Abstract—The precipitation of bismuth(III) from nitrate solutions on addition of aqueous solutions of tartaric acid and sodium tartrate was studied by X-ray phase analysis, thermogravimetry, IR spectroscopy, and chemical analysis. Conditions for the formation of $[Bi(NO_3)(H_2O)_3]C_4H_4O_6$ and $[Bi(C_4H_4O_6)(C_4H_5O_6)]\cdot 3H_2O$ were determined.

Bismuth(III) compounds with tartaric acid and its salts are widely used in medicine for treatment of various diseases and also in the synthesis of bismuth-containing oxide materials [1, 2]. Usually they are prepared by precipitation of bismuth(III) from nitrate solutions with tartaric acid or its alkali metal salts [3]. As the composition ot the precipitated products is sensitive to the synthesis conditions [pH of the medium, ratio of tartrate ions and bismuth(III) in the aqueous phase, temperature, etc.], and tartaric acid itself has several donor centers and four labile protons, compounds of various compositions can be formed in these systems. It was shown that bismuth(III) can form the following compounds with tartrate ions: $BiC_4H_5O_7\cdot nH_2O$ [3, 4], $Bi(OH)_2Bi(OH)(C_4H_3O_6)$ [5], and $Bi(C_4H_4O_6)(C_4H_5O_6)\cdot 3H_2O$ [4, 6]. Reactions of these compounds with solutions of ammonia and of alkali metal hydroxides and acetates yield three-component complex compounds, both insoluble, e.g., $C_4H_3O_6BiM$ ($M = K^+$, Na^+, Li^+, NH_4^+) [3], $[Bi(C_4H_4O_6)_2]NH_4\cdot nH_2O$ [7], and soluble in water, e.g., $C_4H_4O_7BiNa$ [3], $Na(BiO)_2C_4H_3O_6$ and $Na(BiO)_3C_4H_2O_6$ [8], $Bi(HC_4H_4O_6)_4^-$, and $[Bi(OH)_3\cdot C_4H_4O_6]^{2-}$ [9].

Bismuth(III) compounds are usually synthesized by hydrolytic processing of nitrate solutions obtained by dissolution of metallic bismuth in HNO_3. Therefore, it is of practical interest to study the precipitation of Bi(III) tartrate from nitrate solutions of the composition similar to that of the process solutions.

In this work, we studied how the concentration of tartrate ions, temperature, and pH affect the degree of Bi(III) precipitation from nitrate solutions, and also the composition and purity of the precipitated products.

Precipitation of Bi(III) was carried out by adding aqueous solutions of sodium tartrate $C_4H_4O_6Na_2$ or tartaric acid $C_4H_6O_6$ to a solution of $Bi(NO_3)_3$ containing (g l^{-1}): Bi(III) 440 and free nitric acid 74. The solution of $Bi(NO_3)_3$ was prepared by dissolving Vi 00 grade metallic bismuth (no less than 99.98% Bi) in 9 M HNO_3; its composition corresponded to solutions usually used in the technology of bismuth(III) compounds. The volume ratio of the initial and final bismuth-containing solutions was 1 : 10; it was adjusted by adding distilled water. The experiments were carried out in fluoroplastic vessels equipped with stirrers. The mixture was stirred for 2 h. After sedimentation for 1 h, the precipitate was filtered off, washed on the filter with distilled water, and dried in air. The X-ray phase analysis of the precipitated products was carried out on a DRON-3 diffractometer using CuK_α radiation (rotation rate of the counter 0.5 deg min^{-1}, I = 1000). The DTA and TG curves for the samples under study were taken on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1}. The IR absorption spectra in the range 400–4000 cm^{-1} were recorded on a Specord IR-75 spectrophotometer. Samples were prepared in the form of pellets with calcined KBr. The electron micrographs of products were taken on a JSMT-20 scanning microscope with a 200 Å resolution. The specific surface area of the samples was measured by thermal desorption of argon, monitored chromatographically. Macroamounts of Bi(III) in the liquid and solid phases were determined by EDTA titration using xylenol orange as indicator, and its microamounts were determined photocolorimerically in the presence of KI. The concentrations of metal ions (Bi, Pb, Ag, Cu, Fe, Zn) were determined by the atomic absorption method on a Saturn 2M spectrophotometer. The precipitated products were

1070-4272/03/7601-0001$25.00

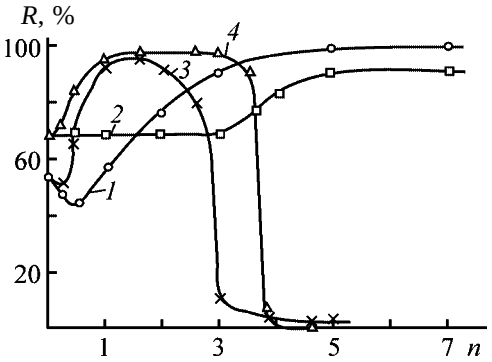

Fig. 1. Degree of Bi(III) precipitation *R* as a function of the molar ratio *n* of tartrate ions to Bi(III) in solution. Agents added to a bismuth-containing solution: (*1, 2*) tartaric acid and (*3, 4*) sodium tartrate. Temperature, °C: (*1, 3*) 23 and (*2, 4*) 60.

preliminarily dissolved in HNO_3 (1 : 1). The concentration of nitrate ions was determined photometrically with sodium salicylate after dissolution of the precipitates by treatment with a sodium hydroxide solution (2 M) at 70–90°C.

The study of the influence of the tartaric acid concentration on the degree of bismuth precipitation *R* (Fig. 1, curves *1* and *2*) shows that, as the concentration of tartrate ions in solution increases, the degree of bismuth(III) precipitation at 23±1°C first slightly decreases, passes through a minimum at the molar ratio of tartrate ions and Bi in solution *n* equal to 0.5, and then increases, reaching 98.8% at *n* = 5. Increased process temperature results in decreased degree of Bi(III) precipitation. The degree of Bi(III) precipitation at 60±1°C remains constant and independent of tartaric acid concentration up to *n* = 3, and at higher *n* the degree of precipitation grows, reaching 91.1% at *n* = 5.

According to the X-ray analysis (Fig. 2), the basic nitrates $[Bi_6O_4(OH)_4](NO_3)_6 \cdot 4H_2O$ (23°C) and $[Bi_6O_4(OH)_4](NO_3)_6 \cdot H_2O$ (60°C) are formed in the system in the absence of tartrate ions. The X-ray patterns of these compounds (Fig. 2, curves *1*, *2*) contain the characteristic diffraction peaks: *d*/*n* 1.68, 2.11, 2.39, 2.77, 2.82, 3.30, 3.81, and 8.42 Å for the tetrahydrate and 1.51, 1.73, 2.17, 2.50, 2.84, 3.75, 4.31, and 7.37 Å for the monohydrate [10, 11]. The precipitates obtained at the initial molar ratio of tartrate ions and bismuth in solution less than 1 are X-ray amorphous; in this case, Bi(III) seems to be precipitated as a mixture of oxohydroxonitrate and nitratotartrate. At *n* equal to 1, diffraction peaks with *d*/*n* 2.24, 3.72, 5.57, and 10.92 Å are clearly seen in the X-ray patterns of the precipitates (Fig. 2, curve *3*). This pattern does not correspond to any of the known bismuth compounds. However, according to the chemical analysis, the samples contain (%) Bi 49.00, C 9.74, H 1.42, and N 2.46; the molar ratio of Bi(III) and tartrate and nitrate ions in the precipitate is 1 : 1.1 : 1.2, which suggests that, under these conditions, a compound of the composition $[Bi(NO_3)(H_2O)_3]C_4H_4O_6$ mainly precipitates. The possibility for its formation was reported in [12].

The precipitates obtained at 23°C and *n* no less than 2 and also at 60°C and *n* no less than 3 consist of a compound with the composition $[Bi(C_4H_4O_6) \cdot (C_4H_5O_6)] \cdot 3H_2O$, which contains two different tartrate ligands, (+)-tartrate$^-$ and (+)-tartrate^{2-}. This is confirmed by the X-ray phase and chemical analyses. The diffraction peaks characteristic of this compound (*d*/*n* 1.84, 2.15, 2.46, 3.31, 4.36, 6.74, and 9.08 Å) [6] are present in the X-ray pattern (Fig. 2, curve *4*), and the molar ratio of Bi(III) and tartrate ions in the precipitate is 1 : 2 (the product contains 37.00% Bi, 17.61% C, and 2.64% H). The orthorhombic crystal structure of this compound (space group $P2_12_12_1$) includes a three-dimensional network with bridging and chelating bonds of polydentate hydroxocarboxylate ligands, and the coordination number of Bi(III) is 4 [6].

The thermal (DTA, TG, DTG) analysis of Bi(III) oxohydroxonitrates and tartrates in air reveals a number of endo- and exothermic stages, demonstrating the possibility of obtaining α-Bi_2O_3 by thermal decomposition of Bi(III) tartrates. Comparison of the thermograms of the samples obtained by Bi(III) precipitation from nitrate solutions in the absence of tartaric acid (Fig. 3a) and at *n* equal to 1 (Fig. 3b) and 5 (Fig. 3c) shows that the total weight loss increases with increasing *n*. This is due to an increase in the content of tartrate ions in the precipitated products. The thermal analysis of bismuth(III) oxohydroxonitrate reveals stepwise dehydration, dehydroxylation, and decomposition of nitrate with the formation of Bi_2O_3 [13]. The thermal decomposition of Bi(III) nitratotartrate starts from water removal (endothermic effect at 100°C) and decomposition of nitrate and tartrate ions (exothermic effects at 130, 240, and 320°C). Bismuth(III) tartrate trihydrate obtained at *n* = 5 loses weight in two stages: first water is removed (endothermic effect at 140°C), and then tartrate ions decompose with endothermic effects at 270 and 340°C. It is seen from the thermograms that heating of all the samples gives Bi_2O_3 as the final product. The endothermic effect at 730°C is due to the polymorphous transition of α-Bi_2O_3 into the high-temperature modi-

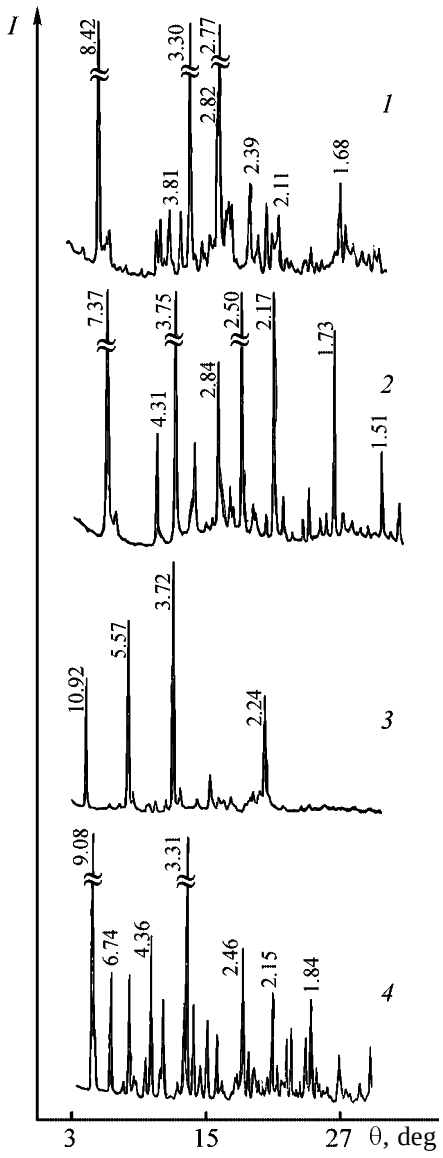

Fig. 2. Diffraction patterns of Bi(III) precipitates obtained from nitrate solutions by adding (*1, 2*) water and (*3, 4*) tartaric acid. (*I*) Signal intensity and (θ) Bragg angle. *n*: (*1, 2*) 0, (*3*) 1, and (*4*) 5. Temperature, °C: (*1*) 23 and (*2–4*) 60.

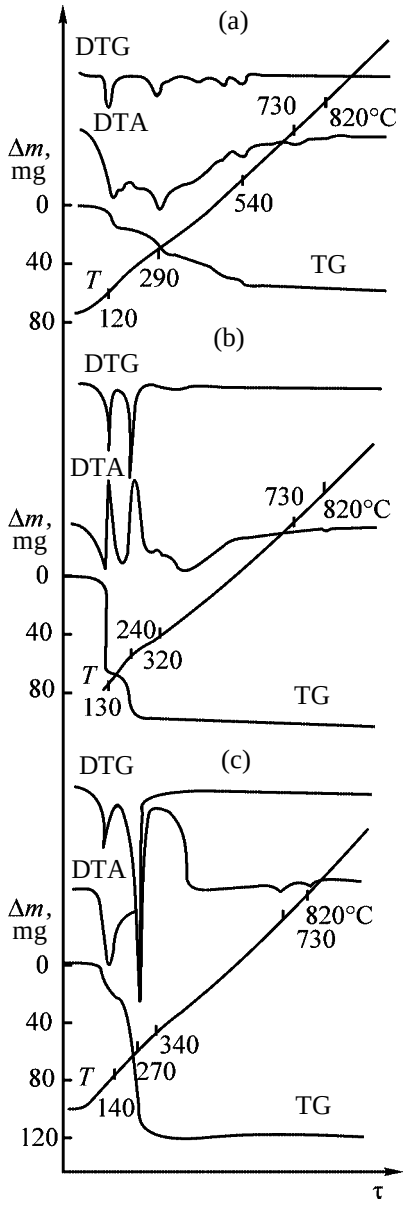

Fig. 3. Thermograms of Bi(III) precipitates obtained from nitrate solutions by adding (a) water and (b, c) tartaric acid. 23°C; sample weight 200 mg. (Δ*m*) Weight loss and (τ) time. *n*: (a) 0, (b) 1, and (c) 5.

fication β-Bi_2O_3, and the endothermic effect at 820°C is due to melting of Bi_2O_3 [14]. To transform Bi(III) oxohydroxonitrate into the oxide, it is necessary to calcine it at a temperature of no less than 540 ± 20°C, whereas Bi(III) tartrates can be transformed into the oxide by their thermal decomposition at 320 ± 20°C.

The study of the effect exerted by pH of the medium on the degree of Bi(III) precipitation has shown that, at the molar ratio of tartrate ions and Bi(III) equal to 2.1, 23°C, and the concentration of H^+ ions of 0.073, 0.34, 0.41, 0.61, 1.03, and 1.33 M the concentration of Bi(III) in solution is 20.9, 2.6, 1.0, 2.1, 11.5, and 12.8 g l^{-1}, respectively, i.e., the maximal degree of Bi(III) precipitation (97.5%) is reached at the 0.4–0.5 M concentration of hydrogen ions. The concentration of free nitric acid in precipitation of bismuth ditartrate by adding tartaric acid to a solution of $Bi(NO_3)_3$ is 0.75 M. To achieve the maximal precipitation, it is necessary to neutralize the solution by adding NaOH or $NH_3 \cdot H_2O$. However, the degree of Bi(III) precipitation sharply decreases at the concen-

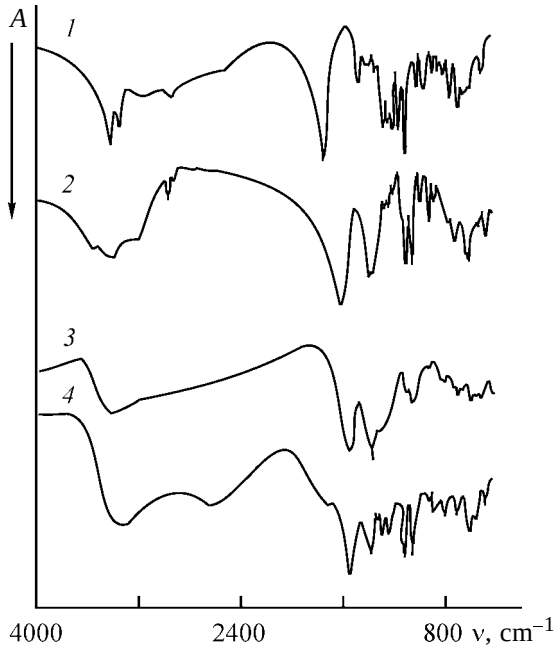

Fig. 4. IR absorption spectra of (*1*) tartaric acid, (*2*) sodium tartrate, (*3*) $[Bi(NO_3)(H_2O)_3]C_4H_4O_6$, and (*4*) $[Bi(C_4H_4O_6)\cdot(C_4H_5O_6)]\cdot 3H_2O$. (*A*) Absorption and (ν) wave number.

tration of free HNO_3 in solution less than 0.3 M, which may be due to formation of soluble tartrate-containing complexes. As the concentration of free HNO_3 in solution increases over 0.6 M, the degree of Bi(III) precipitation as a dihydrate also decreases, and at 1.33 M H^+ it is as low as 70.9%.

The degree of Bi(III) precipitation as a function of the concentration of sodium tartrate is plotted in Fig. 1 (curves *3*, *4*), which shows that this degree first increases, passes through a maximum at the molar ratio of tartrate ions and Bi(III) of 1.6 (R = 98%), and then sharply decreases, i.e., the precipitate dissolves. Such a pattern is due to the capability of Bi(III) to form water-soluble complexes with tartrate ions. The increase in the sodium tartrate concentration initially results in the precipitation of basic Bi(III) nitrates and tartrates of various compositions. The chemical analysis has shown that the products precipitated at n 1 and 2 contain, respectively (%): Bi 49.7, Na 1.43, NO_3^- 11.32 and Bi 35.0, Na 6.1 and NO_3^- 17.13. The sodium–bismuth(III) molar ratio in the precipitate is 0.25 and 1.5, respectively. At $n > 2$ (23°C) and $n > 3$ (60°C), the degree of Bi(III) precipitation sharply decreases, which is due to formation of water-soluble $Bi(HC_4H_4O_6)_4^-$ complex ions [9].

The IR absorption spectra of bismuth(III) tartrates were compared to those of tartaric acid and its sodium salt. The carboxy groups in the IR spectrum of tartaric acid (Fig. 4, curve *1*) give a broad band in the range 3300–2500 cm^{-1} corresponding to O–H stretching vibrations of carboxy groups bound in dimers. A band with a maximum at 1720 cm^{-1} corresponds to stretching vibrations of the C=O bonds of free carboxy groups. A band with well-defined maxima at 3320 and 3400 cm^{-1} corresponds to stretching vibrations of hydroxy groups involved to various extents in the hydrogen bonding.

The IR spectrum of sodium tartrate $C_4H_4O_6Na_2$ (Fig. 4, curve *2*) contains bands of the COO^- group with C–O bonds of the order 1.5 at 1610 (asymmetric stretching vibrations) and 1410 cm^{-1} (symmetric stretching vibrations), indicating the transformation of the carboxy groups to the anionic form. A broad band with several maxima in the range 3560–3200 cm^{-1} corresponds to hydroxy groups involved in various hydrogen bonds and to molecular water present in a certain amount in the associated form.

A similar IR pattern is observed with the compound $[Bi(NO_3)(H_2O)_3]C_4H_4O_6$ obtained at the 1 : 1 molar ratio of tartrate ions and Bi(III) (Fig. 4, curve *3*). However, along with the absorption bands of the deprotonated carboxy group (1590 and 1390 cm^{-1}), broadened bands in the range 1400–1280 cm^{-1} and a pronounced shoulder at 1310 cm^{-1} are observed in the spectrum, which most likely originate from the absorption of nitrate ions. A broad band with a pronounced maximum at 3400 cm^{-1} is due to the O–H stretching vibrations of water molecules and hydroxy groups of tartrate ions involved in hydrogen bonding.

Similar to the spectrum of tartaric acid, the IR spectrum of bismuth ditartrate (Fig. 4, curve *4*) contains, along with the absorption bands of carboxylate groups (1590 and 1390 cm^{-1}), also the bands of carboxy groups: a broad band in the range 3200–2400 cm^{-1}, which corresponds to the stretching vibrations of OH groups of carboxylic acids involved in hydrogen bonding, and a band at 1720 cm^{-1} of the stretching vibrations of the C=O bond in the carboxy group. This spectral pattern is quite consistent with the composition $[Bi(C_4H_4O_6)(C_4H_5O_6)]\cdot 3H_2O$.

The electron micrographs (Fig. 5a) show that Bi(III) nitratotartrates obtained at 23 and 60°C consist of relatively large aggregates of the size from 3 to 40 μm, with signs of a block structure. The aggregates consist of smaller crystals. Bismuth(III) ditartrate trihydrate obtained at 23°C consists of oriented intergrown pieces of elongated prismatic (almost needle-like) crystals of the size of about 3–10 μm, whereas

crystals of the product obtained at an elevated temperature (60°C) have a size of 20–60 μm (Fig. 5*c*).

When Bi(III) is precipitated from nitrate solutions by adding a sodium tartrate solution, an X-ray amorphous product is obtained; its aggregates, having a size of 1–5 μm, consist of submicrometer X-ray amorphous particles (Fig. 5d). The specific surface areas of sodium tartrates obtained at 23 and 60°C are, respectively, for the nitratotartrate 0.8 and 0.7, for the ditartrate 0.6 and 0.4, and for the sodium-containing tartrate 1.5 and 1.1 $m^2\ g^{-1}$, i.e., the specific surface area of Bi(III) tartrates decreases with increasing temperature.

Bismuth(III) compounds are usually synthesized from nitrate solutions starting from Vi-1 grade bismuth which contains Ag and Pb as the main impurities. The Bi(III) tartrate $[Bi(C_4H_4O_6)(C_4H_5O_6)]\cdot 3H_2O$ was precipitated by adding tartaric acid to a solution of $Bi(NO_3)_3$ at 23 ± 1°C and the 5 : 1 ratio of tartrate ions to Bi(III) in solution. Enlarged tests were carried out with a Bi(III)-containing solution, which was obtained by dissolving Vi-1 grade bismuth containing 0.06 wt % Ag and 1.2 wt % Pb. The mixture was stirred for 2 h and settled. The mother solution containing 0.69 $g\ l^{-1}$ of Bi(III) was separated by decanting. The precipitate of Bi(III) tartrate was washed with one portion of a nitrate solution with pH 1.0 and two portions of distilled water. The resulting Bi(III) tartrate contained (wt %) Pb 0.55, Ag 1.5×10^{-4}, Cu 2.5×10^{-4}, Fe 1.0×10^{-3}, and Zn 2.5×10^{-4}, i.e., the removal of Pb(II) from Bi(III) was inefficient. Therefore, to synthesize high-purity Bi(III) tartrate, it is necessary to use the Vi 00 grade metal (≥99.98% Bi) or to preliminarily remove impurity metal ions by precipitating Bi(III) from nitrate solutions as its oxohydroxonitrate [15]. To remove impurity metal ions from Bi(III), we diluted the initial nitrate solution by a factor of 2 with distilled water and added a 2.5 M solution of $(NH_4)_2CO_3$ with stirring to the solution containing 220 $g\ l^{-1}$ of Bi(III) and 37 $g\ l^{-1}$ of free HNO_3, until pH of the pulp became 0.9. The precipitate was washed with two portions of distilled water, and the resulting oxohydroxonitrate $[Bi_6O_5(OH)_3](NO_3)_5\cdot 3H_2O$ was dissolved in 6.0 M HNO_3. The precipitation of Bi(III) ditartrate trihydrate by adding tartaric acid to the resulting solution under the above-mentioned conditions gave a product containing (wt %) Pb 5.0×10^{-4}; Ag 3×10^{-6}; Cu 2×10^{-6}; Fe 1.0×10^{-4}; Zn 8×10^{-5}; and Ca, Mg, and Na $< 1.0 \times 10^{-4}$.

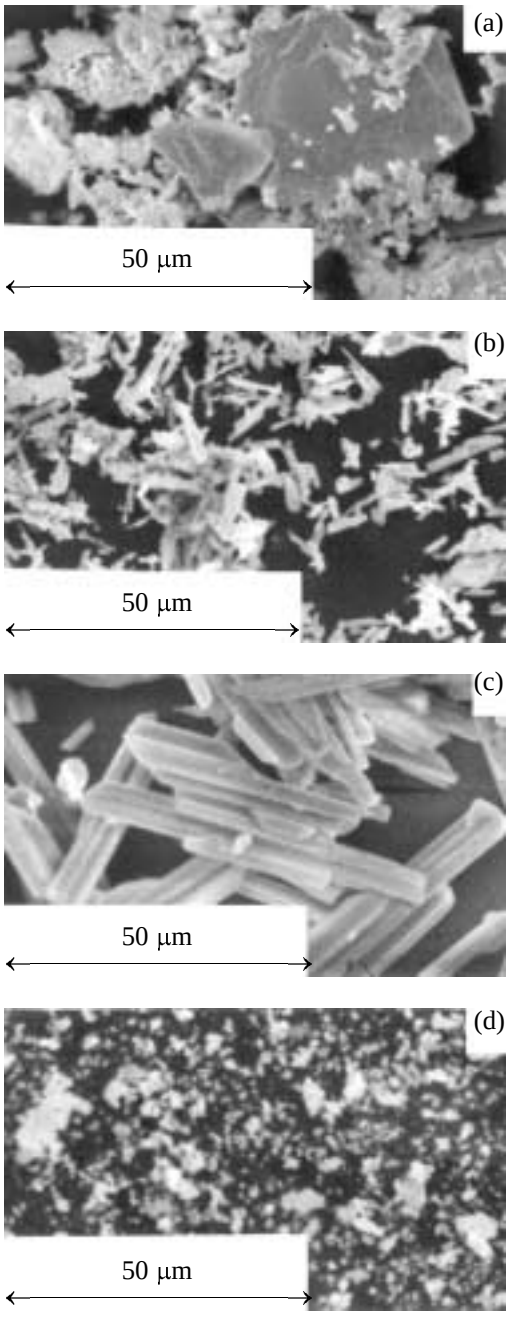

Fig. 5. Electron micrographs of (a) nitratotartrate, (b) ditartrate, and (c) sodium-containing tartrate of Bi(III) obtained on adding (a–c) tartaric acid and (d) sodium tartrate to a solution of $Bi(NO_3)_3$. Temperature (°C): (a, b, d) 23 and (c) 60.

CONCLUSIONS

(1) It is appropriate to synthesize the Bi(III) ditartrate $[Bi(C_4H_4O_6)(C_4H_5O_6)]\cdot 3H_2O$ by its precipitation from bismuth-containing nitrate solutions by adding tartaric acid at the molar ratio of tartrate ions and

Bi(III) in solution no less than 2, H^+ concentration of 0.4–0.5 M, and temperature of 22 ± 3°C.

(2) When synthesizing high-purity Bi(III) ditartrate, it is necessary to use high-purity Bi(III), or, if using technical-grade Bi(III), to preliminarily perform hydrolytic purification of bismuth by its precipitation as oxohydroxonitrate.

(3) Bi(III) is precipitated as the nitrotriaquatartrate $[Bi(NO_3)(H_2O)_3]C_4H_4O_6$ from a solution with the 1 : 1 molar ratio of tartrate ions and Bi(III), whereas the precititation with sodium tartrate gives sodium-containing tartrates.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Interaction of Titanium Tetrachloride with Products of Thermal Decomposition of Basic Magnesium Carbonate

S. A. Morozov, A. A. Malkov, and A. A. Malygin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 4, 2002

Abstract—The interaction of titanium tetrachloride vapor with products formed in thermal decomposition of basic magnesium carbonate in the temperature range 200–800°C was studied.

Published data on modification of magnesium-containing solid matrices with titanium tetrachloride show that application of the gas-phase technique is mainly limited to pure magnesium oxide [1–6]. Other magnesium compounds are mostly modified in the liquid phase. In synthesizing magnesium oxide, various hydroxocarbonate compounds with different phase compositions and structural characteristics have been obtained and characterized [7]. In view of the wide use of compounds of this kind in catalysis, as fillers, and as binder components [2, 3, 8, 9], it is of current interest to consider the possibility of gas-phase modification of these compounds with titanium(IV) chloride.

EXPERIMENTAL

The samples used in the study were obtained by thermal decomposition of basic magnesium carbonate [ultrapure grade, TU (Technical Specifications) 6-09-2118–77] in a flow of dried air (flow rate 50 ml min^{-1}) for 4 h at a temperature chosen from the range 200–800°C. X-ray phase analysis of products formed in thermal treatment was made with a DRON-2 diffractometer (Ni-filtered CuK_α radiation, range of angles θ 2°–40°) using the ASTM file. The specific surface area of the initial samples was determined by the method involving low-temperature adsorption of air [10]. The reaction of titanium tetrachloride with products formed by thermally induced transformations of basic magnesium carbonate was studied at 200°C on a thermogravimetric setup with a quartz spring balance with the spring stretching factor of 3.33 mg g^{-1}. With 0.10–0.12-g samples, this allows monitoring to within ±0.5 mg g^{-1} of mass changes under conditions of a continuous supply of reagent vapor and removal of gaseous reaction products. The products synthesized were analyzed for the content of titanium [11] and chlorine [12].

The phase compositions of products formed in successive transformations of basic magnesium carbonate is listed in Table 1. It can be seen that, at calcination temperatures below 400°C, the solid matrix contains both magnesium oxide and magnesium carbonate. At 400°C and above, the product is entirely composed of magnesium oxide, and the size of coherent domains increases from 4.3 (400°C) to 15.6 nm (800°C).

Analysis of thermogravimetric curves of $TiCl_4$ chemisorption (Fig. 1a) shows that all the samples are characterized by a gradual decrease in the reaction rate in the course of treatment with reagent vapor, which is manifested in decreasing mass gain at equal intervals of time. The overall change in the mass and in the titanium content of reaction products at equal duration of chemisorption as a function of the temperature of sample preparation passes through a maximum at 400°C (Fig. 2). A similar dependence on the temperature of calcination of basic magnesium carbonate has been observed previously for the specific surface area of the samples obtained [7]. Therefore, to characterize the reactivity of the surface of the products, the gains in the mass and titanium content were related to unit surface area (Fig. 2b, Table 2). The dependences obtained indicate that the highest activity in reaction with $TiCl_4$, as regards the change in mass in the initial stage and the maximum gain in mass, both related to unit surface area, is observed with samples obtained at 200 and 300°C.

The Cl/Ti ratio in the composition of all the products (Table 2) is close to the stoichiometric ratio in titanium tetrachloride; moreover, no decrease in mass, common in processes carried out on SiO_2 and Al_2O_3, is observed in the stage of removal of the physically

adsorbed reagent and gaseous reaction products (Fig. 1a). This suggests complete binding of the gaseous reagent with the magnesium-containing compounds of the given series.

As noted in [1, 2, 5], in samples containing solely the magnesium oxide phase, along with the exchange reaction between the gaseous reagent and surface functional groups,

$$–Mg–O–H + TiCl_4 \rightarrow –Mg–O–TiCl_3 + HCl, \quad (1)$$

the reaction with the forming HCl and with $TiCl_4$ yielding magnesium chloride are also possible:

$$MgO + 2HCl \rightarrow MgCl_2 + H_2O, \quad (2)$$

$$–Mg–O–H + HCl \rightarrow –Mg–Cl + H_2O, \quad (3)$$

$$–Mg–O–H + TiCl_4 \rightarrow –Mg–Cl + Ti(OH)Cl_3, \quad (4)$$

$$MgO + TiCl_4 \rightarrow MgCl_2 + TiOCl_2 \begin{matrix} \nearrow 0.5TiO_2, \\ \searrow 0.5TiCl_4. \end{matrix} \quad (5)$$

Formation of E–Cl groups was observed in reactions of vapors of volatile chlorides and hydrogen chloride with Al_2O_3 and ZnO matrices, which are characterized by mainly ionic type of E–O bonds and contain basic centers, in addition to acid centers, on the surface [13–17].

On the assumption that the reagent molecules are fully bound to the matrix, chemical analysis data were used to estimate the possible gain in mass of samples in their interaction with $TiCl_4$:

$$\Delta m = M_{Ti}Ti + M_{Cl}Cl, \quad (6)$$

where Δm is the gain in mass (mg g^{-1}); Ti, the content of titanium in a sample (mmol g^{-1}); M_{Ti}, the molar mass of titanium (g mol^{-1}); M_{Cl}, the molar mass of chlorine (g mol^{-1}); Cl, the content of chlorine in a sample (mmol g^{-1}).

The calculated gain in mass was compared with that determined experimentally during the reaction and and upon its completion by measuring the sample mass (Table 3). For samples obtained at 400–800°C, the calculated and experimental changes in mass are in good agreement, suggesting that, for the given samples containing solely the magnesium oxide phase, the interaction with $TiCl_4$ also proceeds via exchange reactions [1–5].

For samples obtained at 200 and 300°C, which contain a residual phase of magnesium carbonate, the discrepancies between the calculated and experimental gains in mass are significant. In view of the data in Table 1, this may be due to removal of carbon dioxide from the matrix, occurring in parallel with addition of titanium(IV) and chlorine-containing groups under the action of $TiCl_4$ vapor.

Thus, in the case of hydroxocarbonate samples, reactions (1)–(5) listed above presumably occur in parallel with exchange of carbonate ions for chloride ions with the formation of magnesium chloride and titanium oxide as solid products:

$$2MgCO_3 + TiCl_4 = 2MgCl_2 + TiO_2 + CO_2. \quad (7)$$

It is this factor that may lead to additional mass loss and to a decrease in the gravimetrically recorded gain in the sample mass.

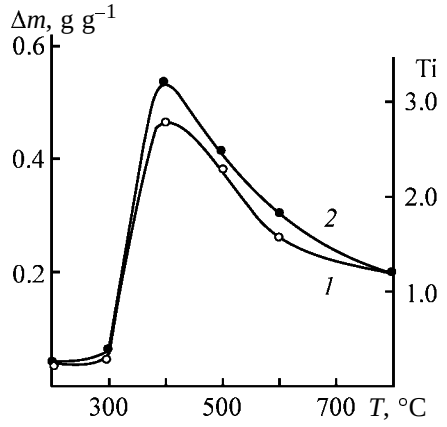

Fig. 2. (*1*) Gain in mass, Δm, and (*2*) content of titanium(IV), Ti, in the product formed upon interaction with $TiCl_4$ vapor vs. sample preparation temperature, *T*.

Table 3. Gain in sample mass upon interaction of $TiCl_4$ with basic magnesium carbonate calcined at 200–800°C

	calculated, Δm_c	experimental, Δm_{exp}	
200	46.95	37.04	1.27
300	66.63	47.82	1.39
400	427.37	463.37	0.92
500	346.78	384.97	0.90
600	271.04	261.36	1.04
800	191.47	201.29	0.95

Table 4. Assessment of the probability that $TiCl_4$ and hydrogen chloride may react with magnesium-containing compounds

Reaction	Gibbs energy ΔG, kJ mol^{-1}, at 200°C
$Mg(OH)_2 + TiCl_4 \rightarrow MgCl_2 + TiO_2 + 2HCl$	–129.9
$2MgCO_3 + TiCl_4 \rightarrow 2MgCl_2 + TiO_2 + 2CO_2$	–136.8
$2MgO + TiCl_4 \rightarrow 2MgCl_2 + TiO_2$(anatase)	–172.6
$MgO + 2HCl \rightarrow MgCl_2 + H_2O$	–71.6

To verify this assumption, we calculated the amount of CO_2 that can be removed by topochemical reaction (7). According to differential-thermal analysis of the starting compound, the content of CO_2 in the products formed upon thermal treatment at 200 and 300°C is, respectively, 15.7 and 19.3 mg g^{-1} [7], which is close to the difference between the calculated and experimental gain in mass in interaction of the matrices with $TiCl_4$ vapor, equal to, respectively, 17.4 and 18.8 mg g^{-1}. At temperatures higher than 400°C, when decomposition of magneisum carbonate in the initial matrix is virtually complete, satisfactory agreement is observed between the gains in mass calculated from chemical analysis data and found experimentally.

Taking into account the aforesaid and proceeding from the interaction schemes considered, we may assume that the amount of titanium(IV) in the products synthesized must exceed its possible content for the case when only surface reactions involving functional groups of the initial matrix occur to give a titanium-containing monolayer. In other words, topochemical reactions presumably occur at the given temperature in parallel with surface reactions of substitution and addition. Thermodynamic assessment of the feasibility of the reactions at 200°C, based on the standard Gibbs energies calculated using the thermodynamic constants of the reaction participants [18], is done in Table 4. The Gibbs energy is negative for all the reactions, which means that they may, in principle, occur at the given temperature.

To confirm quantitatively the above assumption, we calculated the limiting concentration of titanium(IV) on the surface of magnesium oxide for the case of dense monolayer packing of $TiCl_4$ molecules.

The effective landing area w for $TiCl_4$ molecules was calculated using the Brunauer–Emmett formula [19]

$$w = 1.091(M/N_A\rho)^{2/3}, \quad (8)$$

where w is the landing area for a molecule (nm^2); M, the molar mass of the chloride (g mol^{-1}); N_A, Avogadro's constant (at. mol^{-1}); and ρ, the density of liquid $TiCl_4$ (g cm^{-3}).

For titanium tetrachloride, the landing area

$$w = 1.091(190/6.02 \times 10^{23} \times 1.728)^{2/3} = 0.35 \text{ nm}^2. \quad (9)$$

The limiting content of titanium(IV) in the monolayer is, correspondingly, given by

$$N_{Ti} = 1/w = 2.86 \text{ at nm}^{-2}. \quad (10)$$

For all the samples, the experimentally found content of titanium, Ti_S, exceeds the calculated monolayer concentration on the surface (Table 2). Thus, the interaction of TiCl both with intermediates formed in thermal transformation of basic magnesium carbonate and with magnesium oxide under the temperature conditions of the process, considered here, involves, in addition to exchange reactions at the surface, topochemical transformations accompanied by formation of a product layer, presumably composed of bulk magnesium chloride and titanium dioxide.

CONCLUSIONS

(1) The nature of interaction with $TiCl_4$ vapor is determined by the chemical and phase composition of products formed in thermal transformation of basic magnesium carbonate. Exposure to $TiCl_4$ vapor of magnesium-containing products of thermal treatment at 200 and 300°C, which contain a large amount of magnesium carbonate compounds, leads to their replacement magnesium chloride compounds, accompanied by evolution of carbon dioxide into the gas phase.

(2) The general pattern involves, together with surface reactions, topochemical conversions accompanied by formation of a product layer presumably composed of bulk magnesium chloride and titanium dioxide.

Abstract—Thermal expansion of niobium phosphates, new representatives of the family of structural analogs of $[NaZr_2(PO_4)_3]$, was studied. These compounds possess high thermomechanical stability because of the unique ability of their structure to expand–contract along different crystallographic directions under thermal treatment.

Thermal expansion of a material is an important characteristic determining its behavior under conditions of multiple abrupt changes in temperature ("thermal shock"). Crystalline substances, including ceramics with low and ultralow expansion, and particularly those with low anisotropy of thermal expansion, are characterized by high thermomechanical stability.

The family of phosphates, structural analogs of $NaZr_2(PO_4)_3$ (NZP, Nasicon), known from the 1980s, is unique in behavior of its representatives under heating. Their structure is characterized by expansion–contraction along different crystallographic directions, which leads to low average thermal expansion for most of them. Moreover, the ability of their structure to incorporate strongly diverse cations (with oxidation state in the range from +1 to +5) because of the broad isomorphism ensures formation of a large number of compounds and solid solutions with controllable properties, including thermal properties. Therefore, phosphates of the NZP family are of indubitable interest for materials science specialists.

The structure of $NaZr_2(PO_4)_3$ and its analogs [1], which can be regarded as a derivative of the structure of iron sulfate $Fe_2(SO_4)_3$ [2, 3], is formed by a tetrahedral-octahedral framework of the $[T_2(PO_4)_3]^{n-}$ type, composed of PO_4 and TO_6 groups sharing common oxygen vertices, where T stands for elements in various oxidation states, and n is the framework charge. Cations are connected in the framework by strong covalent bonds, and it is this factor that ultimately determines its small deformations under heating.

Various cations, compensating the negative charge n of the framework, may occupy positions of two types, M1 and M2, in framework voids. The general crystal-chemical formula of the compounds, which takes into account the number of positions M, is described as $(M1)(M2)_3[T_2(PO_4)_3]$.

A separate group among framework phosphates of this kind is constituted by compounds with electrically neutral frameworks ($n = 0$), with unoccupied positions M1 and M2. They can be represented as the series

$$T^{IV}T^{V}(P^{V}O_4)_3 \rightarrow T^{III}_{1/2}T^{V}_{3/2}(P^{V}O_4)_3$$

$$\rightarrow T^{II}_{1/3}T^{V}_{5/3}(P^{V}O_4)_3 \rightarrow T^{I}_{1/4}T^{V}_{7/4}(P^{V}O_4)_3.$$

Apparently, cations in the oxidation state +5 (T^V) are involved in formation of any framework of this kind.

Representatives of phosphates with $T^{IV}T^{V}$ and $T^{III}_{1/2}T^{V}_{3/2}$ are known. These are phosphates containing T^{IV} = Zr, Nb, Ti, Ge, V; T^V = Nb, Sb, Ta [4–10], and T^{III} = Sb, Nd, Eu, Bi; T^V = Sb, Nb, Ta [11–13]. Most of these are related to the structural type NZP, space group $R\bar{3}c$ or $R\bar{3}$. One of conditions for formation of such a structure is that the relative difference between the radii of the cations T^{IV}–T^V and T^{III}–T^V, $\Delta r/r_{min}$, should not exceed 0.3.

A study of thermal decomposition of phosphates with the above composition established that all the compounds studied are characterized by nearly zero

1070-4272/03/7601-0012$25.00

thermal expansion with nearly zero expansion anisotropy along different crystallographic directions [6–8, 14].

The set of the already synthesized and studied phosphates described by the above formula series is rather limited. At the same time, it should be kept in mind that the compositions proposed cannot be always obtained. The possible limiting factors are chemical and crystal-chemical features of framework-forming cations.

This study was aimed to synthesize phosphates of the general formula $T^{II}_{1/3}T^{V}_{5/3}(PO_4)_3$ with T^{II} = Mg, Co, Ni and T^{V} = Nb and analyze their thermal expansion. There are no published data on phosphates of such composition. With account of the nature of cations (their radii, charges, electronegativities) and the formation of an electrically neutral framework (n = 0), anticipated in view of the stoichiometry chosen, it would be expected that the new compounds have structure with trigonal crystal system (rhombohedral unit cell) and nearly zero thermal expansion.

EXPERIMENTAL

Phosphates of niobium(V) and bivalent metals of the type $B_{1/3}Nb_{5/3}(PO_4)_3$, where B = Mg, Co, Ni, were synthesized by the solid-phase method. As starting reactants served MgO, $CaCO_3$, $Sr(NO_3)_2$, $CoCl_2 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $(NH_4)_2HPO_4$, and Nb_2O_5. The synthesis included several stages. A mechanical mixture of reactants taken in stoichiometric amounts was ground in an agate mortar and kept at 450°C for 4 h. Then the mixture was subjected to isothermal treatment at 600, 800, 900, 1000, and 1100°C for 24–60 h with intermediate dispersion in each stage.

The phosphates obtained were studied by IR spectroscopy, X-ray phase analysis, electron-microprobe analysis, and high-temperature X-ray diffraction analysis.

The microprobe analysis was made on a Camebax instrument with a Link AN-10 000 energy-dispersive detector, with the ZAF-correction technique used to calculate compositions. The accuracy with which the composition of samples was determined was 2.5 mol %.

IR spectra were recorded on a Specord 75-IR spectrophotometer in the wave number range 1800–400 cm^{-1}. Samples in the form of a finely dispersed suspension in isopropyl alcohol were deposited onto a KBr substrate.

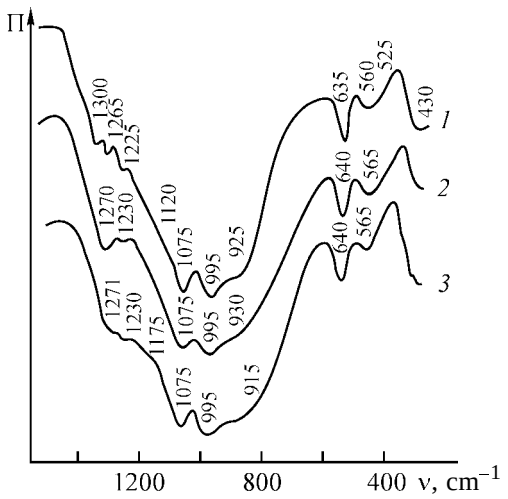

Fig. 1. IR spectra of phosphates of the type $B_{1/3}Nb_{5/3}(PO_4)_3$ with B = (*1*) Mg, (*2*) Co, and (*3*) Ni. (П) Transmission and (ν) wave number.

X-ray diffraction patterns of powder samples were recorded on a DRON-3.0 diffractometer with filtered CuK_α radiation (λ = 1.54078 Å) in the range of angles 2θ 10°–80°. The angle measurement error did not exceed 0.015°. This led to an error in lattice parameters equal to 0.005 and 0.01 Å along the a and c axes, respectively.

The behavior of the phosphates under heating was studied by powder high-temperature X-ray diffraction analysis on a DRON-3M diffractometer with a GPVT-1500 high-temperature attachment in filtered CoK_α radiation (λ = 1.78892 Å) [15]. The samples were heated at an average rate of 10 deg min^{-1}. Reflections were recorded in the temperature range 20–800°C with a temperature step of 200°C. The temperature was measured with a Pt–Pt/Rh thermocouple, whose readings were verified by simultaneous measurement of lattice parameters of a reference substance (Al_2O_3). The axial coefficients α_a and α_c were calculated by a procedure based on the least-squares method [16].

It follows from the results of X-ray diffraction analysis that individual phases are obtained for all the niobium(V) phosphates studied. According to the results of electron-microprobe analysis, these samples are homogeneous and have compositions close to the theoretical composition corresponding to the formula $B_{1/3}Nb_{5/3}(PO_4)_3$. Their X-ray diffraction patterns are similar in positions and relative intensities of diffraction peaks. As regards the distribution of vibration frequencies, the IR spectra (Fig. 1) are also closely similar and indicate that the compounds under study are orthophosphates.

The diffraction patterns were indexed with the use of an analog, $NbTi(PO_4)_3$, which is characterized by rhombohedral symmetry [17] and belongs to the structural type of $NaZr_2(PO_4)_3$ (NZP) (Table 1).

The results of X-ray diffraction analysis are in good agreement with IR data. The spectral pattern characteristic of NZP phases is similar to that of the substances containing tetra- and pentavalent elements, e.g., $TaV(PO_4)_3$ [10].

Table 2. Crystallographic parameters of phosphates of the type $B_{1/3}Nb_{5/3}(PO_4)_3$ (B = Mg, Co, Ni)

Ni	0.69	0.078	8.637	22.08	1429

Table 3. Data of high-temperature X-ray diffraction analysis for phosphates of the type $B_{1/3}Nb_{5/3}(PO_4)_3$ (B = Mg, Co, Ni)

B	$\alpha \times 10^6$, deg^{-1}		
	α_a	α_c	α_{av}
Mg	–2.3	3.4	–0.39
Co	–1.5	4.4	0.45
Ni	–2.2	3.0	–1.92

The unit cell parameters calculated for the phosphates $B_{1/3}Nb_{5/3}(PO_4)_3$ (B = Mg, Co, Ni) (Table 2) are close and vary only slightly within the range from 8.657 to 8.642 Å for *a* and 22.08 to 22.11 Å for *c*.

The double phosphates of niobium(V) and bivalent metals Mg, Co, and Ni, characterized by the above techniques, were studied under heating. First, the thermal limits of existence of the compounds obtained were found. It was established that, having formed at 600°C as crystalline phases, they retained their composition and structure up to 900°C. Raising the temperature led to decomposition of the NZP phosphates, with the high-temperature modification α-$NbOPO_4$ (space group *P*4/*n*) [18] becoming the predominant phase.

Changes in the structure of the phosphates under thermal treatment in the range from room temperature to 800°C were judged from the linear thermal expansion coefficients $\alpha_a = \Delta_a/(a\Delta T)$ and $\alpha_c = \Delta_c/(c\Delta T)$. The coefficients α_a and α_c, calculated from X-ray diffraction data, are listed in Table 3.

As expected, the phosphates under study, having an electrically neutral framework, little expand upon heating. The experimentally determined crystallographic parameters *a* and *c* vary only slightly within the temperature range studied. The structure exhibits anisotropy of thermal expansion: contraction along the *a*-axis ($\alpha_a < 0$) and expansion along the *c*-axis ($\alpha_c > 0$), which is characteristic, as already mentioned, of the family of NZP phosphates. The differences in α_a and α_c values in the series of Mg–Co–Ni phosphates are insignificant, although a certain decrease in

contraction along the *a*-axis and increase in expansion along the *c*-axis are observed for the $Co_{1/3}Nb_{5/3}(PO_4)_3$ phosphate, compared with its Mg and Ni analogs.

Also, the unit cell parameters *a* and *c* at different temperatures were calculated from data furnished by high-temperature X-ray diffraction analysis (Fig. 2). A tendency is observed for the parameter *a* of the hexagonal unit cell in the phosphates $B_{1/3}Nb_{5/3}(PO_4)_3$, (B = Mg, Co, Ni) to decrease and the parameter *c* to increase with increasing temperature. Such a behavior is commonly characteristic of phosphates with NZP structure. Apparently, the crystallographic parameters *a* and *c* change only slightly upon heating.

The average thermal expansion was calculated for the phosphates studied (Table 3). These compounds show either insignificant average thermal expansion, or contraction ($\alpha_{av} < 0$). Apparently, the results of the study supplement published data on phosphates exhibiting low thermal expansion, which are represented now by a small number of compounds. The list includes $NbM(PO_4)_3$, where M = Ti, Zr, Sn, Hf [6, 7, 14].

The unique ability of materials based on phosphates with NZP structure to exhibit virtually zero expansion upon heating may be luckily combined with such properties as high hydrothermal stability and radiation hardness, capacity for forming, high strength and hardness of ceramics prepared on their base, environmental stability, etc. The properties listed above are of value for materials for space and laser technologies, petrochemistry and other fields of chemistry, development of catalysts and catalyst supports, neutron-absorbing ceramics, hard tool ceramics, refractory composites, and other functional materials.

CONCLUSION

Thermal expansion of new compounds, belonging to the class of orthophosphates with framework structure, was studied. Phosphates of niobium(V) and bivalent metals Mg, Co, and Ni, of the type $B_{1/3}Nb_{5/3}(PO_4)_3$, supplemented the family of structural analogs of $NaZr_2(PO_4)_3$ (NZP or Nasicon), which are characterized by low or ultralow thermal expansion and the resulting stability to thermal shocks. It was shown that the low value of the average thermal expansion coefficient, $\alpha_{av} \approx 10^{-6}$–$10^{-7}$ deg^{-1}, is due, as in the case of all phosphates of similar structure, to expansion–contraction along different crystallographic axes.

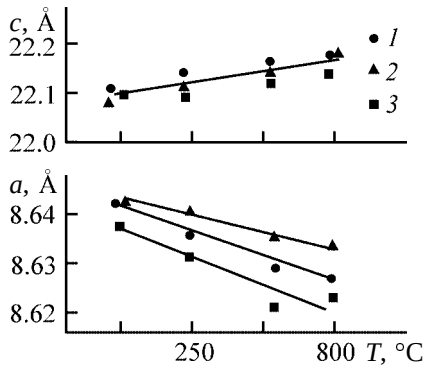

Fig. 2. Unit cell parameters *a* and *c* of phosphates of the type $B_{1/3}Nb_{5/3}(PO_4)_3$ with B = (*1*) Mg, (*2*) Co, and (*3*) Ni vs. temperature *T*.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Complex Formation of Calcium Ions and Monosubstituted Succinic Acid Derivatives in Aqueous Solutions

G. V. Mitrofanova

Mining Institute, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received September 25, 2002

Abstract—Complex formation of calcium ions with succinic acid monoamide and methyl hydrogen succinate at 25°C and ionic strength $I = 0.3$ (KCl) was studied by pH-potentiometric titration. The stability constants of the complexes were determined.

Fatty acid collecting agents used for dressing of phosphorus-containing ores are obtained from vegetable raw materials. They are insufficiently effective for flotation of ores with complicated mineralogical composition, especially under conditions of water recycling. One of promising ways for the development of effective collecting agents that are less sensitive to the salt composition of the pulp liquid phase is the use of compounds containing two different functional groups.

Nitrogen- or oxygen-containing monosubstituted succinic acid derivatives are of interest in this respect [1–3]. They are readily available owing to high reactivity of the anhydride ring in reactions of the anhydride with methanol or ammonia.

The pulp liquid phase formed during dressing of apatite (a calcium-containing mineral) contains a significant amount of calcium ions, which strongly affect the flotation process. Therefore, it was important to estimate stability of calcium compounds in aqueous solutions of succinic acid monoamide and monoester. The complex formation of unsubstituted succinic acid with calcium ions was studied in [4], and the stability constants of the resulting compounds were determined.

The aims of this work were to estimate the effect of amidation or esterification of one of carboxy groups in succinic acid on the stability of calcium salts and to determine the constants of Ca(II) complex formation with succinic acid monoamide and monomethyl ester.

EXPERIMENTAL

Methyl hydrogen succinate [5] and succinic acid monoamide were prepared by the reactions of succinic anhydride with methanol and ammonia, respectively. Succinic acid monoamide was recrystallized three times from ethanol and dried under reduced pressure. Methyl hydrogen succinate was used without additional purification. The compounds synthesized were identified by melting points and neutralization equivalents (see table).

The Ca(II) complex formation with monosubstituted derivatives of succinic acid was studied by pH-potentiometric titration. The experimental conditions were the same as in the earlier study of Ca(II) complex formation with unsubstituted succinic acid [4]: 25°C and ionic strength $I = 0.3$ supported by KCl. The ionization constants B of the compounds HL under consideration, which are required to calculate the complex formation constants, were determined previously under the same conditions [6].

The pH was measured with glass and silver chloride electrodes on an I-120.1 pH meter with an accuracy of ± 0.01 pH unit.

The concentration of monosubstituted succinic acid derivatives was 0.10–0.15 M, and the concentration of the added $Ca(NO_3)_2$ solution, 0.1 M. The concentration ratios Ca(II) : HL were 1 : 5 and 1 : 3.

Characteristics of monosubstituted succinic acid derivatives

Compound	mp, °C		Neutralization, mol-equiv	
	found	[5]	found	calculated
Methyl hydrogen succinate	57	58	131.3	132.1
Succinic acid monoamide	156	157	116.2	117.0

1070-4272/03/7601-0017$25.00

The concentrations of succinic acid monosubstituted derivatives HL in solution were calculated from the precise weights of their portions and refined by pH-potentiometric titration. Chemically pure grade calcium nitrate and potassium chloride were used. The content of Ca(II) in solutions were determined by complexometric titration. The concentration of KOH solution prepared by dilution of its saturated solution [6] was refined by potentiometric titration. All the solutions were prepared in freshly boiled distilled water.

Solutions of a succinic acid monosubstituted derivative, $Ca(NO_3)_2$, and KCl were placed in a temperature-controlled cell. After adding each portion (0.1 ml) of the titrant (0.3 M KOH), the pH values were measured. The equilibrium was considered as attained if pH remained constant for 2–3 min. The glass electrode was calibrated by buffer solutions before each measurement. The calibration straight line was determined by the least-squares procedure and then used to refine the pH values obtained during titration. The pH meter readings were checked by a buffer solution with pH 4.01 after each titration. If the measured pH differed from this value by more than 0.02, the results were discarded. Points of the titration curve in the range pH 3.0–6.0 were used in the calculations.

The protonation constants of succinic acid monoamide and methyl succinate anions,

$$B = \frac{[HL]}{[L^-][H^+]},$$

were determined by the potentiometric titration at 25°C and ionic strength I = 0.3 (KCl). Three to five replicate determinations were performed for each acid. In each determination, the protonation constant was calculated as the average of the calculated values for each point of the titration curve. The error in $\log B$ was taken as the probable deviation of the arithmetic mean at a confidence level of 0.95. The calculated $\log B$ values for succinic acid monoamide and methyl hydrogen succinate were 4.51 ± 0.01 and 4.42 ± 0.01, respectively (I = 0.3, T = 25°C).

The following equilibria were taken into account when calculating the stability constants of calcium complexes with succinic acid derivatives:

$$H^+ + L^- \rightleftarrows HL, \quad (1)$$

$$Ca^{2+} + L^- \rightleftarrows CaL^+, \quad (2)$$

$$Ca^{2+} + 2L^- \rightleftarrows CaL_2. \quad (3)$$

Hydrolysis of Ca^{2+} ions was not taken into account, as being negligible at pH < 6 [7].

The equilibrium concentrations of species in solution were calculated from the following equations of material balance and mass action law:

$$c_L = [HL] + [L^-] + [CaL^+] + [CaL_2],$$

$$c_H = [HL] + [H^+],$$

$$c_M = [Ca^{2+}] + [CaL^+] + [CaL_2],$$

$$B = \frac{[HL]}{[L^-][H^+]}, \qquad \beta_{CaL^+} = \frac{[CaL^+]}{[Ca^{2+}][L^-]},$$

$$\beta_{CaL_2} = \frac{[CaL_2]}{[Ca^{2+}][L^-]^2},$$

where c_L, c_H, and c_M are total concentrations of the ligand, hydrogen ions, and metal ions, respectively; B, protonation constant of a monosubstituted succinic acid derivative; and β_{CaL_2} and β_{CaL^+}, stability constants of the corresponding calcium compounds.

The formation function $\bar{n}$ for the system under study has the following form:

$$\bar{n} = \frac{\beta_{CaL^+}[L^-] + 2\beta_{CaL_2}[L^-]^2}{1 + \beta_{CaL^+}[L^-] + 2\beta_{CaL_2}[L^-]^2}.$$

This equation can be transformed to

$$\bar{n} + (\bar{n} - 1)[L^-]\beta_{CaL^+} + (\bar{n} - 1)[L^-]^2\beta_{CaL_2} = 0.$$

The experimental data were treated by the least-squares procedure. The number of independent determinations of complex formation constants for each compound was 8–10. The obtained β_{CaL^+} and β_{CaL_2} values for Ca(II) complexes with succinic acid monoamide and methyl hydrogen succinate at I = 0.3 (KCl) and T = 25°C were recalculated to zero ionic strength by the Davies equation. The experimental data were approximated by $y = a + bx$ functions with at confidence level of 0.95 and with the confidence interval no greater than 2. The logarithms of the complex formation constants are presented below together with the previous data [4] on the stability of calcium succinates, given for comparison.

Compound	$\log \beta^0_{CaL^+}$	$\log \beta^0_{CaL_2}$
Succinic acid	2.08 ± 0.02	3.41 ± 0.06
Methyl hydrogen succinate	1.91 ± 0.02	3.56 ± 0.03
Succinic acid monoamide	1.86 ± 0.05	3.58 ± 0.06

These data show that the stability of calcium complexes with succinic acid monoamide and methyl hydrogen succinate is virtually independent of the nature of substituted carboxy group. Comparison of the $\log\beta^0$ values for the compounds under study and calcium succinates shows that replacement of one carboxy group by an amide or ester group decreases the stability of the 1 : 1 Ca(II) complexes. Since succinic acid has two carboxy groups, it was suggested [8] that the probable structure of its Ca(II) chelate contains a seven-membered ring. In contrast to the acid, the monosubstituted derivatives under consideration contain one anion and one nonionic (amide or ester) group showing no tendency to form a coordination bond. The composition of the monosubstituted derivatives under study and the stability constants found in this work suggest that succinic acid monoamide and methyl hydrogen succinate behave as monodentate ligands. In the case of 1 : 2 calcium complexes with the monosubstituted derivatives, the $\log\beta^0_{CaL_2}$ values are greater than in the case of the Ca(II) complex with succinic acid.

CONCLUSIONS

(1) The complex formation of Ca(II) with methyl hydrogen succinate and succinic acid monoamide was studied. The stability constants of the 1 : 1 and 1 : 2 Ca(II) complexes were determined by potentiometric titration.

(2) The stability of the 1 : 1 Ca(II) complexes decreases on replacement of one of carboxy groups in the succinic acid molecule by a nonionic ester or amide group.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Iron Oxide Pigments for Mineral Paints from Solid Iron-Containing Waste

A. N. Epikhin and A. V. Krylova

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received June 13, 2002

Abstract—The possibility was examined for preparing various iron oxide pigments for mineral paints from solid industrial waste of metallurgical, chemical, and mechanical engineering plants by synthesizing yellow pigment, goethite, and preparing other pigments on its basis. The influence exerted by the kind of waste and conditions of goethite synthesis on the main properties of the pigments was elucidated.

It is known that hundreds thousands of tons of practically unusable solid waste containing from less than 15 to more than 90 wt % iron are formed annually at metallurgical, chemical, mechanical engineering, and other industrial plants. There are indications in the literature that various iron oxide pigments can be prepared from, e.g., solid waste of sewage treatment at electroplating plants [1, 2] and from ash of sulfuric acid manufacture [3].

Recently, synthesis of goethite (α-FeOOH yellow pigment) from iron sulfate followed by reprocessing into pigments of other colors is the most promising method for production of high-quality finely dispersed iron oxide pigments.

It was shown previously [4, 5] that waste of Severonikel' nonferrous metallurgical plant, spent iron catalyst from Nevinnomyssk chemical plant, and waste of Cheboksary mechanical engineering plant can be used for preparing, via synthesis of goethite, magnetic iron oxide powder γ-Fe_2O_3 for tape recorder carriers; its properties are controlled by the waste composition and conditions of goethite synthesis.

In this work, we examined the possibility of preparing various iron oxide pigments for mineral paints from these types of waste via synthesis of goethite.

The average elemental compositions of the wastes studied, as determined by X-ray spectral analysis, are compared in Table 1.

To prepare iron sulfate solutions, the waste was leached by alternating treatments with sulfuric acid solutions and water. The optimal conditions for leaching and washing, solution compositions, procedures for removing impurities, and features of processes on an enlarged installation have been described previously [4–6].

Goethite was synthesized and converted to other pigments by the following scheme:

$$\text{Solid waste} \xrightarrow{H_2SO_4} FeSO_4 \xrightarrow{OH^-, O_2} \underset{\text{Yellow}}{\alpha\text{-FeOOH}} \xrightarrow{N_2,\ \Delta} \underset{\text{Red}}{\alpha\text{-}Fe_2O_3} \xrightarrow{H_2,\ \Delta} \underset{\text{Black}}{Fe_3O_4} \xrightarrow{O_2,\ \Delta} \underset{\text{Reddish brown}}{\gamma\text{-}Fe_2O_3}.$$

The products of successive transformations yellow goethite → red hematite (α-Fe_2O_3) → black magnetite (Fe_3O_4) → reddish brown maghemite (γ-Fe_2O_3) are commercial pigments. The goethite crystals have acicular shape, which is preserved in all the subsequent stages of goethite conversion.

Table 1. Elemental composition of the waste

	OA, g/100 g	61	48	–	–				

In the course of synthesis of the goethite pigment, we used a new method of nucleus-free precipitation with alkali (KOH) at pH > 13 and, for comparison, the traditional sodium carbonate precipitation. The temperature and the rate of the air feed into the suspension were varied in the course of the synthesis, with the precipitant/$FeSO_4$ volume ratio being constant in most experiments (n = 2). The suspension was stirred with a stirrer at a rate of 200 rpm.

α-FeOOH was dehydrated in a nitrogen flow at 300°C to obtain α-Fe_2O_3, which was reduced with hydrogen at 380°C to Fe_3O_4. The latter was oxidized to γ-Fe_2O_3 in air at 200°C. The space velocities of the gases in various stages of the synthesis were (ml min^{-1} g^{-1}) nitrogen 30, hydrogen 25, and air 60. The quality of the pigments synthesized was characterized by the covering power CP (g m^{-2}) and oil absorption OA (g/100 g), which were measured by standard procedures [7]. The pigment color was evaluated visually.

Table 2 shows how the properties of the pigments synthesized vary depending on the kind of waste and synthesis conditions.

The yellow and red pigments synthesized from different wastes under the similar conditions have high characteristics for all samples (P1, P3, and P7), with the P3 sample (from spent catalyst) having the best covering power and oil absorption. Compared to P1 pigment (from metallurgical sludge), the black and reddish brown pigments P3 are better in covering power and nearly similar in oil absorption.

The characteristics of the samples of all colors depend on the rate of the air feed into the suspension in the W range studied (samples P2–P4). The minimal value of W was optimal for the yellow pigment, and its maximal value, for the red pigment. For the black and reddish brown pigments, the optimal covering power was attained at the minimal value of W, and the optimal oil absorption, at the middle or maximal value.

The yellow pigments from the spent catalyst, obtained by alkali precipitation and precipitation with sodium carbonate (samples P3 and P6, respectively), have similar characteristics, and the red pigment from the spent catalyst obtained by alkali precipitation has better characteristics. The pigments of all the colors synthesized at elevated and standard temperatures (samples P5 and P3, respectively) have similar characteristics, except for the black pigment P5 having lower oil absorption. Thus, by varying various parameters of the goethite synthesis, it is possible to vary within a certain interval the properties of the pigments synthesized.

Among yellow pigments, sample P4 from the spent catalyst has the highest color characteristic. Sample P6 obtained by sodium carbonate precipitation has the middle color characteristic. The color characteristic of the sample P7 from mechanical engineering sludge is

Table 3. Properties of commercial iron oxide pigments [7]

Brand or composition	Color	CP, g m^{-2}	OA, g/100 g
Zh-0	Yellow	12–15	35–50
Zh-1	″	15–20	35–60
Zh-2	″	15–20	35–70
K, grade 1	Red	6–7	26–35
K, grade 2	″	7–8	25–35
English Red	″	10–15	35–50
Indian Red	″	10–15	30–40
Fe_3O_4	Black	6–10	20–30
α-Fe_2O_3	Reddish brown	7–15	30–50

the worst, which may be due to a high content of the manganese oxide impurity. Sample P5 obtained at higher temperature of the goethite synthesis and sample P2 obtained at a low velocity of the air feed have a dark color. The peak of their absorption was shifted toward longer wavelengths, which may be due to increased particle size [7].

The properties of the commercial iron oxide pigments are characterized in Table 3 [7].

Yellow pigments of the indicated brands are used in industry as stencil and special-purpose paints, as additives to color cements, as thermosensitive pigments (up to 280°C), etc. Red pigments are used in construction and for painting ships and plastics. Black pigments are used in paints instead of carbon black, for coloring fiber glass, and as an intermediate in production of artist paints. The Fe_3O_4 powder is used for xerocopying. In pigment properties, γ-Fe_2O_3 is similar to α-Fe_2O_3.

In covering power and oil absorption, the P2 and P4 yellow pigments obtained correspond to Zh-0 commercial standard; samples P3, P5, and P6, to Zh-1 standard; and samples P1 and P7, to Zh-2 standard. Red sample P4 corresponds to K standard, grade 2; sample P3 corresponds to this standard in oil absorption, and sample P5, in covering power. Samples P1, P2, P6, and P7 in their characteristics are similar to English Red pigment. Sample P5 corresponds to the black standard, and samples P2–P5, to the reddish brown standard.

CONCLUSIONS

(1) In the main characteristics, iron oxide pigments (yellow, red, black, and reddish brown) synthesized from solid waste correspond to commercial pigments.

(2) Along with the use of Na_2CO_3, a nucleus-free method of alkaline precipitation is suitable for synthesizing goethite as intermediate in production of pigments.

(3) Choice of the conditions of the goethite synthesis allows control of the main characteristics of pigments.

Received August 16, 2002

Abstract—Conditions for complex formation in aqueous electrolyte solutions containing salts of aluminum and hydroxy carboxylic acids were studied by ^{27}Al and ^{19}F NMR spectroscopy. The formation of complex anions in the electrolytes at various pH and their discharge on the anode under conditions of a microplasma process allowed preparation of surface layers containing α-Al_2O_3 on VT1-0 titanium. The interrelation between the composition and properties of the coatings was studied.

It is known that the physicochemical and service properties of coatings formed on metals and alloys under microplasma anodizing conditions essentially differ from the properties of common anodic films [1]. We have shown in [2] that certain factors should be taken into account when selecting the electrolyte composition and oxidation conditions for directed synthesis of surface layers of required composition on metals and alloys under the microarc oxidation conditions. Among such factors are possible changes in the forms of anionic complexes in solution depending on pH, both in the bulk of the electrolyte and in a local area of the near-electrode space.

Electrolytes containing various anionic complexes were used previously in the microarc oxidation of aluminum [3], titanium [4], and some other metals [5]. The resulting coatings had various physicochemical properties determined by their phase and chemical compositions. At the same time, the composition of the complex anions at various pH of the electrolyte, the interactions between various anions in solutions before and during oxidation, and also the mechanism of the complex formation are poorly understood.

To obtain on aluminum protective coatings exhibiting high resistance to wear and heat owing to the presence of α-Al_2O_3, an electrolyte containing aluminum tartrate complexes and also fluorides [6, 7] was developed. In [6], aluminum alloys were selected as model materials ensuring high concentration of aluminum ions in the near-anode space during oxidation. Depending on pH, the complex formation can involve various functional groups of tartaric acid: carboxy (–COOH), hydroxo (–OH), or both [8]. The presence of such complexes in an electrolyte solution strongly affects the composition and properties of the forming surface structures [9].

Proceeding from model concepts developed for aluminum and its alloys [6, 9], we believe that development of a process for obtaining solid layers on the titanium surface by its oxidation in electrolytes containing anions of hydroxy carboxylic acids should be based on the following principles.

(1) Fluorine compounds do not form insoluble compounds with titanium (in contrast to aluminum); therefore, their presence in the electrolyte will result in active etching of the substrate, thus hindering the formation of a continuous uniform coating.

(2) To ensure formation of anionic complexes with hydroxy acid ligands, aluminum(III)-containing components should be added to the electrolyte.

(3) It is necessary to minimize formation of titanium(IV) complexes with hydroxy acid salts by selecting appropriate electrolyte composition and varying its pH, as the existence of such complexes in solution will result in the formation of coatings based on titanium oxides and in decreased concentration of aluminum oxide in the film.

With the aim to obtain heat-resistant solid coatings on titanium, we studied in this work the complex formation in electrolytes containing aluminum salts and certain hydroxy carboxylic acids, both aliphatic (lactic, tartaric, and citric) and aromatic (salicylic). For this purpose, we created conditions favoring

1070-4272/03/7601-0023$25.00

the formation of aluminum(III) complexes with the above-listed hydroxy acids in solution. Then, using electrolytes containing complex anions, we formed coatings on titanium under the microplasma conditions and studied their composition and properties.

EXPERIMENTAL

Samples of VT1-0 grade titanium (99.4% Ti) in the form of 5×30-mm plates were oxidized. Aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ and oxalate $Al_2(C_2O_4)_3 \cdot nH_2O$, and also hydroxy carboxylic acids and their salts (potassium tartrate $K_2C_4H_4O_6 \cdot 0.5H_2O$, lactic acid $C_3H_6O_3$, potassium citrate $K_3C_6H_5O_7$, and salicylic acid $C_7H_6O_3$) were added to the electrolyte used in the oxidation. The electrolyte pH was adjusted with KOH and H_2SO_4. Sodium fluoride NaF was added when studying the electrolytes by ^{19}F NMR. All the chemicals used in the work were of chemically pure grade. The formation voltage was selected individually for each electrolyte solution within the limits 170–300 V. The current density did not exceed 1 A cm^{-2}, the oxidation time, 5–10 min, and the electrolyte temperature, +25°C. The electrolyte was cooled using a refrigerating unit whose heat exchanger was placed directly in the electrolytic cell.

The phase composition of coatings on a metallic substrate was determined with a DRON 3.0 X-ray diffractometer (CuK_α radiation). The relative contents of phases in films were estimated from the ratios of intensities of their strongest lines. The NMR experiments were carried out on a Bruker WP-80 SY radiospectrometer at room temperature with external stabilization by deuterium. The chemical shifts δ_i of ^{27}Al and ^{19}F are given relative to $[Al(H_2O)_6]^{3+}$ and $CFCl_3$ references, respectively, using the relationship $\delta_i = (\nu_i - \nu_0)/\nu_0$ (ν_0 and ν_i are the frequencies of the signals of the reference and sample under study). The microhardness of coatings was measured on a Neofot-2 device using cross-sectional microsections prepared with the use of epoxy resin. The differential thermal (DTA) and thermogravimetric (TG, DTG) analysis was performed with a Q-1500D derivatograph (MOM, Hungary) in the course of heating coated samples in open platinum crucibles in air or under helium at a rate of 5 deg min^{-1} to 1000°C, with the aim to evaluate the probability of afteroxidation of the titanium substrate during annealing in air. The helium flow rate through the chamber was 10 l h^{-1}.

The mechanism of the complex formation of certain metals in solutions of tartaric acid and its salts was studied in [10, 11]. It was found that, depending on solution pH, aluminum(III) can form cationic, neutral, and anionic tartrate complexes. The formation of complexes involving oxotitanium(IV) ions TiO^{2+} is the most typical for titanium in a strongly acidic medium, where the most stable complexes with tartaric acid ligands are formed. At pH < 1, titanium(IV) forms $[Ti(OH)_2(C_4H_5O_6)(C_4H_6O_6)]^+$ cationic complexes. In the range pH 1–7, the migration of titanium-containing complexes to anode increases, suggesting the conversion of cationic and neutral species into the anionic species $[Ti(OH)_2(C_4H_4O_6)_2]^{2-}$, $[Ti(OH)_2(C_4H_2O_6)]^{2-}$, and $[Ti(OH)_2(C_4H_4O_6) \cdot (C_4H_3O_6)]^{3-}$ with the charge increasing with pH [12]. The migration of complexes to the anode is reduced in an alkaline medium owing to hydrolysis of titanium-containing components with the formation of single-charged ions.

Aluminum(III) anionic complexes, in contrast to titanium(IV) complexes, are more stable in an alkaline medium (pH 9–10); therefore, when aluminum and titanium compounds are present simultaneously in solution, it is appropriate to select high pH values to decrease the probability of the titanium(IV) complex formation with tartrate ions and hence to reduce the effect of titanium-containing compounds on the composition of a film formed on the anode.

Figure 1 shows the ^{27}Al NMR spectra of solutions (pH 2.5–12) containing aluminum salts (sulfate or oxalate), their mixtures with hydroxy acids (salicylic or lactic), and salts of hydroxy acids (potassium tartrate or citrate).

Aluminum(III) cations in solution have either octahedral or tetrahedral environment depending on the solvent properties and the ligand type [13]. The ^{27}Al NMR chemical shifts of octahedral complexes are in the region of 0 ppm, and those of tetrahedral complexes are shited downfield (–70 to –100 ppm). Thus, the ^{27}Al chemical shifts furnish information on the structure of aluminum complexes. A signal with the ^{27}Al NMR chemical shift of 0 ppm corresponding to the $[Al(H_2O)_6]^{3+}$ complex was recorded in an aqueous solution of aluminum sulfate at pH 2.5 (Fig. 1, spectrum *1*). When tartrate anions $[C_4H_4O_6]^{2-}$ are added to the electrolyte at pH 10, a broad signal with δ = –34 ppm corresponding to the aluminum tartrate complex $[Al(OH)(C_4H_2O_6)]^{2-}$ [6] appears (Fig. 1, spectrum *2*). An increase in pH to 11 owing to hydrolysis results in hydrolysis and breakdown of the aluminum(III) tartrate complex, as demonstrated by the appearance of the ^{27}Al NMR signal with δ = –80 ppm corresponding to the tetrahedral aluminum

complex $[Al(OH)_4]^-$ (Fig. 1, spectrum *2*). In a solution of aluminum oxalate at pH 2.5, aluminum exists as the complex $[Al(C_2O_4)_3]^{3-}$ (δ = –10 ppm) (Fig. 1, spectrum *4*). When aluminum oxalate is added to solutions containing potassium tartrate, the complex $[Al(OH)(C_4H_2O_6)]^{2-}$ is formed at pH < 12, giving a broad ^{27}Al NMR signal at δ = –26 ppm (Fig. 1, spectrum *5*). The hydrolysis of oxalate-containing solutions results in the formation of the tetrahedral complex $[Al(OH)_4]^-$ at higher pH (pH 12) than in sulfate-containing solutions (pH 11), which is due to the existence in such systems of the complex $[Al(C_2O_4)_3]^{3-}$ along with $[Al(OH)(C_4H_2O_6)]^{2-}$ (Fig. 1, spectrum *3*).

The ^{27}Al NMR spectra of solutions containing aluminum oxalate and lactic acid are shown in Fig. 1, spectra *6* and *7*. A signal with δ = –13.9 ppm is observed in the spectra at pH 9. This is the signal of an aluminum anionic complex with lactic acid, which exists without changes within a broad pH range, pH 3–10 (Fig. 1, spectrum *7*). The tetrahedral complex $[Al(OH)_4]^-$, which gives a signal with δ = –79.9 ppm (Fig. 1, spectrum *6*), is formed at pH 11.4 as a result of the hydrolysis of the lactate complex. The obtained data agree with the results of studying the structure of aluminum complexes with lactic and citric acids by ^{27}Al NMR [14]. For solutions containing aluminum salts and lactic acid, several signals were observed, originating from the replacement of water molecules in the complex $[Al(H_2O)_6]^{3+}$ by lactate ions (pH 3–5) [14]. An increase in pH to 7–8 resulted in the hydrolysis of this compound up to formation of the anionic complex $[Al(OH)_4]^-$ (pH 10–11).

Aluminum(III) complexes with citrate and salicylate ions have certain specific features. According to [14], the presence of three carboxy groups and one hydroxy group in the citrate ligand complicate the determination of structural characteristics of the complexes (as is also the case with the lactate ligand), because of numerous possible coordination modes of the ligand. In particular, formation of a structure suggested in [15], in which aluminum is linked to two carboxy groups and one hydroxy group, forming two five-membered rings, is quite possible.

Salicylic acid, which belongs to the class of aromatic hydroxy acids, also forms complexes with aluminum(III) ions. Signals with δ = –15.3 and δ = –10.6 ppm are observed in the range of pH 3–10 in the systems aluminum oxalate–potassium citrate and aluminum oxalate–cirtic acid, respectively. These signals suggest formation of aluminum anionic complexes with citrate and salicylate ions in solution (Fig. 1, spectra *8*, *9*).

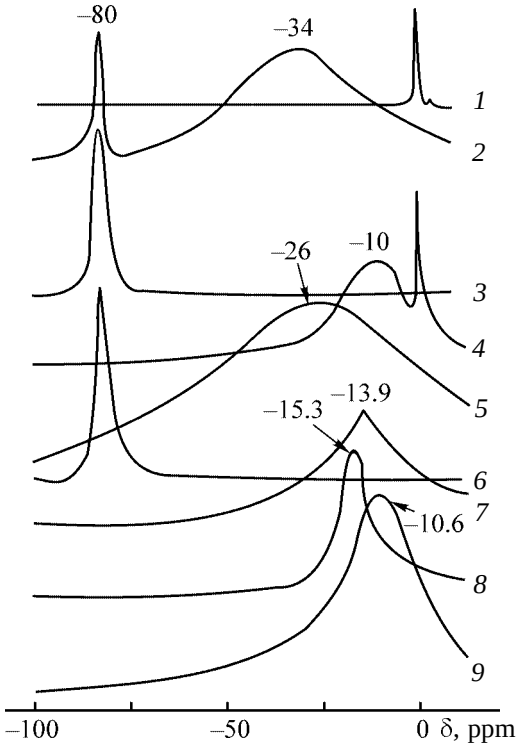

Fig. 1. ^{27}Al NMR spectra of solutions of aluminum salts and hydroxy acids. (δ) Chemical shift; the same for Fig. 2. (*1*) Aluminum sulfate, pH 2.5; (*2*) aluminum sulfate + potassium tartrate, pH 10–11; (*3*) aluminum oxalate + potassium tartrate, pH 12; (*4*) aluminum oxalate, pH 2.5; (*5*) aluminum oxalate + potassium tartrate, pH 10.8; (*6*) aluminum oxalate + lactic acid, pH 11.4; (*7*) aluminum oxalate + lactic acid, pH 9.0; (*8*) aluminum oxalate + potassium citrate, pH 9.85; and (*9*) aluminum oxalate + salicylic acid, pH 9.0.

In contrast to data in [14], the positions of the ^{27}Al NMR signals corresponding to aluminum(III) complexes with anions of the above-listed hydroxy acids or their salts did not change in the range of pH 3–10, i.e., the complexes formed in the solution are stable under these conditions. Based on our experimental data and on the approach developed in [8, 9], we can presume the composition of the aluminum complexes with the hydroxy acids in solutions. The following anionic complexes can be formed in the range of pH 9–10: $[Al(OH)_2(C_3H_4O_3)]^-$, M = 149, with lactic acid; $[Al(C_4H_2O_6)]^-$, M_r = 173 and $[Al(OH)(C_4H_2O_6)]^{2-}$, M = 190, with tartaric acid; $[Al(C_6H_4O_7)]^-$, M_r = 215, $[Al(OH)(C_6H_4O_7)]^{2-}$, M = 232, and $[Al(OH)_2 \cdot (C_6H_4O_7)]^{3-}$, M = 249, with citric acid; and $[Al(OH)_2 \cdot (C_7H_4O_3)]^-$, M 197, $[Al(C_7H_4O_3)_2]^-$, M = 275, and

Table 1. Formation conditions, composition, and microhardness μ of coatings on titanium

* Components are given in the order of decreasing content in the coating.

$[Al(OH)(C_7H_4O_3)_2]^{2-}$, M = 292, with salicylic acid (M is the molecular weight of the complex anion).

Without using other physical methods, the available data do not allow an unambiguous conclusion on the composition and structure of the complexes formed in the electrolytes. The difference in the position of signals in the NMR spectra of these compounds is no more than an evidence for their different compositions and structures.

Since information furnished by the ^{27}Al NMR spectra is relatively poor compared to the ^{19}F NMR spectra, we added fluoride ions to the solutions containing aluminum salts and tartrate ions. Then we studied the aqueous solutions of aluminum fluoride–tartrate complexes by ^{19}F and ^{27}Al NMR spectroscopy. The ^{19}F NMR spectra show that aluminum fluoride–tartrate complexes $[AlF_n(C_4H_4O_6)_{6-n}]^{3-}$ (n = 1–6) are present in aqueous solutions along with aluminum aquafluoride complexes (Fig. 2). In such systems, in contrast to bidentate oxalate ions, tartrate ions behave as monodentate ligands [16].

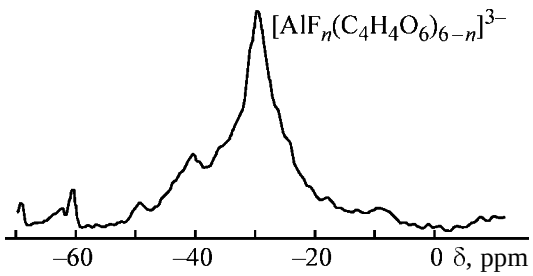

Fig. 2. ^{19}F NMR spectrum of aluminum(III) fluoride–tartrate solution.

A question arises: To what extent are the composition and properties of electrolytic oxide layers affected by the structure of complexes present in the electrolyte? To answer this question, we obtained coatings on titanium from solutions containing aluminum sulfate and oxalate and anions of lactic, tartaric, citric, and salicylic acids, using the microplasma anodizing method. We found that such layers consist of titanium and aluminum oxides (rutile TiO_2, α-Al_2O_3, and Al_2TiO_5) in various combinations depending on pH and composition of the electrolyte (Table 1). According to the X-ray phase analysis, in view of the estimated microhardness of the resulting surface layers, we found that the coatings obtained from the electrolyte at pH from 3 to 5 contain titanium dioxide (rutile) responsible for their moderate microhardness (up to 3200 MPa). Surface layers with a higher hardness (5500 MPa), consisting of the double oxide Al_2TiO_5 and aluminum oxide α-Al_2O_3, were formed in alkaline solutions of the electrolytes at pH 10.0–10.8. At such pH, more favorable conditions are created for the formation of anionic complexes involving aluminum(III) ions and hydroxy acids.

At the same time, with the examined electrolytes, we failed to eliminate the oxidation of the titanium substrate by selecting anodic oxidation modes. It resulted in the formation of titanium dioxide and the double oxide Al_2TiO_5, which reduce the hardness of the coatings compared to the coatings on aluminum consisting of α-Al_2O_3 and having the microhardness of up to 7000 MPa [6].

We estimated the heat resistance of coatings obtained in the microplasma mode at various electrolyte

Table 2. Thermal stability of coatings on titanium

Composition no.	Electrolyte	Concentration, g l^{-1}	Annealing conditions	Temperature, °C		Phase composition of coatings	
				onset of oxidation	onset of intense oxidation	before annealing	after annealing
1	Sample without coating		Helium Air	680 650	780 760	X-ray amorphous phase	TiO_2-rutile
2	$C_3H_6O_3$, $Al_2C_6O_{12}\cdot nH_2O$	10 31.8	Helium Air	780 750	910 900	Al_2TiO_5	Al_2TiO_5 TiO_2-rutile
3	$K_2C_4H_4O_6\cdot 0.5H_2O$, $Al_2C_6O_{12}\cdot nH_2O$	10 10	Helium Air	790 760	920 910	Al_2TiO_5, α-Al_2O_3	Al_2TiO_5, α-Al_2O_3, TiO_2-rutile

5	$C_7H_6O_3$, $Al_2C_6O_{12}\cdot nH_2O$,	6.9 31.8	Helium Air	800 780	915 910	Al_2TiO_5, α-Al_2O_3	Al_2TiO_5, α-Al_2O_3, TiO_2-rutile

pH (within the range 10.0–10.8). It was shown above that this pH range ensures the formation of anionic aluminum complexes with hydroxy acids in solution. The discharge of the complexes on the anode allows preparation of coatings containing aluminum oxide α-Al_2O_3, ensuring their high hardness and heat resistance.

We estimated the temperatures of the initial and accelerated titanium oxidation by the points in which the experimental TG curve deviates from the extrapolated straight lines, and also by the inflection points in the DTG curve. Also, we determined the phase composition of the coatings before and after annealing. The corresponding experimental data are given in Table 2.

Figure 3 shows the DTA, TG, and DTG curves recorded in the course of annealing the samples coated in an electrolyte containing salicylic acid (similar curves are characteristic for all the samples studied). According to Table 2, such coatings have the best protective properties. No thermal effects and weight changes were detected in the DTA curves of all the coated titanium samples (Table 2) up to the temperature of the initial oxidation (680–800°C). The thermal effect originating from the transition of α-Ti (hexagonal modification) to β-Ti (cubic modification) is observed at 880°C. The temperature of this transition should not depend on the annealing atmosphere, which is indeed the case (Fig. 3). Above 890–920°C, the sample weight quickly grows, as seen from the TG curve (the stage of accelerated oxidation). At these temperatures, the coating continuity is broken, which is due to a certain extent to the difference in the thermal expansion coefficients of the coating material and titanium substrate; as a result, oxygen penetrates to the metallic matrix and causes its active oxidation. At the same time, according to the data of [6], aluminum-based coatings exhibited a higher heat resistance. Up to 870°C, the composition, properties, and weight of samples did not change; the coating did not melt, was not destroyed, and acted as a heat-resistant crucible. Weaker protective properties of coatings on titanium, as compared to coatings on aluminum obtained in a similar electrolyte, are attributable not only to the difference in the phase composition of the

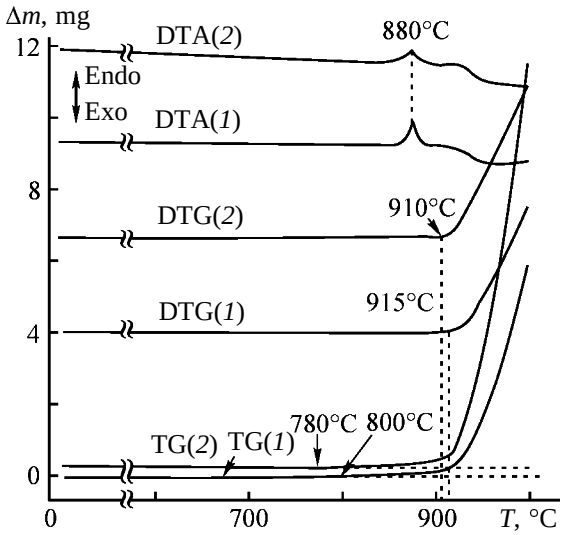

Fig. 3. DTA, TG, and DTG curves for samples coated from the electrolyte containing salicylic acid. Heating rate 5 deg min^{-1}. (Δm) Change in the sample weight and (T) temperature. Annealing (*1*) in a helium atmosphere and (*2*) in air.

layers under study (smaller content of α-Al_2O_3), but also to the effect of the substrate (aluminum or titanium), which is manifested at temperatures higher than 620°C. As the aluminum substrate is completely molten above this temperature [6], the difference in the thermal expansion coefficients of the substrate and coating is of no importance above 620°C and, therefore, it cannot affect the continuity of surface layers responsible for the intensity of oxygen penetration to the matrix. In the case of titanium samples (mp 1668°C) with surface layers obtained by microarc oxidation, the difference in the thermal expansion coefficients of the substrate and coating will be of importance within the temperature range under study.

According to Table 2, all coatings under study exhibit protective properties both in air and in a helium atmosphere, decelerating oxidation of the titanium substrate. The coatings obtained from electrolyte nos. 3 and 5 exibit a higher degree of protection (Table 2), which is due to the presence of α-Al_2O_3 in them. The temperatures of the initial and accelerated substrate oxidation are higher for these samples than for the samples obtained from the other electrolytes. This may be due not only to the coating structure, but also to its morphology, porosity, homogeneity, and presence of cracks. It follows from Table 2 that the phase composition of coatings on titanium before and after annealing, both in air and in helium, changes insignificantly, indicating the high heat resistance and low oxygen permeability of the coatings. The protective properties strengthen as the concentration of aluminum oxide in the surface layers increases. Presumably, the complexes with higher molecular weights, burning down in a plasma channel on the anode, liberate considerable energy, which, in turn, promotes the formation of the high-temperature modification of aluminum oxide in the surface layer. Furthermore, the benzene ring of salicylic acid can affect the nature, temperature, and time of plasma chemical reactions occurring at the anode and, correspondingly, the composition and properties of the forming surface layers.

CONCLUSION

The formation of complexes in electrolyte solutions containing aluminum salts and hydroxy carboxylic acids was proved by the ^{27}Al and ^{19}F NMR spectroscopy. These complexes, being fairly stable in a wide pH range, determine the composition and properties of oxide layers formed in these electrolytes on titanium under the action of microplasma oxidation. The presence of α-Al_2O_3 in the coatings is responsible for their elevated microhardness and thermal stability compared to the substrate. At the same time, differences in the composition and structure of the complexes detected in the electrolyte by NMR do not give rise to considerable differences in the composition and protective properties of the forming layers.

Received March 13, 2002

Abstract—The heats of solution of anabasine hydrochloride $C_{10}H_{14}N_2HCl$ and of the reaction of its aqueous solution with crystalline $AgNO_3$ at various dilutions were determined. The standard enthalpies of formation of anabasine hydrochloride and its 36 analogs were calculated. The temperature dependence of the anabasine hydrochloride heat capacity was studied within the 173–448 K range.

A study of thermochemical and thermodynamic properties of alkaloids is of practical and theoretical interest for purposeful synthesis of new derivatives with preset properties. Up to now, data on thermochemical and thermodynamic constants (both experimental and calculated) of anabasine and its derivatives were lacking. The goal of this work is the experimental study of thermochemical and thermodynamic properties of anabasine hydrochloride and calculation of the standard enthalpy of formation of anabasine hydrochloride and its derivatives.

Calorimetric determination of the enthalpy of $C_{10}H_{14}N_2HCl$ solution in water and of the reaction of its aqueous solution with crystalline $AgNO_3$ was performed at dilutions (salt : water molar ratios) of 1 : 6000, 1 : 9000, and 1 : 18 000 under isothermal conditions. The experimental error and variance homogeneity in determination of thermal effects were calculated using Student and Bartlett tests [1].

We calculated the heat of combustion of anabasine hydrochloride by Karash and Frost methods [2] and the heat of melting, by the empirical equation recommended in [3]. The enthalpies of formation $\Delta_f H^0$ (298.15) of $C_{10}H_{14}N_2HCl$ analogs were calculated using the enthalpy increments of anions [4, 5].

EXPERIMENTAL

Chemically pure grade anabasine hydrochloride was used. The enthalpy of solution of anabasine hydrochloride in water was measured in a DAK-1-1A isothermal differential automatic calorimeter. The thermal effects were recorded with a KSP-4 potentiometer and, in parallel, with an IP-4 precision integrator. The time of prethermostating of the compound to be measured was 2 h. The calorimeter was calibrated by applying a calibrated voltage to a built-in electric motor and was checked by measuring the heat of solution of triple-recrystallized KCl at 1 : 1600, 1 : 2400, and 1 : 3200 (salt : water molar ratios) dilutions. The averaged measured heat of KCl solution, $17\,860 \pm 283$ J mol^{-1}, is in good agreement with the value of $17\,577 \pm 34$ J mol^{-1} obtained in [6].

The heat of solution of anabasine hydrochloride in water ΔH_s^m

$$C_{10}H_{14}N_2HCl(cr) + nH_2O(l) = C_{10}H_{14}N_2HCl(soln, nH_2O) + \Delta H_s^m, \quad (1)$$

was found at n = 6000, 9000, and 18 000 (Table 1).

The experimental values of ΔH_s^m at various dilutions (Table 1) were used for calculating the enthalpy of solution of anabasine hydrochloride at infinite (standard) dilution ΔH_s^0. The molal concentrations m_1, m_2, and m_3 and the corresponding $\Delta H_{s(1)}^m$, $\Delta H_{s(2)}^m$, and $\Delta H_{s(3)}^m$ were calculated. The dependence of the enthalpy of solution (kJ mol^{-1}) on the molal concentration $m^{1/2}$ is described by the equation

$$\Delta H_s^m(C_{10}H_{14}N_2HCl) = 5.29 - 469.59m^{1/2}, \quad (2)$$

similarly to data of [7].

Using Eq. (2), we calculated the standard enthalpy

of solution of anabasine hydrochloride in water, $\Delta H_s^0 = 5.29 \pm 0.33$ kJ mol^{-1}. This value is essential for calculating the standard heats of formation of anabasine derivatives.

The enthalpy of solution was used for determining the heat of the reaction of aqueous anabasine hydrochloride with crystalline $AgNO_3$ (Table 2):

$$C_{10}H_{14}N_2HCl(soln, nH_2O) + AgNO_3(cr) = C_{10}H_{14}N_2HNO_3(soln, nH_2O) + AgCl\downarrow(cr.) - \Delta H_r^m \quad (3)$$

The progress of reaction (3) was monitored by X-ray phase analysis (formation of crystalline AgCl) and NMR spectroscopy (formation of anabasine nitrate). Crystalline $C_{10}H_{14}N_2HNO_3$ was separated from the filtrate.

The isobaric heat capacity of anabasine hydrochloride was measured on an IT-C-400 device with the error not exeeding ±10.0% [8]. The time of measurements over the 173–448 K range, including the treatment of the experimental data, did not exceed 2.5 h. The device was calibrated by measuring the calorimeter heat conductance K_c. Five experiments were performed at each temperature, the results were averaged, and the root-mean-square deviation $\bar{\delta}$ for the heat capacity and the random error $^0\Delta$ for the molar heat capacity were estimated. The calorimeter operation was controlled by measuring the heat capacity of α-Al_2O_3. The $C_p^0(298.15)$ value obtained, 76.0 J mol^{-1} K^{-1}, is in good agreement with the reference value of 79.0 J mol^{-1} K^{-1} [9]. The results are listed in Table 3.

From the data obtained, the equation describing the $C_p^0 = f(T)$ dependence for anabasine hydrochloride over the temperature range 298.15–448 K is as follows (J mol^{-1} K^{-1}):

$$C_p^0 = (145 \pm 8) + (284 \pm 16) \times 10^{-3}T - (24.7 \pm 1.3) \times 10^5 T^{-2}. \quad (4)$$

To calculate $\Delta H^0(298.15)$ of $C_{10}H_{14}N_2HCl$, we estimated its standard heat of combustion by the methods of Karash and Frost [2]. In the Karash's

method, the presence of oxygen, nitrogen, and chlorine in the compound is estimated. In the Frost's method, the effects of cyclenes and double bonds in their rings are additionally taken into consideration. The averaged heat of combustion of $C_{10}H_{14}N_2HCl$ is –5860 kJ mol^{-1}.

Taking into account the heat of combustion of $C_{10}H_{14}N_2HCl$

$$2C_{10}H_{14}N_2HCl(l) + 27.5O_2(g) = 20CO_2(g) + 15H_2O(l) + 2N_2(g) + Cl_2(g) - \Delta H^0_{comb}, \quad (5)$$

we calculated the standard enthalpy of formation of liquid $C_{10}H_{14}N_2HCl$, which is equal to –229.9 kJ mol^{-1}. It should be noted that methods of Karash and Frost are suitable only for calculating ΔH^0 of combustion of liquid hydrocarbons. The data required for calculating $\Delta_f H^0$ (298.15) of $C_{10}H_{14}N_2HCl(l)$ by scheme (5) (excluding ΔH^0_{comb}) are taken from the handbook [10]. Since at 298.15 K anabasine hydrochloride is crystalline, its $\Delta_f H^0$ (298.15) should be calculated for the solid state. We estimated ΔH^0_m(298.15) of $C_{10}H_{14}N_2HCl$ by the empirical equation [3],

$$\Delta H^0_m = 44.4T_m - 4400, \quad (6)$$

valid for highly polar halides, and obtained the value of 17.0 kJ mol^{-1}. The standard enthalpy of formation of crystalline anabasine hydrochloride was calculated by the equation

$$\Delta_f H^0(298.15)C_{10}H_{14}N_2HCl(cr) = \Delta_f H^0(298.15)C_{10}H_{14}N_2HCl(l) - \Delta H^0_m \quad (7)$$

and amounts to –239.9 ± 12.0 kJ mol^{-1}.

Then, using ΔH^0 of solution of $C_{10}H_{14}N_2HCl$ in standard aqueous solution (5.29 kJ mol^{-1}),

$$\Delta_f H^0(298.15)C_{10}H_{14}N_2HCl(soln, H_2O, standard state) = \Delta_f H^0(298.15)C_{10}H_{14}N_2HCl(cr) + \Delta H^0_s, \quad (8)$$

we calculated the standard enthalpy of formation of $C_{10}H_{14}N_2HCl$ in aqueous solution: –234.6 kJ mol^{-1}.

Using the equation

$$[\Delta_f H^0(298.15)C_{10}H_{14}N_2H^+(soln, H_2O, standard state)] = [\Delta_f H^0(298.15)C_{10}H_{14}N_2HCl(soln, H_2O, standard state)] - [\Delta_f H^0(298.15)Cl^-(soln, H_2O, standard state)], \quad (9)$$

Table 3. Experimental heat capacities of $C_{10}H_{14}N_2HCl$

T, K	$C_p \pm \bar{\delta}$, J K^{-1} g^{-1}	$C^0_p \pm {}^0\Delta$, J mol^{-1} K^{-1}
173	0.6027 ± 0.0094	120 ± 5
198	0.6936 ± 0.0096	138 ± 5
223	0.8573 ± 0.0195	170 ± 11
248	0.9248 ± 0.0138	184 ± 16
273	0.9656 ± 0.0311	192 ± 17
298.15	1.0159 ± 0.0315	202 ± 17
323	1.0997 ± 0.0101	219 ± 6
348	1.1273 ± 0.0235	224 ± 13
373	1.1751 ± 0.0358	233 ± 20
398	1.2309 ± 0.0155	245 ± 9
423	1.2776 ± 0.0156	254 ± 9
448	1.3093 ± 0.0333	260 ± 18

we calculated the standard enthalpy of formation of $[C_{10}H_{14}N_2H]^+$ in aqueous solution: – 67.4 kJ mol^{-1}.

This value was used for calculating $\Delta_f H^0$ (298.15) of 36 anabasine derivatives. In [4, 5], the system of thermochemical enthalpy increments was developed, allowing calculation of the standard heats of formation of crystalline compounds by the scheme

$$\Delta_f H^0(298.15)M_m(X_\alpha O_\beta)_n = [m\Delta_f H^0(298.15)M^{n+}(soln, H_2O, standard state)]K + n\Delta_f H^i(298.15)X_\alpha O_\beta^{m-}, \quad (10)$$

where $\Delta_f H^i$(298.15) is the enthalpy increment of the anion, and K is proportionality coefficient.

To calculate $\Delta_f H^0$(298.15) of derivatives by scheme (1), it is sufficient to know $\Delta_f H^0$(298.15, soln, H_2O, standard state) of the cation, since K and $\Delta_f H^i$(298.15) of anions are tabulated in [4, 5]. The error of calculation is ±5.0%. As applied to anabasine derivatives, scheme (10) can be presented as follows (by an example of $C_{10}H_{14}N_2HNO_3$):

$$\Delta_f H^0(298.15)C_{10}H_{14}N_2HNO_3(cr) = [\Delta_f H^0(298.15)C_{10}H_{14}N_2H^+(soln, H_2O, standard state)]K + \Delta_f H^i(298.15)NO_3^-. \quad (11)$$

The $\Delta_f H^0$ values for 36 anabasine derivatives, calculated by scheme (11), are listed in Table 4.

CONCLUSIONS

(1) The enthalpy of solution of anabasine hydrochloride in water at various dilutions was experimentally determined for the first time, and the stan-

Received May 23, 2002

Abstract—The solubility diagram of the ternary fullerene-containing system C_{60}–C_{70}–*o*-xylene at 25 and –20°C was studied.

Up to now, there have been virtually no systematic studies on solubility in fullerene-containing multicomponent systems. At the same time, there are published experimental data on the solubility of fullerenes in a number of binary systems like fullerene C_{60}–solvent or fullerene C_{70}–solvent [including aromatic solvents (e.g., benzene, toluene, dichlorobenzenes, xylenes, etc.), CCl_4, CS_2, alkanols, diols, etc.]. Compared to C_{60}, the solubility of C_{70} is studied less comprehensively, apparently, because of its more difficult accessibility. As to polythermal data on the solubility of C_{60} and C_{70}, there are published data for several solvents only (carbon tetrachloride, toluene, hexane, *o*-xylene, *o*-dichlorobenzene, and a few other solvents). These studies covered the temperature range from –20 to 110°C. The experimental data on the solubility of fullerenes C_{60} and C_{70} in the most common solvents were published, in particular, in [1–5].

According to these works, individual fullerenes C_{60} and C_{70} do not form solid solutions with solvents. However, formation of crystal solvates of a fixed composition, e.g., $C_{60}\cdot 2CCl_4$, $C_{60}\cdot 2C_6H_5CH_3$, $C_{60}\cdot 0.5C_6H_5CH_3$, $C_{60}\cdot 2C_6H_4(CH_3)_2$, etc., was reported in [6, 7]. In some cases (e.g., $C_{60}\cdot 2CCl_4$), polythermal phase equilibria in fullerene–solvent system are complicated by polymorphic (α–β) transitions occurring typically at comparatively low temperatures (<0°C). The same holds for crystal solvates of fullerene C_{70} for which formation of crystal solvates is less typical.

We could not find any published data on mutual solubility of two different fullerenes in one solvent or of an individual fullerene in solvent mixtures, except for the work [8] devoted to solubility diagrams in the C_{60}–C_{70}–toluene system at 25°C and in the C_{60}–C_{70}–*o*-xylene system at 80°C. It should be noted that, along with purely scientific interest, studies of the solubility diagrams of such ternary and more complex systems are of undoubted practical interest, associated with the prospects for a more or less complete prechromatographic separation of fullerene mixture components (above all, the main mixture components, C_{60} and C_{70}) based on the difference in their solubilities.

EXPERIMENTAL

In this work, we used fullerenes C_{60} and C_{70} (99.9 and 99 wt % pure, respectively; content of the main determinable impurities ca. 0.1 wt % C_{70} in C_{60} and ca. 1 wt % C_{60} in C_{70}), available from Klaster, St. Petersburg, as well as analytically puregrade *o*-xylene.

In solubility studies for the C_{60}–C_{70}–*o*-xylene system at 25°C, the solution prepared by isothermal saturation for 24 h was evaporated, which yielded *a fortiori* equilibrium (freshly precipitated) solid phase, which was used for repeated isothermal saturation for 4–6 h at 25.00 ± 0.05°C. Thus, we obtained reproducible solubilities of C_{60} and C_{70}, namely, of 9.25 ± 0.1 and 15.17 ± 0.2 g l^{-1}, respectively.

We studied experimentally the solubility in the C_{60}–C_{70}–*o*-xylene system at –20°C by the freezing-out technique. To this end, the prepared solid solution $C_{60}+C_{70}$ ($m \approx 2$ g) and the solvent, *o*-xylene (≅10 ml), were stirred with a magnetic stirrer at 25°C; the saturation time was 48–72 h. The resulting solution was separated from the solid phase by filtration and then placed into a Peltier cooler and frozen out for

1070-4272/03/7601-0033$25.00

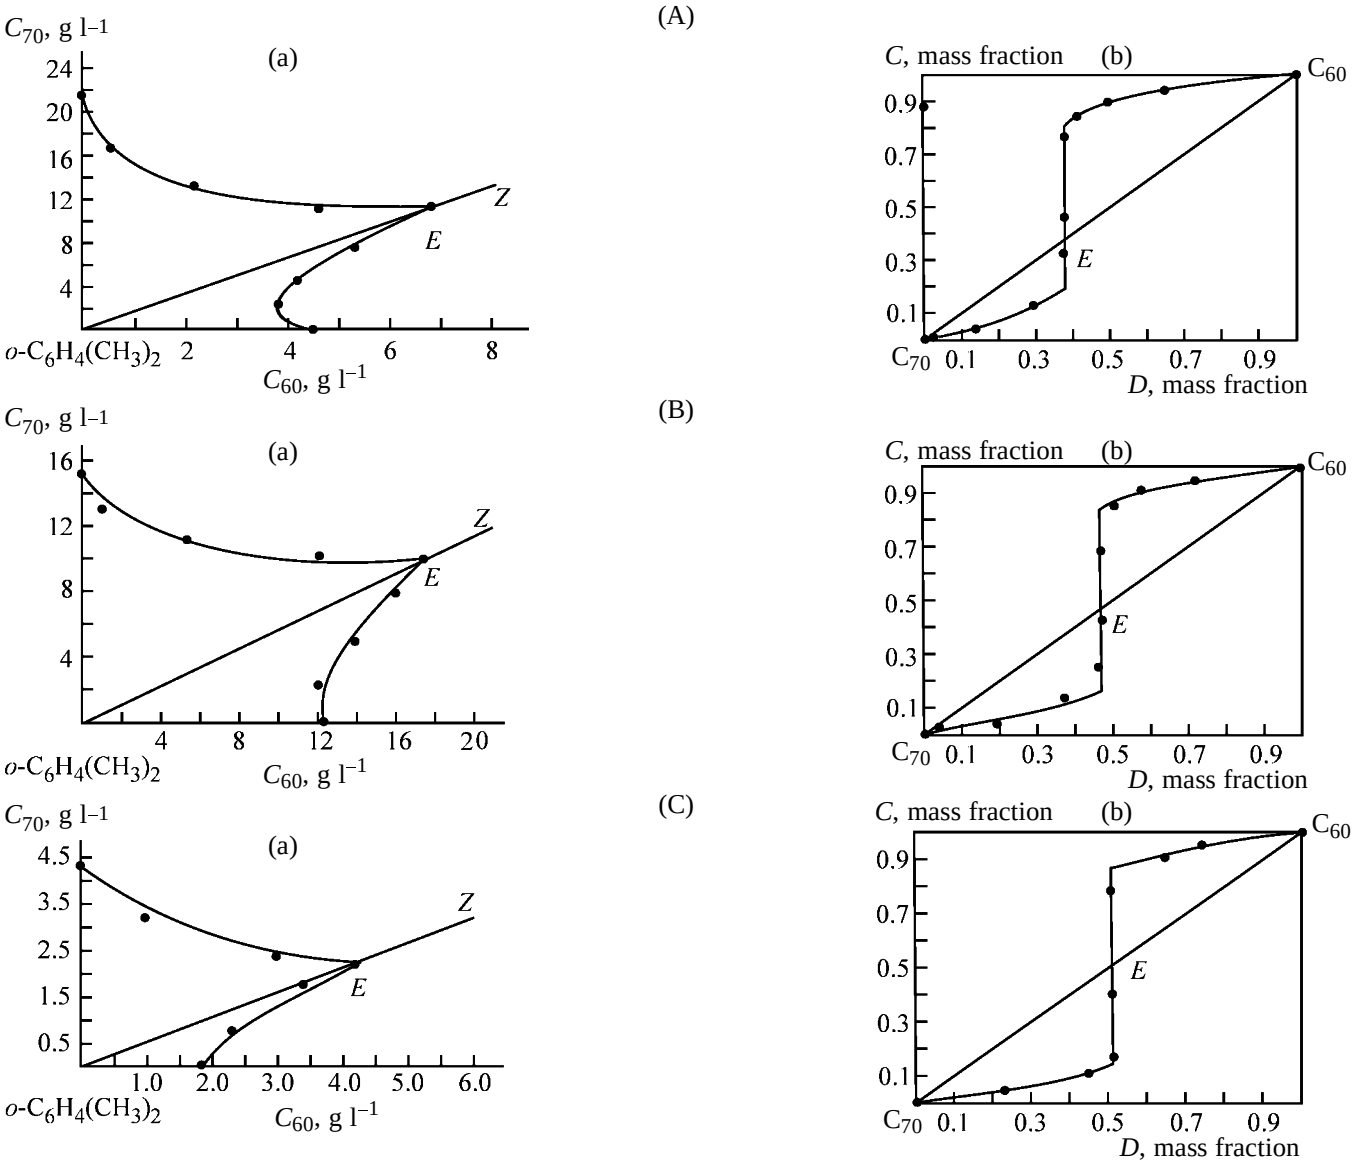

Fig. 1. (a) Solubility diagrams and (b) diagrams of distribution of the fullerene components between the liquid and solid phases in the C_{60}–C_{70}–*o*-xylene system at (A) 80 [8], (B) 25, and (C) –20°C. (C_{70}, C_{60}) Solubility of C_{70} and C_{60}, respectively; (*C*) C_{60} content in solid solution; and (*D*) C_{60} content in liquid solution.

8–10 h at 20 ± 0.2°C with determination of the solution composition at regular intervals. Next, the equilibrium solution of the liquid phase was separated from the solid phase, and the liquid and solid phases were analyzed spectrophotometrically [9]. The solubilities of $C_{60} \cdot 2o\text{-}C_6H_4(CH_3)_2$ and $C_{70} \cdot 2o\text{-}C_6H_4(CH_3)_2$ at –20°C were estimated by this method at 1.81 ± 0.2 and 3.74 ± 0.2 g l^{-1}, respectively.

The content (*x* values) of the fullerene components C_{60} and C_{70} in the solid solutions $(C_{60})_x(C_{70})_{1-x} \cdot n\,o\text{-}C_6H_4(CH_3)_2$ was determined by the Schreinemakers method of wet residues. To determine the content of the solvent in the solid solutions, the solid phase was separated from the mother liquor, washed with diethyl alcohol, dried, weighed, and heated under isothermal conditions at 120°C for 2 h. Next, the solid phase was weighed once again, and the content of the solvent in the solid phase *n* was determined from the mass difference. The experiments yielded for all the solid solutions at –20°C the compositions $(C_{60})_x(C_{70})_{1-x} \cdot n\,o\text{-}C_6H_4(CH_3)_2$ with $n = 2 \pm 0.3$. This is a bisolvate; the deviation from 2 is due to the residual amount of *o*-xylene in the solid phase. At 25°C we observed a mixed pattern: The crystallization branch of C_{60}-rich solid solutions exhibited crystallization of bisolvate solid solutions $(C_{60})_x(C_{70})_{1-x} \cdot$

$2o$-$C_6H_4(CH_3)_2$ with $n = 2 \pm 0.2$, and the crystallization branch of C_{70}-rich solid solutions, crystallization of nonsolvated solid solutions $(C_{60})_x(C_{70})_{1-x}$.

C_{60}–C_{70}–o-$C_6H_4(CH_3)_2$ system (at 80°C). The solubility in this system was studied earlier [8]. For clarity and comparison, we presented in Fig. 1A the solubility diagram and the diagram of distribution of the fullerene components between the liquid and solid phases (the mass fraction of C_{60} in the $C_{60} + C_{70}$ mixture in the liquid and solid phases is the Jaenicke index of the fullerene components).

As seen from Fig. 1A, at 80°C [8] the salting-in effect is observed in the crystallization branch of the C_{60}-rich solid solutions, i.e., the C_{60} solubility tended to increase with increasing C_{70} concentration. By contrast, the crystallization branches of the C_{70}-rich solid solutions exhibited a salting-out effect, i.e., the C_{70} solubility tended to decrease with increasing C_{60} concentration.

At 80°C, substitution solid solution of the composition $(C_{60})_x(C_{70})_{1-x}$ free of o-$C_6H_4(CH_3)_2$ crystallize in the system; a discontinuity is observed in crystallization of solid solutions (the immiscibility region corresponds to $0.21 < x < 0.82$). In addition, there is one nonvariant eutonic point (point *E*) corresponding to mutual saturation with two solid solutions of the same qualitative composition. Also, Ponomarev *et al.* [8] mentioned a peculiar run of the crystallization branch of solid solutions rich in C_{60} [monovariant liquidus curve is almost tangent to the secant *0Z* drawn from the figurative point of the solvent o-$C_6H_4(CH_3)_2$] and showed that this tangency contradicts the criteria of the solution resistance to infinitesimal state changes [10].

Solubility in the C_{60}–C_{70}–o-$C_6H_4(CH_3)_2$ system at 25°C. The experimental data on the composition of the equilibrium liquid phase for this system are presented in Fig. 1B. In this system, the crystallization branch of C_{60}-rich solid solutions also exhibits a salting-in effect (the solubility of C_{60} tends to increase with increasing C_{70} concentration). By contrast, the crystallization branch of C_{70}-rich solid solutions exhibits a salting-out effect (the C_{70} solubility tends to decrease with increasing C_{60} concentration). Figure 1B also shows the distribution diagram (mass fraction of C_{60} in the $C_{60} + C_{70}$ mixture in the liquid and solid phases). The system exhibits a discontinuity in crystallization of solid solutions (it is slightly wider compared to that at 80°C); the immiscibility region corresponds to $0.17 < x < 0.84$; there is one eutonic nonvariant point (point *E*) corresponding to the mutual saturation with two solid solutions of different

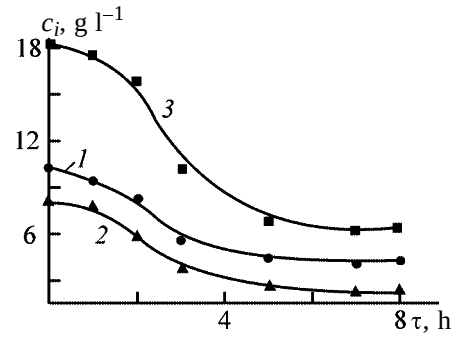

Fig. 2. Variation with the cooling time τ of the concentration of the fullerene components c_i in the solution saturated at 25°C and subsequently cooled in a temperature-controlled cooler at –20°C. (*1*) C_{60}, (*2*) C_{70}, and (*3*) $C_{60} + C_{70}$ (typical data for solution *E* in Fig. 2); the same for Figs. 3 and 4.

qualitative compositions. Figure 1B also shows a peculiar run of the crystallization branch of C_{60}-rich solid solutions: Similar to the case at 80°C, in the close-to-eutonic region, the monovariant liquidus curve is tangent to the secant 0*Z* drawn from the figurative point of the solvent, o-$C_6H_4CH_3$.

Solubility in the C_{60}–C_{70}–o-$C_6H_4(CH_3)_2$ system at –20°C. The solubility diagram at this temperature is of interest in view of the fact that polythermal crystallization in prechromatographic separation of fullerenes always proceeds via low-temperature recrystallization of solid solutions. The melting point of o-xylene is -25.1 ± 0.1, which makes the temperature region much below –20°C inaccessible.

According to our data, the fullerene C_{60}–fullerene C_{70}–o-xylene system at –20°C is characterized by substitution solid solutions of the composition $(C_{60})_x \cdot (C_{70})_{1-x} \cdot 2o$-$C_6H_4(CH_3)_2$ with a discontinuity. The DTA curves of the solid solution $(C_{60})_x(C_{70})_{1-x} \cdot n\,o$-$C_6H_4(CH_3)_2$ obtained for the 25–100°C range suggest the presence of two solvent molecules of crystallization in both kinds of solid solution. The TGA data suggest, for example, that the solid solution $(C_{60})_{0.88}(C_{70})_{0.12} \cdot 2o$-$C_6H_4(CH_3)_2$ loses the crystallization o-xylene in two stages within 43–72°C. The temperature corresponding to the loss of the crystallization solvent is strongly dependent on the composition of the primary bisolvate and decreases by tens of degrees with increasing mass fraction of C_{70} (decrease of *x*).

Figure 1C shows the experimentally determined composition of the equilibrium liquid phase. At –20°C, this system exhibits a salting-in effect in the crystallization branch of C_{60}-rich solid solutions and a salting-out effect in that of C_{70}-rich solid solutions. Figure 1C also shows the distribution diagram indicat-

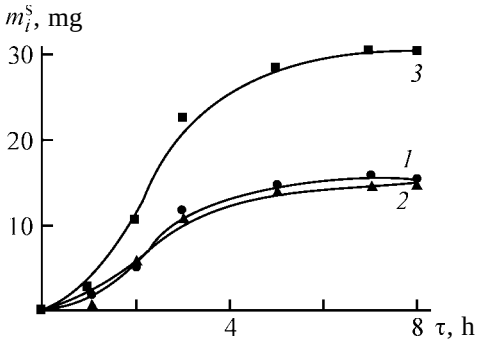

Fig. 3. Variation with time τ of the mass of the fullerene components m_i^s in the solid solutions obtained upon cooling in a temperature-controlled cooler (–20°C) 2.5 ml of the solution saturated at 25°C.

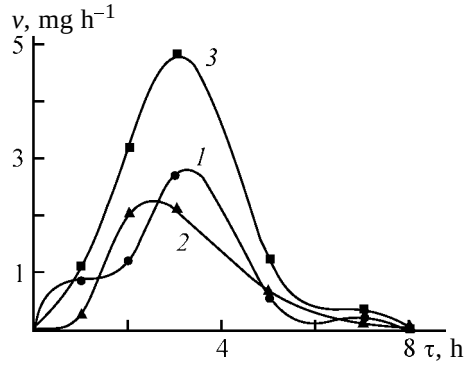

Fig. 4. Variation with the cooling time τ of the freezing-out rate for the solid solution $(C_{60})_x(C_{70})_{1-x} \cdot 2o\text{-}C_6H_4(CH_3)_2$ obtained upon cooling in a temperature-controlled cooler (–20°C) 2.5 ml of the solution saturated at 25°C. $v = dm/dt$ is the solid phase separation rate.

ing that the system exhibits a discontinuity in crystallization of solid solutions; the immiscibility region gets even wider and now corresponds to $0.14 < x < 0.86$. Also, the system has one eutonic nonvariant point (point *E*) corresponding to mutual saturation with two solid solutions of the same qualitative composition. In this case, similar to the cases of 80 and 25°C, the monovariant liquidus curve is nearly tangent to the secant 0*Z* drawn from the figurative point of the solvent *o*-$C_6H_4CH_3$.

Studies of freezing-out of fullerenes at –20°C revealed a peculiar fact. Thermodynamically, the presence of a solid phase in a crystalline form implies "a perturbation of the solution corresponding to finite changes in the state" [10]; hence, in our case, further separation of the solid phase to attain steady-state solution concentrations proceeded at a very low rate, namely, within several hours (Figs. 2–4). This involved changes in the composition of the "supersaturated solution" (Fig. 2) and the mass of the fullerenes separated into the solid phase (Fig. 3). Figure 4 shows that the rate of separation of the fullerene components varies nonmonotonically; this process is characterized by a certain "pseudoinduction" period (0.5–1 h); the separation rate attains a maximum (after 2–4 h), and only then it tends to decrease to zero (after 8–10 h). This period is unusually long, and this very fact by no means fits the classic phase formation theory.

CONCLUSIONS

(1) An experimental study of the phase diagram of the C_{60}–C_{70}–*o*-xylene system at –20°C revealed formation of extremely slowly degrading metastable states corresponding to supersaturated liquid solutions.

(2) Comparison of the solubility diagrams of the ternary system C_{60}–C_{70}–*o*-xylene at 80, 25, and –20°C showed the identity of the phase diagrams at all the three temperatures: Each diagram exhibits two crystallization branches of solid solutions (solvated and nonsolvated) of the fullerenes in each other, exhibiting a discontinuity and a eutonic nonvariant.

(3) The topology of the phase diagrams of the C_{60}–C_{70}–*o*-xylene system in polythermal conditions suggests the principal possibility of separation of C_{60} and C_{70} (and probably of other fullerenes) by polythermal recrystallization.

Abstract—A new method was proposed for separation of light fullerenes C_{60} and C_{70} based on realization of two-phase extraction equilibria in multicomponent fullerene-containing systems C_{60}–C_{70}–solvent I–solvent II and C_{60}–C_{70}–solvent I–solvent II–"inert component." The principal possibility and high efficiency of the extraction separation of light fullerenes were demonstrated.

The presently known regularly structured carbon forms are subdivided into molecular and covalent crystals. Molecular crystals are formed from individual cluster molecules. Covalent crystals are characterized by polymeric structures. It is convenient to describe the structure of covalent clusters in terms of infinite graphs. Diamond is characterized by a fourth-order uniform graph. By realizing this graph in a three-dimensional space, it is possible to depict the diamond structure corresponding to the closest packing of carbon atoms. Graphite is described by a disconnected graph consisting of an infinite number of two-dimensional lattices. Each lattice can be realized on a plane as a hexagonal network. The third allotropic modification of carbon, carbyne, is described in terms of infinite number of simple paths which all can be arranged on a straight line. In 1973, Soviet chemists Bochvar and Gal'perin [1] performed theoretical calculations and concluded that carbo-*s*-icosahedron should be a stable molecule with a singlet ground state.

In the middle 1980s, astrophysicists, using new optical spectrophotometers, revealed in the spectra of "carbon stars" (red giants) and comet tails an absorption band at 216 nm. Researchers assumed that such objects and interstellar dust can contain small clusters of carbon atoms, C_n. American physicists Rolling, Cox, and Calder tested an assumption that C_n can exist under laboratory conditions. They performed high-vacuum evaporation of graphite when exposed to a powerful laser beam. Using a mass spectrometer, these researchers detected in a graphite vapor a set of C_n clusters containing 1–150 carbon atoms. It should be noted that small clusters ($n < 40$) contained both even and odd numbers of carbon atoms, and larger ones, even numbers only. In 1985, Kroto *et al*. [2] reproduced this experiment, though under somewhat different conditions, and obtained mass spectra with peaks corresponding to m/z of 720 and 840. Kroto *et al*. assumed that these peaks correspond to individual molecules, C_{60} and C_{70}, and advanced a hypothesis that the C_{60} molecule has a form of a truncated icosahedron with the I_h symmetry, and the C_{70} molecule, a more extended ellipsoid-like structure with the D_{5h} symmetry. These assumptions were subsequently confirmed. Polyhedral carbon clusters were termed fullerenes.

A detailed mechanism of formation of fullerenes still remains to be elucidated. By now, only general ideas have been advanced concerning the carbon skeleton growth via successive addition of C_2 particles, which, evidently, dominate in graphite vapor [3].

The structural difference between fullerenes and graphite consists, above all, in that the former comprise pentagons. The very first pentagon surrounded by hexagons gives corannulene with a nonplanar structure. The same result can be obtained with formation of a heptagon [4]. The peculiar structural features of fullerenes, namely, all bonds unsaturated and no substituents, allow only two types of primary reactions: detachment of electrons and addition of electrons or groups. Fullerenes exhibit electrophlicity and are good electron acceptors. They are prone to addition of nucleophiles, as well as of free radical and carbenoid moieties. Virtually all the reactions known for fullerenes were realized for C_{60} and C_{70}. As to the chemical properties of higher fullerenes, the information is scarce.

Certain physical properties and structure of ful-

1070-4272/03/7601-0037$25.00

lerene C_{60} were reported by Prassides *et al*. [5]: cubic crystal structure, space group *Fm*3*m* (T > 260 K) and *Pa*3 (T < 260 K); carbon cage diameter 7.1 Å; bond length C=C 1.391, C–C 1.455 Å; nonvalent distance between the C_{60} molecules in a crystal 3.1 Å; volume modulus 18 GPa; density 1.65 g cm^{-3}. Spectral characteristics: electron affinity 2.6–2.8 eV; ionization potential 7.6 eV; band gap 1.9 eV; ^{13}C NMR chemical shift 142.68 ppm; IR frequencies 528, 577, 1183, 1429 cm^{-1}; Raman frequencies 1250, 1422, 1467, 1573 cm^{-1}; and refractive index 2.2 (630 nm). The structure of the C_{70} cluster was determined by electron diffraction [6]. It was found that it has a fullerene-type structure of the ellipsoidal form, point group D_{5h}. The C–C bond length varies from 1.37 to 1.47 Å. The shortest bonds are those linking the vertices of two different pentagons, and the longest are those located in five-membered rings. The "height" of the molecule is equal to 7.8 Å. The equatorial section of C_{70} has a diameter of 6.94 Å. Formally, the D_{5h}-C_{70} cluster can be obtained from two halves of the C_{60} cluster with five pairs of carbon atoms inserted in the equatorial plane.

The D_{5h}-C_{70} cluster, similar to I_h-C_{60}, contains only isolated five-membered rings. The C_{70} molecule contains atoms of five types, and its spectra exhibit the corresponding number of signals. The carbon atoms in C_{70} molecule are nonequivalent, which is responsible for different chemical shifts observed in the ^{13}C NMR spectra. Fowler [7] and Iijima [8] discussed the structures of higher fullerenes with the number of carbon atoms $n \geq 84$, as well as of those with a greater n (giant fullerenes), including extended fullerene-type carbon structures. It was suggested to simulate the structure of giant fullerenes by spherical models. It can be assumed that giant fullerenes have a complex "matreshka" or bulb-like structure. Certain giant fullerenes can have a cylindrical form or give more complex network structures (capsulenes, barrelenes, tubulenes, torenes) [8].

By now, crystalline C_{60} samples and doped systems like M_nC_{60} have been synthesized. Such salts with alkali metals at n = 3 exhibit superconducting properties: compounds with K ions have T_c = 18 K and those with Rb ions, T_c = 28 K [9]. The reliably reproducible critical temperature T_c achieved for the cesium–rubidium salt Cs_2RbC_{60} is equal to 33 K [5]. It was found that superconducting transition temperatures for some halogen-doped fullerenes exceed 60 K [10]. Fullerenes were used for preparing films having nonlinear optical properties suitable for application in optical limiters (shutters) and light diodes, as well as for generation of third harmonics in optical laser radiation. Also described are optical elements consisting of fullerene C_{60}, which exhibits high nonlinear third-order susceptibility, and a polymer or a glass as the binder [11]. Thin fullerene films are used in wave guides. Materials having magnetic properties were prepared by dispersing globular C_n (n = 60, 70, 84) bound to La, Na, K, Cs, or Rb ions in a polymeric material [12]. Magnetic materials containing C_n exhibit stable ferromagnetic properties at room temperature and can be easily prepared. Materials containing C_{60} and its derivatives are suitable for tunnel diodes, electroluminescent devices, organic solar elements, optical memory devices, field-effect transistors, etc. [13].

Fullerenes exhibit photoelectric properties such as photoconductivity and photovoltaic effect. This makes them suitable for manufacturing various devices underlain by induced processes such as current generation by illuminating fullerene interfaces. Semiconductor materials containing C_{60} or C_{70} are responsible for rectifying and photosensitive properties of devices utilizing these materials. It was shown [14] that heterostructures based on semiconducting conjugated polymers and acceptors chosen from amongst fullerenes are suitable as photodiodes and photovoltaics; also described is their use as optical memory cells. The experiments reported in [15, 16] showed that crystalline C_{60} powder can be converted to diamond by nonhydrostatic compression. This allows preparation of diamond-like (possibly, optically transparent in the visible range) films with physical and chemical properties close to those of single-crystalline diamond. This application field of fullerenes and/or their mixtures seems the most promising today.

Intercalation compounds of fullerenes with transition metals exhibit a catalytic effect in hydrogenation; they can be prepared by reaction of transition metal compounds with fullerene or fullerene-containing soot, involving activation in solution [17]. Hydrogenated or fluorinated fullerenes are suitable as solid lubricants or additives to lubricating oils [18]. Fullerene-containing fuel compositions were developed for internal-combustion engines; they include gasoline, allotropic forms of carbon soluble in hydrocarbons, and a dispersing agent [19]. Engines utilizing such fuel compositions are characterized by reduced emissions of undesired exhaust gases. Compounds containing fullerenes and hydrogenated catalysts are suitable for application in adsorption, concentration, and purification processes, as well as for storage, transfer, hydrogen reduction, and regeneration of acid

storage batteries [20]. Electric batteries also utilize fullerene-containing anodes and/or cathodes. Solar cells employ C_{60}-doped semiconductors for creating *n*, *i*, and *p* conductivities in formation of homo- and heterojunctions. Such solar cells have long service lives, and their manufacture requires no toxic materials [21].

In 1990, Kratchmer *et al*. [22] described for the first time a method for preparing several grams of carbon clusters by graphite electrode burning in an electric arc under He. The mass ratio of the main components obtained by this procedure, C_{60}/C_{70}, is typically 4/1. The content of higher clusters is ca. 1% of the fullerene mass. Also, fullerenes can be prepared by heating carbon-containing compounds in a hot plasma in front of a refractory shielding plate for collecting fullerene-containing solid products. Another method for preparation of fullerenes is burning carbon-containing substances (e.g., C_6H_6) at 1400–3000 K followed by collection of fullerene-containing condensates with the C_{70}/C_{60} ratio within 0.26–5.7 [24]. The yield and composition of fullerenes are governed by selectively controlled burning conditions and other parameters such as the C/O ratio, pressure, temperature, keeping time, diluent concentration, and gas supply rate. Also, graphite can be heated by directly passing electric current or using ultra-high-frequency radiation under an inert gas atmosphere [25, 26].

The resulting mixture of fullerene-containing products should be separated. This is usually done by fullerene extraction from fullerene soot [27, 28]. Light fullerenes C_{60} and C_{70} can be separated by different methods: chromatography [28, 29], low-pressure sublimation [30], or a method based on the difference in the polythermal solubilities of light fullerenes [29, 31, 32]. The latter method is of interest, above all, for prechromatographic separation of fullerenes; it allows isolation of individual 90–95% pure fullerenes in a yield of up to 80% of the total fullerene content.

EXPERIMENTAL

In this work, fullerenes were synthesized by the standard method of graphite rod erosion in a high-temperature plasma under helium [22]. This yielded fullerene-containing soot with a total fullerene content of ca. 8.4 wt %. The fractional composition, %, of fullerenes was as follows: C_{60} 81.3, C_{70} 17.9; sum of higher fullerenes C_{76}, C_{84}, etc. 0.8. Next, the fullerene mixture was extracted with *o*-xylene in a Soxhlet-type counterflow extractor. The residual amount of the fullerene sum in the fullerene soot was under 0.1%. The fullerene mixture in the form of *o*-xylene solutions with a total fullerene concentration of ca. 7.8 g l^{-1} was separated chromatographically on two series-connected columns packed with graphite-like filler. This gave C_{60} and C_{70} of 99.9 and 99.0 wt % purity, respectively (the only significant impurity is C_{70} in C_{60} and C_{60} in C_{70}) in the yields of 85 and 60%, respectively. The concentrations of fullerenes C_{60} and C_{70} in the liquid phase were determined spectrophotometrically from the optical densities of solutions in *o*-xylene at the wavelengths λ_1 = 335.7 and λ_2 = 472.0 nm [33]; solid mixtures of fullerenes were first dissolved without residue in *o*-xylene and then analyzed similarly. The concentrations of organic solvents (*o*-xylene, isobutylamine, monoethanolamine, etc.) in the coexisting phases were determined chromatographically on 3700 (Khromatograph plant, Moscow) and LKhM-8MD (N_2 carrier gas, Chromaton N AW DMCS, mobile phase PEG-6000) gas chromatographs. In analysis of liquid phases for H_2O content we used helium as the carrier gas and Porapak Q as the sorbent. The content of the solvents in the solid phases was determined gravimetrically, by evaporation to a constant weight at a temperature of up to 150°C and residual pressure of about 15 mm Hg.

The aim of this work is to test the suitability, in principle, of the extraction methods based on realizing two-phase liquid I–liquid II equilibria for separation and purification of the fullerene components. As far as we know, such equilibria in fullerene-containing systems have not been studied previously.

Suitable for this purpose are systems whose main components (solvents) have a fairly large concentration range of immiscibility. The physicochemical properties of the coexisting phases should differ significantly; in this case, the distribution coefficients of the fullerene components between the phases can be expected to differ significantly from unity. The distribution coefficients should also be significantly different for fullerenes C_{60} and C_{70}. The most rigorous requirement related to the process feasibility is that the solubility of fullerenes C_{60} and C_{70} in both equilibrium phases should be significant, namely, no less than 50–100 mg of fullerenes in 1 l of solution.

Fullerene C_{60}–fullerene C_{70}–*o*-xylene–isobutylamine–H_2O system at 25°C. Analysis of the coexisting phases showed that the content, wt %, of the main components of the solvent (*o*-xylene, isobutylamine, and H_2O) is as follows: *o*-xylene 3, isobutylamine 81, H_2O 16 for the lower (amine) phase and *o*-xylene 65, isobutylamine 35, and H_2O 0.1 for the upper

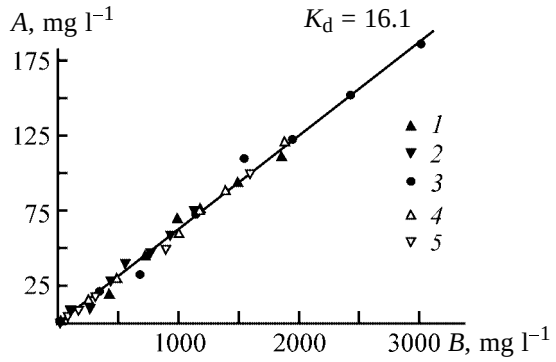

Fig. 1. Distribution of fullerenes C_{60} and C_{70} between the amine and *o*-xylene phases at 25°C. Fullerene content in (*A*) isobutylamine and (*B*) *o*-xylene phase. System: (*1–3*) C_{60}–C_{70}–*o*-xylene–isobutylamine–H_2O, (*4*) C_{60}–*o*-xylene–isobutylamine–H_2O, and (*5*) C_{70}–*o*-xylene–isobutylamine–H_2O. Fullerene: (*1, 4*) C_{60}, (*2, 5*) C_{70}, and (*3*) $C_{60} + C_{70}$.

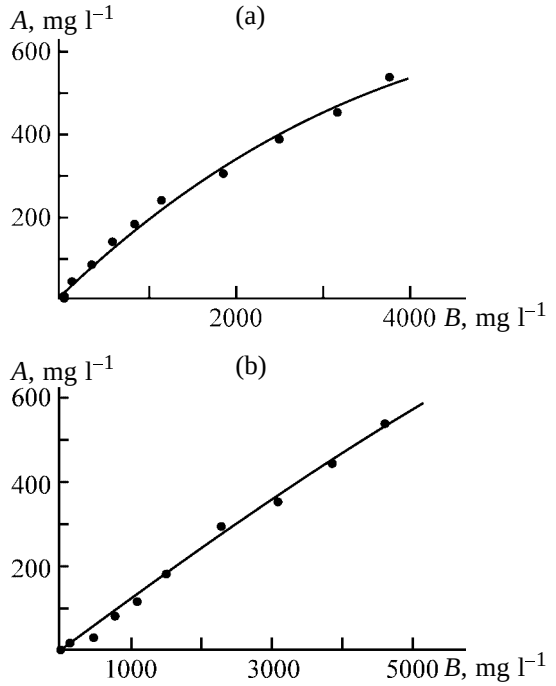

Fig. 2. Distribution of fullerenes (a) C_{60} and (b) C_{70} between the monoethanolamine and *o*-xylene phases in the fullerene C_{60}–fullerene C_{70}–*o*-xylene–monoethanolamine system at 25°C. Content of fullerenes C_{60} and C_{70} in (*A*) *o*-xylene and (*B*) monoethanolamine phase.

(xylene) phase. The content of these components in the phases is virtually independent of the fullerene content, as the coexisting phases are extremely dilute with respect to fullerene components. The total mole fraction of these components was estimated at $X_f \cong 10^{-4}$–10^{-6} and $X_f \cong 10^{-3}$–10^{-5} for the amine and xylene phases, respectively.

Figure 1 shows the distribution of the fullerene components C_{60} and C_{70} between the amine and xylene phases for the quaternary systems C_{60}–*o*-xylene–isobutylamine–H_2O and C_{70}–*o*-xylene–isobutylamine–H_2O and the quinary system C_{60}–C_{70}–*o*-xylene–isobutylamins–H_2O at 25°C. In these diagrams, the content of the macrocomponents (*o*-xylene, isobutylamine, and H_2O) is fixed, as well as the ratio of fullerenes C_{60} and C_{70} in the quinary system. The obtained distribution diagrams proved to have an unexpectedly simple form of straight lines (this allowed their uniform geometric representation in Fig. 1). The distribution coefficients of C_{60} and C_{70} in all the three studied systems proved to be invariant, irrespective of whether both or one of the fullerenes were present in solution (the fullerenes did not compete during extraction and were extracted independently). Moreover, the distribution coefficients of both fullerenes C_{60} and C_{70} proved to be equal, namely, $K_d = 16.1$.

This fact is fairly difficult to interpret. Straight-line distribution diagrams are typical, above all, for systems with ideal (with respect to the components being extracted) phases. It is unlikely that fullerenes are extracted in the form of monomers solvated by solvent molecules (in any case, this contradicts the data reported by Golubkov *et al*. for *o*-xylene solutions [34, 35]). It remains to be suggested that fullerenes form a mixture of individual associates like $(C_{60})_p(Solv)_{rl}$ and $(C_{70})_q(Solv)_{r2}$ and are extracted in these forms, and the coexisting phases are ideal specifically with respect to the extracted species rather than to unassociated monomers.

The fact that the distribution coefficients in extraction of C_{60} and C_{70} are identical means that extraction separation in the fullerene C_{60}–fullerene C_{70}–*o*-xylene–isobutylamine–H_2O system is impossible.

Fullerene C_{60}–fullerene C_{70}–*o*-xylene–monoethanolamine system at 25°C. Figures 2a and 2b show the distribution of the fullerene components C_{60} and C_{70} between the monoethanolamine and *o*-xylene phases in the quaternary system C_{60}–C_{70}–*o*-xylene–monoethanolamine at 25°C.

The content of the macrocomponents, *o*-xylene and monoethanolamine, is fixed in the diagram (because of the extremely low mutual solubility of *o*-xylene and monoethanolamine of ca. 1 wt %). Also fixed is the overall ratio of C_{60} and C_{70} (46.5 wt % C_{60}). Figure 3 presents the relative mass content of C_{60} (in the $C_{60} + C_{70}$ mixture) in the coexisting phases as a function of the C_{70} concentration in the monoethanolamine phase of the C_{60}–C_{70}–*o*-xylene–monoethanol-

amine system at 25°C. For clarity, the overall composition of the fullerene mixture being distributed (Y_{ov} = 46.5 wt % C_{60}) is shown with a dotted line.

The distribution diagrams for the C_{60}–C_{70}–*o*-xylene–monoethanolamine system are more complex than those for the fullerene C_{60}–fullerene C_{70}–*o*-xylene–isobutylamine–H_2O system. The distribution diagrams for C_{60} and C_{70} are curved (concave toward the concentration simplex axes) throughout the concentration range studied. It should be noted that, in the case of fullerene C_{60} (Fig. 2a), the curvature is much stronger compared to C_{70} (Fig. 2b). At all the concentrations, the monoethanolamine phase is richer in both fullerenes than the *o*-xylene phase, since the coefficients of fullerene distribution between these phases are always significantly over unity. Figures 2a and 2b suggest that, with increasing concentration, the distribution coefficients for C_{60} tend to monotonically increase from ca. 2 (for dilute solutions with the total fullerene concentration in the monoethanolamine phase c_f < 100 mg l^{-1}) to 7 (for concentrated solutions with the maximal total concentration $c_f \cong$ 8400 mg l^{-1}). By contrast, the distribution coefficients for C_{70} tend to monotonically decrease with increasing concentration from 12 (for dilute solutions) to 8.5 (for concentrated solutions). Figure 3 shows that, with increasing total fullerene concentration, the relative mass concentration of C_{60} (in the C_{60} + C_{70} mixture) in the coexisting phases gradually approaches the overall composition of the mixture being distributed (Y_{ov} = 46.5 wt % C_{60}), shown in Fig. 3 with a dotted line. In solutions dilute with respect to the fullerene components, fullerene C_{70} passes predominantly (relative to C_{60}) to the monoethanolamine phase, and fullerene C_{60}, to the *o*-xylene phase. In concentrated solutions, this effect is leveled. The relative contents of fullerene C_{60} (in C_{60} + C_{70} mixture) in the coexisting phases approach each other and the overall composition of the fullerene mixture, i.e., the selectivity of the phase distribution for C_{60} and C_{70} is lost.

Thermodynamically, it is fairly clear that the coexisting phases (or even one of them) are nonideal with respect to extractable species (Figs. 2, 3). The fact that both phases are nonideal with respect to nonassociated fullerene components C_{60} and C_{70} was mentioned earlier [34, 35]. However, the appearance of the distribution diagrams suggests that at least one of the liquid phases in the system under study is not even ideally associated, i.e., it is not ideal with respect to the associated and solvated extractable fullerene species. We observed such ideal association in the case of the fullerene C_{60}–fullerene C_{70}–*o*-xylene–isobutylamine–H_2O system. In view of the facts that the system with isobutylamine also contains the *o*-xylene-based phase and that the distribution diagrams for the fullerene components are straight lines, it can be assumed that specifically the monoethanolamine phase is nonideally associated.

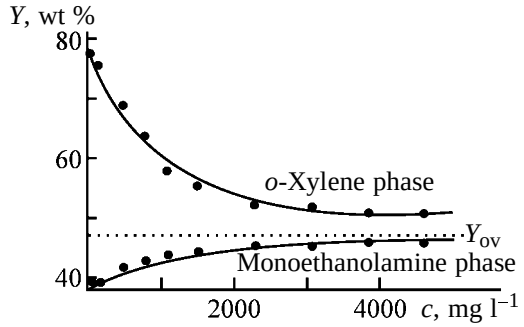

Fig. 3. Relative content of C_{60} (in the C_{60} + C_{70} mixture) *Y* in the coexisting phases as a function of the C_{70} concentration *c* in the monoethanolamine phase of the fullerene C_{60}–fullerene C_{70}–*o*-xylene–monoethanolamine system. Dotted line: overall composition of the fullerene mixture being distributed, Y_{ov} = 46.5 wt % C_{60}.

It should be noted that fullerenes C_{60} and C_{70} can be separated by extraction in the fullerene C_{60}–fullerene C_{70}–*o*-xylene–monoethanolamine quaternary system at 25°C. Figures 2 and 3 suggest that the fullerene components can be efficiently separated only in the case of comparatively dilute solution with the total fullerene concentration c_f < 2000 mg l^{-1}. The best results are obtained at still lower concentrations: c_f < 500 and even $c_f \ll$ 100 mg l^{-1}. It should be mentioned, however, that very dilute solutions (c_f < 100 mg l^{-1}) are unfavorable, because large amounts of the solvents involved, which should be subsequently evaporated, make the process power- and labor-consuming. At high concentrations (c_f > 2000 mg l^{-1}), the separation is also inefficient because of fairly low separation factors. Hence, the optimal concentration for separation of C_{60} + C_{70} mixtures of an averaged composition (from 20 to 80 wt % of C_{60} in the C_{60} + C_{70} mixture) is 500 ± 200 mg l^{-1}.

Fullerene C_{60}–fullerene C_{70}–*o*-xylene–dimethylformamide (DMF)–H_2O system at 25°C. Analysis of the system showed that the content, wt %, of the main solvent components (*o*-xylene, DMF, and H_2O) in the coexisting phases is as follows: *o*-xylene 14, DMF 67, and H_2O 19 in the lower (DMF) phase, and *o*-xylene 48, DMF 44, and H_2O 8 in the upper (*o*-xylene) phase.

Figures 4a and 4b show the distribution of the fullerene components C_{60} and C_{70} between the DMF and *o*-xylene phases in the C_{60}–C_{70}–*o*-xylene–DMF–

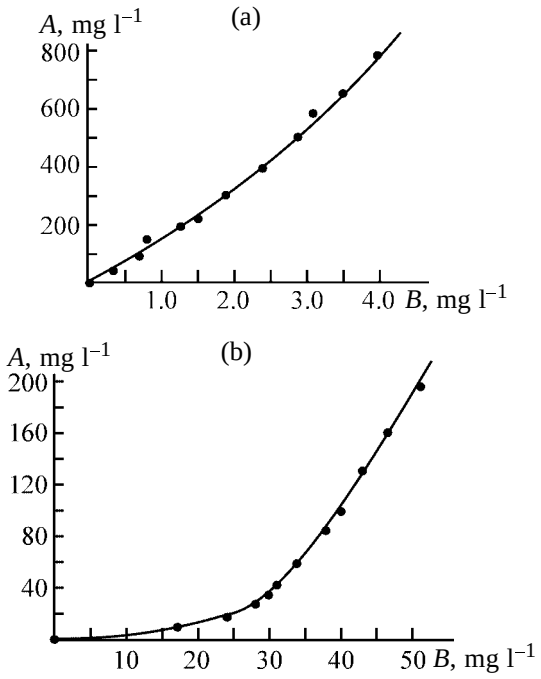

Fig. 4. Distribution of (a) C_{60} and (b) C_{70} between the DMF and *o*-xylene phases in the fullerene C_{60}–fullerene C_{70}–*o*-xylene–DMF–H_2O system at 25°C. C_{60}, C_{70} fullerene content in (*A*) *o*-xylene phase and (*B*) DMF phase.

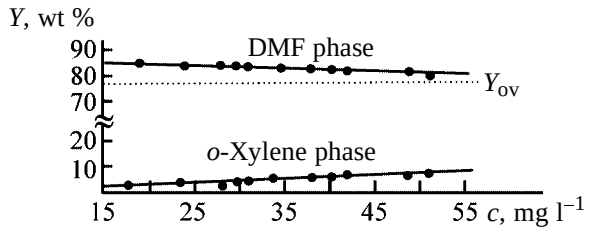

Fig. 5. Relative content of C_{60} in the $C_{60} + C_{70}$ mixture in the coexisting phases *Y* as a function of the C_{70} concentration *c* in the DMF phase of the fullerene C_{60}–fullerene C_{70}–*o*-xylene–DMF–H_2O system at 25°C. Dotted line: overall composition of the fullerene mixture being distributed, Y_{ov} = 77.7 wt % C_{60}.

H_2O quinary system at 25°C. The overall composition of the C_{60}–C_{70} mixture used was fixed at 77.7 wt % C_{60}.

The distribution diagrams for C_{60} and C_{70} also proved to be curved throughout the concentrated range studied. It should be noted that, in the distribution diagram for fullerene C_{70}, the curvature is much stronger compared to C_{60}, and the *o*-xylene phase is always richer in both fullerenes than the DMF phase. The distribution coefficients (the concentration ratio of the *o*-xylene to DMF phase) vary for C_{60} insignificantly with increasing concentration and are estimated at ca. 200 (Fig. 4a). The distribution coefficients for C_{70} vary more strongly with increasing concentration; they monotonically increase from 1 (for dilute solutions with the C_{70} concentration in the *o*-xylene phase of under 20 mg l^{-1}) to 4 (for concentrated solutions with the C_{70} concentration in the *o*-xylene phase of over 200 mg l^{-1}) (Fig. 4b).

Of principal importance is the fact that the separation factor equal to the ratio of the C_{60} and C_{70} distribution coefficients is large, namely, $50 < K_s < 200$, which offers promise for phase separation. Indeed, the *o*-xylene phase predominantly accumulates C_{60} (80–84 wt %), and the DMF phase, C_{70} (92–97 wt %). Figures 4 and 5 suggest that the separation is the most efficient in dilute solutions, though in comparatively concentrated solutions the separation is very efficient as well. Evidently, the optimal concentrations for separation of C_{60} and C_{70} are 800–1000 mg l^{-1}. It is impossible to markedly increase the total fullerene concentration in solution relative to the indicated range, as a solid phase is immediately formed in the DMF phase, which disturbs the extraction equilibrium.

Thermodynamically, Figs. 4 and 5 also suggest that both coexisting phases are nonideal with respect to the extractable species.

CONCLUSIONS

(1) The extraction equilibria liquid I–liquid II were studied in the C_{60}–C_{70}–*o*-xylene–monoethanolamine quaternary system and C_{60}–C_{70}–*o*-xylene–dimethylformamide–H_2O and C_{60}–C_{70}–*o*-xylene–isobutylamine–H_2O quinary systems at 25°C.

(2) The diagrams of distribution of the fullerene components between the coexisting liquid phases were obtained. It is possible to achieve noticeable extractive separation of C_{60} and C_{70} in the monoethanolamine system at the total fullerene concentration in the *o*-xylene phase of 500 ± 200 mg l^{-1}. The optimal concentration for separation in the dimethylformamide system is $c_f = 900 \pm 100$ mg l^{-1}. No extractive separation was achieved in the isobutylamine-containing system.

SORPTION AND ION-EXCHANGE PROCESSES

Modification of Carbon Materials To Impart to Them Fungicidal and Antimicrobial Properties

Abstract—New copper-containing fungicides based on peat and granulated and powder-like anthracite were prepared and studied; the optimal conditions of their preparation were determined.

Although numerous chemical agents for plant protection (in particular, fungicides) are available, search for new more effective and convenient-to-use preparations is still an urgent problem due to increasing requirements to safety for humans and preservation of the activity at prolonged storage.

Though copper-containing fungicides are well known [1–5], in this work we tried to prepare new copper-containing fungicides with carbon materials as supports.

It was found [6–11] that, in sorption of copper(II) compounds on activated carbons, various forms of sorbed copper(II) are formed, depending on the process conditions, chemical nature of the sorbent surface, and structure of the carbon material. The carbon surface is active, it can bear an electrical charge and contain various functional groups. Hence, contact with salt solutions can be accompanied by the exchange of anions (with the release of OH^- ions into solutions) and cations (with acidic functional groups in the oxidized samples). At anion exchange in the presence of copper(II) salts, hydroxides and basic salts are formed in the carbon pores. Also [8–11], at contact with concentrated solutions, the multilayer coverage of the pore surface with copper(II) compounds is possible. Such preparations (impregnated carbons), in which granules (particles) of activated carbon support are filled with a certain compound, are widely used as chemosorbents, catalysts, etc. [8–11].

As for carbon materials modified with copper(II) compounds, it is known [8–10] that they can contain a water-soluble (WS) fraction sorbed in the interlayer or intrapore space and an acid-soluble fraction in the form of basic salts or copper(II) bound by cation exchange. Such a variety of the forms of bound copper(II) allows synthesis of preparations with the controlled amount and rate of release of fungicidal and antimicrobial copper(II) species into the environment. As a result, we can obtain highly active fungicides (bactericides) with a lower content of copper(II) and lower toxicity compared to known copper-containing agents.

The aim of this work was to prepare modified carbon materials with fungicidal and antimicrobial properties, to determine the optimal synthesis conditions, and to obtain a series of experimental samples for full-scale tests. For this purpose we prepared about 30 samples, mainly based on granulated and powdered anthracite.[1] In some cases, natural peat was used as copper support. Modification was performed in the static sorption mode: a weighed portion (5–1000 g) of the carbon material was shaken for 4 h with the required volume (15–5000 ml) of a copper(II) chloride solution of appropriate concentration. To determine the optimal synthesis conditions, we varied the type of the initial material, its granulation, copper(II) salt concentration, pH value, etc. In special tests we recorded the copper(II) sorption isotherms (Fig. 1) and performed washing out of weakly bound (WS) copper(II) (Fig. 2) and desorption of copper(II) (sorbed or bound by ion exchange) from the sorbent surface.

As seen from Table 1, the samples studied contained different amounts of sorbed copper(II). Using sorption isotherms and the ratio of the sample weight to solution volume, we can calculate the required amount of copper(II) in the preparation. Copper(II) is strongly sorbed on both anthracite and peat (Fig. 1).

[1] Due to the short supply of special-purpose activated carbons for rapidly expanding areas of their application, utilization of cheap carbon materials, e.g., activated anthracite, is an urgent problem. Search for new processes to obtain valuable products from the waste of powdered anthracite production is also important.

* (APA) Activated powdered anthracite.
** (AGA) Activated granulated anthracite.

As seen from Table 1, at high copper(II) concentrations the content of sorbed copper(II) is almost independent of the anthracite granulation. With decreasing concentration of the initial $CuCl_2$ solution, the content of sorbed copper(II) on the finer anthracite particles became smaller than that on the coarser particles.

Along with the fractional composition of the carbon material, pH of the initial solution also affects sorption of copper(II) and forms of its binding with

* Antibacterial activity was determined using the phytopathogenic cultures *Predomanas lachrymans* (1_3 and 5_a strains) and *Ervinia* (8982, 8163, and 549 strains); (+) weak sensitivity, sterile area diameter 15 mm; (++) moderate sensitivity (15–25 mm); and (+++) high sensitivity (more than 25 mm).

the sorbent. However, this effect is appreciable only in dilute solutions and at rather low pH values, whereas in concentrated solutions sorption is almost independent of pH.

The conditions of copper(II) desorption are important, because the amount and forms of desorbed copper(II) strongly affect the fungicidal and phytotoxic properties of carbon materials.

Experiments on the kinetics of copper(II) washing out with water from samples with a fairly high metal content showed that copper(II) is actively washed out in the first 5 min. This fact suggests that the diffusion factors do not noticeable affect the copper desorption, and at longer contact with water the copper desorption increases only slightly. The residual copper(II) content after treatment with water for 1 h was 6.4 mg g^{-1}. We failed to remove all the sorbed copper from the samples with water, which suggests that it occurs in activated carbon in different chemical forms.

Based on our experimental results and preliminary data on the fungicidal activity, obtained at the Ukrainian Research Institute of Plant Protection (Kiev, Ukraine), we prepared a pilot series of the samples for the field plant protection tests. We determined the sorption capacity and desorption of copper(II) in single and multiple treatments with water (Fig. 2). As seen, in successive treatments copper(II) is gradually washed out.

Our preparations (Table 1) were tested under the laboratory conditions. We determined the growth inhibition factors for the fungus spores of *Alternaria tenrus, Phytophthora infestans*, etc., which are pathogens of crops, causing potato and tomato phytophthora infection, potato alternariosis, and root rot of many plants (Table 2). For some samples we also determined the antimicrobial activity.

Analysis of our experimental data showed that unmodified carbon materials exhibit no fungicidal and antimicrobial properties (Table 2). With addition of copper(II), almost all the samples acquire the fungicidal activity. It should be noted that the strong inhibition of the spore growth was observed with both the

anthracite samples impregnated with concentrated (1–5 N) copper(II) chloride solutions, which probably contain all the above forms of bound copper and significant amounts of weakly bound water-soluble species, and with the samples treated with dilute solutions, which contain smaller amounts of readily removable copper(II). Therefore, there are good grounds to expect that such preparations can provide the required fungicidal effect at lower copper(II) consumption.

Sample nos. 17 and 18, treated after sorption with alkali, showed high activity; the fungicidal activity of modified peat may be of practical interest. After such a treatment, copper(II) in the sorbent can occur as oxychloride, i.e., in the form similar to the reference compound $3Cu(OH)_2 \cdot CuCl_2 \cdot xH_2O$, $x = 0–3$ or hydroxide; certain its fraction also can be bound by the cation-exchange mechanism.

Comparison of the fungicidal activity of the samples (Table 2) showed that some samples, e.g., modified copper-containing samples of anthracite (sample nos. 8–10) and peat (sample nos. 2–4) are more effective in the spore growth inhibition and in suppression of a series of phytopathogenic bacteria as compared to the reference. Since the above preparations were obtained using concentrated solutions and they contained significant amounts of water-soluble copper(II), we assume that their antimicrobial properties are predominantly determined by the released copper(II).

The results of the laboratory tests on the fungicidal and antimicrobial activity of copper-containing carbon materials suggest that they are promising for agricultural use.

In the field tests, we used the samples with various forms of bound copper(II), prepared by impregnation of carbon material with both concentrated and dilute solutions of copper(II) chloride. After sorption, the samples were washed to remove excess copper(II) with distilled water (sample no. 16) and with water and alkaline solution (sample no. 20). In the latter case, we assume that the major fraction of copper in the sample occurs in the form close to $3Cu(OH)_2 \cdot CuCl_2 \cdot xH_2O$.

The vegetation tests showed phytotoxicity of sample nos. 16 and 20, whereas sample no. 21 with a small content of copper(II) exhibited no such activity; no phytotoxicity was observed in the field tests. Sample no. 21 with the copper content by an order of magnitude smaller than in the reference exhibited a fungicidal activity in the field tests.

CONCLUSION

Copper-modified anthracites show promise as fungicidal and antibacterial preparations for vegetable growing and storage.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Deposition and Stabilization Conditions on the Texture Properties of Aluminum Hydroxides

A. A. Lamberov, O. V. Levin, S. R. Egorova, D. A. Evstyagin, and A. G. Aptikasheva

Kazan State Technological University, Kazan, Tatarstan, Russia
Novokuibyshevsk Catalyst Plant, Limited Liability Company, Novokuibyshevsk, Samara oblast, Russia

Received February 27, 2002

Abstract—Methods of low-temperature adsorption of nitrogen and X-ray phase analysis were applied to study structural characteristics of aluminum hydroxides synthesized under industrial conditions. A mechanism of formation of the porous structure of aluminum hydroxides was suggested.

Aluminum oxide is widely used in manufacture of adsorbents and catalysts, being, therefore, a large-tonnage product of industrial chemistry. Recent studies have shown that synthesis of a support is one of the most important procedures in catalyst manufacture technology. As a support frequently serves active aluminum oxide (AAO), determining the dispersity and distribution of the active component and diffusion limitations on mass-transfer processes in a catalyst [1, 2].

It is commonly believed that there exists the optimal pore size of a catalyst for any particular type of raw materials. However, despite that the literature contains a voluminous material concerning the synthesis techniques and the structure of aluminum hydroxides and oxides of varied morphology, data on the influence of particular industrial procedures on the texture of aluminum oxide obtained by reprecipitation are rather scarce [3–7].

The aim of this study was to establish the mechanism of texture formation in AAO in the course of its industrial synthesis and to analyze the influence exerted by the conventional procedures on its texture characteristics.

EXPERIMENTAL

Aluminum hydroxides (AH) were synthesized under industrial conditions by batch precipitation using the sulfate process. The hydroxide samples were analyzed for the content of impurities: Na^+ ions (in terms of Na_2O), by flame photometry on a Flapho-4 instrument; SO_3^{2-} ions, by a procedure described in [8]. The texture characteristics were determined on an ASAP 2010 Micromeritics universal analyzer of surface area and porosity. Adsorption isotherms were measured at 77 K, degassing was done at 773 K to a residual pressure of 10^{-4} mm Hg. The specific surface area S_{sp} was determined by thermal desorption of nitrogen. S_{sp} was calculated with account of the adopted surface area of the nitrogen molecule (0.162 nm^2). The density of nitrogen in the normal liquid state was 0.808 g cm^{-3}. The relative error in S_{sp} measurements was ±3%. The pore volume

* I is the intensity of pore size distribution peaks.
** The porogram has a peak at 82 Å (intensity 0.002 $cm^3\ g^{-1}\ Å^{-1}$).

V_p and pore size distribution were calculated from the desorption portion of the isotherm, using the standard Barrett–Joyner–Highland procedure [9]. The measurement error was ±13%. X-ray studies were carried out with a DRON-2 diffractometer (FeK_α radiation with β-filter). The range of 2θ angles in which measurements were made was 0°–100°.

It is reasonable to start the discussion of the results obtained with analysis of adsorption isotherms (Fig. 1), since the shape of the hysteresis loop is related to a certain type of the pore structure.

AH precipitated at 40°C shows a type II adsorption isotherm with a hybrid hysteresis loop H2–H3 by the IUPAC classification. The cumulative specific surface area S_Σ exceeds the specific surface area found by BET ($S_\Sigma : S_{BET}$ = 1.27 for the given sample). This indicates that the deposit has tubular pores with constrictions [9, 10].

Raising the precipitation temperature to 50°C changes the type of the hysteresis loop from H2–H3 to H3. The steep slope of the adsorption branch points to the absence of mesopores with medium diameters, and the narrow hysteresis loop, to uniformity of the pores. A hysteresis loop of this type is characteristic of slitlike pores between two parallel plates, open on all sides.

Raising the AH precipitation temperature further does not change the type of isotherms and hysteresis loops; a certain broadening of the hysteresis loop indicates an increasing diversity of pores, and the steeper adsorption branch of the isotherm at medium and high relative pressures confirms the formation of mesopores of large diameter.

The texture characteristics of the AH synthesized are listed in Table 1. In view of the fact that larger part of AH samples had finely porous structure and the peaks in pore size distributions in porograms (Fig. 2) lie fairly close to one another, we used the intensities of these peaks assuming that they are proportional to the contribution of pores of a given diameter to the total pore volume.

The pore structure of AH precipitated at 40°C (S_{sp} = 370 $m^2\ g^{-1}$; V_p = 0.44 $cm^3\ g^{-1}$) is characterized by high-intensity peak of the pore size distribution (0.052 $cm^3\ g^{-1}\ Å^{-1}$) at 37 Å, and, in accordance with the descending run of the porogram in the initial portion of the curve, there is a peak with undeterminable intensity in the range of narrow (<14 Å) pores. The pore volume is 0.31 $cm^3\ g^{-1}$ (68% of V_p) in the range 13–50 Å and 0.043 $cm^3\ g^{-1}$ (9.4% of V_p) in the range 50–100 Å (Table 1, Fig. 2).

With account taken of the type of the hysteresis loop and data of [11], it may be assumed that the hy-

droxide precipitate is formed by fibrillar fragments of "gel-like" boehmite [10].

Raising the precipitation temperature to 50°C leads to the appearance of peak in the pore size distribution at 16 Å with intensity of 0.007 $cm^3\ g^{-1}\ Å^{-1}$, and the intensity of the peak at 37 Å decreases from 0.052 to 0.028 $cm^3\ g^{-1}\ Å^{-1}$. The specific surface area of this AH is 459 $m^2\ g^{-1}$, and the pore volume, 0.63 $cm^3\ g^{-1}$. Such a strong increase in the specific surface area is probably due to dispersion of fibrillar particles of gel-like boehmite to give plates of "microcrystalline boehmite" [10], which form, via undirected mutual coordination, slit-like pores of the diameter exceeding 50 Å. The volume of pores with the diameter less than 50 Å is 0.372 $cm^3\ g^{-1}$, which is close to the corresponding value for AH obtained at 40°C (0.31 $cm^3\ g^{-1}$); however, it constitutes only 59% of V_p. It may be stated that the increase in the pore volume is due to the formation of secondary porosity in the range 50–100 Å,

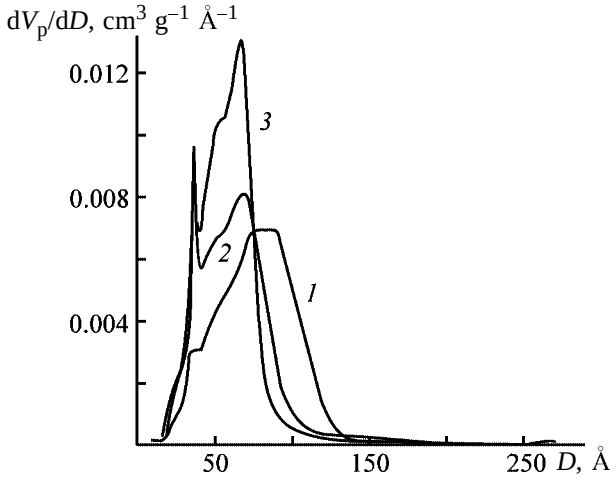

Fig. 3. Pore volume (V_p) distribution curves for AH samples precipitated at low temperature, (*1*) 1, (*2*) 25, and (*3*) 75 days after the synthesis.

without appearance of any peak in the pore size distribution.

Raising the precipitation temperature further leads to a gradual shift of the peak in the pore size distribution at 42 Å to larger diameters (to 50–60 Å), whereas the position of the peaks at 25 and 36 Å remains virtually unchanged. The measured pore volume first grows (T_p = 50–60°C) in the range 50–100 Å (to 0.30–0.36 $cm^3\ g^{-1}$) and then ($T_p \geq 70$°C) at diameters exceeding 100 Å (also to 0.30–0.33 $cm^3\ g^{-1}$), and the specific surface area decreases. In the diameter range 13–50 Å, all the hydroxides synthesized have approximately the same pore volume of 0.30–0.36 $cm^3\ g^{-1}$.

The hydroxides obtained at $T \leq 50$°C are the most labile systems in which crystallization and structuring of a precipitate occur spontaneously in the course of time (Table 2, Fig. 3). For example, a broad peak in the pore size distribution at the pore diameter of 80 Å, observed for AH obtained at 20°C, is probably shifted upon storage to about 66 Å as a result of partial dispersion of pore-forming particles, which is indicated by a considerable increase in the specific surface area of the hydroxide.

To bring crystallization processes in low-temperature AH ($T_p \leq 50$°C) to completion, the hydroxide is stabilized in industrial practice by keeping its dispersion in mother liquor at 102°C for 1 h. Variation of the texture of cold-precipitated AH with the temperature of its stabilization is illustrated in Table 3 and Fig. 4.

The initial cold-precipitated hydroxide has a bidisperse structure with peaks of about the same intensity at 20 and 36 Å in the pore size distribution, low pore volume (0.37 $cm^3\ g^{-1}$), and large specific surface area (357 $m^2\ g^{-1}$) (Table 3, Fig. 4).

102	0.070	1.46	306	0.42	25.4	80	36.6	176	50.0	270

Raising the stabilization temperature to 60°C increases the intensity of the peak in the pore size distribution at 36 Å from 0.173 to 0.560 $cm^3\ g^{-1}\ Å^{-1}$, and the peak at 20 Å is shifted to 25 Å, with its intensity decreasing from 0.175 to 0.058 $cm^3\ g^{-1}\ Å^{-1}$. In the process, the type of the hysteresis loop remains virtually unchanged. It may be assumed that fibrils of gel-like pseudoboehmite with the pore size distribution peak at 36 Å are formed under these conditions. Further increase in the stabilization temperature leads to a decrease in the intensity of the peak at 36 Å from 0.560 to 0.202 $cm^3\ g^{-1}\ Å^{-1}$ (90°C) and appearance of a peak at 40 Å, gradually shifted to around 50 Å with increasing stabilization temperature. No significant change in the specific surface area or pore volume occurs in the process. Consequently, it may be assumed that pores 40 Å in diameter are formed within a structure constituted by fibrillar fragments as a result of hydrothermal transformations of the hydroxide. This is indicated by a change of the type of the hysteresis loop from H3 to H2, which points to formation of bottle-shaped pores. It may be assumed that no microcrystalline boehmite is formed in stabilization of low-temperature hydroxide, which is indicated by the absence of pores more than 100 Å in diameter. The total pore volume remains rather small.

To elucidate the mechanism of texture formation in AH, we studied its morphology by X-ray phase analysis. The results obtained are listed in Table 4, whence follows that, depending on AH precipitation and stabilization temperatures, the precipitate contains pseudoboehmite, gibbsite, and bayerite in various ratios.

Raising the temperature of AH precipitation and stabilization makes the content of bayerite in the precipitate lower and the size of bayerite microcrystals larger. If account is taken of the fact that bayerite microcrystals are characterized by presence of slitlike micropores 15–20 Å in diameter [10, 12], then the high-intensity peaks in the pore size distribution, observed at 18–20 Å for low-temperature AH samples (Table 4, sample nos. 1 and 8) are due to the presence in the precipitate of a hydroxide of just bayerite morphology. Raising the temperature of stabilization or precipitation leads to disappearance of these peaks, with another peak appearing, instead, in the pore size distribution at 22–25 Å. The intensity of this peak does not correlate with the content of gibbsite or bayerite in AH.

The content of trihydroxides decreases when the precipitation is performed at lower pH. For example, the content of gibbsite in AH obtained at 20°C and stabilized at 50°C decreases from 11% to zero with the precipitation pH decreasing from 9.6 to 8.8. As follows from Table 4, the precipitation pH affects the rate of hydrolysis to a much greater extent than the process temperature does. For example, stabilization at 100°C of AH precipitated at 20°C decreases the

content of gibbsite from 21 to 9% (pH 9.4), and lowering the precipitation pH to 8.8 leads to disappearance of gibbsite in the precipitate already at 50°C.

According to the results of X-ray phase analysis, gibbsite and bayerite crystallize in the form of coarse microcrystals 130 to 1000 Å in size, and pores of about the same diameter are not manifested in the porograms. Raising the precipitation and stabilization temperatures leads to higher amount of a hydroxide with the pseudoboehmite morphology in the precipitate, and it is this hydroxide that determines the texture characteristics of the precipitate.

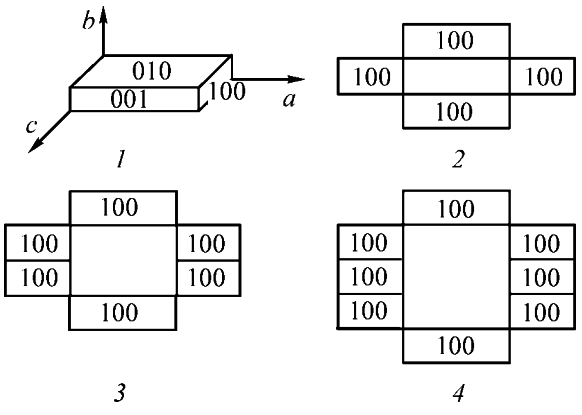

Fig. 5. (*1*) Microcrystalline structure of pseudoboehmite and (*2–4*) ways of its coordination. Fragment: (*2*) I ($D \approx$ 22–25 Å), (*3*) II (D = 37 Å), and (*4*) III ($D \approx 40-60$ Å).

A microcrystallite of pseudoboehmite is shown schematically in Fig. 5. With account of the structure of the double polymeric molecule of pseudoboehmite [10], the (010) plane of the microcrystallite, containing vectors *a* and *c*, is saturated with terminal hydroxy groups, and the (100) plane, containing vectors *b* and *c*, is the most defective (Table 4). This points to a noncoherent coordination of boehmite microcrystalites in this plane [10].

At the same time, coordination between primary microcrystallites of pseudoboehmite is the most probable in the (010) plane via formation of bridging OH groups or hydrogen bonds. The cleavage planes of unit cells of pseudoboehmite contain excess water (up to 1.7 mol per mole of Al_2O_3) firmly bound by H bonds in the interplanar space, which is indicated by strong broadening of diffraction peaks corresponding to the (010) plane. It is this water that ensures lability of contacts between pseudoboehmite microcrystallites.

Comparison of data on the phase composition of AH and their texture characteristics allows the following interpretation of the data obtained. Pores 20–25 Å in diameter, appearing in the course of AH structuring, may be due to mutual coordination of like faces,

formed by the (010) and (001) planes, of pseudoboehmite microcrystallites along the *a*-axis, to give fragment I in Fig. 5.

Pores 32–36 Å in diameter are probably formed via coordination of the (010) planes of microcrystallites to give fragment III (Fig. 5), with translation of the image in the direction perpendicular to the plot plane. Pores with larger diameters are formed via noncoherent dimerization of microcrystallites along the *b*-axis. The calculated and actual values of the pore size distribution peaks are listed in Table 5.

The main criterion characterizing the strength of intercrystallite binding in pseudoboehmite is its unit cell size along the *b*-axis, determined by the amount of interplanar water. For example, at the unit cell size exceeding 12.5 Å (H_2O content higher than 1.4 mol per mole of Al_2O_3), the hydroxide is described as gel-like pseudoboehmite, which is characterized by bottle-shaped pores formed via directed mutual coordination of primary particles of pseudoboehmite, small pore volume, and labile intercrystallite contacts of "coagulation" nature (van der Waals or hydrogen bonds) [10, 11]. The contacts are easily destroyed under peptization or other external actions. Virtually all AH samples precipitated at low temperature can be related to gel-like pseudoboehmites even after stabilization. Further structuring of the precipitate occurs via noncoherent coordination of the (100) planes of pseudoboehmite microcrystallites (which is indicated by high defectiveness along the crystallographic axis *a*) to give fibrillar fragments in the direction perpendicular to the plane of the figure.

If the size of the unit cell of pseudoboehmite along the *b*-axis is less than 12.5 Å, then the hydroxide is a microcrystalline pseudoboehmite with large pore volume formed via undirected mutual coordination of microcrystallites to give slitlike pores without any clearly pronounced peak in the pore size distribution and firm contacts between primary particles. These contacts are of "crystallization" nature [11] (content of interplanar water less than 1.4 mol per mole of Al_2O_3) and do not disintegrate under the action of peptizing agent. Hydroxides obtained at 50°C are formed of microcrystalline pseudoboehmite to a greater extent.

It follows from Table 4 that, for most of the hydroxides synthesized, the crystallite size along the *b*-axis exceeds the size of the unit cell of pseudoboehmite along the same axis. Therefore, it was assumed that the probable dominant "crystallization center" [13] is fragment II (Fig. 5) formed via mutual coordination of dimeric microcrystallites to give pores 33–37 Å in diameter. For example, hydroxides synthesized at 20°C (pH 8.8–9.6) and stabilized at 50°C contain 90% pseudoboehmite and have a virtually unimodal pore structure ($V_p \approx 0.40$ cm^3 g^{-1}) with the pore size distribution peak at 37 Å (60–70% of V_p) having intensity of 0.05–0.07 cm^3 g^{-1} Å^{-1}.

The formation of pores of large diameters in stabilization of AH prepared at low temperature is probably due to occurrence of hydrothermal conversion within fibrillar structures [10], which are accompanied by a discrete local increase in pore diameter (Fig. 5, fragment III). This is indicated by a change in the type of the hysteresis loop from H2–H3 to H2 (bottle-shaped pores). No destruction of fibrillar fragments occurs in stabilization, which is confirmed by insignificant changes in the specific surface area and pore volume.

The diameters of the forming pores were calculated in terms of the suggested mechanism of AH structur-

ing, and the calculated and true values are listed in Table 5.

Synthesis of the hydroxides at temperatures above 50°C leads to destruction of fibrillar particles along the longest axis [in the (100) plane] to give short fragments with pores 37 and 42 Å in diameter (which is indicated by the 30% greater specific surface area of these samples), forming secondary pores of diameter more than 100 Å via undirected mutual coordination [probably, in the (010) plane]. The forming pores of the secondary pore system constitute up to 60% of the pore volume in high-temperature hydroxides.

CONCLUSIONS

(1) Industrial cold-precipitated hydroxides ($T_p \approx$ 50°C) are gel-like pseudoboehmites with small pore volume (up to 0.4 $cm^3 g^{-1}$) associated with pores 25 and 36 Å in diameter. Their pore structure is due to fibrillar pseudoboehmite fragments containing pores with diameters mainly in the range 36–37 Å. Stabilization of cold-precipitated hydroxides leads to formation of bottle-shaped pores as a result of hydrothermal synthesis within fibrillar structures, with distribution peaks appearing in the range 40–60 Å. The specific surface area and pore volume remain virtually unchanged upon stabilization.

(2) Hot-precipitated hydroxides (T_p > 50°C) are formed of finely crystalline pseudoboehmite with slitlike pores open on all sides. The pore structure is due to undirected mutual coordination of platelike particles, with crystalline contacts formed between them. The hydroxides are characterized by large pore volume (>0.6 $cm^3 g^{-1}$) without any clearly pronounced peak in the pore size distribution.

(3) It is proposed that conventional discrimination of hydroxides into microcrystalline and gel-like should be based on the size of the unit cell of pseudoboehmite along the *b*-axis. The unit cell is equal to, or greater in size than 12.5 Å for gel-like pseudoboehmite, and less than, or equal to 12.5 Å for microcrystalline pseudoboehmite.

(4) The morphology of the hydroxides is determined by the conditions of their synthesis and stabilization temperature. Raising the precipitation and stabilization temperature and lowering the pH value favors formation of an aluminum hydroxide with pseudoboehmite morphology. Trihydroxides (bayerite and gibbsite) take no part in the formation of the texture of the precipitate.

(5) Based on the results obtained, a model of texture formation in aluminum hydroxide precipitate is proposed and peaks in pore size distribution are calculated. The calculated and actual positions of peaks in the distribution are close.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Lanthanide(III) and Yttrium(III) Nitrates with a Toluene Solution of Trialkylbenzylammonium Naphthenate

A. K. Pyartman, A. A. Kopyrin, and D. A. Zhikharev

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received June 12, 2002

Abstract—Extraction of lanthanides(III) [La(III)–Lu(III)] and yttrium(III) with toluene solution of trialkylbenzylammonium naphthenate mixture was studied. The equations of extraction isotherms taking into account formation of the extractable complexes $(R_4N)_2[Ln(NO_3)_3A_2]$ (A is naphthenate anion) were obtained. The extraction constants of lanthanides [La(III)–Lu(III] and yttrium(III) were calculated.

Organic solutions of quaternary ammonium base (QAB) salts with organic anions are widely used for extractive recovery and separation of nonferrous and platinum metals [1, 2]. We found no information on extraction isotherms of rare-earth metals(III) (Ln) with such binary extractants. In order to fill this gap in the extraction chemistry of lanthanide(III) and yttrium(III), we studied extraction of theses metals (as nitrates) with a toluene solution of trialkylbenzylammonium naphthenate.

The concentration of trialkylbenzylammonium naphthenate (TABANP) in toluene was 0.42 M. The general formula of TABANP is $C_6H_5(C_7H_{15}–C_9H_{19})_3N^+A^–$, where $A^–$ is the naphthenate anion. In our experiments we used a mixture of naphthenic acids (natural carboxylic acids containing carboxy groups bound to five-membered rings, M_{av} = 220).

Trialkylbenzylammonium naphthenate was prepared as follows: (1) an organic solution of trialkylbenzylammonium chloride was converted to the hydroxide by triple contact with aqueous 5–7 M NaOH; (2) the excess alkali was removed by repeated scrubbing of the organic phase with distilled water until pH of the wash water decreased to 8–9; (3) trialkylbenzylammonium hydroxide was mixed with stoichiometric amount of naphthenic acids and this mixture was dissolved in toluene (chemically pure grade). The resulting binary extractant was washed with distilled water to pH 7.

The concentration of naphthenic acids in the organic phase was determined by two methods: two-phase potentiometric titration [2] and titration with aqueous alkali of the organic phase diluted with ethyl alcohol, with phenolphthalein as indicator. The amount of the QAB salt was determined by the method reported in [3]. Ln(III) nitrates were prepared by dissolving the corresponding Ln(III) oxides (ultrapure grade) in nitric acid (analytically pure grade). Extraction was carried out in graduated tubes at the 1 : 1 ratio of the organic and aqueous phases. Changes in the volumes of the organic and aqueous phases did not exceed 2 rel. %. The Ln(III) concentration in both the initial and equilibrium aqueous phases was determined by titration with a standard aqueous solution of disodium ethylenediaminetetraacetate in the presence of xylenol orange as indicator [4]. The Ln(III) concentration in the organic phase was determined as the difference between its content in the initial and equilibrium aqueous phases taking into account the changes in the volumes of the aqueous and organic phases after extraction.

The relative errors in preparing solutions were within ±0.5%; in determining Ln(III) concentration, ±(0.5–2)%; and in determining the distribution coefficients, ±(1–3)%. The IR spectra of the organic phase (thin liquid layer between KBr plates) were recorded on UR-20 IR spectrometer (Germany) within the 700–1900 cm^{-1} range against the pure solvent (toluene).

Figure 1 shows the extraction isotherms of Ln nitrates with 0.420 M TABANP in toluene at 298 ± 0.5 K. It is seen that all the extraction isotherms show saturation with respect to Ln(III) at $C_S : [Ln^{3+}](o) \rightarrow 2 : 1$ {C_S is the total TABANP concentration in the organic phase and $[Ln^{3+}](o)$ is the equilibrium Ln(III) concentration in the organic phase; the indices (a) and (o) refer to the aqueous and organic phases, respectively}. This fact shows that lanthanides(III) are extracted in the form of mixed-ligand complexes $(R_4N)_2[Ln(NO_3)_3A_2]$ [5].

1070-4272/03/7601-0055$25.00

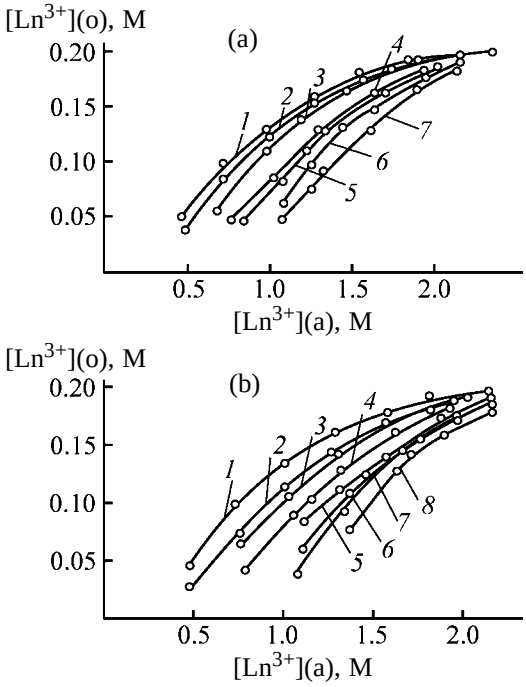

Fig. 1. Extraction isotherms of Ln(III) nitrates with 0.420 M TABANP in toluene at T = 298 K and pH 3. $[Ln^{3+}](o)$ and $[Ln^{3+}](a)$ are the equilibrium Ln(III) concentrations in the organic and aqueous phases, respectively. (a) Ln(III): (*1*) La, (*2*) Pr, (*3*) Sm, (*4*) Gd, (*5*) Dy, (*6*) Er, and (*7*) Yb; (b) Ln(III): (*1*) Ce, (*2*) Nd, (*3*) Eu, (*4*) Tb, (*5*) Ho, (*6*) Tm, (*7*) Lu, and (*8*) Y.

Extraction of Ln(III) with TABANP can be described by the equation of a heterogeneous chemical reaction

$$Ln^{3+}(a) + 3NO_3^-(a) + 2R_4NA(o) = (R_4N)_2[Ln(NO_3)_3A_2](o). \quad (1)$$

The concentration extraction constant is expressed by

$$K_{ex}^2 = \frac{[(R_4N)_2Ln(NO_3)_3A_2](o)}{[Ln^{3+}](a)[NO_3^-]^3(a)[R_4NA]^2(o)} = \frac{D_{ex}}{[NO_3^-]^3(a)[R_4NA]^2(o)}, \quad (2)$$

where D_{ex} is the LnIII) distribution coefficient.

The correlation between the concentration (K_{ex}^2) and thermodynamic ($K_{ex}^{0.2}$) extraction constants is described by

$$K_{ex}^{0.2} = K_{ex}^2 \frac{Y[(R_4N)_2Ln(NO_3)_3A_2](o)}{Y_\pm^4 Y^2(R_4NA)(o)}, \quad (3)$$

where Y_j(o) are the molar activity coefficients of the extractable complex and free TABANP in the organic phase, and $Y_\pm$ is the mean ionic molar activity coefficient of Ln(III) nitrates in the aqueous phase.

Assuming that

$$\frac{Y[(R_4N)_2Ln(NO_3)_3A_2](o)}{Y^2(R_4NA)(o)} = \text{const} = 1,$$

Eq. (3) can be transformed to the form

$$K_{ex}^{0.2} = K_{ex}^2/Y_\pm^4. \quad (4)$$

Analysis of published data on the mean ionic molar activity coefficients of Ln(III) nitrates [6–9] showed that their dependence on the Ln(III) molar concentration is fairly well described by Eq. (5) given in [10]:

$$\ln Y_\pm = C^{1/3}(a) + BC(o), \quad (5)$$

where C(a) is the molar concentration of Ln(III) nitrate in the aqueous solution, and A and B are empirical parameters. The dependence described by Eq. (5) is divided in two separate portions, corresponding to the 0.5–0.6 M and 0.6–3.0 M concentration ranges. The parameters A and B were reported in [5, 11].

The mathematical treatment of the extraction isotherms was performed assuming that two extractable complexes (i = 2 and 3) are formed in the organic phase. The following set of material balance equations was used:

$$C_S = [R_4NA](o) + 2K_{ex}^{0.2}[Ln^{3+}](a)[NO_3^-]^3(a)[R_4NA]^2(o)Y_\pm^4, \quad (6)$$

$$[Ln^{3+}](o) = K_{ex}^{0.2}[Ln^{3+}](a)[NO_3^-]^3(a)[R_4NA]^2(o)Y_\pm^4, \quad (7)$$

where C_S is the total TABANP concentration in the organic phase, $[Ln^{3+}](o)$ and $[Ln^{3+}](a)$ are the Ln(III) equilibrium concentrations in the organic and aqueous phases, respectively, and $[R_4NA](o)$ is the concentration of free TABANP in the organic phase. Equations (6) and (7) were solved for $K_{ex}^{0.2}$ by the nonlinear least-squares technique [12].

Some results of the mathematical treatment of the extraction isotherms performed assuming formation of only one extractable complex, $(R_4N)_2[Ln(NO_3)_3]A_2$, are listed in Table 1. These data show that the calculated values of $\log K_{ex}^{0.2}$ are virtually independent of the composition of the aqueous and organic phases. The calculated Ln(III) concentrations in the organic

phase agree with the experiment to within 1–4 rel. %. Thus, our model adequately describes the extraction isotherms of Ln(III) nitrates with TABANP in toluene.

The average values of the extraction constants with rms deviations are given in Table 2. These results show that $\log K_{ex}^{0.2}$ decreases from lanthanum(III) to lutetium(III), and Y is the least extractable. Thus, trialkylbenzylammonium naphthenates can be used for separating cerium-group lanthanides(III) from other lanthanides(III) and yttrium(III) from lanthanides(III).

Figure 2 shows the IR spectra of $(R_4N)(RCOO)$ and $(R_4N)[M(NO_3)_3(RCOO)_2]$, where M = Er(III),

Pr(III), and Y(III). The bands of antisymmetric (ν^{as}) and symmetric (ν^{s}) stretching vibrations of carboxy groups are the most sensitive to complexation with metal ions [13, 14]. For free TABANP, these bands are observed at approximately 1480 and 1400 cm^{-1}, respectively. The difference between the frequencies of the symmetric and antisymmetric stretching vibrations $\Delta = \nu^{as} - \nu^{s}$ is ~80 cm^{-1}, which indicates that in TABANP the quaternary ammonium cations are bound to naphthenate anions by predominantly electrostatic forces. Formation of the extractable complex $(R_4N)\cdot[Er(NO_3)_3(RCOO)_2]$ results in a high-frequency shift of the antisymmetric absorption band (ν^{as} ~1600 cm^{-1}), and a low-frequency shift of the symmetric absorption band (ν^{s} ~ 1370 cm^{-}) (Fig. 2). As a result, the difference $\Delta = \nu^{as} - \nu^{s}$ increases to approximately 230 cm^{-1}. This means that Ln(III) cations are bound to carboxy groups [13, 14] by coordination bonds.

The spectra of the complexes $(R_4N)[Ln(NO_3)_3\cdot(RCOO)_2]$ also contain the absorption bands of the nitrate anions (ν^{as} ~1320, ν^{s} ~1500, ν_2^{s} ~1040 cm^{-1}, ν_5^{as}/ν_3^{s} ~835, and ν_6 ~730–750 cm^{-1}). The difference $\Delta = \nu_1^{s} - \nu_4^{as}$ is about 200 cm^{-1}, which shows that nitrate anions are coordinated with Ln(III) cations [13, 14]. These IR data confirm our above conclusion about formation of mixed-ligand $(R_4N)[Ln(NO_3)_3\cdot(RCOO)_2]$ complexes in the organic phase.

CONCLUSIONS

(1) Extraction of lanthanide and yttrium nitrates from aqueous solutions with trialkylbenzylammonium naphthenate in toluene was studied within a wide concentration range of these metals at 298.15 K. The extraction isotherms show saturation with respect to Ln(III) at $C_S : [Ln^{3+}](o) \rightarrow 2 : 1$.

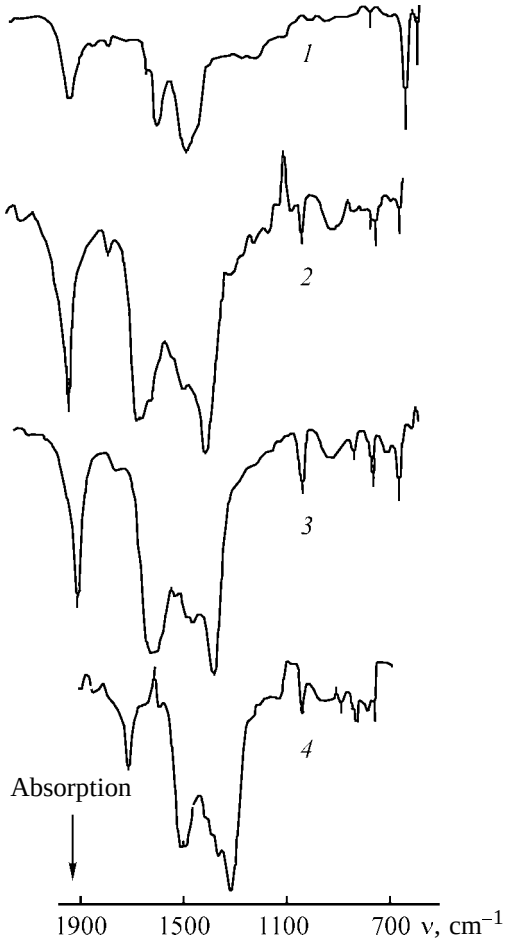

Fig. 2. IR spectra of compounds: (*1*) TABANP, (*2*) $(R_4N)\cdot[Er(NO_3)_3(RCOO)_2]$, (*3*) $(R_4N)[Pr(NO_3)_3(RCOO)_2]$, and (*4*) $(R_4N)[Y(NO_3)_3(RCOO)_2]$. (ν) Wave number.

(2) The complexes $(R_4N)[Ln(NO_3)_3(RCOO)_2]$ are formed in the organic phase. The extraction constants of Ln(III) were calculated. IR spectrosopic studies showed that carboxy and nitrate anions are mainly coordinated with Ln(III) cations.

(3) Extraction of lanthanides (III) with trialkylbenzylammonium naphthenates in toluene decreases in going from lanthanum(III) to lutetium(III). The extractability of yttrium(III) is considerably lower than that of lanthanides (III). Trialkylbenzylammonium naphthenates can be used for separating cerium-group lanthanides(III) from other lanthanides(III) and yttrium(III) from lanthanides(III).

SORPTION AND ION-EXCHANGE PROCESSES

Composite Ion Exchangers Based on KU-23 and KM-2P Cation Exchangers and Nickel(III) Hydroxide and Their Use for Purification of Nickel Sulfate Solutions To Remove Cobalt(II) Impurity

A. A. Blokhin, D. Yu. Maiorov, A. A. Kopyrin, and V. P. Taushkanov

Received May 23, 2002

Abstract—A method of preparing composite ion exchangers based on macroporous cation exchangers and nickel(III) hydroxide was developed, and their suitability for deep purification of nickel(II) sulfate solutions to remove small amounts of cobalt(II) was demonstrated.

Cobalt(II) is the most difficultly removable impurity in nickel(II) salts. On the other hand, the cobalt content in nickel(II) compounds is rigidly limited. The most efficient method of cobalt(II) separation from nickel(II) salts is based on different stability of Co(III) and Ni(III) hydroxides (HO) and involves treatment of nickel(II) salts with freshly deposited $Ni(OH)_3$ [1–4]. Cobalt(II) is oxidized and precipitated as Co(III) HO, while nickel(III) is reduced to Ni(II) and passes into the solution. This method is fairly labor-consuming and does not always provide the required degree of cobalt recovery. As follows from [5], more efficient purification of Ni(II) to remove Co(II) can be attained by passing a solution of Ni(II) salt through a column packed with a granulated ion exchanger containing Ni(III) HO, e.g., with a macroporous cation exchanger with Ni(III) HO introduced into its granules.

The goal of this work is to develop a method of preparing composite ion exchangers based on KU-23 sulfonic cation exchanger or KM-2p carboxylic cation exchanger and nickel(III) HO and assess the suitability of the ion exchangers obtained for purification of Ni(II) salts to remove Co(II).

EXPERIMENTAL

Nickel(III) and cobalt(III) hydroxides were prepared by successive treatment of 0.2 M metal(II) sulfate solutions with 0.5 M solutions of NaOH and $Na_2S_2O_8$. The precipitates formed were kept to mature for 24 h, separated from the mother liquor, washed with water, dried in air at 70°C, crushed, and sieved. Experiments were performed with 0.2–0.5-mm grains of Ni(III) HO.

Preliminarily, the cation exchangers were conditioned by the standard method: successive treatment with NaOH and HCl solutions including intermediate and final washing with water [6]. Experiments were performed under static and dynamic conditions. The ratio of the ion exchanger weight (g) to the solution volume (ml) in the experiments under static conditions was 1 : 100, and time of phase contact, 5–7 days. In experiments under dynamic conditions, we used the preliminarily fractionated composite ion exchangers with 0.5–1.0-mm grains in the air-dry state. Ion exchangers were placed into 10-ml glass columns (the bed height to inner diameter ratio $H : D$ was 15 : 1). The rate of the solution flow through the column was close to 1 specific volume (sp. vol.) per hour. The sorption kinetics was studied by the limited volume method [6, 7]. The effective diffusion coefficients of Co(II) ions were calculated by Dryden–Kay equation [7], and the activation energies were found from the temperature dependence of the diffusion coefficients. The Ni(II) concentration in the solutions was determined complexometrically and (at low concentrations) photocolorimetrically [8]. pH of solutions was measured with glass (ESL-47-07) and AgCl (EVP-AM-3) electrodes and an I-120 ion meter. The nickel(II) content in samples of composite ion exchangers was determined by dissolution of the mineral constituent in 1 M H_2SO_4 with the subsequent determination of Ni(II) in the solution. The Co(II) behavior was

1070-4272/03/7601-0060$25.00

monitored using ^{60}Co tracer. The specific β-radioactivity (counts per unit time) of samples was measured on a KRK-1-01A device with a BDIB-01-1 counter equipped with a PSO2-4 scaler.

To determine the Ni(III) and Co(III) HO redox potentials, the voltage of the cell

$$\begin{array}{c|c|c} \text{Ni, } \underset{[Co(OH)_3]}{Ni(OH)_3} & 1\ \text{M}\ NiSO_4 & \text{Ag,} \\ & & \text{AgCl, } KCl_{sat} \end{array}$$

was measured with an ShCh-1413 digital voltmeter. Preliminarily, electrodes were prepared by pressing one of the compounds studied [composite ion exchanger, Ni(III) or Co(III) HO] ground to the powdered state onto an etched nickel plate with the developed surface. This plate was placed into a fluoroplastic casing equipped with a lead connected to the plate. The mounted electrode was placed in a small bath filled with a 1 M $NiSO_4$ solution. An AgCl electrode was used as a reference electrode.

The first stage of preparing composite ion exchangers based on cation exchangers and Ni(III) HO involved saturation of cation exchangers with Ni(II) ions. The maximal capacity of both cation exchangers with respect to Ni(II) ion was attained at pH close to the onset of the $Ni(OH)_2$ precipitation (pH 6.2–6.3). Therefore, saturation of cation exchangers with Ni(II) ions was performed at pH 6.0–6.2. To find the optimal Ni(II) concentration for saturation of cation exchangers, we measured the isotherms of Ni(II) sorption. It follows from Fig. 1 that the sorption isotherms flatten out at the Ni(II) equilibrium concentration of 0.03–0.04 M.

However, to reduce the volume of the solution passed through the column, a 0.1 M Ni(II) solution was taken. In this case, the total dynamic capacity of the cation exchanger with respect to Ni(II) was 2.2 mmol g^{-1} for KU-23 and 2.8 mmol g^{-1} for KM-2p, which practically coincided with the maximal capacity observed in the sorption isotherms at equilibrium (Fig. 1). After saturation with Ni(II) ions, the cation exchangers were washed with 2–3 sp. vols. of distilled water and were then treated with 5 sp. vols. of 0.5 M NaOH to convert the sorbed Ni(II) into the HO form. Then, the cation exchangers were treated with an $Na_2S_2O_8$ solution to convert $Ni(OH)_2$ into Ni(III) HO. In the process, the cation exchanger color changed from green to black. Observation of microscopic sections of the cation exchanger granules (magnification 100) showed that oxidation of Ni(II) HO to Ni(III) HO was uniform throughout the section. It was noted that the $Na_2S_2O_8$ solution washed out a part of nickel from the column packed with the cation

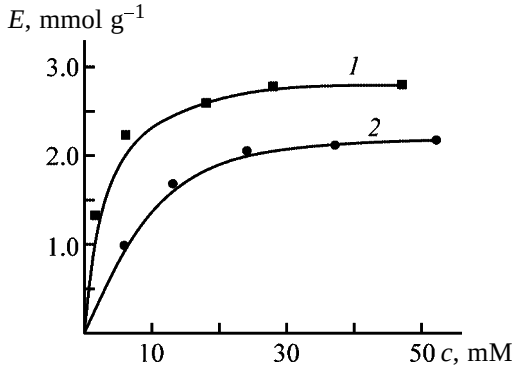

Fig. 1. Isotherms of nickel(II) sorption from solution with pH 6.1 ± 0.05 on cation exchangers (*1*) KM-2p and (*2*) KU-23. (*E*) Capacity of ion exchanger with respect to nickel(II) ion and (*c*) concentration of Ni(II) in the equilibrium solution.

exchanger, especially from the column with KU-23. At the optimal concentration of $Na_2S_2O_8$ (~0.2 M), the washout did not exceed 4–10% (depending on the support), and the cation exchanger grains rapidly turned black. Finally, the ion exchangers were washed to remove excess oxidant. The nickel content was 2.7 and 1.9 mmol g^{-1} in the obtained samples of the composite ion exchangers based on KM-2p and KU-23 cation exchangers, respectively.

The chemical stability of the combined ion exchangers was evaluated by washout of Ni(II) ions with 2 M $NaNO_3$ solutions of various acidities. It was found that the mineral constituent of the composite cation exchangers did not dissolve in solutions with pH 6–8. However, even small acidification caused noticeable dissolution. In solutions with pH 5, 2–3% of the total amount of nickel contained in the composite ion exchangers and in granulated Ni(III) HO dissolved. In solutions with pH < 1, dissolution of the mineral constituent was virtually complete.

Sorption of cobalt(II) ions on Ni(III) HO should proceed due to its oxidation and formation of poorly soluble Co(III) HO in the cation exchanger phase by the reaction

$$Ni(OH)_3 + Co^{2+} \rightleftarrows Co(OH)_3 + Ni^{2+}.$$

In general, the properties of Ni(III) HO in cation exchanger granules may differ from those of Ni(III) HO in the pure form. To predict the use of composite ion exchangers for removing Co(II) from solutions of Ni(II) salts, we compared the redox potentials of both forms of Ni(III) HO and of Co(III) HO. As seen from Table 1, the $Ni((OH)_3/Ni(OH)_2$ redox potential for Ni(III) HO in the composite ion exchanger based on KM-2p resin and pure Ni(III) HO are virtually the

Table 1. Redox potentials of materials containing Ni(III) and Co(III) HO

** ($\varphi_{M(OH)_i/H^+,H_2}$) Potential vs. hydrogen electrode.

same and close to the reference data [9]. At the same time, they are noticeably higher than the potential of $Co((OH)_3/Co(OH)_2$ couple. Therefore, at the contact of an ion exchanger containing Ni(III) HO with a solution containing Co(II), Co(II) should undergo oxidation and precipitate in the form of Co(III) HO.

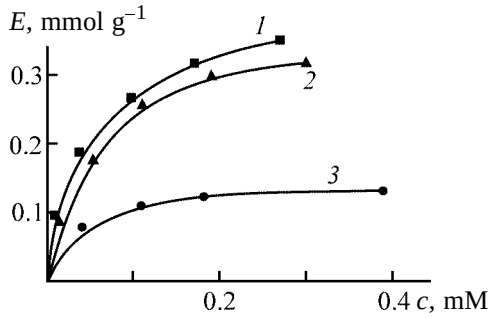

Fig. 2. Isotherms of cobalt(II) sorption from 1 M $NiSO_4$ solution at pH 6.1 ± 0.05 on ion exchangers (*1*) KM-2p–Ni(III) HO, (*2*) Ni(III) HO, and (*3*) KU-23–Ni(III) HO.

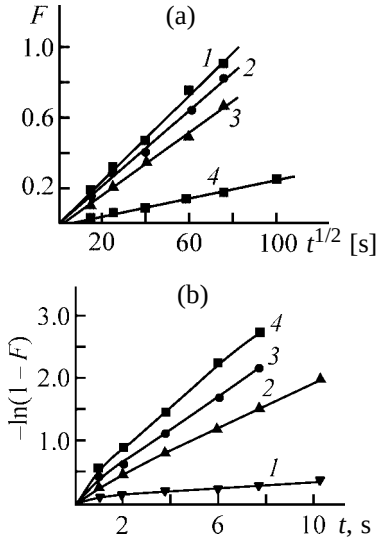

Fig. 3. Plots (a) F–$t^{1/2}$ and (b) $-\ln(1-F)$–t for Co(II) sorption from 1 M $NiSO_4$ on KM-2p–Ni(III) HO ion exchanger. Initial concentration of Co(II) 1 mM, pH 6.10 ± 0.05. Temperature, K: (*1*) 293, (*2*) 308, (*3*) 324, and (*4*) 338.

To find optimal conditions of sorption of Co(II) ions from 1 M solution of $NiSO_4$, we studied the influence of the solution acidity and measured the sorption isotherms. The capacity of the ion exchangers with respect to Co(III) increases with increasing pH and reaches a maximum at pH 6.0–6.3 [at higher pH, Ni(II) HO starts to precipitate]. Within the entire range of Co(II) concentrations in the solution, the capacity of the composite ion exchanger based on KM-2p resin with respect to cobalt(II) is practically equal to the capacity of pure Ni(III) HO (Fig. 2). The capacity of the composite ion exchanger based on KU-23 resin is substantially lower, which is caused by the lower content of Ni(III) HO in it.

The study of the kinetics of Co(II) sorption from 1 M $NiSO_4$ on the composite ion exchanger based on KM-2p resin and on pure Ni(III) HO showed that the rate of Co(II) sorption on both ion exchangers depends on the ion exchanger grain size and is virtually independent of the intensity of solution agitation. This shows that the internal diffusion is the rate-determining stage of the sorption. This is confirmed by the noticeable increase in the sorption rate after interrupting the process for 30 min, the linear dependence of the degree of equilibrium attainment F on $t^{1/2}$ (time), deviation from the straight line of the $-\ln(1-F)$ vs. t plot in the region of low F values (Fig. 3), and the value of Biot B' test (Table 2). It follows from Table 2 that the composite ion exchanger KM-2p–Ni(III) HO has better kinetic characteristics than pure Ni(III) HO. The effective diffusion coefficient D of Co(II) in sorption on the composite ion exchanger is approximately three orders of magnitude higher than that on pure Ni(III) HO. The activation energy E_a (59–62 kJ mol^{-1}) is close to the limiting value of E_a characteristic for processes controlled by internal diffusion [7]. Presumably, the rate of the chemical reaction also affects the process kinetics.

Removal of the Co(II) impurity from Ni(II) salt solutions under dynamic conditions was studied as

* ($t_{0.5}$) Half-time of exchange (sorption).

applied to purification of 1 M $NiSO_4$ solution to remove cobalt (1 mM) at pH 6.0. When the solution was passed through a column with pure granulated Ni(III) HO, the flow rate rapidly decreased and, after passing 10 sp. vols., did not exceed 0.1% of the initial value at fully opened clips at the input and output of the column and excess hydraulic pressure of about 0.1 MPa. This is caused by mechanical breakdown of the ion exchanger, which makes it useless in columns, although that, presumably, under other conditions a stronger ion exchanger can be obtained, as demonstrated in [5]. With composite ion exchangers, there are no such problems. When KM-2p cation exchanger containing Ni(III) HO was used, the Co(II) content in the solution of Ni(II) sulfate was decreased by a factor of more than 100 (to the background level) after passing 80 sp. vols. of the solution (Fig. 4a). The composite ion exchanger based on KU-23 resin gives somewhat worse results.

Since the mineral constituent of the composite ion exchangers readily dissolves in acids, the regeneration was performed as follows. After saturation with Co(II), the ion exchanger was washed with water to remove the initial solution, and then 1 M H_2SO_4 was passed through the column. Virtually complete Co(II) desorption is attained after passing 10 sp. vols. of the acid (Fig. 4b). The average concentration of the macrocomponent, Ni(II) in the desorbate, was 0.1–0.12 M. After desorption, the cation exchanger was washed with water, and then it was again saturated with Ni ions and treated with solutions of alkali and oxidant as described above. After three cycles of preparation–sorption–regeneration, the total dynamic capacity of the composite ion exchanger based on KM-2p resin with respect to cobalt(II) did not change noticeably as compared to the first cycle.

CONCLUSIONS

(1) A method was proposed for preparing composite ion exchangers based on macroporous cation exchangers and Ni(III) hydroxide by ion-exchange saturation of cation exchangers with Ni(II) ions and successive treatment with alkali and oxidant with intermediate and final washing with water.

(2) The composite ion exchanger based on KM-2p carboxylic cation exchanger is not inferior to pure granulated nickel(III) hydroxide in selectivity to cobalt ions and noticeably exceeds it in kinetic characteristics.

(3) The suitability of the composite ion exchanger based on KM-2p cation exchanger and Ni(III) hydroxide for exhaustive purification of nickel sulfate solutions to remove cobalt(II) impurities was confirmed. The composite ion exchanger based on KU-23 cation exchanger is less efficient.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Chromium–Cobalt Alloy Coatings from Sulfate Electrolytes

B. A. Spiridonov

Voronezh State Technical University, Voronezh, Russia

Received March 11, 2002

Abstract—The influence of electrolysis conditions on the kinetics of formation of the chromium–cobalt alloy in acid sulfate electrolytes containing monoethanolamine was studied along with the composition, current efficiency, and physicochemical characteristics of the coatings.

Electrodeposition of chromium and chromium alloys from nontoxic solutions containing chromium(III) compounds remains an urgent problem. Because of strong tendency of chromium(III) ions to complexation, chromium plating sulfate electrolytes are unstable, which is one of their major drawbacks. The composition of chromium(III) complexes depends on many factors including chromium sulfate concentration, pH, temperature, nature of ligands, etc. [1]. Two chromium(III) sulfate modifications, violet and green, exist, depending on the composition of complexes. Violet chromium(III) sulfate in aqueous solutions forms hexaaqua cations $[Cr(H_2O)_6]^{3+}$ [2], which are slowly hydrolyzed at 20–25°C [3]. At higher temperatures (40–45°C), the hydrolysis is markedly accelerated, and green chromium(III) sulfate (GCS) is formed. The conversion of violet chromium(III) sulfate to GCS is accompanied by a shift of the peaks in their absorption spectra to longer wavelengths [4]. In moderately dilute and concentrated solutions, GCS forms polynuclear anionic complexes consisting of several coordination spheres. In these complexes, Cr^{3+} ions are bound by hydroxo or oxo bridges and by SO_4^{2-} ions [1, 3]. The modification of chromium(III) sulfate solutions essentially affects chromium plating [5–7]. Chromium virtually is not deposited from violet solutions and is deposited with a very low current efficiency (CE_{Cr} = 5–7%) from GCS solutions. The higher current efficiency (up to 35–40%) was attained in chromium plating from "modified" solutions obtained by aging of GCS (keeping at 20–25°C for 20–25 days) [7]. The modified GCS is more stable; it retains its composition for a long time (6 months), as indicated by spectral measurements. The absorption peaks for the modified GCS (λ_1 = 415–416, λ_2 = 582–583 nm; $\varepsilon_1 \approx \varepsilon_2$ = 37) occupy an intermediate position between the peaks for the violet solution and GCS [4].

The addition into the solutions of modified GCS of monoethanolamine (MEA) or urotropin [7] allows deposition of mirror-lustrous protective and decorative chromium coatings 10–15 μm thick. The sulfate electrolytes containing urea [8], glycine [5], formic acid [9], or other complexing additives are more stable. However, chromium coatings deposited from them are also thin. The use of pulsed current makes it possible to increase the thickness of chromium coatings to 40 μm [10]. Recently, new electrolytes containing oxalic acid have been developed, allowing the thickness of chromium coatings to be increased to 100 μm [11, 12].

The thickness of coatings can be increased by increasing electrolysis time τ_{el} at a given current density. At the same time, pH_s and T_s in the near-cathode region vary with increasing τ_{el}. This results in formation of basic chromium compounds and initiates complex transformations in solutions of modified GCS. It was found by thermography [13] that, at the cathodic current density D_c = 30 A dm^{-2}, the temperature T_s of chromium plating electrolyte based on modified GCS increases to 35°C after 10 min and to 45°C after 20 min of electrolysis. As a result, modified GCS in the near-cathode layer is converted into GCS, and the current efficiency by chromium decreases drastically. Therefore, it is appropriate to examine the influence exerted by electrolysis conditions (D_c, pH, etc.) on the current efficiency by chromium and chromium alloys and on their composition and physicochemical properties at τ_{el} not exceeding 10–15 min. At the same time, it should be noted that study of the electrodeposition kinetics of chromium

1070-4272/03/7601-0065$25.00

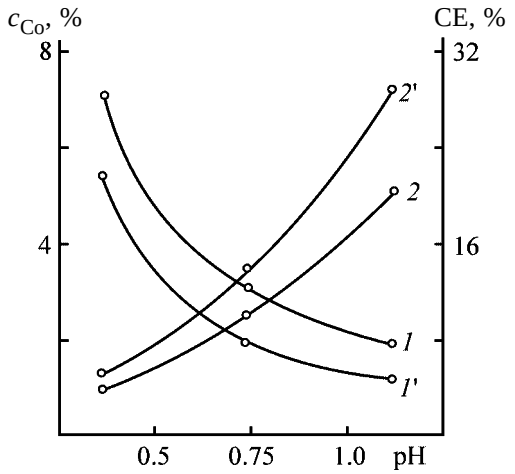

Fig. 1. Influence of electrolyte pH on (*1*, *1*') cobalt content c_{Co} in the chromium–cobalt alloy and (*2*, *2*') current efficiency by the alloy CE. τ_{el} = 5 min, T = 25°C. D_c, A dm^{-2}: (*1*, *2*) 25 and (*1*', *2*') 35.

and chromium alloys at a longer electrolysis time is also of certain interest.

It was established previously [14] that protective properties of chromium coatings deposited from MEA-containing solutions of modified GCS can be improved by electrochemical modification with cobalt. The introduction of $CoSO_4$ into the Cr–Co plating electrolyte based on modified GCS makes it possible to extend the range of D_c values at which lustrous coatings are deposited and increases the throwing power of the electrolyte [15]. The use of pulsed current has been recommended in [16, 17] to stabilize the composition of the plated Cr–Co alloy. In this work, we continued a study of the electrodeposition of Cr–Co alloy from MEA-containing solution of modified GCS along with a study of some physicomechanical properties of the alloy.

EXPERIMENTAL

The study was performed in an electrolyte containing (M) 0.5 modified GCS, 0.5 Na_2SO_4, and 0.032 MEA. To the electrolyte, from 1 to 5 g l^{-1} $CoSO_4$ was added. The current efficiency by the alloy CE_{al} was determined gravimetrically using a copper coulometer and with account taken of the alloy composition. The content of cobalt in the alloy was determined spectrophotometrically with nitroso-R salt, and the chromium content, by oxidation to chromium(VI). The cathodic polarization was studied galvanodynamically (6 mA min) on a P-5827 M potentiostat using a KSP self-recording potentiometer. All potentials are given relative to silver chloride electrode which served as a reference. Platinum was used as auxiliary electrode. The character of the total and partial polarization curves was shown in [17]. Here we report the partial current densities of formation of hydrogen, chromium(II) ions, and metallic cobalt and chromium. The partial currents were determined by decomposition of the total current on the basis of data on the current efficiencies by hydrogen, cobalt, and chromium. The current spent for chromium(II) ion formation by the reaction $Cr^{3+} + e \rightarrow Cr^{2+}$ was determined from the difference between the total current and partial currents of formation of hydrogen, cobalt, and chromium. The polarization curves were taken galvanostatically in a hermetically sealed two-chamber cell for 15 min. The amount of evolved hydrogen was determined volumetrically. The quality of the cathodic deposits was judged from the outward appearance. The reflectivity of the coatings was studied on an FM-58 M photometer, and their morphology, on an MIN-7 microscope. The hardness of the cathodic deposits H_V was determined on a PMT-3 device. The indicator load was 100 g. The internal stresses (ISs) were determined by the method of flexible cathode [18, 19].

The composition of the Cr–Co alloy and the current efficiency by the alloy CE_{al} as functions of the electrolyte pH and D_c are shown in Fig. 1. As seen, with the pH increasing from 0.5 to 1.0, the cobalt content in the alloy decreases from 4 to 2.2% at D_c = 25 A dm^{-2} (curve *1*), and CE_{al} increases from 5.8 to 16.2% (curve *2*). This trend keeps for D_c within 15–30 A dm^{-2}, i.e., in the range corresponding to deposition of lustrous coatings. At D_c = 35 A dm^{-2} the maximal current efficiency by the alloy is attained, 40%.

At pH varied within the indicated range (Table 1), the partial current spent for alloy deposition (at D_c = 20 A dm^{-2}) increases by a factor of about 8.2, that of chromium deposition, by a factor of 7.8, and that of hydrogen formation decreases by a factor of 1.7. The partial rate of cobalt deposition decreases simultaneously. These data explain why the current efficiency by the alloy increases and the alloy becomes enriched with chromium. Apparently, a decrease in the rate of the discharge of Cr^{2+} ions is due to the formation of a cathodic film from basic chromium(III) compounds (the solubility product $SP_{Cr(OH)_3} = 6.31 \times 10^{-31} < SP_{Cr(OH)_2} = 2 \times 10^{-15}$), which exerts a stronger effect at higher pH.

It should be noted that the formation of colloidal $Cr(OH)_3$, which forms a passivation film owing to the

absorption on active sites of the cathode, is fairly efficiently suppressed in the electrolyte containing MEA as a luster-producing and buffer additive [7]. Without MEA, the coatings are deposited in a very narrow D_c range and are dull. In the presence of MEA, the alloy coatings deposited in the indicated pH range are mirror-lustrous. Increasing pH to 1.0 makes narrower the D_c range, and at D_c = 35 A dm^{-2} dull coatings are deposited. At pH > 1.0 and D_c > 35 A dm^{-2}, the quality of the coatings is appreciably impaired, which is evidently due to incorporation of basic chromium(III) compounds. The coatings become coarsely disperse and brittle, with a developed crack pattern.

The development of crack pattern in the cathodic deposits under certain electrolysis conditions is typical not only for chromium alloys but also, and to a greater extent, for chromium coatings deposited from commercial electrolytes [20] (based on CrO_3) and from sulfate electrolytes. One of the reasons why the crack pattern is formed is the appearance of internal stresses owing to incorporation of hydrogen. The forming chromium hydrides are instable and can crystallize in the form of hexagonal crystals Cr_2H–CrH or face-centered cubic crystals CrH–CrH_2 [21]. Spontaneous transformation of the metastable hexagonal modification of chromium into the stable body-centered cubic modification is accompanied by a decrease in the deposit volume and by appearance of large internal stresses. As the cobalt content in the alloy increases, for example, from 1 to 5% (Fig. 2, curve *1*), ISs decrease by a factor of approximately 1.3, which is evidently due to decreased hydrogenation [17].

The cathodic current density markedly affects ISs. For example, with D_c increasing from 30 to 60 A dm^{-2}, ISs increase by a factor of approximately 1.5 (at the cobalt content in the alloy of 5%). This may be due to incorporation of basic chromium compounds and to increased hydrogen absorption. The dependence of ISs on D_c for chromium coatings deposited from sulfate electrolytes is similar [22].

As seen from Fig. 3, increasing the cobalt content in the alloy increases the hardness of the cathodic deposits. The H_V for the 1% cobalt alloy obtained at

D_c = 40 A dm^{-2} (curve *1*) is 490 kg mm^{-2}, and for the 9% cobalt alloy obtained under similar conditions it increases to 620 kg mm^{-2}. The increase in H_V may be due to the formation of a solid solution in the alloy containing up to 10% cobalt [17]. As known [23], the hardness H_V of solid solutions is always higher than that of the components. The hardness is strongly affected by the cathodic current density. For example, with D_c increased from 40 to 60 A dm^{-2}, the hardness of the Cr–Co alloy containing 5% Co increases from 580 (Fig. 3, curve *1*) to 960 kg mm^{-2} (curve *3*). The similar effect of D_c on the hardness of cobalt coatings has been demonstrated in [24–26]. Electrolytic chromium is characterized by high hardness, which is ascribed to incorporation of hydrogen and oxygen, internal stresses, and grain size [20]. The dependence of H_V of chromium on its hydrogen content was not confirmed by the available experimental data. On heating, hydrogen is comparatively easily evolved from electrolytic chromium, and at 500°C virtually no hydrogen remains, with the hardness remaining the same. The direct correlation of H_V with CE has not been revealed either. The major factors determining H_V of electrolytic chromium are the presence of oxygen in it and the grain size. The effect exerted by oxygen on the chromium hardness is due to the distribution of dispersed chromium oxide in its bulk. The dependence of H_V of the chromium–cobalt alloy on the electrolyte pH is presented in Fig. 4. With pH increasing, e.g., from 0.5 to 0.75 (D_c = 60 A dm^{-2}), H_V increases from 720 (curve 1) to 925 kg mm^{-2} (curve *2*), which can be explained by incorporation of basic chromium(III) compounds into the cathodic deposit, increasing the oxygen content.

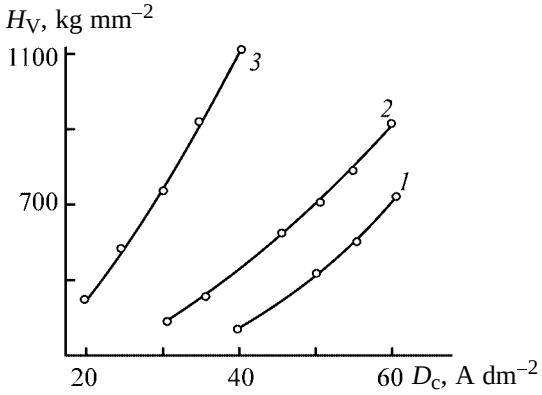

Fig. 4. Influence of the cathodic current density D_c on the microhardness H_V of the Cr–Co alloy. Electrolyte pH: (*1*) 0.5, (*2*) 0.75, and (*3*) 1.0.

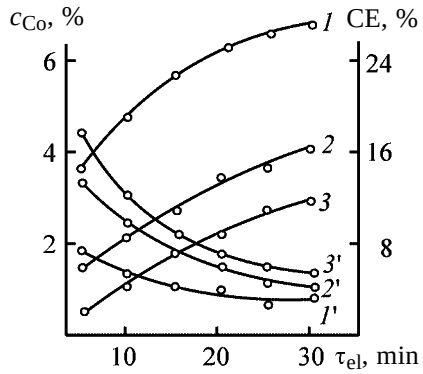

Fig. 5. Influence of the electrolysis time τ_{el} on (*1–3*) cobalt content in the alloy c_{Co} and (*1'–3'*) current efficiency by the alloy CE. D_c A dm^{-2}: (*1, 1'*) 30, (*2, 2'*) 40, and (*3, 3'*) 60.

Table 2 shows that, as τ_{el} increases from 5 to 20 min, the partial current of hydrogen evolution increases and that of Cr–Co alloy formation decreases. As a result, CE_{al} decreases, e.g., from 14 to 6.5% at D_c = 40 A dm^{-2} (Fig. 5, curve *2'*). It should be noted that the partial current of hydrogen evolution decreases at D_c = 20–40 A dm^{-2}, with the decrease being more pronounced at longer τ_{el}, and the alloy is enriched with cobalt. For example, the alloy deposited at D_c = 40 A dm^{-2} contains 1.5% cobalt after τ_{el} = 5 min and 3.5% cobalt after 20 min of electrolysis (Fig. 5, curve *2*). With the electrolysis time increased to 30 min, the cobalt content increases by about 4%. One of the reasons why the alloy becomes chromium-depleted at longer τ_{el} is the pH_s growth favoring formation of chromium(III) hydroxide impeding chromium deposition. Another reason is the increase in T_s after 20 min of electrolysis, which is accompanied by GCS formation and by even sharper decrease in the chromium current efficiency. Evidently, this tendency is retained when chromium is deposited jointly with cobalt.

It should be noted that, with increasing τ_{el}, the chromium(II) ion formation accelerates (Table 2). For example, at D_c = 40 A dm^{-2} the partial current of chromium(II) formation increases from 15.42 to 16.62 A dm^{-2}. Accumulation of Cr^{2+} ions should increase the rate of the formation of metallic chromium, in accordance with the reaction $Cr^{2+} + 2e \rightarrow Cr^0$. At the same time, Table 2 shows that actually the rate of chromium formation decreases by a factor of 2.2 with increasing τ_{el} (Table 2). This suggests occurrence of the more probable three-electron reaction $Cr^{3+} + 3e \rightarrow Cr^0$. Such a scheme of electrolytic reduction of chromium from sulfate electrolytes has been considered previously [27, 28].

With increasing τ_{el}, the ISs in the cathodic deposits grow, which is due to increase in pH_s and hydrogen absorption of the coatings promoted by incorporation of chromium(III) hydroxide. As a result, the quality of the coatings is impaired. Lustrous coatings are deposited at τ_{el} shorter than 30–35 min; semilustrous coatings, at longer electrolysis times; and dull coatings, at τ_{el} > 60 min.

CONCLUSIONS

(1) The method of partial curves showed that, as pH of the electrolyte is increased from 0.5 to 1.0, the partial current of hydrogen and cobalt formation decreases and that of chromium formation grows. Under these conditions, the alloy is enriched with chromium, and the current efficiency by the alloy increases.

(2) With increasing t_{el}, the partial currents of chromium and cobalt formation decrease and that of hydrogen formation grows, the relative content of cobalt in the alloy increases, and the current efficiency by the alloy decreases substantially, especially after 30 min of electrolysis. The fact that the partial current of chromium(III) ion formation increases with electrolysis time and the current efficiency by the alloy does not grow suggests occurrence of the three-electron reaction of the formation of metallic chromium at its joint deposition with cobalt.

(3) The internal stresses decrease with increasing cobalt content in the alloy and grow with increasing cathodic current density. The cathodic current density markedly affects the alloy hardness. For example, with D_c increased from 20 to 40 A dm^{-2}, the hardness grows from 480 to 1100 kg mm^{-2}.

(4) To obtain protective and decorative Cr–Co alloy coatings up to 20 μm thick, we recommend an electrolyte containing modified green chromium(III) sulfate and monoethanolamine.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Composition of the Cobalt Sulfide Coating after Its Electrochemical Reduction

G. Valiuliene, A. Žeriene, V. Jasulaitiene, and I. Možginskiene

Institute of Chemistry, Vilnius, Lithuania

Received July 19, 2002

Abstract—X-ray photoelectrom spectroscopy was used to study the composition of the initial and electrochemically reduced cobalt coating formed by the adsorption procedure involving treatment of a carbon glass electrode in a solution of Co(II) ammine complexes, hydrolytic washing in water, and conversion to sulfide in Na_2S solution.

Sulfides of many metals have low electrical resistivity [1] and can be used as electroconducting sublayers for decorative metal plating of plastics and in manufacture of printed-circuit boards. Nonstoichiometric copper sulfide ($Cu_{2-x}S$), whose formation, composition, and electrochemical properties are studied in detail [2–8], is widely used for this purpose. Electrochemical deposition of metals can occur only after reduction of $Cu_{2-x}S$ to metal [7, 8]. To obtain a reliable metal coating, it is, however, necessary to perform plating in two or three cycles.

Cobalt sulfide coatings [9] formed in one cycle are also used today as electroconducting layers. Nickel can be deposited on it in two or three cycles, as on $Cu_{2-x}S$. Formation, electrochemical activity, and modification of the cobalt sulfide layer have been described in [9–12]. At the same time, the composition of such coatings after reduction was not studied.

In this work, we used X-ray photoelectron spectroscopy (XPS) to determine the composition of the cobalt sulfide coatings before and after electrochemical reduction.

EXPERIMENTAL

The cobalt sulfide coating was formed by the adsorption procedure involving treatment of the working electrode in a solution containing 0.18 M $CoSO_4 \cdot 7H_2O$ and 0.12 M $(NH_2OH)_2 \cdot H_2SO_4$, to which NH_4OH (25% solution) was added to pH 11.0. This was followed by hydrolytic washing with distilled water, conversion to sulfide in 0.13 M Na_2S aqueous solution, and washing with distilled water. This comprised one cycle of formation of the cobalt sulfide coating. The coatings studied by XPS were formed in three cycles, each 30 s, at $25 \pm 1°C$.

The sulfide coatings were electrochemically reduced in a 0.1 M $KClO_4$ solution at $T = 20 \pm 1°C$ in a YaSE-2 standard cell. An SU-1200 carbon glass with a working surface area of 1 cm^2 was the working electrode. Saturated silver chloride electrode was the reference electrode, and platinum gauze, the auxiliary electrode. The potentials E were recalculated relative to standard hydrogen electrode. The voltammograms (VA) were measured with a PI-50-1 potentiostat and a PR-8 programmer and were recorded with an XY RECORDER A3 self-recording potentiometer. The scanning rate of the potential was 6×10^{-2} V s^{-1}.

The composition of the sulfide coatings was studied by X-ray photoelectron spectroscopy (XPS) on an ESCALAB-MK II Vacuum Generator Scientific spectrometer (the United Kingdom). As a source of soft X-ray radiation served a magnesium anode (1253.6 eV, 300 W). The pressure in the analytical chamber of the spectrometer was 1.33×10^{-8} Pa. An AG-2 argon gun (beam energy 20 eV, current 20 μA) in a preparative chamber was used to study the depth distribution of elements. The rate of the surface etching was 2 nm min^{-1}, and etching time, 30, 60, and 120 s. The accuracy of the method was ±0.1 at. %. In study of the Co sulfide coatings by XPS, we recorded the Co2$p_{3/2}$ photoelectron spectra. The empirical factors of sensitivity of these elements were taken from the literature [13], and the recorded spectra were compared with the reference spectra [14].

In [10], the electrochemical behavior of a cobalt sulfide coating in 0.1 M $KClO_4$ was studied by cyclic voltammetry. It was found that the Co(III) compounds

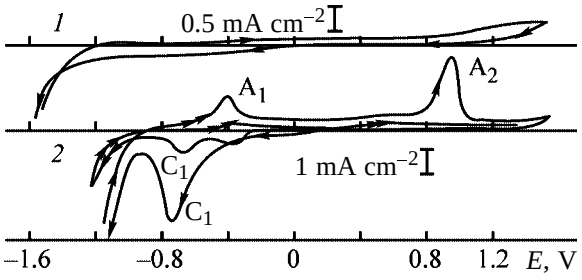

Fig. 1. Cyclic potentiodynamic curves taken in 0.1 M $KClO_4$ solution. Two deposition cycles; T = 20°C; V_{sc} = 5×10^{-2} V s^{-1}. Electrode: (*1*) carbon glass and (*2*) carbon glass coated with cobalt sulfide.

are reduced to Co(II) in the potential range from –0.4 to –0.9 V (Fig. 1). Namely, reduction of CoOHS to CoS and $Co(OH)_2$ (cathodic current peak C_1) was suggested.

In the XPS study of the sulfide coating, we paid attention to the distribution of Co, O, and S elements over the surface and throughout the depth of the coating (Fig. 2). Our results show that the surface of the initial and reduced coatings contains up to 65 at. % oxygen. About 20 at. % oxygen was found in deeper layers of the coating. The measured binding energies E_b of Co2$p_{3/2}$ (780.6±0.1 eV) and O1*s* (531.0±0.3, 529.7±0.1 eV) electrons (Table 1; Figs. 3a, 3b) sug-

gest that oxygen occurs in the forms of $Co(OH)_2$, $Co^{III}OHS$, and $CoSO_3$. These compounds were detected not only on the surface, but also in deeper layers of the coating. At the same time, a large amount of oxygen on the surface may be due to adsorption and chemisorption of the oxygen compounds of cobalt and also of water and oxygen molecules.

Apart from oxygen compounds of cobalt, the cobalt sulfide coatings formed in three cycles contain CoS (E_bS2p = 166.7 ± 0.1 eV) (Table 1, coating no. 1). This compound was detected after the upper layer 1 or 2 nm thick was etched with Ar^+ ions. The amount of $CoSO_3$ abruptly decreases with depth. The intensity ratios calculated from the S2p and Co2$p_{3/2}$ spectra for cobalt(II) sulfide and sulfate are different on the surface of the sulfide coating and at a depth of 2 nm (Table 1). Compared to $CoSO_3$, the amount of CoS amount is larger by a factor of approximately 2.6 on the surface and by a factor of 5.6 and 7.5 at a depth of 1 and 2 nm, respectively. This fact suggests that $CoSO_3$ is formed solely on the coating surface, whereas in deeper layers CoS dominates. $CoSO_3$ may be formed owing to oxidation of S^{2-} with Co(III) [15]:

$$6CoOOH + 6S^{2-} + 3H_2O = CoSO_3 + 5CoS + 12OH^-. \quad (1)$$

Accprding to reaction (1), the amount of forming $CoSO_3$ should be smaller by a factor of 5 than that of CoS. The S2p spectra (Fig. 3c) shows that the amount of sulfite ($E_b \approx$ 166.7 eV) is smaller than that of sulfide ($E_b \approx$ 162.1–162.7 eV). The coating contains about 19 at. % S on the surface and from 29 to 34 at. % S in deeper layers (Fig. 2a). The binding energies in the S2p spectrum do not correspond to elemental sulfur (E_b = 164.1 ± 0.1 eV), i.e., it is absent in the coating. This result is in agreement with the voltammetric data. The current peak of sulfur reduction was not revealed in the voltammograms of reduction of the cobalt sulfide coatings (Fig. 1).

In the sulfide coating reduced at the potential E scanned from the steady-state potential E_{st} to –0.85 V, the $CoSO_3$ amount on the surface (I_S/I_{Co} = 5.2) is two times that in the initial coating (I_S/I_{Co} = 2.7). The $CoSO_3$ amount in deeper layers abruptly decreases (I_S/I_{Co} = 0.12).

In the coating partially reduced to E = –0.85 V, cobalt sulfide CoS (E_b = 778.0 ± 0.1 eV) is present both on the surface and in deeper layers, because the reduction occurs at E < –1.0 V [10], i.e., in the range of hydrogen evolution [16]. The CoS content on the surface is 1.5 times higher than in initial coating. The I_S/I_{Co} ratio for CoS, as calculated from the Co2$p_{3/2}$ and S2p spectra (Figs. 4a, 4c), is 10.4 and 7.0 for the initial and reduced coatings, respectively (Table 1, coating nos. 1, 2). Apparently, the increased amount of CoS on the surface of the reduced coating is due to the reduction of the Co(III) compound, i.e., CoOHS (Fig. 1, curve *2*, cathodic current peak C_1), which occurs in the range of E from –0.4 to –0.9 V with formation of CoS and $Co(OH)_2$. The results obtained confirm the assumption [10] that the current peak C_1 at E = –0.75 V in the cyclic voltammogram taken in a 0.1 M $KClO_4$ solution is due to the reduction of the Co(III) compound containing not only oxygen but also sulfur, i.e., of CoOHS.

CoS obtained by deposition from aqueous solutions of salts is sparingly soluble (SP 10^{-22}) [17]. The solubility of the CoS precipitate decreases further with time. This is explained by appearance of new bonds

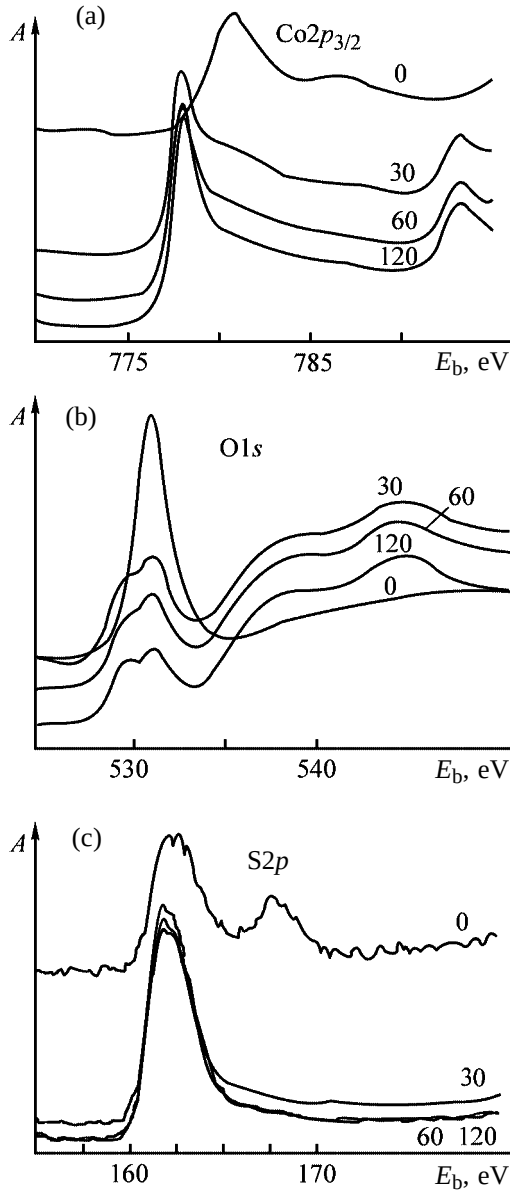

Fig. 4. XPS of the cobalt sulfide coatings reduced in 0.1 M $KClO_4$ solution at the potential E scanned from E_{st} to –0.85 V.

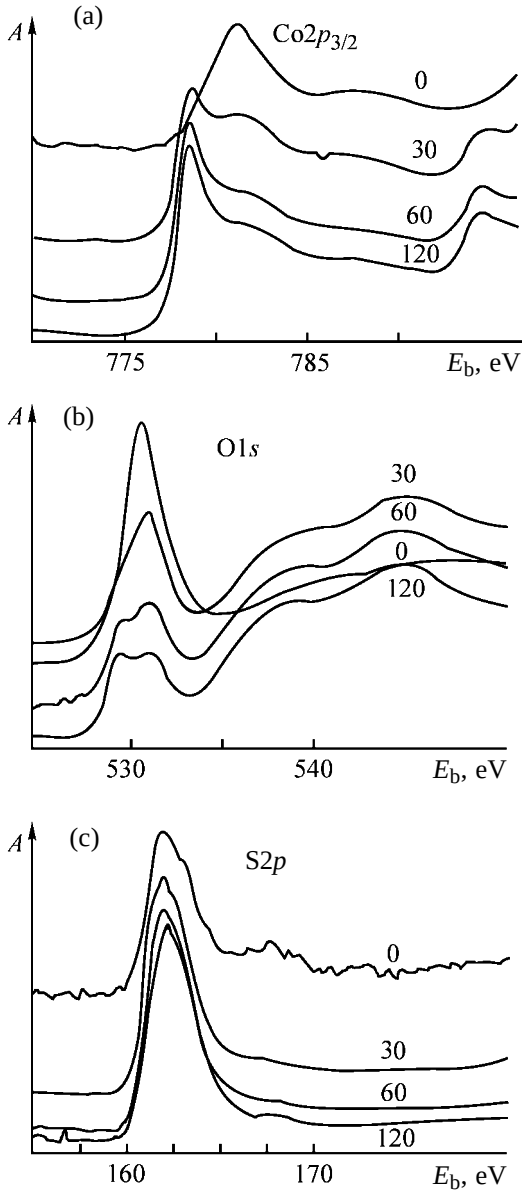

Fig. 5. XPS of the cobalt sulfide coatings reduced in 0.1 M $KClO_4$ solution at the potential E scanned from E_{st} to –1.3 V.

due to oxidation of Co(II) to Co(III) and hydrolysis to $Co^{III}OHS$. We found no published XPS data for CoOHS.

After the reduced coating was etched with Ar^+ ions for 30 and 60 s, the I_S/I_{Co} intensity ratio decreased to 1.35 and 1.25, respectively (Table 1, coating no. 2). Probably, the decrease in the CoS decrease at depths of 1 and 2 nm is due to the formation of $Co(OH)_2$, which is a product of CoOHS reduction. Cobalt(II) hydroxide, $Co(OH)_2$, can block the electrode surface, change its electrical properties, and impede further reduction of CoOHS.

We studied the composition of the sulfide coatings reduced at the potential E scanned from E_{st} to –1.3 V, i.e., after the potential of CoS reduction was attained. The results (Table 1, Figs. 5a–5c) show that the surface layer of the coating consists of $Co(OH)_2$, CoS, and $CoSO_3$. Cobalt sulfite was present solely on the surface and was absent at a depth of 1 nm. The oxygen to cobalt intensity ratio I_O/I_{Co} (Table 1, coating no. 3) for $Co(OH)_2$ and CoS decreases. Cobalt(II) sulfide was detected both on the surface and at a depth of 1–2 nm.

The I_S/I_{Co} ratio for CoS, calculated from the

spectral data (Figs. 5a, 5c) is 5.16. This value is lower than that for initial sulfide coating (Table 1, coating no. 1). This result may be due to the reduction of CoS to metallic Co at the potential *E* scanned down to –1.3 V, which is supported by the Co L_3VV Auger spectra (kinetic energy E_k 772.5, 774.3 eV). Metallic cobalt was found both on the surface and at a depth of 1–2 nm. It should be noted, however, that the CoS reduction after electrochemical treatment to –1.3 V is incomplete. This conclusion was confirmed not only by X-ray photoelectron spectroscopy but also by cyclic voltammetry.

CONCLUSIONS

(1) The composition of the cobalt sulfide coating was studied by X-ray photoelectron spectroscopy. The coating reduced in 0.1 M $KClO_4$ solution and the initial coating contain about 60 at. % oxygen on the surface and ~20 at. % oxygen in deeper layers. This result may be due to adsorpton and chemisorption of oxygen compounds of cobalt and also of water and oxygen molecules.

(2) The initial cobalt sulfide coating is a mixture of the compounds CoS, $CoSO_3$, $Co(OH)_2$, and CoOHS, whereas the reduced coating is a mixture of Co^0, CoS, $CoSO_3$, and $Co(OH)_2$. The presence of Co(II) compounds shows that the reduction is incomplete, even after attaining the potential of extensive hydrogen evolution.

(3) The large amount of CoS in the partially reduced (to –0.85 V) cobalt sulfide coating shows that the cathodic peak in the cyclic voltammograms at *E* = –0.75 V is due to the reduction of CoOHS.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Separation of Platinum(IV) and Iron(III) with Liquid Membranes under Electrodialysis Conditions

T. Zh. Sadyrbaeva

Institute of Inorganic Chemistry, Riga Technical University, Salaspils, Latvia

Received September 3, 2002

Abstract—The recovery of platinum(IV) from hydrochloric acid solutions containing an excess amount of iron(III) with liquid tri-*n*-octylamine–1,2-dichloroethane membranes under conditions of galvanostatic dialysis was studied. The influence exerted by the current density and by the composition of aqueous solutions and liquid membranes on the rate of platinum(IV) transport and efficiency of separation of the metals was analyzed and the optimal process conditions were determined.

Recovery of platinum metals from hydrochloric acid solutions in the presence of macroscopic impurities of non-noble metals is of primary practical interest. The ability of platinum metals to form stable anionic chloro complexes under the conditions under which the nonferrous metals and iron are present as impurities allows use of anion-exchange extraction with amine salts [1, 2] and high-voltage dialysis [3] for their separation. However, in systems with amines, the high stability of the forming compounds makes back extraction of platinum metals difficult, which hinders application of the extraction techniques [4]. It has been shown previously that application of an electric field facilitates back extraction of platinum, palladium, and ruthenium from tri-*n*-octyalime (TOA) solutions [5]. Electrodialysis of liquid TOA-containing membranes has been used to recover palladium from dilute acid solutions [6] and separate the metal from excess amounts of iron, nickel [7], and copper [8].

The aim of this study was to analyze electrodialytic transport of platinum from binary hydrochloric acid mixtures with iron(III) across TOA-based liquid membranes bounded by cellophane films.

EXPERIMENTAL

Electrodialysis was carried out in an assembled five-chamber fluoroplastic cell comprising electrode chambers, feeding and receiver solution chambers, and a liquid membrane in the system

(–)Pt, H_2SO_4	H_2PtCl_2 $FeCl_3$ HCl	TOA Dichloroethane	HCl	Pt,(+) H_2SO_4
	MK		MK	

The volume of the liquid membrane was 2 cm^3; its thickness, 0.2 cm; phase contact area, 7.1 cm^2. Cellophane films bounding a liquid membrane were preliminarily soaked in water. The electrode chambers filled with 0.15 M H_2SO_4 solution (volume 17 cm^3) were separated from the chambers containing the feeding and receiving solutions (volume 13 cm^3) with MK-40 solid cation-exchange membranes. Direct current was fed through platinum electrodes.

The liquid-membrane solution was prepared by dissolving a weighed portion of TOA (pure grade, main substance content 95%) in 1,2-dichloroethane. In view of the possible reaction of TOA with the solvent to give a salt of quaternary ammonium base [9], freshly prepared solutions were used. The feeding solution was prepared by dissolving H_2PtCl_6 (pure grade) and $FeCl_3 \cdot 6H_2O$ (analytically pure grade) in hydrochloric acid of appropriate concentration (0.1 M HCl, as a rule). Commonly, 0.1 M HCl was used as receiving solution.

The concentration of metals in aqueous solution was determined spectrophotometrically: platinum, with tin(II) chloride [10]; iron, with sulfosalicylic acid [11]. In determining the content of iron(III) in the presence of a large excess of platinum, the optical density was measured relative to the solution being analyzed. The measurements were done on an SF-46 spectrophotometer.

Platinum(IV) forms highly stable complexes with chloride ions and exists in hydrochloric acid solutions mainly as the hexachloride complex $[PtCl_6]^{2-}$ [10]. Tri-*n*-octylamine recovers platinum(IV) in a wide range of HCl concentrations by, predominantly, the

1070-4272/03/7601-0076$25.00

interphase anion exchange mechanism [4]:

$$H^+(a) + Cl^-(a) + R_3N(o) \rightleftarrows R_3NHCl(o), \quad (1)$$

$$2R_3NHCl(o) + [PtCl_6]^{2-}(a) \rightleftarrows (R_3NH)_2[PtCl_6] + 2Cl^-(a), \quad (2)$$

where (a) stands for the aqueous phase, and (o), for the organic phase; R_3N is TOA.

On applying an electric field, the platinum complex being extracted is transported across the liquid membrane and disintegrates at the interface with the receiving solution by a reaction reverse to (2). The membrane recovery of platinum occurs by co-directed transport of $[PtCl_6]^{2-}$ anions and chloride ions, and, therefore, high HCl concentration in the receiving solution is not required, in contrast to dialysis processes. The electric field intensifies the transport of $[PtCl_6]^{2-}$ across each of the liquid membranes and ensures back extraction into a weakly acidic receiving solution. In the zero-current mode, there is virtually no transmembrane transport of platinum in the system studied.

The rate of platinum recovery from a binary mixture containing 2.14×10^{-2} M $H_2[PtCl_6]$ and 3.64×10^{-2} M $FeCl_3$ is proportional to the current density in the range 0–8.5 mA cm^{-2} (Fig. 1). Platinum is recovered into the receiving 0.1 M HCl solution selectively; the degree of iron(III) recovery in 1 h is about 0.1%. The metals are separated because amine salts more actively extract iron than platinum at higher HCl concentrations. In dilute HCl solutions, iron(III) forms cationic and neutral complexes [12]. In the course of electrodialysis, loss of Fe^{3+} from the feeding solution is as high as 25–35% because of its adsorption by a solid cation-exchange membrane.

The variation of voltage in the galvanostatic mode is characterized by a steep fall at the beginning of the process, with an "electric breakdown" of the liquid membrane possible at high current densities after several tens of minutes of electrodialysis (Fig. 2). The initial rise in the electrical conductivity of the organic phase is due to an increase in the total concentration of ions in the liquid membrane as a result of extraction of hydrochloric acid and $[PtCl_6]^{2-}$ by amine [reactions (1) and (2)]. The electric breakdown, associated with accumulation of water in the organic phase and formation of through aqueous channels [13], leads to the loss of transporting and selective properties by the membrane. The time when the breakdown occurs depends on the current density and on the nature of organic solvent and ion being recovered. Liquid membranes based on TOA in dichloroethane work without breakdown in recovery of platinum for about 2.5 h at current density of 6.4 mA cm^{-2} and equal acidities of the feeding and receiving solutions, with more than 50% of platinum and about 0.3% of iron transferred across the liquid membrane (Fig. 3). The

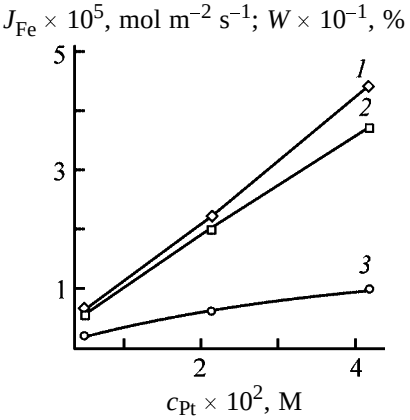

Fig. 6. Rates of transfer, J_{Pt}, into (*1*) liquid membrane and (*2*) receiving solution and (*3*) current efficiency W by platinum(IV) vs. its concentration c_{Pt} in the feeding solution. c_{TOA} 0.1 M, i = 6.4 mA cm^{-2}, τ = 60 min.

best separation of the metals is achieved under the experimental conditions in 2 h of electrodialysis. The efficiency and stability of liquid membranes with TOA in recovery of platinum exceeds that in the previously studied process of palladium transport [6].

The effect of the carrier concentration in the organic phase on the rate and selectivity of platinum recovery is shown in Fig. 4. In contrast to dialysis membrane extraction, raising the concentration of TOA to 0.15 M impairs the rate of platinum transport since chloride ions compete with $[PtCl_6]^{2-}$ in current transport across the interface between the membrane and the receiving solution. The excess of carrier acts in electrodialysis as supporting electrolyte. It should be noted that raising the TOA concentration leads to a pronounced increase in the electrical conductivity of the liquid membrane (Fig. 5).

Raising the concentration of platinum in the feeding solution to 4.2×10^{-2} M at constant concentration of iron leads to a proportional increase in the rate of $[PtCl_6]^{2-}$ transfer across both phase boundaries and in the current efficiency (Fig. 6). However, under excess of hydrochloric acid in the feeding solution, current is mainly carried across the liquid membrane by chloride ions and the current efficiency by $[PtCl_6]^{2-}$ anions does not exceed 10%.

Lowering the concentration of HCl in the feeding solution to 1×10^{-3} M makes higher the degree of platinum recovery, current efficiency, and metal separation factor (Table 1). The increase in the rate of platinum transport is due to a decrease in the content of chloride ions competing with $[PtCl_6]^{2-}$ anions for the trioctylammonium cation.

The type and concentration of acid in the receiving solution is not an important factor under electrodialysis conditions (Table 2).

The rate of platinum recovery into the liquid membrane is independent of the composition of the receiving solution, and the transmembrane transfer decreases somewhat in those cases when an electric breakdown occurs in the course of an experiment. Liquid membranes are the most stable if recovery is done into hydrochloric acid solutions, whereas systems with nitric acid are characterized by their shortest service life.

CONCLUSIONS

(1) Under electrodialysis conditions, liquid membranes containing tri-*n*-octylamine in dichloroethane ensure transport of $[PtCl_6]^{2-}$ into dilute acid solutions

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Interaction of Electrolyte for Alkaline Zinc Plating with Calcium Compounds in the Course of Chemical Washing

A. Pigaga, A. Selskis, M.-G. Klimantavičiute, and A. Sveikauskaite

Institute of Chemistry, Vilnius, Lithuania

Received June 18, 2002

Abstract—The interaction between diluted electrolyte for alkaline zinc plating and calcium compounds ($CaCl_2$ solutions, phosphogypsum and cement dust suspensions) was studied to determine the promise of their use for chemical washing.

Zinc coatings occupy a distinctive position among corrosion-protection coatings since about 50% of surfaces coated with metals are zinc plated. Originally, cyanide electrolytes were used, then, weakly acidic electrolytes, and now alkaline electrolytes are in use because of their high throwing power and high current efficiency at fast plating rates and owing to the fact that the coatings obtained are nicely lustrous. These electrolytes conform to modern nature preservation requirements because the concentrations of zinc are low and luster-producing agents are environmentally safe.

One of ways to save metals and water and to diminish pollution is to use the so-called chemical washing, first proposed by Lanzi for rendering harmless discharged chromium-plating electrolytes and cyanide-containing solutions directly in the catching bath [1].

In washing of articles after alkaline zinc plating, sludge formation was observed in washing water because of partial decomposition of zincate ions and formation of poorly soluble zinc compounds. In washing in deionized water, formation of a bulky, slowly settling precipitate was observed. In washing in tap water containing 57 mg l^{-1} Ca^{2+} and 13 mg l^{-1} Mg^{2+}, a minor volume of a compact precipitate settled fast, with the residual concentration of zinc in solution being lower. Presumably, cations in tap water favor precipitation of zinc. Additional experiments demonstrated that precipitation of zinc is promoted by solutions of calcium salts, with magnesium salts exerting virtually zero influence on zinc precipitation.

Zincate ions form with calcium(II) hydroxide a poorly soluble finely crystalline precipitate of calcium zincate, $CaZn_2(OH)_6 \cdot 2H_2O$ [2]. Its structure and the conditions and rates of its formation and decomposition have been much studied, and calcium zincate has found application in Zn/NiOOH and Zn/AgO batteries [3–9] and as a component of wood binders [10], luminophores, insulators and glasses, and polymerization catalysts [8].

Calcium zincate $CaZn_2(OH)_6 \cdot 2H_2O$ crystallizes in the monoclinic system [2], with two its forms, tetragonal and hexagonal, known. According to X-ray diffraction analysis, the unit cells of both forms are identical [8]. Hexagonal crystals are formed by slow crystallization (during several days), and tetragonal crystals, by fast precipitation from supersaturated solutions.

The aim of this study was to analyze the interaction of a diluted electrolyte for alkaline zinc plating with calcium compounds ($CaCl_2$ solutions, suspensions of phosphogypsum and cement dust) to determine the promise of their use for chemical washing.

About 4 ton of phosphogypsum is formed in manufacture of 1 ton of orthophosphoric acid [11]. By the content of the main substance, gypsum ($CaSO_4 \cdot 2H_2O$) (up to 98%), it corresponds to natural gypsum of the highest quality (91–95%). The chemical composition of phosphogypsum manufactured by Lifosy Joint-Stock Company (in terms of dry substance) is as follows (%): CaO 31–37, SO_3 44–54, SiO_2 0.3–0.6, R_2O_3 0.5–1.5, Na_2O 0.24–0.32, K_2O 0.04–0.08, P_2O_5 total 0.91–2.86, P_2O_5 water-soluble 0.52–2.65, F total 0.14–0.48, and F water-soluble 0.015–0.33 [12]. Moisture content of phosphogypsum 20–25%, calcination loss (400°C) 37–42%, density 750–800 kg m^{-3}, specific surface area 260–290 m^2 kg^{-1}. Phosphogypsum particles are $CaSO_4 \cdot 2H_2O$ crystals

1070-4272/03/7601-0080$25.00

5–500 μm long, 1–50 μm wide, and 0.05–0.5 μm thick.

Data on the sorption properties of phosphogypsum are scarce. It is known that phosphogypsum can be used to remove Sr^{2+} and Pb^{2+} [13], and also phosphates and borates from industrial wastewater [14], and to perform preliminary purification of concentrated phenol-containing discharges [15]. A method for purification of phosphoric acid to remove fluorine has been developed [16].

Cement dust, exhibiting properties of both an alkaline agent and a sorbent, can be used to remove heavy metals {17–19] and a number of hazardous organic substances [19, 20] from industrial wastewater. In Lithuania, Akmenes Cementas Joint-Stock Company produces annually 20–30 thousand tons of cement dust of the following chemical composition (%): Al_2O_3 3–8, Fe_2O_3 2–5, SiO_2 11–15, CaO 38–48, CaO free 3–7, MgO 2–4, $(Na,K)_2O$ 2–8, and SO_3 3–8. According to X-ray phase analysis, the dust is mainly constituted by calcite $CaCO_3$ (~80%), quartz α-SiO_2 (10–15%), and basic calcium silicate $Ca_5 \cdot (SiO_4)_2(OH)_2$ the rest [16].

EXPERIMENTAL

A Limeda NBTs electrolyte for alkaline zinc plating was used in the study. It was prepared in accordance with GOST (State Standard) 9.305–84 and had the following composition (g l^{-1}): ZnO 15, NaOH 110; luster-producing additives NBTs-0 and Limeda NBTs-K 5 ml l^{-1} each. Immediately before an experiment, the electrolytes were diluted with deionized water.

The concentrations of Zn^{2+} and Ca^{2+} in the solutions under study were determined by plasma atomic-emission spectrometry on a Beckman SpectraSpan VI instrument at wavelengths of 206, 200 and 317, 933 nm, respectively.

X-ray diffraction patterns of precipitates were obtained on a DRON-2 X-ray diffractometer in CuK_α radiation. Micrographs of the precipitates were obtained on a JXA-50A scanning electron microscope–microanalyzer. Reagents of chemically pure and analytically pure grades were used.

Phosphogypsum, a waste formed in industrial processing of Kola apatite, was delivered by Lifosa Joint-Stock Company [TU (Technical Specification) 6 111 045-03–92], and cement dust, by Akmenes Cementas [TU 5 290 342-04–92, GOST (State Standard) 310.2, content of free CaO 4.7%].

3430	3400/3400		115 (19)/150

* After settling for 1 h/24 h.

To determine the efficiency of Zn^{2+} precipitation, 0.2–25 ml of Limeda NBTs electrolyte was mixed with 50 ml of a $CaCl_2$ solution (2 or 10 g l^{-1}), the mixture was filtered after 1 or 24 h of settling, and the residual concentrations of Zn(II) and Ca(II) were found.

Table 1 shows that, upon introduction of the electrolyte into the $CaCl_2$ solutions, the concentration of zinc decreases by up to a factor of 200, compared with the case of the corresponding dilution with deionized water. Precipitate formation was also observed upon 5–250-fold dilution of the electrolyte with deionized water, which is due to decomposition of zincate ions to give ZnO (as established by an X-ray diffraction study):

$$Zn(OH)_4^{2-} \rightleftarrows ZnO + 2OH^- + H_2O. \quad (1)$$

In solutions containing $CaCl_2$, zinc(II) precipitates much faster and to a greater extent, with calcium(II) coprecipitated, which confirms the formation of a mixed compound containing calcium and zinc:

$$2Zn(OH)_4^{2-} + Ca^{2+} + 2H_2O \rightleftarrows CaZn_2(OH)_6 \cdot 2H_2O + 2OH^-. \quad (2)$$

An X-ray diffraction study demonstrated that precipitates obtained upon introduction of the Limeda NBTs electrolyte into solutions with 2 or 10 g l^{-1} $CaCl_2$ to Ca : Zn molar ratios equal to 1 or 2 are composed of $CaZn_2(OH)_6 \cdot 2H_2O$ with a minor impurity of ZnO. The interplanar spacings and the reflection intensities for the compound $CaZn_2(OH)_6 \cdot 2H_2O$

are in good agreement with the data of [2]. The precipitate is mainly formed by rhombic plates 50–250 μm long or aggregates of these, 100–200 μm in diameter.

Another set of experiments was concerned with the kinetics of calcium zincate precipitation upon introduction of a zinc-plating electrolyte into a $CaCl_2$ solution or phosphogypsum (cement dust) suspension under continuous agitation of the reaction mixture with a magnetic stirrer. The results listed in Table 2 indicate that the rates of formation of a poorly soluble calcium zincate are fairly high and are acceptable for chemical washing purposes.

Further, the process of chemical washing was simulated. A 300-ml portion of deionized water or of an aqueous solution of 1.0, 5.0, 10, or 25 g l^{-1} $CaCl_2$ was placed in a volumetric vessel, 15 ml of electrolyte was introduced, the mixture was agitated with a magnetic stirrer for 10 min and settled for 5 min, the precipitate volume was determined, a 15-ml sample of the solution was taken and filtered, and the residual concentrations of zinc and calcium were determined by atomic-emission spectrometry. This procedure of introduction–sampling–analysis of the solutions was repeated nine times. The results of the experiment, which are listed in Table 3, and X-ray diffraction data indicate that the major part of zinc(II) (~90%) is precipitated from solution in the form of calcium zincate.

The efficiency of washing grows with $CaCl_2$ concentration; however, with this concentration raised

from 10 to 25 g l^{-1}, the volume of the precipitated phase increased from 8 to 37% because of the formation of voluminous $Ca(OH)_2$. Therefore, the optimal $CaCl_2$ concentration is 5–10 g l^{-1}, since at lower concentrations the solutions are exhausted fast.

The phosphogypsum suspension acts no less effectively, and the volume of the precipitated phase does not exceed 20%. The precipitate is mainly composed of calcium zincate with impurity of zinc oxide and unreacted gypsum.

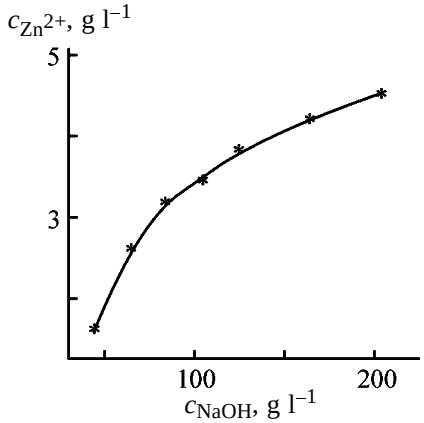
The cement dust suspension is much inferior in efficiency to $CaCl_2$ solutions and phosphogypsum suspension, with this fact not being associated with exhaustion of reactive Ca(II) ions in solution (Table 3). The reason is that the cement dust additionally alkalizes the reaction mixture.

The gradual increase in the concentration of zinc(II) in solution is due to a decrease in the concentration of reactive calcium(II) ions and rise in the degree of calcium zincate dissociation with increasing solution alkalinity.

The solubility of calcium zincate was studied as a function of concentration as follows. To 20 ml of zinc-plating electrolyte was added 10 ml of $CaCl_2$ solution (50 g l^{-1}) and 0–20 ml of NaOH solution (400 g l^{-1}), the mixture was diluted with distilled water to 50 ml, agitated for 4 h, and filtered, and the Zn(II) concentration was determined. The figure shows that the solubility of calcium zincate grows with increasing solution alkalinity.

In the course of chemical washing, the precipitate should be separated from the solution by filtration or centrifugation after a Zn(II) concentration of 300–400 mg l^{-1} is reached, and the filtrate is to be added to acidic and alkaline wastes for neutralization. To separate the precipitate, it is desirable to lower the pH of the reaction mixture. For this purpose, a dilute H_2SO_4 solution is introduced or CO_2 bubbled through to make the pH 11.5–11.7. The Zn(II) concentration in solution decreases to 15–40 mg l^{-1}. It is necessary to avoid pH < 11.5, since in this case voluminous $Zn(OH)_2$ is formed. In manufacture, it is much more convenient to use inexpensive CO_2, which makes it possible to set easily the required pH value. The filtrate can be recycled.

The precipitate obtained from $CaCl_2$ solutions can be used in electroplating, manufacture of trace-element fertilizers and pigments, and ceramic fillers, and also for preparing zinc-phosphating solutions.



Residual concentration of Zn(II), $c_{Zn^{2+}}$, vs. NaOH concentration c_{NaOH}. Initial concentrations of Zn(II) and $CaCl_2$ are, respectively, 4.8 and 10 g l^{-1}.

CONCLUSIONS

(1) A procedure is proposed for washing with calcium chloride solutions or phosphogypsum suspensions of articles after alkaline zinc plating. The optimal process conditions are established. Compared to washing in water, the concentration of zinc in the catching bath is 100–200 times lower because of the formation of poorly soluble finely crystalline calcium zincate $CaZn_2(OH)_6 \cdot 2H_2O$.

(2) The precipitate, mainly composed of calcium zincate with impurity of zinc oxide, can be used in zinc phosphating for preparing phosphating solutions, as trace element fertilizer in agriculture, and in some other industries.

Abstract—The difference of the electrolyte densities in the container and within pores of the active electrode paste was determined in discharge of sealed lead batteries with absorbed electrolyte. The data obtained can be used in designing sealed batteries.

To calculate and plot discharge curves when designing lead batteries, it is necessary to take into account the variation of the electrolyte concentration in the container and within electrode pores. It is known that, during discharge of a lead battery, the densities of electrolyte in the container and within pores of the active electrode paste are different. In [1], the density of electrolyte within pores of the positive and negative electrodes of a starter battery was determined after 5 min and 10 and 20 h of discharge. In the 5-min and 10-h modes of discharge, the difference ΔP of the electrolyte densities in the container and within pores of the positive and negative electrodes was, respectively, 0.18–0.065 and 0.13–0.035 g cm^{-3}. However, data on how the electrolyte density within the electrode pores varies with battery discharge in different discharge modes were not reported in [1].

In order to determine the electrolyte density within electrode pores, we performed an experimental study of nonportable lead batteries with discharge capacity of 600 A h and rated electrolyte density of 1.240 g cm^{-3} at 20°C. During discharge of the batteries in the course of 10, 5, 3, 1, 0.5, and 0.25 h, the circuit was broken after exhausting 25, 50, 75, and 100% of the discharge capacity, and the open-circuit voltage (OCV) and electrode potentials were measured, after which the discharge of the batteries was continued. The discharge was terminated in accordance with the technical specification requirements at final voltage U_f of 1.8 V in the 3–10-h modes and 1.75 V in the 0.25–1-h modes.

During dc discharge of lead batteries, there is a voltage drop across the internal resistance R of the batteries, which is constituted by the active resistance and the polarization resistance R_p. The latter comprises the following resistances: transition resistance R_t, reaction resistance R_r, diffusion resistance R_d, and crystallization resistance R_c. These polarization resistances are determined by the respective overvoltages. When the circuit is broken to determine the OCV, the digital voltmeter only measures the overvoltages of diffusion, η_d, and reaction, η_r (or that of crystallization, η_c). It is difficult to record the transition overvoltage η_t because of the high rate of the process (occurring within micro- or milliseconds), which should be taken into account in calculations [2]. However, the current densities in a nonportable lead battery in 0.25–10-h discharge modes are low and the transition overvoltage η_t is close to zero. Therefore, the experimental data, even if obtained with a digital voltmeter, require no correction.

The results of calculation of the differences of electrolyte densities in the container and within pores of the active paste of the electrodes, ΔP, with account of the experimental OCV values for batteries with different degrees of discharge are shown in Fig. 1. The

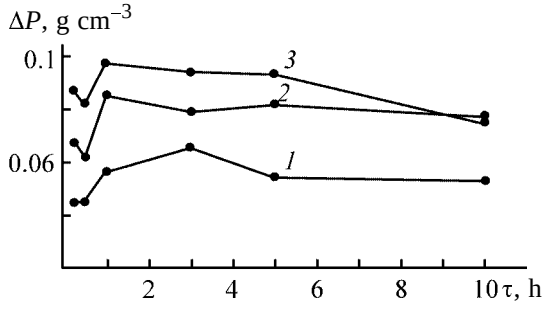

Fig. 1. Variation with the discharge duration τ of the difference ΔP of electrolyte densities in the container and within electrode pores of a battery with liquid electrolyte. Degree of discharge, %: (*1*) 25, (*2*) 50, and (*3*) 100.

1070-4272/03/7601-0085$25.00

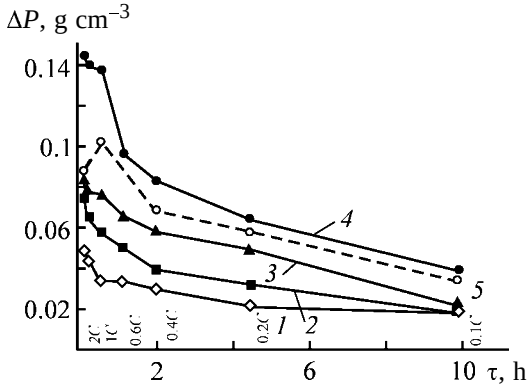

Fig. 2. Variation with the discharge duration τ of the difference Δ*P* of electrolyte densities in the separator and within electrode pores of sealed batteries with absorbed electrolyte. Degree of discharge, %: (*1*) 25, (*2*) 50, (*3*) 75, (*4*) 100, and (*5*) 100 at U_f = 1.75–1.80 V.

data obtained indicate that the difference Δ*P* of electrolyte densities at the same degree of discharge varies in the 1–10-h discharge modes only slightly. With increasing degree of discharge, Δ*P* grows.

Theoretical calculations and experimental determination of the emf (OCV) of lead batteries, carried out by many authors, have been reported with the difference of acid concentration within the pores of positive and negative electrodes disregarded [3]. Here, the Δ*P* value is calculated using experimental data and those reported in [3]. The experimental OCV value corresponds to the real concentration of electrolytes within pores of the positive and negative electrodes at a particular instant of measurement and determines the calculated averaged Δ*P* value. Comparison of the differences of electrolyte densities in the container and in the electrode pores of 100% discharged nonportable batteries with similar data obtained in [1] shows that their values are rather close. For example, for the 0.25–10-h discharge modes considered, Δ*P* is 0.097–0.075 g cm^{-3}. The calculated Δ*P* values obtained for 1–10-h discharge modes are also close to the average Δ*P* values for positive and negative electrodes, reported in [1].

A characteristic tendency in the development of lead batteries is the desire to simplify and make less expensive, to the maximum possible extent, their service maintenance. This is achieved by partly or totally sealing the lead battery. One of specific features of sealed lead batteries is that an immobilized electrolyte, gel-like or absorbed, is used in these batteries. Replacement of a liquid electrolyte with a gel-like electrolyte decreases its electrical conductivity and the diffusion coefficient. According to published data, this also leads to an increase in the discharge capacity of the negative electrode and decrease in that of the positive electrode. In view of the lowering of the freezing point of the electrolyte by 13–15°C, the frost resistance of the battery increases, which affects positively its service characteristics at low temperature [4, 5].

At present, electrolytes are mostly immobilized using a glass-fiber separator with high bulk porosity and good wettability with a sulfuric acid solution. The fine structure of the fibers in such a separator allows it not only to separate electrodes, but also to retain an electrolyte within its pores. Both kinds of immobilization, with gel-like electrolyte or that absorbed by the glass fiber, ensure a high rate of oxygen transport to the negative electrode, where it recombines [5, 6].

In view of the significant difference between the electrode operation conditions in lead batteries with liquid and immobilized electrolytes, a necessity arises for determining, in design of sealed lead batteries, the difference of electrolyte densities in the separator and within pores of the active paste in electrodes.

In the present study, experiments were performed with SG-6 sealed batteries with absorbed electrolyte of the density of 1.280 g cm^{-3}. The OCV and voltage *U* were measured during battery discharge with currents of 0.1*C*, 0.2*C*, 0.4*C*, 0.6*C*, 1*C*, 2*C*, and 3*C* A (where *C* is numerically equal to the rated 20-h discharge capacity) after exhausting 25, 50, 75, and 100% of the discharge capacity. The discharges were terminated in accordance with the requirements of the corresponding technical specifications at final voltages U_f of, respectively, 1.75, 1.70, 1.65, 1.60, 1.55, 1.45, and 1.25 V. In SG-6 batteries, the current density at discharges of 0.05–3*C* is 0.0017–0.1 A cm^{-2}, i.e., the overvoltage η_t is close to zero and can be disregarded in calculations. The results of experimental studies and calculations are shown in Fig. 2 in the form of dependences of Δ*P* on the discharge duration τ.

For all the discharge modes, the difference of electrolyte densities in the container and within pores, Δ*P*, grows with the degree of discharge increasing from 25 to 100%; in particular, in discharge with currents of 0.1*C* and 3*C*, by factors of 2.2 and 3.0, respectively. At equal degrees of discharge, the difference of electrolyte densities, Δ*P*, grows with the discharge current increasing from 0.1*C* to 3*C* by a factor of 2.6 at 25% discharge and by a factor of 3.6 at 100% discharge.

Comparison of the differences Δ*P* of electrolyte densities in batteries with liquid and absorbed electrolytes (Figs. 1, 2) shows that this quantity is 2.9–

3.9 times lower, compared to batteries with liquid electrolyte, in batteries with absorbed electrolyte at 25–50% discharge in the 10-h discharge mode, and 1.3–1.1 times lower in the 0.5-h discharge mode. At 100% discharge, the difference of electrolyte densities, ΔP, in batteries with absorbed electrolyte is 1.9 times smaller than that in batteries with liquid electrolyte in the 10-h discharge mode, and 1.8 times greater in the 0.5-h discharge mode.

It should be noted that these figures will be somewhat different if batteries with absorbed electrolyte are discharged to a lesser extent. The results obtained in calculating the difference of electrolyte densities, ΔP, for 100% discharged SG-6 batteries at the same final voltages as those for the liquid-electrolyte batteries under study are shown in Fig. 2, curve *5*. Comparison of curves *4* and *5* shows a decrease in ΔP with increasing final discharge voltage. ΔP is 2.2 times smaller than that in batteries with liquid electrolyte in the 10-h discharge mode, and 1.1 times greater in the 0.5-h discharge mode.

Despite the fact that the rated electrolyte density in SG-6 batteries exceeds that in the liquid-electrolyte batteries under study (1.28 and 1.24 g cm^{-3}), the ΔP value is smaller in 1–10-h discharge modes for batteries with absorbed electrolyte, which, presumably, can be accounted for by the increasing rate of electrolyte diffusion as a result of the greater difference of electrolyte concentrations in the separator and within electrode pores. In short-discharge modes, the discharge is ensured by acid accumulated within the electrode pores and the adjacent separator layer, and, therefore, the ΔP value for sealed batteries exceeds that for batteries with liquid electrolyte.

The run of curve *5* in Fig. 2 and the curves in Fig. 1 also points to the presence of a certain reserve of electrolyte in batteries with liquid electrolyte in short discharge modes and to the possibility of obtaining higher discharge capacity on lowering the final discharge voltage.

The experimental data on the difference of electrolyte densities in the container and within pores of the active paste in electrodes of sealed batteries, obtained in this study, make it possible to determine how the voltage varies with exhausted discharge capacity for all discharge modes of sealed batteries being designed, prior to fabrication and tests of their prototypes.

CONCLUSIONS

(1) Calculated differences of the electrolyte densities in the container and within pores of the active electrode paste were found for a sealed lead battery with absorbed electrolyte on the basis of experimental data. The dissimilarity between the values obtained and the analogous parameters of a lead battery with liquid electrolyte was demonstrated.

(2) The data obtained make it possible to determine the basic characteristic, variation of voltage during discharge, for sealed lead batteries being designed.

CATALYSIS

Complexes of Copper(I) with Dimercapto Compounds as Catalysts for Oxidation of Mercaptans and Hydrogen Sulfide with Molecular Oxygen in Aqueous Solutions

G. A. Bagiyan, I. K. Koroleva, N. V. Soroka, and A. V. Ufimtsev

Konstantinov Institute of Nuclear Physics, Russian Academy of Sciences, Gatchina, Leningrad oblast, Russia

Received September 2, 2002

Abstract—The conditions for formation of complexes of copper(I) with mercapto compounds in aqueous-alkaline solutions and the catalytic activity of these complexes in oxidation of mercaptans and hydrogen sulfide was studied. The kinetic characteristics of these catalysts were compared with those of catalysts based on cobalt phthalocyanines. A method was proposed for suppressing formation of the thiosulfate ion in oxidation of H_2S to elemental sulfur.

Catalytic oxidation of mercaptans plays a key part in industrial processes for purification of hydrocarbon raw materials to remove sulfur compounds [1] impairing the quality of motor fuels and poisoning catalysts in various stages of manufacture of synthetic rubber. The content of mercaptan sulfur in the raw materials is within the range from hundredths to tenths of a percent. Extraction of hydrogen sulfide from natural gas containing 1 (Orenburg gas field) to 25% (Astrakhan gas field) H_2S and its subsequent oxidation to elemental sulfur involves numerous catalytic stages aimed to convert the maximum possible amount of the initial H_2S into sulfur [2]. Cobalt phthalocyanines (CoPC), proposed in the 1960s, proved to be the most effective catalysts for oxidation of mercaptans into disulfides. In the years that passed, a great number of CoPC derivatives have been tested: from water-soluble mononuclear complexes intended for oxidation of mercaptans in the bulk of an aqueous-alkaline solution formed in Merox extraction process to polynuclear (M > 5000 Da) complexes acting as catalysts at the interface between the aqueous and organic phases in Merox demercaptanization of naphthas [3]:

$$2RSH + O_2 \rightarrow RSSR + H_2O_2, \quad (1)$$

$$4RSH + O_2 \rightarrow 2RSSR + 2H_2O. \quad (2)$$

It is known that, in aqueous-alkaline solutions in an excess of thiol compounds, Cu^{2+} ions are reduced to Cu^+, and further, thiolate anions form either soluble complexes with Cu^+ (if additional hydrophilic functional groups are present in a thiol compound) or poorly soluble Cu^+ mercaptides in the case when Cu^+ has monofunctional mercaptans as ligands [4]. The formation constants of Cu^+ complexes with thiol compounds are so high that the concentration of free Cu^+ ions in aqueous solutions does not exceed 10^{-10}–10^{-17} M, depending on the pH of the medium at total concentration of copper compounds in solution in the range 10^{-4}–10^{-6} M [5]:

$$RSH \rightleftarrows RS^- + H, \quad (3)$$

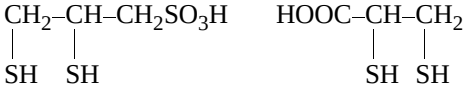
$$2RS^- + Cu^{2+} \rightleftarrows RSSR + Cu^+, \quad (4)$$

$$2RS^- + Cu^+ \rightleftarrows [Cu(SR)_2]^-, \quad (5)$$

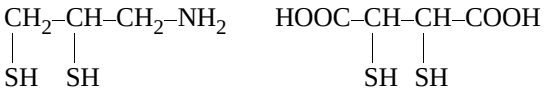
$$RS^- + Cu^+ \rightleftarrows CuSR\downarrow. \quad (6)$$

Hence follows that the catalytic properties of copper(I) in oxidation of thiol compounds are due to complex species rather than to Cu^+ aqua ions.

A study of the catalytic oxidation of thiol compounds in relation to their structure in aqueous solutions revealed that the rate of oxidation of difficultly oxidized aliphatic mercaptans in aqueous-alkaline solutions increases dramatically [6] if into their solutions, along with Cu^+, minor amounts of readily oxidizable dimercapto compounds (DMCs) (I) are introduced, such as dimercaptopropionic, dimercaptosuccinic, and dimercaptopropanesulfonic acids and dimercaptopropylamine (Fig. 1):



1070-4272/03/7601-0088$25.00



In this case, Cu^+ mercaptides are dissolved and the previously inert mercaptans start to oxidize with kinetic characteristics typical of DMC oxidation. This effect can be used to develop novel catalysts for mercaptan oxidation, which have not been used previously in purification of petroleum products to remove mercaptans. Here, the main components of the catalyst are DMCs and their complexes with copper (DMC + Cu^+), introduced into an alkaline solution. In this case, the catalyst complex DMC + Cu^+ does not require development of any special flowsheet in purification of hydrocarbon raw materials to remove mercaptans, being totally compatible with the flowsheets employing CoPC.

The scheme of this process is as follows: hydrocarbon raw materials are brought in contact in an extractor, in a counterflow, with an alkaline (15–20% NaOH) solution of the catalyst, and mercaptans, which are weak acids (pK_a 10–10.5) pass in the form of anions, mercaptides, into the aqueous-alkaline solution. In this solution, when it comes in contact with atmospheric oxygen in the regeneration apparatus, mercaptides are oxidized to disulfides. The disulfides, which are insoluble in aqueous solutions, are extracted from the aqueous phase in the settling apparatus, being accumulated in a small volume of the upper organic layer and then removed from the system [7].

The DMCs mentioned differ only slightly in their catalytic properties in oxidation of mercaptans in the presence of Cu^+ ions, but only dimercaptopropanesulfonic acid (unithiol) is manufactured in Russia on the industrial scale for use in medicine to cure poisoning

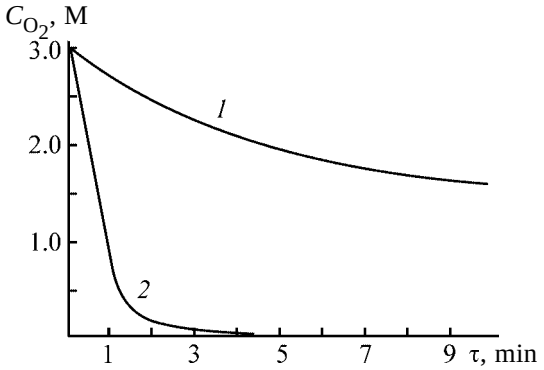


Fig. 1. Catalytic oxidation of butyl mercaptan BuSH. (c_{O_2}) Oxygen concentration and (τ) reaction time. Solution composition (M): (*1*) $CuSO_4$, 1.25×10^{-6}; $BuSH_0$, 1×10^{-2}, pH 11; (*2*) 1 + unithiol, 1×10^{-4}.

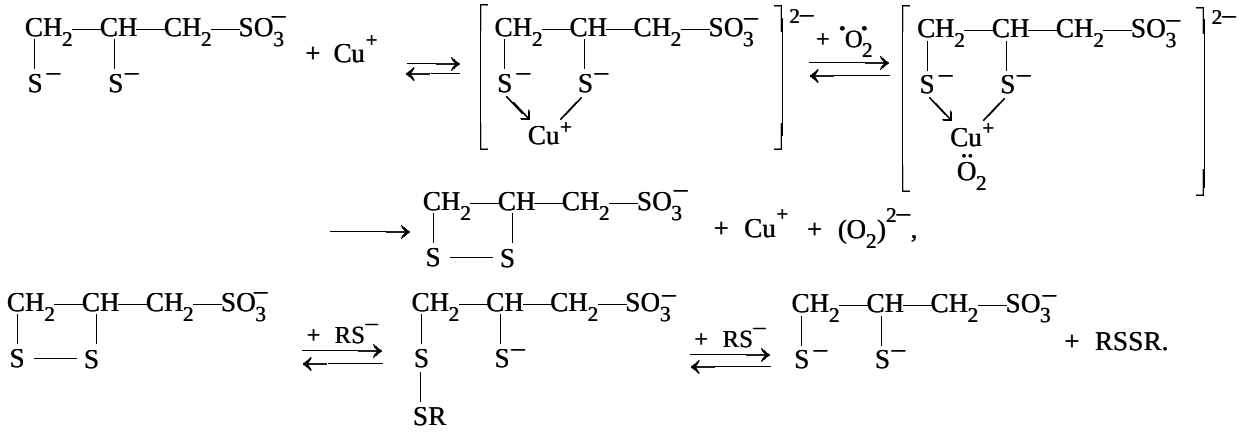
with heavy metals. Therefore, a catalyst on its base is, in principle, of interest for demercaptanization of hydrocarbons. The mechanism of the catalytic action of DMC + Cu^+ catalysts is based on two conjugated reactions: DMC oxidation by molecular oxygen in the coordination sphere of Cu^+ ions and thiol–disulfide exchange, which occurs outside the coordination sphere of the Cu^+ ion and results in that mercaptans dissolved in the alkaline medium are converted into disulfides and DMCs oxidized in the first reaction pass into their original reduced form. At relatively low Cu^+ concentrations the occurring reactions can be represented by Scheme 1.

Effective homogeneous catalysts for mercaptan oxidation must be characterized by high catalytic activity and long-term stability in 15–20% alkali solutions. The kinetics of butyl mercaptan oxidation in the presence of a complex of unithiol with copper(I) was studied in most detail: the dependence of the rate of mercaptan oxidation on the unithiol concentration,

Scheme 1



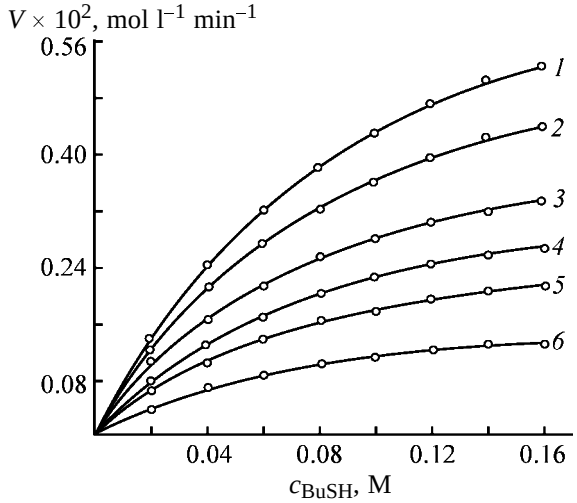


Fig. 2. BuSH oxidation rate V at relatively low Cu(I) concentrations in the catalyst solution. Concentration: $BuSH_0$ 1.75×10^{-1} and unithiol 4×10^{-3}. content of copper(I) ions in solution, and concentration of butyl mercaptan was analyzed.

EXPERIMENTAL

A procedure for determining the catalytic activity was chosen with account taken of the conditions in which the oxidation is kinetically controlled. The most adequate in this regard is the technique described in [8]. The oxidation was done with technical-grade oxygen under atmospheric pressure in an alkaline solution of the catalyst in a batch installation. The reactor was a 0.5-l glass vessel equipped with a three-blade impeller stirrer, bubbler for oxygen supply, reflecting partitions, reflux condenser, and contact thermometer connected to an electric relay. To maintain the temperature at the required level, a cooling finger was inserted into the vessel, and the reactor itself was heated with a Nichrome coil. The temperature was controlled to within ± 0.5°C, the stirrer rotation rate was 2700 rpm. Kinetic curves of butyl mercaptan oxidation were recorded at 20°C. The concentration of copper(I) ions was varied between 1.0×10^{-6} and 1.0×10^{-5} M, and that of unithiol, between 1.0×10^{-3} and 1.0×10^{-2} M. The initial concentration of mercaptides in the alkaline solution was varied between 0.690 and 0.082 M. The solution of mercaptides was prepared by mixing appropriate amounts of freshly distilled butyl mercaptan with a 10% solution of NaOH. The catalyst complex was prepared separately by dissolving weighed portions of unithiol and $CuSO_4 \cdot 5H_2O$ in distilled water. The mercaptide and catalyst solutions were mixed and the reaction mixture was thermostated directly in the reaction vessel in an atmosphere of argon. Oxygen was fed into the vessel at 20°C; the reaction time was counted from the beginning of oxygen supply into the reactor. The oxidation course was monitored by the content of mercaptides in the alkaline solution, by sampling the reaction mixture at certain intervals of time. The content of mercaptides in the reaction mixture was determined by potentiometric titration with 0.01 N $[Ag(NH_3)_2]NO_3$ in conformity with GOSTs (State Standards) 22 985–78 and 17 323–71.

The graphical dependence of the oxidation rate on the mercaptan concentration at different reagent concentrations in solution is shown in Figs. 2–4. It can

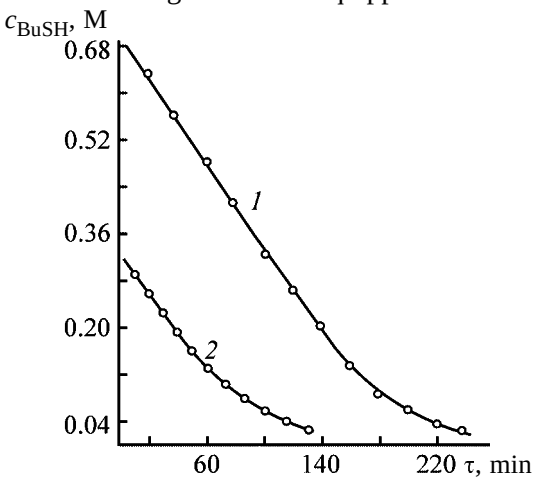

Fig. 3. BuSH oxidation kinetics at varied initial concentrations of mercaptan. Concentration: Cu(I) 1.25×10^{-6} g-ion l^{-1} and unithiol 4×10^{-3} M. (c_{BuSH}) BuSH concentration and (τ) reaction time. Initial BuSH concentration, M: (*1*) 6.5×10^{-1} and (*2*) 3.2×10^{-1}.

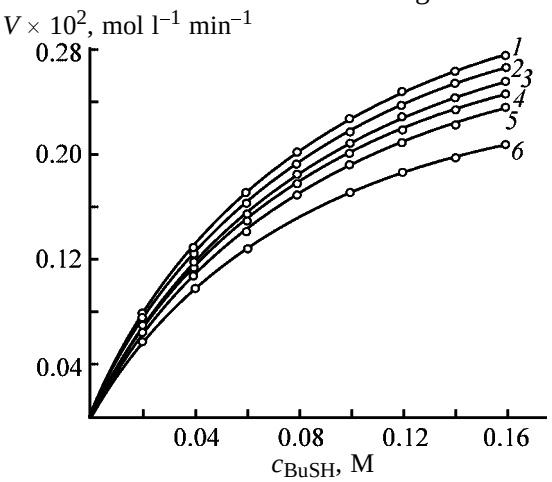

Fig. 4. BuSH oxidation rate V at varied unithiol concentration in the catalyst solution. Concentration, M: $BuSH_0$ 1.75×10^{-1} and $CuSO_4$ 1.25×10^{-6}. Unithiol concentration, M: (*1*) 1×10^2, (*2*) 5×10^3, (*3*) 3.5×10^3, (*4*) 2.2×10^3, (*5*) 1.5×10^3, and (*6*) 8×10^4.

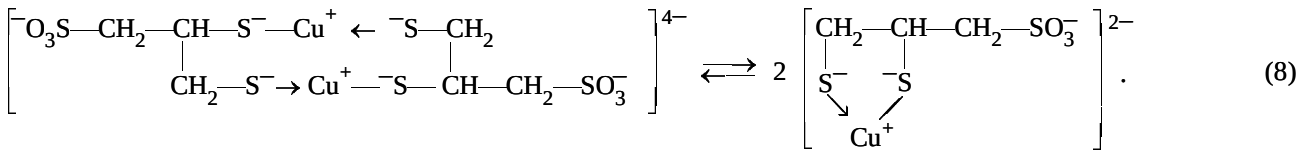
be seen that the reaction kinetics is described by the Michaelis equation [9, 10]

$$V = -\mathrm{d[RSH]}/\mathrm{d}t = V_{max}[\mathrm{RSH}]/([\mathrm{RSH}] + K_m), \quad (7)$$

where V is the reaction rate, [RSH] is the mercaptan concentration, and V_{max} and K_m are constants.

With increasing mercaptan concentration, the reaction rate does not grow unlimitedly, but tends to a value V_{max} reached at the highest concentrations of the catalytically active complex species. The physical meaning of the Michaelis constant K_m is as follows: If the mercaptan concentration is chosen to be [RSH] = K_m, then the reaction rate is equal to half the maximum possible value, i.e., $V = -\mathrm{d[RSH]}/\mathrm{d}t = V_{max}/2$. Such a dependence means that the reaction rate is limited by the concentration of the catalytically active complex species. Their concentration becomes the highest at mercaptan concentrations of about K_m, and then it no longer depends on the mercaptan concentration because of the saturation. Thus, this reaction is first-order at very low mercaptan concentrations and zero-order at a sufficiently high concentration. It is the latter case that occurs in catalytic oxidation of mercaptans in high-sulfur raw materials. Therefore, the quantity τ_1^{-1}, reciprocal of the time of conversion (e.g., 95% oxidation), can serve as a measure of the catalyst performance. Let us consider how the reaction rate depends on the concentrations of the catalyst components. The rate is virtually independent of the unithiol concentration in a wide range (Fig. 4). As for the dependence of the reaction rate on the copper(I) concentration, the situation is complicated by the following circumstance. As shown previously [6], the complex of copper(I) with unithiol exists in two forms, monomeric and dimeric, characterized by different catalytic activities. In the dimeric complex, the O_2 molecule is a bridging ligand, in which connection the steady-state concentration of the catalytically active oxygen-containing complex is higher for the dimeric form of the complex, compared to its monomeric form:



(8)

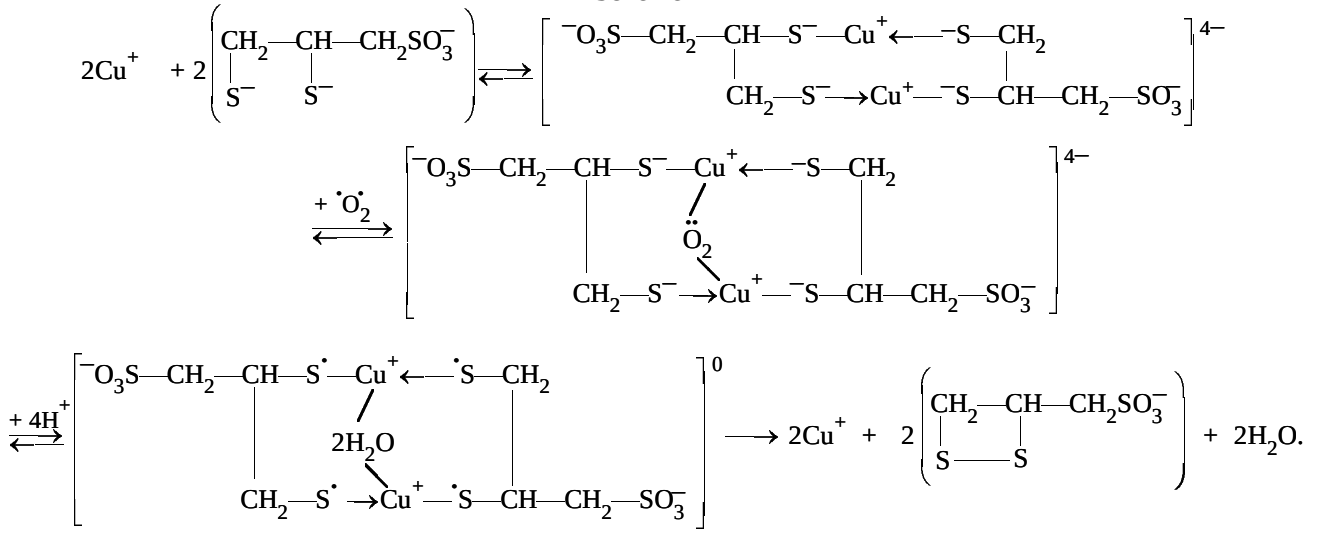
Therefore, the mechanism of oxidation of coordinated dimercapto compounds in such a dimeric complex differs from the scheme presented for the monomeric form of the complex: electrons pass from four thiolate anions to the bridging O_2 molecule, and water molecule, rather than the O_2^{2-} anion, is the reduction product in this case (Scheme 2). At low copper(I) concentrations, the reaction is first-order with respect to copper(I), since the dimeric complex is mainly dissociated; whereas at sufficiently high copper(I) concentrations the reaction order must be 0.5, i.e., the reaction rate is to be proportional to a square root of the copper concentration. It is this behavior that is observed experimentally (Fig. 5).

As shown by experiments, the oxidation rates of butyl and ethyl mercaptans are the same under comparable conditions, and that of the sulfide ion is half the oxidation rate of mercaptans, which would be expected since the sulfide ion loses two times greater number of electrons in oxidation, compared to the mercaptide ion. By contrast, in the presence of CoPC catalysts, high-molecular-weight mercaptans are oxidized more readily than low-molecular-weight mercaptans. For example, Co disulfophthalocyanine oxidizes butyl mercaptan 4.5 times faster than ethyl mercaptan, which, in turn, is oxidized several times faster than the sulfide ion. Moreover, in contrast to the kinetic characteristics of the DMC + Cu^+ systems, the reaction is first-order with respect to the catalyst and mercaptan concentrations [11].

In view of the fundamentally different kinetic characteristics of the catalysts compared, the time necessary for 95% oxidation of butyl mercaptan with the initial concentration of 0.2 M was chosen as a catalytic activity criterion.

Experiments demonstrated that butyl mercaptan is 95% oxidized in an alkaline solution at copper(I) and unithiol concentrations of, respectively, 5×10^{-6} and 5×10^{-4}–5×10^{-3} M in 35–40 min, whereas the industrial Co disulfophthalocyanine ensures the same conversion in 100 min at a concentration in solution of 5×10^{-6} M. With Co polyphthalocyanine, 95% conversion of butyl mercaptan into disulfide is reached in 20 min. It is noteworthy that the activity of the catalyst based on Cu^+ and dimercaptopropionic acid ensures the same conversion in 20 min. Thus, compar-

Scheme 2



ison of the activity of DMC + Cu^+ catalysts with that of the industrially used CoPC catalysts shows that the unithiol-based system is 2.5 times more active than Co diphthalocyanine and 1.5 times less active than Co polyphthalocyanine, and the system based on Cu^+ and dimercaptopropionic acid exhibits higher activity than Co polyphthalocyanine.

The above data on the catalytic activity are an important, but insufficient characteristic of the catalysts, since, at their close catalytic activities, of key importance for the effective industrial use of the catalysts must be their stability in alkaline solutions. That is why experiments were performed on prolonged keeping of the catalysts in a 10% NaOH solution, with periodic sampling to measure the dependence of the catalytic activity on the time of keeping of the catalyst solutions. The initial concentrations (M) of the catalysts compared were the same as those in industrial processes, i.e., 3×10^{-4} disulfophthalocyanine, 1.5×10^{-4} polyphthalocyanine, and 5×10^{-3} unithiol + 1×10^{-3} $CuSO_4$. The variation of the activity of the catalyst solutions with time is shown in Fig. 6. It can be seen that after 7 days the activity of the DMC + Cu^+, disulfophthalocyanine, and polyphthalocyanine catalysts decreased by, respectively, factors of 1.4, 17, and 60. After 2 weeks the respective figures were 2.5, 120, and 120. In subsequent sampling, the activity was only measured for the DMC + Cu^+ catalyst, to decrease 5-fold in 6 weeks, compared with that of a freshly prepared solution. Thus, it was established that the DMC + Cu^+ catalysts much better retain their

activity in prolonged storage in alkaline solutions than the CoPC catalysts do [12, 13].

It is known that CoPC catalysts cannot sustain elevated temperatures in alkaline solutions: their activity falls dramatically at 70–80°C. The DMC + Cu^+ catalysts show no changes in catalytic activity on being kept for 1 h in a 10% NaOH solution at 95°C and subsequent cooling of the solution to 20°C. The same result was obtained on heating a DMC + Cu^+ catalyst solution in a 20% diethanolamine solution at 107°C for 1.5 h.

It was of interest to test the capabilities of DMC + Cu^+ catalysts in a more intensive process involving purification of natural gas to remove hydrogen sulfide, with elemental sulfur obtained simultaneously. Most frequently, natural gas with high H_2S content (≥1.5%) is purified in the industry by intensive processes associated with preliminary H_2S absorption by ethanolamine solutions, subsequent desorption of H_2S from ethanolamine solutions at 120°C, and its oxidation in a flow of O_2 to elemental sulfur (Claus process). This technique has an important disadvantage, high sorbent loss of up to 100 g of ethanolamine per ton of natural gas. All other "wet" methods for H_2S oxidation do not compare in intensity with this process and can only be used at low H_2S content in natural gas (<0.5%), because Na_2CO_3 solutions should not be strongly saturated with hydrogen sulfide. Such a saturation could lead to predominant formation of thiosulfate and sulfate ions in the solutions, with the H_2S absorption capacity of the solutions decreasing in proportion to this accumulation [14]. Preliminarily, the oxidation of H_2S to polysulfides and elemental sulfur in sodium carbonate solutions in the presence of DMC + Cu^+ catalysts was studied and it was established that, in H_2S oxidation, elemental sulfur is not the only and even not the major reaction product. Indeed, experiments aimed to determine the stoichiometry of H_2S (1.5 M) oxidation in Na_2CO_3 solutions containing 2×10^{-3} M unithiol and 4×10^{-4} M Cu^+ demonstrated that elemental sulfur and thiosulfate ions are formed in a 1 : 4 molar ratio. The short-chain polysulfides formed in the catalytic stage react outside the coordination sphere of the complex with excess O_2 by the radical-chain mechanisms, finally yielding thiosulfate ions [15]:

$$HS^- + RSSR \rightleftarrows RSSH + RS^-, \quad (9)$$

$$RSSH \rightleftarrows RSS^- + H^+, \quad (10)$$

$$RSS^- + RSSR \rightleftarrows RSSSR + RS^-, \quad (11)$$

$$RSS^- + RSSSR \rightleftarrows RSSSSR + RS^-, \quad (12)$$

$$RSS^- + R(S)_7R \rightleftarrows R(S)_8R + RS^-, \quad (13)$$

$$R(S)_8R \rightarrow S_6\downarrow + RSSR. \quad (14)$$

The undesirable appearance of radicals can be prevented by introducing effective radical scavengers into the system. For example, 0.2–1 M ammonium thiosulfate and 0.03–3 M elemental sulfur are introduced, together with CoPC, into the absorbing solution. However, these measures ensure quantitative conversion of H_2S into sulfur at H_2S concentration in solution not exceeding 2×10^{-2} M in 3–20 min [16] and, therefore, cannot be used in processing of gases with high H_2S content. In the present study, an aminodisulfide, $(H_2NCH_2CH_2S–)_2$, cystamine, manufactured in Russia industrially, was used to effectively suppress radical-chain reactions in H_2S oxidation. Aminodisulfides are known to be, together with aminothiols, active scavengers of many kinds of radicals. Here, it should be emphasized once more that the oxidation of both mercaptans and hydrogen sulfide occurs in the thiol–disulfide reaction, including that with active short-chain polysulfides, rather than in the coordination sphere of the complex. Thus, it would be expected that, as a result of consecutive reactions, these active polysulfide species will be transformed into $R(S)_nR$ species, which are inert toward O_2. With the chain of sulfur atoms growing, as a result of these reactions, to $R(S)_8R$ or $R(S)_{10}R$, 6- and 8-membered sulfur rings are formed from them. Indeed, the presence in the absorbing solution of cystamine with concentration of 1–1.5 M, in addition to DMC + Cu^+, totally suppresses formation of oxygen-containing sulfur compounds in oxidation of 1.5 M S^{2-} with half-oxidation time of 6 min in the presence of 2×10^{-3} M unithiol and 4×10^{-4} g-ion l^{-1} Cu^+.

Thus, the system proposed ensures a two orders of magnitude more intensive process than that in the above-considered conventional technique with CoPC. Analysis for the content of thiosulfate ions in solutions shows that their concentration does not exceed 1%. The difficulty of analysis of thiosulfate ions in the presence of a large excess of cystamine gives no way of determining with sufficient accuracy in laboratory conditions how much less than 1% is the amount of thiosulfate ions formed in the system. This could be done reliably in experiments on a continuous pilot installation from the extent of preservation of the buffer capacity of the absorbing solution in the stage of H_2S absorption.

Calculations show that, if by-product thiosulfate ions are formed in amount less than 0.1%, the catalytic system developed is more attractive economically than separate ethanolamine treatment of natural gas to

remove H_2S with elemental sulfur subsequently obtained by the Claus method. An additional advantage of cystamine introduction into the catalytic system is that cystamine as a base can also be employed as an effective absorbent binding the H_2S acid from the gas flow, instead of using the conventional ethanolamine, and can perform, in the stage of catalytic interaction between H_2S and O_2, a second important function by suppressing the undesirable radical-chain reactions.

CONCLUSIONS

(1) New effective catalysts for oxidation of mercaptans and hydrogen sulfide are proposed, based on complexes of copper(I) with dimercapto compounds, which can be used in purification of the wide fraction of light hydrocarbons to remove mercaptans and in purification of natural gas to remove hydrogen sulfide, with elemental sulfur obtained simultaneously.

(2) A study of the kinetic characteristics of the new catalysts demonstrated that the catalytically active species in the practically important range of concentrations is the dimeric form, which binds more effectively an oxygen molecule in the coordination sphere of copper(I).

(3) In oxidation of H_2S to elemental sulfur, the undesirable formation of a by-product, thiosulfate ions, was suppressed by introducing cystamine into the catalyst solution, with the high intensity of catalytic oxidation of H_2S into elemental sulfur preserved.

Abstract—The effect of high-temperature steam treatment of high-silica zeolites of the ZSM-5 type on their acidity and selectivity of formation of lower olefins from straight-run naphthas was studied.

High-silica zeolites (HSZs) of the ZSM-5 type exhibit high activity in many transformations of hydrocarbons [1–4]; however, they are rapidly deactivated owing to active coking. The coking on the catalyst surface can be supressed by addition of special modifying components or appropriate pretreatment [5–13]. In this connection, it is advisable to study how the high-temperature steam treatment affects the acid and catalytic characteristics of HSZs of the ZSM-5 type in conversion of straight-run naphtha (SRN) to lower olefins and aromatic hydrocarbons.

EXPERIMENTAL

High-silica zeolites of the ZSM-5 type with silica modulus of 30 were produced by hydrothermal synthesis from alkaline aluminosilica gels by the procedure described previously [14]. The resulting samples of zeolites were decationized by treatment with 25% aqueous NH_4Cl at 90°C for 2 h, dried at 110°C, and calcined at 550°C for 8 h (Na_2O content less than 0.1%). As shown by IR spectroscopy and X-ray analysis (Mo anode, Ni filter), the synthesized zeolites correspond to HSZs of the ZSM-5 type with 90–95% degree of crystallinity. The coke amount in the samples was determined by thermal gravimetric analysis on an MOM derivatograph (Hungary). After completion of the catalytic experiments, the reaction products adsorbed on the catalyst surface were removed with a flow of gaseous nitrogen. The carbon-containing residue remaining on the catalyst surface under these conditions was considered as coke. After removal of adsorbed hydrocarbons with gaseous nitrogen, the reactor was cooled and the coked catalyst was discharged into a hermetically sealed vessel. A weighed portion of the catalyst sample was placed into a platinum crucible and heated in air at a rate of 10 deg min^{-1} with the simulatneous recording of the thermal and weight loss effects. The sensitivity of the derivatograph in the weight measurements was 5×10^{-4} g.

To study the influence of high-temperature steam treatment (HTST) on the acid and catalytic characteristics, the HSZ samples were subjected to high-temperature steam pretreatment at 550 and 700°C. The acid characteristics of HSZs were studied by thermal desorption of ammonia by the procedure described previously [15]. The catalytic characteristics of HSZs in conversion of SRN were studied on a flow-type installation [13]. As the initial hydrocarbon raw material we used SRN produced by the Surgut Gas-Processing Plant with the following composition: paraffins 56.89, naphthenes 32.76, and aromatic hydrocarbons 8.54% (here and hereinafter, wt %).

The results of studying the effect of HTST on the activity and selectivity of HSZs in conversion of SRN are listed in Table 1. With increasing reaction temperature from 500°C to 650°C at the space velocity of SRN of 3 h^{-1}, the degree of SRN conversion increases from 85 to 90%. With heating, the yield of lower olefins C_2–C_4 increases from 6.7 to 26.0%, and the yield of aromatic hydrocarbons, from 33.5 to 37.8%. The content of aromatic hydrocarbons C_6–C_9 in the liquid catalyzate at the pyrolysis temperature of 600°C is 88.3%. With increasing duration of HTST of HSZ at 550°C from 7 to 15 h, the yield of lower olefins in the products of SRN pyrolysis at 700°C abruptly increases to 40.9%. An increase in the temperature of

1-h HTST of HSZ from 550°C to 700°C results in decreased SRN conversion; however, the yield of lower olefins is 35.7% at the pyrolysis temperature of 700°C. An increase in the duration of HTST of the catalyst at 700°C to 6 h abruptly decreases the catalyst activity and the yield of lower olefins C_2–C_4. Apparently, prolonged action of steam on the catalyst sample partially destroys the crystal structure of zeolite.

Thus, the optimal condition of HTST of the catalyst is treatment of HSZ at 550°C for 15 h. Under these conditions, at the SRN pyrolysis temperature of 700°C and the space velocity of 3 h^{-1}, we obtained on HSZ 40.9% yield of lower olefins C_2–C_4, among them ethylene 15.2% and propylene 16.9%; the conversion of HSZ was 71% (Table 1). This behavior of HSZ subjected to HTST at various high temperatures and for a long time is caused by variation of the acid characteristics of the zeolite-containing catalysts. In this connection, we studied how HTST affects the acid characteristics of HSZs. The acid characteristics were evaluated by thermal desorption of ammonia.

Two forms of ammonia desorption are observed in the thermal desorption curve of the initial HSZ: low-temperature form I of ammonia desorption with the peak temperature T_{max} 194°C and high-temperature form II with T_{max} 406°C. The concentrations of acid centers are 623 and 526 μmol per gram of the catalyst, respectively (Fig. 1a, Table 2). High-temperature steam pretreatment of HSZ at 550°C for 7 h shifts the two peaks of ammonia desorption to lower temperatures and significantly decreases the concentration of acid centers: the low-temperature form I of ammonia desorption is characterized by the peak at T_{max} 179°C (289 μmol per gram), and high-temperature form II, by T_{max} 298°C (171 μmol per gram). The total concentration of acid centers in comparison with the initial HSZ decreases by a factor of 2.5. As the time of HTST of HSZ at 550°C is further increased to

Table 2. Effect of HTST on the acid characteristics of HSZ

Treatment conditions		T_{max}, °C		Amount of acid centers, μmol g^{-1}		
T, °C	τ, h	form I	form II	form I	form II	total
Initial HSZ		194	406	623	526	1149
550	7	179	298	289	171	460
550	15	165	295	170	62	232
700	1	174	290	138	93	231
700	2	155	290	155	69	224
700	6	179	260	87	55	142

15 h, both forms of ammonia desorption are shifted to lower temperatures, and the concentration of acid centers of both types decreases (Fig. 1a, Table 2).

The study of effect exerted by HTST of HSZ at 700°C on its acid characteristics showed that, as a result of treatment of the catalyst for 1 h, the concentration of acid centers, especially that of strong (Brønsted) acid centers [6, 8–9, 11], considerably decreases. On the contrary, weak (Lewis) acid centers are more resistant to HTST and are not destroyed even at prolonged HTST for 15 h and more (Fig. 1b, Table 2) [7, 12].

Thus, when the HTST temperature is increased to 700°C and HTST time, to 15 h and more, the strong Brønsted centers are destroyed, the strength and concentration of weak Lewis acid centers decrease, and, as a result, the selectivity of formation of lower olefins from SRN increases. It is advisable to perform HTST of zeolite-containing catalysts at a temperature not exceeding 550°C, since under these conditions strong acid centers transform to moderately strong Brønsted acid centers and the rates of aromatization and coke formation, proceeding actively on strong Brønsted acid centers, decrease. HTST of zeolite-containing catalysts at elevated temperatures results in hydrolysis of the Si–O–Al bonds and removal of aluminum from the zeolite skeleton (conversion into Al_2O_3) owing to dehydroxylation [16]. Variation of the selectivity of SRN conversion on zeolite-containing catalysts under the effect of HTST is caused primarily by removal of aluminum from cationic sites during HTST. This increases the selectivity of formation of C_2–C_4 olefins from SRN and decreases the rates of aromatization and coke formation.

The DTA of the samples after their operation in pyrolysis of SRN revealed an exothermic effect in the range 450–650°C with a clearly pronounced peak at 580°C and a high-temperature shoulder; this suggests a wide spectrum of coke deposits. The total weight of the coke deposit in the spent HSZ sample is 7.2%. As a result of HTST of HSZ, the weight of the coke deposit in the spent catalyst sample after pyrolysis of SRN decreases to 5.6%. The peak (T_{max}) in the DTA curve is shifted to lower temperatures (560°C), and an additional exothermic peak with a maximum at 330°C appears, i.e., a more "friable" low-temperature coke is formed in the course of SRN pyrolysis.

CONCLUSIONS

(1) Upon high-temperature steam treatment of high-silica zeoilites of the Pentasil type (ZSM-5), the acid centers in the zeolite are redistributed, which

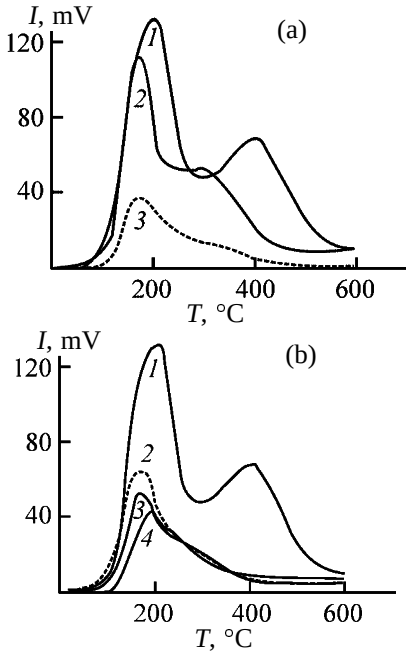

Fig. 1. Spectra of thermal desorption of ammonia. (*I*) Signal intensity and (*T*) temperature. (*1*) Initial HSZ; HTST time, h: (a) (*2*) 7 and (*3*) 17; (b) (*2*) 1, (*3*) 2, and (*4*) 6. Temperature of HTST, °C: (a) 550 and (b) 700.

results in predomination of weak Lewis acid centers over strong Brønsted acid centers.

(2) In pyrolysis of straight-run naphthas, high-temperature steam treatment of high-silica zeolites results in increased yield of lower olefins C_2–C_4 and decreased yield of aromatic hydrocarbons and coke deposits, formed more actively on strong Brønsted centers of the zeolite-containing catalyst.

Abstract—Mass exchange in absorbers having the form of fluid–gas jet apparatus with elongated mixing chamber is considered. An approach to calculation of the mass-exchange coefficients and gas absorption rate in a flow of a gas–fluid emulsion in the mixing chamber is proposed. Results obtained in industrial operation of the absorber are presented.

Use of jet apparatus with elongated mixing chamber as small-size absorbers seems to be promising for the modern industry [1, 2]. Absorbers of this kind can be used both for physical absorption and (most effectively) for chemisorption. In this case, engineering calculation of jet absorbers requires that, in addition to hydrodynamic parameters, mass-exchange characteristics (phase boundary area and mass-exchange coefficient) should also be calculated.

The phase contact surface is produced in a jet absorber as a result of mixing of flows of the working fluid (absorbent) and gas being sucked in and has the form of a gas–fluid emulsion or foam, depending on the volume content of the dispersed phase. In [1, 2], studies of dispersion and coalescence in fluid–gas jet apparatus with elongated mixing chamber for the water–air system were reported. On the basis of the results obtained, expressions were proposed for determining the area of the phase boundary formed via disintegration of gas bubbles by the fluid jet and for finding how this area changes upon coalescence in motion of a two-phase flow in the mixing chamber of the jet apparatus.

At the same time, there are no published data on mass transfer in jet apparatus with elongated mixing chamber, which could be used to calculate the mass-transfer coefficient. In view of this fact, the aim of this study is to propose expressions for determining the mass-transfer coefficient in absorption in a jet apparatus with elongated mixing chamber.

As is known, the mass-transfer coefficient is determined by the coefficients of mass transfer from the gas phase to the phase boundary and from the phase boundary to the fluid phase [3]. In absorption at small size of gas bubbles and developed turbulent flow of the fluid–gas emulsion, the main resistance to mass transfer is exhibited by the fluid phase since, for poorly soluble gases, the rate of molecule diffusion in a gas much exceeds that of molecules in the fluid. In this connection, the resistance in the gas phase is commonly neglected in calculating the mass-transfer coefficient under conditions of both physical adsorption and chemisorption, with the mass-transfer coefficient being approximately equal to the coefficient of mass transfer from the phase boundary to the liquid phase [3–5]. This coefficient, β_f, is commonly determined under turbulent flow conditions in terms of the Higby model accounting for the nonstationarity of the mass transfer [4, 5]:

$$\beta_f = 2(D_f/\pi t)^{1/2}, \quad (1)$$

where D_f is the molecular diffusion coefficient of the component being absorbed in the fluid phase ($m^2\ s^{-1}$), and t is the period of surface renewal (s).

As the surface renewal period t can be taken the time in which a bubble moves relative to the flow to a distance equal to its diameter. If the velocity of relative motion of a bubble in the flow is denoted by w, then the time of surface renewal can be found from the expression

$$t = d_b/w, \quad (2)$$

where d_b is the bubble diameter (m), and w is the relative velocity of bubble motion in the flow ($m\ s^{-1}$).

Substitution of (2) into Eq. (1) brings this equation to the form

$$\beta = 2(D_f w/\pi d_b)^{1/2}. \quad (3)$$

1070-4272/03/7601-0099$25.00

In the criterial form, expression (3) takes the form [5]

$$\mathrm{Sh} = 1.13\,\mathrm{Pe}^{1/2}, \quad (4)$$

where $\mathrm{Sh} = \beta_f d_b/D_f$ is the Sherwood number, and $\mathrm{Pe} = w d_b/D_f$ is the diffusion Peclet number.

The main difficulty in applying Eq. (4) to calculation of the mass-transfer coefficient consists in determining the velocity w of the relative motion of a bubble. This velocity in a turbulent flow can be found in terms of Kolmogorov's theory of isotropic turbulence. In this case, as relative motion velocity of particles of the dispersed phase in a flow is employed the difference of velocities of turbulent pulsations on the particle scale, $(w^2)^{1/2}$, found using the Kolmogorov–Obukhov "two-thirds rule" [6, 7] from the expression

$$w^2 = (\varepsilon_{fr} d_b/\rho)^{2/3}, \quad (5)$$

where ε_{fr} is the rate of energy dissipation in the mixing chamber of the jet apparatus (W m^{-3}), and ρ is the continuous phase density (kg m^{-3}).

For a cylindrical mixing chamber, the ε_{fr} value is defined as the rate of hydraulic loss of the flow energy for friction against pipe walls [1, 8]:

$$\varepsilon_{fr} = \lambda \frac{\rho v_m}{2D}, \quad (6)$$

where λ is the hydraulic friction coefficient; v_m, velocity of the two-phase flow in the mixing chamber (m s^{-1}); D, the mixing chamber diameter (m).

The hydraulic friction coefficient can be found for a two-phase flow from the known expressions [5, 9].

Mass transfer across the phase boundary from the gas phase to the fluid is described by the material balance equation [3]

$$G_g = -\beta_f F(c_f^* - c_f), \quad (7)$$

where G_g is the flow rate of the gas-phase component being absorbed (kg s^{-1}); F, the phase boundary area (m^2); c_f^*, the equilibrium concentration of the gas phase component in the fluid at the phase boundary (kg m^{-3}); c_f, the concentration of the gas-phase component in the fluid core (kg m^{-3}).

It has been noted [3, 4] that gas absorption is the most effective in the case accompanied by an irreversible instantaneous chemical reaction between the gas-phase component and absorbent, dissolved in a fluid. In this case, the concentration of the gas-phase component in the core of the fluid flow, c_f, is zero, and the driving force of the mass-transfer process is the highest. In this connection, calculation of jet absorbers for fast isothermal chemisorption is considered additionally in what follows.

In general form, the rate of mass transfer is defined by the differential equation

$$G_g = \frac{d V_g \bar{c}_g}{d\tau} = V_g \frac{d\bar{c}_g}{d\tau} + \bar{c}_g \frac{dV_g}{d\tau}, \quad (8)$$

where V_g is the volume of the gas being absorbed (m^3) and c_g is the concentration of the component being absorbed in the gas phase (kg m^{-3}).

Of interest for experimental verification of the appropriateness of the approach proposed are two extreme cases of the mass-transfer process: (1) gas mixture is 100% composed of gases that can be absorbed by the absorbent and (2) the absorbable gases constitute a lesser fraction of the mixture.

As shown in [1], absorption in a jet apparatus is a complex phenomenon involving simultaneously occurring processes of dispersion, coalescence, and mass transfer in a dispersed system. Coalescence leads to an increase in bubble size in the course of their residence in the mixing chamber of the jet apparatus, whereas mass transfer acts in the opposite direction. If the gas phase contains only absorbable gas, the rate of chemisorption is high. In this case, the change in the phase boundary area as a result of coalescence can be neglected and calculation can be done for the case of dissolution of a single gas bubble by the absorbent. In another case, when the gas phase contains a large amount of gases unabsorbable by the absorbent, the absorption rate should be calculated with account of the volume content of the gas phase in the emulsion.

In the first case, the concentration of the gas being absorbed within a bubble remains constant during the entire time of bubble dissolution in the fluid. The first term in Eq. (8) is zero, and the mass transfer from the gas phase into the fluid is accompanied by a change in the gas bubble volume:

$$G_g = \bar{c}_g \frac{dV_g}{d\tau}. \quad (9)$$

With the bubble assumed to be spherical, the decrease in the bubble volume by dV_g can be expressed via a decrease in its diameter by dd_b:

$$dV_g = V_{in} - V_{fin} = \frac{\pi d_b^3}{6} - \frac{\pi(d_b - dd_b)^3}{6}. \quad (10)$$

On the assumption that $d d_b$ is negligible as compared to d_b, expression (10) can be simplified to

$$dV_g = \frac{\pi d_b^2 d d_b}{2}. \quad (11)$$

Expressing the phase boundary area in (7) in terms of bubble diameter and using Eqs. (11) and (9), we obtain an equation relating the bubble diameter and the time of its residence in the absorbent:

$$\frac{d d_b}{d\tau} = -2\beta_f \frac{c_f^*}{\bar{c}_g}. \quad (12)$$

Substitution of the expression (3) for the mass-transfer coefficient brings Eq. (12) to the form

$$\frac{d d_b}{d\tau} = -2.26 (D w/d_b)^{1/2} \frac{c_f^*}{\bar{c}_g}. \quad (13)$$

Integration of Eq. (13) within the limits from d_b^0 to d_b and from 0 to τ yields

$$d_b = \left[(d_b^0)^{3/2} - \frac{3.39 (D w)^{1/2} \tau c_f^*}{\bar{c}_g} \right]^{2/3}, \quad (14)$$

where d_b^0 is the bubble diameter at the initial instant of time (m), and τ is the time of bubble residence in the absorbent (s).

Expression (14) defines the running diameter of a single bubble composed of an entirely absorbable gas as a function of the time of its contact with the absorbent. The time of total dissolution of a gas bubble is given by

$$\tau = \frac{(d_b^0)^{3/2} \bar{c}_g}{3.39 (D w)^{1/2} c_f^*}. \quad (15)$$

The study demonstrated that the sizes of gas bubbles in gas–fluid emulsions are not the same, being described by the corresponding particle size distributions. In determining the time necessary for gas to be absorbed in polydisperse emulsions, the maximum bubble size d_{max}, which is stable against the action of turbulent pulsations in emulsion, should be used in (15) as d_b^0. In accordance with experimental data, the maximum bubble diameter is proportional to the volume surface mean diameter and can be found using the formula [10]

$$d_{max} = C d_{32}^0, \quad (16)$$

where C is the proportionality coefficient.

According to [10], the coefficient C was found to vary within the range 1.47–2.63 in a study of fluid emulsions in stirred vessels. In a study of dispersion and coalescence in a jet apparatus, the average value of C was 1.5 [1, 2].

The volume surface mean diameter d_{32}^0 of bubbles formed at the initial instant of time in disintegration in the mixing chamber of the jet apparatus can be found from the expression [1, 2]

$$d_{32}^0 = 1.05 \frac{\sigma^{3/5}}{\rho^{1/5} \varepsilon^{2/5}} (1 + 9\varphi), \quad (17)$$

where σ is the surface tension (N m^{-1}); ε, the rate of energy dissipation in the initial part of the mixing chamber (W m^{-3}); φ, the volume gas content of the emulsion.

The rate of energy dissipation can be found from the expression [1, 2]

$$\varepsilon = \frac{\rho v^3 d^2}{10 D^3} (1 - d^4/D^4), \quad (18)$$

where v is the fluid jet velocity at the nozzle exit (m s^{-1}), and d is the nozzle diameter (m).

In the case when the concentration of the component being absorbed from the gas phase is low, the volume of the gas phase in a unit volume of the emulsion is virtually constant and the second term in Eq. (8) can be neglected. The mass transfer, which is accompanied by a change in the concentration of the component being absorbed in the gas phase, is given by

$$G_g = V_g \frac{d \bar{c}_g}{d\tau}. \quad (19)$$

Substitution of (19) into (8) gives the material balance equation

$$\frac{d \bar{c}_g}{d\tau} = -\beta_f \frac{F c_f^*}{V_g}. \quad (20)$$

The quantity F/V_g, which determines the ratio of the phase boundary area to the gas phase volume, is the specific phase boundary area for the gas phase and is related to the volume surface mean diameter d_{32} by

$$F/V_g = 6/d_{32}. \quad (21)$$

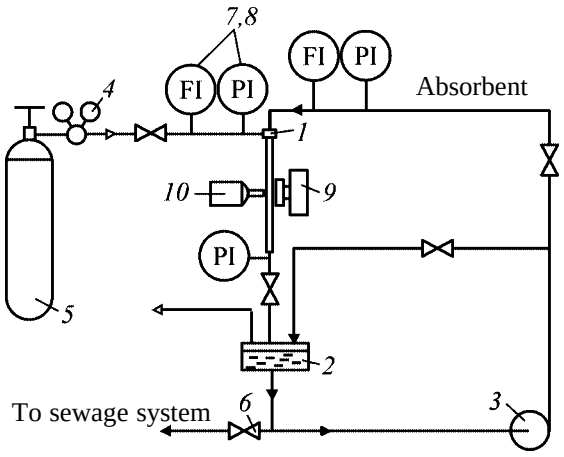

Fig. 1. Schematic of the experimental setup. For explanations, see text.

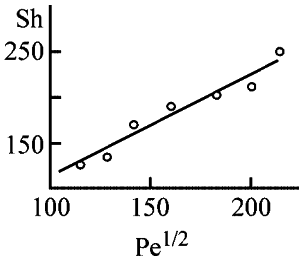

Fig. 2. Mass transfer in a system constituted by CO_2 and 3% aqueous solution of NaOH in the form of a criterial dependence $Sh = f(Pe^{1/2})$.

At a considerable volume content of gas in the emulsion, the phase boundary area decreases with time as a result of coalescence. In this case, the quantity d_{32} in expression (21) varies with the time of bubble residence in the apparatus in accordance with the dependence suggested in [1]:

$$d_{32} = d_{32}^0\left[1 + K_{\text{eff}}\frac{\varphi^{1/2}(\varepsilon_{\text{fr}}/\rho)^{1/3}\tau}{(d_{32}^0)^{2/3}}\right]^{3/2}, \qquad (22)$$

where K_{eff} is the coefficient of collision efficiency (for the water–air system, $K_{\text{eff}} = 0.014$ [1]).

Thus, in calculating the residence time of bubbles in the mixing chamber that would be sufficient to reduce the concentration of the gas being absorbed to a prescribed level, Eq. (20) is to be solved for τ together with expressions (3), (5), and (22).

To verify the validity of our approach to calculation of mass exchange in jet absorbers, we performed experiments on chemisorption of a totally absorbable gas.

EXPERIMENTAL

Experiments were performed on a setup shown schematically in Fig. 1. The setup comprises a vertical jet apparatus *1* with changeable nozzles and changeable elongated cylindrical glass mixing chamber, tank *2* for the working fluid (absorbent) with a cooling jacket, and a centrifugal pump *3*. The pipe for gas supply into the apparatus is connected through a pressure reducer *4* to a cylinder *5* with compressed CO_2. The flow rates of fluid and gas are controlled with valves *6* in the fluid and gas pipelines. The flow rate and pressure of the flows of the working fluid and gas being ejected are monitored with rotameters *7* and pressure gages *8*. To record bubble sizes, the setup is equipped with a photographic camera *9* and a synchronized flash-lamp *10*.

The setup described was used in a study of absorption in a jet apparatus with elongated mixing chamber. A vertical jet apparatus had a nozzle 6 mm in diameter and a glass mixing chamber with the diameter of 10 mm and length exceeding 35 chamber diameters. A 3% aqueous solution of NaOH served as working fluid (absorbent), and pure CO_2, as the phase being absorbed. The gas content of the emulsion in the experiments did not exceed 0.1. The bubble size was determined by taking photographs at the main part of the mixing chamber at a distance of 50 to 800 mm from the nozzle exit.

The photographs taken were used to determine the volume surface mean diameter of bubbles. With the flow velocity in the mixing chamber known, the residence time of bubbles in the absorbent and experimental values of the mass-transfer coefficient were calculated from the variation of bubble sizes with time, using expression (12). The diffusion coefficient was calculated by the Arnold formula [3, 4].

The results of experiments on mass exchange in a jet absorber are represented by points in Fig. 2 in the form of a criterial dependence $Sh = f(Pe^{1/2})$. The solid line shows the data obtained by calculation with expressions (4)–(6). The results of the experiments are described by expression (4) with the maximum deviation of ±10%. The rather good agreement between the experimental and calculated data demonstrates the applicability of our approach to calculation of the mass-transfer coefficient in jet apparatus with elongated mixing chamber under chemisorption conditions in terms of the Higby model, with averaged difference of the velocities of turbulent pulsations on the bubble scale used as the relative velocity of bubble motion.

The results of the experiments demonstrated that, for the largest CO_2 bubbles to dissolve, it suffices that the mixing chamber length should be 1 m at a velocity of the two-phase flow in the mixing chamber equal to 1.5 m s^{-1}.

Our results allow calculation of the geometric dimensions of absorbers based on jet apparatus with elongated mixing chamber. A hydrodynamic calculation can be done to determine the optimal size (diameter) of the nozzle and the mixing chamber and to choose the optimal flow rates of the fluid and gas phases and the injection coefficient with the use of expressions proposed for calculation of hydrojet pumps [11, 12]. The parameters obtained are used as input data for a mass-exchange calculation, which, carried out using expressions proposed in [1, 2], yields the phase boundary area and, with expressions (15) and (20), the residence time sufficient for total absorption of a noxious gas or for lowering its concentration in the discharge to below the maximum permissible concentration. The residence and the flow velocity in the chamber can be used to determine the length of the mixing chamber, which may have smooth cylindrical or stepped shape.

The results obtained were employed to design a jet absorber used in an industrial installation for purification of gas discharges formed in synthesis of ethyl α-bromoisovalerate. The installation comprises a jet apparatus, a tank for absorbent, and a centrifugal pump. The jet apparatus, which is made of fluoroplastic, has a nozzle *1* of diameter 16 mm and an elongated cylindrical mixing chamber *2* of diameter 38 mm and length 800 mm (Fig. 3). The exit from the mixing chamber is turned by 90° with respect to the axis of the mixing chamber to create a counterpressure.

The chemical reactions occurring in synthesis of ethyl α-bromoisovalerate yield hydrogen chloride, hydrogen bromide, and sulfur dioxide. In addition, the heating in the course of the reaction leads to evaporation of minor amounts of the reactants and liquid reaction products, which are also noxious. The purification of gas discharges is carried out continuously during the entire synthesis process. The degree of purification of gas discharge at the apparatus outlet is about 99.9%, which conforms to the sanitary regulations.[1]

[1] The absorption installation based on a jet apparatus with elongated mixing chamber, described in this communication, has been working at Altaivitaminy Private Company (Biisk) since 1997.

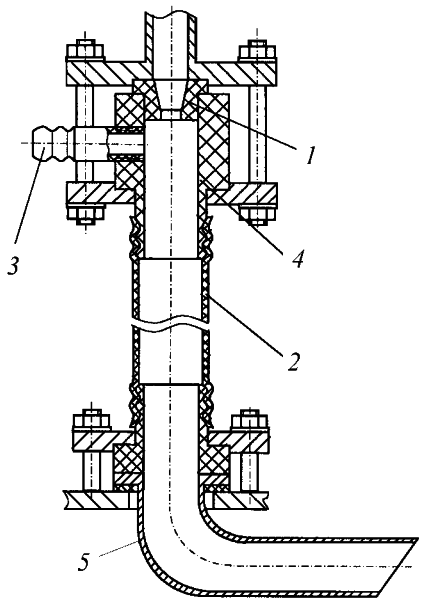

Fig. 3. Diagram of jet apparatus with elongated mixing chamber: (*1*) nozzle, (*2*) mixing chamber, (*3*) gas feed pipe, (*4*) receiving chamber, and (*5*) drain tube.

CONCLUSIONS

(1) An approach to calculating mass exchange in absorption in jet apparatus with elongated mixing chamber is suggested.

(2) Expressions for calculating the absorption rate are suggested.

(3) The expressions have been verified experimentally under conditions of chemisorption of a totally absorbable gas.

(4) An absorption installation based on a jet apparatus with elongated mixing chamber has been designed and put into industrial service.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparative Synthesis of Functionally Substituted Esters of 1-Adamantanecarboxylic Acid

N. G. Kozlov, E. A. Dikusar, and V. I. Potkin

Institute of Physical Organic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

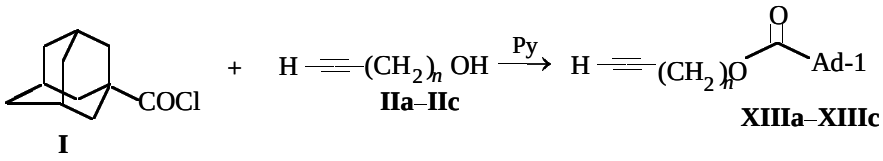
Received July 2, 2002

Abstract—A procedure was developed for preparing 1-adamantanecarboxylic acid esters functionally substituted in the alcoholic moiety.

Compounds of the adamantane series exhibit high and diverse biological activity. Effective drugs based on adamantane have been developed, such as Midantane, Memantine, Gludantan, Remantadine, and Adapromine [1]. Some of adamantane derivatives exhibit antiviral, curare-like, myorelaxing, anti-choline esterase, psychostimulating, neurotropic, and local anesthetic activity [2]; compounds with a high surface activity were also found [3]. The main synthetic route to adamantane derivatives involves chemical modificatiomn of substituents in the hydrocarbon framework. Nitrogen-containing adamantane derivatives have been studied most comprehensively [4, 5].

One of promising routes to new adamantane-containing biologically active compounds is preparation of esters. In this case, it is possible to combine in one molecule an adamantane moiety with other functional groups, e.g., aromatic, acetylenic, or bicyclic [6].

Here we report on a new convenient route to functionally substituted esters of 1-adamantanecarboxylic acid, involving the reactions of 1-adamantylcarbonyl chloride **I** with alcohols **II**–**XII** in diethyl ether in the presence of pyridine [7]. Esters **XIII**–**XXIII** are formed under mild conditions (room temperature). No prolonged stirring, heating, or precipitation is required; the reactants can be mixed in any order. The reaction, performed in sealed vessels, is complete in 24–36 h; the yield of esters is 65–83%.



I **IIa**–**IIc** **XIIIa**–**XIIIc**

Primary alcohols (**IIa**–**IIc**, **IX**), secondary alcohols (**III**–**VIII**), and phenols (**X**–**XII**) are readily esterified with chloride **I**. Dihydric phenols **X** and **XI** form momoesters only, even at the reactant ratio **I** : (**X** or **XI**) = 3 : 1. Tertiary alcohols (e.g., 2-methyl-2-propanol or 2-methyl-3-butyn-2-ol) do not form the corresponding esters even under severe conditions (prolonged refluxing in dioxane at 100–102°C in the presence of pyridine).

1-Adamantanecarboxylic acid esters are colorless viscous liquids (**XIIIa**, **XVb**, **XVI**) or crystalline substances (**XIIIb**, **XIIIc**, **XIV**, **XVa**, **XVII**–**XXII**); their characteristics are listed in the table.

The IR and NMR spectra of the synthesized esters are consistent with their structure. The IR spectra contain stretching vibration bands of the C=O (1727 ± 5; for **XXIII**, 1742 cm^{-1}) and C–O (1225 ± 15 and 1070 ± 15; for **XXIII**, 1290 and 1155 cm^{-1}) groups. The spectra of acetylenic derivatives **XIIIa**–**XIIIc** and **XIV** also contain absorption bands at 3280 ± 25 (≡C–H) and 2150 ± 15 cm^{-1} (C≡C). Aromatic esters **XXI**–**XXIII** exhibit C–H absorption bands at 3090, 3070, 3030 ± 5; 858, 777, 767, and 680 (**XXI**); 830 and 800 (**XXII**); 865 and 785 cm^{-1} (**XXIII**), and also the bands belonging to the aromatic ring at 1604 and 1487 (**XXI**); 1600 and 1511 (**XXII**); 1601, 1593, and 1509 cm^{-1} (**XXIII**). The spectra of phenols **XXI** and **XXII** contain O–H absorption bands at 3375 (**XXI**) and 3445 cm^{-1} (**XXII**), and also C–OH bands at 1065 ± 5 cm^{-1}. The IR spectrum of aromatic methoxy aldehyde **XXIII** contains the bands of the HC=O (1697 cm^{-1}) and C–O–C (1110 cm^{-1}) groups.

The ^1H NMR spectra of all the esters **XIII**–**XXIII** contain multiplets at 1.6 (6H), 1.9 (6H), and 2.1 ppm (3H), typical of 1-substituted adamantane derivatives. Compounds **XIIIa**–**XIIIc** and **XIV** containing terminal acetylenic groups also give a proton signal at 2.0–2.4 ppm. The CH_2O proton signals in the spectra of **XIIIa**–**XIIIc** and **XX** are observed at 4.1 ppm, and in esters **XV**–**XIX** derived from alicyclic alcohols the α-CH proton in the alcoholic residue gives a signal at 4.7–4.9 ppm. The spectra of these esters also contain signals characteristic of cyclohexane (**XV**), menthane [**XVI**; a doublet of the C^1–CH_3 protons at 0.74 ppm (^3J 1.6 Hz) and a doublet of two methyl groups in the isopropyl substituent at 0.94 ppm (^3J 6.7 Hz)], and camphane [**XVII, XVIII**; singlets of three methyl groups at C^1 (0.8 ppm) and C^7 (1.0 ppm) atoms]. The aryl protons in **XXI**–**XXIII** are manifested at 6.4–7.5 ppm. Also, the spectrum of **XXIII** exhibits a CHO singlet at 9.9 ppm and an OCH_3 singlet at 3.9 ppm.

EXPERIMENTAL

The IR spectra were recorded on a Protege-460 IR Fourier spetrophotometer (Nicolet) from thin films (**XIIIa**, **XVb**, **XVI**) or KBr pellets. The ^1H NMR spectra were recorded on a Tesla BS-567A spectrometer (100 MHz) from 5% solutions in $CDCl_3$, with TMS as internal reference.

The molecular weight was determined by cryoscopy in benzene.

* Numerator, d_{20}^{20}; denominator, n_D^{20}.

Column chromatography was performed with neutral alumina, Brockmann grade II.

1-Adamantanecarboxylic acid chloride **I** was prepared by refluxing 1-adamantanecarboxylic acid with a 1.5-fold excess of $SOCl_2$ in benzene [5].

1-Adamantanecarboxylic acid esters XIII–**XXIII**. Anhydrous pyridine (3.5 mmol) was added to a solution of 3 mmol of chloride **I** and 3 mmol of alcohols or phenols **II**–**XII** in 70 ml of absolute diethyl ether. The mixture was slightly shaken and allowed to stand at 18–23°C for 24–36 h. The precipitate of pyridine hydrochloride was filtered off and washed with 30 ml of diethyl ether; the combined filtrates were washed with water and saturated aqueous solution of sodium hydrogen carbonate. The ether solution was dried over $CaCl_2$, the solvent was distilled off, and the residue was dried in a vacuum. Ethers **XIIIa**, **XVb**, and **XVI** were purified by column chromatography on Al_2O_3, eluent hexane. Compounds **XIIIb**, **XIIIc**, **XIV**, **XVa**, and **XVII**–**XXIII** were purified by low-temperature crystallization from hexane.

CONCLUSIONS

(1) Functionally substituted primary and secondary alcohols and phenols are readily esterified under mild conditions with 1-adamantanecarboxylic acid chloride in the presence of pyridine.

(2) Dihydric phenols form monoesters only; tertiary alcohols do not undergo esterification.

Received July 2, 2002

Abstract—Oxidation of sulfides with hydrogen peroxide to sulfoxides and then sulfones was studied. The conditions optimal for the formation of sulfoxides and sulfones were found.

Oxidation of sulfides with hydrogen peroxide is a widely used synthetic route to sulfoxides and sulfones [1]. Although sulfoxides are readily oxidized further to sulfones, under definite conditions the reaction can be stopped at the stage of sulfoxide formation. Oxidation of sulfides to sulfoxides occurs at relatively low temperatures and in short time. The second stage, oxidation of sulfoxides to sulfones, requires higher temperatures and longer time. Sulfones can be prepared both by direct oxidation of sulfides and by oxidation of sulfoxides. In some cases, the latter route is preferable, since each oxidation stage can be performed under optimal conditions; as a result, higher yield and purity of the target product can be attained [2].

In this work we studied oxidation of dimethyl sulfide (DMS), tetramethylene sulfide (TMS), and petroleum sulfide concentrate (PSC) with hydrogen peroxide to the corresponding sulfoxides and oxidation of these sulfoxides to sulfones.

EXPERIMENTAL

The reaction mixtures were analyzed by GLC with a Tsvet 4-67 chromatograph [flame ionization detector; 2100 × 4-mm column; stationary phase 10% polyethylene glycol succinate on Chromaton N-AW-HMDS, 0.2–0.25 mm fraction, washed with water and treated with hexamethyldisilazane; carrier gas nitrogen, GOST (State Standard) 9293–74]. The stationary phase used retains water and allows determination of the nonaqueous oxidation products [3]. Analysis conditions: column temperature 140–180°C, vaporizer temperature 200–240°C, carrier gas flow rate 40–60 ml min^{-1}, sample volume 0.1–0.2 μl. The component contents were determined by internal normalization of the peak areas using benzene as reference. The absolute determination error was 0.4% at a confidence level of 98%.

The oxidation products of petroleum sulfides cannot be analyzed chromatographically because of the low thermal stability of petroleum sulfoxides and high boiling temperature of the sulfone concentrate obtained from them. Therefore, the content of sulfoxide sulfur in the oxidation products was determined by nonaqueous titration of the product with a solution of $HClO_4$ in dioxane [4], and the content of sulfones, by IR spectroscopy, from the intensity of the absorption band of the sulfone stretching vibrations at about 1320 cm^{-1} [5]. The concomitant compounds, mainly sulfoxides, do not absorb in this range. Also, the content of sulfonic and carboxylic acids was determined by potentiometric titration [6].

Oxidation was performed as follows. A flask was charged with a required amount of the starting compound and heated to a required temperature, after which H_2O_2 was added. The mixture was heated at the prescribed temperature with vigorous stirring. The instant of H_2O_2 addition was considered as the reaction start. After the reaction completion, the flask was cooled, and samples of the product were taken. The content of H_2O_2 in the oxidation products was determined by titration with a $KMnO_4$ solution [7]. To each sample we added MnO_2 to decompose the unchanged H_2O_2 and terminate oxidation. After that, the sample was filtered and analyzed.

Hydrogen peroxide was used as 27.5% (here and hereinafter, wt %) aqueous solution [GOST (State Standard) 177–88]. TMS and DMS were 98 and 99.5% pure, respectively. The sulfide concentrate was recovered from the 260–360°C fraction of Arlan crude oil

[8]; it contained 8.8% sulfide sulfur and 12.8% total sulfur and had the average composition $C_{14.5}H_{27.0}S$.

In experiments on oxidation of DMS to dimethyl sulfoxide (DMSO), we examined the influence of temperature and H_2O_2 : DMS ratio on the yield of reaction products (Table 1). Oxidation was performed at 0.5 and 10°C. The very low boiling point of DMS (37.2%) caused certain problems. Since the reaction is exothermic, even at 10°C it is necessary to take special measures to prevent evaporation of DMS in the initial oxidation stage. In the range 0–10°C, the temperature affects the product composition insignificantly; the yield of DMSO is fairly high. The major influence on the product composition is exerted by the H_2O_2 : DMS molar ratio. When this ratio is as low as 0.7–0.8, the products contain a large amount of unchanged DMS, and dimethyl sulfone (DMSF) is absent. At the H_2O_2 : DMS molar ratio increased to 1.1–1.2, DMS is fully consumed and DMSF appears. This fact suggests the consecutive mechanism of DMSF formation via DMSO. The product obtained by oxidation of DMS is a transparent aqueous solution. To isolate DMSO, the oxidation product was heated at reduced pressure (30–40 mm Hg) on a water bath (40–50°C) to remove water, after which DMSO was distilled in a vacuum (bath temperature 72–82°C, 10–15 mm Hg). The purity of the distilled DMSO was 99.6%, bp 189°C, n_D^{20} 1.4785, d_4^{20} 1.1000.

Found, %: C 30.82; H 7.62; S 41.01.

C_2H_6OS. Calculated, %: C 30.76; H 7.69; S 41.02.

Oxidation of DMSO to DMSF was studied at 40, 60, and 80°C (Table 2). The H_2O_2 : DMSO molar ratio was varied from 1.1 to 1.3, and the oxidation time, from 10 to 30 min. The oxidation product obtained under the above conditions was evaporated at 700 mm Hg to remove about 30–40% of water. Then the oxidation product was cooled to 5°C to crystallize dimethyl sulfone. The crystals were separated, re-

crystallized from water, and dried in a water-jet-pump vacuum. The resulting DMSF is a colorless crystalline substance readily soluble in organic solvents; purity 99.8%, mp 109°C, bp 238°C.

Found, %: C 25.59; H 6.36; S 34.02.

$C_2H_6O_2S$. Calculated, %: C 25.53; H 6.38; S 34.04.

Oxidation of TMS to tetramethylene sulfoxide (TMSO) was studied at 20, 40, and 60°C (Table 3). These data show that, after oxidation for 1 h at 20°C, the content of DMSO in the dehydrated oxidation products was 94%, and after oxidation for 3 h it reached 97%. The content of TMSO after oxidation for 1 h at 60°C was 98%. Thus, oxidation of TMS to TMSO occurs with a high rate. At all the examined temperatures, the formation of TMSO is virtually complete in 1–3 h. Oxidation occurs in a two-phase system and is accompanied by a large heat release in a short time. The reaction mixture undergoes autocatalytic self-heating, which results in intense decomposition of excess H_2O_2. Therefore, H_2O_2 was added gradually to maintain its optimal concentration in the mixture in the course of the process.

The oxidation product obtained by oxidation of TMS under the above conditions is a single-phase transparent colorless aqueous solution. To isolate TMSO, the oxidation product was treated with MnO_2 to remove residual H_2O_2, heated at reduced pressure (30–40 mm Hg) to remove water (bath temperature 40–50°C), and vacuum-distilled (bath temperature 140–160°C, vapor temperature 85–100°C, residual pressure 3–5 mm Hg).

Tetramethylene sulfoxide is thermally unstable. Its loss in the course of distillation was evaluated from the decrease in the content of sulfoxide sulfur. The average loss of sulfoxide sulfur is 3%, which corresponds to 10% loss of TMSO. Under the optimal conditions, the yield of TMSO is 89–91%. The purity of the distilled product is 99.6%, bp 45°C (3 mm Hg), n_D^{20} 1.5203, d_4^{20} 1.1816.

Found, %: C 45.72; H 7.83; S 30.5.

C_4H_8OS. Calculated, %: C 46.1; H 7.7; S 30.8.

Oxidation of TMSO to tetramethylene sulfone (TMSF) was performed at 60, 70, 80, 90, and 100°C (Table 4). The reaction occurs in the homogeneous system with a lower heat effect and at a lower rate than oxidation of TMS to TMSO. After oxidation for 8 h at 60°C, the content of TMSF in the dehydrated oxidation product was 60%, and after oxidation for 10 h, 88%. After oxidation for 5 h at 80°C, the content of TMSF was as high as 99%. The optimal oxidation temperature is 80–90°C. To attain a high yield of TMSF, H_2O_2 should be taken in a 35% excess. The product obtained by oxidation of TMSO under these conditions is an aqueous solution containing 35–40% TMSF, 60–50% water, and 4–7% impurities. Tetramethylene sulfone is infinitely miscible with water, forms no binary azeotrope with water, and strongly differs from water in the boiling point. However, TMSF cannot be isolated from the oxidation products by common distillation, since it is thermally unstable and starts to decompose at temperatures above 170°C, forming in the presence of oxygen acidic compounds and condensation products. According to analyses, the oxidation product always contaions residual H_2O_2, which promotes decomposition of TMSF in the course of distillation to acetic and sulfuric acids. Therefore, prior to distillation, the oxidation product was treated with 6% aqueous alkali to decompose H_2O_2, after which it was fractionated on a 2–3-TP batch distillation column; the temperature in the still was 100°C, and the residual pressure, 20 mm Hg. TMSF was isolated from the oxidation product in 96% yield and was 99.7% pure.

We also examined the possibility of recovering TMSF from the oxidation product by extraction with organic solvents. The extractant should selectively recover TMSF with minimal extraction of impurities; it should be sparingly soluble in water and should also meet such general requirements as availability, stability under regeneration conditions, and low cost [9]. The best suited are aromatic hydrocarbons, in particular, benzene. Study of the phase equilibria showed that, in extraction of TMSF from the oxidation product with benzene, the separation of TMSF from impurities is fairly efficient; the impurities mostly remain in the aqueous phase. Under the optimal extraction conditions (benzene : oxidation product weight ratio 2.4 : 1, 25°C, six extraction steps), the recovery of TMSF from the oxidation product is 94–96%. Distillation of benzene from the extract was performed at 200 mm Hg. The energy consumption for distillation of benzene from the extract is much less than that for distillation of water from the oxidation product (because of considerably higher heat capacity and heat of vaporization of water).

Tetramethylene sulfone obtained by this procedure is a colorless hygroscopic solid (at room temperature) with pleasant odor, soluble in water, ethanol, benzene, acetone, and other organic solvents; the product purity

Oxidation of PSC to sulfoxides was performed at 80, 90, and 100°C (Table 5). With increasing temperature, products with SO_3H and COOH groups are actively formed, and the PSC oxidation rate grows. For example, as the temperature is increased from 80 to 100°C, the acidity of the aqueous phase obtained after oxidation for 15 min grows from 0.9 to 2.6 g KOH l^{-1} and the content of sulfoxide sulfur in the oxidation product increases by a factor of 2. The sulfonic and carboxylic acids that are formed effectively catalyze oxidation of sulfides to sulfoxides, as demonstrated by the example of PSC oxidation in the presence of butane-, hexane, and *p*-toluenesulfonic acids and CH_3COOH. Oxidation of PSC in the presence of sulfonic and acetic acids occurs with a higher yield of sulfoxides than oxidation on the presence of only one of these acids [10]. Sulfones appear in the oxidation product only after conversion of the major fraction of sulfides to sulfoxides, whereas acids are formed already in the very first minutes of oxidation simultaneously with sulfoxides. After oxidation, the aqueous and hydrocarbon layers were separated. The hydrocarbon layer (sulfoxide concentrate) was neutralized with an Na_2CO_3 solution, washed with an Na_2SO_4 solution, and kept under reduced pressure (80–100 mm Hg) to remove emulsified and dissolved water.

The composition of the dehydrated sulfoxide concentrate was determined with a Finnigan Type 4021 gas chromatograph–mass spectrometer (the United States). Because of the low thermal stability of sulfoxides, it was impossible to analyze the sulfoxide concentrate directly. Therefore, the sulfoxides were preliminarily reduced to sulfides with HI [11]. The chromatograms and total mass spectra of the initial sulfides used to prepare sulfoxides and of sulfides obtained by back reduction of sulfoxides proved to be identical. Hence, oxidation of sulfides is not accompanied by structural changes. The sulfoxide concentrate from the 260–360°C fraction of Arlan crude oil mainly consists of heterocyclic sulfoxides, in particular, 15–18% monothiacycloalkanes, 38–40% dithiacycloalkanes, 23–25% trithiacycloalkanes, and 18–20% tetrathiacycloalkanes.

The sulfoxide concentrate also contains unoxidized sulfides, substituted thiophenes, and hydrocarbons.

The sulfoxide concentrate is a viscous oily liquid of light yellow color with a weak characteristic odor; it is soluble in the majority of organic solvents, and the solubility in water is 7.8 g l^{-1}. The glass transition point is –67°C. The product starts to decompose at 120–140°C. The sulfoxide sulfur content is 7.4%, and the total sulfur content, 11%; n_D^{20} 1.5092, d_4^{20} 1.0195, *M* 267; $C_{12.8}H_{24.7}SO_{1.3}$.

The dependence of the content of sulfones in the oxidation product as influenced by the amount of acid catalysts and time of oxidation of sulfoxides to sulfones was studied at 100°C (Table 6). It was found that, in the absence of catalysts, the oxidation is slow. The presence of acids in the reaction medium also leads to increased yield of sulfones. As in oxidation of PSC, in the presence of a mixture of acids the reaction rate and the yield of the target product increase. For example, when oxidation of the sulfoxide concentrate to sulfones is performed for 5–7 h in the pres-

ence of CH_3COOH and H_2SO_4, the yield of sulfones increases to 95–97%. After oxidation in this mode, the aqueous acid layer was separated after settling for 30 min. The oxidation product was washed with water to remove traces of acids, dried in a water-jet-pump vacuum, and vacuum-distilled (1 mm Hg, bath temperature 110–165°C).

The composition of the resulting sulfone concentrate was studied by mass spectrometry. The sulfone concentrate is a mixture of various thiacycloalkane 1,1-dioxides, aromatic sulfides, and alkylthiophenes; it is a brown viscous liquid with a specific petroleum odor, readily soluble in organic solvents and virtually insoluble in water; n_D^{20} 1.4814, d_4^{20} 1.0312, total sulfur content 12.4%, sulfoxide sulfur absent, *M* 298, average composition $C_{12.0}H_{22.6}SO_{2.4}$.

CONCLUSION

The yield of sulfoxides and sulfones in oxidation of sulfides and sulfoxides, respectively, with hydrogen peroxide was studied in relation to the reaction temperature, time, and substrate : H_2O_2 ratio. Formation of sulfoxides occurs under milder conditions and at considerably higher rates than formation of sulfones.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Lightfastness of Polymeric Color Filters with Metal-Containing Dyes and Heterocyclic Azo Dyes as Absorbing Agents

Abstract—Color filters containing in the cellulose acetobutyrate matrix a combination of a metal-containing organic dye and an azo dye derived from thiophene or furan were prepared, and their lightfastness was studied.

Polymeric film color filters are widely used in modern optical devices and well compete with glass filters, being light, elastic, convenient in service, and cheap. However, in the lightfastness they are inferior to glass filters prepared, as a rule, using inorganic salts and metal oxides. Therefore, one of major problems in development of film color filters is the choice of the most lightfast dye formulations. In this case, either available dyes with a high lightfastness are used, which is not always possible, or dyes enhancing the lightfastness of each other are combined.

Yellow-orange dyes are used in color filters most widely, both as absorbing agents in cutting filters and as additives to blue, green, and red dyes for suppressing "parasitic" transmission in the blue range. Such dyes include monoazo dyes derived from five-membered heterorings: pyrazole, thiophene, furan, etc. The lightfastness of these dyes, taken separately, in various polymeric matrices and their photodecomposition in binary mixtures with triphenylmethane, anthraquinone, and azo (derived from benzene) dyes were studied previously [1–4]. In this work, we studied mixtures of monoazo dyes of the thiophene and furan series with metal-containing green and green-blue dyes.

Among numerous azo dyes of the thiophene and furan series, we chose anthranilic acid and *m*-xylidine derivatives **I**–**IV** as the most and the least lightfast dyes, respectively [1, 2], and among hydrophobic metal-containing dyes, Alcohol-Soluble Blue Z (C.I. 74350) (**V**) and iron complexes of 1-nitroso-2-naphthol (**VI**), 1,2-naphthylenediamine (**VII**), and 1,2-anthracenediamine (**VIII**):

Color filters were prepared on the cellulose acetobutyrate base (film thickness 0.15 mm). To obtain the required spectral characteristic, we studied the spectra of the dyes in the solvent (chloroform : acetone, 85 : 15 by volume) and calculated the required concentrations of the dyes in the film, taking into account the thicknesses of the cell and film. We prepared 8 films with individual dyes **I**–**VIII** and 16 films with combinations of one of dyes **I**–**IV** with one of dyes **V**–**VIII**.

The lightfastness of dyes in films containing individual dyes and their combinations was studied in an installation for accelerated photochemical aging. Samples were irradiated with a xenon lamp whose spectrum is the most similar to the spectrum of solar light. The total irradiation time was 10 h; during this period, we monitored photochemical degradation of dyes by recording at regular intervals (15 and 30 min; 1, 2, 3, ..., 10 h) the electronic absorption spectra of the film against the colorless cellulose acetobutyrate film sample irradiated under the same conditions.

As analytical wavelength we chose λ_{max} of the dye absorption. In films with binary dye formulations, we first measured the optical density at the analytical wavelength of the metal-containing dye and then calculated the optical density originating from the heterocyclic azo dyes as the difference between the measured optical density at the analytical wavelength of the yellow component and the optical density at the same wavelength, generated by the metal-containing dye. Then we calculated separately the degrees of photodegradation (PD, %) of the yellow (azo dyes derived from thiophene and furan) and blue-green (metal-containing dyes) components:

$$\mathrm{PD} = \frac{D_0 - D_t}{D_0} \times 100\%,$$

where D_0 is the optical density of the nonirradiated sample at the analytical wavelength and D_t is the optical density at the same wavelength after irradiation for time t.

Data on photodegradation of films containing individual dyes and their binary mixtures were analyzed to reveal the effect of the dyes on the lightfastness of each other. For this purpose, we determined the difference ΔPD in photodegradation of the dye in the individual (PD_i) film and binary formulation (PD_f):

$$\Delta\mathrm{PD} = \mathrm{PD_i} - \mathrm{PD_f}.$$

Photodegradation of individual yellow monoazo dyes derived from thiophene and furan was studied previously [4]. Data on the photodegradation of dyes after irradiation for 1 h are compared in Tables 1 and 2. This irradiation time allows comparison of our data on the metal-containing dyes with available data for other dyes [2–4].

Table 1. Photodegradation of azo dyes **I**–**IV** in cellulose acetobutyrate films using mixtures of dyes **I**–**IV** with metal-containing dyes **V**–**VIII** (irradiation for 1 h)

Dye	PD	ΔPD
	%	
I + **V**	21.1	+2.9
I + **VI**	17.3	+6.7
I + **VII**	16.0	+8.0
I + **VIII**	20.2	+3.8
II + **V**	92.0	–3.0
II + **VI**	16.2	+72.8
II + **VII**	29.9	+59.1
II + **VIII**	42.1	+46.9
III + **V**	12.8	+2.2
III + **VI**	16.0	–1.0
III + **VII**	3.0	+12.0
III + **VIII**	8.1	+6.9
IV + **V**	62.0	+8.0
IV + **VI**	7.8	+62.2
IV + **VII**	52.1	+17.9
IV + **VIII**	60.3	+9.7

These data allow the following conclusions.

(1) The lightfastness of azo dyes derived from thiophene and furan, as a rule, increases when these dyes are used in combination with metal-containing organic dyes. The effect of metal-containing dyes is more pronounced with less lightfast dyes derived from *m*-xylidine. The lightfastness of dyes derived from anthranilic acid, which are more resistant to photochemical degradation, increases also but to a lesser extent. It is advisable to use dyes based on *m*-xylidine in combination with **VI**, and dyes based on anthranilic acid, in combination with **VII**.

(2) Metal-containing organic dyes **V**–**VIII**, when taken separately, exhibit considerably higher lightfastness than heterocyclic dyes; when used in combination with azo dyes, dyes **V**–**VIII** exhibit either the same (dye **V**) or still higher lightfastness. It is interesting that this variation of the lightfastness is independent of the structure of the azo dye added (Table 2). Most probably, this is due to the fact that all the metal-containing dyes studied degrade photochemically

Table 2. Photochemical degradation of metal-containing dyes **V**–**VIII** in acetobutyrate films containing individual dyes **V**–**VIII** and their binary mixtures with azo dyes **I**–**IV** (irradiation for 1 h)

by the reductive mechanism and, being oxidants, stabilize azo dyes [2]. Also, in the case of iron quinonimine complexes **VII** and **VIII**, heterocyclic azo dyes, probably, additionally coordinate with the iron atom, which stabilizes both dyes.

Thus, binary mixtures of heterocyclic azo dyes and metal-containing organic dyes are good absorbing agents for polymeric film color filters, since they enhance the lightfastness of each other. In preparing a filter with required spectral characteristics, it is always possible to choose a pair of dyes ensuring the maximal lightfastness of the filter.

EXPERIMENTAL

Heterocyclic monoazo dyes were prepared by procedures described in [1], and dyes **VI**–**VIII**, according to [5–7]. Commercially produced Alcohol-Soluble Blue Z dye (Blue for Nitrolacquer) was purified by column chromatography on silica gel, eluent ethanol.

Polymeric film color filters on cellulose acetobutyrate base were prepared by casting the polymeric formulations containing appropriate dyes onto polished glass with a restricting frame determining the filter size [4].

The lightfastness of color filters in the polymeric matrix was studied in a Standard Xenon Long-Life Fade Meter XFL-1 installation for accelerated photochemical aging [2]. The progress of photodegradation was monotored spectrophotometrically at the analytical wavelength with an SF-16 spectrophotometer. The spectra were recorded against a colorless acetobutyrate film irradiated under the same conditions.

CONCLUSION

To obtain lightfast band color filters on polymeric film base, it is advisable to attain the required spectral characteristic by using metal-containing hydrophobic green-blue dyes in combination with monoazo dyes derived from thiophene and furan.

ACKNOWLEDGMENTS

The study was performed within the framework of the project supported by the program “Scintific Research of Higher Schools in Priority Fields of Science and Engineering,” section 203.02 (P-06.015).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Comparative Study of Intercalation of Zero-Valent Silver into the Cellulose Matrix by Raster and Transmission Microscopy

Abstract—Diffusion–reduction interaction between microcrystalline cellulose and aqueous solution of $AgNO_3$ was studied in the absence (taking into account the reducing properties of cellulose) and in the presence of specific reductants. The resulting intercalates of cellulose and zero-valent silver were examined by raster and transmission electron microscopy. The morphological changes in cellulose after intercalation of silver nanoclusters as well as the nanocluster size distribution in the cellulose matrix were characterized.

Electron microscopy is widely used to study the structure of natural materials such as wood and cellulose [1]. Cellulose interaction with various agents starts under heterogeneous conditions on its surface and causes changes in the chemical structure of cellulose and/or in the supramolecular structure of cellular membranes. This leads subsequently to structural modification of the entire fiber [2].

Our recent studies concerned preparation and properties of new metal-containing derivatives of microcrystalline cellulose (MCC) [3–7]. Examination by raster electron microscopy (REM) showed that the cellulose morphology substantially changed when its sodium, potassium, and lithium derivatives were obtained [3, 4]. REM examination also clearly demonstrated that intercalation of clusters of zero-valent metals (silver, platinum, palladium) into the cellulose matrix also led to changes in the cellulose morphology. The intercalation procedure affects the cluster distribution on the fiber surface. The use of transmission electron microscopy (TEM), a direct method making it possible to observe the inner fiber structure, allowed evaluation of the size and distribution of nanosize clusters not only on the sample surface but also in the bulk [5, 6].

It has been shown [7] that, in cellulose samples containing silver clusters obtained by various methods, the silver content on the surface [data of X-ray photoelectron spectroscopy (XPS)] appreciably exceeds that in the bulk [data of elemental and X-ray fluorescence analysis (XFA)]. After intercalation, the chemical composition of samples changes, with the decrease in the carbon content corresponding to increase in the silver content.

In this work, using REM and TEM, we made a comparative study of the initial MCC and the MCC samples containing silver nanoclusters (cellulose–Ag), with the aim to elucidate in detail the changes in the cellulose fiber morphology upon intercalation of silver clusters and to characterizate the cluster size and size distribution in the fiber bulk.

EXPERIMENTAL

Raster electron microscopy. Micrographs were obtained with a Leitz/AMR 1200B raster electron microscope at 15 kV. The samples were placed in a special chamber on aluminum supports coated with carbon and were subjected to spraying in an argon atmosphere using a gold–palladium target. Raster microscopy was carried out in combination with energy dispersive X-ray spectral analysis, which was performed with the same microscope equipped with a Kevex 7000 X-ray spectrometer. For this analysis, the samples placed on carbon-coated aluminum supports were used without spraying. The electron beam was focused on the chosen object or point, and measurements were carried out at different magnifications at 25 kV for 300 s.

* no. 1, initial MCC; nos. 2-10, cellulose-Ag samples; no. 11, Ag^0 sample.

MCC and cellulose–Ag intercalates were dried with water–ethanol mixtures with increasing content of ethanol. Then they were placed in a standard spurr epoxy resin and heated at 70°C. Ultrathin sections were placed on carbon-coated nets and examined with a Zeiss EM 10C transmission electron microscope equipped with an amplifier at 80 kV.

Some characteristics of cellulose–Ag samples are listed in Table 1. The morphological structure of MCC obtained from cotton cellulose (CC) somewhat differs from that of the initial CC. Thus, the main structural element of CC is a fiber having the shape of a strongly twisted ribbon [8]. The main structural element in its inner part is the primary wall. Cellulose of this wall forms thin fibrils visible under the polarizing microscope or after dyeing with certain dyes.

Fig. 1. REM micrographs of MCC sample (sample no. 1): (a) general fiber view, magnification 5000; (b) butt part, magnification 3000.

Fibers located in the primary wall form a typical surface relief with a helical fibrillar structure. This relief is retained in MCC (Figs. 1a, 1b, sample no. 1) and can be clearly seen at high magnification. Fibers 10–20 mm in diameter form long flexible bands. At low magnification, MCC bands have the shape of short rodlike particles tending to aggregate.

When MCC is obtained by mild acid hydrolysis of natural cellulose, its main part (over 90 wt %) does not dissolve in the hydrolyzing mixture, and the unit cell of crystalline cellulose is neither destroyed nor changed [9]. The surface relief of cellulose probably changes after its hydrolysis and subsequent drying, leading sometimes to fibril aggregation. However, the fibers themselves look swollen and porous, which is especially pronounced in their inner craters (Fig. 1b).

Silver intercalation into the cellulose matrix proceeds in two stages [5]: diffusion of the aqua complex $[Ag(H_2O)_2]^+$ into the cellulose matrix and reduction of silver ions to zero oxidation state. These stages mostly occur simultaneously. Cellulose itself exhibits reducing properties because of the presence of terminal aldehyde groups. Therefore, ionic silver can be reduced to zero-valence state without adding specific reductants. Sample no. 2 obtained in this way contains a very small amount of Ag^0. Nevertheless, it is sufficient to change markedly its morphological structure

as compared to that of the initial cellulose. Large cracks appear on the fiber surface and on butt ends. Inner voids swell and become deeper, and large pores with the diameter ranging from 0.1 to 1.0 μm can be observed inside the fiber (Fig. 2a).

The reaction medium strongly influences the reducing power of cellulose. Sample no. 3 obtained in aqueous ammonia contains more Ag^0 on the fiber surface than sample no. 2. However, the amount of Ag^0 is still small and cannot be visualized by electron-microscopic examination.

Temperature also exerts a pronounced effect on the redox reaction of cellulose with Ag(I). The reducing power of cellulose increases after its preliminary heating at high temperatures. Cellulose heating at 250°C (sample no. 4) (Fig. 2b) increases the amount of Ag^0 but considerably alters the morphological structure, which is due to degradation of inner layers of MCC fibers. Fibers degrade in the transverse direction. Many small fibers appear and their shape changes: the length-to-width ratio is close to unity (Fig. 2b).

At combined effect of elevated temperatures and complexing medium, the effect of Ag^+ reduction with the cellulose matrix becomes still more pronounced. For example, the Ag^0 content on the surface of a sample obtained in aqueous glycerol medium at heating to high temperatures is 12.5 wt %, and that in the bulk is 6.1 wt % (sample no. 5). Aggregations of light-colored particles located on the MCC fiber surface (Figs. 3a–3c) are agglomerates of giant silver clusters. The cluster distribution on the surface where their concentration is high is irregular (Fig. 3a). The presence of voids and a large number of thin pores in butt fiber parts (with the diameter ranging from 0.02 to 0.2 μm) suggests that specifically these voids and pores facilitate penetration of reagents inside the fibers (Fig. 3b). The energy-dispersive X-ray analysis of the sample confirms the presence of silver in fibers (Fig. 3c) [7]. Silver clusters are strongly bound to the fiber surface. Their amount does not decrease after repeated washing with hot water. Silver agglomerates formed on the surface of MCC fibers during reduction were compared with the surface of a model sample of metallic silver powder obtained by reduction of $AgNO_3$ with sodium borohydride $NaBH_4$ (in the absence of cellulose) (sample no. 11, Fig. 3d). This comparison shows that they belong to different morphological types and the morphological elements on the surface of silver powder in the model sample are much larger than those in sample no. 5.

If the reaction takes place in aqueous glycerol medium in the presence of 1,10-phenanthroline (a competing ligand), giant silver clusters are obtained in sample no. 6 (Figs. 4a and 4b). Their concentration on the surface of MCC fibers is 4.1 wt %, and that in the bulk is 3.0 wt %. Globular silver particles and large silver agglomerates can be seen (Fig. 4a). They are strongly bound to the fiber and are not removed from the surface even after washing with hot water. Considerable additional fiber splitting is observed (Fig. 4b), and a system of pores 0.2–0.6 μm in diameter appears inside the fibers (Fig. 4b, lower right corner).

(a–c) REM and (e, f) TEM micrographs of cellulose–Ag sample no. 5 and (d) sample no. 11 (metallic silver powder): (a) general fiber view, magnification 2000; (b) butt part, magnification 5000; (c) energy-dispersive X-ray analysis of silver particle distribution on the fiber surface; (d) magnification 5000; (e) fiber cross section, magnification 60000; and (f) longitudinal fiber cross section, magnification 14400.

Table 2. Characteristics of silver clusters [10–12]

Sample color	Plasmon line in the diffuse reflection spectrum, λ, nm	Number x of silver atoms in clusters Ag_x	Cluster size
Yellow	440–480	3–11	Small
Reddish-brown	480–490	11–22; 1000	Small; giant
Red	490–500	3000	Giant
Purple-red	500–580	5000	″
Green	590–605	5000–10 000	″
Grey	–	> 10 000	Giant; colloidal particles

The amount of reduced silver and the size of the resulting silver clusters in the cellulose matrix strongly depend not only on the reductant type, reaction temperature, and reaction medium but also on the procedures of sample washing and subsequent drying. Some published data on the relationship between the number x of silver atoms in Ag_x clusters, on the one hand, and sample color and wavelength λ in the diffuse reflection spectrum of silver clusters [10–12], on the other hand, are given in Table 2. These data, in combination with the results listed in Table 1, suggest that intercalation results in formation of giant silver clusters as major silver species in the cellulose matrix. Moreover, the color of many samples after reduction corresponds to that of small silver clusters, but after drying the samples become darker. Cluster growth is evidently initiated by the temperature effect during sample drying. For example, sample no. 2 having a low silver content is yellow immediately after reduction but becomes grayish-green after drying. In other words, the resulting sample contains a mixture of silver clusters of different size ranging from very small to giant.

(a) (b)

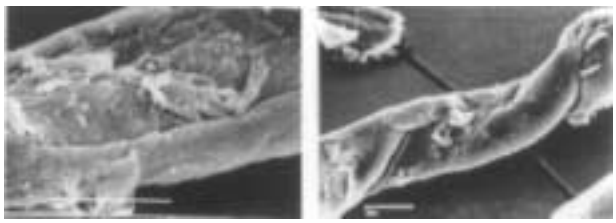

Fig. 5. REM micrographs of cellulose–Ag sample no. 8. Magnification: (a) 2900 and (b) 1600.

The use of specific reductants gives MCC samples with a high Ag^0 content both on the fiber surface and in the bulk. The largest amount of reduced silver in cellulose samples was obtained with $NaBH_4$ or KH_2PO_2 used as reductants.

With $NaBH_4$, only small silver clusters were obtained in the cellulose matrix (Table 1, sample no. 7). The amount of intercalated silver attains 4.9 (elemental analysis) or 5.3 wt % (XFA). Repeated reduction with $NaBH_4$ leads to additional growth of silver clusters and to the appearance of large cluster agglomerates on the surface (Fig. 5a, sample no. 8). The sample surface and fiber ends swell, and fibers additionally degrade. The cracks and breaks formed are parallel to fibril direction (Fig. 5b).

When KH_2PO_2 was used as a reductant, a sample with a high silver content on the surface (16.5 wt %) was obtained (Fig. 6a, sample no. 9). Giant silver clusters were formed. A strong destructive effect was detected on butt ends of greatly swollen fibers (Fig. 6b). The inner surfaces of voids also markedly swell and stick together. This probably prevents penetration of reagents inside the fibers. Helical fibers also appear. A similar effect has already been observed in cotton fluff nitration [2].

With hydroquinone as reductant, 3.4 wt % of Ag^0 with the average silver content of 300 atoms per cluster is intercalated into the cellulose matrix in the first stage (sample no. 10) [7]. As the reduction proceeds further, cluster continues to grow, with its size reaching 1000 and more atoms. When the reaction is complete, subsequent cooling and drying lead to the closure of butt end passages (Fig. 7a). Silver clusters are weakly bound to the fiber surface. Thorough washing causes their complete removal. The surface relief (Fig. 7b) resembles that of the cellulose sample subjected to thermal treatment. Regular crack distribution after silver removal probably indicates that clusters (before their removal) were regularly distributed in fibers. The distance between cracks is a multiple of 10, being mainly 10 or 20 μm. These data confirm previous results, which indicate that cellulose fibers contain periodical structural elements formed by a fibrillar ribbon twisted in a helix [13]. A similar pattern, as indicated by REM, is observed in cellulose nitration [2].

When viewed under a transmission electron microscope, fibers of the initial MCC have a shape of cross sections. The presence of Ag^0 clusters in fibers of cellulose–Ag intercalates was first visualized by us using TEM (Figs. 3e, 3f, 4c, 6c).

The micrographs of sample no. 5 (Figs. 3e, 3f) show spherical silver particles distributed relatively regularly in the sample bulk. This distribution is retained regardless of the method of fiber preparation for microscopic examination (Fig. 3e, fiber section transverse to its axis; Fig. 3f, fiber section along the axis). Large agglomerates of silver clusters are also located on the fiber surface. These conclusions agree with data obtained by REM and XPS. The histogram of numerical size distribution of silver clusters obtained by statistical processing of micrographs has a single maximum, i.e., the distribution is unimodal (Fig. 8). The calculation based on the histogram of the root-mean-square diameter distribution of silver clusters d_s shows that most of the clusters have the diameter less than 30 nm. The area occupied by silver clusters in the fiber section is about 4% of the total section area. It was established that the cluster distribution in these fibers exhibits certain regularity. The greatest number of clusters is on the surface. With increasing distance from the surface, it gradually decreases, with this decrease being described by a hyperbolic function.

Figure 4c shows the transverse section of fiber of sample no. 6. In contrast to sample no. 5, the distribution of silver clusters is irregular and bimodal

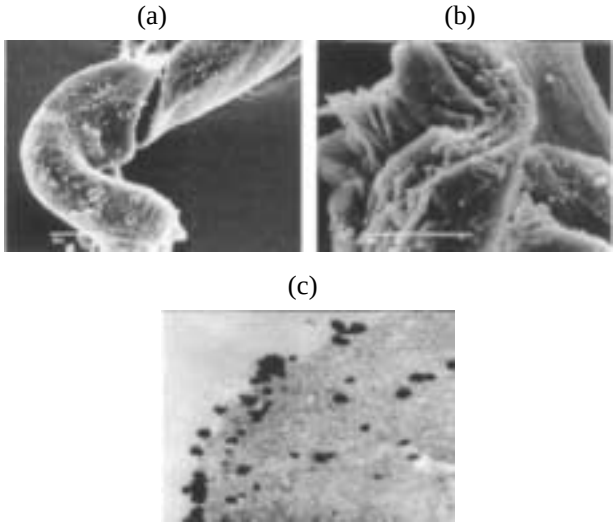

Fig. 6. (a, b) REM and (c) TEM micrographs of cellulose–Ag sample no. 9. Magnification: (a) 3000, (b) 2000, and (c) 60000.

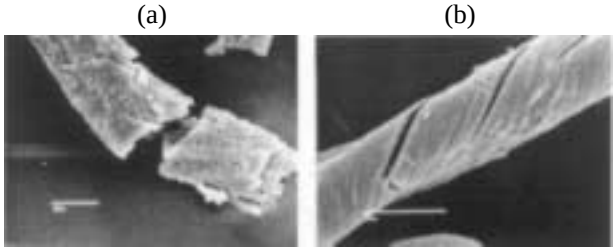

Fig. 7. REM micrographs of cellulose–Ag sample no. 10. Magnification: (a) 1600 and (b) 2600.

with the maxima corresponding to d_s 10 and 60 nm (Fig. 9). The silver content in the fiber bulk is smaller than in sample no. 5, which agrees with analytical data. The area occupied by silver clusters is 1.5% of the total cross-sectional area.

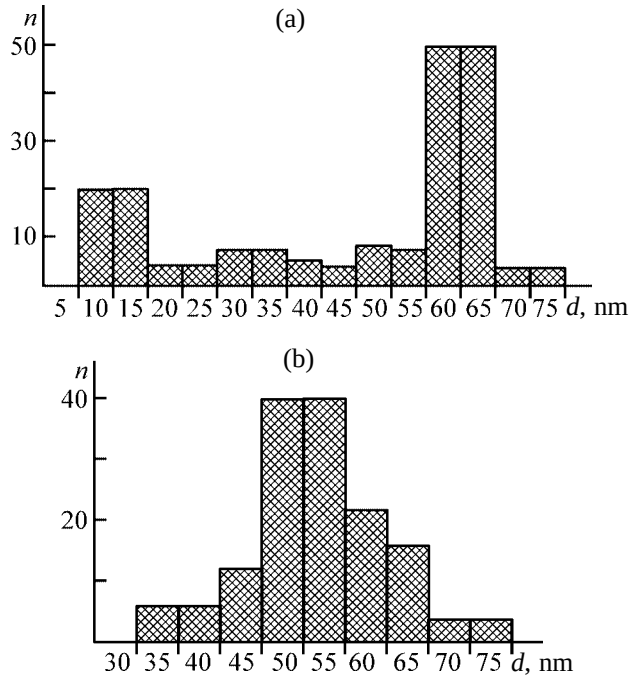

Fig. 9. Histograms of numerical silver cluster size distribution in cellulose–Ag samples according to TEM data. Sample no.: (a) 6 and (b) 9. For designations, see Fig. 8.

Silver clusters in sample N 9 (Fig. 6c) are large and are also concentrated both on the surface (16.5 wt %) and in the fiber bulk (7.6 wt %). In some places on the surface they form giant agglomerates. The cluster distribution is unimodal. However, it is not so regular as that in sample no. 5 (Fig. 8), and the average cluster size is 1.5–2.0 times greater (Fig. 9b). The d_s value for the maximum number of clusters is 48–58 nm. The area occupied by them in the fiber cross section is 5.1% of the total cross-sectional area.

Thus, the observed silver clusters in the samples have different sizes but can be characterized as nanoclusters. Note that the resolution of the transmission microscope used in this study does not allow observation of clusters smaller than 1 nm. Smaller clusters probably also exist in the samples. However, it may be assumed that the histograms reflect the real distribution patterns.

It should be emphasized that the use of high-resolution TEM allowed the first observation of intercalated silver nanoclusters directly in the cellulose matrix bulk and the characterization of their size and size distribution. The use of mutually complementing REM and TEM methods also furnished detailed information about changes in the MCC morphology accompanying intercalation of silver clusters. The main changes are observed on the surface of MCC fibers, because diffusion of reagents and reduction of silver ions occur under heterogeneous conditions. Thus, on the surface the texture changes: fibrils become disordered, reconstructed, and in some cases the surface becomes completely smooth. In many cases fibers become curved and twisted. Moreover, REM examination furnished additional information about inner fiber layers. Intercalation leads to the degradation of these layers, making the inner surface open. The butt ends of fibers are often open for observation, and thin pores appearing as a result of chemical processes can be seen.

CONCLUSIONS

(1) The diffusion–reduction interaction of microcrystalline cellulose with aqueous $AgNO_3$ solutions directly in the cellulose matrix and in the presence of $NaBH_4$ and KH_2PO_2 reductants was studied by REM and TEM, which allowed visualization of intercalation of zero-valent silver nanoclusters into the cellulose matrix.

(2) Morphological changes in cellulose both on the fiber surface (fibril disordering and crack formation) and in the inner layers (distribution of inner voids and appearance of a pore system) were compared and characterized.

(3) Nanocluster sizes and their distribution in the matrix were characterized; it was shown that these parameters depend on the reduction conditions and on particular reductant.

Abstract—IR and X-ray photoelectron spectra of the products of chemical carbonization of polyvinylidene fluoride were recorded and discussed.

Synthesis of high-quality carbyne which is a unidimensional modification of carbon is an urgent problem. These are several chemical methods for preparing carbynoid materials[1] in the form of powders, fibers, or films [1]. One of the simplest procedures for preparing carbynoid materials is chemical dehydrohalogenation of some halogen-containing polymers [1]. To determine the prospects for practical application of carbynoids, their structural stability and properties should be studied.

In this work the dehydrofluorination products of polyvinylidene fluoride (PVDF) films were studied by IR and X-ray photoelectron (XPE) spectroscopy. We studied two sample series chemically treated under different conditions. The first series was obtained by treatment of the initial PVDF films at room temperature for a time from 2 min to 2 h with a mixture of a saturated ethanolic solution of potassium hydroxide (20%) and acetone in a 1 : 9 volume ratio. The samples of the second series were treated for a time from 10 min to 16 h with a mixture of saturated ethanolic solution of potassium hydroxide and tetrahydrofuran (THF) in a 2 : 3 ratio. Then the samples were successively washed with ethanol, acetone, and water. No additional treatment was performed.

The IR absorption spectra were recorded in the range 400–4000 cm^{-1} at room temperature on a double-beam Specord 75-IR spectrometer. The standard spectrometer error in the ranges 400–2000 and 2000–4000 cm^{-1} is ±1 and ±2 cm^{-1}, respectively. The shapes of the spectra are well reproduced. In the far IR region (400–1200 cm^{-1}), we failed to record the IR spectra owing to strong absorption of C–F bond at the film thickness of about 0.1 mm.

The X-ray photoelectron spectra were recorded on an ES IFM-4 spectrometer [2]. Two coaxial cylindrical coils producing magnetic filed with required configuration along the photoelectron beam were used as the energy analyzer. The transmission energy was 320 eV. The residual pressure in the vacuum chamber was no higher than 10^{-9} mm Hg. Photoelectrons (E 1486.6 eV) were excited with Al$K_{\alpha_{1,2}}$ radiation.

The IR spectra of the partially dehydrofluorinated PVDF films of the first series are shown in Fig. 1, and those of the initial PVDF film and the films of the second series, in Fig. 2. The shape of the spectra in the 1500–4000 cm^{-1} range strongly depends on the treatment time, with the spectral transformations being more pronounced after prolonged dehydrofluorination. This may be due to a change in the concentration of the double carbon–carbon bonds (1500–1800 cm^{-1}) [1, 3], water molecules (1700, 3400 cm^{-1}) [4], CH bonds (2900–3100 cm^{-1}) [3], hydroxy groups (3000–3700 cm^{-1}) [5, 6], and HF molecules (3000–4000 cm^{-1}) [5]. In addition, the absorption in the range 2200–3700 cm^{-1} increases after the treatment.

The fact that the band in the range 1500–1800 cm^{-1} grows with the treatment time is likely due to an in-

[1] Carbynoids are carbon macromolecular compounds having mainly chain structure and containing carbyne [polyyne or(and) cumulene] fragments along with defective liner carbon chains [interchain cross-linking, heteroatom substituents (atoms and groups), etc.].

1070-4272/03/7601-0124$25.00

crease in the number of conjugated double carbon–carbon bonds [1]. A weak band at 1720 cm^{-1} in the spectra of all the films indicates the presence of carbonyl groups in small amounts [3, 4]. This band appears as a shoulder on the main band in the range 1500–1800 cm^{-1} and does not contribute to the intensity of this band. Probably, the carbonyl groups were formed in the course of film preparation by heating of a PVDF solution in DMF on a support [7]. These groups can behave as local initiators of dehydrofluorination [7].

It should be noted that water molecules can contribute to the absorption in this range. At first glance, this is indicated by a strong increase in the absorption in the 3200–3700 cm^{-1} range with the treatment time. However, the increase in the intensity of the band in the range 1500–1800 cm^{-1} does not correlate with that of the band in the range 3200–3700 cm^{-1}: the maximal growth of the first band is observed in the first dehydrofluorination steps when the intensity of the second band remains virtually the same. Thus, the absorption of water molecules in the first examined range is negligible.

The absence of the band at 2175 cm^{-1} indicates the absence of triple carbon–carbon bonds in the films [3]. The presence of double bonds and the absence of triple bonds in the films would indicate formation of $–(–CH=CF–)_n–$ intermediate in the first dehydrofluorination step. Finally, in this step the hydrogen and fluorine concentrations decrease approximately by half as compared to those in the initial film. Hence, the fluorine content in these films should not be lower than a half of the carbon content. To confirm this assumption, we studied the XPE spectra in a wide range of binding energies for the samples of the first and the second series treated for 2 and 16 h, respectively. The spectra were recorded 2 months after dehydrofluorination. In both cases, fluorine and oxygen were detected, along with carbon, on the sample surface. The fluorine and oxygen concentrations were determined relative to the carbon concentration by the conventional procedure [8] taking into account the photoionization cross sections, sample thickness, and transmission function of the spectrometer. The oxygen content in the samples was about 20 and 16 at. %, respectively. The fluorine content (23 and 28 at. %, respectively) was appreciably lower than the expected values. Probably, this fact does not prove formation of exclusively the cumulene structure after the treatment and may be a result of a lower fluorine concentration in the surface layer as compared to the deeper layers inaccessible for XPE analysis. At the same time, the absence of triple carbon–carbon bonds may be due to

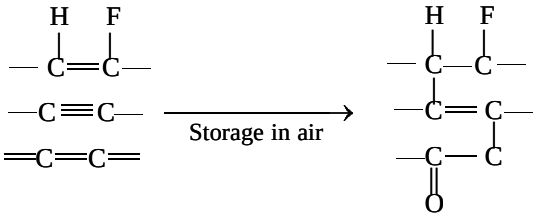
strong interchain cross-linking and oxidative degradation of carbynoid fragments (both polyyne and cumulene) on storage:



This assumption is confirmed by the fact that the films lose flexibility and are destroyed on prolonged storage.

The XPE spectra of the films were repeatedly recorded 7.5 years after their treatment. We failed to

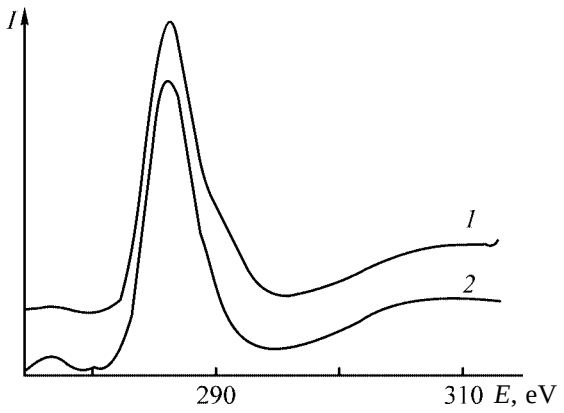


Fig. 3. XPE spectra (range of carbon inner electron shell) of a carbynoid film of the second series dehydrofluorinated for 16 h, recorded in (*1*) 1994 and (*2*) 2001. (*I*) Intensity and (*E*) binding energy.

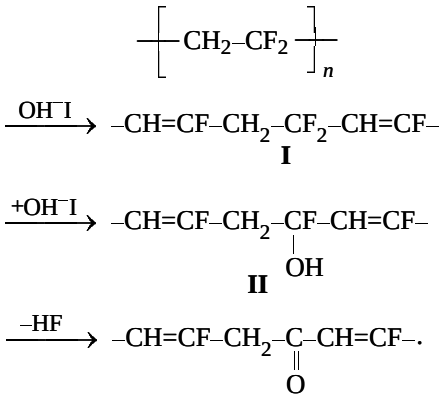
record the spectra of the first film since it completely degraded to a fine powder. The second film was broken down into large fragments which were glued without gaps on an adhesive tape. When the spectra were recorded (~335 min), the relative oxygen and fluorine concentrations monotonically decreased from 22 to 14 and from 9.4 to 6.4%, respectively. Thus, during storage of the samples, the oxygen content increased and the fluorine content appreciably decreased. Furthermore, the film was defluorinated when the XPE spectra were recorded. Defluorination of the samples stored for 7.5 years is also confirmed by a change in the shape of the C1*s* band (Fig. 3): the intensity of the shoulder assigned to the inner electron shell of the carbon atom of the CF_2 groups appreciably decreased.

Defluorination of the initial [9] and dehydrofluorinated PVDF films [10] exposed to X-ray radiation was observed previously. We also found that the fluorine content in the surface layer of dehydrofluorinated PVDF films increased during prolonged storage of the samples, which was due to spontaneous elimination of hydrogen fluoride from labile groups and its diffusion from the bulk of the sample to its surface. We failed to quantitatively characterize this process by the elemental composition of the surface layer due to desorption of HF from the sample. We suggest that the surface fluorine concentration in the samples dehydrofluorinated to a small extent, i.e., with a high initial fluorine content in the surface layer, will decrease on prolonged storage. On the contrary, since chemical carbonization develops in the direction from the surface to the bulk of the sample, prolonged fluorine diffusion form the bulk to the surface of strongly dehydrofluorinated samples can increase (as compared to the fluorine concentration measured immediately after the synthesis) the fluorine concentration in the surface layer accessible for XPE analysis.

Two bands in the 2900–3100 cm^{-1} range of the spectra shown in Figs. 1 and 2 and three closely located bands in this range in the spectra of strongly carbonized samples are assigned to stretching vibrations of the CH bonds. The intensity of the CH bands of the samples of both series, dehydrofluorinated for a short time, is slightly higher than that of the initial film. As the decarbonization time increases, the intensity of this band changes nonmonotonically. In the first series, the overall trend toward a decrease is more pronounced than in the second series. The nonmonotonic decrease is due to the fact that the contribution of side reactions of nucleophilic substitution of halide anions with ethoxy anions to the total dehydrofluorination changes in the course of the process. When dehydrofluorination of PVDF film is activated with acetone, the contribution of these reactions is lower than in the case when THF is used for this purpose.

The absorption in the range 2200–3700 cm^{-1} also depends on the dehydrohalogenation time and procedure. We divided this range into regions S_1 (2200–2800 cm^{-1}) and S_2 (3200–3700 cm^{-1}). Bellamy [6] assigned the absorption in the first range to vibrations of hydroxy groups bonded by strong hydrogen bonds. The bands in the second region were assigned to the stretching vibrations of OH groups [4]. The formation of H-bonded hydroxy groups can be semiquantitatively estimated from the ratio of the peak areas in the first and the second regions (S_1/S_2). The most reliable measurements of these areas can be performed for the highly dehydrofluorinated samples (first series, dehydrofluorination time 15–60 min). In this case, S_1/S_2 is almost constant and close to 0.6. This probably indicates that the content of OH groups bonded by strong hydrogen bonds is appreciable and constant. This assumption is correct at least for the samples dehydrofluorinated for a long time.

Formation, accumulation, and transformation of hydroxy groups is one of the main features of PVDF dehydrofluorination and aging of the reaction products. Nucleophilic substitution of fluorine atoms with hydroxy groups occurs most readily in allyl fragments owing to the effect of allyl activation [11]. This reaction yields reactive hydroxyallyl groups II. On storage of the samples, these groups degrade to form HF and carbonyl groups:



Since atmospheric oxygen has virtually no effect of PVDF dehydrofluorination [3], in the course of the alkali treatment, oxygen-containing groups are formed mainly by the nucleophilic substitution pathway. Secondary transformation of hydroxy groups contribute mainly to the accumulation of carbonyl groups in the course of sample storage. Thus, transformation of the broad band in the range 2200–3700 cm^{-1} on storage of the dehydrofluorinated samples may be due to multistage process involving oxidation, hydrolysis, isomerization, and(or) tautomerization. In addition, as the carbynoid structure is formed, the absorption due to free and localized electrons can appear. To confirm this assumption, special studies in a wide spectral range are required.

CONCLUSIONS

(1) Dehydrofluorination of PVDF in the presence of acetone is more effective than that in the presence of THF.

(2) The IR spectra of modified polyvinylidene fluorides contain the bands of C=C, CH, and OH groups.

(3) The structural differences in the samples dehydrofluorinated for different times in the presence of various activators are preserved after prolonged storage of these samples in air.

(4) Films of polyvinylidene fluoride and products of its partial dehydrofluorination eliminate HF in the course of recording the XPE spectra.

Received June 2, 2002

Abstract—Preparation of concentrated solutions of natural silk fibroin in *N*-methylmorpholine-*N*-oxide and its mixtures with protonic and aprotic solvents was experimentally studied. Solutions with the fibroin concentration of 6 wt % and more were prepared.

Active efforts are made today to develop processes for producing various materials from wastes of natural fibers [1]. These processes involve preparation of working solutions of natural polymers and their conversion into, in particular, fibers and films. Natural fibers, e.g., cellulose, can be dissolved without derivatization in tertiary amine oxides [2].

Fibers of polymer blends can be produced from solutions of proteins such as fibroin of natural silk. These fibers are characterized by improved hydrophilicity, dyeability, folding resistance, etc. Dissolution of a protein depends on its structure, molecular weight and structure of its macromolecules, and polarity and steric arrangement of the side groups. Mutual interaction of side groups of fibroin (Fig. 1) restricts free rotation around single bonds of the peptide chain, thus making it relatively rigid. A fibroin macromolecule contains nonpolar amino acid residues (aliphatic residues of alanine, leucine, isoleucine, valine, and proline and aromatic residues of phenylalanine and tryptophan), polar amino acid residues (serine, threonine, and tyrosine residues containing hydroxy groups, cysteine residues with SH groups, carboxy and amide groups of aspartic and glutamic acids, and amino groups of lysine) [3, 4]. The fibroin macromolecules are closely packed owing to higher content of hydrophobic residues as compared to that of hydrophilic polar groups. The content of oriented chains reaches 40–60%. Fibroin sparingly swells in water and is soluble in concentrated solutions of LiCNS, LiBr, $CuCl_2$, $Ca(CNS)_2$, and $ZnCl_2$, copper ammonia solution ($CuSO_4$ + NH_4OH), phosphoric acid, and some other inorganic solvents [3–8].

The mechanism of dissolution of fibroin in concentrated aqueous solutions of salts and acids is not understood. Probably, ions of the solvent interact with charged groups of the side chains of the fibroin, thus cleaving hydrogen bonds between the macromolecules. These ions indirectly affect the macromolecular conformation via a change in the solvent structure. The internal regions of the ordered polymer do not contact with the solvent. Hydration of side polar groups results in loosening of the water structure and its diffusion inside polymeric fibrils. Structuring of water by interaction with the nonpolar groups

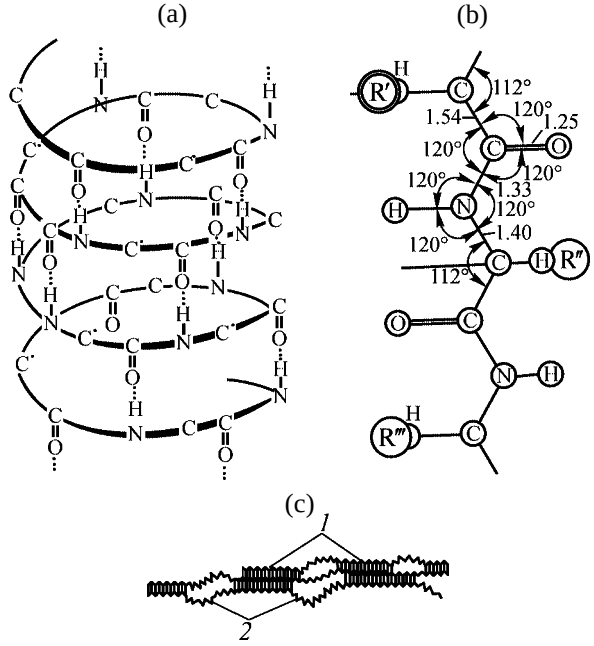

Fig. 1. Scheme of a polypeptide chain [4]: (a) helical structure, (b) unfolded chain, and (c) arrangement of polypeptide chains in the fiber. Region: (*1*) crystalline and (*2*) amorphous.

1070-4272/03/7601-0128$25.00

prevents its diffusion into the protein. Degradation of the water structure in the presence of salts results in conformational transformations of the macromolecule and penetration of water into the crystalline regions of the polymer.

Structural transformations of macromolecules are observed not only in the presence of ions breaking the water structure but also under the action of structure-making ions which become surrounded by a shell of water molecules ordered owing to interaction with nonpolar side groups of the protein. Disordering of water around hydrophobic fragments results in conformational transformations of the polymer, followed by its dissolution [9]. We suggest that fibroin of natural silk is dissolved in concentrated aqueous solutions of salts owing to interaction of the solvent ions with the side groups and a change in the conformation of the macromolecules, which favors their unwrapping and penetration of water inside the protein. Disadvantages of salt solutions of fibroin are their structure-breaking effect on the polymer and the necessity of subsequent dialysis of the solution to remove the salt.

Dissolution of silk fibroin in nonaqueous solvents is of special scientific and technological interest. As shown previously [2], up to 1.96 and 3.84% of silk is dissolved in *N*-methylmorpholine-*N*-oxide monohydrate (NMMO) at 120°C and in *N*-methylazacycloheptane-*N*-oxide at 140°C, respectively.

EXPERIMENTAL

To prepare silk solutions suitable for industrial processing, we studied dissolution of silk fibroin in NMMO. We used silk fibroin of silkworm, treated to remove sericin, fats, waxes, and mineral compounds and stapled in samples 34.6 μm in diameter and 3.6 mm long. The solubility was studied by polarizing microscopy at 160× magnification. The fiber did not dissolve after keeping in the solvent at 95–130°C for 4 h. The fiber diameter increased by a factor of 1.5 (105°C) and 2–3 (120, 130°C). Thus, silk fibroin only swells in NMMO monohydrate (13.3 wt % water, mp 71–74°C) at temperature of 105°C and higher. As determined by X-ray diffraction, the crystallite size does not noticeably change after swelling (Fig. 2, curves *1*, *2*), i.e., NMMO monohydrate interacts only with amorphous fibroin. Clearly, critical (threshold) energy of interaction of fibroin macromolecules with the solvent, which is required for the rupture of intermolecular hydrogen bonds in crystalline parts of the polymer and dissolution of the polymer, is higher than that of cellulose macromolecules.

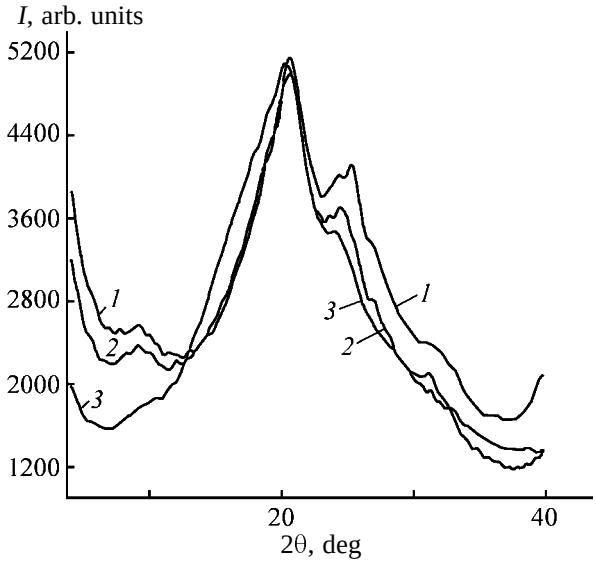

Fig. 2. X-ray patterns of (*1*) the initial washed silk, (*2*) swollen and dried sample, and (*3*) sample precipitated from a solution in $NMMO \cdot 0.8H_2O$. (*I*) Intensity and (θ) Bragg's angle.

Previously [10, 11] we analyzed the influence of the water content in the solvent on the energy of interaction of the solvent with cellulose macromolecules. Thermochemical studies and theoretical calculations show that the energy of interaction of NMMO with hydroxy groups of cellulose is inversely proportional to the water content in the solvent. In this work we studied the fibroin solubility in NMMO with different water content, which was adjusted by removing water at 95–110°C and a pressure of 30–60 mbar. The residual water content was determined gravimetrically and by the melting point of NMMO. As seen from Table 1, the fibroin is dissolved at the water content in NMMO no more than 10 wt %, which corresponds to the composition $NMMO \cdot 0.8H_2O$. Transparent light yellow fibroin solutions with the polymer concentration of 5 wt % and higher are formed. The X-ray

pattern of fibroin precipitated from the solutions (Fig. 2, curve *3*) differs from those of the initial (curve *1*) and swollen and dried polymer (curve *2*). As compared to the initial sample, the reflections in the range 8°–10° and 25°–27° of the X-ray pattern of precipitated fibroin are absent.

To decrease the melting point of the solvent and hence the dissolution temperature, we introduced low-molecular-weight organic diluents. It is important that the diluent should not decrease the solubility. Our previous comparative studies of aprotic and protic diluents show [12] that aprotic compounds effectively breakdown the NMMO structure, thus accelerating the dissolution and decreasing the viscosity and T_m of the solvent. On the contrary, protic diluents are structure-making additives which compete with hydroxy groups of cellulose for formation of hydrogen bonds with the N–O group of the amine oxide. In [13] we studied the influence of aprotic diluents on the enthalpy of interaction of binary solvent with cellulose. It was found that the heat effect of the interaction of cellulose with the DMSO complex of NMMO monohydrate is higher than that of pure NMMO monohydrate. We suggest that DMSO additionally polarizes the N–O groups. Here we tested as diluents aprotic [DMSO, dimethylformamide (DMF), dimethylacetamide (DMAA)] and protic solvents (lower alcohols $C_nH_{2n+1}OH$, where n = 1–5, 2-pyrrolidone, [14] ε-caprolactam, and δ-valerolactam).

As seen from Tables 2–4, only limited amounts of protic solvents can be added to NMMO. The fibroin is soluble in a $NMMO \cdot nH_2O \cdot m$ diluent mixture when $(n + m)$ is no higher than 0.8. At higher $(n + m)$ values the solubility sharply decreases. In the case of aprotic solvents, especially DMSO, the fibroin solubility is retained in a wider concentration range (Table 3), which allows control of the melting point of the solvent and hence of the dissolution temperature. The most efficient additive is DMSO. Introduction of up to 2–3 mol of DMSO per mole of NMMO

Table 4. Fibroin solubility in NMMO–water–lactam systems

Lactam	NMMO : water : lactam molar ratio	T_m, °C	Fibroin solubility

	1 : 0.3 : 1	Liquid	–

Table 5. Thermolysis temperature T_{therm} of fibroin solutions

Molar composition of the solvent	Fibroin concentration in the solution, wt %	T_{therm}, °C
NMMO · $0.3H_2O$	–	174
NMMO · $0.3H_2O$	5	160
NMMO · $0.3H_2O$ · 0.9DMSO	5	152
NMMO · $0.3H_2O$ · 1.8DMSO	5	162
NMMO · $0.3H_2O$ · 0.4pyrrolidone	5	174
NMMO · $0.3H_2O$ · 0.4valerolactam	5	158

does not decrease the fibroin solubility and effectively lowers the melting point and viscosity of the solution.

The onset temperature of thermolysis of amine oxide in 5% fibroin solutions ranges from 150 to 170°C depending on the solvent composition (Table 5).

CONCLUSIONS

(1) Dissolution of silk fibroin in *N*-methylmorpholine-*N*-oxide was studied. The threshold energy of interaction between the solvent and the polymer, required for polymer dissolution, is reached at a 10 wt % water content in *N*-methylmorpholine-*N*-oxide, which corresponds to the composition *N*-methylmorpholine-*N*-oxide · $0.8H_2O$.

(2) The melting point of the solvent decreases when water is partially replaced by an equimolar amount of alcohol. Branched alcohols are more efficient for this purpose.

(3) Partial replacement of water in the solvent by 2-pyrrolidone, ε-caprolactam, and δ-valerolactam decreases the melting point of the solvent with no loss of its solvency.

(4) Additives of aprotic compounds, especially DMSO, effectively decrease the melting point and viscosity of fibroin solutions in *N*-methylmorpholine-*N*-oxide, with the solvency of *N*-methylmorpholine-*N*-oxide being preserved in a wide range of components ratios in the solvent.

CHEMISTRY OF FOSSIL FUEL

Fuel Oil Pyrolysis Initiated by Propane–Butane–Oxygen Flame

V. V. Makarov, G. I. Ksandopulo, and V. M. Potekhin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 16, 2002

Abstract—The parameters of fuel oil pyrolysis initiated by propane–butane–oxygen flame were studied as influenced by the temperature in the pyrolysis zone, time of the fuel oil contact with the initiating flame, and fuel oil feed rate. The experimental data on thermal and flame-initiated fuel oil pyrolysis were compared.

One of the major lines in development of petrochemical industry is increase in the production of lower olefins, e.g., ethylene and propylene. Ethylene is produced in industry by pyrolysis of hydrocarbons with steam in tubular furnaces; the best raw material for ethylene production is ethane, and its treatment under fairly severe conditions yields up to 76–78 wt % of ethylene [1].

Naphtha fractions with various boiling ranges are widely used as raw materials for pyrolysis. In contrast to the pyrolysis of gaseous hydrocarbons, pyrolysis of naphtha fractions yields, along with pyrolysis gas rich in C_2–C_4 unsaturated hydrocarbons, also significant amount of liquid products containing aliphatic and cyclic C_5 and higher olefins, C_6–C_8 aromatic hydrocarbons, and other valuable materials [2].

However, the composition of materials for pyrolysis gradually changes. At present, heavy oil distillates are widely used for pyrolysis along with gaseous materials and light oil fractions. Further improvement of common pyrolysis furnaces is performed and new alternative pyrolysis processes are developed [1]. Such alternative processes involve pyrolysis in the presence of heterogeneous catalysts, high-temperature pyrolysis using gaseous heat carriers, pyrolysis in the presence of initiating additives, hydropyrolysis, pyrolysis in molten metals and metal salts, thermal contact processes, and pyrolysis in the initiating flame [3–7]. An example of the latter process is the flame-initiated pyrolysis (FIP) of fuel oil.

EXPERIMENTAL

In the experiments we used M-40 fuel oil with the following main parameters: density (at 293 K) 1 kg m^{-3}, ash residue 0.15 wt %; content (wt %): solid impurities 1, water 2, and sulfur 0.5–3.5; the heat of combustion recalculated on the dry fuel oil 39770 J g^{-1}.

The scheme of a flow-type unit for FIP of the fuel oil, operating under atmospheric pressure, is shown in the figure. The reactor is made of Cr1849TiCu stainless steel and consists of three zones, mm: zone of preheating (573 K) 160 mm long, pyrolysis zone (773–923 K) 140 mm, and initiation zone (combus-

tion and pyrolysis) 30 mm. The initiating burner was placed in the reactor at the boundary of the pyrolysis and initiation zones. The composition of the propane–butane gas mixture was as follows, vol %: propane 76.2, butane 17.6, isobutane 5.9, and ethane 0.3; oxygen was supplied to the burner in stoichiometric amounts.

The type of the initiating flame is selected is accordance with its physicochemical parameters such as the temperature of the stoichiometric flame (1900°C), shape and size of the flame (elongated flare, 30–40 mm height), length of the area in which the H atoms are detected (30–45 mm along the axis of the flow of reaction products), and maximal concentration of H atoms in the flame (4×10^{15} cm^{-3}) [3].

In the course of pyrolysis initiation with propane–butane–oxygen flame at 1800–1900°C flame temperature, significant amounts of hydrogen atoms (up to 4×10^{15} cm^{-3}) and other reactive radicals (HO_2, $OH^{\bullet}$, $CH_3^{\bullet}$, $C_2H_5^{\bullet}$, $CHO^{\bullet}$, $O^{\bullet\bullet}$, etc. [3]) diffuse into the fuel oil, which strongly accelerates pyrolysis of the feed. The flame capacity in the experiments was characterized by the content of oxygen relative to the feed (wt %). In all the cases the (propane–butane) : oxidant ratio was 1 : 5; the flow rates of the oxidant and propane–butane mixture at the burner inlet were 710 and 140 $cm^3\ min^{-1}$, respectively.

The gaseous products (vol %) of the fuel oil pyrolysis were analyzed by gas chromatography; for quantitative analysis of the chromatographic patterns, we used the method of internal normalization taking into account the sensitivity coefficients and also the absolute calibration procedure.

The aim of this work was to increase the yield of lower olefins (ethylene, propylene, and butenes). In our experiments we varied the pyrolysis temperature, contact time, and the fuel oil feed rate. The contact time was changed by varying the steam flow rate at the pulverizer inlet or the fuel oil feed rate at a constant steam flow rate. The temperature of the steam and fuel oil in the experiments was 423 and 383 K, respectively. The results of fuel oil pyrolysis are listed in Tables 1–3.

As seen from published data [1], pyrolysis of fuel oil is characterized by extensive coking. Taking into account this fact, we varied the temperature in the pyrolysis zone within 773–923 K, whereas the temperature in the preheating zone was constant (573 K).

Along with studying the effect of temperature on the fuel oil pyrolysis initiated by propane–butane

flame, we performed the experiments on the pyrolysis without initiator. The operation parameters and experimental conditions were determined in the course of thermal pyrolysis, and then the initiating flame was added.

As seen from Table 1, as the temperature is increased from 773 to 923 K, the content of ethylene in the hydrocarbon fraction of the pyrolysis gas gradually increases, and at 923 K it comprises 42.8 vol %; the content of propylene and butenes in the pyrolysis gas varies within 6.5–9.0 and 3.1–8.4 vol %, respectively. As compared to thermal pyrolysis at the residence time in the flame of 0.5 s and 923 K, initiation with propane–butane flame increases the content of ethylene in the hydrocarbon fraction of pyrolysis gas by 13.3 vol %, whereas the content of propylene and butenes decreases by 7.9 and 4.3 vol %, respectively. It should be noted that the variation of the pyrolysis temperature by 150°C only slightly affects the volume content of the target products. However, in the entire temperature range studied the content of ethylene in the pyrolysis gas at initiated pyrolysis is higher than that in the noninitiated process.

The gasification degree varies within 11.5–13.2 and 3.6–5.9% for initiated and thermal processes, respectively. The gasification degree is defined as the amount of fuel oil (wt %) that passed into the gas phase.

The effect of the residence time of fuel oil in the initiating flare zone is illustrated in Table 2. The residence time was varied by changing the flow rate of the supplied steam. As seen, as the residence time of fuel oil in the initiating flare zone is decreased from 0.1 to 0.03 s, the volume content of ethylene and methane in the pyrolysis gas decreases, whereas the volume content of ΣC_4H_8, C_3H_6, and C_3H_8 increases; the ethane concentration remains almost constant.

When the contact time in the pyrolysis zone was decreased to 0.2 s and the residence time in the initiating flare zone, to 0.03 s, the gasification degree in flame-initiated fuel oil pyrolysis became close to that in thermal pyrolysis. As seen from the comparison of experimental results obtained in initiated (Table 2) and noninitiated (Table 1) pyrolysis at similar gasification degrees, the volume content of unsaturated hydrocarbons in the pyrolysis gas increases relative to saturated hydrocarbons. Initiation of the fuel oil pyrolysis at gasification degree of 6.2 wt % as compared to thermal pyrolysis (gasification degree 5.9 wt %) increases the content of ethylene and butenes in the hydrocarbon fraction of the pyrolysis gas by 8.1 and 0.2%, respectively, whereas the content of propylene decreases by 4.2%. In this case, the temperature difference in the thermolysis zone was 150 K.

The residence time in the reaction zone is predominantly determined by the rate of steam supply to the fuel oil pulverizer, whereas the increase in the feed rate of the fuel oil, which falls into the reactor as fine drops (with size less than 100 μm), does not noticeably affect the residence time of the fuel oil in the reaction zone. At the same time, the composition of the pyrolysis gas changes with changing the fuel oil feed rate (Table 3). With increasing fuel oil feed rate, the content of hydrocarbons in the pyrolysis gas increases from 27.9 to 35.2 vol %. Simultaneously, despite the increase in the gasification degree, the content of ethylene in the pyrolysis gas decreases from 42.1 to 35.8 vol %.

As seen from the comparison of experimental data obtained in the course of thermal and flame-initiated pyrolysis (Table 3) at similar feed rates of the fuel oil, the yield of unsaturated hydrocarbons in the course of pyrolysis strongly increases with respect to saturated hydrocarbons. At low feed flow (1 : 1.4 fuel oil : steam ratio), the content of lower olefins in the pyrolysis gas strongly increases , whereas the content of saturated C_3–C_4 hydrocarbons decreases. Thus, in initiation of pyrolysis with propane–butane flame, with increasing fuel oil feed rate the volume content of ethylene and methane in the pyrolysis gas decreases and the content of heavier hydrocarbons C_3–C_4 increases.

Our experimental data showed that, despite variation of the process conditions in a fairly wide range, the flame-initiated fuel oil pyrolysis mainly follows the "olefin" pathway. We identified only C_1–C_4 components in the gaseous mixture. The absence of heavier hydrocarbons in the pyrolysis products suggests that the process involves profound breakdown of the fuel oil molecules with formation of lower unsaturated and saturated C_1–C_4 hydrocarbons, which determine the final composition of the hydrocarbon fraction of the pyrolysis gas.

Among the pyrolysis products we also detected carbon oxides and hydrogen, probably arising from combustion of the initiating propane–butane mixture and fuel oil pyrolysis.

CONCLUSIONS

(1) In the course of pyrolysis of fuel oil initiated by propane–butane–oxygen flame (29 wt % capacity) and performed at 773–923 K and gasification degree of about 6 wt %, the content of ethylene and butenes

in the hydrocarbon fraction of the pyrolysis gas increases by 7.9–8.1 and 0.2 vol %, respectively, whereas the content of propylene decreases by 4.0–4.2 vol %.

(2) At pyrolysis temperature from 773 to 923 K, residence time of the fuel oil in the initiating flame zone of 0.1 s, flame capacity of 29 wt %, and fuel oil : steam ratio of 1 : 1.7, the gasification degree is 13–14%, and the content of ethylene in the hydrocarbon fraction of the pyrolysis gas reaches 40–42 vol %.

CHEMISTRY OF FOSSIL FUEL

Oxidation of Diesel Oil in the Presence of Metallic Copper

Abstract—The kinetic parameters of autooxidation of DL-0.2 diesel oil in the presence of copper were determined in the range 120–140°C. The possibility of using Ionol for stabilization of diesel oil under these conditions was studied.

High efficiency of diesel engines in comparison with carburetor engines causes great interest in stabilization of diesel oils (DOs) [1–3]. At a temperature of 100–140°C, providing proper operation of fuel system units of diesel engines, DO contacting structural materials is rather actively oxidized with dissolved oxygen, whose content reaches 4–5 vol % [4]. Oxidation of DO is accompanied by formation of tarry compounds which are deposited on filters and units of fuel-controlling and fuel-supplying apparatus and fuel injectors. This disturbs the normal operation of engines and, as a result, increases the toxicity and smoke content of exhaust gases. It is known that copper is a highly active catalyst of oxidation of hydrocarbon fuels [5]. In this work we examined the effect of copper on the kinetics of DO oxidation and the possibility of DO stabilization with classic oxidation inhibitor, Ionol.

EXPERIMENTAL

Uptake of O_2 in oxidation of DL-0.2 commercial diesel oil was studied on a gasometric installation of the static type [6]. Into a 15-ml temperature-controlled conical glass reactor equipped with a stirrer, 5 ml of the fuel was placed, and oxygen was bubbled for 10 min. The amount of oxygen taken up, $\Delta[O_2]$ (mol l^{-1}), was evaluated by the formula

$$\Delta[O_2] = V_{O_2}/V_f \times 22.4,$$

where V_{O_2} is the oxygen uptake (ml) and V_f is the fuel volume (ml).

Autooxidation of DO proceeds with acceleration, and the kinetics of O_2 uptake is described by the relationship $\Delta[O_2]^{1/2} = bt$ characteristic of hydrocarbon fuels [6]. In the coordinates $\Delta[O_2]^{1/2}$–t, the experimental points fall on a straight line. The parameter b characterizing the susceptibility of DO to autooxidation is determined as the slope of the experimental straight line.

Metallic copper was used as a powder, plate, or ring. The particle size of the powder was determined with a BIOLAM microscope and a micrometric network of the OS type with the scale factor of 1×10^{-2} mm. Based on numerous measurements, the average radius of copper particles was taken equal to 2×10^{-2} mm.

These results allowed estimation of the copper particle volume, assuming that particles are spherical ($V = 4/3\pi r^3 = 3.2 \times 10^{-5}$ mm^3), the average weight of one particle ($m = \rho V = 2.7 \times 10^{-7}$ g at $\rho_{Cu} = 8.4 \times 10^{-3}$ g mm^{-3}), the total number of particles in the weighed portion of 5.4×10^{-3} g Cu per 5 ml of fuel (2×10^4 particles), and also the surface area of one particle ($S = 4\pi r^2 = 50 \times 10^{-4}$ mm^2) in the weighed portion of copper powder (1 cm^2 per 5 ml of fuel or 200 cm^2 per 1 l of fuel).

The size of the copper plate was $10 \times 15 \times 0.2$ mm. The copper ring was made from a copper tube 10 mm in diameter (the element of the fuel system of a diesel engine), the wall thickness of the ring was 1 mm, and the ring width was 2 mm.

Experiments on autooxidation of crude DO with oxygen in the presence of metallic copper at 120°C for 7 h with parallel measurement of the oxygen uptake, $\Delta[O_2]$, and the optical density of fuel, A, characterizing tarring in the system, showed that these parameters reach the limiting values by the end of the run and are 0.22 and 1.6 mol l^{-1}, respectively (Fig. 1). Cessation of DO autooxidation is apparently due to

1070-4272/03/7601-0137$25.00

deactivation of the catalytically active metal surface.

Adsorption purification of DO on silica gel significantly enhances the thermal oxidation resistance of fuel: the limiting values of $\Delta[O_2]$ and A decrease by factors of 5 and 2, respectively. The kinetic curves of O_2 uptake in the initial stage of DO oxidation ($\Delta[O_2] \le 1 \times 10^{-2}$ mol l^{-1}) in the presence of copper powder are typical of autoaccelerating processes (Fig. 1); the curves are made linear in the coordinates $\Delta[O_2]^{1/2}$–time, which allows characterization of the process using the parameter b ($\Delta[O_2]^{1/2} = bt$). The temperature dependence of b in the range 120–140°C is reasonably adequately described by the Arrhenius equation

$$\ln b = 9.32 - 64 \times 10^3/(RT),$$

where $R = 8.31$ J $mol^{-1}\ K^{-1}$.

As known, in heterogeneous catalytic oxidation, the specific activity of a material having a catalytic effect is characterized by the b/b_0 value and by the ratio $(b - b_0)/(b_0S)$, where b_0 and b are the quantitative measures of the susceptibility of the fuel to autooxidation in the absence and in the presence of this material, respectively; S is the metal surface area, cm^2 per liter of fuel [4]. The results of the study (Table 1) showed that the specific activity of copper powder with respect to DO at 120°C is $(13.6 \pm 4.6) \times 10^{-3}$ $l\ cm^{-2}$ and the ratio $b/b_0 = 2.4 \pm 0.5$. It should be noted that similar values are characteristic of copper in T-6 jet engine fuel: $(b - b_0)/(b_0S) = 5 \times 10^{-3}$ $l\ cm^{-2}$ and $b/b_0 = 2.51$ [4].

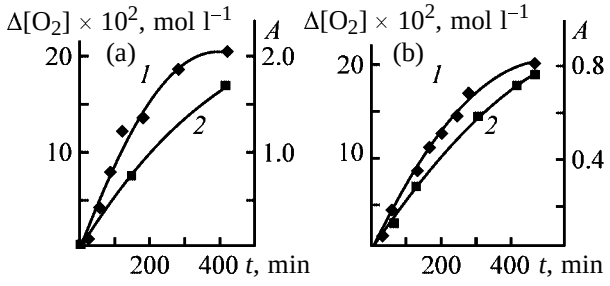

Fig. 1. (*1*) Kinetics of oxidation of diesel oil $\Delta[O_2]$ and (*2*) variation of optical density A in the presence of copper at 120°C. (*t*) Time. Diesel oil: (a) crude and (b) purified on silica gel.

It is evident that the increased oxidizability of DO is caused by accelerated decay of hydroperoxides ROOH to radicals under the action of metallic copper. This is suggested by the parabolic dependence of O_2 uptake on time (Fig. 1) and the fact that the dependence of the autooxidation parameter b on S_{Cu} tends to a certain limit (Table 1). According to the data obtained, with increasing surface area of copper from 0 to 50 cm^2 per liter of fuel, b is doubled, whereas further increase in S_{Cu} does not result in significant growth of the autooxidation rate. It is apparent that, at $S_{Cu} \ge 126$ $cm^2\ l^{-1}$, hydroperoxide molecules formed in the bulk are adsorbed at the copper surface and a constant initiation rate ($b = 0.5ak_i^{12}$) is maintained in the system owing to heterogeneous decay of ROOH. Replacement of the copper powder by copper plate or copper ring (fragment of copper tube, the element of fuel apparatus of diesel engine) does not disturb the shape of the dependence of b on S_{Cu} (Table 1).

A conventional inhibitor of radical-chain oxidation, Ionol PhOH, added to the fuel containing copper powder ($S_{Cu} = 126$ $cm^2\ l^{-1}$), efficiently inhibits oxidation, causing appearance of induction periods (t_i = 37–90 min at 120°C); their duration is in direct proportion to PhOH concentrations in the range $(1.3–2.7) \times 10^{-4}$ M. These results allow estimation of the initiation rate W_i:

$$W_i = 2[PhOH]/t_i = (1.1 \pm 0.1) \times 10^{-7}\ mol\ l^{-1}\ s^{-1}.$$

Table 2. Influence of inhibitor concentration [PhOH] and temperature on the parameter of DO autooxidation b and inhibition coefficient n in the presence of copper powder, S_{Cu} = 126 $cm^2\ g\ l^{-1}$

T, °C	[PhOH] × 10^2, wt %	[PhOH] × 10^3, M	$b \times 10^5$, $mol^{1/2}\ l^{-1/2}\ s^{-1}$	$n = b_0/b$

	3.3	1.26	3.7	2.1

The study of the dependence of the autooxidation parameter b and inhibition coefficient n ($n = b_0/b_{PhOH}$) on the Ionol concentration showed that, at 120°C and [PhOH] > 0.06 wt %, b decreases by a factor of 7 and then does not vary noticeably (Table 2). However, with increasing temperature, the inhibition activity of Ionol noticeably decreases: the inhibition coefficient n is 4.3, 2.6, and 1.3 at 120, 130, and 140°C, respectively. At 140°C and concentration of 0.02 wt % ([PhOH] = 7.6×10^{-4} M), virtually no inhibition of autooxidation is observed; therefore, other inhibitors are required for stabilization of DO at elevated temperatures.

CONCLUSIONS

(1) Diesel oil contacting metallic copper at 120–140°C is subject to active oxidation and tarring in the initial stage of the process. The factor of the copper catalytic effect at 120°C is 2.4 ± 0.5.

(2) Adsorption purification of diesel oil on silica gel appreciably suppresses its susceptibility to autooxidation. Ionol added to the fuel decreases its oxidizability at 120°C by a factor of 7 but is ineffective at higher temperatures.

Received May 30, 2002

Abstract—A raffinate meeting the requirements for the transformer oil body was obtained from the 300–350°C fraction of low-paraffinicity oil by five-step countercurrent extraction of aromatic hydrocarbons and organoelement compounds with aqueous methyl Cellosolve in the presence of pentane.

Hydraulic oils and transformer oil body are produced from the 200–300 and 300–350 or 300–400°C fractions of low-paraffinicity oil, respectively. Low-paraffinicity oils, among them Troitsk-Anastasievsk oil, contain virtually no *n*-alkanes, which allows production of low-freezing oils without dewaxing as the most expensive stage. However, the aromatic hydrocarbon content in the fraction 200–430°C of the Troitsk-Anastasievsk oil amounts to 40% (hereinafter, wt %, unless otherwise stated) [1]. According to the existing technical specifications, the optimal content of arenes in it should be within 18–22%, the major part of arenes being represented by monocycloarenes [2, 3].

Transformer oils can be produced from the 300–400°C fraction by solvent extraction followed by hydrogenation. For example, this combined method is used in production of T-1500U transformer oil [TU (Technical Specification) 38.401-58-107]. The advantage of solvent-extracted oils is in high gas resistance coefficient, which is caused by the optimal content of aromatic hydrocarbons (18–22%). As their drawbacks, we can indicate high dielectric loss tangent tan α, which is due to excessive resin content, resulting in deteriorated insulating characteristics and oxidation resistance of the oil. The resin content can be reduced from 3.2 to 1.2–1.3% by additional adsorption refining of a solvent-extracted oil. In this case, tan α decreases from 2.2 to 0.24–0.29%, meeting the requirements of the technical specifications to T-750 transformer oil [3].

Solvent extraction of oil fractions is performed with phenol, furfural, or *N*-methylpyrrolidone [4, 5]. However, all these solvents are relatively high-boiling, which complicates their regeneration. *N*-Methylpyrrolidone, the most selective and high-boiling of them, forms azeotropic mixtures with a series of saturated hydrocarbons of the 200–400°C fraction, which causes oiling of the solvent and complicates its regeneration, thus deteriorating the solvent extraction efficiency [6]. Regeneration of a solvent by aqueous backwashing or back extraction of arenes from the extract phase with saturated hydrocarbons is insufficiently efficient, causing complication of the process flowsheet and increase in the power consumption. Furthermore, all the indicated solvents have certain inherent drawbacks: phenol, low selectivity with respect to arenes and high toxicity; furfural, low thermal oxidation resistance; and *N*-methylpyrrolidone, high cost and corrosion activity [7–9].

To obtain the transformer oil body from low-paraffinicity oil fractions, sulfuric acid refining is used. However, this method does not longer meet the modern environmental criteria, because of formation of large amounts of acid tar to be utilized or disposed of.

The goal of this work is to examine the possibility of production of the transformer oil body from the 300–350°C fraction of low-paraffinicity oil by solvent extraction using a low-boiling extraction system readily regenerable by distillation.

Since the oil in hand contains no *n*-alkanes, one may draw an analogy between the composition of its kerosene–gas-oil fractions and that of 200–320°C fraction dewaxed by adsorption on zeolites (denormalization product of the Parex plant). Previously we

reported on extraction of aromatic hydrocarbons from such denormalization product to obtain a component for a pollution-free diesel fuel with an arene content of no more than 10–15% [10–13].

Oils from the West Siberian oil-and-gas province (raw material for most of the Russian refineries) are classified with A^1 type [1]. This is essentially paraffin-base crude, in which naphthenes are represented primarily by monocycloalkanes. It is known that the solubility of saturated hydrocarbons, having the same amount of carbon atoms, in polar solvents increases in the order *n*-alkanes < isoalkanes < monocycloalkanes < polycycloalkanes.

The solubility of alkanes in polar solvents increases with increasing degree of branching. For example, the solubility of 2-methylheptane and 2,5-dimethylhexane in 2-methoxyethanol (methyl Cellosolve) at 50°C is 26.0 and 31.1%, respectively [14].

In contrast to West-Siberian oils, in the kerosene–gas-oil fractions of low-paraffinicity oils polycycloalkanes and isoalkanes predominate. Therefore, extraction of organoelement compounds and aromatic hydrocarbons from low-paraffinicity oils is a more difficult problem as compared to separation of denormalization products, more so of straight runs of West Siberian oils with high *n*-alkane content. The success in solving this problem depends primarily on the solvent selectivity. Among the known relatively low-boiling solvents, methyl Cellosolve is one of the most selective solvents with respect to arenes. For example, at 25°C, its selectivity with respect to toluene in the octane–toluene system, expressed as the limiting activity coefficient ratio of these hydrocarbons in a diluent, was found to be 7.92, whereas that of methanol, acetone, and pyridine is 4.57, 5.45, and 6.46, respectively [15].

More selective solvents are known (compared to methyl Cellosolve) such as sulfur dioxide, 2,2,2-trifluoroethanol, hexafluoro-2-propanol, acetonitrile, and nitromethane [16]. However, each of these solvents has drawbacks complicating its practical use as a solvent. Sulfur dioxide demonstrates high corrosion activity and high reactivity towards unsaturated hydrocarbons. Also, a refrigerating medium is required in extraction with this solvent. Polyfluoro alcohols are highly expensive, and nitromethane is dangerously explosive. Acetonitrile has a density close to that of the raw material, making it difficult to separate the extract and raffinate phases; also, at high temperature of regeneration, hydrolysis of aqueous acetonitrile can occur with formation of acetic acid, thus initiating corrosion of the equipment.

Among the advantages of methyl Cellosolve are high thermal and hydrolytic stability, sufficiently high density (ρ_4^{20} = 0.996), relatively low toxicity (MPC = 80 mg m^{-3} [17]), and low cost. Also, an important advantage of this solvent is in higher selectivity with respect to polycycloarenes [18, 19] and sulfur-containing components of oil fractions [20].

As in solvent extraction refining of the denormalization product of the Parex plant [11], in this work, to improve the selectivity of methyl Cellosolve, we used the heterogeneous solvent system containing 5% water and pentane as a nonpolar diluent.

As a raw material we used a fraction of Troitsk–Anastasievsk oil, whose characteristics were as follows: boil-off range (standard distillation) 302–354°C, refractive index n_D^{20} 1.5026, density ρ_4^{20} 0.901, sulfur content 0.16%, sulfury content 30 vol % (31.9 wt %), kinematic viscosity at 50°C 7.4 $mm^2\ s^{-1}$, and flash point (open vessel) 168°C.

Extraction experiments were performed in two modes, namely, pilot and optimal (Table 1). Five-step countercurrent extraction was carried out according to the classical flowsheet using a system of separating funnels [21]. Results obtained in the pilot experiments are given in Table 2.

Table 2 shows that the resulting raffinate contains the desired amount of arenes, but rather large amount of saturated hydrocarbons still remains in the extract

Table 2. Characteristics of the raffinate and extract obtained in experiment nos. 1 and 2

(their loss with the extract is about 7% of the estimated total in the raw material).

To increase the solvent extraction selectivity and the arene content in the extract, we increased the pentane : raw material weight ratio to 1 : 1. Simultaneously, the aqueous methyl Cellosolve : raw material weight ratio was increased from 3 : 1 to 4 : 1, to maintain the attained degree of recovery of arenes and also their content in the raffinate. The other conditions of countercurrent extraction remained unchanged. The results of experiment no. 2 are given in Table 2.

The results show that the arene content in the extract increased by more than 10%, and the raffinate yield, by 2.4% (Table 2). The loss of saturated hydrocarbons with the extract decreased from 7 to 3.4% of the theoretical total amount in the raw material, i.e., by more than half. The higher aromaticity of the extract in experiment no. 2 is demonstrated also by the physicochemical characteristics (increased density and refractive index). In this case, the raffinate quality was somewhat improved also, i.e., in experiment no. 2, we reached more selective separation of the raw material into aromatic and paraffin fractions.

Pentane and the major part of methyl Cellosolve were removed from the extract and raffinate phases by distillation on a 20 TP column. Small amount of residual methyl Cellosolve (1.5–3.0% against the total in the raffinate and extract) was stripped with water. The methyl Cellosolve can be also removed from the raffinate and extract by purging with an inert gas as in the industrial process for selective refining of Texaco oils [7].

The raffinate obtained under the optimized condi-

tions was additionally refined by adsorption on bleaching clay, which was taken in amount of 3% against the raffinate. Then Agidol oil additive was added (3%). Test results for the resulting transformer oil revealed that the product meets the requirement of TU (Technical Specifications) 38.401-58-49–92 for TKp transformer oil in all respects (Table 3).

CONCLUSIONS

(1) Five-step countercurrent extraction of arenes and organoelement compounds from the 300–350°C fraction of low-paraffinicity oil at 4 : 1 aqueous (5% water) methyl Cellosolve to raw material and 1 : 1 pentane to raw material weight ratios allowed a decrease in the sulfury content from 30 vol % in the initial raw material to 18 vol % in the extract. In this case, the yield of the raffinate was about 82%, and the arene content in the extract, 87%, demonstrating sufficiently high selectivity of the process.

(2) Transformer oil obtained on the basis of the above raffinate meets the requirements of TU 38.401-58-49–92 in all respects leaving a wide margin. For example, the dielectric loss tangent was 0.24% against 2.2% by standards.

CHEMISTRY OF FOSSIL FUEL

Manufacture of Hydraulic Oil by Solvent Extraction Refining of 225–290°C Fraction of Low-Paraffinicity Oil

Received May 30, 2002

Abstract—A raffinate meeting the requirements for the hydraulic oil body was obtained from the 225–290°C fraction of low-paraffinicity oil by extraction refining with aqueous methyl Cellosolve in the presence of pentane.

At the Slavneft–Mendeleev Yaroslavl Oil Refining Plant, Open Joint Stock Company, hydraulic oils are produced from the 200–300°C fraction of Troitsk-Anastasievsk oil. The aromatic hydrocarbon content in this fraction is about 25% (hereinafter wt %, unless otherwise stated). However, according to existing technical specifications, the optimal content of aromatic hydrocarbons in environmentally friendly low-viscous hydraulic oils and fluids should be no more than 5.5% [1–3].

Low-aromaticity neutrals are obtained by hydrogenation of the kerosene–gas-oil fraction of aromatic-base crude oil; however, to prevent cracking, hydrogenation of arenes into cycloalkanes should be performed at high pressure (~28 MPa), which requires high capital investments and power inputs [2]. White oils (medicinal, perfume, compressor, and cable oils) with an arene content of 0.5–2% are produced by sulfonation with oleum or sulfuric anhydride [4].

Sulfonation of arenes is also used for manufacture of AMG-10 hydraulic oil. However, this method does not meet the modern environmental requirements, because of formation of large amounts of acid tar to be neutralized or disposed of.

Therefore, white oils are now produced beyond Russia mostly using a two-stage process involving hydrofining (to remove organoelement compounds) followed by hydrocracking at a pressure of 25–35 MPa on Pt, Pd, and Ni catalysts [4]. Realization of such a high-pressure two-stage process also requires high capital investments and power inputs. The goal of this work is to check the possibility of manufacturing hydraulic oil body by extraction refining of the 225–290°C fraction of low-paraffinicity oil using a relatively low-boiling extraction system readily regenerable by distillation. Previously, a procedure was proposed for manufacturing the component of pollution-free diesel oil from the dewaxed 200–320°C fraction using the methyl Cellosolve–water–pentane extraction system [5]. The same extraction system was successfully employed for manufacture of the transformer oil body from the 300–350°C fraction of low-paraffinicity oil [6]. However, hydraulic oil production requires deeper dearomatization of the raw material as compared to both transformer oil and diesel fuel production.

EXPERIMENTAL

As a raw material we used a fraction of Troitsk–Anastasievsk oil, whose characteristics were as follows: fraction composition (°C): 225 (initial boiling temperature), 233 (10%), 248 (50%), 273 (90%), 283 (95%), and 290 (dry point); density ρ_4^{20} 0.861, refractive index n_D^{25} 1.4750, arene content 22.8%, sulfur content 0.07%, kinematic viscosity at 50°C 2.2 $mm^2\ s^{-1}$, and flash point (open vessel) 96°C.

For extraction refining of the 225–290°C fraction, we selected the methyl Cellosolve–water–pentane extraction system (process temperature 30°C, five steps of countercurrent extraction). These basic parameters of the process were taken the same as in extraction refining of the 300–350°C fraction, in order to use the same installation for manufacturing both the hydraulic and transformer oil bodies from different raw materials.

1070-4272/03/7601-0144$25.00

Table 1. Parameters of countercurrent extraction refining of the 225–290°C oil fraction (1 : 1 pentane to raw material weight ratio)

Experiment no.	Water content in methyl Cellosolve, wt %	Solvent : raw material weight ratio
1	2	4 : 1
2	2	7 : 1
3	4	8 : 1

To adapt the processes to the 225–290°C fraction, we only changed the water content in the solvent and the solvent to raw material weight ratio (Table 1).

Extraction experiments were carried out using a system of five thermostatically controlled separating funnels [7]. In light of the need in deeper refining of the 225–290°C fraction as compared to the transformer oil fraction, to enhance the solvency of methyl Cellosolve, in pilot experiment nos. 1 and 2 we reduced the water content in the solvent from 5 to 2%. Note that the use of anhydrous methyl Cellosolve is impracticable because of the low critical temperature of dissolution in pentane (32°C).

Table 2 shows that, in experiment no. 1, we failed in attaining the desired arene content in the raffinate. To increase the degree of arene recovery, in experiment no. 2 we increased the solvent to raw material volume ratio from 4 : 1 to 7 : 1, all other conditions being equal. In this case we obtained the raffinate of the desired quality. However, in this case, the extraction selectivity was insufficient: the arene content in the extract was below 60%, and the loss of saturated hydrocarbons with the extract, 13.16% (counting on the raw material) or 17% of their potential content in the raw material.

Therefore, to increase the process selectivity, in experiment no. 3 we increased the water content in methyl Cellosolve to 4%. At the same time, we increased the solvent to raw material volume ratio to 8 : 1, to maintain the desired quality of the raffinate. The results of experiment no. 3 are better in all respects as compared to experiment no. 2: lower arene content in the raffinate and higher raffinate yield, arene content in the extract, and degree of arene recovery. The loss of saturated hydrocarbons with the extract in experiment no. 3 decreased to 11.58% (counting on the raw material) or to 15% of their potential content in the raw material.

It is possible to further improve the process selectivity, i.e., to increase the raffinate yield and arene content in the extract and to decrease the loss of saturated hydrocarbons with the extract. However, for this purpose, we should further increase the solvent to raw material and pentane to raw material ratios, which will inevitably increase the power consumption for regeneration of the solvents and also in the capital cost due to the need in increasing diameter of the extractor and distillation columns.

The results show that extraction refining of the 225–290°C fraction of Troitsk–Anastasievsk oil requires more stringent process conditions, including higher solvent to raw material ratio, as compared to those used in extraction of arenes from the denormalization products from the Parex plant (Kirishinefteorgsintez Production Association) [8]. This is caused by predominance in Troitsk–Anastasievsk oil of polycycloalkanes and highly branched alkanes, which are more readily soluble in polar solvents, particularly, in methyl Cellosolve, as compared to monocycloalkanes and monomethylalkanes of the diesel fraction of West Siberian oils.

In this work, methyl Cellosolve and pentane were recovered from the extract and raffinate phases by distillation on a 20 TP column. Small residual amounts of methyl Cellosolve (~2%) were removed from the

extract and raffinate by aqueous stripping. In the large-scale process, methyl Cellosolve residuals can be removed from the extract and raffinate not by aqueous washing, but by live steam distillation or purging with an inert gas.

In extraction refining of relatively light fractions with methyl Cellosolve, the possibility of formation of azeotropic mixtures with hydrocarbons boiling below 200°C should be taken into account.

It is known that azeotropic mixtures characterized by positive deviation from the Raoult's law are formed if the following condition is realized [9]:

$$\gamma_1^0 > P_2^0/P_1^0$$

where γ_1^0 is the activity coefficient of the hydrocarbon at infinite dilution in the azeotropizer component and P_1^0 and P_2^0 are the saturated vapor pressures of the hydrocarbon and azeotropizer component at the boiling point of the azeotropic mixture.

With arenes, methyl Cellosolve forms systems characterized by small deviations from ideality (activity coefficient of arenes in methyl Cellosolve at infinite dilution γ^0 ~3–5). Therefore, methyl Cellosolve having bp 124.4°C can form azeotropic mixtures only with arenes whose boiling point differs from that of methyl Cellosolve by no more than 30°C, i.e., with such solvents as toluene, xylenes, and cumene, but not with mesitylene (bp 164.7°C) and arenes C_{10}.

The limiting activity coefficients of saturated hydrocarbons in methyl Cellosolve are considerably higher. Therefore, methyl Cellosolve can form azeotropic mixtures even with decane (bp 174.6°C) [10]. Also methyl Cellosolve can form tangential azeotropic mixtures with undecane (bp 195.6°C) and branched alkanes C_{11}.

The initial boiling temperature of the fraction in hand is 225°C (standard distillation), which corresponds to an initial boiling temperature of about 200°C on the actual boiling point curve. Therefore, the 225–290°C fraction should contain no C_{11} alkanes, and we observed no formation of azeotropic mixtures of methyl Cellosolve with hydrocarbons in solvent regeneration.

However, if the initial boiling temperature of a fraction were lower by 10–15°C, it is not improbable that C_{11} alkanes capable of forming azeotropic mixtures with methyl Cellosolve would enter this fraction. In this case, the process flowsheet should include separators for these azeotropic mixtures. However, no oiling of methyl Cellosolve with hardly removable trace arenes will occur even if the initial boiling temperature under standard distillation conditions is lowered to 190–200°C.

The raffinate obtained after extraction refining of the 225–290°C fraction of low-paraffinicity oil meets the basic requirements of TU (Technical Specifications) 38.301-29-21 for AMG-10 hydraulic oil body (Table 3).

Thus, AMG-10 hydraulic oil body can be manufactured by extraction refining of the 225–290°C fraction of low-paraffinicity oil. This method should be con-

sidered as an alternative to sulfuric acid refining as an environmentally unfavorable process, as well as hydrogenation as requiring the use of pure hydrogen and high-pressure equipment.

CONCLUSION

Five-step countercurrent extraction refining of the 225–290°C fraction of low-paraffinicity oil containing 23% arenes, at 8 :1 solvent (methyl Cellosolve–4% H_2O) to raw material and 1 : 1 pentane to raw material weight ratios, allowed decrease in the sulfury content in the raffinate to 4.5 vol % (raffinate yield about 69%). The raffinate thus obtained meets the requirements to the AMG-10 hydraulic oil body.

CHEMISTRY OF FOSSIL FUEL

Ozonolysis of Asphaltenes from Semicoking Tar of G17 Coal

V. V. Platonov, A. N. Kudrya, and S. V. Proskuryakov

Leo Tolstoy Tula State Pedagogical University, Tula, Russia
St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 3, 2002

Abstract—Liquid-phase ozonolysis of asphaltenes from the semicoking tar of G17 coal was studied.

In structural studies of asphaltenes, ozone is of particular interest as a specific agent cleaving double bonds [1–9]. Identification of low-molecular-weight (water-soluble) and high-molecular-weight (water-insoluble) products of asphaltene ozonolysis by ^{1}H and ^{13}C NMR spectroscopy, gas chromatography–mass spectrometry (GC–MS), gas–liquid (GC) and thin-layer (TLC) chromatography, UV/Vis spectroscopy, and ESR allows detailed characterization of the molecular structure of asphaltenes of various origins, which, in turn, is necessary for their efficient application.

In this work we studied liquid-phase ozonolysis of asphaltenes from the semicoking tar of G17 coal.

EXPERIMENTAL

Coal characteristics: moisture content W^{d} 2.9, ash residue A^{c} 8.7, yield of volatiles V^{daf} 36.6% (based on air-dry coal); elemental composition, % daf: C 80.8, H 5.7, N 1.0, O 11.7, S_{tot} 0.8. Yield of semicoking tar, % of organic matter of coal (OMC): 15.1; chemical group composition of semicoking tar, % of anhydrous tar: organic bases 1.15, carboxylic acids 0.85, phenols 18.96, hydrocarbons 32.90, neutral oxygen-, nitrogen-, and sulfur-containing compounds 25.11, asphaltenes 86, and resinous substances + loss 12.43 [10].

Characteristics of asphaltenes: molecular weight M = 277.5; elemental composition, % daf: C 77.8, H 8.2, N 2.6, O 11.4; functional composition, g-equiv mol^{-1}: phenolic groups (PG) 0.42, quinoid groups (QG) 0.40, keto groups (KG) 0.27, alcoholic groups (AG) 0.38, alkoxy groups (AOG) 0.22, and heterocyclic oxygen (O_c) 0.76.

In the mineral fraction of asphaltenes, we identified by emission spectrum, X-ray fluorescence, and X-ray phase analyses the following elements: Fe, Mg, Al, Si, Ti, Ni, Sn, Sb, V, Mn, Cr, Zn, Zr, Pt, Rh, Hg, Ge, Ga, Pb, Ca, Na, K, Ce, Co, and Nd. The IR spectra of asphaltenes contained absorption bands (ν, cm^{-1}) of the following structural fragments: aromatic rings (3030–3080, 1600, 1500, 1440–1465), with the increased intensity of the bands at 1600 and 1500 suggesting formation of fused structures; CH_2 groups exhibiting stretching (2840, 2940, 2925, 2850) and bending (720–740, 970, 1470) vibration bands, whose high intensity suggests high content of hydrogenated rings; phenolic hydroxyls (3570–3670, 1140–1230, 1310–1410); methoxy groups (2850); quinoid groups (1645, 1665, 1675, 1745); cyclic and naphthenic alcohols (1030–1120, 1260–1350, 3630–3700); oxygen- and nitrogen-containing heterocycles (1565, 1500, 1015–1030, 845–870, 740–800).

Asphaltenes have relatively high molecular weight (154–589); they contain alicyclic, aromatic, and heterocyclic rings fused in the linear or angular fashion.

From the practical viewpoint, one of promising ways of asphaltene processing is homogeneous pyrolysis, as it can yield additional amounts of hydrocarbons and other valuable products. However, the yield of pyrocarbon is relatively high, which calls for development of alternative procedures for processing asphaltenes. One of such procedures is ozonolysis.

Homogeneous ozonolysis of asphaltenes was performed in an installation consisting of an ac generator, an ozonizer equipped with a water-cooled jacked and tungsten electrodes, a bubbling reactor, a temperature control system, a control valve for feeding air, and a bottle packed with silica gel ASKM for drying the air fed to the ozonizer. The volume fraction of ozone in the ozone–air mixture was 2.5%. The reaction was performed in chloroform at $20 \pm 1°C$ for 30 h. The optimal reaction time was chosen in a series of pre-

1070-4272/03/7601-0148$25.00

liminary experiments in the course of which samples of the reaction mixture were taken and analyzed by TLC and IR and UV/Vis spectroscopy. The reaction performed for a time longer than 25–30 h caused no further significant changes in the composition of the ozonolysis products.

Active transformations of asphaltenes under the action of ozone start after an induction period (2–3 h) and are the most significant in the first 12–15 h. The ozonolysis mechanism is not unambiguous and constant throughout the process, as judged from the trends in variation of the content of various functional groups with time.

In the first stage of the process, the content of aromatic rings drastically decreases, and ozonides are formed. The content of phenolic groups and heterocyclic oxygen drastically decreases also, but the relative content of quinones somewhat increases.

This is followed by decomposition of ozonides and formation of carboxy and keto groups with dramatic decrease in the content of quinoid groups. Finally, the amount of aliphatic substituents decreases and naphthenic rings are cleaved, which is indicative of the occurrence of radical oxidation with atomic and molecular oxygen formed by partial decomposition of ozone.

Thus, the revealed trends in transformations of asphaltenes in the course of ozonolysis allow an important conclusion that there are two reaction pathways: classical ozonolysis involving cleavage of peripheral aromatic rings and heterocycles via ozonides and radical oxidation with atomic and molecular oxygen, apparently occurring after saturation with ozone of the multiple bonds in aromatic rings.

The mechanism of cleavage of "internal" aromatic rings in fused asphaltene structures is different and apparently involves intermediate formation of quinones, which accounts for a certain increase in their content in the initial stage of ozonolysis.

The induction period is most probably due to the slowest stage of the process, addition of ozone to multiple bonds with the formation of ozonides. Then, as the ozonides decompose, the rate of asphaltene oxidation by various pathways sharply grows.

Thus, the kinetic features of ozonolysis revealed by prompt analytical procedures form a theoretical basis for controlling the process so as to stop it at the required stage, in particular, at the stage of ozonide formation.

After ozonolysis completion, the reaction mixture was refluxed with distilled water for 2 h to fully decompose ozonides, and the organic and aqueous phases were separated in a separatory funnel. The weight gain of the organic phase after removal of the solvent was 66.15 wt %.

To identify acidic components of the aqueous layer, the aqueous phase was chromatographed on an activated Silufol plate in the system ethanol–25% ammonia–water (volume ratio 50 : 15 : 2.5). A reference mixture of acids was chromatographed simultaneously. The plates were developed under UV light (254 and 366 nm) and then sprayed with a 0.25% solution of Bromocresol Purple (reagent for carboxylic acids) and a 0.2% solution of diazotized *p*-nitroaniline (reagent for phenols).

We identified oxalic (the major component of water-soluble products), salicylic, succinic, benzoic, and phthalic acids.

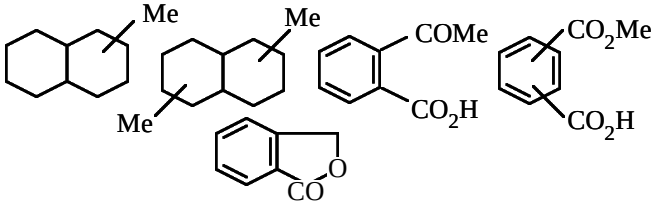
An aliquot of the aqueous layer was titrated potentiometrically with 1 N aqueous-alcoholic KOH. From the first potential jump corresponding to titration of oxalic acid, we evaluated its yield: 22.5% based on the initial asphaltenes.

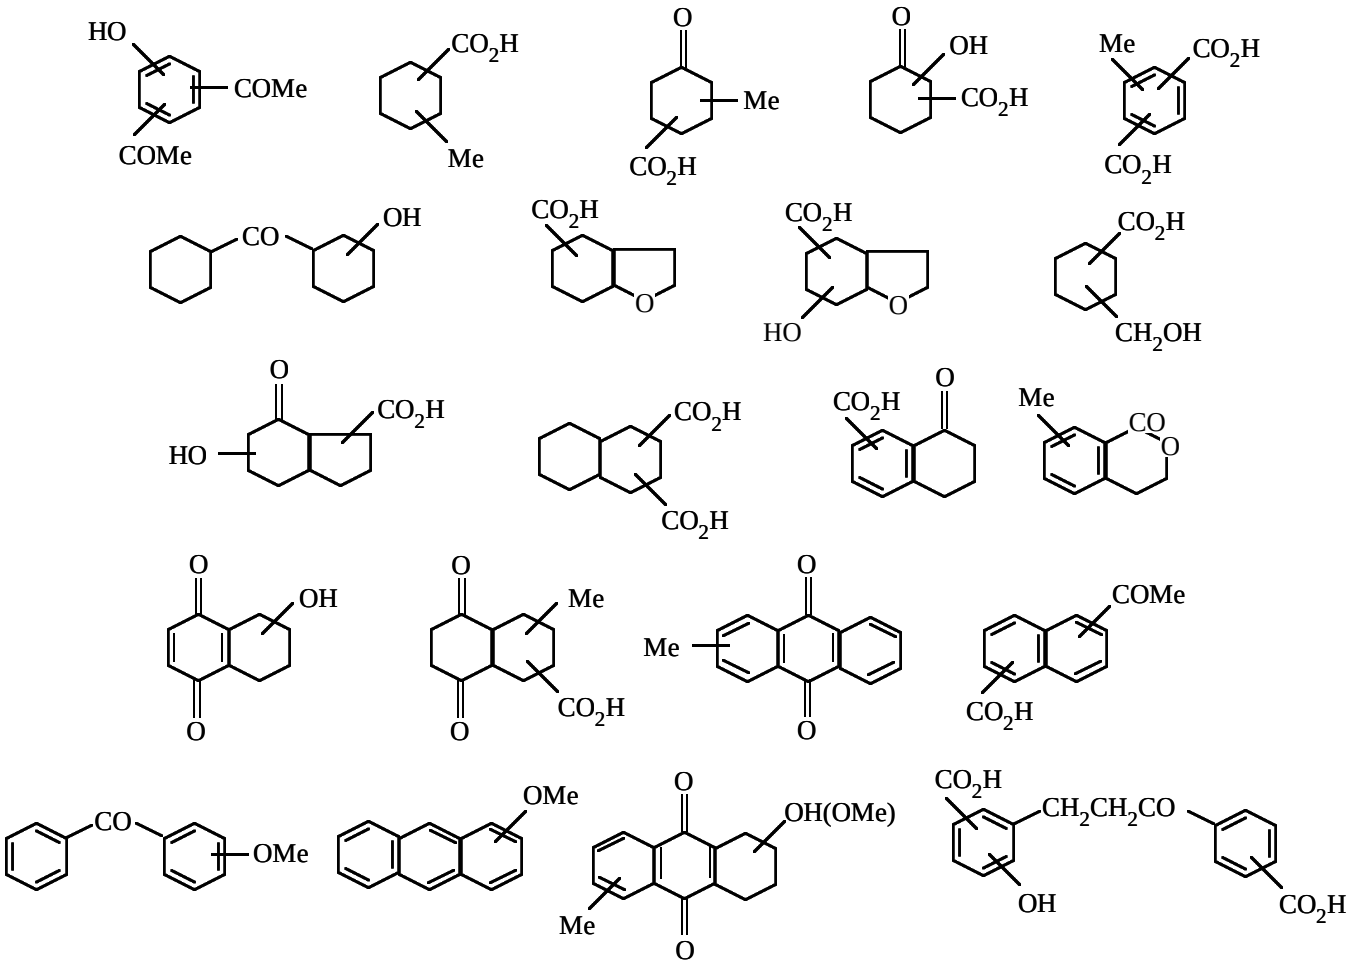
The composition of organic products of asphaltene ozonolysis was found by combination of the data of IR and UV/Vis spectroscopy, cryoscopy, elemental and quantitative functional analysis, and TLC.

Under the optimal TLC conditions (petroleum ether–acetone–benzene, volume ratio 25 : 40 : 15), we obtained 26 close-cut fractions (see table).

It is seen that the isolated components are characterized by broad ranges of the molecular weight (150–295) and composition (% daf: C 53.2–86.8, H 3.7–13.3, and O 7.7–35.6). Among functional groups, the carboxy and keto groups are present in the largest amounts: 0.74–1.92 and 0.60–1.62 g-equiv mol^{-1}, respectively. The content of hydroxy groups is also significant: 0.49–0.81 g-equiv mol^{-1}. Quinoid groups were identified in four compounds, with the content of 1.70–1.99 g-equiv mol^{-1}. Alkoxy, ester, and lactone groups and heterocyclic oxygen are untypical of the isolated components: only two or three structures were detected.

The presumed structural formulas of the isolated compounds are listed below.



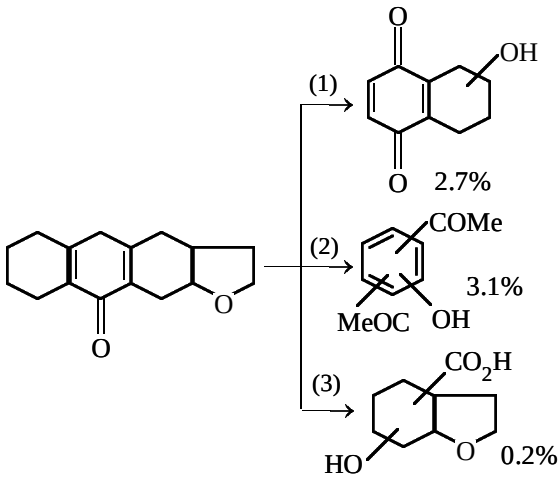


Except methyl- and dimethyldecalins, which are the only detected hydrocarbons, the organic phase mainly consists of functional (mostly bifunctional) mono-, bi-, and tricyclic compounds containing carboxy, keto, and hydroxy groups. The high content of aromatic rings along with naphthenic rings may be due to secondary formation of aromatic rings in the course of ozonolysis by oxidative dehydrogenation of naphthenes. Quinoid structures are all the more secondary; they are formed by intermediate oxidation of "internal" aromatic rings of the initial asphaltenes. The carboxy and keto groups are formed by oxidative degradation of alkyl substituents and naphthenic rings.

The whole set of our results allows certain practical conclusions.

Firstly, mild ozonation can be successfully used as an additional procedure for confirming the structure of high-molecular-weight asphaltenes by converting them into low-molecular-weight compounds, and also for revealing the structural correlations between the initial and oxidized asphaltenes and for elucidating possible transformation pathways of various components of oxidized asphaltenes.

For example, for several pathways of possible transformations of one of the initial asphaltenes, we calculated the activation energy E_a by the procedure [11] based on the assumption that the bond energies in the activated complex are additive:



The calculated activation energies are as follows:

Characteristics of asphaltene ozonolysis products*

* (CG) Cresol groups, (EG) ester groups, and (LR) lactone rings.

E_a^1 = 148.75, E_a^2 = 168.02, and E_a^3 = 338.55 kJ mol^{-1}.

It is seen that pathway (3) with the highest activation energy is characterized by the yield as low as 0.2%, whereas the two other pathways whose activation energies are approximately two times lower give ~15 times higher product yields: 2.7 and 3.1%.

The contribution of pathway (1) is somewhat lower than that of pathway (2), despite lower E_a. This may be due to further degradation of the product of reaction (1), involving the quinone ring and occurring before the product concentration is measured.

Secondly, we have found a way of efficient processing of asphaltene raw materials which are accumulated in large amounts at petrochemical and coal-tar chemical plants and have no applications yet.

High-molecular-weight asphaltene compounds can be converted by ozonolysis into valuable products and raw materials for organic synthesis. In particular, high yield of oxalic acid (22.5% based on the initial asphaltenes) makes economically feasible its recovery from water-soluble ozonolysis products. Succinic and salicylic acids can be obtained as by-products.

Among the components of the organic phase, of considerable interest are polycarboxylic acids as additional significant source of raw materials for heat-resistant fibers, plastics, and lubricants, and also quinones as starting compounds for preparing dyes.

CONCLUSIONS

(1) Homogeneous ozonolysis of asphaltenes from the semicoking tar of G17 coal was studied, and variation of the structure of products was monitored.

(2) The ozonolysis products contain aromatic and alicyclic structures substituted with phenolic, quinoid, carboxy, keto, and ester groups, oxygen-containing heterocycles, and six-membered lactones.

(3) The major pathways of asphaltene ozonolysis were suggested.

Conversion of Tantalum(V), Niobium(V), and Titanuim(IV) Sulfates and Chlorides to Their Fluorides

V. G. Maiorov and A. I. Nikolaev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received September 3, 20002

Abstract—A process was developed for converting tantalum(V), niobium(V), and titanium(IV) sulfate and chloride to their fluorides in order to improve separation of these elements.

Large deposits of rare-earth titanoniobates, loparite and perovskite, are located on the Kola Peninsula. Some procedures of their breakdown yield acidic sulfate and chloride solutions containing tantalum(V), niobium(V), and titanium(IV) [1–5]. Numerous studies on separation of rare metals from these solutions were summarized in [6]. Especially numerous papers deal with extractive recovery of Ta(V), Nb(V), and Ti(IV) from chloride solutions. For example, more than twenty papers on extraction of these metals with tributyl phosphate were published. Increased interest in this problem was caused by researchers' attempts to develop an extraction procedure for treatment of loparite chlorination products formed in industrial processing of loparite ore in Russia [7]. However, these attempts failed. Serious problems originated from the dependence of the extractability of Nb(V) and especially Ta(V) on the history (preparation procedures) of the solutions of these metals, from deterioration of extractive recovery and separation of Nb(V) from Ta(V) due to copolymerization of Nb(V) with Ta(V), and of Nb(V) and Ta(V) with Ti(IV) and Zr(IV) and other metals, and a sharp decrease in the extractability of Ta(V) on standing or heating of solutions [6]. These facts, along with such negative factors as relatively low solubility of Nb(V) and Ta(V) in hydrogen chloride solutions, active joint extraction of foreign metals, and their difficult removal from the target metals make extractive separation of Ta(V), Nb(V), and Ti(IV) from chloride solutions unfeasible. Still greater problems arise in extractive separation of Ta(V), Nb(V), and Ti(IV) from sulfate solutions [6].

The most efficient separation and purification of the metals under consideration is attained with fluoride system, which is successfully used in industry [8]. In this system, Ta(V), Nb(V), and Ti(IV) are jointly extracted with organic acids from solutions prepared by breakdown of rare-metal titanoniobates with sulfuric or hydrochloric acids [1–5] and then are backwashed with hydrofluoric acid. Ta(V) and Nb(V) are recovered from the resulting fluoride solutions by extraction with tributyl phosphate (TBP) [9] or octanol [10]. Owing to conversion of sulfate and chloride complexes into fluoride derivatives and the fact that organic acids recover metals by the ion-exchange mechanism virtually without mineral acids, the liberated H_2SO_4 and HCl can be reused for breakdown of the initial titanoniobate [6]. After extractive recovery of Ta(V) and Nb(V), the spent aqueous fluoride solutions can be subjected to dialysis or pyrolysis [1, 2] to obtain commercial titanium dioxide and regenerate HF for its reuse for backwashing metals from the organic extracts. The above-noted procedures are promising for developing a low-waste procedure for processing of rare metal raw materials.

Among effective organic acid extractants, the cheapest and the most commercially available is di(2-ethylhexyl) hydrogen phosphate (HDEHP). Our experimental results on extractive recovery of Ta(V), Nb(V), and Ti(IV) with HDEHP from sulfuric acid process solutions obtained by different procedures of breakdown of loparite, perovskite, and sphene with sulfuric acid are listed in Table 1. The data on backwashing of the metals are given in Table 2. In our experiments we used technical-grade HDEHP containing about 7 vol % of main component, about 7 vol % of mono(2-ethylhexyl) dihydrogen phosphate (H_2MEHP), and isooctyl alcohol. Kerosene and RED-1 (C_{12}–C_{16} paraffins hydrocarbons) were used as diluents.

The extraction was performed at 18–20°C. After one or two contacts of the organic phase with the

aqueous hydrogen fluoride solution, Ta(V), Nb(V), and Ti(IV) are virtually exhaustively backwashed from the organic phase. Because V_o is substantially larger than V_a, the target metals are concentrated in the aqueous fluoride backwashes by a factor of about 10. Table 1 (run nos. 7 and 8) shows that heating considerably improves the extraction of the rare elements with HDEHP. We found also that addition of neutral oxygen-containing solvents (e.g., TBP) improves the extractive recovery of Ta(V) and Nb(V). The amount of this additive, however, should not be large (e.g., for TBP, no more than 3–5 vol %), because higher concentrations of additives prevent backwashing of the metals with aqueous HF. The similar technique was successfully used by us for converting Ta(V), Nb(V), and Ti(IV) chlorides to their fluorides [4]. In this process, both the degree of extracive recovery of the rare metals with HDEHP and the degree of their backwashing were close to 100%.

In conclusion it should be noted that the contact of HDEHP with concentrated mineral acids should be avoided. For example, contact of HDEHP with aqueous HF and H_2SO_4 with concentration exceeding 8 and 10 M, respectively, results in fast decomposition of this extractant [11].

CONCLUSIONS

(1) Ta(V), Nb(V), and Ti(IV) are virtually completely recovered from aqueous sulfuric acid with di(2-ethylhexyl) hydrogen phosphate and are backwashed from the organic phase with aqueous HF.

(2) Conversion of Ta(V), Nb(V), and Ti(IV) to their fluorides by backwashing from the organic phase with aqueous hydrogen fluoride is promising for development of low-waste procedures for processing rare-earth titanoniobates.

Solubility of Calcium Sulfate Dihydrate in Nitric Acid at 20°C

Yu. A. Vershkova, O. A. Tareeva, K. G. Ivlev, and E. P. Lokshin

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received June 18, 2002

Abstract—The solubility of gypsum in 0–30 wt % nitric acid solutions at 20°C was studied. The data were compared with the results obtained at 60°C.

Methods involving preliminary leaching of calcium ions with nitric acid show promise for recovery of calcium-containing rare-metal raw materials (perovskite, sphene) [1–3]. The forming solutions contain free nitric acid, nitrates of calcium and rare-earth elements, and, to a small extent, nitrates of other impurity elements. Most of calcium ions can be precipitated from the leaching solution by addition of sulfuric acid, and the nitric acid solution after concentrating can be reused to break down the concentrates. Reuse of nitric acid solutions is also of interest due to the fact that under certain conditions rare-earth elements do not precipitate jointly with calcium sulfate [4] and can be accumulated in the solution and subsequently recovered by extraction.

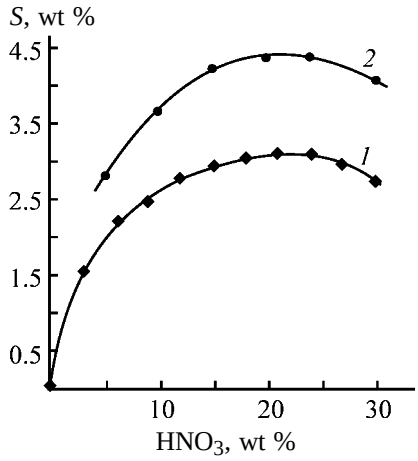
Methods are being developed for extracting lanthanides by nitric acid leaching of phosphogypsum, $CaSO_4 \cdot 2H_2O$, and phosphohemihydrate, $2CaSO_4 \cdot H_2O$, which are by-products in production of wet-process phosphoric acid from Khibiny apatite concentrate [5–7]. In the course of leaching, phosphohemihydrate recrystallizes into phosphogypsum, and calcium sulfate dissolves in the nitric acid solutions.

To estimate the efficiency of the calcium ion precipitation from nitric acid leaching solutions and the amount of calcium sulfate dissolving in nitric acid during leaching of phosphogypsum, we determined experimentally the dependence of the solubility of calcium sulfate dihydrate on the nitric acid concentration at 20°C.

The solubility of calcium sulfate dihydrate in nitric acid was studied by the isothermal method. Analytically pure grade chemicals were used. The initial solutions with a prescribed HNO_3 concentration and excess $CaSO_4 \cdot 2H_2O$ were kept in hermetically sealed temperature-controlled flasks at 20 ± 0.5°C with stirring until the equilibrium was attained. The process was monitored by analysis of the liquid phase at regular intervals for the content of Ca^{2+} and SO_4^{2-} ions by standard photometric and gravimetric procedures. The presence of two endothermic peaks in the ranges 124–150 and 178–192°C in the thermograms and the X-ray phase analysis data for the samples of the bottom phase confirm the existence of $CaSO_4 \cdot 2H_2O$ under the examined conditions.

As seen from the results obtained (see figure), the dependence of the gypsum solubility on the nitric acid concentration at 20°C passes through a maximum in the range 22–25 wt % HNO_3. Data on the $CaSO_4 \cdot 2H_2O$ solubility at 60°C [8] are presented for comparison. The observed direct temperature dependence of the $CaSO_4 \cdot 2H_2O$ solubility in nitric acid confirms the previous results [4].

The results obtained are useful for engineering calculations and physicochemical substantiation of flowsheets for reprocessing of calcium-containing rare-metal raw materials. In particular, we can state that



Solubility S of $CaSO_4 \cdot 2H_2O$ in nitric acid at (*1*) 20 and (*2*) 60°C [8].

the low residual concentration of calcium ions in recycled nitric acid solutions must not impede their reuse for breaking down sphene concentrate.

Electrotreatment of Wastewaters from High-Octane Fuel Production To Remove Methyl *tert*-Butyl Ether and Methanol

S. V. Vorob'eva and O. V. Smirnov

Tyumen Center, International Academy of Ecology and Life Protection Sciences, Tyumen, Russia

Received October 2, 2001; in final form, January 2002

Abstract—The possibility is examined of removing methyl *tert*-butyl ether from wastewaters by electrotreatment.

Industrial wastes from gas-condensate stabilization plants contain methanol, sodium carbonate and hydrocarbonate, *tert*-butanol, isobutene dimers, and methyl *tert*-butyl ether $CH_3OC(CH_3)_3$ (MTBE). The standard flowsheet of wastewater treatment in such plants includes hydrocyclones, oil removers, floatation machines, and tanks for treated wastewater. A line of wastewater treatment to remove MTBE and associated acetone, dimeric isobutene, methanol, and hydrocarbons is connected in parallel. MTBE cannot be oxidized biochemically. At the input of the line, the MTBE concentration amounts to 20–40 mg g^{-1}. At the output, it should be no more than 0.001 mg g^{-1}. The facilities and pipelines should be leakproof.

At the Surgut gas-condensate stabilization plant, the output of the treatment plant for removal of MTBE is 4.0 m^3 day^{-1}. The chemical oxygen demand (COD) of the wastewater to be treated is 7 g l^{-1}, the oil product content, 100–200 mg l^{-1}, and pH 6.5–8.5. The MTBE concentration at the output is 10 mg l^{-1} and that of the suspended material, up to 100 mg l^{-1}.

The use of electrotreatment for such wastes was reported in [1–5]. In this work we studied the efficiency of electrotreatment to remove MTBE from wastewaters containing 14.5 mg l^{-1} MTBE in the presence of 68 g l^{-1} methanol. The concentrations of MTBE, methanol, *tert*-butanol, and hydrocarbons were determined chromatographically, using a thermal conductivity detector. Electrotreatment was performed with an Akvalon electrode array [3, 4] (voltage on the flat electrodes 24 V, interelectrode distance 3–4 mm, and power consumption 40 W).

The electrode array consisted of four plates 14.5 cm high (two of them 6.4 cm wide, and two, 3.9 cm). Such an electrode arrangement allowed both uniform or nonuniform electrical field conditions. As filters we used foamed propylene fiber cartridges (horizontal filtration to the center; countercurrent washing with water). In one series of experiments we used aluminum electrodes (treatment time 120 min using 6-min pulses and 1-min breaks) and in the other series, large-width aluminum internal electrodes and small-width iron external electrodes (treatment time 60 min with the same pulses). The dispersion formed in the course of electrotreatment was agitated in breaks between pulses.

After electrotreatment with the aluminum electrode array, the MTBE concentration decreased from 14.5 to 6.8 mg l^{-1}. More considerable effect was observed with the combined electrode array. We failed to recover MTBE exhaustively. The methanol concentration decreased to 60.7 g l^{-1} after electrotreatment with combined electrode array for 30 min and to 42 g l^{-1} after treatment with Al electrode array for 60 min.

One more series of experiments was performed, to determine the efficiency of electrotreatment of wastewaters formed after regeneration of reforming columns, containing Na_2CO_3, Na_2SO_3, and 1.01 mg l^{-1} of iron ions (pH 7.5, dry residue 9500 mg l^{-1}). After electrotreatment with Al electrode array for 60 min, the dry residue was 9540 mg l^{-1} and iron concentration, 0.41 mg l^{-1}; and with the combined electrode array, 9340 and 0.7 mg l^{-1}, respectively.

Increased efficiency of wastewater treatment in the electrical field is due to the fact that, in this case, coagulation with participation of organic molecules [5] and associates is followed by their chemisorption on some coarser aggregates formed from the regenerated coagulant [$Fe(OH)_2$ + $Fe(OH)_3$ + $Al(OH)_3$] and multiple-charged Al and Fe cations. Because of the weak polarity, the common electrokinetic effects can

1070-4272/03/7601-0158$25.00

be only partly manifested in the course of coagulation. At the same time, certain contributions to this process are provided by dielectrophoresis, including dipolophoresis [1].

CONCLUSION

The use of external uniform or nonuniform electrical fields at a strength of up to 100 V cm^{-1} for treating industrial wastewaters from gas condensate stabilization plants allows reduction of the contents of such oxygen-containing organic fuel additives as methyl *tert*-butyl ether and methanol.

Received July 9, 2002

Abstract—1,3-Bis(trialkylammonio)-2-propanol dihalides were prepared, and their retardant activity was studied in relation to the chemical structure.

No retardants (compounds inhibiting the growth of plant pedicels and increasing their productivity) effective toward rape are known [1]. Relatively low retardant activity is exhibited by *N,N*-dimethylmorpholinium [2, 3] and *N,N*-dimethylpiperidinium [4] chlorides.

With the aim of revealing a correlation between the retardant activity and chemical structure and of searching for new retardants effective toward rape, we have converted 1,3-bis(dialkylamino)-2-propanols **Ia**–**Ic** [5–7] into 1,3-bis(trialkylammonio)-2-propanol dihalides **IIa**–**IIc**, **IIIa**–**IIIc**, and **IVa**–**IVc** and studied their biological activity. Quaternization was performed with iodomethane, 1-chloro-2-propene, or benzyl chloride:

$$\underset{\textbf{Ia–Ic}}{R_2NCH_2CHOHCH_2NR_2} \xrightarrow{R'X} \underset{\textbf{IIa–IIc, IIIa–IIIc, IVa–IVc}}{[R'R_2N^+CH_2CHOHCH_2N^+R_2R']2X^-},$$

where NR_2 = $N(C_2H_5)_2$ (**Ia**), piperidino (**Ib**), morpholino (**Ic**); NR_2 = $N(C_2H_5)_2$; R' = CH_3, X = I (**IIa**); R' = $CH_2CH{=}CH_2$, X = Cl (**IIb**); R' = $CH_2C_6H_5$, X = Cl (**IIc**); NR_2 = piperidino; R' = CH_3, X = I (**IIIa**); R' = $CH_2CH{=}CH_2$, X = Cl (**IIIb**); R' = $CH_2C_6H_5$, X = Cl (**IIIc**); NR_2 = morpholino; R' = CH_3, X = I (**IVa**); R' = $CH_2CH{=}CH_2$, X = Cl (**IVb**); R' = $CH_2 \cdot C_6H_5$, X = Cl (**IVc**).

The yield was 85–99%. The composition and structure of the compounds were proved by UV and ^{1}H NMR spectroscopy and by elemental analysis (see table). The absorption band of the aromatic ring in the UV spectra of **IIc**–**IVc** is located at about 264 nm ($\log\varepsilon$ = 2.8–3.0), and the chemical shift of the hydroxyl proton in the ^{1}H NMR spectra of **IIa**–**IVa**, in the region of δ = 4.9 ppm.

The retardant activity was studied with respect to rape plantules and roots under laboratory conditions [8] and in field experiments.[1]

The height, diameter, anatomic structure, and resistance to lodging of pedicels, and the plant productivity were estimated [9].

We found that salt **IVb** inhibits the growth of rape plantules and pedicels, appreciably increases the green and dry weight of roots, and stimulates formation of components of rape harvest as compared to the control. Compounds **IIa**, **IIc**, **IIIa**–**IIIc**, **IVa**, and **IVc** are considerably less active or inactive at all. Thus, replacement of the morpholine fragment in the molecule of **IVb** by the piperidine or diethylamine fragments, as well as replacement of the 2-propenyl substituent by methyl or benzyl substituents, sharply decreases the retardant activity toward rape.

EXPERIMENTAL

The UV spectra were taken on a Specord UV-VIS spectrophotometer in 95% ethanol, and the ^{1}H NMR spectra, on a Tesla BS-487C spectrometer (80 MHz, solvent CF_3CO_2H, internal reference TMS).

1,3-Bis(*N*, *N*-dialkyl-*N*-methylammonio)-2-propanol diiodides IIa–IVa. Iodomethane (42.6 g, 0.3 mol) was added dropwise with stirring to 0.1 mol of **Ia**–**Ic**. The mixture was kept at 50–60°C for 0.5 h

[1] Field experiments were performed in the pilot area of the Lithuanian Institute of Agriculture (Dotnuva Academy).

and cooled to 20°C; the precipitate was filtered off, washed with anhydrous diethyl ether, dried in a vacuum, and recrystallized from acetone–ethyl acetate (1 : 3 by volume).

1,3-Bis(*N*, *N*-dialkyl-*N*-2-propenylammonio)-2-propanol dichlorides IIb–IVb. A mixture of 0.1 mol of **Ia**–**Ic** and 30.6 g (0.4 mol) of 1-chloro-2-propene was refluxed for 60 days and cooled; the precipitate was worked up as described for **IIa**–**IVa** and recrystallized from acetone–ethyl acetate (1 : 5 by volume).

1,3-Bis(*N*, *N*-dialkyl-*N*-benzylammonio)-2-propanol dichlorides IIc–IVc. A mixture of 0.1 mol of **Ia**–**Ic** and 50.6 g (0.4 mol) of benzyl chloride was heated at 100°C for 50 h and cooled; the precipitate was worked up as described above for **IIa**–**IVa.**

CONCLUSIONS

(1) A procedure was developed for preparing 1,3-bis(trialkylammonio)-2-propanol dihalides by N-alkylation of 1,3-bis(dialkylamino)-2-propanols.

(2) Among the compounds prepared, 1,3-bis(*N*-2-propenylmorpholinio)-2-propanol dichloride exhibits retardant activity toward rape.

BOOK REVIEWS

Gaile, A.A., Proskuryakov, V.A., Semenov, L.V., Pul'tsin, N.M., Parizheva, N.V., Zakharov, A.P., Apter, Yu.M., and Solodova, N.I., *Predel'nye koeffitsienty aktivnosti uglevodorodov: Spravochnik* (Limiting Activity Coefficients of Hydrocarbons in Specific Solvents: A Handbook), Gaile, A.A., Ed.

St. Petersburg: Sankt-Peterburg. Gos. Univ., 2002

The handbook covers experimental activity coefficients of hydrocarbons C_5–C_9, including alkanes, cycloalkanes, alkenes, alkadienes, alkynes, and arenes at infinite dilution in more than 500 polar solvents, obtained by GLC at the St. Petersburg State Technological Institute. Note that a significant part of these data was previously published only in dissertations.

It follows from comparison with the fundamental handbook (Gmehling, J., Menke, J., and Schiller, M., *Activity Coefficients at Infinite Dilution*, Frankfurt on Main, 1994) that the reviewed handbook covers more than a half of all the known selective solvents. Data given in this handbook are of importance for choosing optimal separating agents in extraction, extractive and azeotropic distillations, and absorption, i.e., in the processes widely used in oil-refining and petrochemical industries. Data on the limiting activity coefficients of hydrocarbons can be used for predicting their solubility, and the selectivity of a solvent can be judged from the activity coefficient ratios of components to be separated. Also these data are widely used in modeling phase equilibria liquid–liquid and liquid–vapor using semiempirical Wilson, NRTL, UNIQUAC, and other equations.

The handbook is of interest for specialists working in the fields of physical chemistry, oil processing, and petrochemistry.

BOOK REVIEWS

Blinov, L.N., *Khimiko-ekologicheskii slovar'-spravochnik* (Chemical-Ecological Dictionary—Reference Book)

St. Petersburg: Lan', 2002, 272 pp.

In recent decades, such disciplines as ecology, safe mode of life, ecological chemistry, and chemistry of the environment have appeared in the curricula of secondary- and higher-school institutions. The increasing attention is given to preservation in quite a number of other general and special courses. In this connection, numerous special terms have appeared, not used widely previously. The chemical-ecological dictionary—reference book under discussion is the first publication of this kind, which is intended to serve to a wide audience of readers, and schoolchildren and junior students in the first place. The book, written in well-understandable manner, presents interpretation of about 1400 various terms of generally chemical and ecological nature.

The first edition of the reference book, considered here, proves to be much more "chemical" than "ecological," despite the apparent conventionality of such a distinction. No more than 8–10% of the total number of entries are devoted, according to our estimate, to ecological terms proper. Sufficiently detailed evidence is given about all elements of the periodic table, much attention is given to the terminology used to describe the chemical bond (atomic and molecular orbitals, bonding molecular orbital, metal–metal bond, chemical bond), to issues concerning the nomenclature of chemical compounds (systematic nomenclature of anions, cations, acids, acid and basic salts, bases, oxides, organic compounds).

The book written by L.N. Blinov, a known specialist, professor of St. Petersburg State Polytechnic University, can well be used as additional textbook of chemistry in a wide variety of educational institutions. It seems advisable to enhance, in subsequent editions of the book, its ecological component by including entries concerning the pollution of the environment with heavy metals, and mercury in the first place, evidence about radiation accidents that have occurred in Russia and their consequences. Such compounds as tetraethyllead, fluorochloromethanes, and dioxins deserve separate consideration. It would be well to characterize potassium superoxide, the most important component of formulations serving to evolve oxygen and absorb carbon dioxide in self-contained objects. When considering metals, it would be appropriate to specify the amount of their production in Russia and, in some cases, place emphasis on the environmental problems associated with their manufacture. This, in particular, refers to aluminum, whose manufacture inflicts severe damage on the environment, is accompanied by discharge of fluoride compounds, and possibly leads to formation of benzopyrene in anode mass baking.

Blinov has demonstrated a rather valuable initiative, which deserves any kind of support.

ANNIVERSARIES

Nataliya Aleksandrovna Smirnova (to 70th Anniversary of Her Birthday)

On January 4, 2003, Nataliya Aleksandrovna Smirnova, a corresponding member of the Russian Academy of Sciences, professor, and head of the Chair of Physical Chemistry at St. Petersburg State University, was 70.

N.A. Smirnova is a prominent physical chemist and honorable representative of the physicochemical school of St. Petersburg University. Her basic research made a significant contribution to several parts of modern physical chemistry: molecular theory of solutions, theory of phase equilibria, and molecular-statistical theory of complex fluid systems of various kinds.

Smirnova is the author of about 300 scientific publications, including monographs and textbooks. Wide acceptance has been gained by the monograph *Metody statisticheskoi termodinamiki v fizicheskoi khimiii* (Methods of Statistical Thermodynamics in Physical Chemistry), the first and very successful manual of statistical thermodynamics for chemists (1st edition, 1973; 2nd edition, 1983; translated abroad). Numerous Smirnova's original investigations were summarized in her monograph *Molekulyarnye teorii rastvorov* (Molecular Theories of Solutions, 1988), she was the author of the most important chapters in collective monographs *Termodinamika razbavlennykh rastvorov* (Thermodynamics of Dilute Solutions) and *Termodinamika ravnovesiya zhidkost'–par* (Thermodynamics of the Liquid–Vapor Equilibrium), and in IUPAC publication *Uravneniya sostoaniya* (Equations of State).

The investigations carried out by Smirnova and her disciples have the fundamental nature and are characterized by high scientific level, being, at the same time, aimed at solution of important applied problems. These include development of effective methods for calculation of phase equilibria in order to optimize separation processes, methods for calculation of thermodynamic properties and phase equilibria in systems composed of oil and natural gas in a very wide range of conditions, analysis of factors influencing precipitation of asphaltenes from crude oil, establishment of regular trends in physicochemical behavior of mixed surfactant solutions, etc.

Also fruitful are Smirnova's pedagogic activities:

She has been delivering general courses of lectures on physical chemistry and statistical thermodynamics and special courses at the chemical faculty and working with graduates, postgraduates, and doctoral candidates. Among Nataliya Aleksandrovna's disciples are doctors and candidates of science and known scientists. Smirnova has been delivering lectures at leading universities in many countries all over the world and participating in the work of international scientific conferences, both as speaker and as conference organizer. Smirnova's works have been twice honored with awards of St. Petersburg University and a State Prize of the USSR. She conducts important scientific-organizational work, being a member of a number of Scientific Councils and a member of Editorial Boards of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) and *Zhurnal Fizicheskoi Khimii* (Russian Journal of Physical Chemistry).

Editorial Board of *Zhurnal Prikladnoi Khimii*, Russian Academy of Sciences

Russian Journal of Applied Chemistry, Vol. 76, No. 1, 2003, p. 165. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 1, 2003, p. 171.

OBITUARIES

Sergei Sergeevich Markov (October 23, 1906–November 20, 2002)

Prikladnaya Khimiya Russian Scientific Center and the entire domestic chemical science have suffered an irreplaceable loss.

On November 20, 2002, Sergei Sergeevich Markov, research worker at the Center, doctor of chemistry, professor, laureate of Lenin and State Prizes, passed away at the age of 96. Having graduated from the Leningrad Pharmaceutical, and then from the Leningrad Technological, institutes, Sergei Sergeevich started his scientific activities at the State Institute of Applied Chemistry (GIPKh) and devoted to this institute 73 years of his working life, having worked his long way up from laboratory assistant to deputy director of the Institute for scientific work.

Death deprived us of an outstanding scientist, prominent specialist and organizer in the field of technical chemistry and space technology. All Prof. Markov's activities have been associated with the development of domestic chemical industries and creation of the Russian school of chemical engineers with a broad spectrum of capabilities.

Technology for nepheline processing, production of aluminum oxide from bauxites, synthesis of compounds of magnesium, iodine, and bromine and inorganic fluoro compounds—all these issues have been the subject of his interests and have been powered by his ideas.

Special mention should be made of Sergei Sergeevich's works on organization of industry for manufacture of manganese compounds, on whose synthesis he has been working till the last days of his life.

The originality and national importance of these investigations and industrial implementation of research developments are characterized by the fact that, in 1937, the scientific degree of the candidate of science was conferred to Markov without backing a dissertation, and in 1943, he was awarded the State Prize of the USSR for the development of GAP (GIPKh active pyrolusite).

During the World War II, Sergei Sergeevich remained in besieged Leningrad and supervised, together with the staff members of GIPKh, manufacture of defense-related products for the Leningrad front.

In postwar years, continuing his work on problems concerning the technology of manufacture of fluoride and manganese compounds, compounds of magnesium, iodine, and bromine, and various nitro compounds, Prof. Markov devoted his efforts to the developing space technology.

His works on creation of rocket propellant components and their use in special technologies culminated in that, in 1967, Markov was awarded, together with other members of a group, his second State Prize, and in 1976, a Lenin Prize for works on technology for synthesis of a new class of nitro compounds.

Sergei Sergeevich has trained a sizable pleiad of specialists working in various fields of the national economy. His disciples include candidates and doctors of science and directors of companies, and with all of them he unselfishly shared his ideas, professional and everyday experience, and knowledge.

Production shops to which Sergei Sergeevich made a prominent creative contribution are still working at plants in Slavgorod, Perm, Nevinnomyssk, Dneprodzerzhinsk, Samara, Moscow, St. Petersburg, Saki, Krasnoperekopsk, Baku, Novotroitsk, Nebit Dag, Neftechala, Salavat, and Biisk; his studies in chemistry of manganese have gained worldwide acceptance.

Markov's merits have been honored with high State awards.

The rich legacy bequeathed to us by Sergei Sergeevich is constituted by his disciples, his numerous papers and inventions, and fruitful scientific ideas he had no time to implement himself.

An attentive and sensitive person and manager, he has been always deeply respected by staff members of the Institute and plants where he has ever been and worked.

The unexceptionable honesty, culture, devotion to work and colleagues, and enormous working capacity and energy of Sergei Sergeevich have always caused sincere delight of those around him.

Together with his relatives and friends, we deeply grieve over the irreplaceable loss and will preserve Sergei Sergeevich Markov's respectful memory in our hearts.

Staff members of the Prikladnaya Khimiya Russian Scientific Center

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Calcium Chloride Purification

A. A. Fakeev, L. V. Vasil'eva, and A. I. Sukhanovskaya

State Research Institute of Chemical Reagents and Ultrapure Chemical Substances, Moscow, Russia

Received February 27, 2002

Abstract—Two methods of calcium chloride purification were studied: crystallization from aqueous solutions and joint precipitation of impurities from aqueous solutions onto inorganic collectors (hydrated aluminum or zirconium oxides). The purification factors were calculated and a high efficiency of purification of calcium chloride solutions with hydrated zirconium dioxide as collector was established.

Calcium chloride is widely used in metallurgical, chemical, chemical-pharmaceutical, aircraft, and coal industries, in glass manufacture, agriculture, everyday chemistry, etc. [1].

In chemical industry, calcium chloride is, along with calcium nitrate, a key compound for preparing the most practically important calcium products (calcium carbonate, phosphate, chromate, etc.) [2].

In recent years, ultrapure calcium compounds (calcium carbonate, fluoride, and phosphate) have found application in fabrication of optical fibers, single crystals, and luminophores, [3, 4]. This required the development of novel methods for thorough purification of the accessible raw material, calcium chloride.

In the system $CaCl_2$–H_2O, compounds of the following compositions crystallize: $CaCl_2 \cdot 6H_2O$, $CaCl_2 \cdot 4H_2O$, $CaCl_2 \cdot 2H_2O$, $CaCl_2 \cdot H_2O$, and $CaCl_2$, whose solubilities are 42.9, 53.60, 67.20, and 77.32, and >80 wt %, respectively [1, 5].

The efficiency of crystallization purification of calcium chloride could be estimated from data on phase equilibria in water–salt systems containing this salt. However, the relevant data are scarce. The systems $CaCl_2$–M^nCl_n–H_2O, where M^n is Co(II) [6, 7], Cu(II) [8], NH_4^+ [9], K [10], or Mg(11) are of simple eutonic type at 25°C; those in which M^n is Cu(I) [8], Mn(II) [12], Zn [13], or Cd [14] are binary compounds. Analysis of the data presented suggests that crystallization from aqueous solutions is an effective method for separation of calcium chloride from Co(II), Cu(I), Cu(II), Mn(II), Zn, Cd, NH_4^+, K, and Mg chlorides.

Crystallization of $CaCl_2$ from HCl solutions is promising, since in this case, the yield of the target product increases substantially ($CaCl_2$ solubility in a 26–28% HCl solution is 4 times lower at 0°C and twice lower at 15°C than that in H_2O [1]); however, this process has not been studied. It has been proposed to purify $CaCl_2$ solutions to remove iron ions by treatment with carbonate-containing compounds (ammonium carbonate solution) at 71–100°C and pH 4–7. A product containing 8×10^{-5} wt % iron has been obtained [15].

A way to prepare $CaCl_2$ phosphors by precipitation of sparingly soluble sulfide and phosphate impurities, separation of precipitate, and boiling of the solution with activated carbon has been described. The quality of the product obtained has not been reported [16].

Joint precipitation of impurities with calcium carbonate at 60–80°C and pH 5–7 has been proposed as a method for purification of $CaCl_2$ solutions, and the possibility of using purified solution for preparing luminophore has been demonstrated [17, 18].

Treatment of $CaCl_2$ solutions with complexing reagents (sodium diethyldithiocarbamate [17–19], 8-oxyquinoline [20]) is highly efficient in removal of iron, heavy metals, and other impurities.

Analysis of the above data on $CaCl_2$ purification shows that published data are rather scarce. Promising among the known purification methods are crystallization of $CaCl_2$ from aqueous solutions and joint precipitation of impurities onto inorganic collectors.

The aim of the present study was to analyze the process of calcium chloride purification.

joint precipitation of impurities from aqueous solutions onto inorganic collectors.

The study was performed using radioactive tracers ^{59}Fe, ^{60}Co, ^{54}Mn, ^{51}Cr, ^{64}Cu, and ^{63}Ni. The radiation was recorded simultaneously from several isotopes using an IN-96B automated multichannel gamma spectrometer (France) and a semiconductor detector (single-crystal germanium). The relative measurement error was ±2–3%. Beta radiation (^{63}Ni) was measured with a BDIS 3-05 transducer with detector (thallium-activated NaI), PS-2 counter unit, and scintillating granules. The relative accuracy of the measurement was ±10%. The results of radiometric analysis were used to calculate the crystal purification factors K_{pur} as the ratio of the specific activities of crystals (solution) before and after crystallization (purification), related to unit mass of $CaCl_2 \cdot 6H_2O$), and the degree α of precipitation of the main substance ($CaCl_2 \cdot 6H_2O$) into the solid phase during crystallization [21].

The purification of $CaCl_2$ by crystallization was studied as follows: radioactive isotopes of the corresponding metals were introduced into 100 ml of a 78% solution of $CaCl_2 \cdot 6H_2O$ [14–1 ultrapure grade, TU (Technical Specification) 6-09-3834–80], and the mixture was stirred and kept for 1 day for isotopic exchange to occur. Then, the solution was evaporated on a water bath to obtain solid phase in varied yield and cooled to room temperature under continuous agitation. The crystals precipitated were separated on a Büchner funnel ("blue tape" filtering paper) and firmly squeezed between two sheets of filtering paper to remove mother liquor. The squeezed crystals were twice washed with a saturated solution of initial $CaCl_2$, whose volume was equal to the crystal mass, and then squeezed again. The specific activities of the initial solution, mother liquor, squeezed crystals before washing, and doubly washed crystals (after dissolution in water) were determined, and K_{pur} were calculated.

Analysis of the results obtained (Table 1) shows that the degree of $CaCl_2$ purification by crystallization from aqueous solution to remove iron, manganese, chromium, nickel, and cobalt ion impurities is not too high. The low degree of purification of the $CaCl_2 \cdot 6H_2O$ crystals (Table 1) is due to occlusion of the mother liquor, since additional washing of the crystals makes K_{pur} higher for all of the impurities studied. According to published data, calcium and cobalt (copper and manganese) chlorides do not form solid solutions in joint crystallization from aqueous solutions [6–8, 12].

The results obtained are accounted for by the characteristic high solubility of $CaCl_2$ and stability of metastable supersaturated solutions. This leads to changes in the crystal growth mechanism, facilitates formation of aggregates, closed cavities, and capillaries, and causes surface deterioration and the resulting pronounced entrapment of mother liquor by the crystals, which is responsible for the low degree of purification of unwashed crystals (Table 1).

Additional washing of the isolated $CaCl_2 \cdot 6H_2O$ crystals with a saturated aqueous solution of this compound markedly increases the degree of purification (Table 1). Despite the necessity for processing of large volumes of mother liquors, the crystallization method shows industrial promise. Compared with calcium nitrate crystallization [21], the method in question is more efficient for preparing small amounts of ultrapure calcium salts in laboratory.

Also, purification of $CaCl_2$ solutions with inorganic collectors was studied. It has been established previously [21] that purification of calcium nitrate solutions to remove 3*d*-metal impurities with the use of hydrated aluminum and zirconium oxides is highly effective. It has been proposed to purify calcium chloride solutions by coprecipitation of impurities onto a $CaCO_3$ collector [15, 17, 18]. However, this collector is, as a rule, effective only for iron impurity [15, 21]. Therefore, hydrated aluminum, $Al_2O_3 \cdot nH_2O$, or zirconium oxides, $ZrO_2 \cdot nH_2O$, precipitated in a solution being purified were used in this study for purification of $CaCl_2$ aqueous solutions.

* $CaCl_2 \cdot 4H_2O$.

Solutions of radioactive isotopes were introduced into a 20 wt % solution of $CaCl_2$ (25 ml), the solution was stirred for 3 h for the isotope exchange to occur, and a sample was taken for radiometric measurements. Then, calculated amounts of a 20% solution of $Al(NO_3)_3$ (17-3 ultrapure grade, TU 6-09-3657–74) or $ZrOCl_2$ (chemically pure grade, TU 6-09-3677–74, 2.0 wt % relative to the $CaCl_2 \cdot 6H_2O$ mass by analogy with the data of [21]) were introduced into the solution, and a 10% solution of NaOH [18-3 special-purity grade, OST (All-Union Standard) 6-01-302–74] was gradually added under agitation to pH 8.0. The mixture was stirred for 1 h, the precipitated hydrated aluminum or zirconium oxides were separated on a TsLN-2 centrifuge, and the purified solution was sampled for radiometric analysis. The method of analysis and the procedure for calculating K_{pur} are described above.

Analysis of the results obtained (Table 2) shows that the purification of $CaCl_2$ solution with $ZrO_2 \cdot nH_2O$ collector is a highly effective process. For $Al_2O_3 \cdot nH_2O$, the degree of $CaCl_2$ purification is somewhat lower and differs significantly from the results obtained previously for $Ca(NO_3)_2$ solutions [22]. This can be accounted for by higher stability of chloride complexes in aqueous solutions [23].

The data on coprecipitation of metal ions onto $ZrO_2 \cdot nH_2O$ (Table 2) correlate well with the values of the first constants of their hydrolysis [24] and supplement the previously established selectivity series [25].

Large-scale laboratory experiments on $CaCl_2$ purification by crystallization from aqueous solutions were performed. An aqueous solution of $CaCl_2$ was prepared by dissolving an analytically pure reagent at 70°C, filtering the solution on a "blue tape" filtering paper, evaporating it on a water bath to about 60% yield, and cooling the mixture to room temperature under continuous agitation. The crystals precipitated were carefully separated and washed with a saturated solution of $CaCl_2$ (14-1 special-purity grade), whose volume was equal to the mass of the separated $CaCl_2 \cdot 6H_2O$ crystals. Then the crystals were dried at 25–28°C and subjected to spectrochemical analysis [26].

A comparison of the quality of the initial $CaCl_2$ samples and those purified by crystallization from aqueous solution (Table 3) showed that this method is

promising for preparing a special-purity-grade product. For preparing ultrapure calcium salts, the $CaCl_2$ crystallization is a more effective method than the previously described technique using calcium nitrate [21].

CONCLUSIONS

(1) Purification of $CaCl_2$ by crystallization from aqueous solutions was studied using radioactive tracers. The purification factors were calculated. It was found that the low values of K_{pur} for $CaCl_2 \cdot 6H_2O$ crystals are due to occlusion of the mother liquor. It was shown that $CaCl_2$ crystallization is promising method for preparing an ultrapure product.

(2) Purification of aqueous $CaCl_2$ solutions by coprecipitation of impurities onto inorganic collectors ($Al_2O_3 \cdot nH_2O$ or $ZrO_2 \cdot nH_2O$) was studied using radioactive tracers. A high efficiency of the $ZrO_2 \cdot nH_2O$ collector for purification of $CaCl_2$ solutions was demonstrated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Optimization of Olivine Processing To Obtain Magnesium Meliorant

V. N. Makarov, N. K. Manakova, T. N. Vasil'eva, and A. T. Belyaevskii

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received September 16, 2002

Abstract—Problems associated with the optimization of processing of olivine from mining wastes and, in particular, from dressing tailings of vermiculite ores with sulfuric acid in order to obtain a magnesium meliorant characterized by alkaline reaction were considered. The influence of a seed on the course of silica gel coagulation and on the filtration of the forming solutions was studied.

Atmospheric precipitation near mining and smelting plants is characterized by increased acidity. Although the strongest impact of acid rains on the environment is observed on territories closely adjacent to nonferrous metallurgy plants, the influence of these rains is also pronounced at a considerable distance from the plants. In particular, acid rains in Kola peninsula also fall in regions virtually lacking any industrial plants, including nature reserves. This atmospheric precipitation, which is characterized by pH ranging from 3.6 to 4.7, contains 2.1 to 52.7 mg l^{-1} of sulfate ions [1].

Under the action of acid rains, a number of necessary nutritious elements, Mg^{2+}, Ca^{2+}, and Mn^{2+} cations in the first place, are selectively leached from plants and soil of forest ecosystems [1].

To compensate for the deficiency of cations, it is necessary to use meliorants that would replenish the nutritious substances. In view of the increased acidity of soil in zones affected by acid rains, the meliorants must possess a neutralizing capacity and also improve the soil structure. With account of the large areas of deteriorated forests, the meliorants must be comparatively low-cost and readily accessible.

An important factor in making lower the cost of a meliorant is cheapness of raw materials. The most promising in this regard are mining wastes. Annually, industrial countries produce hundreds of millions of tons of ferrous and various nonferrous metals. Most part of ores is separated, in the course of ore dressing, in the form of nonmetalliferous minerals from the valuable minerals and discarded as waste into tailing dumps. The maintenance of tailing dumps is rather expensive. Finely dispersed tailings react with atmospheric agents. Flotoreagents, which are sorbed on the surface on nonmetalliferous minerals, and products of oxidation of sulfides are leached into surface and ground waters. In the course of oxidation of ore dressing tailings, readily soluble sulfates of heavy metals pass into the environment [2]. The large volume of the mining waste accumulated gives no reason to believe that they could be processed in near future. Therefore, the primary objects of study and targets for utilization technologies are mining wastes that can be reprocessed into ecological-purpose materials [3].

Meliorants can be manufactured from mining wastes mainly composed of silicates (olivinites, dunites, etc.) or magnesium hydrosilicates (serpentinites).

In particular, meliorants can be obtained from serpentine-containing materials, which are wastes formed in processing of copper-nickel, vermiculite, and some other ores. However, serpentine materials are to be activated in order to obtain the final product. This involves certain energy expenditure, which is not always justified.

Use of mining wastes mainly composed of anhydrous magnesium silicates, olivines, which are frequently richer in magnesium oxide than serpentines, offers more promise for manufacture of meliorants. In this case, strip-pit olivinites of the Kovdor phlogopite deposit, dressing tailings of vermiculite ores, strip-pit

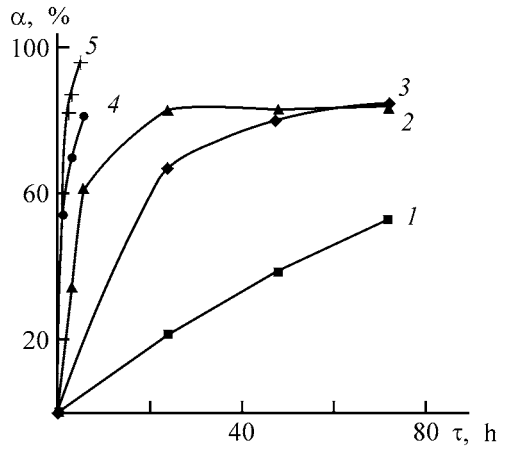

Fig. 1. Degree of olivine processing, α, vs. processing time τ. Processing temperature (°C): (*1*) 20; (*2*) 40; (*3*) 60; (*4*) 80; (*5*) 80, with addition of a seed.

dunites from chromite deposits of the Monchegorsk region, and other products of this kind can serve as raw materials. Although vermiculite tailings are characterized by lower content of magnesium oxide, they contain minerals including other nutritious substances: calcium and phosphorus in apatite, potassium in hydrophlogopite, and manganese in olivine and vermiculite, which can also be converted into assimilable form. At the same time, the dressing tailings are rather cheap and readily accessible.

In acid treatment of olivine, nutritious substances contained in it are converted into a form assimilable by plants [4]. However, the technique proposed in [4] has two important disadvantages; olivine processing takes a long time (72 h) and the product obtained is characterized by a stable acid reaction. Formation of a silica gel poses considerable difficulties, since, in producing a magnesium fertilizer, silica passes into the final product because of the impossibility of filtration. At the same time, there is no way of neutralizing acid salts and acid residues formed in olivine processing, since magnesium hydrosilicates are formed in the neutral or alkaline medium in the presence of silicic acid.

To manufacture a neutral meliorant, it is necessary to optimize the olivine processing so as to enable separation of silica and to prevent reverse reactions in neutralization of acid salts and acid residues.

EXPERIMENTAL

In studying the reaction of olivine with H_2SO_4, dressing tailings of vermiculite ores were used. In view of the fact that fine fractions of this product contained a large amount of sungulite, and coarse fractions contained pieces of dike rocks, which are poor in magnesium minerals, the vermiculite tailings were subjected to preliminary sizing. The +0.125–3.0-mm fraction was used in the experiments.

Mineral composition of the raw material (%): olivine 45.3, vermiculite 12.65, apatite 10.04, magnetite 8.66, diopside 21.17, and sungulite 0.8.

Chemical composition of the raw material (wt %): MgO 25.0, K_2O 0.12, CaO 14.0, Na_2O 0.26, Al_2O_3 0.92, FeO 4.25, Fe_2O_3 5.81, H_2O 1.12, SiO_2 33.46, and P_2O_5 4.46.

A 15-g portion of the material was poured over with 50 ml of a 40% H_2SO_4 solution. The temperature was varied between 20 and 80°C, and the processing time, between 3 h and 3 days.

After the experiment was complete, the solid residue was washed with distilled water and dried. A white powder containing new formations was separated from the product obtained. Then the granulometric composition of the residue was studied and residual contents of the starting minerals—olivine, pyroxenes, vermiculite, and apatite, were determined mineralogically. A finely dispersed product was additionally subjected to X-ray diffraction analysis on a DRON-2 diffractometer (Cu_{K_α} radiation), and also studied on a FLOUSORB II 2300 laboratory electronic device for measuring the specific surface area and porosity and on a Hitachi scanning electron microscope.

The washing solutions were analyzed chemically for the content of calcium, magnesium, and iron ions.

The degree of olivine processing, measured in the course of time at different temperatures, is shown in Fig. 1. At room temperature, the process is slow, and, therefore, the subsequent experiments were done at 40, 60, and 80°C. On raising the temperature, the olivine conversion is much accelerated: at 80°C olivine is virtually entirely (80%) processed in 6 h.

Equation (1) describes the reaction of olivine with acid

$$Mg_2SiO_4 + 4H^+ + (n - 2)H_2O = 2Mg^{2+} + SiO_2 \cdot nH_2O. \quad (1)$$

The study performed demonstrated that, together with acid processing of olivine, formation of magnesium hydrosilicates with serpentine-like structure is observed:

$$6Mg^{2+} + 4SiO_2 \cdot nH_2O = Mg_6(OH)_8[Si_4O_{10}] + 4(n - 1)H_2O. \quad (2)$$

In this case, a considerable amount of magnesium ions recovered into solution are bound. Raising the temperature promotes the olivine processing, but, even to a greater extent, accelerates the formation of hydrosilicates. As a result, the recovery of magnesium ions into solution decreases. It seems reasonable that, for reverse reactions to occur, the solution pH should be made higher. Therefore, it is impossible to obtain a neutral meliorant directly by acid processing of olivine. Presumably, a technology for obtaining such a product must include several stages, with neutralization only carried out after separating the active silica.

It is known that the longest characteristic time in silica coagulation is the induction period of nucleation of primary colloid particles, which then combine into coarse aggregate. Silica coagulation is much accelerated in the presence of specially introduced particles of amorphous SiO_2, acting as nuclei [5]. To prevent formation of magnesium hydrosilicates and to accelerate silica coagulation, a seed, having the form of amorphous SiO_2 obtained from nepheline, vermiculite, or sungulite, was introduced into the reaction vessel together with raw materials and acid. The experiments were done with vigorous stirring. The solutions were filtered in hot state to prevent $MgSO_4$ crystallization. After an experiment was complete, the solid residue was washed with hot distilled water (70°C).

The experiments demonstrated that addition of amorphous SiO_2 as a seed makes it possible to obtain coagulated silica and well filterable solutions, to prevent a reverse reaction of binding of magnesium ions from solution, and to decrease the H_2SO_4 concentration to 25%, with total recovery of magnesium ions into solution ensured.

Figure 2 shows kinetic curves describing the completeness of recovery of magnesium ions in relation to the amount of seed. With the amount of a seed additive prepared from nepheline increasing to 15% relative to the amount of the starting material, the recovery of magnesium ions reaches 100%. A sungulite seed is less effective, with the recovery equal to only 76%. It is not improbable that the closeness of the inherited structure of the seed to magnesium hydrosilicates gives no way of ruling out the reverse reactions. However, a vermiculite-based seed is nearly as effective as that based on nepheline. With increasing amount of the seed added (Fig. 3), the humidity of the final product decreases.

Electron-microscopic studies demonstrated that newly formed silica has a lamellar structure (Fig. 4), whereas amorphous SiO_2 obtained by sulfuric acid treatment of nepheline [5] is represented by densely packed rounded particles.

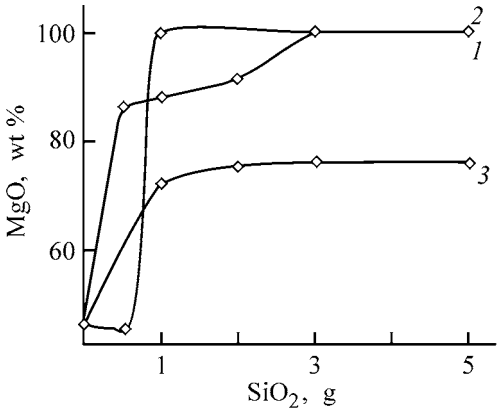

Fig. 2. Amount of recovered MgO vs. amount of SiO_2 seed introduced. Seed: (*1*) nepheline, (*2*) vermiculite, and (*3*) sungulite; the same for Fig. 3.

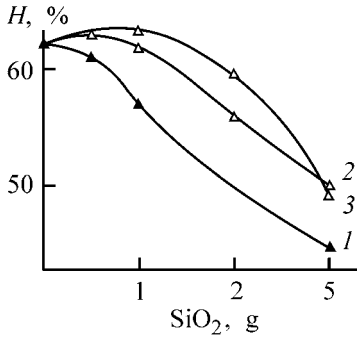

Fig. 3. Sample humidity *H* vs. amount of SiO_2 seed introduced.

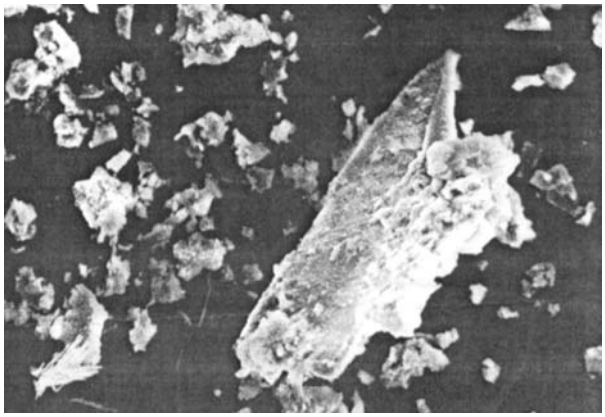

Fig. 4. Electron micrograph of a finely dispersed sample obtained with addition of a vermiculite seed.

CONCLUSIONS

(1) Complete processing of olivine and vermiculite contained in vermiculite tailings takes 6 h in 25% sulfuric acid at 80°C.

(2) Addition of amorphous SiO_2 as a seed precludes the reverse reaction of magnesium ion binding from solution and ensures complete leaching-out of magnesium.

(3) The optimal amount of the silica seed in terms of dry substance is 15 wt % relative to the amount of the starting raw material.

(4) Separation of a silica precipitate from the magnesium-containing solution enables manufacture of a neutral meliorant by a known method.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Distribution of Copper, Nickel, Cobalt and Iron between Products of Smelting of Copper Concentrate Obtained by Flotation of Converter Matte

N. A. Fedorova, L. B. Tsymbulov, and L. Sh. Tsemekhman

Institut Gipronikel' Joint-Stock Company, St. Petersburg, Russia

Received November 21, 2002

Abstract—An experimental study of the equilibrium between the bottom phase (sulfide melt or copper) and slag in neutral and oxidizing atmospheres yielded dependences of the content of dissolved copper, nickel, and cobalt in the slag on that of sulfur in the sulfide melt and also the dependence of the content of dissolved copper and nickel on that of nickel in the metallic melt. The distribution coefficients of the metals between copper and slag were determined and compared with the results of other investigations.

Nickel-containing copper concentrate obtained by flotation of the converter matte (composition, wt %: Cu 67–70, Ni 2–5, Fe 2–5, Co 0.1–0.3, S 20–21) is processed in various ways [1–7].

The distribution of the metal between a target product (sulfide melt or metallic melt based on copper) and the slag is one of the most important characteristics of any smelting technology. Commonly, this factor is evaluated by the metal distribution coefficient L_M defined as the ratio of metal weight fractions in the sulfide (metallic), $X_{[M]}$, and slag phases, $X_{(M)}$:

$$L_M = X_{[M]}/X_{(M)}.^1 \quad (1)$$

It is a common practice to subdivide copper-based metallic melts, depending on their copper and sulfur content, into blister copper containing 0.5–1 wt % Ni and 0.03–0.05 wt % S and "sulfurous" copper containing 5–6 wt % Ni and 1.5–2.0 wt % S.

The wide variety of technologies used in smelting of the copper concentrate assumes significant differences in the L_M values. The reason is that the compositions of the sulfide (metallic) melts and slag are different, as also are the compositions of the gas phase over the melt, which is characterized by partial oxygen pressure P_{O_2}.

The available published data obtained in studying the distribution of nickel and copper in processing of the copper concentrate produced by flotation of the converter matte are considered in this study.

Yazawa [8, 9] studied the distribution of metals between a sulfur-free copper-based metallic melt and the slag under partial oxygen pressure of 10^{-11}–10^{-8} atm in the gas phase at a temperature of 1200°C. The equilibrium between iron-silicate slag saturated with silicon dioxide, on the one hand, and copper, on the other, in the temperature range 1217–1307°C at partial oxygen pressure varied from 10^{-11} to 10^{-7} atm was studied in [10]. The solubility of copper in the iron-silicate slag saturated with silicon dioxide was determined in [11] under the conditions of equilibrium with a liquid Cu–Au melt at $P_{O_2} = 10^{-10}$–10^{-7} atm and 1250–1350°C. The coefficients of copper, nickel, and iron distribution at 1500°C between the liquid Cu–Ni–Fe alloy and the slag (which is a mixture of FeO_x–SiO_2–CaO oxides saturated with MgO) were calculated from the activity coefficients of the alloy components at partial pressures of oxygen in the range 10^{-10}–10^{-6} atm [12]. These activity coefficients were determined by the quasi-equilibrium gas-flow method using Knudsen's double mass-spectrometric cell. In [13], the results obtained in an experimental study of the distribution of metals in equilibrium in the systems constituted by (i) sulfurous copper, sulfide melt, and slag and (ii) blister copper and slag in an atmosphere of argon and in an oxidizing atmosphere with $P_{O_2} = 1.6 \times 10^{-5}$–$2.9 \times 10^{-5}$ atm at 1300°C were considered. Abramov *et al.* [14] studied the influence exerted by the content of silicon dioxide in a slag at $P_{O_2} = 1.4 \times 10^{-5}$ atm and 1300°C on the distribution of metals in

[1] A reverse ratio between the metal weight fractions can also be found in the literature. In the present study, the L_M values are represented as the $x_{[M]}/x_{(M)}$ ratio.

the equilibrium system constituted by sulfurous copper, sulfide melt, and slag. The dependence of the distribution coefficients on the SO_2 concentration in the gas phase (P_{O_2} = 6.1×10^{-5}–2.1×10^{-4} atm) at 1280°C was studied under equilibrium conditions in the system formed by sulfurous copper, sulfide melt, and slag [15]. The distribution coefficients found in these studies are listed in Table 1.

Analysis of the data obtained indicates that the majority of the investigations [8–13, 15] are concerned with the effect of P_{O_2} on the solubility of copper in slag.

The copper content in slag grows (L_{Cu} value decreases) with increasing P_{O_2}. The effect of slag composition on the distribution of nonferrous metals has been studied to a lesser extent [13–15]. The least studied is the influence exerted by the activities of components in a copper-rich melt (sulfide melt, sulfurous copper, or blister copper) on the distribution of copper and impurities concomitant in cooper–nickel production (nickel, cobalt, and iron). The only study [11] was concerned with the influence of the activity of copper on its distribution between metallic melt and slag. It was found that copper solubility in the slag linearly grows with its increasing activity in the Cu–Au melt, with this dependence becoming more pronounced with increasing partial pressure of oxygen.

It follows from Table 1 that the most topical issue to be studied is the effect of the composition of sulfide and metallic melts on the distribution of copper and metal impurities between the smelting products. Such a study would cover all versions of technologies for processing of the nickel-containing copper flotation concentrate, from smelting to give copper sulfide to that producing blister copper.

Three sets of experiments were performed in this study. The first of these was concerned with the effect of the sulfide melt composition on the distribution of metals between products of smelting in an argon atmosphere. The second and the third sets were devoted to the effect of copper composition (sulfurous and blister copper, respectively) in an oxidizing atmosphere. In the first and second sets, a neutral atmosphere was created using high-purity argon which contained (wt %): O_2 0.0002, N_2 0.001, H_2 0.0002, CH_4 0.0001, and CO_2 0.00002. The partial pressure of oxygen in this gas mixture was 4×10^{-8} atm at 1300°C.

In the first set of experiments, a synthetic iron-silicate slag (7 g) containing 20–23 wt % SiO_2 and copper (45 g) with varied sulfur content (17–22 wt %) were used. Mattes of varied composition were obtained by taking an industrial sulfide melt from a reverberatory furnace and the starting concentrate in various proportions.

In the second and third set of experiments, a synthetic iron-silicate slag (7 and 20 g, respectively) containing 22–30% SiO_2 was mixed with copper (45 g in the second set and 20 g in the third) containing various amounts of nickel and sulfur. Copper of varied composition was obtained by taking sulfurous and blister copper in various proportions. The composition of the starting materials is listed in Table 2.

A weighed sample of a stock consisting of slag and a sulfide component (or metal) in an alundum crucible was placed in a high-temperature furnace with $LaCrO_3$ heater. The stock was heated to 1300°C with an inert gas flowing over its surface. To attain the equilibrium faster, the melt was agitated by bubbling of argon[2] ($P_{O_2} = 4 \times 10^{-8}$ atm) in the first and second sets, and with a SO_2–CO_2 gas mixture[3] ($P_{O_2} = 6 \times 10^{-5}$ atm) in the third, for 20 min and allowed to stay for the same time. In the first and second sets, the melt was cooled after settling in the reactor to 700°C in an atmosphere of argon and then in air. In the third set, a slag sample was taken after settling of the melt, and the melt remaining in the crucible was gradually cooled within the furnace to 1000°C under a flow of the working gas mixture and then in air.

The sulfide component and copper formed in smeltings were subjected to chemical analysis.

The content of metals in the slag was determined by scanning electron microscopy (SEM) and X-ray fluorescence microanalysis (XFMA). In the authors' opinion, it is this approach that makes it possible to obtain reliable data on the concentrations of metals dissolved in the slag. As is known [16], slag also includes mechanical aggregates (beads of the sulfide or metallic phase), which strongly distort the equilibrium distribution pattern obtained, e.g., by chemical analysis.

The experimental data on the equilibria between sulfide melts and slag are given in Fig. 1.

Figure 1 shows that the content of Cu, Ni, and Co is virtually independent of the sulfur content in a sulfide melt within the range of compositions under study and the observed scatter of data has random nature and is determined by the experimental error.

The coefficients of metal distribution between the sulfide melt and slag are listed in Table 3. They are also virtually independent of the composition of the sulfide melt. Together with the data obtained in the present study, Table 3 also lists the results of [14, 15].

The difference in the distribution coefficients of copper, found in this study and in [14, 15], is attributable not only to a difference in partial oxygen pressures, but also to the fact that, in the former case, copper dissolved in the slag was determined by the XFMA method, and in [14, 15], chemical methods taking into account not only dissolved copper, but also mechanical losses were used. The distribution coefficients of nickel obtained in the present study are also higher than those reported in [14, 15], which is due to higher nickel content in the sulfide melt. The distribution coefficients of iron and cobalt are in good agreement with the data of [15].

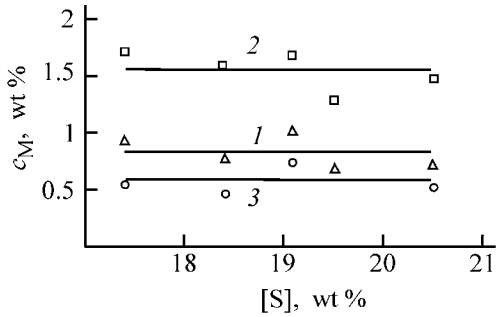

Fig. 1. Metal content c_M in the slag vs. sulfur content in the sulfide melt. M: (*1*) Cu, (*2*) Ni, (*3*) Co.

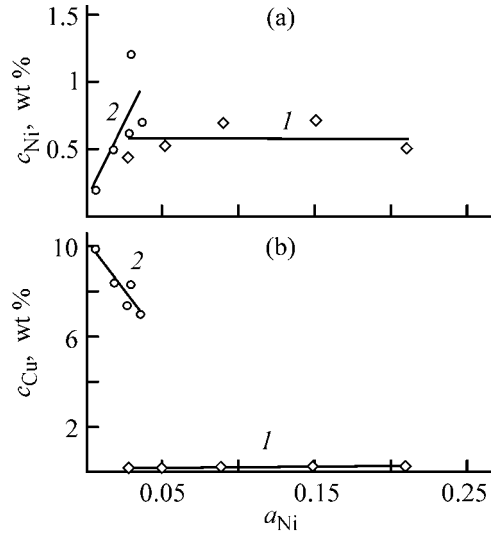

Fig. 2. Dependence of the content of (a) nickel and (b) copper in the slag on nickel activity a_{Ni} in copper in the equilibrium system copper–slag in (*1*) neutral and (*2*) oxidizing atmosphere. (*1*) Ar, (*2*) SO_2.

The results obtained in studying of the copper–slag system in an argon atmosphere are presented in Figs. 2a and 2b, curves *1*. The activities of nickel in copper containing up to 1.2 wt % nickel and about 3 wt % oxygen were taken from [17], where activities of copper and nickel in melts saturated with oxygen were determined. The activities of nickel at its content in copper higher than 1.2 wt % were taken from [18],

[2] The necessity for using argon in the first set of experiments was due to the fact that it is impossible to obtain a sulfide melt with varied sulfur content in an oxidizing atmosphere with rather high P_{O_2}.

[3] The composition of the oxidizing gas mixture was chosen in accordance with the composition of the gas phase formed in smelting of the copper concentrate to obtain blister copper.

0.6	584	1.35	0.22	9.98	1.10	4.4	267	6.34	1.15	11.77	0.95
1.3	391	2.57	0.68	13.92	1.36	6.4	302	12.54	1.41	11.68	2.01
2.4	311	3.31	1.05	13.23	1.75						

where oxygen-free copper–nickel melts were studied, since in this case, the concentration of sulfur in copper grows, and even its minor content results in a dramatic decrease in the concentration of oxygen in copper, which, therefore, can be neglected.

It is seen from the data obtained that the copper content in slag remains almost unchanged (c_{Cu} = 0.2–0.3 wt %) with the nickel activity varying within a rather narrow interval. The content of nickel in the slag also remains virtually unchanged (c_{Ni} = 0.5–0.7 wt %) when its activity in copper is varied.

The coefficients of copper and nickel distribution in the copper–slag system in an argon atmosphere ($P_{O_2} = 4 \times 10^{-8}$ atm) are listed in Table 4. The variation of the nickel distribution coefficients is completely dependent on the variation of the nickel content. It is well seen that the copper distribution coefficient is only slightly affected by the variation of the bottom phase composition.

The results obtained in studying the copper and nickel distribution between copper and slag in an oxidizing atmosphere are shown in Figs. 2a and 2b, curves *2*, and in Table 4. It is seen from Fig. 2 that the content of nickel in the slag markedly grows with its increasing activity in the metallic melt. The copper content in the slag decreases rather sharply even upon a minor increase in the nickel activity in an alloy.

The data obtained are in good agreement with the data of [11], which show that the copper solubility in a slag grows with increasing partial pressure of oxygen (distribution coefficients decrease). However, the content of copper in the slag is almost independent of the copper activity in the alloy at high copper content (95–100 wt %) and low partial pressures of oxygen.

As seen from Table 4, the distribution coefficient of copper decreases substantially on passing from argon to an oxidizing atmosphere, which is due to the increasing content of dissolved copper in the slag. Raising the partial pressure of oxygen has virtually no effect on the nickel distribution coefficient, which lies in the range 1–2 in both cases at nickel content in copper of up to 1.5%. However, a certain tendency toward an increase in the content of nickel dissolved in the slag is observed in the oxidizing atmosphere (Fig. 2a).

Now, it is appropriate to compare the coefficients of copper and nickel distribution between copper and slag, obtained in this study, with the results of other studies, listed in Table 1.

The distribution coefficients of copper in an argon atmosphere are in good agreement with the coefficients obtained at low partial pressures of oxygen (10^{-11} atm) [9, 10]. The distribution coefficients of nickel in an argon atmosphere are much lower than the values obtained in [13] for compositions of copper and slag close to those in the present study. The difference in L_{Ni} is mainly related to the higher nickel

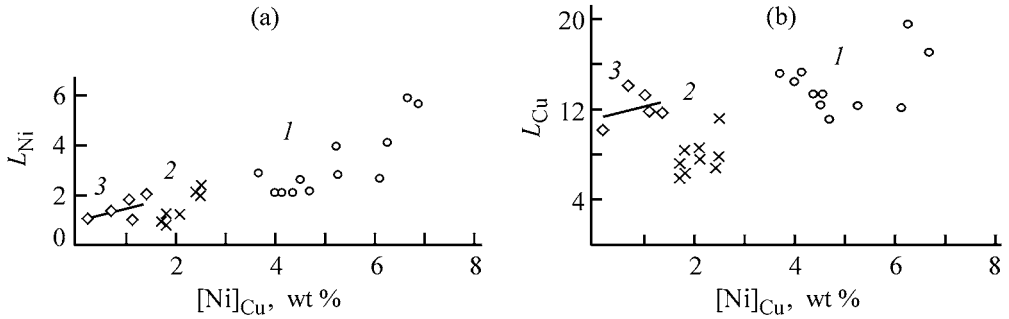

Fig. 3. Distribution coefficients of (a) nickel, L_{Ni}, and (b) copper, L_{Cu}, vs. $[Ni]_{Cu}$ in copper in the equilibrium system copper–slag according to different references. (*1*) [14], (*2*) [15], (*3*) present study. Experimental conditions: P_{O_2} (atm), c_{SiO_2} (wt %): (*1*) 1.4×10^{-5}, 13.4–29.2; (*2*) 6.1×10^{-5}–2.05×10^{-4}, 16–23; (*3*) 6×10^{-5}, 25–30.

content in the slag in the present study. A similar pattern is observed when the L_{Ni} values obtained here are compared with the data of [13] for an oxidizing atmosphere. The copper distribution coefficients in the oxidizing atmosphere with $P_{O_2} = 6 \times 10^{-5}$ atm (present study) are in good agreement with the data of [14, 15] obtained at close P_{O_2} values. For convenience of comparison, these data are presented graphically in Figs. 3a and 3b. In the authors' opinion, the distribution coefficients of copper are somewhat underestimated in [14, 15], since the content of copper in the slag was determined by chemical methods.

CONCLUSIONS

(1) The solubility of copper, nickel, and cobalt in a slag in an argon atmosphere is independent of the content of sulfur in a sulfide melt (17–21 wt %), being, on the average, 0.7–1.0 wt % Cu, 1.3–1.7 wt % Ni, and 0.5–0.7 wt % Co.

(2) The content of dissolved copper and nickel in an argon atmosphere is also independent of the composition of the metallic bottom phase, being, on the average, 0.2–0.3 wt % Cu and 0.5–0.7 wt % Ni, at nickel activity a_{Ni} 0.027–0.211.

(3) The solubility of copper and nickel in the slag in an oxidizing atmosphere increases from 7 to 10 wt % for Cu and from 0.2 to 1.2 wt % for Ni with increasing activity of nickel in the bottom phase (a_{Ni} 0.006–0.036).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Distribution of Rare and Radioactive Elements in Processing of Baddeleyite Concentrate from Kovdor Deposit

V. N. Lebedev, E. P. Lokshin, and N. A. Mel'nik

Tananaev Institute of Chemistry of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Russia

Received September 19, 2002

Abstract—Specific features of the distribution of rare elements and radionuclides in processing of the baddeleyite concentrate by various methods to obtain pure zirconium compounds and in its chemical purification were studied. The products in which they are concentrated can be regarded as concentrates of niobium(V), tantalum(V), scandium(III), and radionuclides.

The main Russia's source of zirconium is the baddeleyite concentrate (BC) manufactured by Kovdorskii GOK Joint-Stock Company. The commercial BC, containing no less than 97.5–98.5% ZrO_2 + HfO_2, is commonly used without chemical processing in manufacture of refractory materials, ceramics, and abrasives. Zirconium dioxide in BC is twice as expensive as that in zircon. Therefore, use of BC for production of zirconium compounds is inexpedient. However, account should be taken of the fact that the Kovdor BC contains, in addition to hafnium, which is present in zirconium minerals and is of limited use, also the deficient niobium, tantalum, and scandium. According to chemical and X-ray fluorescence analyses, commercial BC contains (wt %): Nb_2O_5 0.6–0.8, Ta_2O_5 0.18–0.23, and Sc_2O_3 0.045–0.055. The total cost of these components at world prices is close to the cost of BC, and the ratio of their costs is 1 : 4 : 6. Consequently, if the problem of recovery of accessory rare elements in chemical processing is solved, BC may become quite competitive with zircon as regards the manufacture of various zirconium-containing chemical products. In addition, the high content of ZrO_2 in BC (low content of impurities) leads to lower reagent expenditure and simpler technology of its processing, compared with that for zircon, which may also improve the economical attractiveness of BC as raw material for manufacture of zirconium compounds.

In studying the methods for BC processing [1–6], the behavior of compounds of niobium, tantalum, and scandium (further, rare elements) and radioactive elements has not been analyzed. Incomplete data on their distribution in chemical processing of BC were reported in [7].

Approximately 80% of niobium(V) and tantalum(V) is present in the commercial concentrate in the form of isomorphic impurities, and 20%, as constituents of accessory minerals—uranopyrochlore, pyrochlore, zirkelite, etc. Radioactive elements are represented by uranium and thorium (specific activity of up to 70 kBq kg^{-1}). The radionuclides are mainly associated with the minerals mentioned above. In minor amounts, they are present as isomorphic impurity. Scandium(III) is virtually completely present in baddeleyite as an isomorphic impurity.

Various methods for BC decomposition are known: (1) high-temperature sintering with compounds of alkali and alkaline-earth metals [1–3], (2) sulfuric acid processing [1, 4], (3) sintering with ammonium sulfate [1, 5], (4) decomposition with the use of fluorinating reagents [1, 6], and (5) chlorination [1].

The present study is concerned with the behavior of rare and radioactive elements in chemical purification of BC by the method described in [8], and also in production of pure zirconium compounds with methods 1–3 used to process BC.

003-00186759–2000 was commonly used in the study. Occasionally, the content of impurities, especially those radioactive, in the BC was higher.

Rare and impurity elements in precipitates were analyzed by X-ray fluorescence and spectral methods, and those in solutions, by chemical-analytical and atomic-adsorption techniques. The specific radioactivity of ^{232}Th and ^{226}Ra and the content of U and Th were determined by radiometry and gamma-spectrometry on certified instruments.

In chemical purification of BC with hydrochloric [1] or sulfuric [7, 8] acid, the content of main components can be brought to 99–99.5 wt %; however, hydrochloric acid does not react with accessory minerals containing radionuclides, niobium(V), and tantalum(V). Under the optimal conditions, sulfuric acid decomposes these minerals, but virtually does not react with baddeleyite. The most complete purification achieved in sulfuric acid processing is that to remove compounds of phosphorus, calcium, magnesium, iron, and radioactive impurities. Silicon present in the form of olivine and some other silicates is separated in the course of purification, but silicon contained in zircon, pyroxenes, and garnets is not removed from BC. In the course of purification, rare and radioactive elements are converted, together with most of other impurities removed from the concentrate, into an insoluble form, specifically hydrate cake. Table 1 lists the distribution of admixtures of rare and radioactive elements in sulfuric acid purification of BC.

Rare elements isomorphically incorporated in the ZrO_2 lattice remain in the purified product. This is confirmed by the fact that their concentration in the product purified remains the same upon additional grinding of the initial BC. Although the concentrations of tantalum, niobium, and uranium compounds in the hydrate cake are rather high, their recovery from this product is hardly justified economically because of the relatively low amount of rare elements finding their way into this product (recovery into the cake less than 0.5% for Sc, 17–18% for Nb_2O_5, and 12–15% for Ta_2O_5). However, deep processing of the hydrate cake may be advisable for ecological reasons.

In BC processing by sintering, the concentrate was ground and simultaneously mixed with CaO and $CaCl_3$ at mass ratio of 1 : 0.55 : 0.12. The stock was sintered at 1150°C for 4 h. The degree of BC decomposition in sintering was 80–85%. The cake was decomposed with hydrochloric or nitric acid. In cake dissolution, most of impurities passed into solution simultaneously with zirconium(IV), with the insoluble residue enriched with niobium(V) and tantalum(V) and depleted of radionuclides.

The niobium(V) to tantalum(V) ratio varied from 3.4 for BC to 2.5 in the insoluble residue and 5.9–6.2 in solutions. The recovery of zirconium(V) into solution in decomposition of the cake with nitric acid was somewhat lower than that in the case of hydrochloric acid and occurred at higher acidity. The enrichment of the insoluble residue with niobium(V) and, to a greater extent, tantalum(V) occurred as a result of hydrolysis. Chloride solutions were purified by crystallization of zirconium(IV) oxochloride, and nitric acid solutions, by extraction.

Recrystallization of zirconium(IV) oxochloride is a standard procedure for obtaining pure zirconium(IV) compounds [9, 10]. After dissolution and separation of the insoluble residue, the solution was evaporated and the resulting precipitate of zirconium(IV) oxochloride was repulped in 20% hydrochloric acid at s : l ratio of 1 : 4.5. The amount of acid necessary for repulpation corresponded to its expenditure for cake decomposition. After three counterflow washings-repulpations with one intermediate dissolution of the oxochloride under heating, ZrO_2 obtained from the oxochloride by calcination was close to special-

purity 9-2 brand (TU 6-09-4709–79), with calcium compounds removed to residual level of 0.01 wt %. Average composition of the mother liquor obtained after precipitation of zirconium(IV) oxochloride (g l^{-1}): ZrO_2 + HfO_2 4–7, CaO 150–170, Fe_2O_3 8–13, Sc 0.13–0.16, Nb_2O_5 1.8–2.4, Ta_2O_5 0.28–0.35, U 0.1–0.13, Th 0.07–0.09; A = 1.25–1.5 kBq kg^{-1}. The yield of the mother liquor was 100 ml per 100 g of cake. After its neutralization with an $NH_3 \cdot H_2O$ solution, a precipitate was isolated into which the rare and radioactive elements contained in the mother liquor passed.

The content of rare impurities and radionuclides in the products obtained is given in Table 2.

Judging from the composition of the precipitate, the main part of scandium(III), niobium(V) and radionuclides (Sc 72, Nb 80.5, U 77.8, and Th 87.2% relative to their respective amounts in BC) and nearly half of Th(V) find their way into it.

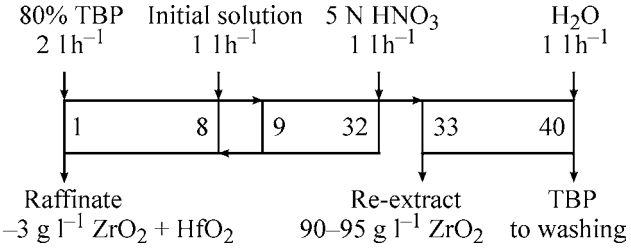
The extraction technique for processing of nitric acid solutions of zirconium(IV) is, as a rule, analyzed for the case of hafnium(V) isolation [9–11]. The extraction process was studied in order to obtain pure compounds of zirconium(IV). The nitric acid solution contained 103.1 g l^{-1} ZrO_2 at acidity of 7.4 M HNO_3. Zirconium(IV) was extracted with solution of 80% tributyl phosphate (TBP) in dodecane. The experimentally found distribution coefficients of the components are listed in Table 3.

The distribution coefficients of the impurities decreased with increasing acidity because of their salting-out by the better extractable zirconium(IV). Introduction of hydrochloric acid raised somewhat the separation coefficient of zirconium(IV) and hafnium(IV), but favored passing of admixtures of iron- and calcium-containing compounds into the organic phase. On the whole, the distribution data are close to the known values [12] and indicate that purification is possible. Radioactive elements can be isolated in the reextraction stage. Difficulties may be only encountered when dealing with compounds of silicon.

The extraction was carried out on a cascade comprising 40 stages of the mixer–settler type, with stage

volume of 450 ml (see scheme). In accordance with the values of the separation coefficients, 3 to 4 stages are necessary for purification; however, it has been found previously in a similar system [12, 13] that 12 stages are insufficient for obtaining pure zirconium(IV) at phase ratio org : aq = 2.5 : 1 in the washing stage because of the gradual accumulation of admixtures of silicon and titanium compounds, mainly as gels in the organic phase.

Scheme of extraction purification of zirconium.



To separate radionuclides, the organic phase obtained after reextraction was periodically removed from the process and treated with a Na_2CO_3 solution or a fluorine-containing reagent. It was found that there exist unextractable forms of zirconium(IV), bound to silicon and calcium. The precipitate isolated from the fluoride or carbonate reextract contained (wt %): ZrO_2 20–50; CaO 5–20; SiO_2 3–20; Al_2O_3 1–5; Nb_2O_5, Fe_2O_3, and TiO_2 <0.01 each.

Zirconium(IV) was isolated from the reextract in the form of basic sulfate or oxalate. In the content of controllable impurities, ZrO_2 obtained by calcination of oxalate was also close to special-purity 9-2 brand (TU 6-09-4709–79) and contained no (<0.01 wt %) hafnium. The activity of samples was 0.9–1.4 kBq kg^{-1}, including $(2–4) \times 10^{-4}$ wt % U and $(0.5–2) \times 10^{-3}$ wt % TH. The content of radionuclides was lowered to 0.4–0.6 kBq kg^{-1} by single preliminary extraction with 10% TBP from the initial solution and from the reextract.

The operation of the extracting apparatus was complicated by the formation and motion along the cascade of interphase gel-like precipitates, which had to be removed periodically. Their composition approximately corresponded to that of the precipitate formed in the carbonate reextract and differed only in lower activity and presence of admixtures of titanium, niobium, and tantalum compounds. The precipitate formed in the raffinate with an $NH_3 \cdot H_2O$ solution contained (wt %): Sc 0.2–0.4, Nb_2O_5 7–9, and Ta_2O_5 1.1–1.3. This indicated that the impurities nearly completely passed into this product, with the exception of the amount lost with interphase precipitates. The content of hafnium(IV) in the sum of zirconium(IV) and hafnium(IV) was 45–65%.

The distribution of less-common and radioactive elements in BC processing by sintering with $(NH_4)_2SO_4$ was evaluated [3]. Sintering of BC with $(NH_4)_2SO_4$ at 500°C and a 10-fold excess of the decomposing agent yields 99% decomposition [1]. Zirconium is present in the cake as ammonium sulfate-zirconate (ASZ).

The baddeleyite concentrate was decomposed in a 6-fold excess of $(NH_4)_2SO_4$ at 400–450°C, the cake was dissolved in water, and the insoluble residue was filtered off. The degree of decomposition was 95–96.5%. Niobium(V) and tantalum(V) were distributed approximately evenly between the solution and insoluble residue because of their poor solubility in sulfuric acid solutions, whereas scandium, uranium, and thorium mainly passed into solution in amount proportional to the degree of BC decomposition. ASZ with $NH_4 : Zr : SO_4$ ratio of 1 : 1 : (1.3–1.75), to which the formula $(NH_4)_4[Zr_4O_2(OH)_4(HSO_4)_2(SO_4)_5 \cdot 8H_2O$ has been ascribed [14], was isolated from the resulting supersaturated solution after keeping for 8–24 h with periodic agitation. The isolation process was accelerated upon introduction of an ASZ seed. The yield of zirconium(IV) into the precipitate was 68–72%, rare elements could be concentrated in the mother liquor after its evaporation and recrystallization, or by using the mother liquor to dissolve the cake.

The slow crystallization favored a high degree of purification to remove virtually any of the impurities. Washing of ASZ with a saturated $(NH_4)_2SO_4$ solution and calcination gave ZrO_2 containing admixtures of Sc, Mg, Ca, Fe, Al, Ti, Nb, Ta, and Cr in amount of less than 0.01 wt % each. The highest degree of purification, compared with other techniques, was achieved in removing silicon: its content decreased from 0.69 wt % in the concentrate to 0.001 wt % in ZrO_2. Sufficiently successful was purification to remove uranium, to 2.0×10^{-3} wt %, but the whole amount of thorium remained in ASZ and could not be removed by recrystallization. To achieve deeper purification, ASZ was converted into a hydroxide, the hydroxide was dissolved in hydrochloric acid and basic zirconium sulfate (BZS) was precipitated. After calcination of ASZ, ZrO_2 contained (wt %): Mg, Ca, Sc < 0.01; Fe, Al, Mn, Si, and Cr < 0.001; Cu < 0.0001; Ti < 0.005; U < 0.002; Th < 0.003; Nb_2O_5 < 0.005; Ta_2O_5 < 0.005.

Table 4. Impurity content of zirconium sulfates

Extraction technique	Yield, %	Content, wt % relative to ZrO_2						Specific activity *A*, kBq kg^{-1}
		Sc	Nb	Fe	Si	Ca	Ti	
Evaporation	50	0.069	N.f.	0.03	0.02	0.1	0.01	3.9
	80	0.042	0.01	0.03	0.02	0.1	0.01	3.9
	70	0.09	N.f.	0.01	0.003	0.03	0.01	3.1
Salting-out	50	0.09	N.f.	<0.01	0.003	0.1	0.01	2.8
	80	0.046	N.f.	<0.01	0.003	0.1	<0.01	2.6
Recrystallization	70	0.11	N.f.	<0.01	0.001	0.03	<0.01	2.2

Thus, niobium(V) and tantalum(V) are approximately evenly distributed among the insoluble residue and the mother liquor formed upon ASZ precipitation, and major amount of scandium(III) is accumulated in the mother liquor. An acceptable level of separation of radionuclides can only be achieved by multistage processing.

The baddeleyite concentrate is decomposed by sulfuric acid at 300°C in the course of 4–5 h [1, 4]. Because of the high rate of H_2SO_4 evaporation, the process is carried out either in a large excess of the acid, or with the use of an autoclave or reflux condenser. At H_2SO_4 expenditure of 150% with respect to the stoichiometry (2.5 kg of $H_2SO_4 \cdot H_2O$ per 1 kg of BC), the degree of decomposition was 86–91% for the –0.074-mm fraction. The decomposition became somewhat more pronounced in a 3–5-fold excess of the acid (not used in the experiments). Presumably, the decomposition was not complete because of the blocking of baddeleyite particles by a precipitate of the forming zirconium sulfate. According to the results of X-ray phase analysis, zirconium(IV) was present in the reaction mass as $Zr(SO_4)_2 \cdot 4H_2O$; in thermal treatment of the sulfate mass, $Zr(SO_4)_2 \cdot H_2O$ and $Zr(SO_4)_2$ were formed successively.

Zirconium sulfate readily dissolved to a concentration of 120–170 g l^{-1}, depending on the concentration of sulfuric acid in solution. Although the undecomposed residue (0.12–0.15 kg per 1 kg of BC) is enriched with niobium(V) and tantalum(V) (1.5–2.0 and 0.8–0.9 wt %, respectively) because of their hydrolysis, a major part of niobium (~65%) and tantalum (~40–45%) passes into solution. The specific activity of the residue increases by 15–20% because of the precipitation of radium sulfate. Scandium and other impurities pass into solution in proportion to the degree of BC decomposition. The solution obtained was used to recover various zirconium(IV) compounds.

Since the undecomposed residue is recycled into the sulfatization process, the extent to which niobium(V) and tantalum(V) pass into solution increases significantly.

Crystallization of $Zr(SO_4)_2$ has been used to obtain pure zirconium dioxide [9]. Zirconium sulfate crystallized when the acidity increased to 6–8 M, which was effected by introduction of H_2SO_4 or by evaporation. Table 4 lists data on the composition of $Zr(SO_4)_2$ obtained by various techniques (the content of impurities is given in terms of ZrO_2). The content of tantalum(V) was not determined, but it may be assumed that its behavior in sufficiently concentrated sulfuric acid solutions is similar to that of niobium.

As follows from Table 4, extraction and recrystallization of $Zr(SO_4)_2$ leads to its purification to remove all impurities except scandium(III), which is concentrated in the first fractions of the precipitates formed. Presumably, the bridging bonds of zirconium sulfate can accommodate anionic complexes of scandium, which are predominant in the sulfuric acid medium [15]. The insufficient degree of purification to remove radioactive impurities is presumably due to coprecipitation of radium sulfate. The content of niobium(V) and tantalum(V) in the precipitate formed in the mother liquor with ammonium was 3.5–7.5 and 0.65–1.3 wt %, respectively.

Ammonium sulfate-zirconate was isolated from solutions formed in sulfuric acid decomposition of BC by neutralization with $NH_3 \cdot H_2O$ to an $NH_3 : Zr$ molar ratio of no less than 2 and acidity of 0.75–1.0 M. The amount of precipitated zirconium(IV) was 85–90%. Judging from the relative concentrations of the components, the composition corresponded to the $(NH_4)_2SO_4 \cdot ZrOSO_4$ salt. The content of controllable impurities in ASZ approximately corresponded to that in zirconium sulfate, but the whole amount of scandium remained in solution, and niobium(V) and tantalum(V) were distributed among the solution and

precipitate, depending on the precipitation conditions. Purification to remove radioactive impurities proceeded to a fuller extent, to 1.4 kBq kg^{-1}, with uranium removed better than thorium.

Potassium fluorozirconate was extracted from the sulfuric acid solution upon introduction KF and NH_4F into a hot solution in amount of 110% with respect to the stoichiometry. A single phase, K_2ZrF_6, was revealed by X-ray phase analysis in the precipitate formed upon cooling. Niobium(V) and tantalum(V) remained in solution, although formation of potassium fluorometallates is also characteristic of these metals. Scandium(III) partly precipitated in the form of scandium trifluoride or potassium fluoroscandate with distribution coefficient of 0.3, and remained in the concentrate of hafnium(IV) upon recrystallization of the preciopitate. The precipitate formed in the mother liquor with $NH_3 \cdot H_2O$ contained (wt %): Nb_2O_5 3.7, Ta_2O_5 0.49, and Sc 0.19. Niobium(V) and tantalum(V) can be selectively recovered from fluorine-containing sulfate solutions by extraction.

Thus, in various methods for BC processing by decomposition with H_2SO_4, niobium(V) and tantalum(V) are distributed among the insoluble residue and the mother liquor, and the major part of scandium(III) is accumulated in the mother liquor. Nonradioactive zirconium(IV) compounds can be obtained in all variants; however, techniques for final concentration of radionuclides require further development.

CONCLUSIONS

(1) A study of specific features of the distribution of rare elements and radionuclides in various methods for processing of the baddeleyite concentrate to obtain pure zirconium compounds and in its chemical purification revealed the products and wastes in which the rare and radioactive elements are concentrated.

(2) Comparison of the behavior of rare elements and radionuclides in chemical purification of the baddeleyite concentrate with that in processing of the concentrate to obtain zirconium compounds confirms that uranium and thorium are mainly contained in accessory minerals, whereas scandium(III) and major part of niobium(V) and tantalum(V) crystallize isomorphically to baddeleyite.

(3) The possibility of concentrating radionuclides and part of niobium(V) and tantalum(V) in sulfuric acid purification of the baddeleyite concentrate was demonstrated.

(4) Simultaneous production of pure zirconium compounds and recovery of rare and radioactive elements into separate concentrates is achieved the most effectively by processing the baddeleyite concentrate by the sintering method, with the formation and subsequent recrystallization of zirconium oxychloride or extraction processing of nitric acid solutions.

Received September 19, 2002

Abstract—The influence exerted by sulfur contained in petroleum coke on sulfidization of acid-soluble barium compounds formed in reductive calcination of recycled barium sulfate in sodium sulfide production was studied.

A low-waste technique for manufacture of sodium sulfide [1–3] is based on the interaction of barium sulfide with sodium sulfate by the reaction

$$BaS + Na_2SO_4 = BaSO_4 + Na_2S. \quad (1)$$

Barium sulfide is regenerated by reductive calcination of the forming barium sulfate

$$BaSO_4 + 2C = BaS + 2CO_2, \quad (2)$$

and, consequently, the barium raw material is not spent, and only its replenishment is necessary. However, in reduction of $BaSO_4$ with carbon, the main reaction (2) is accompanied by side reactions [4] associated with loss of sulfur and formation of acid-soluble (as) barium compounds:

$$BaS + CO_2 + 1.5O_2 = BaCO_3 + SO_2, \quad (3)$$

$$BaS + 4CO_2 = BaCO_3 + SO_2 + 3CO, \quad (4)$$

$$BaS + H_2O + CO_2 = BaCO_3 + H_2S, \quad (5)$$

$$2BaSO_4 + C = 2BaSO_3 + CO_2, \quad (6)$$

$$BaSO_4 + CO = BaSO_3 + CO_2. \quad (7)$$

Admixtures of a barite concentrate, added to compensate for the loss of barium, also form silicates, ferrites, and other acid-soluble barium compounds.

The industrial BaS melt contains 65–75% water-soluble (ws) barium compounds in terms of BaS_{ws} and 15–20% acid-soluble barium compounds in terms of BaS_{as}. In manufacture of $BaCl_2$ by the hydrogen chloride technique [4], acid-soluble barium salts react with HCl to give the target product. In the technique for Na_2S production in aqueous leaching of the melt, acid-soluble barium compounds are not involved in the formation of the target product and, being accumulated in $BaSO_4$ being recycled, affect adversely the technical and economic characteristics of the process.

The aim of this study was to minimize the yield of acid-soluble barium compounds in reductive calcination of the stock by converting them into BaS, e.g., by the reaction

$$2BaCO_3 + 2S + C = 2BaS + 3CO_2, \quad (8)$$

with the use of sulfurous petroleum coke as sulfidizing agent.

Petroleum coke manufactured from domestic oils with 1–2% sulfur content contains sulfur in the form of cyclic structures possessing high thermal stability. The extent of desulfurization of sulfurous petroleum cokes at 900–1000°C does not exceed 10–17% [5, 6], which points to the possibility of using the sulfur contained in petroleum coke in reduction-sulfidization processes. Sulfur-containing components of volatiles can also be used as active sulfidizing agents.

* Water-insoluble residue upon leaching of BaS melt.

EXPERIMENTAL

To carry out the study, samples of a water-insoluble residue containing a complex of acid-soluble barium compounds, together with $BaSO_4$ being recycled, were prepared. The samples were obtained by leaching in water a BaS melt from Soda Joint-Stock Company, Sterlitamak, separating the water-insoluble residue, reacting a BaS solution with powdered Na_2SO_4 of pure grade [GOST (State Standard) 4166–76], and filtering the suspension to obtain recyclable $BaSO_4$. The resulting substances were thoroughly washed with hot water to remove S^{2-} ions (with the process monitored with indicator paper impregnated with lead acetate) and dried.

The chemical composition of the samples obtained and of those used to study the barite concentrate and petroleum coke is listed in Table 1. The grain size of all the stock components is 0.25 mm.

The study was carried out as follows. The stock was prepared, with the petroleum coke taken in amount (in terms of 100% C) of 125% with respect to the stoichiometry of reaction (2); reductive calcination of the stock was done in static mode in a muffle furnace at 1000°C for 15 and 30 min in alundum crucibles with caps; then the resulting BaS melt was subjected to chemical analysis. The melt was analyzed, after being cooled in desiccator, for BaS_{I_2} and BaS_2O_3 by iodometry, for BaS_{ws} and BaS_{as} by complexonometry, and for water-insoluble residue and carbon by gravimetry.

The results of chemical analysis were used to calculate the degree of $BaSO_4$ reduction (η_1), and degrees of $BaSO_4$ conversion into BaS_{I_2} (η_2), BaS_{ws} (η_3), and BaS_{as} (η_4) and of BaS_{as} conversion into BaS_{ws} (η_5) and BaS_{I_2} (η_6) by the formulas

$$\eta_1 = \frac{(m_{st}BaSO_{4st} - m_mBaSO_{4m}) \times 100}{m_{st}BaSO_{4st}},$$

$$\eta_2, \eta_3, \eta_4 = \frac{1.3778 m_{st}BaS_m \times 100}{m_{st}BaSO_{4st}},$$

$$\eta_5, \eta_6 = \frac{m_mBaS_m \times 100}{m_{st}BaSO_{4as.st}},$$

where m is the stock mass (g); m_m, the melt mass (g); $BaSO_{4st}$, $BaSO_{4m}$, and BaS_m, the contents of $BaSO_4$ in, respectively, the stock and the melt and the content of water- or acid-soluble barium compounds in terms of BaS in the melt (wt %); $BaS_{as.st}$, the content of acid-soluble barium compounds in terms of BaS in the stock (wt %); 1.3778, the coefficient of BaS recalculation to $BaSO_4$.

The results obtained in the experiment are listed in Table 2. In the first stage of the study, experiments on calcination of reactive $BaCO_3$ of pure grade (GOST 4158–80) (run nos. 1–6) and WIR (run nos. 7–12), in a mixture with petroleum coke, were conducted.

In the second stage (run nos. 13–27), petroleum coke was used to reduce mixtures of reactive $BaSO_4$ of pure grade (GOST 3158–75) with $BaCO_3$ (run nos. 13–18), of recycled $BaSO_4$ with WIR (run nos. 25–27), and of the barite concentrate of class A, KB-2 brand (GOST 4682–84) (run nos. 19–24).

The effect of sulfur contained in petroleum coke on the sulfidization of acid-soluble barium compounds was assessed in run nos. (1–12) on the basis of η_5 and

Table 2. Results obtained in a study of the influence exerted by sulfur contained in petroleum coke on the sulfidization of acid-soluble barium compounds (reduction temperature 1000°C, amount of petroleum coke in terms of 100% C 125%)

* Numerator, formed; denominator, spent.

** Less the content of BaS in the raw material.

η_6 values and the amount of spent BaS_{as}, related to that introduced into the stock in the form of $BaCO_3$ and WIR; in run nos. 13–27, this was done on the basis of the η_4 value. In addition, the completeness of the process was assessed on the basis of η_1–η_3.

As seen from Table 2, run nos. 1–6, in which $BaCO_3$ was calcined, clearly reveal an increase in the conversion of BaS_{as} into BaS_{wr} (η_5) in relation to the sulfur content of the petroleum coke. However, the degree of BaS_{as} conversion into BaS_{I_2} (η_6) shows another behavior: it reaches a higher value with petroleum coke no. 2 as reducing agent. This coke is characterized by higher content of volatiles containing methane, hydrogen and organosulfur compounds, which intensify the reduction process [5]. The low content of sulfur in petroleum coke no. 3 accounts for the virtually zero extent of sulfidization of acid-soluble barium compounds in run nos. 3 and 6 (η_6 of 0.2 and 0.1%, respectively), although η_5 has rather high values. Apparently, in these runs, as also in some others (run nos. 1, 2, 4, and 5), $BaCO_3$ is reduced in the presence of carbon [14] in accordance with the equation

$$BaCO_3 + C = BaO + 2CO \quad (9)$$

with the subsequent conversion of BaO into $Ba(OH)_2$ upon melt dissolution, with the latter barium compound determined as BaS_{ws}.

Raising the time of stock reduction to 30 min leads to oxidation of the BaS formed to BaS_2O_3 and $BaSO_4$,

with the corresponding decrease in η_5 and η_6. The same behavior is observed in experiment nos. 7–12, devoted to WIR calcination. In this case, too, keeping the melt in the reaction zone for 30 min resulted in a decrease in η_5, with a dramatic fall of the amount of spent BaS_{as} relative to that introduced into the stock: from 25.7 to 8.8% (petroleum coke no. 1), from 17.4 to 8.5% (petroleum coke no. 2), and from 15.4 to 7.1% (petroleum coke no. 3). The apparent increase in the η_5 and η_6 values in these runs, compared with the results obtained in run nos. 1–6, occurred because of the reduction of $BaSO_4$ contained in WIR.

In the following set of experiments (run nos. 13–27), the same tendency toward a decrease in the degree of $BaSO_4$ conversion into BaS_{as} (η_4) with increasing content of sulfur in a petroleum coke was revealed, and higher degree of $BaSO_4$ reduction (η_1) was obtained in run nos. 14 and 17 with petroleum coke no. 2 containing the largest amount of volatiles. In this case, raising the duration of calcination from 15 to 30 min exerts positive influence on the process characteristics, and, therefore, reduction of a mixture of $BaSO_4$ being recycled and WIR was done at a single experiment duration of 30 min.

Noteworthy is the fact that the reduction in a mixture with WIR of the barite concentrate and $BaSO_4$ being recycled occurs to a fuller extent (η_1 of 99.8 and 98.4%, respectively), compared with the case of a mixture of reactive reagents $BaSO_4$ and $BaCO_3$ (η_1 = 95.4%). Apparently, in the first case, the high intensity of the process is achieved because of the presence of catalyzing components (Fe_2O_3 etc.) in the stock [5, 7], with additional increase in the case of $BaSO_4$ being recycled resulting from the more developed phase boundary in the freshly precipitated product.

However, of practical interest for the method of Na_2S production is the degree of $BaSO_4$ conversion into BaS_{I_2} (η_2), since it is BaS that is the supplier of S^{2-} ions to the finished product, Na_2S. The reduction of a mixture of $BaSO_4$ being recycled and WIR with a petroleum coke containing 2.45% sulfur yielded a η_5 value of 95.5%. In this case, the loss of acid-soluble barium compounds, caused by their sulfidization, was 12.79% relative to their content in the initial stock (η_4 = 0).

Calculations performed on the basis of the experimental data obtained demonstrated that, in processing the barite concentrate of the KB-2 brand, the content of sulfur in the petroleum coke should not exceed 3.0%, since an excess of sulfur complicates neutralization of furnace gases. The requirements to the content of sulfur in a petroleum coke should be determined in relation to the amount of SiO_2, Fe_2O_3, and Al_2O_3 impurities in the barite concentrate and that of acid-soluble barium compounds in $BaSO_4$ being recycled.

CONCLUSIONS

(1) The sulfidizing action of sulfurous petroleum coke on the reductive calcination of barite raw materials is established. This favors minimization of the yield of acid-soluble barium compounds, which is important for the technology of sodium sulfide manufacture.

(2) It is shown that, with a petroleum coke containing 2.45% sulfur used, a 95.5% conversion of $BaSO_4$ into BaS_{I_2} is achieved in reduction of $BaSO_4$ being recycled, and the conversion of $BaSO_4$ to BaS_{as} is zero, compared with 87.3 and 0.18%, respectively, for the petroleum coke containing only 0.68% of sulfur.

(3) Noteworthy is the positive influence exerted by catalyzing components of the stock, e.g., Fe_2O_3, and by developed phase boundary in freshly precipitated $BaSO_4$ on the process of reduction with sulfurous petroleum coke of the barite concentrate and $BaSO_4$ being recycled, with 98.9–99.8% $BaSO_4$ reduction achieved.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Refining of Lead To Give Bismuth-Enriched Drosses

O. G. Zarubitskii

Vernadskii Institute of General and Inorganic Chemistry, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received June 3, 2002

Abstract—The results obtained in testing an improved technique for reagent refining of crude lead, which yields bismuth-enriched drosses in the form of a powder, are presented. The advantages of the method put into industrial practice are described.

The pyrometallurgical method proposed by Kroll and Betterton [1, 2] is mainly used at lead works to remove bismuth admixtures from refined crude lead (lead bullion). This, the most complicated procedure is carried out after silver removal. It involves dissolution of blocks of circulating bismuth drosses at 400°C and subsequent introduction of magnesium and calcium into melted crude lead at 360–370°C. These metals react with bismuth to form intermetallic compounds: Ca_3Bi_2, Mg_3Bi_2, Mg_2CaBi_2, which are poorly soluble in lead and are deposited on the bath surface. They are extracted as the so-called "enriched" bismuth drosses with bismuth content of 3–5%. Then the bath is cooled to 340–350°C and "lean" circulating drosses containing 0.5–2% Bi are extracted. Repeated circulation of drosses can increase the bismuth content up to 5–11%, to give a lead–bismuth alloy containing 8–15% Bi [1]. The increase in the bismuth content from 5–11 to 8–15% results from removal of magnesium and calcium from the drosses with molten NaOH. A 5–6% fraction of Bi passes into the resulting alkaline melts.

The existing technology for Pb–Bi alloy production does not ensure isolation of bismuth-enriched (to more than 8–15%) products and is characterized by repeated dross circulation, which leads to loss of the target metal and involves additional consumption of reagents (magnesium, calcium, and sodium hydroxide).

Various methods for dross enrichment with bismuth have been proposed. For example, centrifugal refining can enrich drosses to Bi content of 18–21% at its initial concentration of 5.7% [3]. Air bubbling through liquid metal (cupellation) at 900–950°C can raise the bismuth content of a Pb–Bi alloy being treated from 14 to 40–60%, with simultaneous removal of antimony, tin, arsenic, and tellurium [4]. This method has been implemented in industry.

Of special interest are the publications [5–7] describing the possibility of using organic compounds in pyrometallurgical processing of lead–bismuth alloys. For example, in purifying bismuth to remove lead and copper by adding sulfur to a metallic melt, friable yields can be obtained if carbon or masut is introduced into the metal being refined [5]. It is recommended [6] that coal-tar pitch should be added to a melt to enrich dross with bismuth, which yields an alloy containing 40% Bi and 60% Pb. Dry drosses are obtained by adding sawdust to crude lead (modified Kroll and Betterton method [6, 7]). However, the authors of [5, 7] did not consider the mechanism by which the above-mentioned organic compounds affect the metallurgical processes under consideration.

EXPERIMENTAL

Our experiments and pilot tests made it possible to develop and put into industrial practice an improved method for lead refining, which provides lead alloys with high bismuth content. The technological process consists in the following. First, magnesium and calcium are introduced into crude lead at 375–400°C (rather than the commonly used circulating dross), and then the temperature of the refining bath is raised to 475–490°C and circulating drosses are loaded. After settling for 25–35 min, dead oil (0.13–0.18 kg per 1 ton of lead to be refined) is introduced in portions with continuos agitation at 400–470°C. After liquation, solid powdered drosses (30–40% Bi, 50–60 Pb, 5–10 Zn, 0.015–0.02 Ag) are extracted, cooled to room temperature, and classified by sieving with 0.10–0.15 mm mesh. Drosses remaining on the sieve

1070-4272/03/7602-0191 $25.00 © 2003 MAIK "Nauka/Interperiodica"

are loaded in the lead bath for recirculation, whereas sifted drosses (–0.10–0.15-mm class) are remelted to obtain a lead–bismuth alloy. After the removal of dry drosses, the temperature is lowered to 330°C, and circulating bismuth drosses are taken off. The refining process is finished according to the standard scheme.

Powder drosses of the +0.10–0.15-mm class, containing (%) 12–17 Bi, 50–55 Pb, 25–40 Zn, and 0.06–0.07 Ag, are purified to remove silver, which diminishes the expenditure of metallic zinc by approximately 50%, and loss of silver and bismuth, by approximately 30%. Thus, in contrast to the common technologies, this method does not involve a labor-consuming procedure of lead bullion purification to remove zinc introduced into lead to recover silver.

Powder drosses of the –0.10–0.15-mm class are remelted under a layer of slam (spent $PbCl_2$–$ZnCl_2$–KCl–NaCl electrolyte used at the plant in electrochemical reactors for separating lead–bismuth alloys in ionic melts [8]). In this case, the following reactions occur

$$Mg_3Bi_2 + 3PbCl_2 = 3MgCl_2 + 3Pb + 2Bi,$$

$$Ca_3Bi_2 + 3PbCl_2 = 3CaCl_2 + 3Pb + 2Bi.$$

Such a procedure is expedient because lead, which was previously dumped as a salt in a chloride mixture, is returned into the production cycle. The resulting lead–bismuth alloy contains 55–65% Bi and the balance lead.

In pilot tests, we used dead oils of BN-IV and BN-V brands, which have softening points of 70 and 90°C, respectively. Special bitumens of A and G brands, and also pitches and other products of straight-run masut distillation, can be used for this purpose.

The tests have shown that the initial introduction of calcium and magnesium into crude lead at 375–400°C and subsequent addition of circulating drosses at higher temperature (475–490°C) diminish the loss of active metals (magnesium and calcium) and thus make lower the process costs. According to this technique, the purification to remove bismuth is carried out at bath saturation with bismuth higher than 2%. The introduction of calcium and magnesium at 375–400°C ensures high dissolution rate at minimum loss of the active metals, which can be oxidized by atmospheric oxygen or moisture. At 475–490°C the dissolution of circulating drosses proceeds faster, the solubility of all the components added is higher at elevated temperature, and, simultaneously, lead is deoxidated and cooled. Thus, complete use of the reagents is achieved, and drosses very rich in bismuth are obtained in small amounts. This is also important for the subsequent introduction of a solid product of heavy oil residuals, e.g., dead oil, to be carried out successfully. Under these conditions, fine particles of bismuth intermetallics do not aggregate, which makes it possible to obtain bismuth-rich drosses.

In carrying out this operation, dry powder drosses with high bismuth content (33–37%) are formed as a phase on the lead surface. The results of X-ray diffraction, mass-spectrometric, microscopic, and chemical analyses suggest that the forming particles of intermetallic compounds, and especially bismuth intermetallide Mg_3Bi_2, are wetted with bituminous hydrocarbons (asphaltenes etc.). This phenomenon eliminates wetting of intermetallic particles by liquid lead, because the adsorption energy of hydrocarbons on the surface of solid intermetallic particles is higher than the energy of lead adsorption. Consequently, bismuth drosses are formed as powders containing no coarse conglomerates with adsorbed or adhering lead. This results in that the bismuth drosses are obtained in powdered (dry) form and contain much lesser amounts of lead and greater amounts of bismuth. According to a mass-spectrometric analysis of the gas content of samples, the fine powder contains 2.5 and 3 times greater amount of, respectively, hydrogen and carbon dioxide than the coarse fraction does. This may indicate that bitumen is mostly adsorbed on fine-fraction particles of bismuth drosses.

Our physicochemical study has shown that powder drosses with particle size less than 0.10–0.15 mm are largely composed of bismuth intermetallides (mainly Mg_3Bi_2 in amount of 30–35%, according to X-ray analysis). Drosses with particles larger than 0.10–0.15 mm additionally contain intermetallic compounds of zinc and lead. It was established that the fine fraction of dry powder drosses with particle size less than 0.15 mm contains (%) 43–50 Bi, 35–45 Pb, 0.1–0.5 Zn, 0.002–0.003 Ag, and Ca and Mg the rest. Drosses of the +0.10–0.15-mm class are complex intermetallic compounds of zinc, bismuth, lead, silver, calcium, and magnesium.

The expenditure for production of bismuth from an alloy containing 55–65% Bi is considerably less than that for production of the same amount of Bi from an alloy with bismuth content of 15% (this is the maximum Bi content ensured by the currently existing procedures). In this case, the expenditure of electric power and electrolyte, number of electrolyzers, floor

area, and maintenance staff are diminished. This is confirmed by the following simple calculation of, e.g., the electric power expenditure.

Let us assume that a plant accomplishes electrochemical separation of a lead–bismuth alloy containing, on average, 12% Bi and 88% Pb by the formerly used technology, i.e., it is necessary to transfer electrochemically 88 tons of Pb from anode to cathode in order to produce 12 tons of Bi. If, however, a lead–bismuth alloy enriched with bismuth to 60% by the new technology is subjected to electrolysis, it is necessary to dissolve at the anode and precipitate at the cathode only 8 tons of Pb in order to obtain the same amount of Bi (12 tons). Consequently, the amount of lead to be electrolyzed in the second variant is 11 times less than that in the case of the standard technology. The expenditure of electric power, number of electrolyzers, etc. will be equally diminished.

The results obtained in industrial tests of the lead refining technique under consideration, which yields a bismuth-enriched Pb–Bi alloy, are presented below.

The experiments were carried out in cauldrons with capacity of 125–130 tons of crude lead (lead bullion). The sequence of operations was described above. The size classification of powder drosses yielded 5.3–6.0 tons of a fine fraction containing 43.7–50.6% Bi and 2.8–3.8 tons of grit with Bi content of 12.6–17.2%. After remelting of the fine fraction under a fluxing agent ($PbCl_2$–$ZnCl_2$–KCl–NaCl), 4.2–4.5 tons of alloy with Bi content of 55.1–59.9% were obtained. The process was implemented industrially and ensured a significant technological and economic effect. The environmental safety was improved, because we used a lesser number of electrochemical reactors producing lead by high-temperature electrolysis of a lead chloride melt.

A somewhat different technique for lead–bismuth alloy enrichment was also developed and applied in industry. At one of lead-manufacturing plants, a Bi–Pb alloy is separated by electrolysis in hexafluorosilicon electrolyte, following the Betts procedure [1, 9]. A semi-finished product with Bi content of 8–15% is used as the starting alloy. It is desirable to raise the content of this metal, but to no more than 30%. If the bismuth content in Pb–Bi anode plates is greater, the anodic process is significantly complicated. As lead is dissolved, the solid alloy lattice is disrupted and narrow channels are formed, in which lead hexafluorosilicate is crystallized. At the same time, a large amount of bismuth is dissolved and deposited at the cathode. Small pieces of the anode are crumbled and entrained by slam. The surface layer of the pieces consists of virtually pure bismuth, and the inner layer, of electrochemically unreacted lead. Industrial tests have shown that the Betts method for processing of Pb–Bi alloys containing more than 30% Bi is inexpedient.

Taking into account the aforesaid, we proposed, developed, and implemented industrially a somewhat different method for enrichment of bismuth drosses. The method, which is simpler and less expensive, consists in the following. To refine lead containing 0.5 ± 0.1% Bi, a mixture of bitumen (45–75 wt %) and sawdust (25–55 wt %) is added, and the process is performed at lower temperature (370–390°C). As a result, powder drosses containing 23–27% Bi are obtained and delivered to hydroelectrolytic processing by the Betts method. This procedure involves separation of drosses and thus eliminates the additional stage of bath heating to a temperature of 400–470°C, at which drosses are separated in the method described above. The addition of sawdust (which is less expensive than bitumen) prevents the possible inflammation of bitumen particles floating-up to the surface of a lead bath. Sawdust contains moisture, which evaporates to cool the upper layers of molten lead. It should be noted that sawdust is introduced into the liquid metal being refined not simultaneously with dead oil, but later, when obtaining "dry" powder drosses. In addition, sawdust plays the same part in the separation of intermetallic compounds of bismuth as dead oil.

This method makes lower the cost of bismuth removal from lead because of the use, in addition to bitumen, of such a less expensive material as sawdust. Labor conditions are improved owing to the elimination of the possibility of bitumen inflammation. The energy expenditure, labor intensity, and reagent consumption are much lowered owing to a significant decrease in the amount of lead–bismuth alloy to be processed by an electrolyzer in a hexafluorosilicon acid solution.

CONCLUSIONS

(1) A modified Kroll and Betterton method for lead purification to remove bismuth has been proposed and subjected to pilot tests. The improvement consists in that dead oil or its mixture with sawdust is introduced into metal melt in a certain stage of refining to yield rich bismuth drosses in the form of a powder. The separation of the product is also a specific feature of the process.

(2) The method for lead and bismuth separation, which was developed and implemented industrially, makes it possible to produce a bismuth–lead alloy containing up to 55–65% Bi.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of Rectification and Liquid–Vapor Phase Equilibrium in Systems Phenol–Water–Hydroxyacetone and Phenol–Water–α-Methylstyrene

V. Yu. Aristovich, Yu. V. Aristovich, A. Yu. Sokolov, and J. V. Fulmer

Received July 30, 2002

Abstract—Distillation processes and the liquid–vapor phase equilibrium in the systems phenol–water–hydroxyacetone and phenol–water–α-methylstyrene at atmospheric pressure were studied. The direction of the distillation lines was established and the possibility of preparing pure phenol and concentrating other components, i.e., impurities, in various regions of distillation of the systems was determined.

Owing to the increasing stringency of requirements to the quality of phenol used for production of various polymers, including those exhibiting heat resistance, it is necessary to study in more detail processes of distillation of a mixture of phenol with concomitant impurities in the stage of phenol isolation as a commercial product. Among the main impurities determining the quality of commercial phenol are water, α-methylstyrene, and 2-methylbenzofuran, with the last compound being a product of reaction between hydroxyacetone and phenol in the final stages of phenol isolation.

Data on liquid–vapor phase equilibrium in mixtures of phenol with water, α-methylstyrene, and hydroxyacetone form a physicochemical basis for determining the optimal conditions of phenol rectification to remove concomitants. Published data are only available for the system phenol–water–α-methylstyrene at 66.65 hPa [1]. At the same time, commercial phenol is commonly isolated from aqueous solutions under nearly atmospheric conditions.

Experiments on determining the liquid–vapor equilibria were performed on a Bushmakin device modified by Smirnova and Morachevskii in order to study stratification liquids [2]. The presence of an azeotrope in the hydroxyacetone–water system was judged from data of gas-liquid chromatography (Hewlett–Packard 5890 chromatograph). The mixtures were distilled on a film rectification column with efficiency of 25 theoretical plates. Prior to all experiments, nonvolatile antioxidants were added to the solutions to prevent oxidation of the active components of the mixtures studied. The rectification of aqueous hydroxyacetone mixtures did not reveal presence of an azeotrope with the lowest boiling point, since the hydroxyacetone concentration in the first fractions (T_b =100.0°C, P = 1013 hPa) was less than 0.01 wt %.

Data on the liquid–vapor equilibrium are listed in Table 1 for the binary system water–hydroxyacetone

and in Table 2 for the ternary phenol–water–hydroxyacetone system.

The experiments performed made it possible to construct diagrams of distillation lines and regions (Fig. 1a). The family of the distillation lines is divided into two distillation regions *1* and *2*. The strong dependence of the concentrations and the relative volatility of hydroxyacetone on the phenol : water ratio is characteristic of the distillation lines in region *1* adjacent to phenol and occupying the major part of the concentration triangle. In some cases, the relative volatility is lower than unity.

Analysis of the curve of the extremal concentrations of hydroxyacetone (Fig. 1a, *dashed line*) shows that, at a given hydroxyacetone concentration in the initial mixture, pure commercial phenol can be isolated

in region *1* only up to a certain phenol/water ratio. The most complete concentrating of hydroxyacetone is possible in region *2*, which is adjacent to water. The distillation line separating regions *1* and *2* is shown in Fig. 1a by dashed line.

Table 3 lists data on the liquid–vapor equilibrium in the phenol–water–α-methystyrene system at atmospheric pressure. In run nos. 1, 2, 6, and 7, the condensate of sampled vapor stratified. The compositions of its lower and upper layers are given in Table 4. The diagram of the distillation lines and regions for the system is shown in Fig. 1b. There exist three distillation regions. Pure phenol can be isolated in region *1*, which is adjacent to phenol. Isolation of pure α-methystyrene is possible in region *3*, which is adjacent to water.

CONCLUSIONS

(1) The experimentally obtained data on the liquid–vapor equilibrium in the systems water–hydroxyacetone and in the ternary system phenol–water–hydroxyacetone made it possible to assess conditions of phenol rectification in its mixtures with water and hydroxyacetone.

(2) The experimental data on the liquid–vapor equilibrium in the phenol–water–hydroxyacetone ternary system at atmospheric pressure were used to determine the conditions of phenol rectification in mixtures with water and α-methylstyrene.

Abstract—The method of sorption of tetrachloromethane vapor at the solid/gas interface was applied to study the sorption and structural properties of a mesoporous aluminum oxide material obtained by deposition of amorphous hydrated silicon(IV) oxide onto α-aluminum oxide particles submerged in decationized silica sol.

Varieties of colloid silica, from silicic acids to sols, are commonly deposited on surfaces in order to diminish or raise their adhesion to other substances. The resulting thin SiO_2 films enable modification of the surface properties of the substrate and expand the application fields of its valuable volume properties. For example, a dense coating on a titanium oxide pigment can protect it from photocatalytic degradation [1], and a porous coating deposited on a selective catalyst and exhibiting a sieving effect precludes undesirable side reactions in the catalytic process [2]. However, despite the interest in properties and deposition of various silica coatings [1–5], there are virtually no published data on how the sorption characteristics of substances change upon SiO_2 deposition. In contrast to the structure of the conventional bulk silica gel, whose formation is much contributed by stages of gel formation, syneresis, and drying [6], the structure of thin SiO_2 films is the most sensitive to the last stage, which is more important than the others, and the time of structure formation is much shorter than that in xerogel SiO_2 [5].

The aim of the present study was to apply the method of sorption of tetrachloromethane vapor at the gas/solid interface to analysis of the structural properties of aluminum oxide materials obtained by deposition of amorphous hydrated SiO_2 onto α-Al_2O_3 particles submerged in decationized silica sol. Upon drying, such substances, which are densified when necessary to a desirable extent, are potential sensors, membranes, or catalysts, and mixtures of a colloid silica with highly dispersed Al_2O_3 may serve as thin-layer coatings in cellular supports with developed surface [7].

As substrate for a silica coating was used α-Al_2O_3 with specific surface area $S_{sp} = 27 \times 10^3$ m^2 kg^{-1} and density of 3700 kg m^{-3}. A decationized silica sol with pH 3.5 and SiO_2 content of 2.0 wt % was obtained by passing diluted aqueous solution of Na_2SiO_3 through a column packed with KU-2 sulfo cation-exchange resin in hydrogen form [8]. Then, a certain amount of silica sol, corresponding to Si : Al molar ratios of 0.1 : 0.9, 0.3 : 0.7, 0.5 : 0.5, 0.6 : 0.4, and 0.7 : 0.3 was delivered by a dosing pump to a vessel with aqueous suspension of aluminum oxide powder, which contained 2.5×10^{-3} kg α-Al_2O_3 per 1 kg of H_2O. Simultaneously, $NH_3 \cdot H_2O$ was added to pH 7.5, and then hydrochloric acid to pH 5.6. After keeping the gel in liquid state for 0.5 h the solid phase was separated by decantation, washed with distilled water to complete absence of a reaction for Cl^- ions in washing water, and dried in air, first at room temperature and then at 393 K for 4 h. The corresponding bulk silica gel was prepared from acidic decationized silica sol in the absence of α-Al_2O_3.

Adsorption–desorption isotherms of CCl_4 vapor were measured gravimetrically at 293 K after preliminary vacuum treatment of samples at 413 K for 16 h. The specific surface area was calculated from the monolayer capacity by the BET equation in linear form at relative pressures $p/p_0 = 0.05–0.25$ with surface area occupied by a CCl_4 molecule taken to be 0.322 nm^2. The amount of adsorbed vapor was expressed in volumes V of the liquid adsorbate per 1 kg of adsorbent. The limiting sorption volume of pores, V_p, was found by the Gurvich method [9] from the amount of vapor sorbed at saturation. The shape of mesopores was assessed in accordance with IUPAC

1070-4272/03/7602-0198 $25.00

recommendations from the shape of the adsorption–desorption hysteresis loop [10]. The average pore radius r_p was found using the relation

$$r_p = 2V_p/S_{sp}, \quad (1)$$

and the radius of globules of aluminum oxide materials, r, by the formula

$$r = 3/\rho S_{sp}, \quad (2)$$

where ρ is the density of the solid.

To analyze the isotherms of adsorption of CCl_4 vapor, comparison curves were also plotted, in which the adsorption on a sample under study (ordinate) was represented as a dependence on the adsorption on a standard sample at the same relative vapor pressure (abscissa). The latter adsorption was expressed as reduced adsorption $V/V_{0.4}$, where $V_{0.4}$ is the amount of vapor adsorbed at $p/p_0 = 0.4$. As standard served Fransil EL nonporous SiO_2 with hydroxylated surface [11].

The thickness of the SiO_2 monolayer was calculated on the assumption that silicon dioxide tetrahedra form a densely packed hexagonal structure. With this kind of packing, the SiO_2 mass per 1 m^2 of the aluminum oxide surface $m = 103.75 \times 10^{-6}$ kg, in accordance with the expression

$$m = \frac{Mu}{a}, \quad (3)$$

where M is the relative molecular weight of SiO_2; u, the atomic mass unit equal to 1.66×10^{-27} kg; a, the area occupied by a silicon dioxide tetrahedron, equal to 0.096×10^{-18} m^2.

Then the SiO_2 volume per 1 m^2 $V = 0.47 \times 10^{-9}$ m^3 in accordance with the expression

$$V = \frac{Mu}{a}\frac{1}{\rho}, \quad (4)$$

where ρ is the silica density, equal to 2200 kg m^{-3}.

Since the calculation was done for 1 m^2 of the aluminum oxide surface, the SiO_2 monolayer thickness was taken to be 0.47 nm.

IR spectra of samples compacted in pellets with KBr were measured on MIDEC M 2000 IR Fourier spectrometer (USA) in the spectral range 4000–400 cm^{-1} at resolution of 4 cm^{-1} and number of scans equal to 4. The spectra obtained were processed using Galactic GRAMS/32 software (USA).

The data presented in Fig. 1 show that sample nos. 1 and 8, i.e., α-Al_2O_3 and SiO_2 obtained from decationized sol at pH 5.6, have mesoporous and microporous structure and are described, according to the IUPAC classification [10], by isotherms of, respectively, type IV and I. The shape and reversibility of isotherm *8* (SiO_2) indicate that the calculated specific surface area and average sizes of pores and globules are effective, apparent, and the effective pore radius of the sample is less than 1 nm [10]. To summarize, to dense α-Al_2O_3 globules (r = 30 nm) corresponds a specific surface area of 27×10^3 m^2 kg^{-1}, and to SiO_2 ($r \approx 1$ nm), an apparent specific surface area of 1120×10^3 m^2 kg^{-1} (see table).

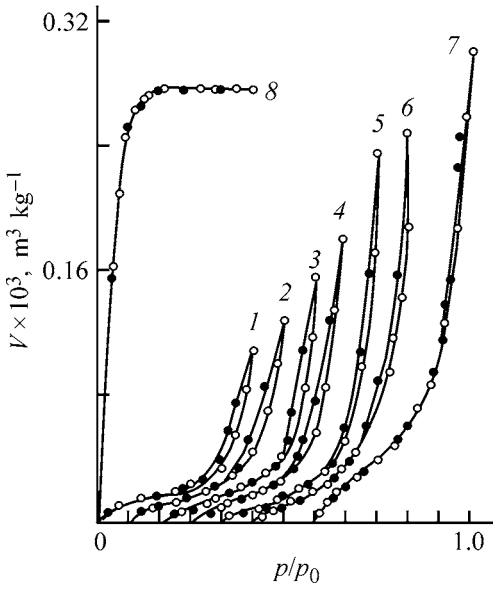

Fig. 1. Isotherms of adsorption–desorption of CCl_4 vapor on α-Al_2O_3 samples (*1*) without treatment with decationized silica gel and (*2–7*) after such treatment and (*8*) silica gel obtained from acidic decationized silica sol. (V) Amount of CCl_4 vapor adsorbed in volume of liquid adsorbate per 1 kg of adsorbent, (p/p_0) relative vapor pressure of the adsorbate, and (p_0) saturated vapor pressure of the adsorbate. *Digits at curves* correspond to sample numbers in the table.

The starting decationized SiO_2 sol is composed of minute globules ($r \approx 1.5$–2.0 nm), which corresponds, at SiO_2 density of 2200 kg m^{-3}, to a mass of a separate particle of about $(3.9–9.2) \times 10^{-24}$ kg, or, if it were a separate molecule, to relative molecular mass of 2300–5500 [8]. The increase in capillary contraction forces in the course of dehydration of the silica gel obtained leads to an isotherm of type I, characteristic of microporous gels (Fig. 1).

ible at low relative vapor pressures, and show hysteresis loops at higher p/p_0, which corresponds to type IV of isotherms of physical sorption [10]. The shape of the irreversible part of isotherms in Fig. 1 varies between the samples, which points to the presence of mesopores with different shapes and sizes, formed by various ensembles of particles. The hysteresis loop in isotherms *2–7* narrows and shifts somewhat to the right with increasing isotherm number. The very narrow hysteresis loops of isotherms *2–7* are a combination of hysteresis H1 at the beginning of the loop and H3 at its end at high p/p_0. The first kind of hysteresis is characteristic of open cylindrical pores formed by agglomerates of contacting globules and connected with neighboring pores by several throats, and the second kind is tipical of particle aggregates with other types of packing.

The initial portions of comparison curves *2–6* for samples obtained at Si : Al molar ratios in the range from 0.1 : 0.9 to 0.8 : 0.2 are, in contrast to isotherm *7*, straight lines passing through the origin of the coordinates, which points to the absence of micropores (Fig. 2). The rise observed in curves *5–7* begins at $V/V_{0.4}$ values corresponding to p/p_0 of 0.59, 0.52, and 0.40 and precedes the beginning of hysteresis loops in the isotherms shown in Fig. 1 ($p/p_0 \approx 0.70$). Such upward deviations of the comparison curves of the samples in the region preceding the beginning of the hysteresis loop point to the occurrence of capillary condensation not accompanied by hysteresis [12]. For sample nos. 2–4, the points of rise in adsorption in the comparison curves coincide with the onset of hysteresis in the sorption isotherms.

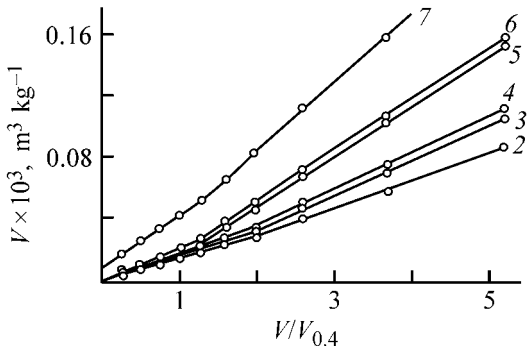

Fig. 2. Comparison curves for the samples obtained. (V) Volume of CCl_4 vapor adsorbed on a sample under study, ($V/V_{0.4}$) reduced adsorption of CCl_4 vapor on a standard Fransil EL sample at the same p/p_0 values as those for the sample under study, and ($V_{0.4}$) amount of CCl_4 vapor adsorbed at equilibrium p/p_0 equal to 0.4.

It can be seen from the table that, with the Si : Al molar ratio changing from 0.1 : 0.9 to 0.8 : 0.2, the average particle radius in sample nos. 2–6 increases from 30.8 to 45.3 nm, the thickness of the silica coating, from 0.8 to 15.3 nm, and the number of silica layers on the surface at monolayer thickness of 0.47 nm, from 1.7 to 32.6. The limiting sorption volumes of pores in sample nos. 1–8 increase from 0.11×10^{-3} $m^3\ kg^{-1}$ for the starting α-Al_2O_3 to 0.30×10^{-3} $m^3\ kg^{-1}$ for a sample obtained at Si : Al molar ratio of 0.9 : 0.1. The steep rise in the thickness of the silica coating occurs at Si : Al molar ratios exceeding 0.5 : 0.5. The adsorption of a CCl_4 monolayer is virtually the same for all porous sample nos. 1–6 (Fig. 1), and, consequently, the set of mesopores formed as a result of SiO_2 deposition on the surface of aluminum oxide at Si : Al molar ratios in the range from 0.1 : 0.9 to 0.8 : 0.2 affects the adsorption in the monolayer region only slightly. The average pore radius increases from 8.1 nm in sample no. 1 to 18.5 nm in sample no. 6 and 14.3 nm in sample no. 7.

Figure 3 shows an IR spectrum of α-Al_2O_3 treated with decationized silica sol at a ratio of 0.5 : 0.5. The sample is characterized by a narrow band of stretching vibrations (SiO) at 1093 cm^{-1} and retains most of its hydroxy groups. The configuration of the formula unit of silica in modified α-Al_2O_3 is not distorted. Presumably, deposition of hydrated SiO_2 on the aluminum oxide surface, which acts in acid medium as anion adsorbent, begins with the interaction of SiOH groups with surface AlOH groups and continues as growth of silica layers. It is difficult to determine what polymeric variety of SiO_2: discrete particles of silica sol, particles formed directly on the surface of α-Al_2O_3, or silica gel floccules, are responsible for this growth.

As a rule, narrowing of the hysteresis loops and their rightwards shift are observed with increasing size of contacting globules and decreasing coordination number of their packing [13]. In the presence of firmly bound agglomerates of aluminum oxide globules, the former assumes filling of contacts with SiO_2 being deposited, with loss of a part of the surface area, and the latter is meaningless. The loop width also decreases when the capillary condensation with hysteresis is overlapped by a condensation not accompanied by hysteresis, as in the case of cylindrical mesopores closed at one end [12]. Such a capillary condensation without hysteresis is revealed by comparison curves of sample nos. 5–7 (Fig. 2). To summarize, cylindrical mesopores constituted by spaces between α-Al_2O_3 globules, in which noticeable capillary condensation may occur, change their shape upon treatment with decationized silica sol, with one of their ends closing.

The formation of a silica coating, which is very fast process, strongly differs from gelation, aging, and drying the corresponding SiO_2 bulk gel, which leads to fundamental difference between their physical properties [5]. Even at high SiO_2 content in sample no. 7, its porous structure strongly differs from that of sample no. 8: volume filling of pores is replaced by polymolecular filling, and the isotherm changes from type I to type IV. The comparison curve for this sample in Fig. 2 makes an intercept on the ordinate axis and has steeper slope than the curves for other samples, which points to an increase in the surface area, accompanied by a decrease in the average pore radius in the sample from 18.5 to 14.3 nm. This circumstance and the fact that CCl_4 vapor adsorption on sample no. 7 occurs as adsorption on a mesoporous material whose globule radius of 29.3 nm is close to a similar value for α-Al_2O_3, but the limiting sorption volume exceeds nearly 2.7-fold the same parameter for α-Al_2O_3, are both due to the appearance of a phase of aggregated SiO_2 particles, which introduces a certain volume of shallow mesopores into the structure.

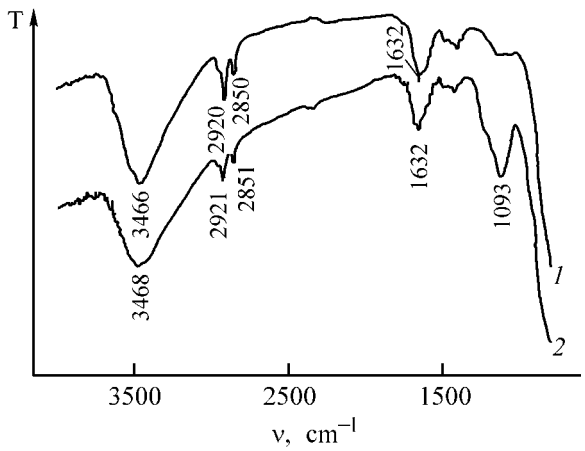

Fig. 3. IR spectra of α-Al_2O_3 samples (*1*) without treatment with decationized silica sol and (*2*) after such treatment. (T) Transmission, and (ν) wave number. Si : Al molar ratio: (*1*) 0 : 1 and (*2*) 0.5 : 0.5.

CONCLUSIONS

(1) Deposition of amorphous hydrated SiO_2 on α-Al_2O_3 particles submerged in decationized silica sol allows control over the size and shape of pores in the aluminum oxide and their limiting sorption volume. Raising the Si : Al molar ratio leads to an increase in the limiting sorption volume and average radii of pores and α-Al_2O_3 globules. The type IV of the isotherm of adsorption–desorption of tetrachloromethane vapor, the shape of the hysteresis loop, and the occurrence of adsorption in the monolayer region, which are all characteristic of α-Al_2O_3, do not change significantly.

(2) The hysteresis loop in the isotherm becomes narrower and is shifted to higher p/p_0 values.

Abstract—The chemical interaction between dimethylchlorosilane and silica of varied degree of hydroxylation was subjected to a systematic study. The optimal conditions for complete substitution of isolated silanol groups with dimethyl hydride silyl groups were found. It is suggested that the reaction of dimethylchlorosilane with the surface of silicon dioxide can be used to determine the concentration of free silanol groups in the surface layer of silica.

It is known that main active centers on the surface of silica are isolated ≡Si–OH groups [1, 2]. Most of chemical reactions occurring on the silica surface involve the silanol groups of silicon dioxide [3–5]. The silanol groups on the silica surface play an important part in adsorption and ion exchange [1, 2, 5]. Residual silanol groups on the surface of chemically modified silicas strongly affect the adsorption, chromatographic, and catalytic properties of silica-containing materials.

There exist various methods for determining the concentration of silanol groups on the silica surface [4]. These methods are mostly based on a chemical reaction between the silanol groups and an appropriate reagent, with subsequent quantitative analysis of the reaction products formed.

In this study, it is suggested that the concentration of isolated silanol groups on the silica surface should be determined by means of chemical reaction between dispersed silicon dioxide and dimethylchlorosilane (DMCS).

Silica was studied in the form of aerosil subjected to vacuum treatment at 200, 400, or 600°C. These pretreatment temperatures are frequently used in studying the adsorption and chemisorption properties of silicon dioxide [3].

As established previously [6], the chemical reaction of silica with DMCS proceeds quantitatively with only free silanol groups involved:

$$\equiv Si–OH + (CH_3)_2Si(Cl)H \rightarrow \equiv Si–O–Si(CH_3)_2H + HCl\uparrow. \quad (1)$$

To determine the optimal conditions for complete substitution of isolated silanol groups with dimethyl hydride silyl groups, the interaction between DMCS vapor and surface of silica vacuum-treated at 200, 400, or 600°C was studied in relation to temperature (Fig. 1) and time (Fig. 2) of reaction. The conditions

400	350	60	1.08 ± 0.05	0.98 ± 0.05
600	400	30	0.74 ± 0.04	0.72 ± 0.04

* I, by alkaline hydrolysis of dimethyl hydride silyl groups; II, by grafting of trimethyl silyl groups (for the conditions of quantitative substitution of free OH groups with trimethyl silyl groups in chemisorption of hexamethyldisilazane, see text.).

** The absolute error was found using Student's method [7]. The calculation was done at confidence probability of 0.95 and number of degrees of freedom equal to 10 in determining the amount of OH groups with DMCS and 5 when hexamethyldisilazane was used.

for complete substitution of isolated silanol groups with dimethyl hydride silyl groups are summarized in the table. As seen from the data presented (see table and Figs. 1 and 2), in the case of silica vacuum-pretreated at 200°C, complete substitution of silanol groups with dimethyl hydride silyl groups occurs at 200°C already in 1.5 h. In the case of silica vacuum-treated at 400°C, the reaction of electrophilic substitution of the proton from the silanol group occurs at 350°C in 1 h; the optimal reaction temperature and duration for silica vacuum-treated at 600°C are 400°C and 0.5 h. IR spectra of silicas (Fig. 3) modified with DMCS under the conditions of complete substitution of silanol groups contain no absorption band at 3750 cm^{-1}, which is associated with stretching vibrations of the O–H bonds in free OH groups, whereas the absorption bands associated with asymmetric (2970 cm^{-1}) and symmetric (2910 cm^{-1}) stretching and deformation (1420 cm^{-1}) vibrations of the C–H bond, and also the absorption band (2160 cm^{-1}) of stretching vibrations of Si–H bonds in grafted dimethyl hydride silyl groups [8] are present.

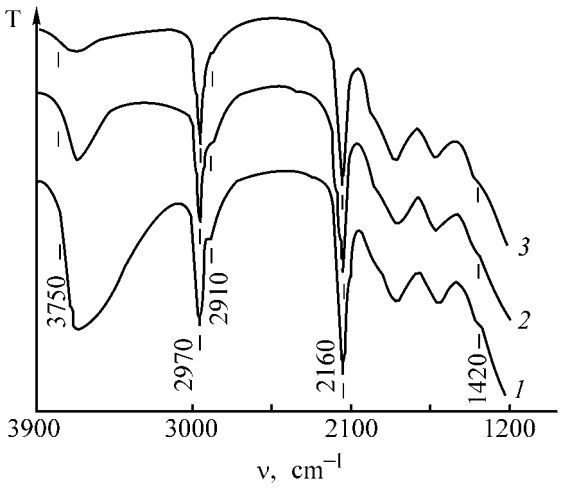

Fig. 3. IR spectra of aerosil modified with DMCS. Vacuum-pretreatment of silica for 2 h at (*1*) 200, (*2*) 400, and (*3*) 600°C. (T) Transmission and (ν) wave number. Reaction temperature (°C): (*1*) 200, (*2*) 350, and (*3*) 400°C. Reaction duration (h): (*1*) 1.5, (*2*) 1.0, and (*3*) 0.5.

It should be noted that the efficiency of DMCS chemisorption on the silica surface depends not only on the temperature and duration of a chemical reaction, but also on the temperature of preliminary vacuum treatment of SiO_2: the higher the temperature of vacuum treatment of silica, the lower the degree of substitution of isolated silanol groups with dimethyl hydride silyl groups at the same reaction temperature (Fig. 1). This is due, as established previously [6, 9], to a decrease in the electron density on oxygen atoms of the silanol groups attacked in the course of dehydroxylation of the silica surface.

Thus, the investigation of the chemical interaction of dispersed silicas with various degrees of surface hydroxylation with DMCS makes it possible to select the optimal conditions for quantitative occurrence of this chemical reaction for any particular case. As follows from scheme (1), in the case of a quantitative course of the reaction, the concentration of dimethyl hydride silyl groups formed on silica surface is equal to that of isolated silanol groups and can be found from the volume of hydrogen evolved in alkaline hydrolysis of dimethyl hydride silanol groups [10]:

$$\equiv Si{-}O{-}Si(CH_3)_2H + H_2O \rightarrow \equiv Si{-}O{-}Si(CH_3)_2OH + H_2\uparrow. \quad (2)$$

This method for determining the concentration of free OH groups on the surface of silicon dioxide does not require any sophisticated equipment or expensive reagents. The table lists the data obtained in determining the concentration of isolated silanol groups by means of alkaline hydrolysis of dimethyl hydride silyl groups (from the volume of hydrogen evolved). Also presented are data obtained gravimetrically (in quantitative chemisorption of hexamethyl disilazane on silica) in a vacuum setup with quartz spring balance [3]. Both the techniques yield virtually the same results.

It should be noted that the indubitable advantage of the method for determining the content of isolated

silanol groups by means of alkaline hydrolysis of preliminarily chemisorbed dimethyl hydride silyl groups consists in that adsorbed water does not hinder determination of the concentration of silanol groups in silica: tetramethyldisiloxane $H(CH_3)_2Si–O–Si(CH_3)_2H$, which is formed when DMCS is brought in contact with water, is a volatile compound and is easily removed from the silica surface in vacuum-treatment of products formed in electrophilic substitution of the proton in silanol groups and an excess amount of DMCS [11].

Thus, the method proposed can be used to determine the concentration of isolated silanol groups on the surface of silicas hydroxylated to varied extent and to find the content of residual (or secondary) silanol groups in chemically modified silicas.

EXPERIMENTAL

The concentration of free silanol groups was determined for highly dispersed amorphous silica, A-300 aerosil with specific surface area of 300 $m^2 g^{-1}$, pretreated in a vacuum at 200, 400, and 600°C.

The modification of silicon dioxide with DMCS was performed as follows. Silica was placed in a quartz reactor, the reactor was evacuated, and silica was kept, first, in a vacuum at 200°C for 2 h and then in saturated DMCS vapor at 200°C for 1.5 h. The excess amount of the reagent and the hydrogen chloride evolved were pumped out of the reactor at 200°C for 1 h. In the case of a pretreatment of silica at 400 and 600°C, the reaction with DMCS was carried out at 350°C for 1 h and at 400°C for 0.5 h, respectively, with subsequent vacuum treatment at the reaction temperature for 1 h.

The extent of the reaction between the silanol groups of the silica surface and DMCS was monitored by IR spectroscopy on an IKS-29 spectrophotometer (LOMO, Russia) in the frequency range 4200–1200 cm^{-1}.

To determine the concentration of isolated OH groups on the silica surface (from DMCS chemisorption), a 0.2–0.4-g portion of silica quantitatively modified with dimethyl hydride silyl groups was taken. The volume of hydrogen evolved in the course of alkaline hydrolysis of chemically attached dimethyl hydride silyl groups was measured on a setup similar to the Tserevitinov device [10]. As locking fluid served water saturated with hydrogen. For this purpose, gaseous hydrogen was passed through water under vigorous stirring for several minutes.

The amount of free OH groups on the silica surface, c_{OH} (mmol g^{-1}), was calculated using the formula

$$c_{OH} = \frac{V_0}{m \times 22.4},$$

where m is the weighed portion of silica (g), and V_0 is the volume of evolved hydrogen, recalculated to the standard conditions (ml).

The hydrogen volume was reduced to the standard conditions by the equation

$$V_0 = \frac{V_T \times 273.2(B - p)}{760(273.2 + T)},$$

where V_T is the hydrogen volume (ml) measured at temperature T and barometric pressure B; B, the barometric pressure (mm Hg); p, the water vapor pressure (mm Hg) at temperature T; T, the temperature at which the gas volume is measured (°C) [12].

The amount of isolated OH groups on the silica surface was determined gravimetrically (on the basis of hexamethyldisilazane chemisorption) in an evacuated installation with McBain–Bakr quartz spring balance [13]. The spring extension (sensitivity 0.53 mm mg^{-1}) was measured with a V-630 cathetometer. The chemical reaction of hexamethyldisilazane with the surface of silicon dioxide was carried out at 200°C in the course of 1 h, with subsequent vacuum-treatment of the excess amount of the reagent and the reaction products at 200°C for 1 h [3].

The content of grafted trimethyl silyl groups, c_{TMS} (mmol g^{-1}), which is equal to the initial amount of free OH groups, c_{OH}, on the silica surface, was calculated by the formula

$$c_{TMS} = \frac{\Delta l \varphi}{mM},$$

where Δl is the difference between the cathetometer readings before and after chemisorption of hexamethyl disilazane (mm); φ, the calibration coefficient of the spring (mg mm^{-1}); M, the molar mass of the grafted fragment (g); m, the true mass of silica (g).

The true mass of silicon dioxide (mass after dehydroxylation) was found using the formula

$$m = m_0 - \frac{\Delta l \varphi}{1000},$$

where m_0 is a weighed portion of air-dried silica (g) and Δl is the difference between the cathetometer readings (mm) before and after vacuum treatment of silica at 200, 400, or 600°C.

CONCLUSIONS

(1) The optimal conditions for complete substitution of free silanol groups with dimethyl hydride silyl

groups were established on the basis of a study of the interaction between dimethylchlorosilane vapor and the surface of silica vacuum-treated at 200, 400, or 600°C in relation to reaction temperature and duration.

(2) A method was suggested for determining the concentration of isolated silanol groups on the surface of silica with varied degree of hydroxylation by means of alkaline hydrolysis of grafted dimethyl hydride silyl groups.

SORPTION AND ION-EXCHANGE PROCESSES

Influence of the Structure of Anion-Exchange Resin on Complexation with Transition Metal Ions

E. E. Ergozhin, A. K. Chalov, R. A. Iskakova, and A. I. Nikitina

Besturov Institute of Chemical Sciences, Ministry of Education of the Republic of Kazakhstan, Almaty, Kazakhstan

Received November 23, 2001; in final form, November 2002

Abstract—Polarography and potentiometry was applied to study the influence exerted by the degree of cross-linking of an ion-exchange resin based on allyl bromide, diglycidil ether of resorcinol, and polyethylenepolyamine on its complexing ability. The shift of the potential of half-wave of reduction of the complex ion and data of potentiometric titration with and without complexing metal were used to calculate the coordination numbers and stability constants of complexes with cations of various metals.

A study of specific features of the complexation between ion-exchange resins and metals and determination of the stability constants and composition of complex compounds are of theoretical and practical interest. The complexing ability of polymers is widely used in hydrometallurgy for recovery and concentration of ions of transition, rare, and noble metals [1].

Complex compounds are commonly studied by spectrophotometry, polarography, high-frequency titration, and potentiometry. However, polarographic studies of complex compounds are scarce [2–4].

The aim of the present study was to analyze the influence exerted by the structure of an ion-exchange resin based on allyl bromide (AB), diglycidil ether of resorcinol (DGER), and polyethylenepolyamine (PEPA) on its complexing ability, by polarography in the stage of prepolymerization and by potentiometry after additional curing.

EXPERIMENTAL

The ion-exchange resin under study was synthesized by a procedure described in [5]. Part of the polymer was precipitated in diethyl ether and dried, and solutions of various concentrations were prepared. The rest of the reaction mass was subjected to additional curing at 80°C.

Polarograms of reduction of metal cations in their complexes with the polymer were measured with solution 0.01 N H_2SO_4 in 25% dimethylformamide (DMF) as supporting electrolyte. The choice of 0.01 N H_2SO_4 and DMF as supporting electrolyte for polarography is due to the fact that it is in this medium that complex compounds of an anion-exchange resin based on AB, DGER, and PEPA with transition metals, including Cu^{2+}, possess sufficient solubility in the necessary range of anion-exchange resin concentrations. In polarographic measurements, the content of the ion-exchange resin was varied from 0.1 to 20 g l^{-1}. The concentration of metal salts, $CoSO_4$, $NiSO_4$, and $CuSO_4$, was 2×10^{-3} M. As reference served saturated calomel electrode. Characteristic of the mercury drop electrode: $m^{2/3}t^{1/6} = 4.28$ mg$^{2/3}$ s$^{-1/2}$. The electrolytic cell was thermostated at 25 ± 0.1°C. Oxygen was removed from the solutions by bubbling argon through them for 10 min.

The apparent dissociation constant pK_α, the Bjerrum complex-formation function n, and the stability constant log K_n were calculated from the data of [1].

The main factor governing the formation of coordination compounds is that metal ions tend to compensate for the electron deficiency at the expense of the electron pairs of the donor contained in the functional groups of the polymer.

Anion-exchange resins absorb metal cations from solutions of their salts by the scheme

$$n\mathrm{R_3N}\ldots\mathrm{HOH} + \mathrm{M^{2+}} \rightarrow [(\mathrm{R_3N})_n\mathrm{M}]^{2+} + n\mathrm{H_2O}.$$

The sorption equilibrium is affected by the following factors: nature of the anion-exchange resin and complexing metal, and also the state of the metal in

1070-4272/03/7602-0207 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Table 1. Potentials of half-wave of reduction of complexes formed by ion-exchange resin based on AB, DGER, and PEPA with various metals (concentration of ion-exchange resin 1 g l^{-1}, that of a salt 2×10^{-3} M)

Cation	$E_{1/2}$, V	$\Delta E_{1/2}$, V	pH value

* Concentration of ion-exchange resin 10 g l^{-1}.

solution; concentration of coordination-active amino groups and the complexing metal; solution composition (pH value, ionic strength of the solution).

It is known [6] that reduction of a complex ion on a mercury drop electrode occurs at rather strong electrode polarization, and complexation is associated with a shift of the potential of half-wave of reduction to more negative values. The $E_{1/2}$ potential of the complex must be more negative than the half-wave potential of the free ion, since the cation must become free of ligands in the course of reduction, and this involves energy expenditure. With a knowledge of how $E_{1/2}$ depends on the concentration of the complexing agent (and this dependence is, as a rule, linear), one can calculate the equilibrium stability constant of the complex, log K, and its composition, The higher the log K value, the stronger the complex and the more negative the half-wave potential of its discharge in solution.

It was established in studying the complexing ability of the ion-exchange resin based on AB, DGER, and PEPA in solution in the presence of various metal

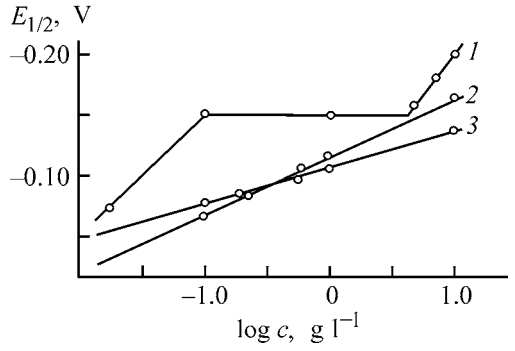

Fig. 1. Potential of half-wave of reduction $E_{1/2}$ of complex ions with various metals on the concentration c of the ion-exchange resin. (*1*) Cu^{2+}, (*2*) Ni^{2+}, and (*3*) Co^{2+}.

ions that the potential of half-wave of reduction of the forming complex and its shift $\Delta E_{1/2}$ relative to $E_{1/2}$ of reduction of a free metal cation depend on the nature of the metal (Table 1).

Analysis of the data in Table 1 shows that the anion-exchange resin forms the strongest complex with copper cations, since the maximum shift $\Delta E_{1/2}$ is observed in this case.

To obtain quantitative characteristics of the composition and stability of complex compounds formed by various metal ions with the ion-exchange resin based on AB, DGER, and PEPA, the change in $E_{1/2}$ of reduction of the complexes on raising the content of the ion-exchange resin was studied in the range 0.1–20 g l^{-1}.

It can be seen from Fig. 1 that the dependence of $E_{1/2}$ on the logarithm of the polymer concentration is linear for the Co^{2+} and Ni^{2+} cations, which points to the existence of a single strong complex in solution [6]. If the stability constants of successive complexes differ strongly, this dependence has the form of a number of linear portions with sharp bends, with the number of the portions corresponding to the number of complexes present in solution. It is the dependence of this kind that is observed for the Cu^{2+} cation. It follows from this dependence that the ion-exchange resin mentioned above gives with copper ions two complexes with different strengths, one of which, as also complexes with Co^{2+} and Ni^{2+}, is formed at pH 3.0 and the other exists in the pH range 5.0–5.5.

The slope tan α of the dependence of $E_{1/2}$ on the logarithm of the sorbent concentration was used to determine the coordination number p by the equation [7]

$$p = \frac{n}{0.059} \tan \alpha,$$

where n is the number of electrons involved in the reaction, i.e., the valence of the metal cation.

The slope can be calculated from two $E_{1/2}$ values and the corresponding logarithms of the concentration of the ion-exchange resin:

$$\tan \alpha = \frac{(E_{1/2})_2 - (E_{1/2})_1}{\log c_2 - \log c_1}.$$

The coordination numbers calculated for complexes of the ion-exchange resin with various metal cations are listed in Table 2. It can be seen that Co^{3+}, Ni^{2+}, and Cu^{2+} coordinate, respectively, one, two, and three or four (depending on the sorbent concentration) amino groups of the anion-exchange resin.

The stability constants of the complexes formed by the ion-exchange resin based on AB, DGER, and PEPA with various metal ions (Table 2) were calculated by the equation [7]:

$$\log K = \frac{n(\Delta E_{1/2} + p\frac{0.059}{n}\log c)}{0.059}.$$

The highest $\log K$ value (Table 2) and the maximum shift $\Delta E_{1/2}$ (Table 1) are observed for complexes of the ion-exchange resin with copper. Metal cations can be arranged in order of decreasing complexing ability as follows: $Cu^{2+} > Ni^{2+} > Co^{2+}$.

The different strengths of the complexes formed by the sorbent with the given cations result in their different sorption capacities for metal ions (Table 2), which decrease in the same order as the strength of the respective complexes.

The composition and strength of the complexes formed with the insoluble sorbent after additional curing of the prepolymer were determined by potentiometric titration of the anion-exchange resins, with ions of the complexing metal absent or present and the pH value and concentration of uncomplexed metal ions monitored simultaneously.

The functional groups of the ion-exchange resins were neutralized to a greater extent using sodium nitrate, which is indifferent toward these groups, creates the ionic strength of a solution, and forms no complexes with anion exchange resins. With increasing ionic strength of a solution, the electron-donor properties of the ionogenic groups of the anion exchange resin become more pronounced, and the density of hydration sheaths of unprotonated amino groups decreases, which favors the higher complexing ability of the anion exchange resin. That is why the sorption properties of ion-exchange resins were studied at an ionic strength of the contacting solution equal to unity.

In potentiometric titration of polyfunctional polyelectrolytes in the presence of transition metal ions, the run of the curves changes because of the complexation (Fig. 2). It can be seen from the dependences obtained that protonation of a part of amino groups or their complexation with metal makes pH lower in all cases, with this decrease the stronger, the greater the amount of metal ions sorbed by the polymer.

The coordination properties of the ion-exchange resin were studied at metal ion concentration of 0.025 M, since at ion concentrations lower than 0.05 M the Bjerrum complex-formation function and the coordinated number of ligand groups have closer values [8].

Table 2. Coordination numbers and stability constants of complexes formed by ion-exchange resin based on AB, DGER, and PEPA with ions of various metals, found by polarography (concentration of the ion-exchange resin 1 g l^{-1}, that of a salt 2×10^{-3} M)

Salt	p	$\log K$	Sorption capacity, mg g^{-1}
$CoSO_4$	1	1.7	114.7
$NiSO_4$	2	3.0	133.4
$CuSO_4$	3	4.4	314.2
$CuSO_4^*$	4	10.1	–

* Concentration of ion-exchange resin 10 g l^{-1}.

For a cellular ion-exchange resin with less rigid 3D lattice, polarography gives the coordination numbers of 3 and 4 for copper ions, 2 for nickel ions, and 1 for cobalt ions; in the case of a densely cross-linked ion-exchange resin $n = 1$ for all the above ions, which points to the formation of a complex of 1 : 1 composition. The stability constants of the complexes, calculated from potentiometric titration data, are as follows: 6.2 for complexes with copper ions, 5.5 for nickel, and 5.3 for cobalt.

These data demonstrate the advantage of cellular sorbents with higher degree of cross-linking over soluble sorbents. This can be presumably accounted for by the following: in the former case, each amino group bounds one ion, and in the latter, 0.25–0.30 metal ions [9].

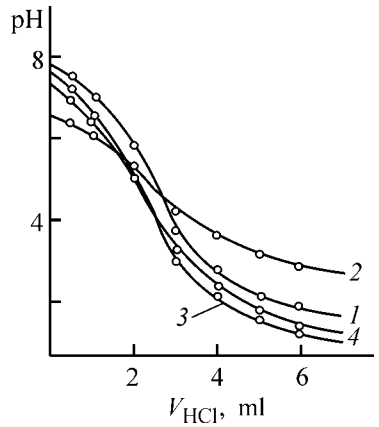

Fig. 2. Potentiometric titration curves for anion-exchange resin (*1*) without metal ions and in the presence of (*2*) Cu^{2+}, (*3*) Ni^{2+}, and (*4*) Co^{2+}. HCl concentration 0.1 M. (V_{HCl}) Volume of acid.

$CuSO_4$***	10/10	–	–	–	–

* Chloromethylated copolymer.

** Polarographic/potentiometric determination method.

*** Concentration of ion-exchange resin 10 g l^{-1}.

Comparison of the stability constants obtained (Table 3) with characteristics of the complexing ability of polyelectrolytes based on PEPA and various copolymers of epichlorohydrin (ECH), polyepichlorohydrin (PECH), and DGER [1] suggests that the strongest complex with copper ions is formed by the polymer based on AB, DGER, and PEPA (polymer concentration in solution 10 g l^{-1}). Practical use of the given ion-exchange resin will allow selective recovery of copper ions.

CONCLUSION

It is demonstrated that the structure of the anion exchange resin strongly affects the complexing ability of ion-exchange resins synthesized from allyl bromide, diglycidil ether of resorcinol, and polyethylenepolyamine. The most stable are complexes with copper ions.

Abstract—Extraction of nitrates of lanthanides(III) [La(III)–Lu(III) and also yttrium(III)] from their aqueous multicomponent systems with a toluene solution of trialkylbenzylammonium naphthenate was studied at 298 K and pH 3. Physicochemical and mathematical models describing the distribution and mutual influence of lanthanides(III) [Ln(III)] in their joint extraction from multicomponent aqueous solutions as influenced by the total Ln(III) concentration in the aqueous phase and composition of their mixture was developed.

Organic binary solutions of salt of quaternary ammonium bases (QAB) with organic anions are widely used for extractive recovery and separation of nonferrous and platinum metals [1]. We found no published information on extraction of lanthanides(III) [Ln(III)] with binary trialkylbenzylammonium naphthenate (TABANP) solutions in organic diluents.

In this study, we developed physicochemical and mathematical models describing the distribution and mutual influence of lanthanides(III) in their joint extraction from multicomponent solutions as a function of the total concentration and composition of Ln(III) mixture in the aqueous phase, taking into account that extractable complexes $(R_4N)_2[Ln(NO_3)_3A_2]$ (A, naphthenate anions) are formed in the organic phase.

The extraction of lanthanide(III) nitrates from aqueous solution with TABANP organic solution is described by the following equations:

$$2R_4NA_{(o)} + Ln^{3+}_{(a)} + 3NO^-_{3\,(a)} \rightleftarrows (R_4N)_2[Ln(NO_3)_3A_2]_{(o)}. \quad (1)$$

The extraction systems under consideration contain N kinds of Ln(III) metals. The main parameters characterizing the composition of these systems are as follows: $c_{Ln\,(a)}$ is the total (analytical) concentration of the sum of Ln(III) in the aqueous phase; $c_{Ln\,(o)}$, the total (analytical) concentration of the sum of Ln(III) in the organic phase; c_s, the total (analytical) extractant concentration in the organic phase; $\{R_4NA\}_{(o)}$, the equilibrium concentration of free TABANP in the organic phase; $\alpha^k_{(a)}$, the fraction of kth Ln(III) in the aqueous phase; $\alpha^k_{(o)}$, the fraction of kth Ln(III) in the organic phase

$$\alpha^k_{(a)} = c^k_{Ln\,(a)}/c_{Ln\,(a)}, \quad (2)$$

$$\alpha^k_{(o)} = c^k_{Ln\,(o)}/c_{Ln\,(o)}. \quad (3)$$

Here $c^k_{(a)}$ and $c^k_{(o)}$ are the total (analytical) concentrations of kth Ln(III) in the aqueous and organic phases, respectively.

For the organic phase, the following material balance equation is valid:

$$c_s = \{R_4NA\}_{(o)} + 2\sum_{k=1}^{N}(R_4N)_2[Ln^k(NO_3)_3A_2]_{(o)}. \quad (4)$$

A correlation between the equilibrium concentrations of the reacting species in both aqueous and organic phases and the concentration constant of the heterogeneous reaction of extraction of Ln(III) with TABANP is described by the equation

$$K^2_{ex,\,k} = \frac{\{(R_4N)_2[Ln^k(NO_3)_3A_2]\}_{(o)}}{\{R_4NA\}^2_{(o)}\{NO^-_3\}^3_{(a)}\{Ln^{3+(k)}\}_{(a)}}, \quad (5)$$

where $\{NO^-_3\}_{(a)} = 3\sum_{k=1}^{N}\{Ln^{3+(k)}\}_{(a)} = 3c_{Ln\,(a)}$.

1070-4272/03/7602-0211 $25.00 © 2003 MAIK "Nauka/Interperiodica"

The main parameters characterizing the extraction systems under consideration and the correlation between them can be determined from the following expressions.

Concentration of *k*th Ln(III) in the organic phase

$$c^{k}_{\mathrm{Ln\,(o)}} = 27\left(c_{\mathrm{Ln\,(a)}}\right)^4 \alpha_{\mathrm{Ln\,(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (6)$$

Total Ln(III) concentration in the organic phase

$$c_{\mathrm{Ln\,(o)}} = 27\left(\sum c_{\mathrm{Ln\,(a)}}\right)^4 \sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (7)$$

Fraction of *k*th Ln(III) in the organic phase

$$\alpha^{k}_{\mathrm{(o)}} = \frac{\alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k}}{\sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k}}. \quad (8)$$

Overall distribution coefficient of the sum of Ln(III)

$$D^{\Sigma}_{\mathrm{ex}} = 27\left(c_{\mathrm{Ln\,(a)}}\right)^3 \sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (9)$$

Distribution coefficient of *k*th Ln(III)

$$D^{k}_{\mathrm{ex}} = 27\left(c_{\mathrm{Ln\,(a)}}\right)^3 K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (10)$$

Correlation between D^{Σ}_{ex} and $D^{\mathrm{k}}_{\mathrm{ex}}$

$$D^{k}_{\mathrm{ex}} = D^{\Sigma}_{\mathrm{ex}} \frac{K^2_{\mathrm{ex},k}}{\sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k}}. \quad (11)$$

Separation factors of Ln(III) pairs

$$\beta_{k/(k+1)} = \frac{K^2_{\mathrm{ex},k}}{K^2_{\mathrm{ex},k+1}}. \quad (12)$$

For the organic phase, the material balance equation can be transformed to the following form:

$$c_{\mathrm{s}} = \{\mathrm{R_4NA}\}_{\mathrm{(o)}} + 54\left(c_{\mathrm{Ln\,(a)}}\right)^4 \sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (13)$$

The total material balance in the extraction system containig (1…, *k*…, *N*) Ln(III) in both aqueous and organic phases can be evaluated by solving the following set of nonlinear equations:

$$c^{0,1}_{\mathrm{Ln\,(a)}} V^0_{\mathrm{a}} = \{\mathrm{Ln}^{3+(1)}\}_{\mathrm{(a)}} V_{\mathrm{a}} + V_{\mathrm{o}} 27\left(c_{\mathrm{Ln\,(a)}}\right)^4 \alpha^{1}_{\mathrm{(a)}} K^2_{\mathrm{ex},1} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}, \quad (14)$$

$$c^{0,k}_{\mathrm{Ln\,(a)}} V^0_{\mathrm{a}} = \{\mathrm{Ln}^{3+(k)}\}_{\mathrm{(a)}} V_{\mathrm{a}} + V_{\mathrm{o}} 27\left(c_{\mathrm{Ln\,(a)}}\right)^4 \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}, \quad (15)$$

$$c^{0,N}_{\mathrm{Ln\,(a)}} V^0_{\mathrm{a}} = \{\mathrm{Ln}^{3+(N)}\}_{\mathrm{(a)}} V_{\mathrm{a}} + V_{\mathrm{o}} 27\left(c_{\mathrm{Ln\,(a)}}\right)^4 \alpha^{N}_{\mathrm{(a)}} K^2_{\mathrm{ex},N} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (16)$$

where $c^{0,k}_{\mathrm{Ln\,(a)}}$ is the concentration of *k*th Ln(III) in the initial aqueous solution; V^0_{a}, V_{a}, and V_{o} are the volumes of the initial aqueous, equilibrium aqueous, and equilibrium organic phases, respectively.

The material balance with respect to nitrate anions is described by the equation

$$3\sum_{k=1}^{N} c^{0,k}_{\mathrm{Ln\,(a)}} V^0_{\mathrm{a}} = \{\mathrm{NO_3^-}\}_{\mathrm{(a)}} V_{\mathrm{a}} + V_{\mathrm{o}} 81\left(c_{\mathrm{Ln\,(a)}}\right)^4 \sum_{k=1}^{N} \alpha^{k}_{\mathrm{(a)}} K^2_{\mathrm{ex},k} \{\mathrm{R_4NA}\}^2_{\mathrm{(o)}}. \quad (17)$$

The system of Eqs. (13)–(17) consists of (*N* + 2) nonlinear equations with (*N* + 2) independent variables. This system of equations can be solved numerically, taking into account the following constraints:

$$0 < \{\mathrm{R_4NA}\}_{\mathrm{(0)}} < c_{\mathrm{s}}, \quad (18)$$

$$0 < \{\mathrm{Ln}^{3+(k)}\}_{\mathrm{(a)}} V_{\mathrm{a}} < c^{0,k}_{\mathrm{Ln(a)}} V^0_{\mathrm{a}}. \quad (19)$$

The system of nonlinear equations (13)–(17) was solved for (*N* + 2) unknown quantities [$c_{\mathrm{Ln\,(o)}}$, $\{\mathrm{R_4NA}\}_{\mathrm{(o)}}$, $\alpha^{k}_{\mathrm{(a)}}$ (*k* = 1, …, *N*) by the Newton–Raphson method with replacement of the partial derivatives with the corresponding finite differences [2].

The revealed general pattern of the mutual influence of Ln(III) cations in their joint extraction from *N*-component aqueous solution with trialkylbenzylammonium naphthenate in toluene can be reduced to the following.

(1) In all the systems, the Ln(III) distribution coefficients are functions of the following parameters: concentration extraction constants K^2_{ex}, free extractant concentration in the organic phase $\{\mathrm{R_4NA}\}_{\mathrm{(o)}}$, fractions of *k*th Ln(III) in the aqueous phase, and equilibrium concentration of nitrate anions in the aqueous phase.

With increasing concentration of nitrate anions in the aqueous phase, the Ln(III) distribution coefficients grow, and, therefore, the Ln(III) concentration in the organic phase grows too. As a result, the concentration of the free extractant $\{\mathrm{R_4NA}\}_{\mathrm{(o)}}$

decreases, which, in turn, makes smaller the distribution coefficients D_{ex}^{Σ} and D_{ex}^{k}. Therefore, with increasing Ln(III) nitrate concentration in the aqueous phase, D_{ex}^{Σ} and D_{ex}^{k} pass through a maximum whose position depends on the nature of a particular Ln(III) and on the extractant concentration.

(2) The fraction of *k*th Ln(III) in the organic phase depends on K_{ex}^{2}; equilibrium concentration of free extractant, $\{R_4NA\}_{(o)}$; and fraction of *k*th Ln(III) in the aqueous phase, $\alpha_{(a)}^{k}$. With increasing $\alpha_{(a)}^{k}$, the $\alpha_{(o)}^{k}$ increases too.

(3) If only one extractable species is formed in the organic phase, the separation factor of the neighboring lanthanides(III) $\beta_{k/(k+1)}$ is determined by the ratio of the concentration extraction constants of these Ln(III), being dependent of the free extractant concentration.

For extraction of the individual Ln(III) nitrates, the dependences of the concentration extraction constants on the ionic strength of the aqueous phase *I* are fitted by the empirical equation [3–5]

$$\log K_{ex}^{2} = \log K_{ex}^{0,2} + \tilde{a}\Delta Z^{2}\sqrt[3]{I} + b_k I, \quad (20)$$

where $\tilde{a} = -0.1942$, $\Delta Z^2 = -12$. is the linear combination of the charge numbers of the species involved in the extraction equilibrium, and b_k is the empirical parameter specific for particular Ln(III).

The results reported in [6, 7] show that the extraction constant of lanthanide(III) nitrate A from binary mixture of lanthanide(III) nitrates A + B at I = const ($I = I_A + I_B$) and variable A/B ratio linearly varies with contribution of lanthanide B to the total ionic strength

$$\log K_{ex}^{2,A}(I = I_A + I_B) = \log K_{ex}^{2,A}(I = I_A) - \lambda_A I_B \quad (21)$$

and similarly for B

$$\log K_{ex}^{2,B}(I = I_A + I_B) = \log K_{ex}^{2,B}(I = I_B) - \lambda_B I_A. \quad (22)$$

In the limiting case

$$\lambda_A \simeq \lambda_B \simeq \lambda,$$

$$\log K_{ex}^{2,A}(I = I_B) \simeq \log K_{ex}^{2,B}(I = I_A).$$

Then

$$\lambda = [\log K_{ex}^{2,A}(I = I_B) - \log K_{ex}^{2,B}(I = I_A)]/2I. \quad (23)$$

Taking into account Eq. (21), Eq. (23) can be transformed to the form

$$\lambda = \left(\log K_{ex}^{i,0,A} - \log K_{ex}^{i,0,B}\right)/2I + (b_A - b_B)/2. \quad (24)$$

For solution containing only two different Ln(III) ($I^{\Sigma} = I_A + I_B$), Eq. (21) can be transformed to the form

$$\log K_{ex}^{2,A} = \log K_{ex}^{2,0,A} + \tilde{a}\Delta Z^{2}\sqrt[3]{I^{\Sigma}} + b_k I^{\Sigma} + \lambda I_B. \quad (25)$$

This equation can be reformulated for *N*-component solution:

$$\log K_{ex}^{2,k} = \log K_{ex}^{2,0,k} + \tilde{a}\Delta Z^{2}\sqrt[3]{I^{\Sigma}} + b_k I^{\Sigma} + \sum_{j=1}^{N}\lambda_{k,j} I_j. \quad (26)$$

where I_j is the contribution of *j*th component to the total ionic strength I^{Σ}; $\lambda_{k,j}$ are the empirical parameters which, to a first approximation, can be evaluated by the equation

$$\lambda_{k,j} = \left(\log K_{ex}^{0,k} - \log K_{ex}^{0,j}\right)/2I^{\Sigma} + (b_k - b_j)/2. \quad (27)$$

Taking into account Eq. (27) describing the concentration extraction constants as functions of the ionic strength of the aqueous phase for multicomponent mixtures, the system of nonlinear equations (13)–(17) can be transformed to the following

$$c_s = \{R_4NA\}_{(o)} + 54\left(c_{Ln(a)}\right)^4 \sum_{k=1}^{N}\alpha_{(a)}^{k} K_{ex,k}^{0,2} F(I)\{R_4NA\}_{(o)}^{2}, \quad (28)$$

$$c_{Ln(a)}^{0,1} V_a^0 = \{Ln^{3+(1)}\}_{(a)} V_a + V_o 27\left(c_{Ln(a)}\right)^4 \alpha_{(a)}^{1} K_{ex,1}^{0,2} F(I)\{R_4NA\}_{(o)}^{2}. \quad (29)$$

$$c_{Ln(a)}^{0,k} V_a^0 = \{Ln^{3+(k)}\}_{(a)} V_a + V_o 27\left(c_{Ln(a)}\right)^4 \alpha_{(a)}^{k} K_{ex,k}^{0,2} F(I)\{R_4NA\}_{(o)}^{2}, \quad (30)$$

$$c_{Ln(a)}^{0,N} V_a^0 = \{Ln^{3+(N)}\}_{(a)} V_a + V_o 27\left(c_{Ln(a)}\right)^4 \alpha_{(a)}^{N} K_{ex,N}^{0,2} F(I)\{R_4NA\}_{(o)}^{2}, \quad (31)$$

$$3\sum_{k=1}^{N} c_{Ln(a)}^{0,k} V_a^0 = \{NO_3^-\}_{(a)} V_a + V_o 81\left(c_{Ln(a)}\right)^4 \sum_{k=1}^{N}\alpha_{(a)}^{k} K_{ex,k}^{0,2} F(I)\{R_4NA\})_{(o)}^{2}, \quad (32)$$

$$F(I) = 10^{\tilde{a}\Delta Z^{2}\sqrt[3]{I^{\Sigma}} + b_k I^{\Sigma} + \sum_{j=1}^{N}\lambda_{k,j} I_j},$$

$$I^{\Sigma} = 6\sum_{k=1}^{N}\{Ln^{3+(k)}\}_{(a)} = 6c_{Ln(a)}, \quad I^{j} = 6\{Ln^{3+(j)}\}_{(a)}.$$

Note. The errors are given as rms deviations σ.

The logarithms of the thermodynamic constants of Ln(III) extraction by reaction (1), $\log K_{ex}^{0,2}$, and the empirical parameters b_k are listed in the table.

In our experiments TABANP was taken as 0.6 M toluene solution. The general formula of TABANP is $C_6H_5(C_7H_{15}-C_9H_{19})_3N^+A^-$, where A^- is the naphthenate anion. We used a mixture of naphthenic acid isomers recovered from crude oil (natural carboxylic acids containing carboxy groups bound to five-membered rings, M_{av} = 220).

Trialkylbenzylammonum naphthenate was prepared from trialkylbenzylammonum chloride as follows. An organic solution of trialkylbenzylammonium chloride was converted to the hydroxide by triple contact with 5–7 M aqueous NaOH. Excess alkali was removed by repeated scrubbing of the organic phase with distilled water until pH of the wash water decreased to 8–9. The resulting solution of trialkylbenzylammonium hydroxide was mixed with a stoichiometric amount of naphthenic acids and this mixture was dissolved in toluene (chemically pure grade). The resulting binary extractant was washed with distilled water to pH 7.

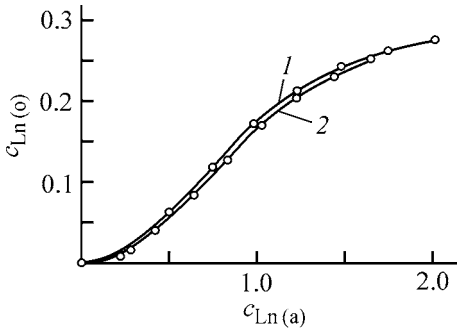

Fig. 1. Isotherms of joint extraction of Ln(III) nitrates from aqueous Ln(III) concentrates of varied composition with 0.60 M TABANP in toluene. ($c_{Ln(o)}$) and ($c_{Ln(a)}$) Ln(III) concentrations in the organic and aqueous phases, respectively. Concentrate: (*1*) no. 1 and (*2*) no. 2

The concentration of naphthenic acids in the organic phase was determined by two methods: two-phase potentiometric titration [8] and titration with aqueous alkali of the organic phase diluted with ethyl alcohol, with phenolphthalein as indicator. The amount of the QAB salt was determined by the method reported in [9].

Solutions of Ln(III) nitrates were prepared by dissolving the corresponding Ln(III) oxides in nitric acid (analytically pure grade). We used two different commercial concentrates containing Ln(III) oxide mixture of the following compositions (wt % recalculated to oxide): (concentrate no. 1) La 8.8, Ce 17.5, Pr 12.5, Nd 6.0, Sm 5.5, Eu 7.3, Gd 9.3, Tb 16.8, Dy 10.6, and Ho 5.7; (concentrate no. 2) La 6.6, Ce 8.2, Pr 7.9, Nd 6.4, Sm 5.2, Eu 1.8, Gd 7.3, Tb 1.2, Dy 6.3, Ho 1.3, Er 3.1, Tm 0.5, Yb 2.1, Lu 0.6, and Y 41.5. Extraction was carried out in graduated tubes at a 1 : 1 ratio of the organic and aqueous phases. Changes in the volumes of the organic and aqueous phases did not exceed 2 rel. %. The ΣLn(III) concentration in both the initial and equilibrium aqueous phases was determined by titration with a standard aqueous solution of disodium ethylenediaminetetraacetate in the presence of xylenol orange as indicator [10]. The ΣLn(III) concentration in the organic phase was determined as the difference between the ΣLn(III) contents in the initial and equilibrium aqueous phases. To determine the concentrations of particular Ln(III) in their mixture, lanthanides were precipitated as oxalates, calcined to oxides, and then subjected to atomic emission analysis on a Labtest device (USA) with ionization in inductively coupled argon plasma [10].

The relative errors were within ±0.5%, in preparing solutions; ±(0.5–2)%, in determining Ln(III) concentration; and ±(1–3)%, in determining the distribution coefficients.

The isotherms of joint extraction of lanthanide(III) nitrates from their concentrates with 0.60 M TABANP in toluene (Fig. 1) show saturation with respect to Ln(III) at $c_S : c_{Ln(o)} \Rightarrow 2 : 1$.

The logarithms of the distribution coefficients of particular La(III)–Ln(III) and Y(III) are plotted against the total equilibrium concentration of Ln(III) in the aqueous concentrate (M) in Fig. 2. In these plots, the solid lines represent the results of our model calculations performed using parameters listed in the table, and the points are our experimental results. Figures 2a and 2b show that the calculated distribution coefficients agree with the experimental values to within 3–5 rel.%. Thus, our model describes adequately the extraction of lanthanides(III) from their multicomponent mixtures with the use of TABANP in toluene.

Figures 2a and 2b show that, with the Ln(III) concentration in the aqueous phase increasing above 250 g/l, the distribution coefficients of particular Ln(III) and the difference between the distribution coefficients of the neighboring elements decrease. The best extraction separation of Ln(III) concentrates into groups and into individual elements using TABANP as extractant was achieved at an equilibrium Σ Ln(III) concentration of 120–200 g/l. Under these conditions, the distribution coefficients and the difference between the distribution coefficients of neighboring Ln(III) are maximal. The difference between the distribution coefficient is the largest for the pairs Ce(III)/Pr(III), Pr(III)/Nd(III), and Eu(III)/Gd(III) for concentrate no. 1, and for pairs Ce(III)/Pr(III), Pr(III)/Nd(III), Eu(III)/Gd(III), Dy(III)/Ho(III), and Er(III)/Tm(III) for concentrate no. 2. It should be noted that Y(III) is the least extractable with TABANP, compared with La(III)–Lu(III).

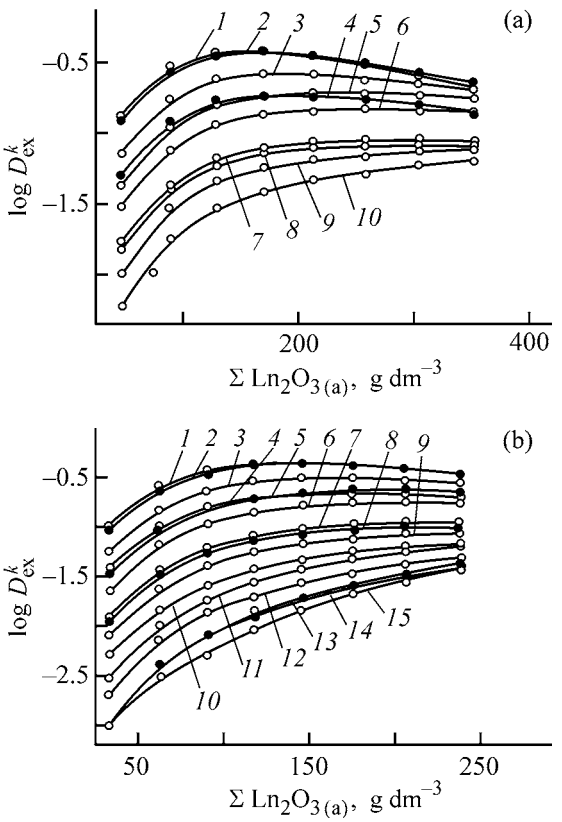

Fig. 2. Logarithm of distribution coefficients of particular Ln(III), $\log D_{ex}^k$, between 0.6 M TABANP in toluene and aqueous concentrate containing sum of Ln(III) as influenced by the total concentration of lanthanides(III) mixture in the aqueous concentrate, $\Sigma\,Ln_2O_{3\,(a)}$. Concentrate: (a) no. 1 and (b) no. 2. Ln(III): (a) (*1*) La, (*2*) Ce, (*3*) Pr, (*4*) Nd, (*5*) Sm , (*6*) Eu , (*7*) Gd , (*8*) Tb, (*9*) Dy, and (*10*) Ho ; (b) (*1*) La, (*2*) Ce, (*3*) Pr, (*4*) Nd, (*5*) Sm, (*6*) Eu, (*7*) Gd , (*8*) Tb, (*9*) Dy, (*10*) Ho, (*11*) Er, (*12*) Tm, (*13*) Yb, (*14*) Lu, and (*15*) Y .

CONCLUSIONS

(1) The physicochemical and mathematical models of extraction of La(III)–Lu(III) and Y(III) nitrates from their multicomponent aqueous solutions with the use of trialkylbenzylammonium naphthenate in toluene was developed taking into account the mutual influence of lanthanides at different concentrations and compositions of Ln(III) mixtures.

(2) Extraction of particular Ln(III) nitrates from their multicomponent aqueous solutions with trialkylbenzylammonium naphthenate in toluene was studied within a wide range of Ln(III) nitrate concentrations in the aqueous phase at 298.15 K. The extraction isotherms were obtained. The extraction isotherms show saturation with respect to Ln(III) at $c_S : c_{Ln\,(o)} \Rightarrow 2 : 1$.

(3) Extraction of lanthanide(III) nitrates with trialkylbenzylammonium naphthenates in toluene decreases in going from lanthanum(III) to lutetium(III). The extractability of yttrium(III) is considerably lower than that of La(III)–Lu(III). Trialkylbenzylammonium naphthenates can be used for separating cerium-group lanthanides(III) from other lanthanides(III) and yttrium(III) from lanthanides(III). The best separation of the sum of lanthanides(III) into groups and individual metals by extraction with TABANP is attained at the equilibrium ΣLn(III) concentration in the aqueous phase 120–200 g/l.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrically Conducting and Photosensitive Polymers Derived from CuSalbn-1,4

Abstract—A new electrically conducting photosensitive polymer was prepared by electrochemical polymerization of [CuSalbn-1,4]. Poly-[CuSalbn-1,4] was studied by X-ray photoelectron spectroscopy, voltammetry, and the photoelectrochemical methods.

Previously [1], we have prepared and isolated crystalline platinum, palladium, nickel, and copper complexes with tridentate bis(salicylidene)-1,4-butylenediamine ligand (Salbn-1,4^{2-}). These complexes contain four methylene groups in the aliphatic diamine moiety, unlike complexes with Salen and Salpn-1,3 [2–6] ligands containing two and three methylene groups, respectively.

Electrochemical synthesis of electrically conducting photosensitive poly-[PdSalbn-1,4] and parameters of reversible electro- and photoredox processes occurring in the bulk of the polymer were reported in our previous paper [1]. In this study, we prepared poly-[CuSalbn-1,4] by an electrochemical procedure and studied its physicochmeical and electrochemical properties.

Copper(II) bis(salicylidene)-1,4-butylenediamine complex [CuSalbn-1,4] was prepared by the modified procedure from [7]. To a methanolic solution of $Cu(CH_3COO)_2 \cdot H_2O$ (2.2 mM, 30 ml CH_3OH) was added a methanolic solution of [Salbn-1,4]$^{2-}$ in 5 wt % excess. To prevent hydrolysis of copper(II) acetate, the solution was acidified with acetic acid. The resulting dark green solution was heated at 100°C, evaporated by half, cooled, and kept at 0°C for 12 h. Dark green crystals were filtered off, washed with CH_3OH and C_2H_5O, and dried in air. Yield 60–65%.

Found (%): C 60.34, H 5.25, N 7.83.

$CuC_{18}H_{18}N_2O_2$.

Calculated (%): C 60.47, H 5.07, N 7.84.

Gruber *et al.* [8] studied the paramagnetic properties of [CuSalbn-1,4] and determined its magnetic moments at room temperature.

The C1*s*, O1*s*, N1*s*, and Cu2*p* binding energies and the atomic concentrations of the elements in different chemical states in the initial ligand H_2Salbn-1,4 and complex [CuSalbn-1,4] are listed in Table 1.

The electronic absorption spectra of H_2Salbn-1,4 in acetonitrile and [CuSalbn-1,4] in various solvents are shown in Fig. 1. The spectrum of the free ligand contains strong π–π^* intraligand charge-transfer band at λ_{max} = 315 nm (ε = 8400 l mol^{-1} cm^{-1}). In the spectrum of [CuSalbn-1,4], a shoulder with λ_{max} = 300 nm (ε = 7500 l mol^{-1} cm^{-1} is observed in the range of absorption of the uncoordinated ligand. The spectrum of an acetonitrile solution of the complex contains an additional band with λ_{max} = 375 nm and high molar extinction coefficient of 9000 l mol^{-1} cm^{-1}. The shape of this band is similar to that of allowed π–π^* elec-electronic transitions. The peak position of this band

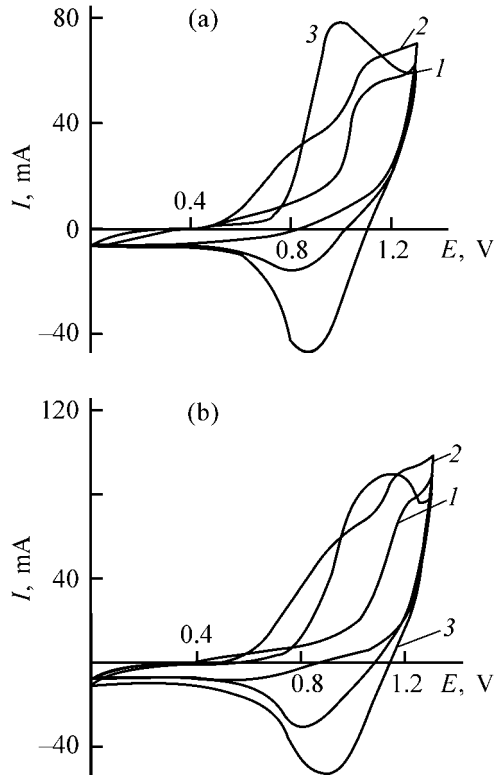

Fig. 3. Cyclovoltammograms of 1×10^{-3} M solution of [CuSalbn-1,4] in (a) CH_3CN and (b) CH_2Cl_2. $v_s = 0.5$ V s^{-1}; the same for Figs. 7 and 8. (*I*) Current and (*E*) potential; the same for Fig. 4. (b) Scale of *I* axis is doubled. Cycle: (*1*) first, (*2*) fifth, and (*3*) twenty-fifth.

depends on the solvent polarity, i.e., the solvatochromic effect is observed. When the solvent polarity increases [z (kcal mol^{-1}) 63.2 ($CHCl_3$), 64.2 (CH_2Cl_2), 71.3 (CH_3CN), 79.6 (C_2H_5OH)], a hypsochromic shift of the band is observed [λ_{max} (nm) 383 ($CHCl_3$), 380 (CH_2Cl_2), 375 (CH_3CN), and 370 (C_2H_5OH)], which is typical of charge-transfer transitions [9].

Polymeric [CuSalbn-1,4] was prepared by the electrochemical procedure previously used to synthesize poly-[PdSalbn-1,4] [1]. Electropolymerization of [CuSalbn-1,4] was performed in CH_3CN and CH_2Cl_2 under potentiostatic and potentiodynamic conditions of accumulation of the electroactive substance on the electrode positively polarized from 0.0 to +1.3 V. The concentration of the complex ranged from 0.5 to 3.0 mM.

(a) Electrochemical polymerization under potentiodynamic conditions was performed in a 1×10^{-3} M solution of [CuSalbn-1,4] in CH_3CN or CH_2Cl_2, containing 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte.

We have recorded the cyclovoltammograms at different potential sweeping rates v to find an optimum (Fig. 2) The fact that the current peak is directly proportional to the sweeping rate at $v_s < 0.05$ V s^{-1} indicates that the electroreduction is controlled by adsorption [10]. At $v_s < 0.05$ V s^{-1}, the complex is completely reduced during the first cycle. Thus, the thickness of a polymeric film h can be calculated by the procedure described in [11] from the quantity of electricity determined from the chronovolatmograms. At potential sweeping rates higher than 0.05 V s^{-1}, the polymeric complex is incompletely reduced and oxidized during a single cycle. In this case, the redox processes occur under conditions of semi-infinite diffusion of the electroactive compound toward the electrode surface. Probably, the rate-determining step of the reduction and oxidation of the polymeric complex is electron transfer across the polymeric film. By analogy with liquid-phase processes, the rate of electron transfer can be characterized by the diffusion coefficient D_{ct}. At these potential sweeping rates, the charge transfer rate was calculated by the Randles–Shevchik equation [12].

Cyclovoltammograms of [CuSalbn-1,4] are shown in Fig. 3. In successive sweeping cycles, the complex

polymerizes. For comparison, we chose the potentiodynamic curves recorded during the first, fifth, and twenty-fifth cycles. As seen from Fig. 3, the anodic current peak at E = 1.1 V is shifted to 1.0 V after continuous potential sweeping in an acetonitrile solution for 23 min (25 cycles). A broad peak at 0.85 V is present in the cathodic region of the voltammogram recorded at the reverse sweeping. The cyclovoltammograms of [CuSalbn-1,4], recorded in CH_2Cl_2, contains an anodic peak at 1.1 V and a cathodic peak at 0.85 V. Poly-[CuSalbn-1,4] films with the maximal thickness (0.06 μm) were grown in a CH_3CN solution in the course of 23–25 min with electrochemical polarization under potentiodynamic conditions. In CH_2Cl_2, 0.04-μm films were prepared in 17–20 min. The film thickness does not change on longer sweeping. The maximal peak current of anodic oxidation in CH_3CN and CH_2Cl_2 is 71 and 50 mA, respectively.

The electrode coated with poly-[CuSalbn-1,4] was placed in a solution of a pure supporting electrolyte. Cyclovoltammograms of poly-[CuSalbn-1,4] were recorded with potential sweeping from 0.0 to +1.3 V (Fig. 4). As seen from Fig. 4, the charge transfer in the polymer is reversible, i.e., the redox transformations of the polymer on the electrode surface are also reversible.

The stability of poly-[CuSalbn-1,4] depends on the solvent in which it has been prepared. The polymer prepared in CH_3CN is less stable on storage in a pure supporting electrolyte exposed to open air than the polymer prepared in CH_2Cl_2. The polymer synthesized in CH_2Cl_2 degrades irreversibly in the course of prolonged potential sweeping.

To obtain thicker polymeric films, we studied the dependence of the thickness of the film grown for τ_{acc} = 500 s on the [CuSalbn-1,4] concentration (Fig. 5). As seen from Fig. 5, the thickness of the poly-[CuSalbn-1,4] film increases with the complex concentration increasing up to 2×10^{-3} M. At higher concentrations, the film thickness decreases owing to partial degradation of the polymer. In CH_2Cl_2, the thickness of the polymeric films linearly increases with the complex concentration. The maximal thickness of the poly-[CuSalbn-1,4] film grown in CH_3CN (0.08 μm) is reached within 500 s at complex concentration of 2.0×10^{-3} M. In CH_2Cl_2, films with the maximal thickness (0.067 μm) were grown by potential sweeping for 1500 s at complex concentration of $(2.5–3.0) \times 10^{-3}$ M.

(b) Complex [CuSalbn-1,4] was electrochemically polymerized on a platinum electrode under the potentiostat conditions in CH_3CN and CH_2Cl_2 solutions at the optimal potentials. The potentiostatic curves were recorded in solutions of pure supporting electrolyte.

	200.6	1.34	200.7	0.52

that the color of the polymers prepared in these solvents under the same conditions (complex concentration 1×10^{-3} M, accumulation time 10 min, optimal potentials) differs. Poly-[CuSalbn-1,4] prepared in CH_3CN is emerald green, whereas the polymer grown in CH_2Cl_2 is red-brown. Probably, the mechanisms of polymer formation in these solvents differ.

The dependence of the thickness of a poly-[CuSalbn-1,4] film on the accumulation time, characterizing the kinetics of polymer growth at the optimal potential, is shown in Fig. 7. The film with the maximal thickness (0.074 μm) was grown in the course of 21 min from an acetonitrile solution of [CuSalbn-1,4] (E_{acc} = 1.1 V). The limiting thickness of the film prepared in CH_2Cl_2 solution (E_{acc} = 1.25 V) in 7 min is 0.093 μm. The film thickness does not grow with increasing accumulation time.

The dependence of the charge diffusion coefficient along the polymeric chain on the thickness of a poly-[CuSalbn-1,4] film is shown in Fig. 8. The maximal diffusion coefficient D_{ct} (1.05×10^{-12} cm^2 s^{-1}) was observed in the film grow in CH_3CN in the course of 21 min. In CH_2Cl_2, the maximum (D_{ct} = 0.57×10^{-12} cm^2 s^{-1}) is attained at accumulation time of 10 min.

Thus, films of poly-[CuSalbn-1,4] with the maximum thickness of 0.093 μm can be grown within 7 min from 1×10^{-3} M solution of the complex in CH_2Cl_2 under potentiostatic conditions at E_{acc} = 1.25 V.

Poly-[CuSalbn-1,4] was analyzed by X-ray photoelectron spectroscopy (XPS). The binding energies and atomic concentrations of the components of XPS spectra of the oxidized and reduced forms of poly-[CuSalbn-1,4] are presented in Table 2. The copper XPS spectrum indicates the presence of Cu(I) (BE = 932.6 eV) and Cu(II) (BE = 934.5 eV) in the polymer. The Cu(I)/Cu(II) ratio in the oxidized and reduced forms differs. The Cu(I) content in the reduced form (33% of the total copper content) is higher than that in the oxidized form (20%). It should be noted that the band with BE of about 937.2 eV, which is typical of Cu(Mesal)$_2$ polymers [13] and is assigned to Cu(II) atoms forming strong Cu–O–Cu bonds, is absent in the spectra. Probably, additional methylene groups of the H_2Salbn-1,4 ligand prevent formation of these dimers.

The electrochemical behavior of poly-[CuSalbn-1,4] is characterized by an electrochromic effect owing to the formation of oxidized and reduced forms of the polymer. The oxidized form was prepared by polymerization under potentiostatic conditions in CH_3CN

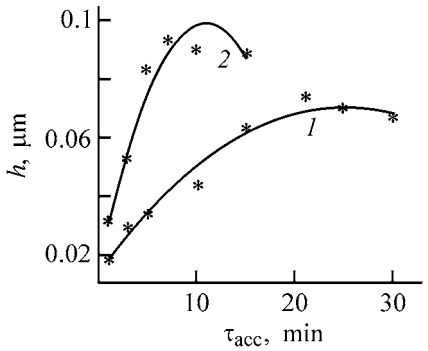

Fig. 7. Thickness *h* of poly-[CuSalbn-1,4] film vs. the accumulation time τ_{acc} (*1*) at E_{acc} = 1.1 V in CH_3CN and (*2*) E_{acc} = 1.25 V in CH_2Cl_2.

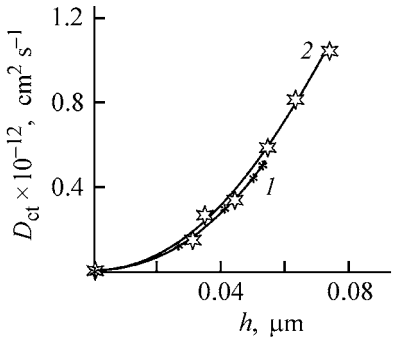

Fig. 8. Charge transfer rate vs. the thickness *h* of poly-[CuSalbn-1,4] film grown (*1*) in CH_2Cl_2 at E_{acc} = 1.15 V and (*2*) in CH_3CN at E_{acc} = 1.1 V. (D_{ct}) diffusion coefficient.

and CH_2Cl_2 at E = 1.1 and 1.25 V, respectively. The color of the oxidized form of poly-[CuSalbn-1,4] prepared in CH_3CN and CH_2Cl_2 is emerald green and red-brown, respectively. The reduced form accumulated at low potential (E = 0.1 V) in 5 min has light green color, irrespective of the color of the oxidized form. When the applied voltage is switched off, an equilibrium potential E_{eq} = 0.51 and 0.56 V is spontaneously attained in several hours in CH_3CN and CH_2Cl_2, respectively. These potentials determine the redox state of the polymer.

The electronic absorption spectrum of oxidized poly-[CuSalbn-1,4] prepared in CH_3CN under potentiostatic conditions (E_{acc} = 1.1 V) is shown in Fig. 9. To record the electronic spectra, the polymeric film was supported on a quartz plate coated with platinum by a vacuum procedure. The spectrum contains two bands with λ_{max} = 395 and 615 nm. We failed to record the electronic absorption spectrum of the reduced form.

The dependence of the photopotential of the reduced form of the polymer on the exposure time is shown in Fig. 10. The polymer was prepared in CH_3CN and was reduced to E = 0.1 V (light green color) in acetonitrile solution of TBAP. The photoelectric experiment was performed by the procedure described in our previous paper [2]. As seen from Fig. 10, reduced poly-[CuSalbn-1,4] (E_{red} = 0.1 V) is photooxidized to the stationary state in 40 s. The maximum photopotential corresponding to the maximum accumulation of oxidized fragments of the complex in the polymer exposed to light is 177 mV. The fact that the photopotential does not change after repeated excitation cycles indicates the stability of the polymeric films to light. The photopotential of the film, measured on a cylindrical electrode, is 100 mV.

CONCLUSIONS

(1) Electrochemical synthesis of poly-[CuSalbn-1,4] was performed for the first time. In spite of the fact that the methylene chain of the [H_2Salbn-1,4] is longer than that of [H_2Salen] and [H_2Salpn-1,3], [MSalbn-1,4] complexes form stable electrically conducting and photoactive polymers characterized by fast charge transfer. The thickness of these polymeric films is typical of compounds of this class.

(2) Poly-[CuSalbn-1,4] with the maximal thickness of 0.24 μm was prepared in CH_2Cl_2 under potentiostatic conditions at E_{acc} = 1.2 V for 7 min. The charge diffusion coefficient in poly-[CuSalbn-1,4] is $D_{ct} = 2.95 \times 10^{-12}$ cm^2 s^{-1}. The maximum photopotential of poly-[PdSalbn-1,4] and poly-[CuSalbn-1,4] is 133 and 177 mV, respectively.

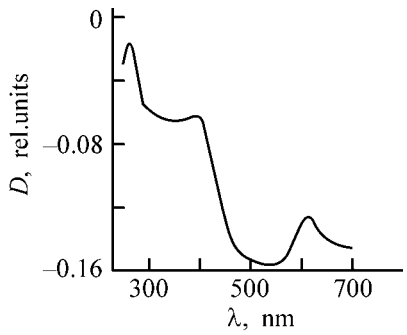

Fig. 9. Electronic absorption spectrum of oxidied poly-[CuSalbn-1,4] (E_{ox} = 1.1 V, CH_3CN, Bu_4NClO_4, τ_{acc} = 20 min, emerald green polymer). (D) Optical density and (λ) wavelength.

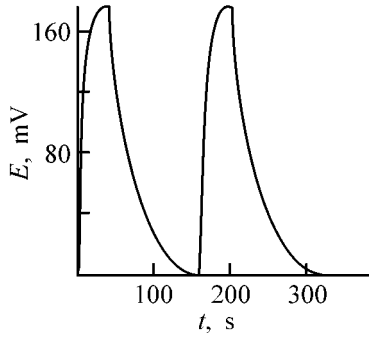

Fig. 10. Photopotential E of poly-[CuSalbn-1,4] in 0.1 M solution of TBAP in CH_3CN vs. the time t of exposure to polychromatic light. Film thickness h = 0.04 μm, E = 0.1 V.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

On Passivating Action of Silicate-Alkaline Solutions on Metals

V. N. Ovchiyan

Institute of General and Inorganic Chemistry, National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia

Received October 10, 2002

Abstract—A mechanism for enhancing the stability of the passive state of metals in silicate solutions is described on the basis of a study of the corrosion-electrochemical behavior of the metals in concentrated alkaline and silicate-alkaline solutions.

Concentrated silicate-alkaline solutions find use in many branches of industry. These solutions serve as technological medium in integrated processing of silicate and aluminosilicate rocks and are used to manufacture silicon dioxide, detergents, etc.

Corrosion of metals, caused by the media mentioned above, is characterized by a number of specific features [1, 2]. Of interest in this context is a study of the electrochemical behavior of steel in solutions of this kind. However, only few investigations have been carried out in this direction [3].

It is known that metallic construction materials used in technology are mostly thermodynamically unstable. They react with the ambient and are frequently passivated through formation on their surface of insoluble (or difficultly soluble) films of oxide, hydroxide, or salt nature.

The stability of the passive state of metals depends on the nature of a protective film and its heterogeneity. Structural defects in the film are either due to imperfection of the surface structure of a metal or arise in the course of film formation. One of ways to improve the corrosion stability of a metal is to form on its surface a less defective protective.

EXPERIMENTAL

In the present study, the electrochemical behavior of 08kp steel in concentrated alkaline (AS) and silicate-alkaline (SAS) solutions was analyzed. Polarization curves were measured by changing the potential stepwise, from the range of active dissolution to repassivation, at 0.1-V intervals and keeping the steel at each potential for 15 min. The measurements were done at elevated temperature in an autoclave whose design was described in [4].

The solutions employed were fabricated using sodium hydroxide of analytically pure grade and high-purity amorphous silicon dioxide with impurity content of less than 10^{-3}%.

Corrosion cracking was studied under continuous stretching stress on wire samples passed through a vessel with a solution.

A study of the corrosion-electrochemical behavior of iron and steel in AS and SAS at 80°C has shown [5, 6] that, under the given conditions, the metals tend to undergo passivation. The region of the passive state is rather wide and lies within –0.8…–0.4 V (relative to silver chloride electrode). The stationary potential of iron and steel in both the solutions is within the range –0.3…–0.4 V, which points to the possibility of a spontaneous transition of metals to the passive state. Therefore, under standard conditions, they spontaneously undergo passivation in an alkaline medium at low temperature and dissolve at a slow rate.

It has been shown [5, 7, 8] that, although the passivating layer formed on iron in AS has complex composition and structure, the passivation of iron is due to formation of an exceedingly thin surface layer of iron oxide γ-Fe_2O_3.

The equilibrium potential of the reaction of γ-Fe_2O_3 formation in an AS containing 300 g l^{-1} NaOH is –0.896 V at 20°C. If account is taken of a minor overvoltage, this value is in good agreement with the experimental passivation potential of iron, equal to –0.85 V [5].

IR spectral and thermogravimetric studies of products formed in reaction of iron with alkaline solutions

1070-4272/03/7602-0223 $25.00 © 2003 MAIK "Nauka/Interperiodica"

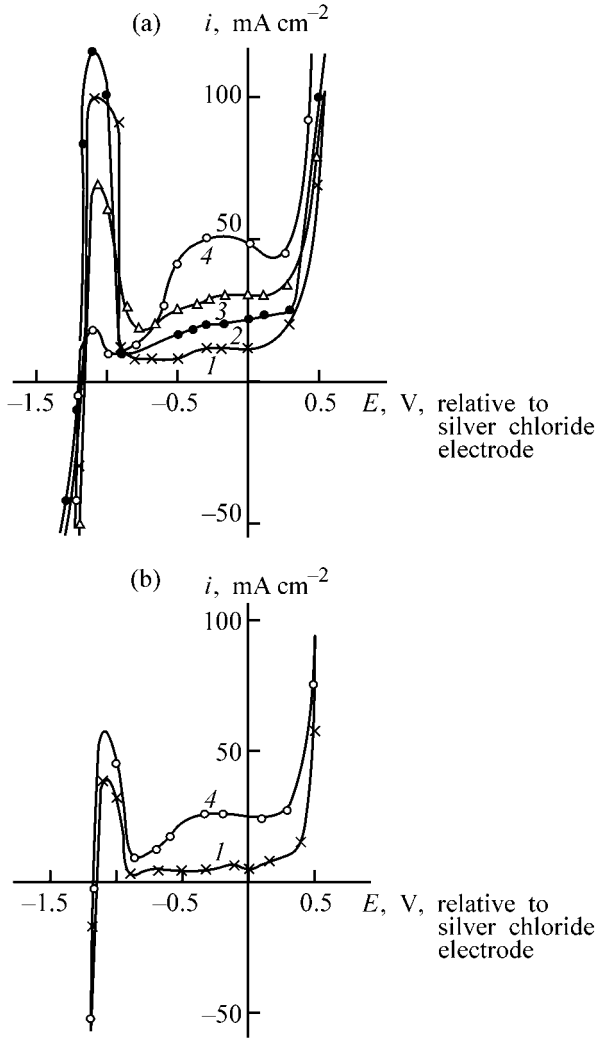

Fig. 1. Potentiostatic polarization curves for carbon steel in (a) AS and (b) SAS at different temeratures. (*i*) Current density, and (*E*) potential. Temperature (°C): (*1*) 160, (*2*) 180, (*3*) 200, and (*4*) 230.

have shown that these products are mostly composed of amorphous hydrated iron oxides, which crystallize in the course of time [9].

The fact that the dissolution rates at the corrosion potential for iron in AS and SAS are equal indicates that the nature of the compound responsible for the metal passivation is the same. However, the corrosion rate in the passive state is much lower in SAS, compared with AS, and, in the state of active dissolution (at potentials more negative than –0.85 V), this difference is also preserved [6].

The thin passivating film formed on iron in an AS is not homogeneous in structure and electrochemical properties. Some of its parts with defective structure, which show the lowest degree of saturation of free valences, become active centers of preferable adsorption of hydroxy ions [10]. Under the conditions of SAS, there further occurs an adsorption-chemical interaction between iron oxide and silicate ions possessing electron-donor properties. Monomeric SiO_4^{4-} ions, which are the most mobile, are adsorbed first. This is also favored by the fact that distances between metal ions in iron oxide and oxygen atoms in the monomeric silicate ion are close (0.27 nm). As a result, first the structurally imperfect regions of the passivating film are healed, which leads to higher stability of the passivated state [6, 11], and then monomeric and more complex ions condense on the silicate compound formed.

The part played by silicate ions in the enhancement of the passive state consists in the formation of ferrosilicates of complex composition [9, 12] on certain, energetically most favorable parts of the surface film of the passivated metal. As a result, the passivated state of the metal in SAS is determined by higher-quality protective film with smaller number of defects.

The experimental data obtained are in good agreement with the results of a study of the surface of passivated iron electrode at its interface with an alkaline medium by impedance measurements. The passivating film formed in SAS has lower capacitance and somewhat higher resistance than the film formed in AS, with the above characteristics only slightly dependent on the ac voltage frequency.

SAS exert similar influence on the corrosion-electrochemical behavior of other metals—chromium, nickel, and molybdenum, and steels alloyed with these elements [1, 13].

At 160–230°C (see Fig. 1a) the stationary potentials of steel in an AS containing 300 g l^{-1} NaOH are shifted with respect to those at low temperatures toward negative values and fall within the active dissolution range. Their values are very close, and, therefore, as a characteristic of the corrosion resistance of steel at various temperatures may serve anodic current peaks in the polarization curves (see Fig. 1a), which are due to the formation of a passivated film. With increasing temperature, the rate of the anodic process passes through a maximum, being the highest at 180°C. These data are in agreement with the results obtained in studying steel corrosion in an AS (300 g l^{-1} NaOH) at various temperatures [14].

The rate of the anodic process in an SAS containing 300 g l^{-1} NaOH + 50 g l^{-1} SiO_2 (see Fig. 1b) at 160°C at a potential of the onset of passivation under

conditions of a stable passive state is lower than that in AS. At 230°C, silicate ions stimulate dissolution of steel in the active state. The onset of passivation is observed at high current densities *i*. In the given case, the abovementioned specific feature of the influence exerted by silicon dioxide is confirmed. This feature consists in that the inhibiting action would only be expected in those cases when the surface layers on the metal possess, to lesser or greater extent, protective properties [6].

Much later, a similar effect of healing action on defects in an oxide film was also observed for molybdate ions in aerated aqueous media [15].

Previously [16], an assumption has been made that the inhibiting action of minor additions of water-soluble silicates on the steel corrosion in boiler water is related to formation of solid ferrosilicate films.

As is known, an alkaline medium may cause corrosion cracking of metals. This frequently occurs with steels in passivated state, whose surface is covered with a protective film. Under the influence of mechanic stresses, the film is weakened in places, and then the construction steel, which, on the whole, retains high stability against uniform corrosion, is subjected to rather intensive intercrystallite or transcrystallite disintegration in separate zones. It can be readily imagined how dangerous is this for apparatus working under pressure.

A study of the kinetics of corrosion cracking demonstrated that, owing to the higher passivating capacity of SAS, compared with AS, higher-quality and stronger protective films are formed on the metal in SAS. As a result, steel becomes more stable against corrosion cracking. Also established was the effect of silicon dioxide in SAS on the duration of tests under stretching stress until appearance of corrosion cracks and disintegration of a wire sample. For example, at a SiO_2 concentration of 100 g l^{-1} in SAS containing 300 g l^{-1} NaOH at 100°C, a wire sample of steel 10 disintegrates after approximately 3 months of tests, whereas in AS with the same concentration of NaOH, disintegration occurs already on the ninth day.

The presence of silicon ions largely eliminates electrochemically heterogeneous regions on the surface of the oxide film on the metal and prevents localization of the corrosion process, with, correspondingly, the stability of steels against corrosion cracking enhanced.

CONCLUSIONS

(1) A significant improvement of the corrosion resistance of metals in concentrated alkaline solutions in the presence of silicate ions is established.

(2) Silicate ions stimulate the corrosion process in the region of active dissolution of metals.

CATALYSIS

Nature of Catalytic Activity of Defective Calcium Hydroxyapatites

A. S. Dykman

Vserossiiskii Nauchno-issledovatel'skii Institut Neftekhimicheskikh Protsessov Joint-Stock Company, St. Petersburg, Russia

Received August 1, 2002

Abstract—The nature of the catalytic activity of defective calcium hydroxyapatites was studied. The activity of synthesized defective hydroxyapatites in vapor-phase dehydration of trimethylcarbinol, methylphenylcarbinol, α-hydroxyisobutyric acid, and in decomposition of 4,4-dimethyl-1,3-dioxane into isoprene was analyzed.

Calcium phosphates, which have been described as catalysts and supports for catalysts for hydration and dehydration, vapor-phase hydrolysis, isomerization, and alkylation [1, 2], were applied to industrial synthesis of isoprene (in the second stage of decomposition of 4,4-dimethyl-1,3-dioxane, DMD) [2–4]. We used in this process basic calcium phosphates whose X-ray pattern is typical of stoichiometric calcium hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ (molar ratio $CaO/P_2O_5 = 3.34$), but differ from it in their composition: the CaO/P_2O_5 ratio in these compounds varies from 2.66 to 3.34. It has been shown in numerous studies [2–7] that such calcium phosphates belong to the series of defective calcium hydroxyapatites (DCHA) with composition $Ca_{10-x}H_x(PO_4)_6(OH)_{2-x}$ or $Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$ (where $0 \le x \le 2$).

These compounds, which are derivatives of the stoichiometric $Ca_{10}(PO_4)_6(OH)_2$ hydroxyapatite, have been given their name because of the presence of a calcium defect (calcium vacancy) in the structure. To maintain the charge balance, one proton is "incorporated" into the lattice instead of each absent calcium ion and one hydroxyde ion "is removed" [3, 6, 7].

Commercial DCHA-based catalysts developed with the author's participation (conventionally designated as KF-70, KBF, and KBF-76) were successively introduced into industrial practice and have been used at Russian synthetic-caoutchouc plants in the second stage of isoprene synthesis from isobutylene and formaldehyde.

The KF-70, KBF, and KBF-76 catalysts have aroused considerable interest of researchers. Results obtained in studying their catalytic activity in dehydration of aliphatic alcohols [8], isoamyl alcohol [9], 2-methyl butanol [10], and esters [11], and in other thermocatalytic reactions [12] have been published. Bett *et al.* [7], having generalized data on the composition and catalytic properties of DCHA, concluded that their acidity and catalytic activity result from the presence of protons in their structure. Protons in DCHA are in the form of the hydrophosphate ions, HPO_4^{2-} [2, 3, 5, 6]. As a proof of the hypothesis, data on dehydration of butanol-2 in the presence of a number of DCHA with varied degree of defectiveness have been reported [10]. According to these data, the activity of the catalysts grows with decreasing CaO/P_2O_5 ratio in a sample, i.e., with increasing amount of hydrophosphate ions in the structure of hydroxyapatites [7, 13].

However, it has been shown by means of IR spectroscopy [4] that, within the operation temperature range of DCHA-based catalysts (250–500°C), hydrophosphate ions react with one another rather rapidly (within several hours) to be converted into condensed phosphate ions $P_nO_{3n+1}^{-(n+2)}$, with the catalyst retaining its initial activity. Consequently, the acidity and catalytic activity of DCHA cannot be directly determined by the presence of HPO_4^{2-} groups [4].

It seems more correct to suggest that the acidity and catalytic activity of DCHA are determined by the presence of a film of phosphoric acid formed on the catalyst surface in the reaction of condensed phosphates with water at elevated temperature. The hydrolytic decomposition of condensed phosphates can be schematically represented by the reaction

$$(n + 1)P_nO_{3n+1(\text{solid})}^{-(n+2)} + H_2O_{(\text{vapor})} \rightarrow (n + 2)P_{n-1}O_{3n-2(\text{solid})}^{-(n+1)} + 2H_3PO_{4(\text{vapor})}.$$

It seems that the greater the amount of phosphoric acid in the film, the greater the amount of acid removed on treating the catalyst with water vapor.

The aim of this study was to reveal the relationship between the composition of defective calcium hydroxyapatites, the amount of phosphoric acid they evolve, and their catalytic activity in dehydration of alcohols and acids and in decomposition of DMD.

EXPERIMENTAL

As objects of study served DCHA samples with varied defectiveness. The physicochemical parameters of these compounds are listed in Table 1. According to X-ray diffraction analysis, the samples have phase composition of hydroxyapatite.

To determine the amount of phosphoric acid released by a catalyst, we put the samples in a quartz reactor, which was placed, in turn, in an electric furnace. Distilled water was delivered to the reactor through an evaporator, using a controlled-volume pump. The water vapor released from the reactor was condensed in a condenser. We determined the content of phosphoric acid in the condensate by the procedure described in [14]. The method used allows phosphorus(V) to be determined only as orthophosphate ions, and, therefore, to convert condensed phosphates into orthophosphates, we boiled the samples before measurements.

We studied the activity of DCHA as catalysts in dehydration of trimethylcarbinol, methylphenylcarbinol, and α-hydroxyisobutyric acid and in decomposition of DMD. We tested the catalysts on the installation described above. The raw material was delivered into the reactor in a mixture with water, the duration of an experiment was 2 h. The catalyzates were analyzed by gas-liquid chromatography.

The dependence of the amount of H_3PO_4 released by 1 m^2 of the DCHA surface on the CaO/P_2O_5 ratio is given in the figure. As the CaO/P_2O_5 ratio decreases, i.e., as the content of condensed phosphates increases, the amount of released phosphoric acid grows. The greatest amount of H_3PO_4 was observed for the sample with the maximum defectiveness (sample no. 1). Stoichiometric hydroxyapatite (sample no. 4) hardly releases any phosphoric acid.

Data on the catalytic activity of DCHA samples in dehydration of trimethylcarbinol, methylphenylcarbinol, and α-hydroxyisobutyric acid (conversion of α-hydroxyisobutyric acid into methacrylic acid), and in decomposition of DMD are listed in Table 2.

Table 1. Physicochemical properties of synthesized DCHA samples with varied degree of defectiveness

Sample no.	CaO/P_2O_5, mol/mol	S_{sp}, $m^2\ g^{-1}$	Bulk density, $g\ cm^{-3}$
1	2.72	86	0.62
2	3.04	85	0.64
3	3.26	71	0.68
4	3.34	79	0.69

Table 2. Conversion of trimethylcarbinol, methylphenylcarbinol, α-hydroxy isobutyric acid, and 4,4-dimethyl-1,3-dioxane at various CaO/P_2O_5 ratios in DCHA (weight ratios: H_2O : trimethylcarbinol = 1 : 1, H_2O : methylphenylcarbinol = 1 : 1, H_2O : α-hydroxyisobutyric acid = 4 : 1, H_2O : DMD = 2 : 1)

T, °C	CaO/P_2O_5, mol/mol	Conversion (%) at indicated volumetric rate of raw material supply, h^{-1}				
		1	2	4	6	8
Trimethylcarbinol						
300	2.72	–	99.7	97.0	91.2	63.0

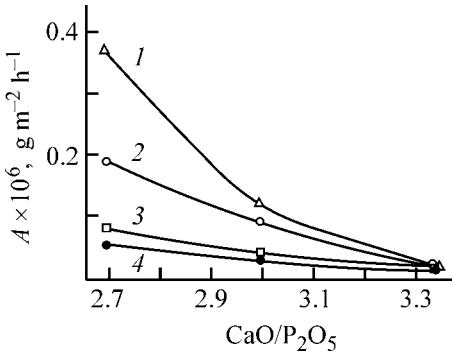
	3.26	30.9	23.2	8.7	–	3.9
	3.34	28.3	22.5	8.5	–	3.3

It was found that defective calcium hydroxyapatite with the highest content of condensed phosphates (sample no. 1) is the most active in the reactions under study and a sample of stoichiometric calcium hydroxyapatite has the lowest activity. Thus, the activity of DCHA in dehydration of alcohols and acids and in



Amount of phosphoric acid released by the DCHA surface, A vs. CaO/P_2O_5 molar ratio. Temperature 300°C. Water supply (vol/vol of catalyst per 1 h): (*1*) 16, (*2*) 8, (*3*) 4, and (*4*) 2.

decomposition of DMD grows with increasing amount of released phosphoric acid, which seems to be present in the form of a film on the catalyst surface and is removed when the catalyst is treated with water vapor.

To elucidate the part played by DCHA in the catalytic reactions under study, we carried out experiments on dehydration of trimethylcarbinol and decomposition of DMD on quartz, to which phosphoric acid was delivered during the experiment. In this case, we hardly observed any dehydration of trimethylcarbinol or decomposition of DMD. This suggests that phosphoric acid released by DCHA is present on its surface as a relatively firmly adhering film, which determines the catalytic activity of calcium phosphates belonging to the hydroxyapatite structure.

CONCLUSIONS

(1) A set of calcium phosphate catalysts with various molar ratios CaO/P_2O_5 has been synthesized. These catalysts are defective calcium hydroxyapatites with composition $Ca_{10-x}(HPO_4)_x(PO_4)_{6-x}(OH)_{2-x}$ ($0 \le x \le 2$).

(2) Hydrophosphate ions HPO_4^{2-} cannot be directly responsible for the catalytic activity of defective calcium hydroxyapatites, since they are converted to condensed phosphate ions $P_nO_{3n+1}^{-(n+2)}$ at the working temperatures of the catalyst (250–500°C).

(3) The catalytic activity of defective calcium hydroxyapatites is determined by the release of phosphoric acid formed in the reaction of condensed phosphates with water. The acid is presumably present on the catalyst surface in the form of a film.

(4) The catalytic activity of calcium hydroxyapatites in dehydration of trimethylcarbinol, methylphenylcarbinol, and α-hydroxyisobutyric acid and decomposition of 4,4-dimethyl-1,3-dioxane grows with increasing amount of phosphoric acid released by the catalysts.

Received June, 13, 2002

Abstract—A comparative study was performed of changes in the composition, structure, and catalytic activity of catalysts in selective hydrogenation of C_5–C_9 fraction of pyrolysis naphtha. The main reasons for catalyst deactivation in the course of industrial exploitation were considered.

At present, the stringent requirements are imposed on the quality and purity of pyrolysis naphtha fraction, in particular, on the content of diene hydrocarbon impurities. One of the most widespread methods for removing such impurities is catalytic hydrogenation [1]. Catalysts containing palladium supported by aluminum oxide are the most efficient in hydrogenation of diene hydrocarbons [2–7]. In spite of successful exploitation of these catalysts in hydrogenation of diene, the decrease in the catalyst activity is a serious problem. Unfortunately, the reasons for catalyst deactivation have not been analyzed previously, and here we try to fill this gap.

It is known [8] that deactivation can occur because of catalyst poisoning with toxic inorganic substances. Another reason is blocking of the active centers of the catalyst surface through deposition of coke.

In this work, we studied deactivation of catalysts for selective hydrogenation of dienes of the C_5–C_9 fraction.

EXPERIMENTAL

Samples of a deactivated catalyst were taken from various levels of a reactor, as shown in the scheme (Fig. 1).

Low-temperature nitrogen adsorption, IR spectroscopy, thermogravimetry, photocolorimetry, X-ray fluorescence analysis, emission spectroscopy, and chemical analysis were used to study the composition, structure, and surface characteristics of the catalyst.

The specific surface area, porosimetric volume, and pore volume distribution were measured by low-temperature nitrogen adsorption on an ASAP-2400 Micromeritics device. To obtain adsorption-desorption isotherms at 77 K, 0.8–1.0 g of the finely crushed catalyst was placed in the analyzer ampule, which was heated to 523 K, evacuated to 0.1 mm Hg for 4 h, and then filled with nitrogen and weighed. Degassing was performed to 0.03 mm Hg. In calculations, $\rho(N_2)$ was taken to be 0.808 g cm^{-3}, and the crosssection area of the nitrogen molecule S, 0.1620 nm^2. The pore volume and size distribution of pores were measured with relative error of ±13%, and the specific surface area, with error of ±3%. The curves of pore volume distribution with respect to pore diameter were calculated in terms of the cylindrical pore model [9].

* Temperature of the feed at the reactor inlet.

The IR spectra were measured at the temperature of adsorption on a Shimadzu 8300 Fourier spectrometer with resolution of 4 cm^{-1} and the number of scans equal to 50. Carbon monoxide was used as a probe for monitoring the state of the palladium surface [10, 11].

The content of Pd and Fe was monitored by X-ray fluorescence and photocolorimetric analyses. The X-ray fluorescence analysis was performed on a VRA-20 analyzer by the method of additives. The catalyst was crushed to 0.2-mm powder, and 0.1-g sample was added to 3 g of H_3BO_3, the mixture was thoroughly mixed, and pellets 39 mm in diameter were compacted. An analytical signal from the pellet was measured and compared with signals of two analogous pellets in which the known portions of the analyzed element were additionally introduced.

The content of palladium in the catalyst was monitored photocolorimetrically by absorption of a green palladium complex with Sn(II) chloride after recovery of the metal from the calcined and finely divided catalyst sample with a boiling mixture of hydrochloric, nitric, and hydrofluoric acids.

The Fe content in the catalyst was monitored photocolorimetrically by absorption of the Fe(III) complex with sulfosalicylic acid in aqueous ammonia.

The macro- and microelemental composition of catalysts was monitored by emission spectrum analysis on a DFS-458 spectrometer and an MF-2 microphotometer, using an external reference (active Al_2O_3 with the known content of elements).

Calorimetric studies were performed on a DSK-111 Setaram calorimeter.

The catalytic activity was tested in a reactor with working volume of the catalyst of 6–10 cm^3 at a working pressure of 46 atm and temperature of 303–353 K, feed space velocity of 2–4 h^{-1}, and hydrogen to feed ratio from 100 : 1 to 300 : 1. Preliminarily, samples were reduced in the reactor. A 0.25–1.00-mm fraction of the catalyst was taken.

The diene number (DN) was determined by the reaction of unsaturated compounds, containing conjugated double bonds, with maleic anhydride in boiling toluene in the presence of iodine. The bromine number (BN) was found as the amount of bromine reacting with an aliquot portion of the feed. BN characterizes the content of components reacting with bromine only and determines the olefinic unsaturation of the compounds.

To monitor the changes in the catalyst activity in the course of exploitation, we studied the activity of the fresh catalyst and catalyst samples after a year of their operation in hydrogenation of the C_5–C_9 fraction (nos. 1 and 11; Table 1).

As seen from Table 1, under the same conditions, the BN of the catalyzate obtained with catalyst samples nos. 1 and 11 is higher than that with the fresh catalyst, which indicates a substantial decrease in the catalyst activity in the course of exploitation. In addition, the catalyst is deactivated to a greater extent in the lower part of the reactor than in the upper part, as indicated by an increase in BN and appearance of diene compounds in the catalyzate for sample no. 11 at a temperature lower than 316 K.

To reveal the reasons for deactivation, we studied evolution of the composition and surface and structural characteristics of the catalyst. The pore structure of the catalyst was monitored in the course of its deactivation by low-temperature nitrogen adsorption. The specific surface area, pore volume, pore diameter distribution, and peaks in the distribution and their intensities are listed in Table 2. The absolute values of the pore volume within various intervals of pore diameters and contribution of these fractions to the total pore volume were also calculated. As seen from Table 2, the content of fine pores (about 35 Å) de-

* Maximum as shoulder.

creases in the course of catalyst exploitation by approximately 10–20% throughout the reactor volume, which insignificantly decreases the specific surface area of the catalyst.

The distribution of pore volumes with respect to diameter for the fresh catalyst and that after 1-year operation, taken from different levels of the reactor (samples nos. 1 and 11), is shown in Fig. 2. Two maxima peaks are seen: narrow at 35 Å and broad at 125–165 Å. The major fraction of the total pore volume belongs to pores with diameter greater than 100 Å (90.0–92.9%).

The greatest changes in the catalyst pore structure occur in the lower part of the reactor (sample no. 11): the fraction of small pores decreases, the peak of large pores shifts from 125–145 to 160 Å (Fig. 2), which corresponds to a decrease in the total pore volume (Table 2). Thus, in the course of the catalyst operation, the pore structure changes, with these changes being the most pronounced for the catalyst in the lower part of the reactor.

To reveal the probable deactivating effect of inorganic substances sorbed on the catalyst surface, we determined the elemental composition of the catalyst samples. It should be noted that the catalyst samples taken from the upper (no. 1) and lower (no. 11) parts of the reactor substantially differ in color. Samples taken from the upper level had reddish color due to substantial amounts of dusty particles, probably, iron(III) oxide. These particles were readily removed by expulsion or by washing with 0.1 M HCl. At the lower levels of the reactor, a part of the catalyst had a dark color. In deactivated samples, the content of the active component, Pd, was determined photocolorimetrically (after chemical dissolution of the catalyst) and by X-ray fluorescence analysis (without preliminary preparation in the form of granules). It was found that the Pd content in the spent catalyst varies insignificantly

(within the limits of the experimental error) as compared to samples of the fresh catalyst. Thus, the decrease in the catalyst activity is not associated with Pd loss.

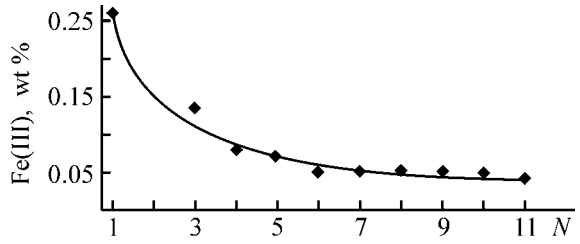

Fig. 3. Distribution of the iron(III) content in the catalyst throughout the reactor. (*N*) number of a sampling point.

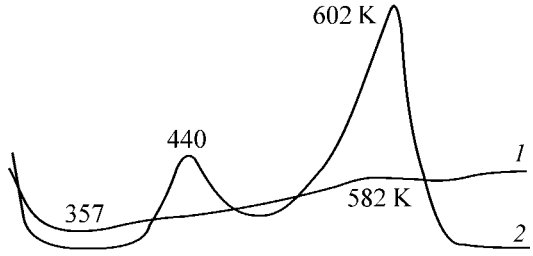

Fig. 4. Calorimetric analysis of spent catalyst samples (*1*) no. 1 and (*2*) no. 11.

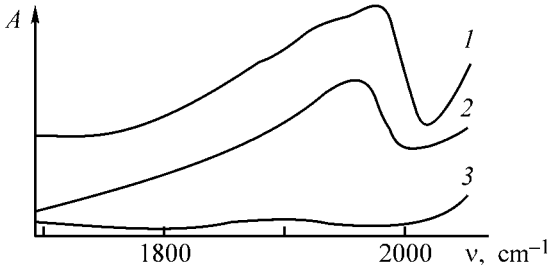

Fig. 5. IR spectra of CO adsorbed on metal Pd particles of (*1*) fresh catalyst, (*2*) spent sample no. 1, and (*3*) spent sample no. 11. (*A*) Adsorption and (ν) wave number.

The Fe(III) content in the catalyst was found by X-ray fluorescence and photocolorimetric analyses. The data obtained show that in the spent catalyst the Fe(III) content increases as compared to the fresh sample (0.023 wt % Fe). The distribution of Fe(III) in the catalyst throughout the reactor is shown in Fig. 3. As seen, a higher Fe(III) content is observed in the upper layers of the catalyst, with the content of Fe(III) in sample no. 1 exceeding by a factor of 6–10 that in sample no. 11). Thus, in the course of exploitation, Fe(III) oxide accumulates in the upper layers of the catalyst, where it forms a dust sediment on the granule surface.

The microelement composition of the catalyst samples determined by emission spectral analysis is shown in Table 3. Preliminarily, samples were cleaned to remove the dust. Granules of reddish (sample no. 1) and dark (sample no. 11) color were taken.

As seen, chromium, copper, magnesium, manganese, and lead compounds are accumulated in the upper part of the reactor. The content of chromium, copper, and manganese in the upper part of the reactor increases as compared to the fresh catalyst sample by approximately a factor of 10, and the content of magnesium and lead, by factors of 6 and 3, respectively. In the lower catalyst layers, the content of the above elements is less than that in the upper catalyst layers. Thus, in the course of the catalyst exploitation, catalytic poisons delivered with the feed are accumulated on the catalyst surface. However, the absolute amount of the above metals is small, and we cannot suggest that their accumulation is the main reason for the catalyst deactivation.

To reveal the nature of agents deactivating the catalyst surface, we performed a DSC study of the fresh catalyst and spent sample nos. 1 and 11 (Fig. 4). All the samples show an endothermic effect at 357 K, which is accompanied by weight loss within the 313–393 K range. This effect is caused by water desorption from the catalyst surface. In addition, two exothermic effects are observed at 423–540 and 582–602 K for samples of spent catalyst. Since Al_2O_3 undergoes no phase transitions within these temperature intervals [12], we can suggest that these effects correspond to combustion of the organic compounds (various polymers, coke) formed on the catalyst surface. The intensities of the effects for sample nos. 1 and 11 relate as about 1 : 4, which indicates that sample no. 11 contains a greater amount of coke, which obviously blocks the catalyst activity.

The IR data also indicate blocking of the catalyst active centers in deactivation. The IR spectrum of CO adsorbed on Pd metal particles (Fig. 5) shows that

the catalyst surface changes in deactivation. The spectrum of the fresh sample is characterized by intense bands at 1927 and 1978–2000 cm^{-1}, assigned to ν(CO) of Pd–CO and Pd–C(O)–Pd groups [13]. The absorption of sample no.1 in this spectral region is similar. By contrast, sample no. 11 shows virtually no absorption in the 1978–2000 cm^{-1} range, and the intensity of the band at 1927 cm^{-1} is substantially lower. These results show that the number of Pd atoms accessible to chemisorption of CO in the catalyst that has operated in the lower part of the reactor decreases. The decrease in the catalyst activity in the course of hydrogenation of pyrolysis naphtha is probably due to a decrease in the number of the reactive Pd particles on the catalyst surface, resulting from their blocking by the organic deposits.

CONCLUSION

Deactivation of the catalyst in the upper and lower parts of the reactor is caused by different factors: in the upper parts, it is due to accumulation of catalytic poisons, namely, chromium, copper, manganese, magnesium, and lead compounds delivered to the reactor with the feed; in the lower parts, it is due to blocking of the active centers by organic deposits. Deactivation substantially affects the catalyst pore structure: the fine pore constituent and the number of Pd particles accessible to molecules of the feed decrease.

Abstract—Hydrogenation and isomerization of α-pinene on heterogeneous catalysts were studied, and conditions were found for hydrogenation of pinene to *cis*-pinane on nickel catalysts and for its dehydrogenation to *p*-cymene on decationized zeolite Y.

α-Pinene, which is a bicyclic monoterpenoid, is an important product of wood chemical industry. α-Pinene widely occurs in nature; it is present in oils obtained from most of coniferous tree species and is the major component of turpentine. Due to the presence of a double bond and a strained four-membered ring, α-pinene readily undergoes various transformations, primarily hydrogenation and skeleton isomerization [1–3].

α-Pinene is widely used in industry, in particular, in production of synthetic camphor, camphene, myrcene, fragrances (linalool, citronellol, geraniol, pinocarveol, myrtenol, etc.), and paint-and-varnish materials [1–3].

The α-pinene hydrogenation product, pinane, is also an important chemical: its autooxidation yields a stable hydroperoxide used as initiator of low-temperature copolymerization of butadiene with styrene [4].

Pinane required for preparing the hydroperoxide is usually synthesized by hydrogenation of α-pinene with molecular hydrogen on metal-containing catalysts [5–10]. In particular, it has been suggested [5, 6] to use supported Ru- and Pd-containing catalysts for α-pinene hydrogenation. Hydrogenation of α-pinene can also be performed on Ni-containing catalysts, but under more severe conditions: $p_{H_2} \geq 1.0$ MPa and reaction time no less than 14–20 h [7–10].

Our goal was to find catalysts effecting hydrogenation of α-pinene to pinane under mild conditions ($p_{H_2} \leq 0.6$ MPa, $T \leq 150$°C). The major attention was given to hydrogenation of α-pinene on Pd- and Ni-containing catalysts for hydrogenation of other organic substances, commercially produced in Russia.

EXPERIMENTAL

Experiments on α-pinene transformations were performed in a 100-ml isothermal pressure reactor containing a finely dispersed (0.04–0.1 mm) catalyst; the ideal mixing mode was ensured by vigorous shaking. The amount of loaded α-pinene was 50 ml, and the amount of the catalytic system relative to substrate, c_c = 1–10 wt %. The temperature in the reactor, T_r, was varied from 20 to 150°C, and the hydrogen pressure, p_{H_2}, from 0.2 to 1.0 MPa. Also, hydrogenation of α-pinene was studied in a tubular bubbling reactor charged with a pelletized catalyst (V_c = 100 ml); the process was performed in a flow of hydrogen, in the batch mode with respect to α-pinene.

The IR spectra were recorded on a UR-20 spectrometer; samples were prepared as KBr pellets, mulls in mineral oil, or neat liquids. The ^{1}H and ^{13}C NMR spectra were recorded on a Jeol FXQ spectrometer (90 and 22.5 MHz, respectively) in $CDCl_3$ solutions; the chemical shifts (δ, ppm) are given relative to TMS. The mass spectra (70 eV) were taken on a Finnigan MAT-112S gas chromatograph–mass spectrometer. A chromatographic analysis was performed with a Chrom-5 chromatograph, column length 1.2 m, stationary phase 5% SE-30 on Chromaton N-AW-HMDS, carrier gas helium.

The reaction was performed with sulfate α-pinene purified by distillation (99.0 wt % purity). The reac-

1070-4272/03/7602-0234 $25.00 © 2003 MAIK "Nauka/Interperiodica"

tion products (pinane, dipentene, terpinolene, camphene, *p*-cymene) were isolated by fractional distillation in a vacuum (purity no less than 98.0 wt %, according to GLC) and identified by IR, ^{1}H NMR, and ^{13}C NMR spectroscopy and by refractive indices, using reference samples and published data [1–11]. The *cis* configuration of pinane prepared on the nickel catalyst follows from the signal pattern given by the gem-dimethyl (C^9, C^{10}; δ 1.02–1.04 ppm) and C^8 methyl groups (δ 1.18 ppm) [1–11].

Preliminary experiments showed that α-pinene undergoes no thermal transformations under the conditions examined ($T \le 160$°C, nitrogen pressure $p \le 0.8$ MPa). In the presence of γ-Al_2O_3, SiO_2 (kieselguhr or KSM synthetic silica gel), or Sibunit [12], used as supports for the tested catalysts, the maximal conversion of α-pinene under the above conditions did not exceed 3–5 wt %, with the major transformation product being the isomer of α-pinene, dipentene. Similar results were obtained with hydrogen taken instead of nitrogen. Thus, the concentration of catalytically active centers on the surface of these supports is low.

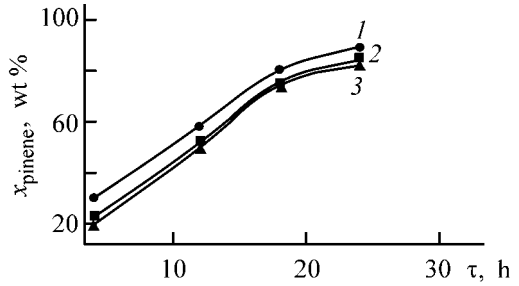

Fig. 1. Variation with time τ of the conversion of α-pinene, x_{pinene}, in its hydrogenation on palladium catalysts (150°C, 2 h, p_{H_2} = 0.6 MPa, c_c = 10 wt %): (*1*) 2 wt % Pd/Sibunit, (*2*) 2 wt % Pd/γ-Al_2O_3, and (*3*) 0.5 wt % Pd/γ-Al_2O_3.

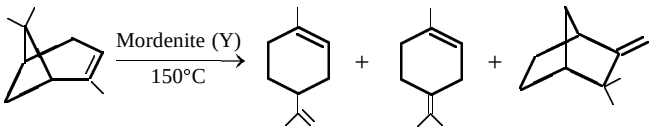
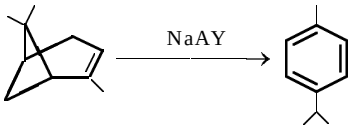
However, α-pinene showed an unusual behavior on decationized zeolites of various structural types (mordenite, Y) whose surface contains Brønsted (B^-) acid centers with different strengths [13].

If the reaction is performed on mordenite in the H form under N_2, the conversion x_{pinene} (wt %) of α-pinene at 150°C, pressure of 0.3 MPa, and c_c = 10 wt % reaches 75% in 2 h. The reaction products contain dipentene, terpinolene, and camphene (1 : 1 : 0.1):



α-Pinene Dipentene Terpinolene Camphene

On ~50% decationized zeolite Y, whose surface contains stronger B^- centers, α-pinene undergoes not only isomerization, but also dehydrogenation yielding *p*-cymene:



α-Pinene *p*-Cymene

This reaction may be of considerable practical interest owing to a high (~80% based on the initial α-pinene) yield of *p*-cymene.

When α-pinene is heated in an H_2 atmosphere in the presence of Pd- and Ni-containing catalysts supported by α-Al_2O_3, SiO_2, or Sibunit, the major reaction pathway is hydrogenation to pinane:

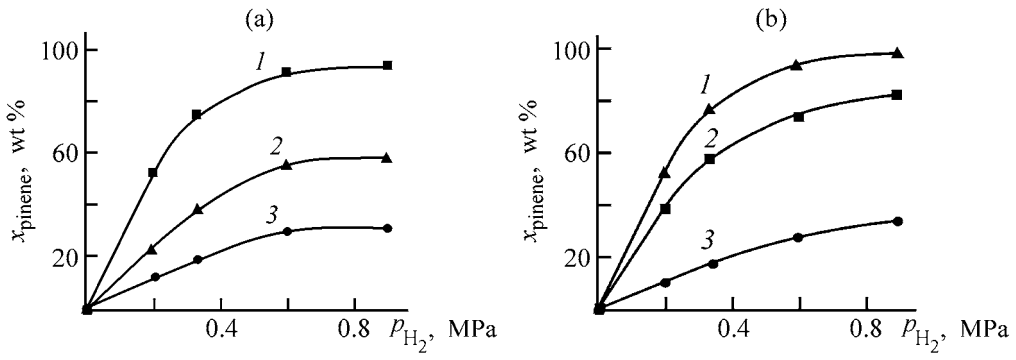


Fig. 2. Conversion of α-pinene, x_{pinene}, on GM-3 catalyst vs. hydrogen pressure p_{H_2}. Reaction time 6 h. c_c, %: (a) 1.5 and (b) 3. *T*, °C: (a) (*1*) 150, (*2*) 100, and (*3*) 75; (b) (*1*) 130, (*2*) 100, and (*3*) 50.

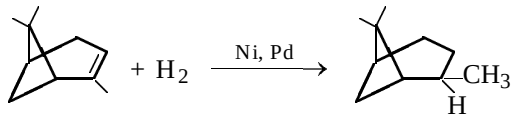

α-Pinene Pinane

Figure 1 shows variation of the α-pinene conversion, x_{pinene}, with time on various Pd-containing catalysts. The highest conversion is observed on 2 wt % Pd/Sibunit (IK-53 brand). The highest activity of this catalyst is probably due to the largest surface area of the metal. At the same time, all the catalysts exhibit similar selectivities: The yield of pinane based on the converted α-pinene is 92–95% with all the catalysts.

Usually, hydrogenation catalysts are subjected before use to reductive hydrogen treatment. It is known [14] that too high treatment temperatures may affect the ratio of the hydride and atomic hydrogen species in the catalyst and hence the catalytic activity. However, when the hydrogen treatment temperature was raised from 100 to 300°C, the Pd-containing catalysts we studied did not show such an effect.

Table 1. Hydrogenation of α-pinene on the commercial Ni/kieselguhr catalyst at p_{H_2} = 0.6 MPa

c_c, wt %	T_r, °C	τ, h	x_{pinene},* wt %
2.5	130	4	78.0
2.5	150	4	100.0
5.0	100	4	45.0
5.0	130	4	100.0
5.0	150	2	100.0

* (x_{pinene}) Conversion of α-pinene (selectivity with respect to pinane is close to 100%).

In production of isoprene, admixtures of acetylenic hydrocarbons are hydrogenated on nickel silicate catalysts which are prepared by precipitation of basic nickel(II) carbonate on kieselguhr, followed by filtration, washing, drying, pelletizing, and reductive decomposition [15]. The catalysts contain 25 to 50 wt % nickel.

Experiments on hydrogenation of α-pinene on the catalyst produced using this procedure by the Kauchuk Private Company showed that the complete conversion of α-pinene with quantitative yield of pinane is attained in 2 h at 150°C and p_{H_2} = 0.6 MPa with the 0.04–0.1-mm fraction of the catalyst obtained by crushing the pellets and activated at 400°C in a hydrogen flow for 2 h (Table 1).

A still more active powdered nickel-containing catalyst GM-3 was obtained [15] when the drying of the catalyst mass and its activation in a hydrogen flow (~400°C, 2–4 h) were combined in a single stage. The results of hydrogenation on the catalyst prepared by this procedure are shown in Fig. 2.

As seen from Fig. 2, GM-3 catalyst is more active than all the catalysts studied previously.

Gan [15] has shown that the pore volume, overall specific surface area, and specific surface area of metallic nickel in GM-3 catalyst are 2–3 times higher compared to the catalyst prepared by the conventional procedure and amount to 0.5–0.56 $cm^3\,g^{-1}$, 250–280 $m^2\,g^{-1}$, and 100–130 $m^2\,g^{-1}$ Ni, respectively. It is known that, after decomposition of basic nickel carbonate, Ni/kieselguhr catalysts contain a readily reducible phase of nickel oxide and also nickel hydrosilicates, which are reduced at temperatures above 300°C. We found that GM-3 catalyst samples prepared by reduction in an H_2 flow at 400–450°C for

Table 2. Influence of temperature T and time τ of reduction of GM-3 catalyst on the conversion of α-pinene, x_{pinene} (100°C, p_{H_2} = 0.3 MPa, hydrogenation time 2 h, c_c = 3.0 wt %)

T, °C	τ, h	x_{pinene}, wt %
350	4	60.2
350	8	60.8
400	2	90.6
400	3	100.0
450	2	95.3
450	3	100.0
500	2	85.0
500	3	79.0

2–3 h are the most active in α-pinene hydrogenation (Table 2).

The lower activity of the catalyst samples reduced at $T \le 350$°C is probably due to incomplete reduction of nickel hydrosilicates; treatment at temperatures exceeding the optimum (at 500°C) also results in lower catalyst activity, probably due to partial sintering of the forming nickel crystallites.

The stability of the catalytic properties of nickel silicate systems in hydrogenation of α-pinene was studied in a tubular bubbling reactor with a commercial sample of pelletized Ni/kieselguhr catalyst reduced in a hydrogen flow at 350°C for 6 h. We found that, at 150°C, outlet hydrogen pressure of 0.4 MPa, and molar ratio α-pinene : H_2 = 1 : 2, complete conversion of α-pinene into pinane was observed within 5–6 h, and the catalytic properties of the sample did not change after ten operation cycles. An important feature of the Ni-containing catalyst is that it allows hydrogenation of α-pinene to pinane with 96% selectivity.

CONCLUSIONS

(1) Hydrogenation of α-pinene on Pd- and Ni-containing heterogeneous catalysts was studied, and conditions were found for selective preparation of pinane: 150°C, 2 h, p_{H_2} = 0.6 MPa, commercial Ni/kieselguhr catalyst activated in an H_2 flow at 400–450°C for 2–3 h.

(2) *p*-Cymene was prepared in high yield (80%) by isomerization and dehydrogenation of α-pinene on 50% decationized zeolite Y at 150°C for 2 h in the presence of N_2 (p = 0.3 MPa).

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Determination of Herbicides of the Chlorophenoxycarboxylic Acid Type in Natural and Drinking Water by Capillary Zone Electrophoresis

N. V. Komarova and L. A. Kartsova

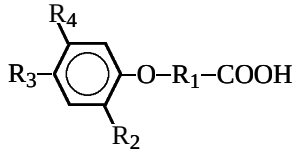
Lyumeks Research and Production Company for Analytical Instrument Making, St. Petersburg, Russia
St. Petersburg State University, St. Petersburg, Russia

Received June 13, 2002

Abstract—The method of capillary electrophoresis was applied to separate and quantitatively determine herbicides belonging to the class of chlorophenoxycarboxylic acids: 2,4-dichlorophenoxyoleic, 2,4-dichlorophenoxypropionic, 2,4,5-trichlorophenoxyacetic, 2,4-dichlorophenoxyacetic, and phenoxyacetic, and the final product of their decomposition in an aqueous medium of 2,4-dichlorophenol. The influence exerted by α- and β-cyclodextrin on the selectivity of the separation system under study was analyzed. The hindering effect of humic acids on the separation and determination of phenoxycarboxylic acids by capillary electrophoresis was assessed.

Gas chromatography [1, 2] and high-efficiency liquid chromatography [3, 4], most widely used to analyze pesticides of the type of chlorophenoxycarboxylic acids, require prolonged sample preparation, which includes derivation, and sophisticated and expensive equipment. A fast, simple, and sufficiently reliable method for analysis of herbicides is capillary electrophoresis [5–10]. This technique for electromigration separation of ions is based on their different velocities of motion in an electric field, depending on charge and ionic radius. Being an intraphase separation technique, the capillary electrophoresis is inferior to gas chromatography and high-efficiency liquid chromatography in selectivity, but much exceeds them in efficiency.

The most widely used as herbicides are chlorophenoxycarboxylic acids (PCA) and their derivatives: 2,4-dichlorophenoxyoleic (2,4-DO), 2,4-dichlorophenoxypropionic (2,4-DP), 2,4,5-trichlorophenoxyacetic (2,4,5-T), 2,4-dichlorophenoxyacetic (2,4-D), 2-methyl-4-chlorophenoxyacetic (2M-4C), and phenoxyacetic (PAA) acids.



The presence of halogen atoms in PCA molecules ensures higher herbicide activity, which is at a maximum with two chlorine atoms in the benzene ring, i.e., in the case of 2,4-D and its homologues.

The properties of some frequently used (and, consequently, controlled for residual content) herbicides are illustrated in Table 1. A relatively low persistence

Table 1. Selected properties of the most frequently used herbicides of the PCA class

Compound	M, g mol^{-1}	T_m, °C	pK_a	Substituent				Solubility in water at 20°C, g l^{-1}	MPC in water, mg l^{-1}
				R_1	R_2	R_3	R_4		
PAA	152.2	99	Not found	CH_2	H	H	H	12	1.0* [11]
2,4-D	221.04	141–142	2.64	CH_2	Cl	Cl	H	0.540	0.03* [11], 1.0** [12]
2M-4C	200.5	118–120	3.07	CH_2	CH_3	Cl	H	1.5	0.02** [12]

has been observed for this class of ecotoxicants; their highest stability (300–500 days) is typical of soils, and the lowest (120 days), of water bodies [13]. The stability of herbicides in various media depends both on their physicochemical characteristics and on the nature of a biological medium, temperature, humidity, UV radiation, etc. The class of PCA belongs to medium-toxicity compounds. Nevertheless some PCA representatives exhibit postponed toxic effects. For example, 2,4,5-T is characterized by embryotropic effect, and use of this preparation in Russia is prohibited. Mention should be made of the importance of determining, together with residual amounts of herbicides, also the content of their decomposition products, many of which also exert toxic influence on the environment. For PCA, such an accesory component is 2,4-dichlorophenol (2,4-DCP).

As already noted, capillary electrophoresis, being highly efficient, is, however, characterized by insufficient selectivity. Use of macrocyclic agents (crown ethers, cryptands, cyclodextrins) as additives to the leading electrolyte allows control over the selectivity of separation of complex mixtures of organic and inorganic compounds, owing to, in the first place, the unique ability of microcycles to form inclusion complexes of the host–guest type with the substances being analyzed [14].

Natural cyclodextrins (CD) are nonionic macrocyclic chiral carbohydrates composed of D–(+) residues of glucopyranose (each in chair conformation) interconnected by α-1,4-bonds. The CD molecules have the shape of a truncated cone with hydrophobic inner cavity and hydrophilic outer part (with primary hydroxy groups at the narrower end, and secondary, at the wider one). The identification is based on inclusion of bulky hydrophobic fragments of substances being analyzed into the CD cavity and interaction of secondary hydroxy groups of the macrocycle with polar groups of a component. The possibility of formation of inclusion complexes is determined by steric factors (matching between the size of the CD cavity and that of a molecule being analyzed), hydrophobic interactions, solvation effects, and hydrogen bonding [15]. The most widely used and commercially available are α-, β-, and γ-CD having, respectively, 6, 7, and 8 glucopyranose residues (β-CD occupying an intermediate position as regards the cavity size is in the highest demand). Figure 1 shows structural formulas and schematic images of α- and β-CD molecules. In capillary electrophoresis, CD is included in the main electrolyte, with the selectivity of the separation system depending on the type and concentration of a macrocycle used, presence of organic modifiers in the buffer solution, and temperature.

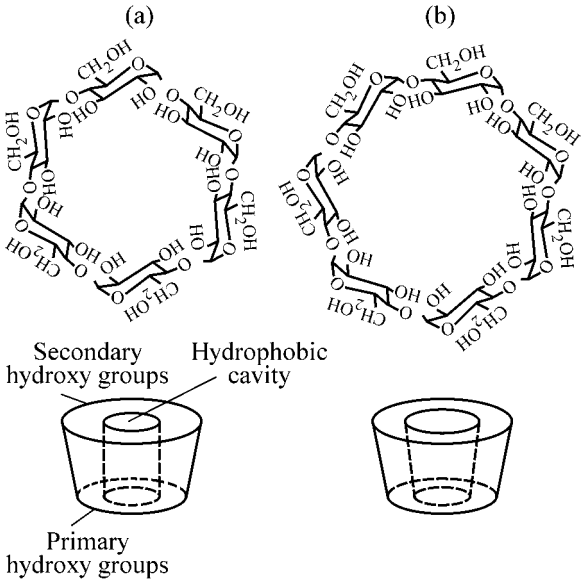

Fig. 1. Structural formulas and schematic images of molecules of (a) α- and (b) β-CD.

The aim of this study was to develop a procedure for determining PCA concentrations in natural, drinking, and waste water that would include their separation and final determination by capillary zone electrophoresis, with preliminary concentration by solid-phase extraction.

EXPERIMENTAL

As standards were used the following acids: PAA, 2,4-D, 2M-4C, 2,4,5-T, 2,4-DP, 2,4-DM (Supelco, USA); 2,4-DCP (Ekros, St. Petersburg). As macrocyclic additives served α- and β-CD (Supelco, USA). The leading electrolyte was prepared from sodium tetraborate (standard buffer solution). The preparation of humic acids was extracted from soil by the standard method [16]. Acetone, acetonitrile, and hydrochloric acid were of chemically pure grade. The cartridges for concentration were of the Diapak S16 type (Bio-KhimMak Joint-Stock Society, Moscow).

A Kapel'-105 unit for capillary electrophoresis with alternating polarity and SF detector (Lyumeks Research and Production Company for Analytical Instrument Making, St. Petersburg) was used.

As auxiliary devices served rotary evaporator, water-jet pump, and centrifuge. The data acquisition and processing were done using an IBM PC with Multikhrom software (Ampersend Joint-Stock Company, Moscow).

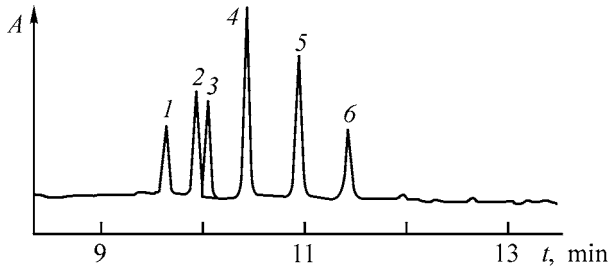

Fig. 2. Separation of PCA and 2,4-DCP by capillary zone electrophoresis. Capillary: quartz, effective length 60 cm, inner diameter 75 μm; leading electrolyte: borate buffer solution, 10 mM, pH 9.2; sample introduction at 30 mbar · 15 s; working voltage +20 kV; detection: UV, 205 nm; temperature +20°C; the same for Fig. 4. Concentrations of components to be determined (mg l^{-1}): (2,4-DM, 2,4-DP, 2,4,5-T) 2 and (2,4-D, 2,4-DCP, PAA) 1; the same for Figs. 3 and 4. Component: (*1*) 2,4-DM, (*2*) 2,4-DP, (*3*) 2,4,5-T, (*4*) 2,4-D, (*5*) 2,4-dichlorophenol, and (*6*) PAA; the same for Figs. 4 and 5.

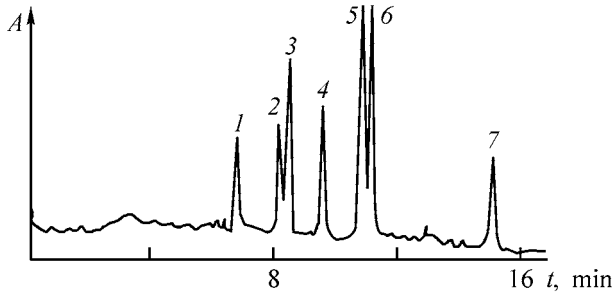

Fig. 3. Separation of PCA by capillary zone electrophoresis in the presence of β-CD. Leading electrolyte: borate buffer solution, 10 mM with addition of 2 mM of β-CD. 2M-4C concentration 2.5 mg l^{-1}. Component: (*1*) 2,4-DM, (*2*) 2,4,5-T, (*3*) 2,4-dichlorophenol, (*4*) 2,4-DP, (*5*) 2M-4C, (*6*) 2,4-D, and (*7*) PAA.

An unused Diapak S16 concentrating cartridge was washed successively with 5 ml of acetonitrile and 5 ml of distilled water acidified to pH 2.0.

A 250-ml water sample was acidified with hydrochloric acid to pH 2.0 and passed through the Diapak S16 cartridge at a rate of 15 ml min^{-1}. Then the cartridge was dried with air for 20 min and the substances to be determined were eluted with 4 ml of acetone. The eluate was evaporated to dryness under a water-jet-pump vacuum at room temperature, and the residue was dissolved in 1 ml of distilled water. The solution obtained was centrifuged (6000 rpm, 2 min) and analyzed by means of capillary electrophoresis.

An unmodified polyimide-coated quartz capillary with total (effective) length of 70 (60) cm and inner diameter of 75 μm was used. As leading electrolyte served sodium tetraborate solution with concentration of 10 mM, pH 9.18. The sample was introduced hydrodynamically at 450 mbar s. The working voltage was +20 kV. Peaks were recorded in the UV spectral range at a wavelength of 205 nm. All the measurements were done at +20°C.

Before analysis, the capillary was successively washed with 0.5 M NaOH solution for 10 min, distilled water for 5 min, and leading electrolyte for 15 min. Between analyses, the capillary was washed with the working buffer solution for 2 min.

Among various kinds of capillary electrophoresis, preference is commonly given to zone electrophoresis [17, 18], in which components of a sample introduced as a separate zone at the capillary inlet are separated in the electric field because of their different electrophoretic mobilities and detected as discrete zones. The electrophoretic motion of ions in the capillary is overlapped by an electrooscmotic flow (EOF), i.e., fluid flow under the action of an applied electric field, which accomplishes passive transfer of the sample zone in the capillary. Chlorophenoxycarboxylic acids dissociate in neutral and alkaline solutions to form organic anions, which favors their determination in the capillary–zone–electrophoresis mode. In optimizing the conditions for separation of a six-component mixture containing five herbicides to be determined and products of their degradation, the geometric dimensions of the capillary, methods and characteristics of sample introduction, composition and concentration of the leading electrolyte, working voltage, and temperature were varied. Figure 2 shows an electrophoregram obtained under the optimal conditions.

Being characterized by high separation efficiency, capillary electrophoresis has insufficient selectivity. For example, it is important to determine, in some analyses for herbicides of the PCA class, 2M-4C acid, whose mobility is close to that of 2,4-D, which hinders their separation in the zone–electrophoresis mode. It is impossible to separate 2M-4C and 2,4-D under the conditions of Fig. 2, since these two compounds form a single peak. Addition of natural unmodified α- and β-CD make it possible to improve the resolution of the system through formation of inclusion complexes, with the selectivity determined, in the first place, by the type and concentration of a CD used [19]. A seven-component PCA mixture containing six herbicides (including 2M-4C) and products of their decomposition was separated using borate buffer so-

lutions with addition of individual α- or β-CD, with the CD concentration varied from 1 to 10 mM at constant sodium tetraborate concentration (10 mM). It was shown that addition of α-CD does not affect mixture separation in the whole range of concentrations studied, with 2,4-D and 2M-4C still yielding a single peak. At the same time, introduction of β-CD improves the efficiency (twice) and selectivity of separation. The optimal amount of the macrocycle added is 2 mM (Fig. 3). In this case, peak inversion is observed: the time of migration decreases for 2,4,5-T and 2,4-DCP to a greater extent than for other components of the mixture, which can be attributed to formation of host–guest complexes with varying stability (apparently, 2,4-DCP forms the strongest complex with β-CD). The increase in efficiency is an independent indication of complexation: moving in the EOF direction, neutral β-CD molecules with anions in cavities favor more effective mass transfer of the anions

It was intended to use natural water as a real medium to be analyzed, and it is for this reason that the hindering effect of humic acids on the separation and determination of PCA by zone electrophoresis was studied. The dominant natural organic components of water bodies are humic (HA) and fulvic acids (FA), which account for 50 to 98% of organic carbon in natural water [20]. The molecular masses of these acids vary between hundreds and tens of thousands of atomic mass units, depending on conditions of HA extraction, sample from which HA are extracted, and degree of their purification and fractionation. The method of zone electrophoresis was applied to perform a set of experiments on model systems for assessing the influence exerted by HA on PCA separation. The HA concentration was varied within the range 0–250 mg l^{-1} at constant PCA concentrations. The electrophoregrams obtained are shown in Fig. 4. These data were used to construct plots reflecting the dependence of the efficiency of PCA separation on the HA concentration in solution (Fig. 5). It was established that HA do not affect the separation of PCA mixtures at concentrations lower than 50 mg l^{-1}. With the HA concentration in the solution being analyzed increasing from 50 to 250 mg l^{-1}, the efficiency of separation of neighboring peaks decreases markedly because of the broadening of zones of individual components, caused by mass overloading of the separation system.

PCA are commonly extracted from water bodies by the classical liquid–liquid [21] or solid-phase extraction with the use of cartridges filled with reversed-phase sorbents [22]. Solid-phase extraction of a mixture of PCA and, separately, HA from model solutions on Diapak S16 concentrating cartridges, with subsequent separation and determination by capillary electrophoresis, was studied. It was shown that PCA and HA are sorbed completely, and desorption of PCA is characterized by degrees of extraction close to 100%, whereas HA are not desorbed from a cartridge under the given conditions. In addition, experiments on solid-phase extraction of a mixture con-

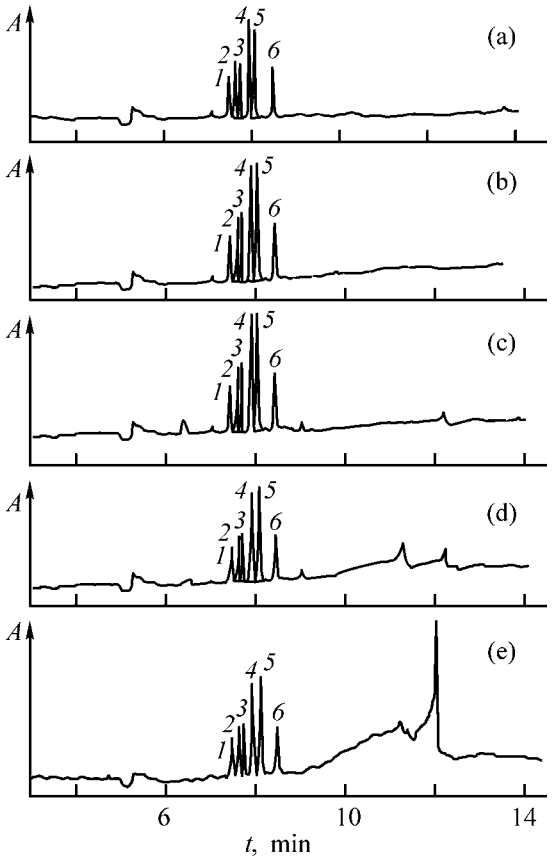

Fig. 4. Effect of HA on the PCA separation by capillary zone electrophoresis. HA concentration in the initial mixture (mg l^{-1}): (a) 0, (b) 10, (c) 50, (d) 100, and (e) 250.

Table 2. Degree R of PCA recovery from model mixtures in solid-phase extraction (n = 15, P = 0.95)

Compound	Area under peak		R, %	S_r^*
	calibration solution	solution after solid-phase extraction		
2,4-DM	8.02	6.52 ± 0.59	81.3 ± 7.4	0.16
2,4-DP	11.99	9.89 ± 1.03	84.3 ± 8.6	0.18
2,4,5-T	11.84	9.82 ± 0.92	84.7 ± 7.8	0.17
2,4-D	24.27	18.81 ± 2.16	81.5 ± 8.9	0.21
2,4-DCP	23.17	2.94 ± 0.99	12.6 ± 4.3	0.60
PAA	11.59	8.04 ± 0.87	71.3 ± 7.5	0.19

* Relative standard deviation.

taining PCA and HA simultaneously revealed total desorption of PCA and partial desorption of HA, which indicates that the substances being determined react with humic acids. The degrees of extraction, calculated for the components under study, are listed in Table 2. The low degrees of extraction of the accessory component 2,4-DCP are due to its ability to be co-distilled with highly volatile substances in evaporation. For each of the acids, linear ranges of the concentrations being determined were established and the detection limit was calculated. For example, the minimum detectable concentrations in water bodies are 0.0005 mg l^{-1} for 2,4-DM, 2,4-DP, 2,4,5-T, and 2,4-D and 0.001 mg l^{-1} for PAA.

Real samples (drinking and tap water, water from artesian wells, and natural water from the Volkhov and Terek Rivers) were analyzed for the PCA content; the determinations were verified by the method of additives.

CONCLUSIONS

(1) The possibility of using capillary electrophoresis for separation and quantitative determination in the form of anions of herbicides belonging to the class of chlorophenoxycarboxylic acids was demonstrated.

(2) It is proposed to improve the selectivity of separation of analytes by adding β-cyclodextrin to the leading electrolyte, with the optimal concentration of the macrocycle equal to 2 mM.

(3) It was shown that humic acids do not hinder analysis of natural water when present in concentration not exceeding 50 mg l^{-1}.

(4) Solid-phase extraction on Diapak S16 concentrating cartridges was used in the stage of sample prepparation; the minimum detectable concentrations of herbicides were 0.0005 mg l^{-1} for for 2,4-DM, 2,4-DP, 2,4,5-T, and 2,4-D and 0.001 mg l^{-1} for PAA at sample volume of 250 ml.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Effect of Impurities on Results of Redoxometric Determination of Molecular Oxygen in Natural and Waste Water by Winkler Method

S. B. Sapogova, A. V. Kaverin, A. M. Pisarevskii, and I. P. Polozova

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received September 18, 2002

Abstract—The possibility of determining dissolved oxygen in natural and waste water by the potentiometric variant of the Winkler method, with samples prepared using the Ross procedure and blank sample technique employed, was studied.

For many decades the Winkler method [1–3] has been the standard technique for chemical analysis for dissolved oxygen in pure and conditionally pure water. Oxygen is determined by the Winkler method in two stages. In the first stage, molecular oxygen is fixed in an alkaline medium via its reduction with Mn(II) ions. In the second stage, the sample is acidified to pH ~ 2 and KI is added. Under these conditions, iodide ions are stoichiometrically oxidized to I_2 by Mn(IV) ions formed in the first stage. Then, I_2 is titrated with a sodium thiosulfate solution, with starch as indicator. The Winkler method allows dissolved oxygen to be determined within a wide concentration range, O_2 0.1–12 mg l^{-1}, with an absolute error of about 0.04–0.06 mg l^{-1} [4].

Shortcomings of the method, associated with the low stability of starch and of dilute solutions of sodium thiosulfate, have been noticed. These shortcomings are especially pronounced at concentrations of dissolved oxygen lower than 2 mg l^{-1}. At these concentrations the relative error of oxygen determination increases to 20 rel.% [5]. At the same time, it is this range of low oxygen concentrations that acquires the highest importance in connection with the deterioration of ecological situation in water reservoirs. The accuracy of O_2 determination by the Winkler method in natural and waste water decreases dramatically because of the systematic errors caused by the presence of contaminants. In particular, presence of reducing impurities (Fe^{2+}, S^{2-}, SO_3^{2-}, etc.) in water being analyzed leads to underestimated concentrations of dissolved oxygen, and, by contrast, presence of oxidizing impurities (nitrites, peroxides, Fe^{3+}, etc.) manifests itself in overestimated results. For this reason, variations of the Winkler method [4, 6–8] are used to neutralize the effect of impurities. These modifications consists in addition of various reagents (complexing substances, oxidants, and reducing agents) to water being analyzed and in choice of conditions under which the interfering effect of one or another impurity can be neglected. Whenever possible, the effect of impurities is taken into account by means of the blank sample method.

Among the existing variants of the classical method, the widest acceptance has been gained by the technique proposed by an American scientist Ross [9]. According to this variant, the Winkler method is supplemented with a procedure for sample preparation: prior to oxygen fixation, a solution of sodium hypochlorite is added to water to be analyzed, with oxidation of the reducing agents contained in water:

$$SO_3^{2-} + ClO^- \rightarrow SO_4^{2-} + Cl^-,$$

$$NO_2^- + ClO^- \rightarrow NO_3^- + Cl^-.$$

Then, the excess amount of hypochlorite ions and some oxidants are decomposed by addition of a potassium thiocyanate solution:

$$4ClO^- + NCS^- + 2OH^- \rightarrow NCO^- + 4Cl^- + H_2O + SO_4^{2-}.$$

In this case, the components of the NCO^-/NCS^- redox system do not impede the second stage of the Winkler analysis [10].

1070-4272/03/7602-0244 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Previously [11], the possibility of determining the dissolved oxygen in the iodine–iodide system (I_3^-/I^- by the Winkler method, with potentiometric measurements used instead of iodometric titration, has been demonstrated. The redoxometry is based on the high selectivity of the platinum indicator electrode toward the I_3^-/I^- system, which is achieved owing to irreversible modification of the electrode surface by the components of this system. It was established that modified indicator electrodes are frequently insensitive to side electrochemical reactions. This allows redoxometric measurements under conditions close to equilibrium in solutions of the iodine–iodide system at concentrations of up to 10^{-6} M (in terms of iodine). The concentration of iodine (dissolved oxygen) was determined from a change in the emf of galvanic cell (I) as a result of coulometric generation of a standard addition of iodine.

$$\text{Ag} \mid \text{AgCl, KCl}_{\text{sat}} \mid \text{Solution of } I_3^-/I^- \text{ system} \mid \text{Pt} \quad (1)$$

The potentiometric measurements and electrochemical generation of iodine were performed in a four-electrode cell with generating unit having unseparated cathode and anode spaces. The determination technique and calculation procedure were described in detail in [11, 12].

It is necessary to note that use of the Ross procedure in potentiometric determination within the framework of the Winkler method yields correct results only when the selectivity of the indicator electrode in the I_3^-/I^- system toward the redox system NCO^-/NCS^- ensures attainment of a partial equilibrium at the electrode–solution interface and provides a 100% current efficiency by iodine in electrochemical generation. Otherwise, it could hardly be expected that the potentiometric determination would yield correct results.

Therefore, the aim of this study was to analyze the possibility of potentiometric determination of dissolved oxygen in contaminated reservoirs with the use of the Ross method. Potentiometric analysis was also used for determining the impurity concentration in a blank test.

EXPERIMENTAL

The problem of reversibility, in principle, of redox measurements in solutions of the coexisting systems I_3^-/I^- and NCO^-/NCS^- was studied in two stages.

In the first stage was studied the current efficiency by iodine in no-diaphragm generation of a standard addition of iodine in mixed solutions of the following composition typical of the Ross procedure: 5×10^{-4} equiv. l^{-1} NCO^-, 1.5×10^{-3} equiv. l^{-1} NCS^-, and 2×10^{-1} M KI, to which H_2SO_4 was added to pH 2.5. The results obtained demonstrated that, under the conditions of the Ross method at generation current density of 20 mA cm^{-1}, the current efficiency by iodine is $99.4 \pm 1.6\%$ ($n = 7$, $p = 0.95$), i.e., the NCO^-/NCS^- system is electrochemically inactive under the experimental conditions.

In the second stage, the reversibility of platinum electrode toward the iodine–iodide system in the solutions containing components of the NCO^-/NCS^- redox system was verified. For this purpose, the dependence E–$\log[I_3^-]$ was studied in pure solutions of the iodine–iodide system (3×10^{-5}–1×10^{-3} M I_2 l^{-1}, 2×10^{-1} M KI, pH 2.5) and in solutions containing Ross reagents (composition indicated above). The iodine concentration in the solutions studied was set by successive electrochemical generation. The E–$\log[I_3^-]$ dependences in pure solutions of the I_3^-/I^- system and in solutions containing the NCO^-/NCS^- system are linear; the slopes of the calibration lines are the same for both solutions and coincide, within the measurement error, with the theoretical value [29.6 mV $\times$ $(pI_3^-)^{-1}$].

The experiments performed demonstrated that equilibrium redoxometric measurements can be performed in the system I_3^-/I^-, despite the presence of components of the NCO^-/NCS^- redox system. This makes potentiometry with sample preparation by the Ross procedure suitable for O_2 determination.

The analytical characteristics of the potentiometric variant of the Ross method were studied in model solutions of reducing agents. $NaNO_2$ and Na_2SO_3, typical "contaminants" of natural water, were chosen for this purpose. Their concentration was taken to be 10^{-4} eqiv. l^{-1}, which corresponds to 0.8 mg l^{-1} O_2 (in terms of oxygen). Table 1 compares the results of potentiometric and titrimetric determinations of O_2. It can be seen that the application of the Ross method of sample preparation was successful for the reducing agents used: the results for pure water and model aqueous solutions containing contaminants differ by no more than 0.5%. A large positive error associated with the presence of additional dissolved oxygen introduced by KNCS and NaClO Ross reagents was only observed at lower oxygen concentrations. Comparison of the reproducibility characteristics of titrimetric and redoxometric determinations shows that they are about the same (~1%) at high O_2 concentrations, and only on lowering the O_2 concentration to

Table 1. Results of determination of dissolved O_2 by the Ross method in model solutions of reducing agents (reducing agent concentration 0.8 mg O_2 l^{-1})

Reducing agent	O_2, mg l^{-1}					
	potentiometry			titrimetry		
	By Winkler	by Ross	Δ, %	By Winkler	by Ross	Δ, %
$NaNO_2$	9.41	9.41	0	9.42	9.37	–0.5
	8.43	8.44	+0.1	8.47	8.44	–0.3
	1.95	2.03	+4.1	1.99	2.03	+2.0
	1.41	1.53	+8.5	1.41	1.53	+8.5
Na_2SO_3	9.41	9.42	+0.1	9.42	9.40	–0.2
	8.43	8.39	–0.5	8.47	8.40	–0.8
	1.95	1.92	–1.5	1.99	1.92	–3.5
	1.41	1.52	+7.8	1.41	1.52	+7.8

Note. Results of O_2 determination by Winkler method refer to pure water and are accepted as reference data in comparisons with the Ross method; n = 3–5.

2 mg l^{-1}, the potentiometric method becomes advantageous: the error in determining oxygen by the potentiometric method is 0.04–0.06 mg l^{-1}, i.e., approximately twice lower than that in the case of titrimetry.

In studying the model solutions of other reducing agents (sodium thiosulfate, ascorbic, citric, tartaric, and oxalic acids), underestimated values were obtained, despite the use of the Ross method. The concentration of dissolved O_2, found in this case, was lower than the expected value by 0.5–0.9 mg O_2 l^{-1}. These results indicate that the efficiency of the Ross procedure of sample preparation is insufficient. In other words, the degree of impurity oxidation did not reach 100% in any of the solutions. Since $Na_2S_2O_3$ and ascorbic acid react with molecular I_2 in quantitative yield, it becomes possible to take their contribution into account, in determining oxygen, by means of the blank sample method. In this case, the sequence of analytical operations is as follows:

Table 2. Iodometric determination of reducing agents (O_2^{red})

Reducing agent	O_2^{red}, mg l^{-1}				
	preset	O_2^{pot}	S^{pot}	O_2^{tit}	S^{tit}
Ascorbic acid	0.86	0.86	0.01	0.86	0.02
	3.89	3.89	0.01	3.89	0.03
$Na_2S_2O_3$	0.79	0.78	0.01	0.77	0.04
	3.88	3.88	0.01	3.88	0.02

Note. 1 mg O_2 l^{-1} = 1.25×10^{-4} equiv. l^{-1}, n = 7.

(1) Iodometric determination of active redox impurities. In an electrochemical cell containing a sample of water being analyzed and a supporting electrolyte (0.2 M KI, pH 2.5), an iodine addition $[I_3^-]_1$ was generated. After the stationary emf E_1, indicating the completion of the reaction of I_2 with a reducing agent, was attained, the second addition of iodine $[I_3^-]_2$ was generated. The second emf value, E_2, was recorded. The concentration of the reducing agent in oxygen units (mg l^{-1}) was calculated by the formula common for the standard addition method:

$$O_2^{red} = \left([I_3^-]_1 - \frac{[I_3^-]_2}{(10^{2\Delta E/\theta} - 1)}\right) \times 16\,000.$$

where $\Delta E = E_2 - E_1$; $\theta = 2.3RTF^{-1}$, R is the gas constant (J K^{-1} mol^{-1}), T is temperature (K), and F = 96 500 C.

Table 2 lists the results of an iodometric determination of $Na_2S_2O_3$ and ascorbic acid by potentiometry, in comparison with the data furnished by the commonly accepted titrimetric procedure. As expected, the titrimetic determination is accompanied in this concentration range by large random errors exceeding by a factor of 2–3 the error of the potentiometric method (O_2 concentration 0.01 mg l^{-1}). The same behavior was already observed in the case of the Ross method.

Since the reactions of oxidation of oxalic, tartaric, and citric acids by I_2 are kinetically hindered, it was impossible to determine them in the blank sample.

Table 3. Determination of dissolved O_2 with preliminary analysis for the reducing agent

Reducing agent	O_2^{red}, mg l^{-1}	O_2, mg l^{-1}				Reducing agent	O_2^{red}, mg l^{-1}	O_2, mg l^{-1}			
		without impurity, by Winkler	with impurity					without impurity, by Winkler	with impurity		
			by Winkler	ΣO_2^*	Δ, %				by Winkler	ΣO_2^*	Δ, %
Ascorbic acid	1.66	9.40	7.82	9.48	+0.9	$Na_2S_2O_3$	0.80	9.40	8.57	9.37	–0.3
	1.61	8.46	6.82	8.43	–0.2		0.81	8.45	7.63	8.44	–0.1
	1.60	8.46	6.86	8.46	0		0.77	8.45	7.67	8.44	–0.1

* The concentration of dissolved O_2 in a solution of the reducing agent, ΣO_2, is the sum of the concentration of dissolved O_2, determined in the presence of the reducing agent, and that of the reducing agent, O_2^{red}.

(2) Determination of dissolved O_2 by the classical Winkler method, with correction made for the expenditure of I_2 (O_2) for oxidation of the reducing impurity (Table 3). As in the case of the Ross method, the results obtained using the classical Winkler method for pure water served as reference data. As seen from Table 3, their accuracy is about the same as that for the Ross method. It should be noted that in those cases when O_2 can be determined with preliminary iodometry of a sample, this variant has an advantage over the Ross method, because it yields two parameters of a sample: concentrations of O_2 and impurity.

CONCLUSIONS

(1) The high selectivity of the platinum indicator electrode in the redox system I_3^-/I^-, making it possible to perform reversible measurements despite the presence of components of the NCO^-/NCS^- system and other systems, was confirmed. This circumstance justified the application of the Winkler method with potentiometric determination of I_2 to analysis of contaminated water both in the Ross variant and in combination with the blank sample method.

(2) Potentiometric determination of dissolved O_2 by the Ross method is simple technically and attractive for serial determinations. At the same time, analysis for dissolved oxygen by the Winkler method, with correction made for active redox impurities (blank sample), is more informative. It was shown for several examples that neither the Ross variant nor the blank sample method can serve as a universal technique for analysis of contaminated natural and waste water for dissolved oxygen. The choice of a variant is governed by the nature of a particular impurity.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidant Properties of Bis[ω-(3,5-dialkyl-4-hydroxyphenyl)alkyl] Sulfides

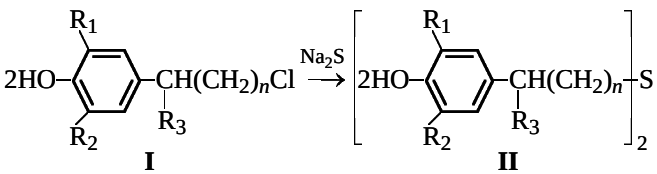
Abstract—The reaction of ω-(3,5-dialkyl-4-hydroxyphenyl)-1-chloroalkanes with sodium sulfide yielded the corresponding sulfides, which were tested as antioxidants in two model reactions: oxidation of lard and Vaseline oil.

Sulfur-containing derivatives of sterically hindered phenols are effective inhibitors of free-radical oxidation of various polymeric materials and lipid substrates [1–4]. A distinctive feature of sulfur-containing phenolic antioxidants (SPAOs) is the presence of two reaction centers: phenolic moiety and bivalent sulfur atom. As a result, these compounds can inhibit oxidation in two ways: by reactions with peroxy radicals and with hydroperoxides. Furthermore, the antioxidant activity of SPAOs is enhanced by intramolecular synergism [3].

Among SPAOs is known bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfide (SO-3 stabilizer, Tiofan), having high inhibiting activity in oxidation of polyethylene, polypropylene [5, 6], and animal fats [1]. Biological studies have shown that SO-3 exhibits hepatoprotective, immunostimulating, and antiischemic effects [7–9]. In this study, we prepared and tested for antioxidant activity a series of structural analogs of SO-3, bis[ω-(3,5-dialkyl-4-hydroxyphenyl)alkyl] sulfides, differing in the extent of steric shielding of the phenolic OH group and in the length of the *p*-alkyl chain linking the phenolic and sulfide moieties.

The sulfides were prepared by the reaction of the corresponding ω-(3,5-dialkyl-4-hydroxyphenyl)-1-chloroalkanes **I** with sodium sulfide nonahydrate:



where $R_1 = R_2 =$ Me, $R_3 = H$, $n = 2$ (**Ia**, **IIa**); $R_1 =$ Me, $R_2 = t$-Bu, $R_3 = H$, $n = 2$ (**Ib**, **IIb**); $R_1 = R_2 = t$-Bu, $R_3 = H$, $n = 1$ (**Ic**, **IIc**), $n = 2$ (**Id**, **IId**), $n = 3$ (**Ie**, **IIe**), $n = 4$ (**Ig**, **IIg**); $R_1 = R_2 = t$-Bu, $R_3 =$ Me, $n = 2$ (**If**, **IIf**).

Syntheses were performed in refluxing 2-propanol for 4–8 h at a molar ratio of the initial chloroalkane **I** to sodium sulfide of 1 : 0.62. Yields of sulfides **II** 57–90%. The compositions and structures of sulfides **II** were confirmed by elemental analysis and NMR spectra.

The antioxidant activity of sulfides **II** was tested in autooxidation of lard (Novosibirsk Meat-Canning Plant) and Vaseline oil (Tatkhimfarmpreparaty Chemical Pharmaceutical Production Association, Kazan). As references we used Ionol (2,6-di-*tert*-butyl-4-methylphenol), TB-3 stabilizer [bis(3,5-di-*tert*-butyl-4-hydroxybenzyl) sulfide], and also a synergistic mixture of Ionol with didodecyl sulfide (DDS) in 1 : 0.5 molar ratio.

The kinetic studies showed that all the sulfides **II** synthesized exhibit high antioxidant activity and efficiently inhibit oxidation of lard and Vaseline oil (see table). They surpass in the antioxidant power the monofunctional antioxidant Ionol and a mixture of Ionol with DDS. This fact suggests that the high inhibiting power of sulfides **II** is due to the bifunctional mechanism of the antioxidant effect and to intramolecular synergism.

In oxidation of Vaseline oil, the mixture of Ionol with DDS exhibits a pronounced synergistic effect due to a combination of the antiradical activity of Ionol and antiperoxide activity of DDS [10]. However, no synergistic effect of these compounds was observed

* R = 2,5-dimethyl-4-hydroxyphenyl, R^1 = 3-methyl-5-*tert*-butyl-4-hydroxyphenyl, and R^2 = 3,5-di-*tert*-butyl-4-hydroxyphenyl.

in oxidation of lard. This result is probably due to different rates of oxidation of lard and Vaseline oil, and also to different thermal stabilities of hydroperoxides formed by oxidation of these substrates.

The susceptibility of hydrocarbons to oxidation is determined by the ratio of the rate constants of chain propagation, k_2, and quadratic chain termination, k_6:

$$RO_2^{\cdot} + RH \xrightarrow{k_2} ROOH + R^{\cdot}, \quad (1)$$

$$RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_6} \text{Products}. \quad (2)$$

Unsaturated compounds are characterized by higher $k_2/k_6^{1/2}$ ratio; correspondingly, under equal other conditions, they are oxidized faster [11]. Lard containing residues of unsaturated fatty acids is oxidized faster than Vaseline oil, which results in accumulation of larger amount of hydroperoxides exhibiting lower thermal stability [12]. Therefore, in oxidation of lard, hydroperoxides are accumulated rapidly, and DDS present in the system has no time to fully deactivate them. In oxidation of Vaseline oil, hydroperoxides are formed at a lower rate and are more stable, and in this case, the mixture of Ionol with DDS exhibits a synergistic effect.

The synthesized sulfides **II** differing in the extent of steric shielding of the phenolic OH group can be ranked in the following order with respect to the capability to inhibit oxidation of Vaseline oil: **IIb** > **IIa** > **IId**. The decrease in the effect of the antioxidants in this order corresponds to a decrease in the rate of their reaction with peroxy radicals [12]

$$PhOH + RO_2^{\cdot} \rightarrow PhO^{\cdot} + ROOH. \quad (3)$$

In oxidation of lard, the antioxidant activity of the sulfides increased as the phenolic OH group became more shielded in the order **IIa** < **IIb** < **IId**, which corresponds to the decreasing reactivity of the phenoxy radicals in the reaction

$$PhO_2^{\cdot} + RH \rightarrow PhOH + R^{\cdot}. \quad (4)$$

It is known that the role of reaction (4) in inhibited oxidation of aliphatic and alkylaromatic hydrocarbons is insignificant. However, in the case of lipid substrates containing relatively weak C–H bond, the contribution of reaction (4) becomes significant, and the inhibiting power of phenolic compounds with respect to oxidation of lipids depends on the stability of the generated phenoxy radicals to a greater extent.

The structure of the *p*-alkyl substituent linking the phenolic and sulfide fragments affected the antioxidant power of sulfides **II** to a lesser extent than did the structure of the *o*-substituents. Among sulfides **IIc**–**IIg**, sulfide **IIe** was the most effective inhibitor with respect to lard, and **IIc**, with respect to Vaseline oil.

TB-3 showed poor antioxidant activity as compared to sulfides **II**, which may be due to the low thermal stability of TB-3 as a benzyl derivative. It is notable that at a lower temperature of 130°C (autooxidation of lard) TB-3 somewhat surpassed Ionol in the antioxidant properties but was inferior to Ionol at 180°C (autooxidation of Vaseline oil).

Thus, sulfides **II** show considerable promise as effective inhibitors of oxidation of various organic substrates and surpass the available analogs in the antioxidative activity.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker spectrometer (500 MHz) in $CDCl_3$ relative to external TMS. The melting points were determined with a PTP device. The initial ω-(3,5-dialkyl-4-hydroxyphenyl)-1-chloroalkanes **I** were prepared according to [13] from the corresponding ω-(3,5-dialkyl-4-hydroxyphenyl)alkanols.[1] TB-3 stabilizer was prepared according to [14].

Bis[3-(3,5-dimethyl-4-hydroxyphenyl)propyl] sulfide IIa. Chloropropane **Ia** (5 g, 25.2 mmol) and sodium sulfide nonahydrate (3.78 g, 15.7 mmol) were dissolved in 30 ml of 2-propanol. The mixture was refluxed for 4 h, cooled, neutralized with HCl, and treated with petroleum ether. The extract was washed with water and dried over Na_2SO_4; the solvent was distilled off. The product was purified chromatographically (silica gel, petroleum ether–diethyl ether, 3 : 1). Yield of **IIa** 2.6 g (57%), mp 63–64°C. ^{1}H NMR spectrum, δ, ppm: 1.86 m (4H, $CH_2C\underline{H}_2CH_2$), 2.23 s (12H, Me), 2.52 t (4H, CH_2S), 2.60 t (4H, $ArC\underline{H}_2$), 4.55 s (2H, OH), 6.79 s (4H, H_{arom}).

Found, %: C 73.99; H 8.38; S 8.77.
$C_{22}H_{30}O_2S$.
Calculated, %: C 73.70; H 8.43; S 8.94.

Bis[3-(3-methyl-5-tert-butyl-4-hydroxyphenyl)-propyl] sulfide IIb was prepared similarly from 5.0 g (20.8 mmol) of **Ib**. The product was purified chromatographically (silica gel, petroleum ether–diethyl ether, 6 : 1). Yield 2.8 g (61%); a resinous substance. ^{1}H NMR spectrum, δ, ppm: 1.42 s (18H, *t*-Bu), 1.88 m (4H, $CH_2C\underline{H}_2CH_2$), 2.22 s (6H, Me), 2.25 t (4H, CH_2S), 2.62 t (4H, $ArC\underline{H}_2$), 4.64 s (2H, OH), 6.83 s (2H, H_{arom}), 6.96 s (2H, H_{arom}).

Found, %: C 75.64; H 9.44; S 6.89.
$C_{28}H_{42}O_2S$.
Calculated, %: C 75.97; H 9.56; S 7.24.

Bis[2-(3,5-di-tert-butyl-4-hydroxyphenyl)ethyl] sulfide IIc was prepared similarly from 5.0 g (18.6 mmol) of **Ic** (synthesis time 8 h). The reaction product was recrystallized from 2-propanol. Yield 3.2 g (70%), mp 104°C. ^{1}H NMR spectrum, δ, ppm: 1.43 s (36H, *t*-Bu), 2.80 m (8H, $C\underline{H}_2C\underline{H}_2$), 5.08 s (2H, OH), 7.01 s (4H, H_{arom}).

Found, %: C 77.12; H 10.23; S 6.81.
$C_{32}H_{50}O_2S$.
Calculated, %: C 77.05; H 10.10; S 6.43.

Bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propyl] sulfide IId was prepared similarly from 5.0 g (17.7 mmol) of **Id** and recrystallized from 2-propanol. YIeld 4.3 g (90%), mp 71–73°C. ^{1}H NMR spectrum, δ, ppm: 1.43 s (36H, *t*-Bu), 1.89 m (4H, $CH_2C\underline{H}_2CH_2$), 2.55–2.58 t (4H, CH_2S), 2.61–2.64 t (4H, $ArC\underline{H}_2$), 5.03 s (2H, OH), 6.97 s (4H, H_{arom}).

Found, %: C 77.35; H 10.23; S 6.03.
$C_{34}H_{54}O_2S$.
Calculated, %: C 77.51; H 10.33; S 6.08.

Bis[4-(3,5-di-*tert*-butyl-4-hydroxyphenyl)butyl] sulfide IIe was prepared similarly from 5.0 g (16.8 mmol) of **Ie** and recrystallized from 2-propanol. Yield 3.1 g (70%), mp 89–90°C. ^{1}H NMR spectrum, δ, ppm: 1.43 s (36H, *t*-Bu), 1.66 m (8H, $ArCH_2C\underline{H}_2C\underline{H}_2$), 2.52–2.55 m (8H, $ArC\underline{H}_2$, CH_2S), 5.02 s (2H, OH), 6.96 s (4H, H_{arom}).

Found, %: C 77.65; H 10.59; S 6.12.
$C_{36}H_{58}O_2S$.
Calculated, %: C 77.92; H 10.53; S 5.78.

Bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)butyl] sulfide IIf was prepared similarly from 5.0 g (16.8 mmol) of **If** and recrystallized from 2-propanol. Yield 3.4 g (76%), mp 84–85°C. ^{1}H NMR spectrum, δ, ppm: 1.21–1.24 d (6H, $CH\underline{Me}$), 1.43–1.44 s (36H, *t*-Bu), 1.76–1.79 m (4H, $CHC\underline{H}_2CH_2$), 2.38–2.41 t (4H, CH_2S), 2.72 m (2H, $ArC\underline{H}$), 5.02 s (2H, OH), 6.95 s (4H, H_{arom}).

Found, %: C 77.51; H 10.30; S 6.00.
$C_{36}H_{58}O_2S$.
Calculated, %: C 77.92; H 10.53; S 5.78.

[1] The compounds were kindly submitted by A.P. Krysin (Novosibirsk Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences).

Bis[5-(3,5-di-*tert*-butyl-4-hydroxyphenyl)pentyl] sulfide IIg was prepared similarly from 5.0 g (16.1 mmol) of **Ig** and recrystallized from methanol. Yield 3.2 g (69%), mp 76–78°C. ^{1}H NMR spectrum, δ, ppm: 1.43 s (36H, *t*-Bu), 1.46–1.47 m (4H, $ArCH_2CH_2C\underline{H}_2$), 1.60–1.63 m (8H, $ArCH_2C\underline{H}_2C\underline{H}_2$), 2.50–2.53 t (8H, $ArC\underline{H}_2$, CH_2S), 5.00 s (2H, OH), 6.96 s (4H, H_{arom}).

Found, %: C 78.38; H 10.50; S 5.33.

Oxidation of lard was performed at 130°C under conditions of oxygen bubbling; the reaction cell was similar to that described in [15]. The lard sample weight was 50 g, and the concentration of antioxidants, 1 μmol per gram of lard. In the course of oxidation, 1-g portions of lard were withdrawn to determine the concentration of peroxides by iodometric titration [16]. The initial peroxide number of the lard was 0.002% iodine. The kinetic curves of the oxidation were plotted (Fig. 1a), and the induction period (time in which the peroxide number of 0.1 was attained) was determined graphically.

Oxidation of Vaseline oil was performed in a gasometric unit similar to that described in [17] at oxygen pressure of 1 atm. The total volume of the oil sample was 5 ml; the concentration of antioxidants was 2.5 μmol per gram of oil. Oxidation was performed at 175 or 180°C. The kinetic curves were plotted (Fig. 1b), and the induction period was determined as the intersection point of the tangents to the initial and final portions of the kinetic curves.

Three or four replicate runs were performed, and the average induction periods (deviations ≤3%) were determined.

CONCLUSIONS

(1) A series of bis[ω-(3,5-dialkyl-4-hydroxyphenyl)alkyl] sulfides differing in the extent of steric shielding of the phenolic OH group and in the length of the *p*-alkyl chain linking the phenolic and sulfide moieties were prepared.

(2) The sulfides synthesized are bifunctional antioxidants and are characterized by intramolecular synergism; the relative activities of these compounds are different, depending on the substrate.

(3) The sulfides show high performance as inhibitors of lard and Vaseline oil oxidation; they show promise as antioxidants of various fuels, lubricants, polymeric materials, and lipid substrates.

Received October 10, 2002

Abstract—The inhibiting activity of SO-3 antioxidant and its structural analogs in the model reaction of autooxidation of Vaseline oil was compared to that of synergistic mixtures of 2,4,6-trialkylphenols and didodecyl sulfide.

Sulfur-containing derivatives of sterically hindered phenols are highly effective inhibitors of free-radical oxidation of hydrocarbon substrates and occupy a prominent place among antioxidants. The high inhibiting activity of sulfur-containing phenolic antioxidants (SPAOs) is accounted for by a combination of the bifunctional mechanism of the antioxidant effect with the intramolecular synergistic effect, owing to which these compounds surpass in antioxidant activity the synergistic mixture of Ionol with didodecyl sulfide (DDS) [1–4]. Elucidation of the mechanism of intramolecular synergism is of scientific and applied importance, since it would allow development of new SPAOs surpassing the available analogs in activity. To solve this problem, it is necessary to study the interrelation between the SPAO structure and the effect of intramolecular synergism.

In this study, we analyzed the intermolecular synergistic effects in mixtures of 2,4,6-trialkylphenols (TAPs) with DDS and compared the extents of intramolecular synergism in bis[3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)-propyl] sulfide (SO-3 antioxidant) and its structural analogs, as applied to the model reaction of autooxidation of Vaseline oil (Tatkhimfarmpreparaty Chemical Pharmaceutical Production Association, Kazan). The structures of the compounds under consideration are given in Tables 1 and 2.

In the experiments, we determined the induction periods of oxidation of Vaseline oil in the presence of DDS, trialkylphenols, and SPAO taken separately (τ_{DDS}, τ_{PhOH}, and τ_{SPAO}, respectively) and of the synergistic mixtures trialkylphenol + DDS ($\tau_{PhOH+DDS}$). The effects of intermolecular synergism in TAP + DDS mixtures were characterized by the quantities $\Delta\tau_{inter}$ and $\Delta\tau'_{inter}$:

$$\Delta\tau_{inter} = \tau_{PhOH+DDS} - (\tau_{DDS} + \tau_{PhOH}),$$

$$\Delta\tau'_{inter} = \tau_{PhOH+DDS}/(\tau_{DDS} + \tau_{PhOH}).$$

Studies of the antioxidant activity of TAP + DDS mixtures showed that their effect is nonadditive: In all the cases, the induction periods were longer than the sum of the induction periods in the presence of the components taken separately (Table 1). The extent of the synergistic effect in TAP + DDS mixtures largely depended on the qualitative and quantitative composition of the synergistic mixtures.

According to the classification accepted in [5], the synergism observed in this case is of the kinetic type and is due to the effect of mixture components (TAP, DDS) on different oxidation stages. For example, sterically hindered phenol terminates oxidation chains by reacting with peroxy radicals:

$$PhOH + RO_2^{\cdot} \rightarrow PhO^{\cdot} + ROOH, \qquad (1)$$

and DDS decomposes hydroperoxides:

$$R–S–R \xrightarrow{ROOH} R–SO–R \xrightarrow{ROOH} R–SO_2–R,$$

suppressing degenerate chain branching:

$$ROOH \rightarrow RO^{\cdot} + HO^{\cdot}.$$

VII

Thus, both antioxidants protect each other from rapid consumption [6, 7].

Along with the kinetic synergism, TAP–DDS mixtures may also exhibit chemical synergism based on chemical reactions between the antioxidants and their transformation products [5]. For example, as demonstrated by the example of 2,6-di-*tert*-butyl-4-methylphenol (Ionol), DDS can react with oxidation products of phenolic antioxidants, regenerating the initial form of the inhibitor [7–9]. The sophisticated mechanism of synergistic interactions in TAP–DDS mixtures is indicated by the fact that, when the component ratio is varied (DDS concentration increased by a factor of 2), the induction periods grow nonlinearly.

The inhibiting activity of TAP used in combination with DDS varies depending on *o*- and *p*-substituents. The dimethyl substitution is apparently more effective than di-*tert*-butyl substitution. For example, at the molar ratios of TAP and DDS of 1 : 0.5 and 1 : 1, the mean values of $\Delta\tau'_{inter}$ for Ionol and phenols **I** and **IV** are 2.08 and 4.46, respectively, whereas for TMP, α-TP, and phenol **II** they are 3.62 and 6.88, respectively. Among the TAPs examined in combination with DDS, TMP is the most effective.

As for synergistic compositions based on 3-(3,5-dialkyl-4-hydroxyphenyl)-1-propanols **II**–**IV** in which the *p*-substituent is constant and the *o*-substituents are varied, the strongest inhibiting effect was observed with the **III** + DDS mixture, and the weakest, with the **IV** + DDS mixture; compound **III** taken separately is also more effective than **II** and **IV**.

The antioxidant activity of SPAOs was studied with SO-3 and its structural analogs **V**–**VII** as examples. These compounds differ in the extent of the steric shielding of the phenolic OH group and in the molar ratio of the phenolic and sulfide groups.

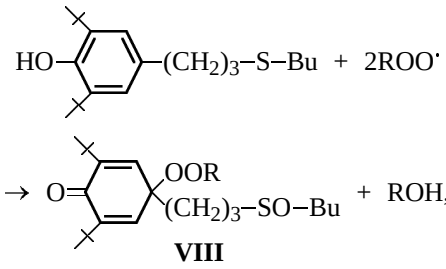
All the sulfides examined efficiently inhibit oxidation of Vaseline oil; in their inhibiting power they surpass both the structurally related TAPs and their synergistic mixtures with DDS (Table 2). This fact suggests that the SPAOs exhibit bifunctional mechanism of the antioxidant effect. The synergistic effect, which can be quantitatively characterized by the parameters $\Delta\tau$ and $\Delta\tau'$

$$\Delta\tau = \tau_{SPAO} - (\tau_{DDS} + \tau_{PhOH}),$$

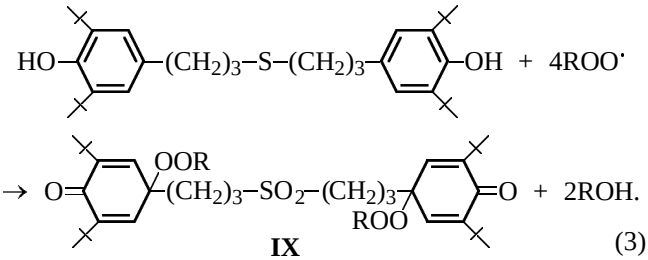
$$\Delta\tau' = \tau_{SPAO}/(\tau_{DDS} + \tau_{PhOH}).$$

is strongly pronounced.

The strong synergistic effect in SPAO is apparently due to its intramolecular nature and to the favorable steric arrangement of the phenolic and sulfide fragments, so that the hydroperoxide molecule formed from the corresponding radical with the participation of the phenolic group of the inhibitor can be inactivated by the sulfide moiety without escaping into the bulk of the substrate:



VIII (2)



IX (3)

Thus, the reaction of the antioxidant with an active radical yields a thermally stable alkanol and not the hydroperoxide.

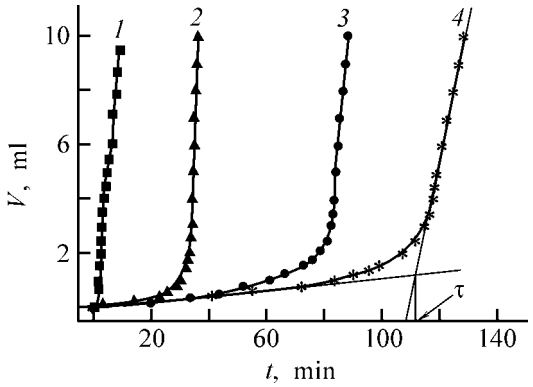
The extent of intramolecular synergism in SO-3 and sulfides **V**–**VII** can be characterized by the quantities $\Delta\tau_{intra}$ and $\Delta\tau'_{intra}$:

$$\Delta\tau_{intra} = \tau_{SPAO} - \tau_{PhOH+DDS},$$

$$\Delta\tau'_{intra} = \tau_{SPAO}/\tau_{PhOH+DDS}.$$

Among the sulfides examined, differing in the structure of *o*-alkyl substituents, the inhibiting activity increased in the order SO-3 > **VI** > **V**. A similar trend was observed with the structural analogs of these SPAOs, phenols **II**–**IV**.

It is known that the antioxidant activity of phenolic compounds is governed by two factors: extent of steric shielding of the phenolic OH group and energy of the PhO–H bond. Making larger the volume of the *o*-alkyl substituents, on the one hand, diminishes the energy of the PhO–H bond, which facilitates reaction (1), but, on the other hand, results in that this reaction becomes more hindered sterically. As a consequence, the most active in radical substitutions are phenolic antioxi-



Kinetic curves of Vaseline oil oxidation. Inhibitor: (*1*) none, (*2*) Ionol, (*3*) Ionol + DDS, and (*4*) SO-3. (*V*) Volume of oxygen taken up and (*t*) time. For comments, see text.

dants with one *o*-methyl group and one *o-tert*-butyl group [10], compounds **III** and **V** in our case.

The extent of intramolecular synergism in SO-3 and sulfides **V** and **VI** was evaluated by comparison of the induction periods in the presence of these sulfides and the mixtures based on structurally related phenols **II**–**IV** containing the same *p*-substituent. No correlation was observed between the antioxidant activity of the sulfides and the extent of intramolecular synergism. The quantity $\Delta\tau'_{intra}$ was maximal for sulfide **VI**, whereas the longest induction period in oxidation of Vaseline oil was observed with sulfide **V**.

The influence of the sulfur content on the antioxidant properties of SPAOs was examined with SO-3 and sulfide **VII** as examples. The extent of intramolecular synergism in SO-3 appeared to be somewhat higher than in **VII**: The mean $\Delta\tau'_{intra}$ values were 1.50 and 1.26, respectively. At the same time, the absolute inhibiting activity of **VII** was higher than that of SO-3 by a factor of 1.75. Apparently, the antioxidant activities of these compounds do not correlate with the extent of intramolecular synergism. The higher antioxidant activity of **VII** is due to the fact that sulfoxide **VIII** formed by reaction (2) can reduce an additional hydroperoxide molecule formed in the substrate without participation of the phenolic groups of the antioxidant. Oxidative transformations of SO-3 [reaction (3)] yield sulfone **IX**, incapable of inactivating additional hydroperoxide molecule; therefore, SO-3 is less effective as inhibitor.

EXPERIMENTAL

Oxidation of Vaseline oil was performed in a gasometric unit similar to that described in [11], at oxygen pressure of 1 atm. The total oil volume was 5 ml; the concentrations of antioxidants were 1.25 and 2.5 μmol per gram of oil. The oxidation was performed at 180°C. The kinetic curves were plotted (see figure), and the induction period τ was determined graphically as the intersection point of the tangents to the initial and final portions of the kinetic curves. Three or four replicate runs were performed; the average induction periods (deviations ≤3%) are listed in Tables 1 and 2.

Ionol and α-TP were purchased from Acros Organics; TMP, from Lancaster; 3-(3,5-dialkyl-4-hydroxyphenyl)-1-propanols **II**–**IV** were prepared at the Novosibirsk Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences); and the other antioxidants were synthesized as described in [12]. The main substance content in the antioxidants was no less than 97–99%.

CONCLUSIONS

(1) Mixtures of 2,4,6-trialkylphenols with dodecyl sulfide show a pronounced synergistic effect in inhibition of Vaseline oil oxidation; the extent of this effect depends on the molar ratio of the components and the structure of the phenolic component.

(2) The sulfur-containing phenolic antioxidants surpass in the inhibiting activity the mixtures of structurally related 2,4,6-trialkylphenols with dodecyl sulfide, suggesting the occurrence of intramolecular synergism. The extent of intramolecular synergism depends on the structure of the *o*-alkyl substituents and relative content of sulfur in the inhibitor molecule.

(3) The results of the experiments performed can be used for development of new high-performance sulfur-containing phenolic antioxidants with pronounced intramolecular synergism.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of New Surface-Active β-Amino Amides, Agents for Fixation of Dyes on Cotton Fibers, from *N*-[Tri(hydroxymethyl)methyl]acrylamide

G. S. Simonyan, R. S. Arutyunyan, N. M. Beileryan, and E. A. Grigoryan

Received July 16, 2002

Abstract—Amines containing amido and hydroxy groups were prepared. Their surface activity was studied, and the possibility of their use as cotton fiber modifiers was examined.

Surface-active amines (SAAs) containing various functional groups are used in various branches of industry [1], in particular, in production and dyeing of fibers [2, 3].

Usually, cotton and cellulose fibers cannot be dyed with acid dyes suitable for wool. For dyeing viscose fibers, small amounts of agents containing basic functional groups, e.g., synthetic resins or amino compounds modifying the fiber surface, are added to viscose spinning solution. Therefore, molecules containing amino, amido, hydroxy, and other functional groups exhibiting affinity for various types of dyes (direct, acid, active) may also be effective as modifiers improving the dyeability of cotton and cellulose fibers.

In this study, we prepared, following the procedure described in [4, 5], new nonionic SAAs **I**–**V** containing amino, amido, and hydroxy groups:

$$CH_2{=}CHC(=O)NHC(CH_2OH)_3 + R^1R^2NH \longrightarrow R^1R^2NCH_2CH_2C(=O)NHC(CH_2OH)_3,$$

where (R^1 + R^2) = $(CH_2)_5$ (**I**), $(CH_2)_2O(CH_2)_2$ (**II**); R^1 = R^2 = C_2H_5 (**III**), C_3H_7 (**IV**); R^1 = H, R^2 = C_6H_{13} (**V**).

We studied the colloidal-chemical properties of these compounds and their modifying effect on cotton fibers in the course of dyeing.

The SAAs were identified by ^{1}H NMR spectroscopy (Bruker ACG 250 spectrometer, D_2O, internal reference TMS) and mass spectrometry (TUEL 1MS-DX 300 device).

The SAAs were prepared as follows. A mixture of equimolar amounts of the amine and *N*-[tri(hydroxymethyl)methyl]acrylamide in water was kept at 293 K until the reaction was complete. The surface-active amines were separated from water by lyophilic drying and dried at room temperature.

3-Piperidinopropanoic acid *N*-[tri(hydroxymethyl)-methyl]amide I. *M* = 260; *m*/*z* = 261; $[M + H]^+$. ^{1}H NMR spectrum, δ, ppm: 3.5 s (6H, CH_2OH), 2.25 t (2H, $CH_2C{=}O$), 2.55 t (2H, NCH_2), 2.45 t [4H, $(CH_2)_2N$], 1.5 m [6H, $(CH_2)_3$], 8.05 s (NH), 4.05 s (3H, OH).

3-Morpholinopropanoic acid *N*-[tri(hydroxymethyl)methyl]amide II. *M* = 262; *m/z* = 263, $[M + H]^+$. ^{1}H NMR spectrum, δ, ppm: 3.5 s (6H, CH_2OH), 2.25 t (2H, $CH_2C{=}O$), 2.5 t (2H, NCH_2), 2.4 t [4H, $(CH_2)_2N$], 3.55 t [4H, $O(CH_2)_2$], 7.9 s (NH), 4.05 s (3H, OH).

3-(Diethylamino)propanoic acid *N*-[tri(hydroxymethyl)methyl]amide III. *M* = 248; *m/z* = 249, $[M + H]^+$. ^{1}H NMR spectrum, δ, ppm: 3.5 s (6H, CH_2OH), 2.2 t (2H, $CH_2C{=}O$), 2.6 t (2H, NCH_2), 2.5 t [4H, $(CH_2)_2N$], 0.95 t (6H, CH_3), 7.85 s (NH), 3.85 s (3H, OH).

3-(Dipropylamino)propanoic acid *N*-[tri(hydroxymethyl)methyl]amide IV. *M* = 276; *m/z* = 277,

$[M + H]^+$. ^1H NMR spectrum, δ, ppm: 3.5 s (6H, CH_2OH), 2.2 t (2H, $CH_2C{=}O$), 2.6 t (2H, NCH_2), 2.4 m [4H, $(CH_2)_2N$], 1.4 m (4H, CH_2CH_3), 0.85 t (6H, CH_3), 7.65 s (NH), 4.05 s (3H, OH).

3-(Hexylamino)propanoic acid *N*-[tri(hydroxymethyl)methyl]amide V. *M* = 276; *m/z* = 276, $[M + H]^+$. ^1H NMR spectrum, δ, ppm: 3.5 s (6H, CH_2OH), 2.2 t (2H, $CH_2C{=}O$), 2.6 t (2H, NCH_2), 2.5 t (2H, CH_2N), 0.9 t (3H, CH_3), 1.3 m [8H, $CH_3(CH_2)_4$], 7.6 s (2H, NH), 4.05 s (3H, OH).

The critical micelle concentration, CMC (M), of SAAs was determined from the isotherms of electrical conductivity (S m^{-1}) and surface tension σ (dyne cm^{-1}). The surface tension of aqueous SAA solutions was measured by the method of the maximum bubble pressure on a Rebinder device [6], and the electrical conductivity, as described in [7]. The measurement temperature was 303 ± 0.1 K.

The foaming power was evaluated by determining the foam stability of 1% aqueous SAA solutions from the ratio of the foam column height measured 5 min after foaming to its initial height [1].

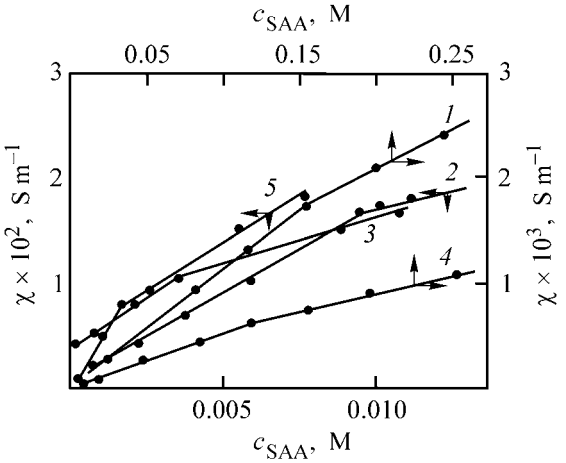
Colloidal-chemical studies showed that the amines synthesized are micelle-forming surfactants (see table). As expected (see table, figure), the CMC and σ decrease with increasing length of the alkyl groups in SAA molecules (σ of water at 303 K is 71.18 dyne cm^{-1}).

The SAAs examined show no foam stability, which is significant for modifiers of cotton and cellulose fibers. Taking into account the structures of SAAs and their σ values, we chose compounds **II** and **V** as modifiers of cotton tricot fabrics.

Two modification procedures were used. In the first procedure, tricot fabrics (bath ratio 50) were treated for 20–30 min at 353–363 K with 5–10% aqueous solutions of **II** and **V**. After treatment, the fabric was gently squeezed, washed with two portions of water, and dried in air. In the second procedure, to enhance the effect of SAAs, dimethylolurea was added at the end of treatment performed according to the first procedure. After that, the fabric was squeezed without washing and dried in air. For cross-linking and fixation of the modifier on the fibers, the fabrics were heat-treated for 5 min. Then the modified fabrics were dyed with a 3 g l^{-1} aqueous solution of Acid Blue anthraquinone dye for 30–40 min at 358–363 K (bath ratio 30). The fabrics dyed were washed with water and dried.

The tests showed that the tricot fabrics modified by the first procedure are dyed to moderate tints; with **V**, the tints are lighter than with **II**. It should be noted that the second procedure makes it possible to obtain darker tints fairly resistant to wet treatment.

Thus, amine-containing acid amides improve the dyeability of cotton fibers with acid dyes.



Isotherms of specific electrical conductivity χ of SAAs in water at 303 K. (c_{SAA}) SAA concentration. SAA: (*1*) **I**, (*2*) **III**, (*3*) **IV**, (*4*) **II**, and (*5*) **V**.

CONCLUSIONS

(1) Amines containing amido and hydroxy groups were prepared; they exhibit micelle-forming power and are poor foaming agents.

(2) The surface-active amines synthesized are active modifiers of cotton fibers in their dyeing with acid dyes.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Modification of Coal Humic Acids with Formaldehyde

I. N. Ryabova and G. A. Mustafina

Institute of Organic Synthesis and Coal Fuel Chemistry of the Republic of Kazakhstan, Karaganda, Kazakhstan

Received May 31, 2002

Abstract—Optimal conditions for condensation of coal humic acids with formaldehyde in alkaline medium were determined. The conversion of formaldehyde as influenced by temperature, reaction time, component ratio, and catalyst content was studied.

Humic acids (HAs) and products based on them are extensively studied today, because they contain various functional groups and can be used as environmentally safe and available raw materials for production of ion-exchange materials, soil structuring agents, etc.

However, low mechanical strength, strong swellability in water and aqueous acidic solutions, and complete dissolution in alkaline solutions hinder wide use of humic acids. Modification of HAs can enhance their reactivity, thermal and chemical resistance, and sorption properties and can affect their solubility [1, 2]. It was found that the modified products surpass HAs in some respects and show promise for industrial use.

In particular, HAs can be modified with formaldehyde (FA) and urea. However, if it is assumed that, in the case of FA, the reaction mechanism is similar to that by which phenol-formaldehyde oligomer is formed {schemes (1) and (2) [3]}, then, for the subsequent condensation with urea, the intermediate hydroxymethyl derivatives should be preserved to the maximum possible extent [scheme (1)]:

$$ArH + CH_2O = ArCH_2OH, \quad (1)$$

$$ArCH_2OH + ArH = ArCH_2Ar + H_2O. \quad (2)$$

If curing by the resol type is intended, then the highest content of FA is possible and desirable.

The aim of this study was to find the optimal conditions of polycondensation of HAs and FA in alkaline medium and to determine the effect of modification on the ion-exchange properties of the reaction products.

EXPERIMENTAL

We studied condensation as influenced by temperature (x_1), reaction time (x_2), molar component ratio (x_3), and catalyst content (x_4). Alkali was taken in a minimal amount required for complete conversion of the acid into salt, and only in this case, the reaction proceeds in aqueous solution under the homogeneous conditions; in neutral and acidic solutions, HAs are insoluble.

The process was optimized using the mathematical experimental design [4] based on a 4×5 matrix. The experimental results were obtained, and partial dependences $y_i = f(x_i)$ for the above process parameters (Fig. 1) plotted, in accordance with the spec-

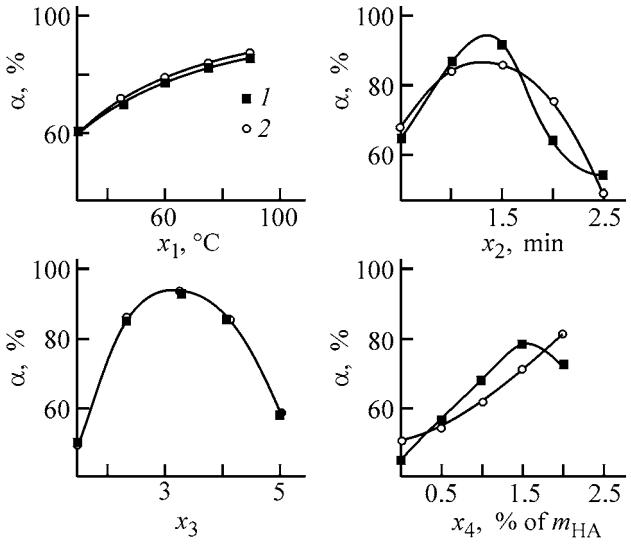

Fig. 1. Conversion α of FA in reaction with HAs vs. temperature x_1, reaction time x_2, HA : FA molar ratio x_3, and weight fraction of catalyst x_4. (*1*) Experimental and (*2*) calculated data.

Table 1. Levels of the parameters studied

Parameter	Level				
	1	2	3	4	5
x_1, K	303	318	333	348	363
x_2, h	0.5	1.0	1.5	2.0	2.5
x_3, HA : FA	1 : 1	1 : 2	1 : 3	1 : 4	1 : 5
x_4, % relative to m_{HA}	0	0.5	1.0	1.5	2.0

Table 2. Properties of the initial and modified compounds

Compound	SEC(Ca^{2+}), mg-equiv g^{-1}	Content of acid groups, mg-equiv g^{-1}	pK_i	pH of aqueous suspension
Initial coal	0.27	2.93	–	5.4
HA	0.88	4.35	4.50	3.8
HFP-1	1.40	5.48	4.54	3.3
HFP-2	1.39	5.87	4.51	2.9

ified conditions (Table 1). The reaction course was monitored by FA conversion.

The partial dependences of FA conversion y_i on parameters x_i were approximated with the following functions:

$$y_1 = 0.049\exp(-16.73/x_1), \quad (3)$$

$$y_2 = 0.38 + 0.74x_2 - 0.28x_2^2, \quad (4)$$

$$y_3 = 0.224 + 2.54x_3 - 2.19x_3^2, \quad (5)$$

$$y_4 = 0.74\exp(0.266x_4). \quad (6)$$

The generalized equation in terms of optimization parameters [4] is as follows:

$$y = y_1y_2y_3y_4 \times 0.69^{-4}. \quad (7)$$

The maximal FA conversion is observed under the following conditions: HA : FA molar ratio 1 : 3, 75°C, reaction time 1 h, and concentration of base catalyst 2% relative to the HA weight.

The kinetic curves of formation of hydroxymethyl derivatives are shown in Fig. 2; the highest yield is observed in the first 10–30 min, depending on the ini-

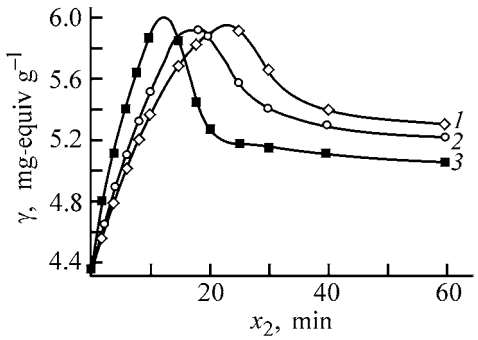

Fig. 2. Variation with time of the content of the acid groups γ at 333 K and HA : FA molar ratio of (*1*) 1 : 1, (*2*) 1 : 2, and (*3*) 1 : 3. (x_2) Reaction time.

tial component ratio. In all the cases, the maximal content of the hydroxymethyl groups is constant and equal to 5.9 mg-equiv g^{-1}, or about 25% of the initial content of the acid groups. The increase in the FA content only makes earlier the onset of condensation. Hence, to obtain the highest content of the hydroxymethyl derivatives at HA : FA molar ratio 1 : 3, catalyst weight fraction 2%, and 60°C, the reaction time can be decreased to 10 min.

Since an increase in the complexity of the polymeric chain can affect the sorption capacity of the ion exchanger, it was necessary to compare the polyelectrolytic and sorption properties of the modified products with those of the initial HAs. For this purpose, we determined the ionization constants (pK_i) and static exchange capacities (SEC) for calcium cations of the initial compound and two modified humic-formaldehyde polymers (HFPs) differing in the preparation conditions, namely, in the component molar ratio and reaction time [1 : 1 and 60 min for HFP-1; 1 : 2 and 15 min for HFP-2).

Addition of FA may cause redistribution of the electron density in the condensed HA system, enhancing the acid properties of weak acid groups and thus increasing the SEC. However, nearly similar pK_i values for the compounds in question suggest that this is hardly the case, and SEC is more probably determined by the content of the acid groups.

As seen from Table 2, the sorption capacity of the modified products increases by nearly a factor of 2, and the decrease in the reaction time does not affect noticeably the sorption capacity. This is probably due to the fact that the steric environment of the hydroxymethyl groups sorbing calcium cations hinders their participation in condensation. Thus, hydroxymethyl derivatives, as well as the condensation products, can be used as sorbents or soil-structuring agents. However, preparation of HFP-2 type products is preferable for the subsequent curing, because formation of meth-

ylene bridges from hydroxymethyl groups allows preparation of partially cross-linked polymers with higher molecular weight. As a result, the mechanical strength of these compounds increases, whereas their solubility in alkaline medium decreases, which expands the range of application of the modified polymers.

Humic acids were prepared from oxidized coal of the Oikaragaiskoe field; first the coal was treated with alkali and then humic acids were precipitated from aqueous solution with hydrochloric acid. Formaldehyde was used as 33% aqueous solution; the content of FA was monitored potentiometrically by oximation [5].

The resulting products were precipitated with 2 M hydrochloric acid; the precipitates were filtered off and washed to negative reaction of the filtrate with silver nitrate. The content of the acid groups in the products was determined by conductometry [6]. The experimental results were processed using the QUATTRO PRO 4.0 software.

The exchange capacity was determined under static conditions, using the ion exchangers in the H^+ form. Weighed portions of the samples (~0.4 g) were equilibrated with 50 ml of a 0.02 M calcium chloride solution. The concentration of metal cations in the equilibrium solutions was determined by complexomeric titration [7].

The averaged apparent ionization constants were evaluated graphically from potentiometric titration curves, for which purpose weighed portions of the samples (~0.4 g) were placed in 30 ml 1 M NaCl solution and titrated with 0.1 M NaOH solution.

CONCLUSIONS

(1) The optimal conditions for polycondensation of humic acids with formaldehyde are as follows: molar ratio of reagents molar ratio 1 : 3, 60°C, reaction time 60 min, catalyst weight 2% relative to that of humic acids.

(2) The maximal amount of the intermediate products is formed in the first 10–30 min, depending on the reagent ratio, but the magnitude of the maximum is independent of this ratio.

(3) Modification of humic acids with formaldehyde increases the sorption capacity for calcium cations, with the average ionization constant remaining unchanged.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Fast Reactions in Polymer Syntheses

Abstract—Specific features of fast polymerization processes necessitate use of new highly productive compact plug-flow tubular turbulent reactors. Theoretical examination of turbulent mixing in the reaction zone is made, allowing control of fast polymerization in polymer synthesis.

It has been demonstrated in studying liquid-phase synthesis of macromolecular compounds that many of such reactions are very fast (characteristic reaction time $\tau_{ch} < 0.1–0.01$ s). In this case, even very slow delivery of a polymerization initiator, use of dilute reagent solutions, and vigorous stirring cannot ensure isothermal polymerization. Chemical reactions of this type start long before the reagents delivered to the reaction zone are mixed. These reactions are diffusion controlled, being limited by reagent mixing kinetics, primarily, by the turbulence level in the reaction space, since the reagent mixing time is mostly longer than the characteristic reaction time ($\tau_{mix} > \tau_{ch}$).

This essentially new class of chemical reactions including syntheses of many polymeric products appears to be virtually not understood [1]. Among them are electrophilic polymerization of isobutylene, styrene, *p*-chlorostyrene, and cyclopentadiene; ionic polymerization of formaldehyde; irreversible polycondensation; copolymerization of isobutylene with isoprene and styrene; synthesis of chlorobutyl rubber; cationic polymerization of piperylene; formation of growth centers with Ziegler–Natta catalytic systems; initiation, particularly, in syntheses of stereoregular isoprene and butadiene rubbers and ethylenepropylene elastomers.

It has been demonstrated in a simple experiment modeling fast electrophilic polymerization of isobutylene in the presence of $AlCl_3$ (243 K) that the reaction proceeds essentially (to 80–95 wt %) locally, i.e., directly in the catalyst delivery zone [2]. In this case, the reaction mass temperature is not the same in different zones of the apparatus, depending on the local monomer and catalyst concentrations. Topochemically, fast polymerization is brush flame-like, with typical gradients of temperature, reagent concentrations (Figs. 1c, 1d), and product along the reaction zone. In this case, the reaction zone resembles a combustion front. In performing fast polymerization in bulk mixer apparatus, it is virtually impossible to achieve isothermal conditions in the reaction zone, so that, in actual processes, the temperature in the bulk of the reactor may rise by tens of degrees and no adequate modeling of the kinetic parameters can be made by the classical methods. As a result, among the specific features of fast polymerization are nonuniform molecular structure of the resulting polymeric products and, therefore, their performance characteristics, scatter of molecular characteristics of the polymer (molecular weight MW and molecular-weight distribution MWD), and, finally, irreproducibility of experiments.

An important result obtained analyzing experimental data and solving the inverse problem for the case of cationic polymerization of isobutylene, as an example of fast polymerization, was the establishment of the possibility of attaining a macroscopic

1070-4272/03/7602-0264 $25.00

quasiideal plug-flow mode in turbulent flows confined by an impermeable cylindrical wall, having no match in the present-day technology. This mode provides quasi-isothermal reaction conditions by virtue of formation of a plane front of reagent concentrations and temperature over the interval confined by strictly fixed radii R_{max} and R_{min} of the jet reaction zone (Figs. 1a and 1b). Also, this mode ensures highly efficient mixing of the reagents and, as a result, leads to uniform radial distribution of the reagent concentrations and temperature throughout the reaction zone. Taking into account the longitudinal turbulent mixing of reagents distinguishes this mode from the known ideal plug-flow mode in laminar flows.

The quasi-ideal plug-flow mode is achieved at reagent flow velocity V in the reaction zone sufficiently high to provide high turbulence level. In this case, important factors influencing the reagent mixing time τ_{mix} and molecular-weight characteristics of the resulting polymeric products (MW and MWD) are the geometry and design of the reaction volume. Conditions of establishment of the quasi-ideal plug-flow turbulent mode (planar reaction front) in fast polymerization are determined by the relationship $\tau_{mix} = R^2/D_{turb} < \tau_{ch} = 1/k_t$ (Figs. 1a and 1b), where D_{turb} is the turbulent diffusion coefficient ($m^2\ s^{-1}$) and k_t, chain termination rate constant (s^{-1}). Therefore, there exists a critical radius R_{cr} corresponding to transition from the quasi-ideal plug-flow mode to the brush flame mode:

$$R_{cr} = \sqrt{D_{turb}/k_t}. \quad (1)$$

With decreasing reaction mixture velocity V within the turbulent mode limits, the "erosion" of the temperature front in the reaction zone through longitudinal turbulent diffusion and heat transfer in the direction opposite to that of flow motion results in that the temperature is virtually constant throughout the reaction volume (quasi-isothermal mode). This is the basic distinction from the ideal plug-flow mode. Making D_{turb} higher by raising V or changing design of the reaction zone leads to the corresponding increase in the reagent conversion. In this case, the residence time of the reagents in the reaction zone, τ_r, decreases, and the reaction zone itself becomes more compact (Fig. 2). Furthermore the temperature fluctuations in the reaction zone are smoothed, regardless of the fact that the total product yield and heat liberation increase [2].

The establishment of the possibility of attaining the quasi-ideal plug-flow mode described by Eq. (1) in the reaction zone allowed development of a new class of chemical apparatus, based on tubular turbulent reactors (Fig. 3) [3, 4]. The use of such compact highly productive power- and resource-saving reactors operating in the quasi-ideal plug-flow mode

(Fig. 3) is the optimal solution of the problem of fast polymerization.

This new type of apparatus combines the advantages of plug-flow tubular reactors and stirred continuous reactors, also demonstrating its own distinctive features and technological advantages such as (a) possibility of achieving high turbulence level along the anture length of a divergent-convergent apparatus (Fig. 4) [5]; (b) effect of the kinetic and hydrodynamic parameters of the process on the optimal size of the reaction zone [2]; (c) influence of the reaction zone geometry on the yield and composition of the product (Fig. 2); (d) possibility of attaining the ideal plug-flow turbulent mode at $\tau_{ch} \geq \tau_{mix}$, which is of great importance, allowing the process to be performed under quasi-isothermal conditions; (e) possibility of obtaining self-similar flows at Reynolds number Re $\geq 800/f$, where $f = 0.117 + 0.0488\gamma - 0.0012\gamma^2 + 1.374 \times 10^{-5}\gamma^3 - 5.9 \times 10^{-8}\gamma^4$ and γ is the diffuser divergence angle, specifically, at $\gamma = 30-80°$ and Re $\geq 950 \pm 50$ [6]; (f) possibility of controlling fast polymerization by, e.g., varying the reaction zone geometry (d, L) and hydrodynamic parameters in the reactor (V, D_{turb}) [7].

Previously we obtained for divergent-convergent tubular turbulent reactors operating in the self-similar flow mode relationships for the mean turbulent diffusion coefficient D_{turb}, specific kinetic energy K of turbulence and its dissipation ε, and also for the characteristic times of turbulent (τ_{turb}), micro- (τ_{micro}), and mesomixing (τ_{meso}), which allow optimization of the reactor design and operation mode [7]:

$$D_{turb} = 0.012 f V_c d_c,\ K = 0.048 f^2 V_c^2,\ \varepsilon = 0.021 f^3 V_c^3/d_c,$$

$$\tau_{turb} = 80.65 l^2/f V_c d_c,\ \tau_{micro} = 119.4[\nu d_c/(f^3 V_c^3)]^{0.5},$$

$$\tau_{meso} = 3.62(l^2/d_c)^{1/3}/(f V_c). \quad (2)$$

Here V_c is the reagent flow velocity in the confuser (m s^{-1}), d_c, the diameter of the narrow section of the reaction zone (m); ν, the kinematic viscosity (m^2 s^{-1}); l, the reaction zone length (m).

Comparison of the characteristic times can reveal the mechanism controlling the smoothing of the reagent concentration fields in the reaction zone, which, in its turn, allows control of the mass transfer and optimization of the reactor design.

Performing fast polymerization in plug-flow turbulent tubular reactors (planar reaction front) allowed development of a new method for estimating some kinetic parameters, particularly, the chain propagation

and termination rate constants k_p and k_t for cationic polymerization of isobutylene [2]. It is typical of the plug-flow mode that the effective time of reagent residence in the reaction zone, $\tau_r = (L/V)_{ef}$, controlling the reaction zone length L at which the polymer yield amounts to 90%, is related to with kinetic parameters of the process by

$$\left(\frac{L}{V}\right) = -\frac{1}{k_t}\ln\left\{1 + \frac{k_t}{k_p[\mathbf{A}^*]_0}\ln\left[0.1 + 0.9\exp\left(\frac{k_p[\mathbf{A}^*]_0}{k_t}\right)\right]\right\}, \quad (3)$$

where $[\mathbf{A}^*]_0$ is the initial catalyst concentration.

A study of the polymer yield as a function of L or V at various catalyst concentrations and $R_{cr} > R$ allowed experimental determination of the rate constants for certain elementary reactions occurring in fast polymerization of isobutylene. For example, at 243 K, k_p and k_t were estimated to be 10^6 l mol^{-1} s^{-1} and 17.5 ± 5 s^{-1}. Note that the experimental k_p is, in general, consistent with published data, and k_t was estimated for the first time.

From the experimental characteristic residence time τ_r we estimated the rate constant of chlorination of butyl rubber with chlorine ($k \sim 150 \pm 50$ l mol^{-1} s^{-1} [8, 9]). This polymer-analogous reaction was carried out in a divergent-convergent tubular turbulent reactor (diffuser radius R_d = 0.025 m, confuser radius $R_c = R_d/2$, L = 2 m, reactor volume ~0.004 m^3) filled with special Teflon packing. Based on the results obtained, the indicated reaction was related to a new class of fast chemical reactions [1], and it was concluded that it is advisable to perform this reaction in tubular turbulent reactors.

In many cases, polymer synthesis among them, the major stages of the process are slow themselves, but are preceded by some primary fast reactions. For example, this is the case in polymer synthesis with Ziegler–Natta catalytic systems.

With the use of such systems as V–Al, Ti–Al, Nd–Al, etc. for synthesis of, e.g., ethylene–propylene, *cis*-1,4-isoprene, *trans*-1,4-isoprene, and *cis*-1,4-butadiene rubbers, the characteristic time of chain propagation is about 10^2 s or more. At the same time, the rate of initiation to give growth centers is faster by many orders of magnitude, i.e., it is a fast reaction controlled by reagent mixing. As a result, when a catalyst and a co-catalyst are delivered directly to a mixing vessel, the resulting distribution of the forming growth centers is nonuniform at both micro- and macrolevels. This leads also to a nonuniform monomer distribution throughout the reactor, which deteriorates molecular characteristics of the resulting polymers and, therefore, their quality.

Characteristics of ethylene–propylene–ethylidenenorbornene terpolymer rubbers obtained without and with divergent-convergent pre-reactor

Characteristic	Flow chart	
	without stage separation	with stage separation
Content of monomeric units, %:		
ethylidenenorbornene	28	29
terminal vinylidene	0.29	0.19
Content of blocks of ethylene units, %		
long	0.17	0.06
short	1.1	0.9
Fraction of propylene units in long blocks, %	1.9	2.6
Degree of branching, %	0.29	0.17

It appeared expedient to separate the fast stage of growth center formation from the slow stage of copolymerization of olefins and dienes on Ziegler–Natta catalysts. It was demonstrated that, for each of these stages, it is possible to provide ideal or practically ideal conditions. For the first, fast stage, this can be done using a divergent-convergent tubular turbulent pre-reactor [4], and for the second, slow stage, with a stirred continuous reactor. With the use of a divergent-convergent tubular turbulent pre-reactor, the reagent mixing time τ_{mix} is always shorter than the reaction mixture residence time τ_r. This guarantees that all the potential growth centers of polymerization enter the continuous polymerizer in the already formed state, and the ideal mixing model appears to be valid in this case.

Such measures as optimization of the V–Al catalytic system composition and homogenization of flows going to the polymerizer (including separation of the fast stage of formation of growth centers and slow stage of copolymerization of ethylene and propylene using a divergent-convergent tubular turbulent pre-reactor) remarkably improved the quality of ethylene-propylene rubbers (see table) and reduced the amount of off-grade products and wastes [10].

In manufacturing ethylene-propylene rubbers, the presence of a gas–liquid interface result in that the diffusion limitations and reaction mixture separation into components (diluent, monomers, hydrogen, etc.) occur upon delivery of the initial flows directly in

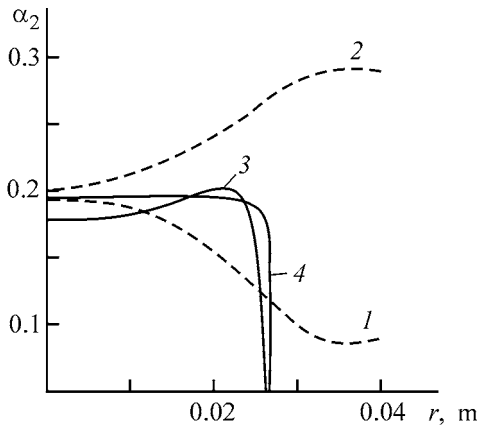

Fig. 5. Distribution of the volume fraction of the dispersed phase, α_2, across the radius of the tubular reactor, *r*, in (*1, 2*) diffuser and (*3, 4*) confuser parts. d_d = 0.08 m, d_c = 0.05 m, L_{dc} = 0.27 m, and V = 16 m s^{-1}. Continuous phase density ρ_1 (kg m^{-3}): (*1, 3*) 6.93, (*2*) 1111, and (*4*) 998.2. Dispersed phase density ρ_2 (kg m^{-3}): (*1, 3*) 640, (*2*) 0.689, and (*4*) 1111.

stirred continuous reactor are responsible for formation of the compositionally inhomogeneous copolymer both in a single polymerizer and in reactors connected in parallel. The use of divergent-convergent tubular turbulent pre-reactor allows efficient saturation of a hydrocarbon diluent with gaseous monomers and hydrogen and continuous supply of a homogeneous gas–liquid mixture to continuous polymerizers connected in parallel. In this case, the multiphase flow in the tubular channels of the divergent-convergent reactor is characterized by the occurrence of some circulation zones. Near an impermeable wall, the particles start to move in the direction opposite to the main flow under the action of a pressure gradient. In this region, the liquid flow is in rotatory motion, which results in an unexpected phenomenon: under the action of the centrifugal force, phase separation starts, depending primarily on the density of components involved in dispersion [11]. With remarkable difference between the densities of the continuous (ρ_1) and dispersed phases (ρ_2) and at $\rho_1 < \rho_2$, in the peripheral parts of the reactor, the volume fraction of the dispersed phase α_2 decreases by virtue of rejection of particles toward the impermeable wall or reactor periphery under the action of the centrifugal force (Fig. 5). In the case of $\rho_1 > \rho_2$, α_2 in the circulation zone increases. However, a uniform two-phase flow characterized by a homogeneous distribution of α_2 throughout the reactor section is formed in the narrow section of the reactor, i.e., in the confuser (Fig. 5).

Based on a numerical solution of the equations of two-phase flow motion with the corresponding boundary condition with respect to the geometrical parameters of the mixing zone and physical and dynamic parameters of the disperse system, Takhavutdinov *et al.* [12] derived a relation for the specific interfacial area, i.e., for the size of dispersed inclusions [12]:

$$\varepsilon = 0.625\left(\frac{f_E f^3 V^3}{d_c}\right)\left[1 + \left(\frac{U_2}{U_1 + U_2}\right)^2\left(\frac{\rho_1}{\rho_2}\right)^{-0.3}\right], \quad (4)$$

$$d_2 = 0.099(\sigma/\rho_1)^{0.6}\varepsilon^{0.4}, \quad (5)$$

$$f_E = -0.221 + 0.362(d_d/d_c) - 0.186(d_d/d_c)^2 - 0.031(d_d/d_c)^3 - 0.048(L_{dc}/d_d) - 7.92 \times 10^{-3}(d_d/d_c)(L_{dc}/d_d) - 3.08 \times 10^{-3}(L_{dc}/d_d)(d_d/d_c)^2 - 0.015(L_{dc}/d_d)^2 + 5.15 \times 10^{-3}(d_d/d_c)(L_{dc}/d_d)^2,$$

where U_1 and U_2 are the flow rates of, respectively, continuous and dispersed phases (m^3 s^{-1}); L_{dc}, the length of the diffuser-confuser unit (m); σ, the surface tension (mPa s).

The results obtained allow optimization of the operational parameters of a divergent-convergent tubular turbulent pre-reactor with account taken of the effects of phase separation and inhomogeneous distribution of components in the disperse system. For example, such an optimization has been done for the case of full-scale copolymerization of ethylene with propylene on Ziegler–Natta catalysts [10].

In synthesis of stereoregular *cis*-1,4-isoprene rubbers on Ti–Al (SKI-3) and Nd–Al catalytic systems (SKI-5), the above-described separation of the stages of formation of growth centers and polymerization with the use of a tubular turbulent pre-reactor also allows improvement of molecular characteristics of the resulting products [13, 14]. In the standard process, a catalyst and a monomer are introduced in the first reactor of the cascade of stirred continuous polymerizers. In this case, mixing of the reagents and formation of a catalytic system are inefficient.

Installing a divergent-convergent pre-reactor before the cascade of stirred continuous polymerizers provided an increase in the *cis*-1,4-units in the macromolecules of stereoregular polyisoprene and also improvement in the product homogeneity [15]. This ensured for the first time a correlation between the plasticity of the industrial product and its Mooney viscosity. As a result, it became possible to improve the product quality to the theoretical level and to obtain SKI-5 stereoregular 1,4-isoprene rubber of various grades in

the same apparatus, which could not be done with the existing stirred continuous reactors. Furthermore, in synthesis of SKI-5, the process output increased from 34 ± 1 to 40 ± 1 t h^{-1}, the amount of the Nd–Al catalyst was reduced by a factor of 2–4, and the rate of skin formation on the inner walls of process equipment decreased by about an order of magnitude. Also, the efficiency of the chain-transfer agent, diisobutyl aluminum hydride, increased. It was demonstrated in laboratory experiments that, in performing the stages of formation of growth centers and initiation of isoprene polymerization with the Ti–Al catalytic system, use of divergent-convergent tubular turbulent reactors ensures an increase in the molecular weight of the resulting polymers (Fig. 6).

Polymeric products synthesized on Ziegler–Natta catalysts mostly demonstrate wide MW distribution. One of the reasons is the occurrence of several types of growth centers with different kinetic activities.

Solution of the inverse MWD problem allows derivation of growth center activity distribution functions (Fig. 7). Each maximum in the distribution curve corresponds to at least one type of growth centers characterized by certain chain termination probability. The curves $\Psi(\ln \beta)\beta = \beta^2\varphi(\beta) - \ln M$, where β is the reciprocal of the mean degree of polymerization M_p characterizing the chain termination probability and equal to $(1/m)(r_0/r_p)$ (r_p is the chain propagation rate, r_0, integral termination rate, and m, molecular weight of the monomer), allow estimation of the number and relative contribution of each type of growth centers separately, using normal distribution functions [16].

A study of the growth center activity distribution for the case of isoprene polymerization on Ti–Al catalytic systems revealed that, with reactive turbulent mixing instead of standard mixing used in synthesis of isoprene rubber in the growth center formation and initiation stages, the active centers responsibe for formation of the low-molecular-weight fraction disappear (Fig. 7), allowing production of polymers with higher MW and narrow MWD [17].

Finally, performing the fast stage (growth center formation and initiation) in tubular turbulent jet reactors and the slow stage (copolymerization olefins and dienes), in stirred continuous reactors, with the resulting considerable increase in the turbulence level in the first stage, allows a significant improvement of the molecular-weight characteristics of the polymeric products obtained, control over the number of growth centers, and decrease in catalyst consumption in industrial processes.

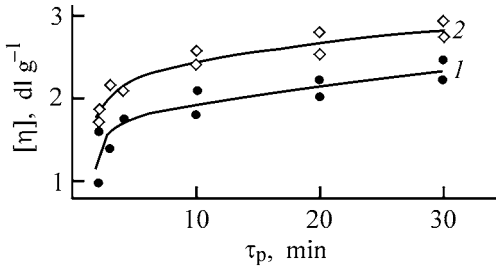

Fig. 6. Intrinsic viscosity [η] vs. the polymerization time τ_p in polymerization of isoprene on the $TiCl_4$–$Al(i\text{-}C_4H_9)_3$–piperylene catalytic system. c_{Ti} = 3.2 mM, $c_{\mathbf{M}}$ = 1.5 M, Ti : Al : piperylene = 1 : 0.83 : 4. (*1*) Without stage separation and (*2*) with stage separation using a tubular turbulent pre-reactor; the same for Fig. 7.

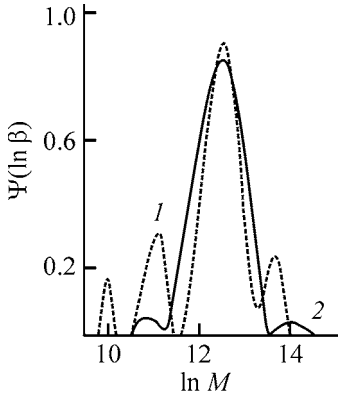

Fig. 7. Growth center activity distribution for the $TiCl_4$–$Al(i\text{-}C_4H_9)_3$–piperylene catalytic system in polymerization of isoprene in toluene. $c_{\mathbf{M}}$ = 1.5 M, c_{Ti} = 7 mM, Ti : Al : piperylene = 1 : 1.02 : 4. (*M*) Degree of polymerization.

CONCLUSIONS

(1) The specific features of fast polymerization processes make it expedient to use compact tubular turbulent reactors in industrial synthesis of polymers.

(2) Slackening of the diffusion limitations in polymer synthesis by virtue of intensification of turbulent mixing in the reaction zone allows estimation of kinetic parameters of polymerization and polymer-analogous reactions, optimization of the molecular-weight characteristics of the resulting polymeric products, and, finally, control of the process as a whole.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Copolymers of Unsaturated β-Diketones with Styrene and Methyl Methacrylate

Mechnikov National University, Odessa, Ukraine

Received June 3, 2002

Abstract—Copolymerization of styrene and methyl methacrylate with various unsaturated β-diketones was studied. The influence exerted by the reaction temperature, structure of β-diketone, and its content in the comonomer mixture on the kinetic parameters of copolymerization and molecular weights of the products was examined.

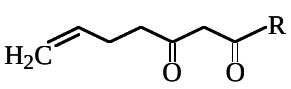
In the past decades, there has been a great deal of interest in synthesis and application of polymers containing various functional groups in the pendant chains [1, 2]. Functional polymers are prepared by polymer-analogous transformations, polycondensation, or homo- and copolymerization of appropriate monomers. The last procedure seems to be more efficient; however, it has been studied relatively poorly because the initial monomers are difficultly accessible.

β-Diketones are well-known chelating agents. However, there have been only few reports of polymers prepared from unsaturated β-diketones. Homo- and copolymerization of methacryloylacetone (MAC) [3, 4] and its derivatives [5] have been studied fairly well. Polymeric ligands and metal complexes derived from *p*-vinylbenzoylacetophenone have been prepared [6]. β-Diketone monomers suitable for preparing functional polymers have been reported [7, 8].

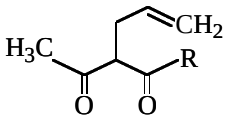
Our goal was to carry out a kinetic study of copolymerization of various unsaturated β-diketones with styrene or methyl methacrylate (MMA).

EXPERIMENTAL

In the experiments, we used linear



{R = CH_3 [7-octene-2,4-dione (lin.CH_3)], CF_3 [1,1,1-trifluoro-7-octene-2,4-dione (lin.CF_3)], C_6H_5 [1-phenyl-6-heptene-1,3-dione (lin.C_6H_5)]} and branched β-diketones:



{R = CH_3 [3-allylpentane-2,4-dione (br.CH_3)], CF_3 [3-allyl-1,1,1-trifluoropentane-2,4-dione (br.CF_3)], C_6H_5 [2-allyl-1-phenylbutane-1,3-dione (br.C_6H_5)].

For comparison, we also tested MAC. The monomers were prepared, purified, and identified according to [3, 9, 10].

All the unsaturated β-diketonates synthesized, except MAC, undergo no radical homopolymerization in the presence of initiators [benzoyl peroxide, BP; azobis(isobutyronitrile), AIBN] at temperatures of up to 90°C. This may be due to steric hindrance and also to appreciable resonance stabilization of the monomers. These factors apparently govern the reactivity in polymerization for all the unsaturated β-diketonates synthesized. However, such monomers as MAC and the β-diketones synthesized, according to the existing concepts, must readily enter copolymerization. Furthermore, the C–C bond linking two different units in the backbone will be stronger if the substituents in the units have different electronegativities [11]. The electronegativity of monomers can be evaluated using the Alfrey–Price *Q*–*e* scheme which quantitatively relates the reactivity (*Q* factor) and polarity (*e* factor) of the monomers. The *e* factor is +0.57 for MAC and –0.80 for styrene [4], which suggests a high stability of MAC–styrene copolymers.

We have studied bulk copolymerization of all the unsaturated β-diketones synthesized with styrene and

* (v_{pol}^{in}) Initial polymerization rate; molecular weight: (M_n) number-average, (M_w) weight-average, and (M_s) sedimentation-average; (M_w/M_n) degree of polydispersity of the polymer; (M_s/M_w) width of molecular-weight distribution.

of some of them with MMA. Experiments were performed in ampules and dilatometers at 80 and 70°C and various volume ratios of the comonomers. The reaction kinetics was monitored dilatometrically. Prior to all the experiments, the ampules and dilatometers were purged with argon to remove oxygen. The molecular weights of the copolymers were determined by gel-permeation chromatography on a Waters-200 device calibrated using monodisperse polystyrene references (Waters).

The kinetic parameters of copolymerization of β-diketones with styrene, intiated by BP, and molecular weights of the copolymers are listed in Table 1. In all the cases, the polymerization rate and the molecular weight of the polymer decrease with increasing concentration of monomeric β-diketone. With both linear and branched monomers (in the latter case, to a greater extent), the copolymerization rate tends to decrease in the order $C_6H_5 > CF_3 > CH_3$.

It is interesting that both the polymerization rate and the molecular weights of copolymers decrease with increasing content of β-diketones. For example, in the case of br.CF_3 and br.C_6H_5, the polymerization rate decreases by approximately a factor of 2.5 and 1.7, respectively, and the molecular weights of the resulting polymers decrease to approximately the same extent. With lin.CH_3, the reaction rate decreases by a factor of 1.5, and the molecular weight of the copolymer, by a factor of 1.7; with lin.C_6H_5, these factors are 1.7 and 1.5, respectively. With increasing content of the unsaturated β-diketone in the initial mixture (for branched β-diketones and MAC), the degree of polydispersity of the copolymers, M_w/M_n, grows (Table 1), this ratio being the highest for MAC copolymers.

These trends might be due to decreased activity of the radicals generated from the β-diketones, which could result in slower chain propagation and hence in slower polymerization and lower molecular weight of the product. Indeed, in polymerization of MAC, the propagating radical is conjugated with the quasiaromatic ring, being therefore less reactive. However, in the other monomers, there is no such conjugation. Nevertheless, the general pattern is similar with all the monomers.

For example, the parameters characterizing copolymerization of MAC, except the molecular weights of the products, are very similar to those obtained with lin.CH_3 (Figs. 1a, 1b). Thus, specifically the quasiaromatic chelating ring in the β-diketone molecules, rather than the decreased activity of the radicals and position of the double bond (in MAC and in the linear and branched monomers it is different) is the major factor responsible for the features observed.

Burnett *et al.* [12] have shown that diethyl malonate forms very stable complexes with nitroxyl radicals

owing to strong interaction of the unpaired electron with two carbonyl groups. In homo- and copolymerization of unsaturated β-diketones, the propagating radicals apparently form similar complexes. Complexation of the radicals makes them incapable of being involved in chain propagation, and polymerization occurs with only the "free" radicals. The system behaves as if the monomer had lower reactivity, but actually decreased is the steady-state concentration of the propagating radicals [13]. A similar effect will apparently be observed with all the monomers containing the β-diketone ring; therefore, such monomers polymerize slowly, yielding polymers with lowered molecular weight. A similar effect has been observed with the metal complexes; in this case, the radicals were scavenged by metal ions [14]. We showed in this study that such an effect is also characteristic of metal-free β-diketones. Complexes with radicals are also formed by simpler electron-rich compounds (alkenes, aldehydes, ketones), but these complexes have considerably lower stability constants [15]. The compounds containing developed π systems (β-diketones, porphyrins) form very stable complexes with radicals. It is interesting that the complexation of monomers containing a heteroatom with radicals involves the lone electron pairs of heteroatoms [13], rather than π electrons of the double bond.

Shapiro *et al.* [16] have studied by ^{1}H NMR spectroscopy the complexation of radicals with metal porphyrins and with their metal-free analogs. In the latter case, π–*p*–(π) complexes involving the porphyrin π system and the *p* electrons of the monomer are formed. Gridnev and Nechvolodova [17] obtained, when studying polymerization of vinylpyrrolidone, direct evidence of termination of propagating radicals on the porphyrin macroring. Depending on the structure of the porphyrin (presence of meso substituents), the propagating radicals add either at the *meso*-position or at the α- or β-position of the pyrrole rings; one porphyrin molecule can terminate two radicals. A similar effect was observed in polymerization of other monomers: acrylic acid, vinyltriazole, 4-vinylpyridine, etc. Formation of peroxy radicals in these experiments was fully excluded, since these radicals decompose porphyrins so that the Soret band disappears. If polymerization is performed in the presence of a metal porphyrin, the polymeric radicals are scavenged by metal atoms [18], similarly to polymerization in the presence of metal β-diketonates. In the process, an adduct containing the Co–C bond is formed, and the nature of the monomer from which the radical has been generated plays a decisive role in the complexation. For example, in polymerization of styrene, a secondary radical is generated, which readily forms a complex with Co(II), whereas tertiary radicals generated from MMA form no adducts because of steric hindrance.

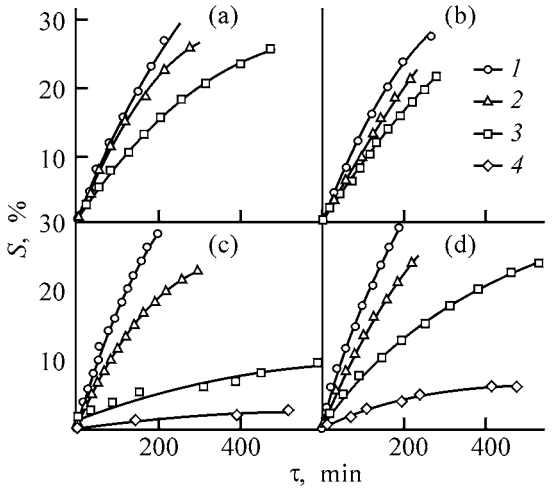

Fig. 1. Extent of polymerization *S* vs. time τ. BP initiator, c_{in} = 0.01 M, 80°C. (a) MAC, (b) lin.CH_3, (c) br.CH_3, and (d) br.CF_3. β-Diketone : styrene volume ratio: (*1*) 1 : 10, (*2*) 1 : 5, (*3*) 1 : 1, and (*4*) 5 : 1.

The kinetic parameters of copolymerization of branched β-diketones with styrene in a wide range of comonomer concentrations are given in Table 2 and in Figs. 1c and 1d. At low concentrations of β-diketones, the polymerization rates are close for all the monomers. At the comonomer ratios of 1 : 1 and especially 5 : 1, the polymerization rates drastically decrease, and the rates become different for different

monomers. The kinetic curves virtually level off, indicating that the polymerization ceases.

The temperature dependence of the copolymerization rate was studied with lin.C_6H_5 as example (Table 3). The calculated effective activation energy E_a is 69 kJ mol^{-1} at low β-diketone concentrations; at higher concentrations, it decreases to 58 kJ mol^{-1}. Comparison of this value with the activation energy of homopolymerization of MAC (0.12 M in ethanol), E_a = 58 kJ mol^{-1} [19], shows that they closely coincide. The results of copolymerization of some β-diketonate monomers with MMA are listed in Table 4. With MMA, compared to styrene, an increase in the β-diketone concentration has a weaker effect on the mean copolymerization rate.

CONCLUSIONS

(1) Copolymerization of unsaturated β-diketones of various structures with styrene or methyl methacrylate yields copolymers containing β-diketone units.

(2) The copolymerization rate and molecular weight of the copolymers decrease, and the polydispersity grows as the content of unsaturated β-diketone in the polymerizing mixture is increased. This may be due to complexation of the propagationg radicals with the quasiaromatic β-diketonate ring.

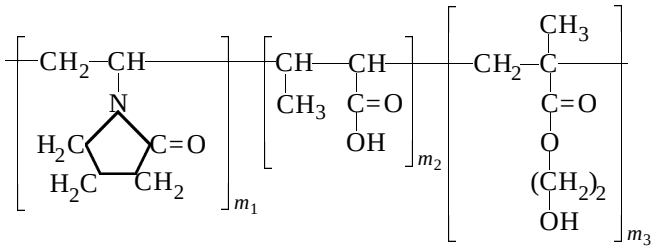
Abstract—Water-soluble branched *N*-vinylpyrrolidone–crotonic acid–2-hydroxyethyl methacrylate terpolymers containing labile interchain urethane cross-links were prepared. Their molecular-weight characteristics were determined, and the hydrolytic stability under conditions close to those in a living body was evaluated. Polymeric salts of gentamicin were prepared from linear and branched chemodegradable *N*-vinylpyrrolidone terpolymers.

Chemodegradable polymers based on *N*-vinylpyrrolidone (VP) and containing labile interchain cross-links readily hydrolyzable in a living body show much promise as carriers for biologically active substances (BASs). Owing to degradability, the molecular weight of such (co)polymers can exceed the limit of 40 000 determined by the possibility of elimination through kidneys. In a living body, such polymers will undergo gradual hydrolysis (biodegradation) to low-molecular-weight fragments that can be removed by kidney filtration. Previously, we prepared branched chemodegradable copolymers of VP with allylamine, containing –CH=N– cross-links which are readily hydrolyzed under conditions close to those in a living body [1]. Another chemically labile fragment is the urethane fragment –O–C(=O)–NH– [2, 3].

The goal of this study was to prepare branched chemodegradable polymers containing interchain urethane cross-links, to analyze their molecular-weight characteristics, to evaluate the rate of their hydrolysis in saline at 37°C, and to test them as carriers for gentamicin antibiotic.

As the initial linear copolymers, we chose previously prepared [4] VP–crotonic acid (CA)–2-hydroxyethyl methacrylate (HEMA) terpolymers **I**:



I

$$m_1 + m_2 + m_3 = 100 \text{ mol \%}.$$

These water-soluble terpolymers, biocompatible with a living body, have been successfully used as carriers for two BASs with different mechanisms of the biological effect [5]. The presence of primary hydroxy groups in terpolymers **I** enabled their cross-linking with hexamethylene diisocyanate (HMDIC), which yielded chemodegradable branched terpolymers **II** with urethane cross-links:

II

The presence of carboxy groups allowed incorporation into **II** of an aminoglycoside antibiotic, gentamicin, via an ionic bond. The properties of the initial terpolymers **I** and conditions of their reaction with HMDIC are listed in Table 1. It is seen that terpolymers **I** have low molecular weights (22000–28000) and relatively low content of functional hydroxy and carboxy groups (11.8–20.7 mol %).

The reaction of terpolymers **I** with HMDIC was performed in DMF at 130°C in an inert atmosphere, i.e., under the conditions of synthesis of linear polyurethanes [6–8]. We varied the copolymer concentration, [HMDIC] : [OH] molar ratio, and reaction time τ. With the other conditions being the same, increased [HMDIC] : [OH] molar ratio resulted in higher intrinsic viscosity of the product (Table 1, terpolymers **IIc** and **IId**). Upon the reaction with the diisocyanate, the intrinsic viscosity of **I** and its molecular weight (Table 2) increased by a factor of approximately 2, suggesting the formation of interchain urethane crosslinks. We determined the conditions under which the

reaction of **I** with HMDIC was not accompanied by gelation. The sedimentation and diffusion coefficients of the initial terpolymer **Ib** and branched terpolymers **IIb** and **IIe** and their molecular weights M_{SD} obtained by a combination of the sedimentation and diffusion methods are listed in Table 2. The molecular weight M_{SD} of **IIb** is 36000, and that of **IIe**, 67000.

The structure of product **IIb** obtained by the reaction of linear terpolymer **Ia** with HMDIC was confirmed by its ^{1}H NMR spectrum (Fig. 1a). Upfield signals at 0.5–1.2 ppm (solvent dimethylacetamide-d_9) belong to the protons of the HEMA and CA units, and the signals at 1.2–1.5 ppm, to backbone methylene protons of the HEMA units, backbone CH proton of the CA units, and four methylene groups of the cross-linking units. The signal at about 3.3 ppm belongs to the NCH_2 protons in the vinylpyrrolidone units and cross-links. The signal at about 3.7 ppm is due to the proton of the vinylpyrrolidone NCH group involved in the backbone (–CH– fragment).

Taking into account the composition of the initial terpolymer, contribution of the CA and HEMA methylene groups to the total integral signal intensity of 3.00 units (Fig. 1b), and contributions of two methylene protons of the HEMA units, one proton of the CA unit, and four methylene protons of the cross-linking unit to the total integral signal intensity of 2.16 units we calculated the composition of branched terpolymer **IIb**. The calculation showed that about 40% of HEMA units (about 6.6 mol %) are cross-linked by

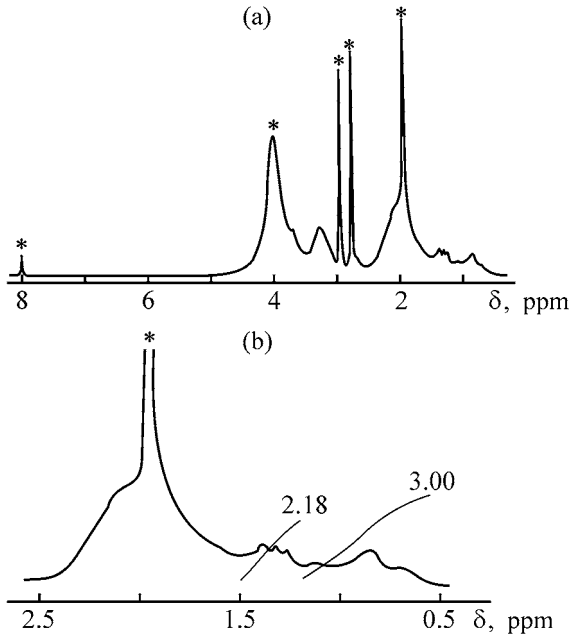

Fig. 1. ^{1}H NMR spectrum of copolymer **IIb** in dimethylacetamide-d_9: (a) total spectrum and (b) upfield region. (δ) Chemical shift. The residual proton signals of the solvent are denoted by *asteriscs*.

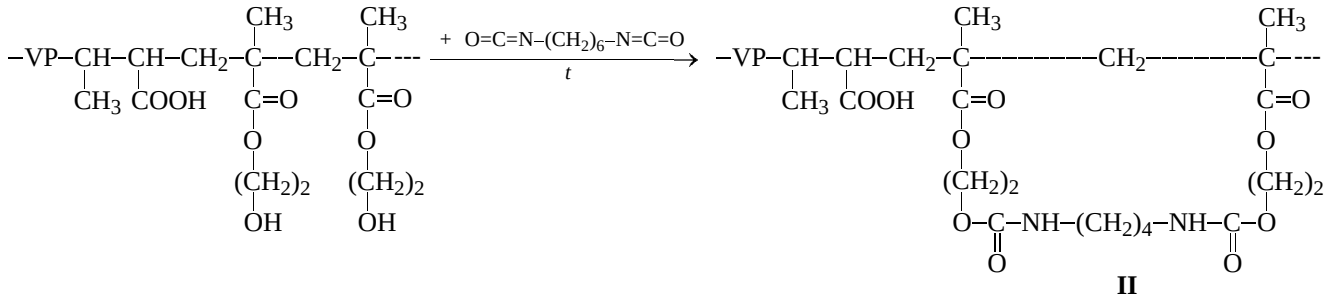
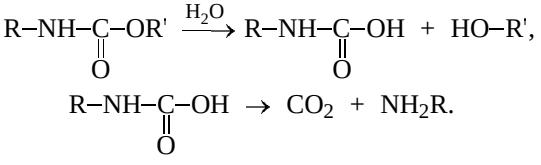
HMDIC; hence, the content of unchanged HEMA units is about 10 mol %.

Actually the content of interchain cross-links is lower than 6.6 mol %, since a part of the cross-linking agent is consumed for formation of intrachain (intramolecular) urethane cross-links:



As for the selectivity of hydrolysis of bonds in interchain cross-links in terpolymers **II**, it may be assumed that the urethane groups are hydrolyzed first. According to [9], CO_2 evolution is observed on keeping polyurethane samples in model solutions (pH 7.0, 37°C). THe degradation of polyurethane in model solutions involves cleavage of C–O bonds in the urethane group and formation of carbamic acid and alcohol. Carbamic acid decomposes with the release of CO_2 and formation of the primary amine:



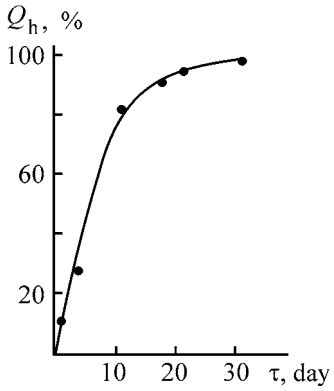


Fig. 2. Kinetics of **IIe** hydrolysis in physiological saline at 37°C. c_{cop} = 10 mg ml^{-1}. (Q_h) Degree of hydrolysis and (τ) time.

Hydrolysis of ester bonds in HEMA units is hindered because of the steric effect of the backbone.

Hydrolysis of branched terpolymer **IIe** (M_{SD} = 67000) in physiological saline (pH 7.0) at 37°C was studied viscometrically. We found (Fig. 2) that terpolymer **IIe** is hydrolyzed under these mild conditions to 96% in 31 days. The high hydrolysis rate is due to the lability of the interchain urethane cross-links and relatively low molecular weight of the terpolymer.

Table 4. Hydrolysis of polymeric gentamicin salts in physiological saline at 25°C

Salt	Elimination of antibiotic from polymeric carrier, %, in indicated time, h						
	1	2	3	4	5	6	24
IIIa	2.8	5.6	8.9	10.0	11.2	12.3	28.0
IIIb	1.6	3.6	5.3	6.7	8.1	9.2	20.1
IIIc	2.9	4.5	5.6	6.7	7.5	8.1	19.2

From terpolymers **Ib** and **IId**, we prepared gentamicin salts by the reaction of gentamicin base with the carboxy groups of the terpolymers, following the procedure described in [10]. Polymeric gentamicin salts **III** (Table 3) were obtained in 73–94% yield; they contained 10–20 wt % bound antibiotic and showed high acitvity against staphylococcus.

We have studied the rate of elimination of gentamicin base from the polymeric carrier (salts **IIIa**–**IIIc**) in physiological saline at 25°C by dialysis through a semipermeable cellophane membrane. We found that 19–28% of the antibiotic is eliminated in 1 day (Table 4). These data show that the antimicrobial activity of gentamicin incorporated in polymeric salts can be prolonged. It is remarkable that the antibiotic is eliminated from branched terpolymer **IId** more slowly than from linear terpolymer **Ib**.

EXPERIMENTAL

Terpolymers **I** were prepared and analyzed according to [4].

The reaction of **Ib** with HMDIC was performed as follows. A 0.5-g portion of **Ib** was dissolved in 3.23 ml of DMF, and 18.72 μl of distilled HMDIC was added. The mixture was transferred into a 50-ml ampule which was purged with argon and placed in an oil bath heated to 130±5°C. After 3 h, the ampule was cooled and opened; the viscous solution in the ampule was diluted with 0.5 ml of ethanol. The reaction product was precipitated into diethyl ether, collected on a glass frit, and vacuum-dried. Yield of branched terpolymer **IIe** 408.8 mg (81.8%), intrinsic viscosity 0.20 dl g^{-1}.

The intrinsic viscosity of terpolymers **I** and **II** was measured in an Ubbelohde viscometer (0.1 N aqueous sodium acetate, 25°C).

The hydrodynamic studies of terpolymers **I** and **II** (solutions in DMF) were performed by diffusion–sedimentation analysis. High-speed sedimentation experiments were performed with an MOM 3180 analytical ultracentrifuge with a Philpott–Svensson refractometric optical system at a rotor rotation rate of 45000 rpm in a cell with artificial formation of the sedimentation boundary at 21.0°C. The forward diffusion was studied in a polarization diffusometer [11]; the concentration gradient was recorded with a Lebedev polarization–interferometric system.

The molecular weights M_{SD} were determined by the Svedberg formula [11] allowing calculation of the molecular weight of a macromolecule without considering its structure and conformation:

$$M_{SD} = \frac{S_0}{D}\frac{RT}{1 - v\rho_0},$$

where S_0 is the sedimentation constant; D, the forward diffusion coefficient; R, the universal gas constant; and T, temperature. The floatability factor $(1 - v\rho_0)$ was taken from [12].

The resulting M_{SD} values are nicely consistent with the molecular weights $M_{S\eta}$ determined by sedimentation-viscometric analysis with the formula [13]

$$M_{S\eta} = \left(\frac{N_A}{\beta}\right)^{3/2}\left(\frac{S_0\eta_0}{1 - v\rho_0}\right)^{3/2}[\eta]^{1/2},$$

where β is the hydrodynamic invariant taken equal to the mean experimental value for flexible-chain polymers, $\beta = 2.3 \times 10^6$ [13]; N_A is the Avogadro number.

Hydrolysis of branched chemodegradable terpolymer **IIe** in physiological saline at 37°C was monitored by a decrease in time of the reduced viscosity of the terpolymer solution (initial concentration of **IIe** 10 mg ml^{-1}). The degree of hydrolysis of **IIe** was calculated by the formula given in [1].

Polymeric gentamicin salts **IIIa** and **IIIb** were prepared from **Ib**, and salts **IIIc** and **IIId**, from **IId**, following the procedure described in [10]. The content of gentamicin base in the polymeric salts was determined by complexation with trinitrobenzenesulfonic acid [14]. The rate of gentamicin release from salts **III** was evaluated according to [10].

The antimicrobial activity of polymeric gentamicin salts **III** against *Staphylococcus aureus*, strain 38, was studied by the method of twofold serial dilutions in a liquid culture medium [15].

CONCLUSIONS

(1) Water-soluble branched terpolymers containing interchain urethane cross-links were prepared by reaction of *N*-vinylpyrrolidone–crotonic acid–2-hydroxyethyl methacrylate terpolymers with hexamethylene diisocyanate.

(2) The hydrodynamic characteristics of the resulting branched terpolymers were studied, and the rate of their hydrolysis in physiological saline at 37°C was evaluated.

(3) Polymeric gentamicin salts exhibiting high antimicrobial activity were prepared from the linear and branched terpolymers. The kinetics of gentamicin elimination from the polymeric carrier was studied.

ACKNOWLEDGMENTS

The study was supported financially by the grants of the Institute of Macromolecular Compounds, Russian Academy of Sciences, within the framework of the Scientific Program of the St. Petersburg Scientific Center (section 2.2).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Polymerization of Acrylamide in Aqueous–Dimethyl Sulfoxide Solutions in the Presence of Sodium Acetate

V. F. Kurenkov and O. A. Antonovich

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 9, 2002

Abstract—The kinetic features of nonisothermal polymerization of acrylamide in aqueous, mixed aqueous–dimethyl sulfoxide, and DMSO solutions in the presence of potassium persulfate as initiator and sodium acetate as complexing agent were studied by differential thermal analysis.

Radical polymerization of acrylamide (AA) in concentrated solutions under nonisothermal conditions is a promising procedure for production of water-soluble high-molecular-weight polyacrylamide (PAA) [1]. In this case, polymerization can proceed at a high rate and to a high degree of conversion [2–6]. In addition, as the reaction temperature grows owing to the heat released in polymerization, the viscosity of the reaction mixture decreases and the flexibility of macroradicals increases, so that they more efficiently suppress intermolecular imidization yielding the water-insoluble polymer. Synthesis of PAA under nonisothermal conditions has not been studied adequately, and data on the influence of the complexing power of CH_3COONa (SA) on polymerization of AA are scarce [7–10]. Here, we report on the main features of nonisothermal radical polymerization of AA in concentrated solutions in water, mixtures of water with dimethyl sulfoxide (DMSO), and straight DMSO in the presence of SA.

EXPERIMENTAL

The substances and experimental procedure are similar to those described previously [9, 10]. The polymerization kinetics were studied by differential thermal analysis. Polymerization was carried out in 15-cm^3 cylindrical glass ampules. A solution of AA and SA was charged into an ampule and the ampule blown with helium for 30 min and hermetically sealed with a rubber stopper. A solution of the initiator, $K_2S_2O_8$ (PPS), was introduced into the ampule by a syringe through the rubber stopper, and the ampule was placed in a heating furnace. All the experiments were carried out at the initial temperature of 25°C, and then the temperature in the furnace was raised at a constant rate of 1.8 deg min^{-1} with a heater used in differential thermal analysis. In the course of polymerization, we recorded the variation of the temperature difference between the reaction mixture and ethanol (reference) with time.

After the polymerization was complete, the solution was diluted with water and the polymer was precipitated into acetone. Then, the polymer was filtered, washed with acetone, and dried under reduced pressure at room temperature to constant weight.

The intrinsic viscosity of PAA [η] was measured with an Ubbelohde viscometer (d = 0.56 mm) in 0.5 M NaCl at 25°C. The viscosity-average molecular weight of PAA $\overline{M}_\eta$ was evaluated by the formula [11]

$$[\eta] = 7.19 \times 10^{-3} \overline{M}_\eta^{0.77}.$$

The experimental data on nonisothermal polymerization were processed under the following assumptions: the total polymerization heat is expended for heating of the reaction mixture, the heat capacities of the monomer and polymer are the same, and evaporation of the solvent is neglected. In this case, the relation between the rate of variation of the reaction mixture temperature, dT/dt, in the course of polymerization and the rate of monomer consumption, –d[AA]/dt, is described by the simplified equation [3, 12]

$$dT/dt = (-\Delta H/C)(-d[AA]/dt),$$

where ΔH is the polymerization heat and C is the heat capacity of the reaction mixture.

* Values for $v \times 10^4$, mol l^{-1} s^{-1}.

The initial polymerization rate $v = dT/dt$ was determined from variation of the temperature of the reaction mixture with time. The results are listed in the table. Based on the experimental linear dependences $\log v = f(\log [AA])$ and $\log v = f(\log [PPS])$, we determined the reaction orders with respect to the monomer and initiator in the absence and in the presence of SA (see table). The positive values of the reaction orders in polymerization in aqueous solutions, in a 1 : 1 water–DMSO mixture, and in DMSO show that v grows with increasing initial concentrations of the monomer and initiator. In all the systems studied, with increasing concentration of AA in the initial mixture, the $\overline{M}_\eta$ values for PAA vary in parallel with v (Fig. 1), in good agreement with the general pattern of radical polymerization. The increased reaction orders with respect to AA and PPS, found in polymerization in the presence of SA, suggest a complicated mechanism of polymerization of AA in the presence of the complexing agent. The increase in the reaction order with respect to the monomer, observed on adding SA, is caused by participation of AA in the complexation with SA. The increase in the reaction order with respect to the initiator suggests an increase in the contribution of monomolecular termination to the total balance of chain termination reactions.

Deviation of the reaction orders with respect to the monomer and initiator from 1.0 and 0.5, respectively, did not allow determination of the individual rate constants of chain propagation, k_p, and termination, k_t. Therefore, we found the $k_p/k_t^{1/2}$ values determined from the dependence of $1/\overline{P}$ on $v/[AA]^2$, where $\overline{P}$ is the average degree of polymerization. The resulting $k_p/k_t^{1/2}$ values are listed in the table. It is seen that v grows upon addition of SA as a result of an increase in the $k_p/k_t^{1/2}$ ratio, which can be assigned to increased k_p.

According to IR, ^{1}H NMR [13], and NMR [14] data, the effect of SA on polymerization of AA is caused by complexation of SA with amide groups of the propagating radical. As a result of the com-

plexation, changes in the conjugation energy and polarity of the macroradical enhanced its reactivity in the events of chain propagation and promoted the increase in the $k_p/k_t^{1/2}$ ratio observed in the experiments.

The influence of SA concentration on the relative rate of AA polymerization, v/v_0 in aqueous solutions, in the 1 : 1 water–DMSO mixture, and in DMSO solutions is shown in Fig. 2. It is evident that, in all the media, the v/v_0 values grow with increasing concentration of SA and, after passing through a maximum, decrease. The observed $v/v_0 = f$[SA] dependence with a maximum is due to the dual function of SA as a complexing agent and a salt additive affecting the conformation of macroradicals in solution. Addition of small amounts of SA leads to higher v and, evidently, when the concentration of macroradicals that form complexes reaches a maximum, the highest v values are observed. The subsequent decrease of the v values in the presence of SA can be assigned to a decrease of root-mean-square sizes of molecular globules $(\bar{r}^2)^{1/2}$ as a result of deterioration of the solvent quality owing to addition of large amounts of SA. A similar decrease of $(\bar{r}^2)^{1/2}$ in solutions of lithium bromate was accompanied by a decrease in the rate of AA polymerization [15].

Data presented in the table and Fig. 1 suggest that, in polymerization of AA in the presence of SA, v and $\overline{M}_\eta$ grow in parallel with increasing water content in the mixed water–DMSO solvent. The v values in aqueous–DMSO media in the absence of SA vary in a similar manner (see table), in good agreement with the results of isothermal polymerization of AA [16, 17]. The observed decrease in v in the series water > water : DMSO = 1 : 1 > DMSO is caused by the increase in the $k_p/k_t^{1/2}$ ratio and in the reaction order with respect to the monomer. According to published data for isothermal polymerization of AA in aqueous–DMSO media [17], the variation of $k_p/k_t^{1/2}$ is caused by rise in k_p owing to an increase in the activation energy of reaction.

The above kinetic effects are mainly due to variation of the reactivity of the reacting species as a result of complexation (H-bonding) of propagating radicals and monomer with the solvent [18]. According to NMR data [19], an increase in the polarity of the medium on adding water (ε = 80) to less polar DMSO (ε = 46.6) enhances the capability of the solvent to form intermolecular H-bonds. Formation of H-complexes between the C=O group of AA and water decreases the electron density at the CH_2= group and increases v. In addition, complexation between the C=O group of AA and S=O group of DMSO may also exert a certain effect on v [20]. This effect becomes more pronounced with increasing content of DMSO in the solvent; it affects the activity of AA during polymerization. One more reason for the above rise in v is an increase in $(\bar{r}^2)^{1/2}$ values with growing content of water in the mixed solvent water–DMSO. In this study, the rise in $(\bar{r}^2)^{1/2}$ was judged from the increased reduced viscosity of PAA solutions η_{sp}/c at c = const (Fig. 3, passing from curve *4* to curve *1*), since, as a first approximation, we can assume that $(\eta_{sp}/c) \sim (\bar{r}^2)^{1/2}$ [21]. It is evident that a rise in $(\bar{r}^2)^{1/2}$ with increasing water content in the solvent leads to higher local concentration of the monomer

in the area of active centers and to higher rate of AA polymerization.

The increase in $\overline{M}_\eta$ on adding water to DMSO can be caused by decreased contribution of chain transfer involving mobile hydrogen atoms of the methyl groups of DMSO.

CONCLUSIONS

(1) With increasing concentration of the monomer and initiator, v grows and the dependence of v on the concentration of CH_3COONa passes through an extremum. The v values, the $k_p/k_t^{1/2}$ ratio, and the reaction order with respect to the monomer increase on adding CH_3COONa and in the order DMSO < water : DMSO = 1 : 1 < water.

(2) The $\overline{M}_\eta$ grows with increasing concentration of acrylamide and water content in the binary solvent water–DMSO.

(3) The influence of CH_3COONa on v is due to complexation of CH_3COONa with the propagating radical, and the influence of the composition of the water–DMSO mixture on v is due to complexation of the propagating radicals with the solvent owing to formation of H-bonds and also to variation of the conformational state of macroradicals.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure and Properties of Zinc-containing Copolymers Based on (Meth)Acrylate Monomers

N. V. Kuznetsova, L. V. Kabanova, M. A. Lazarev, and D. F. Grishin

Research Institute of Chemistry, Lobachevsky State University, Nizhni Novgorod, Russia

Abstract—The kinetic parameters of radical emulsion copolymerization of zinc-containing copolymers with esters of acrylic and methacrylic acids were studied. The effective relative activities of the monomers were calculated from experimental data and the properties of the metal-containing copolymers were assessed as influenced by the structure of the organic monomers.

Thanks to their biocidal, thermal, and physicomechanical properties, zinc-containing polymers are of much interest for preparing special-purpose materials [1]; such polymers can find application as polymer materials with wide biocidal spectrum. Zinc-containing copolymers based on acrylates and methacrylates exhibit enhanced heat resistance and high adhesion to various materials (metal, wood, concrete, etc.), which allows their use for preparing heat-resistant coatings.

It has been found [2–4] that physicomechanical, thermal, and biological properties of zinc-containing polymers and colloidal-chemical characteristics of their latexes are determined by the ligand environment of the zinc atom and by its concentration in the initial monomeric mixture and in the resulting copolymer.

Moreover, synthesis of polymers from zinc-containing monomers is of particular interest because they involve metal atoms able to interact both with the monomer and with the growing macroradical. Similarly to metal halides (Lewis acids) [5, 6], organometallic monomers can directly affect the elementary stages of macromolecule synthesis, including polymeric chain growth.

In this study, we analyzed the reactivity of zinc methacrylate acetate (ZMA) in reactions of emulsion polymerization with esters of acrylic and methacrylic acids.

EXPERIMENTAL

Zinc methacrylate acetate was prepared by the known procedure [1]. Latexes of ZMA copolymers with methyl methacrylate (MMA), ethyl methacrylate (EMA), butyl methacrylate (BMA), and butyl acrylate (BA) were prepared by emulsion polymerization [2].

The size of the latex particles was determined by turbidimetry [7]. To prepare latex films, a required amount of latex was cast on a Teflon plate and dried in air for 5 days at $20 \pm 2°C$.

The content of zinc-containing polymers in the sol–gel fraction were determined by extraction (in the course of 1 month) in a Soxhlet apparatus, using organic solvents with different dielectric constants [8].

The molecular weight of the internodal chain sections (M_c), characterizing the degree of polymer cross-linking, was determined by the Flory–Rener method [9].

The effective relative activities of monomers (r_1 and r_2) were evaluated by the Fineman–Ross procedure [10].

We studied the features of emulsion polymerization of ZMA with monomers of the methacrylate (MMA, EMA, BMA) and acrylate (BA) series. It was found that a stable latex is formed in a wide concentration range only in copolymerization of ZMA with BMA (Table 1). No zinc-containing copolymer is formed in the reactions of ZMA with MMA and EMA. It was demonstrated that, under the conditions studied, homopolymerization of MMA and EMA occurs in relatively low yields (38.3 and 61.3%, respectively); the reaction mixture separates into two phases and no stable latex is formed. Our experimental results are in good agreement with data on emulsion homopolymerization of

* (g) Content of insoluble gel fraction and (γ) conversion of organic monomer.

lower methacrylates in the presence of oxyethylated alkylphenols as emulsifiers [11].

It was found that, with the concentration of ZMA in the reaction mixture increasing to 3.2 wt %, the conversion of the organic comonomer grows appreciably from 38.3 and 61.5 to 81.4 and 98.0 wt % for MMA and EMA, respectively. This is probably due to complexation of zinc atoms with the growing macroradical, which accelerates polymerization and, thus, increases the polymer yield.

The ZMA–BMA copolymer has a cross-linked structure [2, 3], which can be quantitatively characterized by the internodal molecular weight M_c and content of insoluble gel fraction, g.

Using extraction with butyl acetate, we separated the ZMA–BMA copolymers into gel and sol fractions; their washed and dried samples were analyzed. It was found that, in ZMA–MMA copolymers containing from 0.7 to 18.6 wt % zinc, zinc occurs almost exclusively (up to 98%) in the gel fraction.

The gel fraction of ZMA–MMA copolymers was used to determine the internodal molecular weight, which characterizes the network density. For copolymers containing 0.7 to 18.6 wt % zinc, M_c constitutes ~400, which is the lowest value attainable for both acrylate and methacrylate monomers. It should be noted that a slightly lower value was only obtained for rigidly cross-linked polyurethanes [12]. It was found that this value is independent of the conversion of the organic monomer. For example, for ZMA–MMA copolymer containing 3.19 wt % zinc, M_c is constant beginning from 30% conversion of the organic monomer up to its complete exhaustion.

The internodal molecular weight M_c (Fig. 1) in the concentration range studied can be described by the following equations:

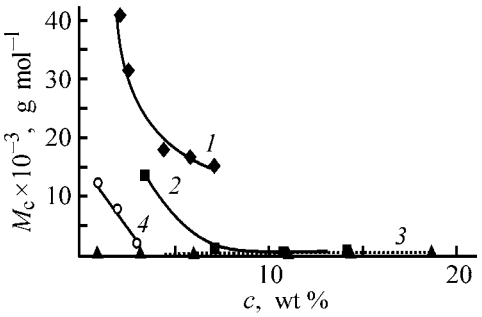

Fig. 1. Internodal molecular weight M_c vs. zinc content c in the monomer mixture for copolymers (*1*) ZMA–BMA, (*2*) ZMA–BA, (*3*) ZMA–MMA, and (*4*) ZMA–EMA.

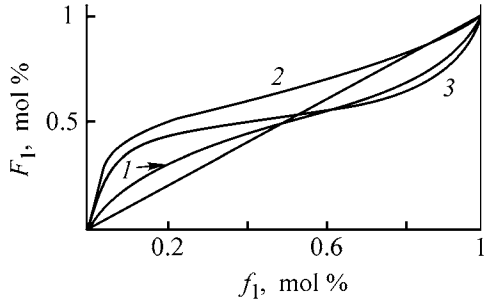

Fig. 2. Composition of copolymers F_1 vs. the composition of the initial monomer mixture f_1 for copolymers (*1*) ZMA–BMA, (*2*) ZMA–BA, and (*3*) ZMA–MMA.

$$M_c(\text{MMA}) = 400 \pm 50,$$

$$M_c(\text{EMA}) = 39\,134[\text{Zn}]^{-1} + 425,$$

$$M_c(\text{BMA}) = 81\,033[\text{Zn}]^{-1} + 2164,$$

$$M_c(\text{BA}) = 6573[\text{Zn}]^{-1} - 5394.$$

A rather abrupt decrease in the internodal molecular weight M_c, characterizing strengthening of the polymer cross-linking on passing from BMA to BA [e.g., at 7-wt % content of zinc in copolymer it constitutes 15 000 and 1500 g mol^{-1}, respectively (Table 1)], is probably due to steric hindrance in copolymerization of ZMA with methacrylate monomers (BMA) as compared with acrylates (BA).

The content of the gel fraction at zinc content in copolymer of up to 10 wt % can be described by the following expressions:

$$g(\text{MMA}) = 19.1[\text{Zn}] + 38,$$

$$g(\text{EMA}) = 7.0[\text{Zn}] + 40,$$

$$g(\text{BMA}) = 5.9[\text{Zn}] + 65,$$

$$g(\text{BA}) = 2.45[\text{Zn}] + 16.8.$$

It should be noted that, in copolymerization of ZMA with methacrylates (MMA, EMA, and BMA) the content of the gel fraction grows with increasing degree of cross-linking (Table 1). The internodal molecular weight M_c and the content of gel fraction g in the copolymer increase in the order BMA < EMA < MMA.

By analogy with the emulsion polymerization of styrene involving metal-containing monomers [13], we suggest that copolymerization of ZMA with MMA and EMA involves formation of a rigidly cross-linked core in the initial stage. Free MMA and EMA are probably linked as blocks to give an unstable coarse dispersion.

As shown previously, a similar polymerization mechanism has been observed by Wojnarowski and coworkers in emulsion polymerization of styrene with disubstituted acrylates and methacrylates of Group I and II metals. In this case, it is assumed that the copolymer blocks grow in different phases [13, 14].

Using the data on the emulsion copolymerization of ZMA with MMA, BMA, and BA, we plotted the dependences of the copolymer compositions on the composition of the initial monomer mixture (Fig. 2) and calculated the effective relative activities of monomers r_1 and r_2 for the above monomer pairs. The alternation of the monomer units in the copolymers was determined (Table 2). As seen from a comparison of

Table 2. Effective relative activities and parameters Q and e for (meth)acrylate monomers in copolymerization with ZMA (M_2)

M_1	r_1	r_2	Q_1	e_1	r_1r_2	Δe
MMA	0.10 ± 0.01	0.20 ± 0.05	0.74	0.40	0.020	2.10
EMA	–	–	0.56	0.17	–	1.87
BMA	0.36 ± 0.05	0.31 ± 0.05	0.72	–0.23	0.112	1.47
BA	0.06 ± 0.01	0.90 ± 0.10	0.50	1.06	0.054	2.76

different methacrylate monomers (MMA and MBA), the strongest tendency toward alternation is observed for the ZMA–MMA monomer pair, for which the copolymer composition is constant in a wide concentration range (Fig. 2, curve *1*, plateau). Moreover, the product of the effective relative activities of monomers $r_1 r_2$ is minimal and close to zero (Table 2). A similar trend is found for the ZMA-BMA monomer pair (Fig. 2, curve *2*). However, in this case, the alternation of the monomer units is less pronounced than in ZMA–MMA copolymer. It should be noted that, on passing from ZMA–MMA to ZMA–BMA pairs, the effective cross-linking density increases to a lesser extent.

We found that (Table 1), at equal content of zinc, the ZMA–BA copolymers have lower internodal molecular weight as compared with ZMA–BMA copolymers. For example, at a zinc content in the copolymer of 7 wt %, M_c of ZMA–BMA copolymer is close to 15000, whereas for ZMA–BA copolymer it is an order of magnitude lower (~1500). At the same time, the product of the relative activities of the monomers ($r_1 r_2$ = 0.054) in ZMA–BA copolymer is smaller than in the case of ZMA–BMA copolymer ($r_1 r_2$ = 0.11) (Table 2).

It is known [15] that the electron-acceptor properties of a monomer in the *Q*–*e* Alfrey–Price scheme are characterized by the electronegativity parameter *e*. For the monomers studied (Table 2) this value increases in the order BMA < EMA < MMA and BMA < BA. The alternation of the monomer units in the copolymer and the degree of polymer cross-linking increase in the same order.

According to the Alfrey–Price scheme [14], the alternation of the monomer units in the copolymer becomes more pronounced with increasing difference in the *e* parameter between the copolymerizing monomers. In particular, the most regular alternation is observed for typical donors and acceptors.

Previous studies of the copolymerization of ZMA with MMA and BMA have revealed the electron-donor nature of MMA ($Q = 3.0 \pm 0.3$, $e = -1.7 \pm 0.2$) [3].

We found that the particle size of latexes of ZMA–BMA and ZMA–BA copolymers grows with increasing effective density of cross-linking in accordance with the following equations (Fig. 3):

$$R(\text{BMA}) = 6.95[\text{Zn}] + 116,$$

$$R(\text{BA}) = 7.27[\text{Zn}] + 94.$$

The specific viscosity of latexes of ZMA–BA copolymers is lower as compared with ZMA–BMA (Fig. 4).

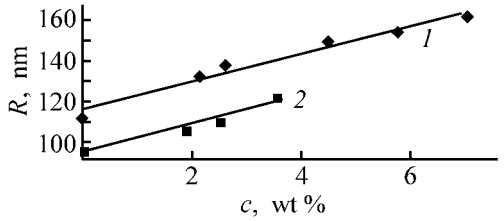

Fig. 3. Size *R* of copolymer latex particles vs. the zinc content *c* in copolymers (*1*) ZMA–BMA and (*2*) ZMA–BA.

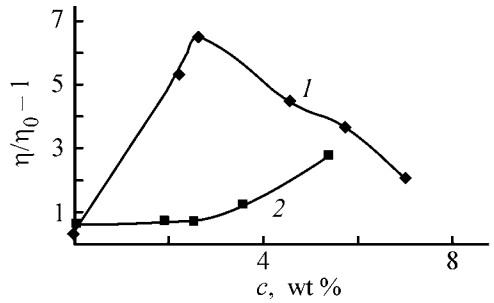

Fig. 4. Specific viscosity $\eta/\eta_0 - 1$ of latexes of copolymers (*1*) ZMA–BMA and (*2*) ZMA–BA vs. the zinc content in the mixture *c*.

As is known [16], the latex viscosity is determined by the interaction of functional groups present on the particle surface. With increasing effective degree of cross-linking, the amount of these groups must decrease. As a result, the viscosity of the latexes of more cross-linked polymers is smaller than that of latexes of ZMA–BMA copolymers at equal zinc content in the copolymer.

CONCLUSIONS

(1) In copolymerization of zinc methacrylate acetate with (meth)acrylate monomers, stable latexes are formed only with butyl methacrylate and butyl acrylate. The initial stage of polymerization involves formation of a rigidly cross-linked core. In the case of methyl methacrylate and ethyl methacrylate, the free (meth)acrylate monomer is linked as a block with the formation of a coarse dispersion.

(2) The effective relative activities of monomers in polymerization of zinc methacrylate acetate with methyl methacrylate, ethyl methacrylate, and butyl methacrylate show that the alternation of the monomeric units in the copolymers becomes more pronounced in the order ethyl methacrylate < butyl methacrylate < methyl methacrylate, i.e., with increasing electron-acceptor properties of the organic monomer. With increasing degree of cross-linking of zinc methacrylate acetate copolymers with methacrylate and

acrylate monomers, the tendency toward alternation of the monomer units is enhanced.

(3) The colloidal-chemical properties of latexes of zinc methacrylate acetate copolymers with (meth)-acrylate monomers depend on the parameters of cross-linking of these copolymers, which are determined by the nature of the organic monomer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synergistic Phenomena in Modification of Polyolefins with Mixtures of Isocyanates and Epoxides

R. R. Spiridonova, S. S. Galibeev, A. M. Kochnev, and V. P. Arkhireev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received October 16, 2001; in final form, July 2002

Abstract—Modification of commercial polyolefins with binary mixtures of isocyanates and epoxides was studied; the influence of the order of adding components on the performance of the modifying system was examined.

Under the impact of severe external factors, polymeric materials undergo irreversible transformations causing changes in the degree of crystallinity, molecular mobility, strength, and other parameters. This results in partial or complete loss of the main properties determining the wide use of polymeric materials in modern engineering. Stabilization of polymers is aimed at suppressing undesirable changes, improving the quality, and prolonging the service life of finished polymeric products. Antioxidative stabilization of polymers [1] can be provided by introducing individual reactive compounds containing functional groups (e.g., epoxy, isocyanato) or synergistic mixtures in which combination of different types of antioxidants ensures considerable enhancement of the stabilizing effect. The second alternative shows much promise.

In this study, we assessed the performance of synergistic mixtures based in isocyanates (ISs) and epoxides (EPs) in chemical modification of polyolefins (POs) and examined regular trends in the effect of these antioxidants. Our goal was to improve the processing and service characteristics of the polymeric products, in particular, to make them less expensive and prolong their service life by retarding aging and reducing the loss of stabilizers due to exudation.

The approach to choosing and formulating effective synergistic mixtures is based on studying the effect of the components taken separately and in combination. The choice of ISs and EPs was governed by the fact that the effect of these compounds, taken separately, on the PO properties has been studied in sufficient detail. The thermostabilizing effect of ISs and EPs, taken separately or in combination, is due to the reaction of their functional groups with terminal unsaturated bonds of POs [2–4], which, being potentially active centers of macromolecule degradation, negatively affect the whole set of properties of commercial POs (Table 1). Deactivation of such centers by reactions with isocyanato and epoxy groups ensures strong stabilizing effect, and the use of ISs and EPs in combination may result in nonadditive enhancement of various properties. The use of binary modifying systems instead of mechanical blending allows incorpora-

tion of active molecular groups directly into the polymer chain; in this way, the process for introducing a stabilizer is simplified and the ideal molecular distribution is attained; furthermore, exudation and evaporation of the stabilizers are excluded.

A study of the heat resistance of PP modified with IS–EP mixtures revealed synergistic effects at certain component ratios. For example, the equilibrium temperature of PP oxidation considerably increases (by 41°C, Fig. 1a), and the induction period becomes 40 min longer (Fig. 1b), on adding a mixture of 0.67 wt % TDI and 0.67 wt % ED-20. Still stronger effects are observed with epichlorohydrin (ECH) used instead of ED-20: T_{ox}^{0} increases by 55°C (Fig. 1c), and $T_{on.ox}$, by 79°C, compared with the unmodified PP. This stabilizing system also retards oxidation of low-density polyethylene (LDPE, Fig. 2).

We also examined how the order of adding the components of the stabilizing mixture affects the stability of POs. Four addition modes were tested: (I) IS was added to PO melt first, and, after rolling for 5 min, EP was added; (II) EP was added first, and IS, 5 min later; (III) IS and EP were added simultaneously; (IV) IS and EP were preliminarily copolymerized for 2 h and then added to the PO melt. As seen from Table 2, the highest $T_{on.ox}$ and the longest induction period of autooxidation τ_{ind} are observed when the components are preliminarily copolymerized.

It should be noted that the copolymerization time τ (h) of the components of the modifying mixture PP + 0.67 wt % ED-20 + 0.67 wt % additive (MDI or SKU-PFL) appreciably affects the induction period τ_{ind} of PP autooxidation (Table 3); the strongest effects were attained in the case when the preliminary copolymerization was performed for 1–2 h. As the copolymerization time is increased further, the stabilizing effect monotonically decreases and, finally, fully disappears. This effect is due to initial formation of a more active species in which the centers capable of reacting with PO unsaturated bonds are preserved; at higher conversions, the content of these centers decreases, and the thermostabilizing effect becomes weaker.

Our assumption is confirmed by an increase, following the hyperbolic law, in the viscosity of the TDI–ECH system in the course of polymerization at 50°C and by changes in the thermal stability of the products formed in model reactions of copolymerization of 1-hexene, TDI, and ECH added in different modes (Table 4). Mode I: An equimolar amount of ECH was added to 1-hexene, then a catalyst (tertiary amine) was

introduced, the mixture was heated at 60°C for 1 h, after which an equimolar amount (with respect to the other components) of TDI was added, and the reaction was continued for an additional 1 h. Mode II: The same except that TDI was added to 1-hexene first. Mode III: all the three components taken in equimolar ratio were mixed, and the mixture was heated at 60°C for 1 h.

The reaction products were transparent solids differing in color (from white to yellow) and insoluble in organic solvents; in view of the functionality of the chosen IS, this fact suggests formation of cross-linked three-dimensional (3D) structures.

The sample prepared using mode II showed the highest thermal degradation temperature. In this case, first the copolymerization of EP with 1-hexene occurred, after which IS was added. This fact confirms that ether fragments grafted to the PO macromolecule are more stable than amide fragments.

Analysis of the temperatures corresponding to the first step of the weight loss (apparently, due to evaporation of unchanged 1-hexene) also gives interesting results. In all the three samples, the weight loss starts at about 50–55°C, which corresponds to the boiling point of 1-hexene, and is complete at different temperatures, with the highest temperature being observed in the case of mode II. This may be due to formation in this case of a more densely cross-linked 3D structure hindering evaporation of the unchanged monomer. Evaporation of 1-hexene is complete only with the onset of degradation.

As shown above, the chemical reactions of ISs and EPs with PP yield grafted amide and ether structures. Also, as known from the literature [5] and shown by analysis of model reactions of ISs and EPs, reactions of bi- and polyfunctional compounds yield 3D cross-linked products insoluble in organic solvents. After performing the reaction in the TDI–ED-20–1-hexene system for 4 h with the temperature gradually raised from 50 to 100°C, the IS and EP taken in equimolar ratio are fully exhausted, and approximately 30% of the olefin remains unchanged.

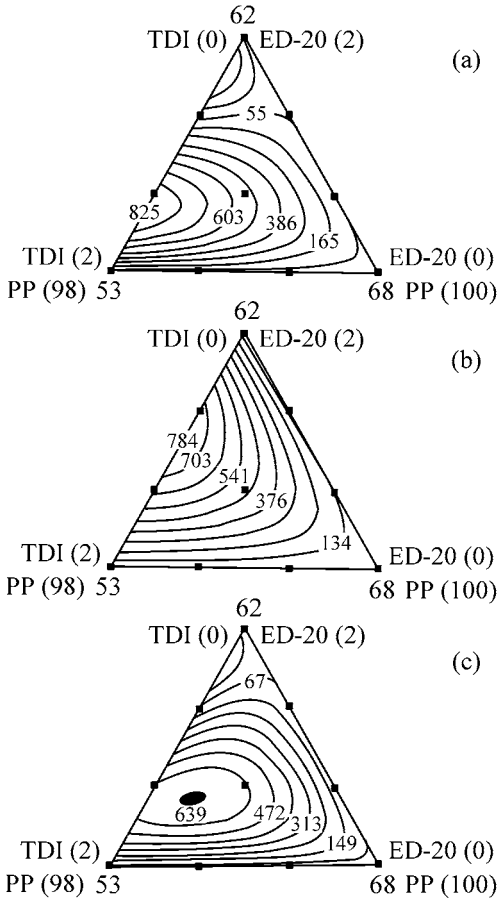

Fig. 4. Isolines of relative elongation for the system PP + TDI + ED-20: (a) modifiers added simultaneously, (b) TDI added first, and (c) ED-20 added first.

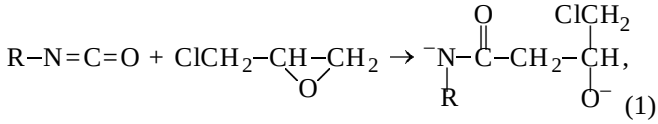
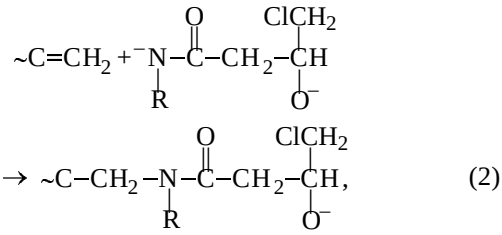
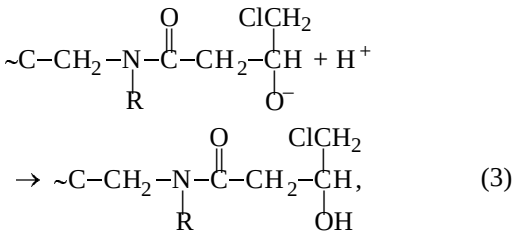
Thus, the synergistic effect of IS–EP mixtures (with ECH as example) may be due to formation of a more active stabilizer in the reaction between the initial monomers and can be enhanced by concurrent grafting of the IS–EP reaction product to residual unsaturated bonds of a PO:



(1)



(2)



(3)

where (1) is the stage of dianion formation; (2), reaction of the dianion with the α-olefin; (3), chain termination.

A kinetic study of the reaction (Figs. 3a, 3b; Table 5) showed that it obeys a second-order equation

$$-\frac{dc_{IS}}{dt} = k c_{IS} c_{EP},$$

where k is the second-order rate constant; c_{IS} and c_{EP} are the IS and EP concentrations, respectively.

Presumably, such reactions occur in POs, yielding fairly large fragments grafted to the polymer macromolecule; these fragments may form a separate phase in the polymeric matrix, thus affecting the heat resistance, processability, and service characteristics of the polymer. For example, only on adding the modifiers in combination, the relative elongation increases by an order of magnitude (Figs. 4a–4c), with the breaking stress growing too.

The considerable rise in the relative elongation on adding TDI and ED-20 to polypropylene may be due to modification of the amorphous phase by lengthy fragments grafted to the PO macromolecule; these fragments must impart rubber-like properties to PO. The contribution of the elastic component to the total

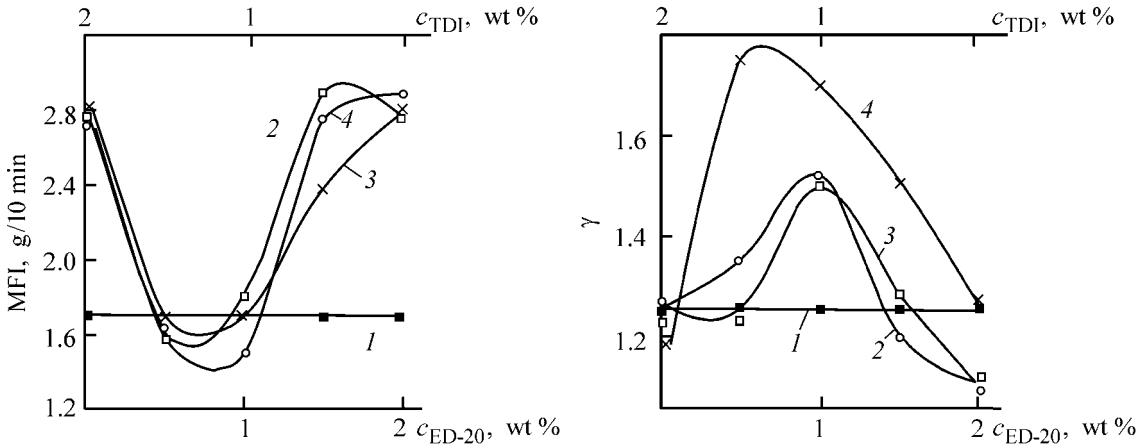


Fig. 5. Melt flow index MFI and intrinsic viscosity γ of PP modified with TDI and ED-20 vs. the content of TDI (c_{TDI}) and ED-20 (c_{ED-20}): (*1*) initial PP, (*2*) ED-20 added first, (*3*) TDI added first, and (*4*) both modifiers added simultaneously.

deformation increases by a factor of 2–4 on adding mixtures of modifiers to PP, compared with the unmodified polymer (Table 6). The elastic deformation grows at the expense of the viscous component.

The stress–strain curves also show that modification of PP with IS–EP mixtures enhances its hyperelastic properties. Whereas the stress–strain curve for the unmodified samples is typical of crystalline POs, addition of binary mixtures makes this curve similar to that obtained for rubbers. In modified samples, no decrease in the stress is observed at the instant of necking; similarly to rubbers, the stress grows with the strain; and the plateau characteristic of crystalline POs is less pronounced.

Formation of grafted 3D structures in the course of PO modification with IS–EP mixtures affects the rheological parameters: The viscosity of solutions and melts grows, the resistance of PO to fivefold extrusion is enhanced, and the melt flow index (MFI) decreases (Fig. 5). Its decrease to the level characteristic of the control sample does not impair the processability of the modified formulations.

Table 6. Contributions of the elastic, viscoelastic, and viscous deformations in the system PP + TDI + ED-20 (modifier: 1.33 wt % TDI + 0.67 wt % ED-20)

Mode of modifier addition*	Deformation, %		
	elastic	viscoelastic	viscous
Initial PP	2.8	2.4	94.8
I	10.5	1.1	88.4
II	4.6	2.1	93.3
III	9.2	1.8	89.0

* (I) TDI added first, (II) ED-20 added first, and (III) both components added simultaneously.

Thus, modification of POs with mixtures of epoxy compounds and isocyanates leads, at certain ratios of the components, to manifestation of the synergistic effect not only in the heat resistance, but also in service properties.

CONCLUSIONS

(1) Copolymerization of isocyanates with epoxy compounds and olefins was studied. Introduction of binary mixtures based on isocyanates and epoxides into crystalline polyolefins enhances their heat resistance and certain physicomechanical properties, with the synergistic effects observed. The modification efficiency was studied in relation to the order of adding components.

(2) The synergistic effect is accounted for by the formation of a more active species upon introduction of the components of the binary mixture into polyolefins.

Abstract—The concentration dependences of the relative viscosity of epoxy-4,4'-isopropylidenediphenol (Epikot 1009, E-05) and phenol-formaldehyde (DFFr) resins in Cellosolve solutions in the concentration range c = 5–60%, as well as the kinetics of thermal precondensation of a mixture of E-05 and DPFr resins in solution at molar ratios N_1/N_2 = 0.6–1.5, were studied by the method of capillary viscometry. The cluster structure of the surface of coatings on the metal sheet formed by cross-linked epoxy-phenol polymer in various kinetic stages of precondensation of the mixture of E-05 and DFFr resins in solution was studied by electron microscopy with gold decoration. The optimal concentrations of resins in solution and the precondensation kinetics of oligomer mixtures essential for formulating the compounds were calculated.

In preparing coatings of epoxy-phenol polymers, account should be taken [1] of the fact that the compatibility of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde resins in solution is determined by the nature of intermolecular interactions of the oligomers in various kinetic stages of thermal precondensation. Markevich *et al*. [1] showed that molecules of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde oligomers (EOs and POs, respectively) are associated in solution. It was found later [2–6] that the size and structure of the EO and PO associates are determined by the molecular weight (MW) of the oligomers, composition of the mixture, and thermal history of the solution. The viscosity of the EO–PO mixture in solutions is determined by the time of thermal precondensation of resins and passes through an extremum, which is due to changes in the size and structure of mixed associates [5, 6].

As shown previously [2–4], the degree of polymerization (DP) of EP and the solvent polarity determine the shape of the concentration dependences of the relative viscosity η_{rel} on c of EO in solutions. These dependences are described by the expression

$$\ln \eta_{rel} = ([\eta]_0 c)^a, \quad (1)$$

Here, $[\eta]$ is the intrinsic viscosity, and c is the concentration [7].

In EO solutions (DP = 2–4) in chloroform, the η_{rel}–c curves for oligomer molecules whose size does not exceed that of the Kuhn statistic segment (27 Å, DP ≅ 5 [8]) satisfy the condition $[\eta]_c > [\eta]$, where $[\eta]_c = d\ln \eta_{rel}/dc$ ($c > 0$) is the running intrinsic viscosity [9]. In this case, the power index a in expression (1) is over unity. For EO with DP > 5, the η_{rel}–c curves are characterized by the conditions $[\eta]_c < [\eta]$ and $a < 1$ [9]. According to [1, 3, 8], stable heterocomplexes are formed in solutions of the EO–PO mixture in Cellosolve (C) via of intermolecular hydrogen bonding between these oligomers.

Studies of the structure of cross-linked epoxy-phenol polymers [10, 11] have shown that a uniform chemical network is formed on the polymer coating surface at EO-to-PO molecular weight ratios close to 4 : 1, the optimal M_n(EO) being close to 3500. Markevich *et al*. [1, 8] believe that thermal precondensation of a resin mixture in solution is required for increasing the compatibility between EO and PO and for the subsequent formation of a uniform chemical network upon thermal curing of EO and PO. This conclusion has been confirmed in studies of the mechan-

ical properties of epoxy-phenol polymer films and the protective characteristics of a coating in various kinetic stages of precondensation of the EO–PO mixture in solution at 393 K [8, 12].

Nizhnik *et al*. [12] studied the precondensates (precondensation time 2 h at 393 K [12]) based on a mixture of epoxy-4,4'-isopropylidenediphenol (E-05) and phenol-formaldehyde (FPF-1) resins in a C solution for a set of 15 E-05 samples differing in molecular weight. A uniform correlation was established between the relative elongation ε/δ of the films of cross-linked epoxy-phenol polymer and the ultimate rupture stress δ (Fig. 1). For films prepared by cold mixing of EO and PO in solution, there is no correlation between ε/δ and δ. It can be suggested that association of oligomers in solution is governed by a uniform mechanism predetermining the precondensation kinetics of the mixture and the structure of the cross-linking sites in the chemical network of the cross-linked polymer in the coating.

The structural changes in various kinetic stages of precondensation of resin mixture in solution must affect the densities of the aggregates (or associates) of oligomers, as well as the degree of association of the molecules, *s*. It is highly probable that, during precondensation of the resin mixture, the EO and PO aggregates break down to give mixed aggregates of oligomers and an infinite cluster. Specifically in this case, the viscosity of the oligomer mixture in solution and the protective properties of coatings based on cross-linked epoxy-phenol polymers must be determined by the kinetic modes of precondensation.

It is known [13] that the correlations between the parameters of the oligomer aggregates in solutions, as well as those between the characteristics of clusters of macromolecules constituting the network of the cross-linked epoxy-phenol polymer, can be studied using the fractal cluster model [13, 14]. This model predicts how the density of aggregates in solution and clusters of macromolecules on the surface of the cross-linked epoxy-phenol polymer varies in different stages of precondensation of resin mixtures. We have shown previously [11] that the distribution and the topology of the cross-linking sites of the chemical network of the cross-linked polymer vary with the molecular weight of EO. At M_n(EO) = 2100, the coating surface contains discrete clusters of macromolecules ("lattice animals") constituting the nonuniform chemical network of a cross-linked polymer, and a single uniform network of the cross-linked polymer corresponds to M_n(EO) ≅ 3400 [11]. At the same time, the fundamental aspects of aggregation of oligomers in various

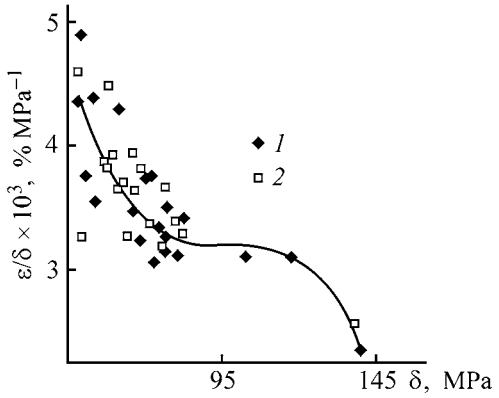

Fig. 1. Relative elongation ε/δ of the films of cross-linked epoxy-phenol polymer vs. the ultimate rupture stress δ for precondensates of (*1*) epoxy-4,4'-isopropylidenediphenol E-05 and phenol-formaldehyde FPF-1 resins prepared at 393 K within 2 h for a set of 15 samples of the E-05 resin and (*2*) cold mixtures of these resins [12].

stages of precondensation of EO and PO in solution and in formation of the chemical network of the cross-linked epoxy-phenol polymer still remain to be understood [1].

The aim of this study was to optimize EO–PO formulations and the kinetic modes of precondensation of a mixture of resins in solution to ensure formation of a uniform chemical network of the cross-linked epoxy-phenol polymer. We studied the hydrodynamic behavior and aggregation of EO and PO molecules and their mixtures in solutions in various kinetic stages of thermal precondensation. Also, we analyzed the cluster structure of the network of the cross-linked polymer based on EO and PO.

EXPERIMENTAL

We studied the concentration dependences of the relative viscosity of epoxy-4,4'-isopropylidenediphenol resins Epikot 1009 (Shell Corporation) and E-05 (Pigment Research and Production Company) and phenol-formaldehyde resin DFFr based on diphenylolpropane and formaldehyde (Pigment Research and Production Company) in C solutions in the concentration range c = 5–60 wt %, as well as that of a mixture of E-05 and DFFr resins in solution with mass ratio varied from 1.5 : 1 to 4 : 1 [15].

The molecular-weight distribution in sample nos. 1–3 (Table 1) was determined by gel-permeation chromatography (Shodex KF-803 columns, solvent tetrahydrofuran, sample volume 5–10 μl, eluent flow rate 1 ml min^{-1}, spectrophotometric detector, λ =

250 nm) [16]. The relative viscosity $\eta_{rel} = \eta/\eta_0$ (η is the solution viscosity and η_0 is the C viscosity) was measured on a Ubbelohde viscometer (capillary thickness 0.6 mm, shear rate 300 s^{-1}, C flow time 89 s, 298 K) (Figs. 2, 3, 4a). The refractive indices of the solutions were measured on a URL-1 refractometer (Fig. 4b). The intrinsic viscosity $[\eta]$ was determined by the procedure described in [7], and the running intrinsic viscosity $[\eta]_c$ at $c > 0$ and the power index *a* in Eq. (1), by the expression

$$[\eta]_c = d\ln\eta_{rel}/dc = a[\eta]([\eta]c)^{a-1} = a\ln\eta_{rel}/c, \quad (2)$$

$$[\eta]c/\ln\eta_{rel} = ([\eta]c)^{1-a}. \quad (3)$$

The parameters *a* and $[\eta]_c$ were calculated to within 7% (Tables 2, 3).

* In the vicinity of the threshold concentration c^*, the aggregate radius $\langle R\rangle$ is close to the correlation radius ξ [11, 17].

The formulations corresponded to EP-547 varnish [15] based on E-05 and DFFr resin containing 5.6% butoxy groups. Precondensation of the resin mixture was carried out in a C solution at 393 K; the N_1(EO)/N_2(PO) molar ratio was varied from 0.6 to 1.5. Precondensation time t = 0.4–4 h. The first sample for measuring the viscosity and refractive index n_D^{20} for the resin mixture in solution was taken 30 min after mixing the resins; further samples were taken during precondensation of the resins at 30-min intervals after the temperature of 393 K was attained (Figs. 4, 5). A catalyst in the form of 25% H_3PO_4 solution in C in amount of 0.24–0.26% of the oligomer mixture content was introduced after thermal precondensation was complete [15].

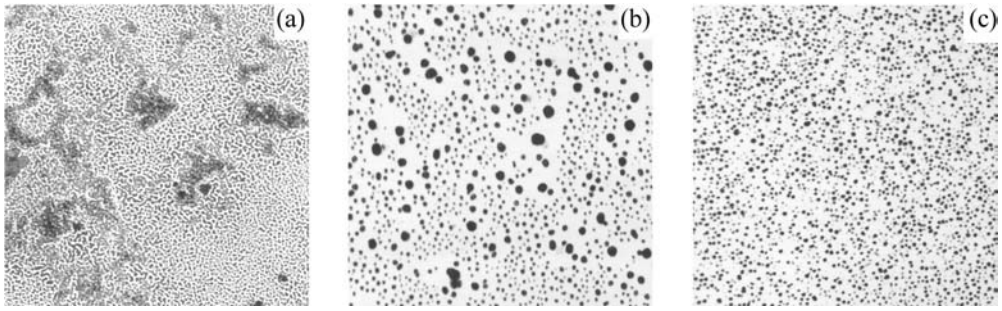

Fig. 5. Electron micrographs of the decorating gold particles on the surface of cross-linked epoxy-phenol polymer based on sample nos. 2 and 3 at N_1/N_2 = 0.7. Magnification: (a) 30 000 and (b, c) 60 000. Time, h, of precondensation of the coating on canning sheet metal: (a) 0.25, (b) 0.5, and (c) 2.0.

Coatings with thickness of 4–6 μm were prepared by casting 20% solution of the precondensate in C, also containing 0.79% organosilicon oligomer KO-815 [15], on tin-plated sheet metal (surface concentration of tin 8.4 g m^{-2}) and cured in air at 452–483 K for 15 min [18, 19]. The chemical stability of the cured coatings was tested in model media; these included 3% aqueous solutions of NaCl and acetic acid, 2% aqueous solution of tartaric acid, and distilled water at 120 atm (393 K) for 1 h [18, 19]. Cured coatings corresponding to the precondensation time t = 2.5 h exhibit satisfactory chemical stability in the model systems studied.

The cluster structure of the samples of cross-linked epoxy-phenol polymer coatings was studied by electron microscopy with gold decoration. The coating surface was preactivated with an aqueous solution of silver nitrate, which was followed by thermal sputtering of gold at 1.33×10^{-3} Pa to effective layer thickness of 0.4 nm. The coating surface activation consisted in partial reduction of $AgNO_3$ by quinonemethide groups of the polymer, yielded by thermal reduction of the secondary hydroxy groups of phenol-formaldehyde resin [20], and subsequent nucleation of silver nanoparticles, which act as nucleation centers for the decorating gold particles. Carbon replicas with decorating gold particles were prepared by the procedure from [21] and examined with an EVM 100 L electron microscope. The electron micrographs of the surface of cross-linked epoxy-phenol coatings (Fig. 5) obtained for precondensates of a mixture of E-05 and DFFr resins at a molar ratio N_1/N_2 = 0.6 were processed on a PC using the cluster lattice model [11, 17].

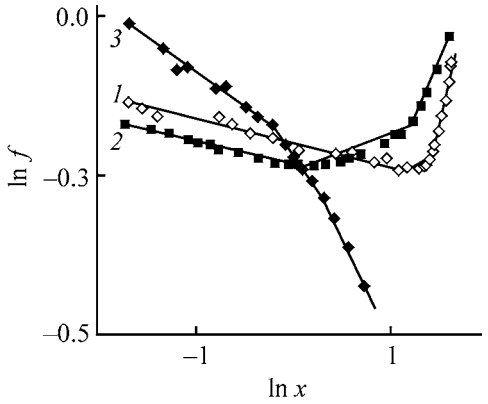

Fig. 6. $f([\eta]c)$ curves for sample nos. 1–3 in C solution, plotted in the $\ln f - \ln x$ coordinates.

When plotted in the $\ln \eta_{rel} - [\eta]c$ coordinates, the concentration dependences of the relative viscosity, $\eta_{rel} - c$, of the EO samples in C solution lie under the bisector of the angle at $[\eta]c = VN$ = 1–6, where $V = [\eta]M$ is the hydrodynamic volume of the oligomer molecules (M is molecular weight), $N = c/MN_A$ is the number of moles, and N_A is the Avogadro number [7]. The $\eta_{rel} - c$ curve plotted in these coordinates for sample no. 3 in C solution in the $[\eta]c < 3$ region lies above the bisector of the angle, since $[\eta]c/[\eta] > 1$ (Fig. 2). For the precondensates studied [N_1(EO)/N_2(PO) = 0.6–1.5], the $\eta_{rel} - c$ curves lie under the angle bisector (Fig. 3).

The $\eta_{rel} - t$ kinetic curves of the resin mixture viscosity exhibit extrema in the course of thermal precondensation of oligomers for all the N_1/N_2 parameters studied (Fig. 4a). With increasing precondensation time t, the refractive index n_D^{20} of the resin mixtures in solution tends to grow, with the dependence leveling off at $t \geq 3$ h (Fig. 4b), which suggests changes in the density of the EO and PO aggregates [9].

To estimate the threshold concentration c^* corresponding to sharp changes in both the $[\eta]c$ parameter and the effective hydrodynamic volume $\langle V \rangle$ of the EO and PO aggregates in solution [11], we calculated the dependences of the $f(x) = [\eta]c/\ln \eta_{rel}$ ratio on the parameter $x = [\eta]c$ (Figs. 6, 7). The $f(x)$ curve plotted in the $\ln f - \ln x$ coordinates for EO solution

in C (Table 1, sample no. 2) consists of three linear portions (Fig. 6, Table 2). A similar curve was obtained for sample no. 1. In the case of the C solution of sample no. 3, the $f(x)$ dependence exhibits a decrease in $f(x)$ in the $[\eta]c$ = 0.1–2 range and, when plotted in the logarithmic coordinates, it consists of three linear portions.

According to the cluster model [14], the density π of the fractal aggregate tends to decrease with increasing hydrodynamic volume $\langle V\rangle$

$$\pi = sV/\langle V\rangle = w^{(D-3)/D}(\langle R\rangle/R)^{(D-3)/D}. \quad (4)$$

Here, $s = w(\langle R\rangle/R)^D$ is the degree of aggregation; D is the fractal dimension; R and $\langle R\rangle$ are the radii of the oligomer and oligomer aggregate, respectively; w = 0.637 is the coefficient of random packing of rigid spheres [13].

To a first approximation, we have for relative viscosity η_{rel} of macromolecules in solution

$$\ln \eta_{rel} = VN_s(\langle V\rangle/V_s) = VN_s/\rho = [\eta]c/\rho s = ([\eta]c)^a. \quad (5)$$

Here, $N_s = c/MsN_A$ is the number of moles of the aggregates of particles, and $a = (3 - D)/D$ [11, 22].

Equations (2)–(5) give

$$\rho s = x/\ln \eta_{rel} = x^{1-a}, \quad (6)$$

$$\rho = (a[\eta]/[\eta]c)^{a/(a-1)} = w^a(x/\ln \eta_{rel})^{a/(a-1)}. \quad (7)$$

Figure 6 shows that the three portions in the $f(x)$ curve for EO solutions in C are due to a successive transitions from isolated oligomer molecules with D_1 = 1.46 (c < 7.2 g dl^{-1}) to aggregates of particles with D_2 = 1.56 (c = 7.2–13.9 g dl^{-1}) and D_3 = 1.83 (c = 14–26.7 g dl^{-1}). For sample no. 2, a transition to a continuous network of intermolecular contacts of macromolecules in the vicinity of $c^* \cong$ 27 g dl^{-1} is characterized by $D_4 \cong$ 1.8 (Table 2). For sample no. 1, the $f(x)$ curve also consists of three portions, namely, those with D_1 = 1.47 (c < 29 g dl^{-1}), D_2 = 1.83 (c = 29–31 g dl^{-1}), and D_3 = 2.4 (c > 31 g dl^{-1}). In the case of PO solutions in C, the three portions of the $f(x)$ curve are due to fractal transitions from D_1 = 1.4 (c < 17.3 g dl^{-1}) to D_2 = 1.34 (c = 17.3–26.4 g dl^{-1}) and D_3 = 1.25 (c > 26 g dl^{-1}, Table 2). Our data show that the degree of aggregation of EO in C solution at $c \cong c^*$ (s > 500 sample no. 1) significantly exceeds that of PO at $c \cong$ 26 g dl^{-1} ($s \cong$ 3, sample no. 3).

The $f(x)$ curves for EO–PO precondensates, plotted in the ln f–ln x coordinates, exhibit three linear portions with D_1 = 1.47 (c < 12 g dl^{-1}), D_2 = 1.54 (c = 12–36 g dl^{-1}), and D_3 = 2.2 (c > 36 g dl^{-1}) (Fig. 7). In the first two portions, the degree of aggregation s of the EO and PO molecules is lower than that of solutions of EO in C, though beeng significantly higher than that of solutions of PO (Tables 2, 3).

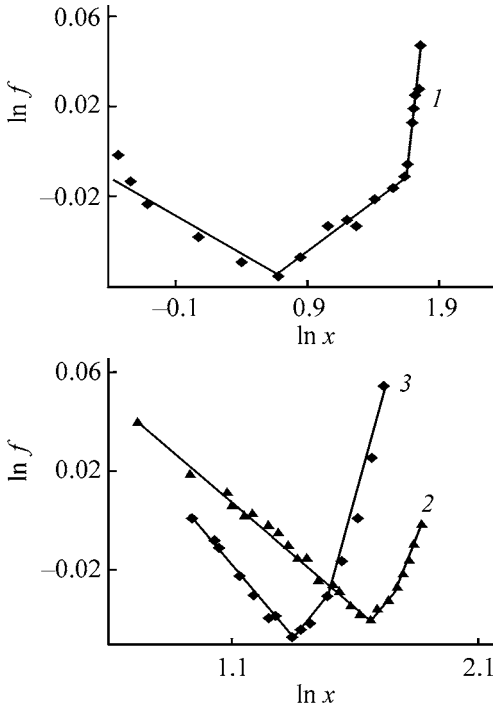

Fig. 7. $f([\eta]c)$ curves for EO–PO precondensates in the C solution plotted in the ln f–ln x coordinates. N_1(EO)/N_2(PO) molar ratio: (*1*) 1.5, (*2*) 0.7, and (*3*) 0.9.

** Figures in parentheses are the parameters of the clusters corresponding to the fraction of large gold particles formed on the silver metal nuclei through reduction with quinonemethide groups of PO.

to $[\eta]c = 2.4$, and that for the EO – PO precondensate, to $[\eta]c \cong 2$. Near the threshold concentration c^*, corresponding to the formation of a physical network of intermolecular contacts, ρ asymptotically approaches $\rho \cong 0.69$ characteristic of percolation of self-similar particles (or clusters of oligomer molecules) in a simple cubic lattice [13] (Table 3).

The radius of the aggregates $\langle R \rangle$ was calculated by the expression

$$\langle R \rangle / R = w^{-1/D}(x/\ln \eta_{rel})^{1/(2D-3)}. \quad (8)$$

Near the threshold concentration c^*, the radius of the EO aggregates sharply grows with increasing molecular weight of the oligomer. For sample no. 1 at $c^* = 29.6$ g dl^{-1}, $\langle R \rangle = 235$ nm, and for sample no. 2 at $c^* = 26.7$ g dl^{-1}, $\langle R \rangle = 93$ nm (Table 2), which is consistent with the Rayleigh scattering data for the EO solutions in C [6]. For example, according to [6], the ratio of the rms radii of the aggregates of oligomers is 2.8 for two EO samples (M_n 5310 and 4954) and 2.5 for sample nos. 1 and 2 (M_n 3600 and 2850).

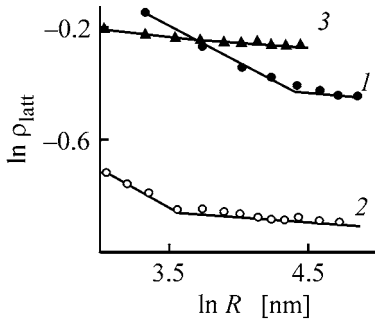

Fig. 9. Lattice density ρ_{latt} of clusters vs. the radius R of the circle circumscribed about the cluster. Coatings on the sheet metal of cross-linked epoxy-phenol polymer, $N_1/N_2 = 0.6$. Precondensation time, h: (*1*) 0.5, (*2*) 0.8, and (*3*) 2.0.

Figure 6 presents the electron micrographs of carbon replicas with gold decorating particles, corresponding to samples of cross-linked epoxy-phenol polymer coatings for various precondensation times t of the resin mixture. In analyzing the micrographs, the space-correlated groups of the gold particles were represented clusters of macromolecules on a two-dimensional lattice [13]. In the coatings corresponding to precondensation times of 0.25, 0.5, and 0.8 h, we revealed two regions where two fractions of particles of different size were localized, as well as two cluster types of different densities and topologies. The fraction of large particles corresponds to the most active centers of gold crystallization on the nuclei of silver metal reduced by quinonemethide groups of the PO units of the cross-linked epoxy-phenol polymer. Large gold particles occur as isolated inclusions in voids of an infinite cluster [11, 13] built from small gold particles corresponding to the EO aggregates.

With increasing precondensation time t, the density of two types of clusters is redistributed. For the coating sample corresponding to $t = 0.8$ h, we revealed a minimum of the lattice density ρ_l of the infinite cluster (Table 4). The fraction of the surface occupied by the PO molecule clusters decreases, which suggests formation of mixed aggregates containing EO and PO. A completely uniform continuous chemical network of a cross-linked polymer whose cross-linking sites contain EO and PO units is formed at $t = 2$ h. Within $t = 0.8$–2.0 h, the lattice density ρ_{latt} and the fractal dimension D of the clusters tend to increase (Fig. 9), and the correlation radius ξ asymptotically approaches $\xi = 50$ nm. These data evidence the formation of an infinite cluster of EO and PO.

The concentration dependences of the relative viscosity η_{rel}–c of EO in C solutions evidence a transition to the continuous fluctuation network of intermolecular contacts at $c^*(EO) \cong 27$ g dl^{-1} (Table 2, sample no. 2). The degree of aggregation for EO significantly exceeds that for EO (~340 against ~3 at $c \cong 26$ g dl^{-1}). In the case of the EO–PO precondensate [molar ratio $N_1(EO)/N_2(PO) = 1.5$, precondensation time 2.5 h], the transition from discrete mixed-type EO–PO aggregates ($D = 1.58$) to infinite cluster ($D \cong 2.1$) occurs at $c^* \cong 35\%$, Table 3).

The extrema in the kinetic curves of the relative viscosity η_{rel}–t for EO–PO mixtures in C solutions (Fig. 4a) suggest, above all, breakdown of the EO

aggregates. The rate of breakdown of the EO aggregates into "simple" particles depends on the degree of aggregation, *s*, of oligomers. The run of the $\eta_{rel}-t$ curves is determined by the N_1/N_2 ratio. A minimum in these curves is due to excess PO molecules in the mixture, and a maximum, to excess EO molecules. For example, breakdown of the EO aggregates in the EO–PO mixture in solution at $N_1/N_2 = 1.5$ is complete in the kinetic stage of precondensation corresponding to the viscosity maximum at $t \cong 1.5$ h. Formation of mixed EO–PO aggregates corresponds to the kinetic stage of the decline in viscosity, $\eta_{rel}-t$ at $t \cong 3$ h (Fig. 4a, curve *1*). Similarly, a viscosity minimum for the EO–PO mixture in solution ($N_1/N_2 = 0.6$) at $t = 0.25$ h is due to breakdown of the EO and PO aggregates. Formation of mixed aggregates is complete at $t > 4$ h (Fig. 4a, curve *3*).

Electron-microscopic data suggest that the uniform chemical network of the cross-linked epoxy-phenol polymer corresponds to the precondensation time $t = 1.5$–2 h ($N_1/N_2 = 0.6$). In this case, the correlation radius ξ of the clusters of macromolecules is 50 nm, $D = 1.94$ (Table 4). In the initial ($t = 0.25$ h) and intermediate ($t = 0.8$ h) stages of precondensation of the resin mixture, EO and PO do not form a single network. With precondensation time increasing from 0.4 to 2.5 h, the correlation radius ξ passes through a minimum: It first decreases from ca. 250 to 50 nm and then increases to 500 nm at $t > 2$ h, which is consistent with the run of the $\eta_{rel}-t$ curves (Fig. 4a) and with the Rayleigh scattering data for EO – PO solutions [6].

Thus, in various kinetic stages of precondensation of the mixture of EO and PO resins in solution, and on the surface of the cross-linked epoxy-phenol polymer, we revealed a cluster structure of the oligomer aggregates and of the cross-linking sites of the chemical network. Thermal precondensation of the resin mixture in solution involves structural evolution of the aggregates, namely, breakdown of the EO and PO aggregates and formation of mixed EO–PO aggregates and of an infinite cluster.

CONCLUSIONS

(1) The cluster mechanism of aggregation of the particles in solution determines the kinetics of thermal precondensation of resin mixtures and the structure of the chemical network of the cross-linked epoxyphenol polymer. This mechanism accounts for the formation of self-similar mixed-type aggregates of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde oligomers from aggregates of the corresponding oligomers in solution, which differ in density and degree of particle aggregation. A uniform network of cross-linked epoxy-phenol polymer is formed when the density of the aggregates of epoxy-4,4'-isopropylidenediphenol and phenol-formaldehyde oligomers approaches that of an infinite cluster in the vicinity of the threshold concentration of particles in solution.

(2) The cluster model of aggregation and distribution of the cross-linking sites of the chemical network on the surface of the cross-linked epoxy-phenol polymer obtained by thermal precondensation of epoxy-4,4'-isopropylidenediphenol and formaldehyde oligomers in solution accounts for the dependence of the relative elongation of polymer films (for a set of samples of epoxy-4,4'-isopropylidenediphenol oligomers with different molecular weights) on the ultimate rupture stress. In this case, the film strength depends on the density of the cross-linking sites, which, in turn, depends on the parameter N_1/N_2. Films prepared by cold mixing of oligomers in solution do not show a uniform chemical network of cross-linked polymer, since mixed-type aggregates and an infinite cluster are not formed.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of Synthetic Latexes with Colloidal Silver

Abstract—Butadiene-styrene and acrylate latexes were studied as matrices for preparing colloidal silver. Colloidal-chemical and strength properties of the modified latexes and Primal E1950 latex films were studied. The heat resistance of these materials was determined.

Development of processes for producing new materials for electronics and medicine (e.g., antiseptic applicators containing finely divided particles) is of great scientific and practical importance [1–3]. The published data on formation of colloidal metals in a latex matrix are scarce [4, 5].

Since metal-containing elastomeric nanocomposites cannot be prepared by direct mixing of a macromolecular binder with finely divided metals, preparation of these materials by a procedure involving generation of colloidal metal in aqueous solution and coagulation of latex rubber is a topical problem.

In this work we studied colloidal-chemical and physicomechanical properties of latexes and latex films modified with colloidal silver. This study was organized as follows: first we chose a procedure for preparing finely divided metal in an aqueous solution, then we performed this reaction in rubber latex, and finally we determined colloidal-chemical, physicochemical, and thermal parameters of the composites.

Colloidal silver in a latex matrix was prepared by a photochemical procedure that allows control of the metal reduction in a matrix of any rigidity by varying the irradiation time [6, 7].

The photolytes were prepared using $AgNO_3$ as the electrolyte.

To choose the latex matrix, we analyzed the properties, first of all the colloidal-chemical behavior, of various polymer dispersions. Special attention was paid to the distribution of polymer particles in the dispersion medium.

We studied latexes of acrylate [Primal E1950 (Room & Haas), Acronal 271 (BASF), DMMA (Voronezhsintezkauchuk)], butadiene-styrene [SB-278, SB-139G, SB-852 (RHODIA), BS-75 (Voronezhsintezkauchuk)], and styrene-acrylate [GB-016, DL-430, DS-910 (RHODIA)] polymers. All latexes were prepared using anionic emulsifiers, presumably RSO_3Na or $ROSO_3Na$, where R = C_{10}–C_{16}.

Since the system can be destabilized at high $AgNO_3$ concentrations [8], the amount of $AgNO_3$ introduced into the latexes ranged from 0.17 to 1.7 wt %.

To prepare colloids in an aqueous medium, latex (8 wt %) was mixed with an electrolyte (2 wt %) with a definite $AgNO_3$ concentration. A latex film was obtained from the resulting solution by the surface renewal method [9]. All the components of the system were concentrated during drying and formation of the film.

The surface tension of the latex modified with the electrolyte was determined with a Du-Nouy tensiometer; the acidity of the dispersions, with a pH-154 pH meter; their viscosity, on a V3-4 orifice [10]; the tensile strength of the films, on an RMI-5 tensile-testing machine [11].

Dry modified films were irradiated with 254- and 365-nm light of UFO-254 and DRT-375 mercury lamps. Formation of colloidal silver was determined spectrophotometrically (SF-46) from the rise in the characteristic plasmon absorption in the range 300 – 800 nm.

Parameters of thermal oxidative degradation of the polymers (temperature range of thermolysis, ac-

tivation energy of thermolysis) were determined on a Thermophlex differential scanning calorimeter (Perkin–Elmer).

We observed coagulation of the latex dispersions after introduction of $AgNO_3$ solutions in concentration higher than 0.85 wt % [12]. This is presumably due to reaction of the electrolyte with the surfactant introduced into the latex during its polymerization. This assumption was confirmed by a model experiment in which an anion-active surfactant, $C_9H_{19}SO_3N$, was reacted with $AgNO_3$.

$$AgNO_3 + C_9H_{19}SO_3Na \rightarrow C_9H_{19}SO_3Ag\downarrow + NaNO_3.$$

This reaction decreases the surfactant concentration [8], thus decreasing the thickness of the electrical double layer. As a result, the dispersion coagulates.

We found that only Primal E1950 latex was stable at electrolyte concentrations higher than 0.85 wt %, since it probably contained nonionic surfactants. Latexes stabilized with nonionic surfactants do not obey the Deryagin–Landau–Verwey–Overbeek (DLVO) law [8] since they are coated with relatively thick hydration shell preventing formation of the electrical double layer at the interface. We used this latex as the optimal matrix for preparing colloidal silver.

An increase in the surface tension after introducing an $AgNO_3$ solution of a prescribed concentration into the latex (Fig. 1) is due to partial binding of the anionic surfactant [13]. The pH (5) and the relative viscosity of the dispersion (17 s) remained the same.

In some experiments, silver alkylsulfonate was irradiated for 1 h. The white precipitate turned cherry-red, which points to the presence of silver nanoparticles. Similar processes were observed in a latex film. Probably, the structure of polymeric particles is transformed into hexagonal packing under the action of capillary forces, and silver alkylsulfonate present between these particles initiates formation of silver clusters.

A kinetic study of silver reduction showed (Fig. 2) that the rate-determining step of the photosynthesis is that preceding cluster formation and initiated by silver alkylsulfonate. Subsequent growth of silver particles occurs mainly by the photocatalytic mechanism. As determined by UV spectroscopy (Fig. 3, curve *1*), an ill-resolved band of metastable clusters and particles of subcritical size is formed in the first steps of UV irradiation of a latex film containing silver cations. Upon longer exposure to UV radiation (Fig. 3, curves *3*, *4*) a strong plasmon band appears at 480 nm. The location of this band remains the same on further irradiation. This indicates the formation of silver nanoparticles of the same size governed by the structure of the latex matrix [14].

Since we failed to determine the final silver concentration in the film by common procedures, we give

Kinetic parameters of thermolysis of Primal E1950 latex modified with $AgNO_3$

* K_0 is the rate constant of polymer thermolysis.

** Data for unirradiated and irradiated films are given in the numerator and denominator, respectively.

in all the dependences the silver concentration in the initial solution.

The strength of the irradiated film of the initial latex (0.270 MPa) is higher than that of the unirradiated film (0.164 MPa). The onset temperature ΔT and the activation energy E_a of thermal degradation of the polymer increases after irradiation (see table). This is probably due to additional intermolecular cross-linking under exposure to UV light [15]. The strength of the irradiated films decreases up to electrolyte concentration of 0.17 wt % (Fig. 4) and then increases up to a concentration of 0.5 wt %. The decrease in the film strength at low concentrations of $AgNO_3$ is possibly due to the structural nonuniformity at the molecular and supramolecular levels and microcracking of the modified latex film upon exposure to UV light [13]. With the electrolyte concentration increasing from 0.17 to 0.5 wt %, the film becomes more rigid. Further increase in the electrolyte concentration to 1.7 wt % has no effect on the rigidity. This complex dependence may be due to the fact that silver nanoparticles are formed only in the definite concentration range of the electrolyte.

The heat resistance of the modified film also grows with the electrolyte concentration increasing from 0.17 to 0.85 wt %.

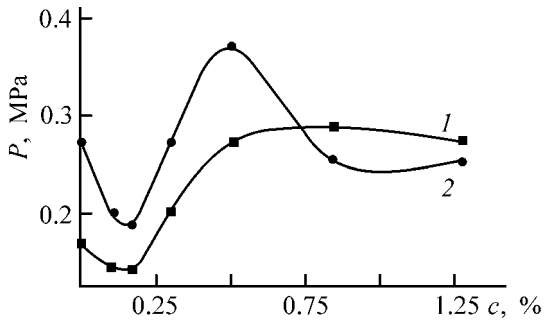

Fig. 4. Tensile strength P of (*1*) unirradiated and (*2*) irradiated Primal E1950 latex films vs. the electrolyte content in the latex, c.

CONCLUSIONS

(1) Silver nanoparticles were prepared by photochemical reduction of Ag^+ in a latex film. The best matrix for preparing silver nanoparticles is Primal E1950 latex.

(2) The formation of colloidal silver in the latex–$AgNO_3$ system is initiated by silver alkylsulfonate.

(3) Modification of Primal E1950 latex film with colloidal silver enhances its strength and heat resistance.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Oxidative Degradation of Caprolactam in Melting and Storage in Molten State in the Presence of Some Trace Impurities

N. P. Gankov

Ekomedbio EAD Business Innovation Center, Sofia, Bulgaria

Received January 22, 2002

Abstract—The influence of trace amounts of cyclohexanol, cyclohexanone, and cyclohexanone oxime on the quality and stability of caprolactam melt was considered.

Caprolactam is the main raw material for production of polycaproamide fibers. It is well known that caprolactam is stable to heat treatment in an inert medium; however, even trace amounts of impurities make it unstable [1]. The presence of concomitant impurities, such as cyclohexanol, cyclohexanone, and cyclohexanone oxime, is inevitable and is caused by the process conditions.

Under conditions of caprolactam melting, these impurities are oxidized under the action of minor amounts of oxygen present in the inert gas or adsorbed on crystalline caprolactam, which can affect its characteristics.

The influence of impurities on the particular characteristics of caprolactam was considered previously [2–5]; however, more specific information on the maximum permissible concentrations of each impurity was not given.

Previously [6], we found that trace amounts of cyclohexanol, cyclohexanone, and cyclohexanone oxime inhibit polymerization and cause formation of a polymer with cross-linked structure and high polydispersity. Up to now, these processes have not been studied adequately.

We found no published data on thermal oxidation processes in melting of impure caprolactam and its storage in the liquid state.

To study the effect of trace impurities, cyclohexanol, cyclohexanone, and cyclohexanone oxime in the amount of 10^{-3}–10^{-1} wt % (the amounts of these impurities in commercial caprolactam are usually smaller) were added to crystalline caprolactam containing 99.9553% main substance. Caprolactam samples with impurities were preliminarily homogenized. The samples were melted at 85°C in hermetically sealed glass ampules. Before sealing, the ampules filled with caprolactam and additives were blown with nitrogen for a long time. The main characteristics of caprolactam were determined by the procedures described previously [7].

The dependences of the main quality characteristics of caprolactam and the degree of oxidation on the type and amount of impurities (wt % relative to caprolactam) are shown in Fig. 1.

Determination of permanganate extinction number (PEN) involves determination of the optical density of a caprolactam solution in sulfuric acid 10 min after addition of a definite amount of a $KMnO_4$ solution.

Figure 1a shows that the presence of cyclohexanone oxime in caprolactam affects PEN insignificantly. Cyclohexanol and cyclohexanone appeared to be more active in this case, with their effect strongly depending on their concentrations. The PEN value noticeably decreases at the content of cyclohexanol and cyclohexanone exceeding 10^{-1} wt % and becomes lower than that prescribed by the standard. Previously [4] it has been established that aniline has the strongest effect on PEN.

The optical density A_{290} of a 50% aqueous solution of caprolactam was determined on a spectrophotometer at a wavelength λ = 390 nm. The color expressed in Hasen degrees X_{390} was determined from the optical density of 50% aqueous solution of caprolactam at wavelength λ = 390 nm.

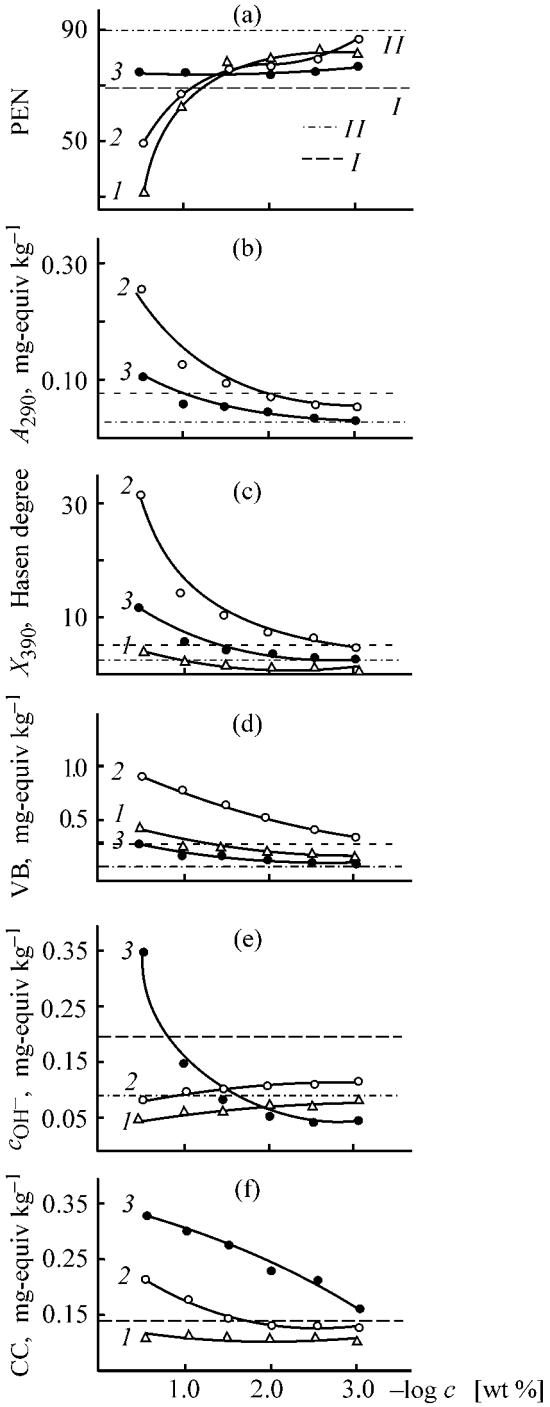

Fig. 1. Dependences of (a) permanganate extinction number (PEN), (b) optical density of 50% aqueous solution of caprolactam at λ = 290 nm A_{290}, (c) coloration of 50% aqueous solution of caprolactam at λ = 390 nm X_{390}, (d) content of volatile bases VBs, (e) alkalinity of caprolactam c_{OH^-}, and (f) content of carbonyl compounds CCs on the impurity content c. Impurity: (*1*) cyclohexanol, (*2*) cyclohexanone, and (*3*) cyclohexanone oxime. (*I*) Level prescibed by BDS (Bulgarian State Standard) 10780–88 and (*II*) value for the initial caprolactam sample.

In studying the variation of the optical density A_{290} and coloration X_{390} of caprolactam, it was found that the concentration dependences of these characteristics are similar (Figs. 1b, 1c). As expected, in comparison with the other impurities, a significant influence is exerted by cyclohexanone, whose carbonyl group gives a peak in the UV range at a wavelength of 290 nm. In parallel, the cyclohexanone impurity increases the integral absorption in a wide UV range. Thus, at the cyclohexanone concentration higher than 10^{-2} wt %, the optical density exceeds the value prescribed by the standard. A similar concentration dependence is observed in the presence of cyclohexanone oxime; however, the optical density reaches the value prescribed by the standard at its concentration exceeding 10^{-1} wt %. The concentration dependence in the presence of cyclohexanol is not shown in Fig. 1, since aliphatic alcohols do not absorb in the near-UV range.

It is well known that, in storage of caprolactam melt, the coloration of caprolactam increases, which is caused by oxidation processes, mainly oxidation of trace impurities. This assumption is based on the fact that the coloration of caprolactam thoroughly purified by sublimation in a vacuum remains constant for a long time, while the coloration of caprolactam contaminated with impurities increases steadily, especially in storage in the liquid state in the light or under UV irradiation.

The coloration of caprolactam is governed by the amount of cyclohexanone. It was established that in the presence of 10^{-3} wt % cyclohexanone, the coloration of caprolactam exceeds the value prescribed by the standard. The amount of cyclohexanone oxime exerts a weaker effect on the coloration of caprolactam: only at concentrations higher than 10^{-1} wt % the degree of its coloration exceeds the prescribed level. At concentrations less than 10^{-1} wt % cyclohexanol decreases the coloration as compared to the initial sample of caprolactam, i.e., it inhibits oxidation processes (Fig. 1c).

It has been established that the coloration is strongly affected by the presence of nitrobenzene and Fe(III) ions [4].

Determination of volatile bases (VBs) involves alkali decomposition of ammonium salts and other VB derivatives contained in caprolactam. The studies showed that cyclohexanone contributes most significantly to the content of VBs. As seen from Fig. 1d, even at 10^{-3} wt % content of this impurity the amount of VBs exceeds the prescribed level. Cyclohexanol affects the content of VBs only slightly, and cyclohexanone oxime, still more weakly. It was found that only at large amounts of cyclohexanone oxime, exceeding

10^{-1} wt %, the content of VBs is higher than the value prescribed by the standard. Aniline is the most critical impurity with respect to the content of VBs [4].

Alkalinity or acidity was determined by titration of aqueous solution of caprolactam with a 0.01 N solution of H_2SO_4 or NaOH in the presence of a mixed indicator (1.0 g of Methyl Red and 0.5 g of Methylene Blue in 1000 cm^3 of ethanol or methanol). The impurities in question excert appreciably different effect on the alkalinity of caprolactam. In this regard, the most active impurity is cyclohexanone oxime, its effect strongly depends on its concentration. Figure 1e shows that, at small content of cyclohexanone oxime, the alkalinity of caprolactam decreases and becomes lower than that of the initial caprolactam. At the cyclohexanone oxime concentration exceeding 10^{-1} wt %, the alkalinity becomes higher than that prescribed by the standard and increases steeply. This influence of cyclohexanone oxime can be accounted for by the fact that, under the conditions of melting and in prolonged storage in the liquid state, caprolactam undergoes hydrolysis to give cyclohexanone and hydroxylamine. The high reactivity of these compounds promotes various side reactions. Hence, the total effect will depend on the relative concentrations of its initial form and products of chemical transformations [4].

In the case of cyclohexanone and cyclohexanol, the pattern is the opposite. With increasing content of the above impurities, the alkalinity of caprolactam decreases. In the presence of 10^{-3} wt % cyclohexanol, the alkalinity of the samples is lower than that of the initial caprolactam. With increasing content of this impurity in the examined range, the tendency for decrease in the alkalinity is retained. Cyclohexanone exerts a similar effect.

Previously [8–10] it has been established that, for production of high-quality polycaproamide fibers, the concentration of carbonyl compounds should not exceed 0.15 mg-equiv g^{-1}.

Figure 1f shows that cyclohexanol hinders thermal oxidation processes and, to some extent, is an inhibitor. This is apparently caused by the ability of cyclohexanol to form complexes with free radicals arising in thermal oxidative degradation [11]. In the presence of cyclohexanol, caprolactam melt is characterized by the lowest content of carbonyl compounds, virtually independent of the amount of impurities. It is also seen that, in the presence of cyclohexanone and cyclohexanone oxime, carbonyl compounds are accumulated in caprolactam melt. With increasing content of these impurities, especially in the case of cyclohexanone oxime, the amount of carbonyl compounds increases.

The increasing content of carbonyl compounds in the presence of impurities may be due to formation and decomposition of hydroperoxides, which are a source of aldehyde groups [12]. In the presence of cyclohexanone, the amount of carbonyl compounds accumulated in caprolactam melt is smaller compared to cyclohexanone oxime.

CONCLUSIONS

(1) A noticeable decrease in the permanganate extinction number and alkalinity of caprolactam in the presence of 10^{-1} wt % cyclohexanol and cyclohexanone was established. The cyclohexanone oxime impurity affects the permanganate extinction number only slightly and has a complex effect on the alkalinity.

(2) Cyclohexanone affects most strongly the optical density and coloration of caprolactam and also the content of volatile bases.

(3) Cyclohexanone oxime and, to a lesser extent, cyclohexanone promote noticeable accumulation of carbonyl compounds in caprolactam. Cyclohexanol inhibits thermal oxidative processes in caprolactam during melting and prolonged storage in the molten state.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Flame Retardants for Wood, Based on Urea-Formaldehyde Resin with Mineral Fillers

G. V. Plotnikova, A. N. Egorov, and A. K. Khaliullin

East-Siberian Institute, Ministry of Internal Affairs, Irkutsk, Russia

Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received March 29, 2001; in final form, November 2002

Abstract—The efficiency of flame retardants for wood, based on urea-formaldehyde resin with mineral fillers is studied.

Wood is among the most widely used materials. Its advantages are well known, as well as the major drawback, namely, high inflammability.

Wood and related materials are virtually equal in fire points and specific heats of combustion [1]. Ignition of wood can occur both from open flame and from hot objects and gases. Heat flow from the flame initiates pyrolysis of wood materials.

Thermal decomposition of wood proceeds in two stages. In the first stage (up to 280°C), endothermic decomposition takes place, and the second stage is divided into two substages, namely, combustion of gases formed in thermal decomposition (flame burning) and combustion of charcoal formed (smoldering).

Raising the charcoal yield at the expense of combustible gaseous decomposition products can considerably reduce the inflammability of wood. This can be achieved by decreasing the heating rate of the material in order to form a layer of charcoal having low thermal conductivity, directing pyrolysis toward formation of incombustible gases, and providing conditions for prevention of charcoal smoldering.

In practice, the methods to decrease the combustibility of wood are as follows: applying flame-retardant coating ensuring formation of a coke layer and impregnation of wood and related materials or introduction of dehydrating agents into their structure.

The most advanced method for flame retardation in timber-based materials under conditions of a building yard is to apply flame-retardant coatings. When affected by a local short-term fire hazard source, flame-retardant coatings hamper burning of wooden structures, facilitate fire extinguishing, and, in some cases, prevent fire events.

Polymers demonstrating a tendency toward carbonization are capable of retarding burning of wood. In recent years, extensive studies of their application for flame retardation has been carried out. For example, it has been demonstrated that wood impregnated with urea oligomers passes into the category of difficultly inflammable materials [1]. However, despite the advances in science and engineering in the field of wood preservation, no efficient method reducing the inflammability of wood, suitable for mass construction application, has been developed. The drawbacks of the existing methods are either the complexity of fireproofing treatment, or in short supply of materials, or the resulting deterioration of mechanical and decorative characteristics.

In this work, we studied the effect of the composition of urea-formaldehyde resin (UFR) filled with natural minerals on the flame-retardant efficiency of coatings on wooden structures.

EXPERIMENTAL

As a binder for the coatings we used KF-Zh urea-formaldehyde resin [GOST (State Standard) 14231–88] ensuring the desired mechanical and adhesion characteristics. The formulations were filled with finely crushed mica (phlogopite), mineral wool, basalt fiber, and graphite. To reduce the combustibility, a fire retardant (diammonium hydrogen phosphate) was added.

The formulations were prepared as follows. First, the fire retardant was dissolved in the resin. Then

7	UFR 100	45	240	290	90

* (τ_{max}) Time of attainment of the maximal temperature, (T_{max}) maximal temperature in the reaction cell, and (ΔT_{max}) maximal temperature rise.

the fillers were added, and the resulting mixture was thoroughly stirred, to obtain a homogeneous mass. To optimize the composition, the contents of all the components were varied.

Sample preparation, finishing, and testing were carried out in conformity with the current regulations [2, 3]. The formulations were applied on the samples of straight-grained pinewood. The side surfaces of the samples were planed, and the ends were filed and rubbed with emery. The samples were 30 × 60 × 150 mm in size. Before applying the flame-retardant formulation, the samples were kept in a disiccator over saturated $Zn(NO_3)_2 \cdot 6H_2O$ solution at 23 ± 5°C to constant weight (to within 0.2 g).

The samples were coated from all sides. Each formulation was applied on ten samples. After finishing, the samples were dried to constant weight at 22°C (relative air humidity 50%).

The flame-retardant efficiency of the formulations was determined with a "Ceramic tube" apparatus. Each sample was held in torch flame for 5 min (initial temperature of flue gases 200°C). In the course of testing, the maximal temperature of the reaction cell and the time at which the maximal temperature was attained were recorded. Cooled samples were weighed, and the weight loss P (%) was estimated as

$$P = \frac{m_1 - m_2}{m_1} \times 100,$$

where m_1 and m_2 are the sample weights (g) before and after testing, respectively.

For each formulation, we determined the arithmetic mean weight loss P_m estimated for 10 parallel runs. This parameter was used as a criterion for evaluating the group of the flame-retardant efficiency. The formulations for which the weight loss was within 9% belong to the top group (group I).

According to COMECON Standard 2437–80, wooden construction materials flame retarded with group I formulations should be tested in a torch flame for 10 min to be classed with nonflammable materials [4].

In this study, the test samples were exposed to torch flame with venting switched on. The flue gas temperature was measured at 30-s intervals. Also the self-maintained burning time was measured for each sample. After testing, we measured the length of undamaged pieces of the samples and their residual weight. From these data, we estimated the extents of damage α_m (by mass) and α_l (by length). These parameters, along with the time τ of self-maintained burning and flue gas temperature T, were accepted as criteria in evaluating the combustibility of the test materials. Flameretarded wood is classified with nonflammable materials if the criteria given below are met.

	T, °C	τ, s	α_l, %	α_m, %
I*	Not higher than 235	30	85	80
II	Not higher than 250	60	90	85

* Estimated from data on three replicate tests: (I) arithmetic mean and (II) maximal value.

From the total amount of samples studied (50), we selected six most efficient flameretardant formulations. The results are given in Table 1.

The smallest weight loss of mass and minimal rise in temperature were observed in samples flame-retarded with formulations nos. 4 and 1. Evidently,

Table 2. Flame-retardation test results*

Characteristic	Composite no.					
	1	2	3	4	5	6

* The numerator represents the arithmetic mean for three replicate runs, and denominator, the maximal value among them.

the flame-retardant properties of the coatings are controlled essentially by the nature of filler rather than by its content. The best protective characteristics were demonstrated by formulation no. 4 containing lower amount of the filler as compared to formulation no. 1.

External examination of the samples after testing revealed no sag or cracking of protecting coating, or wood carbonization. The samples coated with formulation nos. 2 and 3 showed only slightly pronounced evidence of peeling. The formulations obtained provide good protection of wood against thermal decomposition; evolution of combustible gaseous products is insignificant, and, therefore, the time of self-maintained burning is short. In samples treated with formulation nos. 5–7, the coatings partly peeled, and wood exhibited traces of carbonization and indications of burning spread under the coating.

For these samples, the flue gas temperature approached 265°C and higher, which corresponds to the onset of degradation of the macromolecules [5]: anhydrocellulose is subject to deeper degradation (thermally unstable C–C and C–O bonds within the ring are ruptured), which is accompanied by liberation of CO_2, CO, H_2O, CH_4, and H_2. Ignition of the gases leads to initiation of combustion. Burning involves the following reactions:

$$2H_2 + O_2 \rightarrow 2H_2O + Q,$$

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O + Q,$$

$$2CO + O_2 \rightarrow 2CO_2 + Q.$$

The liberated heat partly goes to heating of next sections of a sample, resulting in their pyrolysis and inflammation. Therefore, both the time of self-maintained burning and flue gas temperature increase, i.e., the formulations under consideration do not protect wood against thermal degradation and subsequent burning.

Presumably, the maximal rise in temperature, observed for formulation no. 6 consisting of UFR, graphite, and diammonium hydrogen phosphate, can be attributed to insufficient adhesion of the coating to wood. Apparently, formulation no. 6 (UFR + graphite) has the least adhesion. Introduction of crushed mica (phlogopite) considerably improves the adhesion.

The results obtained allow classification of the formulations given in Table 1 with group I in their flame-retardant efficiency. Therefore, we conducted additional tests, to characterize the combustibility of wainscots finished with the flame-retardant formulations. The results are summarized in Table 2.

Among the formulations studied, formulation nos. 1 and 4 meet the requirements to nonflammable materials; samples finished with formulation no. 4 did not exhibit self-maintained burning and showed lower flue gas temperature and extents of damage by mass and length. Visual inspection of these samples revealed that the flame-retardant coatings have good adhesion to wood. They demonstrated no cracking or evidence of carbonization of wood under the coating.

Finally, the best flame-retardant characteristics were shown by the UFR-based coatings containing diammonium hydrogen phosphate (10%) as a fire retardant, and phlogopite with additions of basalt fiber or mineral wool as a filler. The higher flame-retardant characteristics of the coating containing basalt fiber as compared to similar formulation but containing

mineral wool can be attributed to lower thermal conductivity of the former (thermal conductivity coefficients of basalt fiber and mineral wool are 0.033–0.040 and 0.15–0.19 $W\,m^{-2}\,K^{-1}$, respectively). As a result, considerably lower thermal conductivity of basalt fiber ensures better protective characteristics of the coating even at its content lower by half as compared to mineral wool.

CONCLUSIONS

(1) The composition of flame-retardant coatings for wood, based on urea-formaldehyde resin with mineral fillers, is optimized.

(2) The flame-retardant characteristics of the formulations are controlled essentially by the nature of filler, rather than by its percentage.

Rheological Characteristics of Moist Microcrystalline Cellulose Pastes

I. N. Pavlov, V. A. Kunichan, and Yu. N. Denisov

Biisk Technological Institute, Altai State Technical University, Biisk, Altai krai, Russia

Received June 4, 2002

Abstract—The suitability of the contact method for drying moist finely ground product classed, according to its properties, with pastes was considered. The rheological characteristics of microcrystalline cellulose pastes were studied experimentally in relation their moisture content. The study was based on the Metzner procedure with the moist product with mechanical stirrers in a mixer.

Microcrystalline cellulose (MCC), which is a finely ground powder in the ready-for-use form, finds wide application in various industries [1–3]. The MCC production is expanding, and the corresponding technology is being improved. Among the most important characteristics of ready-for-use MCC is its particle-size distribution [4–6]. For preparing MCC with the desired particle-size distribution, it was suggested to combine the MCC drying and grinding in the framework of the contact method involving mechanical stirring in a horizontal twin-shaft blade mixer [7, 8].

In the contact method of drying in the MCC production technology, the initial moisture content is 48–52%. Such a product yielded by filtration or centrifugation is classed with pastes [9], despite its being comparatively friable. Designing equipment for processing of moist MCC paste and appropriate control system requires a knowledge of the rheological characteristics of these pastes at varied moisture content. However, there are no published data on these properties of MCC pastes with moisture content within 5–52%.

This work was aimed at determining the rheological characteristics of MCC pastes differing in moisture content.

The rheological characteristics of pastes are largely determined by the solid phase concentration, shape of solid particles, size of the particles, and the nature of interparticle binding [10, 11]. With growing concentration, the paste viscosity tends to vary nonlinearly with the deformation rate or shear stress. This is due to the appearance of a 3D structure in the network, which is responsible for strongly pronounced viscosity anomaly and formation of a strong, elastic structure. Further thickening of the suspension results in the formation of a structured system.

The flow of highly concentrated suspensions and, in particular, pastes is typically described by the Ostwald–de Ville power law [12–14]

$$\tau = K(\mathrm{d}w/\mathrm{d}x)^m, \quad (1)$$

where $\mathrm{d}w/\mathrm{d}x$ is the shear rate, s^{-1}; K, consistency coefficient; m, non-Newtonian behavior coefficient.

Theoretical description of the rheological characteristics of moist MCC pastes is a complex task, which necessitates their experimental study. Since only the apparent viscosity of the product can be considered in the case of MCC, we used the Metzner–Otto procedure for studying its rheological properties [15, 16]. In this case, the apparent viscosity of the medium in mixing of the mass with mechanical stirrers is determined by the equation

$$\mu_{app} = K(\mathrm{d}w/\mathrm{d}x)^{m-1}. \quad (2)$$

EXPERIMENTAL

In our studies, we employed a laboratory setup based on a horizontal twin-shaft blade mixer (see its schematic in Fig. 1). The working elements of the mixer are two Z-shaped blades. To widely vary the blade rotation rate, the drive was equipped with a dc motor, and the rotation rate was controlled with an autotransformer. The rotation rate of the driven shaft of the mixer was monitored with an electronic digital tachometer. The desired temperature was maintained with a ther-

1070-4272/03/7602-0314 $25.00 © 2003 MAIK "Nauka/Interperiodica"

mostat and facilities for monitoring the temperature and varying the flow rate of the heat carrier. For convenience of measuring the useful power expenditure for stirring, the measurement system was preliminarily calibrated by creating the desired torque at the shaft of mixer stirrers with a friction mechanism. We determined the dependences of the electric power on the mechanical power for various rotation rates of the driving shaft of the mixer.

In [17], we studied the stirring of a non-Newtonian medium in a mixer over a wide viscosity range, established the criterial dependence, and determined its constituent empirical coefficients

$$K_N = A\mathrm{Fr}_c^{\alpha}\mathrm{Re}_c^{\psi}, \quad (3)$$

where K_N is the power criterion; Re_c and Fr_c are the Reynolds and Froude centrifugal criteria, respectively; A, α, and ψ are empirical coefficients.

A study of the rheological characteristics of MCC pastes involved the following assumptions: The apparent viscosity of moist MCC under study is equivalent to the viscosity of the Newtonian fluid employed as the model fluid whose stirring under the same conditions (at the same rotation rate of the stirrer) consumes the same power; the viscosity of the Newtonian fluid during stirring is equal to that measured with a capillary viscometer at the same shear rate; the average shear rate in the apparatus is proportional to the rotation rate of the stirrer.

The rheological characteristics of the MCC pastes were studied at mixer filling coefficient of 0.8, at various rotation rates of the blades and in the following operation modes: (1) mixer blades rotate toward each other ("pull" operation mode) and (2) mixer blades rotate in the opposite directions ("push" operation mode).

Based on the data on stirring power, we determined the corresponding Reynolds centrifugal criterion and calculated the apparent viscosity

$$\mu_{app} = \frac{n_{av} d^2 \rho_b}{\mathrm{Re}_c}, \quad (4)$$

where n_{av} is the average stirrer rotation frequency, s^{-1}; D is the stirrer diameter, m; ρ_b is the bulk density of moist MCC, kg m^{-3}.

The shear rate in the apparatus is proportional to the rotation rate

$$\gamma = Bn_{av}, \quad (5)$$

where B is a coefficient depending on the mixer type.

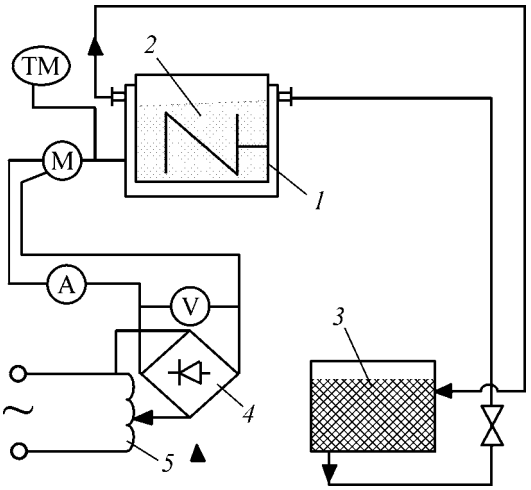

Fig. 1. Schematic of the experimental setup: (*1*) mixer, (*2*) product, (*3*) thermostat, (*4*) rectifier; (*5*) autotransformer, (TM) tachometer, (M) motor, (A) ammeter, and (V) voltmeter.

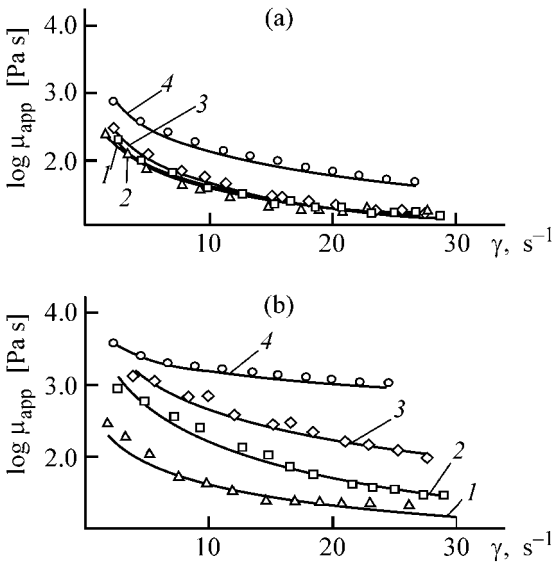

Fig. 2. Apparent viscosity μ_{app} of the MCC pastes vs. the shear rate γ in the (a) "push" and (b) "pull" modes of mixer blade operation modes. Moisture content W, %: (*1*) 10, (*2*) 30, (*3*) 40, and (*4*) 50.

According to [13], for this mixer type

$$B = 4\pi. \quad (6)$$

Our experimental data, namely, the dependence of the apparent viscosity on the shear rate and moisture content of MCC, were subjected to least-squares fitting, and the coefficients for Eq. (2) were obtained [17].

The results are shown in Figs. 2a and 2b. Solid lines represent the least-squares fits, and points, the experimental values.

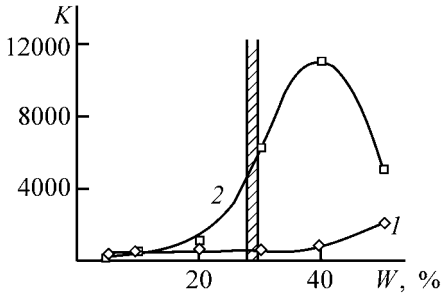

Fig. 3. Consistency coefficient *K* vs. the moisture content *W* of the paste. Mixer blade rotation mode: (*1*) "push" and (*2*) "pull"; the same for Fig. 4.

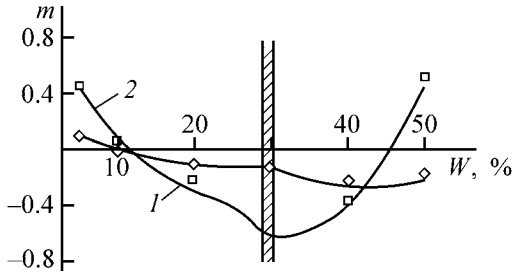

Fig. 4. Non-Newtonian behavior coefficient *m* vs. the moisture content of the paste, *W*.

Figures 3 and 4 show how the consistency coefficient *K* and the non-Newtonian behavior coefficient *m* vary with the operation mode of the mixer. The cross-hatched region denotes the range within which the physical structure of the MCC pastes changes [17].

Also, we studied how the effective viscosity varies with the shear rate for MCCs differing in the moisture content (Figs. 2a, 2b). We found that, unlike the "push" mode, stirring of MCC in the "pull" mode of blade operation is accompanied by its pressing between the mixer blades. This was responsible for a significantly larger power consumed in the latter case for stirring of MCC with moisture content of 30–50%. However, for MCC with moisture content of 5–20%, the results for the "pull" and "push" modes proved to be comparable.

Our results show that, with increasing shear rate, the apparent viscosity of the pastes tends to decrease. Such an abnormal variation of the viscosity of moist MCC pastes allows the media studied to be classed with non-Newtonian pseudoplastic fluids. Figures 2a and 2b show that, with increasing moisture content of MCC, the apparent viscosity of the pastes grows, with the shear rate remaining unchanged.

CONCLUSIONS

(1) Rheological properties of moist pastes of microcrystalline cellulose under mechanical stirring were studied. The nature of the non-Newtonian behavior of the pastes with varying shear rate was elucidated. The pastes studied were classed with pseudoplastic fluids.

(2) The patterns of variation of the apparent viscosity of the pastes with the shear rate and moisture content were elucidated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Rheological and Magneto-Rheological Properties of Formulations Based on Magnetite and Aqueous Emulsions of Water-Soluble Polymers in Transformer Oil

T. G. Lazareva and E. V. Shinkareva

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received May 13, 2002

Abstract—Rheological and magneto-rheological properties of magnetite dispersions in transformer oil were studied as influenced by the concentration of a modifying solution of water-soluble polymers (polyvinyl alcohol and carboxymethyl cellulose) and by the magnetic field strength.

Fluid systems structurizing in an electric or magnetic field are dispersions of electro- and magneto-sensitive materials in nonconducting or weakly conducting media. When an electric or magnetic field is applied to these liquids, their rheological properties change significantly due to formation of anisotropic structures via orientation of the filler particles in the field [1–3].

Such materials can be used in robotics, mechanical engineering, optical, instrument-making, automobile, aircraft, and other industries in various devices such as antivibrators (shock absorbers and buffers), compressors, temperature-controlled cooling fans, valves, clutches, polishing units, etc. The design of such devices is determined by the function of structurizing fluid system and by systems of application of external fields [4–7].

To prepare materials sensitive to mechanical and magnetic fields, we studied the rheological and magneto-rheological properties of magnetite dispersions in emulsions of water-soluble polymers [polyvinyl alcohol (PVA) and carboxymethyl cellulose (Na-CMC)] in transformer oil.

EXPERIMENTAL

In our study, we used commercial magnetite (particle size <5 μm) and dehydrated transformer oil as dispersion medium. The oil was mixed with a 0.5% solution of NaCMC (7HOF and M31F brands) and 1% solution of PVA (16/1 brand); the modifying agent to transformer oil weight ratio was varied from 1 : 99 to 10 : 90. The resulting mixtures were dispersed with a UZDM-2 ultrasonic unit (44 KHz). Then, magnetite (5 wt %) was added to the oil–water emulsion. The rheological measurements were performed on a Rheotest-2 device at 30–70°C.

The magnetite dispersion in dehydrated transformer oil is a non-Newtonian liquid, whose viscosity strongly depends on the shear stress or shear rate (Fig. 1a, curve *1*) [8]. The mode of the fluid flow in a mechanical field, namely, the decrease in the viscosity with increasing shear stress (section *I*) with the subsequent attainment of a uniform flow at which the viscosity is independent of the shear stress (section *II*), indicates that the dispersion can be easily structured and possesses a property of plasticity, i.e., filler particles can be oriented at certain shear stresses (section *I*) with the subsequent attainment of the uniform flow mode (section *II*).

Upon modification of the transformer oil with Na-CMC and PVA solutions, the shape of the flow curves of magnetite dispersion changes, with the appearance of sections in which the fluid viscosity decreases (plasticity) or increases (dilatancy). The nature of the flow curves depends on the viscosity of Na-CMC solutions. With addition of 1 or 5 wt % highly viscous Na-CMC solution (e.g., 7HOF brand), the oil viscosity at 30°C increases to 30–45 MPa s, with peaks at small shear stresses of 0.5–1.0 Pa (Fig. 1a, curves *2*, *3*). With the content of modifying agent increasing to 10 wt %, the oil viscosity increases to

1070-4272/03/7602-0317 $25.00 © 2003 MAIK "Nauka/Interperiodica"

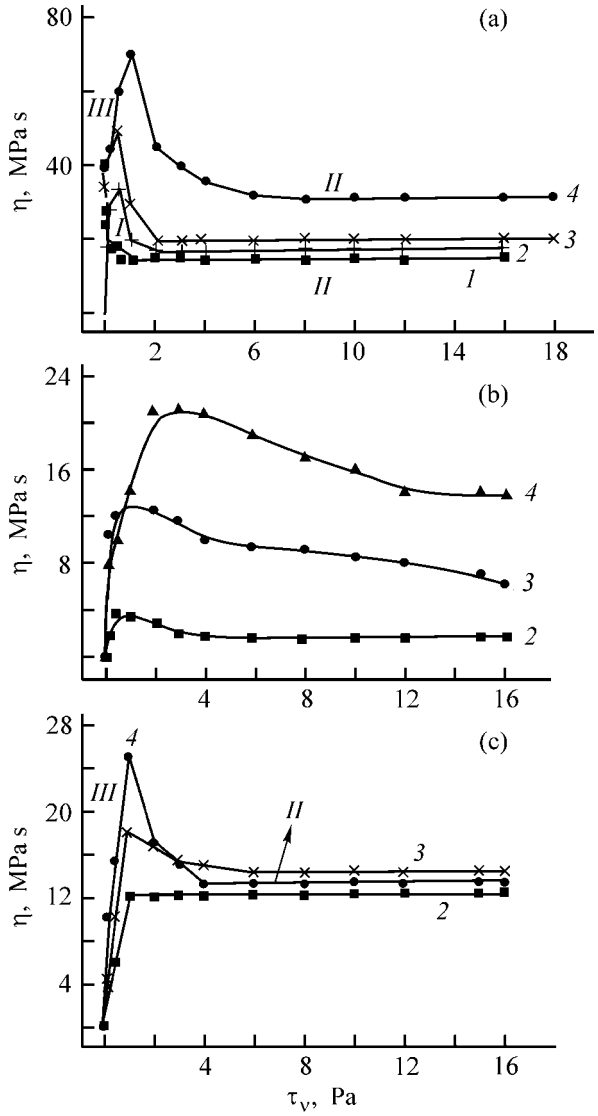

Fig. 1. Viscosity η vs. the shear stress τ_v at 30°C for 5 wt % magnetite dispersion in (*1*) dehydrated transformer oil and (*2*–*4*) transformer oil containing Na-CMC and PVA solutions. Additive: (a) 7HOF, (b) 9M31F, and (c) PVA. Additive content, wt %: (*2*) 1, (*3*) 5, and (*4*) 10.

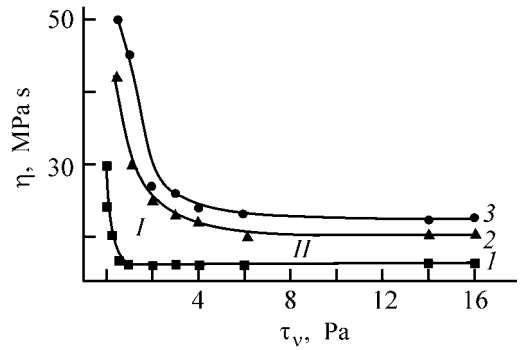

Fig. 2. Viscosity η vs. the shear stress τ_v for magnetite dispersion in dehydrated transformer oil. Magnetic field strength, mT: (*1*) 0, (*2*) 34, and (*3*) 44.

65 MPa s, with the viscosity peak shifting toward higher shear stresses (Fig. 1, curve *4*). On raising the temperature to 70°C, the maxima in the oil viscosity strongly shift toward higher shear stresses. The effect of anisotropic structuring, at which the viscosity is independent of the shear stress (section *II*), is observed at shear stresses of 1.5–2.0 Pa and 5 Pa at concentration of Na-CMC polymer in the transformer oil of 1–5 and 10 wt %, respectively. Similar dependences were observed upon addition of less viscous Na-CMC and PVA solutions.

The effects observed are probably due to changes in the nature of intermolecular interactions of magnetite particles, with molecules of water-soluble polymers sorbed on their surface. In this case, first the system of intermolecular interactions occurring in the system changes under the effect of the mechanical field, with the viscosity increasing and dilatancy appearing (Fig. 1, section *III*); in the next step, the filler particles are structured in the mechanical field, giving rise to plastic properties (section *I*), and then an anisotropic solution is formed (Fig. 1, section *II*).

As seen from Fig. 2, the viscosity of magnetite dispersions in dehydrated transformer oil increases on applying magnetic field, without changes in the flow curves. At the same time, the shape of the flow curves of magnetite dispersions in the transformer oil modified with water-soluble polymers gradually changes in a magnetic field (Fig. 3). With addition of Na-CMC solution (7HOF brand, up to 5 wt %) at the magnetic field strength of 20–34 mT, the peaks in the flow curves become less pronounced (Fig. 3a, curves *1*–*4*), and at H = 44 mT the flow curve changes, i.e., the viscosity of the system decreases with increasing shear strength (Fig. 3a, curve *5*).

Such variations in the rheological properties observed in a magnetic field are probably due to changes in the intermolecular interactions of magnetite particles in the transformer oil modified with water-soluble polymers and orientation (additional to mechanical ordering) of magnetite particles in the magnetic field. As seen from experimental data, the system exhibits either plasticity or dilatancy, depending on the composition of the initial medium and magnetic field strength.

CONCLUSIONS

(1) Magnetite dispersions based on emulsions of transformer oil modified with water-soluble polymer solutions (polyvinyl alcohol and carboxymethyl cel-

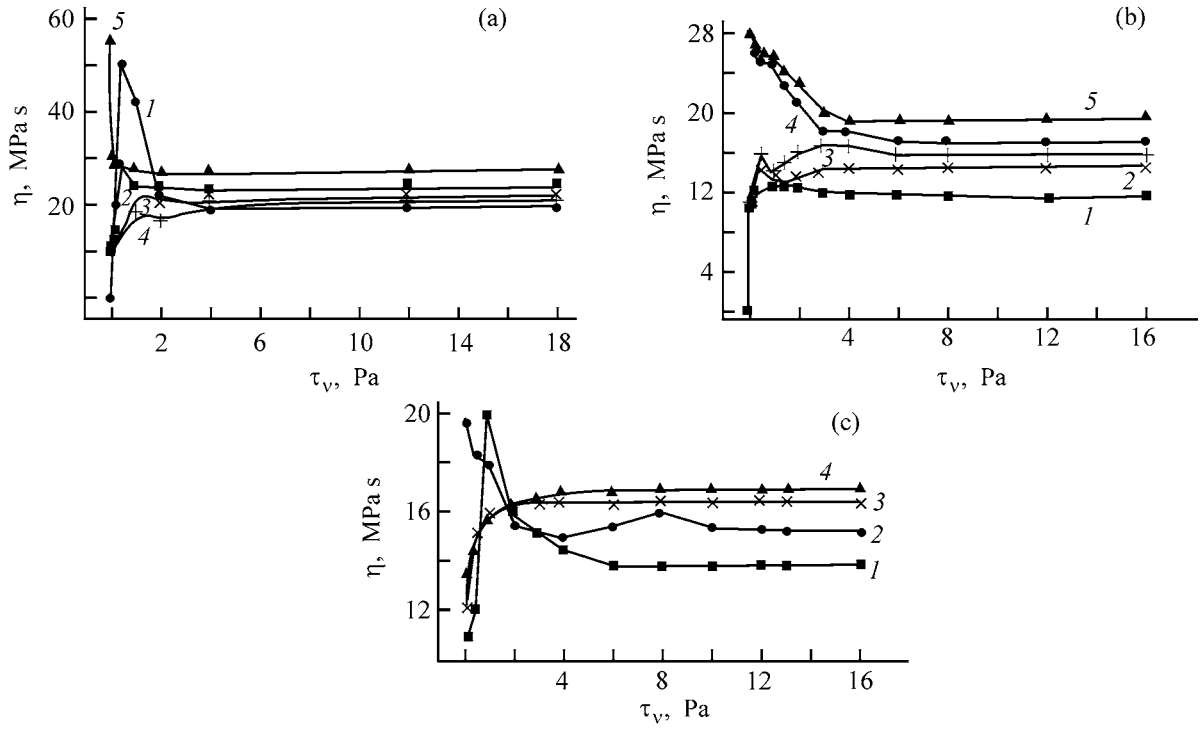

Fig. 3. Viscosity η vs. the shear stress τ_v for magnetite dispersion in transformer oil containing 5 wt % (a) Na-CMC : (7HOF), (b) Na-CMC : (9M31F), and (c) PVA. Magnetic field strength, mT: (*1*) 0, (*2*) 16, (*3*) 20, (*4*) 34, and (*5*) 44.

lulose) exhibit flow curves differing in both plasticity and dilatancy.

(2) Magnetic field strongly affects the flow curves of the system and its rheological properties, with the structuring of the system depending on the composition of the oil–water emulsion and magnetic field strength.

BRIEF COMMUNICATIONS

Estimation of Efficiency of Removal of Heavy Metal Ions as Hydroxides from Sewage

V. P. Svyatokhina, O. Yu. Isaeva, S. V. Pestrikov, and N. N. Krasnogorskaya

Ufa State Aeronautical Technical University, Ufa, Bashkortostan, Russia

Received April 16, 2001; in final form, May 2002

Abstract—The minimum solubilities of heavy metal hydroxides were calculated and compared with the maximum permissible concentrations of metal ions in various water reservoirs. The efficiency of the reagent method for sewage purification, based on precipitation of heavy metal hydroxides, was estimated.

Among various (chemical, physicochemical, etc.) methods for purification of sewage from galvanic industries to remove toxic heavy metal ions, the reagent methods based on precipitation of poorly soluble hydroxides have received the widest acceptance [1]. Taking into account only the low solubility products of the hydroxides [2], we can hardly explain the fact that the maximum permissible concentrations (MPC) of heavy metal ions in sewage subjected to reagent purification are exceeded manyfold.

The evidence concerning the mechanism by which precipitates of metal hydroxides are formed [3, 4] indicates that hydrolysis of heavy metal ions is accompanied by formation of both mono- and polynuclear hydroxide complexes. Therefore, it is impossible to calculate the solubilities of the hydroxides solely on the basis of their solubility products.

The sewage formed in galvanic industries is characterized by low content of metal ions, and, therefore, we can assume that the contribution of polynuclear interactions is insignificant [5]. Thus, the formation of hydroxide complexes in dilute solutions over hydroxide precipitates is described by Eq. (1).

$$M^{z+} + nOH^- \rightleftarrows M(OH)_n^{z-n}. \quad (1)$$

Here z is the charge of an ion; $n = 1, 2, 3,\ldots$

The aim of this study was to calculate the solubilities of heavy metal hydroxides and compare the values obtained with the MPC for metal ions in various water reservoirs.

As the precipitation of metal hydroxides is accompanied by other physicochemical phenomena (adsorption, coprecipitation, formation of basic salts, aging of precipitates, etc.), the approach proposed in the study can be considered the first stage in mathematical simulation of this complicated process.

The solubility of a metal hydroxide, S, is equal to the total concentration of all chemical forms of metal ions in solution, which result from partial dissolution of a precipitate (taking a hydroxide of a double-charged metal as an example):

$$S = [M^{2+}] + [MOH^+] + [M(OH)_2] + [M(OH)_3^-] + [M(OH)_4^{2-}] + \ldots \quad (2)$$

The concentration of the metal ion M^{2+} can be calculated from the solubility product $SP = [M^{2+}][OH^-]^2$, and the concentrations of hydroxo complexes, by using published data on the stepwise [5] or total [6] formation constants, hydrolysis constants [7, 8], or equilibrium constants for cases involving a solid phase. The calculations were carried out as applied to analysis of sewage purification processes, and, therefore, the solubility products were taken for freshly prepared hydroxides having the greatest solubility [9], and the equilibrium constants, for room temperature and nearly zero ionic strength of solution.

We used the hydrolysis constants described by the following equations [8]

$$M^{2+} + H_2O \overset{k_{10}}{\rightleftarrows} MOH^+ + H_3O^+,$$
$$M^{2+} + 2H_2O \overset{k_{20}}{\rightleftarrows} M(OH)_2 + 2H_3O^+,$$
$$M^{2+} + 3H_2O \overset{k_{30}}{\rightleftarrows} M(OH)_3^- + 3H_3O^+,$$
$$M^{2+} + 4H_2O \overset{k_{40}}{\rightleftarrows} M(OH)_4^{2-} + 4H_3O^+.$$

1070-4272/03/7602-0320 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Taking into account the ionic product of water $K_w = [H_3O^+][OH^-]$, we can bring Eq. (2) by simple transformations to the form

$$S = \frac{SP}{K_w^2}\left([H^+]^2 + K_{10}[H^+] + K_{20} + \frac{K_{30}}{[H^+]} + \frac{K_{40}}{[H^+]^2} + \ldots\right). \quad (3)$$

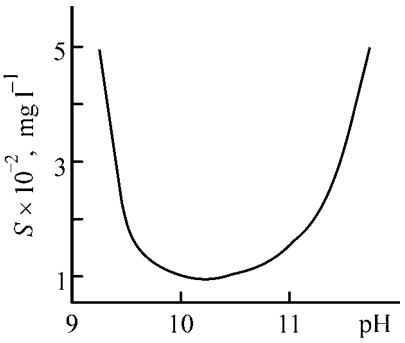
Similarly, Eq. (2) for hydroxides of triple-charged metals can be represented as

$$S = \frac{SP}{K_w^3}\left([H^+]^3 + K_{10}[H^+]^2 + K_{20}[H^+] + K_{30} + \frac{K_{40}}{[H^+]} + \ldots\right). \quad (4)$$

Substituting various $[H^+]$ values in Eqs. (3) and (4), we can determine the pH range in which the solubility S is the lowest.

In this study, we calculated the minimum solubilities for copper(II), zinc(II), cadmium(II), cobalt(II), nickel(II), lead(II), manganese(II), iron(III), and chromium(III) hydroxides and compared the values obtained with MPCs for various water reservoirs. It is ions of these metals that are contained in the sewage of plants having electroplating shops and purifying their wastewater by the reagent method.

As an example, we calculated the solubility of nickel(II) hydroxide as a function of pH with $SP = 10^{-11.89}$ for freshly precipitated nickel hydroxide [10] (2 h after precipitation) and hydrolysis constants [8] $\log K_{10} = -9.86$, $\log K_{20} = -19.0$, $\log K_{30} = -30.0$, and $\log K_{40} = -44.0$. The solubility of nickel hydroxide (mg l^{-1}) as a function of pH is shown in the figure. The calculation demonstrated that the minimum solubility (~110 mg l^{-1}) is observed in the pH range 9.7–10.7.



Calculated content of nickel(II) in solution, S, vs. pH value for the case of nickel precipitation as hydroxide.

The maximum permissible concentration of nickel(II) ions in sanitary-hygienic water reservoirs is 0.1 mg l^{-1}, and that in fish farming pools, 0.01 mg l^{-1}. It follows from the data obtained that, when nickel(II) is precipitated as the hydroxide, its solubility at the optimal pH exceeds the MPC by a factor of 1000–10 000 (depending on a water reservoir). Thus, nickel(II) is among metals easily penetrating into the environment when the reagent method is used for sewage purification.

The calculated values of pH ensuring the minimal solubility of hydroxides of other heavy metals are listed in the table. The data obtained are represented as S_{min}/MPC ratios.

It follows from the table that the reagent method fails to satisfy MPC requirements for fish-farming reservoirs for any of the metal ions except chromium(III). In the case of household-drinking water-supply reservoirs, the MPC level can only be attained for chromium(III), copper(II), and manganese(II).

pH value, minimum solubility of heavy metal hydroxides, and MPC for various water reservoirs*

Cation	pH value	S_{min}, mg l^{-1}	MPC, mg l^{-1}		S_{min}/MPC	
			I	II	I	II
Fe(III)	4–11	2.6	0.3	0.1	9	26
Cr(III)	8.5–10	0.02	0.5	0.07	0.04	0.3
Zn(II)	9–11	3	1.0	0.01	3	300
Cd(II)	11–13	10	0.001	0.005	10 000	2000
Co(II)	10–12	0.15	0.1	0.01	1.5	15
Ni(II)	9.7–10.7	110	0.1	0.01	1100	11 000
Cu(II)	8–12	0.17	1	0.001	0.17	170
Mn(II)	11.2–12.5	0.1	0.1	0.01	1	10
Pb(II)	10.5–11.5	5	0.03	0.1	167	50

* Water reservoir: (I) for household and drinking water supply, (II) for fish-farming.

Sewage is purified to remove heavy metal ions by neutralization with alkaline reagents to pH ≤ 8.5, i.e., at pH values different from the optimal pH listed in the table. Under these purification conditions, the solubility of heavy metal hydroxides [except iron(III) hydroxide] is much higher.

Thus, the reagent method for sewage purification by precipitation of heavy metal hydroxides should be regarded as ineffective.

BRIEF COMMUNICATIONS

On the Possibility of Replacing Standard Chromium-Plating Electrolytes with Sulfate-Oxalate Solutions of Cr(III)

A. A. Edigaryan and Yu. M. Polukarov

Institute of Physical Chemistry, Russian Academy of Sciences, Moscow, Russia

Received February 20, 2002

Abstract—A method for preparing sulfate-oxalate chromium-plating solutions by reducing Cr(VI) from industrial chromium-plating electrolytes to Cr(III) with a Na_2SO_3 solution is proposed.

Replacing environmentally unsafe standard chromium-plating solutions with unharmful electrolytes based on chromium(III) is a priority task of modern electroplating technology. It was shown in [1–3] that the oxalate-sulfate chromium-plating electrolyte makes it possible to obtain with high current efficiency coatings of any thickness, which compare well in mechanical properties and corrosion resistance with coatings formed using standard chromium-plating solutions.

The simplest and technologically most acceptable technique for preparing sulfuric acid chromium-plating solutions in a galvanic shop would be direct reduction of Cr(VI) from standard plating electrolytes to Cr(III). In [4–6], methods were proposed for reducing Cr(VI) to Cr(III). In [4], Cr(III) compounds were obtained by saturating a $CrO_3 + H_2SO_4$ solution with gaseous SO_2 to complete the reduction of Cr(VI) to Cr(III). The excess of SO_2 was removed from the solution by boiling. In [5, 6], CrO_3 or $Na_2Cr_2O_7$ was reduced in a sulfuric acid medium with formaldehyde. However, this failed to ensure complete reduction of Cr(VI). As is known, Cr(VI) inhibits reduction of Cr(III) from sulfuric acid solutions to metal. Therefore, this method cannot be recommended for use to obtain sulfuric acid chromium-plating solutions. Below, a procedure is proposed for reducing Cr(VI) to Cr(III) with a Na_2SO_3 solution directly in standard chromium-plating solutions. The reduction by the reaction

$$2CrO_3 + 3Na_2SO_3 + 3H_2SO_4 \rightarrow Cr_2(SO_4)_3 + 3Na_2SO_4 + 3H_2O \quad (1)$$

yields in solution the necessary components, chromium and sodium sulfates. The reaction proceeds till complete reduction of Cr(VI) ions to Cr(III).

EXPERIMENTAL

A Na_2SO_3 solution was introduced in small portions into a standard $CrO_3 + H_2SO_4$ solution in a certain excess with respect to the amount that was calculated in accordance with Eq. (1) and took into account the hydrolysis of sodium sulfate upon heating the solution. The exothermic reaction of Cr(VI) reduction in an acid medium proceeds vigorously, with strong heating of the solution and evolution of SO_2 as a result of H_2SO_3 decomposition at elevated temperatures. In milder reduction mode, without solution heating, no SO_2 is evolved. The completeness of reduction of Cr(VI) ions was tested by staining the solution with 1,5-diphenylcarbazide. When necessary, the solution was boiled for 1.5–2 h after the reaction was complete, to total removal of SO_2 from the solution. The resulting solution of Cr(III) and sodium was adjusted to $Cr_2(SO_4)_3$ and Na_2SO_4 concentration of 130–140 g l^{-1}. $Na_2C_2O_4$, $Al_2(SO_4)_3 \cdot 18H_2O$, and NaF were introduced into the solution. The recommended composition of the chromium-plating solution is as follows [2] (g l^{-1}): $Cr_2(SO_4)_3$ 130–140, $Na_2C_2O_4$ 25–30, $Al_2(SO_4)_3 \cdot 18H_2O$ 110, Na_2SO_4 130–140, and NaF 15. To stabilize the solution prepared, it was allowed to stay at 90–95°C for 30 min. The working mode was the following: pH 1.0–2.0, temperature 40–45°C, current density 20–50 A dm^{-2}, depending on the solution acidity. The volume current density was up to 10 A l^{-1}. At the above current densities and solution pH values, the electrolyte shows prolonged stable work. The optimal mode for obtaining lustrous chro-

1070-4272/03/7602-0323 $25.00 © 2003 MAIK "Nauka/Interperiodica"

mium deposits is as follows: pH 1.4, current density 30 ± 15 A dm^{-2}, current efficiency 30–35%, rate of coating deposition 1.5–1.8 μm min^{-1}, irrespective of the coating thickness. The electrolyte prepared by reduction of Cr(VI) from standard chromium-plating solutions has the same characteristics as the electrolyte prepared on the basis of Cr(III) sulfate and can be used to deposit protective and decorative coatings and obtain thick chromium layers.

The current efficiency by chromium grows with increasing $Cr_2(SO_4)_3$ concentration and reaches the limiting value at 130 g l^{-1}. Raising the $Cr_2(SO_4)_3$ concentration further does not affect the current efficiency by chromium and, therefore, is inexpedient because of the increasing loss of chromium with finished articles.

Electrodeposition of chromium from an oxalate-sulfate solution allows wide variation of the $Na_2C_2O_4$ concentration in solution. Decreasing this concentration to 40% of that recommended for the composition given above makes somewhat lower the throwing power of the electrolyte, without impairing the coating quality, and raising the concentration by 100% leads to only slight decrease in the throwing power.

Raising the concentration of $Al_2(SO_4)_3 \cdot 18H_2O$ in solution to 100 g l^{-1} leads to an increase in the admissible current densities and improves the throwing power of the electrolyte; however, making this concentration higher than 110 g l^{-1} gives no additional positive effect, being, therefore, inexpedient.

Introduction of NaF into the solution leads to much higher current efficiency without impairing the deposit quality; the optimal salt concentration is 20 g l^{-1}.

The electrolyte proposed contains two expended components, $Cr_2(SO_4)_3$ and $Na_2C_2O_4$, with the concentration of the latter falling as a result of oxidation at the anode and reduction at the cathode. The decrease in the concentration of $Cr_2(SO_4)_3$ in the solution on passing through it about 60 A h l^{-1} of electricity (which corresponds to a decrease in the salt concentration in solution by 50 g l^{-1} relative to the initial value) results in that the current efficiency falls from 30–35% to 25%. To prevent the decrease in the current efficiency, a chromium(III) salt should be added to the electrolyte with account of the amount of electricity passed.

The expenditure of $Na_2C_2O_4$ is compensated for by its introduction into the solution when necessary.

One of factors hindering the industrial use of chromium-plating electrolytes based on Cr(III) ions is oxidation of Cr(III) ions to Cr(IV) at the anode and the resulting necessity for separation of the anode and cathode spaces, which complicates the technology of the galvanic process. Use of sulfate-oxalate solutions and anodes made of platinum-plated titanium makes it possible to carry out the process without separating membranes, since Cr(VI) forming at the anode is 100% reduced to Cr(III) by products of partial cathodic reduction, i.e., by Cr(II) ions. As a result of current expenditure for additional formation of Cr(II) ions, the current efficiency by chromium decreases from 30–35 to 25% without any degradation of the deposit quality [7].

Coatings of thickness 20 μm have (depending on current density) a strength within the range $(8.8–15) \times 10^3$ MPa and internal stretching stresses of $(1.2–7.0) \times 10^2$ MPa. According to X-ray diffraction data, the deposits are X-ray-amorphous; in chemical composition, determined by X-ray photoelectron spectroscopy (XPS), and in the corrosion-protective and electrochemical behavior the deposits are close to chromium carbide $Cr_{23}C_6$ [3, 8].

CONCLUSIONS

(1) A simple method is proposed for obtaining sulfate-oxalate solutions for chromium plating by reducing Cr(VI) from standard electrolytes with sodium sulfite.

(2) Sulfate-oxalate solutions obtained by reduction from standard electrolytes make it possible to deposit chromium coatings of arbitrary thickness with high current efficiency.

(3) The deposits obtained are X-ray-amorphous and close in chemical composition and corrosion-electrochemical properties to chromium carbide $Cr_{23}C_6$.

A Mass-Spectrometric Study of Gaseous Products of Thermal Desorption from Diamond and Graphite

B. Ya. Zorin, S. Yu. Plastinin, and E. P. Smirnov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 10, 2002

Abstract—The method of thermal desorption in a vacuum, with gaseous products recorded by mass-spectrometry, was applied to study the state of the surface of diamond and graphite.

Diamond and graphite are carbon materials widely used in various fields of science and technology. Studying the state of the surface of these materials is of scientific and practical importance.

It has been established by numerous studies using chemical and physicochemical analytical techniques that, when interacting with the surface of diamond and graphite, oxygen forms various functional oxy groups: hydroxy, carboxy, carbonyl, ester and ether, etc. [1, 2].

The aim of the present study was to determine the thermal stability of the functional oxy groups of diamond and graphite by analyzing the gaseous products evolved in linear heating of diamond and graphite, with these products recorded simultaneously by mass-spectrometry.

Thermal desorption spectra (Figs. 1 and 2) were obtained by plotting envelopes in the coordinates molecular ion peak intensity–temperature.

EXPERIMENTAL

As objects of study served initial and modified powders of natural diamond of the AM-3 brand and graphite of the GSM-0.5 brand. The specific surface area of the samples under study was found using the method of low-temperature adsorption of nitrogen before and after modification to be 12 and 1.7 $m^2 g^{-1}$ for, respectively, diamond and graphite. The concentration of modifying elements was 1.0 μmol m^{-2} for sodium ions on the graphite surface and 7.0 μmol m^{-2} for titanium ions in the titanium oxide layer. Before measuring the mass spectra, the samples were heated to 100°C in an inert medium for 30 min to remove physically sorbed water.

A 10–30-mg portion of a sample under study was placed in a quartz reactor connected, with the use of a special seal, to the vacuum system of an MI-1201 mass-spectrometer. To monitor the temperature, a Chromel–Alumel thermocouple was inserted into the bottom part of the reactor. The thermo-emf was measured with a KSP-4 potentiometer. The sensitivity of the MI-1201 mass-spectrometer was improved by using a VEU-1 secondary electron multiplier with an RTO-1 unit (wide-band current recorder). The mass spectra were recorded by an N-117 light-beam oscilloscope. Mass spectra of gaseous products of thermal desorption were recorded 5 or 6 times at any given temperature and then processed mathematically. The results of this processing were used to evaluate the experimental error. The desorption was carried out in a vacuum at residual pressures of 10^{-3}–10^{-5} Pa, with the temperature raised linearly from 20 to 1000°C at a rate of 10–12 deg min^{-1}. Spectra of thermal desorption from the initial diamond and graphite are presented in Figs. 1a and 1b.

The thermal desorption spectrum of diamond shows a peak at about 400°C for CO_2, and a peak at about 450°C and steep rise in the tempeature range 850–1000°C for CO. No peaks are observed in the range 20–960°C in the spectrum of water.

The thermal desorption spectrum of graphite (Fig. 1b) differs significantly from that of diamond. For example, the temperature at which a peak is observed for CO_2 is about 480°C, and the spectrum for CO shows a steady gradual rise, becoming steep only at about 900°C. The spectrum for water exhibits a steep decrease in the range from 20 to 120°C and then decreases steadily and gradually, with a minor peak at 360°C.

The common feature of all the thermal desorption spectra of diamond and graphite samples is desorption of CO_2 at lower temperatures, compared with that of CO. Carbon monoxide makes a greater contribution than carbon dioxide to the total number of carbon atoms removed from the surface.

For diamond, the peaks of CO, CO_2, and H_2O desorption at about 400°C are due to decomposition of oxy groups containing carbonyl, carboxy, and quinone groups. The desorption of water is due to dehydration of oxy groups containing hydrogen atoms, i.e., hydroxy groups.

A similar pattern of distribution among groups is also characteristic of graphite, with a quantitative difference consisting in that the yield of water is, in this case, 2–3 times that for diamond.

The results obtained are in good agreement with the data of Japanese researchers, who heated diamond in a vacuum and recorded the forming gaseous products by mass spectrometry. They established that the onset of intense gas evolution corresponds to a temperature of 360°C, and at 900°C the evolution of carbon dioxides ceases [3].

Modification of oxidized graphite samples with alkali metal ions, and, in particular, sodium ions, leads to proton substitution in the functional oxy groups to give alcoholates or phenolates [4]. A thermal desorption spectrum of the sample obtained is shown in Fig. 2a. It can be seen that a CO_2 peak is observed at about 600°C, with its intensity exceeding approximately 4-fold the corresponding peak for an unmodified sample.

It may be assumed that the substitution of hydrogen ions in the hydroxy groups on the graphite surface with sodium ions catalyzes the surface diffusion of oxygen from oxy groups to the active centers of carboxy groups decomposing at 600°C.

As second type of modification of functional oxy groups on the surface of diamond and graphite was growth of a titanium oxide layer (about 100 Å thick) by the chemical assembly technique [5]. The spectra obtained for diamond are shown in Fig. 2b. Modification of the surface of oxidized diamond with a titanium oxide layer leads to a dramatic increase in the CO yield at temperatures higher than 600°C. In contrast to the preceding set of experiments, this effect can be attributed to occurrence of a solid-phase reaction at the interface between the diamond surface and the titanium oxide layer. In the process, the role of diamond oxidizer is played by oxygen ions diffusing upon heating to these temperatures from the lattice of titani-

um oxide TiO_2, with, presumably, partial reduction of titanium(IV) ions to Ti(III).

CONCLUSIONS

(1) Thermal desorption of CO_2 occurs at lower temperatures than that of CO. Carbon monoxide makes a greater contribution than carbon dioxide to the total amount of carbon atoms removed from the surface in thermal desorption.

(2) Modification of the diamond and graphite surfaces allows control over the shift of temperature ranges in thermal desorption.

Polymeric Formulations Based on Iron and Cobalt Molybdophosphates and Polyacrylates

L. A. Egorova, N. I. Radishevskaya, and T. I. Izaak

Tomsk State University, Tomsk, Russia

Department of Structural Macrokinetics, Tomsk Scientific Center, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received October 2, 2002

Abstract—The possibility of using synthesized iron(III) and cobalt(II) molybdophosphates as dyes in dyeing of copolymers and polymeric formulations based on methacrylic acid and methyl methacrylate and also as pigments deposited onto natural and inorganic supports for heterogeneous dyeing of polymeric materials was studied.

Dyeing of polymeric materials has always been and still is an important problem of modern materials science The widely used organic pigments frequently fail to ensure the necessary working properties and loose brightness in the course of time under the action of light, which impairs the commercial value of plastic building materials and household articles. Some problems can be solved by introducing light-resistant inorganic pigments. Promising in this regard are heteropoly compounds making it possible to obtain brightly colored and light-resistant formulations for finishing building materials and consumer goods. The increased interest in iso-and heteropoly compounds is due to the wide variety of physicochemical and functional properties of the structural forms obtained.

This study is concerned with the properties of polymeric (polyacrylate) materials dyed with iron(III) and cobalt(II) molybdophosphates. Iron(III) and cobalt(II) molybdophosphates were obtained using two methods: (i) directly from 12-molybdophosphoric acid and (ii) from molybdenum(VI) oxide by its alkaline fusion with sodium hydrophosphate and reaction with iron(III) and cobalt(II) chlorides in acid and weakly acid aqueous media [1, 2].

The salts obtained are brightly colored: iron(III) 12-molybdophosphates are yellow, and cobalt(II) 11-molybdophosphates, lylac. Iron(III) and cobalt(II) molybdophosphates, which are soluble in organic solvents, homogeneously dye copolymers of acrylic acid CH_2=CHCOOH and methyl methacrylate CH_2=C(CH_3)$COOCH_3$, obtained by block polymerization (60°C, benzoyl peroxide as initiator). The intermolecular interactions in the polymeric formulations were studied by IR spectroscopy in the spectral range 4000–400 cm^{-1} (Specord-M80). The dominant wavelength and color purity of the salts obtained were calculated from reflectance spectra measured on a Specord-M40 spectrophotometer in the wavelength range 350–900 nm.

Homogeneous introduction of a heteropoly ion into the structure of acrylic polymers leads to a shift of the absorption band at 1730 cm^{-1}, associated with the functional group COO^- of the copolymer, to lower frequencies (1580 cm^{-1}, C=O bond vibrations), which is presumably due to coordination of the COO^- group upon the introduction of a heteropoly compound. The absorption band of the starting polymer, which is observed at 1730 cm^{-1}, corresponds to stretching vibrations of an un-ionized carboxy group and appears because of the partial coordination of COOH groups [3].

The formation of a coordination bond between a metal atom and the oxygen of the carboxy group causes redistribution of the electron density between COO^- bonds and gives rise to two frequencies of a symmetric and an asymmetric vibrations [4, 5]. Similar changes occur, according to IR spectral data, upon introduction of iron(III) and cobalt(II) molybdophosphates into polyacrylate systems. The spectrum of a polymer dyed, e.g., by iron(III) molybdophosphate (Fig. 1) contains absorption bands at ν_{as} = 1580 cm^{-1} and ν_s = 1385 cm^{-1}. The difference of these frequencies $\Delta\nu = \nu_{as} - \nu_s$ is a measure of the covalence of bonding between the heteropoly compound and oxygen. The calculated value of $\Delta\nu$ is 195 cm^{-1}, which is lower than the known value of 225 cm^{-1} [5], and,

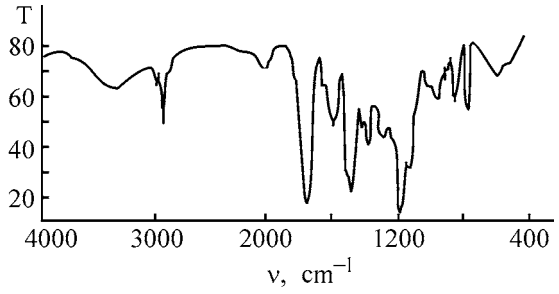

Fig. 1. IR spectrum of acrylic copolymer dyed with iron(III)12-molybdophosphate. (T) Transmission and (ν) wave number.

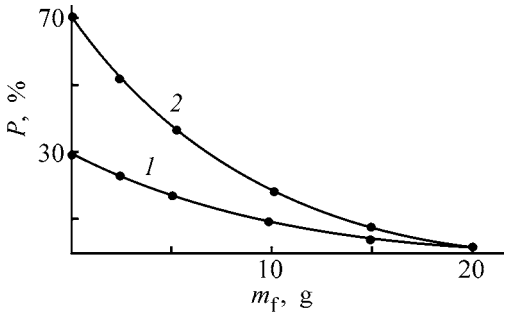

Fig. 2. Color purity P of a pigment vs. mass m_f of filler (silica gel). Pigment mass 1 g. (*1*) Cobalt(II) 11-molybdophosphate and (*2*) iron(III) 12-molybdophosphate.

consequently, the bonding between the heteropoly compound and the carboxy group is mainly ionic. A broad band peaked at 1950 cm^{-1}, characteristic of vibrations of the M–O=C bond, is observed in the range 2000–1900 cm^{-1}. A pronounced peak corresponding to stretching vibrations of the Fe–O bond appears at 520 cm^{-1} [3, 4, 6]. The homogeneous dyeing of the copolymer is apparently due to coordination of the heteropoly compound with oxygen-containing fragments.

Polymers can also be dyed with heteropoly salts deposited onto natural silicate supports. The deposition of heteropoly compounds can be done in the course of their synthesis. The pigments obtained can be further used for heterogeneous dyeing of polymers. The results obtained in a study of how the color purity depends on the mass of silica gel filler are shown in Fig. 2. It can be seen that, with increasing mass fraction of the filler (silica gel), the color purity decreases steadily. For iron(III) molybdophosphate the color purity is higher, and cobalt(II) molybdophosphate has pleasant delicate coloration. The calculations performed demonstrate that the optimal amount of filler is about 5 g per 1 g of pigment.

Dyed fillers, such as silica gel support, diopside, tremolite, and wollastonite, and also ground porcelain, make it possible to decrease dramatically the expenditure of the pure pigment and can be used in heterogeneous dyeing of polymeric materials. As would be expected, the color of the cobalt(II) salt, which has lacunar structure (P : Mo = 1 : 11), is defined by the *d*–*d* transition (455–465 nm). The color of iron(III) molybdophosphate, which has the Keggin structure (P : Mo = 1 : 12), depends to a greater extent on the influence exerted by the environment of the heteropoly ion on the *d*–*d* transition (λ_d = 570 nm).

The polymeric formulations obtained have bright color and are not bleached under sunlight. Dyed methyl methacrylate samples were subjected to the action of a UV light (DRL-400 lamp) for 45 h and to outdoors daylight for half a year. No changes in their optical properties were observed. The formulations obtained on the basis of polymethyl methacrylate and heteropoly compounds show promise as components for modern building materials.

CONCLUSIONS

(1) Iron(III) and cobalt(II) molybdophosphates, which are soluble in organic solvents, homogeneously dye copolymers of acrylic acid and methyl methacrylate, which is due to coordination of the heteropoly ion with oxygen-containing fragments of the acrylic polymer.

(2) Heteropoly salts of iron(III) and cobalt(II), supported by such fillers as silica gel, wollastonite, diopside, tremolite, and ground porcelain can be used in heterogeneous dyeing of polymethyl methacrylate and other acrylic polymers.

BRIEF COMMUNICATIONS

Synthesis of Bis(Amido Sulfimides) from 2-Sulfoterephthalic Acid Imide Chloride

T. A. Aslanov

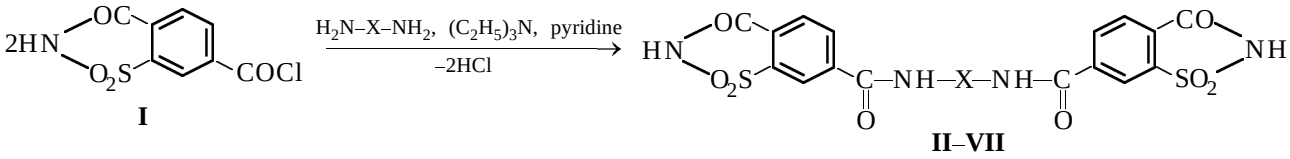
Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgait, Azerbaijan

Received May 13, 2002

Abstract—A series of bis(amido sulfimides) were prepared by condensation of 2-sulfoterephthalic acid imide chloride with aliphatic and aromatic diamines.

Trimellitic acid and its derivatives are widely used as monomers in production of polyimide polymers [1, 2]. Synthesis of less studied 2-sulfoterephthalic acid imide, 4-sulfoisophthalic acid imide, and their esters was reported in [3].

This paper describes previously unknown 2-sulfoterephthalic acid imide chloride **I** [4] and its amide derivatives **II**–**VII** containing amide and imide groups, which show promise as monomers for preparing poly(amido imides).



R = $(CH_2)_2$ (**II**), $(CH_2)_4$ (**III**), $(CH_2)_6$ (**IV**),  (**V**),  (**VI**), and  (**VII**).

Condensations of **I** with diamines were performed at 40–45°C; a solution of acid chloride was gradually added with stirring to a solution of an appropriate diamine in dimethylacetamide, and an equimolar amount of triethylamine was added to bind the HCl released.

The reactions give bis(amido sulfimides) **II**–**VII** in high yields. The compositions and structures of **II**–**VII** were confirmed by elemental analysis (see table) and IR spectroscopy. The IR spectra of **II**–**VII** contain C–N absorption bands at 1660–1600 cm^{-1}, bands at 1380–1300 and 1200–1130 cm^{-1} belonging to asymmetric stretching vibrations of the SO_2 group in the saccharin ring, and N–H bands at 3350–3310 cm^{-1} [4, 5].

EXPERIMENTAL

Dimethylacetamide, triethylamine, and pyridine were purified as described in [6, 7]; diamines, by recrystallization and vacuum distillation; and hexamethylenediamine, by distillation in an argon flow at 198–199°C (mp 40°C).

2-Sulfoterephthalic acid imide chloride I. A 250-ml round-bottomed flask with a reflux con-

denser and a calcium chloride tube was charged with 2.1 g (0.01 mol) of PCl_5 and 2.27 g (0.01 mol) of sulfoterephthalic acid imide. The mixture was stirred. In the process, the mixture spontaneously warmed up to 40–45°C. After completion of the exothermic reaction, the temperature was raised to 95–100°C, and the heating was continued for an additional 2 h. After reaction completion, $POCl_3$ was distilled off in a water-jet-pump vacuum. Then 50 ml of benzene was added, and the mixture was stirred for 10–15 min. The solvent and $POCl_3$ were distilled off from the filtrate. The remaining oily product was successively washed on a glass frit with dry carbon tetrachloride, chloroform, and benzene, after which it was recrystallized successively from dry toluene and acetone. The resulting light brown product was dried in a desiccator to constant weight.

Bis(amido sulfimide) VII derived from 2-sulfoterephthalic acid imide chloride and *p,p*'-diaminobiphenyl. A three-necked round-bottomed flask with a power-driven stirrer and a tube for nitrogen outlet was charged with 30 ml of dimethylacetamide and 1.85 g (0.01 mol) of *p,p*'-diaminobiphenyl. Then 5 g (0.02 mol) of chloride **I** was added in an inert atmosphere. Triethylamine or pyridine was added to neutralize the HCl released. The reaction temperature was maintained at 40–45°C. After adding the whole amount of **I**, the mixture was stirred for an additional 30 min. In the course of the reaction, a dark product formed. After reaction completion, 150 ml of distilled water was added, and the mixture was filtered through a glass frit. The product was dried at room temperature and then brought to constant weight in a vacuum oven.

Bis(amido sulfimides) derived from *m*- and *p*-phenylene-, ethylene-, tetramethylene-, and hexamethylenediamines were prepared similarly.

CONCLUSION

Previously unknown 2-sulfoterephthalic acid imide chloride was prepared, and bis(amido sulfimides) showing promise as monomers were prepared by its reactions with diamines.

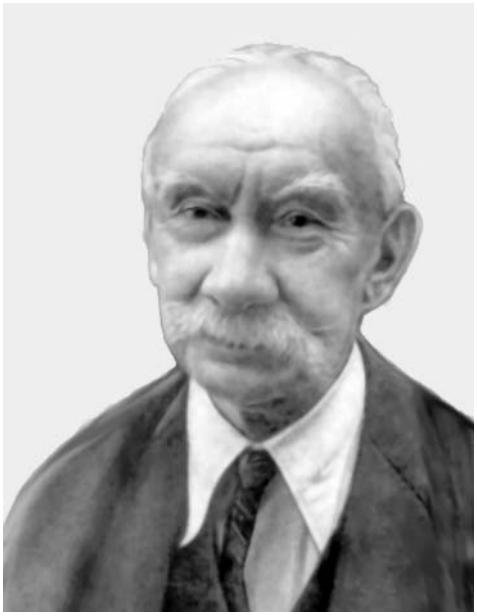
Professor Vladimir Yakovlevich Kurbatov (To 125th Anniversary of His Birthday)

Vladimir Yakovlevich Kurbatov made a major contribution to investigations into the nature of the liquid state, thermal properties of liquids, and their structural features, to improvement of teaching of physical and colloid chemistry at St. Petersburg Technological Institute and other higher-school institutions, and to studies of D.I. Mendeleev's creative heritage; he also was a known historian of architecture, art critic, and student of local lore.

He was born on January 24, 1878, in St. Petersburg into the family of an office employee, court councilor Yakov Ivanovich Kurbatov (1845–1881). The early death of the head of the family with three infants led to severe financial difficulties. Already at the age of 14, when being a secondary-schoolboy, V.Ya. Kurbatov had to do coaching and try to earn a living in other ways. Nevertheless, he finished gymnasium with gold medal in 1896 and entered the natural department of the physico-mathematical faculty of St. Petersburg University. In those years, the university had no special laboratory or chair of physical chemistry; however, D.P. Konovalov (1856–1929, academician of the Academy of Sciences of the USSR since 1923), who headed the chair of inorganic chemistry after D.I. Mendeleev (1834–1907) left the university, delivered a separate course of lectures on physical chemistry beginning in 1895. Since 1897, lectures on some sections of physical chemistry (electrochemistry, photochemistry) were also delivered by privatdocent V.A. Kistyakovskii (1865–1952, academician of the Academy of Sciences of the USSR since 1929). By that time, Konovalov was already very well known; the essential results of his classical study "On Pressure of Solution Vapor" (1884) were described in all courses of lectures and textbooks of physical chemistry, beginning in the 1890s. Detailed recollections of Konovalov's scientific and pedagogical activities were left by one of the most prominent representatives of his school, A.A. Baikov (1870–1946, academician of the Academy of Sciences of the USSR since 1923) [1].

In 1897, V.Ya. Kurbatov, when still being a student, commenced scientific research at the laboratory of inorganic chemistry under Konovalov's supervision. In 1900, Vladimir Yakovlevich graduated from the



university; his diploma work was honored with minor A.M. Butlerov Prize, awarded by the Russian Physicochemical Society. From 1900 till 1907, V.Ya. Kurbatov was a laboratory assistant at the chemical laboratory of the university. Already beginning in 1902, *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva* (Journal of the Russian Physicochemical Society) regularly published interesting results of his experimental studies concerned with the properties and structure of various liquids, temperature dependence of specific heat, and heat of evaporation. Vladimir Yakovlevich took active part in meetings of the Society and made reports of his new investigations.

In 1903–1913, V.Ya. Kurbatov repeatedly went to business trips abroad. In particular, in 1905, he worked at the laboratory of H. Le Chatelier (1850–1936) in Paris. The same laboratory was the place of on-the-job training of other known representatives of Konovalov's school: Baikov, B.G. Karpov (1870–1940), M.S. Vrevskii (1871–1929, academician of the Academy of Sciences of the USSR since 1929), I.I. Zhukov (1880–1949, academician of the Academy of Sciences of the USSR since 1946), and others.

The first summary of the results obtained in experimental studies of more than 30 organic liquids

1070-4272/03/7602-0332 $25.00 © 2003 MAIK "Nauka/Interperiodica"

was given in V.Ya. Kurbatov's monograph *O molekulakh, obrazovannykh soedineniem tozhdestvennykh grupp. Yavlenie assotsiatsii* (On Molecules Formed by Combination of Identical Groups. Association Phenomenon), published as separate edition in St. Petersburg in 1908. The most important concepts of this study have been commented by Yu.I. Solov'ev [2] and V.V. Razumovskii [3]. According to the concepts developed by V.Ya. Kurbatov, various kinds of anomalies in water, alcohols, and other liquids can be accounted for by the existence of complex molecules (associates), which disintegrate when temperature is raised. Based on a study of specific heats and heats of evaporation of liquids, the scientist came to important, by that time, conclusions that, in particular, "crystal-forming forces reflect on the properties of a substance in the liquid state" [3].

In 1907–1909, V.Ya. Kurbatov taught physical chemistry at St. Petersburg Technological Institute; in 1909–1921, he worked at various educational institutions of St. Petersburg (Petrograd). Simultaneously, he continued experimental studies of properties of liquids. By 1916, V.Ya. Kurbatov had studied the properties of more than 150 liquids and generalized the results he obtained in a large paper "On Specific Heat of Liquids," which was published in *Izvestiya Petrogradskogo Tekhnologicheskogo Instituta* (Transactions of Petrograd Technological Institute) (1917, vol. 24, pp. 1–383.

V.Ya. Kurbatov became a professor at the chair of physical chemistry of St. Petersburg Technological Institute in 1921, and head of this chair in 1922; in 1925–1927 he was elected deputy rector for educational work. The main direction of his scientific research remained the same. By 1927, he accumulated a vast body of experimental data on specific heats of various liquids, including some liquid metals (Hg, Na, K, Cd, Pb), heats of evaporation and boiling points of liquids at different pressures, surface tension and capillary properties of liquids. This material was discussed and systematized in his third generalizing paper published in *Izvestiya Teknologicheskogo Instituta im. Lensoveta* (Transactions of Lensovet Technological Institute, 1927, vol. 1, pp. 1–238).

In subsequent years, the total number of organic liquids whose specific heat and other properties were studied by V.Ya. Kurbatov and his pupils became as large as 450 [3]. Such a vast amount of experimental data made it possible to draw certain conclusions about the influence exerted by one or another functional group of a compound on its properties. The results obtained became part of reference books, were regularly published and reported at major scientific conferences and meetings of the All-Union Mendeleev Chemical Society.

Beginning in 1919, V.Ya. Kurbatov carried out a large set of investigations in the field of colloid solutions and jellies. Despite the technological aim of these studies, the author came to a number of important conclusions of general theoretical nature, formulated conditions for formation and preservation of jellies and colloids, and put forward the "crystal-polyamphionic" and then "polyionic-halise" theories of electrolyte solutions. These new approaches to the nature of solutions were described, among other issues, in his monograph *Fiziko-khimicheskie teorii i ikh prilozhenie v tekhnike* (Physicochemical Theories and Their Application in Technology) (Leningrad, 1929, 856 pp.) and other publications [3].

Being Mendeleev's and Konovalov's follower, V.Ya. Kurbatov always closely associated his scientific research with solution of concrete technological problems. Already in the first years of his scientific activities, he carried out a set of investigations concerned with the nature of hardened steels; later, he was invited as consultant in construction of chemical plants and served as a member of Scientific-technological councils at a number of applied institutes. V.Ya. Kurbatov actively cooperated with the Scientific and technological department of VSNKh (Supreme Council of National Economy), created in Petrograd in 1918.

Together with his colleagues from he Technological Institute, V.Ya. Kurbatov was among the authors of the well-known "Memorandum on Importance of Chemistry in Economical Development of the USSR," presented to the Soviet Government in 1928. The Committee for Chemicalization at Council of People's Commissaries of the USSR, created later, played an important part in the restoration and reconstruction of the existing chemical plants and construction of new plants [4]. V.Ya. Kurbatov's idea that a close association between the scientific and applied research is necessary was described in a brochure *Nauka—osnova khimicheskoi promyshlennosti* (Science as Basis of Chemical Industry) (Leningrad, 1929, 69 pp.).

V.Ya. Kurbatov made a major contribution to studies of Mendeleev's scientific legacy and to popularization of his concepts and works. Already at the First Mendeleev Congress, held in the year when the great scientist died (St. Petersburg, December 20–30, 1907), V.Ya. Kurbatov presented a large report "General Survey of D.I. Mendeleev's Scientific Activities" [5]. A detailed analysis of the periodic law discovered by

Mendeelev was made in V.Ya. Kurbatov's monograph *Zakon D.I. Mendeleeva* (D.I. Mendeleev's Law) (Leningrad, 1925, 453 pp.). Vadinir Yakovlevich took part in writing a book of recollections of Mendeleev [6] and wrote a book for schoolchildren about the great Russian scientist [7]. It should also be mentioned that V.Ya. Kurbatov proposed in 1925–1926 a hyperboloid form of Mendeleev's periodic system of chemical elements [3].

During the whole time of his scientific and pedagogical activities, V.Ya. Kurbatov paid much attention to publication of textbooks of widely varying level. In the series *Biblioteka rabochego* (Worker's Library) he wrote in a popular manner *Nachala khimii* (Fundamentals of Chemistry) (Petrograd, 1923, 368 pp.). He wrote *Vvedenie k izucheniyu i prakticheskim zanyatiyam po fizicheskoi khimii* (Introduction to Studies and Laboratory Works in Physical Chemistry) (Leningrad, Leningrad Technological Institute, 1926, 237 pp.) for students of the Technological Institute and *Khimiya kolloidov i studnei* (Chemistry of Colloids and Jellies) for students of the Military Academy (Leningrad, 1925, 232 pp.).

In August 1934, the degree of doctor of chemical science was conferred on V.Ya. Kurbatov. In 1941–1944, Vladimir Yakovlevich taught at Kazan Institute of Chemical Engineering. In 1944, he became Honored Scientist and Technologist of Tatar Autonomous Soviet Socialist Republic.

Having returned from evacuation in 1944, V.Ya. Kurbatov headed the chair of inorganic chemistry at Leningrad Sanitary-Hygienic Institute and became head of the chair of physical chemistry at Lensovet Technological Institute in January 1949.

V.Ya. Kurbatov was not only a prominent scientist in the field of physical and colloid chemistry; he was also well-known as historian of architecture, student of local lore, a connoisseur of Russian art, and that of St. Petersburg and environs in the first place. Vladimir Yakovlevich was very closely associated with members of the *Mir Iskusstva* (World of Art) Society which appeared in the very end of the XIX century, among whose main organizers were such outstanding persons of the Russian culture as A.N. Benua (1870–1960), S.P. Dyagilev (1872–1929), and others. In his reminiscences [8], A.P. Ostroumova-Lebedeva (1871–1955), a known artist and active member of the Society, mentioned more than once this aspect of V.Ya. Kurbatov's activities. St. Petersburg and environs, their gardens and parks, were the favorite subjects in the creative work of Benua, M.S. Dobuzhinskii (1875–1957), and Ostroumova-Lebedeva. The monograph on St. Petersburg [9], written by V.Ya. Kurbatov, was decorated, together with a large number of photographs, with numerous engravings by Ostroumova-Lebedeva. The scientist also wrote books about environs of St. Petersburg: Gatchina, Pavlovsk, Peterhof, and others, a great number of papers about gardens, parks, and museums of St. Petersburg.

Vladimir Yakovlevich Kurbatov passed away on February 12, 1957, at the age of 79. Elder generations of graduates from the Technological Institute remember this comprehensively educated, modest, and well-wishing person, who made a major contribution to the development of the domestic chemical science and training of specialists at the Technological Institute and other higher-school educational institutions. Of high and independent value are his descriptions of the architectural ensembles and museums of St. Petersburg and environs. The whole V.Ya. Kurbatov's life was devoted to science and art.

BOOK REVIEWS

Kozin, L.F. and Volkov, S.V., *Vodorodnaya energetika i ekologiya* (Hydrogen Power Engineering and Ecology), Kiev: Naukova Dumka, 2002, 336 pp.

The monograph by known Ukrainian scientists, Professor L.F. Kozin and Academician S.V. Volkov (National Academy of Sciences of the Ukraine), considers and discusses the state of modern power engineering and global problems encountered, in the first place, by countries not provided to a full extent with domestic natural energy carriers. The authors emphasize that, at present, electric power is mostly generated at thermal and nuclear power plants and hydroelectric power stations, and only its minor part, by ecologically safe devices employing renewable sources of energy.

Electric power generation at thermal power plants, especially those using coal, entails severe contamination of the environment with oxides of sulfur, nitrogen, and metals, and deteriorates life conditions on the Earth.

Nuclear power plants allow large-scale production of electric and thermal power. At present, Ukrainian nuclear power plants produce 39.6–42.2% of the total electric power consumed in the country. However, their operation requires an exceedingly high culture of maintenance and strict observance of the necessary technological mode. The consequences of the Chernobyl disaster will be felt by many generations of those living in the Ukraine and adjacent provinces of Belarus and Russia. The Ukraine has not solved up to now the problem of processing of the nuclear waste, which is still put into storage.

The main attention is given by the monograph to prospects for development of hydrogen power engineering, discusses the possibility of combining this power source with nuclear power plants, with nuclear-hydrogen power plants to be created in, probably, distant future. The authors also consider such problems as origin of oil in the Earth, formation of ozone holes, and put forward their own hypotheses.

The book comprises a brief foreword (pp. 3 and 4), nine sections, conclusion, and a list of references. Small first (pp. 5–13) and second (pp. 14–16) sections analyze energy-related and ecological problems of most general nature. In particular, the authors note that the so-called "post-Chernobyl syndrome" affected adversely the prospects for development of nuclear power engineering, including scientific research in this field not only in the Ukraine, but also in some other countries.

The third section of the monograph (pp. 17–46) contains evidence concerning the resources and consumption of combustibles (oil, natural gas, coal, and lignite) in various countries and presents a vast body of numeric data, mainly for recent years. According to the available estimates, up to 75% of the proven resources of coal and lignite are found in the territory of Russia, United States, and Ukraine. Russia and the United States are leaders in production of natural gas. The authors call attention to the correlation between the gross national product and the consumption of energy resources per capita. It is noted that the deficiency of energy resources in the Ukraine and their high cost favored the breakdown of industry, degradation of agriculture, deterioration of the living standards of the population, and other negative phenomena of the last decade.

The fourth section (pp. 47–96) is devoted to the development of nuclear power engineering in the Ukraine and to analysis of its scientific, technological, and ecological problems. At present, nuclear power plants of the country have in operation 16 power units, with the problem of utilization of nuclear waste being topical. The authors pay special attention to the Chernobyl disaster, the reasons why it occurred, and elimination of its consequences. After the disaster at the fourth power unit of the Chernobyl nuclear power plant in 1986, three power units had been in operation, with the last of these removed from service in December 2000.

The fifth section (pp. 86–96) presents evidence concerning the scale of energy production in the Ukraine. The thermal power plants produce about 54.5–57.1% of the electric and thermal power generated in the country; however, the industry is in deep crisis. The charges for fuel transportation have increased, and the overwhelming majority of units have exhausted their expected service life. Their being worn out and obsolescence lead to increased fuel expenditure and impair other operation characteristics. The Ukraine's

1070-4272/03/7602-0335 $25.00 © 2003 MAIK "Nauka/Interperiodica"

hydroelectric power stations have nearly totally exhausted the potential resources of hydroelectric energy and can produce no more than 5.0–5.5% of the total output of electric power in the country. Various unconventional power sources can only satisfy 1–2% of the country's demand.

The sixth (pp. 97–200) and seventh (pp. 201–216) sections, which are devoted to hydrogen and hydrogen power engineering, in fact occupy the central position in the monograph and contain the results of numerous investigations carried out by the authors of the book in this field. Hydrogen is the most widely occurring element in the Earth and the ecologically unique type of fuel whose combustion products are water vapor or liquid water. The physicochemical properties of hydrogen and metal hydrides and methods for obtaining hydrogen are considered in detail. Particular attention is given to hydrogen production by reacting water with aluminum alloyed with various components positively influencing the rate of the process. According to the data presented by the authors, world's output of hydrogen was 83 million tons in 2000.

The eighth section of the book (pp. 272–292), devoted to ecology and environment, contains an analysis of reasons for various negative natural phenomena and processes. To these belong the greenhouse effect, ozone holes, acid rains, and "thermal contamination" of the planet. The authors, in particular, believe that freons have nothing to do with the appearance of ozone holes over Antarctic, and put forward their own considerations on the issue. It is also noted that the human technological activities do not exert, as yet, any detrimental effect on the thickness of the ozone layer over the planet. The reasons for the appearance of acid rains and the pollution of the human environment with harmful combustion products of natural gas, oil, coal, lignite, and combustible shale are discussed.

The ninth section (pp. 293–315) prognosticates what power sources will be in use in the third millennium. In the authors' opinion, the main power sources will be solid fuel (coal, shale, peat), hydrogen, nuclear sources of heat and electric power, and various renewable power sources.

In the conclusion (pp. 316–319), the authors note once again the deficiency of energy resources in the Ukraine and formulate concrete proposals aimed at satisfying the country's demand for energy carriers. At present, not only the nuclear fuel cycle, but also the conventional thermal fuel cycle, are not provided with energy carriers. Their deficiency creates real difficulties in manufacture of competitive industrial goods and poses a threat to the stability of the national economy and to the national safety.

The bibliographic list (pp. 320–334) contains 373 references to studies published mostly in recent years.

The monograph written by scientists with rather wide range of interests luckily combines an analysis of the concrete situation with energy in the Ukraine and discussion of quite a number of global problems. The main attention is given to the hydrogen power engineering and methods for production of hydrogen. Also presented are the authors' hypotheses concerning the mechanisms of oil formation and appearance of ozone holes. The book is well written, interesting to read, and contains a vast factual material; the authors do not abuse the reader with excess of special terminology. Despite the disputable nature of some of the problems discussed, the book can be recommended for reading to a wide audience of readers. The reference material summarized by the authors will undoubtedly be of interest for specialists in power engineering and ecology.

BOOK REVIEWS

Habashi, F., *Textbook of Pyrometallurgy*, Quebec City: Laval Univ., 2002, 592 pp.

Professor F. Habashi, a Canadian scientist, supplemented the voluminous set of his publications[1] with a new textbook describing pyrometallurgical processes in ferrous and nonferrous metallurgy. The whole material is presented in the form of 38 small chapters grouped into five parts. The first of these, "Introduction" (chapters 1–4, pp. 1–75) contains evidence about the history of high-temperature metallurgical processes. Mention is made of works of leading Western scientists J. Berzelius (1778–1848), H. Bessemer (1813–1898), W. Kroll (1889–1973), and others. The evolution in use of various procedures for isolation and subsequent refining of a great number of nonferrous and rare metals, and also iron, is considered. The first part of the book discusses in the general context theoretical, technological, and equipment-related problems. Temperature dependences of the standard Gibbs energy in a wide range of temperatures are presented for oxides, chlorides, and fluorides of a great number of metals. Special attention is given to environment protection from contamination in performing typical metallurgical processes (steel manufacture, processing of sulfide ores of heavy metals).

The second part of the textbook, "Engineering Aspects" (chapters 5–11, pp. 79–182), considers processes and apparatus of metallurgical shops. Various types of furnaces, refractories used, energy-saving processes, methods for separation of the solid and gaseous phases, oxidation processes, and metallothermic reactions are described.

The third part, "Preliminary Treatment" (chapters 12–19, pp. 183–302), contains evidence about various kinds of preprocessing of raw materials, concentrates, and minerals. The following basic procedures are described: preliminary thermal treatment (smelting, hardening, dehydration, calcination, oxidation); alkaline fusion; sulfatization of oxides by various methods; oxidation of sulfides, disulfides and related materials; formation of mattes; chlorination and fluorination. Each of the procedures discussed is illustrated with concrete examples.

The fourth part, "Metal Separation: Reduction, Conversion and Other Processes" (chapters 20–30, pp. 303–442), groups chapters describing, for the most part, production of metals from their compounds. It considers properties of various reducing agents (coal, coke, carbon(II) oxide and its mixture with hydrogen, hydrogen), discusses in detail reduction of oxides and other compounds of iron, reduction of nonferrous metal oxides with carbon, hydrogen and metals, and also reduction of complex oxides, halides, and sulfides. The same part of the book considers some other processes involving copper, lead, and nickel sulfides.

The fifth part of the book, "Refining" (chapters 31–38, pp. 443–451), is concerned with refining processes. The introductory chapter describes typical processes of purometallurgical refining (refining of iron, copper, and lead) and gives a classification of the main refining procedures: selective oxidation of impurities, removal of dross and mattes from melts, chemical transport reactions involving the gas phase, and physical refining methods (vacuum treatment, zone melting, distillation). The following chapters consider in ample detail the procedures and methods of high-temperature refining, with concrete examples provided.

Appendixes A, B, C, and D describe textbooks and monographs of general nature and those devoted to separate metals or groups of these (A), educational films (B), rather simple worked examples (C), and test questions for the main parts of the textbook (D). The book is provided with an index (pp. 579–592).

In contrast to the conventional practice of the Russian educational literature, F. Habashi's book luckily combines presentation of problems concerning both ferrous and nonferrous metallurgy under the common header "pyrometallurgy." Another important distinction of the book is an excellent set of illustrations, numerous clear photographs, including those in color, and graphic schemes not overburdened with unimportant details. F. Habashi's textbook can serve as an example of concise and clear presentation of a vast and important branch of metallurgy.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Transformation of Calcium Sulfate Hemihydrate into Dihydrate upon Granulation in the Presence of Admixtures

L. P. Firsova

Moscow State University, Moscow, Russia

Received November 14, 2002

Abstract—The effect of admixtures on parameters of granules obtained from calcium sulfate hemihydrate in the course of pelletizing and stimulated phase transition into dihydrate was studied.

Large-tonnage production of phosphoric acid leads to accumulation of production waste in the form of phosphogypsum. A part of this waste is used as secondary raw material in manufacture of construction materials (gypsum cardboard, plaster, cement, etc.). At the same time, the amount of spent phosphogypsum materials increases annually by several millions of tons, thus contaminating the environment. Therefore, it is urgent to develop new methods for phosphogypsum utilization. For example, phosphogypsum can be used in melioration and plant growing as an important source of nutrients, microelements, and other biologically active substances [1, 2]. The amount of granulated meliorant based on calcium sulfate hemihydrate is largely determined by the chemical composition, size distribution, and strength of granules, which are affected by physicochemical processes accompanying the transition of calcium sulfate hemihydrate into dihydrate. The topochemical transformation of $CaSO_4 \cdot 0.5H_2O$ into $CaSO_4 \cdot 2H_2O$, including that in the presence of rare-earth elements (REEs), was studied previously [3–5]. In this work, we studied how the bioactive admixtures of metal [manganese(II) and zinc(II) salts and boron (in the form of boric acid) affect granulation and the topochemical transformation of hemihydrate into dihydrate.

EXPERIMENTAL

Calcium sulfate hemihydrate from the Voskresensk Plant of Mineral Fertilizers was preserved prior to granulation to prevent premature phase transition into the dihydrate. Commercial powder was washed with several portions of hot saturated solution of $CaSO_4 \cdot 2H_2O$ and then with acetone to remove residual phosphoric acid and absorbed water, after which it was dried in air to remove acetone. The resulting $CaSO_4 \cdot 0.5H_2O$ powder consisted of 10–250-μm druses formed by hexagonal prisms 1 to 30 μm long. The preserved phosphogypsum contained 6.5–7.0% H_2O (based on anhydrite), which is higher than the theoretical value, i.e., a minor portion of hemihydrate had time to transform into the dihydrate. The $P_2O_{5\,tot}$ content in phosphogypsum was about 3.2–0.5%, and the powder porosity was 65.1%.

Calcium sulfate hemihydrate was granulated after moistening with aqueous solutions, which were unsaturated with respect to this salt and contained various additives. The wet mixtures were prepared by mixing a weighed portion of air-dry hemihydrate powder with a prescribed volume of aqueous solutions containing 1–5% bioactive salts (manganese or zinc sulfate) and acids (sulfuric, orthophosphoric, or boric). The liquid-to-solid (liq : sol) ratio for wetting the powder was optimized experimentally to obtain chiefly 2–8-mm spherical granules. When the liq : sol ratio was smaller than the optimal value determined for the wetting solution of the prescribed composition, the granulated mixture disintegrated on the plate or too small granules were formed. At the liq : sol ratios exceeding the optimal value, the water-logged mixture spreaded over the plate or coarse irregular clumps were formed instead of spherical granules. The powder was mixed with the solution for 30–60 s. After that, a wet mixture of a specified composition was transferred into a plate-like granulator. The granulator plate made of stainless steel was 250 mm in diameter and had a 75-mm-high edge. The rotation velocity of the plate was varied from 50 to 80 rpm; angle of inclination, from 20° to 40°; and granulation time, from 5 to 60 min.

Strengthening of granules was performed by matur-

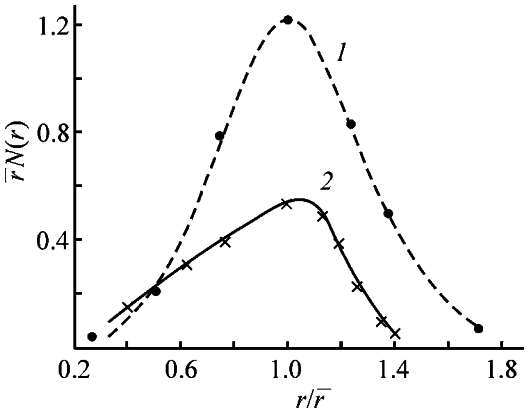

Fig. 1. Distribution $rN(\bar{r})$ of granules with respect to the relative size $r/\bar{r}$, depending on the type of acids added to calcium sulfate hemihydrate. Acid, wt %: (*1*) H_2SO_4, 3; (*2*) H_3BO_3, 2.

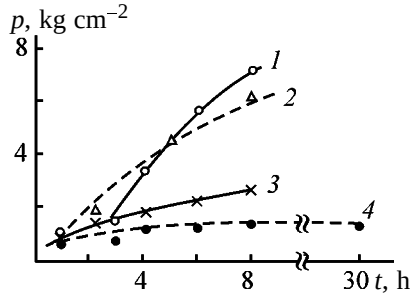

Fig. 2. Mechanical strength p of granules vs. the time t of maturing in the presence of various admixtures. Admixture, wt %: (*1*) H_2SO_4, 2.5; (*2*) $ZnSO_4$, 3.0 (maturing in a desiccator); (*3*) $ZnSO_4$, 2.0 (maturing in a solution); and (*4*) H_3BO_3, 2.0.

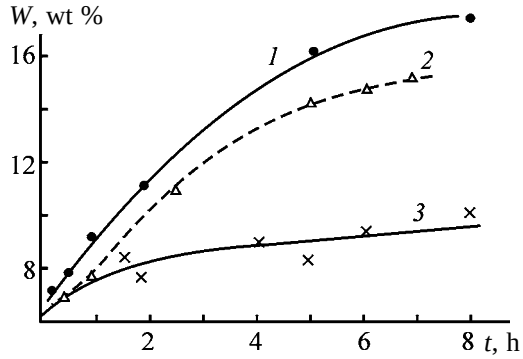

Fig. 3. Content of water of crystallization N in granules vs. the time t of maturing in the presence of various admixtures. Admixture, wt %: (*1*) H_2SO_4, 5.0; (*2*) $MnSO_4$, 3.0 (after 1 h of maturing in a solution); and (*3*) $MnSO_4$, 3.0 (after maturing in a desiccator).

ing. The $CaSO_4 \cdot 0.5H_2O$ granules obtained by pelletizing of a wet powder were carefully transferred from the granulator plate into special vessels, where they were strengthened owing to the topochemical transformation of the hemihydrate into the dihydrate $CaSO_4 \cdot 2H_2O$. Maturing was performed in a wet atmosphere in a dessicator and in the vessels with solutions similar in composition to the wetting solutions.

In the course of the pelletizing and maturing, portions of granules were taken to determine total water and water of crystallization. Absorbed water in the weighed portions of the powdered granules was determined from the mass loss after washing in acetone and drying in air to constant weight. Water of crystallization in air-dry granules and powders was determined thermogravimetrically after calcining the samples to constant weight.

The strength of the granules of a certain size in various stages of maturing and topochemical transition was evaluated from the breaking stress, as the average value obtained in 15–20 replicate measurements on an extensometer. The granules were sampled by sieving through metallic or Nylon sieves. Prior to sieving, wet granules were dried from the surface with a filtering paper.

The results of the study are presented in Figs. 1–3. It was shown that the total moisture content of the charge necessary for maturing, ensuring formation of 1–5-mm granules, was virtually independent of the type of admixture in a wetting solution (27–34%). At the indicated moisture content and under the similar granulation conditions (angle of plate inclination, rotation velocity, and maturing time), the average size of the obtained granules and the character of their size distribution are largely determined by the composition of the wetting solution (Fig. 1). On moistening the charge with solutions containing sulfuric or phosphoric acid, the size distribution density exhibits no marked deviations from the normal distribution. The same is true for manganese and zinc sulfate admixtures. At the same time, in the presence of boric acid, the portion of small granules increases asymmetrically, i.e., deviation from the normal distrubution is observed.

A study of breaking of the 2–3- and 3–5-mm granules obtained and matured under the similar conditions using different wetting solutions showed that the strength and strengthening kinetics also depend on the composition of the wetting solution (Fig. 2).

The granules formed in the presence of boric acid admixture have the minimal strength. Probably, this fact can also be responsible for the particular granulometric distribution of the product obtained in pelletizing of the H_3BO_3-containing charge.

As follows from Figs. 2 and 3, the granule strength-

ening kinetics correlates with the kinetics of the uptake of water of crystallization and reflects the topochemical transformation of the hemihydrate into dihydrate. The kinetics of the uptake of water of crystallization and the corresponding stages of the phase transition (Fig. 3) show that the transformation of calcium sulfate hemihydrate into dihydrate starts virtually simultaneously with the onset of wetting of the phosphogypsum powder, with the phase transition rates during maturing and pelletizing of granules dependent on the composition of wetting solutions and the type and content of admixtures in them.

CONCLUSION

Results obtained in measuring the size and strength of granules obtained in pelletizing of phosphogypsum moistened with solutions containing admixtures of sulfuric, phosphoric, or boric acid and of manganese or zinc sulfate show that the parameters of the granulometric distribution and the breaking stress of granules depend on the type and content of admixtures introduced into the batch being pelletized. These dependences correlate with the corresponding dependences depicting the uptake of water of crystallization and the stages of the topochemical transformation of calcium sulfate hemihydrate into dihydrate.

Abstract—The possibility of enhancing the stability of potassium fluoride hydrogen peroxide solvates by adding various chemical compounds was examined. Solid inorganic and organic acids, amines, and related compounds, and also their mixtures were tested.

Potassium fluoride hydrogen peroxide solvates $KF \cdot nH_2O_2$ (n = 1, 2) are among the most stable compounds containing hydrogen peroxide. The high decontaminating activity of this group of hydrogen peroxide solvates and their stability made it possible to develop a series of disinfectants based on $KF \cdot nH_2O_2$ [1] with a wide spectrum of antimicrobial effect.

Samples of $KF \cdot nH_2O_2$ obtained under laboratory conditions by the removal of water and excess H_2O_2 from a solution of KF in aqueous hydrogen peroxide in a vacuum at 40–60°C decompose with the following rates (% day^{-1}): $KF \cdot H_2O_2$, 0.0124 (observation time τ = 10 years); $KF \cdot 1.5H_2O_2$, 0.0374 (τ = 7 years); and $KF \cdot 2H_2O_2$, 0.0282 (τ = 8 years) [1].

As other solid forms of hydrogen peroxide, potassium fluoride hydrogen peroxide solvates undergo catalytic decomposition under the action of trace impurities originating from the starting substances, air, and surface of vessels and tools during the synthesis. As compared to the samples dehydrated in a vacuum, the samples of $KF \cdot nH_2O_2$ dried in a flow of heated air, and also those prepared in a metallic vessel on a model installation with a film rotary evaporator, are less stable [1]. For example, $KF \cdot 1.5H_2O_2$ or samples of similar compositions kept for one year decompose with the following rates (% day^{-1}): 0.0085 (dried in a vacuum), 0.0131 (dried with heated air), and 0.055 (dried in a rotary evaporator). The considerable increase in the decomposition rate in going from drying in vacuum to drying under conditions similar to those used in industry shows that it is necessary to develop measures for stabilizing the hydrogen peroxide solvates, especially in the case of their long-term storage.

In this work we developed procedures for stabilizing potassium fluoride hydrogen peroxide solvates using compounds of various types: acids, acid salts, amines, other compounds with complexing properties, and also their mixtures.

EXPERIMENTAL

Potassium fluoride forms the following solvates with hydrogen peroxide: $KF \cdot H_2O_2$, $KF \cdot 2H_2O_2$, and $KF \cdot 3H_2O_2$ [2]. The trisolvate is unstable. The other two solvates are sufficiently stable to be used as disinfectants. The equimolar mixture of the mono- and disolvates with the overall composition $KF \cdot 1.5H_2O_2$ also appeared to be stable.

We studied the influence of various additives on the stability of hydrogen peroxide solvates using laboratory samples obtained by dehydration in a vacuum. Stabilizing components were introduced into a solution of hydrogen peroxide and added to solid potassium fluoride dihydrate. The amount of the additives did not exceed 1%, because it was found with others hydrogen peroxide solvates that an increase in the amount of the added stabilizers often decreases the stability of samples owing to the deterioration of crystallization conditions and formation of poor-quality crystals with the reduced stability [3].

The kinetic curves of the thermal decomposition were obtained using potassium fluoride hydrogen peroxide monosolvate $KF \cdot H_2O_2$ in the pure state and also with acid additions. The experiments were carried out in a device described earlier [4]. To study the stability in prolonged storage, we chose the solvate $KF \cdot 1.5H_2O_2$ containing more hydrogen peroxide. The samples were stored in polymer reservoirs in the dark at 20 ± 2°C. As the comparative characteristic we used the coefficient of the decomposition rate K

(H_2O_2 loss, % day^{-1}) at the exposure time from 2 to 10 years. The decomposition rate of the samples after the first 2–3 months of storage became approximately constant.

Potassium fluoride hydrogen peroxide monosolvate decomposes under isothermal conditions in the temperature range 90–125°C. The rate constants of its decomposition in the pure state and in the presence of additions, calculated by Kolmogorov–Erofeev's equation

$$[-\ln(1 - \eta)]^{1/3} = k(\tau - \tau_0),$$

are listed in Table 1. For pure $KF \cdot H_2O_2$ without additions, the rate constant is $k_1 = 1.40 \times 10^{-3}$ min^{-1} at 120°C. The kinetic curves taken in the presence of additions at the same temperature give considerably smaller (by a factor of 2–9) rate constants. The stability of these samples in storage at elevated temperatures appreciably grows.

To study the stability of $KF \cdot 1.5H_2O_2$ in long-term storage, we used not only acids and acid salts, but also other compounds. The data for the compounds that, according to preliminary kinetic data, showed a stabilizing effect are listed in Table 2.

It is seen that inorganic and organic acids exhibit a noticeable stabilizing effect with respect to potassium fluoride sesquisolvate in its long-term storage, reducing the decomposition coefficient by a factor of no less than 2.5. Benzoic, salicylic, and acetylsalicylic acids show the highest stabilizing activity. Amines also have a high stabilizing activity. Mixed stabilizing agents act in various ways. Citric acid in a mixture with oxalic acid or hexamethylenetetramine provides a double increase in the stability as compared to each of these compounds separately. The highest stabilization is reached when potassium hydrofluoride is added to $KF \cdot 1.5H_2O_2$: the rate of the solvate decomposition in the presence of 0.5% KHF_2 decreases by a factor of 8.

It is difficult to unambiguously propose a mechanism responsible for the stabilizing effect of the compounds under study. The stabilizing agents found for $KF \cdot nH_2O_2$ are not a unique example of successful search for stabilizing additives to solid forms of hydrogen peroxide. Numerous stabilizing agents were suggested for $Na_2CO_3 \cdot 1.5H_2O_2$, which is commercially produced as a bleaching component of detergents. The main principle of their selection is based on the necessity to bind transition metal impurities into slightly soluble and catalytically low-active salts and to protect the solvate from the action of moisture [2]. The moisture adsorbed on crystals of sodium carbonate hydrogen peroxide solvate creates a microfilm of an alkaline solution in which hydrogen peroxide rapidly decomposes. However, along with additives that bind transition metals and prevent moistening of the solvate, there are numerous patents concerning the stabilization of sodium carbonate hydrogen peroxide solvate by compounds and mixtures lacking these two priority properties. The mechanism of their stabilizing effect has not been elucidated, nor has it been described even hypothetically.

The assumption that binding of trace transition metal impurities (Fe, Cr, Mn, Cu) with acids into difficultly soluble salts is the factor responsible for a decrease in their catalytic activity seems improbable in the case of potassium fluoride hydrogen peroxide solvates, as fluorides of these metals are also difficultly soluble. A reasonable explanation could be a shift of pH of the solution microfilm on the surface of $KF \cdot nH_2O_2$ crystals toward lower values as compared to the weakly alkaline medium free from stabilizing acids. However, the stabilizing effect of amines and related compounds remains unclear, as some of them, e.g., tetramethylammonium hydroxide, have proper-

ties of strong bases and shift the pH to the opposite direction.

The stabilizing agents effective for $KF \cdot 1.5H_2O_2$ obtained under laboratory conditions were used to prepare disinfecting agents based on potassium fluoride hydrogen peroxide solvates: PFK-1 (based on $KF \cdot H_2O_2$), PFK-2 (based on $KF \cdot 1.5H_2O_2$), and PFK-3 (based on $KF \cdot 2H_2O_2$). The samples were prepared on a model installation using a film rotary evaporator for drying.

The stabilizing effect of the compounds on the PFK-2 sample is similar to their action on the laboratory samples of $KF \cdot 1.5H_2O_2$ (this is shown in Table 2 with the most striking example of the stabilization with KHF_2).

The data on the stabilization of PFK-1 sample with the stabilizing agents that are the most effective for $KF \cdot 1.5H_2O_2$ are shown in Table 3.

Comparison of Tables 2 and 3 shows that the pure PFK-1 sample is approximately three times as stable as PFK-2. In the presence of additives, the degree of the increase in the stability of the PFK-1 sample is the same as in the case of PFK-2.

The data on the effect of additives on the stability of the PFK-3 sample, the richest in hydrogen peroxide, are given in Table 3. It is seen that the pure PFK-3 sample in the case of its long-term storage is somewhat more stable than the PFK-2 sample. This is probably due to the fact that the PFK-3 sample is based on the pure hydrogen peroxide solvate $KF \cdot 2H_2O_2$, whereas the base of the PFK-2 sample is a mixture of two compounds, namely, potassium fluoride mono- and disolvates, which, apparently, prevents formation of the well-shaped crystals of the solvates in their joint crystallization and leads to reduced stability of the sample. In the case of the PFK-3 sample, only potassium hydrofluoride retains a stabilizing effect, increasing the sample stability by a factor of 6.7. The other additives (citric and oxalic acids) only slightly reduce the decomposition coefficients.

We have selected potassium hydrofluoride as the main stabilizing agent for PFK preparations. The disinfectants obtained with this agent have passed tests successfully and have been accepted for the production and application in the Russian Federation [1].

CONCLUSIONS

(1) Various procedures were considered for the stabilization of potassium fluoride hydrogen peroxide solvates and also of disinfectants based on them. Addition of solid organic acids to the solvates in the amount of 0.5–1.0 wt % decreases the rate of their decomposition in long-term storage ($20 \pm 2°C$) by a factor of 3–5; addition of amines, by a factor of 3–6; and addition of potassium hydrofluoride, by a factor of 7–9.

(2) The most effective stabilizing agent KHF_2 was used to obtain the PFK-1, PFK-2 and PFK-3 disinfectants, which were tested under actual operation conditions. The decomposition rate of the samples with KHF_2 added, at the shelf life of no less than 5 years, is as follows: PFK-1 0.0013, PFK-2 0.0050, and PFK-3 0.0042 % day^{-1}.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Conditions for the Chemical Precipitation of the Starting Substances from Solutions for the Synthesis of Aluminospinels

Abstract—The precipitation of hydroxides from the Mg^{2+}–Al^{3+}–An^{-}–H_2O system (An = NO_3^-, Cl^-, SO_4^{2-}) at the initial spinel molar ratio Mg^{2+} : Al^{3+} = 1 : 2 was studied. The optimal conditions were found for obtaining the precipitates exhibiting the best properties in the manufacturing sense; their subsequent heat treatment yields a single phase of aluminomagnesium spinel.

Aluminomagnesium spinel is a promising structural material combining a number of valuable properties [1–3]. It is difficult to obtain a compact ceramics from spinel, though numerous attempts were undertaken to carry out such a synthesis using mineralizers, pulverizing pyrolysis, and thermal treatment of polycrystalline samples of oxide mixtures [1, 4]. One of possible ways to prepare high-density oxide ceramics may be the coprecipitation of ultrafine powders followed by thermal decomposition of the intermediate product.

According to [5], the use of ultradispersed powders with the particle sizes less than 1 μm, obtained by coprecipitation from concentrated solutions of salts, makes it possible to reduce the temperature of sintering ceramic products based on aluminomagnesium spinel to 1600°C. Moreover, it is possible to obtain the stoichiometric MgO–Al_2O_3 spinel as powders with a prescribed degree of dispersion by adjusting the pH and temperature of solutions [6]. Contrary to the traditional method of synthesizing powders of the $MgAl_2O_4$ spinel by a solid-phase reaction between the oxides at 1600°C, their preparation by coprecipitation from aqueous solutions reduces the temperature of the spinel synthesis (1450°C) and increases the activity of the powders [7]. When magnesium and aluminum nitrates are used as starting materials, the powders contain only the spinel phase with the average particle size of about 14 μm, and when chlorides are used, traces of Al_2O_3 are detected in the powders along with the spinel phase, the average size of the spinel particles being about 12 μm [7].

The aim of this work was to study the precipitation of hydroxides in the Mg^{2+}–Al^{3+}–An^{-}–H_2O system and to substantiate the optimal conditions for obtaining precipitates for the subsequent synthesis of the single-phase aluminomagnesium spinel $MgO \cdot Al_2O_3$ at a temperature as low as possible.

EXPERIMENTAL

We studied the precipitation of hydroxides in the Mg^{2+}–Al^{3+}–An^{-}–H_2O system by pH-metric titration (an I-160 pH meter equipped with a microprocessor and a temperature-controlled cell), turbidimetric titration (an FEK-56M photocolorimeter with a TPR titration outfit), and chemical analysis.

We used 1 M solutions of aluminum and magnesium nitrates, chlorides, and sulfates (analytically pure grade) as the starting solutions for obtaining hydroxides. The concentration of magnesium(II) was determined by complexometric titration with Eriochrome Black T in ammonia buffer [8], and the concentration of aluminum(III), by complexometric back-titration with a zinc salt and Xylenol Orange in an acidic solution [9].

To study the precipitation, we prepared 0.4 M solutions with the exact ratio Mg^{2+} : Al^{3+} = 1 : 2. A 1 M KOH (analytically pure grade) solution was a precipitating agent. The pH was monitored with an I-160 pH meter. The equilibrium pH after adding the KOH solution was attained slowly; therefore, we determined pH in 1 h after adding the whole amount of the alkali.

After separating the precipitate by filtration, we determined the residual amounts of magnesium(II) and aluminum(III) in the filtrate as described above. Under these conditions, Mg^{2+} ions, which were present in

1070-4272/03/7603-0346$25.00

combination with Al^{3+} ions, did not interfere with the determination of Al^{3+}, whereas Al^{3+} ions interfered with the determination of Mg^{2+}, as they bound the indicator. Therefore, we used triethanolamine to mask Al^{3+} ions [10].

The aim of the pH-metric studies was to find regular trends in the precipitation of Mg^{2+} and Al^{3+} hydroxides. In these experiments, we varied the temperature (25 and 40°C) and composition of the solution being titrated (solutions of Mg^{2+}, Al^{3+}, and Mg^{2+}–Al^{3+}). A 0.1 M KOH solution was the titrant (Fig. 1). The titration curves of the solutions for each composition at 25 and 40°C are almost indistinguishable, i.e., the temperature only slightly affects the precipitation.

A single weakly pronounced step is observed in the curves of pH-metric titration of 0.01 M Mg^{2+} solution at the OH/M ratio of about 2 (Fig. 1a). The buffer region of the titration curve is in the range of pH ~10–10.5. As the first drops of alkali are added, pH almost immediately reaches 10, and the hydroxide starts to precipitate.

The buffer region corresponding to the hydrolysis of aluminum(III) in the range pH 3–4 starts in the titration curves of the 0.01 M solution of Al^{3+} immediately after adding the first portions of alkali. At the end of this region, a single step is observed at the OH/M ratio of about 3 (Fig. 1b). The hydroxide starts to precipitate at the onset of the step at pH ~5; the precipitation is complete at the end of the step at pH ~11. On the further addition of alkali, the precipitate of aluminum hydroxide dissolves to give hydroxoaluminate ions. However, this process occurs without any steps in the titration curves.

The buffer region in the titration curves of the Mg^{2+}–Al^{3+} solution with the molar ratio $Mg^{2+}:Al^{3+}$ = 1 : 2 (the same as in spinel) starts just after adding the first portions of alkali. This region corresponds to the aluminum(III) hydrolysis and lies at pH ~4–5 as in the titration curves of pure Al^{3+} (Fig. 1c). It ends with a step at OH/M ≈ 2, which corresponds to the complete transformation of aluminum(III) into aluminum hydroxide. After the end of the step, a short buffer region is observed at pH ~9. This region is completed with the second step at the OH/M ratio of about 2.5–2.75, which corresponds to the end of the magnesium(II) hydrolysis. At the same time, the titration curves of the ion mixture show some distinctive features. When magnesium(II) is titrated (Fig. 1a), the buffer region before the step is in the range of pH ~10–10.5. The titration of aluminum(III) is completed at almost the same pH (Fig. 1b). In the titration curve of the mixture, the buffer region at pH ~9 corresponds to the titration of magnesium(II) after the complete neutralization of Al^{3+}. Correspondingly, the step at the end of the magnesium(II) titration is substantially larger than in the case of the titration of pure Mg^{2+}. This means that the precipitate of aluminum(III) hydroxide exerts certain effect on the precipitation of magnesium(II) hydroxide.

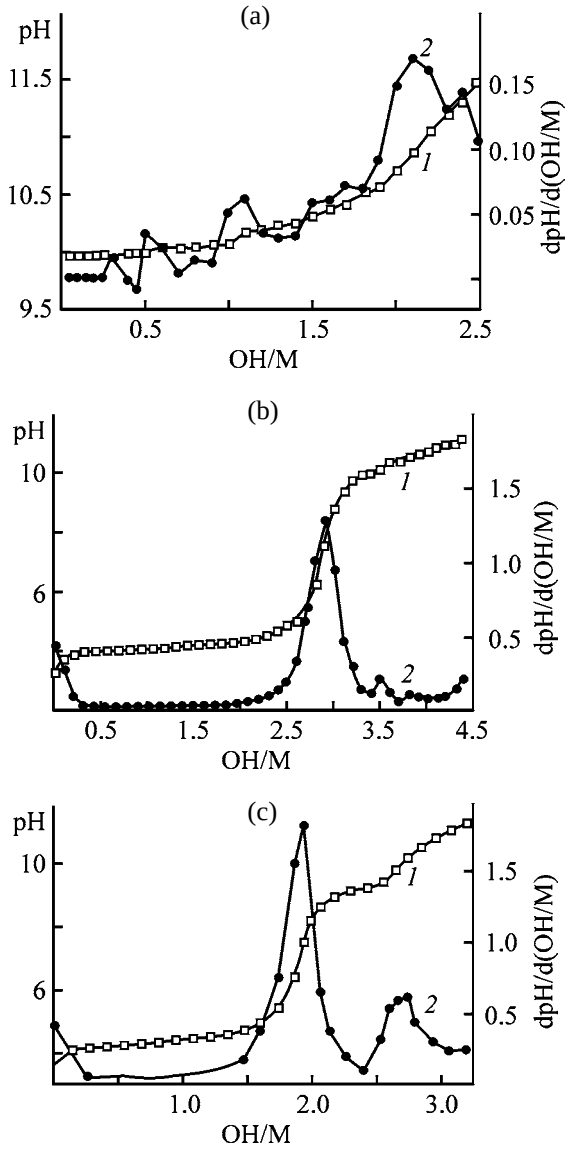

Fig. 1. Titration curves [(*1*) integal and (*2*) differential] of 0.01 M solutions of (a) Mg^{2+}, (b) Al^{3+}, and (c) Mg^{2+}–Al^{3+}.

The precipitation of hydroxides in the Mg^{2+}–Al^{3+}–NO_3^-–H_2O system was studied by the turbidimetric titration with an alkali, and the titration curves for aluminum(III), magnesium(II), and aluminum(III)–

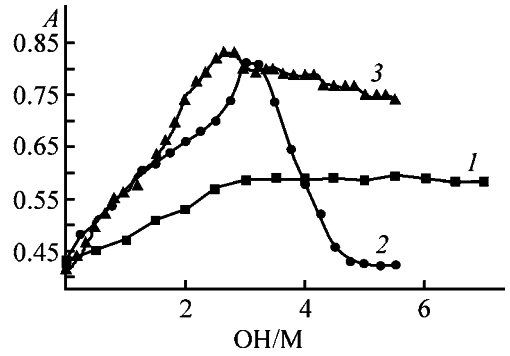

Fig. 2. Curves of turbidimetric titration of solutions of (*1*) Mg^{2+}, (*2*) Al^{3+}, and (*3*) Mg^{2+}–Al^{3+}. (*A*) Light absorption; the same for Fig. 3.

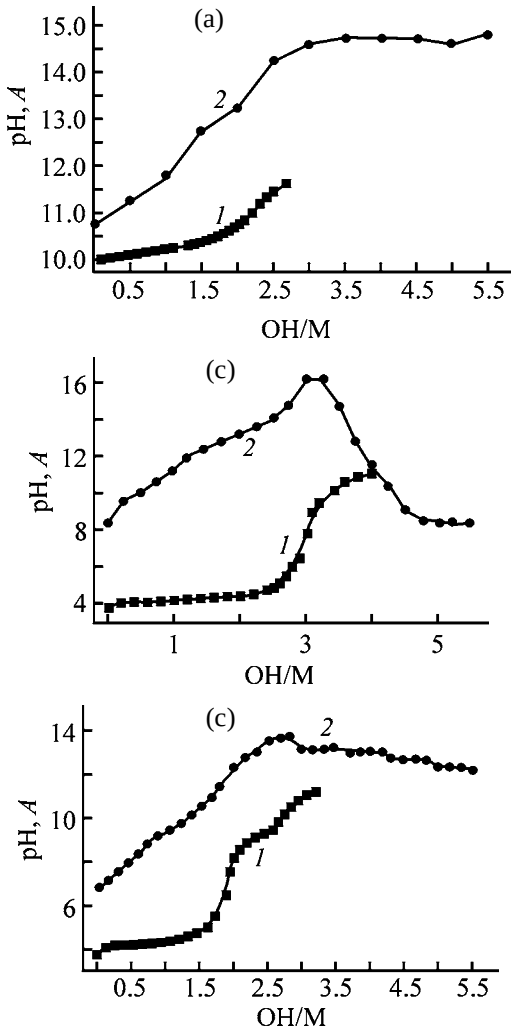

Fig. 3. Curves of (*1*) pH-metric (*2*) and turbidimetric titration of solutions of (a) Mg^{2+}, (b) Al^{3+}, and (c) Mg^{2+}–Al^{3+}.

magnesium(II) solutions were obtained (Fig. 2). The experimental technique and conditions were as follows. The apparent light absorption A_{app} of a colorless suspension was measured with a yellow–green color filter in a cell with the 25-mm-thick absorbing layer, which ensured the measurement of A_{app} under optimal conditions. Before the beginning of the titration, the starting spinel molar ratio $Mg^{2+} : Al^{3+}$ = 1 : 2 was set in the solution. The titrating agent was 0.1 M KOH. To construct the titration curves, we recalculated the added volume of alkali to the OH/M ratio.

As the alkali was added in the course of the turbidimetric titration, precipitates were gradually formed, and, correspondingly, the turbidity of all the solutions in the initial portions of the curves increased (Fig. 2, curves *1–3*). The precipitation of magnesium(II) was complete at OH/M = 2.5, as above this value the turbidity remained unchanged (Fig. 2, curve *1*). The titration curve of aluminum(III) has a more complicated shape (Fig. 2, curve *2*), which is caused by the amphoteric nature of its hydroxide. The precipitate is formed up to OH/M = 3 (A_{app} increases), whereas at OH/M > 3.25 it dissolves, as evidenced by the fact that the solution turbidity decreases as alkali is added. At OH/M ≈ 4.75, A_{app} does not noticeably change since the precipitate has completely dissolved. The titration curve of the aluminum(III)–magnesium(II) solution (Fig. 2, curve *3*) differs from both curves described above. The main difference is associated with the fact that aluminum(III) hydroxide does not dissolve in the presence of magnesium(II). Consequently, during joint precipitation of the hydroxides, a chemical reaction between the ions occurred. The maximal amount of the precipitate determining the maximal A_{app} values is formed in the range of OH/M = 2.5–2.8. At OH/M ≈ 3.0, the precipitate partially dissolves; however, the decrease in the turbidity is insignificant as compared to the titration curve of aluminum(III).

To compare the data obtained by two independent methods, we plotted the curves of turbidimetric and pH-metric titration in Fig. 3. To bring the curves to the same scale along the *y*-axis, the A_{app} values were normalized in the course of the computer processing by multiplying by a correction coefficient. The turbidity of the solutions changes only at the expense of the formation or dissolution of precipitates, and pH is determined by several processes occurring successively and in parallel. Hence, by comparing the curves obtained, we can refine the optimal pH range within which the precipitation becomes complete. To do this, we must draw a perpendicular from the maximum point in the $A_{app} = f(\text{OH/M})$ curve to the *x*-axis. Then, from the point of its intersection with the pH = f(OH/M) curve, we must draw a perpendicular to

Influence of pH and starting salts on the completeness of Mg^{2+} and Al^{3+} precipitation

	20	9.47	0.000525	0.000375
	20	9.26	0.001	0.0025

the *y*-axis and determine the pH value. For magnesium(II) it is 11.5 (Fig. 3a), for aluminum(III), 8.9–9.9 (Fig. 3b), and for the solution containing both ions, 9.5–10.0 (Fig. 3c). It is noteworthy that, in all the cases, the pH value determined by this procedure appears to be higher than the pH in the points of equivalence.

These results are in full agreement with the experimental data on the apparent volume of the precipitates [11]. Specifically in the above-given pH ranges the precipitates have the smallest volume, are deposited quickly, and are easily filtered, i.e., they are the most compact and the easiest to process [11]. Therefore, based on the data obtained by the three independent methods, the range of OH/M = 2.5–2.7 is optimal.

As follows from the results of pH-metric and phototurbidimetric titration, Mg^{2+} and Al^{3+} hydroxides are precipitated in a fairly wide pH range. At the same time, to obtain hydroxide precipitates that will be subsequently used as precursors for obtaining spinels, the stoichiometric ratio $Mg^{2+} : Al^{3+} = 1 : 2$ must be kept. Therefore, to find the optimal pH range and examine the influence of the anion, we studied the precipitation of aluminum(III) and magnesium(II) hydroxides at different pH using different Mg^{2+} and Al^{3+} salts. The results (table, Fig. 4) show that the dependences of the residual ion concentrations on pH of the Mg^{2+} and Al^{3+} solutions differ from each other. At low pH, Mg^{2+} ions are precipitated incompletely, and at high pH so do Al^{3+} ions. Temperature does not exert a substantial effect on the precipitation completeness but affects the rate of the equilibrium attainment. The optimal pH range in which Mg^{2+} and Al^{3+} precipitate almost completely is 9.5–10.5, which corresponds to the second step in the titration curve (Fig. 1c). Such a value of pH can be obtained when using ammonium hydroxide as a precipitant. According to the reference data on the precipitation of Mg^{2+} and Al^{3+} ions from their individual solutions [10], on the one hand, Mg^{2+} ions should not precipitate in the range of pH 9.5–10.5, and on the other hand, Al^{3+} ions should be converted almost completely into hydroxoaluminate ions. Therefore, the chemical analysis of the filtrate suggests a chemical reaction between Mg^{2+} and Al^{3+} ions during the precipitation with alkali.

It was found that heating of the samples synthesized under the above-given optimal conditions to 1000°C results in 41.07–43.57% weight loss [11]. This is almost twice lower than the weight loss reported in [5] for the samples prepared in a similar manner. The weight loss is completed at a lower temperature compared to the other precipitates, especially those obtained from nitrate solutions (865°C instead of 1000–1100°C) [11]. Moreover, the peaks corresponding to the interplanar spacings typical for the $MgO \cdot Al_2O_3$ spinel (0.2014, 0.243, 0.143 nm) were

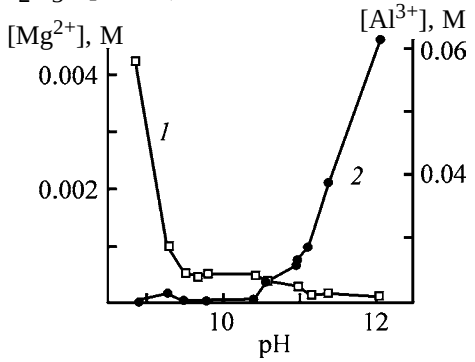

Fig. 4. Influence of pH on residual concentrations of (*1*) Mg^{2+} and (*2*) Al^{3+} ions.

observed even in the samples calcined at 320°C, and this is the only phase detected in the temperature range 320–1250°C.

The results of our studies allow us to develop scientific principles of synthesizing the $MgO \cdot Al_2O_3$ spinel from chemically precipitated mixtures. This will allow preparation of the spinel in a highly dispersed state with a high yield and the subsequent sintering of materials based on it at a considerably lower temperature.

CONCLUSIONS

(1) The optimal pH range for the precipitation of precursors for the synthesis of aluminomagnesium spinel was found by a combination of independent research methods.

(2) The single phase of aluminomagnesium spinel is formed by the heat treatment of the precipitates obtained under the optimal conditions.

Abstract—The method of low-temperature adsorption of nitrogen was applied to study structural characteristics of commercial peptized aluminum hydroxides. An increase or decrease in the porometric volume, depending on the nature and concentration of the peptizing agent, was analyzed. The phenomena observed are explained in terms of the mechanism suggested for formation of the pore system in commercial aluminum hydroxides. The dependence of the physicomechanical properties of active aluminum oxide on synthesis conditions and texture characteristics of commercial aluminum hydroxides was studied.

It is known that texture is formed in active aluminum oxide (AAO) not only during precipitation of aluminum hydroxide (AH), but also in the course of subsequent process operations. One of stages of the process used to obtain γ-Al_2O_3 by reprecipitation of alumina is peptization of washed hydroxide with pseudoboehmite morphology. This procedure is performed to impart to AH masses the necessary thixotropic and strength characteristics [1–4].

As a rule, commercial AHs are blended, i.e., obtained by mixing in a necessary ratio (most frequently, 1 : 1) hydroxides formed by hot and cold (after stabilization) precipitation. The influence exerted by the conditions of industrial precipitation and stabilization on the AH structure was studied previously [5].

The aim of this study was to analyze the influence exerted by the nature and concentration of a peptizing agent on the texture of cold- and hot-precipitated AH, and a mixture of these, and to reveal a correlation between the texture and physicomechanical properties of industrial AH.

EXPERIMENTAL

Aluminum hydroxides were synthesized under industrial conditions by the method of batch precipitation using the sulfate process. Blended AHs were prepared by mixing cold- and hot-precipitated hydroxides in 0.8 : 1.0 ratio. The peptization was done by treating AH with mineral acid solutions in a mixing machine at 160°C. The measurement conditions have been described previously [5].

The mechanical strength was determined on a semiautomatic device with a knife with blade width of 0.8 mm [8]. The bulk density ρ_b was found using a vibrator device [8]. The porometric volume V_p and pore size distribution were calculated from the desorption branch of an isotherm by the standard Barrett–Joyner–Highland procedure [6, 7].

It is known [6, 9] that cold-precipitated AH have the most labile structure because of the weak intercrystallite bonds (coagulation contacts, van der Waals interactions) between primary particles and the considerable content of interlayer water in the unit cell of pseudoboehmite. Therefore, the influence exerted by the nature of peptizing agent on the texture of cold-precipitated AH was studied in the first place. The data obtained are listed in Table 1 and shown in Fig. 1a.

The hysteresis loop of the adsorption isotherm of the initial AH is of the H2 type, which points to the presence of bottle-shaped pores in fibrillar fragments of the gel-like pseudoboehmite.

The initial cold-precipitated AH (Fig. 1a) is characterized by a broad peak of height 0.007 $cm^3\ g^{-1}\ Å^{-1}$ in the pore size distribution at around 78 Å, which accounts for about 72% of the porometric volume. It may be assumed that the observed peak in the pore size distribution is a sum of two peaks at 72 and 90 Å with close heights. Also seen in the porogram are shoulders at 52 (~0.0045 $cm^3\ g^{-1}\ Å^{-1}$), 34 (0.0030 $cm^3\ g^{-1}\ Å^{-1}$), and 24 Å (0.0012 $cm^3\ g^{-1}\ Å^{-1}$). The specific surface area of AH is 225 $m^2\ g^{-1}$, and

1070-4272/03/7603-0351$25.00

the porometric volume, 0.50 cm^3 g^{-1}.

Treatment with 0.4 M nitric acid shifts (Fig. 1a) the main peak (78 Å) with height of 0.0092 cm^3 g^{-1} Å^{-1}, which accounts for 61% of the porometric volume (0.28 cm^3 g^{-1}), to smaller values (72 Å). The heights of peaks in the pore size distribution increase by 60, 66, and 50% for the peaks at, respectively, 52, 34, and 24 Å. The specific surface area of AH increases by approximately 10% (from 225 to 257 cm^3 g^{-1} Å^{-1}), with the porometric volume remaining virtually unchanged. Peptization with 0.04 M acetic acid leads to complete disappearance of peaks at 72 and 90 Å, with only three peaks with much greater height observed in the porogram (Fig. 1a). As seen from Table 1, the heights of almost all peaks in the pore size distribution grow to the same extent, by a factor of 3, whence follows that CH_3COOH much exceeds HNO_3 in the peptizing activity.

Peptization with orthophosphoric acid breaks down the hydroxide to a lesser extent. The height of the peak in the pore size distribution at 90 Å decreases from 0.007 to 0.004 cm^3 g^{-1} Å^{-1}. The height of the peaks in the pore size distribution at 72 and 34 Å grows to a much greater extent than in the case of nitric acid, from 0.007 to 0.010 cm^3 g^{-1} Å^{-1} and from 0.003 to 0.007 cm^3 g^{-1} Å^{-1}, respectively.

The high reproducibility of the diameters of pores in AH and their discrete breakdown in peptization can be understood in terms of the previously suggested mechanism of AH texturing. It is most probable that the peptizing agent attacks places of contact between microcrystallites at (010) planes; breakdown of pore-forming fragments can be represented by the scheme in Fig. 2.

Probably, intermediate structures with another number of microcrystallites in the fragment coordinated along the *b* axis, which are not revealed in porograms of the samples studied, may also exist.

Starting from the fact that the porometric volume of AH remains virtually unchanged upon peptization, as also does the type of the hysteresis loop, it may be assumed that acid peptization leads to rearrangement of the pore system within fibrillar structures, with the liberated microcrystallites involved in formation of more "stable" AH fragments with pore size close to that of the already existing pores, which is indicated by the increase in the specific surface area of the hydroxide (Table 1). The most stable structural units in a fibrillar particle are, probably, fragments I and II, which contain the minimum number of coordinated particles.

This is confirmed by the increase in the height of peaks in the pore size distribution at 25 and 36 Å upon peptization. Irrespective of the nature of the acid anion, the peptizing agent attacks the places of contact between pseudoboehmite microcrystallites [probably, at the (010) plane]], which is accompanied by partial deaggregation of the porous system. The peptizing activity of the acids studied, judged from the degree of breakdown of pores with largest diameters, decreases in the order $CH_3COOH > HNO_3 > H_3PO_4$.

Acid peptization leads to partial dissolution of the hydroxide to give basic salts, which, as shown in [10, 11], diffuse into the thinnest pores and fill them, thus reducing the contribution of these pores to the porometric volume. In the case of peptization with HNO_3 and CH_3COOH, the forming basic salts are

water-soluble, which reduces the height of the peak in the pore size distribution at 34 Å. With H_3PO_4, no diffusion of basic phosphates occurs because of their low solubility [12]. It may be assumed that basic salts are accommodated in pores with diameter exceeding 40 Å, which must diminish the corresponding peaks in the pore size distribution. However, account should also be taken of the formation of an additional porometric volume (pores 25 and 34 Å in diameter) by products formed in breakdown of larger pores. The observed changes in the heights of peaks in the pore size distribution at 25 and 34 Å are due to occurrence of both these processes.

The texture of hot-precipitated AH is characterized by a shoulder at around 24 Å (0.0021 $cm^3\ g^{-1}\ Å^{-1}$), a peak at 35 Å (0.0094 $cm^3\ g^{-1}\ Å^{-1}$), and a broad asymmetric peak at 48 Å, which is probably a superposition of peaks at 46 and 60 Å (Table 1, Fig. 1b).

Acid peptization affects the specific surface area most strongly, and the porometric volume, to much lesser extent. Treatment with 0.04 M nitric acid (Fig. 1b) makes larger the height of the peak at 48 Å, with the heights of the other peaks either remaining unchanged (25 Å) or decreasing (35 Å). The last fact may be due to filling of these pores with basic salts of aluminum, which are formed in peptization. The volume of pores less than 68 Å in diameter increases from 0.24 to 0.34 $cm^3\ g^{-1}$, and that of pores with diameter exceeding 68 Å decreases from 0.47 to 0.40 $cm^3\ g^{-1}$, and it is this circumstance that leads to a certain decrease in the total porometric volume from 0.78 to 0.74 $cm^3\ g^{-1}$, with S_{sp} = 319 $m^2\ g^{-1}$ unchanged. Peptization with 0.04 M acetic acid (Fig. 1b) leads to similar changes in texture.

The peptizing action of 0.04 M H_3PO_4 on the AH texture is somewhat different from that considered above (Fig. 1b). It follows from porograms that porometric curves of the samples subjected to peptization with HNO_3 and CH_3COOH run above the porometric curve of the initial AH at 17–78 Å, and below it at pore diameters exceeding 78 Å. It may be assumed that, in AH peptization, the rise in the porometric volume is due to breakdown of pore-forming particles responsible for porosity at diameters larger than 78 Å.

The higher peptizing activity of H_3PO_4 with respect to AH is indicated by the fact that the point of intersection of the porometric curves measured before and after AH peptization lies at 53 Å. The significant increase in the height of the peak at 35 Å, from 0.0094 to 0.0151 $cm^3\ g^{-1}\ Å^{-1}$, is probably due to stronger beakdown of pores with diameters in the range 53–78 Å to give fragments with pores 35 Å in diameter, and also to the absence of water-soluble salts of aluminum and H_3PO_4, which could fill these pores.

In the given case, the increase in the specific surface area from 319 to 364 $m^2 g^{-1}$ is probably due just to the formation of thin pores with the distribution peak at 35 Å, rather than to breakdown of pore-forming fragments, which is indicated by the preservation of the total porometric volume (0.78 $cm^3 g^{-1}$).

Thus, in peptization of hot-precipitated AH, the porometric volume changes to a much lesser extent, which is probably due to higher strength of contacts between microcrystalline pseudoboehmite particles forming the secondary porosity, and the peptizing activity of the acids under study decreases in the order $H_3PO_4 > CH_3COOH \geq HNO_3$.

In mixing of precipitates [9], finely porous cold-precipitated hydroxide is accommodated within pores of high-temperature AH, which leads to a certain decrease in the porometric volume and formation of a precipitate with intermediate type of texture (Table 2, Fig. 3a).

The AH texture is defined by a strong peak at 36 Å (0.011 $cm^3 g^{-1} Å^{-1}$) and a broad peak at 170 Å (0.0023 $cm^3 g^{-1} Å^{-1}$). The porogram also shows a peak in the pore size distribution at 25 Å in the form of a shoulder (0.0008 $cm^3 g^{-1} Å^{-1}$). The porometric volume is distributed as follows ($cm^3 g^{-1}$): <50 Å, 0.105 (18%); 50–100 Å, 0.094 (16%); >100 Å, 0.387 (66%).

Peptization of blended AH with nitric acid does not lead to any significant change in the pore size distribution: no new pores are formed, with only the heights of the peaks in the pore size distribution changing (Table 2). A virtually similar pattern is observed in peptization of the same hydroxide with other acids (H_3PO_4, H_3BO_3) taken in about the same concentrations; however, the change in the total porometric volume and specific surface area of AH is less pronounced in this case.

Use of acetic acid (0.01 and 0.02 mol mol^{-1} Al_2O_3) favors even greater increase, to 0.0041 $cm^3 g^{-1} Å^{-1}$, in the height of the peak in the pore size distribution at 170 Å. However, even at such a high concentration of the peptizing agent, there occurs no breakdown of fragments responsible for pores 170 Å in diameter. And only raising the CH_3COOH concentration to 0.04 M (Table 2) leads to an increase in the height of the peak at 36 Å and to partial breakdown of secondary pores, which is indicated by the increasing height of the peak in the pore size distribution at 170 Å and to its shift to smaller values (140 Å) (Fig. 3b).

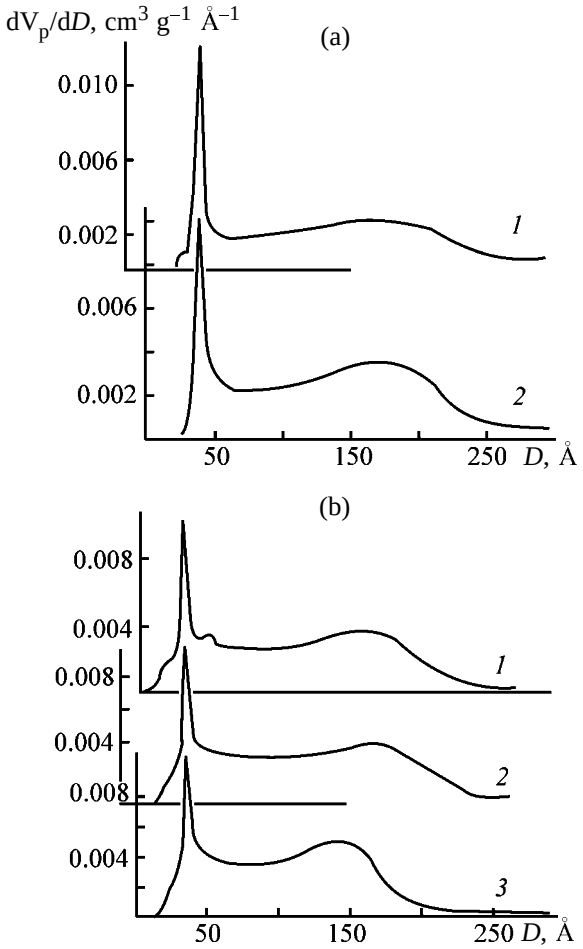

Fig. 3. Pore volume (V_p) distribution curves for blended AH peptized with (a) HNO_3 and (b) CH_3COOH. Acid concentration (M): (a) (*1*) 0.003 and (*2*) 0.007; (b) (*1*) 0.01, (*2*) 0.02, and (*3*) 0.04.

The formation of the peak in the pore size distribution at 170 Å is probably due to the appearance of a secondary porous system via mutual coordination of the fragments shown in Fig. 2. As "binder" serve basic aluminum salts, whose minor amounts are contained in the cold-precipitated hydroxide. In the course of peptization, gel-like pseudoboehmite (cold-precipitated hydroxide) is partly dissolved to give an additional amount of basic aluminum salts, with the resulting further mutual coordination of the fragments mentioned above.

Thus, the texture of the blended AH changes in stages. In the first stage, the partial dissolution of gel-like pseudoboehmite and the formation of basic salts give rise to a secondary porous system. With increasing concentration of the peptizing agent (to approximately 0.02 M for CH_3COOH), the share of secondary pores grows, which leads to a rise in the total porometric volume. The forming basic salts of alumi-

num partly fill the thinnest pores 36 Å in diameter, which is indicated by a decrease in the height of the corresponding peak in the distribution. In the second stage (at concentrations exceeding 0.04 M for CH_3COOH), probably, the pore-forming fragments responsible for the primary porosity partially break down, as shown in Fig. 2. This leads to a decrease in the overall size of these fragments and to a shift of the peak in the size distribution of secondary pores to lower values. The mutual coordination of fragments formed in breakdown gives rise to pores 36 Å in diameter, which is indicated by the increasing height of the corresponding peak in the pore size distribution upon peptization with 0.04 M acid.

The strength characteristics of the cold- and hot-precipitated hydroxides are listed in Table 1.

As shown in [13], the mechanical properties of dispersed materials are commonly related to pore volume and radius, to strength of a unit contact between the particles, and to number of contacts per unit grain cross-section area.

The not-too-large porometric volume and the high bulk density (0.73 g cm^{-3}) of the cold-precipitated hydroxide point to a high packing density and large number of contacts between AH particles. As a result, forming with such an AH gives extrudates with high strength coefficient of 3.08 kg mm^{-1}, which substantially shrink in calcination (Table 1).

The strength of contacts between primary AH particles is determined by the interplanar spacing (along the *b* axis) in the unit cell of pseudoboehmite. The contacts between particles in low-temperature AH are of coagulation nature and can be easily disintegrated under the action of the peptizing agent, which leads to a decrease in the average pore diameter, and the breakdown makes larger the specific surface area. No significant increase in the packing density occurs in peptization, which is indicated by the observed change in the bulk density and pore volume. The intensity of disintegration of contacts between particles in gel-like pseudoboehmite under the action of an acid forms a basis for the practical definition of the "chemical activity" of AH [14], which, in combination with the shrinkage upon drying [9], can be used to determine the formability and strength characteristics.

Another reason for the increase in the strength coefficient in peptization is the formation of basic salts of aluminum with anions of the peptizing acid, which are situated at places of contact between AH particles and form a thin X-ray amorphous film in inner cavities and on the outer surface of grains, which improves the physicomechanical properties of AH. A similar process occurs when Al_2O_3 grains are treated with aluminum nitrate solutions [15]. The diffusing ability of the forming aluminum salts is determined by the solubility of these salts in water, and aluminum phosphates are water-insoluble [6, 12], which, probably, results in that the increase in the strength coefficient upon peptization is the smallest. Owing to the processes listed above, the strength coefficient of cold-precipitated AH increases by 11–32% upon peptization. The absence of correlation between the shrinkage of extrudates in calcination and their strength characteristics [9] is probably due to different diffusing abilities of basic aluminum salts formed in peptization.

Hot-precipitated hydroxide is more aggregated, which is indicated by the large porometric volume (0.78 cm g^{-1}) and low bulk density (0.28 g cm^{-3}). Peptization of hot-precipitated hydroxides also leads to partial dissolution of gel-like pseudoboehmite (but its amount is much smaller than in the preceding case). The insignificant changes in the texture characteristics of AH indicate that intercrystallite contacts are virtually not disintegrated at all because of their higher "crystallinity." For the above reasons, aluminum salts are formed in AH of this kind in much lesser amounts, and, therefore, the absolute value of the strength coefficient of grains is much lower than that in the case of cold-precipitated AH. However, the relative increase in the strength characteristics in peptization of hot-precipitated AH with a solution of H_3PO_4 is 21 to 100%, which much exceeds that in the case of cold-precipitated AH. The porometric volume, bulk density, and texture characteristics indicate an insignificant densification of the hydroxide upon peptization. Therefore, it may be assumed that the rise in the strength coefficient of grains is largely due to the formation of basic aluminum salts.

Commercial blended AHs (Table 2) are characterized by intermediate, between those for cold- and hot-precipitated AH, values of bulk density, strength coefficient, and grain shrinkage.

As follows from the data obtained, peptization leads to a decrease in the bulk density of AH from 0.54 to 0.51 g cm^{-3}, with the porometric volume increasing from 0.59 to 0.71 cm^3 g^{-1}. Despite the rise in the degree of precipitate aggregation, the strength characteristics increased from 2.51 to 2.70 kg mm^{-1}. The phenomenon observed can be attributed to hydroxide strengthening by the forming basic aluminum salts, which is indicated by the substantial decrease

in the height of the pore size distribution peak at 36 Å from 0.0118 to 0.0088 $cm^3 g^{-1} Å^{-1}$.

Raising the concentration of the CH_3COOH peptizing agent to 0.04 M leads to a decrease not only in the porometric volume, but also in the bulk density of AH, which points to an increase in the degree of aggregation of the precipitate, whose effect on the strength characteristics cannot already be compensated for by the action of the basic salts, with the result that the strength parameters of the grains are impaired.

Thus, the increase in the strength characteristics of blended hydroxides in peptization is determined by the amount of cold-precipitated AH and the nature of the peptizing agent. All the factors leading to a decrease in the content of gel-like pseudoboehmite in synthesis of a hydroxide (higher temperature and pH of precipitation) impair the physicomechanical characteristics of the support grains.

In peptization, the gel-like pseudoboehmite is dispersed and interacts with the acid to give basic salts. These salts diffuse into the AH cavities and places of contact between pseudoboehmite particles and form in calcination an X-ray amorphous film improving the physicomechanical properties of AAO. It is for this reason that peptization with an acid yielding water-insoluble aluminum salts leads to a much lesser improvement of the strength characteristics of AH.

CONCLUSIONS

(1) Pore-forming fragments of cold-precipitated aluminum hydroxide are discretely broken down at places of contact between primary particles at (010) planes to give pores of smaller diameter and basic aluminum salts, which are situated at places of contact between primary particles and within the thinnest pores.

(2) Hot-precipitated hydroxides change their texture characteristics upon peptization to a much lesser extent, which is probably due to higher strength of intercrystallite contacts. Peptization probably leads to partial transformation of finely crystalline pseudoboehmite into a gel-like substance through rehydration of the unit cell of pseudoboehmite [incorporation of interlayer water at the (010) plane].

(3) Secondary pores are probably formed in blended hydroxides in the stage of peptization as a result of sticking of the fragments responsible for the primary porosity (<100 Å) by basic salts formed in peptization.

(4) The physicomechanical properties of cold- and hot-precipitated aluminum hydroxides are determined by the packing density and nature of contacts between pseudoboehmite particles. Peptization of the hydroxides with acids leads to an increase in the mechanical strength of grains because of the disintegration of coagulation contacts between particles of gel-like pseudoboehmite and its partial dissolution to give basic aluminum salts, which make stronger the places of contact between the pseudoboehmite particles.

(5) The mechanical strength of grains based on blended aluminum hydroxides is determined by the amount of gel-like pseudoboehmite (cold-precipitated aluminum hydroxide) introduced and by the nature of the peptizing agent.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Gibbs Energy and Entropy of Mixing in the $NaNO_2$–KNO_3 System

V. I. Glazov, G. P. Dukhanin, and M. Kh. Dkhaibe

Volgograd State Technical University, Volgograd, Russia

Received November 14, 2002

Abstract—The activity and activity coefficients of the components of the $NaNO_2$–KNO_3 system, determined from the experimental data on the saturated vapor pressure at 798, 823, and 848 K, are used to calculate the relative and excess partial molar Gibbs energies ($\Delta\bar{G}_i$ and $\Delta\bar{G}_i^{exc}$), entropies ($\Delta\bar{S}_i$ and $\Delta\bar{S}_i^{exc}$), and integral relative and excess thermodynamic functions (ΔG, ΔG^{exc}, ΔS, and ΔS^{exc}) of the system.

Among various physicochemical properties of salt systems, of particular importance are the thermodynamic functions, which reflect rigorous laws associated with the structure of melts and interionic interactions and are common for all chemical systems.

When a melt is formed from pure components, the thermodynamic functions characterizing the given system change. These changes are characterized by the Gibbs energy ΔG, enthalpy ΔH, and entropy ΔS of mixing.

Based on the activities a_i and activity coefficients γ_i of the system components determined from the data on the saturated vapor pressure [1–3], we calculated the relative partial Gibbs energy $\Delta\bar{G}_i$ and the excess partial molar Gibbs energy $\Delta\bar{G}_i^{exc}$ for potassium nitrate and sodium nitrite [4].

$$\Delta\bar{G}_i = 2.3RT\log a_i$$

$$\Delta\bar{G}_i^{exc} = 2.3RT\log\gamma_i$$

The calculation results are presented in Table 1.

The relative and excess partial Gibbs energies were used to calculate the relative integral molar and excess integral molar Gibbs energies and the excess integral molar Gibbs energy.

$$\Delta G = x_1\Delta\bar{G}_1 + x_2\Delta\bar{G}_2,$$

$$\Delta G^{exc} = x_1\Delta\bar{G}_1^{exc} + x_2\Delta\bar{G}_2^{exc},$$

where x_1 and x_2 are mole fractions of potassium nitrate and sodium nitrite in the binary system.

The calculation results are presented in Table 2 and Fig. 1. The integral molar Gibbs energy of the ideal system at 798 K is plotted as a dashed line (Fig. 1, curve *5*).

We calculated the partial molar relative and excess

entropies of mixing of KNO_3 and $NaNO_2$ in their binary system [5]:

$$\Delta\bar{S}_i = -2.3R \log a_i$$

$$\Delta\bar{S}_i^{exc} = -2.3R \log \gamma_i$$

The calculation results are presented in Table 3.

The $\Delta\bar{S}_i$ and $\Delta\bar{S}_i^{exc}$ values were used to calculate the integral molar relative and excess entropies [5] of the system $NaNO_2$–KNO_3:

$$\Delta S = x_1\Delta\bar{S}_1 + x_2\Delta\bar{S}_2,$$

$$\Delta S^{exc} = x_1\Delta\bar{S}_1^{exc} + x_2\Delta\bar{S}_2^{exc},$$

The calculation results are given in Table 4.

The integral molar relative and excess entropies [5] of the system $NaNO_2$–KNO_3 are plotted in Fig. 2. The integral entropy of mixing for the ideal system [5] at 798 K is plotted as a dashed line (Fig. 2, curve *5*).

80	3.56	3.18	2.97	1.70	1.36	1.11
90	1.70	1.55	1.42	0.84	0.69	0.52
	KNO_3 melt					
$NaNO_2$:						
90	1.36	1.23	1.15	0.42	0.35	0.25
80	2.97	2.74	2.62	1.15	0.88	0.79
60	6.45	6.28	5.76	2.28	1.93	1.45
50	8.50	8.04	7.62	2.84	2.28	1.86
40	10.90	10.30	9.75	3.33	2.51	2.18
20	17.63	16.96	16.35	4.25	3.72	2.97
10	24.76	23.20	22.43	5.61	4.06	3.33

The partial and integral enthalpies, Gibbs energies, and entropies are interrelated as follows [4]:

$$\Delta\bar{H}_i = \Delta\bar{G}_i + T\Delta\bar{S}_i,$$

$$\Delta H = \Delta G + T\Delta S,$$

Table 4. Integral molar relative and excess entropies of the $NaNO_2$–KNO_3 system

c_{KNO_3}, mol %	Extensive property, kJ mol^{-1}, at indicated temperature, K					
	ΔS			ΔS^{exc}		
	798	823	848	798	823	848
10	4.06	3.71	3.46	1.25	1.00	0.75
20	6.31	6.04	5.57	2.18	1.86	1.43
40	8.60	8.20	7.67	3.07	2.54	2.03
50	8.77	8.33	7.85	3.09	2.44	2.33
60	8.80	8.09	7.69	3.18	2.51	2.11
80	6.37	5.94	5.65	2.21	1.83	1.48
90	4.01	3.72	3.52	1.32	1.03	0.80

Substituting the above values of $\Delta\bar{G}_i$, $\Delta\bar{S}_i$, ΔG, and ΔS into these relations, we obtain

$$\Delta\bar{H}_i = 0 \text{ and } \Delta H = 0.$$

The lack of thermal effect in mixing the components is characteristic of ideal systems [4]. At the same time, for certain nonideal systems, referred to as athermal systems, the heats of mixing are also low [6]. In this case,

$$\Delta G^{exc} = -T\Delta S^{exc},$$

and the properties show deviations from ideality mainly owing to the entropy term.

As seen from Fig. 1, the curves of the integral relative and excess molar Gibbs energies exhibit negative deviations from ideal behavior and pass through a minimum at 50 mol %. The integral curves of the relative and excess molar entropies of mixing show positive deviations from ideality and pass through a maximum at the same composition (Fig. 2).

This behavior of the integral thermodynamic functions shows that the component particles in the system studied are to a certain extent ordered, i.e., the interaction Na(I)–K(I) of unlike particles dominates over that of like particles.

In the $NaNO_2$–KNO_3 system, the properties show smaller deviations from ideality than in the previously studied system KNO_3–$NaNO_3$ [6]. This may be due to a decrease in the interaction of unlike cations upon replacement of the NO_3^- anion by NO_2^-.

CONCLUSIONS

(1) The relative and excess partial molar Gibbs energies ($\Delta\bar{G}_i$ and $\Delta\bar{G}_i^{exc}$) and entropies ($\Delta\bar{S}_i$ and $\Delta\bar{S}_i^{exc}$) were calculated from the activities and activity coefficients of the system components.

(2) The relative and excess partial molar Gibbs energies and entropies were used to calculate the integral relative and excess thermodynamic functions ΔG, ΔG^{exc}, ΔS, and ΔS^{exc} in the system $NaNO_2$–KNO_3.

(3) The concentration dependences of the thermodynamic functions are presented. The integral molar Gibbs energy of the system exhibits negative deviations from the ideal behavior and passes through a minimum at 50 mol %. The entropy of mixing shows positive deviations and passes through a maximum at the same composition. This behavior of the thermodynamic functions shows that the component particles in the system studied are ordered to a certain extent.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Behavior of Copper(II) on Freshly Precipitated Aluminum Hydroxide

S. A. Evtyukhov and V. G. Berezyuk

Ural State Technical University, Yekaterinburg, Russia

Received August 28, 2002

Abstract—The isotherms of copper(II) sorption from aqueous solutions on freshly precipitated aluminum hydroxide obtained by hydrolysis of pentahydroxomonochlorodialuminum were studied. The sorption efficiency of copper(II) was studied as influenced by pH. Sorption of copper(II) by two different mechanisms is discussed.

Sorption of contaminants on freshly formed precipitates is widely used for decontamination of natural and wastewater. Numerous published data on theoretical and practical aspects of sorption of microelements on metal hydroxides were analyzed and generalized in [1]. This analysis showed that sorption is a complicated phenomenon depending on numerous parameters. Therefore, it is impossible to develop a general model adequately describing diverse sorption systems.

At the same time, simplified models based on a limited set of the main parameters can be developed and successfully used for calculation of sorption equilibrium isotherms characterizing the efficiency of industrial sorption processes.

In this work we studied sorption of copper(II) from aqueous solution on freshly precipitated aluminum hydroxide prepared by hydrolysis of pentahydroxomonochlorodialuminum, the most efficient modern flocculant, which is directly introduced into solution to be decontaminated from copper. This study is of interest because copper(II) is a typical toxic metal contaminating wastewater.

All experiments were carried out under static conditions at 18–20°C. The volume of the working solutions was 100 ml. The Cu^{2+} cations were introduced by dissolution of $CuSO_4$ in a solution containing a prescribed amount of $Al_2(OH)_5Cl$. Aluminum hydroxide was precipitated by adding the stoichiometric amount of NaOH. The required pH was adjusted by adding H_2SO_4 or NaOH. The resulting suspension was stirred and allowed to stand for 2 h to attain the equilibrium. On settling, the liquid phase was separated by filtration and the equilibrium Cu^{2+} concentration was determined by the standard method [2]. The mathematical treatment of the experimental results was performed by the common technique of mathematical statistics [3].

Figure 1 shows the typical isotherms of copper(II) sorption on aluminum hydroxide. The shape of the initial portions of these isotherms is fitted by the equations of Henry isotherm [4, 5]:

$$c_s = Kc_l, \quad (1)$$

where c_s is the sorbate concentration in the solid phase, c_l is the sorbate concentration in the liquid phase, and K is the constant of sorption equilibrium related to the Gibbs free energy of sorption by the equation

$$\Delta G = -RT\ln K, \quad (2)$$

where R is the gas constant and T is temperature (K).

This equation shows that K characterizes the sorbate–sorbent affinity. The degree of the sorption recovery of a sorbate S (%) can be determined by the expression

$$S = K/(K + 1). \quad (3)$$

The type of model isotherm suitable for describing the nonlinear portion of the experimental sorption isotherm should be thermodynamically consistent and sufficiently simple. We believe that the most favorable is so-called exchange sorption isotherm [6] which in the case of equivalent exchange is described by the equation

$$c_s = \frac{K\Gamma c_l}{c_0 + (K-1)c_l}, \quad (4)$$

1070-4272/03/7603-0361$25.00

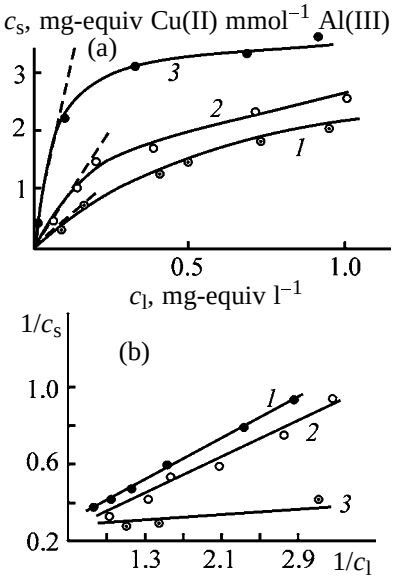

Fig. 1. (a) Isotherms of Cu^{2+} sorption on freshly precipitated aluminum hydroxide and (b) linearized form of Cu^{2+} sorption isotherms. V = 0.2 l, sorbent weight 10.8 mg. (c_s) Cu(II) concentration in the aluminum hydroxide phase; (c_l) Cu(II) concentration in the liquid phase. pH: (*1*) 4.78, (*2*) 5.65, and (*3*) 6.18.

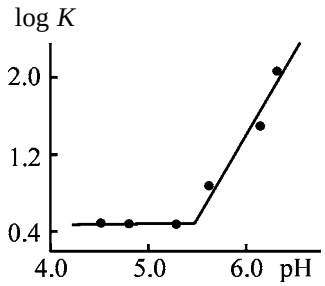

Fig. 2. Plot of log$K$ vs. pH in sorption of Cu^{2+} on freshly precipitated aluminum hydroxide. (K) Sorption constant characterizing thermodynamics of sorption.

where Γ is the limiting sorption capacity of a sorbent, c_0 is the initial sorbate concentration in the liquid phase, and K is the sorption constant.

The K values listed in the table show that sorption of Cu^{2+} on $Al(OH)_3$ is thermodynamically favorable.

Parameters of Eq. (4) describing sorption of Cu^{2+} ions on freshly formed $Al(OH)_3$

pH_{eq}	K	Γ, mg-equiv/mol	c_0, mg-equiv/l
4.52	3.36	6.88	7.02
4.78	3.01	20.1	30.4
5.32	2.92	19.3	22.0
5.65	7.02	9.82	18.8
6.18	28.6	3.68	3.82
6.32	144	3.68	5.84

Equation (4) can be transformed to the form

$$c_s^{-1} = \frac{c_0 c_l^{-1}}{K\Gamma} + \frac{K-1}{K\Gamma}. \quad (5)$$

This equation shows that $1/c_s$ is a linear function of $1/c_l$ (Fig. 1).

The values of the limiting sorption Γ given in the table show that, at the limiting saturation of sorbent sites of aluminum hydroxide with Cu^{2+}, the ratio of Cu^{2+} and Al^{3+} ions in the aluminum hydroxide matrix varies from 2 to 10. Thus, the amount of Cu(II) ions sorbed on aluminum hydroxide exceeds the amount of aluminum atoms in the aluminum hydroxide phase. We believe that this excess sorption of copper(II) is caused by incorporation of Cu^{2+}-containing species into the aluminum hydroxide polymeric matrix by the mechanism of formation of mixed polymeric chains. Thus, the total adsorption Γ of copper(II) is a superposition of the ion-exchange sorption and sorption by the mechanism of copper(II) incorporation into the aluminum hydroxide. This superposition can be expressed by the equation:

$$\Gamma = x_1\Gamma_1 + x_2\Gamma_2, \quad (6)$$

where x_1 and x_2 are the copper(II) fractions sorbed by the incorporation and ion-exchange mechanisms, respectively; Γ_1 and Γ_2 are the values of copper(II) sorption by the first and second mechanisms.

To better understand the contribution of these mechanisms to the total sorption, we studied how the sorption constant K is influenced by pH.

These data show also that, at pH < 5.4, K remains virtually constant, whereas at pH > 5.6 K substantially increases with increasing pH.

It is known that, if a metal is sorbed by the ion-exchange mechanism, the following equation is valid [1]:

$$\log K = A + z\text{pH}, \quad (7)$$

where A is constant and z is the charge of exchangeable ion.

As seen from Fig. 2, the plot of log$K$ vs. pH is divided into two different portions: at pH < 5.5 $z \sim 0$ and at pH > 5.5 log$K$ is expressed by the equation

$$\log K = -9.69 + 1.82\text{pH}, \quad (8)$$

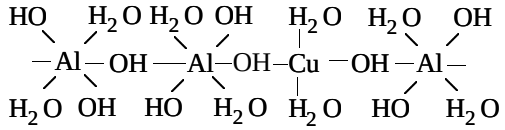
which shows that z is approximately 1.8.

Mechanisms of sorption of ionic species on metal hydroxides were analyzed in detail in [1]. This analysis showed that, from the thermodynamic viewpoint, the sorption by ion-exchange mechanism

$$R\text{–}OH + 0.5M^{2+} \rightleftarrows R\text{–}O(0.5M^{2+}) + H^{+} \quad (8)$$

via replacement of protons of hydroxy groups of the metal hydroxide by hydrated sorbable ions is indistinguishable from the electrochemical mechanism treating sorption as fixation of potential-determining ions.

Taking into account that at pH < 5.5 $z \sim 0$, we can assume that the main mechanism of sorption in this pH range is incorporation of electroneutral species of Cu(II) into the polymeric $Al(OH)_3$ chains ($z \sim 0$).



At the same time, at pH > 5.5 z is close to the value corresponding to the sorption by the mechanism of ion exchange. These data show also that sorption by the mechanism of incorporation is increasing with increasing pH.

Because the hydration number of Al^{3+} (as a rule, equal to 6) is higher than that of Cu^{2+}, incorporation of copper(II) into $Al(OH)_3$ polymers can be accompanied by elimination of water molecules from the Cu^{2+} coordination sphere. These effects should occur for all cations of transition metals with the coordination number less than 6 in their coprecipitation with aluminum hydroxide.

CONCLUSIONS

(1) Isotherms of copper(II) sorption on aluminum hydroxide were obtained and treated in terms of the model of equivalent exchange sorption.

(2) Assumption was made that sorption of copper(II) on aluminum hydroxide is a superposition of the ion exchange of Cu^{2+} ions for protons of the hydroxy groups of aluminum hydroxide and incorporation of Cu(II) species into the polymeric matrix of the sorbent.

SORPTION AND ION-EXCHANGE PROCESSES

Formation of Hydroxide Complexes in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O System

A. E. Sokolovskii and E. V. Radion

Belarussian State Technological University, Minsk, Belarus

Received November 6, 2002

Abstract—Hydrolysis in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system was studied by spectrophotometry, pH-metric titration, dialysis, and sorption techniques. Mutual influence of cations in their hydrolytic and sorption behavior was discussed from the viewpoint of the heteronuclear complex formation.

Iron(III) salts are widely used as collectors in water treatment to remove toxic metal ions. Particularly, Hg^{2+} ions are precipitated in the course of hydrolysis of Fe^{3+} ions [1]. The formation of an iron(III)–mercury(II) heteronuclear hydroxide complex was established [2]. The hydrolytic interaction of Fe^{3+} and Cd^{2+} ions was not studied previously, and this was the subject of the present work.

EXPERIMENTAL

The initial solutions of iron(III) and cadmium(II) nitrates were prepared by the dissolution of carbonyl iron and cadmium hydroxide in chemically pure grade nitric acid.

The concentrations of Cd^{2+} and Fe^{3+} in solutions were determined by direct complexometric titration with Eriochrome Black T [3] and sulfosalicylic acid in acetate buffer solution [4], respectively. When Fe^{3+} and Cd^{2+} ions were present simultaneously in solutions, their total content was determined by direct complexometric titration in the presence of sulfosalicylic acid and then the concentration of Fe^{3+} was determined by iodometric titration in a separate aliquot. The contents of free HNO_3 in the initial solutions was determined potentiometrically in the presence of EDTA [5].

The initial iron(III) and cadmium(II) solutions were used to prepare Cd^{2+}–NO_3^-–H_2O and Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions with various OH/M molar ratios. The concentrations of metal ions and free nitric acid in the initial solutions were determined. The amount of KOH required to neutralize the free acid and to establish a certain OH/M ratio and the amount of $NaNO_3$ required to maintain a constant ionic strength were calculated from these data. Then the calculated amounts of the initial solutions of metal salts, 0.2 M KOH, and 1 M $NaNO_3$ were mixed. In the case of partial neutralization of the free acid, the OH/M molar ratio was designated by the minus sign. The solutions prepared were kept at a required temperature for 7 days to attain the equilibrium.

The experiments were carried out under the following conditions: concentration of metal ions 0.01 M, total concentration of metal ions in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system 0.02 M at the $Fe^{3+} : Cd^{2+} = 1 : 1$ molar ratio, temperature 25 ± 0.1°C, and ionic strength 0.3 M ($NaNO_3$).

Hydrolysis was studied by pH-metric titration, spectrophotometry, dialysis, and sorption (KB-4P-2 cation exchanger in the H^+ form). An I-160 ionometer with a temperature-controlled cell was used to measure the pH values. The absorption spectra were recorded on an SF-46 spectrophotometer. The procedures of dialysis and processing of its results are described elsewhere [6]. Solutions were aged in the dialyzer for 7 days.

KB-4P-2 cation exchanger was pretreated and analyzed for the moisture content according to [7, 8]. Sorption was studied at 25 ± 0.1°C under static conditions; the establishment of the equilibrium distribution of ions between the solution and resin was always proved. The solution was in contact with the cation exchanger for 7 days. The data of the chemical analysis of equilibrium solutions were used to calculate the value S of sorption of metal ions by the resin (mmol per gram of the resin dried at 105°C).

The absorption spectra of cadmium(II) solutions with various molar ratios OH^-/Cd^{2+} are shown in

1070-4272/03/7603-0364$25.00

Fig. 1a. In the UV region of all the spectra, there are a weak band (λ = 255 nm, $\varepsilon \approx 35$) caused by the charge transfer [9] in cadmium(II) aqua complex and a still weaker band (λ = 330 nm, $\varepsilon \approx 0.9$) caused by the charge transfer in cadmium(II) mononuclear hydroxo complexes [9]. As the OH^-/Cd^{2+} ratio is increased, the absorption bands grow in intensity, which suggests occurrence of equiliblia involving protons [9]. Within the examined pH range (1.82–1.90), cadmium(II) exists as aqua ions and $Cd(OH)^+$ hydroxo complexes [10]. Therefore, the changes in the spectra with changing pH are attributable to the formation of hydrolyzed cadmium(II) species.

On the whole, the spectra of Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions (Fig. 1b) are similar to the spectra of the Fe^{3+}–NO_3^-–H_2O system [11]. The maximum at 250 nm corresponding to the absorption of iron(III) aqua complexes [9, 12] is retained. The dependence of the ratios of the light absorption in Fe^{3+}–Cd^{2+}–NO_3^-–H_2O and Fe^{3+}–NO_3^-–H_2O solutions at λ = 320 nm [11] on the OH/M ratio is shown in Fig. 2. Two almost linear portions are clearly seen. The inflection is observed at OH/M = 0, indicating that, with increasing OH/M ratio, the iron(III) hydrolysis is enhanced in the presence of cadmium(II) to a greater extent than in the straight Fe^{3+}–NO_3^-–H_2O solution.

The pK_a of the $Cd(H_2O)_4^{2+}$ aqua complex is 10.2 [10]; therefore, the first jump in the titration curve of the Cd^{2+} solution corresponds to the neutralization of free nitric acid, and the second, to the formation of a cadmium hydroxide precipitate. The precipitation starts at pH 7.3 and is complete at the OH/M ratio of 1.8.

Three jumps are observed in the titration curve of the Fe^{3+}–Cd^{2+} solution (Fig. 3). The precipitation starts at pH 2.7, which corresponds to the onset of the first jump. The first jump is observed at the ratio OH/ΣM = 1.7, the second, at 1.8, and the third, at 2.5. Judging from the pH values, the first jump is attributable to the neutralization of iron(III) ions [11], and the third, to the neutralization of cadmium(II) ions. The presence of the second jump cannot be explained on the basis of the neutralization curves of the individual ions, suggesting occurrence of a reaction between the hydrolyzed iron(III) and cadmium(II) species.

The values of cation sorption in the systems Cd^{2+}–NO_3^-–H_2O and Fe^{3+}–Cd^{2+}–NO_3^-–H_2O by the weakly acidic cation exchanger KB-4P-2 (H^+) are plotted vs. OH/M ratio in Fig. 4. As the OH/M ratio is increased, the sorption of Cd^{2+} ions considerably increases, probably owing to the formation of mononuclear hydroxo complexes. The KB-4P-2 cation exchanger sorbs both cations from Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions in approximately equal amounts (curves *2*, *3*). At the OH/ΣM ratios from –1 to 0, the sorption of iron(III) (curve *2*) is somewhat greater than that of cadmium(II) (curve *3*) and is virtually independent of the OH/ΣM ratio. Sorption of both ions rises sharply as OH/ΣM is increased further. Sorption of cadmium(II) (curve *3*) is significantly lower than that from the individual solution (curve *1*), and

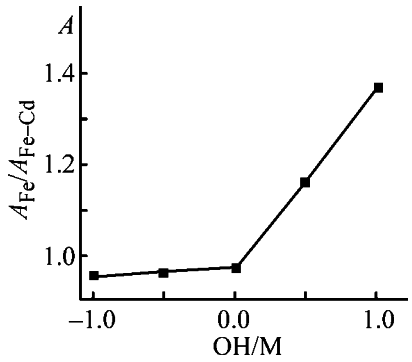

Fig. 2. Ratio A_{Fe}/A_{Fe-Cd} of Fe^{3+}–NO_3^-–H_2O and Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions at λ = 320 nm as a function of the OH/M ratio.

Dialysis coefficients K_d of iron(III) and cadmium(II)

OH/M	Fe^{3+}–NO_3^-–H_2O, K_d (Fe)	Fe^{3+}–Cd^{2+}–NO_3^-–H_2O,		Cd^{2+}–NO_3^-–H_2O, K_d (Cd)
		K_d (Fe)	K_d (Cd)	
–1	0.91	0.9	1	1
–0.5	0.89	0.88	1	1
0	0.82	0.80	0.98	1
0.5	0.64	0.59	0.89	1
1	0.34	0.24	0.75	

sorption of iron(III) (curve *2*) is close to that from the Fe^{3+}–NO_3^-–H_2O solution [11]. Thus, in the system Fe^{3+}–Cd^{2+}–NO_3^-–H_2O, cadmium(II) ions lose their individuality, and their sorption changes in parallel with that of iron(III), suggesting formation of heteronuclear hydroxo complexes in the system.

The dialysis coefficients of iron(III) and cadmium(II) in individual and mixed solutions are given in the table. The distribution of various cadmium(II) and iron(III) species in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system was calculated from the data obtained according to [13] (Fig. 5). In the Cd^{2+}–NO_3^-–H_2O system, the dialysis coefficient of cadmium(II) is 1 for all OH/M ratios, which agrees with the conclusions of [10] that only aqua complexes and mononuclear hydroxo complexes are present in cadmium(II) solutions. The dialysis coefficients of iron(III) and cadmium(II) in mixed and individual solutions differ. Up to the ratio OH/ΣM = 0, the dialysis coefficients of iron(III) in Fe^{3+}–NO_3^-–H_2O and Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions are approximately equal, whereas, as the OH/ΣM ratio is increased further, the dialysis coefficients in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system become less than those in the individual solution. This fact suggests enhancement of iron(III) hydrolysis in the presence of cadmium(II), with an increase in the content of Fe(III) in polynuclear hydroxo species.

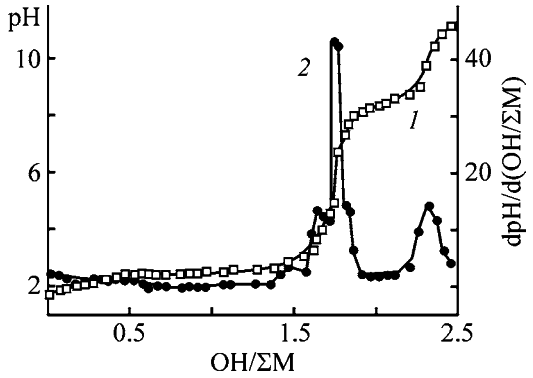

Fig. 3. Curves of pH-metric titration of Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions: (*1*) integral and (*2*) differential.

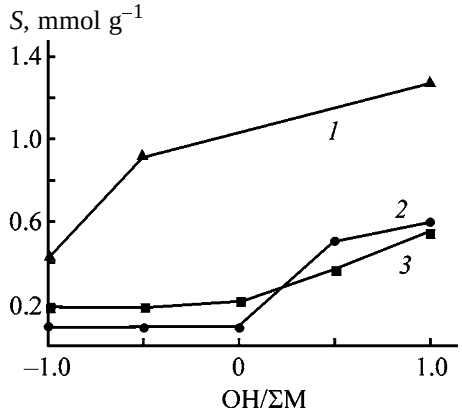

Fig. 4. Sorption *S* of iron(III) and cadmium(II) from Cd^{2+}–NO_3^-–H_2O and Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solutions by KB-4P-2 cation exchanger. Sorption of (*1*) Cd^{2+} in the Cd^{2+}–NO_3^-–H_2O system; (*2*) Fe^{3+} and (*3*) Cd^{2+} in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system.

The content of aqua complexes in the iron(III) solution decreases and that of mononuclear species increases in the OH/ΣM range from –1 to 0 (Fig. 5). The content of hydroxo complexes is relatively low. A further increase in the OH/ΣM ratio results in a fast growth of the content of polynuclear species, which agrees well with the spectrophotometric data. In the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O solution, cadmium(II) is in the form of aqua ions in the OH/ΣM range from –1 to 0. The relative content of its mononuclear species, which is not shown in the diagram, is several orders of magnitude lower. As the OH/ΣM ratio increases, the relative content of cadmium(II) aqua complexes decreases, and the content of its polynuclear species grows. As polynuclear complex formation is untypical of cadmium(II), the data obtained suggest the presence of iron(III)–cadmium(II) heteropolynuclear hydroxo complexes in the solution. The dialysis coefficients of cadmium(II) are higher than those of iron(III), suggesting that the relative content of cadmium(II) in polynuclear species is less than that of iron(III) at their equal concentrations.

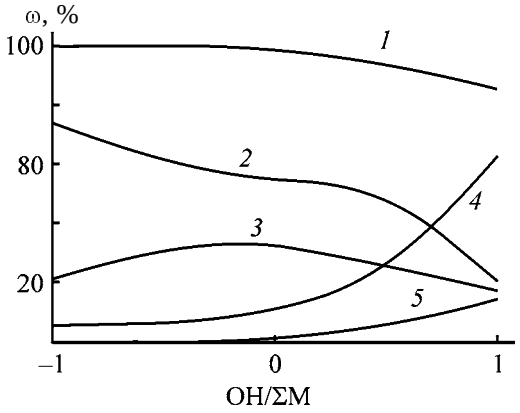

Fig. 5. Relative content of species ω in the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system as a function of OH/ΣM ratio. Species: (*1*) $Cd(H_2O)_4^{2+}$, (*2*) $Fe(H_2O)_6^{3+}$, (*3*) $FeOH(H_2O)_5^{2+}$, (*4*) Fe(III) in polynuclear species, and (*5*) Cd(II) in polynuclear species.

CONCLUSIONS

(1) It was found by independent methods that, in Fe(III)–Cd(II) solutions, the cations interact with each other, which causes their mutual influence in sorption and hydrolytic processes.

(2) Heteronuclear hydroxo complexes are formed in solutions of the Fe^{3+}–Cd^{2+}–NO_3^-–H_2O system at the ratios OH/ΣM > 0.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis of Calcium and Magnesium Phosphates from Natural Carbonates and Study of Their Activity in Reactions with Lead(II) Ions

Abstract—Chemical and thermal methods for obtaining calcium and magnesium phosphates from natural carbonate raw materials were studied. The activity of these compounds in uptake of lead(II) ions from solution was evaluated.

Phosphates and carbonates of alkaline-earth metals are actively studied as sorbents for ions of heavy and non-ferrous metals [1–14]. The mechanism of their action is peculiar. The recovery of metal ions from a solution is a result of chemical reactions occurring between solid phosphates or carbonates of alkaline-earth metals and multicharged metal cations, yielding compounds with lower solubility products. By this process, metal ions are removed from solutions to a significant extent. It was shown earlier [4–9] that 1 g of calcium phosphate binds up to 25 mg-equiv of ions of heavy and non-ferrous metals in these reactions. This exceeds by almost an order of magnitude the capacity of ion-exchange materials traditionally used to recover metal ions from solutions.

Unlike phosphates, carbonates are cheap natural materials. However, phosphates have significant advantages in using for water treatment.

First, the pH range for the formation of phosphates of heavy and nonferrous metals to be recovered is very wide, namely, from 1 (iron phosphate [4, 9]) to 10–12. Carbonates can be used for the removal of metal ions from solutions only in neutral or alkaline media to yield either carbonates or hydroxides of multicharged metal ions [11, 13].

Second, the solubility of phosphates of heavy and non-ferrous metals is lower than that of the corresponding carbonates and hydroxides by several orders of magnitude [15]. Correspondingly, when phosphates are used, the degree of solution purification is many times higher.

In view of these advantages of using phosphates for the removal of metal ions from solutions and also of the fact that natural carbonates are often chemically inactive and require preliminary activation by chemical, thermal, or mechanical methods [16] for the use in sorption processes, it becomes economically expedient to convert calcium and magnesium carbonates to the phosphates.

A simple way of obtaining calcium and magnesium hydrophosphates by the treatment of natural dolomite with phosphoric acid at room temperature is described in [17]. The resulting phosphates have a cost quite reasonable for the practical use.

Phosphates can be also obtained from natural carbonates by chemical or thermal methods, which would expand the assortment of sorption materials intended for water treatment and water preparation required to meet sanitary regulations concerning noxious metal ions.

Unlike phosphates, hydrated phosphates precipitated from aqueous solutions do not lose chemical activity on dehydration up to 800–900°C [18], which is important for their practical application. They can be obtained in the granular form by the calcination of granules with a clay binder at 600°C.

Here we report on the synthesis of calcium magnesium phosphates from natural chalk $CaCO_3$ and dolomite $CaMg(CO_3)_2$ by chemical and thermal methods and also on their activity in the treatment of aqueous solutions to remove lead(II) ions.

EXPERIMENTAL

Dolomite and chalk industrially produced in the Vitebsk oblast of Belarus Republic were used as raw

1070-4272/03/7603-0368$25.00

materials. According to the DTA data, dolomite contained 84% calcium magnesium carbonate, and, according to X-ray phase analysis (XPA), it contained impurities of quartz, iron oxide, and mica. Natural chalk (Volkovysk) was calcite containing 96% main substance. Our experiments were carried out using sifted fractions of dolomite and chalk with the particle size of 0.09–0.25 mm.

Phosphates were synthesized from natural carbonates by two methods: by chemical precipitation at pH 10 after preliminary dissolution of the carbonate in concentrated HNO_3 and by sintering $CaCO_3$ and $MgCO_3$ with ammonium phosphate in the stoichiometric amounts at 900°C.

The chemical precipitation was performed by two procedures. According to the first procedure [19], a Ca- and Mg-containing solution was alkalized to pH 10 using $NH_3 \cdot H_2O$ and rapidly combined with a solution of ammonium phosphate with pH 10, which was obtained by the addition of $NH_3 \cdot H_2O$ to H_3PO_4. In the second procedure, an acidic solution of dolomite or chalk was mixed with a solution of H_3PO_4, and then calcium and magnesium phosphates were precipitated with concentrated $NH_3 \cdot H_2O$ at pH 10. In both cases, the molar ratio $M_{in} : P$ (M_{in} = Ca or Ca + Mg) in the initial solution was varied from 1.5 to 2.0. The samples synthesized were washed with a dilute ammonia solution, filtered, and dried in air, first at room temperature and then at 70°C.

The phase composition of the synthesized samples was determined by XPA (DRF-2 diffractometer, CuK_α radiation) and IR spectroscopy (UR-20 spectrometer, KBr pellets, weighed sample 2 mg).

The chemical compositions were determined after dissolution of the weighed samples of 50.00 ± 0.01 mg in concentrated nitric acid. The content of calcium(II), and also the total amount of calcium(II) and magnesium(II) were determined by complexometric back-titration with a solution of zinc sulfate [20]; the content of magnesium(II), by titration of the solution after preliminary precipitation of calcium oxalate [21]; and the content of ammonia, by distilling off from an alkaline solution (Kjeldahl's method) [22]. The content of phosphorus(V) was determined by the colorimetric method in the form of a phosphorovanadomolybdate complex [21]. The error in the determination of the elements was ± 0.02 mmol g^{-1}.

The value of the absorption of lead(II) ions under static conditions A_{Pb} (mg-equiv g^{-1}) by the phosphates synthesized was used, as previously [13, 17, 18], as the measure of their chemical activity in recovery of heavy and non-ferrous metal ions from solutions. For this purpose, a weighed sample of the sorbent (0.2 g) was placed in 25 ml of a 0.2 N solution of lead(II) nitrate and kept for a day with intermittent stirring at 18 ± 2°C. The solution was separated from the solid phase, and the residual content of lead(II) in the solution after filtration was determined by complexometric back-titration [20]. The error of the determination of A_{Pb} was ± 0.02 mg-equiv g^{-1}.

The chemical composition of the synthesized phosphates (Tables 1, 2) strongly depends on the nature of the starting natural material. According to the XPA data, the products dried at 70°C are amorphous substances. When natural chalk is used as a raw material (Table 1), the molar ratio Ca : P and the water content allow the resulting compounds to be identified as the phosphate $Ca_3(PO_4)_2 \cdot 2H_2O$ exhibiting slight deviations from the stoichiometry. The samples obtained by the first procedure correspond to the stoichiometry to a greater extent. When phosphates are precipitated from dolomite solutions, cations of calcium, magnesium, and ammonium enter into the resulting materials (Table 2), and the composition of these products corresponds to the empirical formula $Ca_3Mg_2NH_4(PO_4)_{3.67} \cdot 8H_2O$ or $Ca_6Mg_4NH_4(PO_4)_7 \cdot 14H_2O$. Thus, the chemical composition of the triple phosphates corresponds to the neutral salts with the ratio $M_{nat} : P = 1.5$ (M_{nat} = Ca + Mg + NH_4). The composition of the samples was closer to the stoichiometry when they were synthesized by both the first and the second precipitation procedures in the presence of excess calcium and magnesium ions in the starting solutions. Furthermore, at excess of metal cations in solution, the content of ammonium ions in the product was lower (sample nos. 11, 12).

The IR spectra of the phosphates obtained from a solution of chalk (see figure, curves *1, 2*) contain strong absorption bands with maxima at 1060–965 and 620–570 cm^{-1}, corresponding to the stretching, $\nu(PO_4)$, and bending, $\delta(PO_4)$, vibrations of orthophosphate ions PO_4. The spectra of the phosphates obtained from dolomite solutions (curves *3, 4*) contain, along with these bands, also bands with maxima at 1475 and 1410 cm^{-1}, corresponding to the bending vibrations of ammonium ions $\delta(NH_4^+)$, and 1275, 910, and 800 cm^{-1}, corresponding to the bending vibrations δ(POH) and γ(POH) of $H_2PO_4^-$ anions [23, 24].

Along with the above-mentioned methods for determining the phase composition of the synthesized materials, we also used the thermal method. Almost all of the known phosphates crystallize on heating at temperatures of up to 900°C [25]. It is seen from

* Dissolved carbonate was preliminarily filtered to remove insoluble impurities.

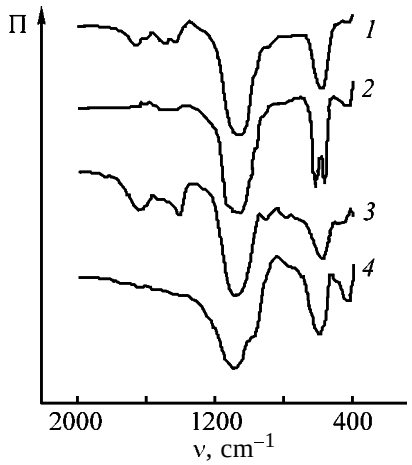
Tables 1 and 2 that the heat treatment of the phosphates obtained from a chalk solution results in crystallization of β-$Ca_3(PO_4)_2$. We have shown earlier [18] that the crystallization of phosphates free from impurities on heat treatment indicates that the starting compounds are also phosphates. The heat treatment of the phosphates precipitated from the dolomite solution results in the crystallization of compounds identified as double calcium and magnesium orthophosphates $Ca_3Mg_3(PO_4)_4$ and $Ca_7Mg_2(PO_4)_6$, and also of the pyrophosphate $Mg_2P_2O_7$. The formation of magnesium pyrophosphate $Mg_2P_2O_7$ is due to the presence of ammonium ions in the synthesized compounds. The removal of ammonia results in the release of hydrogen ions participating in the polymerization [26]. This salt was not detected in the X-ray pattern of sample nos. 11 and 12, which may be due to the low content of ammonia.

The IR data agree with the XPA results for the heat-treated samples. The bands in the spectra of the samples precipitated from chalk solutions become stronger owing to the formation of a crystalline structure. The bands at 425 and 450 cm^{-1} of the bending vibrations of phosphate ions $\delta(PO_4)$ appear. The spectrum as a whole characterizes only orthophosphate anions. The spectra of samples synthesized from dolomite solutions contain, along with the bands characteristic of orthophosphate, weak bands with the maxima corresponding to stretching antisymmetric, $\nu_{as}(POP)$ (1010 and 980 cm^{-1}), and symmetric, $\nu_s(POP)$ (780 and 740 cm^{-1}), vibrations of the P–O–P bonds in condensed phosphate species [26, 27].

Thus, according to our data, the synthesized compounds are calcium and magnesium phosphates free from impurities of acid phosphates, and the lower $M_{nat} : P$ ratio, as compared to the stoichiometry, is apparently due to the presence of impurities of other metal ions, e.g., iron ions.

Our data on the chemical activity of the materials synthesized under various conditions are also given in Tables 1 and 2, which contain the data for both the starting materials dried at 70°C and the products of their heat treatment at 900°C. As indicated above, calcium and magnesium phosphates preserve the chemical activity after the heat treatment. As these data were obtained for the sample synthesized from reagent-grade salts [25], it seemed appropriate to find whether calcium and magnesium phosphates obtained from natural raw materials containing certain soluble and insoluble impurities have similar properties.

The absorption capacity for lead(II) ions of calcium phosphates obtained from chalk (Table 1) before the heat treatment is 16–20 mg-equiv g^{-1}, and it only slightly depends on the synthesis conditions. The X-ray phase analysis of the products of the reaction of the phosphates synthesized by the first procedure with lead(II) ions shows that the compound $Pb_5(PO_4)_3OH$ is the main product. A similar reaction with phosphates synthesized by the second procedure yields also lead nitrate phosphate $Pb_2PO_4NO_3 \cdot H_2O$, which is responsible for a slight increase in the absorption of lead(II) ions by samples synthesized by the second way. The increase in the chemical activity of the phosphates based on chalk after their heat treatment is due to the removal of water of crystallization.



IR spectra of phosphates synthesized from (*1, 2*) chalk and (*3, 4*) dolomite: (*1, 3*) before and (*2, 4*) after heat treatment. (*T*) Transmission and (ν) wave number.

The phosphates precipitated from dolomite solutions (Table 2) absorb less lead(II), and their activity is 12.6–16.0 mg-equiv g^{-1} lead(II). As shown above, the precipitation conditions affect the chemical activity of the forming phases. The heat treatment of ammonium-containing phosphates results in a decrease in their chemical activity owing to the formation of $Mg_2P_2O_7$, which is chemically inert in reactions with metal ions.

No appreciable difference was observed in properties of the compounds obtained by precipitation in the presence or in the absence of insoluble impurities, i.e., with or without filtration of the solutions of the initial carbonates.

Anhydrous calcium and magnesium phosphates were also obtained by sintering with carbonates. The $M_{in} : P$ ratio in the starting mixtures was 1.5. The phase composition and chemical activity of the phosphates obtained by sintering of natural carbonates with ammonium phosphates at 900°C are presented in

Table 3. Phase composition and chemical activity of calcium and magnesium phosphates obtained by sintering of chalk and dolomite with ammonium phosphates at 900°C

System	Phase composition	A_{Pb}, mg-equiv g^{-1}
$CaMg(CO_3)_2$ (natural)–$NH_4H_2PO_4$	$CaMgP_2O_7$ + $(CaMg)_3(PO_4)_2$	6.38
$CaMg(CO_3)_2$ (natural)–$(NH_4)_3PO_4$	$CaMgP_2O_7$ + $(CaMg)_3(PO_4)_2$	2.50
$CaCO_3$ (natural)–$NH_4H_2PO_4$	β-$Ca_2P_2O_7$ + β-$Ca_3(PO_4)_2$	6.25
$CaCO_3$ (natural)–$(NH_4)_3PO_4$	β-$Ca_2P_2O_7$	1.94
$CaCO_3$ (cp grade)–$NH_4H_2PO_4$	β-$Ca_3(PO_4)_2$	1.64
$CaCO_3$ (cp grade)–$(NH_4)_3PO_4$	β-$Ca_2P_2O_7$	0

Table 3. To examine the possible effect of impurities present in natural minerals, we used two samples of calcium carbonate, namely, natural chalk and chemically pure grade calcium carbonate.

The sintering of natural carbonates with ammonium phosphates at 900°C yields orthophosphates containing impurities of calcium diphosphate and amorphous calcium oxide (Table 3). The capacity of this mixture for lead(II) is 1.9–6.4 mg-equiv g^{-1}. Fairly high A_{Pb} values (about 6 mg-equiv g^{-1}) for the products of sintering natural carbonates with ammonium phosphates at 900°C are due to the presence of unchanged amorphous calcium oxide when chalk is used and by the presence of a mixture of calcium and magnesium oxides when dolomite is used. Therefore, the phosphates obtained from chalk and dolomite have almost equal chemical activity. The use of ammonium phosphates considerably affects the chemical activity. When ammonium hydrophosphate is applied, the chemical activity is much higher, which is due to incomplete reaction between the carbonates and ammonium phosphate. According to the published data [25], to obtain pure orthophosphates, the temperature should be raised to 1100°C. At the same time, the sintering of chemically pure reagent chalk with ammonium phosphates results in the formation of the pure orthophosphate β-$Ca_3(PO_4)_2$ at 900°C. Its capacity for lead(II) is 0–1.64 mg-equiv g^{-1}. Impurities present in natural calcite cause the temperature of $Ca_3(PO_4)_2$ crystallization to increase.

The comparison of the chemical activities of the anhydrous phosphates obtained by sintering of carbonates with phosphates and by dehydration of the hydrates precipitated from solutions (Tables 1–3) shows that samples of the first type, in contrast to those of the second type, are inactive in reactions with metal ions. Thus, the genesis of calcium and magnesium phosphates is an important factor determining their chemical activity.

CONCLUSION

Neutral calcium and magnesium phosphates can be obtained from natural carbonates by chemical and thermal methods. The precipitated phosphates are sorption-active up to the temperature of 900°C, whereas anhydrous phosphates obtained by sintering of carbonates with ammonium phosphates at 900°C are chemically inactive in reactions with multicharged metal ions.

SORPTION AND ION-EXCHANGE PROCESSES

Conversion of Respirator Charge into Carbon Sorbents

S. S. Stavitskaya, V. M. Vikarchuk, T. P. Petrenko, and N. T. Kartel'

Institute of Sorption and Endoecology Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received March 13, 2002

Abstract—A simple and efficient liquid-phase procedure was developed for the oxidative-degradation regeneration of the spent respirator charge yielding oxidized carbon with fairly high sorption capacity to heavy metal ions with a minimal loss in the strength and in the amount of the carbon material.

Gas protection is the oldest field of the activated carbon application [1]. To improve the protection efficiency, the respirator carbons are treated with various modifying agents containing metal oxides, hydroxides, carbonates, and other salts. In the case of modified carbons, detrimental and toxic compounds are removed from respirable air by physical sorption, chemisorption, and catalytic conversion into harmless products.

The typical composition of modifying agents is well known. According to [2, 3], 100-kg portion of activated carbon is impregnated using three solutions: (1) copper hydroxycarbonate (6 kg), ammonium carbonate (5 kg), 25% aqueous ammonia (10 l), and water (10 l); (2) potassium dichromate (6 kg) and water (34 l); and (3) silver nitrate (170 g) and water (0.5 l).

As seen from the above data, the resulting activated carbon sorbent-catalyst contains 12–15 wt % of inorganic additives.

Due to accumulation of spent respirators and aging of strategic stocks, their complete utilization (especially for the sake of national economy) becomes an urgent problem. However, high content of modifying agents hinders direct use of the sorbent-catalyst charge as activated carbon because of its environmental impact. Thus, it is necessary to develop procedures for conversion of the respirator charge into activated carbon.

Depending on the nature of the modifying agent to be removed, regeneration and reactivation of activated carbons can be performed by various procedures [4, 5]: displacement desorption, thermal treatment in an inert or oxidizing atmosphere or in a vacuum, desorption with superheated or live steam, extraction with various organic solvents, and external high-energy treatment (ultrahigh frequency fields, radiation-chemical or electrochemical processes, etc.).

In this work we developed a simple and efficient procedure of conversion of the spent respirator charge into a sorbent with a minimal loss of the carbon material. This procedure is based on the liquid-phase oxidative-degradation treatment of the respirator charge with a nitric acid solution, i.e., on demineralization with simultaneous partial oxidation of carbon surface and organic compounds occurring in the pores of the initial material.

Regeneration can be accompanied by partial loss of carbon material (due to burning out, corrosion, and dissolution) and surface oxidation of carbons to form proton-donor functional groups capable of ion exchange. These processes are accelerated (catalyzed) by transition metal ions, whose content in the charge is fairly high. Hence, optimization of the regeneration conditions is required.

EXPERIMENTAL

The respirator charge sample was regenerated in refluxing 25% HNO_3 for 4 h. The sample was separated from the liquid phase, washed with water to pH 7, and then successively treated with 5% ammonia, distilled water, 3% hydrochloric acid (conversion into the H form [1]), and again with distilled water to pH 7. After drying, the structural and sorption properties of the resulting sorbent were determined by common procedures [6]: static sorption capacity for Na^+ cations and Cl^- anions, by titration with NaOH and HCl solutions; sorption capacity for Methylene Blue and iodine in aqueous solutions, spectrophotometrically; pore structure and pore volume distribution, by mercury porosimetry; and specific

pore area, chromatographically, by thermal desorption of argon.

Then, the oxidized carbon was additionally annealed at 850°C for 1 h in an argon flow to decompose surface oxides and to convert the oxidized material into common activated carbon [1]. The resulting activated carbon was tested in parallel with the sample of the oxidized carbon by the standard procedures.

Our experimental data (Tables 1, 2; Fig. 1) allowed us to classify the resulting carbon sorbents and to determine their analogs in accordance with [7].

As seen, the samples prepared by regeneration of respirator charge mainly correspond to commercial carbon SKT-3, whose properties are regulated by

TU (Technical Specifications) 6-16-2727–84 "SKT-3 Activated Carbon."

It was found that, after prolonged oxidative regeneration, the ash content decreased from 19.9 to 6.4%. Probably, due to the removal of the impregnating salts (13.5% content), the sorption pore volume for benzene W_s (determined by the desiccator procedure [6]) and the total pore volume V_Σ also slightly increased: from 0.30 and 0.44 to 0.40 and 0.56 $cm^3\ g^{-1}$, respectively. The resulting sample exhibited the cation-exchange properties with the exchange capacity of 1.8 mg-equiv g^{-1}. Moreover, after such oxidative treatment carbons preserved their strength, and no loss of the carbon material was observed.

Additionally, we studied the catalytic properties of two samples of the carbon material prepared by regeneration of the respirator charge using a 1% model solution of hydrogen peroxide. The results are shown in Fig. 2 as the kinetic curves of H_2O_2 decomposition in the initial and oxidized carbon material. The concentration of hydrogen peroxide in solution was determined by titration with potassium permanganate [1, 8].

As seen, the highest and lowest decomposition rates are observed with activated and oxidized carbons, respectively, which agrees with published data. The initial respirator charge containing ions of copper and other metals exhibits fairly high catalytic activity, because the transition metal ions, as a rule, accelerate decomposition of hydrogen peroxide.

We also studied the ion-exchange properties of the oxidized sample toward copper(II), chromium(III), and iron(III) ions (Fig. 3). It was found that this carbon cation exchanger strongly retains Fe^{3+} and Cu^{2+} ions, whereas the sorption of Cr^{3+} ions is lower; this phenomenon is typical for the majority of oxidized carbons under the similar conditions [1].

Thus, regeneration of the respirator charge by liquid-phase oxidative degradation yields two types of carbon sorbents: activated carbon with the sorption properties similar to those of commercial SKT-3 carbon and its oxidized modification exhibiting cation-exchange properties.

Similarly to SKT-3 carbon, the activated carbon prepared by regeneration (conversion) of the respirator charge can be used to remove organic compounds of various classes (volatile solvents, dyes, gasoline, diesel oil, etc.) from gas exhausts and also as catalyst support to disinfect gas wastes containing organic contaminants, carbon oxides, etc.

CONCLUSIONS

(1) The liquid-phase procedure of oxidative-degradation regeneration (conversion) of spent respirator charge (without loss in the strength and in the amount of the carbon material) was developed. This procedure causes demineralization and simultaneous partial oxidation of the carbon surface, imparting to it cation-exchange properties.

(2) Additional thermal treatment of the oxidized material in an inert atmosphere yields the activated form of the regenerated carbon sorbent.

(3) Some physicochemical, structural, and sorption properties of the initial respirator carbons and modified carbon materials were determined by the standard procedures. In the set of properties, the resulting regenerated carbon is similar to SKT-3 brand commercial carbon.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of the Surface Nonuniformity of Dispersed Diabase on Properties of Composites

E. N. Iordanova, V. G. Korsakov, M. N. Tsvetkova, and D. T. Mitev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 23, 2001; in final form, November 2002

Abstract—Adsorption of acid–base (Hammett) indicators and Fe(III) hydroxo complexes on the surface of dispersed diabase containing 45–52% silica, which is a promising polymer filler, was studied. Changes in the energy-related characteristics of the surface in the course of grinding and chemical modification of diabase with carbon from a mixture of CCl_4 and CH_4 were analyzed.

Controlling the energy-related characteristics of the surface of dispersed solids is a promising direction in developing structural and functional polymeric composites with prescribed properties. By varying the dispersity and the composition of functional groups, one can affect the donor–acceptor properties of components, interactions at the interface between the dispersed component and the polymer, and properties of composites. Wide use of inexpensive natural materials instead of synthetic materials as fillers of polymeric composites is hindered by their inhomogeneity. The reproducibility of properties can be improved, and the interaction energy at the interface between the dispersed filler and the polymer and the structure of the interfacial layer can be optimized by polymer grafting [1], local chemical modification of the surface, or synthesis of nanometer coatings by chemical assembly technique [2]. This is only possible for dispersed materials whose particles have a strong 3*D* (mainly covalent) framework and bear reactive functional groups on the surface.

In this work we examined the possibility of chemically modifying with carbon the surface of dispersed diabase produced as waste in manufacture of building materials and also studied the functional composition and energy nonuniformity of the initial and modified samples.

EXPERIMENTAL

Diabase samples [magmatic rock strongly modified by secondary processes, with silica content of 45–52% [3]; Dzhebel deposit, Bulgaria; mineralogical (phase) composition: plagioclase, pyroxene, olivine, hornblende] were ground in a ball mill and fractionated (particle diameter in different fractions 20–125 μm). The diabase surface was modified with carbon on a laboratory setup (Fig. 1) in fixed bed in a quartz reactor from a mixture of CCl_4 and CH_4 at 500°C for 1 h. Methane was purified with active copper and sorbents to remove oxygen and water vapor in units *1* and *2* and was saturated with tetrachloromethane vapor in a bubbler *3* and fed into reactor *4* having the form of a quartz tube 260 mm long and 46 mm in diameter with external Nichrome coil for heating. A quartz grid with 0.5–1-mm openings was welded within the reactor at a height of 60 mm. The grid was covered with glass fiber fabric on which a 50-g portion of diabase was placed. The temperature of the diabase bed was measured with a thermocouple and controlled and recorded with EPP-09 electronic potentiometers *5* and *6*. The reaction proceeds in accordance with the equation

$$CH_4 + CCl_4 \rightarrow 2C + 4HCl.$$

Hydrogen chloride formed in the reaction was absorbed with a 0.1 N NaOH solution in vessel *7*.

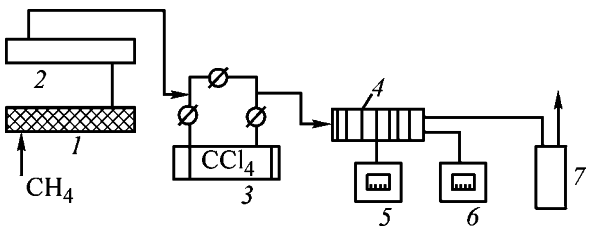

Fig. 1. Schematic of the laboratory setup for modification of dispersed diabase with carbon in fixed bed (for explanations, see text).

Changes in donor–acceptor properties of the diabase surface were evaluated by Tanabe's spectrophotometric version [4] of the indicator method, based on adsorption of acid–base (Hammett) indicators with known pK_a in the range from –4 to 12.8 [4, 5]. The optical densities D_0 of the initial indicator solutions were measured with an SF-26 spectrophotometer, after which suspensions of modified diabase in these solutions were prepared and optical densities D_1 of the solutions were measured after the adsorption equilibrium was attained and the solution was separated from the sediment by decanting or centrifuging. To take into account the influence exerted on the optical density by changes in the pH value on contact of a sample with solution and partial dissolution of the sample, a suspension of the initial and modified diabase in distilled water was prepared, the sediment formed was separated after 30 min, an indicator solution was added, and the optical density D_2 was measured. The content of active centers q_{pK_a} (mmol g^{-1}) with a given pK_a value was calculated by the formula

$$q_{pK_a} = \frac{c_{in}V_{in}}{D_0}\left|\left|D_0 - D_1\right|/m_1 \pm \left|D_0 - D_1\right|/m_2\right|,$$

where c_{in} and V_{in} are the concentration and volume of the indicator solution, m_1 and m_2 are weighed portions of diabase, and the ± sign corresponds to oppositely directed changes in D_1 and D_2 with respect to D_0.

The distribution of adsorption centers over the surface of the samples studied was plotted in the coordinates $q_{pK_a} = f(pK_a)$.

The overall energy-related characteristics of the surface of modified diabase were determined using a high-sensitivity method based on potentiometric recording of the potential curves of adsorption of iron hydroxoaqua complexes from solution [6, 7]. A reversible redox system Fe^{3+}/Fe^{2+} and an electrochemical cell with indifferent (platinum) electrode and calomel reference electrode were used in measurements. The concentration of Fe(III) and Fe(II) ions in the starting solution was 10^{-4} and 10^{-5} M, respectively. The potentials of the indifferent electrode in the starting solution and in a suspension of diabase in this solution were measured. The potential curves were calculated using the equation

$$\Delta\mu_Q = \Delta\varphi_m F + RT\ln Q,$$

where $\Delta\mu_Q$ is the adsorption potential for hydroxo complexes of iron ions; $\Delta\varphi_m$, the difference of potentials of the indifferent electrode in the starting solution and in the suspension; F, the Faraday number. The surface fraction Q (filling of the surface with adsorbed iron hydroxoaqua complexes at constant solution concentration) is determined by the amount m of the solid in the suspension.

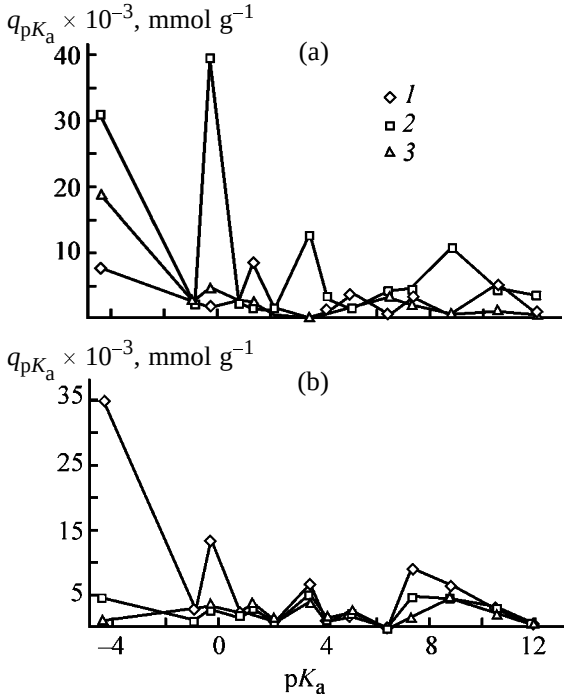

Fig. 2. Distribution with respect to donor–acceptor properties of adsorption centers over the surface of (a) initial diabase of different fractions and (b) that modified with carbon. (q_{pK_a}) Content of centers with the corresponding pK_a value; the same for Fig. 3. Diabase particle size (μm): (*1*) 40, (*2*) 40–80, and (*3*) 80–125.

In the given method, the concentration measurements commonly made in studying adsorption isotherms are replaced by the potential measurements in dilute solutions, which allows a study at low surface filling of dispersed materials with the adsorbate (down to Q = 0.01–0.001). Therefore, this method is used to prognosticate the properties of fillers for polymers, catalysts, and other active materials [8, 9].

Figure 2 [for clarity, the points in 1D distributions (histograms) are connected] shows that the surface of the initial diabase samples is characterized by high nonuniformity depending on dispersity, which is probably due to the complex mineralogical (phase) composition of diabase. Lewis (electron-donor and -acceptor) adsorption centers characterized by pK_a values of –4.4 and –0.29 and Brønsted (proton-donor and -acceptor) centers with pK_a 1.3, 3.4, 5.0, 6.4, 8.8, 10.5 are present on the surface of diabase of different fractions. Figure 3a shows the content Lewis base and Brønsted acid and base centers as functions of the fraction size. The total content of adsorption centers

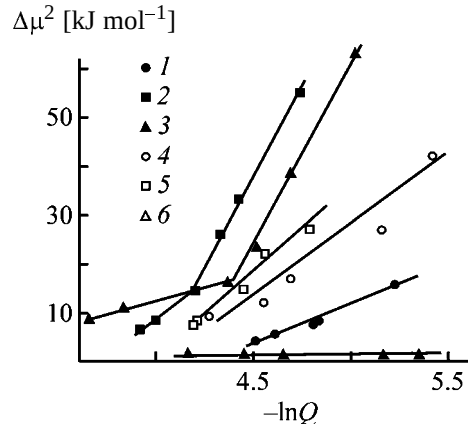

Fig. 4. Potential curves of adsorption of iron(III) ions on (*1–3*) initial and (*4–6*) modified diabase, plotted in the coordinates of the Dubinin equation. (Δμ) Adsorption potential of Fe(III) ions and (*Q*) surface filling. Fraction size (μm): (*1, 4*) 40, (*2, 5*) 40–80, and (*3, 6*) 80–125.

and centers with pK_a –0.29 is the highest for the 40–80-μm fraction. The increase in the content of the centers upon grinding of the initial diabase (80–125 μm) to 40–80 μm is due to a rise in the specific surface area, surface activation (formation of macroradicals), and changes in the phase composition as a result of mechanochemical processes. However, subsequent grinding to less than 40 μm leads to a decrease in the content of the centers, which is probably due to interaction of particles at the most active centers. The most sensitive to grinding are Lewis centers with pK_a –0.29 and –4.4 (radicals formed in dehydration and dehydroxylation of the diabase surface in the course of grinding), Brønsted acid centers with pK_a 3.46 (OH groups), and Brønsted base centers with pK_a 8.8, which may be formed in dissociation of substituted functional groups of the –O–Me type.

In modification of the diabase surface with carbon, the composition of active centers is little dependent on the dispersity, but the number of centers changes (Fig. 2b). A large number of Lewis centers (possibly carbon macroradicals) with pK_a –4.4 and –0.29 appear on the surface of dispersed diabase (<40-μm fraction). Their content increases to a much greater extent than does the surface area upon grinding (Fig. 3b). This points to weaker influence of the phase (mineralogical composition) heterogeneity of particles on the surface properties. For the <40-μm fraction, the number of Brønsted base centers with pK_a 7.3 and 8.8 also grows. However, the content of these centers for all fractions of modified diabase is much lower than that for the 80-μm fraction of the initial sample.

Changes in the qualitative and quantitative composition of active centers upon grinding and modification of diabase lead to changes in the overall energy-related characteristics found potentiometrically. Figure 4 shows the potential curves of adsorption of Fe(III) hydroxoaqua complexes on the diabase surface in the coordinates of the Dubinin equation [10] $\Delta\mu^2 = f(\ln Q)$. The equation was derived in this form by Dubinin [10] for porous adsorbents. However, it is also successfully used for describing monolayer adsorption onto solid surfaces from solutions [11], since only the assumption of a Gaussian distribution of the volume of the adsorption space with respect to potentials was made in deriving this equation.

Figure 4 shows that the potential curves plotted in these coordinates include one or several linear (homotatic) portions corresponding to filling of centers of varied nature. (The term "homotatic" is used in the adsorption theory, e.g., in the Ross–Olivier method [12], for designation of areas of the same type on an energetically nonuniform surface.)

In accordance with the physical meaning of the Dubinin equation, the slopes of the $\Delta\mu^2$ regression with respect to $\ln Q$ characterize the surface nonuniformity and its changes in the course of chemical modification. The surface of the initial diabase is non-

uniform because of the diversity of the mineralogical composition; mechanochemical processes and chemical modification lead to changes in the surface composition. The results are summarized in the table.

Samples of the initial diabase of the 80–125- and 40–80-μm fractions are characterized by high surface nonuniformity. As seen from the table, the slopes of the $\Delta\mu$–$\ln Q$ dependences are only slightly different (82 and 86) for these fractions in the $\ln Q$ range from –4.3 to –5.0. However, the potential curve for the 80–125-μm fraction contains a portion with smaller slope at fillings $Q \geq 0.02$, which may be due to phase heterogeneity of the initial sample before grinding. The potential curve for the <40-μm fraction has only a single portion, i.e., the surface becomes more uniform after grinding.

Much stronger influence is exerted on the surface uniformity by modification of coarsely dispersed diabase with carbon. The slope of the linear dependence $\Delta\mu^2$–$\ln Q$ decreases by two orders of magnitude for the 80–125-μm fraction. The slopes of the linear portions for 40–80- and <40-μm fractions of modified diabase are close (which points to filling of adsorption centers of the same type) and much exceed that for the 80–125-μm fraction. The increase in the adsorption potential and in the slope of the $\Delta\mu^2$–$\ln Q$ regression after modification of the <40-μm fraction of diabase (see table) indicates that the surface activity becomes higher.

The linear regressions of the potential curves intersect the abscissa at $\ln Q$ from –4.0 to –4.2 (Q from 0.01 to 0.15), i.e., the adsorption potential is zero at the surface filling exceeding 0.02.

The low adsorption potentials of modified diabase of the 80–125-μm fraction can be accounted for by the fact that carbon deposited onto the diabase surface blocks oxygen-containing donor–acceptor centers on the surface of the initial coarsely dispersed sample (containing a comparatively small amount of functional groups). This leads to hydrophobization of the surface and precludes adsorption of hydroxo complexes (which are adsorbed by the outer-sphere mechanism into a film of adsorbed water [6]). Naturally, the coefficient of the $\Delta\mu^2$–$\ln Q$ correlation decreases at the exceedingly narrow range of variation of the chemical potential.

The results of potentiometric measurements are in full agreement with the data obtained in studying the distribution of adsorption centers with respect to donor–acceptor properties (Figs. 2 and 3b), according to which the highest content of these centers on the initial diabase is observed for the 40–80-μm fraction, and after modification the content of all the centers decreases. An increase in the adsorption energy after modification is only observed for the <40-μm fraction, i.e., modification must presumably enhance the reactivity of these samples and the interaction energy at the filler–polymer interface.

Regression equation for $\Delta\mu^2$–$\ln Q$ correlation

Diabase fraction size, μm	Regression equation	Correlation coefficient
Initial samples		
80–125	$82\Delta\mu^2 - 310$	0.994
40–80	$86\Delta\mu^2 - 240$	0.996
<40	$16\Delta\mu^2 - 70$	0.982
Samples modified with carbon		
80–125	$0.63\Delta\mu^2 - 1.30$	0.810
40–80	$34\Delta\mu^2 - 130$	0.976
<40	$28\Delta\mu^2 - 110$	0.942

In other words, the initial and modified samples with different dispersities differ both in the composition of adsorption centers and in overall energy-related characteristics of the surface, which must reflect on their properties as fillers for composites and, in particular, for rubbers.

To evaluate the influence exerted by the surface properties of initial and modified diabase samples on the physicomechanical characteristics of rubbers, vulcanizates were prepared from SKMS-30ARKP (nonpolar) and SKN-40AM (polar) rubbers with 50 wt parts of filler per 100 wt parts of rubber. The vulcanization was effected with a sulfur vulcanizing group. For comparison, vulcanizates containing the same volume amount of chalk and PGM-33 carbon black were prepared.

Physicomechanical tests demonstrated that vulcanizates based on SKMS-30ARKP rubber are characterized by weak enhancing effect: nominal rupture strength σ_r ~2 MPa (σ_r = 1.3, 2.7, and 16.7 MPa for, respectively, rubber without filler and that with chalk and carbon black). This is in agreement with the increasing elasticity of the rubbers: relative elongation ε = 430% (ε = 320, 420, and 300%, respectively). The rise in dispersity upon diabase grinding and the surface modification of diabase with carbon improve somewhat the nominal strength and the modulus of elasticity of the rubbers and do not affect the degree of equilibrium swelling of vulcanizates in benzine, i.e., leave unchanged the density of the 3D network. This confirms the weak interaction between nonpolar SKMS-30ARKP rubber and fillers.

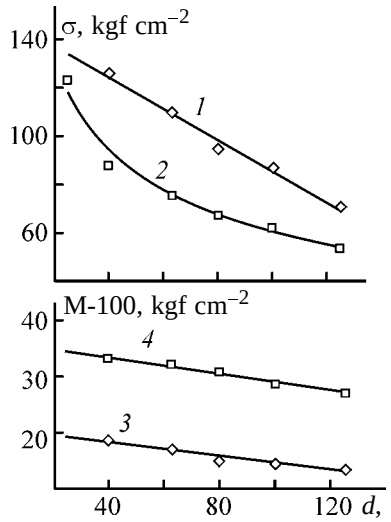

Fig. 5. (*1, 2*) Nominal rupture strength σ and (*3, 4*) stress at 100% relative elongation, M-100, for vulcanizates based on SKN-40AM rubber vs. dispersity *d* of filler: (*1, 3*) initial and (*2, 4*) modified diabase.

Much stronger influence is exerted by the type and dispersity of a filler on the properties of vulcanizates based on SKN-40AM rubber containing nitrile groups. As seen from Fig. 5, the nominal strength, modulus of elasticity, and relative elongation of the rubbers depend on the particle size and on modification of the diabase surface with carbon. The strength of rubbers filled with dispersed diabase of 20-, 40-, 63-, and 80-μm fractions is 10–12 MPa, which is 2 times the value for similar rubbers with chalk (~6 MPa). The strength of rubbers modified with carbon decreases and their modulus grows, which can be accounted for by an increase in their density and decrease in the energy of cross-linking bonds (density and strength of the network). This is also confirmed by the fact that rubbers with carbon-modified diabase of the 20-μm fraction exhibit high oil-and-gas resistance (close to that of rubbers filled with PGM-33 carbon black).

Therefore, the initial dispersed diabase can be used as weakly reinforcing filler for rubbers, together with such widely used mineral fillers as chalk and kaolin. Dispersion and modification of the initial diabase with carbon enhance its adsorption activity. This favors an increase in the number of weak cross-linking bonds and in the density of the 3D network, especially for vulcanizates based on polar rubbers, and leads to substantial improvement of physicomechanical characteristics in comparison with rubbers filled with active chalk.

CONCLUSIONS

(1) The possibility of directed control of energy-related characteristics of the diabase surface by dispersion and chemical modification of diabase with nanometer layers of carbon in fixed bed is demonstrated.

(2) The increase in the content of donor–acceptor centers in dispersion of diabase is due to larger specific surface area, surface activation, and changes in phase composition. Modification of the diabase surface with carbon leads to higher content of Lewis centers and weaker influence of phase heterogeneity on the energy-related characteristics of the surface.

(3) Changes in the composition and content of donor–acceptor centers in dispersion and modification with carbon improve physicomechanical characteristics of vulcanizates based on polar rubbers and diabase, which allows wide use of this inexpensive natural material as filler for composites, instead of deficient mineral fillers.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Separation of Cobalt and Tungsten Carbide by Anodic Dissolution of Hard Alloys in Phosphoric Acid Solutions

V. V. Malyshev and S. A. Butov

Kiev Polytechnic Institute, Ukrainian National Technical University, Kiev, Ukraine

Received June 24, 2002; in final form, January 2003

Abstract—Anodic behavior of the VK–6 alloy in phosphoric acid solutions was studied potentiometrically, voltammetrically, and by X-ray phase and metallographic analyses. The potential range was determined in which the phase of cobalt–tungsten alloy dissolves with formation of soluble compounds of the above metals and the tungsten carbide phase does not dissolve. The results obtained can be used in reprocessing of hard alloy scrap.

Tungsten carbide–cobalt alloys were the first metal–ceramic hard alloys (HAs) applied in industry [1]. Their use is still wide. To return valuable HA components into the production, it is necessary to search for a way for secondary reprocessing of wastes containing these components. Suitable raw materials for the HA production are matrices of spent drilling and cutting instrument and scrap.

Current methods for separating HA components use different treatment conditions and chemical reagents [2]. The drawback of the dissolution of HA components in acids and their mixtures is toxicity of the applied chemicals. In part, this drarwback is avoided in a reprocessing method [3] based on anodic dissolution of spent diamond and HA instrument in a chloride–hydroxide melt. In this method, tungsten and carbon are transferred to the melt in the form of tungstate and carbonate, respectively, whereas materials impregnating HA matrices are accumulated near the cathode in the form of highly disperse metallic powders. The final product in the suggested method is tungsten oxide WO_3, which requires further reprocessing prior to being returned into the manufacture of HA instrument.

In this work, we studied the separation of cobalt and tungsten carbide WC by anodic dissolution in phosphoric acid. A phosphoric acid solution as electrolyte, unlike molten media, allows selective separation of the HA components and ensures separation of WC suitable for return into the production. A strong tendency of tungsten and its carbide to passivation in aqueous solutions determines the specificity of their electrochemical behavior. Mainly, the electrode potentials, cathodic reactions of electrochemical separation of gases, and the oxidation processes involving them have been studied in solutions of hydrochloric and sulfuric acids [4, 5]. The electrochemical separation of hydrogen on WC has been studied in [6], and the recombination of adsorbed hydrogen atoms was believed to be the limiting stage. The shape of the anodic polarization curves for W in H_2SO_4 solutions corresponds to passage of the active dissolution to the passive state of the metal [4, 5].

The anodic dissolution of the electrodes made of WC–Co alloy, metallic cobalt, and tungsten carbide WC was studied in a three-electrode cell. The working electrolyte was 1.25 M H_3PO_4. The solid alloy electrodes were small bars made of VK-6 alloy (WC–6% Co) obtained by traditional technology of powder metallurgy [2]. Tungsten carbide electrodes were prepared by hot pressing of tungsten and carbon powders at 2200°C and 1000 kg mm^{-2}. Cobalt electrodes were plates of ultrapure metallic foil. The surface area of the electrodes was 1–2 cm^2. Prior to measurements, the working electrodes were thoroughly abraded and polished by the procedures proposed for the corresponding materials [7]. Immediately before measurements, the polished surface was washed with alcohol and distilled water. The auxiliary electrode was a platinum plate with a surface area of 1.0–1.5 cm^2. The electrode potentials were measured relative to a saturated calomel electrode located outside the cell and coupled to it with a salt bridge. All measurements were done in nitrogen at 18°C. The steady-state potentiostatic curves were obtained with a PI-50-1 potentiostat by fixing a steady-state current. For measurements of the variations of current with time, the same potentiostat and a PDL-4 recorder were used. The metal-

lographic analysis was performed on a Neophot-21 electron microscope. The phase composition of the samples was identified on a DRON-4.0 diffractometer, and that of gases, on a Selmichrom-1 chromatograph. The carrier gas was argon or helium. The data obtained were processed on an IBM-486 computer. The concentration curves of the Co and W distribution over the cross sections were obtained on an MS-46 Cameca X-ray microanalyzer. The partial currents for metal dissolution were determined from comparison of the recorded current with the value obtained from analysis of the solutions.

The typical steady-state potentiostatic polarization curves for the anodic dissolution of VK-6, Co, and WC and those of the recovery of hydrogen ions on tungsten carbide electrode are presented in Fig. 1. The polarization curves taken on cycling potential are reproduced with virtually no hysteresis. Moreover, the behavior of the curves is not noticeably affected by mixing. The steady-state potential of the VK-6 electrode is –0.32 to –0.34 V, i.e., it lies between the steady-state potentials of the components (–0.55 to –0.57 V for carbon and –0.09 to –0.11 V for tungsten carbide). In the polarization curves taken on VK-6 electrode (curve *1*), three sections are clearly

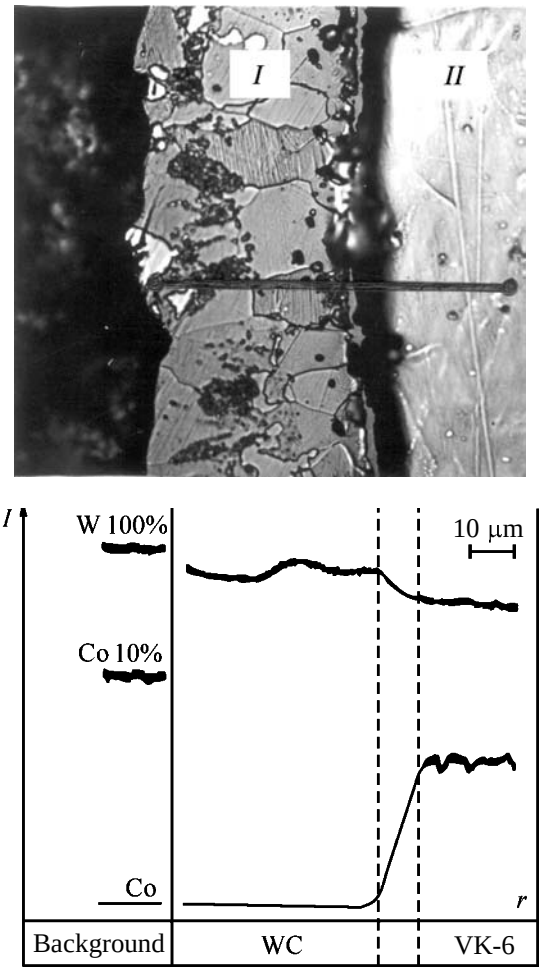

Fig. 3. Photomicrograph of the cross sectional of VK-6 alloy anodically dissolved in 1.25 M H_3PO_4 and the concentration curves *I*–*r* for Co and W distribution between the electrode region subjected to anodic dissolution and the intact region. Electrode potential –0.10 V, dissolution time 10 h, magnification 600. Electrode region: (*I*) subjected to dissolution and (*II*) intact.

observed. The logarithm of the current density increases linearly in the first section (–0.30 to –0.05 V), sharply drops at –0.02 V, remains virtually constant with potential increasing to 0.7 V (section II), and exponentially increases again at higher potentials (section III).

The VK-6 samples were anodically dissolved in the potentiostatic mode at the potentials varied from –0.25 to –0.05 V, i.e., within the first section of the potentiostatic curve. In the process, the current slowly decreases with time (commonly during 10–12 h) and then remains virtually constant (Fig. 2). In the cross-sectional view of the VK-6 alloy subjected to anodic dissolution, two zones are observed (Fig. 3): the base not subjected to dissolution and the partially dissolved

layer. According to the X-ray phase analysis, the layer subjected to dissolution contains WC, whereas metallic cobalt and tungsten are absent. These data are also confirmed by X-ray spectral microanalysis. The W content (93.1–93.8%) in the dissolved layer is lower than that in the tungsten reference, which corresponds to its weight content in the carbide.

To confirm the predicted dissolution mechanism, the VK-6 samples were anodically dissolved at various potentials corresponding to sections I and II of the polarization curve, and at varied dissolution times. The results of analysis of the solutions obtained are presented in the table. With increasing potential, the rate of dissolution of Co and W and the Co/W weight ratio in the dissolved fraction increase. The chromatographic analysis revealed gaseous CO_2 evolving at the anode at the potentials more positive than 0.70 V.

The composition of the solutions after anodic dissolution of the alloys (see table) and the results of the metallographic analysis, X-ray phase analysis, and X-ray spectral microanalysis allow a conclusion that section I of the polarization curve corresponds to separate dissolution of the Co–W phase, with the WC grains remaining in the material. Such dissolution process can be represented by the reactions

$$Co \rightarrow Co^{2+} + 2e, \quad E^0 \approx -0.59 \text{ V}; \qquad (1)$$

$$W + 4H_2O \rightarrow WO_4^{2-} + 8H^+ + 6e, \quad E^0 \approx -0.12 \text{ V}. \qquad (2)$$

The W content in the total mass of the dissolved metals is 11.3–14.2% (Table 1), which corresponds to its solubility in metallic cobalt [8]. It should be also noted that most of the anodic current corresponds to the Co dissolution. Therefore, the polarization curves taken with VK-6 and Co electrodes are similar in appearance and quantitative characteristics (Fig. 1, curves *1*, *3*).

The joint dissolution of Co and W markedly accelerates with increasing potential. As the potential of –0.02 V is attained, the current sharply drops to 15–20% of the maximal value. According to the X-ray phase analysis, tungsten oxide WO_3 and cobalt phosphate are major components of the passivating film. With further increase of the potential, the current starts to grow slowly, and after a potential of 0.7 V is attained, it increases sharply. This is due to the fact that the contribution of the reaction

$$WC + 6H_2O \rightarrow WO_4^{2-} + CO_2 + 12H^+ + 10e,$$

$$E^0 \approx 0.02 \text{ V}, \qquad (3)$$

* (b.s.l.) Below the sensitivity limit of atomic absorption spectroscopy.

to the anodic process considerably increases at the potentials more positive than its reversible potential. In this case, virtually the whole amount of dissolved W, except for a minor amount obtained by reaction (1) and calculated from data on the Co dissolution, is formed by reaction (3). This conclusion is also supported by the data on the contribution of the partial reactions to the total anodic process.

In the absence of oxygen in a solution, the cathodic current is due to hydrogen evolution (Fig. 1, curve *4*). Extrapolation of the polarization curve to the potential axis E_{cor} corresponds to the currents of the same order as for the Co dissolution without polarization. This also suggests that the rate of dissolution of the Co–W phase from the solid alloys depends on the sample thickness, Co content in the alloy, and size of Co and WC grains. Indeed, replacement of the WC–6% Co alloy (1.0–2.0-μm grains) by the WC–5% Co alloy (0.5–1.0-μm grains) increases the dissolution rate by a factor of 1.1–1.3.

Selective dissolution of the Co–W phase can be used for reprocessing of hard alloy scrap. In this case, it is desirable that the separation of Co from WC be performed at low energy consumption. After dissolving the Co–W phase, the residual WC should be ground, and then it can be used again in manufacture of hard alloy instrument.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Tin Electroplating from Sulfate Electrolyte Containing Syntanol, Formalin, and Coumarin

G. I. Medvedev, L. A. Nekrasova, and N. A. Makrushin

Novomoskovsk Institute, Mendeleev Russian University of Chemical Engineering, Novomoskovsk, Tula oblast, Russia

Received April 29, 2002

Abstract—Tin electroplating from sulfate electrolyte containing organic additives was studied. The electrolyte formulation for preparing lustrous smooth tin coatings was developed.

Our previous study [1–4] on tin electroplating from sulfate electrolyte containing organic additives show that introduction of Syntanol, Formalin, butane-, 2-butene-, and 2-butyne-1,4-diols, and benzyl and propargyl alcohols favors formation of lustrous coatings.

In this work we studied tin electroplating from sulfate electrolyte containing Syntanol, Formalin, and coumarin. Coumarin is a luster-producing and smoothing additive to the nickel plating solution [5].

We studied tin electroplating in the electrolyte containing from 5 to 50 g l^{-1} $SnSO_4$ and from 90 to 100 g l^{-1} H_2SO_4. Synthanol DS-10, coumarin, and Formalin (37 % formaldehyde solution) were introduced in amounts of 1–4 g l^{-1}, 0.1–2 g l^{-1}, and 1–10 ml l^{-1}, respectively.

The coumarin solubility in the electrolyte was found to be 2 g l^{-1}. The equilibrium concentration is attained within 20 h. Tin films 6–15 μm thick were deposited on copper supports. The polarization curves were recorded with a P-5828 potentiostat. The luster of the samples was measured on an FB-2 photoelectric luster meter.

The degree of the surface filling with the organic additives θ was estimated from the polarization data by the equation [6]

$$\theta = 1 - \exp(\Delta E/b),$$

where ΔE is the cathodic polarization; b is the constant of the Tafel equation, determined form the polarization curves in the ΔE–$\log i_c$ coordinates.

The smothing power of the electrolytes P was determined by direct profilographic measurements of the sample surface with a sinusoid microprofile. The calculation was performed by the equation [7]

$$P = 2.3a/[2\pi h_{av}\log(H_0/H_i)],$$

where a is the wave amplitude of the sinusoid microprofile (μm), h_{av} is the average thickness of the coating (μm), and H_0 and H_i are the initial and final amplitude of the sinusoid microprofile, respectively (μm).

The capacitance of the electrical double layer in the course of electrolysis was measured by the sequential substitution scheme using a P-5021 ac bridge operating at 30 kHz.

Tin was plated at 18–25°C without stirring or with stirring of the electrolyte with a petal stirrer.

We studied the appearance of the coating as influenced by the organic additives to an electrolyte containing, respectively, 30 and 100 g l^{-1} of $SnSO_4$ and H_2SO_4. Dull coatings were obtained in the presence of 1–4 g l^{-1} Syntanol. Low-quality coatings were plated from the electrolytes containing Formalin (1–10 ml l^{-1}), coumarin (0.1–2 g l^{-1}), or both these additives. Dull coating are formed in the electrolyte containing Syntanol (1–4 g l^{-1}) and coumarin (0.1–2 g l^{-1}), or Syntanol and Formalin (6–8 ml l^{-1}).

The quality of the coatings is substantially improved after addition of coumarin to the electrolyte containing Syntanol (2–3 g l^{-1}) and Formalin (6–8 ml l^{-1}). At the coumarin concentration of 0.5–1 g l^{-1}, lustrous coatings with dark strips along the edges are obtained. At the coumarin concentration from 1.5 to 2 g l^{-1}, the whole cathode surface is lustrous.

When the Formalin concentration is out of the indicated range, silvery coatings are formed. At the Syntanol concentration of 1 g l^{-1}, the range of the current densities providing formation of lustrous coatings strongly narrows down. At the Syntanol concentration of 4 g l^{-1}, the range of the current densities

1070-4272/03/7603-0387$25.00

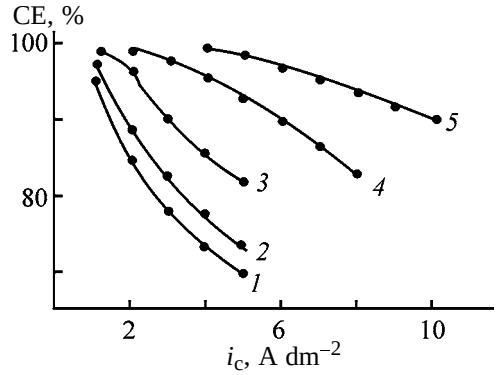

Fig. 1. Current efficiency (CE) of tin electroplating as a function of the current density i_c. Electrolyte contains 100, 2, and 2 g l^{-1} of H_2SO_4, Syntanol, and coumarin, respectively, and 6 ml l^{-1} of Formalin; mechanical stirring. $SnSO_4$ concentration, g l^{-1}: (*1*) 5, (*2*) 10, (*3*) 20, (*4*) 30, and (*5*) 50.

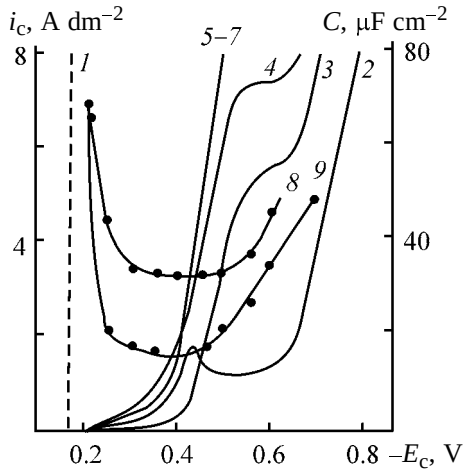

Fig. 2. (*1–7*) Cathodic polarization curves of tin, recorded on a rotating disc electrode, and (*8, 9*) the capacitance of the electrical double layer *C* as a function of cathodic potential E_c (vs. SHE) in the tin plating solutions. Electrolyte contains 30 and 100 g l^{-1} of $SnSO_4$ and H_2SO_4, respectively. (i_c) Cathodic current density. (*1, 8*) Initial electrolyte; (*2–7, 9*) the electrolyte containing Syntanol and coumarin (2 g l^{-1} each) and 6 ml l^{-1} of Formalin. Cathode rotation rate (rpm): (*1, 2*) 0, (*3*) 100, (*4*) 500, (*5*) 900, (*6*) 1500, and (*7*) 2000.

providing formation of lustrous coatings does not change, but the electrolyte foams on stirring, which complicates tin plating.

The range of working current densities providing formation of lustrous coatings was also studied as influenced by the $SnSO_4$ concentration. We found that the current density required to obtain lustrous coating increased as the $SnSO_4$ concentration was increased from 5 to 50 g l^{-1} in the electrolyte containing H_2SO_4 (90–100 g l^{-1}), Syntanol (2–3 g l^{-1}), Formalin (6–8 ml l^{-1}), and coumarin (1.5–2 g l^{-1}). At the $SnSO_4$ concentration of 5, 10, and 20 g l^{-1}, the lustrous coatings are plated at i_c = 1–5 A dm^{-2}; at [$SnSO_4$] = 30 g l^{-1}, at i_c = 2–8 A dm^{-2}; and at [$SnSO_4$] = 50 g l^{-1}, at i_c = 4–10 A dm^{-2}.

The sulfuric acid concentration in the electrolyte should be in the range 90–100 g l^{-1}. At the concentrations below 90 g l^{-1}, the electrolyte is unstable in the course of tin plating and the range of i_c providing formation of lustrous coatings narrows down. At the sulfuric acid concentration higher than 100 g l^{-1}, the range of current densities for obtaining lustrous coatings does not change. It should be noted that high-quality lustrous coatings are plated only in the stirred electrolyte. Without stirring, dull coatings are formed.

The dependence of the current efficiency (CE) on the current density in the electrolyte with the organic additives is shown in Fig. 1. The current efficiency decreases with increasing i_c and grows with increasing the $SnSO_4$ concentration. At the $SnSO_4$ concentration of 5 g l^{-1} and i_c = 1–5 A dm^{-2}, CE ranges from 96 to 71% and at the $SnSO_4$ concentration of 50 g l^{-1} and i_c = 4–10 A dm^{-2}, from 99.9 to 90.1 % (Fig. 1, curves *1, 5*).

To determine the effect of the organic additives on tin plating, we recorded cathodic polarization curves on a rotating disc electrode. As seen from Fig. 2, in the presence of the organic compounds, the cathodic polarization ΔE_c increases and the cathodic polarization curves flatten out at the limiting currents (curves *1, 2*). Curves *1* and *2* were recorded on the stationary disc electrode. At the rotation rate of the disc electrode increased from 200 to 500 rpm, i_{lim} increases, and the cathodic polarization decreases (curves *3, 4*). When the rotation rate increases to 900–2000 rpm, the section of the limiting current disappears and ΔE_c is 320 mV (curves *5–7*).

The plateau of the limiting current in the polarization curves is due to adsorption of the organic compounds on the cathode surface, which is confirmed by variation of the capacitance of the electrical double layer. As seen from Fig. 2 (curves *8, 9*), the capacitance of the electrical double layer decreases after introduction of the organic compounds. In the range of potentials E from –0.3 to –0.4 V, the capacitance decreases from 32 to 18 μF cm^{-2}. At higher cathodic potentials, the organic compounds are desorbed from the electrode surface and the continuity of the adsorption layer gets broken, thus increasing the capacitance of the double layer.

The dependences of the coverage of the cathode surface θ (curve *1*) and of the degree of the coating

luster (curve *2*) on the current density are shown in Fig. 3. The degree of the coating luster increases and the surface coverage decreases with increasing current density i_c. The surface coverage θ ranges from 13.8 to 6.8 % at i_c providing formation of lustrous coatings. It should be noted that the lustrous coatings are plated from the electrolyte with organic additives only in a definite range of i_c and θ. Probably, at the optimal values of these parameters the roughness of the growing films is minimal.

We measured the smoothing power of the sulfate electrolyte as influenced by the cathodic current density and the coumarin and $SnSO_4$ concentrations. The results are shown in Fig. 4. As seen from Fig. 4, the electrolytes containing Syntanol, Formalin, and coumarin smooth the coating surface. When i_c increases from 1 to 5 A dm^{-2} in the electrolyte containing 10 g l^{-1} $SnSO_4$, *S* decreases from 0.5 to 0.4 (Fig. 4, curve *1*). At the same time, at the $SnSO_4$ concentration of 30 g l^{-1} and i_c = 1–8 A dm^{-2}, the smoothing power increases from 0.62 to 0.98 (Fig. 4, curve *2*). The dependences of the smoothing power of the electrolytes containing 10 and 30 g l^{-1} $SnSO_4$ on the coumarin concentration in the range 0.25–2 g l^{-1} differ. As seen from Fig. 4, the *S*–*c* dependence at the $SnSO_4$ concentration of 10 g l^{-1} passes through a minimum (curve *3*), and at the $SnSO_4$ concentration of 30 g l^{-1}, through a maximum (curve *4*). The smoothing power of the electrolyte containing 30 g l^{-1} $SnSO_4$ is higher.

The mechanism of surface smoothing can be explained in the framework of the conventional adsorption–diffusion theory [7] which suggests that the polarization curves recorded on a rotating disc electrode at various rotation rates qualitatively simulate the cathodic process on profile micropeaks (high rotation rate) and microvalleys (low rate). To estimate the influence of various additives, the cathodic potential in the electrolyte with an additive (or additives) was measured at two rates of electrode rotation. If the polarization increases with increasing rotation rate, the additive(s) will have the smoothing effect.

Analysis of the cathodic polarization curves recorded in a tin sulfate electrolyte on a rotating disc electrode (Fig. 2, curves *3*–*7*) shows that these curves do not simulate the distribution of tin plating rates over the microprofile. This is probably due to adsorption of organic compounds on the electrode surface. Intensification of the hydrodynamic conditions affects formation and degradation of the adsorption layer. In this case, tin plating on all microprofile sections ac-

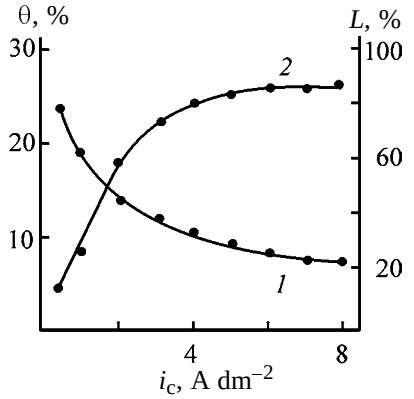

Fig. 3. (*1*) Coverage of the cathode surface θ and (*2*) degree of coating luster *L* as functions of the cathodic current density i_c. Electrolyte contains, respectively, 30, 100, 2, and 2 g l^{-1} of $SnSO_4$, H_2SO_4, Syntanol, and coumarin and 6 ml l^{-1} of Formalin; mechanical stirring.

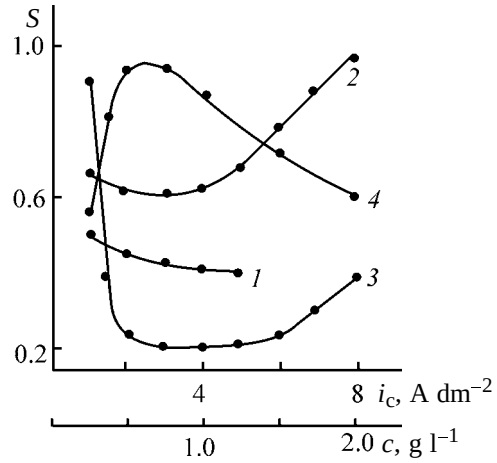

Fig. 4. Smoothing power *S* of tin sulfate electrolytes as a function of the (*1, 2*) cathodic current density i_c and (*3, 4*) coumarin concentration *c*. Electrolyte contains, respectively, 100 and 2 g l^{-1} of H_2SO_4 and Syntanol and 6 ml l^{-1} of Formalin; mechanical stirring. (*1, 2*) Electrolyte + 2 g l^{-1} coumarin + 10 and 30 g l^{-1} $SnSO_4$, respectively; (*3, 4*) electrolyte + 10 and 30 g l^{-1} $SnSO_4$, respectively.

celerates, i.e., the change in the tin plating rate looks like a manifestation of the antismoothing effect. It should be also noted that this phenomenon was observed during tin plating from the sulfate electrolyte with other organic additives [1–4] and during electrodeposition of an Sn–Sb alloy [8].

Based on the above results, we propose the following formulation of the sulfate electrolyte for plating lustrous and smooth tin coatings: $SnSO_4$ (5–50 g l^{-1}), H_2SO_4 (90–100 g l^{-1}), Syntanol DS-10 (2–3 g l^{-1}), coumarin (1.5–2 g l^{-1}), and 37% formaldehyde solu-

tion (6–8 ml l^{-1}); i_c = 1–10 A dm^{-2}. The current efficiency of tin electroplating is 71–99.9%. The electrolyte temperature is 18–25°C. At higher temperature, the electrolyte becomes turbid and low-quality deposits are formed. The electrolyte should be mechanically stirred. To decrease contamination of the electrolyte with the anodic slime, the tin anodes should be placed in woven polypropylene bags.

The electrolyte was highly stable during prolonged lab trials. However, after prolonged operation, a light yellow precipitate deteriorating the film quality was accumulated on the bath bottom. The precipitate should be filtered off at regular intervals.

The IR spectrum of the precipitate (KBr pellet) contains a strong broad band of OH stretching vibrations in the range 3400–3600 cm^{-1} [9]. The band at 895 cm^{-1} can be due to bending vibrations of the Sn–O–H group [10]. In addition, weak coumarin bands are observed at 3040, 1720, 1610, 1260, 1180, 1125, and 760 cm^{-1}. We suggest that the precipitate is a mixture of tin hydroxide and coumarin.

The $SnSO_4$, H_2SO_4, Formalin, and coumarin concentrations in the electrolyte were adjusted on the basis of chemical analysis data [11]. After passage of 100 A l^{-1} of electricity, 1 g l^{-1} of Syntanol should be added to the bath. Coumarin can be added in the amount exceeding its solubility. In this case, the coumarin concentration equal to its solubility is maintained throughout the tin plating. Excess coumarin is introduced in woven polypropylene bags in the amount no less than the weekly consumption. The presence of coumarin in the bags placed between the electrodes is monitored visually. In this case, the analysis of the electrolyte for coumarin is not required, since its concentration is self-adjusted. The coumarin consumption is 0.01 g A^{-1} h^{-1}.

CONCLUSIONS

(1) Lustrous tin coatings are plated from the sulfate electrolyte containing Syntanol, Formalin, and coumarin at i_c = 1–10 A dm^{-2} depending on the $SnSO_4$ concentration.

(2) The organic additives inhibit tin electroplating. The cathodic polarization curves recorded on a rotating disc electrode in the presence of these additives flatten out at limiting current. The length of this plateau increases and the cathodic polarization decreases with increasing rotation rate.

(3) The coverage of the cathode surface decreases and the degree of coating luster grows with increasing i_c. Lustrous coatings are formed at the coverage from 6.8 to 13.8%.

(4) The smoothing power of the sulfate electrolyte containing the organic additives was studied. These electrolytes exhibit the positive smoothing effect which depends on i_c and on the coumarin and $SnSO_4$ concentrations.

(5) The distribution of tin electroplating rate over the microprofile cannot be simulated by the polarization curves recorded at different rates of electrode rotation, since the adsorption layer inhibiting the electrodeposition is sensitive to the hydrodynamic conditions.

(6) A self-adjusted electrolyte for electroplating of smooth and lustrous tin coatings was developed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Potentiometric and Spectrophotometric Determination of the Ionic Composition of Concentrated Sodium Polysulfides

V. S. Vorobets, S. K. Kovach, and G. Ya. Kolbasov

Received June 17, 2002; in final form, January 2003

Abstract—The concentrations of ionic species in polysulfide electrolytes of photoelectrochemical converters, calculated from the results of potentiometric and spectrophotometric measurements in concentrated polysulfide solutions, are presented. The possible processes that occur at the semiconducting CdSe photoelectrode and involve electrically active species are discussed.

Concentrated polysulfide solutions are used as electrolytes in photoelectrochemical converters of solar radiation [1, 2]. Such solutions contain, in addition to water and alkali metal cations, OH^-, HS^-, S^{2-}, MS^- (M = Na, K), and S_x^{2-} (x = 2–5) ions [3–7]. The equilibria between various polysulfide species are described by the equation [3]

$$(x - 1)S_{x+1}^{2+} + HS^- + OH^- = xS_x^{2-} + H_2O, \quad (1)$$

where x = 2–4.

To describe and control processes occurring in electrochemical converters, it is necessary to perform a quantitative analysis of the electrolyte composition.

The aim of this study was to determine the ionic composition of concentrated polysulfide solutions by spectrophotometry and potentiometry.

EXPERIMENTAL

The concentration of sulfide ions was determined by a direct potentiometric procedure assuming the existence of a calibration plot φ-vs-log$[S^{2-}]$, where φ is the potential of the sulfide-selective electrode (SSE) in solution [8]. It is known that the sulfide ion undergoes hydrolysis in aqueous solutions:

$$S^{2-} + H_2O = HS^- + OH^-. \quad (2)$$

It is assumed in [8] that, already at alkali concentration c = 1 M, the entire amount of alkali metal sulfide introduced into solution is present in the form of sulfide ions, and, therefore, it suffices to prepare solutions with just this alkali concentration for constructing the calibration plot. However, as follows from [9] and data on the second dissociation constant of H_2S [4], equilibrium (2) is not completely shifted to the left even at very high alkali concentrations (~8 M), and a perceptible amount of hydrosulfide ions is present in solution. Therefore, the calibration plot should be constructed using the conversion formulas [10]

$$[S^{2-}] = \frac{S_t}{1 + K_h/[OH^-]}, \quad (3)$$

$$[OH^-] = 0.5\{c_{OH^-} - K_h + [(K_h + c_{OH^-})^2 + 4K_hS_t]^{1/2}\}, \quad (4)$$

where $[S^{2-}]$ and $[OH^-]$ are the concentrations of sulfide and hydroxide ions; c_{OH^-}, the concentration of introduced alkali; S_t, the sum of the concentrations of HS^- and S^{2-} ions (for sulfide solutions, $S_t = [HS^-] + [S^{2-}] = c_{Na_2S}$); and K_h, the hydrolysis constant

$$K_h = [HS^-][OH^-]/[S^{2-}]. \quad (5)$$

The potential of the indicator electrode was measured with an OR-205/1 pH-meter with an accuracy of 0.25 mV. An industrial EA-2 argentite electrode served as the indicator electrode, and an EVL-1M silver chloride electrode, as reference. Polysulfide solutions were obtained by dissolving required amounts of $Na_2S \cdot 9H_2O$ (analytically pure), NaOH, and S (both of ultrapure grade) in deaerated double-distilled water, after which argon (ultrapure grade) was bubbled through for 20 min. The resulting solutions

Table 1. Distribution of ionic species in concentrated polysulfide electrolytes*

Species	Concentration, M, at indicated $c_{NaOH} : c_{Na_2S} : c_S$ molar ratio			
	1 : 1 : 1	1 : 1 : 1.5	1 : 1 : 2	1 : 1 : 0
$[S^{2-}]_c$	5.41×10^{-2}	3.16×10^{-2}	1.47×10^{-2}	8.32×10^{-2}
$[HS^-]_c$				6.82×10^{-2}
$[S^{2-}]_p$	5.51×10^{-2}	3.39×10^{-2}	1.44×10^{-2}	
$[HS^-]_p$	5.51×10^{-1}	3.81×10^{-1}	1.88×10^{-1}	
$[OH^-]$	1.55	1.38	1.19	
$[S_2^{2-}]$	6.28×10^{-3}	7.39×10^{-3}	7.94×10^{-3}	
$[S_3^{2-}]$	1.24×10^{-1}	1.67×10^{-1}	2.19×10^{-1}	
$[S_4^{2-}]$	2.49×10^{-1}	3.85×10^{-1}	5.18×10^{-1}	
$[S_5^{2-}]$	1.83×10^{-3}	3.24×10^{-3}	5.025×10^{-3}	
$[NaS^-]$	1.3×10^{-4}	2.25×10^{-4}	4.84×10^{-4}	
$[S^{2-}]_{sp}$				9.36×10^{-2}
$[HS^-]_{sp}$				7.66×10^{-2}

* $[S^{2-}]_c$, $[HS^-]_c$, $[S^{2-}]_p$, $[HS^-]_p$, $[S^{2-}]_{sp}$, and $[HS^-]_{sp}$ are the ion concentrations found, respectively, from the calibration plots, from the difference of SSE potentials in sulfide and polysulfide solutions with the same content of alkali and sodium sulfide, and from spectrophotometric data. The $K_h = 15.5$ value [9] was used in the calculations.

were stored in hermetically sealed vessels. All measurements were done at the ionic strength of solution $I = 5$ M, adjusted with NaCl.

The concentration of sulfide ions $[S^{2-}]_c$, found from the calibration plot for a set of polysulfide solutions, are listed in Table 1.

However, the given method gives no way of determining the concentration of hydrosulfide ions in a polysulfide solution since the sum S_t is unknown. Previously, a method has been proposed for determining the concentrations of HS^- and S^{2-} ions and the total concentration of polysulfide ions $S_n = \sum_{i=2}^{5} S_i^{2-}$ from the difference of SSE potentials in sulfide and polysulfide solutions. The former has the same composition as the latter with respect to alkali and sodium sulfide, but contains no sulfur. The difference between SSE potentials in sulfide and polysulfide solutions is given by the expression [10]

$$\Delta\varphi = \varphi_s - \varphi_n = b\log[c_{Na_2S}/(c_{Na_2S} - S_n) - A],$$

$$A = b\log\frac{\dfrac{2K_h}{c_{OH^-} - K_h + [4K_h c_{Na_2S} + (K_h + c_{OH^-})^2]^{1/2}} + 1}{\dfrac{2K_h}{c_{OH^-} - K_h + [4K_h(c_{Na_2S} - S_n) + (K_h + c_{OH^-})^2]^{1/2}} + 1}. \quad (6)$$

After calculating the total concentration of polysulfide ions S_n by Eq. (6), S_t can be found from

$$S_t = c_{Na_2S} - S_n,$$

and then the concentrations of OH^-, HS^-, and S^{2-} ions can be determined using Eqs. (3)–(5). The results obtained in calculating the concentration of sulfide ions from the difference of SSE potentials ($[S^{2-}]_p$) are also listed in Table 1. As follows from Table 1, the difference between the concentrations of sulfide ions, found by the above methods, does not exceed 7%.

In this study, we examined the absorption spectra of concentrated polysulfide solutions ($c_{NaOH} = c_{Na_2S} = 1$ M) with varied ratio X_S of sulfur and alkali metal sulfide introduced into the solution. The absorption spectra were measured with a Specord M-40 spectrophotometer in the wave number range 25×10^3–50×10^3 cm^{-1} at small thickness of the optical cell ($d = 4.14 \times 10^{-4}$ cm). Figure 1a shows an absorption spectrum of a solution with the composition (M) 1NaOH : 1Na_2S : 2S. Origin 6.0 software was applied to resolve separate absorption bands and determine their parameters: position x_c of a band, its width, and peak height h. It is known that polysulfide ions absorb at wave numbers of 23×10^3–37×10^3 cm, and sulfide and hydrosulfide ions, and also the ion pair NaS^-, at 40×10^3–47×10^3 cm^{-1}. To improve the accuracy of the parameters being determined, the absorption spectra were processed in two stages. In the first stage, the absorption bands of the HS^-, S^{2-}, and NaS^-

ions were subtracted from the overall spectrum and the parameters of the absorption bands of polysulfide ions were determined (see Fig. 1b). In the second stage, the contributions from the absorption bands of polysulfide ions were subtracted from the overall spectrum and the parameters of the absorption bands of the HS^-, S^{2-}, and NaS^- ions were found. The calculated data are listed in Table 2. It can be seen that mainly S_3^{2-} and S_4^{2-} ions are present in solution nos. 1–3, and their redistribution toward higher content of S_4^{2-} occurs with increasing X_S. At $X_S = 2$ a new band corresponding to the ion pair NaS^- appears in the absorption spectra at $(40 \pm 5) \times 10^3$ cm^{-1} [5].

Approximate concentrations of polysulfide ions can be estimated using published values of the constants of equilibria between different polysulfide ions, $K_{2/3}$, $K_{3/4}$, and $K_{4/5}$, by solving a system of equations describing equilibria in concentrated polysulfide solutions.

In addition to equilibria (1) and (2), account should also be taken, in concentrated polysulfide solutions, of ion association processes [5]

$$Na^+ + S^{2-} = NaS^-. \quad (7)$$

Writing the equilibrium constants corresponding to processes (1), (2), and (7)

$$K_{2/3} = \frac{[S_2^{2-}]^2}{[S_3^{2-}][HS^-][OH^-]}, \quad (8)$$

$$K_{3/4} = \frac{[S_3^{2-}]^3}{[S_4^{2-}]^2[HS^-][OH^-]}, \quad (9)$$

$$K_{4/5} = \frac{[S_4^{2-}]^4}{[S_5^{2-}]^3[HS^-][OH^-]}, \quad (10)$$

$$K_h = \frac{[HS^-][OH^-]}{[S^{2-}]}, \quad (11)$$

$$K_t = \frac{[NaS^-]}{[Na^+][S^{2-}]}. \quad (12)$$

(K_t is the ion association constant), together with material balance conditions for sodium sulfide, sulfur, and hydroxide ion introduced:

$$c_{Na_2S} = [HS^-] + [S^{2-}] + [NaS^-] + S_n, \quad (13)$$

$$c_{S_0} = \sum_{i=2}^{5} (i - 1)[S_i^{2-}], \quad (14)$$

$$[OH^-] = c_{OH^-} + [HS^-], \quad (15)$$

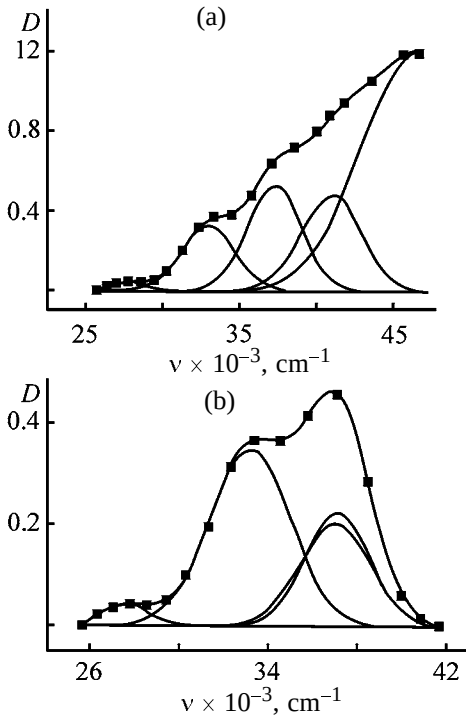

Fig. 1. (a) Absorption spectrum of a solution (M) 1NaOH : 1Na_2S : 2S and results of its processing with Origin 6.0 software and (b) absorption spectrum of the same solution after subtraction of the contributions from absorption bands of the HS^-, S^{2-}, and NaS^- ions. Optical cell thickness $d = 4.14 \times 10^{-4}$ cm. (D) Optical density and (ν) wave number.

yields a system of Eqs. (8)–(15), whose solution enables calculation of the distribution of polysulfide species in concentrated solutions. Since the ionic strength of all the solutions was maintained constant (~5 M) at strongly dominating Na^+ cation, the concentration equilibrium constants in Eqs. (8)–(11) were considered to be invariable.

The results obtained in calculating the concentrations of ion species in solution nos. 1–3 from Table 2 are listed in Table 1. The calculations were done using the constants of equilibrium between different polysulfide ions $K_{2/3}$, $K_{3/4}$, and $K_{4/5}$, and also the constants K_h and K_t [5, 9]. The concentrations of HS^-, S^{2-}, and OH^- ions, and also S_n, were determined from the measured difference of SSE potentials in sulfide and polysulfide solutions, as described above. As follows from Table 1, HS^-, S_3^{2-}, and S_4^{2-} ions predominate in concentrated polysulfide solutions at $c_{NaOH} = c_{Na_2S} = 1$ M and varied X_S (X_S = 1–2). The concentrations of other ion species are much lower, in good agreement with spectrophotometric data (Table 2). A certain discrepancy between the experimental and

Table 2. Parameters of absorption bands of ionic species in polysulfide solutions, obtained with Origin 6.0 software

Solution no.	$c_{NaOH} : c_{Na_2S} : c_S$ molar ratio	$x_c \times 10^{-3}$, cm^{-1}	h	Species
1	1 : 1 : 1	46.3	1.434	HS^-
		37.4	0.181	S_2^{2-}
		37.1	0.104	S_4^{2-}
		33.0	0.138	S_4^{2-}
2	1 : 1 : 1.5	47.0	1.601	HS^-
		36.8	0.088	S_4^{2-}
		36.75	0.112	S_3^{2-}
		32.9	0.262	S_4^{2-}
		27.7	0.041	S_3^{2-}
3	1 : 1 : 2	46.4	1.185	HS^-
		41.0	0.548	NaS^-
		37.1	0.224	S_4^{2-}
		37.0	0.204	S_3^{2-}
		33.1	0.349	S_4^{2-}
		27.6	0.039	S_3^{2-}

calculated data may be due to inadequate extrapolation of the equilibrium constants $K_{2/3}$, $K_{3/4}$, and $K_{4/5}$ to high ionic strengths and also to experimental errors in measuring the absolute values of optical density of strongly absorbing substances in micrometer-size cells. Table 1 lists the concentrations of sulfide and hydrosulfide ions, determined in a solution of composition (M) $1\,NaOH : 1\,Na_2S : 2S$ by potentiometry and spectrophotometry. The error is 12.3%.

It was shown in [11] that singly charged species are potential-determining species on a cadmium selenide semiconductor photoelectrode. The assumption that HS^- ions are electrically active species at the photoelectrode makes it possible to suggest the possible mechanism of the electrochemical process occurring at the CdSe photoelectrode under illumination, which includes discharge of an electrically active HS^- species and desorption of oxidized products from the semiconductor surface

$$HS^- + 2h^+ \rightarrow H^+ + S_{ads}, \quad (16)$$

$$S_{ads} + S_x^{2-} = S_{x+1}^{2-}, \quad (17)$$

where h^+ are holes generated in the valence band of the semiconductor under photoexcitation.

In the range $1.5 < X_S \leq 2$, the HS^- concentration is still sufficiently high (Table 1) to ensure high photocurrents; however, binding of hydroxide ions in solution by H^+ ions formed in accordance with Eq. (16) shifts equilibria (1) toward formation of longer polysulfide ions:

$$3S_3^{2-} + H_2O = 2S_4^{2-} + HS^- + OH^-,$$

$$4S_4^{2-} + H_2O = 3S_5^{2-} + HS^- + OH^-.$$

At high illumination intensity and $X_S \geq 2$, when the concentration of the electrically active species HS^- strongly decreases, diffusion of electrically active species toward the surface of the semiconductor photoelectrode becomes the rate-determining stage of the photoelectrochemical process. A calculation of the limiting diffusion current for typical values of the diffusion coefficient $D = 0.7 \times 10^{-5}$ $cm^2\ s^{-1}$ and diffusion layer thickness $\delta = 1 \times 10^{-2}$ cm in an electrolyte of composition (M) $1NaOH : 1Na_2S : 2S$, with concentration $c_{HS^-} = 0.19$ M of electrically active species, demonstrated that $I_{diff} = 12.8$ mA cm^{-2}. This corresponds to experimental photocurrents on a CdSe photoanode in polysulfide electrolyte [6].

With the concentration of HS^- ions decreasing further at $X_S > 2$, the diffusion current will become smaller, also in agreement with experimental data of [6], according to which I_{SC} (short-circuit current) substantially decreases at $X_S > 2$.

Thus, the electrolyte composition (M) $1NaOH : 1Na_2S : 1.5S$ ensures high stability of CdSe photoelectrodes because of the fast removal of adsorbed sulfur from the surface, with the highest efficiency

achieved in this case owing to the high concentration of the adsorbed electrically active species HS^-. The decrease in efficiency, observed at $X_S > 1.5$, is due to enhancement of ion association (formation of NaS^- species), increasing absorption of visible light in the electrolyte, and more stringent diffusion limitations at $X_S > 2$ (resulting from the significant decrease in the concentration of the electrically active HS^- species).

CONCLUSIONS

(1) Concentrations of the sulfide ion in concentrated sodium polysulfide solutions were determined by direct potentiometry and from the difference of potentials of a sulfide-selective electrode in sulfide and polysulfide solutions, with the discrepancy between the concentrations found by the above methods not exceeding 7%.

(2) It was found that HS^- ions are electrically active species in the system constituted by the CdSe photoelectrode and a polysulfide electrolyte. The possible stage mechanism of transformations occurring in the given system under illumination, which includes discharge of the electrically active HS^- species and desorption of oxidized products from the semiconductor surface, was considered.

(3) A calculation of the limiting diffusion current in an electrolyte of composition (M) 1NaOH : $1Na_2S$: 2S demonstrated that diffusion of electrically active HS^- species toward the photoelectrode surface is the rate-determining stage of the electrochemical process occurring in the system constituted by the CdSe photoelectrode and a polysulfide electrolyte at high illumination intensity and $X_S > 2$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Manufacture of Corrosion Inhibitors from Secondary Raw Materials

Z. A. Tadzhikhodzhaev

Institute of Chemical Engineering, Tashkent, Uzbekistan

Received March 28, 2002

Abstract—Metal corrosion inhibitors based on secondary raw materials from chemical and by-product coke plants are developed and their inhibiting properties are studied in acid and hydrogen sulfide-containing solutions.

Wide range of inhibitors are known, as both individual compounds and various formulations. However, inhibitors currently used are based mostly on reagent-grade components, which, naturally, is reflected in their cost.

In view of increasing demand for special inhibitors, it appears advisable to use secondary raw materials (process wastes, by-products, still bottoms, etc.) for their manufacture [1–4].

It is quite reasonable to expect that the use of secondary raw materials for manufacture of acid and hydrogen sulfide corrosion inhibitors not only should exert a significant influence on progress in many branches of the industry, but it will also allow considerable process advancement, eliminating many power- and labor-consuming operations and thus reducing the production cost. Of course, manufacture of corrosion inhibitors from secondary raw materials is advantageous from the environmental standpoint also. In this work we studied new inhibitors for metal protection against acid and hydrogen sulfide corrosion, based on by-products from caprolactam production.

EXPERIMENTAL

As starting materials for preparation of corrosion inhibitors we used toluene and cyclohexane oxidation products, T-product [5, 6] and Pod oil [TU (Technical Specifications) 113-03-476–82] [7], respectively.

Inhibitor I was prepared as follows. A mixture of T-product and still bottoms of isoquinoline (IsSB) was heated to 60°C, and epichlorohydrin (ECH) was added using a dropping funnel. The reaction mixture was heated at 100–110°C for 5–6 h. Then 5% aqueous NaOH was added, and the mixture was allowed to stand at 100°C for 1 h.

Inhibitor II was obtained similarly using Pod oil and still bottoms of higher pyridinium bases (HPBSB) as starting products.

Inhibitor I was tested in the dynamic mode at 20, 40, and 60°C with stratal water [8, 9] of the Krasnoyarsk oil field (Zhigulevskneft' Oil-and-Gas Production Department), containing 333–408 mg l^{-1} hydrogen sulfide. The inhibitor concentration c_{inh} was varied from 100 to 400 mg l^{-1}. In blank experiments, the corrosion of the same material (St. 3 steel) was studied without inhibitor.

The inhibiting characteristics of inhibitor I are given in Table 1 for the optimal component ratio (T-prod-

Table 1. Protective characteristics of inhibitor I with respect to St. 3 steel in hydrogen sulfide-containing solutions

c_{inh}, mg l^{-1}	Protective action, %, at indicated temperature, °C

400	96.6	93.4	92.8
	T-product		
100	27.2	25.0	Not determined
200	30.0	28.2	〃
300	49.8	48.6	〃
400	56.4	55.4	〃

* For optimal composition.

1070-4272/03/7603-0396$25.00

uct : IsSB : ECH : NaOH = 46.5 : 23.3 : 23.3 : 7.0).

The results show that, at an inhibitor I concentration of 100 mg l^{-1} and a temperature of 20–50°C, the protective action is 82.4–90.2%, depending on the inhibitor formula. With increasing inhibitor concentration from 100 to 400 mg l^{-1}, the protective action increases, approaching 92.8 and 96.6% at 20 and 60°C, respectively. The maintenance of the protective action at elevated temperatures is of no small importance for inhibitors. Table 1 shows that the protective action decreases with increasing temperature from 20 to 60°C, but still remains high.

The results obtained suggest the applicability of I as a metal corrosion inhibitor in hydrogen sulfide-containing solutions.

T-product taken individually is of no interest: it demonstrates the protective action below 56.4%, which is considerably lower as compared to inhibitor I under the same conditions.

The compositions of inhibitors II are given in Table 2.

Inhibitor II was tested with St. 3 steel in acid (HCl, H_2SO_4) solutions (Table 3).

The protective action of inhibitor II in 4 N HCl increases with increasing inhibitor concentration, whereas that in 4 N H_2SO_4 is virtually independent of the inhibitor concentration.

The presence of secondary raw materials from caprolactam production in formulations I and II initiates formation of a film on the sample, thus making a barrier at the metal–solution interface. The presence of pyridinium and quinoline bases provides a synergistic effect in hydrogen sulfide-containing corrosive medium. The use of ECH promotes formation of complex branched radicals, which, along with the inhibiting effect, also demonstrate a blocking action. Generally, it may be suggested that composites I and II demonstrate so-called "intramolecular synergism," as containing oppositely charged groups, each capable of adsorption interaction with the metal surface.

Therefore, the observed high inhibiting performance of formulations I and II is originated primarily from the possibility of formation of a compact adsorption layer on the metal surface. Additionally, some other inhibiting effects can also contribute to the total protective action.

Table 2. Compositions of inhibitors II

Sample index	Component content, wt %			
	Pod oil	HPBSB	ECH	5% NaOH
II*	33.3	23.4	33.3	10.0

ACKNOWLEDGMENTS

The author is grateful to the staff of the Corrosion Inhibitors Laboratory, Research Institute for Development and Use of Oil Field Pipes (VNIITneft', Samara, Russia) and also to employees of the Corrosion Preventing Laboratory, Research and Design Institute for Oil and Gas Production (UzNIPIneftegas) for their help in conducting corrosion tests.

CONCLUSION

Multicomponent metal corrosion inhibitors based on secondary raw materials from caprolactam production are developed. They demonstrate high protective action at relatively high temperatures in hydrogen sulfide-containing and acid solutions (HCl, H_2SO_4).

CATALYSIS

Catalytic Properties of the System Fe_2O_3–Ga_2O_3 in Ammonia Oxidation

N. I. Zakharchenko

Zhukovsky National Aerospace University, Kharkov, Ukraine

Received June 26, 2002

Abstract—The catalytic properties of the system Fe_2O_3–Ga_2O_3 in high-temperature oxidation of ammonia and the influence exerted by the phase composition of the system on the physicochemical and catalytic properties of the catalysts were studied.

Catalytic oxidation of ammonia to nitrogen(II) oxide is the basis for the industrial procedure for manufacture of nitric acid [1]. The high cost, short supply, and irreversible loss of industrial catalysts (Pt, Rh, and Pd alloys) in industrial processes pose a topical problem of a search for effective nonplatinum catalysts (NCs). Iron(III) oxide, which is a promising component of NC, is used in the industry as a component of the second stage of a combined system for ammonia oxidation [1, 2]. The high activity and selectivity with respect to NO is commonly preserved and the thermal and chemical stability of Fe_2O_3 enhanced by using various modifying additives and, in particular, metal oxides [1–9]. Gallium(III) oxide Ga_2O_3 is employed as a modifying additive to catalysts containing iron oxide [1, 10], but the Fe_2O_3–Ga_2O_3 system has not been studied in a wide range of compositions.

This study is concerned with the catalytic and physicochemical properties of the system Fe_2O_3–Ga_2O_3 for NH_3 oxidation at high temperatures in a wide range of compositions.

The catalysts were prepared according to [11] by thermal decomposition in air of hydrated iron and gallium nitrates $Fe(NO_3)_3 \cdot 9H_2O$ and $Ga(NO_3)_3 \cdot 9H_2O$ of chemically pure grade, taken in appropriate proportions. The temperature of the final treatment of catalyst grains was 1143 K. X-ray phase analysis was made on a Siemens D-500 powder diffractometer with CuK_α radiation and graphite monochromator in the path of the diffracted beam. The phases in X-ray diffraction patterns were identified using the JCPDS file included in the software package shipped with the diffractometer. The phase composition of the catalytic system studied is listed in Table 1.

IR absorption spectra were measured on a Perkin–Elmer 577 spectrophotometer in the range 200–2000 cm^{-1} using KBr technique.

The selectivity of the catalysts with respect to NO was determined on a flow-through installation with a quartz reactor 2×10^{-2} m in diameter [12]. The height of the bed of catalyst grains, 2×3 mm in size, was $(4–12) \times 10^{-2}$ m; content of ammonia in the ammonia–air mixture (AAM), about 10 vol %; contact time, 6.89×10^{-2} s (normal conditions), which is the optimal value according to previously obtained data [4]; pressure, 0.101 MPa. The test temperature of 1123 K was close to the optimal value for a single-component iron oxide catalyst; in some sets of experiments it was varied within 913–1273 K.

The composition of products formed in NH_3 oxidation and thermal decomposition of NO on the catalysts was determined chromatographically by the known procedure [13], with the gas mixture analyzed for the content of NH_3, O_2, N_2, NO, NO_2 before and after passing through the catalyst bed. The detection limit of the analytical procedure was (vol %) 3.0×10^{-3} for NH_3, 3.5×10^{-3} for NO, and 5.0×10^{-3} for O_2, N_2, and N_2O.

The limiting NH_3 load on the catalysts was determined using a procedure [3] consisting in that the load on the catalysts is raised to the critical state of "estinguishment," i.e., to disturbance of the heat balance of the catalysts upon transition of the reaction from the diffusion to the kinetic region.

Te specific surface area of the catalysts was measured by low-temperature adsorption of nitrogen and calculated by the BET equation using the standard technique [14].

The particle size of the catalysts was determined on a JEM-7Y electron microscope [15]. Suspensions of

82.7	$\beta_{s.s}$ saturated	Monoclinic, θ-Al_2O_3 type	a = 0.5854
82.8–99.9	$\beta_{s.s}$	"	a decreases linearly with α-Fe_2O_3 content in β-Ga_2O_3 increasing from 0.5802 to 0.5854 wt %
100.0	β-Ga_2O_3	"	a = 0.5802, b = 0.3040, c = 1.2230

* $\alpha_{s.s}$ is a solid solution of gallium(III) oxide in rhombohedral α-Fe_2O_3; $\chi_{s.s}$, $Ga_{2-x}Fe_xO_3$ solid solution with x = 0.7–1.4 and structure of χ-Al_2O_3; $\beta_{s.s}$, solid solution of α-Fe_2O_3 in gallium(III) oxide, with β-Ga_2O_3 structure.

catalyst samples were prepared by diluting weighed portions of a substance in distilled water with ultrasonic dispersion on a UZDV-2 device. As substrates served carbon films deposited by thermal sputtering of graphite.

The binding energies of surface oxygen to the catalysts were determined from the temperature dependence of the equilibrium oxygen pressure over the surface of the compounds [16].

The catalytic properties of the system Fe_2O_3–Ga_2O_3 are presented in Fig. 1 and Table 2. In the products formed in NH_3 oxidation on the catalysts under study, only N_2 and NO were found, with no "breakthrough" Y of ammonia observed. Thus, the overall conversion of the starting substance is 100%, with only the ratio of the amounts of NO and N_2, i.e., the selectivity of the catalysts with respect to NO (or to nitrogen), varying. Thermal dissociation of NO leads to a decrease in the apparent selectivity of the

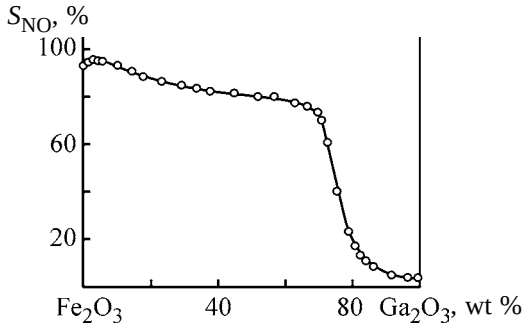

Fig. 1. Catalyst selectivity with respect to nitrogen(II) oxide, S_{NO}, vs. composition of the system Fe_2O_3–Ga_2O_3.

catalysts with respect to nitrogen(II) oxide:

$$2NO = N_2 + O_2. \quad (1)$$

Experimental data on the degree of thermal dissociation of nitrogen(II) oxide on the catalysts of the given system are listed in Table 3.

At the chosen test temperature and the optimal contact time of 6.89×10^{-3} s, from 0.3% (low-active and poorly selective β-Ga_2O_3) to 2.1% (the most active and highly selective composition with Ga_2O_3 content of 3.0 wt %) NO undergoes thermal dissociation. The process leads to a 2.0% decrease in selectivity with respect to nitrogen(II) oxide for the most active catalyst; the selectivity of the low-active β-Ga_2O_3 is virtually not affected (Table 3). Catalysts of other compositions are characterized by intermediate values of these quantities relative to the catalysts considered above (Table 3).

With increasing linear flow velocity of reactants, i.e., with the contact time decreasing to 1.1×10^{-3} s (critical conditions of catalyst extinguishment), no thermal dissociation of NO is observed, in agreement with data on other NCs for NH_3 oxidation [1, 4, 5, 8, 9].

According to the results of X-ray phase analysis, a number of solid solutions based on Fe_2O_3 and Ga_2O_3 are present in the system at the chosen test parameters (temperature, partial pressure of oxygen). A similar conclusion was made in [17, 18], concerned with the phase diagram of the system Fe_2O_3–Ga_2O_3. At a gallium oxide content of up to 14.2 wt %,

* S_{NO} is the catalyst selectivity with respect to NO; s, the specific surface area of a catalyst; X, the limiting load of ammonia on a catalyst.

iron(III) oxide forms a rhombohedral solid solution $x\alpha$-$Fe_2O_3 \cdot (1 - x)Ga_2O_3$ with the structure of the α-Al_2O_3 type (Table 1). For example, in the X-ray diffraction pattern of the catalyst containing 3.0 wt % Ga_2O_3, the main reflections correspond to interplanar spacings of 0.3682, 0.2693, 0.2511, 0.2214, 0.1846, 0.1695, 0.1484, and 0.1454 nm, which are typical of the rhombohedral structure of α-Fe_2O_3 (hematite) [19], but are shifted to greater reflection angles, which corresponds to a decrease in the lattice constant a from 0.5434 to 0.5423 nm. As the Ga_2O_3 concentration in the solid solution $x\alpha$-$Fe_2O_3 \cdot (1 - x)Ga_2O_3$ is increased further, the lattice constant a decreases to 0.5384 nm (Table 1). No Ga_2O_3 lines were observed in the diffraction patterns of the rhombohedral solid solutions with $c_{Ga_2O_3} \leq 14.2$ wt %. This indicates that, in this composition range, the catalysts are solid solutions of Ga_2O_3 in α-Fe_2O_3.

Table 3. Degree of NO decomposition, R_{NO}, and decrease in selectivity with respect to nitrogen(II) oxide, ΔS_{NO}, for catalysts of the system Fe_2O_3–Ga_2O_3 at 1123 K Gas mixture composition, vol %: NO 9.5, N_2 71.3, O_2 4.6, $H_2O_{(vapor)}$ 14.6; contact time 6.89×10^{-2} s; $R_{NO} = 0$ at $\tau = 1.1 \times 10^{-3}$ s

In the Ga_2O_3 content range 0.1–3.0 wt %, the selectivity and specific surface area of the catalytic system grow with increasing Ga_2O_3 content (Fig. 1, Table 2). Raising the content of Ga_2O_3 in the system Fe_2O_3–Ga_2O_3 to more than 3.0 wt % leads to a monotonic decrease in the selectivity and specific surface area of the catalysts (Fig. 1, Table 2).

The composition of a two-component catalytic system with Ga_2O_3 content of 3.0 wt % is the most efficient as regards its selectivity (95.3%) and is characterized by the largest specific surface area (9.0 $m^2\ g^{-1}$); this composition exceeds in catalytic parameters the individual components of the system.

An increase in the specific surface area of a system, compared with that of the starting oxide components (Ga_2O_3 content range 0.1–3.0 wt %), is a common trend in the practice of catalyst fabrication [1, 20–22]. Klyachko-Gurvich and Rubinshtein [20] attributed this phenomenon to a decrease in the lattice energy of a solid solution, compared with the lattice energies of the starting components forming such a solid solution. Milligan [21] accounted for the increase in the surface area of a binary system, compared with the starting oxides, by mutual protective action in the process of catalyst preparation, which consists in adsorption of one component onto the surface of crys-

tallites of the other component, with the result that their growth is hindered and the forming system becomes even more dispersed.

In the Ga_2O_3 content range 82.8–99.9 wt %, there is another solid solution, that of hematite in β-Ga_2O_3, in the Fe_2O_3–Ga_2O_3 system. The main reflections in the X-ray diffraction patterns for, e.g., a composition containing 90 wt % Ga_2O_3 (0.3702, 0.2960, 0.2821, 0.2553, 0.2400, 0.2342, 0.2113, 0.1981, 0.1884, 0.1600, 0.1523, 0.1448, 0.1342, and 0.1037 nm) are characteristic of a solid solution of α-Fe_2O_3 in β-Ga_2O_3, with monoclinic lattice of the θ-Al_2O_3 type [19]. No lines of Fe_2O_3 were observed in the monoclinic solid solution. With increasing Fe_2O_3 content of the solid solution based on Ga_2O_3, the lattice constant grows linearly from 0.5802 to 0.5854 nm (Table 1). Raising the Ga_2O_3 content of the monoclinic solid solution leads to a monotonic decrease in the selectivity and specific surface area of the catalysts in the given range of compositions (Fig. 1, Table 2). The selectivity with respect to NO and the specific surface area of the catalysts, solid solutions of hematite in β-Ga_2O_3, are the lowest, being much exceeded by the similar characteristics of catalysts of the system Fe_2O_3–Ga_2O_3 with other quantitative compositions (Fig. 1, Table 2). The selectivity of β-Ga_2O_3 (3.5%) and its specific surface area (1.6 $m^2\ g^{-1}$) are the lowest among all the compositions from the system Fe_2O_3–Ga_2O_3.

In the Ga_2O_3 content range 34.0–70.2 wt %, solid solutions $Ga_{2-x}Fe_xO_3$ (x = 0.7–1.4) with rhombic structure of the χ-Al_2O_3 type were found in the system Fe_2O_3–Ga_2O_3. With the composition of Ga_{2-x}·Fe_xO_3 changing from $Ga_{0.6}Fe_{1.4}O_3$ to $Ga_{1.3}Fe_{0.7}O_3$, the selectivity (82.9 and 73.1%) and the specific surface area (4.4 and 3.6 $m^2\ g^{-1}$) of the catalysts decrease steadily (Fig. 1, Table 2). Catalysts with χ-Al_2O_3 structure ($Ga_{2-x}Fe_xO_3$) are characterized by relatively high values of selectivity and specific surface area (Fig. 1, Table 2).

In the Ga_2O_3 content ranges 14.3–33.9 and 70.3–82.6 wt %, χ-type solid solutions $Ga_{2-x}Fe_xO_3$ coexist, according to X-ray phase and electron microscopic analyses, with a rhombohedral solid solution of Ga_2O_3 in hematite ($\alpha_{s.s}$) and monoclinic solid solution of α-Fe_2O_3 in β-Ga_2O_3 ($\beta_{s.s}$), respectively, in the form of their mixtures. With the content of the low-active β-type solid solution increasing in the Ga_2O_3 content range 70.3–82.6 wt %, the selectivity and specific surface area of catalysts fall dramatically (Fig. 1, Table 2). The differences between the catalytic properties of χ-type solid solutions $Ga_{2-x}Fe_xO_3$ and rhombohedral solid solutions of Ga_2O_3 in α-Fe_2O_3 ($\alpha_{s.s}$) are less significant (Fig. 1).

Thus, the selectivity of the system depends on the composition and, in particular, on the content of the components (Ga_2O_3, Fe_2O_3) in solid solutions based on iron(III) and gallium(III) oxides and the quantitative relationship between solid solutions of two-phase systems.

High-temperature oxidation of ammonia on catalysts proceeds by two parallel pathways [1, 23]:

$$4NH_3 + 5O_2 = 4NO + 6H_2O, \quad (2)$$

$$4NH_3 + 3O_2 = 2N_2 + 6H_2O. \quad (3)$$

The occurrence of reactions by the redox mechanism [23] predetermines a regular relationship between the selectivity and the strength of binding of chemisorbed oxygen to the catalyst surface [23, 24]. As measure of the strength of oxygen binding to a catalyst may serve the heat of chemisorption [23, 24]. For catalysts of certain nature (metals, metal oxides), there exists the optimal energy of oxygen binding to the surface of compounds at which the selectivity with respect to NO is the highest [23–25]. Deviations from the optimal oxygen binding energy make the selectivity of the catalysts with respect to NO lower, and that with respect to N_2 higher.

The experimental binding energies of surface oxygen to solid solutions, q_s, are listed below (oxidized state of the catalyst surface):

Composition of a system	q_s, kJ mol^{-1} O_2
α-Fe_2O_3	144.6
β-Ga_2O_3	231.5
$\alpha_{s.s}$ (2.0 wt % Ga_2O_3)	135.2
$\alpha_{s.s}$ (3.0 wt % Ga_2O_3)	134.3
$\alpha_{s.s}$ (10.0 wt % Ga_2O_3)	144.8
$\alpha_{s.s}$ saturated (14.2 wt % Ga_2O_3)	146.3
$\alpha_{s.s}$ + $\chi_{s.s}$ (29.0 wt % Ga_2O_3)	151.4
$\chi_{s.s}$ (34.0 wt % Ga_2O_3)	153.2
$\chi_{s.s}$ (70.2 wt % Ga_2O_3)	161.9
$\chi_{s.s}$ + $\beta_{s.s}$ (76.0 wt % Ga_2O_3)	194.3
$\beta_{s.s}$ saturated 82.7 (wt % Ga_2O_3)	223.0
$\beta_{s.s}$ 92.0 (wt % Ga_2O_3)	229.8

The energies of oxygen binding to the β-Ga_2O_3 surface and to catalysts, solid solutions at Ga_2O_3 content higher than 9.9 wt %, exceed the corresponding value for Fe_2O_3.

When a product of deeper NH_3 oxidation, namely, NO, is formed, a greater number of oxygen–catalyst

bonds is ruptured as compared to formation of molecular nitrogen. This means that the catalyst selectivity with respect to NO decreases with increasing binding energy of adsorbed oxygen [23, 25], and such a behavior is, indeed, observed for β-Ga_2O_3 and most of solid solutions in the system Fe_2O_3–Ga_2O_3 with Ga_2O_3 content exceeding 9.9 wt % (Fig. 1, Table 2). The dramatic increase in the binding energy of adsorbed oxygen to the surface of catalysts, solid solutions based on β-Ga_2O_3 and also two-phase systems $\chi_{s.s}$ + $\beta_{s.s}$ (70.2–99.9 wt % gallium oxide; Tables 1 and 2), in comparison with α-Fe_2O_3 leads to a pronounced decrease in the selectivity of these catalysts with respect to NO (Fig. 1). Upon introduction of gallium(III) oxide (up to 9.9 wt %) into α-Fe_2O_3, the binding energy of oxygen to the surface of modified catalysts decreases as compared to that for α-Fe_2O_3. This means that a complex interaction changing the energy state of the surface of the rhombohedral solid solution, compared to α-Fe_2O_3 and Ga_2O_3, occurs between separate components in the catalytic system (in the given range of compositions). The specific surface area of the catalysts increases in comparison with that of separate components (Table 2), which can be attributed to a decrease in the lattice energies of solid solutions, compared to the lattice energies of the constituent substances [20]. There appear areas on the catalyst surface that are characterized by lower oxygen binding energies, compared to that of a single-component iron oxide catalyst. The decrease in the energy of oxygen binding to the surface of modified catalysts, compared to α-Fe_2O_3, leads to higher selectivity of the catalysts with respect to NO (Table 2).

Probably, the composition of a modified catalyst with the Ga_2O_3 content of 3.0 wt % is the optimal as regards the energy-related characteristics of the catalyst surface and, consequently, also the catalyst selectivity with respect to NO. Both raising and lowering the Ga_2O_3 content relative to the optimal value lead to a decrease in the specific surface area of the catalyst (Table 2), increase in the binding energy of adsorbed oxygen to the catalyst surface, and decrease in the catalyst selectivity with respect to NO (Fig. 1).

The limiting NH_3 load on the catalysts grows with an increase in their specific surface area (Table 2) determined at the given technique of catalyst preparation by the composition of the system. The limiting load depends on the rate of the surface chemical reaction, which, in turn, is determined by the number of active centers and the chemical composition of the catalysts [3, 23, 24]. In fact, all active centers of a heterogeneous catalyst come into play under critical conditions, and the number of these centers grows with increasing specific surface area of the system. The limiting load characterizes the activity and the maximum output capacity of the catalysts [1, 26]. The highest limiting load is observed for the catalyst with the largest specific surface area, solid solution of Ga_2O_3 (3.0 wt %) in α-Fe_2O_3 [9.92×10^3 m^3 $NH_3/(h\ m^2)$], and the lowest, for the catalyst with the smallest specific surface area, β-Ga_2O_3 [1.76×10^3 m^3 $NH_3/(h\ m^2)$] (Table 2).

Under the critical conditions of the process ($\tau = 1.1 \times 10^{-3}$ s), no successive decomposition of NO by scheme (1) is observed (Table 3), but a part of unchanged NH_3 is detected after passing through the catalyst bed, i.e., ammonia breakthrough occurs (Table 2). With increasing specific surface area of the catalysts, the breakthrough becomes less pronounced, in agreement with the higher activity of such catalysts under critical conditions of the reaction course, which varies with the composition of the Fe_2O_3–Ga_2O_3 system. The strongest breakthrough is observed for the β-Ga_2O_3 catalyst (1.22 rel. %), i.e., for a catalyst with the smallest specific surface area, and the weakest, for a solid solution of Ga_2O_3 (3.0 wt %) in α-Fe_2O_3 with the highest activity (0.04 rel. %).

The characteristics of the system Fe_2O_3–Ga_2O_3, analyzed in this study, pass through extrema for a solid solution of Ga_2O_3 (3.0 wt %) in α-Fe_2O_3. The catalyst of this composition has the highest selectivity with respect to nitrogen(II) oxide (Fig. 1), largest specific surface area and limiting load, and lowest amount of ammonia breakthrough under critical conditions of the reaction (Table 2). Gallium(III) oxide β-Ga_2O_3 is characterized by the lowest selectivity with respect to NO, smallest specific surface area and limiting load, and highest level of ammonia breakthrough under the critical conditions of the process (Table 2).

The components of the Fe_2O_3–Ga_2O_3 system form a number of solid solutions, including two-phase mixtures of solid solutions (Table 1). As follows from the data obtained, the properties of catalysts in such systems vary continuously from characteristics of one component to those of the corresponding saturated solid solution (within the range of existence of a single phase); from characteristics of one solid solution to those of another (two-phase regions of existence of solid solutions (Fig. 1; Tables 1 and 2). The only exception is the region of solid solutions of Ga_2O_3 (up to 14.2 wt %) in α-Fe_2O_3, in which the physicochemical characteristics pass through extrema at 3.0 wt % Ga_2O_3 (Fig. 1; Tables 2 and 3).

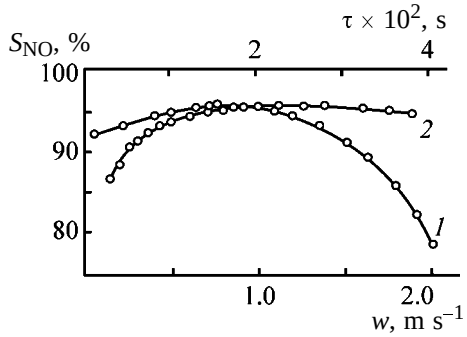

Fig. 2. Selectivity of iron–gallium catalyst, S_{NO}, vs. (*1*) linear flow velocity of AAM, w, at $\tau = 2.25 \times 10^{-2}$ s (operating conditions) and (*2*) contact time τ (operating conditions) at $w = 0.77$ m s^{-1}. Test temperature 1103 K; catalyst composition (wt %): Fe_2O_3 97.0 and Ga_2O_3 3.0; the same for Fig. 3.

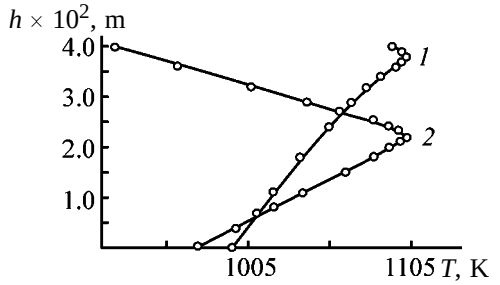

Fig. 3. Distribution of temperature T along the height h of the iron–gallium catalyst bed. Linear flow velocity of AAM (m s^{-1}): (*1*) 0.77 and (*2*) 2.22.

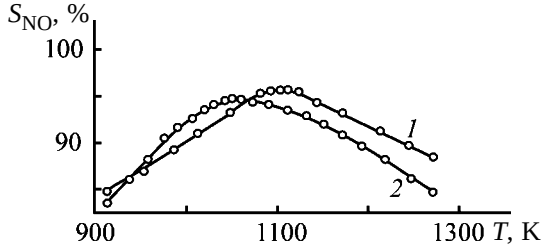

Fig. 4. Catalyst selectivity S_{NO} vs. process temperature T. Linear flow velocity of AAM 19 m s^{-1} (normal conditions). Catalyst: (*1*) σ-Fe_2O_3 97.0, Ga_2O_3 3.0 wt %; (*2*) α-Fe_2O_3.

Of practical interest among catalysts belonging to the system Fe_2O_3–Ga_2O_3 are only compositions with gallium(III) oxide content $c_{Ga_2O_3} \leq 9.9$ wt %, which are the most active and selective and even outperform α-Fe_2O_3. The properties of a two-component catalyst of the optimal composition (Fe_2O_3 97.0 and Ga_2O_3 3.0 wt %), a highly active and selective catalyst in the Fe_2O_3–Ga_2O_3 system, have not been studied [1] and, therefore, are considered below.

The dependence of the selectivity on the contact time (Fig. 2) points to a kinetically complicated mechanism of NH_3 oxidation [1, 3–5, 7–9] on a heterogeneous catalyst.

The abrupt decrease in the catalyst selectivity at a contact time $\tau < 1.0 \times 10^{-2}$ s is due to the occurrence of a side reaction of nitrogen defixation [1, 27] in accordance with the equation

$$4NH_3 + 6NO = 5N_2 + 6H_2O. \quad (4)$$

The slow decrease in the selectivity at a contact time $\tau > 3.2 \times 10^{-2}$ s is mainly due to NO dissociation by scheme (1) [1]. The optimal contact time of the catalyst is 6.89×10^{-2} s under normal conditions, n.c. (2.25×10^{-2} s under operating conditions, o.c.).

The influence exerted by the linear flow velocity of reactants on the catalyst selectivity (Fig. 2) points to the outer-diffusion control of the process [1, 3–5, 7–9], in which the reaction rate is limited by NH_3 diffusion from the flow core to the catalyst surface.

The optimal linear flow velocity of AAM for the catalyst is 0.77 m s^{-1} (o.c.) (0.19 m s^{-1} under n.c.). Raising the linear flow velocity of the reactants shifts the "hot zone" toward the end of the catalyst bed, i.e., lowers the temperature of its "front" layer (Fig. 3). For example, at $w = 2.22$ m s^{-1} the temperature of the front layer of the catalyst falls to 933 K, which favors the occurrence of side reactions. In particular, the rate of nitrogen defixation in accordance with Eq. (4) at this temperature is close to its maximum value [1, 27]. In addition, the low temperature of the front layer, within which oxidation of NH_3 is the most intensive, favors the occurrence of a parallel process (3) [1], which impairs the catalyst selectivity with respect to NO. According to [1, 4, 5, 8, 9], the low linear flow velocities of AAM favor the occurrence of a side reaction of NO dissociation, which leads to a gradual decrease in the catalyst selectivity with respect to nitrogen(II) oxide, since the rate of NO decomposition at 1103 K is slow [1, 28].

Raising the linear flow velocity of reactants to critical values ($\tau = 1.1 \times 10^{-3}$ s) leads to catalyst "extinguishment," i.e., to disturbance of the heat balance because of the dramatic increase in heat losses.

The temperature dependence of the catalyst selectivity is shown in Fig. 4. As compared to iron(III) oxide, the two-component catalyst is characterized by higher selectivity at $T \geq 1073$ K, thus being an effective high-temperature catalyst for NH_3 oxidation [1, 3–5, 8, 9].

The peak selectivity of the catalyst (95.5%) is shifted to higher temperatures, compared to α-Fe_2O_3 (1103 and 1053 K, respectively). The catalyst is characterized by wide interval of temperatures (90 K) with

high selectivity (at the level of 94.0%), compared to Fe_2O_3 for which this interval is only 50–60 K.

The kinetic characteristics of the reaction were determined from the temperatures of "ignition" and "extinguishment" of a catalyst pellet, i.e., the temperatures at the critical points. The reaction rate was calculated using the method for determining the temperature limits of the outer-diffusion region with the use of the effect of catalyst pellet extinguishment on lowering the temperature of AAM [29]. The surface temperature of the catalyst was measured with a Chromel–Alumel thermocouple inserted into the lower side of the pellet relative to the AAM flow direction. To prevent heat loss, a layer of catalyst grains (2.0_3.0) × 10^{-3} m in diameter was placed between the pellet and the reactor walls.

The kinetic parameters of the process were calculated using the equation proposed by Buben [30] and solved for two reaction rates at constant oxygen concentration. The Buben equation has the form

$$(1 + a)^2[1 + (m - 1)a/b] - [a(1 - a/b)]/\varepsilon = 0, \quad (5)$$

$$a = T/T_0 - 1, \quad b = Q\beta c_0/(\alpha T), \quad \varepsilon = RT_0/E,$$

where m is the reaction order with respect to ammonia; T, the temperature of the catalyst surface at the critical point (K); T_0, the AAM temperature; c_0, the NH_3 concentration in the flow; α and β, the mass- and heat-transfer coefficients, respectively, calculated by the known equations [31]; Q, the heat effect of the reaction; E, the activation energy of the reaction.

The kinetic parameters of the reaction of NH_3 oxidation on a two-component catalyst are as follows: catalyst ignition temperature 531 K, content of ammonia in AAM 10.0 vol %, activation energy E of the reaction 9.62 kJ mol^{-1}, and reaction order with respect to ammonia 0.20.

The data on the catalytic properties of the system Fe_2O_3–Ga_2O_3 can be used in developing theoretical and practical foundations for design of high-performance modified catalysts for NH_3 oxidation.

CONCLUSIONS

(1) The catalytic properties of the system Fe_2O_3–Ga_2O_3 in high-temperature NH_3 oxidation were studied at component contents in the range 0–100.0 wt %.

(2) The influence exerted by the phase composition of the system on the physicochemical and catalytic properties of the catalysts and, in particular, on their activity and selectivity with respect to NO was demonstrated. It was established that the activity and selectivity of the system depend on composition, in particular, on the content of solid solution components and quantitative relationship between the solid solutions of the system.

(3) The characteristics of the process occurring on an iron–gallium catalyst with 3.0 wt % Ga_2O_3, which is the most active and selective catalyst in the system Fe_2O_3–Ga_2O_3, were determined.

CATALYSIS

Development of Pyrolysis Catalysts Based on Barium Chloride for Industrial Use

S. V. Kolesov, M. A. Tsadkin, and R. N. Gimaev

Bashkir State University, Ufa, Bashkortostan, Russia

Received July 2, 2002

Abstract—The catalysts of pyrolysis of straight-run naphtha, platforming raffinate, and thermal cracking naphtha, based on barium chloride, were developed. The strength characteristics of preformed catalysts with addition of graphite, alkylamide of synthetic fatty acid (SFA), phenol-furan resin, and clay were studied.

Catalytic pyrolysis of naphtha fractions formed in petroleum refining to ethylene/propylene in the presence of $BaCl_2$ [1, 2] can be feasible only if the form of the salt catalyst will be suitable for the industrial process. Since in a fixed-bed reactor the use of a finely divided catalyst results in significantly increased hydrodynamic resistance to flow of the feed, and in the case of coking the catalyst bed becomes impermeable at all, $BaCl_2$ in the form of crystalline powder cannot be used as a catalyst in the industrial process. Finely dispersed powder is unsuitable for a fluidized-bed reactor (fluid-process) either, because the catalyst particles can be carried away with the flow of the feed and products. The feed flow rate under conditions of catalytic pyrolysis (τ = 5–20 s) is insufficient to produce a fluidized bed [2]. Hence, the catalyst form should provide its efficient operation in a fixed-bed reactor.

Many promising catalysts, in particular potassium metavanadate, were mainly considered in the supported form [3, 4]. With the available and cheap active component, $BaCl_2$, simpler and more efficient procedures of production of commercial catalysts can be considered. For fixed-bed reactors, the optimal shapes are granules, pellets, rings, etc., produced by pressing and extrusion. Along with the possibilities of imparting the required geometric parameters, these procedures allow modification of catalysts owing to introduction of various additives, from auxiliary substances facilitating molding to components serving as cocatalysts.

The pelletized catalysts were produced by molding on a highly productive pelletizing machine Fette-Exacta-21 in the form of 5 × 6-mm pellets, providing minimal hydrodynamic resistance to the flow of the feed [5].

The study of molding process allowed determination of the main conditions for production of suitable catalyst forms.

Variation of the degree of dispersion of the $BaCl_2$ powder showed that the best strength characteristics of pellets are obtained with the 0.25–0.50-mm fraction (Table 1). The strength of pellets is significantly enhanced with thermal pretreatment of the catalyst mass or in subsequent calcination of pellets. Preliminary calcination of the powder fraction at 175–300°C, i.e., at a temperature higher than the temperature of dehydration of $BaCl_2$ crystal hydrates [6], increases the strength of the resulting pellets by a factor of 2–5. Further heating to 500°C produces no positive effect (Table 1).

The structural-mechanical characteristics of pelletized catalysts are largely determined by the features of contacts between the solid particles in molding of the catalysts, namely, by the strength of adhesion between the particles. This strength can be enhanced by decreasing the surface energy in the contact area as a result of formation of adsorption layers of surfactants added to the system. The granule strength can also be enhanced by using lubricating agents which decrease the concentration of internal stresses in the contact areas of particles in the course of compaction. The strengthening effect of some additives can be caused by formation of a three-dimensional skeleton in the form of a chemically cross-linked network, e.g., when using thermosetting resins.

Moistening of the catalyst mass before molding (up to 5% water) enhances the strength of the catalyst pellets. However, in this case, the granule strength varies in a wide range. Addition of surfactants, e.g., alkylamide of SFA of the C_{10}–C_{13} fraction in the amount of 0.25–3 wt %, does not result in strengthen-

* The strength characteristics were determined on an Erweka-TBH28 device.

ing of granules. The use of superfine graphite in the amount of 1–5 wt % (based on the catalyst) as a forming additive is more efficient. At a graphite concentration of 3 wt %, the strength of the resulting catalysts is 8–16 kgf per pellet with a narrow spread in values. At the optimum choice of characteristics of components (dispersion), formulation, and the conditions of pretreatment of the raw materials, we were able to obtain the catalyst with the crushing strength in the axial and radical directions of 55 and 35 kgf per pellet, respectively. Such catalysts are quite acceptable for operation in industrial reactors with a fixed catalyst bed.

As a rule, the strength of pellets in the radical direction is lower than the strength in the axial direction [5], which results in their destruction during random loading and discharge. From this standpoint, the catalyst forms isotropic in strength are desirable, which is reached by using thermosetting resins as an

auxiliary additive in molding. In particular, we tested Polifuron-321 phenol–furan resin. The strength of the catalyst pellets containing 0.5–5 wt % phenol–furan resin and calcined at 300–400°C for 30–60 min reaches 50–60 kgf per pellet in all directions (Table 1).

The thermal treatment and additive affect not only the strength but also the structural characteristics of the catalysts: the specific surface area and pore volume change. Calcination of the initial $BaCl_2$ and the resulting pellets increases the surface area (Fig. 1a). Addition of water, graphite, and diethanolamide of SFA significantly decreases the specific surface area as compared to the initial catalyst.

The influence of the above factors on the pore structure of the catalyst granules is ambiguous. Whereas thermal treatment of the initial material and the resulting catalyst always increases the pore volume, the influence of additives strongly depends on their nature and content in the mixture. Addition of up to 5 wt % water does not noticeably affect the pore volume, and addition of diethanolamide of SFA (1 wt %) significantly increases the pore volume. Graphite added in the amount of 1 wt % somewhat increases the pore volume as compared to the catalyst molded without thermal treatment and additives. Larger amounts of graphite decrease the porosity of the pellets.

According to published data [7], only the outer surface of a catalyst operates in catalytic pyrolysis, and an increase in the inner surface area plays a negative role, promoting undesirable side processes.

In production of molded catalysts, it is possible to add agents that not only modify the mechanical and structural characteristics but also enhance the catalytic activity. It is of interest to produce catalysts using natural clays as binding agents. Aluminosilicates, zeolites, and zeolite-containing catalysts are widely used in catalytic pyrolysis [8–11]. Despite the presence of Brønsted and Lewis acid centers at the catalyst surface, the trends in the yield and composition of gaseous products of hydrocarbon pyrolysis at 700–800°C are similar to those in the thermal pyrolysis [11]. It is assumed that the active centers arising in dehydroxylation of the aluminosilicate surface participate in high-temperature pyrolysis. Centers containing acid–base pairs Al^+O^- can serve as such centers [12].

We studied the catalysts containing natural clay of the montmorillonite group of the Kuganak deposit, based on aluminosilicates with the structure of $xAl_2O_3 \cdot ySiO_2 \cdot H_2O$. With the clay content of up to 5 wt %, the catalysts are easily molded by pelletizing and give the products with satisfactory strength (Table 1). The catalysts with a higher content of clay (30 and 50 wt %) are best molded by extrusion with preliminary moistening to water content of 25%. After drying and calcination of extruded granules at 350–400°C, the catalysts with the crushing strength of

OD-102 derivatograph; heating rate 15 deg min^{-1}.

178–240 kgf per granule in the axial direction and 140–205 kgf per granule in the radial direction are obtained. In molding with clay, the structural characteristics of the catalyst are improved with increasing content of additive from 1 to 30 wt % (Fig. 1b).

Extrusion molding from a plastic mixture allows production of catalysts in the form of continuous regular macroscopic lattice or cellular structures. These structures of the catalysts primarily ensure favorable gas-dynamic condition in the reactor. With increasing pressure in the reactor above 0.1 MPa, the yield of the main target products of pyrolysis (ethylene and propylene) decreases and the yield of methane grows. The pressure in the reaction area also depends on the pressure differential in flow of the reaction gas mixture through the catalyst bed, which is governed by the size and shape of the catalyst particles. For example, in a bed of a catalyst in the form of cylindrical granules, the pressure is, on the average, 1.5–1.7 times higher than in the catalyst bed with particles in the form of Raschig rings. In a bed of a catalyst based on potassium vanadate modified with boron compounds and molded as Raschig rings, the yield of ethylene at 790–795°C is, on the average, 0.5–1.0% higher than that in a bed of the catalyst with cylindrical granules. It is evident that the regular cellular or lattice structure ensures the best gas-dynamic regime.

Attempts to produce catalyst blocks by addition of $BaCl_2$ to the initial plastic clayey mixture resulted in production of fragile blocks easily breking after calcination. Applying barium chloride from aqueous solution to a preliminarily formed alumino ceramic block allowed us to increase the $BaCl_2$ content to 45 wt %. However, cellular blocks with such a content of $BaCl_2$ are destroyed upon subsequent calcination at 800°C. The strength of alumino ceramic block is retained if the amount of added $BaCl_2$ does not exceed 18 wt %. In this case, the surface characteristics and pore structure of the alumino ceramic matrix do not change.

In molding of catalysts, additives modifying the catalytic activity can be introduced relatively easily. The catalysts based on a mixture of $BaCl_2$ with sodium tetrachloroaluminate $NaAlCl_4$ are of interest. These catalysts exhibit high activity in cracking and isomerization. The physical state of $NaAlCl_4$ (melt) at the temperature of the catalytic pyrolysis hampers its use. However, on its addition with graphite or clay binder to the catalytic mixture to be molded, suitable catalyst granules can be produced. On addition of the complex in the amount of 3–25 wt % based on the catalyst, the strength appreciably grows: to 98 kgf per pellet (Fig. 1c).

The other, no less important characteristic of heterogeneous pyrolysis catalyst is the thermal stability. The results of thermal gravimetric studies of the pelletized catalyst prepared from noncalcined and preliminarily calcined $BaCl_2$ powder are presented in Fig. 2.

The resulting catalysts were tested in catalytic pyrolysis in the range 500–800°C on a pilot installation equipped with a flow-type reactor with a fixed bed of granulated catalyst, a line for preheating of the feed, and a system of series-connected condensers for condensation of liquid products.

The results of pyrolysis of straight-run naphtha, platforming raffinate, and thermal cracking naphtha on the pelletized catalyst containing 3 wt % graphite are listed in Table 2. The catalyst produced with addition of natural aluminosilicate (clay) as a binder showed satisfactory activity in naphtha pyrolysis (Table 3).

In the range 650–750°C, with the catalyst containing 10 wt % $NaAlCl_4$, the pyrolysis pathway changes considerably. In pyrolysis of straight-run naphtha at 650–700°C, the yield of ethylene is lower than the yields of propylene and butylenes (Table 3), and the

* (τ) Contact time.

content of these latter in pyrolysis gas noticeably exceeds the characteristics of the thermal process. This is in good agreement with published data on the catalytic activity of $NaAlCl_4$ in cracking of hydrocarbons with primary formation of C_4 olefins. However, at 725°C and higher temperatures, the content of ethylene in the products increases, and that of butylenes decreases. In this case, the yield of ethylene exceeding 38% based on the feed was reached, with the degree of gas formation exceeding 80%. On the whole, the product composition becomes typical for a high-temperature radical process.

It is well known [13, 14] that, for activation of electrophilic catalysts based on complex metal chlorides in low-temperature catalytic degradation of hydrocarbons, participation of water or other proton donors is required. The role of water in activation of $MAlCl_4$ is governed by its dissociative adsorption on the catalyst surface. Correspondingly, metal chlorides catalytically active under these conditions play the role of Brønsted acids.

The degree of dilution of the feed with superheated steam affects the yield of ethylene (Table 4). Some increase in the total gas formation and increase in the yield of ethylene take place at steam supply of no more than 75% of the feed. In addition, a noticeable amount of carbon oxides appears in the gas.

The liquid products of pyrolysis are enriched with aromatic hydrocarbons (Table 5).

Testing for the operation life of the catalyst showed that the catalyst formed with 3 wt % graphite retains its activity in the total gas formation and selectivity with respect to the yield of ethylene and propylene for

700 h at 500°C. In this case, the coke yield based on the feed does not exceed 2.5 wt % in 30 h at 700°C for all the catalyst modifications (Fig. 3). It is particularly remarkable that the catalyst containing $NaAlCl_4$ as an additive is characterized by insignificant coking. Depending on the modification, the coke deposit at the catalyst surface can reach 10–20 wt %, which does not affect the process characteristics.

* Catalyst molded (I) with 3 wt % graphite, (II) with 30 wt % clay, and (III) with 10 wt % $NaAlCl_4$.

Auto-retardation of coking in the course of the process is characteristic for all modifications of the catalysts.

The study of the coke deposit distribution on pellet sections showed that coke is formed mainly in a thin near-surface layer. In the process, the variation of the pore structure and specific surface area of the catalyst is insignificant. In particular, the specific surface areas of the initial catalyst and catalyst coked at 500°C are 3.62 and 3.43 $m^2 g^{-1}$, and the pore volume is 0.22 and 0.28 $cm^3 g^{-1}$, respectively. In this connection, some decrease in the rate of coke deposition at the catalyst may be due to partial desorption of intermediate condensation products, precursors of coke, into the gas phase. This results in some increase in the yield of heavy resins at the expense of a decrease in the coke yield, and it does not affect the yield of the main gaseous products of pyrolysis.

CONCLUSION

Effective catalysts for production of light olefins by naphtha pyrolysis can be produced on the basis

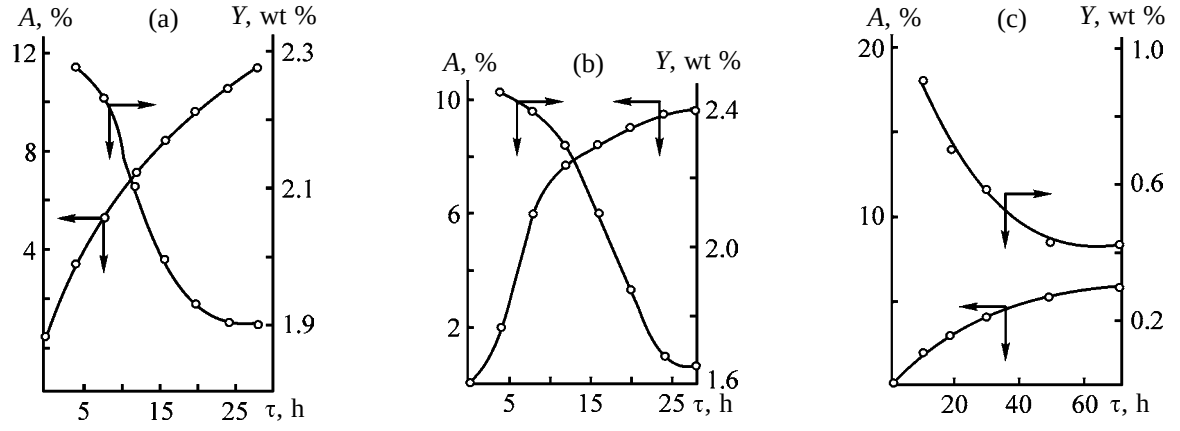

Fig. 3. Coking *A* (% of the catalyst weight) in the course of pyrolysis of straight-run naphtha on barium-containing catalysts molded with various additives. Process temperature 700°C, feed space velocity 0.5 h^{-1}. (*Y*) Coke yield (wt % based on feed) and (τ) process duration. Additive, wt %: (a) 3 graphite, (b) 30 clay, and (c) 10 $NaAlCl_4$.

of barium chloride. These catalysts fully meet the requirements to heterogeneous pyrolysis catalysts.

Received June 14, 2002

Abstract—X-ray phase and differential thermal analyses, IR spectroscopy, and temperature-programmed reduction method were applied to study the formation of a manganese–aluminum–calcium system prepared by mixing manganese hydroxocarbonate and calcium aluminates in water, which can be used as catalyst in deep oxidation of organic substances. The influence exerted by preparation conditions on the extent of chemical interaction in the system was considered.

Catalysts prepared by mixing metal hydroxocarbonates (MHC) with calcium aluminate in water or aqueous ammonia are successfully used to accelerate various chemical processes [1].

It was found previously that, in formation of formulations of this kind from MHC and calcium aluminates, carbonate ions from the MHC structure are partly or completely replaced by aluminate and(or) hydroxide ions formed in dissolution and hydrolysis of calcium aluminates. In this case, the replacement of CO_3^{2-} with aluminate ions may occur both with structural rearrangement of MHC into metal hydroxoaluminate (e.g., for ZnHC and MgHC in water and aqueous ammonia) and without it (CoHC, MnHC, NiHC in water). In the latter case, solid solutions of aluminum ions in the MHC lattice are formed. The involvement of hydroxide ions in the exchange leads to formation of metal hydroxides, which may further decompose to oxides.

In preparing catalysts from the given systems, it is preferable that products of replacement of carbonate ions with aluminate ions should be formed, since such compounds enhance the properties of the resulting catalysts (activity, thermal stability, service life, etc.) [1]. Thus, a key issue in obtaining catalysts based on calcium aluminates is directed synthesis of compounds incorporating ions of an active metal and aluminum.

There is virtually no published evidence concerning cement-containing systems with manganese hydroxocarbonate. At the same time, it is known that manganese compounds are effective catalysts for redox reactions and, in particular, deep oxidation of organic substances. In this context, it was of interest to study in detail the manganese–aluminum–calcium catalytic system, in which the high activity of manganese ions would combine with such properties of cements as high mechanical strength and thermal stability.

The aim of this study was to analyze specific features of formation of catalysts based on a system comprising MnHC and calcium aluminates by the method of "chemical mixing" widely used in the technology of cement-containing catalysts. The so-called chemical mixing assumes that the interaction of the starting components to give precursors of the active phase occurs in the stage of mixing of the starting substances with a liquid reagent. The stock obtained in mixing is then dried, calcined, and pelletized. In the given case, calcium aluminates are mainly involved in formation of the active phase of the catalysts, and their binding properties are employed to a lesser extent. The properties of the catalysts obtained are strongly affected by the mixing conditions: temperature, time, liquid : solid ratio (l : s), and medium (water or aqueous ammonia). The use of aqueous ammonia as liquid reagent in preparing many of the cement-containing systems developed previously is due to the fact that MHCs dissolve in this solution to form ammine complexes, which facilitates further interaction with the products formed in dissolution and hydrolysis of calcium aluminates to give metal hydroxoaluminates (or hydroxocarbonatoaluminates). In the case of catalyst formation in an aqueous medium, the interaction is localized at the interface between the solid phase of virtually insoluble MHC and solution

1070-4272/03/7603-0415$25.00

of calcium aluminates, and, therefore, the extent of the occurring transformation is lower. Nevertheless, water was used as liquid reagent in the given case, since, in contrast to other MHCs studied, MnHC does not dissolve under the action of aqueous ammonia to give ammine complexes [8], and the degree of hydration of calcium aluminates in the presence of $NH_3 \cdot H_2O$ markedly decreases [1, 4]. Thus, it is inadvisable to use ammonia water in the given case; moreover, adoption of an aqueous medium markedly improves the environmental characteristics of the technology.

The goals of this study were to reveal how preparation parameters affect the formation of the active phase of manganese–aluminum–calcium catalysts and to analyze the structural, strength, and catalytic properties of the catalysts developed with varied content of the active component.

EXPERIMENTAL

As starting components for preparing catalyst samples served manganese hydroxocarbonate $MnCO_3 \cdot m\mathrm{Mn(OH)}_2 \cdot nH_2O$ [GOST (State Standard) 7205–77] and high-alumina cement of the talum[1] type [$CA : CA_2$ = 0.26), TU (Technical Specification) 5737-006-00 284 345–99]. Manganese hydroxocarbonate was mixed with calcium aluminates in water, and the resulting stock was dried at 100°C and calcined at 400°C; dried and calcined catalysts were pelletized (specific compaction pressure P_{sp} = 200 MPa). The temperature and time of mixing were varied in the experiments; the l : s ratio was varied within the range (1.5–3) : 1. Simultaneously, mechanical mixtures of the starting components were studied.

X-ray phase analysis (XPA) was performed on DRON-2 and DRON-3 diffractometers with CuK_α radiation and graphite monochromator. IR spectral study of samples compacted into pellets with KBr was carried out on a Specord 75-IR spectrophotometer. Differential-thermal analysis was made on an OD-102 derivatograph; samples were heated in air to 1000°C at a rate of 5 deg min^{-1}. The temperature-programmed reduction was done on a KL-1 integrated installation in a hydrogen flow, at a heating rate of 5 deg min^{-1}. The specific surface area was measured by the BET technique on the basis of low-temperature adsorption of nitrogen. The total porosity was found from the true and apparent densities of the samples. The pore volume distribution with respect to radii was studied on a Carlo Erba Sorptomatik instrument. The mechanical strength of pelletized catalysts was determined under static conditions by crushing grains with load applied to the sample edge (Shkol'nik and MP-2S instruments). The activity of the samples was tested in deep oxidation of benzene on a laboratory flow-through setup at W = 30 000 h^{-1} and initial concentration of benzene in the air flow of 4–6 g m^{-3}. The activity was evaluated by the temperature at which 50% conversion of benzene was reached ($T_{\alpha=50\%}$).

It was shown previously that mixing of MnHC with talum in water leads to partial replacement of carbonate ions in the structure of MnHC by aluminate and hydroxide ions formed in dissolution and hydrolysis of calcium aluminates. This gives calcium carbonate (in the form of calcite) and aluminum-containing precursors of the active phase of the catalysts: solid solutions based on the crystal lattice of MnHC, with partial replacement of carbonate ions by aluminate ions, and on the gibbsite lattice with introduction of manganese ions. The maximum amount of interaction products is formed at middle compositions: 30–40% manganese compounds in terms of Mn_3O_4. Therefore, a composition with 40% Mn_3O_4 was chosen for a more detailed study of the basic aspects of manganese–aluminum–calcium catalyst formation under various conditions.

An X-ray phase analysis of samples prepared by mixing in water for 5 h demonstrated that, with increasing mixing temperature, the interaction rate grows (Fig. 1a): the intensity of reflections from the initial phases (MnHC, CA, CA_2) decreases and the intensity of lines corresponding to the forming compounds, $CaCO_3$ (in the form of calcite) and gibbsite, increases. The highest rate of the occurring transformations is observed at 75–90°C.

Figure 1b shows for a sample prepared at 90°C how the intensity of diffraction reflections from the starting and forming compounds varies with time. Calcium monoaluminate was completely hydrated within the first 2 h of treatment, and the degree of conversion of calcium dialuminate after 5 h of mixing was about 70%. By the end of the process, the intensity of the lines corresponding to MnHC was 40–45% of the initial value. The amount of forming gibbsite increased during the entire time of mixing; in addition, in contrast to hydrated talum (without MnHC additives), samples contained a minor amount of bayerite. The intensity of the lines corresponding to calcium carbonate increased only during the first 4 h of treatment. After 3 h of mixing, the formation of

[1] Talum is a mixture of calcium monoaluminate $CaO \cdot Al_2O_3$ and calcium dialuminate $CaO \cdot 2Al_2O_3$. Hereinafter the common designations of the chemistry of cements are used: A = Al_2O_3, C = CaO, H = H_2O.

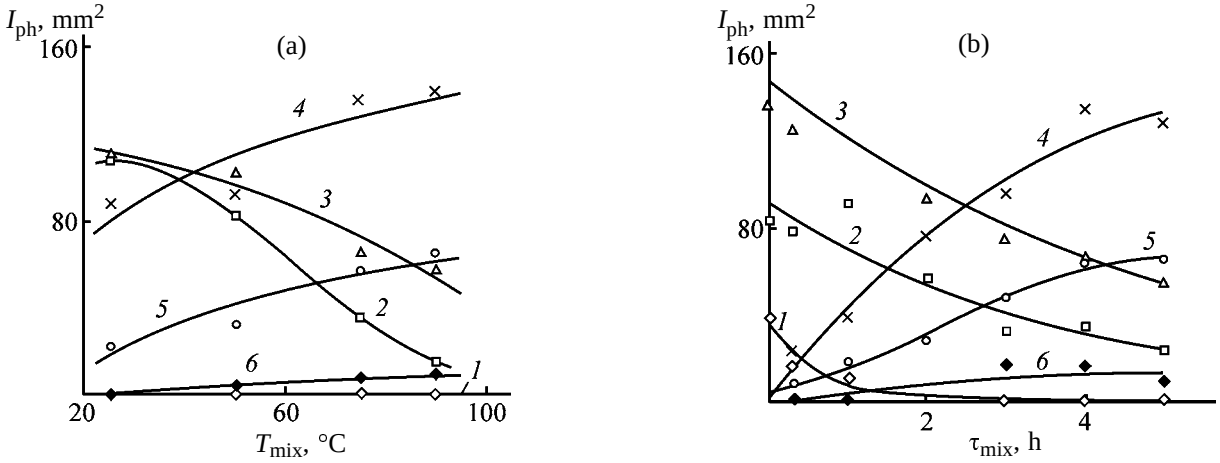

Fig. 1. Intensity I_{ph} of diffraction reflections from the forming and initial phases for samples prepared by mixing in water vs. (a) temperature T_{mix} and (b) time τ_{mix} of mixing (90°C). Phase: (*1*) CA, (*2*) CA_2, (*3*) MnHC, (*4*) $CaCO_3$, (*5*) gibbsite + bayerite, and (*6*) CCA.

calcium hydroxocarbonatoaluminate $C_3A \cdot CaCO_3 \cdot 12H_2O$ (CCA) was observed, with its amount in a sample remaining further unchanged. Thus, the maximum extent of reaction between the starting substances is reached in 3–5 h.

The IR data obtained are in good agreement with the results of XPA. In particular, with increasing time (Fig. 2) and temperature of mixing, the intensity of the absorption bands at 870 and 730 cm^{-1} belonging to MnHC decreases and the bands at 880 and 720 cm^{-1} corresponding to $CaCO_3$ appear. In addition, an increase in intensity and change in profile are observed for absorption bands in the range of stretching (3400–3700 cm^{-1}) and bending (900–1100 cm^{-1}) vibrations of OH^- groups of gibbsite, which results in that its spectrum becomes similar to that of bayerite. On the whole, raising the time of mixing to more than 3 h, and the temperature of mixing to above 75°C does not lead to any significant changes in the spectra of the samples.

The formation of $CaCO_3$ and the decrease in the intensities of diffraction reflections from MnHC in X-ray diffraction patterns and absorption bands associated with MnHC in the IR spectra of the samples result from partial replacement of carbonate ions in the structure of MnHC by hydroxide and aluminate ions formed in dissolution and hydrolysis of calcium aluminates [7].

The exchange of CO_3^{2-} ions for hydroxide ions leads to partial disintegration of the MnHC structure to give, probably, X-ray amorphous compounds $Mn(OH)_2 \cdot nH_2O$ and $MnO_x \cdot yH_2O$, with the possible incorporation of manganese ions into the lattice of the forming gibbsite. In the process, a system of new hydrogen bonds is formed in the structure of $Al(OH)_3$, the characteristics of the existing OH^- groups are changed, and new OH^- groups appear, which leads to partial transformation of its structure into bayerite. As a result, the profile of the absorption bands associated with stretching and bending vibrations of the OH^- groups of gibbsite in the IR spectra and X-ray diffraction characteristics change, and it is this fact that was observed in studying the samples. In particular, a detailed X-ray diffraction study revealed a shift of the diffraction reflections from gibbsite with respect to tabulated values. For example, depending on the mixing temperature, values ranging from d = 4.81 Å (90°C) to d = 4.78 Å (25–50°C) were observed for the reflection with d = 4.82 Å. This means that lowering the mixing temperature leads to stronger

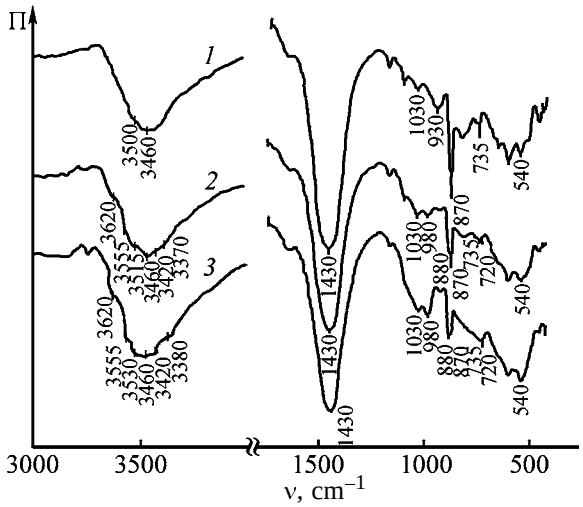

Fig. 2. IR spectra of samples prepared by mixing for varied time. (П) Transmission and (ν) wave number. Mixing time (h): (*1*) 0.5, (*2*) 2, and (*3*) 3.

disordering of the structure of aluminum hydroxide, probably, owing to an increase in the content of manganese ions in its lattice.

Formation of disordered $MO–Al_2O_3$ solid solutions based on the MO lattice in thermal treatment [1–7] is an evidence of the involvement of aluminate ions in the exchange. Calcination of the samples in a hydrogen flow at 500°C yielded manganese oxide MnO whose diffraction peaks do not superimpose on reflections corresponding to other phases [7]. According to X-ray diffraction data, the forming MnO has a smaller lattice constant, compared to that for MnO obtained from MnHC (4.438 Å). In this case, a_{0MnO} = 4.431–4.437 Å for catalysts obtained under various conditions, and a_{0MnO} = 4.438 Å for the starting mechanical mixture of substances. In addition, depending on the mixing conditions, the intensity of reflections from MnO, I_{MnO}, in the samples under study was 30–50% of the intensity of MnO lines in a reduced mechanical mixture of the reagents. This may be due, first, to binding of manganese compounds into difficultly reducible solid solutions with the result that only a part (30–50%) of manganese compounds is reduced and, second, to formation in the course of reduction of highly dispersed, X-ray amorphous particles of MnO, which leads to broadening of its reflections in X-ray diffraction patterns and to a decrease in their intensity. The dispersity α (Å) of the resulting manganese oxides also depends on the mixing temperature, being equal to 120 Å for a sample prepared at 90°C and 145 Å for catalysts obtained at 25–75°C, in contrast to a mechanical mixture of MnHC with talum, for which α_{MnO} = 180 Å.

These results point to the formation in calcined samples of $MnO_x–Al_2O_3$ solid solutions based on the MnO_x lattice and, consequently, to the presence (as a precursor) in the initial uncalcined samples of a solid solution of aluminate ions in the MnHC lattice.

In view of the partial decomposition of manganese hydroxocarbonate in the course of the reaction [7], an assumption was made that both incorporation of manganese ions into the lattice of $Al(OH)_3$ formed in hydration of calcium aluminates and incorporation of aluminum ions into the structure of $Mn(OH)_2$ are possible under conditions of simultaneous formation of X-ray amorphous manganese and aluminum hydroxides. In addition, modification with Al ions of the forming X-ray amorphous $MnO_x \cdot yH_2O$ is also not improbable, i.e., X-ray-amorphous manganese compounds $Mn(OH)_2$ and $Mn_x \cdot yH_2O$ with incorporation of aluminum ions may serve as another precursor of the $MnO–Al_2O_3$ solid solutions.

Noteworthy is the fact that the minimum values of I_{MnO} and the largest deviations of a_{0MnO} of reduced catalysts from the tabulated values are characteristic of catalysts prepared at medium temperatures (50–75°C). Presumably, the greatest extent of interaction between MnHC and talum to give manganese–aluminum-containing solid solutions based on the MnHC, $Mn(OH)_2 \cdot nH_2O$, and $MnO_x \cdot yH_2O$ lattices is achieved under these conditions.

Figure 3 shows DTG curves of samples obtained at varied mixing time. These curves were interpreted on the basis of the results obtained in [7, 9, 10] and XPA data. It is noteworthy that the intensities of effects associated with $Al(OH)_3$ decomposition (260–290°C) and $CaCO_3$ dissociation grow with increasing mixing time, and also there appear minor thermal effects at 180 and 230–250°C, related to decomposition of calcium hydroxocarbonatoaluminate (CCA). With increasing mixing time, the intensity of the thermal effect associated with the $Mn_3O_3 \rightarrow Mn_3O_4$ transformation at 920–940°C decreases and it is shifted to higher temperatures (950–990°C). Of particular interest is the change in the curve profile in the range 350–600°C. The effects associated with MnHC decomposition (380, 420°C) and $MnO_2 \rightarrow Mn_2O_3$ transformation (510°C), observed for a mechanical mixture of the starting components (Fig. 3, curve *1*), are shifted to higher temperatures and partly overlap after 30 min of mixing (Fig. 3, curve *2*), with the peak at 380°C shifted to 400°C, the effect at 420°C shifted to 480°C and superimposed on the $MnO_2 \rightarrow Mn_2O_3$ effect (530°C), and an effect appearing at 590°C. Further increase in the mixing time makes lower the intensity

of the effect at 530–540°C, with the result that the profile of the DTG curves at 400–600°C is gradually smoothed; after 3 h of mixing the profile virtually does not change any more. The data presented indicate that a chemical reaction occurs in the course of mixing, with the maximum extent of this reaction reached after 3–5 h of treatment. The profiles of the DTG curves of samples prepared at different temperatures are similar; however, the intensities of the effects associated with $Al(OH)_3$ and $CaCO_3$ decomposition grow with increasing mixing temperature, and a minor effect related to decomposition of calcium hydroxocarbonatoaluminate appears at 230°C, with the maximum extent of the occurring transformations reached at 75–90°C.

Thus, according to differential-thermogravimetric analysis, the optimal mixing conditions are the following: temperature 75°C and time 3 h.

In discussing the results obtained by the method of temperature-programmed reduction of samples in a flow of hydrogen, the following is noteworthy. The thermochromatogram of the initial mechanical mixture of the components shows effects of MnHC decomposition (300–470°C). The chromatogram of a "mixed" sample contains peaks associated with dehydration of gibbsite (250–350°C) and dissociation of calcium carbonate (550–670°C): in the interval 400–630°C, a number of minor effects is observed, which can be attributed to decomposition of residual MnHC modified with aluminum ions and to reduction of manganese oxides. Thus, the data furnished by the method of temperature-programmed reduction are in good agreement with the derivatographic data; however, decomposition of $CaCO_3$ in a reductive medium (H_2) occurs at a temperature lower by nearly 150°C than that in the oxidative medium (air). This phenomenon, which has also been observed in studying other cementcontaining systems, is associated with the catalytic action of reduction products on the thermal dissociation of $CaCO_3$.

Noteworthy is the fact that manganese oxide MnO forming in the course of reduction at temperatures of up to 750°C has lattice constant rather close to the tabulated value (4.445 Å): 4.441 for mixed catalyst and 4.444 Å for a mechanical mixture, in contrast to 4.431 and 4.437 Å for the same samples heated to 500°C, which is probably due to ordering of its structure in the course of heating. The intensity of diffraction reflections from MnO for a mixed sample (I_{MnO} = 250 mm^2) is lower than that for a mechanical mixture (I_{MnO} = 570 mm^2), and its dispersity α_{MnO} = 300 Å is 2 times higher. Comparison of these data with the results for catalysts reduced at temperatures of up to 500°C shows that raising the temperature of heating in a flow of hydrogen from 500 to 750°C leads to caking of MnO, and in the case of the initial mixture of MnHC with talum, its dispersity changes from 180 to 600 Å, whereas for a sample obtained by mixing in water, the decrease in MnO dispersity is less pronounced: from 145 to 300 Å. This phenomenon points to higher thermal stability of the mixed catalyst and, consequently, to positive effect of the solid solutions formed in fabrication of catalysts on their stability.

On the basis of the analytical data and the results of XPA and thermogravimetric analysis of samples prepared under different conditions, the degrees of conversion of the starting substances into reaction products were calculated. It was found that, with increasing temperature and time of mixing, the extent of the reaction grows and reaches a maximum at temperatures of 75–90°C and mixing times of 3–5 h. It should be noted that the overall conversion of Al_2O_3 in the composition of calcium aluminates exceeds its conversion into $Al(OH)_3$ and calcium hydroxocarboaluminate (DTG data). At the same time, a good agreement was obtained as regards the conversion of CaO in the system. On the basis of these data and the results of [7], it may be assumed that the discrepancy for Al_2O_3 can be attributed to formation of a solid solution based on the MnHC lattice. For a sample prepared at 75°C in the course of 5 h, approximately 10% of the total amount of Al_2O_3 is presumably introduced into the lattice of manganese compounds.

To refine the optimal composition of manganese–aluminum–calcium catalysts, which must ensure the best structural, strength, and catalytic properties, a set of samples with varied content of the active component was prepared. The catalysts were obtained with account of the optimal preparation parameters (75°C, 3 h).

The dependence of the specific surface area of samples calcined at 400°C on composition shows a maximum at 30–40% Mn_3O_4 (140 $m^2 g^{-1}$). The maximum extent of surface development at medium compositions is presumably due to formation of talum hydration products: highly dispersed $Al(OH)_3$ phases, and to reaction of MnHC with talum to give at these compositions the greatest amount of highly dispersed compounds, manganese–aluminum-containing solid solutions.

The total porosity of calcined samples increases somewhat with increasing manganese content, being at the level of 28–35%. A study of the pore volume distribution with respect to radii demonstrated that, for

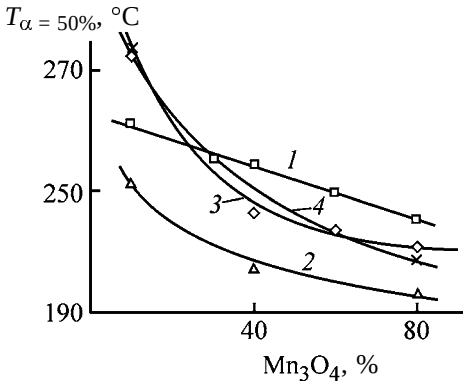

Fig. 4. Activity of samples in test reaction of deep oxidation of benzene vs. manganese content Mn_3O_4. ($T_{\alpha=50\%}$) Temperature of 50% conversion. (*1*, *2*) Uncalcined and calcined (400°C) mechanical mixtures of components, respectively; (*3*, *4*) uncalcined and calcined (400°C) catalysts, respectively.

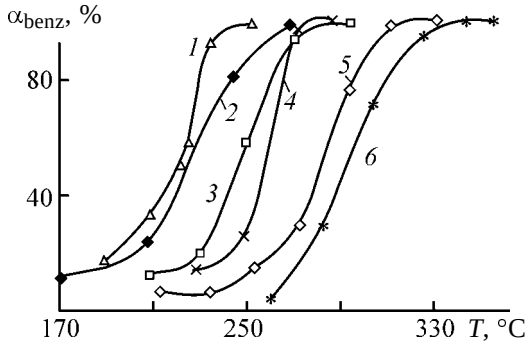

Fig. 5. Conversion of benzene, β_{enz}, vs. temperature *T* of the process, obtained on various catalysts. Catalyst: (*1*) sample with 40% Mn_3O_4, (*2*) GTT, (*3*) NTK-10-7f, (*4*) NTK-4, (*5*) NTK-10-2f, and (*6*) NKO-2-5.

a calcined mechanical mixture containing 40% Mn_3O_4 (S_{sp} = 53 $m^2 g^{-1}$), the main contribution to the surface development comes from pores with radii of 50–100 Å (60%) and 195–405 Å (25%); pore with radii of 100–195 Å account for 12% of the volume, and the volume of very fine pores (0–50 Å) is very small (about 3%). In the case of a finished catalyst (S_{sp} = 140 $m^2 g^{-1}$), the distribution pattern changes significantly: the share of fine pores (0–50 Å) increases dramatically (to 28%); the volume of coarse pores (395 Å) is small (7%); the volume of medium pores constitutes 28% (50–100 Å) and 38% (100–150 Å).

With increasing content of manganese compounds, the mechanical strength of calcined catalysts grows, falling within 20–40 MPa at compositions with 20–80% Mn_3O_4, which corresponds to the strength level of other cement-containing catalysts prepared by similar technology.

Figure 4 shows how the activity of manganese–aluminum–calcium catalysts in the test reaction of deep oxidation of benzene depends on the content of manganese. The activity of uncalcined mechanical mixtures of the starting components (curve *1*) grows with increasing content of manganese; that of calcined (400°C) mixtures of MnHC with talum (curve *2*) also grows with increasing content of manganese compounds, especially at Mn_3O_4 contents of up to 30–40%. In the case of finished catalysts [uncalcined (curve *3*) and catalysts calcined at 400°C (curve *4*)], a considerable rise in activity is also observed at compositions of up to 30–40% Mn_3O_4, and, therefore, raising further the content of the active component in the samples is inadvisable.

The maximum activity is observed for mechanical mixtures of MnHC with talum, calcined at 400°C, which is probably due to the formation (evidenced by XPA data) of a considerable amount of β-MnO_2, which exhibits the highest activity in deep oxidation reactions. However, the activity of mechanical mixtures is unstable and decreases in the course of time. For example, it was found in testing the initial mixture of MnHC with talum (containing 40% Mn_3O_4) that the conversion of benzene decreases from 97 to 58% after 1.5 h of tests at 210°C.

The activity of finished samples remains virtually unchanged after calcination at 400°C; in addition, it is somewhat lower than that of calcined mechanical mixtures, which is in all probability due to formation of solid solutions containing Mn compounds. However, the catalysts are stable in the course of time and, as shown by further experiments, possess high thermal resistance, which is more important as regards the catalyst operation.

To evaluate the thermal stability, a finished sample (75°C, 5 h) and the starting mechanical mixture with 40% Mn_3O_4 were subjected to superheating in the reaction medium at 650°C for 1.5 h, with the activity at the working temperatures determined after that. The tests demonstrated that superheating leads to a certain decrease in the activity of the mixed sample: the temperature of 50% conversion increases by 35°C; in the case of a mechanical mixture of the starting compounds, the decrease in activity is more pronounced; the temperature of 50% conversion increases by nearly 70°C. Thus, the binding of a part of Mn compounds into solid solutions, which occurs in the interaction of MnHC with talum, stabilizes the active component and thus exerts positive effect on the thermal stability of the catalysts. The data presented are in good agreement with changes in the dispersity of manganese

oxides MnO after high-temperature calcination in a reductive medium.

Figure 5 shows the dependence of the conversion of benzene on the process temperature, obtained on different catalysts: copper–zinc–chromium–aluminum NTK-4, copper–nickel–aluminocalcium NKO-2-5 with addition of palladium, copper–nickel–manganese–aluminocalcium GTT, copper–zinc–aluminocalcium NTK-10-2f, copper–zinc–manganese–aluminocalcium NTK-10-7f, and mixed manganese–aluminocalcium sample (40% Mn_3O_4). It can be seen from Fig. 5 that the last catalyst is one of the best in the given set. Its cost price is not too high, compared with that of the other catalysts, and its preparation technology is rather simple and virtually waste-free. Therefore, use of the catalysts developed in this study for purification of waste gases to remove organic impurities may prove effective and economically advantageous, which confirms that further investigations in this direction are promising.

CONCLUSIONS

(1) A combined study of the formation of catalysts obtained on the basis of the system constituted by manganese hydroxocarbonate and calcium aluminates by the method of chemical mixing revealed that the extent of interaction between the starting components to give precursors of the active phase (manganese–aluminum-containing solid solutions) is affected by the conditions of the mixing stage: temperature and time.

(2) A study of the structural, strength, and catalytic properties of samples with varied content of the active component led to a conclusion that raising the content of manganese to more than 30–40% Mn_3O_4 is inadvisable.

(3) It was found that partial binding of manganese compounds into solid solutions stabilizes the active component and has positive effect on the thermal resistance of the catalysts.

CATALYSIS

Fabrication of Manganese–Aluminum–Calcium Catalysts by "Hydrothermal Synthesis"

Received July 19, 2002

Abstract—X-ray phase and differential thermal analyses, IR spectroscopy, and temperature-programmed reduction method were applied to study the formation of manganese–aluminum–calcium catalysts prepared by "hydrothermal synthesis."

Cement-containing formulations find increasing use as catalysts for a number of chemical processes. In particular, a great number of catalysts based on the system comprising metal hydroxocarbonates (MHCs, where M = Cu, Zn, Ni, Co, Mg) and calcium aluminates are known [1].

Manganese–aluminium–calcium formulations showed high performance as catalysts of redox reactions and, in particular, afterburning processes. In this context, a necessity arose for developing an efficient method for preparing catalysts of this kind with widely varied properties.

Previously, we studied formation of catalysts prepared on the basis of the system comprising manganese hydroxocarbonate (MnHC) and calcium aluminates by the method of "chemical mixing" [2]. In this method, the interaction of starting components to give precursors of the active phase occurs in the stage of mixing of the starting substances with a liquid reagent, with the role of calcium aluminates mainly consisting in the formation of the active phase and their binding properties used to a lesser extent. Further experiments demonstrated that these catalysts can also be obtained by such an efficient and convenient process as hydrothermal synthesis (HTS), which includes forming of granules and their subsequent keeping in a humid air medium [humid air treatment (HAT)] and then in hot water in the stage of hydrothermal treatment (HTT). In this case, the interaction of the starting components to give precursors of the active state proceeds in a finished catalyst granule and is accompanied by strengthening of the granule through hydration of calcium aluminate components [1, 3]. This method assumes involvement of calcium aluminates both in the formation of the active phase and in the creation of a mechanically strong structure. The HTS technology makes it possible to combine these processes and to replace the labor-consuming stage of pelletizing by the more efficient forming.

The aim of this study was to analyze specific features of formation of catalysts prepared on the basis of the system comprising MnHC and calcium aluminates by the HTS technique and to examine the influence exerted by conditions of preparation of samples on their catalytic properties.

EXPERIMENTAL

As starting components for preparing samples served $MnCO_3 \cdot mMn(OH)_2 \cdot nH_2O$ [GOST (State Standard) 7205–77] and high-alumina cement of the talum[1] type ($CA : CA_2 = 0.26$), TU (Technical Specification) 5737-006-00 284 345–99. A mechanical mixture of MnHC and talum was mixed with water at a low l : s ratio (0.3 : 1); the resulting plastic mass was formed on a laboratory forming device into extrudates (d = 4 mm), which were subjected to humid air treatment and then to HTT: keeping in hot water at 90°C. The granules obtained were dried at 100°C and calcined at 400°C. In the course of experiments, the conditions of HAT and HTT were varied.

A composition with 40% Mn_3O_4 was chosen for the experiment, since the extent of interaction between MnHC and talum to give solid solutions containing manganese and aluminum was the highest at this composition [2].

[1] Talum is a mixture of calcium monoaluminate $CaO \cdot Al_2O_3$ and calcium dialuminate $CaO \cdot 2Al_2O_3$. Hereinafter the common designations of the chemistry of cements are used: A = Al_2O_3, C = CaO, H = H_2O.

1070-4272/03/7603-0422$25.00 © 2003 MAIK "Nauka/Interperiodica"

The procedures used to study the samples were described in [2].

To analyze the transformations occurring in a catalyst grain in relation to the time of its keeping in humid air at room temperature (20–25°C), an additional experiment was carried out in order to observe "in slow motion" the overall pattern of active phase formation in manganese–aluminum–calcium catalysts obtained using the technology in question.

An X-ray phase analysis (XPA) of the samples obtained demonstrated that, during the first 10 h of HAT, the amount of calcium monoaluminate decreases substantially (Fig. 1a, curve *1*) and a calcium carbonate phase appears in the form of calcite (curve *4*). The formation of $Al(OH)_3$ (gibbsite) was observed after 36 h of HAT (curve *5*). A pronounced decrease in the intensity of MnHC lines was observed after approximately 48 h of HAT (curve *3*); in the same time interval, consumption of CA_2 started (curve *2*) and the calcium hydroxocarbonatoaluminate (CCA) phase, $C_3A \cdot CaCO_3 \cdot 12H_2O$ (curve *6*), appeared. With the time of HAT increasing from 2 to 20 days, hydration of CA_2, decomposition of MnHC, and formation of $CaCO_3$ and $Al(OH)_3$ (in the form of gibbsite and bayerite) became more intensive; further keeping in humid air did not result in any significant changes in the content of these phases in the system. The reflections from calcium mono- and dialuminates completely disappeared after 42 days of HAT, with the minimum intensity of lines associated with residual MnHC, about 30% of the initial value, reached in the process.

It has already been noted previously [2, 4] that the decrease in the intensity of X-ray lines associated with MnHC and the appearance of reflections characteristic of $CaCO_3$ is due to partial extraction of carbonate ions from the MnHC lattice and their replacement by aluminate and hydroxide ions.

The involvement of OH^- ions in the exchange assumes that X-ray amorphous manganese compounds of the $MnO_x \cdot yH_2O$ type are formed in the system. In this case, introduction of manganese ions into the lattice of gibbsite formed in hydration of calcium aluminates is possible, with the X-ray diffraction characteristics of gibbsite changed. Indeed, an X-ray diffraction study of the samples revealed that the positions of the diffraction peaks of the forming gibbsite differ from the tabulated values. The maximum shift of the diffraction lines of gibbsite was observed for samples kept in humid air for 15–20 days and more. For example, a shift to d = 4.78 Å was observed for the peak with d = 4.82 Å.

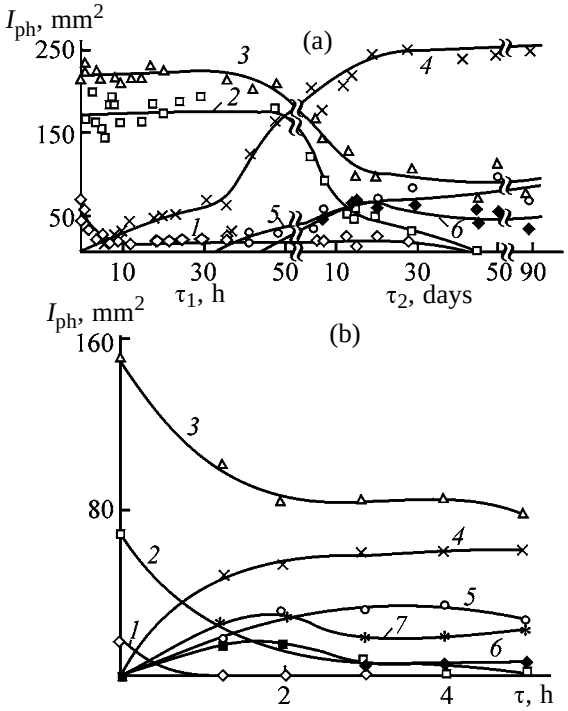

Fig. 1. Intensities of diffraction peaks from the forming and initial phases, I_{ph}, in catalyst granules vs. duration of HAT, τ_1 and τ_2, and (b) HTT, τ, stages. Phase: (*1*) CA, (*2*) CA_2, (*3*) MnHC, (*4*) calcite, (*5*) gibbsite + bayerite, (*6*) CCA, and (*7*) aragonite.

The involvement of aluminate and hydroxide ions in the exchange leads to formation of Mn–Al-containing solid solutions based on the lattices of manganese compounds, from which $MnO–Al_2O_3$ solid solutions based on the crystal lattice of MnO are formed in subsequent heating to 500°C in a hydrogen flow [2, 4]. An X-ray study of samples heated to 500°C in H_2 flow also revealed the presence of a defective MnO phase. In this case, the maximum deviation of the lattice constant of MnO, compared with the tabulated value of 4.445 Å, was observed for the samples kept in humid air for 20 days and more. For these samples, a_{0MnO} = 4.430 Å and the dispersity α_{MnO} = 145 Å, whereas for a mechanical mixture of the starting reagents the respective values are 4.437 and 175 Å. The results obtained indicate that calcined samples contain $MnO–Al_2O_3$ solid solutions based on the crystal lattice of MnO, and, consequently, Mn–Al-containing solid solutions based on MnHC, $MnO_x \cdot yH_2O$, and $Mn(OH)_2$ lattices are formed in uncalcined samples as precursors. The binding of a part of manganese compounds into solid solutions is also evidenced by the fact that the intensity of MnO reflections in reduced samples is about 40% of that in a mechanical mixture of the starting components.

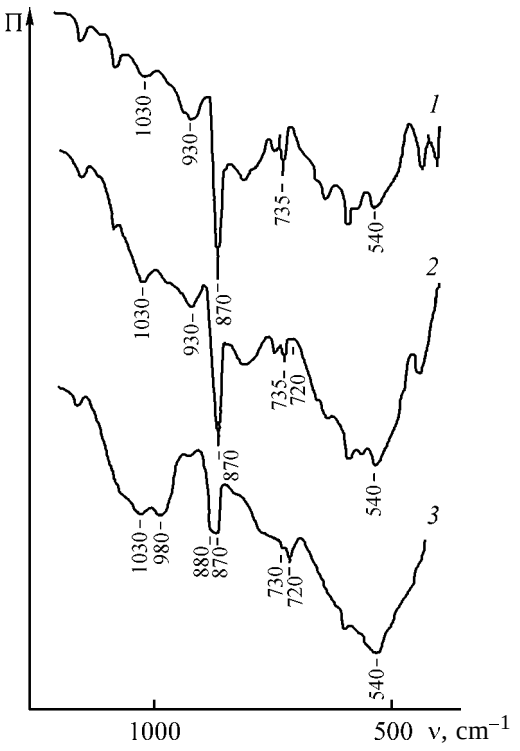

Fig. 2. IR spectra of samples subjected to HAT of varied duration without HTT. (∏) Transmission and (ν) wave number. Sample after forming with HAT for time (days): (*1*) 0, (*2*) 2, and (*3*) 20.

Thus, according to XPA data, chemical transformation occur in catalyst granules in the HAT stage at room temperature. The extent of these transformations grows with increasing time of treatment. However, the rate of the reaction is very slow, and, therefore, more than 20 days are necessary for the maximum content of the forming phases to be reached, which is unacceptable for commercial technology.

To accelerate the chemical reactions occurring in forming of catalysts by the HTS technique, an HTT stage is used. To study the transformations occurring in the catalyst granules in this stage, a formed and dried sample obtained without HAT was subjected to prolonged hydrothermal treatment at 90°C with sampling at certain intervals (Fig. 1b). According to XPA data, the rate of chemical transformations is high in this stage. Calcium monoaluminate was completely consumed in 1 h, and calcium dialuminate, in 4 h of HTT. The intensity of lines associated with residual MnHC after 3–5 h of treatment was 40–45% of the initial value. During the first hour of treatment, the formation of a considerable amount of gibbsite with shifted diffraction peaks (for instance, the peak with d = 4.82 Å was shifted to d = 4.79 Å) and a minor amount of bayerite was recorded. The content of these phases remained virtually unchanged during HTT for more than 3 h. An increase in the intensity of lines related to calcium carbonate was also observed during HTT for up to 3–4 h, with this compound formed as calcite and aragonite. Thus, virtually 100% extent of interaction is reached in the HTT stage in 3–4 h.

To reveal the influence exerted by preliminary HAT on the properties of granules in preparing manganese–aluminum–calcium catalysts, sample reduced in a hydrogen flow after HTT without HAT was compared with that subjected to preliminary HAT and then HTT and characterized by the same conversion of the starting reagents. It was found that for the latter sample the deviations of the lattice constants of the forming MnO are somewhat larger (4.430 Å against 4.434 Å), and the dispersity is higher (145 Å against 180 Å). For the sample with HAT, the intensity of MnO reflections is somewhat lower (190 mm^2 as compared to 240 mm^2 for a catalyst without HAT). The data obtained indicate that, for a sample subjected to preliminary HAT, the extent of interaction between the starting substances to give solid solutions containing manganese and aluminum ions is greater.

An attempt was made to intensify the HAT stage by raising the process temperature. For this purpose, a formed sample was kept in humid air at a temperature varied within 10–90°C for 5 h. Raising the HAT temperature accelerated the transformations occurring in this stage. This is indicated by the fact that, with increasing temperature, the intensity of reflections associated with calcite (the amount of aragonite formed was virtually temperature-independent) and $Al(OH)_3$ (gibbsite and bayerite) grows, and that of reflections associated with the starting compounds, MnHC and calcium aluminates, falls, with the maximum reaction rate reached at 75–90°C. At the same time, a study of samples subjected to HTT demonstrated that raising the temperature of preliminary HAT to above 50°C does not appreciably accelerate the interaction in the subsequent HTT stage. Thus, according to XPA data, it is advisable to perform the stage of HAT of catalyst granules at temperatures not exceeding 50°C.

The results of an IR study of the samples obtained are given in Fig. 2. Only the region in which the spectral changes are the most pronounced is shown. With increasing HAT duration (Fig. 2), the intensity of absorption bands at 870 and 730 cm^{-1}, characterizing the bending vibrations of CO_3^{2-} in MnHC, decreases. New absorption bands, associated with bending vibrations of carbonate groups in the forming calcium carbonate, appear at 880 and 720 cm^{-1}, and their

intensity grows. The intensity of absorption in the range of bending vibrations of hydroxide groups of the forming $Al(OH)_3$, and the profile of the absorption band becomes characteristic of bayerite, with peaks at 1030 and 980 cm^{-1} [5]. Analysis in the range of stretching vibrations of OH^- groups is hindered by pronounced broadening of the corresponding bands. The spectrally detected presence of $Al(OH)_3$ in the form of bayerite, rather than gibbsite, can apparently be accounted for by introduction of manganese ions, which leads to a shift of double layers in packages of the gibbsite structure [6], thus transforming this structure into that of bayerite. The maximum extent of the occurring transformation is achieved in approximately 20 days of HAT (Fig. 2, curve *3*).

The IR spectra of samples subjected after HAT to hydrothermal treatment show that, with increasing time of preliminary HAT, the intensity of the absorption bands at 870 and 730 cm^{-1} decreases and that of the absorption bands at 880 and 720 cm^{-1}, associated with bending vibrations of carbonate groups in, respectively, MnHC and $CaCO_3$, increases. A steady increase in intensity and change in the profile of the OH^- bending vibraiton bands at 1030 and 980 cm^{-1} is observed, which points to the appearance of a bayerite structure. In accordance with spectral data, the greatest extent of interaction in the HTT stage is reached after preliminary HAT for 2 days.

The spectra of samples subjected to only HAT at different temperatures show that, with increasing process temperature, the extent of the occurring transformations grows to reach a maximum at 75°C. For samples subjected to subsequent HTT, the most pronounced spectral changes, similar to those described above, are observed at temperatures of preliminary HAT of up to 30°C, and, therefore, raising the treatment temperature further is inadvisable.

Figure 3 shows the results of a differential thermogravimetric (DTG) analysis of the samples. The thermal effects were identified on the basis of published [2, 4, 7, 8] and XPA data. The DTG curves of catalysts kept for varied time in humid air (Fig. 3) show that, upon treatment of a mixture of MnHC and talum with water, the thermal effects of MnHC decomposition (385°C) and β-MnO_2 conversion into β-Mn_2O_3 (520, 540°C) are shifted to higher temperatures, compared with a mechanical mixture of the starting components, and their superposition is observed. This leads to the appearance of a strong effect peaked at 550°C (curve *2*) [2]. As the time of HAT becomes longer, the intensity of this effect decreases and it is first gradually shifted to the low-temperature region

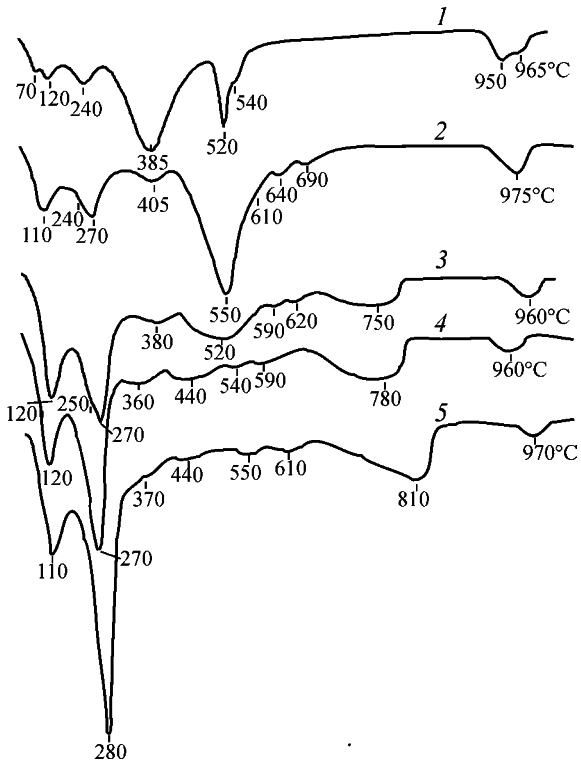

Fig. 3. DTG curves of samples subjected to HAT of varied duration without HTT. (*1*) Starting mechanical mixture of MnHC and talum; sample after forming with HAT for time (days): (*2*) 0, (*3*) 2, (*4*) 5, and (*5*) 20.

(510–520°C) and then, with the HAT duration increasing further (to 5 days), starts to split into two effects, those at 440–460 and 540–550°C. On the basis of a comparison with XPA data, these effects can be attributed to decomposition of MnHC modified with aluminum ions and to MnO_x conversion. In addition, the DTG curves show effects of decomposition of gibbsite (270–290°C) and calcium carbonate (720–810°C), whose intensity grows with increasing HAT duration; however, the profile of the DTG curves remains virtually unchanged after 2–5 days of treatment.

The DTG curves of the same samples subjected to HTT show that, at longer time of preliminary HAT, the effects associated with decomposition of gibbsite (290–300°C) and $CaCO_3$ (800–830°C) grow in intensity, and the profile of the effects in the range 400–650°C is gradually smoothed. These changes are mainly characteristic of catalysts kept in humid air medium for up to 2–5 days; further preliminary HAT does not lead to any significant changes in the DTG curves of the samples.

Raising the temperature of preliminary HAT to above 30°C does not cause any substantial changes,

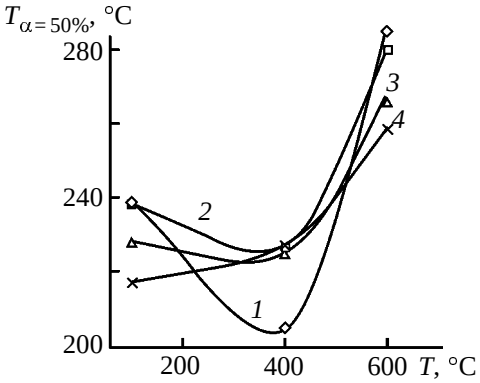

Fig. 4. Activity of samples prepared under various conditions vs. temperature *T* of calcination in air. ($T_{\alpha=50\%}$) Temperature of 50% conversion. Sample: (*1*) starting mixture of MnHC and talum, (*2*) no. 1 (after HTT without preliminary HAT), (*3*) no. 2 (2 days of HAT + HTT), and (*4*) no. 3 (>20 days of HAT after HTT).

either, in the profile of the DTG curves for samples subjected to HTT. Thus, the results of the differential thermogravimetric study confirm that it is advisable to perform preliminary HAT at temperatures not exceeding 30°C.

Comparison of a thermochromatogram of a catalyst after HTT without preliminary HAT and that subjected to prolonged HAT (>20 days) and then to HTT shows that, in the case of a sample without HAT, the intensity of the effect at 200–300°C, which corresponds to liberation of water in the course of gibbsite decomposition, is much lower, and that of effects at 350–450°C, related to liberation of water and CO_2 in decomposition of residual MnHC modified with aluminum ions, is much higher, indicating much higher conversion of the starting substances into the reaction products for the sample subjected to preliminary HAT. MnO formed in the course of catalyst reduction at temperatures of up to 750°C has the lattice constant close to the tabulated value (4.445 Å): 4.444 for a sample after HAT and 4.446 Å for a catalyst without HAT. For these catalysts, the intensities of diffraction peaks related to manganese oxide, I_{MnO}, are 350–370 mm^2, and the MnO dispersity α_{MnO} = 220–225 Å. For a mechanical mixture of MnHC with talum, reduced under similar conditions, I_{MnO} = 570 mm^2 and α_{MnO} = 600 Å. Thus, the dispersity of MnO in the samples obtained is more than 2 times higher than that of the starting mixture of MnHC with talum, and the intensity of diffraction peaks corresponding to MnO is much lower, which points to the formation of X-ray amorphous compounds of manganese. All this indicates a higher thermal stability of the given catalysts and, consequently, a positive influence of the transformations occurring in catalyst fabrication to give solid solutions.

We showed previously that the activity of manganese–aluminum–calcium catalysts in deep oxidation of benzene grows with increasing content of the active component, with the rise being the steepest at Mn_3O_4 concentrations of up to 30–40% [2].

Tests with the catalysts containing 40% Mn_3O_4, prepared by the HTS technique, show that the activity of uncalcined catalysts grows after prolonged preliminary keeping in humid air. The highest activity is observed for the samples kept in humid air for 20 days and more; in particular, for these samples the temperature of 50% conversion, $T_{\alpha=50\%}$, is 215–220°C. The lowest activity is exhibited by the samples after short HAT or without it, and also by a mechanical mixture of the starting components; for instance, for uncalcined samples $T_{\alpha=50\%}$ is 235–240°C.

Thus, the increase in the extent of reaction between MnHC and talum to give Mn–Al-containing solid solutions, favored by preliminary HAT of granules, has a positive effect on the activity of the catalysts obtained.

A distinctive feature of the catalysts under consideration is that their activity changes after calcination in air at various temperatures. Figure 4 shows the dependence of the activity on the calcination temperature for samples prepared under different conditions. In the case of a mechanical mixture of MnHC with talum, the dependence passes through a maximum at 400°C (curve *1*). For a sample without preliminary HAT this dependence also shows an extremum, but the decrease in the temperature of 50% conversion after calcination at 400°C is not so pronounced (curve *2*). A study of a catalyst subjected to preliminary HAT for 2 days and then to HTT demonstrated that its activity remains virtually unchanged after thermal treatment at 400°C (curve *3*). For a sample kept for more than 20 days in humid air and then subjected to HTT, the dependence of $T_{\alpha=50\%}$ on the calcination temperature is somewhat different: the activity decreases steadily with increasing temperature of thermal treatment (curve *4*).

A mechanical mixture of MnHC with talum exhibits the highest activity among the samples studied ($T_{\alpha=50\%}$ = 205°C), which is due to the formation of a large amount (according to XPA) of active β-MnO_2; however, the activity of the mixture decreases substantially in the course of time, probably because of the caking of β-MnO_2. Binding of a part of manganese compounds into solid solutions makes lower the

initial activity of the samples, compared with calcined mechanical mixture, but they are stable with time [2].

Among the uncalcined catalysts, the highest activity is observed for sample no. 3 subjected to prolonged (>20 days) treatment and characterized by the greatest extent of interaction between MnHC and talum: for this catalyst, $T_{\alpha=50\%}$ = 217°C. In addition, its activity decreases after calcination to a lesser extent, compared with other samples and, especially, mechanical mixture. For example, $T_{\alpha=50\%}$ = 285°C for the starting mixture of MnHC with talum, calcined at 600°C, and $T_{\alpha=50\%}$ = 259°C for the catalyst under consideration, i.e., this sample is not only more active, but also more thermally stable. These facts well correlate with data on MnO dispersity in samples reduced at high temperature.

Thus, the extent of interaction between MnHC and talum, which occurs in fabrication of manganese–aluminum–calcium catalysts, affects their activity and thermal stability. The increase in the extent of interaction to give defective structures, Mn–Al-containing solid solutions based on the lattices of MnHC, $Mn(OH)_2$, $MnO_x \cdot yH_2O$, and $Al(OH)_3$, favored by preliminary HAT of granules, leads to an increase in the activity and stability of catalysts.

The catalysts obtained show fairly high activity in deep oxidation, compared with other catalysts [2], which confirms that further investigations in this direction are promising.

CONCLUSIONS

(1) A comprehensive study of the formation of catalysts prepared on the basis of the system constituted by manganese hydroxocarbonate and calcium aluminates by the method of hydrothermal synthesis revealed that the extent of interaction between Mn hydroxocarbonate and talum to give Mn–Al-containing solid solutions based on the lattices of manganese hydroxocarbonate, $Mn(OH)_2$, $MnO_x \cdot yH_2O$, and aluminum hydroxide depends on the temperature and time of humid air and hydrothermal treatment.

(2) An increase in the extent of interaction between the starting components, favored by prolonged humid air treatment of granules, has positive effect on the catalytic properties of the catalysts obtained and, in particular, on their activity and thermal stability.

CATALYSIS

Chemical Purification of Ultrafine Cutting Diamonds

I. I. Obraztsova and A. N. Eremenko

Institute of Coal and Coal Fuel Chemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received June 13, 2002

Abstract—A procedure was developed for recovery and purification of ultrafine diamonds.

Superdispersed systems based on clusters or ultrafine diamonds (UFD) are actively studied today, because of theoretical interest and wide possibilities of their practical use.

Ultrafine diamonds are widely used in preparation of abrasive materials, tools, and pastes, in composite and electrochemical plating, in production of mechanical rubber goods, and as additives to diesel oils and lubricants. Diamonds show much promise in systems of magnetic recording, in superfine surface finishing, when the surface quality is a decisive factor, and in preparation of new cutting ceramic materials. At the same time, growth of diamond films and composites based on them is also urgent.

One of the main problems in chemical processing of coal is the low selectivity of catalysts, because coal contains compounds of various structures (C–C, C–N, C–S bonds, etc.), whose selective conversion occurs under different conditions. Therefore, development of versatile catalysts is hardly possible, and it seems necessary to search and study catalysts selective with respect to separate types of compounds. In this connection, it is interesting to study the reactivity of the C–C bonds using cluster diamonds as a model.

Explosion method is the main procedure for UFD synthesis; it is based on the detonation conversion of carbon-containing explosives with a negative oxygen balance [1, 2]. This process yields a carbon blend containing UFD (20–60%) and non-diamond impurities (micrographite, carbon black). The detonation blend has a developed and active surface (~400 $m^2 g^{-1}$) and exhibits specific adsorption and colloidal properties due to elevated reactivity of superdispersed carbon structures characterized by high density of defects. The explosion synthesis procedure is well developed, and several modes of its process are patented. However, relatively low efficiency of purification and recovery of diamonds from the carbon- and metal-containing reaction blend hinders the growth of the cluster diamond production.

The reactivity of diamonds and composition of impurities determine selection of the treatment and purification procedures. The aim of the process is the recovery of the target product with minimal losses, and relatively high chemical stability of the diamond phase allows this process to be performed fairly efficiently.

As seen from published data [3], in the first stage of the diamond recovery the catalyst and carbide phase are dissolved in acids or their mixtures [3]. In the second stage, the non-diamond carbon phases are selectively oxidized with various reagents. In the third stage, the compounds insoluble in water and acid solutions (except hydrofluoric acid) are removed if their content is greater than 1%. Then, the purified diamond crystals are washed with water and dried.

It should be noted that the separation of diamond from graphite, which can be performed by physical and chemical methods [4], is the most difficult stage of the process. In the chemical procedure, graphite is selectively oxidized to carbon oxides. In contrast to physical procedures, chemical treatment provides higher purification and, in some cases, smaller loss of the target product.

However, the main disadvantages of physical and chemical purification procedures are rather complex equipment, large losses of the diamond powder, and use of extremely aggressive compounds with release of environmentally hazardous components.

We developed chemical procedures for recovery and purification of UFDs from the carbon–diamond blend providing a high yield of the diamond phase with a high quality of the target product. These procedures can be performed without additional equipment under milder conditions as compared to the known methods.

1070-4272/03/7603-0428$25.00

EXPERIMENTAL

The diamond blend prepared by the explosion procedure is a specifically smelling viscous black mass.

In the oxidation stage, the diamond blend was washed, dried, and oxidized; then the resulting product was washed and dried.

First the blend sample was washed with distilled water to pH 7 and complete removal of the strange smells; fivefold washing was usually sufficient. The washing water was decanted and, after neutralization, transmitted into a sewage system.

The washed sample was filtered and centrifuged. Then it was dried at 200°C with intermittent stirring to the residual content of water of 5–7%. After drying, the resulting black mass could be readily broken in pieces. The yield of the dry carbon-containing blend was 15–20 wt % based on the initial reaction product.

This pretreatment removes a significant fraction of impurities from the blend and yields a pure friable product appropriate for subsequent treatment.

Then, the blend was treated with an oxidizing mixture consisting of HNO_3 (64–89 wt %) and H_2SO_4; the blend : oxidizing mixture weight ratio was 1 : (20–25). The oxidation was performed in the batch mode by addition of nitric acid in small portions after complete decomposition of the previous portion.

Addition of HNO_3 in small portions provides loosening of the blend and increases its volume and thus improves the UFD recovery.

Sulfuric acid was added only in the initial step to accelerate oxidation. No overheating of the reaction mixture was observed under the above operation conditions, and, thus, the temperature control of the reaction mixture can be eliminated.

As the reaction proceeds, the color of the reaction mixture changed from black to gray. The number of oxidation cycles and the amount of acids required for complete oxidation varied insignificantly. When the blend became gray, the reaction vessel was cooled. The total oxidation time was about 20 h.

The reaction product was washed with distilled water. The gray diamond phase after stirring was settled, and the solution containing acids was decanted and transferred into a sewage system after neutralization. This operation was performed several times up to neutral reaction (pH 7) of the washing solution.

Then, the diamond phase was separated from excess water by centrifuging and treated with acetone. The mixture was stirred and centrifuged; acetone was separated and used in washing of the other portions of the diamond blend. This procedure was repeated 2–3 times.

The resulting mass was dried in air at room temperature, ground in a porcelain mortar, and put into a vessel for storage.

The yield of the gray diamond blend was 40–50 wt % of the dry black mass. According to published data, the UFD yield obtained by the other procedures varies within 20–30%. As seen from XRD data, the average particle size in the UFD blend was 4–5 nm and the content of nonoxidized impurities in the final product was less than 0.1%, whereas in the previously reported procedures [5] the content of impurities reaches 1.1–5.7%.

To accelerate the recovery of the diamond phase, K_2SO_4, $K_2Cr_2O_7$, or MnO_2 was added into the reaction mixture, which loosens the blend, increases its volume, and thus improves the recovery of the UFD particles. These compounds accelerate the oxidation of the carbon blend by a factor of 2–3. The yield of the product increases to 60% based on the dry blend weight.

The experimental data on the oxidation of the diamond blend under various conditions are listed in the table. As seen, the resulting UFDs are characterized by elevated dispersity with a stable particle size.

Our procedure for recovery and purification of UFD phase from the diamond–carbon blend allows wide variation of the experimental conditions (temperature, pressure, medium, etc.) and thus provides control of the UFD properties. The surface of diamonds recovered by this procedure contains various functional groups: nitrate, keto, carbonate, sulfate, etc.

We found that, at thermal treatment of the diamond powder under an inert gas atmosphere at 400–800°C, nearly 1.7 mmol of CO_2 per gram UFD is liberated. The presence of various functional groups on the diamond surface suggests the possibility of its use as sorbent. We studied the UFD sorption power with respect to copper(II), cobalt(II), and nickel(II) sulfates. The sorption power was characterized by the amount of the salt sorbed from solution per gram of the diamond powder.

It was found that the UFD surface sorbed 0.15 mmol g^{-1} $CuSO_4$, liberating in solution 0.09 mmol g^{-1} of H^+ ions. In the case of $CoSO_4$, these parameters were 0.38 and 0.024 mmol g^{-1}. No sorption of $NiSO_4$ was observed.

* Concentrated acid.

It is known [6] that the storage of ultrafine products is a complex problem. Owing to excess Gibbs energy related to the large contribution of the surface component, the system of superdispersed particles tends to aggregate. The UFD powder prepared by our procedure is characterized by elevated dispersity and fairly stable particle size. Moreover, our UFD powder shows no tendency to graphitization in prolonged storage and successive use, and its quality meets the international standards (according to the data of Tajrinu Trading Co., Ltd., Japan). Our procedure for the recovery of ultrafine diamonds from the diamond–carbon blend is patented [7].

CONCLUSIONS

(1) A procedure is developed for purification and recovery of ultrafine diamonds under milder conditions without additional process equipment; the yield of the high-quality diamond phase is higher by a factor of 1.5–1.7 as compared to the known procedures.

(2) Addition into the reaction mixture of small amounts of various metal salts decreases the reaction time by a factor of 2–3 and increases the product yield to 60%.

(3) The resulting ultrafine diamonds exhibit the elevated dispersity and uniformity with a stable particle size; they show no tendency to graphitization in prolonged storage and use.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Flocculation of Kaolin Suspensions with Poly-1-vinyl-1,2,4-triazole, Its Quarternary Ammonium Salt, and Their Mixtures with Anionic Polyelectrolytes

V. A. Izvozchikova, O. G. Zakharova, G. A. Voskoboinik, and Yu. D. Semchikov

Research Institute of Chemistry, Lobachevsky State University, Nizhni Novgorod, Russia
Lobachevsky State University, Nizhni Novgorod, Russia

Received April 19, 2002

Abstract—Homo- and copolymers of 1-vinyl-1,2,4-triazole with acrylamide and quarternary salt of polyvinyltriazole were prepared. The flocculation power of these (co)polymers was studied using model kaolin suspensions.

The majority of natural and artificial suspensions consists of negatively charged particles, and, thus, positively charged polyelectrolytes are preferable for their flocculation. At present, such flocculants are predominantly prepared using polymers and copolymers of two main groups: ammonium and pyridinium.

The most available commercial flocculants are the Praestols (copolymers of acrylamide with sodium acrylate and with *N*,*N*'-trimethylammoniopropylacrylamide chloride, Akromidan (copolymer based on poly(methacroyloxyethyl)trimethylammonium methyl sulfate), and KF copolymer based on quarternary poly-2-methyl-5-vinylpyridine, developed at the Volgograd University.

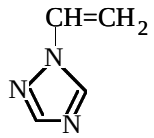
The comparative data on the flocculation power with respect to model and real systems showed that the Praestol, Akromidan, and KF domestic cationic flocculants are competitive products [1, 2].

Since the assortment of available cationic flocculants is very limited and their flocculation properties are similar, search for new flocculants of this type is urgent. It was found [3] that vinyltetrazole polymers are effective flocculants.

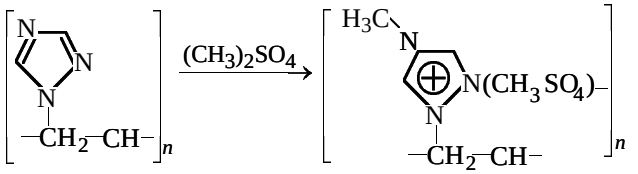
In this work, we studied the flocculation power with respect to model kaolin suspensions of homo- and copolymers of 1-vinyl-1,2,4-triazole (VT), its quarternary ammonium salts, and their mixtures with anionic polyelectrolytes.

EXPERIMENTAL

In our work we used of 1-vinyl-1,2,4-triazole with the following properties: bp 49°C (1 mm Hg); n_D^{20} 1.51, and d^{20} 1.0857.



The VT polymers and quarternary salts of poly-VT were prepared by the procedures given elsewhere [4]. Polymerization of VT to high conversions (80%, monitored gravimetrically) was performed in a 40% aqueous solution at 60°C under argon in the presence of the redox system [polyethylenepolyamine : $(NH_4)_2S_2O_8$ = 1 : 3]. The intrinsic viscosity [η] of the resulting polymer was 2.75 dl g^{-1} (distilled water, 25°C). Then, the quarternary salt was prepared.



For this purpose, dimethyl sulfate (2.6 g) and poly-VT (0.85 g) were mixed in DMSO (6.65 ml) and heated for 11 h at 60°C under argon. The resulting salt was washed with isopropyl alcohol and dried to constant weight in a vacuum desiccator. The polymer yield was 85%, and the degree of alkylation was 84% (elemental analysis). The copolymerization of VT with acrylamide (AA) was performed up to 95% conversion (VT content in copolymer ~80 wt %).

The flocculation power of the polymers was evaluated from the kinetic dependences of the suspension

1070-4272/03/7603-0431$25.00

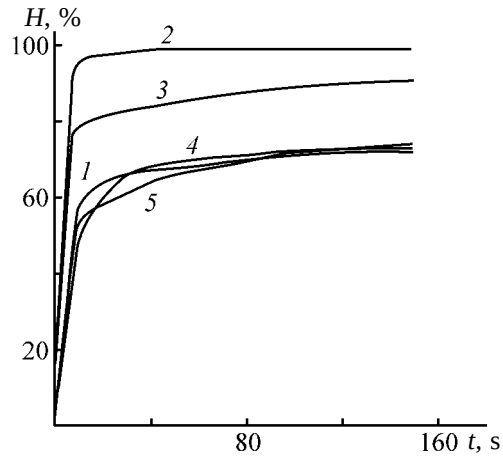


Fig. 1. Optical transmission H of 0.4 wt % aqueous kaolin suspensions as a function of time t; (co)polymer concentration 0.05 wt %. Flocculant: (*1*) none, (*2*) polyacrylamide, (*3*) polyvinyltraizole, (*4*) polyacrylamide–polyvinyltraizole mixture (1 : 1 weight ratio), and (*5*) copolymer of acrylamide with vinyltriazole (0.2 : 0.8 molar ratio).

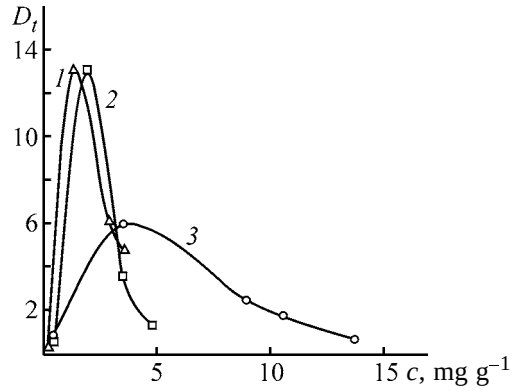

Fig. 2. Suspension clarification efficiency D_t as a function of the concentration of poly-VT c at various contents of kaolin. Kaolin content, wt %: (*1*) 1.0, (*2*) 0.8, and (*3*) 0.4.

clarification efficiency D_t and optical transmission H (%):

$$D_t = \tau_0/\tau - 1, \quad \tau = 2.3A/l,$$

where τ_0 is the supernatant turbidity in the absence of the flocculant; τ, supernatant turbidity after the flocculant addition; l, cell thickness, and A, optical density.

The optimal flocculant concentration (mg flocculant per gram kaolin) corresponding to maximal D_t was determined.

The kaolin concentration was varied in the 0.1–1.0 wt % range. The kaolin weighed portion was placed in water (20 ml), and after 30 min the polymer solution was added; the suspension volume was brought to 100 ml, it was stirred for 2 min and stored for 1 h. Then, the optical density of the supernatant was measured on a KF-77 photocolorimeter (λ 490 nm). When the clarification kinetics was studied, the measurements of the optical transmission were started immediately after the stirring.

The kinetic dependences of the optical transmission of suspensions in the presence of various polymers are shown in Fig. 1. As seen, polyacrylamide exhibits the greatest flocculation power, the flocculation power of poly-VT is significantly lower, and the copolymers of VT and AA and the mixtures of poly-AA and poly-VT exhibit virtually no flocculation power. This is probably due to the fact that, as compared to homopolymers, the VT-AA copolymers have a lower thermodynamic affinity for water, and thus more compact conformations are typical for the copolymer macromolecules. This assumption agrees with the intrinsic viscosities of poly-VT and VT-AA copolymers, which are 2.75 and 0.76 dl g^{-1} (water solvent, 25°C). The lower intrinsic viscosity of the copolymer compared to the homopolymer is probably due to lower molecular weight and compression of macromolecular aggregates with decreasing thermodynamic affinity of copolymers.

In any case, the decrease in the intrinsic viscosity of the copolymer is directly related to the hydrodynamic globule radius and correspondingly to its flocculation power.

Then, the flocculation power of quarternary poly-VT (poly-1-vinyl-4-methyl-1,2,4-traizolium methyl sulfate) was determined. The dependences of the clarification efficiency of various flocculants in suspensions with various kaolin concentrations are shown in Fig. 2. As seen, the best flocculation is observed for suspensions with the kaolin concentration of 0.8–1.0 wt %. The dependences of the clarification efficiency on the polymer concentration pass through a maximum, typical for flocculants.

It is known that, in some cases, the flocculation efficiency can be improved by adding mixtures of cationic and anionic polyelectrolytes [5]. In our tests, we used copolymer of AA with sodium acrylate (0.75 : 0.25 molar ratio); the kinematic viscosity of 0.5% solution was 394 cSt [6]. The required suspensions were prepared by the procedure given above; the concentration of polyelectrolytes in all the cases was 0.001%. As seen from Fig. 3, in the case of fairly concentrated solutions (0.4–1.0 wt % kaolin content) the clarification efficiency decreases with polyelectrolyte addition, but it increases in the case of dilute low-turbid dispersions (<0.4 wt % kaolin content).

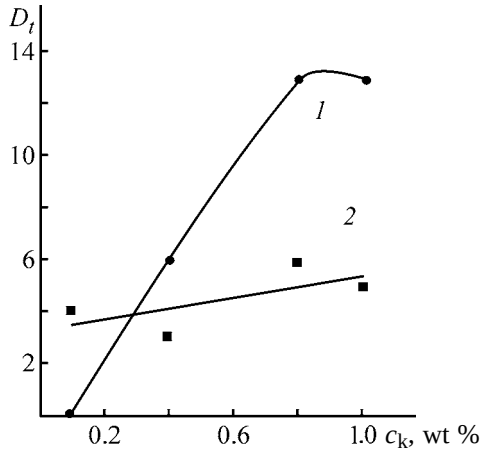

Fig. 3. Suspension clarification efficiency D_t as a function of the kaolin content c_k. Flocculant, mg g^{-1}: (*1*) poly-VT salt, 1–4, and (*2*) mixture of poly-VT with anionic polyelectrolyte, 0.1–1.0.

As known, the dependence of the flocculation efficiency on the polymer molecular weight should be considered to evaluate the feasibility of the flocculants prepared. For example, the intrinsic viscosity of such effective flocculants as KF and Praestol (650 and 655 brands) varies within 4.02–6.89 dl g^{-1} [2], which is greater than that of the polymer studied in this work by a factor of 4–5. The Praestol molecular weight is $(2.62–5.13) \times 10^6$. It was found [7] that the highest performance of the nitrogen-containing flocculants based on poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate is observed for the samples with the molecular weight of 3×10^6. At the same time, the clarification efficiency with respect to kaolin suspensions of the samples with the molecular weight $\bar{M}_\eta \leq 2 \times 10^6$ did not exceed that of the agents studied in this work.

CONCLUSION

The flocculation powers of homo- and copolymers of 1-vinyl-1,2,4-triazole with acrylamide and of quaternary ammonium salt of polyvinyltraizole were compared. The highest flocculation power was found for polyvinyltriazolium dimethyl sulfate, whose performance with respect to dilute suspensions (less than 0.4 wt % kaolin content) can be improved by addition of anionic polyelectrolyte (copolymer of acrylamide with sodium acrylate).

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Influence of Surfactants on the State of Starch Hydrogels under High Shear Stresses

A. A. Yusova, I. M. Lipatova, and A. P. Moryganov

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received November 18, 2002

Abstract—Specific influence of high shear loads on starch hydrogels containing oxyethylene-based surfactants was studied. It was found that a number of oxyethylated fatty alcohols can produce a steady thickening effect on starch hydrogels under high-rate shear strains owing to mechanochemically initiated complexing with starch amylose.

Starch hydrogels (pastes) are widely used in various industries. They are made technologically suitable by heat treatment with chemical cleaving agents aimed at breaking down their primary structure formed by swollen starch grains. One way to significantly reduce the process time and the heat consumed in starch cleavage is mechanical treatment of paste in a rotary pulse flow apparatus (RPA) [1]. For technological purposes, in particular, for improving the film-forming and wetting powers, starch hydrogels are often added with surfactants. In [2], we studied how surfactants affect the efficiency of the mechanical cleavage of starch hygrogels. Studies of the properties of mechanically (using RPA) produced starch hydrogels as influenced by various surfactants revealed an interesting phenomenon which has not been previously described in the literature: Oxyethylated fatty alcohols can cause steady thickening of starch hydrogels when exposed to strong mechanical loads. In view of the fact that this phenomenon can be of not only theoretical but also practical interest, it is reasonable to study in more detail the influence of high shear loads on starch hydrogels containing oxyethylene-based surfactants.

EXPERIMENTAL

Our study was concerned with corn starch [GOST (State Standard) 7697–82]. Starch hydrogels intended for subsequent mechanical treatment were prepared by cooking a starch suspension on a water bath at 90°C for 15 min.

Sonication was performed in a UZDN-2T disintegrator at the frequency F = 22 kHz. The treatment time was 4 min, and treatment temperature, 80°C. The volume density of the acoustic energy was estimated calorimetrically at 1.34 W cm^{-3}.

Mechanical treatment was carried out on a laboratory RPA [3]. The rotor rotation rate was varied from 1000 to 5000 rpm. The treatment time was 4–30 s, and temperature, 80°C.

The relative viscosity of the hydrogels was measured with a VPZh-2 capillary viscometer according to GOST (State Standard) 33–36 at 80°C.

Rheological characteristics of starch hydrogels were measured on a Rheotest-2 rotary viscometer with a coaxial-cylinder working unit at a rate gradient within 1.5–1312 s^{-1} at 30°C.

The surface tension of starch hydrogel at the air interface was measured with a Rebinder's instrument [4] at 80°C.

The surfactants studied in this work were all oxyethylated, primarily fatty, alcohols with the general formula $C_nH_{2n+1}O(C_2H_4O)_mH$ (see table) [5]. Sample nos. 6 and 8 were oxyethylated alkylphenols with the general formula $C_nH_{2n+1}C_6H_4O(C_2H_4O)_mH$. The surfactant concentrations were varied within 0–0.01 M.

Figure 1 shows how the viscosity of starch hydrogels, mechanically treated in an RPA, varies with the concentration of the surfactant added before the treatment (curves *3–5*). It is seen that, with increasing concentration of the surfactant added before the treatment from 0 to 3×10^{-3} M, the viscosity of the starch hydrogels tends to substantially increase. Further increase in the concentration of the added surfactant tends to somewhat decrease the viscosity. Curve *2* in Fig. 1

shows how the viscosity of starch hydrogel varies with the concentration of the surfactant added after the treatment. There is no significant thickening in this case. Thus, starch hydrogels thicken upon introducing the surfactant only when exposed to strong mechanical loads. In an RPA, the liquid material is exposed to a combined effect of high shear stresses and ultrasonic cavitation. To find out which of these factors plays the deciding role in the thickening effect, we exposed the starch hydrogels containing surfactants to sonication not complicated by shear loads. The sonication conditions were such that the integrated ultrasonic energy transferred to the unit mass of the gel was identical to that in the RPA. The acoustic power for calculations was determined by chemical dosimetry. Curve *1* in Fig. 1 shows how

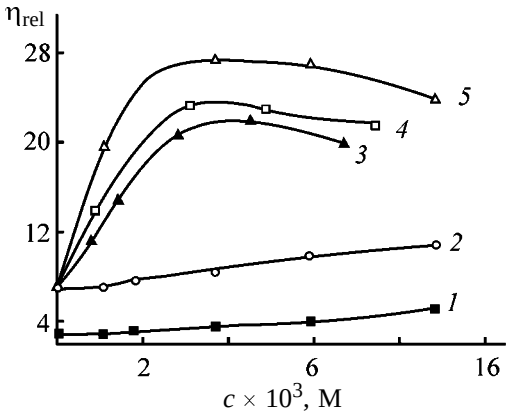

Fig. 1. Relative viscosity η_{rel} of starch gels (3 wt %) as a function of the surfactant concentration c. Mechanical treatment of starch gels: (*1*) in a UZDN-2T disintegrator, (*2–5*) in an RPA (n = 3000 rpm, τ = 4 s); (*1, 3–5*) joint and (*2*) separate treatment. Sample nos.: (*1–3*) 2, (*4*) 5, and (*5*) 4.

the viscosity of starch paste sonicated in the presence of the added surfactant varies with its concentration. The run of this curve is similar to that for the starch hydrogels mechanically treated in an RPA with subsequent introduction of surfactant additives (curve *2*). Sonication in the presence of surfactants did not cause starch hydrogels to thicken. Similar curves were obtained for the other agents studied in this work. This means that the deciding role in thickening of starch hydrogels in the presence of surfactants studied is played by high-rate shear strains rather than by ultrasonic cavitation.

Another issue to be clarified before making any assumptions concerning the thickening mechanism was the possibility/impossibility of such a thickening in aqueous gel-like materials based on other polysaccharides. To clarify this issue, we subjected Na-CMC hydrogels and sodium alginate solution to mechanical treatment in an RPA in the presence of surfactant in various concentrations. Such a treatment did not increase the viscosity of the studied polysaccharides relative to those treated without surfactant. Thus, it seems likely that only starch is able of substantial thickening when mechanically treated in an RPA in the presence of a number of surfactants. This suggests that the viscosity of starch hydrogels increases owing to complexing between starch amylose and surfactant molecules under high shear stresses.

It is known [6] that amylose is capable of forming nonstoichiometric compounds with alcohols and some hydrocarbons. The X-ray diffraction patters obtained by Zavadskii *et al.* [7] proved formation of such complexes with certain surfactants at elevated temperatures under static conditions. The agents utilized in this work do not cause any marked changes in

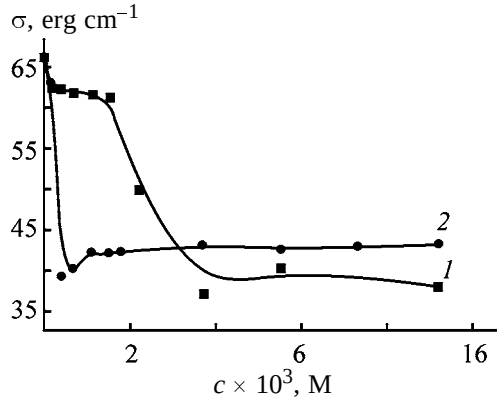

Fig. 2. Surface tension isotherms σ for the starch gel (3 wt %)–surfactant system (sample no. 2) in the case of (*1*) joint and (*2*) separate mechanical treatment in an RPA. n = 3000 rpm, τ = 4 s; the same for Fig. 6. (*c*) Surfactant concentration.

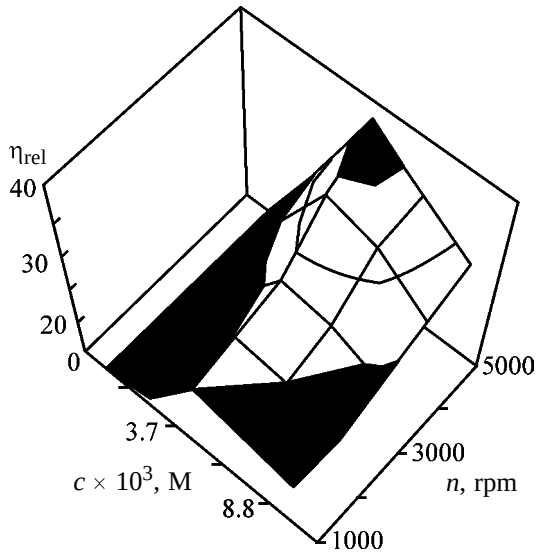

Fig. 3. Relative viscosity η_{rel} of starch hydrogels (3 wt %) vs. the concentration c of the surfactant additive (sample no. 2) and vs. the rate n of treatment in an RPA. Time of treatment in an RPA τ = 4 s.

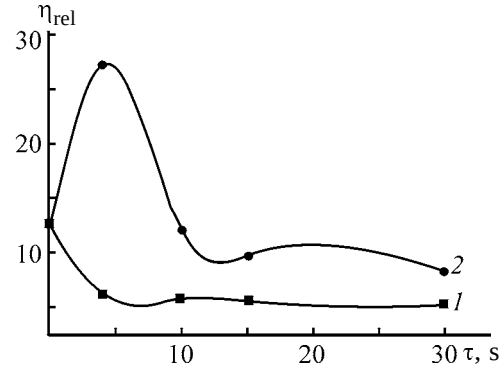

Fig. 4. Relative viscosity η_{rel} of the gel (3 wt %)–surfactant system (sample no. 2) as a function of the time τ of mechanical treatment in an RPA. Surfactant concentration 1.8×10^{-3} M, n = 3000 rpm.

starch hydrogels indicative of formation of amylose–surfactant complexes both under ordinary conditions and at elevated temperatures. Intensive mechanical treatment and, above all, high-rate shear strains seem to be responsible for conformational changes of the helical amylose molecules. At the same time, a combination of high shear loads and ultrasonic cavitation causes breakdown of the micelles and degradation of the surfactant molecules [8]. All this favors formation of complexes between highly mobile surfactant molecule and unfolded amylose macromolecules. This assumption is supported by the surface tension isotherms obtained for the 3% starch hydrogels added with the surfactants either before (Fig. 2, curve *1*) or after (Fig. 2, curve *2*) treatment in an RPA. It is seen that, in the latter case, the isotherm exhibits an ordinary pattern: Even insignificant amounts of the added surfactant tend to substantially decrease the surface tension. In the case of treatment of starch added with a surfactant, the surface tension did not decrease at the surfactant concentration of up to 2.0×10^{-3} M. Similar surface tension isotherms were obtained for the other surfactant samples studied in this work (see table, sample nos. 1–5). The concentrations of the additives at which the isotherms exhibit the ordinary pattern varied within $(1.5–2.5) \times 10^{-3}$ M. Such a "lag" in the onset of decrease in the surface tension with increasing surfactant concentration suggests that the surfactant molecules are bound by the amylose macromolecules. The isotherms for sample nos. 6–10 exhibit an ordinary pattern. Evidently, at the concentration corresponding to the onset of a sharp decline of the surface tension, amylose, occurring in the hydrogel in the free form, exhibits the most pronounced complexing power.

The degree of thickening of starch hydrogels with oxyethylated alcohols is determined both by the concentration of the additive and the intensity of mechanical treatment, i.e., by the shear rate $\dot{\gamma}$. Both dependences have extrema. The 3D diagram in Fig. 3 illustrates the combined effect of these factors. When both c_{add} and $\dot{\gamma}$ take extremal values, the viscosity can increase by several orders of magnitude.

Figure 4 shows how the viscosities of the mechanically treated 3 wt % starch hydrogels vary with the time of treatment in an RPA when the surfactant is added before (curve *2*) and after (curve *1*) treatment. The viscosity of the hydrogels mechanically treated in the presence of surfactants passes through a maximum at the treatment time of 4 s. Further increase of the time of mechanical treatment causes the viscosity to decrease, i.e., the forming complexes seem to break down.

It was of interest to elucidate whether the increase in the viscosity of starch pastes is related to increase in their structurization, which is manifested in enhancement of the viscosity anomaly. The degree of deviation of the rheological behavior of liquid systems from that of Newtonian fluids can be judged from the position of the flow curves, which are, essentially, the logarithmic dependences of the dynamic viscosity on the shear stress. Figure 5 presents the flow curves for the 6% starch pastes mechanically treated in an RPA in the presence of the surfactant in various concentrations. The viscosity tends to grow with increasing additive concentration, but the slope of the curve does not change. This means that the viscosity increases owing to growing asymmetry of the structural elements, rather than to the structural component, i.e., to strengthening of the fluctuation network of the gel. For example, in the ordinary state, the helical amylose macromolecules have a loose coil conformation [9]. Under mechanical treatment, they unfold in the shear field and remain unfolded owing to complexing with oxyethylated alcohols, which is specifically responsible for a steady viscosity increase.

Thus, thickening of starch hydrogels when treated in an RPA in the presence of oxyethylated alcohols under high-rate shear strains is due to complexing with amylose initiated by this treatment and ultrasonic cavitation. It was of interest to correlate the structure of the surfactant with its capability to cause thickening of starch hydrogels when treated in an RPA.

The table presents the degrees of oxyethylation *m* for the studied surfactants, as well as the lengths of the alcohol residues characterized by the number of carbon atoms *n* in the alkyl radical of the alcohol. Also, the table lists the hydrophilic-lipophilic balances (HLBs) of the agents utilized, as well as the degrees of thickening. The latter are, essentially, the ratios of the viscosities of starch hydrogel treated in an RPA in the presence and absence of surfactant, respectively. Clearly, there is no correlation between the above-listed characteristics and the degree of thickening. However, there is a certain relationship between the decrease in the thickening power of the surfactant and increase in its molecular weight (Fig. 6). Sample nos. 6 and 8 virtually do not cause the viscosity to increase, and sample nos. 7, 9, and 10 cause the viscosity to decrease, i.e., behave as conventional noncomplexing surfactants.

Thus, we showed the possibility of widely varying the viscosity of the mechanically cleaved starch hydrogels without affecting the starch concentration. This can be utilized, e.g., in mechanical preparation of

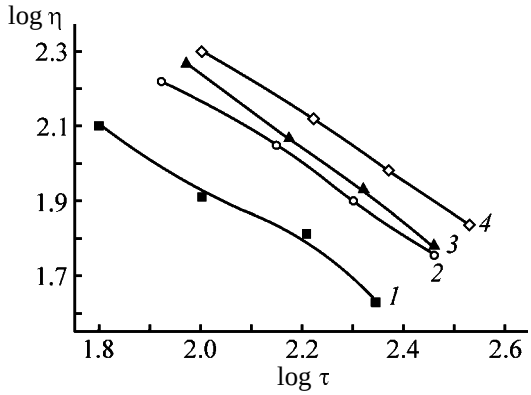

Fig. 5. Flow curves $\log\eta$–$\log\tau$ of the jointly mechanically treated starch (6 wt %)–surfactant system (sample no. 2). Surfactant concentration, M: (*1*) 0, (*2*) 1.1, (*3*) 2.2, and (*4*) 4.4.

starch size with easily controllable viscosity. By varying the size viscosity without affecting the starch content and the mechanical treatment conditions, in accordance with the thread density, it will be possible to easily optimize the size distribution over the thread cross section.

CONCLUSIONS

(1) Certain surfactants from the series of oxyethylated fatty alcohols can exert a steady thickening effect on starch hydrogels under high-rate shear strains realized in rotary pulse apparatuses. The plots of the degree of thickening vs. the surfactant concentration and the rate gradient have extrema.

(2) The thickening effect of surfactants is due to the high-rate shear-initiated complexing between the starch amylose and surfactant molecules.

(3) The capability of oxyethylated fatty alcohols for mechanochemically initiated complexing with amylose tends to weaken with increasing molecular weight of the surfactant.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Properties of Photosensitive Complex Perchlorates of *d* Metals with 3(5)-Hydrazino-4-amino-1,2,4-triazole as Ligand

I. A. Ugryumov, M. A. Ilyushin, I. V. Tselinskii, and A. S. Kozlov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 13, 2002

Abstract—A number of complex perchlorates based on 3(5)-hydrazino-4-amino-1,2,4-triazole were synthesized. The physicochemical properties and the sensitivity of these complexes to laser monopulse were studied, as well as their photosensitivity as influenced by the metal cation.

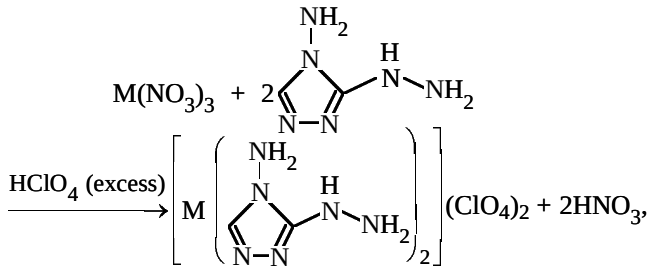
Over 70% of the Russia's mineral raw materials is extracted now using explosives. Increasing the efficiency and safety of blast-hole drilling activities is one of the high-priority lines of development of mining and oil and gas industries in the XXI century.

Optical priming charges (OPCs) find ever widening application in various branches of science [1, 2]. In view of the fact that detonation excitation in charges of photosensitive explosives is due to absorption of the laser pulse energy, OPCs are favorably distinguished by safer and more reliable performance from the presently used conventional priming charges.

In the search for new photosensitive energetic compounds suitable for OPC applications among the series of *d*-element complexes and with the aim to elucidate the influence exerted by the central ion on the sensitivity of the metal complex to laser monopulse, we synthesized and studied complex perchlorates of Cu(II), Co(II), Ni(II), and Cd(II) with 3(5)-hydrazino-4-amino-1,2,4-triazole (HATr) as ligand. The choice of the latter was dictated by a high sensitivity to laser monopulse exhibited by di(3(5)-hydrazino-4-amino-1,2,4-triazole)copper(II) perchlorate (**I**) [3, 4].

EXPERIMENTAL

The complexes were synthesized by the general scheme



where M = Cu^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}.

The reactions were run in an excess of perchloric acid at room temperature.

To a 0.002 M solution of HATr in 10 ml of 2-propanol acidified with 5 ml of $HClO_4$ (57%), a 0.01 M solution of appropriate metal nitrate in 10 ml of 2-propanol was added. The resulting mixture was stirred for 1 h at room temperature. The precipitate that formed was filtered off, washed with water and 2-propanol, and dried in a vacuum desiccator at 50°C.

The IR spectra (films or Nujol mulls) were recorded on a Perkin–Elmer M-457 spectrometer.

The thermograms were obtained with an MOM derivatograph (Hungary) (20–500°C temperature range, heating rate 5 deg min^{-1}).

The sensitivity to laser monopulse was studied on a laser setup with the following parameters: λ = 1.06 μm, τ_{pulse} = 30 ns, and d_{beam} = 0.48 mm. The samples were pressed into copper capsules, 5 mm in diameter and 2 mm high, under the pressure of 400 kg cm^{-2}.

The absorption bands in the IR spectra of the complexes in the region of the stretching vibrations of the triazole ring (1560, 1320 cm^{-1}) are shifted by 15–30 cm^{-1} relative to those of the free ligand. The absorption bands corresponding to the stretching and bending vibrations of the $–NH_2$ groups did not change noticeably on complexing (3320, 1650–1670 cm^{-1}). Also, a strong absorption band of the ClO_4^- ion was recorded at 1100–1110 cm^{-1}. The fact that this band is not split suggests that the ClO_4^- ion occurs in the outer sphere of the complex and takes no part in coordination.

Since elemental analysis confirmed the fact that, in all cases, we obtained complexes containing two inner-sphere ligands, the coordination number M being equal to 4(6), and that the perchlorate ion took no part in coordination, it can be suggested that these compounds contain a bidentate ligand. The invariant position of the absorption bands of the exocyclic $–NH_2$ groups and a blue shift of the bands of the triazole ring relative to the free ligand suggest that the ligand is coordinated via the nitrogen atoms in the heterocyclic. The presence of a substituent at the heterocycle nitrogen atom N^3 and the assumed bidentate nature of this ligand suggest, most probably, coordination via the N^1 and N^2 atoms in the heterocycle, which is common for such complex salts of triazole [5].

A study of thermal decomposition of the resulting salts under nonisothermal conditions at the heating rate of 5 deg min^{-1} revealed a fairly high thermal stability of the products with the onset temperature of intensive decomposition T_{OID} above 230°C (Table 1).

Compounds **II**–**IV** decomposes in three stages. In the first stage, at 230, 250, and 290°C, respectively, they exhibit exothermic peaks with the mass loss corresponding to decomposition of one ligand and one perchlorate ion (45.2, 43.8, and 40.8%, respectively), which is, evidently, due to oxidation of the heterocycle with the outer-sphere cation. The second stage also involves exothermic effects with T_{OID} of 285, 335, and 350°C, respectively, corresponding to decomposition of the second ligand and of the remaining pechlorate ion. At 380–390°C, the residue decomposes into the corresponding metal oxide.

Thermal decomposition of **I** involves one stage, due, evidently, to a higher catalytic activity of copper(II) cation compared to cobalt(II), nickel(II), and cadmium(II) cations, which is responsible for more intensive oxidation in thermal decomposition of this compound.

The complex salts prepared in this work were tested for sensitivity to laser monopulse; the results are presented in Table 2. Here, E_{cr} is the minimal energy required for initiating detonation of a complex.

The results of the tests performed in this work suggest that compounds **I**–**IV** are energetic photosensitive substances. Their sensitivity to laser monopulse is governed by the oxidative power of the metal ion expressed as the sum of the ionization potentials $I_1 + I_2$ (Table 2). The larger this sum, the higher the sensitivity of the compound to laser radiation: Cu > Cd > Ni > Co.

Koroban *et al.* [6] elucidated the role played by the metal cation in decomposition of complex *d*-metal perchlorates based on hydrazine derivatives. That study revealed the predominant inner-sphere oxidation of the ligand by the anion, with the metal cation participating in the initial stages. The data reported in [6]

Table 2. Laser initiation of the detonation of the complexes synthesized

Complex	E_{cr}, J	Sum of the ionization potentials of the metal cation $I_1 + I_2$, eV
$[Cu(HATr)_2](ClO_4)_2$	1.1×10^{-5}	28.02
$[Cd(HATr)_2](ClO_4)_2$	5.03×10^{-4}	25.90
$[Ni(HATr)_2](ClO_4)_2$	5.75×10^{-4}	25.78
$[Co(HATr)_2](ClO_4)_2$	1.36×10^{-3}	24.92

and in the present study suggest the following oxidation mechanism for the studied complexes in the initial stages:

$$2ClO_4^- + M^{2+} \rightarrow ClO_4^\bullet + M^+ + ClO_4^-, \quad (2)$$

$$ClO_4^- + M^+ \rightarrow ClO_4^\bullet + M^0. \quad (3)$$

A two-stage reaction between the metal cation and perchlorate anion yields a highly active perchlorate radical participating in the subsequent oxidation of the ligand.

CONCLUSIONS

(1) New energetic photosensitive compounds were synthesized. The role played by the metal cations in these complex salts under laser initiation was elucidated.

(2) The compounds synthesized are suitable for application in commercial optical priming charges.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Structure of Nanocomposites in the Aromatic Ester Dendrimer–SiO_2 System

Abstract—The possibility for preparing an organic–inorganic nanohybrid without chemical bonds between its components by the sol–gel procedure was studied.

Nanocomposites are intensively studied in modern materials science [1]. These studies gave rise to fundamentally new materials with peculiar optical, nonlinear optical, ion-conductive, and other properties [2–4].

Among nanocomposites known to date, we chose organic–inorganic hybrids prepared by the sol–gel method, which is one of the simplest, environmentally cleanest, and most convenient procedures [5]. To a first approximation, this method involves (in the case of formation of SiO_2 matrix) hydrolysis of tetraalkoxysilane with subsequent polycondensation of the liberated silanols to form a three-dimensional network incorporating the components added in advance. Nanocomposites are formed owing to various interfacial interactions between the organic (i.e., polymers) and inorganic (the three-dimensional network or its fragments) components. The nanocomposites in which the organic and inorganic components are chemically bound are characterized by the best mechanical properties and highest heat resistance. Preparation of these systems requires modification of the organic component with, e.g., commercially available derivatives of tetraalkoxysilanes: (3-glycidoxypropyl)trimethoxysilane [6], (3-aminopropyl)triethoxysilane [7], and 3-(triethoxysilyl)propyl isocyanate [8].

The trialkoxysilane derivatives are cohydrolyzed with tetraethoxysilane, which provides uniform distribution of the organic component chemically bonded with the inorganic matrix. Nanohybrids can be also formed without special binders. In this case, the active functional groups of the organic component (OH or NH_2) polycondense with silanol liberated in the hydrolysis of tetraalkoxysilanes to form chemical bonds between the components of the system [9, 10].

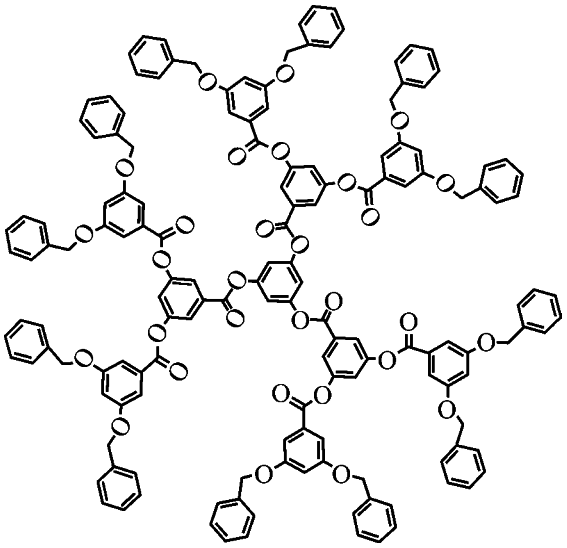
However, there are nanohybrids with the microstructure formed exclusively by van der Waals and hydrophilic–hydrophobic interactions or hydrogen bonds [11]. To our knowledge, organic–inorganic hybrids with the microstructure determined mainly by physical interactions of the components have not been prepared previously by the sol–gel procedure. This is due to the fact that the organic components of these systems should be sufficiently hydrophobic and should not contain active functional groups, whereas polar solvents such as alcohols and water are necessarily used in modern sol–gel organic synthesis [2]. This confines the range of organic components introduced into the SiO_2 matrix to strongly polar structures soluble in aqueous solutions.

The systematic studies of sol–gel synthesis of monolithic silica gel [12–14] show that this process can be performed in low-polar nonaqueous systems. This prevents uncontrolled phase separation (introduction of a lyophobic organic component into the lyophilic system) and formation of a nonuniform material in the first steps of the sol–gel process. In this work we studied features of formation of organic–inorganic hybrids with the microstructure mainly determined by van der Waals and hydrophobic–hydrophilic interactions of the organic an inorganic components.

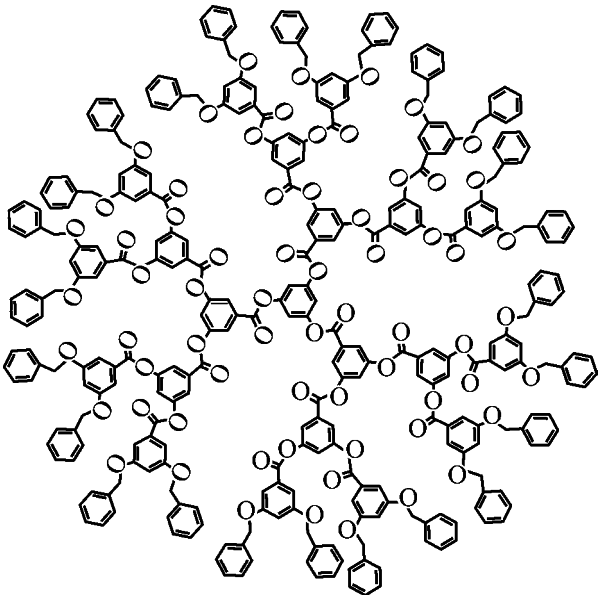
EXPERIMENTAL

The organic component of the composite was an ester dendrimer of the second (1) and third (2) generations with benzene groups in external layer:

1070-4272/03/7603-0442$25.00

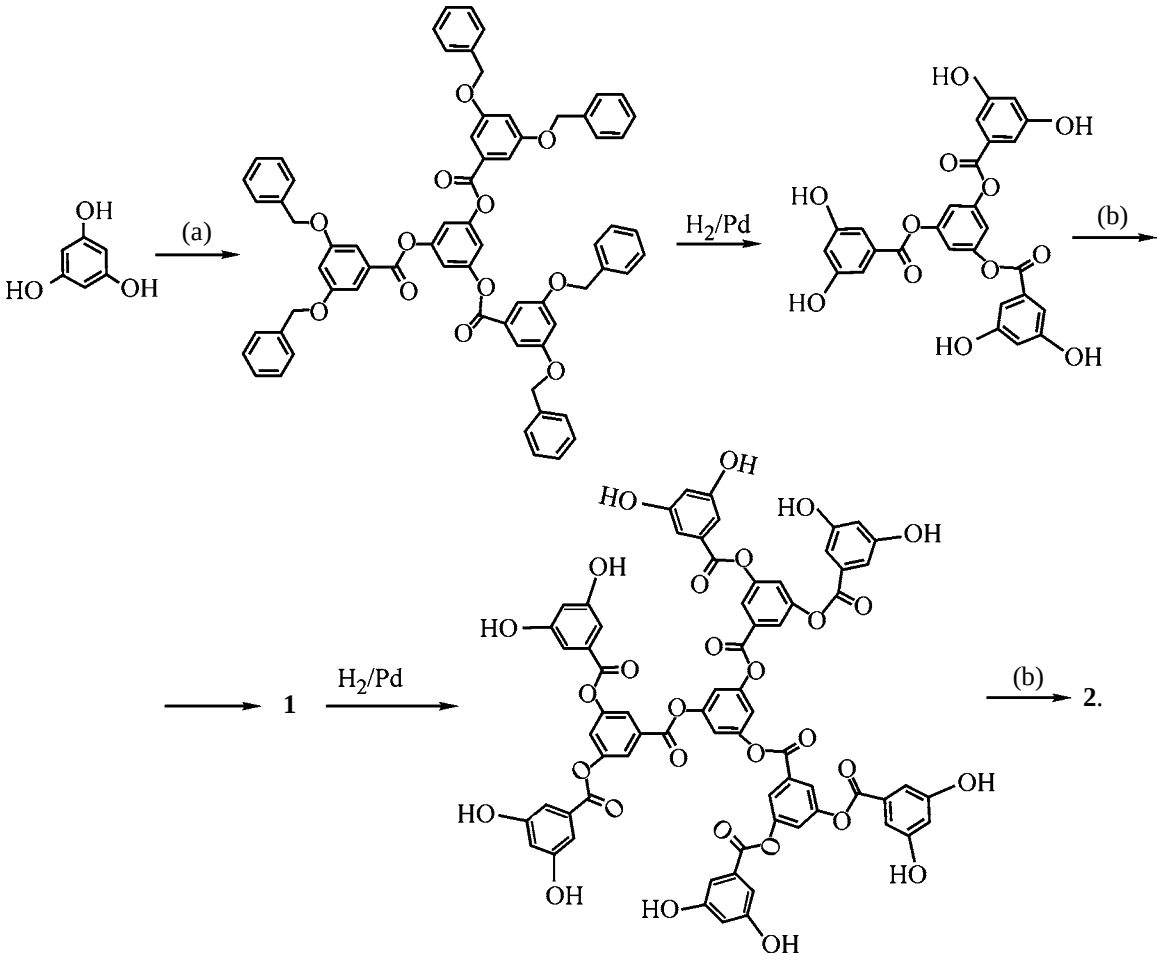


1, $C_{153}H_{114}O_{30}$; MW 2430.74.



2, $C_{321}H_{234}O_{66}$; MW 5147.25.

Compounds **1** and **2** were prepared by the divergent procedure schematically shown below:



Phloroglucinol and 3,5-dibenzyloxybenzoic acid were used as the central core and the branching agent, respectively. (a) CH_2Cl_2, 3,5-dibenzyloxybenzoyl chloride, *N*,*N*-dimethylaminopyridine, 20°C; (b) dry acetone, 3,5-dibenzyloxybenzoic acid, dicyclohexylcarbodiimide, complex of *N*,*N*-dimethylaminopyridine with *p*-toluenesulfonic acid, 20°C.

The procedure for preparing **1** and **2** [15] was substantially modified. In particular, to increase the purity and yield of 3,5-dibenzyloxybenzoyl chloride [16], it was prepared in a benzene solution of thionyl chloride. We failed to perform hydrogenolysis of benzyl esters on the palladium catalyst by the procedure in [15]. These compounds were hydrogenated using dimethylacetamide as the solvent. Compounds **1** and **2** were purified by preparative column chromatography on a silica gel (40–100 μm) using petroleum ether–dichloromethane (gradient form 10 : 1 to 1 : 1) as the eluent. The purity was determined by ^1H and ^{13}C NMR spectroscopy (Bruker dpx-300, 300 MHz).

$CDCl_3$ and DMSO-d_6 were used as solvents, and tetramethylsilane, as internal reference. Compound **1**:

Found, %: C 75.23, H 4.60.
$C_{153}H_{114}O_{30}$. Calculated, %: C 75.54, H 4.72.

^1H NMR, δ, ppm, $CDCl_3$: 5.12 (24H, s, CH_2), 6.91 (6H, t, *J* 2.0 Hz), 7.24 (3H, s), 7.3–7.55 (75H, m), 8.01 (6H, d, *J* 2.0 Hz). ^{13}C NMR, δ, ppm, $CDCl_3$: 70.2, 108.3, 113.1, 121.0, 124.2, 127.6, 128.0, 128.4, 130.4, 131.1, 136.2, 151.1, 151.3, 159.7, 162.5, 164.1.

Compound **2**:

Found, %: C 74.70, H 4.58, O 20.32.
$C_{321}H_{234}O_{66}$. Calculated, %: C 74.90, H 4.58, O 20.52.

^1H NMR, δ, ppm, DMSO-d_6: 5.15 (48H, s, CH_2), 7.01 (12H, s), 6.2–7.5 (147H, m), 7.76 (6H, s), 7.88 (3H, s), 8.05 (12H, s), 8.12 (6H, s). ^{13}C NMR, δ, ppm, DMSO-d_6: 70.5, 108.9, 114,3, 122.1, 123.1, 128.5, 128.7, 129.3, 129.8, 131.2, 131.8, 137.4, 141.3, 153.0, 153.8, 160.5, 163.7, 165.1.

The nanocomposites containing **1** and **2** were prepared as follows. To a solution of tetramethoxysilane (TMOS) (2.0 g) in acetic acid (5.0 g), a toluene solution of **1** and **2** or pure toluene was added with vigorous stirring at 70°C. Five samples were obtained. The amounts of **1** and **2** m_1 and m_2, used in preparation of nanocomposites **1a**, **1b**, **2a**, and **2b** and gel **3** at the acetic acid : TMOS : toluene ratio of 5 : 2 : 5, are given below:

Sample	**1a**	**1b**	**2a**	**2b**	**3**
m_1, g	0.075	0.15	–	–	–
m_2, g	–	–	0.075	0.15	–

The resulting homogeneous solutions were placed without cooling in hermetically sealed polypropylene test tubes 15 mm in diameter (three test tubes for each sample) and kept at 70°C for 5 days. Then the test tubes were cooled, and their content was transferred into test tubes with 1-mm holes. Wet samples were dried at 60°C for 8 days, 80°C for 1 day, 90°C for 1 day, and 100°C for 3 days at the heating rate of 5 deg h^{-1}.

We measured the open porosity W_{open} and apparent porosity of the samples by the Archimedian procedure. Of course, these measurements were performed with the samples that did not crack during drying or measurements. The sample hardness was determined on a PMT-3 microhardness gage. The thermal analysis curves were recorded on a Q-1500D derivatograph by heating to 1000°C at a rate of 20 deg min^{-1}. The percentage of SiO_2 in composites **1a** and **2a** and gel **3** was determined from the thermal analysis curves. Electron microscopic study of the gels was performed on an EM-125 electron microscope at the accelerating voltage of 75 kV. For this purpose, cellulose–carbon replicas of the surface of fresh chips of the samples were prepared. TMOS, toluene, acetic acid, and organic amides were distilled on a 10 TP column, collecting 0.1–0.3°C fractions.

We used dendrimer molecules of the second and third generation as the organic component of the nanohybrid, since these molecules, owing to their monodispersity and spherical structure of their framework, are convenient models for studying interphase interactions of the components. Unfortunately, complex synthesis of dendrite molecules restricts their use for preparing nanocomposites. Experiments on introduction of dendrimers in the three-dimensional silica framework are mainly performed with polyamidamines, the most available dendrimers to date [6, 9, 17, 18]. The aromatic ester dendirmes studied here as the organic components have the following advantages over polyamidamines: more symmetrical structure and the presence of benzene rings in the internal sphere of the molecules. This structure of aromatic ester dendrimers (contrary to polyamide dendrimers whose internal sphere consists of mobile aliphatic chains) increases their rigidity, makes their molecules more spherical, and provides the absence of nucleophilic groups in the internal sphere of the molecules.

At the same time, compounds **1** and **2** differ only in the generation degree, i.e., in the size of their molecules, spherical to a first approximation. The sizes for the dendrimers of the second **1** and third **2** generation, indirectly estimated from the data of [19], are 2–3 and 3–5 nm, respectively. As shown below, this has a key effect on formation of nanocomposites.

Chemical reactions occurring in the course of transformation of TMOS into the SiO_2 matrix under the action of acetic acid without adding water were described in detail in our previous paper [20]. It should only be noted that no visual deterioration of the homogeneity and monolithic charter of the dispersed phase during syneresis was observed. However, the content of the initial dendrimer in the disperse phase of **1a** and **2a** it is low (<1–2%); in **1b** it reaches 10, and in sample **2b** is high as 25% of the initial content.

Dried composites **1a** and **2a** were obtained in the form of monolithic transparent cylinders; **1b**, in the form of partially cracked cylinders; and sample **2b** was completely cracked. Gel **3** prepared as the reference without the organic component was a monolithic transparent cylinder. The physicochemical properties of the samples are summarized in the table.

These results can be explained as follows. The components of sample **2b** and, to a lesser extent, **1b** are in the form of a mechanical mixture. A sharp decrease in the density and hardness of these samples and an increase in their porosity as compared to gel **3** indicate that the organic component interferes with the sol–gel process. On the contrary, an increase in the density and a decrease in the porosity and hardness of samples **1a** and **2a** suggest formation of the organic–inorganic hybrid.

In addition, a sharp increase in the hardness of composite **1a** and a decrease in the carbon content in the composite (as indicated above, the dendrimer was introduced in the same amounts in the samples) as compared to samples **2a** and **3** indicates more complete formation of the SiO_2 matrix with lower residual content of the $Si–O–CH_3$ bonds. This can be due to definite physical interactions of the organic component with the three-dimensional SiO_2 matrix.

This assumption is confirmed by TG and DTA curves of samples **1a**, **2a**, and **3** (Fig. 1). The characteristic peaks in the DTA curves in the range 100–250°C are due to intense evaporation of volatile products of the sol–gel process (methanol, excess acetic acid, methyl acetate, water, etc.). It should be noted that the maxima of these peaks in the curves for **1a** and **2a** are shifted by 20°C to high temperatures as compared to that of gel **3**. At 300–650°C, the unhydrolyzed methoxy groups and the organic components burn out and thermally decompose. The exothermic peaks in the DTA curves of **1a** and **2a** are strongly shifted to high temperatures as compared to gel **3**. Of special note is the fact that the DTA curve of **1a** contains a sharp peak at 610°C, and an inflection point at 500°C is observed in its TG curve. Clearly, both organic components are structurally similar and consist of the same fragments. Thermolysis of these components (evaporation of these high-molecular-weight compounds is improbable) should occur by the similar mechanism and at close temperatures. Hence, the fact that the hardness and thermolysis temperature of composite **1a** are appreciably higher than those of **2a** suggests the presence of an appreciable amount of the organic component of composite **1a** in the SiO_2

Physicochemical properties of the samples

3	77	1.20	34.0	23.0

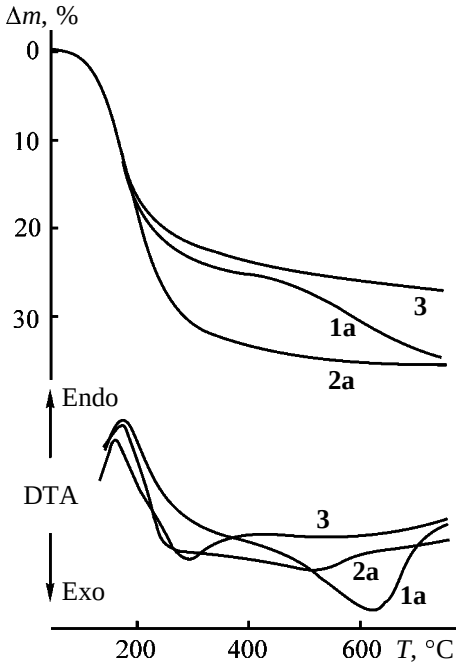

Fig. 1. TG and DTA curves for composites **1a** and **2a** and gel **3**. (Δ*m*) Weight loss and (*T*) temperature.

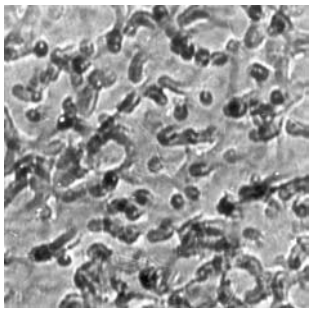

Fig. 2. Electron micrograph of gel **3**. Magnification 90 000.

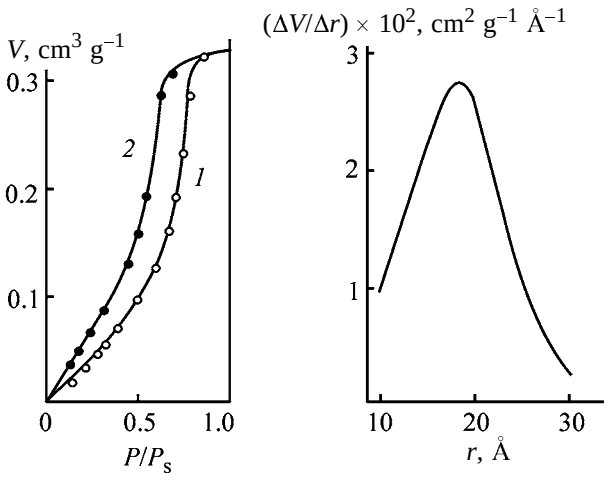

Fig. 3. Isotherm of (*1*) adsorption and (*2*) desoprtion of ethanol on gel **3** at 18°C and (*3*) pore-size distribution derived from the isotherm. (*V*) pore volume in 1 g of the sample, (P/P_s) ratio of ethanol pressure to its saturated vapor pressure, and (*r*) pore radius.

matrix. This is possible only owing to hydrophilic–hydrophobic and van der Waals interactions. To account for substantially higher energy of this interaction in composite **1a** as compared to sample **2a**, let us consider the structure of these samples.

Hybrids **1a** and **2a** are structurally similar to gel **3** (Fig. 2). The diameter of visible nanopores is 22–26 nm. However, the number of channel pores in hybrid **1a** is seemingly higher, and their nanostructure differs. It is known [4] that the pores of the SiO_2 matrix prepared by the sol–gel procedure form TMOS are filled with particles of a fine dispersion. The size of these particles can be estimated from the isotherm of ethanol adsorption on gel **3** and from the pore-size distribution (Fig. 3). Clearly, the molecular size of dendrimer **1** is slightly smaller than the pore diameter. At 9% content of dendrimer **1** in composite **1a** W_{open} = 29.5; however, introduction of the organic component in the amount of 6–7% sharply deteriorates the composite properties. It is also evident that the molecular size of the organic component matches the diameter of pores of the inorganic matrix, which provides strong intermolecular interaction between them. Since the size of dendrimer molecules in hybrid **2a** is substantially larger (3–5 nm), the energy of intermolecular interaction of the component in this system only negligibly compensates the energy loss in formation of the SiO_2 matrix under nonoptimal conditions.

CONCLUSIONS

(1) Organic–inorganic hybrids were prepared by the sol–gel procedure. The properties of these hybrids are exclusively determined by hydrophilic–hydrophobic and van der Waals interactions.

(2) The energy of these interaction at a definite molecular size of the organic component can be so high that it can provide sharp increase in the hardness and heat resistance of the composite.

(3) Unlike chemically bound organic–inorganic hybrids, even a slight change in the concentration of one of the components of a composite formed by hydrophilic–hydrophobic and van der Waals interactions strongly deteriorates its properties.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Degree of Cross-Linking of Epoxy–Acrylate Polymers Prepared by Photopolymerization

G. V. Gatiyatullina, E. M. Battalov, Yu. A. Prochukhan, and R. R. Muslukhov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received May 13, 2002

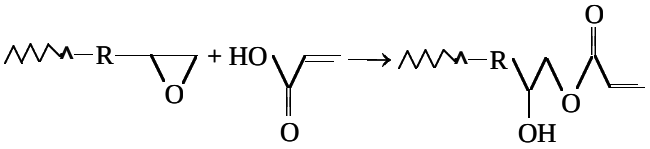
Abstract—The degree of cross-linking of epoxy–acrylate polymers prepared by photopolymerization of epoxy–acrylate oligomers was evaluated from the swellability in trichloroethylene.

UV-curable epoxy–acrylate oligomers are used as adhesives, sealants, as protective coatings in waveguide systems, and in radioelectronics for protection of printed-circuit boards [1, 2]. The properties of these polymers are largely determined by the degree of their cross-linking. The degrees of cross-linking of epoxy–acrylate polymeric compounds prepared, e.g., by radiation curing were studied previously [3]. At the same time, no data are available on the degree of cross-linking of epoxy–acrylate polymers prepared by photopolymerization.

In this study we evaluated the density of cross-linking of some UV-cured epoxy–acrylate polymers from their swellability in trichloroethane.

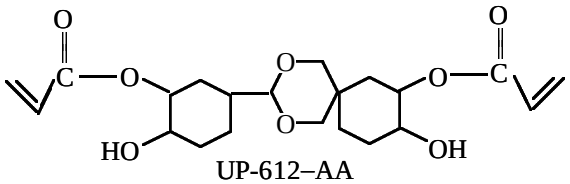
EXPERIMENTAL

Epoxy–acrylate oligomers were prepared by esterification of acrylic acid (AA) with equimolar amounts of epoxy oligomers at 120°C in the presence of polymerization inhibitor (hydroquinone) and tertiary amine as a catalyst of epoxy ring opening:

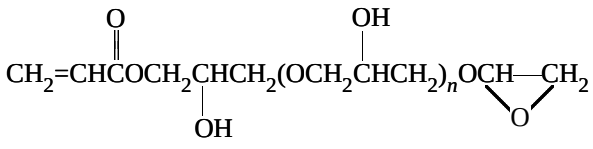


where R is an oligomeric block of an epoxy oligomer.

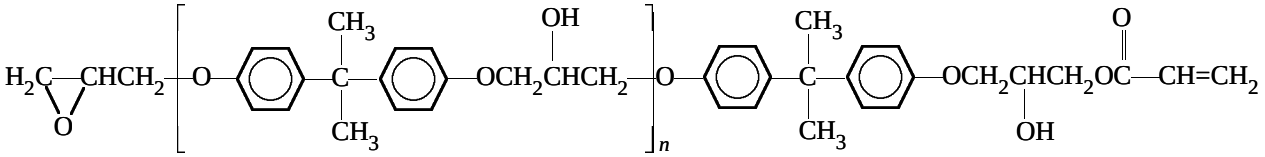
As epoxy oligomers we used UP-612, Oksilin (product of etherification of glycerol with epichlorohydrin), and ED-16. Acrylic acid was distilled before use. The oligomers mainly contain diacrylates and epoxy acrylates. Their structural formulas are given below.



UP-612–AA



Oksilin–AA



ED-16–AA

The structures of the oligomers were determined by ^{13}C and ^{1}H NMR spectroscopy. The NMR spectra were taken on a Bruker AM-300 spectrometer (^{1}H, 300 MHz; ^{13}C, 76.46 MHz; solvent $CDCl_3$; internal reference TMS). The spectra were interpreted using two-dimensional correlation technique (COSY H–H, C–H). The molar content of epoxy groups in the epoxy–acrylate oligomer decreases from 24 (in the

1070-4272/03/7603-0448$25.00

initial epoxide) to 9 mol % (oligomers studied in this work). The composition of the oligomers does not change in the course of 6-month storage. The molecular weights and molecular-weight distributions of the oligomers were determined by GPC using polystyrene references. The double bonds and epoxy number in the oligomers were determined by elemental analysis.

Samples of UP-612–AA, Oksilin–AA, and ED-16–AA polymers for studying the degree of cross-linking were prepared as films from acetone solutions of the initial oligomers in the presence of a photoinitiator. Benzophenone (BP) was recrystallized from ethanol; benzoin isobutyl ether (IBEB) was purified according to [4–6]. The UV-induced polymerization was performed using a PRK-400 medium-pressure mercury lamp. The distance from the lamp to the irradiation objects was 14 cm in all the runs. The film thickness was about 20 μm. The sol fraction was extracted from the polymers with trichloroethylene in a Soxhlet apparatus. The cross-linking density was calculated from the sol–gel analysis data. First, the number-average molecular weight of chains between the network points $\overline{M}_c$ was determined according to the Charlesby theory [7]:

$$\overline{M}_c = \overline{M}_w(s + s^{1/2})/2(1 + s),$$

where s is the sol fraction content. Then, the degree of cross-linking was evaluated as

$$\overline{M}_w/\overline{M}_c - 1 = \delta,$$

where δ is the cross-linking coefficient.

The volumetric degree of equilibrium swelling of epoxy–acrylate polymers was determined with a Dogadkin device in various solvents at 50°C:

$$q = V_1/m_0,$$

where V_1 is the volume of the solvent absorbed by the polymer and m_0 is the weight of the cross-linked polymer sample.

The deformation and strength properties of films were measured with an IR 5047-50 tensile-testing machine, with automatic data recording.

The degrees of swelling of epoxy–acrylate polymers derived from ED-16–AA and UP-612–AA are plotted in Fig. 1 vs. irradiation time. All the epoxy–acrylate polymers tested swell only slightly in any solvents; the swellabilities of the polymers prepared in an inert medium and in air differ insignificantly (Fig. 1, curves *1*, *3*). It is seen that the degree of

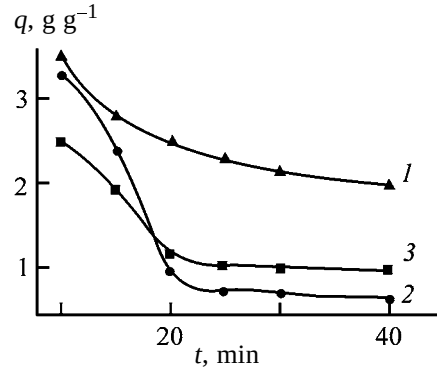


Fig. 1. Degree of swelling of polymers q as a function of UV irradiation time t (5% BP, trichloroethylene, 50°C): (*1*, *2*) ED-16–AA and UD-612–AA, respectively, polymerized in air; (*3*) ED-16–AA polymerized in an inert atmosphere.

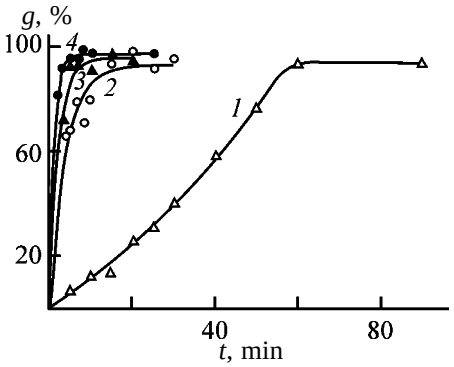

Fig. 2. Gel fraction content g in the polymer derived from ED-16–AA as a function of UV irradiation time t. Initiator, wt %: (*1*) BP, 5; (*2*) BP, 10; (*3*) IBEB, 5; and (*4*) IBEB, 10; the same for Figs. 4 and 5.

cross-linking of the polymer derived from UP-612–AA is higher compared to ED-16–AA at the same time of UV curing. The kinetic curves of gelation of ED-16–AA oligomer during irradiation in the presence of various polymerization initiators (BP, IBEB) are shown in Fig. 2. At IBEB concentrations of 5 and 10 wt % and BP concentration of 10 wt %, the gelation is mainly complete in 3–7 min (curves *2*–*4*), and at a BP content of 5 wt % the gelation of the oligomer follows approximately linear law (curve *1*).

Although, according to the IR spectra, the content of hydroxy and epoxy groups decreases in the course of UV irradiation (Fig. 3), we cannot unambiguously evaluate the contributions of epoxy and secondary hydroxy groups to the mechanism of the polymer cross-linking. Our results agree with those obtained in [8, 9].

The participation of hydrocarbon fragments of the oligomer in cross-linking under conditions of UV curing cannot be ruled out either. For example, Kachan

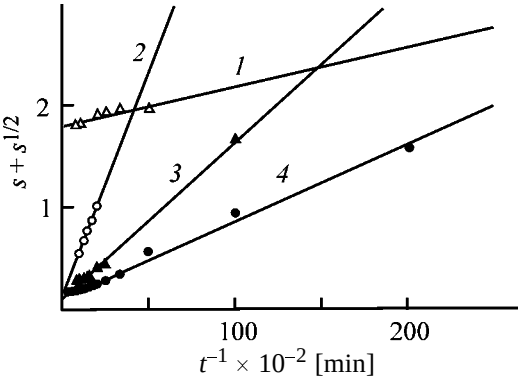

Fig. 4. Variation of the parameter $s + s^{1/2}$ of the polymer derived from ED-16–AA with UV irradiation time *t*.

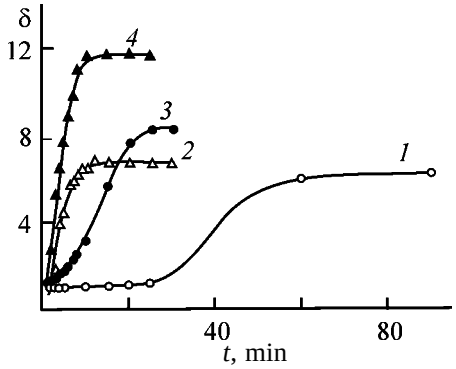

Fig. 5. Kinetic curves of cross-linking of the polymer derived from ED-16–AA. $\delta = M_w/M_c - 1$; (*t*) irradiation time.

and Shrubovich [10] reported on structural changes in benzophenone upon its UV irradiation in saturated hydrocarbons and polyethylene. The structures of both BP and saturated hydrocarbon undergo changes. The possibility of reaction of hydroxy groups with singlet oxygen in polymers is assumed in [11]; singlet oxygen can be generated by quenching of singlet and triplet excited states of BP. It should be particularly emphasized that the photoinitiator consumption during the polymerization is large, suggesting that BP is directly involved both in the cross-linking of epoxy acrylates (Fig. 3) and in formation of by-products of BP photolysis.

Figure 4 illustrates the dependence

$$s + s^{1/2} = p_0/q_0 + 1/q_0 nU,$$

where *s* is the content of the soluble fraction corresponding to definite irradiation dose *U*; *n* is the degree of polymerization calculated from the weight-average molecular weight of the oligomer; and q_0 and p_0 are the probabilities of cross-linking and degradation.

We assumed that the UV energy is absorbed linearly throughout the polymerization period. The ratio of the probabilities of degradation and cross-linking of the epoxy–acrylate polymer derived from ED-16–AA, p_0/q_0, calculated from data in Fig. 3, is 0.10–0.14, i.e., cross-linking is much more probable than degradation. For comparison, the ratio p_0/q_0 for polyethylene subjected to ionizing radiation is close to 0.3 [10].

The parameter M_c was calculated from the strain–stress dependences for the same samples of polymers derived from ED-16–AA, UP-612–AA, and Oksilin–AA as those taken for swellability measurements, using the formula [12]

$$\sigma = \frac{RT\rho_2}{M_c}(\alpha_c - \alpha_c^{-2}),$$

where $\alpha_c = l/l_0$, *l* and l_0 are the lengths of the strained and initial samples, ρ_2 is the polymer density, and *T* is temperature.

We obtained M_c ranging from 190.0 to 1000. The parameters M_c evaluated for the same polymers from the swellability range from 100 to 1000. The physical and chemical methods can give different values of M_c; however, in any case, the epoxy–acrylate polymers can be classed with densely cross-linked materials.

The kinetic curves of cross-linking of ED-16–AA (Fig. 5) upon UV irradiation show that the cross-linking rate depends both on particular photoinitiator and on the irradiation time. The flattening out of the kinetic curves of cross-linking indicates that the polymerization under these conditions is complete. The induction period (Fig. 5, curve *1*) is probably due to BP consumption for formation of benzpinacones [10, 11]. With benzoin isobutyl ether as photoinitiator, the gelation occurs at a higher rate than with benzophenone.

CONCLUSIONS

(1) Polymers with a high degree of cross-linking are prepared by photopolymerization of epoxy–acrylate oligomers in the presence of various initiators.

(2) The degree of cross-linking of the final product can be controlled by varying the UV irradiation time.

(3) With respect to the degree of cross-linking, epoxy–acrylate polymers can be ranked in the following order: UP-612–acrylic acid > ED-16–acrylic acid > Oksilin–acrylic acid.

Abstract—Reactions occuring in mixtures of polyacrylonitrile with fullerene C_{60} at 20–1000°C were studied by thermal analysis. The greatest thermal effects were observed in diffusion-controlled reactions of anionic polyacrylonitrile with fullerene. Carbonizate is formed with the yield of about 60%, which is of practical interest.

Polyacrylonitrile (PAN) is one of the most interesting polymers, and features of its formation and transformation are still the matter of discussion [1–4]. In this work, we studied structural features of PAN caused by the presence of reactive groups. These groups govern the reactivity of PAN toward fullerene, whose influence on formation and properties of other polymers was described earlier [5–8].

Generally, three types of PAN reactions with fullerene can be distinguished. Firstly, fullerene can affect PAN formation in the course of acrylonitrile polymerization. Secondly, fullerene can react with PAN prepared in advance by one or another procedure; depending on polymerization conditions, PAN can contain various reactive groups. Thirdly, fullerene can add to numerous products of PAN thermal transformation at various temperatures. In this case, both the direct reactions of fullerene with PAN at elevated temperatures and reactions with low-molecular-weight products of PAN thermal transformation are of the most interest.

Since PAN, similarly to its low-molecular-weight analogs (nitriles), is an electrophilic agent and fullerene is also an electrophilic molecule and, in addition, a strong radical inhibitor, it will suppress radical polymerization of acrylonitrile. It was shown previously [9] that, under the specific conditions of anionic polymerization, only small amounts of fullerene can add to PAN molecules, exerting no substantial influence upon the properties of modified PAN.

Therefore, of the most interest are thermochemical transformations of PAN in a broad temperature range in the presence of fullerene. In this work, we considered reactions of PAN synthesized by both radical and anionic mechanisms with fullerene C_{60} at heating in an inert atmosphere and in a vacuum within the 20–1000°C range.

EXPERIMENTAL

PAN was prepared by both radical [10] and anionic [11] methods, The PAN–C_{60} mixtures of known composition were homogenized by grinding in air. Covalently bound PAN·C_{60} was synthesized by anionic polymerization of the monomer in the presence of fullerene [9].

The thermal analysis of the reaction mixtures (50-mg samples) in the self-generated atmosphere was performed on a MOM derivatograph in crucibles with lids and Al_2O_3 covering layer at 10 deg min^{-1} heating rate. The thermal analysis in an inert atmosphere was performed on a NOETSCH device in special crucibles with 5-mg samples at 10 deg min^{-1} heating rate. The thermolysis in a vacuum was performed on a TVA device by the method described in [12] at variable heating rate (from 3 to 10 deg min^{-1}) and sample weight (from 50 to 200 mg).

It was shown in [3, 4, 13] that thermal transformations of PAN (homolytic and heterolytic) synthesized mainly by radical polymerization are accompanied by liberation of a number of low-molecular-weight volatile products such as hydrogen, hydrogen cyanide, ammonia, dicyan, acrylonitrile, vinylacetonitrile, pyrrole, pyridine, naphthyridine, etc. Their content

1070-4272/03/7603-0452$25.00

depends on the surrounding atmosphere, temperature and time of heating, PAN structure, etc. Intermediates are formed in the initial stage of elimination of volatile nitrogen derivatives as a result of secondary transformations of partially cyclized PAN. It is known that cyclic structures appear in PAN at 170–210°C in the form of naphthyridine rings [14, 15]. At further temperature rise, along with increase in the content of cyclic successions in the PAN chains, volatile products (HCN, acrylonitrile, sometimes NH_3) appear, i.e., PAN starts to lose weight, which is detected by TGA.

It is seen from Fig. 1a that noticeable weight loss due to secondary degradation of partially cyclized PAN starts at 261°C for PAN prepared by the radical mechanism (R-PAN). Below this temperature, R-PAN loses about 9 wt % at the expense of elimination of the sorbed solvent. In the first stage of R-PAN degradation, which proceeds at a high rate within the 261–298°C range, the sample loses 13.5 wt %. This process is accompanied by a strong exothermic effect with a maximum at 268°C, which is assigned to a combination of spontaneous cyclization of PAN and liberation of volatile products of thermal rearrangement of nitrogen-containing rings formed at this temperature. At further temperature rise, the second stage of R-PAN degradation and cyclization (300–420°C) starts with decreasing rate of the weight loss. At 420°C, R-PAN loses another 18.5 wt %, and this is followed by carbonization, which gives the carbonized residue of about 27 wt %. In this stage, no substantial thermal effects are observed except certain change in the heat capacity caused by carbonization.

Curves in Fig. 1a characterize the kinetics of the weight loss of PAN containing various amounts of fullerene. As seen, both the initial weight loss below 261°C and the loss in the first stage of thermal degradation of the R-PAN structure are virtually the same as for R-PAN without fullerene. Thus, the mechanisms of initiation of the polymer thermal degradation related to the R-PAN structure are not radical for which fullerene could be an inhibitor. As for the subsequent stage of the R-PAN carbonization, fullerene starts to gradually escape from the R-PAN carbonizate within the 400–600°C range; the process becomes especially noticeable at 600–750°C. However, the amount of carbonized residue obtained at 1000°C indicates that the part of fullerene remains in the carbonizate; this amount does not correspond to its content in the initial mixture.

Fig. 1b shows that the samples containing 20–30% fullerene exhibit the exothermic effects in the 266–268°C range, almost equal in the temperature and

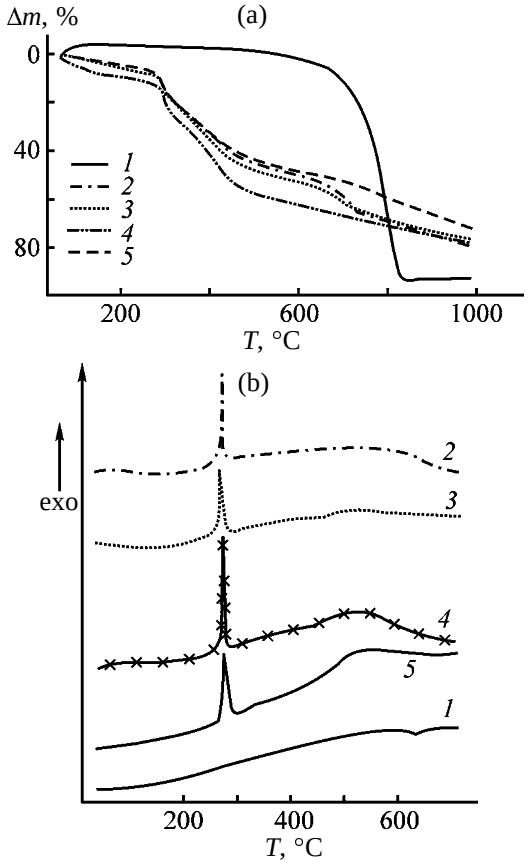

Fig. 1. (a) TG and (b) DSC curves of R-PAN mixtures with fullerene. (Δ*m*) Weight loss and (*T*) temperature; the same for Figs. 2 and 3. Fullerene content (%): (*1*) 100, (*2*) 30, (*3*) 20, (*4*) 0.7, and (*5*) 0.

enthalpy, and their heat capacities become similar in the carbonization region.

It follows from Fig. 2 that, under similar conditions, anionic PAN (A-PAN) is more sensitive to the presence of fullerene.

(1) In the stage of removal of the adsorbed solvent before the onset of cyclization, almost twofold decrease in the weight loss is observed.

(2) Although in the first stage of cyclization the thermal degradation of A-PAN is kinetically similar to that for R-PAN, the quantitative parameters for samples with various fullerene contents differ. For instance, the temperatures of the onset of the first stage of intense cyclization–degradation vary in the 30°C range, and the weight loss recalculated to pure A-PAN (14 wt %) varies from 9 to 20 wt %. Approximately the same difference is observed in the second stage of the thermal degradation at 300–450°C.

(3) Similarly to R-PAN in the carbonization stage, a part of fullerene remains in the carbonizate structure,

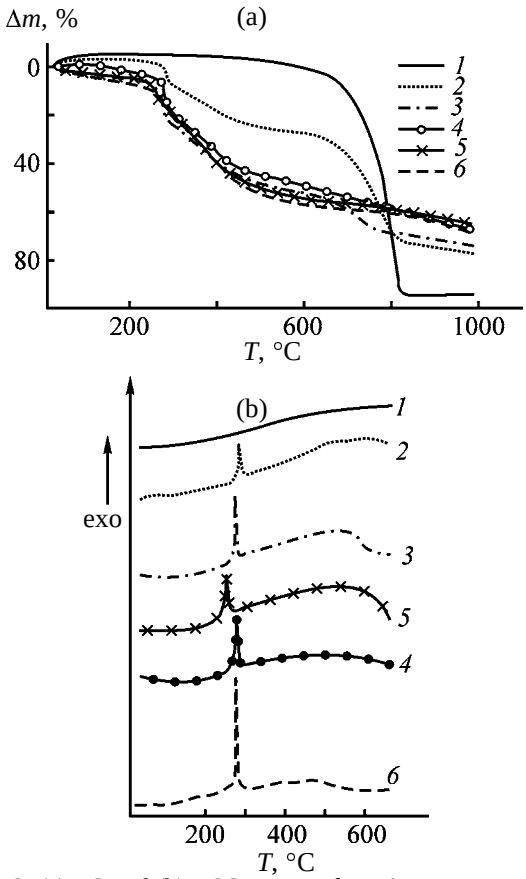

Fig. 2. (a) TG and (b) DSC curves of R-PAN mixtures with fullerene. Fullerene content (%): (*1*) 100, (*2*) 50, (*3*) 30, (*4*) 10, (*5*) 0.7, covalently bound, and (*6*) 0.

but the quantitative ratios of the carbonized residues depend on the amount of the introduced fullerene in a more complicated manner, which is especially clear at the A-PAN : fullerene ratio of 50 : 50. Such a sample is characterized by the lowest content of adsorbed solvent and the highest temperature of the initial stage of weight loss. In addition, in spite of noticeable acceleration of the weight loss at the temperatures higher than 700°C caused by fullerene sublimation, the carbonized residue (about of 25%) at 1000°C contains approximately half of fullerene.

(4) The DSC data show differences in the heat release accompanying the first stage of cyclization. For pure A-PAN, this stage is characterized by a very narrow and large in amplitude exothermic effect. Small amounts of fullerene draw apart the temperature boundaries of this peak and shift its maximum to lower temperatures. Increase in the fullerene content to 30–50% again narrows the exothermic peak and somewhat elevates the temperature of its maximum.

In view of the above differences in the kinetics of A-PAN thermochemical transformations in an inert atmosphere in the presence of fullerene as compared to R-PAN, the behavior of A-PAN containing covalently bound fullerene under the same conditions is of interest [9]. In accordance with TG and DSC data, the release of volatile products in the first stage of the thermal degradation starts at a lower temperature, 239°C with a maximum at 249°C. In this stage, the release of thermal degradation products decreases to 6.5 wt %. In the subsequent stages of carbonization, the content of the carbonized residue exceeds by 5–10% this value for samples with unbound fullerene. These differences show that fullerene covalently bound with A-PAN definitely affects the kinetics of PAN carbonization.

The features of A-PAN carbonization in the presence of substantial amounts of fullerene and their comparison with the behavior of A-PAN, in which even small amounts of fullerene are covalently bound with the macromolecule, allows the conclusion that there is a definite critical concentration of C_{60} below which the reagents do not react thermochemically. Probably, in an inert atmosphere and at small masses of the reactants, the reaction is kinetically controlled, which is confirmed by small difference in the heat effects in the majority of the experiments. The similar trend was found earlier, when the thermal effects of PAN fiber transformation were studied in relation to various kinetic and diffusion factors [10, 16].

Taking this into account, we performed a series of experiments with tenfold larger portions of PAN at heating in the self-generated atmosphere. The TG and DTA curves for certain A-PAN samples with various fullerene contents are shown in Fig. 3. In spite of general similarity of the thermochemical degradation pattern in an inert atmosphere, sample weights, and heat treatment conditions, which were similar to those of the industrial process, additions of fullerene noticeably affected the quantitative characteristics (temperatures of thermal effects and weight loss). The weight losses in the stage of PAN cyclization in the 270–350°C range differ substantially. On the one hand, the relative amount of volatile products in the initial stage of the A-PAN thermal degradation increases; on the other hand, fullerene strongly affects the kinetics of the release of these products. This is confirmed by an increase in the exothermic effects of the initial stage and shift of their maxima to higher temperatures. As above, the thermal effect of decomposition of A-PAN with covalently bound fullerene is particularly intense, which confirms noticeable role of the chemical bond of fullerene with PAN in its thermo-

chemical transformations. The main difference suggesting active participation of fullerene in A-PAN carbonization is noticeable increase in the amount of the carbonized residue at 1000°C: to almost 60%. Apparently, an increase in the sample weight favors carbonization at temperatures higher than 500°C under conditions of diffusion control. This facilitates cross-linking owing to suppressed elimination of volatile products of thermal degradation by the scheme of the framework microreactor.

The composition and state of the surrounding atmosphere is a substantial parameter in cross-linking of the samples studied. Under conditions of thermal transformations of PAN with fullerene in the self-generated atmosphere, a number of aggressive products exist in the reaction mixture, whose reactions with fullerene lead to formation of numerous bonds, similarly to coke synthesis, and formation of carbonizates in high yield.

To confirm this assumption, we performed a series of experiments on vacuum thermolysis of the samples on a TVA device, which allows differential recording of the pressure variation and of the amount of the carbonized product. Figure 4 shows the TVA curves for mixtures of A-PAN with fullerene, similar to those in Fig. 3. As seen, release of volatile thermal degradation products in the stage of PAN cyclization starts at 130–190°C. The reaction, as under the other conditions of heating, is avalanche-like with a sharp maximum at 160–210°C. The samples lose up to 50–60% of their weight at 230°C. Then, above 350°C, further release of volatile products is observed, which is complete at 530°C (the curve with a maximum), and from 750 to 900°C the next carbonization stage proceeds. The effect of fullerene on A-PAN vacuum thermolysis is appreciable: fullerene shifts the onset of the first stage of gas liberation by 30–50°C to lower temperatures. However, the total amount of the carbonized residue at 900°C does not exceed 30% and does not differ from the same value for A-PAN without fullerene. Thus, the use of the heat treatment method ensuring fast removal of reactive products of the stepwise degradation of PAN sharply shifts carbonization to the kinetic region. The prevalence of degradation over cross-linking leads to complete decomposition of the product in accordance with the previously noted features of this process [17].

CONCLUSIONS

(1) It was shown by thermal analysis that, in the course of thermal treatment of mixtures of polyacrylonitrile prepared by anionic mechanism with fullerene, they react with formation of carbonizate in a yield to 60%.

(2) The carbonization parameters depend on conditions of thermal treatment and the amount of the reac-

tion mixture. The yield of the carbonization product is appreciable when the reaction is diffusion-controlled.

Abstract—The structure of aggregates of fullerene C_{60} introduced into films of radical polymethyl methacrylate in the stage of solution preparation was studied by wide-angle X-ray diffraction.

Previously, we have studied the effect of small additions of fullerene C_{60} on thermal degradation of polymers [1–3]. Preparation of fullerene–polymer compositions can be accompanied by microphase segregation with formation of fullerene aggregates in the polymer matrix. In turn, the structure of such aggregates can affect the composition properties [3]. In this work, we studied the structure of fullerene C_{60} aggregates in a film of atactic polymethyl methacrylate (PMMA) prepared by radical polymerization.

EXPERIMENTAL

Atactic PMMA with the molecular weight M = 85000 was dissolved in *o*-dichlorobenzene to obtain 10 wt % concentration. The same solution of fullerene C_{60} was also prepared. Then, these solutions were mixed in proportions required to obtain the fullerene concentration in the PMMA film of 1 and 10%. Films were prepared by casting on a cover glass. The solvent was evaporated from the PMMA and PMMA + fullerene solutions at room temperature in air. The film thickness was about 70 μm.

A study with a MIN-8 polarization optical microscope showed that the films were transparent, i.e., they were homogeneous on the optical level (<0.5 μm). Wide-angle X-ray diffraction patterns of films was measured on a DRON-2.0 diffractometer with graphite crystal monochromator in CuK_α irradiation.

The powder pattern of fullerene C_{60} powder on a glass support is shown in Fig. 1. The reflections are indexed in the face-centered cubic crystal lattice of fullerene C_{60} [4]. The fullerene reflections are narrow and intense, so that the scattering from the support can be neglected. The relative reflection intensities and the corresponding interplanar spacings (with the error of 0.01–0.02 Å) are in good agreement with the reference data [4].

The average crystallite dimensions L_{hkl} in [*hkl*] direction were calculated by the Scherrer formula [5] using measured widths of the reflection profiles. The minimal crystallite size (neglecting the effects of the lattice distortion and primary beam width) calculated from the width of a series of the most intense reflections is 300–400 Å.

Fullerene aggregates in the PMMA matrix show no similar ordering. The diffraction patterns of PMMA films with fullerene on a glass support are shown in Fig. 2. To take into account the scattering from the support, the scattering pattern was subtracted from the difraction patterns. The difference patterns allowed refinement of the position and shape of diffuse maxima.

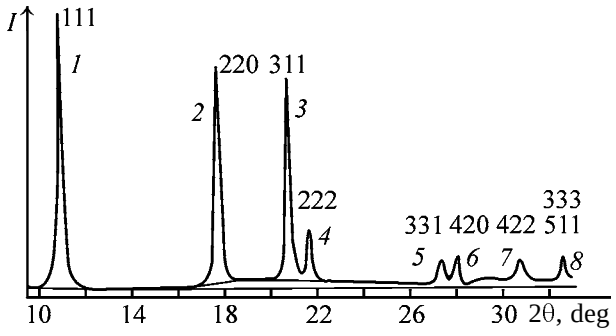

Fig. 1. Wide-angle powder pattern of C_{60} fullerene powder: (*I*) intensity and (2θ) Bragg angle; the same for Fig. 2. Indices of the face-centered crystal lattice are indicated. Bragg angle corresponding to peak maximum, deg: (*1*) 10.83, (*2*) 17.77, (*3*) 20.91, (*4*) 21.82, (*5*) 27.63, (*6*) 28.30, (*7*) 31.01, and (*8*) 32.94.

	18	4.9
Face-centered cubic lattice of C_{60}, reflection:		
200	12.47	7.09
220	17.77	5.01

* CuK_α radiation.

In diffraction patterns of pure PMMA, two orders of the amorphous halo correspond to intermolecular distance $d \sim 6$ Å. The C_{60} introduced into the PMMA matrix does not form a strictly ordered crystal lattice. However, microphase segregation occurs in the system, i.e., weakly ordered C_{60} aggregates are formed. In films with 1% fullerene, its weak aggregation is due either to the small amount of fullerene aggregates or to weak C_{60} aggregation, when the most part of the fullerene is dispersed to separate molecules.

The data for samples containing 10% fullerene allow more definite conclusions. The interplanar spacings corresponding to two diffuse maxima were estimated as 6.8 and 4.9 Å. The shortest interplanar spacings calculated for the C_{60} crystal lattice are listed in the table, and only the second one (4.9 Å) is manifested in the experimental powder pattern as a strong 220 reflection, while the interplanar spacing of 6.8 Å is not manifested in the C_{60} powder pattern (Fig. 1), in spite of the conformity with the calculations for the C_{60} crystal lattice. It should be noted that the calculated reflections 200 and 220 for the C_{60} crystal lattice are the most intense [4]. The corresponding crystallographic planes determine the structure and are the main in the nucleation of the C_{60} crystal lattice. However, the PMMA matrix prevents further ordering, "freezing" the nucleus structure.

The dimensions of the coherent scattering regions for C_{60} aggregates in the PMMA matrix, estimated by the Scherrer formula at 15–25 Å, are evidently underestimated. They were obtained without taking into account distortions, which are obviously very strong. In addition, to reveal the reflection, the repetition of at least three or four motives (4–5 planes) is required. The interplanar spacing in the C_{60} crystal lattice in the [110] direction is 10 Å. Taking into account that

$$L_{hkl} = \bar{N} d_{hkl}, \quad (1)$$

where $\bar{N}$ is the average number of planes in the L_{hkl} distance and d_{hkl} is the interplanar spacing, we can suggest that the lower limit of the real size of the C_{60} nucleus is 40–50 Å. In each plane (110) of the unit cell, six C_{60} molecules are arranged (Fig. 3). Hence, only in the [110] direction the nucleus contains 24–30 C_{60} molecules. Since for C_{60} aggregates the second reflection (close to reflection 100) is observed, in the [100] direction the nucleus contains also at least 4–5 planes. Hence, the nucleus volume corresponds to 100 C_{60} molecules.

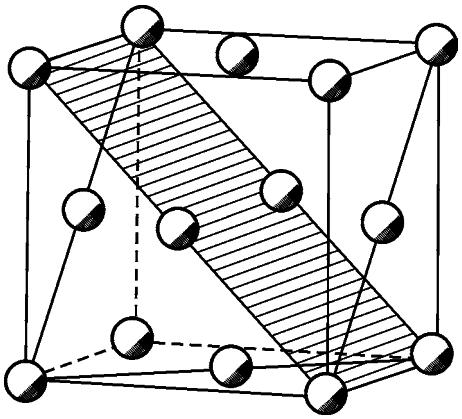

Fig. 3. Scheme of the unit cell of face-centered crystal lattice of C_{60} fullerene. The (100) plane is cross-hatched.

Thus, when the method for preparing PMMA films from common solutions with fullerene C_{60} is used, the microphase segregation occurs, and 40–50-Å C_{60} aggregates with imperfect mesomorphous ordering, containing about 100 fullerene molecules, are formed.

Abstract—Radical polymerization of a disubstituted monomer derived from monoethanolamine vinyl ether and 1,4-benzoquinone was studied by classical polarography. The optimal conditions for the synthesis of the redox polymer were found. The polymerization rate constants, preexponential term in the Arrhenius equation, and activation energy were calculated.

The versatility of redox and ion-exchange polymers, on the one hand, and the limited range of monomers suitable for their synthesis, on the other hand, require more intense studies in this field, with the aim to develop novel sorption processes [1, 2]. The problem of preparing new redox monomers from cheap and readily available precursors remains very urgent, since the available redox resins do not always meet the existing requirements. Among promising precursors are quinones, which widely occur in the nature and are fairly comprehensively studied. Previously [1–5] we described redox polymers based on various quinones and prepared by chemical modification of polystyrene and styrene–diene copolymers with quinones, di- and trihydroxybenzenes, and their halo derivatives.

With the aim to extend the assortment of redox resins and simplify their preparation, we developed a procedure for single-stage synthesis of new unsaturated monomers [6] from readily available and cheap monoethanolamine vinyl ether (MEAVE) and various quinones. This reduced the cost of redox ion exchangers and made their production profitable; the capability for reversible oxidation–reduction allows repeated use of these resins, which is important for commercial applications.

One of reliable, highly sensitive, and quick methods for analysis of macromolecular compounds is polarography. It is widely used in kinetic studies of polymerization of vinyl monomers [7–12]. It is known that the principal characteristic of the reactivity of unsaturated monomers is the polymerization rate constant. However, only in a few papers [12–14] this quantity was determined polarographically. The relationship between the rate constants of radical polymerization of monomers and the potentials of the half-waves of their reduction on a mercury dropping electrode were established in [13].

In this work we studied by classical polarography the kinetics of radical polymerization of a disubstituted monomer derived from MEAVE and 1,4-benzoquinone (MEAVE–1,4-BQ), calculated the polymerization rate constants at various temperatures, the activation energy, and the preexponential term in the Arrhenius equation.

EXPERIMENTAL

Monoethanolamine vinyl ether was dried over freshly distilled K_2CO_3 and distilled from calcium hydride; bp 114°C, n_D^{20} 1.4382.

1,4-Benzoquinone (pure grade) was recrystallized from methanol; mp 116°C after purification.

Azobis(isobutyronitrile) (AIBN) was recrystallized from absolute methanol; mp 102–103°C.

The monomer, 2,5-bis[*N*-(2-vinyloxy)ethyl]amino-1,4-benzoquinone $C_{14}H_{18}N_2O_4$, was prepared as follows. MEAVE was added in 6 : 1 ratio to a solution of 1,4-BQ in 1,4-dioxane (28.2 g l^{-1}, or 0.26 M) at 25°C with continuous stirring. After 15 min, distilled

** The density and static exchange capacity were determined according to [15].
*** The redox capacity was determined according to [1].

water was added, the precipitate was filtered off, reprecipitated, and dried first in air and then in a vacuum oven at 40–50°C to constant weight. The chemical composition and some physicochemical properties of the MEAVE–1,4-BQ are listed in Table 1.

Polymerization of MEAVE–1,4-BQ was performed as follows. AIBN, 1–7 wt % relative to the monomer, was added into an ampule containing a solution of the monomer in dimethylformamide (DMF; 0–44 g l^{-1}). The ampule was purged with argon, sealed, thoroughly shaken, and placed in a thermostat heated to 55–75°C. After reaction completion, the ampule was quickly transferred in a beaker filled with ice, cooled, and opened. The precipitate was filtered off and dried first in air at 20–25°C and then in a vacuum oven at 40–50°C. The polymer yield was 50.0–67.8%. The optimal conditions are as follows: monomer concentration in DMF 25 g l^{-1} (0.0899 M); AIBN amount 5 wt % relative to the monomer (1.25 g l^{-1}, or 0.762 × 10^{-2} M); 68°C; 120 min. The main physicochemical characteristics of the polymer are given in Table 1.

The IR spectra of the new quinoid derivative of MEAVE contains the following absorption bands, cm^{-1}: NH stretching 3256; NH bending 1552; C=O stretching 1660; C=C stretching 1568, 1440; =C–N stretching 1328; and C–O–C stretching 1200. The absorption band of quinoid rings in the spectrum of the polymer becomes broader, which is typical of polymeric quinones, and these bands are shifted toward higher frequencies to 1680 cm^{-1}. The bands at about 3040 cm^{-1} characteristic of the vinyl group disappear, whereas the bands at 2936 and 1496 cm^{-1} belonging to the –CH_2– groups grow in intensity.

The polarograms were taken in a temperature-controlled cell at 25±0.5°C with a PU-1 polarograph equipped with a mercury dropping electrode having the open-curcuit capillary characteristic $m^{2/3}t^{1/6}$ = 4.38 mg$^{2/3}$ s$^{1/2}$. As reference electrode was used saturated calomel electrode. Prior to polarographic measurements, the solutions were purged with argon to remove oxygen. The half-wave potentials were determined by graphic solution of the wave equation in the coordinates $\log i/(I - i)$ vs. E, where i is the current at voltage E and I is the diffusion current [16, 17].

Experiments on studying the kinetics of radical polymerization of the new disubstituted redox monomer based on MEAVE and 1,4-BQ, 2,5-bis[*N*-(2-vinyloxy)ethyl]amino-1,4-benzoquinone (MEAVE–1,4-BQ), were performed as described above; after a certain time, the ampules were successively opened, and samples were taken for polarographic analysis. The samples were diluted with DMF to stop the reaction. Polarographic measurements were performed in 25% DMF, with phosphate buffer solution (pH 7.4) as supporting electrolyte. The conversion was judged from the amount of the unchanged monomer. Experiments revealed a linear relationship between the heights of the polarographic waves and the monomer concentration in the solution. The monomer content was determined from the calibration plot.

Analysis of the reaction mixture furnished information on the degree of conversion and allowed construction of the polymerization curves (Fig. 1).

To calculate the overall polymerization rate constants, we determined the reaction order. The logarithmic dependence of the polymerization rate on the initiator concentration (Fig. 2) and the linear depen-

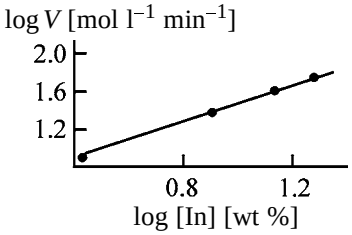

Fig. 2. Logarithmic plot of the polymerization rate, $\log V$, vs. initiator concentration $\log[\mathrm{In}]$.

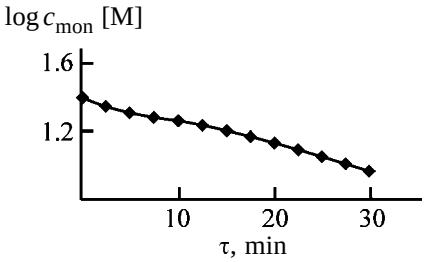

Fig. 3. Plot of $\log c_{mon}$ vs. time τ of MEAVE–1,4-BQ polymerization.

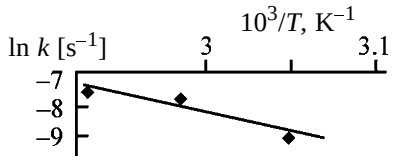

Fig. 4. Logarithm of the rate constant $\ln k$ of MEAVE–1,4-BQ polymerization as a function of temperature T.

dence of $\log c$ of the monomer on the reaction time (Fig. 3) show that the reaction is first-order with respect to the initiator (n = 0.80) and monomer (m = 0.86) and is described by relationships characteristic of first-order reactions.

The rate constants of MEAVE–1,4-BQ polymerization calculated by the first-order kinetic equation [18, 19] and the preexponential terms k_0 in the Arrhenius equation $k = k_0 e^{-E/RT}$ are listed in Table 2.

The plot of $\ln k$ vs. $1/T$ is a straight line; from its slope, we determined the activation energy of the process, $E = 4.57 \left|\tan\alpha\right| \xi$, where α is the slope of the straight line and ξ is the scale ratio of the abscissa and ordinate (Fig. 4).

Table 2. Kinetic characteristics of polymerization of the monomer based on MEAVE–1,4-BQ

T, K	$10^3/T$, K^{-1}	$k \times 10^4$, s^{-1}	$\ln k$	$k_0 \times 10^{15}$, s^{-1}
328	3.05	1.22	–9.015	1.379
335	2.99	3.72	–7.898	1.681
341	2.93	5.38	–7.530	1.141
348	2.87	5.48	–7.508	0.498

In the chosen scale, $\tan\alpha = \tan 32° = 0.6249$, $\xi = 10^3$, and activation energy $E = 4.571 \times 0.6249 = 2.86$ kcal mol^{-1} (11.95 kJ mol^{-1}).

The synthesized disubstituted monomer derived from MEAVE and 1,4-BQ readily polymerizes, in contrast to the starting MEAVE, which, as reported in [20, 21], does not form homopolymers in the presence of radical initiators. Apparently, this is due to the reactivity of the radical, which is the decisive factor in homopolymerization. The higher the electron density localized on the double bond, the more reactive is the monomer [7, 10]. The polarographic parameters are also determined by the electron density localized on the double bond: the higher the electron density, the more negative is the half-wave potential of the reduction of the double bond, i.e., the more negative the potential, the readier is the polymerization, which is indeed the case with MEAVE–1,4-BQ.

CONCLUSIONS

(1) Radical polymerization of the new disubstituted derivative based on monoethanolamine vinyl ether and 1,4-benzoquinone was studied, and optimal conditions were found for formation of the polymeric redox resin.

(2) The kinetics of radical homopolymerization was studied, and the rate constants, activation energy, and preexponential term in the Arrhenius equation were calculated.

Abstract—The pore structure of filled films of xerogels of ultra-high-molecular-weight polyethylene prepared by gel-casting technique was studied by Fourier IR spectroscopy, attenuated total internal reflection spectroscopy, and optical microscopy. The influence of the filler nature, particle shape, and concentration on the pore structure formation of filled xerogels of ultra-high-molecular-weight polyethylene was examined.

Much attention is given today to development of new polymer materials, among which a special place is occupied by composite materials with a set of properties offering wide application prospects. In particular, filled composites with crystallizing polymers as binders came recently into active use. These materials can be prepared by various methods, in particular, gel casting, which enables various fillers to be combined with dilute polymer solutions. It was shown previously that this method is suitable for preparing efficient sorbents for oil products in the form of porous xerogel films of ultra-high-molecular-weight polyethylene (UHMWPE) filled with sorption-active peat [1, 2]. Mercury porometric, IR attenuated total internal reflection (ATIR) spectroscopic, and optical microscopic studies revealed the influence exerted by the hydrophilic dispersed filler (peat) on the nature of the forming pore structure of filled UHMWPE xerogels [3–5].

In this work we studied the pore structure of filled films of UHMWPE xerogels as influenced by the filler nature, particle shape, and concentration. To this end, we utilized IR Fourier and ATIR spectroscopy and optical microscopy.

EXPERIMENTAL

Our study was concerned with films of xerogels of UHMWPE with the average molecular weight of 4.0×10^6 and different contents of the filler. As fillers we used polyacrylonitrile (PAN) fibers (fibril length 2×10^3 μm, average diameter 19 μm) and talc (particle diameter 1 μm), as well as polydisperse ferrocyanide and swollen vermiculite with the particle size varying within 150–1500 and 150–3000 μm, respectively. For our studies we selected ferrocyanide and vermiculite with the particle diameter of 150–250 μm.

The fillers were combined with a 2% UHMWPE solution in paraffin at 160°C [6]. The choice of the solvent was substantiated in [3, 7]. The solution containing 5–80 wt % of fibrous or disperse filler was transferred into gel by cooling on a metal table whose surface temperature was varied from 160 to 20°C at a rate of 1.6 deg min^{-1}. The filled UHMWPE gel films were converted to filled xerogel films by removing the solvent (paraffin) via extraction with heptane in a fixed state in a Soxhlet apparatus at 70–75°C, followed by drying at room temperature.

To determine the bulk and surface porosities of the filled UHMWPE xerogel films, we recorded the IR absorption spectra of the samples on an Equinox-55 IR Fourier spectrometer and the ATIR spectra of the film surfaces on a Specord M80 spectrometer. ATIR elements were KRS-5 plates with the reflection index $n_1 = 2.4$ and the incidence angle of 62°. A combination of the IR absorption and ATIR spectroscopic methods allows separate monitoring of the structural changes occurring in the bulk and on the surface of filled film of UHMWPE xerogel. The porosity (pore concentration) of the xerogel films on the surface and in the bulk of the sample was estimated using the IR absorption band corresponding to the rocking vibrations $r_R(CH_2)$ at 730 cm^{-1} [8, 9]. The porosity of the sample (rel. units) was calculated by the formula

$$\varepsilon = D/d,$$

1070-4272/03/7603-0464$25.00

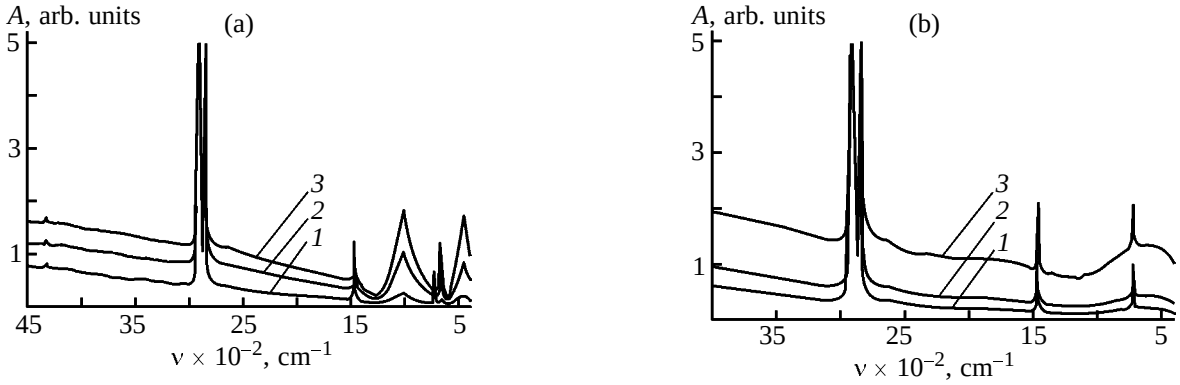

Fig. 1. IR absorption spectra of UHMWPE films filled with (a) talc and (b) PAN fibers with different degrees of filling. (*A*) Absorption and (ν) wave number. Degree of filling, %: (*1*) 10 (talc) and 20 (PAN), (*2*) 30, and (*3*) 50.

where ε is the extinction coefficient, which is a measure of the bulk porosity of the sample; *D*, the optical density at the maximum of the IR absorption band chosen; and *d*, the film thickness.

The surface of the filed films of UHMWPE xerogels was also analyzed by optical microscopy on an Neophot 30 metallographic microscope in the dark field mode with a 500 × magnification. The image was transmitted via the optical channel of the microscope to a video camera and then, via video multiplier, to the PC interface.

Figure 1 presents the IR spectra of the UHMWPE xerogel films filled with talc powder and PAN fibers. It is seen that, with increasing filler concentration, scattering by the filler particles tends to increase (the background of the IR spectrum tends to rise). Also, the absorption bands of the filler itself get more pronounced, especially in the case of the films filled with talc. Indeed, in the IR spectrum of the talc-filled UHMWPE fibers (Fig. 1a), the absorption bands with maxima at 500, 700, and 1000 cm^{-1} corresponding, most probably, to vibrations of the Si–O groups in the talc structure [10] significantly increase in intensity. Figure 2 presents the electron micrographs of films filled with talc and PAN fiber. The filler particles and fibers occurring in the UHMWPE matrix are clearly seen.

Figure 3 presents the extinction coefficient of the IR band at 730 cm^{-1} as a function of the filler type and concentration in the UHMWPE xerogel film. It is seen that the porosity of the xerogel films is strongly influenced by the filler added. For example, samples filled with swollen vermiculite, talc, and PAN fiber exhibit a decrease in the extinction coefficient with increasing filler concentration, which suggests a significant increase in the sample porosity. Similar dependence was also observed for the surface porosity of these samples (Fig. 4b). This can be due to changes in the ultra-high-molecular-weight structure of UHMWPE (spherulite size and shape) whose formation is governed by the crystallization conditions strongly

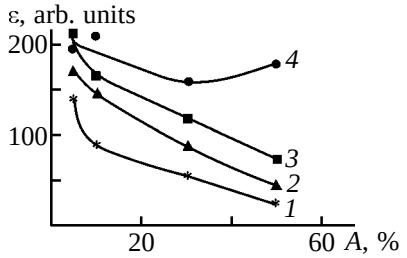

Fig. 3. Extinction coefficient ε of the IR band at 730 cm^{-1} for UHMWPE xerogel films as a function of the degree *A* of filling with (*1*) vermiculite, (*2*) PAN fibers, (*3*) talc, and (*4*) ferrocyanide.

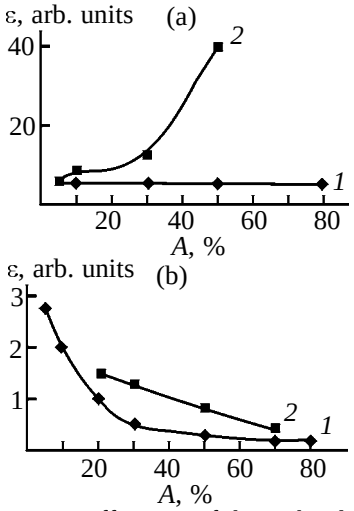

Fig. 4. Extinction coefficient ε of the IR band at 730 cm^{-1} calculated from the ATIR spectra as a function of the degree of filling *A* for UHMWPE xerogel films. Filler: (a): (*1*) talc and (*2*) ferrocyanide; (b): (*1*) vermiculite and (*2*) PAN fiber.

modified by the filler introduced. Low content of the filler favors more rapid and uniform crystallization accompanied by a decrease in the spherulite size and, in some cases, formation of the polymer structure with the highest degree of ordering. The reason for structural ordering is, probably, lower viscosity of the filled UHMWPE solution in crystallization, which is responsible for enhanced mobility of the polymer macromolecules. Further increase of the filler concentration results in formation of an excessive amount of a foreign solid phase. This precludes segmental mobility of the polymer macromolecules near the filler surface, which suppresses crystallization. This is responsible for a larger proportion of a UHMWPE amorphous phase, which yields a looser spherulite structure and, therefore, a filled UHMWPE xerogel film with a higher porosity [11, 12].

Fillers of different nature with differently shaped particles can be differently distributed within the polymer matrix and can differently affect the polymer structure. Probably, specifically these characteristics, rather than the filler concentration, govern the pore structure formation in UHMWPE films. Introduction of ferrocyanide with its spherical particles can favor structure formation, thereby increasing the packing density for the supramolecular UHMWPE structures. Ferrocyanide particles can accumulate in less ordered domains of the polymer and, acting simultaneously as nucleation centers, can exert a structurizing effect on the matrix. As a result, the surface porosity of the UHMWPE films filled with disperse ferrocyanide decreases throughout the concentration range studied, and in the bulk of the sample the porosity remains unchanged at a filler content above 30%.

Introduction of dispersed swollen vermiculite (a highly porous mineral substance) resulted in formation of a more porous structure both in the bulk (Fig. 3) and on the surface (Fig. 4) of the film, as compared to other samples. This is due to a poor wetting power exhibited by the UHMWPE solution with respect to vermiculite, which is responsible for formation of pores acting as stress concentrators and yielding additional defects [13, 14]. Also, the intrinsic pores in the structure of swollen vermiculite will contribute to the total porosity of the filled xerogel films.

A better wetting power of UHMWPE with respect to PAN fibers than to vermiculite, probably, favors formation of a more uniform adsorbed polymer microlayer on the fibrous filler surface. Further adsorption of the polymer molecules increases their packing density, though to a level still sufficient for formation of voids separating the crystallites having anisodiametric structure like spherulite tapes. Crystallites of this type are yielded by polymer crystallization in the presence of fillers with anisometric shape, as is the case of PAN fibers [11, 14]. It should also be taken into account that PAN fibers with their facial ends can also be responsible for formation of a less perfect structure of the UHMWPE films.

With introducing talc into the polymer matrix, the bulk porosity of the UHMWPE films tends to decrease as compared to the samples filled with PAN fibers or vermiculite (Fig. 3). This is probably due to aggregation of its scale-shaped particles at a high content of talc, yielding a continuous network formed by the filler. The continuous network can exert an orienting effect in the interior of the UHMWPE film, which favors formation of a less porous structure in the bulk of the sample than on its surface.

CONCLUSIONS

(1) The bulk and surface porosities of the filled xerogel films of ultra-high-molecular-weight polyethylene were determined by IR absorption and ATIR spectroscopy.

(2) The filler nature, particle shape, and concentration affect the pore structure formation in filled xerogels.

(3) For samples filled with swollen vermiculite, talc, and PAN fibers, by contrast to those filled with ferrocyanide, both the bulk and surface porosites of

filled xerogels of ultra-high-molecular-weight polyethylene tend to significantly increase with the degree of filling increasing from 5 to 80 wt %.

Abstract—The activity of a polyether derived from ethylene and propylene oxides (Laprol 5003) and of *N*,*N*,*N*',*N*'-tetra(hydroxypropyl)ethylenediamine (Lapramol 294) in glycolytic degradation of elastic foamed polyurethane was studied.

Glycolysis is a promising route of chemical degradation of polymers; it is widely used in reprocessing of polyurethane (PU) wastes to obtain secondary raw materials [1–3]. Oxypropylated hydroxyl-containing compounds were suggested previously [4–6] as degrading agents (DAs) for polyurethanes. In this work, we consider the relationship between the structure of these compounds and their reactivity in glycolysis of elastic foamed polyurethane (FPU).

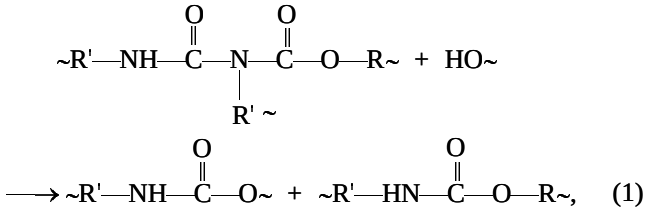
EXPERIMENTAL

Glycolysis experiments were performed with wastes of cold-molded elastic FPU. This material is produced by reaction of toluene diisocyanate with Elastofom A hydroxyl-containing component [7] (Nizhnekamskneftekhim Joint-Stock Company).

As DA we used a polyether based on ethylene and propylene oxides (Laprol 5003, molecular weight M = 5000, functionality with respect to OH groups 3) and *N*,*N*,*N*',*N*'-tetra(hydroxypropyl)ethylenediamine (Lapramol 294, M = 290, functionality with respect to OH groups 4). The weight ratio FPU : DA was 40 : 60, which is optimal for efficient degradation of FPU wastes. Degradation was performed at 180°C with stirring; finely divided waste was continuously added to the DA loaded in advance. The rate of adding FPU crumb was chosen so that it corresponded to the rate of its dissolution. In the course of glycolysis, samples were taken and analyzed for the content of OH groups, c_{OH}, by the chemical method [8]. The moment when the whole amount of FPU was added was considered as the start of degradation.

IR spectroscopic studies were performed with a Bruker Vector 22 Fourier spectrometer (resolution 4 cm^{-1}). Liquid samples were prepared as thin films between KBr plates or as solutions in CCl_4 with the layer thickness of 2 and 5 cm. Computer resolution of the absorption bands was performed using Opus software (Bruker).

Figure 1 shows that the equilibrium in degradation of FPU at the allophanate [reaction (1)], biuret [reaction (2)], and urethane [reaction (3)] groups under the action of DA hydroxy groups is 3 h for Lapramol 294 and 10 h for Laprol 5003. The degrading power of Lapramol is so high that, after certain stabilization, c_{OH} sharply decreases owing to glycolysis of more heat-resistant urea bonds in FPU with the formation of amino groups [reaction (4)]:



(1)

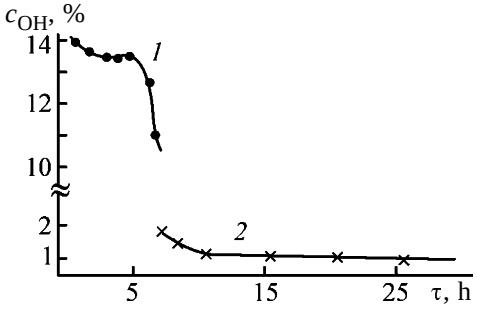


Fig. 1. Concentration of OH groups c_{OH} in products of FPU glycolysis with (*1*) Lapramol 294 and (*2*) Laprol 5003 as a function of time τ at 180°C.

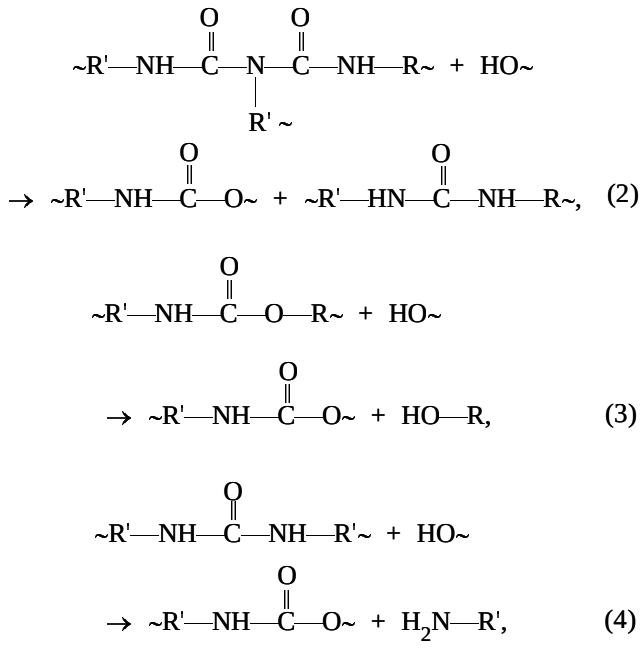
1070-4272/03/7603-0468$25.00



where R is the fragment of Laprol 5003 or Lapramol 2194; R' is the isocyanate fragment; OH~ denotes the hydroxy groups of Laprol 5003 or Lapramol 294.

The strong degrading power of Lapramol 294 is apparently due to the high content of OH groups: the content of OH groups is 23.2 wt % in Lapramol 294 and 1.15 wt % in Laprol 5003. Furthermore, Lapramol contains tertiary nitrogen atoms enhancing the reactivity of the OH group in glycolysis owing to formation of strong hydrogen bonds. This is indicated by the IR spectra of Lapramol 294 (Fig. 2a) and Laprol 5003 (Fig. 2b) in the range of stretching vibrations of hydroxy groups (ν_{OH}, 2200–3800 cm^{-1}). In neat films (curves *1*), broad absorption bands ν_{OH} have maxima at about 3350 (Lapramol 294) and 3480 cm^{-1} (Laprol 5003), characteristic of hydrogen-bonded hydroxyls (ν^b_{OH}). Free (not involved in hydrogen bonding) alcoholic hydroxy groups absorb above 3600 cm^{-1} (ν^f_{OH}). For secondary alcohols, ν^f_{OH} is about 3620 cm^{-1} [9, 10]. The spectra of dilute solutions (Figs. 2a and 2b, curves *2* and *3*), indeed, contain peaks at 3616 cm^{-1}. It is also known that, the stronger the hydrogen bond involving OH group, the greater the low-frequency shift, width, and intensity of the ν^b_{OH} band. The shift $\Delta\nu_{OH} = \nu^b_{OH} - \nu^f_{OH}$ is about 270 cm^{-1} for Lapramol 294 and only about 140 cm^{-1} for Laprol 5003. The corresponding hydrogen bond energies, according to the Iogansen rule, $(\Delta H)^2 = 1.92(\Delta\nu - 40)$ (kJ mol^{-1}) [11], are as follows: ΔH = 21 kJ mol^{-1} (5 kcal mol^{-1}) for Lapramol 294 and 13.9 kJ mol^{-1} (3.3 kcal mol^{-1}) for Laprol 5003. However, contrary to, e.g., amino-

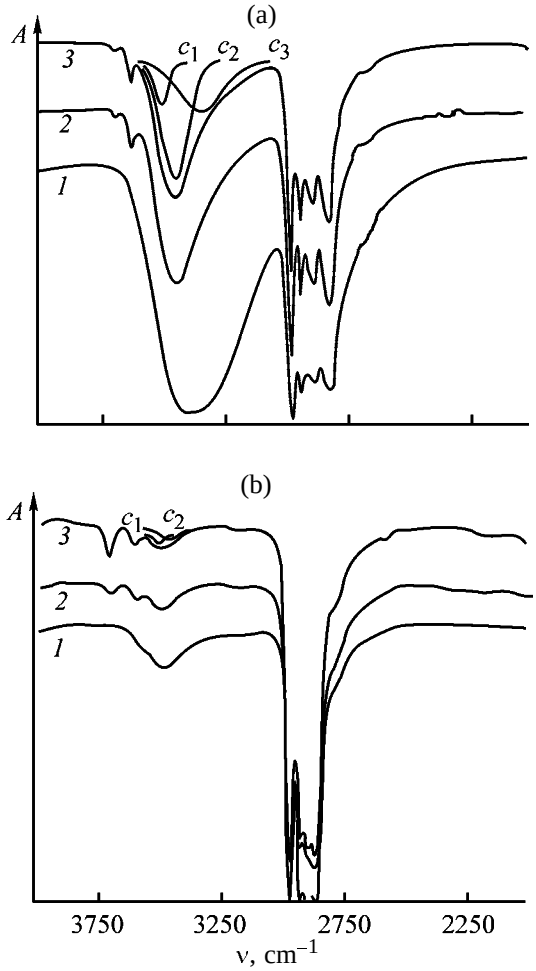


Fig. 2. IR spectra of (a) Lapramol 294 and (b) Laprol 5003: (*A*) transmission and (ν) wave number. (*1*) Thin film between KBr plates; (*2*) ~10^{-4} M solution in CCl_4, cell thickness 2 cm; and (*3*) ~5×10^{-5} M solution in CCl_4, cell thickness 5 cm. (c_1–c_3) Bands obtained by computer resolution of the experimental bands at (a) 3400 and (b) 3500 cm^{-1} into possible components.

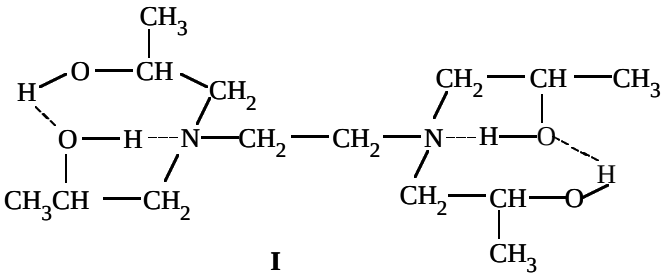
phenols [12], the proton is not fully transferred with formation of a zwitterionic structure. Otherwise the spectra would contain a characteristic absorption band of the N^+H group at appreciably lower frequencies, less than 3000 cm^{-1} [9, 13].

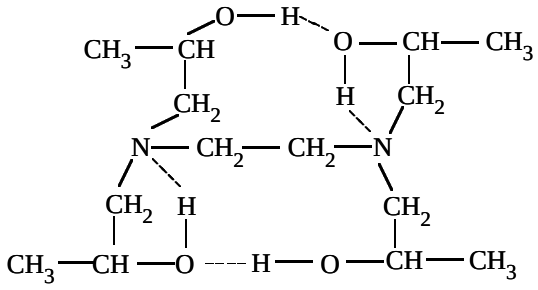
Thus, the IR data show that the OH groups of the Lapramol 294 molecules are considerably more activated than the OH groups in Laprol 5003.

It is well known that tertiary amines form stronger hydrogen bonds than alcohols [9, 10, 14]. Hence, the stronger activation of OH groups in Lapramol, shown above, can be accounted for by formation of OH···N hydrogen bonds. In Laprol, apparently, only OH···O bonds can form. As seen from Figs. 2a and 2b (curves *2* and *3*), in CCl_4 solutions the maximum of the ν^b_{OH}

bands is shifted to higher frequencies. With dilution, their low-frequency component decreases in intensity (Fig. 2a, c_3; Fig. 2b, c_2), and the intensity ratio of the high-frequency components, as shown by band resolution (Fig. 2a, c_1, c_2; Fig. 2b, c_1), is preserved. On this basis, the above-given frequencies ν_{OH}^{b} of neat Lapramol and Laprol, and also the low-frequency components (3331 cm^{-1} for Lapramol and 3467 cm^{-1} for Laprol) of the bands in the solution spectra, disappearing on dilution, should be assigned to intermolecular hydrogen bonds. The peaks at 3493 and 3437 cm^{-1} for Lapramol (Fig. 2a, c_1, c_2) and at 3515 cm^{-1} for Laprol (Fig. 2b, c_1) are retained even in strongly dilute solutions. Therefore, these bands should be assigned to intramolecular hydrogen bonds OH···OH, OH···N, and OH···OH, respectively [14]. The probable molecular structures **I** and **II** of Lapramol with intramolecular hydrogen bonds are shown below:

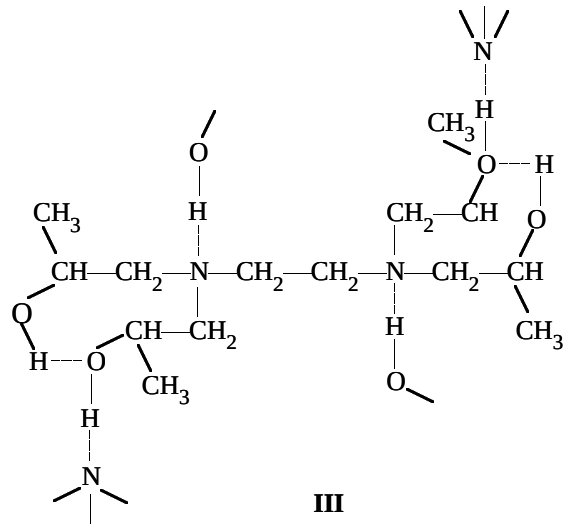


I



II

A cooperation of the OH···O and OH···N intramolecular hydrogen bonds in Lapramol explains the lower hydroxyl vibration frequency in its OH···O fragment, as compared to Laprol. In the condensed phase (neat film), including the reaction mixture, the intramolecular hydrogen bonnds OH···N in structures **I** and **II**, having an unfavorable geometry (five-membered ring), apparently, transform into intermolecular hydrogen bonds OH···N. Correspondingly, in neat Lapramol, structures of type **III** are probable, with the hydroxy groups activated by both weak intramolecular hydrogen bonds OH···O and relatively strong intermolecular hydrogen bonds OH···N:



III

In Laprol, compared to Lapramol, the OH···O hydrogen bonds (both intra- and intermolecular) are less strong, which accounts for the lower activity of Laprol in glycolysis.

CONCLUSIONS

(1) In glycolytic degradation of elastic foamed polyurethane, Lapramol 294 is considerably more active than Laprol 5003.

(2) The increased degrading power of Lapramol 294 is due to the higher content of OH groups and to their activation, mainly by OH···N intermolecular hydrogen bonding. According to IR data, these bonds cause greater shifts of the OH stretching bands and correspondingly have higher enthalpies, as compared to OH···O intermolecular hydrogen bonds in Laprol 5003.

Received April 9, 2002

Abstract—Specific features of thermal degradation of polystyrene–polydimethylsiloxane blends were studied, and the effect of the organosilicon polymeric additive, polydimethylsiloxane, on the heat resistance of polystyrene was examined. The thermal degradation products were analyzed by gas chromatography–mass spectrometry. A mechanism of the joint pyrolysis was suggested.

It is well known that polymer blends differ in the physical and mechanical properties from their components taken separately. Specific features of thermal degradation of polymer blends are discussed in numerous papers [1, 2]. Richard and Salter studied thermal degradation of polystyrene (PS) blended with poly-α-methylstyrene (P-α-MS) [3]. They explained the increased yield of styrene in the process by the capability of P-α-MS radicals to initiate chain propagation in depolymerization.

Mizutani *et al.* [4] suggested that degradation of polypropylene accelerates in the presence of vinyl polymers such as PS and polymethyl methacrylate (PMMA) [4]. In the course of thermal degradation, these polymers are inserted into the polypropylene chain to form block copolymers. The mechanism of their formation involves the reaction of the vinyl polymeric radical with the polypropylene chain.

Gardner *et al.* [5] studied the rate of polystyrene and P-α-MS degradation in the presence of polyacrylates. They found that the degradation rates of the blends considerably differ from those of the polymers taken separately.

Grassie *et al.* [6] compared the degradation behavior of PMMA–PS blends and methyl methacrylate (MMA)–styrene copolymers and revealed substantial differences in their behavior.

McNeill *et al.* [7–9] studied thermal degradation of various polymer blends. They suggested that the course of degradation is mainly influenced by two processes: migration of small molecules and migration of radicals. They also suggested that, in blends of polyvinyl chloride (PVC) with such polymers as PMMA, PS, and P-α-MS, the low degradation temperature of the second polymer promotes (induces) formation of $Cl^{\bullet}$ radicals.

In turn, Bate and Lehrle estimated the rate and mechanistic features of degradation of polymer blends (PMMA–PS, PMMA–HDPE, PMMA–PVC) as influenced by the following factors [10]: compatibility of polymers, physical parameters of the system (diffusion, viscosity), and cross-linking reactions. Their results show that heterogeneous blends mainly degrade within the component phases, but cross-linking due to interphase migration of small radicals or molecules is also possible. For the examined systems, cross-linking was a secondary process in most cases. It was shown that the observed rate of formation of MMA monomer in heterogeneous blends only slightly differs from the rate of its formation in a homogeneous blend. Pyrolysis of homogeneous blends involves mechanisms that can yield cross-linking products. However, it was shown that the capability to form major pyrolysis products varies significantly. These results were interpreted from the viewpoint of the thermal degradation mechanism. In partituclar, additional stages of thermal degradation were considered: cross termnation in the course of propagation of depolymerization chains results in stabilization of macroradicals; intermolecular transfer of the hydrogen atom in the course of propagation of depolymerization chains promotes the degradation of the first component and stabilizes the second component; diffusion limitations to intramolecular transfer are manifested in the case when one of the components acts as an "inert diluent," and this effect decreases the chain termination rate in depolymerization of the second component; if both components of a homogeneous blend degrade independently

1070-4272/03/7603-0472$25.00

of each other, the cross termination does not noticeably affect the overall degradation rate.

In this work, we studied the heat resistance of PS–polydimethylsiloxane (PDMS) blends, the specific features of the thermal degradation mechanism, and the possibility of controlling the heat resistance of polymeric materials by mechanical blending.

EXPERIMENTAL

The starting polymers were commercial products: PS (Aldrich), M_w 280 000, T_g 100°C; PDMS (Wacker), M_w 10^7, methyl terminal groups. Polymer blends were prepared with a laboratory extruder at 200°C.

Pyrolysis of PS, PDMS, and PS–PDMS blend (80 : 20 by weight) was performed at 300, 400, 500, 600, 700, and 800°C in a tubular cell in an air flow (flow rate about 30 ml min^{-1}). Gaseous products were condensed in a glass trap with hexane (4 ml), cooled to 0°C.

Thermogravimetric analysis (TGA) of the polymers and their blends was performed on a 950Q deriovatograph in nitrogen and in air (flow rate 100 ml min^{-1}).

Pyrolysis products were analyzed with a Tsvet 500-M gas chromatograph equipped with an electron capture detector and a glass column (4 m long, 3 mm i.d.). The stationary phase was OV-17 phenylmethylsilicone. The column and injector temperatures were 230°C, and the detector temperature, 290°C. The carrier gas was N_2 (25 ml min^{-1}). The sample volume was 2 μl.

The GC–MS analysis was performed on a Varian 3300 gas chromatograph equipped with a Finnigan MAT ITD-800 mass-spectrometric detector (ion trap). Separation was performed with a quartz capillary column (30 m long, 0.32 mm i.d.) coated with DB-5 phenylmethylsilicone (film thickness 0.25 μm). The column temperature was raised from 50 to 270°C at a rate of 10 deg min^{-1}; the injector temperature was 200°C. The carrier gas was helium (inlet pressure 0.1 MPa). Samples (1 μl) were introduced without flow division; the time before the start of purging of the sample inlet unit was 30 s.

The mass spectra were taken with ionization by electron impact (70 eV). The scanning rate was one mass spectrum per second, and the scanning range, 40–650 amu.

The kinetics of thermal degradation of PS, PDMS, and their blends was studied by dynamic TGA. The differential method (Kissinger) was used to determine the activation energy and preexponential term for thermal degradation of blends [11].

Table 1. Experimental values of the activation energy E_a and preexponential term A for thermal degradation of PS, PDMS, and their blend (heating rate 1–10 deg min^{-1})

Polymer	E_a, kcal mol^{-1}	A, min^{-1}
PDMS	26.8	0.5×10^6
PS	36.0	0.7×10^{10}
PS in PS–PDMS blend (80 : 20)	46.0	1.0×10^{11}
PDMS in PS–PDMS blend (80 : 20)	20.2	0.37×10^6

Using the equation

$$A/r = E/RT_{max}^2 \exp(E/RT_{max}),$$

where A is the preexponential term; r, heating rate, deg min^{-1}; E, activation energy; R, universal gas constant; and T_{max}, temperature corresponding to the maximal reaction rate [11], we determined the apparent activation energies and preexponential terms (Table 1).

We found that, for PS as a component of the blend, the activation energy and preexponential term for thermal degradation in a nitrogen flow are 30% higher than for pure PS. At the same time, for PDMS as a component of the blend, these parameters are 25% lower than for pure PDMS [12, 13].

The products of pyrolysis of the polystyrene component of the blend diffuse through the phase boundary and can react with the polysiloxane component.

PDMS, apparently, behaves as an inert component (diluent), decelerating the chain termination reactions with macroradicals generated by PS degradation. This stabilizes PS by intermacromolecular recombination yielding products containing styrene and siloxane fragments (cross products).

Usually dilution decelerates the chain termination reactions and increases the overall rate of thermal degradation of the PS component. As a result, the apparent activation energy of degradation of the PS component can decrease. However, actually the PS component is, on the contrary, stabilized, which can be accounted for by intermacromolecular reaction of PS with PDMS, resulting in stabilization of PS as the component degrading first.

For the second component, PDMS, the activation energy and preexponential term are 25% lower than for pure PDMS [13]. This means that the second com-

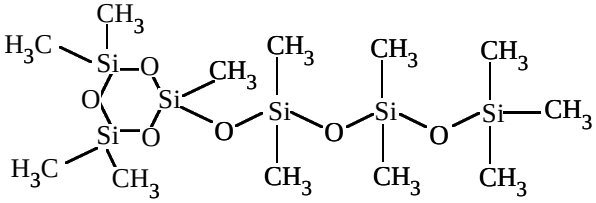
ponent becomes less heat-resistant in the blend, as compared to the pure state.

After formation of the cross-linking products in the course of pyrolysis of this polymer blend was proved by GC–MS analysis, we explained the behavior of the blend by kinetic factors. In the course of PDMS degradation, intermacromolecular reaction (recombination) terminates radical depolymerization of PS. At the same time, thermal degradation of the PDMS component is initiated by formation of PS radical fragments, which is responsible for a decrease in the PDMS heat resistance in the blend.

The chromatograms and mass spectra show that the major pyrolysis product of pure PS at 300, 400, 500, 600, 700, and 800°C is styrene (56.2, 75.6, 67.1, 58.0, 58.3, and 51.9%, respectively). Apparently, radical depolymerization initiated with oxygen remains the major pathway of PS degradation in this temperature range [14].

At 300°C, the major products of PS pyrolysis are styrene (56.2%) and benzaldehyde (30.1%); α-methylsrtyrene (2.6%) and acetophenone (2.5%) are also detected; a few other products are formed in trace amounts. At 400°C, the number of degradation products increases; styrene remains the major product (75.6%), with the other most intense peaks in the chromatogram belonging to toluene (8.3%), ethylbenzene (2.2%), benzaldehyde (3.5%), α-methylstyrene (5.4%), and styrene oligomer (1.5%). At 500°C, the number of pyrolysis products increases further; styrene is still the major product (67.1%), with the other most intense peaks corresponding to toluene (3.2%), benzaldehyde (7.2%), α-methylstyrene (4.2%), benzacetaldehyde (4.6%), and styrene oligomer (2.9%). The minor products are ethylbenzene (0.9%), phenol (0.5%), β-methylstyrene (0.9%), acetophenone (1.3%), diphenylethane (0.9%), 1,3-diphenylpropane (0.8%), and styrene pentamer (0.8%). At 600°C, the number of pyrolysis products increases further. Along with the above-mentioned products, compounds with fused benzene rings [benzofuran (0.3%) and naphthalene (0.6%)] and biphenyl (0.1%) are formed. At 700 and 800°C, the amount of compounds with fused benzene rings increases, whereas such compounds as phenol, benzaldehyde, diphenylpropane, styrene pentamer, and others disappear. The results are given in Table 2.

In pyrolysis of PDMS, the major decomposition products are oligomers (cyclic and linear methylsiloxanes). The major degradation product is octamethylcyclotetrasiloxane (OMCTS); the other most intense peaks in the chromatograms correspond to hexamethylcyclotrisiloxane (HMCTS) and decamethylcyclopentasiloxane (DMCPS). With increasing temperature, higher-molecular-weight cyclosiloxane oligomers appear, with their amount increasing: dodecamethylcyclohexasiloxane (DdMCHS), tetradecamethylcycloheptasiloxane (TdMCHpS), and tetracosamethylcyclododecasiloxane (TcMCDdS), as described in [12]. It is known that depolymerization of PDMS occurs by the molecular mechanism [12]. At 400°C and higher temperatures, along with HMCTS, we identified one more compound, 1,3,3,5,5-pentamethylcyclotrisiloxane-1-heptamethylpentasiloxane:



The characteristic peaks in the mass spectrum of this compound are *m*/*z* 73, 102, 193, 341, and 429. The products of thermal degradation of PDMS are listed in Table 3.

Analysis of the pyrolysis products formed from the PS–PDMS blend revealed the presence of several new products along with the degradation products of both components. At 300°C, the benzaldehyde content is abnormally high (42.9%), whereas the styrene content is as low as 13%, and the content of PDMS degradation products is insignificant. The pyrolysis products formed at 400 and 500°C have similar composition, being mixtures of degradation products of PS (toluene, 2.0 and 6.2%; ethylbenzene, 0.8 and 1.6%; styrene, 61.7 and 59.8%; benzaldehyde, 7.4 and 3.9%; α-methylstyrene, 4.4 and 3.0%, respectively) and PDMS (HMCTS, 3.7 and 6.1%; OMCTS, 3.1 and 5.0%; DMCPS, 6.0 and 7.8%; DdMCHS, 0.8 and 0.9%, respectively). At 600°C, compounds with fused benzene rings (benzofuran, 0.7%; naphthalene, 0.5%; phenanthrene, 0.1%) and biphenyl (0.2%) are formed. At this temperature, we detected two new compounds absent in pyrolysis products of PS and PDMS taken separately (retention times 8.5 and 11.0 min). The first compound, apparently formed by the cross reaction (termination) of two macroradical fragments of the PS and PDMS chains, was identified as 3-phenyl-1-(3',3',5',5',7',7',9',9'-octamethylcyclopentasiloxy)butane

Its mass spectrum is shown in Fig. 1. The second compound is probably the PS degradation product; its content in samples is low (≤0.5%), which complicates its identification. In pyrolysis at 700°C, the PDMS degradation products prevail; the contribution of HMCTS, OMCTS, and DMCPS grows (39.1, 27.4, and 12.3%, respectively), and the content of higher-molecular-weight products decreases. At 800°C, compounds with fused benzene rings are formed in increased amounts. At this temperature, a new product with the retention time of 6.33 min was detected; this product is apparently formed by the reaction of radical fragments of PS and PDMS degradation (cross reaction). The compound was identified as phenyl(3',3',5',5',7',7'-hexamethylcyclotetrasiloxy)propane

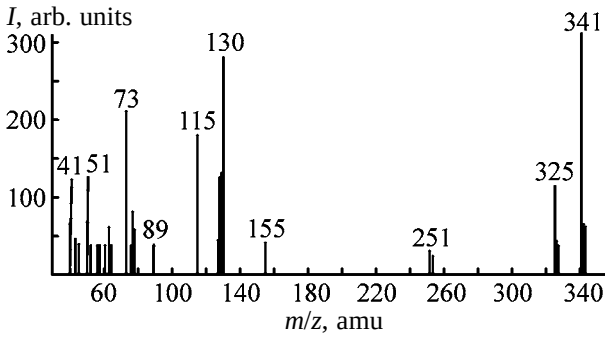

Fig. 1. Mass spectrum of 3-phenyl-1-(3',3',5',5',7',7',9',9'-octamethylcyclopentasiloxy)butane. (*I*) Intensity and (*m*/*z*) weight; the same for Figs. 2 and 6.

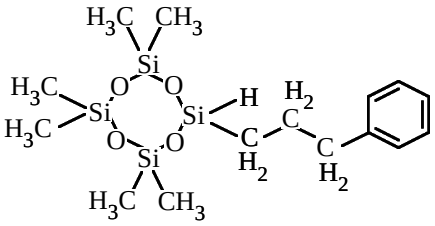
or



Its mass spectrum is shown in Fig. 2. The products of thermal oxidative degradation of the PS–PDMS blend are listed in Table 4.

A brief scheme illustrating the radical chain kinetic model of thermal degradation of PS in the presence of PDMS fragments was presented previously [15]. In particular, the main process includes chain initiation

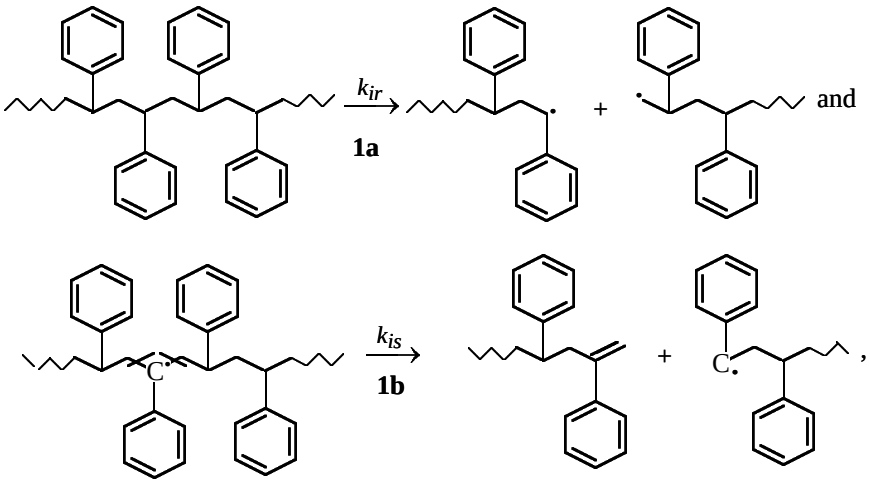
with formation of primary radical (initiation at terminal groups, *e*)

$$P_n \xrightarrow{k_{ie}} R^{\bullet\bullet}_{n-1} + R^{\bullet}_1, \quad (1)$$

random initiation (*r*),

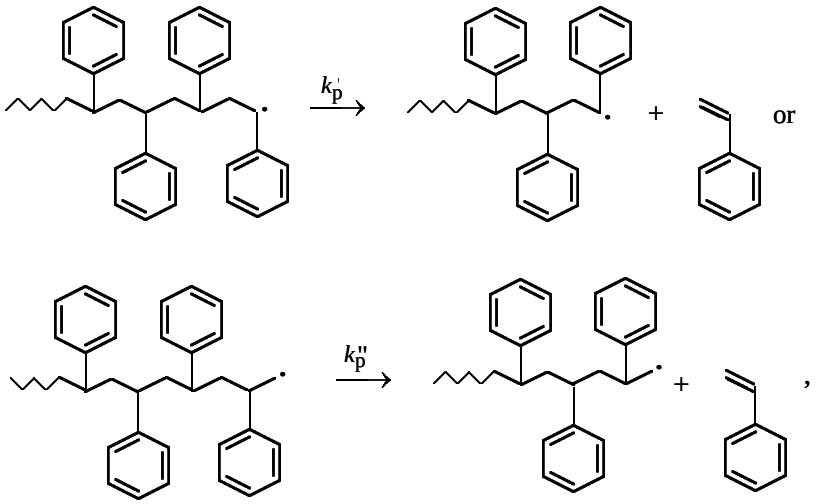
$$P_n \xrightarrow{k_{ir}} R^{\bullet}_m + R^{\bullet}_{n-m},$$

β-cleavage



chain propagation due to intramolecular transfer

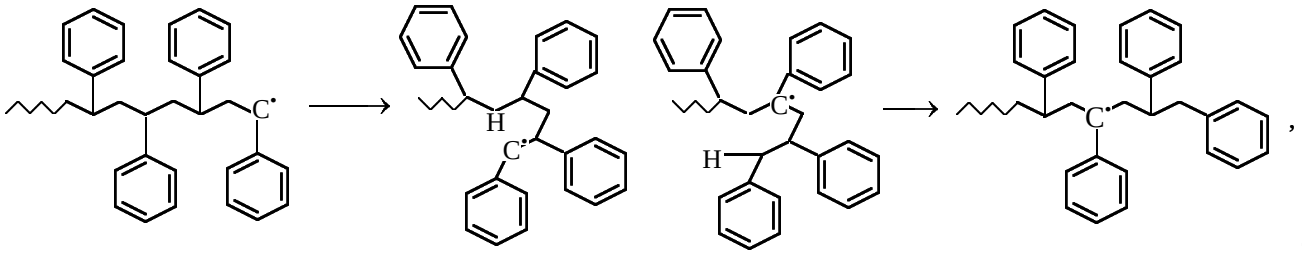
$$R^{\bullet}_n \xrightarrow{k_p} R^{\bullet}_{n-1} + P_1 \quad \text{(monomer, M)}, \quad (2)$$



chain propagation due to intermolecular reaction

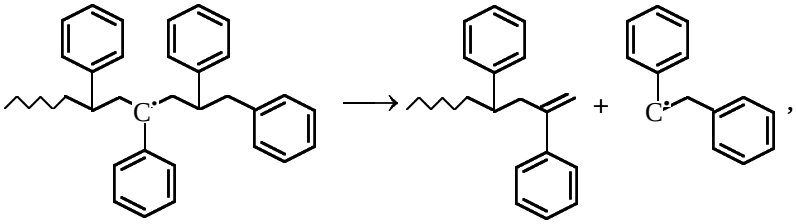
$$R^{\bullet}_n + P_s \longrightarrow R^{\bullet}_{s-r} + P_n + P_s, \quad (3)$$

intramolecular transfer (back-bitting)



(4)

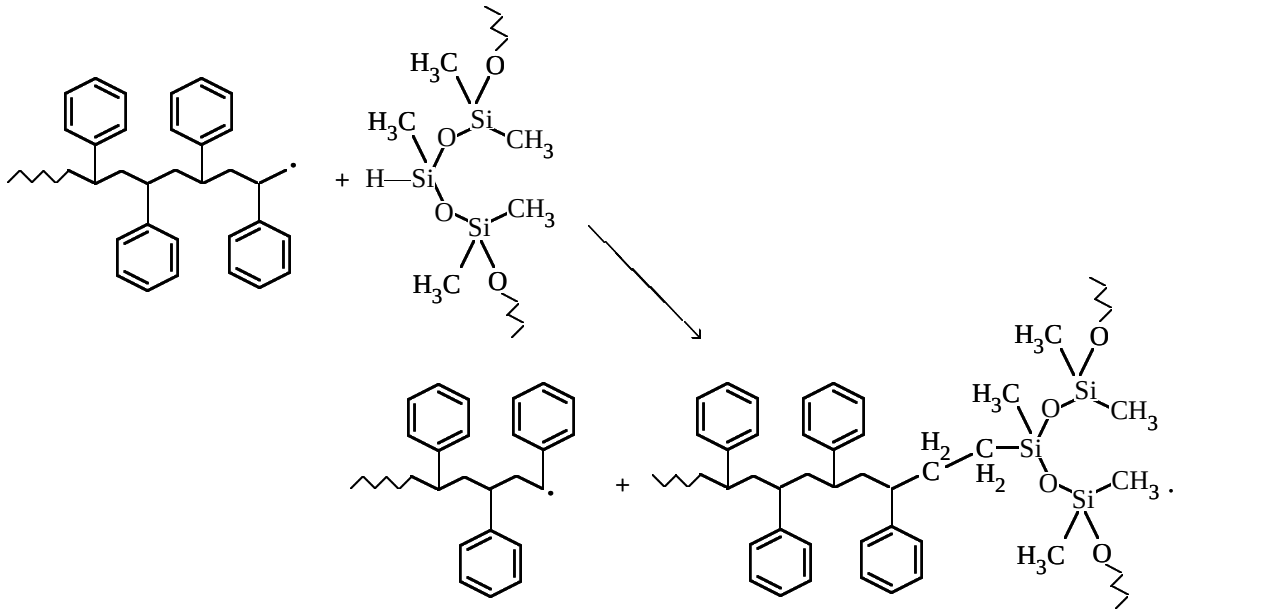
primary and(or) secondary radical termination and β-cleavage



(5)

intermolecular reaction of PS and PDMS chains (cross termination), yielding cross-linking products in thermal degradation of the PS–PDMS blend

$$R_n^{\bullet} + \text{PDMS} \xrightarrow{k'_{tr}} R_{n-m}^{\bullet} + R_m\text{–PDMS}, \quad (6)$$



Chain termination stage: first-order

$$R_n^{\bullet} \xrightarrow{k_{tr,1}} P_n, \quad (7)$$

second-order

$$R_n^{\bullet} + R_m^{\bullet} \begin{cases} \nearrow P_n + P_m & \text{(disproportionation)} \\ \searrow P_{n+m} & \text{(recombination).} \end{cases}$$

Figures 3–5 show the differences in thermal degradation of PS, PDMS, and their blend on heating at a rate of 10 deg min^{-1} in nitrogen and in air. The effect of oxygen on the degradation is clealry seen. Thermal degradation of PDMS was studied in [12]. The two-stage pattern of PDMS degradation can be explained in terms of the mechanism involving oxygen-catalyzed depolymerization at the terminal groups, leading to random termination and cross oxidation processes

[12]. The limiting stage of this process is eventually diffusion and vaporization of monomeric fragments.

Comparison of the TG and DTG curves suggests that the same PS component in a blend with PDMS degrades at a higher temperature. At the same time, PDMS as a component of the blend tends to degrade at lower temperatures. This effect is observed only when thermal degradation is performed in air.

In the PS–PDMS blend, dissolution of PS (major component) in PDMS results in stabilization of PS and destabilization of PDMS. This can be explained from the viewpoint of interpolymeric recombination. Two degradation products, phenyl(3',3',5',5',7',7'-hexamethylcyclotetrasiloxy)propane and 3-phenyl-1-(3',3',5',5',7',7',9',9'-octamethylcyclopentasiloxy)butane, were interpreted as products of interpolymeric recombination cross-linking, which may accelerate depolymerization of PDMS via radical initiation by PS fragments [13]. The possible scheme of formation of 3-phenyl-1-(3',3',5',5',7',7',9',9'-octamethylcyclopentasiloxy)butane as the product of interpolymeric cross-linking is shown below.

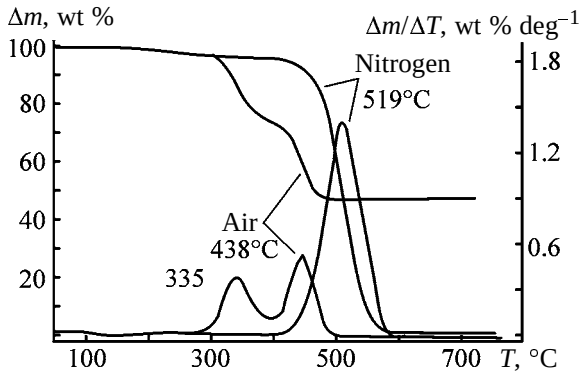

Fig. 3. TG and DTG curves of PDMS samples in nitrogen and in air. Heating rate 10 deg min^{-1}; the same for Figs. 4 and 5. (Δm) Weight loss, ($\Delta m/\Delta T$) weight loss per unit variation of temperature, and (T) temperature; the same for Figs. 4 and 5.

CONCLUSIONS

(1) Kinetic features of thermal degradation of a polystyrene–polydimethylsiloxane blend were studied. The organosilicon additive affects the heat resistance of polystyrene.

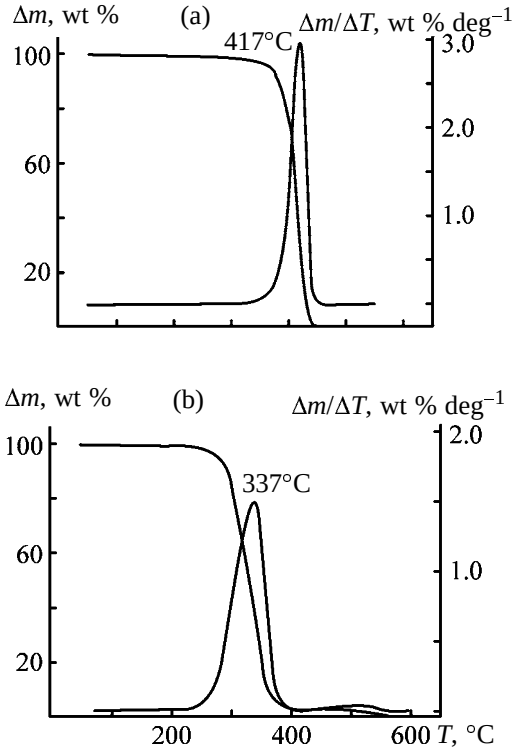

Fig. 4. TG and DTG curves of PS samples (a) in nitrogen and (b) in air.

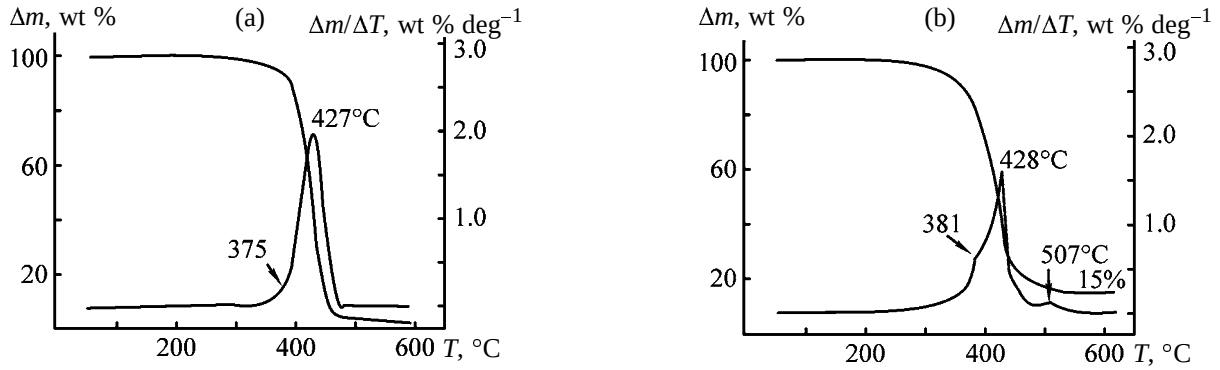

Fig. 5. TG and DTG curves of samples of 80 : 20 PS–PDMS blend, taken (a) in nitrogen and (b) in air.

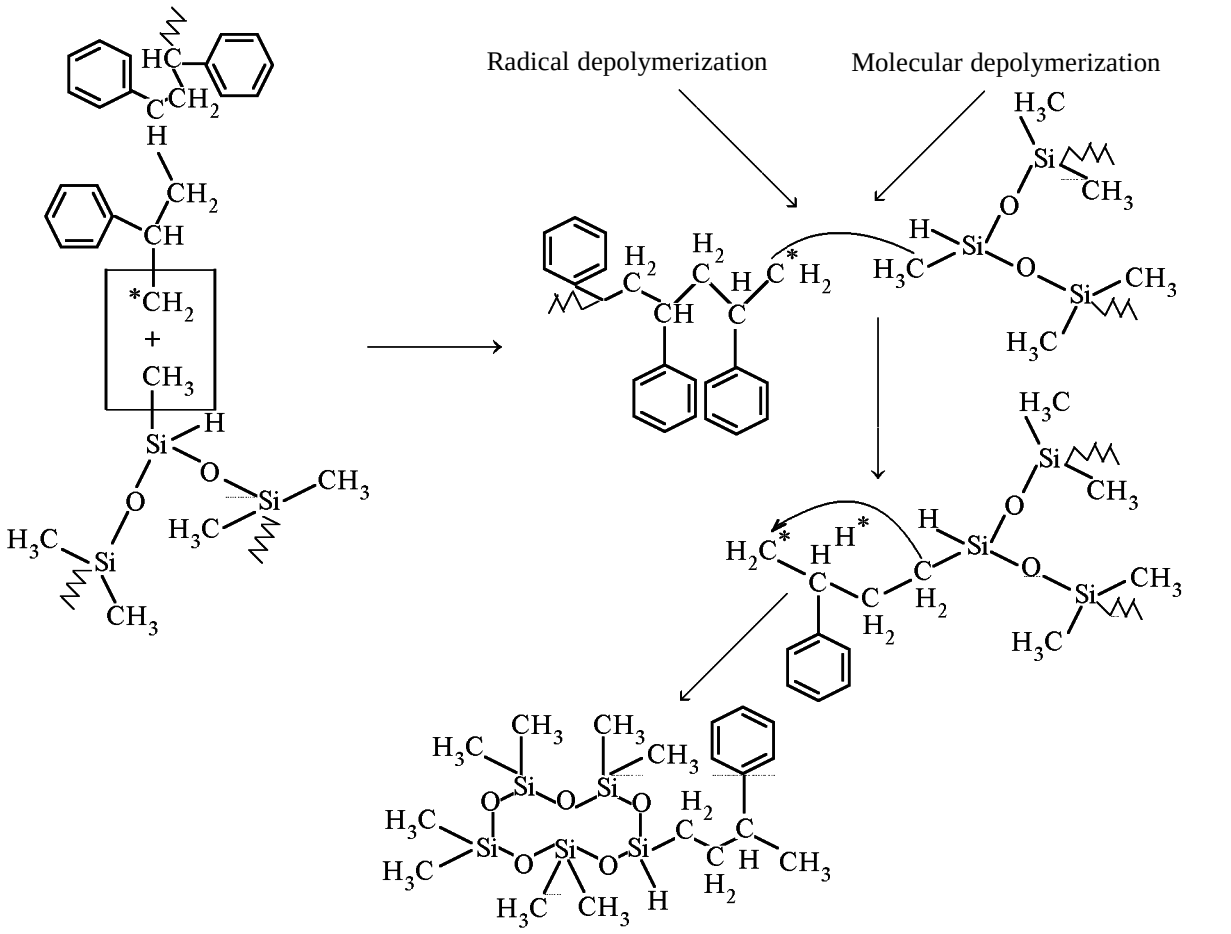

(2) In a blend with polydimethylsiloxane, polystyrene, which is less heat-resistant than polydimethylsiloxane, degrades at higher temperatures compared to pure polystyrene, i.e., it is stabilized. The stabilization in this stage is mainly due to kinetic factors. On the contrary, the subsequent stage of polydimethylsiloxane degradation starts at lower temperatures. The thermal destabilization of the system in this stage is due to cross reactions of styrene and dimethylsiloxane fragments.

(3) In the products of pyrolysis of the polystyrene–

polydimethylsiloxane blend, trace amounts of phenyl-(3',3',5',5',7',7'-hexamethylcyclotetrasiloxy)propane and 3-phenyl-1-(3',3',5',5',7',7',9',9'-octamethylcyclopentasiloxy)butane were detected.

(4) A possible mechanism of pyrolysis of the polystyrene–polydimethylsiloxane blend was suggested.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Process Factors on the Structure of Urea–Formaldehyde Resin

V. Z. Maslosh, V. V. Kotova, and O. V. Maslosh

Institute of Applied Chemistry, Ministry of Education and Science of the Ukraine, Rubezhnoe, Lugansk oblast, Ukraine

Received March 25, 2002

Abstract—The influence of preparation conditions on the structure of low-toxic urea–formaldehyde resins and the possibility of preparing resins of linear-branched structure and resins containing urone rings were examined.

Urea–formaldehyde resins (UFRs) are produced in large amounts and are widely used in various branches of industry depending on the properties. The reactions involved in production of UFRs have been comprehensively studied [1–3], their order and constants have been determined [4, 5], and the structure of the reaction products of urea and formaldehyde was studied in relation to the reaction conditions [6–10]. However, the relationship between the process factors and UFR structure virtually was not examined.

The reaction of urea with formaldehyde can yield a number of products whose content depends on the process factors: component molar ratio, pH, temperature, etc.

The complex structure of UFRs is also due to the high functionality of urea and formaldehyde (4 and 2, respectively), making possible formation of a large set of structures [6].

Our goal was to study the structure of low-toxic UFRs in relation to the preparation conditions. Exhaustive structural information on these materials is furnished by ^{13}C NMR spectroscopy [11].

EXPERIMENTAL

Urea–formaldehyde resins were prepared at various pH values in steps at urea : formaldehyde molar ratios of 1 : 4, 1 : 1.45, and 1 : 1.33 by two procedures.

In the first procedure, urea in each step was added in a single portion (see table, run nos. 1–4). Step I: A 250-ml three-necked flask equipped with a stirrer, a thermometer, and a condenser was charged with 58.8 g of Formalin and 29.4 g of urea; pH 9.5–10 was adjusted with NaOH (or pH 4.0–4.5, with $KHSO_4$). The stirrer was switched on, and the mixture was heated to 82–85°C and kept at this temperature for 60–90 min. Step II: $KHSO_4$ was added to adjust pH 4.0–4.5 (or NaOH, to adjust pH 9.5–10), and the mixture was kept at 82–85°C for 30–120 min. Step III: the second 51.7-g portion of urea was added, and the mixture (pH 9.5–10) was kept at 82–85°C for 120 min. Step IV: the third 7.3-g portion of urea was added, and the mixture (pH 9.5–10) was kept at 82–85°C for 90 min. Then it was cooled to 40°C, and the UFR was unloaded.

The second procedure involved addition of urea in divided portions (see table, run nos. 5–7). Step I: A 250-ml three-necked flask equipped with a stirrer, a thermometer, and a condenser was charged with 58.8 g of Formalin, and urea was added in 2.67-g portions at 10-min intervals (a total of 11 portions, pH 10, 82–85°C, total time 120 min). The total amount of the urea added was 29.4 g. After adding the 11th portion of urea, the mixture was kept for 10 min. Step II: $KHSO_4$ was added to pH 4.0–4.5 (or pH 2), and the mixture was kept for 30 min (or for 60 min at pH 9.5–10). Step III: NaOH was added to adjust pH 9.5–10, and 11 4.7-g portions of urea were added in 10-min intervals. After adding the 11th portion, the mixture was kept for 10 min. Step IV: At pH 9.5–10, nine 0.81-g portions of urea were added at 10-min intervals; the mixture was kept for 10–20 min and cooled to 40°C, after which the UFR was unloaded.

The ^{13}C NMR spectra were recorded with a Varian Gemini spectrometer (digital resolution 0.25 Hz) in a 1 : 3 water–DMSO mixture at room temperature. Samples were taken after completion of each step. The signals were assigned according to [11].

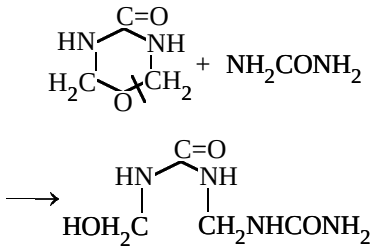
Polycondensation of urea and formaldehyde in a 1 : 4 ratio in alkaline solution at 82–85°C for 90 min yields, even in the first step, methylol groups at the secondary and tertiary nitrogen atoms (signals *p* and *n*), and also methylene ether groups at secondary nitrogen atoms (*o*) and methylenemethoxy groups at tertiary nitrogen atoms (*k*). Signals belonging to the middle groups in the polymethylene oxide chain (*h*), methylene glycol (*j*), and monosubstituted urea (*b*) are also detected.

Thus, in step I of base condensation, products of linear-branched structure are formed (see table, run no. 4, and figure, spectrum *1*). At longer (120 min) reaction time, urone rings are formed (155 ppm). However, these fragments are unstable and disappear upon further heating.

The urone rings and middle groups of the polymethylene oxide chain disappear upon loading additional portions of urea to the urea : formaldehyde molar ratio of 1 : 1.45 and 1 : 1.33 (alkaline solution). This is accompanied by formation of methylene ether groups at tertiary nitrogen atoms (*i*) and di- and trisubstituted ureas (*d*, *q*). Presumably, these processes follow the scheme



As the reaction in alkaline solution is performed further, the signals of methylene glycol and urea fully disappear, with appearance of the signals of methylenemethoxy groups at tertiary (*k*) and secondary (*m*) nitrogen atoms, methylene ether groups, disubstituted urea derivatives (*d*), methylol groups at secondary nitrogen atoms (*p*), and methylene bridges between secondary and tertiary nitrogen atoms (*v*, *g*). The final UFR obtained under base condensation conditions (see table, run no. 4, and figure, spectrum *2*) has mostly linear structure with small branchings.

When UFR is prepared under base condensation

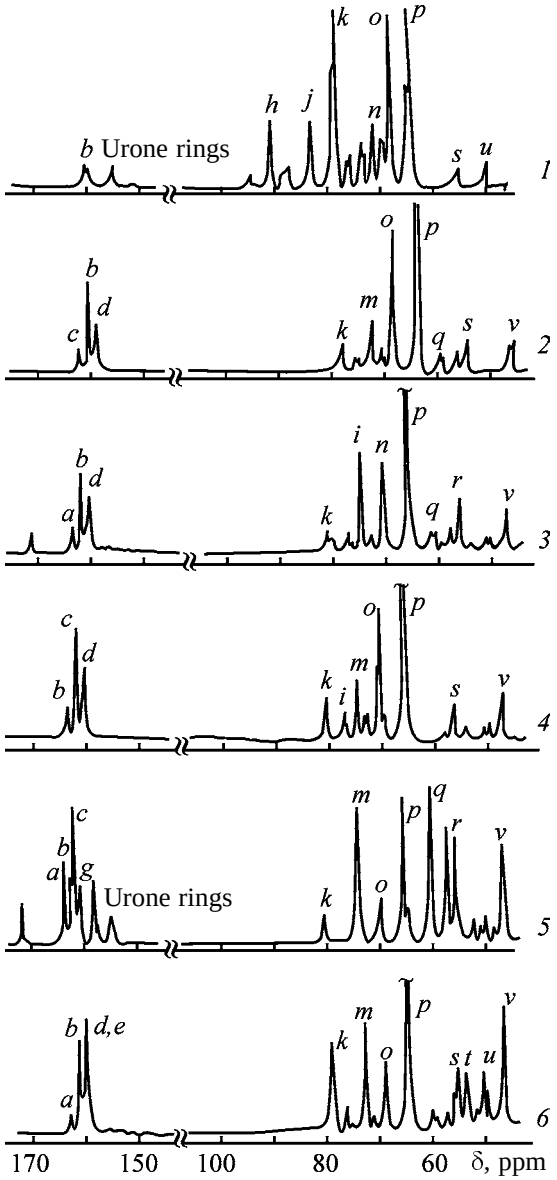
conditions with the addition of urea in divided portions (see table, run no. 7), the products are similar in structure to those obtained in run no. 4 (see table and spectrum *2* in figure) with the addition of urea in single portions, with the only difference that, in the former case, methylenemethoxy, methylol, and methylene ether groups at tertiary nitrogen atoms (*r*, *n*, *i*) prevail, whereas in the latter case these groups are chiefly located at secondary nitrogen atoms.

These data show that, under conditions of base condensation with the addition of urea in divided portions (see table, run no. 7, and figure, spectrum *3*), more branched UFR is formed. This result is consistent with that reported in [6].

Urea–formaldehyde resins prepared at varied pH in steps (see table, run nos. 1–3, 5, 6) exhibit certain specific structural features. Polycondensation of urea and formaldehyde with the addition of urea in single portions and at pH 4–4.5 in step II (see table, run no. 2) yields products containing methylenemethoxy groups at tertiary nitrogen atoms (*r*, *k*) and terminal groups of the methylene oxide chain (*j*), along with methylol (*p*) and methoxy (*m*) groups at secondary nitrogen atoms. Urone rings (155 ppm) are also formed in this step. However, addition of the second portion of urea in alkaline solution in step III results in their disappearance. The final UFR obtained in run no. 2 with the addition of urea in single portions is a product of linear-branched structure consisting of mono-, di-, and trisubstituted urea derivatives (*b*, *c*, *d*, *q*) containing methylene ether (*j*), methylenemethoxy (*k*), and methylol (*n*) groups at tertiary nitrogen atoms, and also methylene bridges between two secondary nitrogen atoms (*v*) (see figure, spectrum *4*).

Preparation of UFR under the similar conditions but with the addition of urea in divided portions (see table, run no. 5) yields products of a more branched structure. Along with the above-mentioned groups, these resins contain methylene bridges between two tertiary nitrogen atoms (*q*), and also methylene ether and methylmethoxy groups at tertiary nitrogen atoms (*i*, *r*). Also the resins contain urone rings, which are formed in step I and are preserved upon acidification (to pH 4–4.5 or 2 in step II) and further addition of urea in alkaline solution; these rings are preserved even in the final product (see table, run nos. 5 and 6, and figure, spectrum *5*).

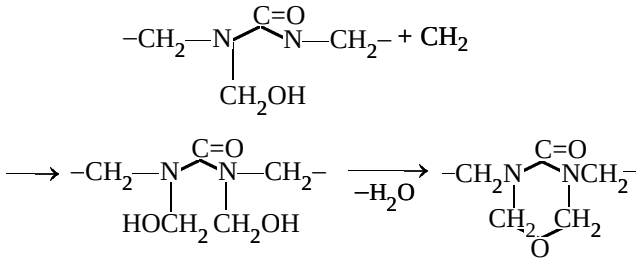
Thus, synthesis at varied pH and addition of urea in divided portions allows preparation of UFR of a branched structure, containing urone rings. The possibility of formation of stable urone rings in both acidic and alkaline solutions is also confirmed in other papers [12, 13].



^{13}C NMR spectra of reaction products of urea and formaldehyde. (δ) Chemical shift. (*1*) step I, urea : formaldehyde 1 : 4, base condensation, urea added in single portions (run no. 4); (*2*) base condensation, final product, urea added in single portions (run no. 4); (*3*) base condensation, final product, urea added in divided portions (run no. 7); (*4*) final product obtained at varied pH and addition of urea in single portions (run no. 2); (*5*) final product obtained at varied pH and addition of urea in divided portions (run no. 6); and (*6*) final product obtained at addition of urea in single portions (run no. 1). For signal assignments, see text.

The presence of a large excess of formaldehyde is one of the necessary conditions for the formation of urone rings [7]; in our case, this is provided by the

addition of urea in divided portions in steps. Urone rings are presumably formed by intramolecular condensation of urea methylol derivatives or by their condensation with amino and imino groups. The reaction of formaldehyde with an imino group to form urone rings [14] is also possible:



However, the UFR prepared with the addition of urea in divided portions also contains free urea (*a*).

The stronger acidity (pH 2) in step II of UFR preparation with the addition of urea in single portions (see table, run no. 3) had no appreciable effect on the structure of the final product. The structures of UFRs prepared in run nos. 2 and 3 (see table and figure, spectrum *4*) are, on the whole, identical.

Preparation of UFR with the addition of urea in single portions, acidic medium (pH 4–4.5) in step I, and alkaline medium in the subsequent steps (see table, run nol. 1) yields the resin of a linear-branched structure containing as the major structural fragments the methylene bridges between two secondary nitrogen atoms (*v*) and between secondary and tertiary nitrogen atoms (*t*). Along with methylene ether (*o*) and methylenemethoxy (*m*) groups at secondary and tertiary nitrogen atoms (*k*, *s*), the resins also contain mono- and disubstituted ureas (*b*, *d*, *e*; see table, run no. 1, and figure, spectrum *5*). Methylene bridges (*v*, *t*) are formed already in step I.

CONCLUSIONS

By varying the process parameters, it is possible to obtain urea–formaldehyde resins of both linear and branched structures with various contents of formaldehyde, and also resins containing urone rings.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sealants Based on Oligodiene Urethane Epoxides

Kazan State Technological University, Kazan, Tatarstan, Russia

Received March 7, 2000

Abstract—Sealants in which oligodiene urethane epoxide is used as polymeric base were studied. Sulfur-containing oligomers were used for additional cross-linking via double bonds. The reaction with a polysulfide oligomer at the terminal functional groups was studied taking into account the region of thermodynamic compatibility of the reactive oligomers. Application fields were suggested for the sealants developed.

Advances in chemistry and chemical technology of oligomers open the possibilities of widely using urethane epoxy oligomers as a polymeric base for sealing compounds. Oligodiene urethane epoxide (ODUE) of PDI–ZAK brand [TU (Technical Specification) 38-10-34-10–78] based on butadiene and isoprene with terminal urethane epoxy groups exhibits good cohesion and adhesion properties and is cured with amines. In principle, any of the known mechanisms of polymerization and polycondensation via terminal epoxy groups is possible. In this work, we examined the possibility of using an amine interchange product of phenolic Mannich bases, ethylenediaminomethylphenol (aminophenol Agidol AF-2, TU 33.303340–88), for curing ODUE at room temperature to obtain elastomeric materials with satisfactory physicomechanical parameters [1].

EXPERIMENTAL

The working life of compounds was determined according to TU 38-105463–72; nominal tensile strength and relative elongation at break, according to GOST (State Standard) 21751–76; adhesion strength with metal, according to GOST 21981–76; and hardness in TIR scale, according to GOST 263–76.

The optimal curing agent dosage is 1–5 wt parts per 100 wt parts of ODUE, with active filler (carbon black, Table 1) added. At higher contents of the aminophenol, the physicomechanical parameters, especially the deformation properties of the sealants, get worse. With inert fillers (chalk, diatomite), the curing agent dosage can be increased to 6 wt parts. The maximal cohesion strength may be due to the effect of carbon black on formation of the polymer network. Fairly strong physical interactions of the oligomer and active filler make the curing more efficient.

Oligodiene urethane epoxide is an unsaturated oligomer. In this connection, the possibility of additional cross-linking via double bonds is of interest. The main parameters of sealants prepared with addition of various cross-linking agents are listed in Table 2. The enhanced cohesion strength and hardness of the composite vulcanized with a sulfur vulcanizing mixture confirms the occurrence of such cross-linking. However, the use of powdered ingredients appreciably complicates compounding, the adhesion gets worse, and sulfur particles appear on the surface of composites. These drawbacks can be eliminated by using a sulfur–styrene copolymer (SSC) containing 39 wt % chemically bound sulfur. In this case, the adhesion is enhanced. Another possible source of sulfur in sealing compounds is a copolymer of sulfur with a resin binder (SRBC), containing 15 wt % chemically bound sulfur. The compounds developed can be used for preparing corrosion-protective coatings and sealing rubber–metal articles.

To enhance the deformation and elastic properties of sealants based on ODUE, we modified the compounds with EDOS (a mixture of dioxane alcohols and formals, by-product from isoprene production), polyoxyalkylenepolyol (POAP), and polyoxyalkylene epoxide (POAE) (Table 3). POAE exerted a favorable effect: The relative elongation increased to 380–500%, and the working life decreased to 40 min. These compounds can be suggested for use in repair works when high curing rate is required. The maximal cohesion strength of the composites is observed with 20 wt parts of EDOS per 100 wt parts of ODUE. To obtain additional information on cross-linking of ODUE in the presence of EDOS, we examined the effect of heating for various times on the viscosity of the composites (Table 4).

1070-4272/03/7603-0487$25.00

Table 1. Effect of fillers on properties of composites

Parameter	Chalk (65 wt parts)		Diatomite (50 wt parts)		Carbon black (40 wt parts)	
	at indicated aminophenol content, wt parts					
	2	6	4	6	1	5
Nominal tensile strength, MPa	2.8	3.3	2.5	3.6	2.0	4.0
Relative elongation, %	210	100	100	160	240	180

Table 2. Effect of cross-linking agent on properties of composites

Parameter	Sulfur (5 wt parts)	SSC (20 wt parts)	SRBC (25 wt parts)
Working life, min	30	200	120
Nominal tensile strength, MPa	4.2	4.0	3.0
Relative elongation, %	100	200	80
Adhesion to duralumin, kN m^{-1}	0.3	2.3	2.0
Hardness, arb. units	75	65	50

Table 3. Effect of modifier on properties of composites

Parameter	EDOS			POAP			POAE		
	wt parts								
	10	20	30	10	20	30	10	20	30
Working life, min	45	75	105	35	105	125	40	60	70
Nominal tensile strength, MPa	3.3	4.2	1.4	4.1	4.0	2.7	2.1	3.0	3.2
Relative elongation, %	140	160	460	200	210	220	500	530	380

An oligomer was thermostated at 70°C for a definite time, and the time of its outflow from a Hoeppler viscometer was determined. A traditional plasticizer of sealing compounds, dibutyl phthalate (DBP), considerably reduces the viscosity of ODUE, whereas EDOS participates in formation of a three-dimensional structure: The viscosity increases by a factor of almost two. This, apparently, accounts for the increased (to 4.2 MPa) nominal tensile strength of the composites and decreased (to 160%) relative elongation.

Table 4. Viscosity of ODUE in the presence of plasticizers at 70°C

Composition	Viscosity after indicated thermostating time, h			
	0	1	2	4
ODUE	9 min 41 s	8 min 25 s	6 min	6 min
ODUE + DBP	34 s	23 s	28.6 s	40.8 s
ODUE + EDOS	1 min 23 s	45 s	1 min 15 s	2 min 13 s

Thus, curing of ODUE with ethylenediaminomethylphenol in the presence of various modifiers involves formation of a three-dimensional polymeric network enhancing the cohesion strength and hardness of the composites.

The next step in development of sealants with ODUE as polymeric base was study of its copolymerization with polysulfide oligomer (PSO, GOST 12 812–80). It was proved previously [2] that catalysis of reactive oligothiols with ethylenediaminomethylphenol and their copolymerization with oligoepoxide follow

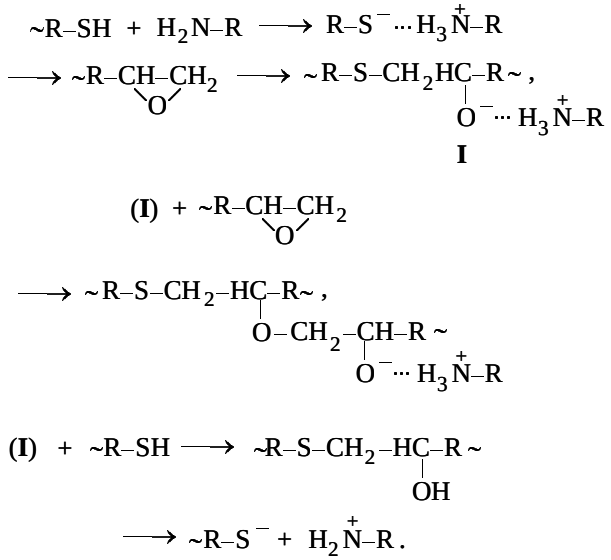
the scheme



The catalytic effect of aminophenols is due not only to their capability to activate oxirane rings, but also to their proton-acceptor power, facilitating the proton detachment from the oligothiol molecule (the oxygen atom in the epoxy group is less nucleophilic than the sulfur atom in the mercapto group). This means that, at room temperature, oligothiol–ODUE block copolymers are formed first, which suggests formation of an interpenetrating polymer network, enhancing the deformation and elastic parameters of the composites. However, formation of block copolymers requires not only formation of an interpenetrating polymer network of the oligomers, but also efficient contact of terminal functional groups. In this case, the thermodynamic compatibility of the reacting groups becomes a significant factor, suppressing aggregation of the oligomers. In practice, it is advisable to use a mixture containing 10–20 wt parts of ODUE per 100 wt parts of PSO, or 25–30 wt parts of PSO per 100 wt parts of ODUE [3].

The use of traditional PSO curing agents in cocuring of the polymers does not appreciably enhance the physicomechanical parameters of the composites (Table 5).

For practical purposes, it is advisable to use the second region of thermodynamic compatibility of the polymers, i.e., 50 wt parts of PSO per 100 wt parts of ODUE; in this case, the dosage of aminophenol is 2–4 wt parts. The properties of thio urethane epoxy sealants modified with various agents, including oligodienepolyol (ODP), are listed in Table 6.

All the composites exhibit increased cohesion strength (3.3–4.6 MPa) and stable elasticity (260–440%), compared to commercial thiokol sealants

U-30MES-5 and U-30MES-10 (TU 38-10-54-62–80), characterized by the nominal strength of 2.5–3.0 MPa and relative elongation of 250–350%.

CONCLUSION

Oligodiene urethane epoxide is suitable as a polymeric base for sealing compounds if the oligomer is homocured to form a three-dimensional network and cocured with a polysulfide oligomer to form an interpenetrating polymer network, taking into account the region of thermodynamic compatibility of the reactive oligomers.

Abstract—Sulfur dissolved in oil components of asphalt is a binder, filler, and chemical co-reagent at once. The structure of sulfur-extended asphalt depends on its formula and heating temperature. Road pavement based on sulfur-extended asphalt demonstrates higher durability as compared to that with the conventional binders.

Road pavement based on sulfur-extended asphalt demonstrates better mechanical characteristics and durability as compared to that based on the conventional binders. Recently there has been a steadily growing interest in sulfur-extended asphalts, because of the need in more rational utilization of great amounts of sulfur compounds from petroleum refining [1].

Sulfur is readily soluble in bitumen, especially in its aromatic components. The solubility of elementary sulfur in oxidized paving asphalts[1] at 120–150°C is at least 20 wt % [2].

Addition of sulfur in amount of up to 20 wt % to asphalt initiates chemical reactions whose type depends on the sulfur content and heating temperature and time of a given mixture. For example, some competing reactions can occur, including those with sulfur incorporation into the bitumen molecules or dehydrogenation with liberation of hydrogen sulfide. At heating temperature $T < 140$°C, elementary sulfur forms polysulfides in which unreacted sulfur dissolves. Along with asphaltenes, the indicated sulfur-containing compounds play a role of a structure-forming agent, i.e., they initiate formation of a network in which asphaltenes, paraffin, and sulfur stand as a dispersed phase, and molecules of resins and oils (malthenes), as a dispersion medium. Such structures differ considerably in the chemical and thermal stability from similar structures in unmodified oil asphalts.

Above 140°C, dehydrogenation of saturated components of bitumens can occur, whose depth depends on the final temperature of the reaction mixture. Also linear polysulfides can transform into stable cyclic thiophene structures. With increasing temperature, highly reactive asphaltenes and tars and also naphthene–aromatic compounds can react with sulfur through formation of the C–S bond.

It is known [3] that, at about 240°C, the reaction of sulfur with naphthene-aromatic compounds of bitumens gives asphaltenes, which play the crucial role in formation of a complex structural colloidal unit of bitumen.

Therefore, sulfur, as a chemical coreagent and filler, can have a considerable effect on the performance characteristics of paving asphalts. This effect was studied in this work.

EXPERIMENTAL

In experiments we used elementary sulfur, BND 60/90 paving asphalt and tar from the KINEF Limited Liability Company, broken granite (fraction 3–5 mm) from the Pulkovo asphaltic concrete plant, and gabbrodiorite (fraction 3–5 mm) from the Kuznechnoe deposit (Leningrad oblast).

The initial BND 60/90 paving asphalt has a softening point (T_s) of 49°C and penetration (Π_{25}) of 78 mm × 0.1.

Sulfur-extended composites were prepared as follows. A weighed portion of BND 60/90 was heated in a metallic crucible to 120°C, and then a fixed amount of elementary sulfur was added with vigorous stirring of the reaction mixture for 30 min.

The ring and ball softening point was determined according to GOST (State Standard) 9950; penetra-

[1] Paving asphalts from West-Siberian crude oil.

1070-4272/03/7603-0491$25.00

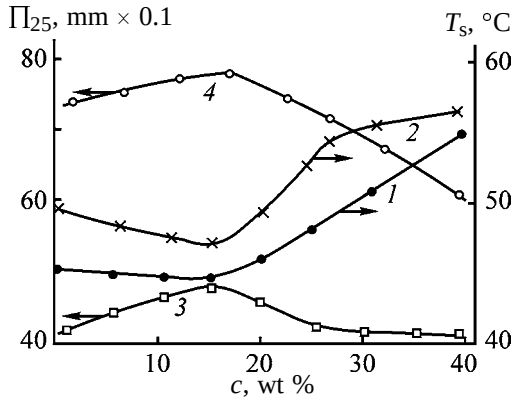

Fig. 1. Penetration Π_{25} (mm × 0.1) and softening point T_s of the composite as a function of the sulfur content (wt %): (*1*, *4*) before and (*2*, *3*) after heating.

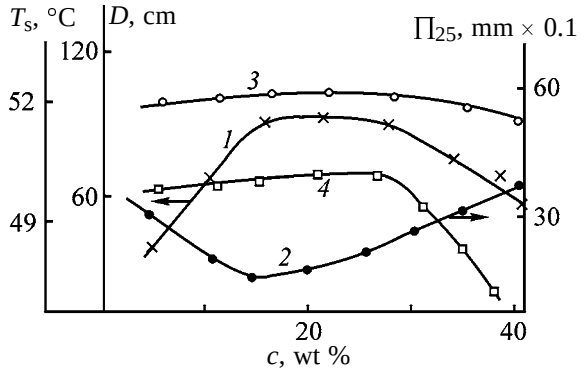

Fig. 2. (*1*) Softening point T_s, (*2*) penetration Π_{25}, and (*3*, *4*) ductility of the sulfur-extended composite *D* as functions of the sulfur content *c* during 2-month laboratory storage at 22°C: (*3*) before and (*4*) after heating.

tion, according to GOST 11508; ductility, according to ASTM D2872; and brittle point, according to GOST 11507 and also theoretically using the Gun equation [4]:

$$T_s - T_{br} = 70 - 7PI,$$

where T_s is the softening point (°C); T_{br}, brittle point (°C); and PI, penetration index (determined from a nomogram) [6].

The thermal stability of asphalts and their analogs (composites) was determined by the standard method. A weighed portion of a sample (60 ± 1 g) was placed into a stainless steel cup to form a 4-mm layer. The sample was heated at 160°C for 5 h. After heating, the softening point T_s, penetration Π_{25}, ductility *D*, and weight loss Δm (%) were measured.

The adhesion of a binder to a mineral filler was determined by the aqueous boiling method with granite and gabbrodiarite (3–5-mm fraction) at a 15 : 0.6 filler to bitumen ratio. Samples were placed onto a standard gauze and boiled for 30 min. The adhesion was estimated from the weight loss due to washing the binder off from the filler surface. Note that the 3–5-mm fraction used is the best suited to model the specific surface area of asphaltic concrete mixtures from the domestic plants.

The moisture content *W* (%) in the binder was estimated as

$$W = (W_1/W_2) \times 100,$$

where W_1 is the dry ball weight (g) and W_2, weight of the ball after saturation with water (g).

To obtain unmodified asphalt without oxidation of tar, a fixed amount of tar was placed into a metallic stirred reactor, the temperature was adjusted to 140–160°C, and powdered elementary sulfur was added. The reaction was performed for 30 min under stirring.

Evolution of properties of sulfur-extended asphalt before and after heating is shown in Fig. 1. In both cases, with small sulfur additions (5–10%), the hardness of BND 60/90 paving asphalt decreases, which is reflected in decreasing T_s and increasing penetration. The material becomes more plastic as compared to the initial material. With further increasing sulfur content, the softening point passes through a minimum and then gradually increases to the starting value. The penetration and softening point of sulfur-extended composites vary in opposite directions.

Thus, small additions (up to 10%) of sulfur to paving asphalt increase its plasticity, and large additions increase its hardness by virtue of higher degree of structuring and chemical interaction with asphalt components.

Transformation of the structure of asphalt modified with sulfur occurred not only in the preparation stage, but also in subsequent storage in the laboratory at 25°C (Fig. 2). During 2-month storage, the plasticity of sulfur-extended composites increased or decreased, depending on the sulfur content. In all cases, the penetration and softening point of sulfur-extended composites varied in opposite directions. Aging of the sulfur-extended composites is, evidently, accompanied by transformation of the micellar structure of asphalt. Here asphaltenes, paraffin, and various allotropic modifications of sulfur form a dispersed phase, and malthenes and tars form a dispersion medium. Reorganization of the solvate shell of primary micellar aggregates with formation of more compact structures proceeds slowly, being temperature-sensitive. It is of importance that, in the course of aging, T_s and pene-

tration vary within rather narrow ranges, i.e., sulfur-extended composites are relatively stable.

One more important characteristic of asphalt is the ductility reflecting the cohesion interaction between asphalt molecules. Sulfur additions (up to 20%) to paving asphalt appeared to have a positive effect on the ductility of the composites both before and after heating (Fig. 2). Note that heating at 160°C simulates the behavior of asphalt in the course of preparation of asphalt concrete hot mix.

The adhesion of the initial paving asphalt and sulfur-extended composites to a mineral filler (granite) is shown in Fig. 3 as a function of the heating time. Adhesion–cohesion interaction in both the initial paving asphalt and sulfur-extended composites depends on the contact time of the binder with granite. All the curves demonstrate the tendency to saturation at a contact time of about 2 h. It is important that, in the case of sulfur-extended composites with a sulfur content of 5–20%, the amount of asphalt retained on granite is higher as compared to the initial paving asphalt. This is consistent with the above-mentioned increase in the ductility of sulfur-extended composites.

With large sulfur additions (40%), the composite becomes loose, and its adhesion to the mineral filler is minimal.

In recent years, in laying roadbeds in the Russian Northwest, basic mineral fillers, particularly, gabbrodiorite have been widely used. This filler rapidly interacts with paving asphalt and sulfur-extended composites, so that establishment of the equilibrium takes shorter time (<30 min) as compared to granite. The composites with a sulfur content of up to 10% demonstrate higher adhesion than the initial paving asphalt. However, the composites containing 10–40% sulfur demonstrate lower adhesion than the initial material even at longer heating time. As in the case of granite, the strongest adhesion (adhesion–cohesion interaction) was observed in sulfur-extended composites containing 5% sulfur. At a heating time of 2 h, the maximal retention of the binder was 74.5 and 89% with granite and gabbrodiorite, respectively.

Based on tar from KINEF (T_s 39.3°C, $\prod_{25}$ 320 mm × 0.1), we prepared sulfur-modified composite binders (sulfur content 5, 10, and 20%). The heating temperature was 240°C, i.e., in this case sulfur was a chemical coreagent and filler. The performance characteristics of these composites (T_s, T_{br}, and $\prod_{25}$) are shown in Fig. 4. All the characteristics pass through an extremum at a sulfur content of about 10 wt %.

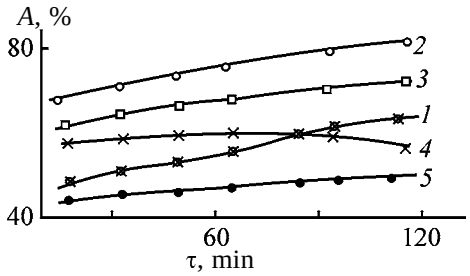

Fig. 3. Effect of the heating time τ of (*1*) paving asphalt and (*2–5*) sulfur-extended composites on the adhesion of asphalt to granite *A*. Sulfur content (%): (*2*) 5, (*3*) 10, (*4*) 20, and (*5*) 40.

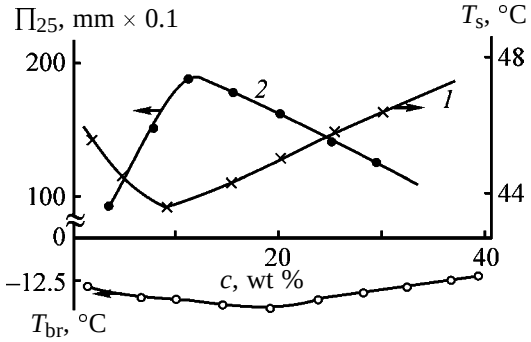

Fig. 4. Penetration $\prod_{25}$, softening point T_s, and brittle point T_{br} of sulfur-extended asphalts as functions of the sulfur content *c*.

The composite with a sulfur content of 5% meets the requirements of the GOST (State Standard) for BND 90/130 paving asphalt.

It should be pointed out that, at T < 95°C, sulfur exists as a cyclooctasulfane crown with an S–S bond length of 0.206 nm and S–S–S bond angle of 108°. At 119°C (melting point of sulfur), cyclooctasulfane turns partly into polymeric zig-zag chains (bond length 0.204 nm) [3]. At 119–159°C, molten sulfur exists essentially as cyclooctasulfane (λ-S). Above 159°C, eight-membered rings rapidly break down into biradicals [3]. In their turn, biradicals recombine to form polymeric chains with the maximal length of up to 10^6 sulfur atoms:

$$S_8 \rightleftarrows S^0\text{–}S_6\text{–}S^0$$

$$S^0\text{–}S_6\text{–}S^0 + S_8 \rightleftarrows S^0\text{–}S_6\text{–}S\text{–}S_8 \text{ etc.}$$

At 159–180°C, less stable (than S_8) cyclic structures having less or more sulfur atoms can occur in the melt. Linear sulfur biradicals are in equilibrium with large cyclic structures. The equilibrium sulfur species detected by ESR spectroscopy are as follows.

$$n\text{S}_8\text{(ring)} \rightleftarrows n\text{S}_8\text{–(chain)} \rightleftarrows (\text{S}_8)_n\text{(chain).}$$

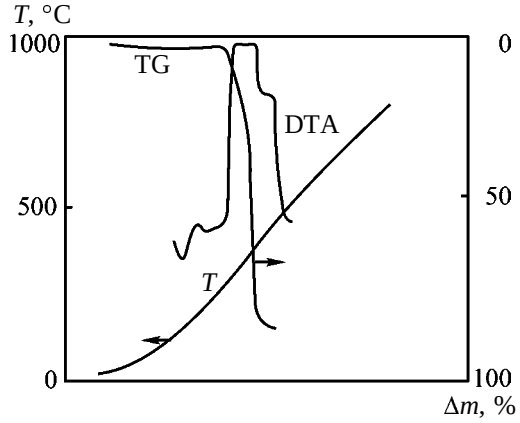

Fig. 5. TG and DTA curves of elementary sulfur. (*T*) Temperature and (Δ*m*) weight loss; the same for Fig. 6.

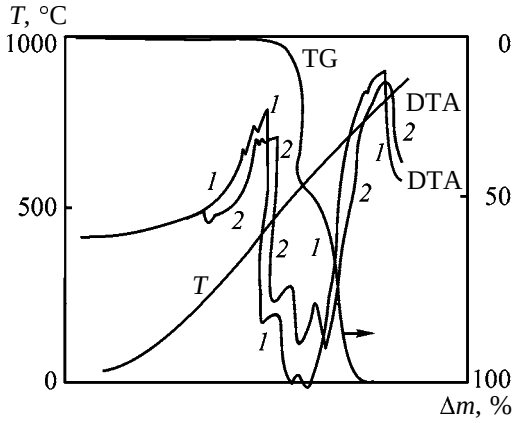

Fig. 6. TG and DTA curves of (*1*) BND 60/90 paving asphalt and (*2*) BND 60/90 + 5% S.

At T >200°C, sulfur is mahogany in color, and its melt contains S_3, S_4, and, possibly, S_2 fragments.

It was demonstrated in [5, 6] that alkanes C_7–C_{12} actively react with sulfur at lower temperatures (110–190°C) with formation of mercaptans, sulfides, and disulfides. It is known from the literature that arenes actively react with sulfur at 220–250°C, and in the presence of Lewis acids ($AlCl_3$), at 80–140°C.

Elementary sulfur was demonstrated to be the most reactive in the temperature range from 220 to 260°C (remarkable exothermic effect in the DTA curve in Fig. 5). Comparison of the DTA curves of BND 60/90 and the sulfur-extended composite (5% S) shows that at 240°C paving asphalt actively reacts with sulfur (Fig. 6). In the DTA curve, the exothermic effect of the composite is slightly weaker as compared to the initial asphalt. The maximal thermal effect due to reaction of asphalt components with sulfur was observed at 320–340°C, which was accompanied by active liberation of hydrogen sulfide. At lower temperatures, no noticeable liberation of hydrogen sulfide was observed.

At 390–425°C, active thermal decomposition of relatively thermally unstable paraffin–naphthene compounds takes place, which is reflected in clearly pronounced endothermic effect at 425°C. The IR data revealed the formation of a C–S bond at T >300°C. In this case, primarily, radical sulfur species react with unsaturated fragments of resins and alkenes (=C–S–S–C= or =C–S_{n+1}–C=).

Therefore, the major part of sulfur in asphaltic concrete mix (ACM) serves as a filler. The size of sulfur grains formed depends on the ACM preparation conditions (temperature; contacting time of tar, sulfur, and mineral filler; stirring rate; and cooling rate of the resulting composite).

It was demonstrated that the strength of sulfur-modified ACMs increases with time. Slow cooling of ACM samples results in formation of rigid mechanical contacts by virtue of sulfur crystallization. The structure of these contacts can be changed (damaged) in rapid cooling or mechanical failure (in compaction). With time, monoclinic sulfur transforms into orthorhombic sulfur, which is accompanied by increase in its strength. Therefore, structure formation in sulfur-containing organic binders is an important problem in view of development of durable sulfur organomineral materials.

It should be pointed out that, at T >100°C, the viscosity of the sulfur-extended asphaltic binder is lower by a factor of 1.6 than that of the initial paving asphalt, allowing reduction in the power consumption by virtue of decreasing temperatures of binder heating and ACM preparation by 25–30°C. Therefore, addition of 5–10% sulfur to asphalt or tar allows up to 30% saving of paving asphalt without deterioration in the characteristics of the resulting asphaltic concrete. It appeared that sulfur additions improve not only the binder ductility (Fig. 2), but also its viscosity–temperature characteristics, as clearly illustrated in Fig. 7. The T_{br}–c and D–c curves show extrema clearly pronounced at a sulfur content of 5–10%. Further increase in the sulfur content in the binder results in increasing brittle temperature and decreasing ductility. These results suggest that sulfur in the asphalt occurs in both liquid and crystalline states. Sulfur dissolved in oil components of asphalt has a plasticizing effect. Since the compounded paving asphalt based on tar and sulfur contains more oils and its dispersion medium is less structured with resins, the solubility of

sulfur in such asphalt is higher as compared to BND 60/90.

With decreasing temperature, the relative amounts of liquid and crystalline sulfur change in favor of the latter by virtue of decreasing solvency of the oil fraction. As a result, the maximal plasticizing effect is observed at low sulfur contents (Figs. 1, 2). Sulfur-extended binder has a wider operational range than the conventional paving asphalts. Additions of up to 10–15% sulfur provide such positive effect as decreasing brittle point of the binder, which is caused by improved low-temperature characteristics. At a sulfur content above 15%, the positive effect is caused by increasing T_S, i.e., as a result of increasing hardness of the paving asphalt.

Electron microscopic study of a sulfur-extended asphalt film confirmed the presence of dispersed sulfur uniformly distributed in the asphalt. This result was also supported by X-ray diffraction data (Fig. 8).

The plasticizing effect disappears in the course of prolonged storage (Fig. 4). Presumably, dissolved sulfur gradually crystallizes, thus increasing the degree of crystallinity of the material. Hence, with time, initially plastic thixotropic coagulation structure turns into rigid coagulation-crystalline structure, which is accompanied by changing properties of the binders (they turn from one rheological status into another typical of each type of the disperse structure), reflected in the binder viscosity (Fig. 7).

Note that, at T >119°C, liquid sulfur, being vigorously stirred with asphalt, is dispersed in it, forming an emulsion; and at T <119°C sulfur crystallizes. The crystallization features are affected by such factors as chemical reaction of sulfur with asphalt components and its dissolution or dispersion in the asphalt mass. The effect of newly formed structural links on properties of asphalts should largely depend on the asphalt structure. If the structure represents a maximally stabilized suspension of free asphaltenes (structure no. 11 by Kolbanovskaya), the effect of sulfur forming a crystallization network of a sort in the asphalt structure will be more distinctly pronounced than in the presence of a coagulation framework of asphaltenes (structure no. 111 by Kolbanovskaya). This effect should be reflected in increasing thermal stability, frost resistance, and elasticity of asphalt at low temperatures.

One of the features of sulfur is the manifestation of cementing properties in crystallization, i.e., in this case, sulfur is a structure-forming and binding agent simultaneously. Therefore, the desired combination of coagulation and crystallization structures in asphalt concrete and, therefore, its maximal durability can be attained by optimizing the sulfur content in asphalt.

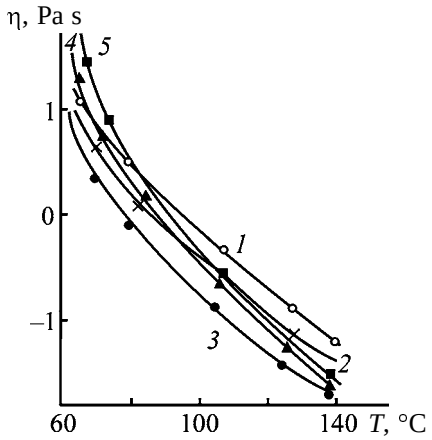

Fig. 7. Viscosity η of the binder as a function of the temperature T: (*1*) initial paving asphalt and (*2*–*5*) sulfur-extended BND 60/90. Sulfur content (wt %): (*2*) 5, (*3*) 10, (*4*) 30, and (*5*) 40.

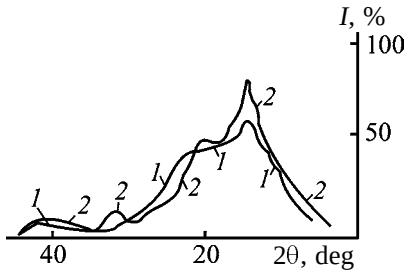

Fig. 8. X-Ray diffraction pattern of (*1*) initial paving asphalt and (*2*) sulfur-extended composite. (*I*) Relative intensity and (2θ) Bragg angle.

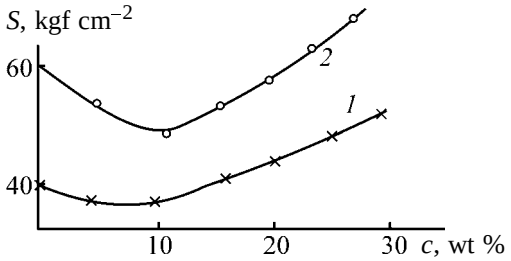

Fig. 9. Compressive strength of asphaltic concrete S as a function of the sulfur content c. Temperature (°C): (*1*) 20 and (*2*) 60.

Based on BND 60/90 paving asphalt, we prepared a cementing material by mixing the asphalt with molten sulfur at 140°C, followed by adding granite heated to the same temperature into the stirred apparatus. The strength of the resulting asphalt concrete passes through a minimum at a sulfur content of about 5% and then increases (Fig. 9). The strength is higher as compared to ACM based on conventional oil asphalt.

CONCLUSIONS

(1) With small additions of sulfur (below 10%), BND 60/90 paving asphalt becomes more plastic, and at high sulfur content, the bitumen structure becomes harder, as compared to the initial material.

(2) Adhesion–cohesion interaction of the initial paving asphalt and sulfur-extended composites depends on the time of contact of a binder with the mineral filler. The amount of paving asphalt retained on granite in a sulfur-extended composite (sulfur content 5–10%) is higher than that in the initial material.

(3) After heating for a short time (30 min), the sulfur-extended composites demonstrate higher adhesion to gabbrodiorite as compared to granite. The maximal amount of retained binder, determined by the aqueous boiling extraction method, was 74.5 and 89% on granite and gabbrodiorite, respectively, at a contact time of 120 min.

(4) Road paving based on sulfur-extended composites demonstrates better mechanical characteristics and durability as compared to the conventional binders.

Abstract—With the aim of developing new fluorine-conducting solid electrolytes, the compound NH_4SnF_3 was synthesized and its electrical conductivity and thermal behavior were studied.

Tin(II) fluoride SnF_2 forms compounds $MSnF_4$ (M is Pb, Ba, or Sr) and MSn_2F_5 (M is NH_4, Na, K, Rb, Cs, or Tl), which have high unipolar electrical conductivity with respect to fluoride ions [1, 2]. Increased interest in solid electrolytes derived from SnF_2 is stimulated by prospects of their application in all-solid-state power sources, sensors, and other electrochemical apparatus. At the same time, successful application of solid electrolytes in practice requires reliable synthesis procedures to obtain materials with well reproducible chararacteristics.

In this work, ammonium trifluorostannate(II) NH_4SnF_3 was prepared and its electrical conductivity was studied.

EXPERIMENTAL

Ammonium trifluorostannate(II) was synthesized from tin(II) oxide, which, in turn, was prepared from $SnCl_2$ solution by adding a solution of $NH_3 \cdot H_2O$ to pH 9.5, separating the precipitate, repeatedly washing with distilled water, and heating the $Sn(OH)_2$ suspension for 4–5 h. The SnO and NH_4HF_2 weighed portions in a molar ratio of 1 : 1.5 were dissolved in distilled water at 60–70°C, and the solution was evaporated on a water bath until a precipitate formed, which was filtered off after cooling the solution and dried at room temperature.

Chemical analysis was performed as follows. Approximately 0.2-g portion was dissolved in hydrochloric acid, and tin(II) was determined by direct titration with an iodine solution in the presence of starch. The relative eror of the determination was less than 2%. The ammonia content was determined according to [3]. The relative determination error was less than 1%. The content of fluoride ions was not determined.

Found, mol %: NH_3 9.5; Sn(II) 59.5.
NH_4SnF_3. Calculated, mol %: NH_3 9.31; Sn(II) 61.34.

The product yield with respect to tin(II) was 92.4%. According to the X-ray phase analysis (HZG-4 diffractometer, CuK_α radiation), the samples studied are single-phase, and their structure (trigonal crystal system, a = 6.841(1) and c = 15.930(4) Å, Fig. 1a) corresponds that of NH_4SnF_3 [4]. The values available from Powder Diffraction File, Data Cards, JCPDS, no. 33–0081, are a = 6.842 Å and c = 15.92 Å.

Electrophysical properties were studied by impedance spectroscopy with a VM-507 impedansometer (frequency range 5 Hz–500 kHz, resistance range 1 Ω–10 MΩ) in a vacuum (~0.1 Pa). The electrodes were made from DAG-580 graphite paste (the Netherlands). The electrical conductivity σ was measured on pellets 5 mm diameter and 2–4 mm thick, obtained

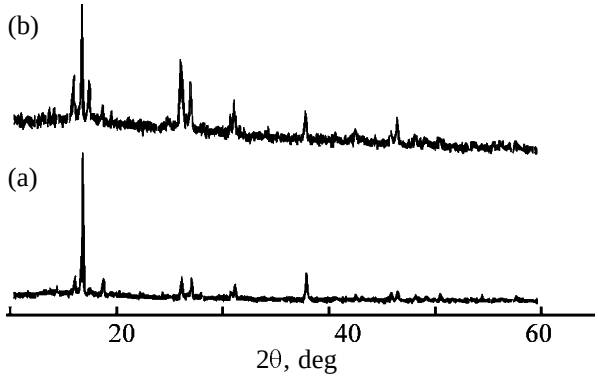

Fig. 1. X-ray diffraction patterns of ammonium fluorostannates(II). Sample: (a) initial (NH_4SnF_3) and (b) subjected to temperature measurements (NH_4SnF_3 + $NH_4Sn_2F_5$). (2θ) Bragg angle.

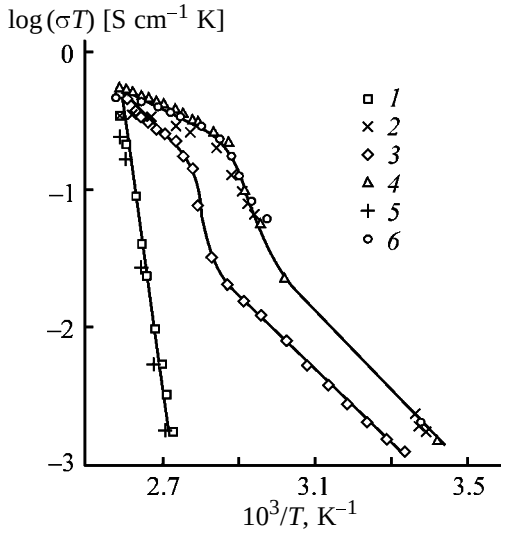

Fig. 2. log(σ*T*)–*T* plot. (σ) Conductivity of ammonium fluorostannates(II). Sample 1: (*1*) heating 1, (*2*) cooling 1, (*3*) heating 2, and (*4*) cooling 2; sample 2: (*5*) heating 1 and (*6*) cooling 1.

from thoroughly ground NH_4SnF_3 powder under a pressure of 4–5 MPa. The error in measuring σ was less than 5%. The activation energy E_a of the electrical conductivity was found from the formula

$$\sigma T = A\exp(-E_a/kT),$$

where A is the preexponential factor.

In σ measurements, the temperature was increased and decreased in steps, during each measurement it was kept constant.

The conductivity of the NH_4SnF_3 samples heated for the first time to 90°C remained lower than the sensitivity of the device (the total resistance exceeded 10^7 Ω). The low values of the NH_4SnF_3 conductivity in this temperature range are close to σ of alkali metal trifluorostannates at room temperature {σ ~ 10^{-9} S cm^{-1} [1]}. Above 90°C, σ dramatically grows (Fig. 2). On cooling and secondary heating, the compound showed a complex behavior indicative of hysteresis and phase transition. The transition region is recorded at 84±5 on heating and at 74±5°C on cooling. The temperature of the onset of the transition, as determined from both cooling and heating curves, is 78±2°C.

To interpret the results, we measured the diffraction patterns of the sample after measurements of σ at various temperatures and performed thermogravimetric analysis (Pt crucible, heating/cooling rate 10 deg min^{-1}, heating to 115°C). In addition to the NH_4SnF_3 lines, the lines due to $NH_4Sn_2F_5$ [rhombic crystal system, a = 12.4(3), b = 10.12(9), and c = 7.911(6) Å] appeared in the diffraction pattern (Fig. 1b). The values available from Powder Diffraction File, Data Cards, JCPDS, no. 16-0795, are a = 12.86, b = 10.05, and c = 7.91 Å.

Heating to 100°C is accompanied by weight loss (1.4 wt %). On cooling to 80°C, a clear endothermic peak, lacking in the heating curve, was recorded. This peak can be assigned to decomposition:

$$2NH_4SnF_3 \longrightarrow NH_4Sn_2F_5 + NH_3\uparrow + HF\uparrow.$$

This reaction is complete at a weight loss of 9.6 wt %, i.e., in the course of taking DTA curves 15% of the initial NH_4SnF_3 decomposed.

Thus, the samples were NH_4SnF_3 after the first heating to 90°C and an NH_4SnF_3 + $NH_4Sn_2F_5$ mixture after cooling and the second heating–cooling cycle. Apparently, a comparatively high electrical conductivity observed in this case in the samples studied (NH_4SnF_3 + $NH_4Sn_2F_5$) is completely determined by the formation of ammonium pentafluorostannate(II). The obtained data on the phase transition agree with the results of [2, 5, 6], according to which the phase transition in $NH_4Sn_2F_5$ occurs at 75°C [2, 5] or 70–84°C [6]. A small thermal effect accompanying this transition shows that the $NH_4Sn_2F_5$ polymorphous modifications being formed have similar structures. The conductivity value σ = 3×10^{-6} S cm^{-1} at 20°C is close to the published value (σ = 1×10^{-6} S cm^{-1} at 27°C [7]), and the activation energy E_a = 0.52 eV (20–75°C) reasonably agrees with the published values for $NH_4Sn_2F_5$ (E_a = 0.5 [2, 5] and 0.65 eV [7]).

The phase transition in $NH_4Sn_2F_5$ is accompanied by an approximately twofold increase in the activation energy of the ionic transfer and increase in the electrical conductivity by an order of magnitude. The ionic conductivity reaches 10^{-3} S cm^{-1} at 100°C. The high conductivity of $NH_4Sn_2F_5$ above 80°C was also observed in [5–7]. The obtained value of the activation energy for the high-temperature modification (E_a = 0.3 eV) is close to the published value (E_a = 0.34 eV at T > 84°C [6]).

The measurement of the transferrence numbers for electrons (t_e) in MSn_2F_5 shows that the contribution of electronic transfer to the total electrical conductivity is insignificant: for $RbSn_2F_5$ $t_e \sim 2\times10^{-5}$ at 122–168°C [7]. The structural elements of $NH_4Sn_2F_5$ are ammonium ions $[NH_4]^+$ and complex anions $[Sn_2F_5]^-$. Therefore, it was important to reveal their role in

the ionic transfer. NMR studies [1, 8] showed that reorientation of $[NH_4]^+$ ions is the main relaxation process in $NH_4Sn_2F_5$ at low temperatures, and diffusion of fluoride ions, above –20°C. In addition, according to the ^{19}F NMR data, fluoride ions occupy dynamically nonequivalent positions and this nonequivalence disappears after the phase transition. All this shows that the transfer of fluoride ions is responsible for the observed temperature dependence of the electrical conductivity in $NH_4Sn_2F_5$.

CONCLUSIONS

A study of the electrophysical properties of ammonium fluorostannate(II) shows that the NH_4SnF_3 conductivity is low ($\sigma < 10^{-6}$ S cm^{-1} below 90°C). Apparently, comparatively low values of σ in NH_4SnF_3 and alkali metal trifluorostannates(II) are due to a long distance between the $[SnF_3]^-$ complex anions in the crystal lattice. It was confirmed that at 74–84°C $NH_4Sn_2F_5$ undergoes the phase transition into the state with a high ionic conductivity ($\sigma \sim 10^{-3}$ S cm^{-1} at 114°C).

BRIEF COMMUNICATIONS

Turbidimetric Titration of Ethyl Acetate Extracts of Halo- and Aminobenzoic Acids

Ya. I. Korenman, N. A. Konstantinova, and S. I. Niftaliev

Voronezh State Technological Academy, Voronezh, Russia

Received September 10, 2002

Abstract—The extraction of halo- and aminobenzoic acids from aqueous solutions with a hydrophilic solvent (ethyl acetate) was studied. Conditions for turbidimetric titration of these acids in the organic extract were optimized. Procedures for reliable nonaqueous titration of acids were developed.

Wastewaters from paint-and-varnish industry and production of chemical agents for plant protection, polymeric materials, drugs, and vitamins are contaminated with halo- and aminobenzoic acids [1, 2]. Supply of these acids into water of storage basins and sewage treatment plants affects pH, destroys microflora, and prevents biological treatment of water.

We found that these acids can be extracted from aqueous solutions with a hydrophilic solvent (ethyl acetate) and then determined in nonaqueous extract without backwashing.

The aim of this work was to develop an extraction-titrimetric method for determination of monoamino- and also mono- and polyhalo-substituted benzoic acids in aqueous solutions.

EXPERIMENTAL

The acids under consideration were extracted at pH ~ 2 and 20 ± 2°C. In order to prevent mutual dissolution of the organic and aqueous phases in extraction, ethyl acetate and water were preliminarily saturated with water and ethyl acetate, respectively. Before extraction, an aqueous solution of an organic acid to be determined was acidified with H_2SO_4, and then a prescribed amount of ethyl acetate was added. Extraction was performed at the organic to aqueous phase ratio of 1 : 10 (by volume) for 10–15 min. Under these conditions, the extraction equilibrium was attained. The equilibrium extract was quantitatively separated from the aqueous phase, transferred to titration cell, and titrated potentiometrically with 0.01 M KOH in ethanol using a glass indicator electrode and an electrochemical circuit with charge transfer

$$\mathrm{GE}\,|\,\mathrm{H^+BA}\,|\,\mathrm{AgCl}\,|\,\mathrm{KCl},$$

where GE is a glass electrode; BA, substituted benzoic acid; and AgCl/KCl, silver chloride electrode filled with saturated ethanolic solution of KCl.

The distribution factor D and degree of recovery of acids in single extraction step were calculated by known equations [3].

The concentration of substituted benzoic acid in the nonaqueous concentrate obtained by extraction of this acid with ethyl acetate was determined as follows. The concentrate, preliminarily diluted with ethyl acetate if necessary, was poured into a photometric cell and then titrated with 0.01 M KOH in ethanol. In titration, 0.02-ml portions of the titrant were added from a microburet to the titrated solution at its continuous stirring with a mechanical stirrer. The changes in the optical density of the solution in the course of titration was registered in 20 s after addition of each portion of the titrant on a KFK-2MP photocolorimeter.

The amount of acid in the solution analyzed m (mg) was calculated by the equation

$$m = 0.01cVMR,$$

where c is the titrant concentration (M); V, titrant volume (ml) consumed in titration; M, equivalent weight of acid (g mol^{-1}); and R, degree of extractive recovery of the acid (%).

It is known that the degree of extractive recovery of weak acids from aqueous solution is dependent on pH of the aqueous phase [4]. With lowering pH, ionization of weak acids in the aqueous phase is suppressed, and, as a result, the degree of their transfer into the organic solvent (i.e., the extraction efficiency) increases. To ensure favorable conditions for extrac-

1070-4272/03/7603-0500$25.00

tion of the acids under consideration, the aqueous phase was acidified to pH ~ 2. The distribution factors of acids determined in our experiments are listed in the table.

Extraction of acids with ethyl acetate is influenced by the water and ethyl acetate concentrations in both organic and aqueous phases. In going from benzoic acids with hydrophobic substituents to those with hydrophilic substituents, the distribution factors decrease.

It was found in [5] that, in extraction of acids with ethyl acetate, virtually anhydrous extracts are formed. Therefore, ethyl acetate is a poor extractant for organic acids with hydrophilic substituents (OH, NH_2).

Owing to specific steric configuration of the *meta* and *para* isomers of acids [6], these compounds are characterized by stronger hydration. As a result, their solvation with ethyl acetate weakens and the distribution factor decreases. Therefore, 3- and 4-aminobenzoic acids are extracted poorly. The increase in the distribution factor *D* of 2-aminobenzoic acid can be explained in terms of the Hildebrand theory of the regular solutions [7]. According to this theory, the intramolecular hydrogen bonding decreases both the enthalpy of vaporization and the cohesion energy density, and the latter parameter becomes close to the solubility parameter of ethyl acetate. Therefore, the solubility of 2-aminobenzoic acid in ethyl acetate increases, and, as a result, its extraction with ethyl acetate also increases.

Halobenzoic acids containing hydrophobic halide atoms are virtually completely extracted with ethyl acetate. The *ortho*-substituted halobenzoic acids are characterized by strong mesomeric conjugation between the halogen atoms and benzene ring. This effect strengthens the hydrogen bonding, which, in turn, increases the extractability of halo-substituted acids [8]. Their extractability decreases with decreasing electronegativity of halide substituents (chlorine > bromine > iodine [9]).

With increasing number of substituents, the distribution coefficient of halo-substituted acids increases owing to increase in their hydrophobicity. An exception is 2,4-dichlorobenzoic acid, which is more soluble in water than 2-chlorobenzoic acid [10].

We found that potassium 2-bromo-, amino-, and chlorobenzoates are insoluble in ethyl acetate. Therefore, the corresponding benzoic acids were titrated turbidimetrically with a KOH solution in ethanol.

To provide reliable and sufficiently accurate determination, the poorly soluble salt of the titrated acid should be formed in the course of titration and this salt should form a sol exhibiting aggregative stability and strong light scattering [11].

Distribution factors and degrees of extraction of halo- and aminobenzoic acids from aqueous solutions with ethyl acetate $r = 10$, $n = 4$, and $P = 0.95$

Acid	*D*	*R*, %

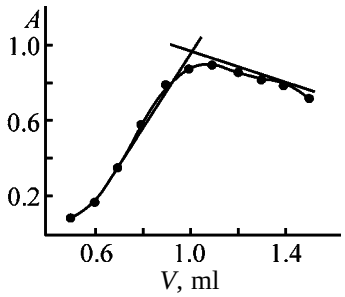
3-Aminobenzoic	61 ± 3	85.3
4-Aminobenzoic	10 ± 1	50.0
2-Chlorobenzoic	515 ± 8	98.1
2,4-Dichlorobenzoic	220 ± 5	95.7
2-Iodobenzoic	190 ± 4	95.0
2,5-Diiodobenzoic	273 ± 6	96.5
2,3,5-Triiodobenzoic	300 ± 7	96.8
2-Bromobenzoic	460 ± 9	97.9
5-Bromosalicylic	108 ± 6	91.4

The sols formed in titration of aminobenzoic acids with KOH do not meet these requirements. The curves of their turbidimetric titration do not show clear inflection points necessary for determining the equivalence point.

In order to choose the optimal wavelength for turbidimetric titration of the acids studied, Rayleigh spectra of their ethyl acetate extracts treated with excess KOH were registered against the initial transparent extract. These studies showed that the optimal light scattering occurs at a wavelength of 440–540 nm. To ensure the maximal accuracy, the optical density was registered in a 2-cm optical cell.

Our experiments showed that the curves of turbidimetric titration of 2-chlorobenzoic, 2,4-dichlorobenzoic, and 2-bromobenzoic acids are identical (see figure). This figure shows that, in the course of turbidimetric titration, the optical density passes through



Curve of turbidimetric titration of 2,4-dichlorobenzoic acid in the ethyl acetate extract. Titrant: 0.01 M KOH solution in ethanol; $\lambda = 490$ nm. (*A*) Optical density and (*V*) titrant volume.

a maximum corresponding to the equivalence point and then decreases owing to coagulation of the sol and its dilution with excess titrant. The linear parts of the titration curve before and after the maximum were extrapolated to their interception, and the abscissa of the interception point was taken as the equivalence point. The turbidimetric titration provides fast and precise determination of substituted benzoic acids without using expensive chemicals. The determination error does not exceed 8%. The detection limit is about 0.1 mg l^{-1}. The presence of foreign mineral acids does not interfere with determination of benzoic acids.

CONCLUSIONS

Extraction of monoamino-, 2-chloro-, 2,4-dichloro-, 2-iodo-, 2,5-diiodo-, 2,3,5-triiodo-, and 2-bromobenzoic and 5-bromosalicylic acids from aqueous solutions with ethyl acetate was studied, and the optimal conditions for their turbidimetric titration in the organic extracts were found. The simple and reliable techniques for extraction-turbidimetric determination of acids in aqueous solutions at their concentration of about 0.1 mg l^{-1} were developed.

Water Treatment To Remove Phenols in a Bubble Extractor

B. A. Alimatov and V. M. Sedov

Fergana Polytechnic Institute, Fergana, Uzbekistan
Russian Research Institute of Petrochemistry, St. Petersburg, Russia

Received June 6, 2002

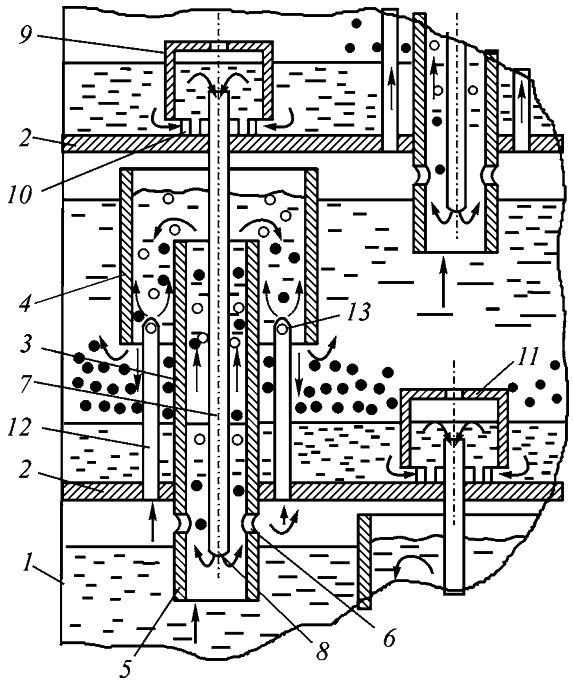
Abstract—Water treatment to remove phenols using a bubble extractor is studied for specific conditions of the Fergana Refinery.

In oil-refining industry, to remove phenols, water is treated using such methods as extraction and evaporation, since the phenol concentration in wastewater is mostly high (above 3–4 g l^{-1}), and recycling of phenols completely covers the expenses for their recovery [1]. In extractive recovery, such solvents are used as carbon tetrachloride, butyl acetate, benzene, etc.

For wastewater treatment to remove phenols, a bubble extractor was proposed [2], whose design and operation are shown in the figure.

Vertical housing *1* of the extractor is divided into separate settler sections with horizontal baffle plates *2*. Mixing elements consisting of inner (*3*) and outer (*4*) concentric pipes are arranged on baffle plates *2*. The lower ends of the pipes *3* run out under the baffle plate *2*, being gas-distributing nozzles *5* with holes *6* in their sidewalls. Downpipes *7* with holes *8* at the lower blanked-off end sides are also arranged at the baffle plates *2*. The downpipes *7* are covered from above with caps *9* having cuts *10* at the lower section and holes *11* in the upper covers. Gas-intake pipes *12* are also arranged at baffle plates *2*. At the upper blanked-off ends they have holes *13* for supply of an inert gas to the annular channel between concentric pipes *3* and *4* of the mixing element.

The extractor flowsheet is as follows. A light fluid is supplied to pipe *3* through the lower section of gas-distributing nozzle *5*. A heavy fluid is supplied right there through holes *8* in downpipes *7*. Moving together bottom-up along pipe *3*, the fluids are vigorously mixed with a part of the inert bubbling gas that is fed through holes *6* and collected after mixing in a "gas bag" under baffle plate *2*. Another part of the inert gas is supplied through holes *13* of gas-intake pipes *12* to the annular channel between concentric pipes *3* and *4*. Moving bottom-up through a countercurrent flow of the fluids, the inert gas vigorously



Bubble extractor (for explanation, see text).

mixes them and is then collected in a "gas bag" under baffle plate *2*.

Fluids mixed with the inert gas bubbles in pipe *3* and additionally in the annular channel between con-

Table 2. Physicochemical characteristics of liquid systems

Phase	c, g l^{-1}, for indicated extractor step			ρ, kg m^{-3}	$\mu \times 10^3$, Pa s	σ, N m^{-1}
	I	II	III			
Wastewater	0.12* 0.017	0.017 0.0037	0.0037 0.0007	1000	1.28	42.8×10^{-3}
Benzene	0 0.0015	0.0015 0.007	0.007 0.04	870	0.65	

* Initial and final concentrations are given in the numerator and denominator, respectively.

centric pipes *3* and *4* go to the settling section, where they are separated into phases. Drops of the heavy fluid settle, forming a continuous layer on baffle plate *2*, from which the heavy fluid flows through cuts *10* to downpipes *7* and then spills over to the underlying section. In this case, the position of the phase boundary between the light and heavy fluids is controlled by the position of the upper section of downpipes *7*.

The cross section of the annual channel is set so as to meet the requirement that the bottom-up fluid flow velocity is lower than the velocity of gas bubble flotation from holes *13* of pipes *12* to this channel. The arrangement of holes *13* of gas-intake pipes *12* below the lower section of pipe *4* guarantees getting of gas bubbles only to the annular channel between concentric pipes *3* and *4*.

Additional mixing of fluids in the annular channel between the concentric pipes of the mixing element is equivalent to increase in the residence time of the fluid mixture in the turbulence zone of the mixing element, thus improving the extraction efficiency.

The extractor efficiency is controlled by its diameter and the number of mixing elements per section. The desired degree of recovery of a target component is controlled by the number of sections.

We selected benzene as an extractant, because of its easy availability and relatively low distribution coefficient (according to [3], the distribution coefficient of phenols is 0.4, 2.4, and 8–12 in carbon tetrachloride, benzene, and butyl acetate, respectively).

It is of no small importance also that, because of a small phenol concentration in the extractant (benzene), the latter can be regenerated by the phenol–phenolate method [1].

Characteristics of the multistep bubble extractor proposed for wastewater treatment to remove phenols [2] are given in Table 1. The characteristics of extraction apparatuses of other types used in industry for this purpose are given for comparison.

In this work, first, we theoretically determined the overall mass transfer coefficient and single step efficiency (K_v = 0.04 s^{-1} and η = 0.92) using the relationships proposed in [4]. Then we estimated the required number of extraction steps using the grapho-analytical method [5]. This number is 3.

Experiments were conducted with industrial fluid systems from the Fergana Refinery using a model three-step bubble extractor. The benzene : water ratio was 3 : 1. The maximal water consumption was 0.13 $m^3 h^{-1}$, and that of benzene, 0.39 $m^3 h^{-1}$. The initial and final phenol concentrations in the phases are given in Table 2. The table also includes data on physicochemical characteristics of the fluid systems used (density ρ, viscosity μ, and interfacial tension σ), determined by standard methods.

Finally, it was demonstrated that treatment of 120 m^3 of wastewater with the initial phenol concentration of 0.12 g l^{-1}, to obtain the final concentration of 0.0007 g l^{-1}, requires a three-step bubble extractor with a working height of 3.2 m and a diameter of 1.96 m. The expected annual cost efficiency due to utilization of recovered phenols is 175 000 rubles.

Mechanism of Deuterium Distribution in Ethanols

A. G. Sakhabutdinov, N. V. Kulagina, D. F. Kushnarev, A. G. Proidakov, and G. A. Kalabin

Institute of Petroleum and Coal Chemical Synthesis, Irkutsk State University, Irkutsk, Russia

Received October 10, 2002

Abstract—Deuterium distribution in ethanols produced by sulfuric acid hydration of ethylene was studied by quantitative NMR spectroscopy.

It is well known that the natural content of deuterium and the features of its distribution in structural fragments of molecules bear information on the origin of organic compounds [1]. In synthetic ethanol the deuterium content is 0.0134–0.0136%, and in food-grade ethanol its level is lower, from 0.0114 to 0.0122% [2]. However, irrespective of the ethanol origin, the deuterium content in the methyl group is higher than that in the methylene group by a factor of 1.1–1.4 in all cases [3]. Since all deuterated molecules occur in the form of d_1 isotopomer owing to minor content of deuterium, it was of interest to establish the mechanism of distribution of deuterium atoms between methyl and methylene groups of alcohol.

For this purpose, we simulated formation of ethanol by sulfuric acid hydration of ethylene and studied the deuterium distribution in this process, using deuterated sulfuric acid or [1,1-$^2H_2$]ethylene.

It was found that, in the ^2H NMR spectrum of ethanol produced by hydration of [1,1-$^2H_2$]ethylene in the presence of sulfuric acid, the intensities of signals of the methyl and methylene groups are the same. This means that proton is added to both carbon atoms of ethylene with equal probability, irrespective of deuterium substitution. Thus, the deuterium atom in the initial ethylene molecule does not affect the direction of proton addition and hence cannot be responsible for the different natural deuterium content in methyl and methylene groups of ethanol.

The ^2H NMR spectrum of ethanol produced by hydration of ethylene in deuterated sulfuric acid showed that addition of acid is accompanied by predominant deuteration of the methyl group, since the intensity of its signal is greater by a factor of more than 25 than the intensity of the signal of the methylene group. It is evident that, under the reaction conditions, the reverse decomposition of ethyl hydrogen sulfate to the initial substances proceeds to no more than 8%, and hydrogen atom of the acid mainly participates in formation of the methyl group.

The data obtained show that natural enrichment of ethanol with deuterium is caused by two sorts of deuterium atoms, deuterium of the substrate (ethylene) and reagent (acid). The deuterium content in the initial ethylene determines the amount of ethanol molecules deuterated in the methylene group, while higher fraction of molecules deuterated in the methyl group is caused by deuterium from acid.

EXPERIMENTAL

The reaction was carried out by the improved procedure in [4]. A mixture of 20 g of sulfuric acid and 0.2 g of the catalyst Ag_2SO_4 were vigorously stirred at 60°C in an ethylene medium until complete saturation. The resulting ethyl hydrogen sulfate was decomposed with a mixture of ice and water. The yield of ethanol after twofold distillation was 60%.

Ethanol was analyzed by ^2H NMR spectroscopy on a VXR-500S spectrometer operating at 76.7 MHz. The pulse length was 25 μs (90°), and delay, 8 s.

CONCLUSION

The deuterium content in methyl and methylene groups characterizes the components forming ethanol and can be used for determining its origin.

ANNIVERSARIES

Petr Anatol'evich Kirpichnikov (1913–1997)

On January 5, 2003, Petr Anatol'evich Kirpichnikov, a corresponding member of the Russian Academy of Sciences, Honorary Academician of the Academies of Sciences of the Republics of Tatarstan and Bashkortostan, Honored Scientist and Technologist of the Russian Federation and the Republic of Tatarstan, Laureate of a State Prize of the USSR, would be 90.

P.A. Kirpichnikov is a prominent scientist in the field of basic organic synthesis and macromolecular compounds. He made a major contribution to the theory and practice of development of new materials, especially rubbers and other elastomers, and to solution of problems concerning the aging and stabilization of polymers.

He was the first in the country to develop a new class of noncoloring stabilizers based on organophosphorus compounds, which effectively protect many kinds of polymers in their processing and exploitation.

He studied in detail the mechanism of their action in polymers, established the dependence of their performance on structure, determined the kinetic conditions for the appearance of a synergistic effect with organophosphorus compounds upon addition of second components. A set of investigations concerned with organophosphorus compounds resulted in that process regulations and feasibility calculations were developed and introduced into industrial practice.

Based on these studies, Kirpichnikov succeeded in solving a practically important problem of inhibiting the thermally induced polymerization of isoprene; in particular, this was done at the Nizhnekamsk combine.

An important direction in Kirpichnikov's works were studies in the field of synthesis and modification of polysulfide oligomers and polyurethane rubbers, which were used to synthesize new types of polymers, many of which are manufactured commercially and find wide application.

Kirpichnikov developed and introduced new processes into industrial practice.

Kirpichnikov was the author of more than 500 publications, 12 textbooks, manuals for higher school, monographs, and reviews; he received 330 inventor's certificates and patents. His disciples include 12 doctors and 60 candidates of science.

Kirpichnikov was an excellent pedagogue and tutor of young scientists. His services in organization of training of engineers for chemical industry are great.

When being the rector of Kazan Institute of Chemical Technology for 24 years, Kirpichnikov succeeded in making it one the most prominent higher school institutions of the country, in organizing new faculties, chairs, and branches, and in training highly skilled scientific and pedagogical workers. The institute became a center at which large conferences, symposia, workshops, schools, and All-Union, Russian, and republican schoolchildren contests were held.

Kirpichnikov was a prominent and talented science organizer, many years' head of the Kazan Branch of the Academy of Sciences of the USSR and Russian Academy of Sciences and the Tatarstan Division of the Mendeleev All-Union Chemical Society, and a member of the Editorial Board of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry).

Kirpichnikov participated in the Great Patriotic

1070-4272/03/7603-0506$25.00

War. He served in the Air Force and was awarded orders and medals for service in battle.

Having been demobilized in 1947, Kirpichnikov was sent to Germany where he worked as chief engineer at a large chemical combine Buna, and, after Soviet plants were transferred to Germans in 1953, remained at this plant as adviser. For his contribution to the national economy of the German Democratic Republic, he received a government award "For Services in Foundation and Development of the GDR."

Kirpichnikov was a prominent public man, he was elected at member of the Supreme Soviet of the Republic of Tatarstan and Kazan City Soviet of People's Deputies, a member of the board of directors of the Soviet Foundation for Peace, and chairman of the committee for assistance to the Foundation for Peace of the Republic of Tatarstan.

The outstanding contribution of Kirpichnikov to the scientific, scientific-organization, and pedagogic activities was honored with numerous State awards and prizes.

The spirits and optimism of Petr Anatol'evich, his encyclopedic knowledge and culture in personal contacts won him deep respect of the scientific and pedagogic community, students, and industry managers.

Petr Anatol'evich was an outstanding, brilliant, and life-loving man. Despite that already 6 years have elapsed after he passed away, the pain of loss is still perceptible and the gratifying memory of him is still alive in those for whom he was a friend, co-participant in scientific creative work, and patient tutor. Petr Anatol'evich's disciples and colleagues continue to develop his ideas and hold jubilee conferences and sessions in his memory. This primarily refers to Kirpichnikov Readings, first held in 2000. These readings constitute a new tradition of the Kazan chemical school; in March 2003, Third Jubilee Kirpichnikov Readings will be held, devoted to problems of synthesis, study of properties, and processing of macromolecular compounds, and also to modern problems of education in chemical technology.

G. S. D'yakonov

Russian Journal of Applied Chemistry, Vol. 76, No. 3, 2003, p. 508. Translated from Zhurnal Prikladnoi Khimii, Vol. 76, No. 3, 2003, p. 523.

BOOK REVIEWS

Zainullin, Kh.N., Babkov, V.V., Zakirova, D.M., Chulkov, A.N., and Iksanova, E.M., *Utilizatsiya osadkov stochnykh vod gal'vanicheskikh proizvodstv* (Utilization of Sediments from Electroplating Shop Wastewater)

Moscow: Ruda i Metally, 2003, 272 pp.

Electroplating shops for various purposes are numerous in the country. According to the data presented by the authors of the monograph, about 5000 plants in Russia have such shops. However, utilization of their wastes, and sediments (sludge) formed in wastewater treatment in the first place, are far from being properly organized everywhere. This leads to pollution, significant excess over the maximum permissible concentration of heavy metals in soil and water bodies, and loss of valuable components. The monograph by Kh.N. Zainullin *et al*. is concerned with topical problems, which are important in environmental and economical regard. The authors have collected and analyzed a vast body of factual data.

The book comprises an introduction, eight chapters, conclusion, and bibliographic list. The introduction (pp. 4–16) discusses the possibility of using wastes from galvanic shops as secondary raw materials. It is noted that only 30–40% of metals and 5–20% of acids and alkalis constitutes useful expenditure. Small Chapter 1 (pp. 17–24) classifies sediments formed in wastewater at sewage treatment facilities. As examples serve typical data for electroplating shops of machine-building plants of the Republic of Bashkortostan. A practically convenient classification is that based on methods for utilization of sediments formed in wastewater of electroplating shops. Also possible are other approaches.

Chapter 2 (pp. 25–60) is devoted to the problem of waste disposal. Disposal is to be regarded as a forced measure, caused by the lack of acceptable processes for utilization of one or another kind of waste. At the same time, reliable disposal techniques are expensive and pose quite a number of environmental problems. Chapters 3 (pp. 61–83) and 4 (pp. 84–92) consider use of electroplating sludges in metallurgy. The main difficulties are posed by the pronounced inhomogeneity of composition, high moisture content, and presence of impurities hindering the recovery of the main component. A great number of flowsheets is considered. The depletion of resources of nonferrous metallurgy and the necessity for use of lean ores make processing of various kinds of secondary raw materials, including electroplating sludges, particularly topical. In their processing, both pyrometallurgical and hydrometallurgical techniques can be employed. The problems associated with recovery of valuable components from electroplating sludges by various techniques are also discussed in Chapter 5 (pp. 93–111).

Use of sludges for direct manufacture of a number of important products is the subject of Chapter 6 (pp. 112–123). As example serves production of catalysts, complex ferrites, paint-and-varnish materials, pigments, and means of corrosion protection. Chapter 7 (pp. 123–237) analyzes the possibility of utilizing wastes from electroplating shops in building-materials industry. The possibilities and prospects in this field are rather broad, but it is necessary to clearly establish the environmental safety level when using the materials thus obtained. There is no escape from mentioning that utilization of electroplating wastes by introducing them into building and pavement materials leads to irreversible loss of nonferrous metals. Chapter 8 (pp. 238–252) considers the possible organization measures for centralized utilization of electroplating wastes in cities or industrial regions. The brief conclusion (pp. 253–254) also contains organizational recommendations. The bibliographic list (pp. 255–271) includes references to 251 papers of mainly Russian authors.

The monograph gives a large number of useful recommendations concerning utilization of wastes from electroplating shops and discusses in most detail the problems associated with the use of wastes in building-materials industry. The book has technological purpose, is written in easily understandable language, and can be recommended for a very wide audience of engineers working at electroplating shops. Probably, the large number of the authors of the monograph resulted in that the text contains repetitions and the structure of the first six chapters is insufficiently clear. The book is well published and contains illustrative graphic material.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Calcium Phosphates Coprecipitated from Aqueous Solutions of Sodium Monophosphate and Diphosphate

V. A. Sinyaev, L. V. Levchenko, E. S. Shustikova, and J. Griggs

Institute of Chemical Sciences, Alma-Ata, Republic of Kazakhstan

Baylor College of Dentistry, The Texas A and M University System Health Science Center, Dallas, TX, USA

Received July 11, 2002

Abstract—Calcium phosphate compounds obtained by coprecipitation from sodium monophosphate and diphosphate aqueous solutions under the action of calcium chloride are described.

Materials based on crystalline hydroxyapatite are widely used in modern orthopedics and stomatology [1–3]. Recently, increasing interest has been expressed in calcium phosphate substances, which are close in composition to hydroxyapatite, but have amorphous nature. The enhanced reactivity, which results from thermodynamic instability, is an advantage of such substances over crystalline materials. Therefore, amorphous apatites can be regarded as promising compounds for regeneration of bone tissue and as precursors of bioceramics.

Crystalline hydroxyapatite is usually obtained by precipitation from aqueous solutions. This technique is based on ion-exchange reactions between soluble monophosphates and calcium salts [4]. If the precipitation is carried out in the presence of crystallization inhibitors, amorphous apatite-containing materials are formed. Various substances, such as fluorides, magnesium salts, polymeric phosphates, and calcium diphosphate can be used as inhibitors [4–7]. The last compound is of interest because it is rather close to hydroxyapatite in elemental composition and relative content of phosphorous(V) and calcium(II). An additional reason why the precipitated materials are amorphous may be formation of a nonstoichiometric hydroxyapatite

$$Ca_{(5-x/2)}(HPO_4)_x(PO_4)_{(3-x)}(OH)\cdot nH_2O,$$
$$0 < x < 1,\ n = 0\text{–}2.5,$$

which is promoted by low pH values. Since the presence of HPO_4^{2-} groups in the products is not always desirable, the acidity is usually maintained at pH 7–8 by adding an alkali in the course of precipitation or by using buffer solutions [4–7]. However, even under these conditions, a local momentary decrease in the pH value may occur at the surface of the forming particles as a result of liberation of an acid by the reaction

$$3Na_3PO_4 + 5CaCl_2 + H_2O \rightarrow Ca_5(PO_4)_3OH\downarrow + 9NaCl + HCl.$$

As a consequence, HPO_4^{2-} ions are incorporated, despite all the efforts, into the structure of the precipitated substance. To make lower the probability of this process, it is advisable to carry out precipitation in an alkaline medium where the local decrease in pH is minimized.

The aim of the study was to reveal the influence of the relative content of diphosphate ions on the nature of compounds precipitated with calcium chloride from sodium mono- (MP) and diphosphate (DP) aqueous solutions in the presence of an alkali, i.e., under conditions that hinder formation of a nonstoichiometric hydroxyapatite.

EXPERIMENTAL

Sodium hydrophosphate and diphosphate, Na_2HPO_4 and $Na_4P_2O_7$, of analytically pure grade were used in the study. Their 5% aqueous solutions were mixed in required proportions. The relative content of the salts in solutions was represented as DP/(DP + MP) ratio (MP and DF are, respectively, the numbers of moles of mono- and diphosphate in the starting solutions). Preliminarily, NaOH was added to phosphate solutions in amount sufficient to neutralize the whole

amount of acid liberated upon the hydroxoapitite formation. Calcium chloride (5% solution) was gradually added dropwise to the phosphate solutions under vigorous stirring. The precipitation terminated at pH 8. All the procedures were carried out at room temperature. The precipitates obtained were washed many times with a dilute NaOH solution with pH 8 until the washing water became free from chloride ions. After that the suspension was settled for 1–2 days and separated from water first by decanting and then by filtering on a porous glass filter. The substances dried at 60–80°C were studied by X-ray diffraction analysis and IR spectroscopy. A DRON-3 diffractometer (Co_{K_α} radiation) and a Jasco IR-810 IR spectrometer were employed for these purposes. KBr pellets were used to record the IR spectra. The content of sodium ions in the precipitated substances was determined by flame photometry on a FLAPHO var device.

In storage, aqueous suspensions separate into two layers: water and a more concentrated suspension. Products obtained from solutions with DP/(DP + MP) molar ratio of 0.4 separate into layers at the lowest rate. In all cases, the process is in fact complete within 5–7 h, and after that the suspensions become relatively dense precipitates which slowly loose moisture when stored in air.

The precipitates include sodium ions. It is seen from Fig. 1 that the content of sodium ions in the products obtained from solutions with molar ratios DP/(DP + MP) < 0.3–0.4 is rather small and depends on the composition of the starting solutions only slightly. The content of sodium ions in substances precipitated from solutions with higher relative DP content is higher and grows with increasing DP fraction in the starting solutions. It may be assumed that products containing sodium ions as an impurity are formed from DP-poor solutions, and calcium-sodium phosphates are precipitated from solutions with high relative content of sodium diphosphate.

According to the X-ray diffraction data, the product obtained from a solution of only sodium monophosphate is crystalline hydroxyapatite (Fig. 2a). Substances formed in the presence of even small amounts of sodium diphosphate show indications of amorphicity (Figs. 2b and 2c). The corresponding diffraction patterns suggest that these substances are based on hydroxyapatite. X-ray-amorphous products are precipitated from solutions with molar ratios $0.2 \le$ DP/(DP + MP) ≤ 0.4 (Figs. 2d–2f). If the relative content of sodium diphosphate is greater than 50%, substances containing crystalline diphosphates of calcium β-$Ca_2P_2O_7$ and calcium-sodium α-$Na_2CaP_2O_7 \cdot 4H_2O$ are formed (Figs. 2g–2j).

To elucidate the effect of the composition of starting solutions on the molecular base of the products, we studied these latter by IR spectroscopy. We found

two bands of medium intensity, which are peaked at 570 and 600 cm^{-1}, in the low-frequency region of the IR spectrum of the substance precipitated from sodium monophosphate solution, and a group of intense mutually overlapping bands peaked at 1030, 1060, and 1090 cm^{-1} in the range 950–1200 cm^{-1} (Fig. 3a). All these bands correspond to P–O stretching vibrations in hydroxyapatite monophosphate groups PO_4^{3-} [8–10]. The hydroxide ion is a structural unit of hydroxyapatite. Usually this group gives rise to a weak band ν_L(OH) at 630–640 cm^{-1} in IR spectra and also to a higher-intensity narrow band peaked at 3560–3570 cm^{-1}, which corresponds to ν_S(OH) vibrations [8–10]. In the spectrum under consideration, the first band appears as a weak peak with frequency of about 630 cm^{-1}. As for the ν_S(OH) band, it is replaced by a very broad and intense band at around 3420 cm^{-1}in the high-frequency region. This band is typical of stretching vibrations of O–H bonds in water molecules [11]. It is possible that this band and the ν_S(OH) band overlap.

When even a minor amount of diphosphate is present in a monophosphate solution, the IR spectrum of the precipitated product contains all the above-mentioned bands, but some of them become less distinct (Fig. 3b). The possible reason is the onset of disordering in the structure of the precipitate.

The IR spectrum of the substance obtained from a solution with mole ratio DP/(DP + MP) = 0.1 contains several weakly pronounced peaks, a shoulder above 1130 cm^{-1}, and a weak broadened band with frequency of about 900 cm^{-1} in addition to the group of mutually overlapping intense bands, (Fig. 3c). This shoulder becomes better pronounced in the spectrum of the product precipitated from a solution with diphosphate mole fraction of 0.2 (Fig. 3d). Among the bands typical of hydroxyapatite, only the band peaked at 1030 cm^{-1} survives, whereas all other components of the spectrum undergo changes. In particular, all the peaks within the range 500–600 cm^{-1} merge into a single broad band.

In the IR spectrum of the substance precipitated from a solution with mole ratio DP/(DP + MP) = 0.4, all the strongest bands in the range 950–1200 cm^{-1} merge into a single broad band without any clearly pronounced peaks (Fig. 3e). This band resembles in shape the IR bands of such typical amorphous phosphates as glasses [12].

Changes in the spectra of products precipitated from solutions with higher diphosphate content are caused by the appearance and growth of the fraction of calcium and calcium–sodium diphosphates (Figs. 3e–3i).

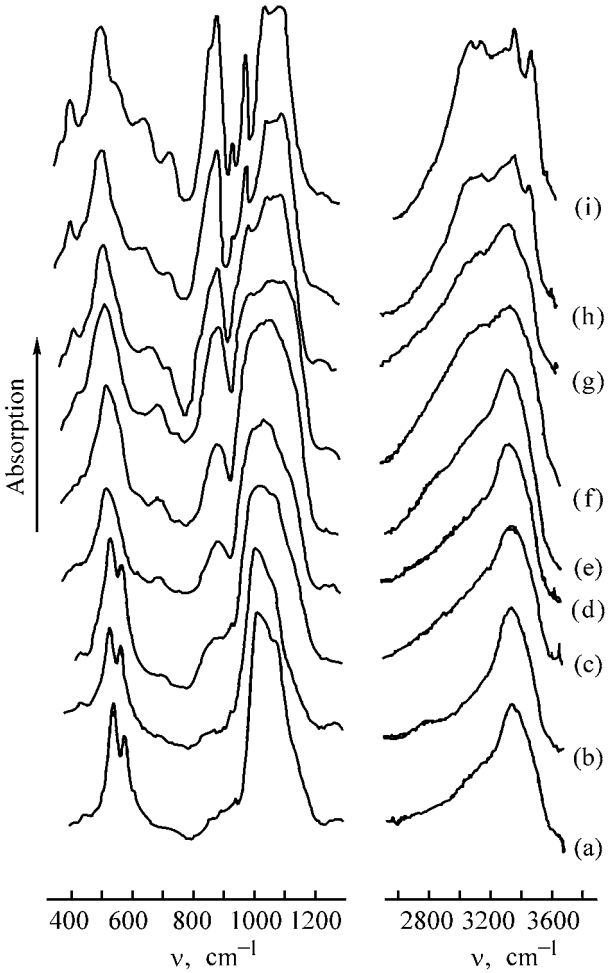

Fig. 3. IR spectra of precipitated products. (ν) Wave number. Content of sodium diphosphate in starting solutions (mol %): (a) 0, (b) 5, (c) 10, (d) 20, (e) 40, (f) 50, (g) 70, (h) 80, and (i) 100.

The IR spectra of substances precipitated from solutions with mole ratios DP/(DP + MP) = 0.2–0.4 are not a simple superposition of individual spectra of hydroxyapatite and diphosphate. In addition, the main bands are strongly broadened. As before, mono- and diphosphate groups form the molecular base of the substances, but we can assume that they have changed their nature as compared with hydroxyapatite and diphosphates. The possible reason is the mutual influence of such groups under direct contact conditions. In such a case, the amorphous substances under discussion can be regarded as an aggregate of chaotically distributed PO_4^{3-}, $P_2O_7^{4-}$ groups, and also OH^- groups, which are linked by calcium cations Ca^{2+}.

Special attention should be paid to the high-frequency range of the IR spectra, which shows stretching vibrations of O–H bonds in water molecules.

The presence of a high-intensity high-frequency band in all the spectra is attributable to strong hydration of the products. As seen from Fig. 3a, the corresponding band is asymmetric: its low-frequency wing shows a pronounced shoulder. This suggests that two forms of water are present in apatite, and one of these predominates. According to the other IR spectra, the water prevailing in hydroxyapatite is gradually replaced by the second form of water when the substance is enriched with a diphosphate.

It should be noted that none of the above-described IR spectra contains clear lines typical of nonstoichiometric hydroxyapatite [11]. This suggests that the amorphicity of substances precipitated from solutions with mole ratios DP/(DP + MP) = 0.2–0.4 is caused by the inhibiting action of diphosphate on the crystallization of hydroxyapatite.

CONCLUSIONS

(1) Crystalline or slightly amorphous products containing hydroxyapatite are precipitated with calcium chloride from alkaline sodium monophosphate solutions in the presence of minor amounts of sodium diphosphate.

(2) Crystalline calcium and calcium–sodium diphosphates are precipitated from monophosphate-lean solutions. Totally amorphous products are formed from solutions with diphosphate/(diphosphate + monophosphate) mole ratios of 0.2–0.4. These substances mainly consist of chaotically arranged discrete PO_4^{3-}, $P_2O_7^{4-}$ groups, and also OH^- groups, linked by Ca^{2+} cations. Molecular water is incorporated in the structure of all the substances precipitated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

On Reaction of Sulfur Dioxide with Aqueous Solutions of Carbamide

R. E. Khoma, V. I. Nikitin, and M. I. Gavrilenko

Mechnikov National University, Odessa, Ukraine

Received October 17, 2001; in final form, November 2002

Abstract—A mechanism of SO_2 chemisorption by aqueous solutions of carbamide was suggested. The effective rate constants of accumulation of hydrogen ions in the reaction of sulfur dioxide with aqueous solutions of carbamide in the range 278–313 K were determined.

One of the main tendencies in the use of methods for desulfurization of waste gases consists in that simple absorption purification methods of nonregenerating type with limestone, lime, or other sorbents give way to technological processes of regenerating type, which enable removal of absorbed sulfur dioxide from the system, with its subsequent utilization [1]. The possibility of generation of sulfur dioxide in the form of a virtually 100% gas can be ensured with the use of aqueous solutions of nitrogen-containing bases as sorbents [2].

The problems of SO_2 dissolution in water and aqueous solutions are widely discussed. The mechanism of sulfur dioxide dissolution in water and aqueous solutions in the ionic form was rather well described in [3–5]. This mechanism can be, in general terms, represented as follows:

gas–liquid equilibrium

$$SO_2^g \rightleftarrows SO_2^l, \quad (1)$$

specific equilibrium

$$SO_2^l + H_2O \rightleftarrows SO_2 \cdot H_2O, \quad (2)$$

$$SO_2 \cdot H_2O \rightleftarrows H^+ + HSO_3^-, \quad (3)$$

$$2HSO_3^- \rightleftarrows S_2O_5^{2-} + H_2O, \quad (4)$$

$$HSO_3^- \rightleftarrows H^+ + SO_3^{2-}, \quad (5)$$

where SO_2^g and SO_2^l stand for sulfur dioxide in the gas phase and that dissolved in water, respectively.

Also, Labutin *et al.* [6] suggested the molecular mechanism of sulfur dioxide dissolution in water

$$SO_2^g \rightleftarrows SO_2^l, \quad (6)$$

$$SO_2^l + H_2O \underset{k_2}{\overset{k_1}{\rightleftarrows}} SO_2^g \cdot H_2O, \quad (7)$$

$$SO_2^l + SO_2 \cdot H_2O \underset{k_4}{\overset{k_3}{\rightleftarrows}} H_2S_2O_5, \quad (8)$$

$$H_2S_2O_5 + H_2O \underset{k_6}{\overset{k_5}{\rightleftarrows}} SO_2 \cdot H_2O. \quad (9)$$

Based on the assumptions that the first stage of physical dissolution [Eq. (6)] is fast and obeys the Henry law and the third stage [Eq. (8)] has equilibrium nature with account of the limiting action of the second and fourth stages [Eqs. (7) and (9)], the authors of [6] note that

$$\frac{dc_{SO_2 \cdot H_2O}}{d\tau} = K_I - K_{II}c_{SO_2 \cdot H_2O} - K_{III}c^2_{SO_2 \cdot H_2O}, \quad (10)$$

where $K_I = k_1p/m$, $K_{II} = k_2 - (2k_5k_3p/k_4m)$, $K_{III} = 2k_6$, p is the partial pressure of SO_2, and m is the Henry constant. The total content of sulfurous acid, $c_{SO_2 \cdot H_2O}$, is directly proportional to the total content of the disulfurous acid, $c_{H_2S_2O_5}$:

$$c_{H_2S_2O_5} = K_{IV}c_{SO_2 \cdot H_2O}, \quad (11)$$

$$K_{IV} = k_3p/k_4m.$$

At the same time, a particular place among the existing widely diverse absorption methods for desul-

1070-4272/03/7604-0513 $25.00 © 2003 MAIK "Nauka/Interperiodica"

furization of discharged gases [1, 7–9] is occupied by the carbamide technique [2, 10, 11]. This can be accounted for by the fact that carbamide is a virtually nontoxic product manufactured on large scale and its aqueous solutions have high absorption capacity and are easily regenerated [2], which allows their further utilization. However, the mechanism of reaction between sulfur dioxide and aqueous solutions of carbamide remains poorly understood.

In the opinion of the authors of [10, 11], the reaction of SO_2 with aqueous solutions of carbamide proceeds via its acid hydrolysis to give CO_2, H_2O, and $(NH_4)_2SO_4$. However, according to [12, 13], the rate of hydrolysis of carbamide is so slow that, in actual practice, its solutions in water can be considered stable up to 80°C. Only heating to 90–100°C or presence of the urease enzyme accelerates the hydrolysis of carbamide.

In [14, 15], a mechanism of SO_2 chemisorption by aqueous solutions of carbamide was suggested. This mechanism consists in that the acid–base reaction of the generated forms of sulfurous acid with carbamide occurs via complexation. The inorganic acid neutralizes the weak organic base via protonation [Eqs. (12)–(14)] or direct addition to its molecule to give associates [Eq. (15)]:

$$[CO(NH_2)_2H]^+ + HSO_3^- \rightleftarrows [CO(NH_2)_2H]HSO_3, \quad (12)$$

$$2[CO(NH_2)_2H]^+ + S_2O_5^{2-} \rightleftarrows [CO(NH_2)_2H]_2S_2O_5, \quad (13)$$

$$2[CO(NH_2)_2H]^+ + SO_3^- \rightleftarrows [CO(NH_2)_2H]_2SO_3, \quad (14)$$

$$CO(NH_2)_2 + SO_2 + nH_2O \rightleftarrows CO(NH_2)_2 \cdot SO_2 \cdot nH_2O. \quad (15)$$

According to published data, carbamide exhibits weak basic properties ($pK_a \sim 0.5$ [16], 0.18, 0.31 [17]). This indicates that the uronium cation is a stronger acid than $SO_2 \cdot H_2O$ ($pK_a \sim 2.0$ [4]). Consequently, formation of salts [Eqs. (12)–(14)] in aqueous solutions is unlikely.

It is not improbable that donor–acceptor reaction of SO_2 with carbamide, which acts as a ligand with respect to sulfur dioxide, results in that associates are formed in water [Eq. (15)].

A model proposed by the authors of [6] can be well applied to description of the reaction of sulfur dioxide with aqueous solutions of carbamide.

The total content of sulfur dioxide in solution, Q, at temperatures higher than 278 K is given by

$$Q = c_{SO_2 \cdot H_2O} + c_{H_2S_2O_5} + [SO_2^l]. \quad (16)$$

With account of (11) and (15), Eq. (10) takes the form

$$\frac{dc_{SO_2 \cdot H_2O}}{d\tau} = K_I - K_{II}\left(\frac{Q - p/m}{1 + K_{IV}}\right) - K_{III}\left(\frac{Q - p/m}{1 + K_{IV}}\right)^2. \quad (17)$$

The total content of sulfurous acid in solution

$$c_{SO_2 \cdot H_2O} = [SO_2 \cdot H_2O] + [HSO_3^-] + [SO_3^{2-}]. \quad (18)$$

Since it is known [5] that disulfurous acid does not exist in free form, the accumulation of hydrogen ions apparently occurs mainly via dissociation of sulfurous acid by the first stage. Since sulfurous acid is a weak acid, it can be written at its low concentrations that

$$\frac{d[H^+]}{d\tau} = k\frac{dc_{SO_2 \cdot H_2O}}{d\tau}. \quad (19)$$

After rearrangements Eq. (19) can be written as

$$\frac{d[H^+]}{d\tau} = K_I' + K_{II}' Q + K_{III}' Q^2, \quad (20)$$

where K_I', K_{II}', and K_{III}' are empirical constants:

$$K_I' = kK_I + k\frac{K_{II}}{1 + K_{IV}}\frac{p}{m} - k\frac{K_{III}}{(1 + K_{IV})^2}\frac{p^2}{m^2}, \quad (21)$$

$$K_{II}' = k\frac{2K_{III}}{(1 + K_{IV})^2}\frac{p}{m} - k\frac{K_{II}}{1 + K_{IV}}, \quad (22)$$

$$K_{III}' = -k\frac{K_{III}}{(1 + K_{IV})^2}. \quad (23)$$

To verify the adequacy of the model developed, published data on the reaction of sulfur dioxide with 0.1 and 0.25 M aqueous solutions of carbamide [15, 14] were processed in terms of this model and the reaction of SO_2 with 0.5 M carbamide solutions was studied in the interval 278–313 K.

EXPERIMENTAL

The experimental procedure employed was described in detail in [15, 16].

Model solutions were prepared with distilled water and carbamide of analytically pure or pure grades, additionally purified by recrystallization. The concentration of carbamide in the systems studied was monitored by photometry [18].

Purified sulfur dioxide [19] was continuously bubbled at constant volumetric flow rate of 8 ml min^{-1} through a model solution placed in a thermostated cell (solution volume 250 ml). Together with pneumatic

agitation, mechanical stirring was also used, which ensured ideal mixing of the components. The concentration of hydrogen ions was measured in the course of experiments with an ESL-43-07 glass electrode. An EVL-1M3 silver chloride reference electrode was filled with a saturated aqueous solution of potassium chloride at 298 K.

The measurements were done at 278–313 K.

In the course of an experiment, c_{SO_2} was monitored after the reaction mixture at 15–30-s intervals by iodometry [20]. The amount of reacted SO_2 was determined by the Scheniger method [21] and calculated using the formula

$$Q = \frac{q(c^{in}_{SO_2} - c^{fin}_{SO_2})}{V_1 \cdot 64}, \quad (24)$$

where V_1 is the solution volume (ml); $c^{in}_{SO_2}$ and $c^{fin}_{SO_2}$, the SO_2 concentrations before and after the reaction (M); q, the volume of the reaction mixture (ml) passed through the reactor during a time τ.

The experiments were performed to constant determined parameters of the system. During an entire experiment, there was no sulfur dioxide at the outlet, which points to its nearly 100% absorption. It was established experimentally that raising the intensity of stirring to more than 50 rpm has no effect on the run of the pH curves, i.e., the reaction of SO_2 with aqueous solutions of carbamide proceeds under these conditions in the kinetic region. In addition, the authors of [6] maintain that, at SO_2 content in the gas phase exceeding 4 vol %, the overall rate of sulfur dioxide dissolution in aqueous solutions is limited by the rate of the SO_2 hydration stage.

As shown by the experiments, the concentration of carbamide sorbing SO_2 remains virtually constant in each set of runs over the entire range of the temperatures studied. No sulfate ions were found in the systems under study, which contradicts the model proposed in [10, 11].

The curves describing how the pH value varies with the amount of absorbed SO_2, Q (M), in solutions are shown in Figs. 1a [15], 1b [14], and 1c. Processing of these data by the least-squares method yielded dependences $[H^+] = f_{T,c_{KA}}(Q)$ in the form of third-order polynomials

$$[H^+] = A_{T,c_{KA}} + B_{T,c_{KA}}Q + C_{T,c_{KA}}Q^2 + D_{T,c_{KA}}Q^3, \quad (25)$$

where $A_{T,c_{KA}}$, $B_{T,c_{KA}}$, $C_{T,c_{KA}}$, and $D_{T,c_{KA}}$ are constants for each of the runs, which depend both on tempera-

ture T and on the total content of carbamide, c_{KA}, in the reaction mixture.

With account of the fact that SO_2 was delivered during an entire run at a constant volumetric flow rate and virtually its whole amount reacted with the absorbers, it can be written that

$$Q = a\tau, \quad (26)$$

where a is a constant dependent on the gas supply rate, and τ is the time during which the gas is supplied. Substitution of (26) into Eq. (25) and subsequent differentiation with respect to time yields

$$\left(\frac{\partial[H^+]}{\partial\tau}\right)_{T,\,c_{KA}} = aB_{T,\,c_{KA}} + 2a^2C_{T,\,c_{KA}}\tau + 3a^3D_{T,\,c_{KA}}\tau^2 \quad (27)$$

or

$$\left(\frac{\partial[H^+]}{\partial\tau}\right)_{T,\,c_{KA}} = aB_{T,\,c_{KA}} + 2aC_{T,\,c_{KA}}Q + 3aD_{T,\,c_{KA}}Q^2. \quad (28)$$

If Eqs. (19) and (23) are compared, it can be written

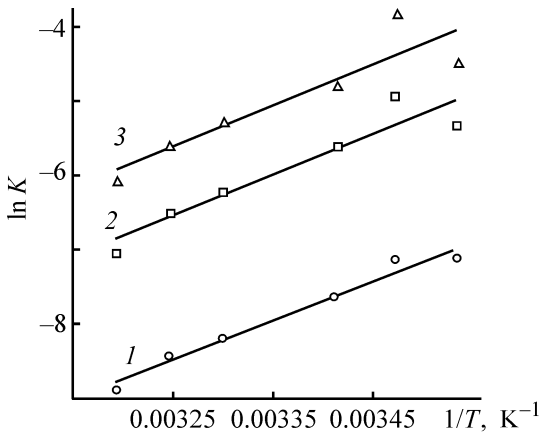

Fig. 2. Parameters of Eq. (20) for 0.5 M carbamide solution vs. temperature T. (*1*) K_I', (*2*) K_{II}', and (*3*) K_{III}'.

$$K_I' = aB_{T,c_{KA}},\ K_{II}' = 2aC_{T,c_{KA}},\ K_{III}' = 3aD_{T,c_{KA}}.$$

The processing of the data in Figs. 1a–1c made it possible to determine the average values of the empirical constants K_I', K_{II}', and K_{III}' (see table). The temperature dependences of these constants for a 0.5 M solution of carbamide can be represented in the interval 283–313 K as

$$K_I' = 8.722 \times 10^{-10}\exp(\Delta\theta_1/RT),$$

$$K_{II}' = -1.322 \times 10^{-10}\exp(\Delta\theta_2/RT),$$

$$K_{III}' = 1.106 \times 10^{-10}\exp(\Delta\theta_3/RT),$$

where $\Delta\theta_1$ = 38.94, $\Delta\theta_2$ = 41.38, and $\Delta\theta_3$ = 42.80 kJ mol^{-1}.

Analysis of the temperature dependence of the empirical constants (Fig. 2) shows that their absolute values decrease with increasing temperature, i.e., the exponents in the temperature dependences of K_I', K_{II}', and K_{III}' are positive by virtue of the relationship between the activation energies (k_1–k_6) and the exponent in the temperature dependence of the Henry constant.

However, the temperature dependences of K_I', K_{II}', and K_{III}' for 0.1 and 0.25 M solutions (see table) are more complicated and can be represented as $K_I' = f(T)$. For example, for a 0.25 M carbamide solution with sulfur dioxide concentration $0 \le Q_{SO_2} \le 0.12$ M at 288–313 K

$$K_I' = 3 \times 10^{-8}T^4 - 3 \times 10^{-5}T^3 + 0.015T^2 - 3.0189T + 228.25,$$

$$K_{II}' = -7 \times 10^{-7}T^4 + 0.0009T^3 - 0.4105T^2 + 82.672T - 6241.8,$$

$$K_{III}' = 4 \times 10^{-6}T^4 - 0.0044T^3 + 1.9847T^2 - 399.6T + 30\,162.$$

For a 0.1 M carbamide solution with sulfur dioxide concentration $0 \le Q_{SO_2} \le 0.05$ M in the range 278–313 K

$$K_I' = -2 \times 10^{-10}T^6 + 4 \times 10^{-7}T^5 - 0.0003T^4 + 0.1018T^3 - 22.129T^2 - 2565T - 123819,$$

$$K_{II}' = -3 \times 10^{-8}T^6 + 5 \times 10^{-5}T^5 - 0.0373T^4 + 14.634T^3 - 3232.7T^2 + 380754T - 2 \times 10^7,$$

$$K_{III}' = 8 \times 10^{-7}T^6 - 0.0014T^5 + 1.0154T^4 - 398.32T^3 + 87863T^2 - 10^7T + 5 \times 10^8.$$

It should be noted that in all cases the approximation is characterized by a correlation factor $R^2 > 0.97$.

Apparently, the acidity of the medium is a measure of sulfur dioxide hydration by water, since this gives $SO_2 \cdot H_2O$ [Eq. (2)] and one of products of its dissociation are hydrogen ions [Eqs. (3) and (5)].

Thus, aqueous solutions of carbamide strongly affect solvation of SO_2 by water, probably forming various associates with sulfur dioxide. The effect of carbamide on the hydration of sulfur dioxide has complex nature. For example, the acidity of the medium decreases in a 0.5 M carbamide solution with the temperature increasing from 278 to 313 K. This can be accounted for by the fact that, under the specific action of carbamide, the affinity of water for sulfur dioxide decreases in solutions with increasing temperature.

CONCLUSIONS

(1) The possibility of effective absorption of sulfur dioxide by carbamide solutions in the temperature range 278–313 K was established.

(2) It was found that the temperature of the reaction medium and its composition strongly affect the acid-base reaction in SO_2–water–carbamide systems.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of Heat Conductivity of Methanol–*n*-Nonanol Binary Mixtures in a Wide Range of Temperatures and Pressures

M. M. Bashirov

Azerbaijani Technical University, Baku, Azerbaijan

Received May 14, 2002; in final form, November 2002

Abstract—The heat conductivity of liquid binary mixtures of the system methanol–*n*-nonanol was measured at different temperatures, pressures, and concentrations. A relationship between the heat conductivity of the binary mixtures and the concentration of their components was established.

A sufficient body of experimental data on the heat conductivity λ of neat methyl and *n*-nonyl alcohols is available in the literature. At the same time, the heat conductivities of mixtures of methyl and *n*-nonyl alcohols have only been reported once [1] for atmospheric pressure and a narrow temperature interval (20–80°C) at concentrations of 25, 50, and 75 wt %.

Results obtained in measuring the heat conductivity of neat methyl alcohol at high pressures were reported in [2–4]. Previously, the λ value has been measured for methanol [5] in a wide range of temperatures and pressures (T = 293–600 K, P = 0.1–60 MPa), and the results obtained are in good agreement with the data of [3]. The heat conductivity of *n*-nonanol was measured at high pressure in [6, 7], with the results reported being well consistent.

In the present study, the heat conductivity of liquid binary mixtures of methanol and *n*-nonanol was measured in the temperature interval 293–600 K at pressures ranging from atmospheric to 60 MPa. The experiments were carried out on a modified cylindrical high-pressure tricalorimeter [8–10].

The heat conductivity of neat methanol and *n*-nonanol and of their mixtures were measured on similar setups to eliminate systematic experimental errors constituting ~1.3% for heat conductivity (for the regular-mode method).

Basic geometric dimensions of the measuring device (mm): diameter of inner measuring cylinder 12.255, inner diameter of the outer cylinder 12.931, measuring clearance 0.338, outer diameter of the outer cylinder 37, inner diameter of the autoclave 40, length of measuring cylinders 140, length of compensating cylinders 40.

The error in determining the heat conductivity coefficient did not exceed 1.8%.

The results obtained in determining experimentally the heat conductivity for methanol–*n*-nonanol mixtures are listed in Table 1.

The scatter of experimental points around the averaging curve is less than 0.3%. Analysis of the data in Table 1 shows that the concentration dependence of heat conductivity of methanol–*n*-nonanol mixtures shows negative deviations from the additivity line and is symmetric with respect to the concentrations of the constituent components. It should be noted that the deviation δλ observed in [1] in measurements under atmospheric pressure has the same direction and magnitude. However, the effect of temperature varies. Raising the pressure and temperature makes the deviation δλ ($\delta\lambda = \lambda - \lambda_{ad}$) smaller at mass concentration x = 0.5; here, λ_{ad} is the heat conductivity of a solution, calculated using the additivity law.

On the basis of the experimental data obtained, the following empirical equation is proposed:

$$\lambda = \lambda_1 x_1 + \lambda_2 x_2 + 10^{-4} x_1 x_2 (\alpha \Delta T + \beta P - \gamma), \quad (1)$$

where λ_1 and λ_2 are the heat conductivities of the first and second components (W m^{-1} K^{-1}); x_1 and x_2 are the mass fractions of the components; α, β, and γ are constants for a given system. The following values

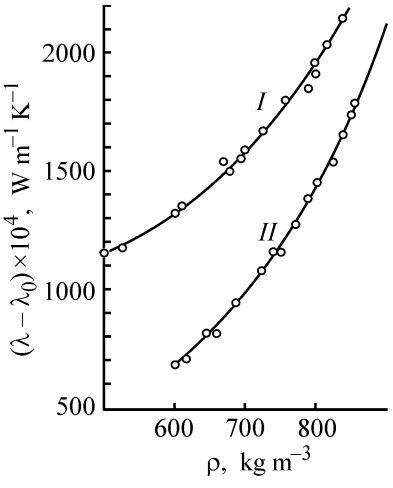

Fig. 1. ($\lambda - \lambda_0$) for (*I*) methanol and (*II*) *n*-nonanol vs. density ρ of the liquid phase.

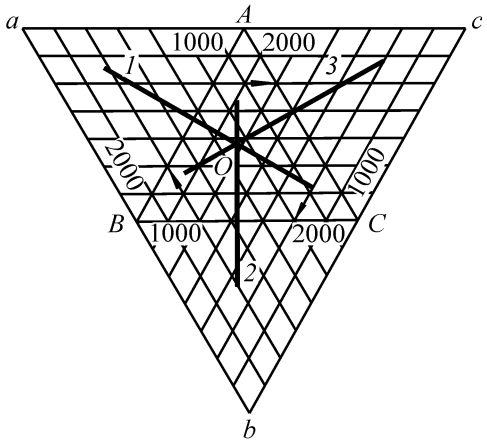

Fig. 2. Relationship between the heat conductivities $\lambda \times 10^4$ of the system methanol–*n*-nonanol at different component contents. Mixture: (*1*) *A*–*B*, (*2*) *B*–*C*, and (*3*) *C*–*A*. Methanol + *n*-nonanol (wt %): *A* = 25 + 75, *B* = 50 + 50, and *C* = 75 + 25.

were obtained: α = 0.2143, β = 0.80, γ = 215.08; $\Delta T = T - T_0$, T_0 is the base temperature, $T_0 = (T'_m + T''_m)/2$; T'_m and T''_m are the melting points of the first and second components (K), for methanol T'_m = 1 75.49 K, for *n*-nonanol T''_m = 260.60 K; *P* is pressure (MPa). The λ_1 and λ_2 values were taken from [3, 7].

Table 2. Constants a_i in Eq. (3) for methanol and *n*-nonanol

a_i	Methanol	*n*-Nonanol
a_0	890.00	–350.00
a_1	0.4167	4.1167
a_2	–0.0015	–0.0090
a_3	0.00000333	0.00000833

Equation (1) describes the experimental values of λ for binary mixtures of methyl and *n*-nonyl alcohols with an error not exceeding the experimental error.

Of practical interest is generalization of the data on heat conductivities of neat alcohols and mixtures of these. There exists a relationship between the excess heat conductivity and density of liquids and gases

$$\lambda - \lambda_0 = f(\rho), \quad (2)$$

where λ_0 is the heat conductivity of a substance at atmospheric pressure in the gas phase, λ is the heat conductivity at given *T* and *P*, and ρ is the substance density at *T* and *P*.

As seen from relation (2), a knowledge of the ρ value in a wide range of pressures and temperatures is necessary for generalization. Unfortunately, this is not the case for mixtures of methanol and *n*-nonanol. The density of neat methanol and *n*-nonanol has been determined with high accuracy [11–19]. These results enable processing of data on heat conductivities of neat liquid methanol and *n*-nonanol at high pressures. The results obtained are shown in Fig. 1, whence it can be seen that the experimental points fall on averaged parabolic curves. The maximum scatter of the points around the averaging curves is 3.5% for methanol and 3.3% for *n*-nonanol.

Processing of the data on λ_0, λ, and ρ yields the following dependence (3)

$$\lambda - \lambda_0 = \sum_{i=0}^{3} a_i \rho^i, \quad (3)$$

where a_i are constants for a given substance. The a_i values are listed in Table 2. With data on density available, relation (3) can be used to prognosticate the excess heat conductivity.

Data on λ for binary methanol–*n*-nonanol mixtures can be conveniently processed using the method of comparative calculations in a three-axis coordinate system [20], in which each axis corresponds to a mixture [three axes and three mixtures (wt %): 25, 50, and 75].

The method consists in the following. To establish a relationship between the properties of the mixtures, a closed three-coordinate system is used. The coordinate axes are arranged one after another at angles of 60° (Fig. 2). The sides of the equilateral triangle *ABC* are the coordinate axes. On each of the axes, the heat conductivities of one of the three mixtures is plotted. Here, the relationship between the three substances at once is considered. This technique makes it possible

to prognosticate the heat conductivity of a third mixture on the basis of two others and to perform interpolation and extrapolation of the λ value for the system.

The results of processing are shown in Fig. 2. It can be seen that a single curve (straight lines *1–3*) is obtained for each pair of mixtures (25 wt % methanol + 75 wt % *n*-nonanol and 50 wt % methanol + 50 wt % *n*-nonanol; 50 wt % methanol + 50 wt % *n*-nonanol and 75 wt % methanol + 25 wt % *n*-nonanol; 75 wt % methanol + 25 wt % *n*-nonanol and 25 wt % methanol + 75 wt % *n*-nonanol). All these lines intersect within the inscribed triangle at the same point. It should be noted that parts of the curves related to low heat conductivities go outside the inscribed triangle *ABC*. Therefore, the system is supplemented with a circumscribed triangle *abc*.

Each of the lines *1–3* can be described by an equation of the type $\lambda_1 = m\lambda_2 + n$, where *m* and *n* are coefficients. Correspondingly, the following empirical equations were obtained for lines *1–3*:

$$\lambda'' = 0.9812734\lambda' + 122.7266, \quad (4)$$

$$\lambda''' = 0.96473\lambda'' + 175.540, \quad (5)$$

$$\lambda' = 1.06422\lambda''' - 325.2523, \quad (6)$$

where λ', λ'', and λ''' are, respectively, the heat conductivities of the first, second, and third mixtures (25, 50, and 75 wt % methanol).

CONCLUSIONS

(1) The heat conductivities of methanol–*n*-nonanol binary mixtures were determined experimentally at content of 25, 50, and 75 wt % in the temperature interval 293–600 K and pressures ranging from 0.1 to 60 MPa. The experiments were carried out on a modified setup developed by the authors with the use of a cylindrical tricalorimeter operating in the regular mode. The results obtained are processed using the method of comparative calculations.

(2) An equation is proposed for determining the heat conductivity. This equation reflects the dependence of heat conductivity on concentration, temperature, and pressure. Experimental data for methyl and *n*-nonyl alcohols are processed using data on their densities.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Heat Conductivity of Methanol–*n*-Dodecanol Binary Solutions in a Wide Range of Temperatures and Pressures

Ya. M. Naziev and M. M. Bashirov

Azerbaijani Technical University, Baku, Azerbaijan

Received May 14, 2002; in final form, November 2002

Abstract—The heat conductivity of mutual methanol–*n*-dodecanol solutions was measured at various pressures, temperatures, and concentrations. The measurements were carried out on a modified cylindrical tricalorimeter.

The heat conductivity λ is an important physicochemical property of liquids and gases. Consequently, studying the heat conductivity is of indubitable practical importance.

The already carried determinations of λ for alcohols were reviewed in [1]. Three values are known from the literature for the heat conductivity at high pressure, with the differences between these values being unacceptably large. Therefore, the heat conductivity of methyl alcohol has been measured previously at temperatures of 293–600 K and pressures in the range 0.1–60 MPa [2]. A comparison of the newly obtained data on the heat conductivity λ of methanol demonstrated that they are in satisfactory agreement only with the data of [3].

The heat conductivity of *n*-dodecyl alcohol was measured at pressures of up to 50 MPa and temperatures of 326–624 K in [4]. The present study supplements data on the λ value for the system methanol–*n*-dodecanol, which makes it possible to obtain mutual dependences of binary solutions.

The experiments were carried out on a modified setup [2, 5]. The same setup was used to measure the λ value for neat *n*-dodecyl alcohol [4] and to make a control measurement of λ for a model liquid, methanol [2].

The heat conductivity of the system methanol–*n*-dodecanol was studied in the liquid state up to 600 K and 60 MPa at component content of 25, 50, and 75 wt %.

The basic dimensions of the device were as follows (mm): diameter of inner measuring cylinder 12.255, inner diameter of the outer cylinder 12.931, annular clearance 0.338, length of measuring cylinders 40, length of compensating cylinders 40. The maximum error in determining the heat conductivity was 1.8%. In the experiments, the Rayleigh number was much smaller than 1000, and, therefore, any convection was ruled out. No corrections for heat radiation across the liquid layer were made since the alcohols are strongly absorbing media.

The results obtained in determining λ are summarized in the table. The reproducibility of the experimental points was better than 0.33%.

The heat conductivities of neat methanol and *n*-dodecanol were taken from [2, 4].

The components taken for preparing the solution had the following characteristics. For methanol: ρ_4^{20} = 791.14 kg m^{-3}, melting point T_m = 175.49 K, boiling point T_b = 337.70 K, critical temperature T_{cr} = 512.64 K, critical pressure P_{cr} = 8.096 MPa, critical density ρ_{cr} = 272 kg m^{-3}; for *n*-dodecanol, respectively: ρ_4^{20} = 829.69 kg m^{-3}, T_m = 297.07 K, T_b = 537.79 K, T_{cr} = 720 K, P_{cr} = 2.080 MPa.

The data in the table suggest that the curves describing the concentration dependence of the heat conductivity in the system methanol–*n*-dodecanol show negative deviations from additivity in the range of state parameters studied, with these curves being symmetrical with respect to the additivity line.

Analysis of the experimental data suggests the following empirical equation reflecting the dependence of the heat conductivity of solutions on concentration, pressure, and temperature:

$$\lambda = \lambda_1 x_1 + \lambda_2 x_2 + 10^{-4} x_1 x_2 (\alpha \Delta T + \beta P - \gamma), \quad (1)$$

where, λ_1, λ_2 are the heat conductivities of the first and second components; x_1, x_2 the concentrations in mass fractions; $\Delta T = T - T_0$, $T_0 = (T'_m + T''_m)/2$, where T_0 is the base temperature; T'_m, T''_m are the melting points of the first and second components; α, β, and γ are constants for a given system, found from experimental data to be $\alpha = 0.1571$, $\beta = 0.533$, and $\gamma = 161.008$.

Equation (1) describes the experimental data with an error not exceeding the experimental error.

As seen from Eq. (1), the deviation from additivity for liquid mutual solutions of the system methanol–*n*-dodecanol depends not only on concentration, but also on temperature and pressure. Raising the temperature and pressure affects negatively the magnitude of the maximum deviation $\delta\lambda$[1]. For example, at 5 MPa and 300 K $\delta\lambda = 35.0$ W m^{-1} K^{-1} and $\delta\lambda/\lambda = 1.9\%$, and at 50 MPa and 500 K $\delta\lambda = 23.0$ W m^{-1} K^{-1} and $\delta\lambda/\lambda = 1.45\%$ ($x_1 = x_2 = 0.5$).

A theoretical expression is known, which relates the heat conductivity and the thermal pressure [6]:

$$\lambda = \lambda_0 + a(P_t/T)^n, \quad (2)$$

where λ is the heat conductivity at given T and P; λ_0 is the heat conductivity of the substance at atmospheric pressure in the gas phase; a, n are constants for the given substance; T is absolute temperature; P_t is the thermal pressure, $P_t = T\left(\frac{\partial P}{\partial T}\right)_\rho$.

The a value depends on density only slightly, and n can be considered invariable.

Expression (2) was derived from the Enskog equation [7].

The following equation can be written for determining the thermal pressure:

$$P_t = -T\left(\frac{\partial \nu}{\partial T}\right)_P \Big/ \left(\frac{\partial \nu}{\partial P}\right)_T, \quad (3)$$

where ν is the specific volume of the liquid, $\nu = 1/\rho$.

As seen from Eqs. (2) and (3), detailed experimental data on density or the equation of state is to be known for calculating the heat conductivities of liquids. Unfortunately, the density of methanol–*n*-dodecanol solutions has not been studied as a function of pressure, temperature, and concentration, and, therefore, Eq. (2) is inapplicable to the solutions.

[1] $\delta\lambda = \lambda - \lambda_{ad}$; λ_{ad} is λ value calculated on the basis of the additivity rule at $x = 0.5$.

The *PVT* dependence has been studied for *n*-dodecyl alcohol in the liquid phase in sufficient detail [8] (at $T = 308.15$–598.15 K, $P = 0.1$–50 MPa), and, therefore, Eq. (2) was tested for the case of *n*-dodecyl alcohol. Preliminarily, the thermal pressure was calculated in relation to P and T. It was found that at $a_0 = -1.0610286$, $a_1 = 0.003718$, $a_2 = -0.0000027143$, and $n = 0.992$ the error of the equation is the largest (3.0%), where $a = \sum_{i=0}^{2} a_i \rho^i$.

It has been proposed [9] to use a closed three-coordinate system in processing data on thermal properties, including heat conductivity, of solutions. However, this method allows data processing for only three solutions with different concentrations or compositions. The three-axis coordinate system is inapplicable to the case of simultaneously four solutions. Thus, a four-axis coordinate system should be used. In the present study, an attempt is made to apply such a technique to four binary systems. The use of a four-axis coordinate system will make it possible to relate in a simple way the heat conductivities of the solutions, to process these data graphically and prognosticate the heat conductivity of a solution under study on the basis of the other three solutions, and to perform, when necessary, interpolation and extrapolation. Below, the essence of the method is described.

The heat conductivities of the systems studied: methanol–*n*-hexanol, methanol–*n*-nonanol, methanol–*n*-undecanol, and methanol–*n*-dodecanol, are processed in a four-coordinate system (see figure). Four coordinate axes, *OA*, *OB*, *OC*, and *OD*, are set in the square *ABCD*. On each axis, the heat conductivity of a single solution is plotted (methanol with an alcohol). As an example serve (50 + 50%) solutions of the above alcohols. For simplicity, the heat conductivity scales are taken to be the same. For all the axes, the origin of coordinates lies at point *O*. Rectangular grids are used to find the intersection points of the heat conductivities at given P and T. Solution pairs give curves within the rectangular coordinate system. The four possible combinations of pairs give four curves *1*–*4*. It was found that, to within the experimental error, these curves are straight lines described by simple mutual-dependence equations $\lambda' = m\lambda'' + n$.

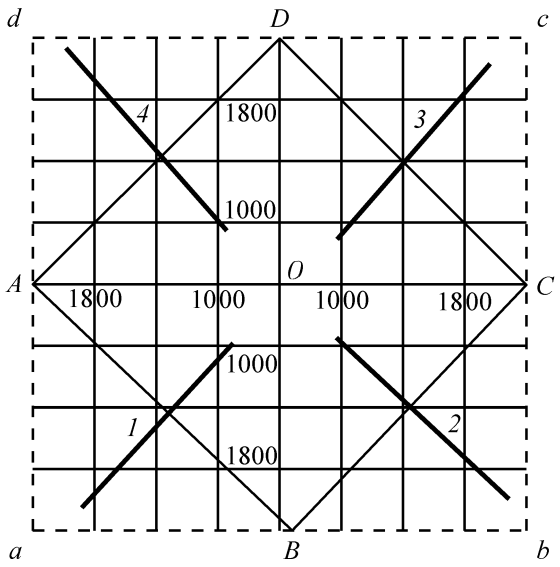
Processing gives the following equations:

$$\lambda_2 = 1.052\lambda_1 - 37.81, \quad (4)$$

$$\lambda_3 = 1.051\lambda_2 - 60.05, \quad (5)$$

$$\lambda_4 = 1.097\lambda_3 - 159.24, \quad (6)$$

$$\lambda_1 = 0.873\lambda_4 + 140.5, \quad (7)$$



Mutual dependences of the heat conductivities of the systems methanol–*n*-hexanol, methanol–*n*-nonanol, methanol–*n*-undecanol, and methanol–*n*-dodecanol at 50 wt % methanol. Solution: (*1*) *OA–OB*, (*2*) *OB–OC*, (*3*) *OC–OD*, and (*4*) *OD–OA*, where *O*, *A*, *B*, *C*, and *D* stand for, respectively, methanol, *n*-hexanol, *n*-nonanol, *n*-undecanol, and *n*-dodecanol.

where λ_1, λ_2, λ_3, and λ_4 are the heat conductivities of the first (methanol–*n*-hexanol), second (methanol–*n*-nonanol), third (methanol–*n*-undecanol), and fourth (methanol–*n*-dodecanol) solutions. In all the solutions, the content of methanol is 50 wt %.

Equations (4)–(7) make it possible to find the heat conductivity of a given solution on the basis of the other three solutions, which is very important for mutual verification of the accuracy of calculation.

It should be noted that *P* and *T* can be used as determining parameters for the properties of solutions that are far from the saturation line and the critical region. At the same time, for the zone close to the saturation line and the pseudocritical point, the respective reduced parameters π and τ should be used, where π is reduced pressure and τ is reduced temperature.

CONCLUSIONS

(1) An experimental study of the heat conductivity of methanol–*n*-dodecanol mutual solutions at temperatures of 300–600 K and pressures in the range 0.1–60 MPa was carried out at methanol content of 25, 50, and 75 wt %. The experiments were performed on a modified setup by the regular-mode method. The results obtained were processed graphically and analytically. A four-coordinate system making it possible to calculate the heat conductivity of a solution on the basis of the three others is proposed for the first time.

(2) The heat conductivity of *n*-dodecanol was related to thermal pressure, and a corresponding equation was obtained.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Influence of SiO_2 on the Equilibrium in the Cu–Ni–Cu_2O–NiO System

N. A. Fedorova, L. B. Tsymbulov, and L. Sh. Tsemekhman

Institut Gipronikel' Open Joint-Stock Company, St. Petersburg, Russia

Received February 11, 2003

Abstract—The equilibrium between a copper–nickel alloy and an oxide melt in the Cu_2O–NiO–SiO_2 system was studied experimentally. The distribution coefficients of nickel were determined as a function of the content of silicon dioxide, and the ratio of activity coefficients of nickel and copper oxides at 1300°C was found.

The information on thermodynamic properties of molten metallic and oxide systems makes it possible to solve a great number of problems related to the development of technological processes. The equilibrium between a metallic melt of copper with admixture of nickel and iron silicate melts with high concentration of copper and nickel oxides is of interest when analyzing pyrometallurgical processes associated with the production of copper from nickel-containing copper raw materials. To processes of this kind, in particular, belong oxidizing fusion of a copper concentrate obtained by flotation of converter matte in converters with oxygen overdraft to give nickel-containing [1, 2] and blister copper [3, 4], fusion of a similar concentrate to yield nickel-containing copper in a converter with bubbling oxygen [5], and a number of other processes.

This study is a continuation of [6], in which the equilibrium between a cooper–nickel metallic melt and Cu_2O–NiO oxide melt was analyzed. The aim of the present study was to assess the influence exerted by the main components of an industrial slag melt on the equilibrium in this system.

The equilibrium distribution of copper and nickel between metallic and oxide-silicate phases is governed by the exchange reaction

$$(Cu_2O) + [Ni] = (NiO) + 2[Cu]. \quad (1)$$

The parenthesis traditionally denote the oxide-silicate phase, and square brackets, the metallic phase.

The coefficients L_m of metal distribution between a copper–nickel alloy and an oxide-silicate melt are expressed as

$$L_m = (Ni)/[Ni]. \quad (2)$$

Since the activities of copper and nickel in metallic melts saturated with oxygen can be found in the literature [7], we can calculate the ratios of activity coefficients in Cu_2O–NiO–SiO_2 melts, using the known equilibrium constant of reaction (1):

$$\gamma_{NiO}/\gamma_{Cu_2O} = K_a/\left[\left(x_{NiO}/x_{Cu_2O}\right)\left(x_{Cu}^2/x_{Ni}\right)\left(\gamma_{Cu}^2/\gamma_{Ni}\right)\right]. \quad (3)$$

The equilibrium constant of reaction (1) was calculated from the melting heat $\Delta H_m = 50.6$ kJ mol^{-1} [8], with account of nickel oxide supercooling, to be 8.9 at 1573 K.

It was expedient to begin this study with consideration of the phase diagram of Cu_2O–NiO–SiO_2. Since this diagram could not be found in the accessible publications, we consider the available data on the binary systems Cu_2O–SiO_2 and NiO–SiO_2.

The first results obtained in studying the system Cu_2O–SiO_2 by chemical methods for determining melting points are indicative of the presence of various copper silicates: $Cu_2O \cdot SiO_2$, $2Cu_2O \cdot SiO_2$, $3Cu_2O \cdot SiO_2$, $5Cu_2O \cdot SiO_2$, and $CuO \cdot SiO_2$. However, the majority of later studies ruled out the existence of these or any other chemical compounds in the system. In particular, the systems Cu_2O–SiO_2 and CuO–SiO_2 have been studied in detail by Berezhnoi [9, 10] on quenched samples, using microscopic and X-ray methods, and then by Gadalla [11] by means of gravimetry. They also found that there are no chemical compounds in this system. In [12], the system Cu_2O–SiO_2 was subjected to X-ray diffraction analysis, and the phase diagram of the CuO–SiO_2 sys-

1070-4272/03/7604-0526 $25.00 © 2003 MAIK "Nauka/Interperiodica"

tem in air was constructed on the basis of a critical consideration of published data and the authors' own experimental data. It was found that copper(II) oxide completely dissociates at 1025°C into copper(I) oxide and oxygen and the eutectic containing 92 wt % Cu_2O + 8% SiO_2 melts at 1050°C.

The system NiO–SiO_2 belongs to eutectic systems with broad stratification region. It is seen from the phase diagram presented in [13] that a single compound, specifically, nickel orthosilicate Ni_2SiO_4 with olivine structure, exists in the system. It was shown in [14] that, unlike other olivines, which melt congruently, nickel orthosilicate dissociates in the solid state at 1545°C.

Using the EMF method, Rog and Borchardt [15] determined the standard molar Gibbs energy of Ni_2SiO_4 formation from oxides by reaction (4) and also found its temperature dependence:

$$2NiO + SiO_2 = Ni_2SiO_4, \quad (4)$$

$$\Delta G^0 = -0.0089T + 15.941. \quad (5)$$

It is seen from dependence (5) that, with increasing temperature, the Gibbs energy inevitably becomes higher and the reaction equilibrium is shifted toward the starting compounds.

The standard molar Gibbs energy of nickel orthosilicate formation by reaction (4) was determined in a similar manner in [16, 17]. The resulting Gibbs energies for Ni_2SiO_4 agree well with each other and are equal at 1300°C to –2.5 [16] and –2.6 kJ mol^{-1} [17]. These values indicate that the equilibrium constant is small and, hence, the compound obtained is rather unstable.

The available published thermodynamic data for the systems Cu_2O–SiO_2 and NiO–SiO_2 suggest that introduction of silicon dioxide into the system Cu_2O–NiO will virtually not affect the activity coefficient of copper oxide, but, in all probability, the activity coefficient of nickel oxide will decrease owing to the existence of a chemical compound in the system.

To determine the dependence of L_{Ni} on the composition of the oxide melt Cu_2O–NiO–SiO_2 and the numerical values of the $\gamma_{NiO}/\gamma_{Cu_2O}$ ratio, we performed a set of experiments by a technique similar to that described in [6], except that varied amounts of silicon dioxide were introduced into the stock. The experiments were carried out at 1300°C in an argon atmosphere. In addition to analyzing the obtained metallic alloys and oxide melts by chemical methods, part of samples of the oxide melts was quenched on a copper disc (cooling rate of about 10^3 deg s^{-1}) and studied by scanning electron microscopy and X-ray fluorescence microanalysis.

Content of nickel $[Ni]_m$ in copper and silicon dioxide (SiO_2) and nickel (Ni) in slag, and distribution coefficients of nickel L_{Ni}, as determined from experimental data

The content of nickel in copper and silicon dioxide in nickel and slag, and also the distribution coefficients of nickel, found in our experiments, are listed in the table.

The main difficulty in studying the equilibrium between metallic and oxide melts of the system Cu_2O–NiO is that its phase diagram and, in particular, the liquidus line are unknown. Therefore, we subjected the samples obtained to chemical analysis only if we were sure that the oxide melt was homogeneous. In this case the ratio of the amounts of the starting

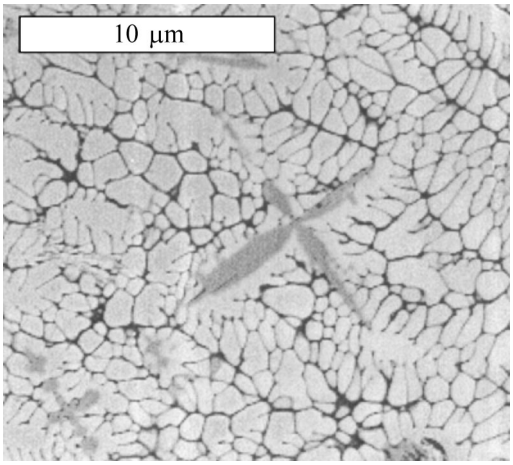

Fig. 1. Microstructure of a homogeneous oxide melt of the system Cu_2O–NiO–SiO_2.

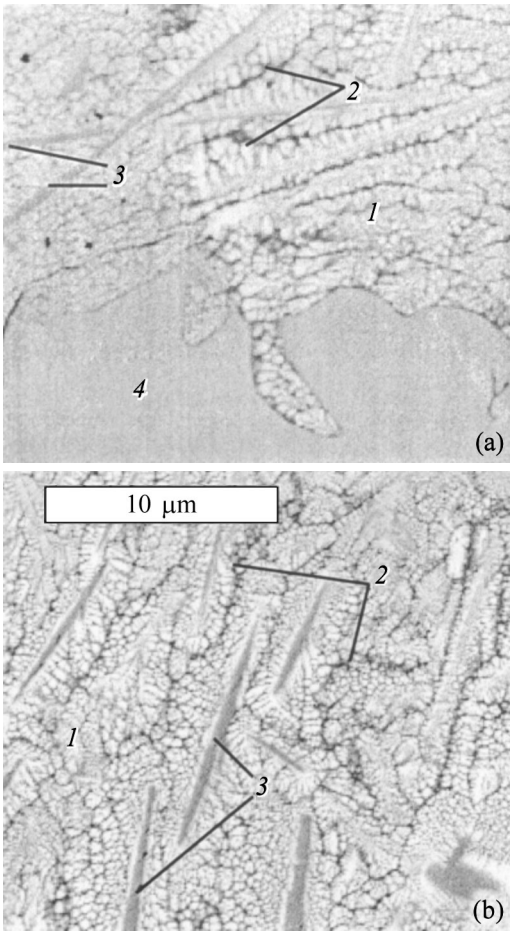

Fig. 2. Microstructure of quenched oxide melt with NiO/Cu_2O ratio of 0.13. Microstructure of (a) melt with inclusions of nickel oxide and (b) homogeneous oxide melt. Phase close in composition to (*1*) Cu_2O, (*2*) SiO_2; (*3*) nickel silicate (wt %): SiO_2 29, NiO 65.4, Cu_2O 5; (*4*) nickel oxide (wt %): SiO_2 0.2, NiO 96.7, Cu_2O 2.5. Average composition of the homogeneous part of the melt (wt %): SiO_2 6.72, NiO 6.67, Cu_2O 83.87.

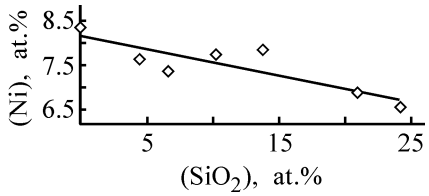

Fig. 3. Dependence of nickel content (Ni) in an oxide melt on the silicon oxide content (SiO_2) in the melt at NiO/Cu_2O ratio equal to 0.11.

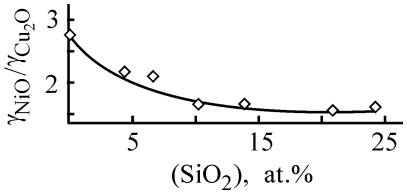

Fig. 4. Dependence of the ratio of activity coefficients of nickel and copper oxides $\gamma_{NiO}/\gamma_{Cu_2O}$ on the content of silicon dioxide (SiO_2) in an oxide melt.

materials was selected in such a way that, first, the NiO/Cu_2O ratio of molar concentrations in the oxide melt was less than 0.11 (limiting ratio of molar concentrations for a homogeneous melt in the system Cu_2O–NiO [6]) and, second, the concentration of SiO_2 was negligible (see phase diagram for Cu_2O–SiO_2 in [12]). The homogeneity of the melt was selectively monitored by its quenching.

A typical microstructure of a homogeneous oxide melt of the system Cu_2O–NiO–SiO_2 is shown in Fig. 1. It is evident that the melt is formed of copper(I) oxide on a matrix of silicon oxide with inclusions of nickel silicate. In our opinion, the phase based on nickel silicate is of secondary origin, i.e., it is formed in the course of crystallization because of the insufficient cooling rate. The size of other components of the sample also indicates that the melt is homogeneous.

When burdening involved possible going beyond the limits of the homogeneity area, the use of quenching and subsequent microanalysis to determine the phase composition and the composition of directly the homogeneous part of the melt was mandatory.

The typical microstructure of samples with inclusions of nickel silicate and oxide is shown in Figs. 2a and 2b. As a rule, these are melts with high NiO/Cu_2O ratios, in which nickel oxide crystals are irregularly distributed in the bulk of a sample. The size of these crystals is indicative of their primary origin, i.e., the crystals are present in the melt in the solid state.

We determined the concentrations of the components of the oxide melt with inclusions of nickel oxide for the subsequent calculation of L_{Ni}, with the analysis disregarding the solid phase. In this case, the maximum possible NiO/Cu_2O ratio in a slag melt at the boundary of saturation with nickel oxide in the system Cu_2O–NiO–SiO_2 was 0.13. As noted above, this ratio is 0.11 for the system Cu_2O–NiO. Thus, the introduction of silicon dioxide somewhat increased the ratio.

To assess the effect produced by raising the content of silicon dioxide on the content of nickel in a slag and on the ratio of the activity coefficients of nickel and copper oxides, we consider separately experiments in which the oxide melt was characterized by the same ratio NiO/Cu_2O (0.11) and varied SiO_2 content. The dependence of the nickel content in the oxide phase on the silicon dioxide content is shown in Fig. 3. It is seen that, with increasing concentration of silicon dioxide in a slag, the content of nickel in it decreases. However the dependence of $\gamma_{NiO}/\gamma_{Cu_2O}$ on SiO_2 shows different behavior (Fig. 4). On addition of up to 10 at.% silicon dioxide, the $\gamma_{NiO}/\gamma_{Cu_2O}$ ratio

decreases rapidly to become 1.7 times smaller than the $\gamma_{NiO}/\gamma_{Cu_2O}$ ratio in the system Cu_2O–NiO; further increase in the content of silicon oxide leaves this ratio virtually unchanged. A noticeable drop in the $\gamma_{NiO}/\gamma_{Cu_2O}$ value at small content of SiO_2 seems to be due to the fact that silicon oxide forms associates with nickel oxide, which makes lower the activity coefficient of nickel oxide, but virtually does not affect the activity coefficient of copper oxide.

At the NiO/Cu_2O ratio in an oxide melt equal to 0.11 and at silicon dioxide content in the slag exceeding 10 at.%, the whole amount of nickel oxide (in terms of the stoichiometry of the compound Ni_2SiO_4) is already associated with silicon oxide, and, therefore, an excess amount of the latter does not affect the activity coefficient of nickel oxide and, hence, the ratio of the activity coefficients.

There is good reason to believe that NiO and SiO_2 are associated in the melt in the same proportions as in Ni_2SiO_4. This is evidenced by the data of X-ray fluorescence microanalysis (Figs. 2a and 2b), which indicate that the compositions of nickel silicate and the compound in the phase diagram are close.

The coefficients of nickel distribution between an oxide melt and a metallic alloy, obtained in this study and in [6], are shown in Fig. 5a as functions of the oxide melt composition. It is seen that L_{Ni} becomes greater on addition of SiO_2 to the Cu_2O–NiO system. This is due to the fact that silicon dioxide tends to form associates with nickel. The dependence of the nickel distribution coefficient on the composition of the oxide melt in the presence of silicon dioxide is described by the equation

$$L_{Ni} = 20.285(NiO)/(Cu_2O) + 2.472. \quad (6)$$

Here (NiO) and (Cu_2O) are the concentrations (at.%).

The ratios of activity coefficients of nickel and copper oxides, found in this study, are shown in Fig. 5b. Also presented in the figure is a similar dependence obtained in [6] for the equilibrium with a binary NiO–Cu_2O melt. It is seen from Fig. 5b that the presence of silicon dioxide in a system decreases somewhat the ratio of the activity coefficients of the oxides.

As already mentioned, this is due to a drop in the activity coefficient of nickel because of its association with silica in the melt.

The dependence of the activity coefficients of nickel and copper oxides on the ratio of their concentrations in the Cu_2O–NiO–SiO_2 melts at 1300°C is described by the analytical equation

$$\gamma_{NiO}/\gamma_{Cu_2O} = 3.631 - 14.759(NiO)/(Cu_2O). \quad (7)$$

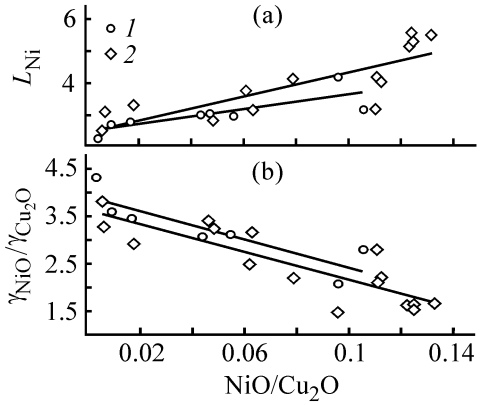

Fig. 5. Dependence of (a) nickel distribution coefficient L_{Ni} and (b) ratio of activity coefficients of nickel and copper oxides $\gamma_{NiO}/\gamma_{Cu_2O}$ on the ratio of the contents of nickel and copper oxides in an oxide melt. (*1*) Cu_2O–NiO, (*2*) Cu_2O–NiO–SiO_2.

CONCLUSIONS

(1) Silicon dioxide affects the coefficient of nickel distribution between a copper–nickel alloy and an oxide melt, which increases in proportion to the content of silicon dioxide and nickel in a slag.

(2) Addition of silicon dioxide to the NiO–Cu_2O system results in an insignificant decrease in the $\gamma_{NiO}/\gamma_{Cu_2O}$ ratio. The decrease in the $\gamma_{NiO}/\gamma_{Cu_2O}$ ratio in the Cu_2O–NiO–SiO_2 melts results from the formation of associates between NiO and SiO_2. This is confirmed by the results obtained in studying quenched oxide melts by X-ray fluorescence microanalysis.

(3) The data obtained can be used in analyzing the refinement of nickel-containing blister copper in the presence of silicon dioxide in the forming slag.

SORPTION AND ION-EXCHANGE PROCESSES

A Study of Adsorption-Structural Properties of Natural and Processed Diatomites

Received August 19, 2002

Abstract—The effect of alkaline, acid, and lime treatment on the chemical composition and sorption-structural characteristics of natural diatomites was studied. The efficiency of the lime treatment of natural diatomites for obtaining adsorbents was substantiated.

Diatomites, which belong to the group of sedimentary siliceous rocks, are composed of diatom shells having the form of an X-ray-amorphous variety of opal. Despite the large volume of mining of diatomites on the territory of CIS countries, their use is mainly limited to manufacture of cement, claydite, and bricks [1]. It is known that more promising and economically effective is use of these valuable mineral resources for manufacture of adsorbents, filter powders, fillers, and catalysts [2–5].

Synthesis of adsorbents and filter powders by lime and acid treatment of natural diatomites was studied in [3, 5–9].

The present communication reports the principal results of a study of the adsorption and structural characteristics of natural diatomites and products obtained in their alkaline, acid, and lime treatments. As objects of study were chosen typical representatives of diatomite rocks containing 44.16 to 81.00 wt % amorphous silica and 13 to 35 wt % accessory minerals (Table 1). Depending on the content of total and amorphous silica and that of accessory minerals, these rocks are conventionally termed high-quality (1), medium-quality (2), and low-quality (3) rocks.

EXPERIMENTAL

The diatomites under study were subjected to treatment with various reagents (5% NaOH solution, 6–27% HCl solution, milk of lime with CaO content of 150 g l^{-1} at $CaO : SiO_2$ molar ratio of 0.1–1.5 in the initial mixture) at 95°C and mass ratio l : s = 7. The duration of alkaline, acid, and lime treatments was 2, 4, and 1–16 h, respectively.

Washed, filtered, and dried products were subjected to comprehensive physicochemical studies.

The sorption properties of natural and processed diatomites were assessed by determining their specific surface area by the BET method [10] from low-temperature adsorption of nitrogen. For all of the samples studied, isotherms of adsorption of water and benzene vapors were measured, and porous structure param-

Diatomite: (A) (*1*–*3*) low-quality, (*4*) medium-quality, and (*5*) high-quality; (B) (*1*) medium-quality, (*2*) high-quality, and (*3*–*5*) low-quality.

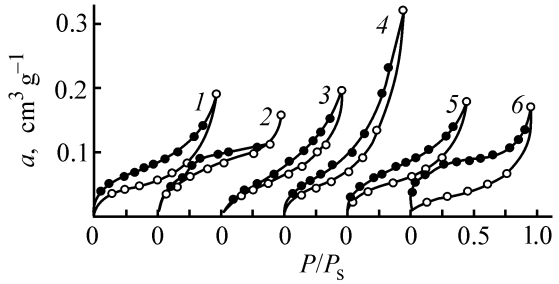

Fig. 2. Isotherms of water vapor adsorption at 20°C on diatomites treated with (*1*, *3*, *5*) alkali and (*2*, *4*, *6*) acid. Diatomite: (*1*, *2*) high-quality, (*3*, *4*) low-quality, and (*5*, *6*) medium-quality.

eters were calculated on their basis [11, 12]. A spectroscopic analysis was carried out on a Specord IR instrument in the spectral range 400–4000 cm^{-1}, and X-ray diffraction analysis, on a DRON-1,5 diffractometer [13, 14]. The chemical composition, density ρ, and volume mass m_V were found using the known procedures [15, 16].

The results obtained indicate that natural diatomites mainly possess macroporous structure with predominance of pores of the same radius, but the structure also contains intermediate pores.

As seen from Fig. 1A, the isotherms of benzene vapor adsorption on the surface of high- and medium-quality diatomites (curves *5* and *4*) have similar shapes and show hysteresis at P/P_s = 0.2–0.7. At P/P_s > 0.75, a dramatic increase in benzene adsorption is observed for all the three types of diatomites (Table 2, Fig. 1A), which points to the presence of a developed macroporous structure.

Isotherms of water adsorption (Fig. 1B) on diatomites of all types show, except in the case of sample no. 1 (curve *2*), hysteresis characteristic of swelling sorbents. The adsorption and desorption branches do not coincide in the entire range of relative pressures P/P_s (0–1). The width of hysteresis in the isotherms of water vapor adsorption in the initial region (P/P_s < 0.2) depends on the content of impurities (clayey materials). The only exception is sample no. 2 (curve *1*), whose hysteresis is wider in the initial region than that for other samples, presumably, because of the fact that the clayey component of this diatomite has an expanding structural unit (mainly of montmorillonite type) [17]. The desorption branches of the isotherms of water vapor adsorption on all the diatomites studied show a bend at P/P_s = 0.2–0.3, which corresponds to pores whose radii calculated by the Kelvin method [7] are equal to 7 Å. The presence of pores with radii of 7–8 Å in high- and medium-quality diatomites, which are nearly totally composed of intact diatom shells, suggests that pores with this radius belong to silica of organic origin.

With the content of accessory minerals increasing from 13.0 to 18.5 wt %, the density of natural diatomites grows and the porosity decreases (Tables 1 and 2). An inverse relationship between the content of diatom shells (beginning with 60–70 million shells per gram) in diatomites and their vol-

ume mass (140–1350 $kg\ m^{-3}$) is observed, in good agreement with published data [18]. The specific surface area of all the diatomites studied is small, with high- and medium quality diatomites, in which the content of the main component (diatom shells) exceeds that in low-quality diatomites, characterized by smaller specific surface area and total pore volume than these latter (Table 2). A conclusion can be made on the basis of Tables 1 and 2 that the adsorption capacity of natural diatomites is low and they cannot be effectively used in sorption processes without preliminary treatment.

As seen from Figs. 2 and 3A and Table 3, alkaline, acid, and lime treatment of natural diatomites strongly modifies their chemical composition and physicochemical and adsorption-structural properties.

The desorption branches of the isotherms of water vapor adsorption on diatomites subjected to alkaline treatment (Fig. 2) show no bend at P/P_s = 0.2–0.3, and, consequently, there are no pores with radius of 7–8 Å. By contrast, pores with this radius are preserved in the diatomites after acid treatment. It has been shown [18] that, in the course of an alkaline treatment of the diatomites, amorphous silica contained in them is completely dissolved, whereas clayey materials remain unchanged (Table 1). Acid treatment has nearly no effect on the diatom shells and silica of chemical origin, whereas the clayey component of the diatomites partly disintegrates [18].

Reflections at 3.5–4.5 Å and absorption bands at 800 and 1100 cm^{-1}, which are characteristic of amorphous silica, disappear from X-ray diffraction patterns and IR spectra of diatomites after alkaline treatment. In the IR spectra of diatomites subjected to acid treatment, the intensity of absorption bands at 535, 430, and 3620 cm^{-1}, which are associated with montmorillonite, decreases.

The isotherms of adsorption of water and benzene vapor on diatomites subjected to lime treatment, which show hysteresis of type B according to de Boer's clas-

* In addition total CaO, the sample contains 2.84 wt % free CaO.

sification, are characteristic of layered adsorbents. The bend in the desorption branches (Fig. 3A) at P/P_s 0.20–0.25 (in adsorption of benzene vapor) and 0.25–0.30 (in adsorption of water vapor) is due to adsorption of benzene and water vapors in the interlayer space of the newly formed calcium hydrometasilicates. The width of hysteresis grows with increasing CaO/SiO_2 molar ratio in the initial mixture, which points to a rise in the content of calcium hydrometasilicates of the C–S–H (1) type (according to Taylor's classification [20]) in the products obtained (Table 4). Raising the duration of the lime treatment of diatomites from 1 to 10 h at CaO/SiO_2 molar ratio in the initial mixture equal to 0.4 has virtually no effect on the run of the isotherms of water adsorption (Fig. 3A), despite the significant change in the specific surface area of the samples (Table 3). With the duration of treatment raised to 16 h, the bend in the desorption branches of the isotherms of water adsorption on the surface of diatomites treated with milk of lime and the hysteresis become more pronounced (Fig. 3B).

At CaO/SiO_2 molar ratio in the initial mixture of 0.2–0.5, the average pore radius calculated from the isotherms of benzene vapor adsorption on high-quality diatomites remains unchanged after lime treatment (11 Å), at CaO/SiO_2 = 0.6 it has the minimum value of 9 Å, and at CaO/SiO_2 molar ratios in the range from 0.7 to 1.25 it increases to 13 Å (Table 3). At constant CaO/SiO_2 molar ratio in the initial mixture (0.4), the average pore size (11–10 Å) and specific surface area remain unchanged when the treatment duration is raised from 1 to 16 h. The maximum specific surface area and pore volume are observed at CaO/SiO_2 = 0.4 (Table 3). This behavior is characteristic of all kinds of diatomites.

Analysis of the experimental data obtained and published evidence suggests that, in contrast to the other above-mentioned treatments, lime treatment of diatomites results in that active centers appear in the form of unsaturated C–S–C bonds on the surface of silica of chemical origin [20–23]. Owing to their amorphous uniform surface and structural features, diatomites treated with milk of lime have enhanced sorption capacity.

CONCLUSIONS

(1) A comprehensive study of the adsorption-structural properties of natural and treated diatomites demonstrated that, in contrast to other methods, lime treatment of diatomites leads to a pronounced increase in the specific surface and total pore volume of natural diatomites.

(2) The optimal CaO/SiO_2 molar ratios in lime treatment of diatomites were revealed, at which the treatment products have the highest adsorption capacity and most developed pore structure.

(3) It was shown that, with increasing duration of lime treatment of diatomites, the average pore radius remains virtually constant.

(4) Strong differences in the structure of diatomites subjected to treatments with different reagents were revealed.

SORPTION AND ION-EXCHANGE PROCESSES

Structure and Functional Composition of the Surface of Cambrian Clay as Influenced by Modification Conditions

Yu. A. Novikova and V. G. Korsakov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 18, 2002

Abstract—The possibility of directed modification of the functional composition of the surface and sorption properties of a disperse Cambrian clay was examined. The concentration of donor–acceptor centers was determined and changes in the structure and composition of the adsorption centers in the course of the acid-base treatment were evaluated. The mineralogical composition of the Cambrian clay and of the products of its chemical modification was analyzed by the successive dissolution procedure.

Clays from various deposits are used as raw materials in production of ceramics and as sorbents. In these cases, the requirements to the structure and properties of clays are fundamentally different. The plasticity, phase stability, and refractoriness of clays are the most important in ceramics production, whereas the surface area, functional composition, and sorption capacity are the decisive properties for sorbents. The sorption capacity of natural clays is low and is determined by secondary porosity. The particle size and crystal structure (i.e., the nature of the clay-forming minerals) also affect the sorption capacity. The static sorption capacity of kaolins, illites, and montmorillonites is 3–15, 10–40, and 80–150 mg-equiv per 100 g dray clay, respectively [1]. The exchange capacity of natural aluminosilicates can be improved by treatment with mineral acids. The optimal activation conditions (acid concentration, activation time, liquid-to-solid phase ratio) for bentonites and zeolites from Turkmenistan were determined in [2].

To prepare inexpensive and available sorbents for treatment of soil to remove transition (heavy) metals, we examined the possibility of chemical modification of finely dispersed Cambrian clays mined in subway tunneling. The directed modification of the clay sorption properties was based on a physicochemical study of the structure and functional composition of the surface of the initial and modified samples. To study the functional composition of the clay surface and to monitor its changes in the course of modification, we used the indicator procedure for evaluation of the donor–acceptor properties, which define the possibility of using the modified clays as sorbents. The sensitivity of this procedure, proposed by Tanabe [3], was significantly improved by modern spectroscopic methods [4, 5], in particular, by diffuse reflection spectroscopy [4]. In this study we used the procedure developed by Nechiporenko [5], which allows determination of both Brønsted (protonic) and Lewis (aprotic) centers.

EXPERIMENTAL

We studied samples prepared by treatment of Cambrian clay with sulfuric acid and sodium hydroxide solutions at 20 ± 0.5 and 105 ± 0.5°C. The clay samples were ground and treated with H_2SO_4 of various concentrations (100 g clay per 100 ml acid). After that, the samples were washed with water to pH ~ 7 and then treated with NaOH solution at the same temperature as that of H_2SO_4 treatment. Our preliminarily data showed that the most pronounced differences in the structure and composition of the modified clays appear after treatment with 0.5 and 5.0 M solutions of sulfuric acid, and all further experiments on clay modification were performed using these acid concentrations.

* Total relative intensity.

The functional composition of the surface was characterized by the distribution of donor–acceptor active centers on the clay surface, which was determined by adsorption of colored acid–base indicators with pK_a varying from –4.4 to 12.8; the procedure is described elsewhere [6]. The optical density of the indicator solutions was recorded on an SF-26 spectrophotometer, then the concentration of the active centers q_{pK_a} (μg-mol g^{-1}) with given pK_a and the Hammett function of the surface acidity H_0 were evaluated. In accordance with [5], the optical density of the blank sample was also taken into account.

The specific surface area of the samples, S_{sp}, was determined by the Klyachko–Gurvich procedure (low-temperature adsorption of air), whose sensitivity was improved using the silicone oil as a pressure-gauge fluid. The particle size was tentatively evaluated from the following equation:

$$l = K_f/(\rho S_{sp}),$$

where ρ is the average density of aluminosilicates (3.5 g cm^{-3}, particle shape was disregarded) and K_f is the coefficient for the spherical and cubic particle shapes (K_f = 6).

The crystal structure of the initial and modified clays was studied by powder X-ray diffraction (XRD) on a DRON-3.0 diffractometer (Cu_{K_α} radiation, Ni filter). The samples were ground in an agate mortar and sifted with a sieve no. 004. The interplanar spacing was calculated from the Bragg equation:

$$d/n = \lambda/2\sin\theta.$$

The size of the coherent scattering regions was evaluated from the broadening of the diffraction peak, using the Selyakov equation:

$$D = k\lambda/B\cos\theta,$$

where D is the size of the coherent scattering region (nm), B is the half-width of the diffraction peak (rad), and k is the constant approximately equal to 1.

The content of heavy metals in the initial and modified Cambrian clay was analyzed on a KVANT-AFA atomic-adsorption spectrometer. The content of the majority of heavy metals in the clays of the Leningrad oblast, except iron [7, 8] (14 g per kg dray clay), is small (≤1 g kg^{-1}). Furthermore, these metals mostly occur in the form of polyanions, and only a minor fraction, in the cationic form; therefore, unchanged clay cannot act as a source of soil pollution with heavy metals.

Data on the crystal structure, composition of the surface donor–acceptor centers, and specific surface area of the initial and modified clays are listed in the table.

Figure 1a shows the distribution of the donor-acceptor centers over the sample surface in the $q_{pK_a} = f(pK_a)$ coordinates (spectra of the adsorption center distribution (ACD) [5]), where q_{pK_a} is the content of the active centers, equivalent to the amount of the sorbed indicator with the corresponding pK_a. Shifts in the entire ACD spectrum or its separate bands and variations in the band intensity indicate changes in the energy state of the modified clay surface.

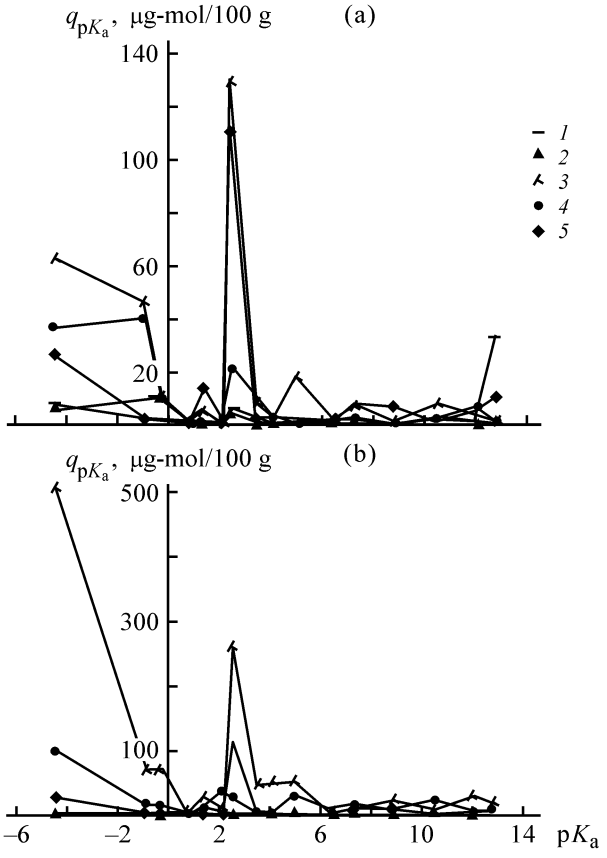

Fig. 1. Distribution of the adsorption centers in the samples treated with (a) 0.5 and (b) 5.0 M solutions of H_2SO_4 and NaOH at 20 ± 0.5 and 105 ± 0.5°C. Treatment: (*1*, *3*) acid, (*2*, *4*) base, and (*5*) initial clay. Temperature, °C: (*1*, *2*) 20 and (*3*, *4*) 105.

Since H_0 of the surface is a statistic mean value, it can be approximately evaluated from the ACD spectra, using the following equation:

$$H_0 = \Sigma\, pK_a q_{pK_a} / \Sigma\, q_{pK_a}.$$

It is known that the adsorption surface centers can be identified as Lewis and Brønsted acid and base centers. The initial clay contains both Lewis base (pK_a –4.4) and Brønsted acid (pK_a 2.5) centers; the Hammett function of the surface acidity H_0 3.9 and S_{sp} 19.3 $m^2\ g^{-1}$.

As seen from Fig. 1, after the clay treatment with 0.5 M H_2SO_4, the content of centers with pK_a –4.4 (Lewis centers providing hydrolytic adsorption of water) and 2.5 (OH groups on the anionic complex surface) strongly decreases, whereas the concentration of active centers with pK_a 10.5 (Brønsted base centers, substituted acid centers) increases.

The subsequent treatment with dilute NaOH solution makes lower the content of the active centers, and H_0 decreases from 5.9 to 1.3. The specific surface area after acid treatment slightly increases, and after base treatment it decreases to 15.2 $m^2\ g^{-1}$. When the sample is treated with 0.5 M H_2SO_4 at 105 ± 0.5°C, the specific surface area decreases to 15.7 $m^2\ g^{-1}$, and new active centers with pK_a –0.9, 5.0, and 10.5 (absent in the initial clay) appear; simultaneously, the concentration of the Brønsted acid centers increases. This is probably due to partial dissolution of the clay skeleton.

The content of the sorption centers after the base treatment decreases, although after treatment at 105 ± 0.5°C it is slightly greater, probably due to the precipitation of amorphous and finely crystalline silicates and aluminosilicates. Also possible is formation of porous crystalline aluminosilicates, zeolites [4]. Nevertheless, in all the cases, the final specific surface area does not exceed the specific surface areas of the initial Cambrian clay. The total content of the active centers increases from 0.19 (initial clay) to 0.31 mg-mol/100 g (after treatment with NaOH solution at 20°C) (see table).

After treatment of the clay with 5.0 M H_2SO_4, the content of the active centers (Fig. 1b) and specific surface area (see table) decrease appreciably; after treatment with 5 M sodium hydroxide solution, the content of the Lewis acid and base centers increases, and the content of the Brønsted centers decreases. The specific surface area after the acid treatment strongly decreases, whereas after the base treatment it increases, but remains smaller than that of the initial clay. After heating of the sample with concentrated sulfuric acid, the intensity of the bands of the Brønsted acid centers (pK_a 2.5) grows; simultaneously, the content of the other centers also increases, but to a lesser extent. After treatment with NaOH solution, the content of the active centers and the specific surface area decrease in parallel.

The powder diffraction patterns were obtained with ionization recording of the diffraction maxima at room temperature at a scanning rate of 2 deg min^{-1}. Location of the reflection maxima was determined with accuracy of 0.5 mm. The reflections were indentified using the ASTM database.

As seen from Fig. 2, the diffraction patterns of the initial and modified clays are complex and contain a series of intense reflections, which remain unchanged even after treatment of the clay with sulfuric acid and

sodium hydroxide at 20 ± 0.5 and 105 ± 0.5°C (3.29, 1.8, 1.36, 1.53, and 4.18 Å, in order of decreasing intensity). This fact suggests that the clay contains a crystalline skeleton with rather large coherent scattering regions. The most intense reflection (*d* 3.29 Å) is close to that of α-quartz (*d* 3.34 Å).

The identification of the sample structure using the database is rather difficult, because the reflections (typical of various clay-forming minerals) are shifted and superimposed. The preferred orientation of the crystals may also pead to significant error, especially in the analysis of anisotropic materials with nonspherical particles. All the defects in the crystalline sample cause diffuse scattering under angles different from the Bragg angles. Moreover, the reflections may shift owing to close atomic numbers of aluminum and silicon.

Thus, to identify the clay structure, we used the successive dissolution procedure [9]. As the amorphous fraction of the sample is dissolved in an acid, the number of reflections decreases and the diffraction pattern becomes simpler, whereas the crystalline structure represented by the reflections at 3.29, 1.8, 1.36, 1.53, and 4.18 Å remains unchanged. In particular, after treatment of the clay with 0.5 M H_2SO_4 at 20°C, the number of reflections in the XRD pattern and their intensity decrease. After subsequent treatment with 0.5 M NaOH, the intensity of the weak reflections increases somewhat. After treatment with H_2SO_4 at 105 ± 0.5°C, we obtained a sample with pronounced reflections typical of the initial clay, whereas all the other reflections disappeared. When this sample was treated with sodium hydroxide at the same temperature, the weak reflections observed in the initial clay (e.g., 2.26, 1.65 Å) appeared again. This suggests that the acid treatment removes the amorphous fraction of the clays, whereas the base treatment promotes precipitation of crystalline aluminosilicates from solutions retained in the pores after dissolution of amorphous or finely crystalline inclusions. In the course of treatment, the reflection width does not change noticeably, i.e., the size of the structural elements in the polycrystalline clay skeleton remains constant.

After subtraction of the reflections of the quartz and crystalline compounds precipitated after acid and base treatments, the spectrum contains the reflections allowing identification of kaolin with crystallite size of 202 nm (see table). Thus, in the Cambrian clay samples studied, about 33% is dispersed α-quartz (see table, 0.89/0.35). The rest contains kaolin or clay minerals and alumina. In the course of acid–base treatment, the compounds with a three-dimensional

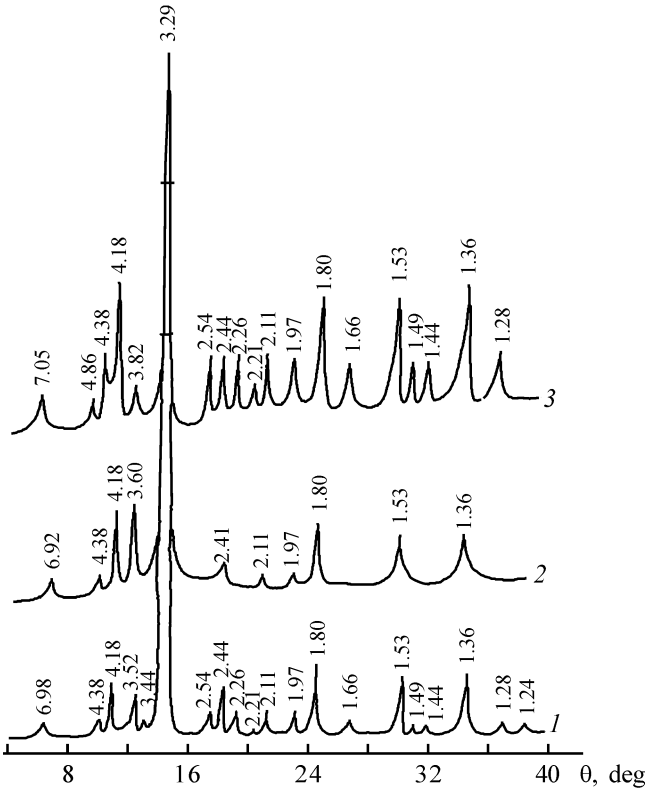

Fig. 2. Diffraction patterns of the (*1*) initial clay and (*2*, *3*) samples treated with 0.5 and 5.0 M solutions of H_2SO_4 and NaOH at 20 ± 0.5 and 105 ± 0.5°C. (θ) Bragg angle. Treatment: (*2*) 0.5 M H_2SO_4 and 105°C and (*3*) 5 M NaOH and 20°C.

skeleton (in contrast to the initial lamellar materials) precipitate. In this case, a decrease in the specific surface area is accompanied by an increase in the content of donor–acceptor centers, which increases the sorption activity of the surface in the ion-exchange stage of sorption.

The sorption capacity of the sorbents prepared was tested using lead(II) solutions (compound of hazard class I). The concentration of the initial solution was 40 mg l^{-1} and the s : l ratio was 10 g sorbent per 100 ml solution.

As seen from Fig. 3, the sorption of lead(II) cations on the modified clay samples proceeds in two steps. After the ion-exchange sorption, dissolution of the skeleton becomes predominant. The second stage includes bulk conversion of the initial silicate and aluminosilicate compounds, i.e., the degradation epitaxial transformation involving dissolved silicate polyanions proceeds. This leads to a pronounced rise in the clay sorption capacity and decrease in the residual concentration of lead(II) cations in the solution with increasing sorption time.

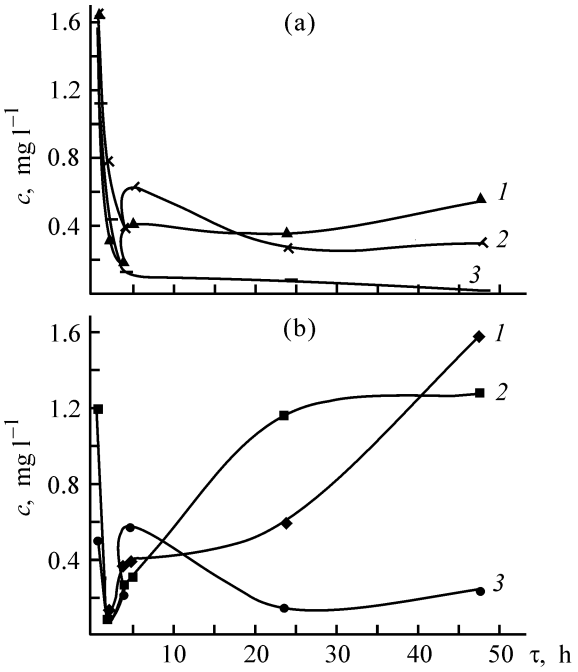

Fig. 3. Sorption of lead(II) ions on clay samples treated with (a) 0.5 and (b) 5.0 M solutions of H_2SO_4 and NaOH at 105 ± 0.5°C. (*c*) Concentration of lead(II) and (τ) time. Treatment: (*1*) first acid, (*2*) second acid, and (*3*) base.

CONCLUSIONS

(1) The possibility of directed control of the sorption properties of the Cambrian clay surface in the course of acid–base treatment was shown.

(2) The content of donor–acceptor centers on the Cambrian clay surface was studied as influenced by the conditions of chemical modifications, using the indicator procedure.

(3) The mineralogical composition of the Cambrian clay and of the products of its chemical modification was assessed by the successive dissolution method.

(4) The sorption of lead(II) cations proceeds in two steps: ion-exchange sorption and degradation epitaxial conversion.

SORPTION AND ION-EXCHANGE PROCESSES

Gel Filtration of Model Albumin–Analgin Mixture through Sephadex To Isolate Albumin

V. V. Khasanov, K. A. Dychko, A. V. Labutin, and I. V. Ramus'

Tomsk State University, Tomsk, Russia

Received August 14, 2002; in final form, March 2003

Abstract—The preparative isolation of albumin from a model albumin–analgin mixture by filtration through Sephadex G-25 was studied. The conditions providing optimal protein decontamination to remove low-molecular-weight impurities were established, and recommendations on both laboratory and industrial application of this technique were made. Based on laboratory experiments, a commercial installation for production of refined vaccines was designed.

One of the most important applications of gel filtration through Sephadex is fast separation of organic mixtures into macromolecular (MMF) and low-molecular-weight (LMW) fractions. This technique has been successfully used for desalination of aqueous proteins, polysaccharides, and nucleic acids, replacement of buffering components, and decontamination of macromolecular compounds to remove low-molecular-weight impurities. Owing to the ease of operation, gel filtration can be successfully applied to pretreatment of multicomponent mixtures in analysis of natural objects. However, in spite of its relative simplicity, gel–chromatography requires high skill, especially in the case of preparative gel filtration involving treatment of large amounts of expensive substances.

In a common analytical version of gel chromatography, efficient separation is achieved when using long chromatographic columns, slow elution, and small samples [1]. As opposed to analytical gel chromatography, the preparative gel filtration is, as a rule, applied when it is necessary to separate macromolecular components of initial multicomponent mixture from low-molecular-weight impurities. In order to decrease the reagent consumption and accelerate the separation process, the preparative and semipreparative gel filtration should be performed under the optimal chromatographic conditions.

In this study, we analyzed gel filtration of a model aqueous analgin–albumin mixture through Sephadex G-25 to determine the conditions providing maximal decontamination of the albumin fraction to remove analgin.

EXPERIMENTAL

All experiments were carried out on a FPLC (Pharmacia-Biotech, Sweden) liquid-chromatographic device. A UV photometer (λ = 280 nm) was used as detector.

Gel filtration was performed on a column with inner diameter of 26 mm, packed with Sephadex G-25 F (Amersham Pharmacia, Sweden). At gel-bed height of 24 cm, the working volume of the column was 127 cm^3. The stock solution used in the gel filtration experiments contained albumin (5 $g\ l^{-1}$) modeling a protein (macromolecular fraction, MMF) and analgin (5 $g\ l^{-1}$) modeling a low-molecular-weight ionic component (LMWF). In gel filtration experiments, the volume of filtered albumin–analgin mixture and the eluent flow velocity were varied. Analysis of gel chromatograms allows determination of the main parameters characterizing the efficiency of separation of the filtered mixture: degree of separation R_s; degree of dilution F of the macromolecular fraction relative to its concentration in the initial mixture; separation efficiency N measured in the number of the theoretical plates (tp), determined by a common method; total eluent consumption in single separation; and content of low-molecular-weight impurity in the isolated macromolecular fraction.

The degree of separation (resolution) R_s was calculated by the formula

$$R_s = 2(\tau_{r2} - \tau_{r1})/(W_1 + W_2),$$

where τ_{r2} and τ_{r1} are the retention times of low-molecular-weight and macromolecular fractions, re-

spectively, measured as the time elapsed from the beginning of filtration to the appearance of the elution peak; W_1 and W_2 are the widths of the elution bands of the macromolecular and low-molecular-weight fractions, respectively, measured at their bottoms.

The eluent flow velocity *v* was varied fom 60 to 90 cm h^{-1}, and the filtered sample volume *V*, from 5 to 30 cm^3, or from 4 to 24% of the working volume of column. A 0.025 M phosphate buffer solution with pH 7 was used as eluent.

The contamination of the macromolecular fraction with low-molecular-weight components was evaluated by ion-exchange chromatography on a Mono S HR5/5 column, Pharmacia-Biotech, packed with a strong cation exchanger. In elution of analgin–albumin mixture through such a column, analgin is eluted completely by the solvent, which makes the detection sensitivity the highest.

We found that, in filtering the albumin–analgin mixture, albumin is completely separated from analgin without any sorption of analgin on albumin macromolecules. Table 1 shows how the separation efficiency *N* and the degree of separation (resolution) R_S depend on the eluent flow velocity. With increasing eluent flow velocity, the efficiency of protein separation increases, whereas the band of the analgin fraction is smeared. As a result, the degree of separation of low-molecular-weight and macromolecular components (resolution) remains virtually unchanged. As expected, the eluent consumption in single separation grows somewhat with increasing eluent flow velocity. Owing to an increase in the separation efficiency, the macromolecular fraction volume decreases.

Table 2 shows how the sample volume influences the principal separation factors.

Although, with increasing sample volume, the macromolecular fraction volume grows, its dilution decreases. We found that, at the ratio of the Sephadex bed diameter to its height of 1 : 10 and the sample volume of about 1/4 of the column working volume, the bands of macromolecular and low-molecular-weight components overlap. In order to evaluate the degree of separation of the filtered mixture and choose the optimal zone of elution of the target macromolecular fraction, we determined the content of LMWF impurity in the macromolecular fraction.

Table 3 shows the main characteristics of separation of macromolecular components from low-molecular-weight impurities. It is seen that, even at a excessively large sample volume (1/4 of the Sephadex volume), approximately 99% of the macromolec-

ular component is isolated with the minimal dilution. A similar separation efficiency was obtained on a column with 1 : 10 ratio of the Sephadex bed diameter to its height.

Based on our experimental results, the following practically important conclusions can be made.

(1) In gel filtration, the eluent flow velocity is not a critical parameter. The separation efficiency grows only slightly with increasing eluent flow velocity. Therefore, gel filtration can be successfully performed using any available columns and devices for eluent feeding and sample introduction. In the case of gel filtration on the commercial scale, the eluate flow velocity should be the maximum possible. Even at minor increase in the eluent flow rate, the separation time decreases significantly and the separation efficiency increases.

(2) In order to provide efficient separation of a mixture, the sample should have the optimal volume. At approximately 1 : 10 ratio of the diameter to height of the Sephadex bed, this volume is about 20–25% of the Sephadex bed volume.

(3) In the course of gel filtration, the eluent flow velocity should not be more than 2/3 of that in the process of column packing. Under these conditions, the Sephadex bed is not compacted, and, therefore, both the separation efficiency and the adapter functioning remain stable. In filtration of more viscous solutions, still lower flow velocity should be maintained.

CONCLUSION

The most efficient decontamination of macromolecular components to remove low-molecular-weight impurities by gel filtration is achieved at the highest possible eluent flow velocity, and 1 : 10 diameter-to-height ratio of the Sephadex bed and sample volume equal to about 1/4 of the gel bed volume. Taking into account that the mechanism of gel filtration is independent of the gel nature, our recommendations can be extended to other gel materials suitable for gel filtration. The maximum permissible eluent flow velocity depends on the mechanical properties of a gel.

SORPTION AND ION-EXCHANGE PROCESSES

Calculation and Control of Solid–Liquid Extraction with Characteristic Function

E. B. Simeonov and A. D. Minchev

University of Chemical Technology and Metallurgy, Sofia, Bulgaria

Received July 8, 2002

Abstract—The kinetics of extraction of practically interesting vegetable raw materials: carsil (*Silibium marianum L.*), amorpha (*Amorpha fructicosa L.*), and coriander (*Coriandrum sativum L.*), was studied experimentally. The results obtained were represented as a characteristic function. The optimal conditions of the extraction process were studied.

The wide diversity of vegetable raw materials used for solid-phase extraction, combined with the complexity of mass transfer in the solid–liquid system, leads to a number of methodological and mathematical difficulties in describing the extraction process.

To ensure versatility of extraction apparatus, it is necessary not only to determine the extractor parameters, but also to control the process when changing the type of vegetable raw materials. This is possible with the use of the characteristic function. The method is especially valuable in the case of processing of a vegetable raw material characterized by a complex mechanism of diffusion extraction [1, 2].

The characteristic function takes into account, in an integral manner, specific structural features of the solid phase and the amount of outer-diffusion resistance. The function is derived from an experimental kinetic curve $c_1 = f(\tau)$ on the condition that the concentration c_1 is the same for all particles. The characteristic function $\Theta(\gamma)$ is most easily found with the use of kinetic curves obtained in the batch mode of the process under ideal mixing conditions [3, 4].

The aim of the present study was to demonstrate the applicability of the characteristic function to calculations and control of the extraction process.

Three solid–liquid systems were studied:

System	T, °C	ξ, $m^3\ kg^{-1}$	n, s^{-1}	c^*, $kg\ m^{-3}$
Carsil–methanol (**I**)	30	0.02	7.5	889.80
Amorpha–petroleum ether (**II**)	40	0.01	7.0	921.31
Coriander–petroleum ether (**III**)	50	0.01	7.0	735.21

Note. ξ is the specific volume; n, the rate of worm rotation; c^*, the saturation concentration.

The experiments were carried out in a batch extraction apparatus under ideal mixing conditions. The instants of sampling were varied, depending on a raw material under study. It was established experimentally that the process is limited by inner diffusion—transport within pores of the solid phase. The outer-diffusion resistance is virtually eliminated at the indicated stirring rate.

The kinetics of extraction is described by the expression

$$c_1 = A - B\exp(-H\tau), \quad (1)$$

where c_1 is the concentration of the component being extracted in the liquid ($kg\ m^{-3}$); A, B, and H are constants; τ is the process duration (s).

For systems (**I**)–(**III**), respectively,

$$c_1 = 0.980 - 0.966\exp(-2.20 \times 10^{-4}\tau), \quad (2)$$

$$c_1 = 4.600 - 4.400\exp(-3.40 \times 10^{-3}\tau), \quad (3)$$

$$c_1 = 2.050 - 1.950\exp(-1.20 \times 10^{-3}\tau). \quad (4)$$

Figures 1a–1c [respective Eqs. (2)–(4)] show the experimental data obtained. In system (**I**), silimarine (the solid phase contains silibine, silidianine, and silichrytine, with the flavolignan complex having general name silimarine) is extracted under the conditions specified. The content of the complex was analyzed by spectrophotometry. Silimarine is used in manufacture of an important pharmaceutical product Legalon (Carsil). In the case of system (**II**), the extracted solid phase contains isoflavonoids (or, more

1070-4272/03/7604-0544 $25.00 © 2003 MAIK "Nauka/Interperiodica"

precisely, rotenoids)—amorphigenine and dehydroamorphigenine. They are extracted with low-temperature fractions of petroleum ether (57°C). In system (**III**), the solid phase is a plant producing oil and essential oil. This plant contains coumarin, flavonoids, sitosterol, etc. The extraction was done with the same fraction of petroleum ether as in the case of system (**II**). The extracts obtained for systems (**II**) and (**III**) were analyzed gravimetrically with an error of 10^{-3} g.

Constants A, B, and H in Eqs. (2)–(4) were found numerically on the basis of experimental results. The statistical-average error of the experimentally determined concentrations and those calculated using Eqs. (2), (3), and (4) $\Delta = \pm 2.07$, ± 3.30, and $\pm 1.09\%$, respectively.

In [1, 2], the method of characteristic function for calculation and control of extraction from solids was described in detail. The integral (5) is a characteristic function

$$\Theta(\gamma) = -\int_i^\gamma \frac{d\gamma}{\psi(\gamma)}, \qquad (5)$$

where $\psi(\gamma) = D_e F/m_0\left(\frac{\partial c}{\partial n}\Big|_F\right)$, F is the mass-exchange surface area (m^2), and D_e is the effective diffusion coefficient ($m^2\ s^{-1}$).

The characteristic function was derived from the experimental kinetics on the condition that c_1 = const and is the same for all particles. In this case, the following sequence is observed:

$$c_1(\tau) \rightarrow \gamma(\tau) \rightarrow \Theta(\tau) \rightarrow \Theta(\gamma), \qquad (6)$$

where

$$\gamma(\tau) = 1 - \xi[c_1(\tau) - c_1(0)], \quad \Theta(\tau) = \int_0^\tau [c^* - c_1(\tau)]d\tau.$$

The calculation of continuous and batch processes with the use of $\Theta(\gamma)$ is based on the following set of equations:

$$\left.\begin{aligned} d\Theta/d\tau &= c^* - c_1 \\ \Theta &= \Theta(\gamma) \\ (1-\gamma)^{\xi^{-1}} &= c_1 - c_m \end{aligned}\right\} \qquad (7)$$

where c_m is the final concentration in the case of counterflow and initial concentration for direct flow and periodic processes in the liquid ($kg\ m^{-3}$).

Substitution of $\Theta(\gamma)$ and c_1 from the material balance equation into the differential equation of system (7) yields the dependence $\tau(\Theta)$ and, as a result, the relationship between the running time of extraction and the extractor coordinate (worm length) can be found:

$$\tau(\Theta) = \int_0^\Theta \frac{d\Theta}{c^* - c_m \pm \xi^{-1}[1-\gamma(\Theta)]} \rightarrow \gamma(\tau) \rightarrow \tau \rightarrow X = V\tau.$$

Characteristic functions were found for the three systems under study, with the kinetic equations (2)–(4) used as a basis. The method of characteristic function was used to determine for system (**I**) (Fig. 2) at a given solid-phase output capacity G and degree of extraction, η, the basic design dimensions of the worm extractor: diameter D, pitch S, and length X of the worm. The characteristic functions of systems (**II**)

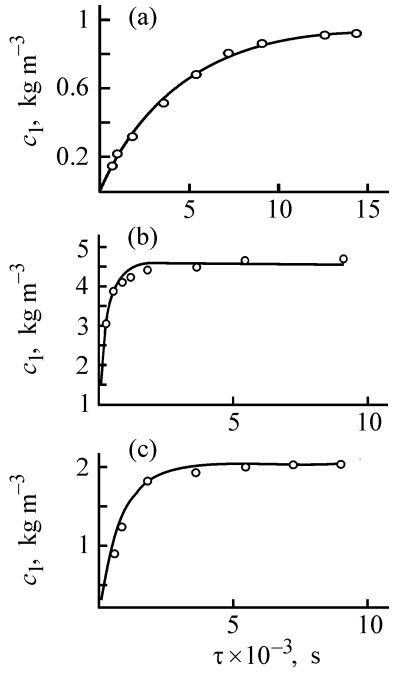

Fig. 1. Variation of the concentration c_1 in the liquid phase with time τ for systems (**I**)–(**III**). *Curve*, calculation; *points*, experiment.

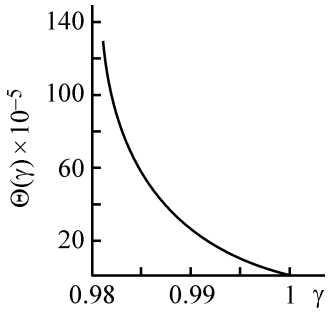

Fig. 2. Characteristic function $\Theta(\gamma)$ for system (**I**).

Parameters of the solid–liquid system (D = 0.127 m, X = 1.29 m, S = 0.057 m)

System	$G \times 10^4$, kg s^{-1}	V, m s^{-1}	$n \times 10^3$, s^{-1}	τ, s
(**I**)	6.94	2.12	3.71	6100
(**II**)	25.60	7.37	12.90	1750
(**III**)	11.70	3.30	5.79	3910

and (**III**) have been used to calculate the necessary rate n of worm rotation for the extractor designed for system (**I**) at a prescribed degree of extraction, η, and the solid-phase output capacity of the apparatus has been obtained [1, 2].

The table lists the parameters calculated for the above three solid–liquid systems.

Of interest for technological and engineering purposes is calculation of the linear motion velocity V of the solid phase in the extractor, corresponding to the rate n of worm rotation. This ensures the required time τ of extraction at which a prescribed degree of recovery, η, of a component being extracted is achieved.

CONCLUSIONS

(1) The obtained experimental data on the kinetics of the process in batch extraction from the systems constituted by carsil and methanol, amorpha and petroleum ether, and coriander and petroleum ether were used to calculate the characteristic functions $\Theta(\gamma)$.

(2) The use of $\Theta(\gamma)$ and the method of characteristic function for the carsil–methanol system yielded the basic design dimensions of the worm extractor. The same $\Theta(\gamma)$ functions were used for two other systems for calculating the rate of worm rotation and the output capacity of the apparatus at a prescribed degree of extraction.

(3) It was shown that the method of characteristic function enables not only calculation, but also control of the processes by varying certain technological parameters. In doing so, there is no need to rely upon simplifications, which are commonly inevitable in solving numerically or analytically the complicated problem of extraction from vegetable raw materials.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Enhancement of the Corrosion Resistance of Aluminum–Lithium Alloys by Microalloying with Calcium

M. T. Norova, I. N. Ganiev, and Kh. M. Nazarov

Nikitin Institute of Chemistry, Academy of Sciences of the Republic of Tajikistan, Dushanbe, Republic of Tajikistan

Received September 16, 2002

Abstract—The potentiodynamic method was applied to study the corrosion-electrochemical behavior in an electrolyte (3, 0.3, and 0.03% NaCl solution), of an aluminum–lithium alloy (6% Li) alloyed with calcium (0.01–0.5%).

Alloying of aluminum alloys with lithium leads to a significant decrease in their density and increase in strength, heat resistance, and modulus of elasticity. Depending on the nature of a third alloying component, the density decreases by approximately 11% and the modulus of elasticity, by 4%, compared with the D16 alloy. Commercial alloys VAD-23, 1420, 1430, 1450, etc., which exceed in corrosion resistance the D16T alloy and approach the AMg6M alloy, have been developed on the basis of alloys of the Al–Li system. Compression-molded and rolled semifinished products are fabricated from these alloys [1–5]. To enhance the corrosion resistance of aluminum alloys with lithium, they are additionally alloyed with manganese, cadmium, and zirconium [3].

In the present study, the influence of calcium additions on the electrochemical behavior of Al–Li alloys with 6% Li was analyzed on the basis of the scientific concept assuming that the corrosion resistance of passivating alloys is enhanced by their alloying with anodic microadditives [1, 6]. As is known, Ca is an anodic additive (–2.8 V) for the aluminum–lithium alloy. The standard electrode potential of lithium is –2.87 V [7]. According to [8], minor additions of Ca make slower the rate of aluminum corrosion, with the corrosion potential shifted to the negative region, whereas major additions of calcium raise the rate of aluminum dissolution in 3% NaCl because of the formation of an intermetallic compound Al_4Ca.

EXPERIMENTAL

As object of study served aluminum of A 995 brand, LE1 lithium, and KM1 calcium. These metals were used to prepare alloys in corundum crucibles in a resistance furnace at 750°C under a layer of flux of composition (%): NaCl 32.5, KCl 32.5, LiCl 35. The chemical compositions of the alloys are listed in Tables 1–3.

The melt obtained was used to cast cylindrical samples 8–10 mm in diameter and 60–100 mm long for a study of the corrosion-electrochemical properties of the alloys. Prior to being placed in an electrochemical cell, the samples were ground and polished with fine emery paper, washed with ethanol and distilled water, and dried in a desiccator.

The measurements were done with a PI-50-1 potentiostat with LKD-4-002 recorder in a 3, 0.3, or 0.03% NaCl solution. A silver chloride reference electrode and platinum auxiliary electrode were used.

Forward and reverse potentiodynamic curves were measured at potential sweep rate of 2 $mV\,s^{-1}$. The alloy samples were polarized potentiodynamically in the positive direction from the steady-state potential attained

0.05	0.480	0.580	0.670				

on submerging a sample in a solution, until a steep rise in the current was observed (to a constant current of 2 mA, and then in the reverse direction to a potential of –1600 mV), with the result that the oxide film was reduced. Finally, the samples were polarized in the positive direction to the pitting potential.

According to the phase diagram of the Al–Li–Ca system, the alloys obtained lie in the single-phase region of an aluminum–lithium solid solution or in the double-phase region of Al + Al_4Ca [9], i.e., are single-or double-phase, depending on the content of the alloying component. The results obtained in the study are shown in Figs. 1 and 2 and listed in Tables 1–3.

Figure 1 shows the time dependence of the corrosion potential of the initial Al + 6% Li alloy and alloys with various amounts of Ca. It was found that, during the first minutes after an alloy is submerged in an electrolyte solution, the potential is strongly shifted toward the positive region. In the process, a steady-state corrosion potential is reached in 40 min for an alloy without alloying additives, and in a 2 times shorter time, in 20–25 min, for alloyed alloys, which points to their relatively strong passivation under the action of calcium additions. For example, after keeping an unalloyed alloy in a 3% NaCl solution, its corrosion potential is –1.020 V, whereas for an alloy containing 0.50 wt % Ca, the potential is –0.780 V.

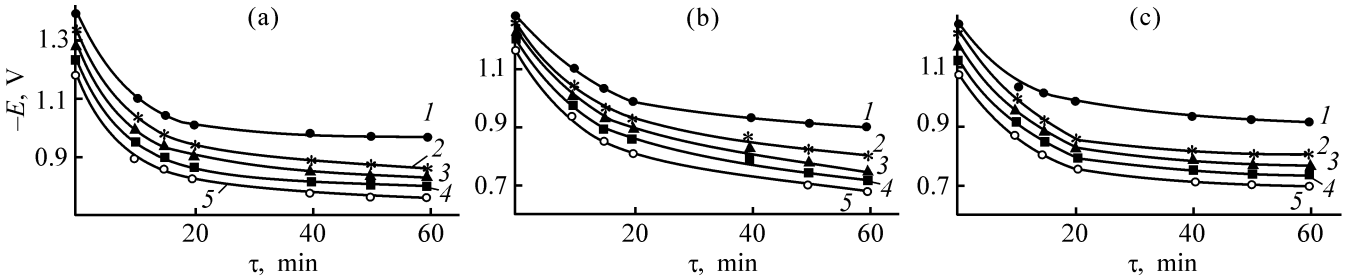

Fig. 1. Variation of the corrosion potential E with time τ for (*1*) Al + 6% Li alloys and (*2*–*5*) the same alloys with calcium. Ca content (wt %): (*2*) 0.01, (*3*) 0.05, (*4*) 0.10, and (*5*) 0.50; the same for Fig. 2. Electrolyte, NaCl solution (wt %): (a) 3.0, (b) 0.30, and (c) 0.03.

Figure 2 shows the anodic of potentiodynamic curves measured for aluminum–lithium alloys containing varied amount of Ca in a 3% NaCl solution. It can be seen that alloying with calcium shifts the corrosion potential of the alloys toward the positive region, with the pitting potential growing with the content of the alloying component increasing to 0.5 wt %.

The corrosion-electrochemical behavior of the alloys was studied at various concentrations of the NaCl electrolyte. With increasing concentration of chloride ions (Table 1), the corrosion potential decreases, which indicates that the corrosion resistance of the alloys falls. This is confirmed by studies of the rate of corrosion in NaCl solutions of alloys with varied content of Ca (Table 2).

Ca additions of up to 0.05 wt % improve the corrosion resistance of the alloys in all the solutions studied. Raising the content of the alloying component further, to 0.5 wt %, makes the corrosion rate of the alloys somewhat higher, but still lower (8.04 g m^{-2} h^{-1} in 0.03% NaCl solution) than that of the alloy without Ca (11.7 g m^{-2} h^{-1}). With increasing concentration of chloride ions, the corrosion rates of both the initial, Ca-free alloy and alloys with calcium grow. A certain increase in the corrosion resistance of alloys containing up to 0.05 wt % calcium can be accounted for by the solubility of calcium in the aluminum–lithium solid solution. According to the phase diagram of the Al–Li–Ca system, the aluminum–lithium alloys containing up to 0.05 wt % lithium lie in the single-phase region of a solid solution of lithium in aluminum. Further increase in the content of Ca leads to formation of primary crystals of an intermetallic compound, Al_4Ca, which, in all probability, acts as anode with respect to the aluminum–lithium solid solution. This, in turn, favors an increase in the corrosion rate of the alloys in the solutions studied.

The change in the pitting potential of the alloys in electrolytes with varied content of chloride ions indirectly confirms the aforesaid (Table 3). It can be seen that, with decreasing concentration of chloride ions in the electrolyte, the pitting potential grows, which indicates that the resistance of the alloys against pitting corrosion improves. Additions of the alloying component also shift the pitting potential to the positive region.

CONCLUSIONS

(1) Calcium, which is alloying anodic additive, improves the resistance of the aluminum–lithium alloy to general corrosion and pitting in 0.03, 0.3, and 3% NaCl solutions at 298 K.

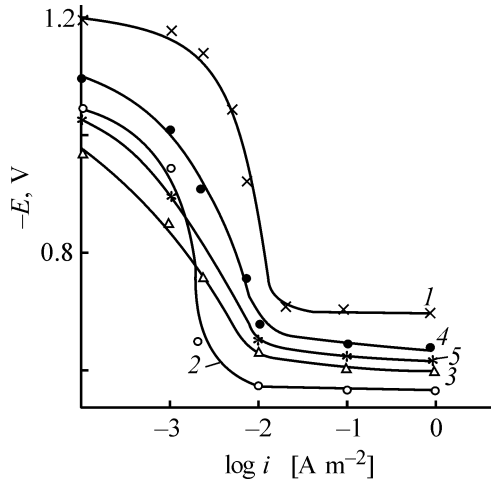

Fig. 2. Potentiodynamic anodic polarization curves (2 mV s^{-1} sweep rate) for (*1*) Al + 6% Li alloys and (*2–5*) the same alloys containing Ca. Electrolyte, 3% NaCl solution; 298 K. (*E*) Potential and (*i*) current density.

(2) The action of calcium as an effective anodic additive can be accounted for by its dissolution in the aluminum–lithium solid solution. The optimal content of calcium for improving the corrosion resistance of aluminum–lithium alloys should not exceed 0.05%.

CATALYSIS

Alkylation of Isobutane with Butenes on Zirconium Sulfate Catalysts

Received November 29, 2002

Abstract—Sulfated zirconia catalysts supported on silica gel and aluminum oxide were prepared by impregnation, and their structure and acid–base and catalytic properties were studied. The parameters of synthesis and characteristics of this catalyst, which ensure high activity and selectivity in liquid-phase alkylation of isobutane with butenes, were determined.

Alkylation of isobutane with butenes is one of the most important processes in production of high-quality gasolines. Industrial alkylation is performed with sulfuric and hydrofluoric acids as catalysts. Their main drawbacks are high specific consumption, toxicity, corrosion activity, and the necessity for separation of the alkylate from the catalyst-product mixture and utilization of spent acids. The progress in the technology of alkylate gasoline production is associated with passing to solid acid catalysts [1] to avoid the above problems.

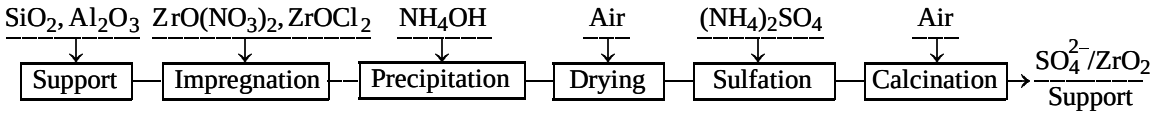
The strong acidity of sulfated zirconia (SZ) allows its use as catalyst for isomerization, alkylation, acylation, and many other processes [2]. However, in spite of increased interest in this catalyst, studies of SZ catalytic properties in isobutane alkylation with butenes are few in number [3–11]. The expectancies associated with SZ as industrial alkylation catalyst have diminished in recent years because of its low stability. The studies of the synthesis of catalytic systems based on SZ, their chemical composition, and structure of active centers were systematized in [2, 12, 13]. However, the patterns established are mainly related to synthesis of catalysts for light alkane isomerization, whereas data on the chemical and phase composition, acidity, and other characteristics of such catalysts as applied to isobutane alkylation with butenes are extremely scarce [3, 6].

Dispergation of a catalytic component on the surface of a porous matrix frequently provides substantially higher activity, selectivity, and stability of the catalyst in comparison with the bulk substance. Indeed, numerous studies have shown that SZ in the form of finely divided particles fixed on the surface of porous supports is more active in isomerization [14–17] and alkylation [18].

The goal of this study was to develop a procedure for commercial synthesis of supported SZ and to analyze the texture, structural, and acid–base properties of SZ supported on silica gel and aluminum oxide, in order to understand the origin of its activity and selectivity in isobutane alkylation with butenes. In the choice of the synthesis conditions, we made an attempt to take into account the known experience, especially that concerning the support properties and conditions of zirconium hydroxide precipitation, sulfation, and calcination.

EXPERIMENTAL

Impregnation [19] is the simplest and the most practically feasible method for preparation of supported catalysts. The main stages of synthesis of "impregnated" catalysts based on SZ are shown in the scheme.



Flow sheet of the synthesis of supported zirconium sulfate catalysts.

1070-4272/03/7604-0550 $25.00 © 2003 MAIK "Nauka/Interperiodica"

Silica gel and aluminum oxide were taken as SZ supports. Their main advantages are the possibility of varying the texture characteristics, high thermal stability, low catalytic activity in side reactions of butene oligomerization, and wide experience in their industrial production and preparation of supported catalysts.

Silica gel and Al_2O_3 with specific surface area of 290 and 203 $m^2 g^{-1}$ and total pore volume of 0.95 and 0.64 $cm^3 g^{-1}$, respectively, were used. Both supports consisted of 0.4–1.0-mm particles. Silica gel was washed with 1 M HCl to remove metal impurities. Aluminum oxide was treated with 1 M H_2SO_4. This preliminary sulfation of the aluminum oxide support was performed to neutralize its basicity and thus to eliminate its influence on the subsequent precipitation of zirconium hydroxide. The thus treated supports were calcined in a muffle furnace at 600°C for 4 h.

During catalyst synthesis, both multiple and single impregnation of supports were performed (samples SZS-*X*-*Y* on silica gel, SZA-*X*-*Y* on aluminum oxide, *X* is ZrO_2 content, and *Y*, the number of impregnation runs). The supports were impregnated with $ZrO(NO_3)_2$ solutions with zirconium concentration varied from 25 to 300 g l^{-1} in terms of ZrO_2.

The above zirconium salt is a commercial product. Zirconium hydroxide formed by its hydrolysis is less contaminated with impurities, which can later uncontrollably affect the structural and acid properties of a catalyst prepared. In contrast to $ZrOCl_2$ and, the more so, to zirconium sulfate-containing compounds, which give precipitates with Cl^- or SO_4^{2-} ions virtually unremovable by washing, nitrate ions are well washed out with ammonia water at pH 8–9 and completely decompose in calcination.

The known tendency for zirconium salts to form polymeric structures in solutions complicates preparation of zirconium hydroxide with required properties [20]. Therefore, the impregnating solution was stored for a week at pH < 1 before use. After impregnation, the excess solution was separated by filtration, and the sample was dried in air at room temperature to eliminate liquid drops and then covered with the amount of ammonia water required to obtain zirconium hydroxide precipitate in the matrix pores at pH 9–10.

When preparing bulk SZ, the zirconium hydroxide precipitate is aged in some cases. The processes occurring in aging (reprecipitation, polycondensation, etc.), as a rule, favor increase in size of amorphous particles and formation of a more perfect structure and give larger specific surface area of the oxide phase after calcination. Aging of zirconium hydroxide precipitated in the support pores is hardly useful; by contrast it may lead to uncontrollable modification of the catalyst. In an alkaline mother liquor, acidic supports may break down. Silica gel will undergo partial dissolution to give ammonium silicates. The surface of sulfated aluminum oxide may also change under the action of ammonia solution. Therefore, we excluded the aging stage from the procedure for synthesis of supported catalysts.

After drying at 150°C, samples were calcined at 400°C to convert the precipitated hydroxide into zirconium oxide. Dried zirconium hydroxide actively reacts with sulfating agents already in the stage of impregnation. During the subsequent thermal treatment, the zirconium hydroxide–oxide transition is superimposed on the complex sulfation processes. From the standpoint of reproducibility and stability of synthesis, it is necessary to avoid simultaneous occurrence of these chemical processes and to subject to sulfation specifically the zirconium oxide phases obtained by calcination at 350–400°C, when dehydration and crystallization are 70–80% complete. This is confirmed by the fact that the preliminary calcination of zirconium hydroxide at 200–400°C gives catalysts with the maximal selectivity in alkylation [3]. After the formation of supported ZrO_2, each of the samples prepared was used both for further impregnation and for sulfation to obtain a finished catalyst.

It is believed that the specific kind of a sulfating agent is of no importance. Similar results were obtained when H_2SO_4, $(NH_4)_2SO_4$, $(NH_4)_2S_2O_8$, or gas mixtures $SO_2 + O_2$ and $H_2S + O_2$ were used. Probably, $(NH_4)_2SO_4$ should be preferred as the least reactive and neutral reagent. Its use allows the best control over sulfation and the highest preparation reproducibility. This is especially important in sulfation of finely dispersed supported ZrO_2 particles. Samples were sulfated with an excess of a $(NH_4)_2SO_4$ saturated solution for 1 h. Then, the samples were separated by decanting, dried, and calcined in a flow of purified air at 300°C for 1 h and then at 550°C for 2 h.

The content of SO_4^{2-} ions after sulfation followed by calcination is the most important parameter of the catalyst, since it determines the number and activity of the catalyst acid centers. In the case of bulk SZ, a monolayer coating of the ZrO_2 surface with SO_4^{2-} ions is considered to be optimal [13].

The monolayer capacity is estimated to be 4 SO_4^{2-} nm^{-2}, which gives a sulfur content of approx-

Table 1. Composition of IBF and BBF raw material fractions

Component	Content, wt %	
	IBF	BBF
Propane	0.01	0.55
Isobutane	99.81	42.64
1-Butene + isobutene	0.15	26.65
n-Butane	0.03	8.76
trans-2-Butene	0.00	12.54
cis-2-Butene	0.00	8.86

imately 2 wt % for SZ with specific surface area of 100–150 $m^2 g^{-1}$. Actually, a set of different S^{6+} coordination states exists in the catalyst [21]. Sulfate ions may be situated under the surface layer of zirconium atoms and form bulk nonstoichiometric dispersed oxysulfate phases. In addition, the surface sulfate ions may differ in denticity in complexation, and also can form disulfate ions and polymeric structures. Thus, the structure of the active center and optimal S : Zr ratio are indefinite. For a supported catalyst, the $SO_4^{2-} : ZrO_2$ molar ratio, whose optimal value can be determined only experimentally, is the most important characteristic of the active component.

For comparison, we prepared bulk sulfated zirconia under the same conditions as in the synthesis of the supported catalysts. The Zr and S content in the catalysts was monitored by X-ray fluorescence analysis on a VRA-20 spectrometer. The texture characteristics of samples were studied on a Sorptomatic-1900 device, using nitrogen adsorption–desorption isotherms at –195.6°C. The 0.4–0.6-mm fraction was used in measurements. Before the measurements, the initial samples were kept at 300°C in a vacuum, at a residual pressure of no more than 104 Pa, for 4–6 h. The adsorption measurements and data processing were performed using Milestone-200 software. The BET specific surface area, S_{sp}, was calculated at equilibrium relative nitrogen pressures of 0.05–0.33. The landing area of the nitrogen molecule in the filled monolayer was taken equal to 0.162 nm^2. The adsorption pore volume was determined from the nitrogen sorption at a relative pressure of 0.996. The molar volume of the liquid adsorbate at the temperature of the experiment was taken to be 34.68×10^{-6} $m^3 mol^{-1}$.

The X-ray diffraction analysis (XDA) was performed on a DRON-3 diffractometer (Cu_{K_α} radiation, β-filter). The phase composition and particle size were determined from X-ray diffraction patterns, using the ASTM file.

High-resolution electron microscopy (HREM) was applied to study the catalyst structure. Samples were prepared by "dry" and "wet" methods. The "wet" method involved sample grinding and preparation of suspensions in ethanol or hexane, followed by ultrasonic dispergation. The suspensions prepared were applied to perforated carbon films (supports) on copper grids. In the "dry" method, a sample was mechanically ground in an agate mortar, applied to a copper grid, and transferred into the electron microscope.

The acid centers on the catalyst surface were studied by IR spectroscopy after low-temperature adsorption of CO [22]. Carbon monoxide can form various single-ligand complexes with the surface acid centers and, depending on the center type, give H-bound states or coordinate with aprotic centers. As a rule, a spectroscopic study of adsorbed CO allows identification of the strongest Brønsted (BAC) and Lewis (LAC) acid centers, which must be primarily responsible for the catalytic properties. Samples were compacted into 4–12-mg cm^{-2}-"thick" pellets. Before CO adsorption, samples were calcined in a vacuum (0.00133 Pa) at 500°C for 1 h. Carbon monoxide was sorbed in portions at liquid nitrogen temperature and maximal pressure of 400 Pa. The IR spectra were recorded on IFS-113v Bruker and Shimadzu 8300 spectrometers within the 1000–5000 cm^{-1} range, with resolution of 4 cm^{-1} and accumulation of 50 to 128 scans. The LAC concentration c (μmol g^{-1}) was determined as $c = A/A_0$, where A is the integral intensity of the CO absorption band within the 2186–2200 cm^{-1} range, normalized to the pellet thickness, and A_0 is the integral absorption coefficient, equal to 0.8.

The catalytic properties of the samples in alkylation were studied in a 180-cm^3 stainless steel autoclave. Preliminarily purified (by treatment with solid alkali and NaA zeolite) commercial isobutane (IBF) and butane–butylene (BBF) fractions (their compositions are presented in Table 1) were used as starting reagents. A 4-g portion of a catalyst with 0.4–1-mm particle size and 40 g of IBF were loaded into the autoclave. During the experiment, BBF was introduced into the autoclave with a syringe at a rate of 0.5 to 1 g h^{-1}. The autoclave with the reaction mixture was agitated with a shaker. The alkylation was performed at a temperature of 40°C maintained by heated water circulating through the autoclave jacket. The composition of the liquid phase in the autoclave was monitored every hour by GLC, using a special syringe for sampling liquid hydrocarbons under pressure and a Hewlett–

Packard 5890 Series II chromatograph with a DB-1 capillary column and a flame-ionization detector. A Multi-Chrom computerized chromatographic system was used for recording and processing of the chromatograms.

The following parameters were determined to characterize the reaction in the autoclave: degree of butene conversion, $X_{C_{4=}}$ (%); weight yield of the C_{5+} products based on converted butenes, $Y_{C_{5+}}$ (g g^{-1}); their fractional composition. All these parameters were calculated from the material balance for every hour of the process, with subtraction of the accumulated initial substances and reaction products.

In preparing the catalysts by multiple impregnation, gradual formation of the SZ phase on the support surface allows successive monitoring of the stepwise formation of catalytically active surface state and probable reactions with the support, control over the dispersity of SZ particles, and determination of the optimal catalyst composition.

The characteristics of the texture and chemical and catalytic properties of the supported catalysts, depending on the number of impregnations, are shown in Tables 2 and 3 and in Fig. 1. Silica gel was impregnated up to ten times; the ZrO_2 content was varied from 9.5 to 39 wt %. The catalysts prepared by impregnation of aluminum oxide contained from 6.2 to 29.8 wt % ZrO_2 (1 to 5 impregnations).

At similar amounts of supported ZrO_2 and sulfation conditions, the sulfate content in the samples supported on Al_2O_3 was substantially higher than that in catalysts supported on silica gel. This is caused by the fact that sulfate ions are incorporated not only in the zirconium oxide phase but also in the aluminum oxide support during both preliminary and main sulfation. The SO_4^{2-} : ZrO_2 molar ratio in the finished catalysts varied between samples from 0.4 to 1 for the silica gel support, reaching 3 for the aluminum oxide support.

The specific surface area and pore volume of the supported catalysts are, of course, lower than those of the initial supports because of the filling or blocking of the pore space with the supported phase.

The XPA of the supported catalysts revealed no zirconium oxide or zirconium sulfate phase. The diffraction patterns of the SZS catalysts contain a broad reflection of silica gel; in the SZA catalysts, the phase of crystalline $Al_2(SO_4)_3$ with particle size (determined from the size of the coherent scattering region) of about 15 nm was identified. This suggests either high dispersity of the supported particles, exceeding the method sensitivity (~3 nm), or strong amorphization of the zirconia component, e.g., due to reaction with the support.

Table 2. Properties of silica gel–supported SZ catalysts

Sample	Number of impregnations	Composition, wt %		Pore volume, cm^3 g^{-1}	S_{sp}, m^2 g^{-1}
		ZrO_2	SO_4^{2-}		
SZS-9-1	1	9.5	5.3	–	–

SZS-30-7	7	29.8	11.9	0.56	266
SZS-35-8	8	34.8	10.0	0.55	–
SZS-39-10	10	39.0	14.5	0.50	–

Table 3. Composition of aluminum oxide–supported SZ catalysts

Sample	Number of impregnations	Composition, wt %	
		ZrO_2	SO_4^{2-}
SZA-6-1	1	6.2	15.6
SZS-11-2	2	11.4	19.3
SZS-18-4	3	17.8	18.0
SZS-24-5	4	24.2	–
SZS-30-5	5	29.8	–

The formation of finely divided ZrO_2 particles on the catalyst surface on the silica gel support was confirmed by HREM. It is seen on an electron micrograph of the SZS-9-1 sample (one impregnation) (Fig. 2a) that ZrO_2 forms crusts on the support particles, with

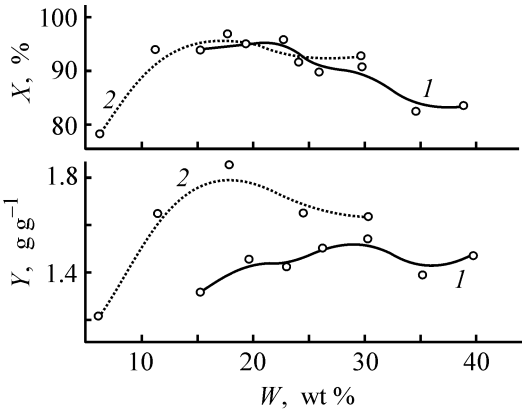

Fig. 1. Effect of the content of supported zirconium dioxide *W* on the degree of butene conversion *X* and on the yield *Y* of C_{5+} products based on converted butenes in isobutane alkylation. Support: (*1*) silica gel and (*2*) aluminum oxide.

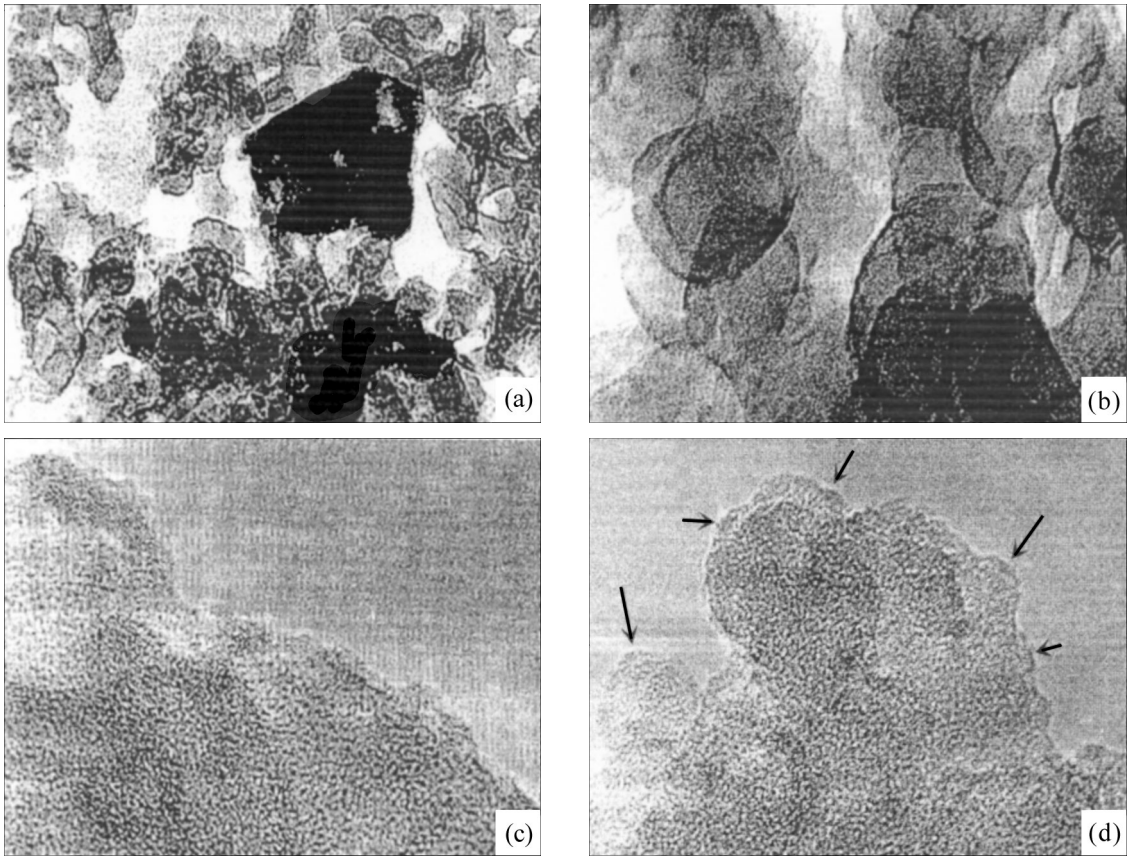

Fig. 2. Electron micrographs of samples: (a) SZS-9-1, (b) SZS-23-5, (c) SZS-35-8, and (d) SZS-19-1 (ZrO_2 particles are shown by arrows).

fairly uniform surface distribution. However, part of the zirconium oxide phase exists in the form of large aggregates (more than 100 nm), seen as a contrasting spot in the electron micrograph. The number of such particles does not grow with increasing number of impregnations (Fig. 2b, 2c), and the crust form of supported ZrO_2 remains. Flat particles of supported ZrO_2 on the surface of the silica gel globules are seen in electron micrographs of the SZS-23-5 and SZS-35-8 samples. The regions of ordered structure are 1–3 nm in size. In these formations, distorted planes of the crystal lattice with interplanar spacing of about 0.29 nm are observed. This value is characteristic of basal planes of the crystal lattice, forming the structure of known modifications of the ZrO_2 phase. For the SZS-35-8 sample (eight impregnations), the amount of such crystalline structures increases as compared with the SZS-23-5 sample, but qualitatively these samples are virtually the same.

Table 4. Properties of bulk and supported SZ catalysts

Catalyst	S_{sp}, $m^2\ g^{-1}$	Composition, wt %	
		ZrO_2	SO_4^{2-}
SZ	138	95.9	4.1
SZS-19-1	230	19.0	7.0
SZA-11-1	170	11.4	26.4

All the samples of the SZS and SZA series prepared by successive impregnation showed activity in alkylation of isobutane with butenes. The results of their tests (Fig. 1) demonstrated that satisfactory parameters of the catalytic activity (degree of butene conversion no less than 90%, yield of liquid alkylate 1.5–1.8 g per g of converted butenes) were observed beginning from the catalysts prepared by two- and three-fold impregnation. For catalysts supported on Al_2O_3, this corresponds to a ZrO_2 content of no less than 10–15 wt % and, for catalysts supported on silica gel, 15–20 wt %. Further increase in the amount of supported SZ does not affect the catalyst properties substantially. Comparison of the test results with the data of electron microscopy allows a conclusion that the alkylation catalysis is ensured by formation of highly dispersed phases of crystalline sulfated ZrO_2 on the catalyst surface.
