative dynamooptical Maxwell effect (or flow birefringence) in PAPCPM solutions [9], which is, essentially, birefringence in solutions under shear forces of the flow. The sign of the flow birefringence of a polymer in solution is directly related to that of the anisotropy of the optical polarizability of the repeating unit in the chain [10].

Many of comb-shaped polymers characterized by enhanced equilibrium (Kuhn segment length $A \sim 100 \times 10^{-8}$ cm and over) and kinetic rigidity owing to orientation interaction of the pendant groups exhibit in the Gaussian MW range the Maxwell and electrooptical Kerr effects with identical signs [6, 8]. This is a common property of Gaussian chains for which, on the average, the three main directions in the polymer coil, namely, the directions of the greatest geometric extension and of the orientation-axis and orientation-polar ordering typically coincide. This suggests that such properties of polymers as polarizability anisotropy and the total dipole moment should be analyzed in axes related to the chain propagation direction or, in accordance with the Gaussain statistics of polymer chains, to the direction of the vector **h** connecting the ends of the macromolecule (Fig. 4) [11].

Table 2. Eigenvalues of the optical polarizability tensor, a_i, (i = 1, 2, 3) calculated by PM3 quantum-chemical method and dipole moment projections μ_i onto the main optical axes of MP molecule

Value of i	$a_i \times 10^{25}$, cm^3	μ_i,* D
1	84.5	2.33
2	70.5	1.84
3	45.9	–1.44

* $\mu = (\mu_1^2 + \mu_2^2 + \mu_3^2)^{1/2}$ = 3.3 D is the total dipole moment of the MP molecule.

The behavior of PVP, observed in studies of the birefringence of its solutions in a flow and in electric field suggests that the properties of PVP and PAPCPM are identical, although these polymers substantially differ in the structure of their pendant substituents and PVP by no means belongs to polymers with enhanced chain rigidity. The equilibrium rigidity of PVP was estimated hydrodynamically [12] from the Kuhn segment length of $(21 \pm 1) \times 10^{-8}$ cm. This means that correlation in the PVP chain can extend over approximately seven monomeric units. The birefringence in electric field, measured for PVP solutions in chloroform and mixed chloroform–CCl_4 solvent, has negative sign. The polarizability anisotropy of the monomeric unit of PVP, as estimated by the birefringence method (Table 1), is also negative. Also, similarly to PAPCPM [9], the electrooptical specific Kerr constants for PVP and its monomeric unit analogue, MP, differ in magnitude and sign (Table 1). Our experimental data allow a more detailed analysis of the correlation between the dipole structure of PVP and its electrooptical and dielectric properties. Let us consider an analogue of the PVP monomer unit, low-molecular-weight MP.

Measurements of the electrooptical Kerr effect for MP solutions in chloroform showed that MP has a positive specific Kerr constant of $+(1.75 \pm 0.09) \times 10^{-10}$ g^{-1} cm^5 (300 V)$^{-2}$. Theoretically, the specific Kerr constant of a low-molecular-weight substance is related to the anisotropy of optical polarizability, Δa, and the magnitude and direction of the constant dipole moment μ of its molecules by

$$K = \frac{2\pi N_A (n_0 + 2)^2 (\varepsilon_0 + 2)^2}{1215 kT n_0 M} \Delta a \left[2\Delta a + \frac{\mu^2}{kT} \left(3\cos^2 \beta - 1 \right) \right]. \quad (3)$$

Here, β is the angle between the greatest polarizability axis of the molecule and the μ direction.

Based on the experimental value of K and value of Δa and μ, it is possible to estimate the angle β and, thus, to gain insight into the dipole geometry of MP. The MP molecule is relatively small, and we calculated its optical polarizability tensor and dipole moment by the PM3 semi-empirical quantum-chemical method [13], using the HyperChem software [14]. The results are summarized in Table 2.

Using the eigenvalues of the polarizabilty tensor, a_1, a_2, a_3, we calculated the anisotropy of optical polarizability of MP, $\Delta a = [(a_1 - a_2)^2 + (a_2 - a_3)^2 + (a_3 - a_1)^2]/2 = 33.9 \times 10^{-10}$ cm^3. Also, the calculations showed that MP has large constant dipole moment μ = 3.3 D. Next, we calculated by formula (3) the angle β between the directions of the greatest optical polarizability of the MP molecule and of its constant dipole moment. The resulting β = 45.7°, estimated from electrooptical measurements, agrees well with the quantum-chemical data:

$$\beta = \arccos(|\mu_1|/\mu) = 45.1°.$$

The dipole geometry of the MP molecule is characterized by the main directions shown in Fig. 5. The constant dipole moment is directed along the –C=O bond of the pyrrolidone ring; a_1 is directed along the axis of the greatest optical polarizability of the MP molecule, as predicted by the theoretical calculation. Such a dipole geometry of MP is responsible for the fact that, in the PVP chain, the dipole moment of each pyrrolidone ring in the polymer structure is directed at a large angle to the backbone direction.

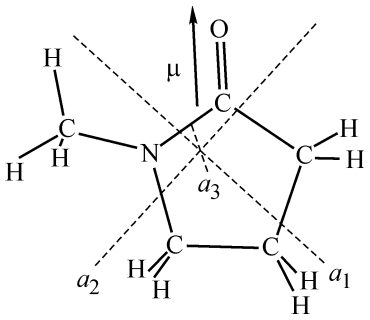

Fig. 5. Directions of the main axes of optical polarizability and constant dipole moment in the MP molecule.

The angle θ between the direction of the constant dipole moment of the pyrrolidone ring and the PVP backbone direction can be estimated using the theoretical expression for the Kerr constant K_∞ of the polymers in the Gaussian range of properties, where it is independent of the molecular weight [8]:

$$K_\infty = 2B\Delta b(\mu_1^2 \cos^2 \theta / M_1) s^2. \quad (4)$$

Here, $B = \pi N_A(n_0^2 + 2)^2(\varepsilon_0 + 2)^2/(1215 n_0 k^2 T^2)$ is the optical coefficient; Δb, the optical anisortopy of the monomer unit; μ_1 and M_1, the dipole moment and molecular weight of the monomer unit of the polymer, respectively; and s, the number of monomer units in the statistical Kuhn segment of the polymer.

Using the experimental values $K_\infty = -0.8 \times 10^{-10}$ g^{-1} cm^5 (300 V)$^{-2}$ for PVP-1 in chloroform, $\Delta b = -10 \times 10^{-25}$ cm^3 [4], $s = 7$ [12], and the μ_1^2/M_1 value corresponding to the experimental value for the MP analog of the PVP monomer unit (Table 1), we can estimate θ at 84.4°.

A similar calculation based on the data for the equilibrium Kerr effect for PVP-1 in the mixed solvent yielded $\theta = 86.4°$.

A close value was obtained using the experimental specific dielectric polarizations μ^2/M of the PVP-1 and PVP-2 samples in the mixed solvent, listed in Table 1. As known [11], the total dipole moment μ of the polymer molecule modeled by a Gaussian chain varies with the number of the monomer units in the statistical Kuhn segment, s, in the region of large MWs as

$$\mu^2/M = (\mu_1^2 \cos^2\theta/M_1)s. \quad (5)$$

Here, $\mu_1\cos\theta$ is the component of the constant dipole moment of the monomer unit of the polymer in the backbone direction.

By substituting into formula (5) the experimental value of μ^2/M for PVP-2 in the mixed solvent, the value $\mu^2/M_1 = 0.167 \times 10^{-36}$ D^2 g^{-1} corresponding to the monomer, and $s = 7$, we obtain $\theta = 82°$.

Thus, the electrooptical properties and dielectric polarization of the PVP solutions suggest that the constant dipole moment of the pyrrolidone ring is virtually perpendicular to the backbone. This, evidently, results from steric hindrance to orientation of bulky and strongly polar rings linked by weakly polar flexible vinyl chain. Large constant dipole moments of the pyrrolidone rings are perpendicular to the backbone and virtually cancel out in the bulk of the PVP polymer coil in the equilibrium state. This decreases the specific dielectric polarizations of PVP in solutions by almost an order of magnitude relative to low-molecular-weight MP and is responsible for small and negative electrooptical effect in solutions of this polar polymer. This is illustrated by Fig. 6 demonstrating the structure of the PVP hexamer, optimized by the PM3 quantum-chemical semiempirical method. The arrows show the directions of the dipole moments of the pyrrolidone rings. It is seen that the dipoles

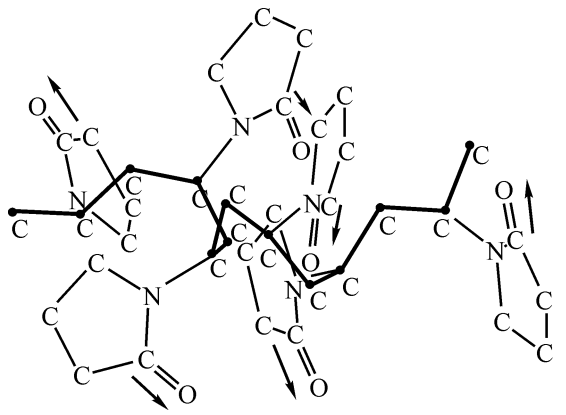

Fig. 6. Structure of the PVP hexamer, optimized by PM3 quantum chemical method. The PVP backbone is shown by a thick line; the hydrogen atoms are not indicated; *arrows* show the directions of the constant dipole moments of the pyrrolidone rings.

are not ordered along the PVP chain propagation direction; they are oriented in the neighboring monomeric units toward one another and are predominantly orthogonal to the vinyl chain.

CONCLUSIONS

(1) Dipole moments of polar pyrrolidone rings in the polymer molecule are oriented, on the average, at large angles of ~82°–87°, i.e., are virtually perpendicular, to the backbone.

(2) The orientation of the pyrrolidone rings is weakly correlated with the chain propagation direction, and their dipole moments virtually cancel out in the PVP bulk and do not contribute to the total dipole moment of the macromolecule.

(3) The above-mentioned specific features of the dipole structure are responsible for the fact that PVP, in which each monomeric unit has a significant dipole moment of ~3.3 D, exhibits a weak electrooptical Kerr effect which differs in sign and magnitude from that in its monomeric unit analogue, MP. PVP is also characterized by a small, relative to MP, specific dielectric polarization in solutions.

The results of this study are suitable for further analysis of the electrooptical and dielectric properties of PVP, in particular, fullerene-containing derivatives [2, 3].

Received June 10, 2003

Abstract—The photostabilizing properties of nickel and platinum ethylenedithiolate complexes used as IR absorbents in polymeric film light filters containing heterocyclic azo dyes were studied.

The majority of modern optical filters, along with having the main spectral characteristic in the visible range, also exhibit IR absorption bands suppressing the "parasitic" transmission of the filter in the IR range. Addition to dye formulations of IR-absorbing substances may affect the properties of dyes and, in particular, their lightfastness.

Among various classes of IR-absorbing substances, nickel and platinum ethylenedithiolate complexes form a particular group [1]; their solutions have no pronounced absorption bands in the visible range. Thus, these complexes do not affect noticeably the main spectral characteristics of the filters. One more advantage of transition metal ethylenedithiolate complexes is their capability for photostabilization of some polymeric compounds [2].

In this study, we prepared five ethylenedithiolate complexes **I**–**V** (Table 1) and examined their effect on yellow-orange filter dyes **VI**–**IX** of the thiophene and furan series (Table 2). These dyes are frequently used in cutoff and band-pass polymeric light filters on the cellulose acetobutyrate base. This polymer is the most convenient as the film-forming component, thanks to its high transparency, absence of shrinkage, moisture resistance, etc. [3].

Table 1. Filter IR absorbents 
Dye	Name	R_1	R_2	M	λ_{max}, nm
I	Bis(1,2-dimethylethylenedithiolato)platinum	CH_3	CH_3	Pt	740
II	Bis(1,2-dimethylethylenedithiolato)nickel	CH_3	CH_3	Ni	770
III	Bis(1,2-diphenylethylenedithiolato)nickel	C_6H_5	C_6H_5	Ni	850
IV	Bis[1,2-di(3',4'-dimethoxy)phenylethylenedithiolato]nickel	3,4-$(OCH_3)_2C_6H_5$	3,4-$(OCH_3)_2C_6H_5$	Ni	950
V	Bis[1-(4'-dimethylamino)phenyl-2-phenylethylenedithiolato]nickel	*p*-$N(CH_3)_2C_6H_5$	C_6H_5	Ni	1070

Table 2. Filter yellow-orange azo dyes of the thiphene and furan series 
Dye	Name	X	R_1	R	λ_{max}, nm
VI	2-Phenyl-4-(2'-carboxy)phenylazo-5-hydroxyfuran	O	COOH	H	440
VII	2-Phenyl-4-(2',4'-dimethyl)phenylazo-5-hydroxyfuran	O	CH_3	CH_3	440
VIII	2-Phenyl-4-(2'-carboxy)phenylazo-5-hydroxythiophene	S	COOH	H	470
IX	2-Phenyl-4-(2',4'-dimethyl)phenylazo-5-hydroxythiophene	S	CH_3	CH_3	480
